Abstract

Background: Machine learning–enabled clinical information systems (ML-CISs) have the potential to drive health care delivery and research. The Fast Healthcare Interoperability Resources (FHIR) data standard has been increasingly applied in developing these systems. However, methods for applying FHIR to ML-CISs are variable.

Objective: This study evaluates and compares the functionalities, strengths, and weaknesses of existing systems and proposes guidelines for optimizing future work with ML-CISs.

Methods: Embase, PubMed, and Web of Science were searched for articles describing machine learning systems that were used for clinical data analytics or decision support in compliance with FHIR standards. Information regarding each system's functionality, data sources, formats, security, performance, resource requirements, scalability, strengths, and limitations was compared across systems.

Results: A total of 39 articles describing FHIR-based ML-CISs were divided into the following three categories according to their primary focus: clinical decision support systems (n=18), data management and analytic platforms (n=10), or auxiliary modules and application programming interfaces (n=11). Model strengths included novel use of cloud systems, Bayesian networks, visualization strategies, and techniques for translating unstructured or free-text data to FHIR frameworks. Many intelligent systems lacked electronic health record interoperability and externally validated evidence of clinical efficacy.

Conclusions: Shortcomings in current ML-CISs can be addressed by incorporating modular and interoperable data management, analytic platforms, secure interinstitutional data exchange, and application programming interfaces with adequate scalability to support both real-time and prospective clinical applications that use electronic health record platforms with diverse implementations.

Introduction

Data analytic tools provide essential contributions to scientific investigation and clinical decision-making [1]. These tools are in turn fueled by the volumes of data that have been generated since the passage of the Health Information Technology for Economic and Clinical Health Act in 2009, which incentivized the adoption of electronic health record (EHR) systems [2-4]. EHR data, however, remain nonstandardized across institutions and, within an institution, may not be readily available for real-time analysis, thus impairing multi-institutional research efforts and care for individual patients across institutions [5-8]. The standards herein refer to the structure, organization, representation, and transmission of data. Health information exchange systems can mitigate these issues by using the Fast Healthcare Interoperability Resources (FHIR; pronounced "fire") data standard [9]. The Health Level 7 (HL7) International standard developing organization sought to reduce the

complexity of the HL7 version 3 Reference Information Model while maintaining semantic interoperability and thus adopted the FHIR standard in 2011 [10]. It supports multiple development platforms and has been embraced by major industry and government organizations. Since 2016, developers have engaged with Substitutable Medical Applications and Reusable Technologies (SMART) on FHIR to build EHR and commercial applications [11,12]. Despite the growth of technologies using FHIR standards, there is limited literature summarizing differences among machine learning–enabled clinical information systems (ML-CISs), and the best methods for applying FHIR remain unclear.

This review describes the functionalities, strengths, and weaknesses of clinical applications that use the FHIR standard and have been described in the medical literature, and we propose guidelines for improved multi-institutional research initiatives and clinical applicability.

Methods

Given the rapidly evolving nature of this field, we performed a scoping review to provide a critical appraisal of the current literature, with the goal of informing future studies. We followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines; the PRISMA-ScR checklist is available in Multimedia Appendix 1.

Research Protocol

We sought articles describing clinical decision support (CDS) systems (CDSSs) or risk prediction systems using FHIR standards. FHIR standards define resource types (ie, patients, medications, and clinical observations), data elements (ie, medication name and dosage), data formats (ie, JSON and XML files), and the use of standard ontologies (ie, Systematized Nomenclature of Medicine-Clinical Terms [SNOMED CT] and Logical Observation Identifiers Names and Codes [LOINC]), among others. Our initial search was performed on April 23, 2020, and given the progress of the field, it was updated again on October 11, 2022. Inclusion criteria involved all full-text articles published in English. We excluded abstracts, poster presentations, and meeting summaries. Embase, PubMed, and Web of Science were searched for cohort studies, case-control studies, and reviews. Our search terms for each database are found in Multimedia Appendix 2. Despite their increasing use by commercial entities, we did not search for commercial applications of FHIR, as their lack of peer review and limited reportability prevented a formal evaluation of their methods. Following the removal of duplicates, 153 articles were identified. Titles and abstracts were reviewed by 2 authors independently, with disagreements resolved by a third. Full-text articles that did not adequately describe system functionality, data sources, formats, security, performance, resource requirements, scalability, strengths, and limitations were excluded. We also excluded articles that described a model architecture using FHIR but did not incorporate it into a CDSS. A total of 39 full-text articles were included for full analysis.

Article Evaluation

Strengths and limitations of the applications were evaluated in terms of functionality, data sources, formats, security, performance, resource requirements, and scalability. *Functionality* was defined as the intended purpose of the algorithm and its capabilities, ranging from the integration of genomic data into the EHR [13,14] to CDSSs [15-17] and predictive models [18,19]. Data sources included information within electronic health care records and external sources, such as wearable devices [20]. Formats were evaluated based on system architecture and the technologies underlying the algorithms (eg, use of Bayesian networks [16], transformers [21], or rule-based methods [22]). Security was evaluated based on how the application handled sensitive health information, including encryption [23], use-and-access control mechanisms [24], or authorization platforms [25,26]. Performance and resource requirements refer to the processing time, memory, and computing needs of the applications. Finally, scalability refers to the likelihood of adoption by other health care systems or platforms (eg, use of open-source components [27] or cloud-based repositories [28]). Knowledge from the included articles was used to propose avenues of future development for optimizing machine learning–enabled systems.

Results

A total of 39 clinical tools that used FHIR standards were divided into the following three categories according to their primary focus: CDSSs (n=18), interoperable data management and analytic platforms (n=10), or auxiliary modules and application programming interfaces (APIs; n=11) that enhance ML-CISs.

The CDSSs

CDSSs are algorithms that use health information to provide assistance for clinical decision-making tasks. Table 1 shows articles that focused on these support systems. Although many CDSSs lacked interoperability and external validity, several characteristics of CDSSs harbored potential for improving both efficacy and efficiency.

Table . Summary of intelligent clinical decision support systems.

Source, year	Functionalities	Strengths	Limitations
Curran et al [15], 2020	Summarizes chronic obstructive pulmonary disease information, provides decision support, and suggests orders	Dynamic embedding within EHR[a] and compatible with SMART[b]-on-FHIR[c] submodules	Limited generalizability due to single center and single disease
Dolin et al [13], 2018	Uses drug-gene interaction data for clinical decision support triggered by EHR medication orders	Accesses a rules engine containing level A recommendations from a pharmacogenetics consortium	Difficult to query the rules engine for level A recommendations when triggered by EHR medication orders
El-Sappagh et al [28], 2019	Uses mobile health technologies to monitor and manage type 1 diabetes	Most system processes are executed in the cloud; once configured, it runs on any EHR system	The diabetes treatment ontology did not address emergency conditions and was not embedded within an EHR system
Gaebel et al [16], 2016	Generates digital patient models for clinical decision support for laryngeal cancer	Bayesian networks are well-suited for representing complex diseases	System architecture was described, but the system was not implemented clinically
Gruender et al [14], 2019	Combines next-generation sequencing genomics data with FHIR clinical data	Open-source system that combines data formats and is portable	Manual data extraction and web-based filtering tool
Gordon et al [29], 2017	Displays patients' thrombocytopenia trends along with computer-generated calculated panel reactive antibody levels	Provides real-time services and effective visual cues	Data sources are limited
Henry et al [18], 2018	Predicts sepsis among intensive care unit patients in real time	Cloud-based system that provides alerts to clinicians	Public cloud-based solutions present safety issues
Hong et al [27], 2019	Phenotypes diabetes based on free-text notes and other structured data	Converts unstructured, semistructured, and structured data to appropriate FHIR components	Performance is not stable across different data sets
Kawamoto et al [30], 2021	Takes data from multiple EHRs and incorporates them into existing risk calculators	Performance measured with end user satisfaction studies and used existing application programming interface	Tested at a single institution and had data security concerns
Park et al [31], 2022	Personal health record application for employees, with links to health care resources	FHIR-based cloud application that is applicable to multiple EHRs and provides secure access through Azure	Limited integration of hospital data
Schleyer et al [32], 2021	Integrates selected data from statewide data systems into local EHR	Translates data from diverse sources into a common database	Experience limited to a single EHR
Semenov and Kopanitsa [20], 2018	Recommends clinical decisions and actions based on EHR data	Free-text output for both physicians and patients	No standard performance evaluation
Semenov et al [33], 2018	Recommends clinical decisions and actions based on EHR data	Free-text output for both physicians and patients and improved analytic workflow relative to prior versions	No standard performance evaluation
Séroussi et al [34], 2018	Produces clinical practice guideline services for patients with breast cancer	Uses both data models and knowledge models and provides effective data analytic visualizations	Implemented on a small scale, proposed guidelines were not validated, and interguideline conflicts need to be resolved manually
Tarumi et al [35], 2021	Modeling of treatment outcomes for type 2 diabetes	Effective use of SMART on FHIR for integration in local EHR, and design incorporated clinician feedback	No external validation, limited access to cost data, and not yet compatible with all EHRs
Thayer et al [36], 2021	Automated graphical display of asthma history	Smoothly integrated into EHR	Not based on SMART, limiting interoperability
Wang et al [37], 2019	Comparison of machine learning algorithms for prediction of end-stage renal disease in type 2 diabetes	Extraction of EHR data using FHIR	Single institution, no imputation of missing data, and no external validation

Source, year	Functionalities	Strengths	Limitations
Whitaker et al [38], 2022	Machine learning algorithm to identify blood transfusion adverse events	Synthesized structured and unstructured data from EHR to achieve reasonable accuracy compared to clinicians	Retrospective study more aligned toward research than clinical care

[b]SMART: Substitutable Medical Applications and Reusable Technologies.

[c]FHIR: Fast Healthcare Interoperability Resources.

CDSS ontologies are a central tenant of CDSS interoperability. Generally, ontologies are a hierarchy of concepts that are defined by both a set of attributes and their relationships to other concepts, and they must meet several internal consistency and version control objectives [10]. Common ontologies include the SNOMED CT, LOINC, and National Cancer Institute Thesaurus (NCIT). Separate ontologies may conflict, such as in cases where models use different organizing principles, have varying degrees of granularity, or even exhibit contextual differences between clinical applications and biomedical research. Séroussi et al [34] faced this problem when creating a guideline for the optimal management of breast cancer by integrating a collection of pre-existing ontologies (NCIT and LOINC). They were able to resolve this conflict by using data visualization techniques and rules-based inference engines, though often their methods required the manual resolution of conflicts. Common ontologies can also omit essential elements. Dolin et al [13] were able to transform a library of drug-gene interactions into an FHIR standard to alert physicians when prescriptions are likely to cause adverse drug reactions. Specific disease classes may lack an interoperable ontology. For cancer, there are active efforts in the CodeX HL7 FHIR Accelerator community to capture oncologic data from the EHR by using the mCODE (minimal Common Oncology Data Elements) ontology [39,40].

Advanced CDSSs have been integrated with machine learning algorithms to process data, especially unstructured data, such as clinician notes. Gaebel et al [16] created a physician-facing CDSS that used Bayesian networks and medical language modules to identify the optimal management strategy for laryngeal cancer. Bayesian networks and other modeling approaches can estimate and infer unobserved but relevant variables, which is advantageous in representing complex diseases. Natural language processing is becoming an increasingly common tool. Hong et al [27], Semenov et al [20,33], and Whitaker et al [38] used semantic tags, rules-based extraction, and the scispaCy-based natural language processing pipeline to extract their concepts, though these methods require arduous labeling—the process of manually highlighting terms and classifying them—and lack validation on external data sets. Vocabulary and expressions often differ outside of the training context, requiring developers to further refine their language models after release by using test data and real-life examples.

Cloud-based solutions have made it possible to process large-scale and heterogeneous data and push the boundaries of CDSSs to encompass broader scenarios. El-Sappagh et al [28] developed a mobile app that integrates data from wearable monitors (eg, vital signs, physical activity, and blood glucose levels) with the EHR to provide recommendations for managing type 1 diabetes mellitus. The system delivers spoken education and lifestyle recommendations to patients' mobile devices, using an ontology generated from clinical practice guidelines, expert opinions, and other published sources. Meanwhile, in countries with nationally integrated health systems, citizens may be able to assemble their data across different institutions by using a secure server, such as Azure [31]. Henry et al [18] created a real-time prediction system for critically ill patients that alerts staff to elevated sepsis risk and tracks trends in vitals by using cloud-based technology. In the outpatient setting, Kawamoto et al [30] incorporated data from several EHRs into an existing risk prediction model.

A total of 3 studies described visualization tools. Gordon et al [29] generated visual aids to show patients' thrombocytopenia trends, along with computer-generated calculated panel reactive antibody levels, to facilitate the judicious use of platelet transfusions by physicians and blood banks, and Thayer et al [36] used translated FHIR concepts to graphically display a patient's asthma history within a chart. Xiao et al [41] were able to use knowledge graph ontologies to map FHIR and Observational Medical Outcomes Partnership (OMOP) data standards.

Despite the considerable benefits of cloud-based systems, they can present additional security challenges. These range from traditional cybersecurity problems (including problems related to data security, access control, and the transmission of data over a network) to more CDSS-specific concerns (such as privacy leakage, whereby models can be queried by outside parties). HL7 FHIR has put forward specific security protocols in response to safety concerns, including the use of secure http communication channels, open authorization, and provenance (documentation of the origin, possession, and history of a piece of data) techniques, among others [42].

Data Management and Analytic Platforms

The rise in computing power and distributed system technologies facilitates general-purpose platforms that provide data standardization, data analysis, and model integration. Of the 39 included articles, 10 described FHIR-compliant data management and analytic platforms, as listed in Table 2. Although CDSSs require interoperability and multicenter clinical implementation, many clinical platforms did not support the real-time data integration that is necessary for clinical adoption.

Table . Summary of interoperable data management and analytic platforms.

Source, year	Functionalities	Strengths	Limitations
Gruendner et al [14], 2019	Data analysis and model deployment in clinical environments	Applied Docker virtualization that facilitates deployment across different environments	Poor performance on Extract, Transform, Load processing; relatively inefficient (bottleneck) FHIR[a] transformation; and does not support real-time data processing
Haarbrandt et al [24], 2018	Integrating and transforming health data for oncology, cardiology, and infection control	Open-source platform that allows for patient-level data sharing	Does not support real-time data processing
Helm et al [43], 2022	Builds interoperability between FHIR and BPMN[b]	Supports BPMN clinical process models and improves explainability	Lacks some functionalities of the systems when used independently
Khalilia et al [25], 2015	Clinical predictive modeling using web services via HL7[c] FHIR standards	Maintains good performance across many different algorithms	Does not support real-time data processing
Kopanitsa [44], 2019	Connects multiple health data systems	Has clear, effective workflows	Does not support real-time data processing
Marteau et al [45], 2022	Increases availability of clinical pediatric data using OMOP[d] on FHIR	Implementation across multiple local environments	Not yet tested on real-word applications
Metke-Jimenez et al [46], 2018	Data searching, upgrading, and analyzing within multiple concept and category maps.	Syndication models automatically update the data	Does not support real-time data processing
Semenov et al [47], 2019	Clinical predictive analytics with text outputs to physicians and patients	Produces free-text outputs and graph visualizations pertaining to model recommendations	Limited support for real-time data processing.
Thiess et al [17], 2022	Application for support of shared decision-making in context of drug-drug interactions	Embedded interoperability functions within modular CDSS[e] architectures	Performance testing limited to electronic health record training module
Xiao et al [41], 2022	Enables FHIR and OMOP interoperability with generated clinical knowledge graphs	Semantic foundation for development of explainable tools	Future iterations will require expansion of mapping systems

[a]FHIR: Fast Healthcare Interoperability Resources.

[b]BPMN: Business Process Model and Notation 2.0.

[c]HL7: Health Level 7.

[d]OMOP: Observational Medical Outcomes Partnership.

[e]CDSS: clinical decision support system.

Several papers addressed the challenge of integrating data from heterogeneous sources. Haarbrandt et al [24] proposed a platform that addresses this problem by developing techniques for converting disparate sources to FHIR standards prior to integration. The system is protected via fine-grained use-and-access control mechanisms that ensure secure data transmission among participating data sources. Metke-Jimenez et al [46] proposed an alternative approach to integrating several ontologies into a single web ontology language, allowing for updates to the ontology without changing the underlying data. For example, one could update the definition of *sepsis* and readily find all patients meeting the new definition. Distributed processing systems can be further enhanced via compartmentalization. Kopanitsa [44] and Semenov et al [47] developed a microservice platform that connects multiple systems via FHIR APIs. This platform was used to successfully deploy 400 CDSS models and 128 Bayesian diagnostic models in real time. Important to precision medicine, genomics data can now be linked to FHIR clinical data; 2 groups have created interoperability between the Variant Call Format for next-generation sequencing and FHIR [13,14].

Clinical information systems can aid in medical research, if properly designed. Although a prototype system proposed by Khalilia et al [25] ran 9 different machine learning models to generate data-driven, patient-level predictions, it lacked a researcher interface for the development and training of new models. In contrast, the KETOS platform proposed by Gruendner et al [14] allows researchers to request data sets, define cohorts, develop models, and deploy them as a web service. Both systems use Extract, Transform, Load pipelines to convert EHR data from their native format to the OMOP common data model format before storage. The KETOS platform's comprehensive approach to data management and model deployment can aid researchers with limited backgrounds in data science.

Auxiliary Modules and APIs

Artificial intelligence clinical information systems depend on robust and secure APIs to interact with the clinical environment. APIs define quality and security standards for each type of interaction with external systems (eg, EHR systems, web browsers, and medical devices). Article summaries are shown in Table 3.

Table . Summary of auxiliary modules and application programming interfaces (APIs).

Source, year	Functionalities	Strengths	Limitations
Altamimi [23], 2016	Provide security for FHIR[a] functions to ensure patients' privacy	Policies can be adjusted for circumstances (eg, emergency medical conditions can override privacy constructs)	There is no description of a user-side module, which would be necessary for clinical application
Alterovitz et al [48], 2015	Link clinical and genomic data with an FHIR-compliant API for clinical decision support	Ensures consistent semantics in clinical data and handles multiple types of genomic data	Effects of clinical decision support apps on decision-making and outcomes were not reported.
Dolin et al [49], 2021	Variant Call Format–to–FHIR genomic standard converter	Readily deployable to CDSS[b]	Limited independent data analysis and does not support real-time data processing
Kasparick et al [50], 2019	Model an FHIR-compliant protocol for artificial intelligence–based systems	Supports multiple devices and multiple domains of data	No clinical testing
Kopanitsa and Ivanov [51], 2018	FHIR-compliant APIs for data modeling	High data exchanging efficiency	No clinical testing
Gabetta et al [52], 2021	FHIR-on-OMOP[c] platform to support data storage and retrieval	Use of standard OMOP vocabularies	No clinical testing
Guinez-Molinos et al [53], 2021	Reports COVID-19 test results to central authority	Interoperable and portable; functionally verified with a pilot study	Developed using a predecessor system
Mandel et al [26], 2016	Updating an API platform with FHIR standards	Improves API interoperability	Establishes feasibility, but effects on clinical decision-making and outcomes are unknown.
Rafee et al [54], 2022	LOINC[d]-mapped core data set for eligibility screening	Rapid EHR[e] screening for patient recruitment	Relied on expert labeling, which limits scalability
Wood et al [55], 2021	Allows sharing of patient data among care provision sites for hematologic disorders	Compatible across EHRs	Framework alone; awaiting evidence of implementation
Yoo et al [56], 2022	Method for integrating CDSS applications with EHR	Transformation of EHR data into FHIR format for input into a reasoning engine	No validation of performance indices and usability of tested models

[a]FHIR: Fast Healthcare Interoperability Resources.

[b]CDSS: clinical decision support system.

[c]OMOP: Observational Medical Outcomes Partnership.

[d]LOINC: Logical Observation Identifiers Names and Codes.

[e]EHR: electronic health record.

Of the included articles, 5 described auxiliary modules and APIs. Mandel et al [26] applied FHIR standards to the SMART platform, improving its interoperability by providing standard authentication, authorization, and profiling. The prototype genomics standard developed by Alterovitz et al [48], meanwhile, is currently in trial use to facilitate the consistent integration of clinical and genomic information through SMART-on-FHIR application. The application developers found the FHIR v4.0.1 specification easy to leverage, even without prior experience with FHIR.

Although FHIR has predefined resources and mechanisms for transmitting orders and values, methods for creating and validating orders are not predefined. To address this issue, Kopanitsa and Ivanov [51] proposed an FHIR-based mechanism for integrating laboratory and hospital information systems. The system generated laboratory orders, using the available tests in the laboratory information system, and prompted the user for relevant information (such as how many laboratory samples should be collected and when they should be collected). It is challenging to make clinical information systems both highly interoperable and secure without compromising data workflows. SecFHIR is an XML-based security approach to FHIR resources. Using schema permissions built into XML documents, Altamimi [23] generated robust security profiles that were context-aware (eg, privacy constraints can be overridden in emergency care situations).

Timely data availability is another barrier to implementing CDSSs in high-acuity environments. Kasparick et al [50]

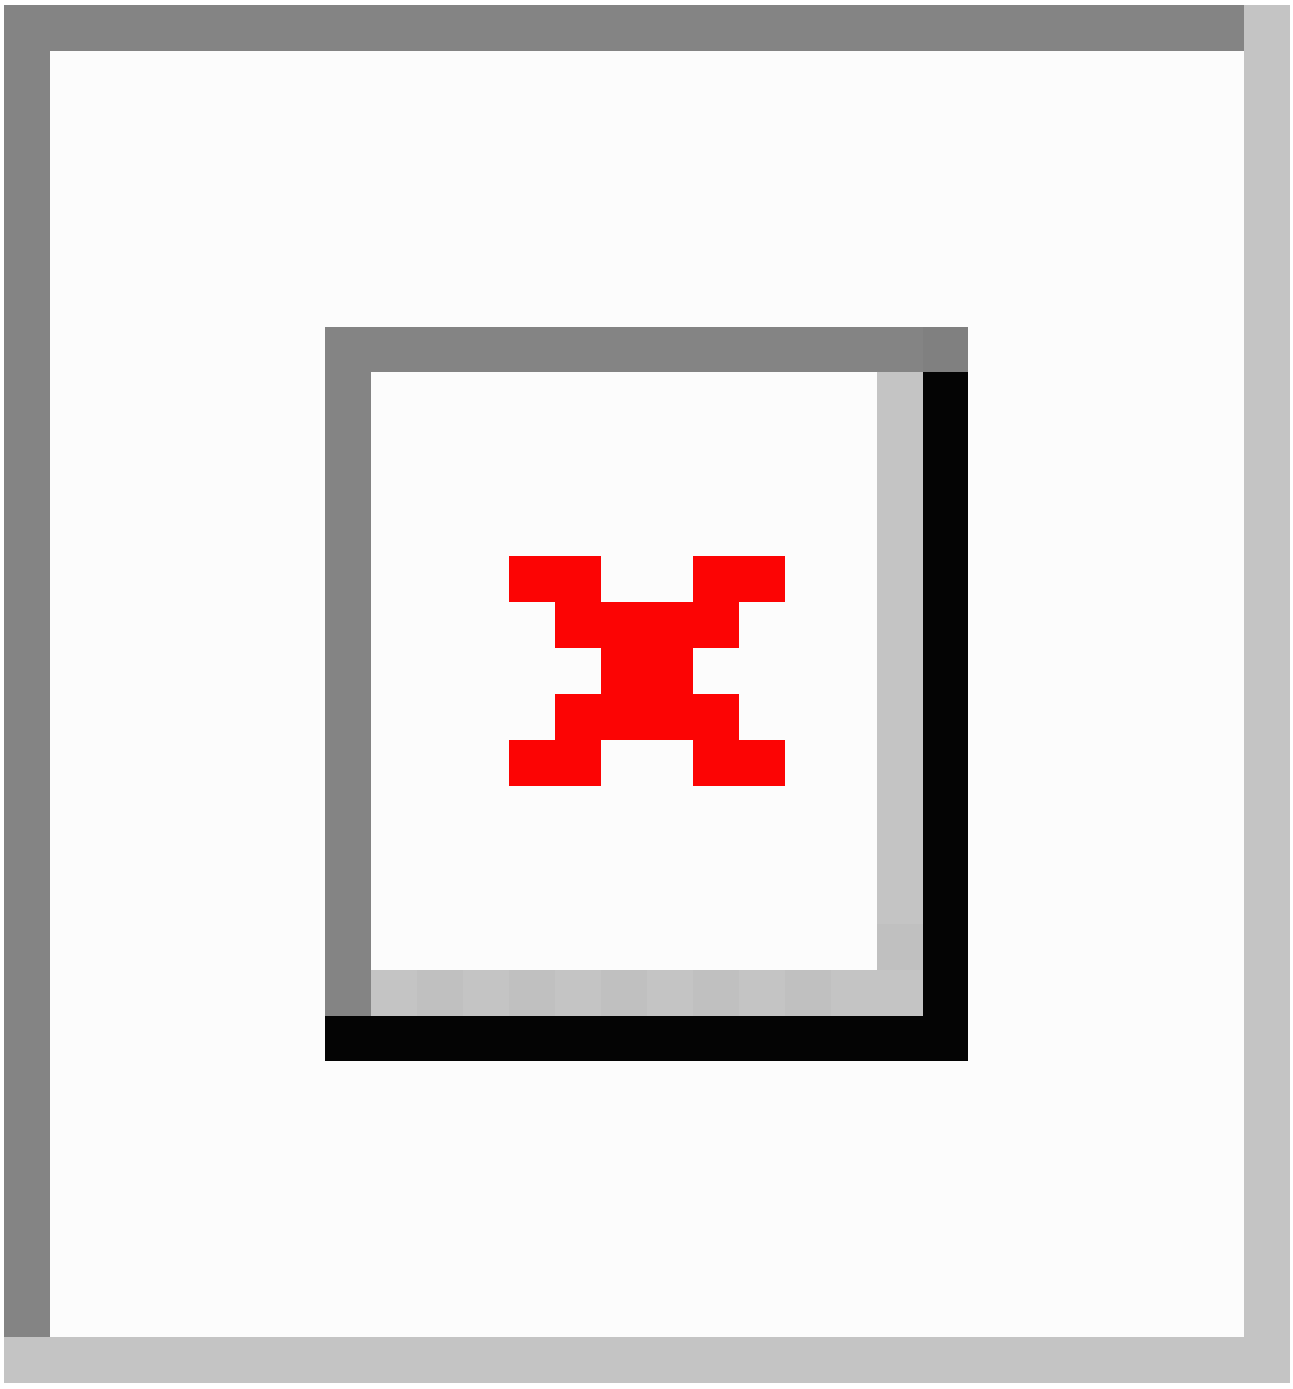
proposed a reference model to address the timeliness challenge by connecting medical devices to FHIR servers. This approach allows the APIs to function as data sources for predictive analytic and decision support systems. By using these methods, clinical information systems can maintain high interoperability and security without compromising data workflow. This has allowed for the development of disease-specific data hubs, which facilitate research on rare conditions or for reporting the results of COVID-19 polymerase chain reaction tests from disparate testing sites to a central authority [53,55]. CDS hooks are another technology that permit the integration of EHR data into external health care applications [57]. Used in collaboration with SMART on FHIR, CDS hooks are triggered by a specific action within the EHR (ie, ordering a medication). The CDS hooks then link the corresponding EHR data to an environment of decision support applications [58]. These CDS applications can then push recommendations in the form of "CDS cards" to the clinician. These technologies are currently being tested in real-word settings [59,60].

Discussion

Key Findings

Although significant progress has been made in the field of FHIR data standards, this scoping review demonstrates that most CDSSs lack interoperability and actionable content. Several modules and APIs demonstrate the potential to enhance these systems, but they were not comprehensively integrated into the existing clinical workflows or were not validated on external patient populations. These limitations collectively reveal several opportunities to improve on existing methods to produce ideal clinical information systems, as illustrated in Figure 1.

Figure 1. Sample model of a proposed machine learning–enabled clinical information system using FHIR data standards. AI: artificial intelligence; API: application programming interface; FHIR: Fast Healthcare Interoperability Resources; HL7: Health Level 7; IoT: Internet of Things; OMOP: Observational Medical Outcomes Partnership.



Foundational Infrastructures Tailored to Individual Needs

Ideally, clinical information systems would function as innovation hubs for patient care and health care research. Due to the proprietary nature of hardware and software systems in institutions, infrastructure components (eg, data transformation, model development, authentication, and monitoring) are often painstakingly created de novo. Platforms, such as KETOS, however, can enable the sharing of core infrastructure, greatly accelerating the development and deployment of applications that are tailored to the needs of individual researchers, groups, and projects [14]. This "health care application development hub" would be shared for different applications to reuse models and for data processing and analyzing services.

Facilitating Interoperability Among Data Systems

Interoperability represents the goal of successful, cross-institutional sharing of data without additional, special effort. This remains in contrast to the current environment of fragmented data systems. Several elements of the current system impede progress toward integration and should be addressed. Sources of patient health information are numerous. At the point of data collection, clinicians may opt to store information in separate departments, erroneously duplicate patient descriptors, preferentially format or describe data, or use older data standards

(HL7 v2 and v3). Further complexity may arise from the use of siloed systems, as exemplified by legacy systems built with local, stand-alone data conventions and incompatible ontologies [61]. The road to full interoperability is therefore paved with standards built to define, represent, transfer, and protect data as they travel between actors. Common communications standards, such as FHIR, have provided a useful framework for standardizing data transmission while maintaining semantic integrity at the patient level [15,56]. Importantly, these standards are built to mobilize data from legacy systems, making closely held data more publicly available [17]. By using OMOP-on-FHIR algorithms, pediatric data from Shriners Hospitals for Children can now be shared more widely by researchers [45]. More recently, 2 studies have examined the use of deep learning and transformer techniques to convert data elements in the EHR to interoperable FHIR standards, with subsequent application in prediction models [21,62]. Automation in data capture has the potential to reduce the costs and time associated with manual extraction.

Overcoming Organizational Resistance to Interoperability Standards

Despite the benefits of an interoperable health data ecosystem, stakeholders are rarely incentivized to implement data standards. Organizational resistance to interoperability may stem from cultural differences, unfamiliarity with new technologies, or the fear that a newly adopted information-sharing standard may quickly become obsolete [63,64]. Among organizations, concerns regarding the loss of autonomy, a lack of trust, and the failure to realize financial gains impede interoperability and lead to so-called "information blocking." The policies contained within the 21st Century Cures Act aim to improve information flow among actors in the system [65,66]. Apple, Google, and Samsung now have patient-facing health records that were developed along with FHIR standards to comply with these policies. In addition, while implementation models exist to help streamline the adoption of CDSSs, they contain important methodical flaws [67].

Hiring Specialists to Manage Standards Adoption

Unfamiliarity with interoperability standards may represent a substantial hurdle to adoption and subsequent interoperability. This challenge creates demand for subject matter experts who are familiar with the architecture, function, and implementation of data standards. Such experts must be able to anticipate the specific challenges of adapting their particular legacy systems to the interoperable standard but also recognize the benefit of successful adoption to guide organizational buy-in [68].

Timely Data Acquisition

The need for timeliness in data sharing is driven both by data availability and by opportunities for real-time treatment support. An obvious example of this can be seen with continuous glucose monitoring units for patients with diabetes, which provide a regular source of data that can be implemented immediately to adjust insulin therapy [69,70].

System scalability is also essential to this task. Many of the systems evaluated in this review cannot scale in real time, as data volume or velocity increases dynamically (eg, processing 1000 patients in real time vs processing 100 patients in a static, retrospective training cohort). When scalability is impaired, predictions may not be delivered in time to augment clinical decision-making. Health Insurance Portability and Accountability Act (HIPAA)–compliant cloud platforms can scale allocated resources on demand. Therefore, optimal clinical information systems must offer scalability that is commensurate with the expected volume and velocity of data.

Minimizing Discoverable Patient Data

Each institution has policies that comply with municipal and federal security and privacy laws, making it challenging to share and aggregate data across multiple institutions. These challenges have been met with creative methods for aggregating multicenter data while maintaining patient privacy. One such method is to request only the minimum necessary information. This approach is emphasized heavily in the HIPAA and exemplified by El-Sappagh et al [28], who described a system that requests only the required EHR data elements for a specific patient. Other such mechanisms include authorization programs (enables specialized control over access to patient data), https, and WebSockets (Internet Engineering Task Force; provides secure communication over networks).

Alternatively, models can benefit from the knowledge derived from other data sets—usually in the form of model gradients or coefficients—without sharing the underlying data. This is known as *federated learning*—a system that trains on many local models with the same architecture and then aggregates the knowledge derived from each center into a global model (Figure 1). Although such an approach greatly reduces security and privacy risks by keeping the source records under the control of each local institution, even the gradients themselves pose a minor risk due to privacy leakage [28,71-75]. This risk, however, can be further reduced via the automated obfuscation of high-risk records or by adding noise to the gradients and coefficients before transmitting them to the central model. Given these advantages, federated learning is poised to supplant other methods for ensuring the data security and privacy of clinical information systems.

Finally, the recent explosion of large language models has raised further concerns regarding data privacy, as they are trained on clinical notes. This is an active field of study with multiple avenues for further research [76,77].

Conclusions

Machine learning–enabled clinical analytic and decision support systems have the potential to improve health care by automating standardized workflows and augmenting clinical decision-making. Nevertheless, most CDSSs lack interoperability and evidence of clinical utility. Common data models and interoperable data management platforms can address these limitations, but most intelligent clinical platforms are also compromised by the inadequate scalability for supporting real-time data processing. Existing clinical information systems could be improved by using foundational code infrastructures, common data models, and secure data processing and analytics on real-time platforms. Further progress in implementing these elements can generate information

systems that improve care by helping patients, caregivers, and clinicians make effective, well-informed clinical decisions.

Abstract

Background: Clinical decision support systems (CDSSs) are important for the quality and safety of health care delivery. Although CDSS rules guide CDSS behavior, they are not routinely shared and reused.

Objective: Ontologies have the potential to promote the reuse of CDSS rules. Therefore, we systematically screened the literature to elaborate on the current status of ontologies applied in CDSS rules, such as rule management, which uses captured CDSS rule usage data and user feedback data to tailor CDSS services to be more accurate, and maintenance, which updates CDSS rules. Through this systematic literature review, we aim to identify the frontiers of ontologies used in CDSS rules.

Methods: The literature search was focused on the intersection of ontologies; clinical decision support; and rules in PubMed, the Association for Computing Machinery (ACM) Digital Library, and the Nursing & Allied Health Database. Grounded theory and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines were followed. One author initiated the screening and literature review, while 2 authors validated the processes and results independently. The inclusion and exclusion criteria were developed and refined iteratively.

Results: CDSSs were primarily used to manage chronic conditions, alerts for medication prescriptions, reminders for immunizations and preventive services, diagnoses, and treatment recommendations among 81 included publications. The CDSS rules were presented in Semantic Web Rule Language, Jess, or Jena formats. Despite the fact that ontologies have been used to provide medical knowledge, CDSS rules, and terminologies, they have not been used in CDSS rule management or to facilitate the reuse of CDSS rules.

Conclusions: Ontologies have been used to organize and represent medical knowledge, controlled vocabularies, and the content of CDSS rules. So far, there has been little reuse of CDSS rules. More work is needed to improve the reusability and interoperability of CDSS rules. This review identified and described the ontologies that, despite their limitations, enable Semantic Web technologies and their applications in CDSS rules.

KEYWORDS

clinical decision support system rules; clinical decision support systems; interoperability; ontology; Semantic Web technology

Introduction

For more than half a century, clinical decision support systems (CDSSs) have been developed and used in clinical care delivery [1-5]. Some early CDSS examples include Dialog [6], INTERNIST-1 [7-9], Quick Medical Reference [8], and Iliad [10-12]. The effectiveness of CDSSs in clinical care has been established [13-15], with some pioneering researchers' work on CDSS effectiveness particularly noteworthy [16]. Researchers have examined CDSS users' and developers' experiences, discussed their CDSS vision for the future [17], and recommended best practice guidelines in CDSSs [18-22]. Meanwhile, the challenges of CDSSs have been well documented [23]. Meeting clinician information needs is one way a CDSS can help health care providers improve clinical care quality. Many studies, such as Infobutton [13,24], have demonstrated the effectiveness of CDSSs in this aspect. CDSSs are currently routinely used in clinical care, with rates ranging from 68.5% to 100% in primary care settings based in offices [25] in the United States as part of electronic health record (EHR) systems. CDSSs can take many forms, including but not limited to reminders for preventive services (eg, immunizations and screening tests) [26-28], alerts for drug-drug interactions [22,29,30], diagnostic or treatment plan recommendations [31-33], clinician content assistance [34-38], and recommendations for adhering to current clinical practice guidelines [39-41]. CDSSs have played an important role and are widely used in practice to provide safer and better clinical care services.

CDSS rules, which function similarly to the human central nervous system, direct the behaviors of a CDSS during operations by incorporating patient data, contextual information, and medical domain knowledge. The central role of CDSS rules is a decisive factor in the relevance and usefulness of a CDSS in the overall clinical workflow, which impacts whether a CDSS is adopted and routinely used. CDSS rules can be written in Arden syntax [42], Semantic Web Rule Language (SWRL), Jess, Jena, and other programming languages, and the processes are labor intensive. Only specially trained personnel are qualified to write such rules. Moreover, regular updating of CDSS rules is required to keep CDSSs relevant and useful in clinical care delivery. However, the process of developing, updating, and maintaining CDSS rules is time-consuming and resource intensive [4,43], making it difficult for both large institutions and resource-constrained small-scale practices. CDSS rule usage data, such as rule fire rates, overwrite rates, successful rates, and user feedback data, can be collected to improve and customize CDSSs and manage CDSS rules. Typically, CDSS rule maintenance entails adding, deleting, and updating CDSS rules.

Ontologies have been successfully applied to generate and supply domain knowledge in the use, reuse, sharing, and interoperability of information. Ontologies are seen as promising solutions to the challenges of managing and maintaining CDSS rules across institutional boundaries. The Semantic Web is a technology enabled by ontology [44] that is critical in information sharing and reuse [45,46], medicine [47], and CDSSs [48,49]. Although there are numerous definitions of ontology, we used Gruber's definition in this manuscript: "an ontology is a specification of conceptualization" [45]. Interoperability has been identified as a major challenge for health care information technologies, particularly when it comes to sharing health information across institutional or national boundaries. Ontologies have the potential to shorten the interoperability gap.

Reusing and sharing CDSS rules are important, but they are not yet routine operations; thus, we conducted this systematic literature review. This study aims to expand on the current state of using ontologies in CDSS rules by conducting a systematic review of the literature on the intersection of CDSS rules, Semantic Web technologies (particularly ontologies), and use of ontologies in CDSSs. The review is expected to provide a comprehensive view of using ontologies in CDSS rules, with granular details. The results could serve as a basis to form a knowledge framework of the topic that may inspire future research. The research question we intend to answer with this systematic literature review is as follows: What is the current state of using semantic technologies, particularly ontologies, to leverage CDSS rule interoperability? Furthermore, the manually annotated results of selected publications could serve as gold standards for automatically identifying relevant entities in the literature.

Methods

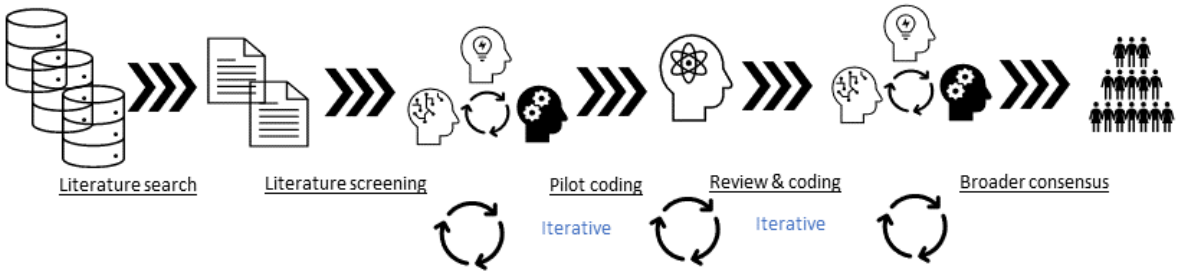
Databases and Search Strategies

Figure 1 illustrates the general workflow we used to conduct this literature review. An initial set of literature searches was conducted on June 2, 2020, which was followed by a review and discussions. The reviewers (XJ, HM, and YG) refined and agreed with the search strategies and searched PubMed, the Association for Computing Machinery (ACM) Digital Library, and the Nursing & Allied Health Database (NAHD) for literature, using the search strategies mentioned below. A final search was conducted on January 5, 2022, in the 3 literature databases as an update.

For PubMed, the following search was conducted: (clinical decision support systems[MeSH Terms]) AND (ontolog*[Title/abstract] OR rule*[Title/abstract]). For ACM Digital Library, the following search was conducted within the scope of the ACM Guide to Computing Literature: [[Publication Title: "clinical decision support*"] OR [Publication Title: cds*]] AND [[Publication Title: ontolog*] OR [Abstract: ontolog*] OR [Publication Title: rule*] OR [Abstract: rule*]]. For the NAHD, the following search was limited to peer-reviewed publications: mesh(clinical decision support) AND (ti(ontology)

OR ti(ontologies) OR ab(ontology) OR ab(ontologies) OR ti(rule) OR ti(rules) OR ab(rule) OR ab(rules)).

Figure 1. General workflow of the systematic literature review.



Inclusion and Exclusion Criteria

The inclusion criteria were as follows: text was written in English; full-text publication was available; ontologies were designed to be implemented or were already implemented in CDSSs, particularly related to CDSS rules; content included the granularity of CDSS rules; ontologies were designed to be integrated or were already integrated with health information systems (eg, EHRs), either in a production system or a prototype, with at least one architecture diagram, applied in clinical domains or designed for clinical domains to support health care providers; the publication was peer-reviewed; and details on the integration of CDSSs and EHRs were present for evaluation studies.

The exclusion criteria were as follows: only CDSS rules were included, regardless of the stage of the CDSS rule lifecycle (ie, development, identification, refinement, validation, evaluation, or implementation) or there was no mention of integration or ontologies; only ontologies were developed, evaluated, and validated, or there was no mention of integration or a CDSS; the system was designed without mentioning the granularity of CDSS rules or ontologies; and nonclinical decisions, such as administrative or management decisions (eg, supply chain management), were described.

General Workflow for Screening Papers

The first 100 papers were screened by all 3 authors (XJ, HM, and YG) independently. The first 100 retrieved papers were initially screened by 1 author (XJ) to draft initial inclusion and exclusion criteria. The inclusion and exclusion criteria were refined and adjusted by 2 authors (HM and YG) during the iterative screening, review, analysis, and discussions. Further, 2 authors (HM and YG) replicated the screening, and all 3 authors discussed and validated the results. The rest of the papers were then screened by at least 2 authors (XJ and HM, or XJ and YG) independently to determine inclusion. Disagreements were discussed and resolved via iterative rounds of group meetings.

The screening and manual review processes were conducted independently and approved by at least 2 authors. The literature was first screened based on titles, abstracts, and full-text publications when needed. The papers that were included were then manually coded to provide more content analysis and synthesized evidence. The final results were shared among all the authors. All disagreements were settled through group discussions.

Reviewing, Coding, Analyzing, and Synthesizing Processes

We followed grounded theory during the reviewing and manual coding of the included publications. One author (XJ) randomly selected 10 papers from the included 81 papers to start the coding (annotating) based on the focus of this literature review. ATLAS.ti 9 (desktop and web versions; ATLAS.ti Scientific Software Development GmbH), a qualitative data analytic tool, was used for coding. The coding results were discussed by 3 authors (XJ, HM, and YG). The discussion results formed the first draft of codes and code groups (Multimedia Appendix 1), that is, data items. Three coders (XJ, HM, and YG) then reviewed and coded the first 40 of the included papers using the initial principles and code groups, and added new codes and code groups when needed. Then, a second set of meetings was used to obtain consensus on updated principles and code groups. Refined codes and code groups were used to code the remaining papers. Every paper was coded by at least 2 coders independently. The coding results were then compared, and any discrepancies were resolved by group discussions. The code groups and codes were revised, consolidated, and updated during each discussion. Multimedia Appendix 2 presents the refined code groups and examples. Data items emerged during the review and were refined via discussions instead of predefinition before reviewing. Multimedia Appendix 3 lists all included papers.

After coding, the literature was analyzed and synthesized with a focus on several aspects, including CDSS application domains, CDSS mechanisms used in clinical settings, CDSS rule formats, authoring, management, and the roles of ontologies. The 3 authors worked together in an iterative process of analysis and synthetization. After obtaining consensus among all 3 authors, the results were then shared and discussed among all authors. Any concerns, confusions, or disagreements among the authors were resolved through iterative discussions. We followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist [50] for reporting the systematic review with all relevant items (Multimedia Appendix 4 and Multimedia Appendix 5).

Results

Overview

By January 5, 2022, literature searches retrieved 1235 publications from 3 sources. After removing duplicates and examining according to the inclusion and exclusion criteria, 81

publications (Multimedia Appendix 3) were included in the final review and analysis [26,27,29,31-33,51-125]. Figure 2 depicts the literature search, screening, selection flow, and results. Figure 3 summarizes the main components covered by the literature review and the summary findings, and serves as an initial knowledge framework on CDSSs, CDSS rules, and ontology applications in CDSSs.

Figure 2. Flowchart of the literature search, screening, and selection. ACM: Association for Computing Machinery.

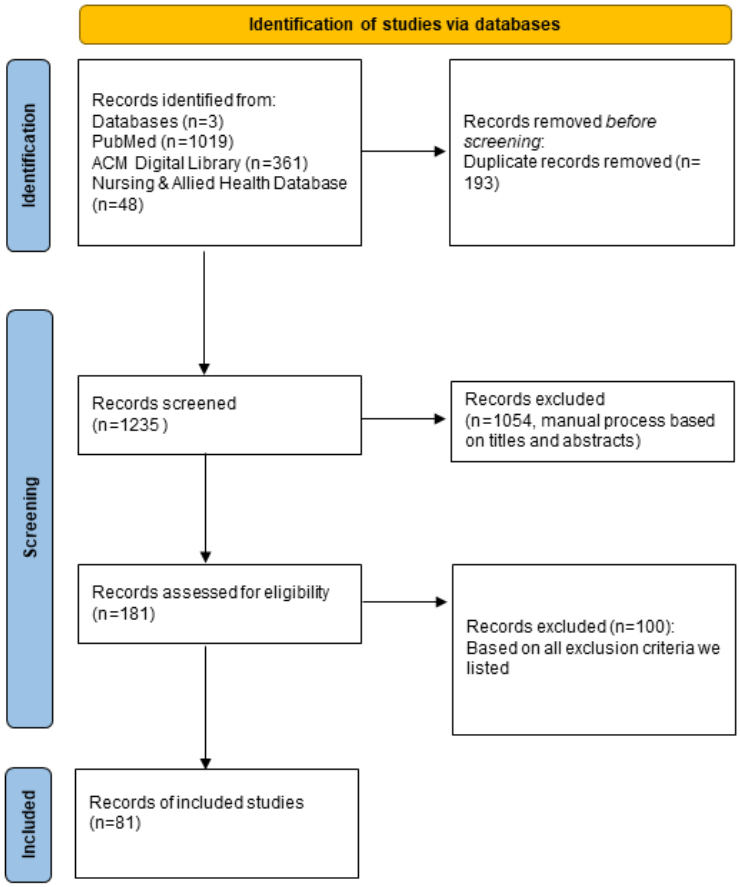


Figure 3. Initial knowledge framework on clinical decision support systems (CDSSs), CDSS rules, and ontology applications in CDSSs. ICD-10: International Statistical Classification of Diseases and Related Health Problems, 10th Revision; LOINC: Logical Observation Identifiers Names and Codes; MLM: medical logic module; OWL: Web Ontology Language; SNOMED CT: Systematized Nomenclature of Medicine-Clinical Terms; SWRL: Semantic Web Rule Language; UMLS: Unified Medical Language System; XML: Extensive Markup Language.

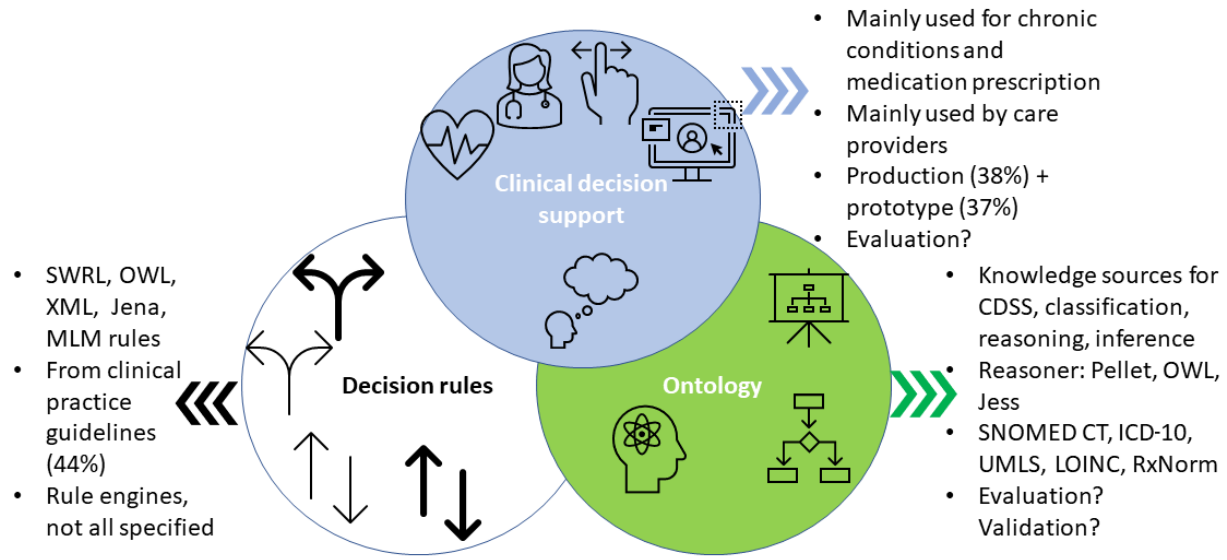

The majority of the publications (73/81, 90%) included in the review were from PubMed, a dominant source. After removing duplicates, the ACM Library added 8 new publications. After cleaning, discussion, and consolidation, 30 code groups and

221 final codes were used in ATLAS.ti (Multimedia Appendix 2). These codes and code groups guided our analysis and synthesis of the results. Multimedia Appendix 6 shows a word cloud image generated by ATLAS.ti that reflects the codes coded in the publications included.

PRISMA 2020 is designed to guide the reporting of outcome-oriented studies. Our systematic literature review focused on the design, development, and implementation of CDSSs, particularly related to CDSS rules and ontologies. Therefore, effect measures or certainty assessments were irrelevant items. We reported 19 categorical items (out of 27 categorical items, 26 items out of 42 items; Multimedia Appendix 4) for the full-text papers and 10 for the abstracts (out of 12 items; Multimedia Appendix 5).

Results Related to CDSS Characteristics

Over one-third (29/81, 36%) of CDSSs were designed and used for chronic condition management, prediction, or risk assessment, including but not limited to type 1 and 2 diabetes, hypertension, and asthma. Medication prescriptions (13/81, 16%), such as medication ordering, detection of adverse drug events, drug-drug interactions, and cancer care (8/81, 10%), were also significant application domains. Multimedia Appendix 7 illustrates the clinical domains of CDSSs within the included publications. Most CDSSs were designed for health care providers, but only 11% (9/81) were intended for patients. Most CDSSs provided recommendations, suggestions, alerts, or reminders. Among all the items in our comparison (Multimedia Appendix 8), EHR evaluation studies within the operational systems or prototypes exhibited the least complete information. Evaluations of CDSSs have been listed in multiple columns in Multimedia Appendix 8. Some CDSSs were implemented in production systems (31/81, 38%), whereas others were implemented in prototypes (30/81, 37%), which included experimental systems. Multimedia Appendix 8 summarizes the key features of CDSSs identified in the publications. In all tables, we adopted the original terms used in the corresponding papers. Some papers, for example, referred to “physicians” as CDSS users, whereas others referred to “clinicians” as CDSS users.

Results Related to CDSS Rules

Most CDSS rules were written in Web Ontology Language (OWL; 11/81, 14%), Extensive Markup Language (XML; 10/81, 12%), SWRL (9/81, 11%), Jena rules (5/81, 6%), and medical logic module (MLM; 3/81, 4%). Moreover, 2 publications [117,119] used N3 Language and 2 [90,117] used Natural Rule Language (NRL). Multimedia Appendix 9 presents 54 publications with more details on the CDSS rules, that is, publications that can fill out 3 or more cells (except for authors and publication year).

The most significant CDSS rule source is from clinical practice guidelines (36/81, 44%). Other sources of CDSS rules included domain expert input, publications (eg, textbooks and papers), multimedia sources, and internet resources. Data mining results were involved in CDSS rule sources [67,73]. CDSS rule authoring and editing tools were not routinely specified in the publications. Protégé [115] was the most prevalent tool to edit and author CDSS rules. Several publications also described developing authoring and editing tools [57,65,91].

There was a lack of technical details regarding rule engines, among which Jena (6/81, 7%), inference engine (6/81, 7%), Jess (4/81, 5%), JBoss (3/81, 4%), guideline engine (3/81, 4%), Drools (2/81, 3%), and Bayes (2/81, 3%) were frequently mentioned. Multimedia Appendix 9 summarizes how the CDSS rule (operation) works in a simplified manner. Many publications did not specify the working mechanism of CDSS rules within the EHR, electronic medical record (EMR), or hospital information system (HIS) context.

The majority of the publications did not appear to be focused on interoperability. Few papers that discussed interoperability (Multimedia Appendix 9) used HL7 CDA (Health Level 7, Clinical Document Architecture) or HL7 FHIR (Health Level 7, Fast Healthcare Interoperability Resources) standards. However, it is worth noting that such HL7 measures were not specifically designed for CDSS rules but rather for CDSS input and output.

Furthermore, some publications lacked necessary information for explaining the mechanisms of the systems, which can be critical barriers to reproducibility. Some publications lacked critical information, such as CDSS architecture diagrams; CDSS rule engines; CDSS rule languages; backend management methods for CDSS rules; and integration mechanisms among CDSS rules, ontologies, and EHR, EMR, or HIS systems.

Results Related to Ontologies

In the included publications, ontologies were primarily used as knowledge sources for CDSSs (32/81, 40%) to facilitate classification (7/81, 9%), reasoning, and inference (6/81, 7%; eg, identification recommendations or relationships). Moreover, ontologies were used to specify CDSS rules (12/81, 15%) or to provide general knowledge for the EMR or EHR systems. These 2 applications overlapped in some cases (19/81, 24%; ie, the ontologies were used to provide specified CDSS rules and general knowledge).

In the included publications, the terms “reasoner” and “rule engines” were used interchangeably. *Reasoner*, in our opinion, refers to the inference for a consistency check or classification for an ontology. A reasoner can be part of an ontology tool or can be external. For CDSSs, a *rule engine* is the mechanism that generates or provides recommendations by incorporating a patient’s data, contextual information, and medical knowledge (typically from an ontology or knowledge base). However, we kept the authors’ choice of terms in tables without modification. Among the included publications, the most common reasoners were Pellet (11/81, 14%), Jena (4/81, 5%), OWL reasoner (3/81, 4%), Jess (2/81, 3%), and the Euler/EYE inference engine (2/81, 3%).

The content and code systems used to represent the content should be included as ontology sources. The content could come from a popular textbook or a clinical practice guideline. The content can be coded in a specific code system, such as SNOMED CT (Systematized Nomenclature of Medicine-Clinical Terms). Multimedia Appendix 10 includes code systems that served as ontology sources. The most often

used coding systems among the included publications were SNOMED CT (9/81, 11%), the International Statistical Classification of Diseases and Related Health Problems, 10th Revision (ICD-10; 4/81, 5%), Unified Medical Language System (UMLS; 4/81, 5%), Logical Observation Identifiers Names and Codes (LOINC; 3/81, 4%), and RxNorm (2/81, 3%).

Incomplete information for ontology validation is a common issue shown in the literature. Approximately 20 publications mentioned some validation, including validation or evaluation by domain experts (20/81, 25%). Some ontologies were authored by domain experts [55,63]. Multimedia Appendix 10 provides more information on the roles of ontologies in publications, including publications with 3 or more cells (except for authors and publication year; n=36).

Discussion

Summary of the Results

Although ontologies contribute to the content of CDSS rules and have the potential to facilitate interoperable CDSS rules, our systematic review showed that reusing and sharing of CDSS rules have not been achieved. CDSSs have a wide range of clinical application domains, primarily for health care providers, such as chronic condition management, medication ordering, and cancer care. CDSS rules are primarily based on clinical practice guidelines.

Although reusing and sharing CDSS artifacts are well-recognized challenges [1,109], reusability, customization, and shareability of CDSS rules are not yet a common focus, even in publications focusing on CDSS rule editing [43,126,127]. These are important topics to cover in a literature review. Marco-Ruiz et al [109] demonstrated how to use CDSS artifacts in the Linked Data framework [128] by leveraging Semantic Web technologies, particularly ontology. However, that work was at a higher level, describing concepts without tangible tools implemented in clinical practice. To fill this gap, one approach is to build an upper-level CDSS ontology [129] to encourage the reuse of CDSS rules and demonstrate the potential of ontologies. Our effort is in alignment with their vision, as well as other efforts in reusing and sharing CDSS artifacts [1,109].

Ontologies were not at the center of any early examples of CDSSs [6-12]. An early demonstration of using medical terminology in CDSSs was the adoption of Current Medical Information and Terminology (CMIT) in a diagnostic engine [130,131]. Even under our “loose use of ontology” during our systematic literature search, there was no case in which ontology played a central role in sharing CDSS rules, particularly for rule management and maintenance.

Over the years, CDSSs have been successfully applied in clinical care. Unfortunately, CDSS rules are not yet portable. Making CDSS rules more portable is therefore significant work that could be leveraged by ontologies, and our systematic literature review brings us one step closer to that goal. Marco-Ruiz et al also conducted a very relevant systematic literature review. However, their focus was on the interoperability mechanisms used in CDSSs [132,133]. According to the results of their systematic literature review, 32% of the included papers used ontologies and 46% used standard terminologies. The findings related to ontologies are similar [132,133] to those of our paper. However, we presented a more detailed and thorough analysis of these technologies used in CDSS rules. Nevertheless, both papers concluded that complete CDSS interoperability is not a reality. Thus, additional efforts are required to achieve interoperable and reusable CDSS artifacts, such as CDSS rules.

Interpretation of the Results

Rule engines, which execute rules, patient data, and context information to produce a result, such as an alert or a recommendation, are critical components of CDSSs [1]. Jess, a rule engine and development environment in Java [134], was frequently mentioned in the included publications as a tool for developing rule-based CDSSs. SWRL rules can be converted to Jess rules in the popular tool Protégé, using a plug-in application programming interface (API) SWRLJessTab. Jess rules can be used by the Jess rule engine, which is widely used in rule-based expert systems [134]. In addition to Jess, Jena and Drools were used frequently in the publications included. Jena is a Java API that supports rule-based inference and makes use of resource description framework (RDF) graphs [135]. Jena.java API is a popular framework for managing RDF/OWL descriptions and can handle OWL models [96]. Drools is a business rule management system that includes a rule engine [136]. Drools also has the SWRL API that supports SWRL and Semantic Query-Enhanced Web Rule Language (SQWRL). SWRL can be queried by SQWRL.

Reasoning via a reasoner is a critical characteristic of many ontologies, even though the current reasoning is still in first-degree logic. Reasoning can be used for the following 3 main functions: consistency check, classification, and realization [137]. Several publications specified the classification roles of the ontologies and reasoners (Multimedia Appendix 10). The Manchester University OWL group has curated an updated list of OWL reasoners [137]. Parsia et al [137] compiled and compared the current OWL reasoners and their performances via the competition report. Both Pellet and Jena are popular reasoners (Multimedia Appendix 10), and other reasoners include FaCT++ [98], Z3 Solver reasoner [105], Euler/EYE inference engine [117,119], OWL Horst [109], and OWL Cerebra [63] among the included publications. Among these reasoners, Pellet [138] is Java based, and it can work on SWRL rules and ontologies written in OWL2. SWRL was initially designed as a rule language for Semantic Web technologies [139]. A user needs the rule language and an editor (eg, Protégé SWRL tab) to write, revise, and query the rules. SWRL can be queried by SQWRL (a query language for OWL) or SPARQL (SPARQL Protocol and RDF query language). Reasoners can then be used to conduct reasoning based on the rules and facts defined in the ontology or knowledge base. Protégé-OWL [140] provides an editor for SWRL rules. Protégé SWRL editor is another example.

This review has demonstrated unique insights about CDSS rules, ontologies, and ontology applications, particularly in CDSS rule management and maintenance, and has presented several distinct characteristics that complement the existing literature.

An earlier review [40] focused on clinical decision-making in forming ontologies to support complex cognitive processes and reasoning processes comparing evaluation metrics but did not cover the implementation of EHR, EMR, or HIS systems and the mechanisms of these characteristics.

Significance of the Work

Our systematic review demonstrated the state-of-the-art applications of ontologies in CDSS rules. These applications have a lot of potential for reusing and sharing CDSS artifacts. However, none of the existing papers elaborated or demonstrated how ontologies enable portable CDSS rules. Although some authors recognized this benefit [1,43,109], none have conducted a systematic review. Our literature review thoroughly examined the topic, outlined the current frontlines on CDSS rules and ontology uses in CDSSs, established the knowledge framework, and compiled a comprehensive collection of relevant publications that can inform future efforts to design or improve CDSSs. This systematic review focused on the mechanisms of CDSSs in clinical practices or prototypes, CDSS rules, and ontology roles in CDSSs. The detailed information provided in each included publication (Multimedia Appendix 8, Multimedia Appendix 9, and Multimedia Appendix 10) about the reasoners, rule engines, ontologies, and CDSS rule formats used provided valuable references for designing or improving systems. The side-by-side comparison of publications (Multimedia Appendix 8, Multimedia Appendix 9, and Multimedia Appendix 10) also provided structured guidance for preparing future designs and publications or teaching references on the topics in tangible ways.

Missing Information in the Publications and Our Recommendations

Inconsistent or missing information about CDSS rule languages, CDSS rule engines, and CDSS evaluation details was identified. In CDSS evaluation, there was commonly no information about how the evaluation was conducted or who performed the evaluation. There were also inconsistencies in technical details related to ontology purposes, reasoners, connection mechanisms, or communications between CDSSs and EHR, EMR, or HIS systems. Inconsistent or missing information hampered reproducibility and further improvement of published work. We are obviously not the only group that has identified missing critical information as a problem in technical papers on similar topics [141].

Another missing piece is the evaluation and validation of ontologies or knowledge bases. Only 25% of publications mentioned that domain experts conducted evaluation or validation. A formal assessment or validation is critical to ensure the validity of the results from automated processes for some ontologies (or knowledge bases) derived from other automatic methods (eg, machine learning algorithms). Testing has not been conducted consistently across the publications. Some ontologies were authored by domain experts, which provides greater validity than those involving nondomain experts while constructing ontologies.

Thus, it is recommended that authors include essential technical details in publications. These technical details include CDSS application domains, intended CDSS users, CDSS notification types, CDSS evaluations (what, how, and by whom), CDSS rule sources, CDSS rule languages, CDSS rule engines, CDSS operation mechanisms, ontology use purposes, ontology sources (both content and code systems), ontology validation, reasoners, and connection or communication mechanisms between CDSSs and EMR, EHR, or HIS systems. Authors are highly encouraged to include such details to help readers reference, compare, and increase the reproducibility of the reported work.

Limitations

Our review has limitations. Non-English publications or full-text unavailable publications were not included. Publications that focused only on CDSS rules [43,126,127] were also excluded. Moreover, publications without specifying an ontology component were excluded, although such publications had a similar focus to one aspect of our systematic review. We also noticed that most of the publications on CDSS rule authoring and managing tools were from Partners HealthCare/Harvard Medical School. The strengths of Partners HealthCare/Harvard Medical School were shown. On the other hand, a lack of broad adoption, implementation, or publication of such topics was shown.

When “CDSS” is not specified as a keyword, the search results may exclude publications. For example, our 2 previous papers [142,143] were not found via the search strategy because “CDSS” was not used as a keyword, although the content was undoubtedly within the scope of this review. This challenge is common to how our current literature databases are organized and how we conduct a literature search. Even with MeSH (Medical Subject Headings; the controlled vocabulary for PubMed), publications can still be missed without using commonly recognized keywords. This challenge could be minimized and mitigated by carefully developing an exhaustive list of keywords to maximize the possibilities found during a literature search in the future.

Conclusions

The reuse, management, and maintenance of CDSS rules are critical yet challenging for their clinical application. Although ontologies have been used to contribute to the content of CDSS rules, they have not been used to facilitate CDSS rule reuse and sharing. Building a CDSS ontology, which could be the first tangible step, requires bridging high-level visions and operational efforts. Semantic interoperability remains a major challenge that must be overcome to achieve reuse of CDSS artifacts, including CDSS rules. The realization of semantic interoperability will not only allow for the reuse of CDSS artifacts, which are resource intensive to develop and maintain, but also provide practical insights to achieve interoperable patient records. This has been a long-lost aspect, and health care providers will be able to access patients’ complete records to provide safer and higher quality care every time to every patient. We believe that making CDSS rules interoperable can provide insightful guidance for interoperable patient records.

Incomplete technical details on CDSS rules and ontologies presented in publications should be addressed in future publications by including more detailed information about

architectural diagrams; the mechanisms of connection among ontologies, CDSS rules, and EHR, EMR, or HIS systems; CDSS rule languages; reasoners; rule engines; the validation or authorization of ontologies and CDSS rules; the purposes of ontologies; ontology sources; and the management and maintenance of CDSS rules. Such information can help researchers to optimize design and development while also increasing reproducibility. Finally, the knowledge framework and the summarization of included publications are expected to guide future CDSS improvements and innovations, CDSS rules, and the integration and communication of CDSSs with EHR, EMR, or HIS systems.

Acknowledgments

The authors thank professors James J Cimino, Dean F Sittig, and Adam Wright for their valuable feedback and suggestions on the manuscript. This work was supported by the National Institute of General Medical Sciences of the National Institutes of Health (under award number R01GM138589 and partially under award number P20GM121342). The content is solely the authors' responsibility and does not necessarily represent the official views of the National Institutes of Health.

Data Availability

A request for additional data in addition to the results and appendices of this manuscript can be made to the corresponding author, and the final decision on data release will be made on a case-by-case basis, as appropriate.

Authors' Contributions

XJ, HM, and YG designed the study, conducted the review and coding, drafted the first version, analyzed and interpreted the results, and revised the manuscript significantly. PB, DR, TL, CN, AF, LR, NH, and RG participated in the design of the study, analyzed and interpreted the results, and revised the manuscript significantly.

Conflicts of Interest

None declared.

Multimedia Appendix 1
Initial draft of codes and code groups used in reviewing/coding.
[PDF File (Adobe PDF File), 195 KB - medinform_v11i1e43053_app1.pdf]

Multimedia Appendix 2
Refined version of codes and code groups used in reviewing/coding.
[PDF File (Adobe PDF File), 215 KB - medinform_v11i1e43053_app2.pdf]

Multimedia Appendix 3
List of papers included in this systematic literature review (n=81).
[PDF File (Adobe PDF File), 222 KB - medinform_v11i1e43053_app3.pdf]

Multimedia Appendix 4
PRISMA 2020 item checklist reported in our systematic literature review.
[PDF File (Adobe PDF File), 155 KB - medinform_v11i1e43053_app4.pdf]

Multimedia Appendix 5
PRISMA 2020 for Abstracts checklist reported in our systematic literature review.
[PDF File (Adobe PDF File), 37 KB - medinform_v11i1e43053_app5.pdf]

Multimedia Appendix 6
Word cloud generated from ATLAS.ti based on codes in the included publications .
[PNG File , 353 KB - medinform_v11i1e43053_app6.png]

Multimedia Appendix 7
Bar chart generated from ATLAS.ti showing the clinical domains of clinical decision support systems in included publications.
[PNG File , 122 KB - medinform_v11i1e43053_app7.png]

Multimedia Appendix 8

Basic clinical decision support system profiles in included publications (n=81).
[PDF File (Adobe PDF File), 198 KB - medinform_v11i1e43053_app8.pdf]

Multimedia Appendix 9
Comparison of clinical decision support system rule characteristics in included publications (n=54).
[PDF File (Adobe PDF File), 182 KB - medinform_v11i1e43053_app9.pdf]

Multimedia Appendix 10
Comparison of ontology roles in included publications (n=36).
[PDF File (Adobe PDF File), 151 KB - medinform_v11i1e43053_app10.pdf]

Abstract

Background: Real-world data, such as claims, electronic medical records (EMRs), and electronic health records (EHRs), are increasingly being used in clinical epidemiology. Understanding the current status of existing approaches can help in designing high-quality epidemiological studies.

Objective: We conducted a comprehensive narrative literature review to clarify the secondary use of claims, EMRs, and EHRs in clinical epidemiology in Japan.

Methods: We searched peer-reviewed publications in PubMed from January 1, 2006, to June 30, 2021 (the date of search), which met the following 3 inclusion criteria: involvement of claims, EMRs, EHRs, or medical receipt data; mention of Japan; and published from January 1, 2006, to June 30, 2021. Eligible articles that met any of the following 6 exclusion criteria were filtered: review articles; non–disease-related articles; articles in which the Japanese population is not the sample; articles without claims, EMRs, or EHRs; full text not available; and articles without statistical analysis. Investigations of the titles, abstracts, and full texts of eligible articles were conducted automatically or manually, from which 7 categories of key information were collected. The information included organization, study design, real-world data type, database, disease, outcome, and statistical method.

Results: A total of 620 eligible articles were identified for this narrative literature review. The results of the 7 categories suggested that most of the studies were conducted by academic institutes (n=429); the cohort study was the primary design that longitudinally measured outcomes of proper patients (n=533); 594 studies used claims data; the use of databases was concentrated in well-known commercial and public databases; infections (n=105), cardiovascular diseases (n=100), neoplasms (n=78), and nutritional and metabolic diseases (n=75) were the most studied diseases; most studies have focused on measuring treatment patterns (n=218), physiological or clinical characteristics (n=184), and mortality (n=137); and multivariate models were commonly used (n=414). Most (375/414, 90.6%) of these multivariate modeling studies were performed for confounder adjustment. Logistic regression was the first choice for assessing many of the outcomes, with the exception of hospitalization or hospital stay and resource use or costs, for both of which linear regression was commonly used.

Conclusions: This literature review provides a good understanding of the current status and trends in the use of claims, EMRs, and EHRs data in clinical epidemiology in Japan. The results demonstrated appropriate statistical methods regarding different outcomes, Japan-specific trends of disease areas, and the lack of use of artificial intelligence techniques in existing studies. In the future, a more precise comparison of relevant domestic research with worldwide research will be conducted to clarify the Japan-specific status and challenges.

KEYWORDS

claims; electronic medical records; EMRs; electronic health records; EHRs; epidemiology; narrative literature review

Introduction

Background

Medical claims data, electronic medical records (EMRs), and electronic health records (EHRs) are familiar sources of real-world data (RWD). They are often used secondarily to complement limitations in clinical trials. For example, they can characterize patient subgroups that are excluded from clinical trials by following eligibility criteria such as comorbidities or age. Findings obtained through long-term, naturalistic observations of a large and diverse patient population can be easily generalized to other populations. Other advantages are that these data have high external validity, a single data source can be used for different study purposes, and prospective data collection is not required.

Claims data are electronic records of transactions between patients and health care providers. They include information on bills (claims) submitted by providers (hospitals, clinics, and pharmacies) to third-party payers (health insurance associations). There are already some large-scale commercial and nonprofit claims databases available in Japan [1-6] that aggregate information from multiple health care providers for secondary use**.** Recently, the EMR and EHR data have become widely available. The EMR data are the details of the encounters with patients recorded by physicians through EMR systems. They contain rich clinical information such as laboratory test results, diagnostic images, pathology findings, and patient symptoms. As different facilities may use different EMR systems, domestic EMR data are currently available from ≥1 medical institution. The EHR data are electronic records of all health-related information of individual patients created and managed by clinical professionals, which can be shared and used among various medical facilities. Current EHR databases in Japan include both patient claims data and medical records.

In recent years, claims data, EMRs, and EHRs have been increasingly used in clinical epidemiology studies. Such studies include cost-effectiveness analysis of drugs (including disease burden and assessment of medical technology), risk factor analysis, investigation of the actual status of drugs (including preclinical feasibility valuation, marketability study, and detection of prescription patterns), and evaluation of drug efficacy in actual clinical practice. Because these data are not designed for research purposes, the secondary use requires an understanding of their limitations and the ability to generate clinical questions, epidemiological skills to construct a study design, and statistical skills to analyze retrospective observational data. Previous approaches have addressed the limitations and challenges of using these data [7-12]. Understanding their application status based on these advanced guidelines is essential. However, investigations of existing epidemiological studies based on these data are lacking.

Objective

We conducted a comprehensive narrative literature review to clarify the secondary use of claims, EMRs, and EHRs in clinical epidemiology in Japan. We focused on 7 categories of key information, including organization, study design, RWD type, database, disease, outcome, and statistical method. We expect that this review would help in the design of high-quality epidemiological studies.

Methods

Overview

This is a comprehensive narrative literature review that investigated the secondary use of claims data, EMRs, and EHRs in epidemiology in Japan. Referring to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [13] and procedures used in previous review studies [14-18], we conducted this review by searching for biomedical articles in PubMed.

Information Source

We searched peer-reviewed publications that satisfied the eligibility criteria for this narrative literature review in PubMed from January 1, 2006, to June 30, 2021 (the date of search).

Search Strategy

Keywords used to search PubMed consisted of “real world,” “database,” “claim,” “receipt,” “administrative,” “emr,” “ehr,” “japan,” “electronic medical record,” “electronic health record,” and Medical Subject Headings (MeSH) terms including, “Electronic Health Record,” “Administrative Claims, Healthcare,” “Insurance Claim Review/statistics and numerical data,” and “Japan/epidemiology.” We initially identified related articles by using various combinations of these keywords. The details of the search string are available in Multimedia Appendix 1.

Eligibility Criteria

On the basis of the search strategy, we identified articles whose titles and abstracts satisfied the following three inclusion criteria: (1) involvement of claims, EMRs, EHRs, or medical receipt data; (2) mention of Japan; and (3) published from January 1, 2006, to June 30, 2021. Eligible articles were then filtered out by satisfying any of the following six exclusion criteria: (1) review articles; (2) non–disease-related articles; (3) articles in which the Japanese population is not the sample; (4) articles without claims, EMRs, or EHRs; (5) unavailability of full-text articles; and (6) articles without statistical analysis.

Selection Process

The second author (TT) conducted the article search based on the search strategy. Both authors jointly reviewed all searched publications and performed 2 rounds of screening to identify target eligible articles. In the first round, we removed duplicates and articles that met any of the 6 exclusion criteria by screening the titles and abstracts. Review articles were automatically identified by a section classification model [19] trained on the PubMed 200k data set [20], which classified sentences in the abstracts into 5 sections (introduction, objective, method, result, and conclusion). On the basis of the hypothesis that review articles do not have sentences describing the results, we considered those without result sentences as review articles and removed them from the target articles. Artificially, we filtered out articles that met the exclusion criteria (2)-(5). In the second round of screening, the first author (YZ) reviewed the full text

of the remaining articles and removed those that did not include statistical analysis. The 2 authors double checked the results to ensure accuracy and finalized the eligible articles.

Data Collection

Overview

Investigations of the titles, abstracts, and full texts were conducted for eligible articles, from which 7 categories of key information were collected. The information included organization, study design, RWD type, database, disease, outcome, and statistical methods. Details regarding the classifications for each category are provided in Multimedia Appendix 2.

Automated Data Extraction

Four of these categories, including organization, study design, RWD type, and disease, were automatically extracted by keywords matching on the titles and abstracts. Two authors coded the data collection together.

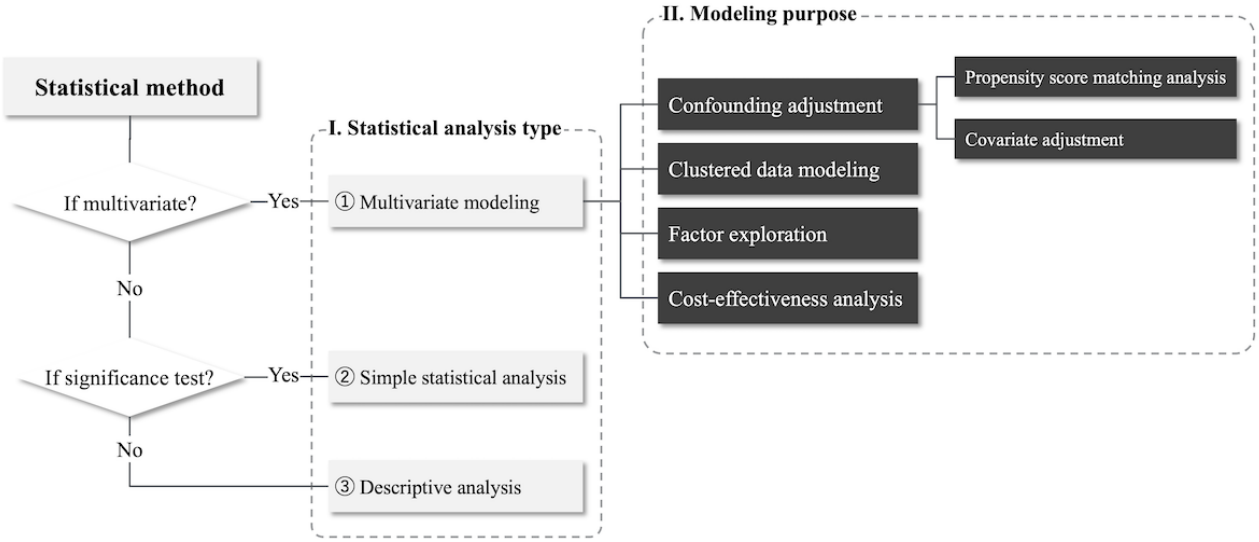
On the basis of authors' address information, organization was classified into 3 groups: "academic," "nonacademic," and "collaboration," which denote that a study was conducted by academia, enterprises (including pharmaceutical companies, biotechnology companies, medical device companies, voluntary associations, and other health care–related companies), or collaboration of academia and nonacademic enterprises, respectively. Study design information was extracted by matching sentences in the abstracts to the categories listed in Multimedia Appendix 2, which consists of cohort studies, case-control studies, case-crossover studies, and cross-sectional studies. Similarly, RWD-type information was extracted by matching sentences in the abstract with 3 keywords, including claims, EMRs, and EHRs. Disease information was classified according to tree codes C01-C26 of MeSH terms [21]. For articles without the corresponding MeSH terms, disease information was collected from their titles using MetaMap [22] and pyMeSHSim [23].

Manual Data Extraction

Subsequently, the first author (YZ) conducted a full-text investigation to collect information on the database, outcome, and statistical method used in the target articles. The second author (TT) cross-checked the results of this data collection.

Database information was collected directly from the full texts. For those articles that did not use a specific database, we categorized them uniformly according to their data source as "other database" or "municipal claims database," where "other database" indicates data from 1 or more medical facilities and "municipal claims database" indicates claims data provided by regional administrative agencies. Because there is no familiar way of categorizing outcomes for RWD studies, we defined 8 classifications of outcomes by referring to the article by Abaho et al [24]. The explanations for these classifications are detailed in Multimedia Appendix 2. We defined a hierarchical approach to collect information on statistical methods in the text. As shown in Figure 1, the method used in these articles was first categorized as multivariate modeling, simple statistical analysis, or descriptive analysis. Then, multivariate modeling was subdivided according to the purposes of confounding adjustment, clustered data modeling, factor exploration, or cost-effectiveness analysis, where confounding adjustment was further classified according to whether propensity score (PS) analysis was conducted.

Figure 1. A hierarchical approach for collecting information on the statistical method.



It should be noted that an article that focuses on multiple diseases, RWD types, study designs, databases, outcomes, or modeling purposes would be double counted for each classification to which it belongs.

Analysis

We performed a descriptive statistical analysis of the collected data by describing their counts and percentages. In addition, we calculated the percentages of outcomes and databases for each disease. The percentages of statistical methods used to assess different outcomes were also analyzed. All codes used for data

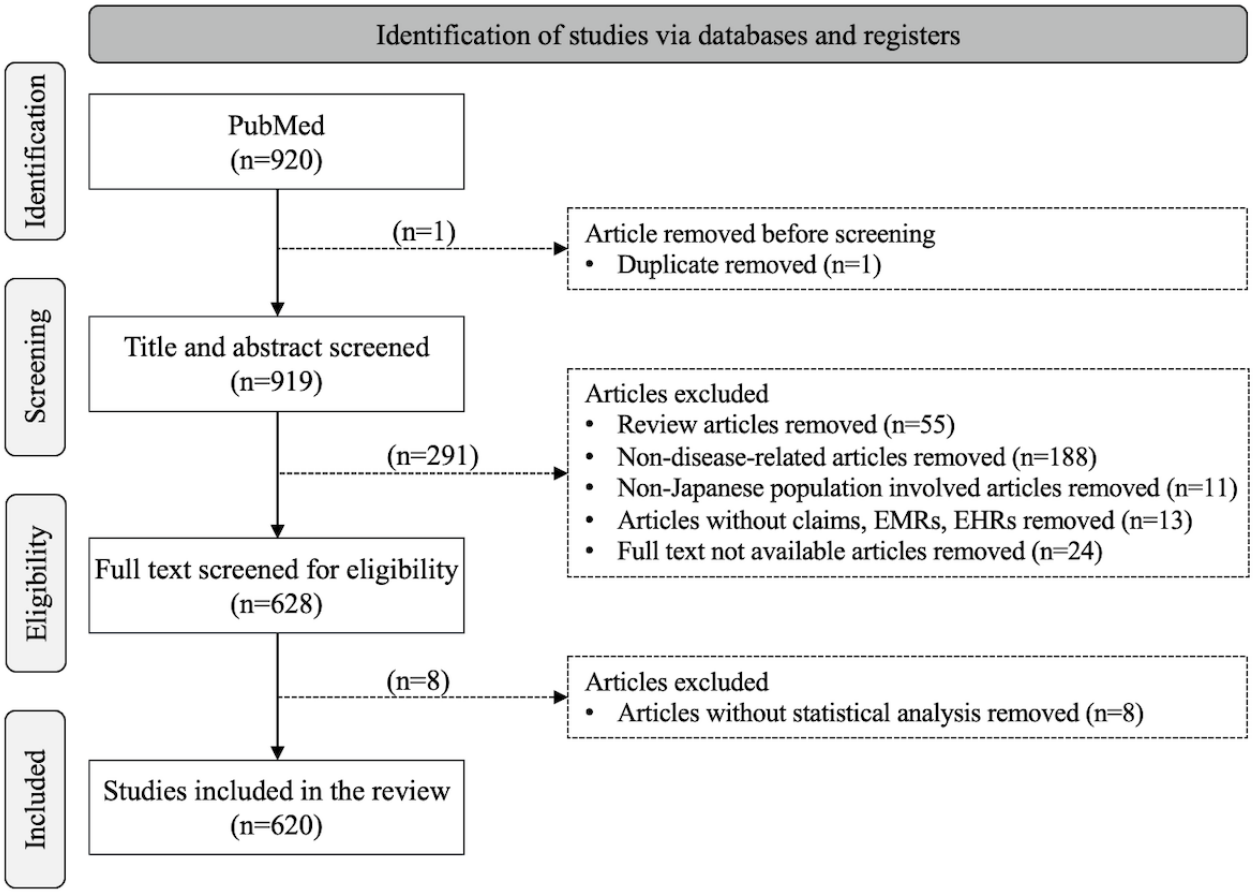
collection and descriptive analyses were performed using Python (version 3.8.8, 2021).

Results

Study Selection

A total of 620 eligible articles were identified for this narrative literature review. Figure 2 [13-18] illustrates the selection process and the results of each screening step. We also illustrate the publication years of these articles in Multimedia Appendix 3. The distribution indicated that 68.7% (426/620) of the articles were published after 2018, suggesting that the secondary use of the 3 RWD types in epidemiological research in Japan was prevalent in approximately the last 5 years.

Figure 2. Search and screening process [13-18]. EHR: electronic health record; EMR: electronic medical record.



Summary of Findings

Overview

We summarize the counts and percentages of information in the 7 categories and illustrate the top-ranked items for each category in Tables 1 and 2. All results are detailed in Multimedia Appendix 4. It should be noted that for an article with multiple diseases, data types, study designs, databases, outcomes, or modeling purposes, it was double counted in each classification to which it belongs. Therefore, the total percentage of these categories may not be 100%. The following subsections present the results for each category.

Table 1. Results of counts and percentages of the 7 categories (n=620).

Category	Count, n (%)
Organization	
Academic	429 (69.2)
Nonacademic	153 (24.7)
Collaboration	35 (5.6)
Study design	
Cohort study	533 (86)
Case-control study	30 (4.8)
Case-crossover study	23 (3.7)
Cross-sectional study	6 (1)
RWD[a] type	
Claim	594 (95.8)

Linear regression	57 (13.8)
Poisson regression	23 (5.6)
GLM[a]	18 (4.3)

[a]GLM: generalized linear model.

Organization

In Table 1, the results of organization show that most (429/620, 69.2%) target articles were conducted by academics, whereas nonacademic firms preferred to collaborate with academic institutions (153/620, 24.7%).

Study Design

The results of study design show 86% (533/620) of the articles that performed cohort studies, whereas only a few (30/620, 4.8%) studies were case-control studies, cross-sectional studies (23/620, 3.7%), and case-crossover studies (6/620, 1%).

RWD Type

Most (594/620, 95.8%) studies used claims data. Only a small number (30/620, 4.8%) of studies used EMRs and (4/620, 0.6%) EHRs. According to the articles that used EMRs or EHRs, we found that these studies commonly collected EMRs or EHRs from private databases (1 or some specific hospitals), which did not have large patient populations.

Database

Table 1 shows the top-ranked databases (n≥10) used in the target articles. The Japan Medical Data Center Claims (JMDC) database, a well-known, large-scale commercial insurance-based claims database operated by JMDC Inc [3,4], was the most used database. JMDC was used in 29.2% (181/620) of the total articles. The second most used database is composed of claims data from diagnosis procedure combination (DPC) hospitals provided by the Ministry of Health, Labour and Welfare (MHLW) [25,26], which we called the DPC database (MHLW). A total of 22.7% (141/620) of articles used the DPC database (MHLW). Medical data vision (MDV) [5], another commercial hospital claims-based database, was used for 16.6% (103/620) of the total articles. Fourth in the ranking is the National Database of Health Insurance Claims and Specific Health Checkups of Japan (NDB) data, which was established by the MHLW in 2009, covering almost the whole population in Japan [1,2]. NDB was used in 10.5% (65/620) of the total articles.

Disease

According to the information on diseases in Table 1, we found that most studies have focused on infections (105/620, 16.9%), cardiovascular diseases (100/620, 16.1%), neoplasms (78/620, 12.6%), and nutritional and metabolic diseases (75/620, 12.1%). In addition, there were a number of studies on psychiatric disorders, indicated here as nervous system diseases (62/620, 10%) and mental disorders (38/620, 6.1%).

Outcome

The results of outcome show that treatment patterns (218/620, 35.2%), physiological or clinical outcomes (184/620, 29.7%), and mortality (137/620, 22.1%) were the most assessed outcomes. Comparatively, few (32/620, 5.2%) articles assessed guideline adherence. Only few studies measured quality indicators (5/620, 0.8%).

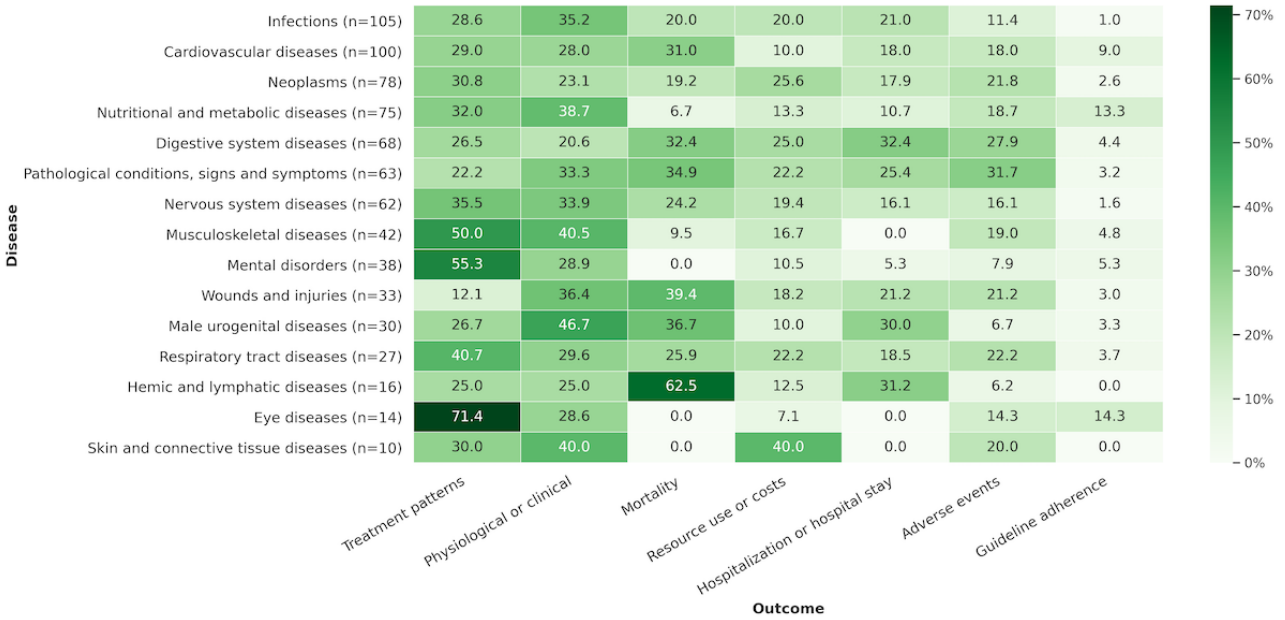
Statistical Method

Table 1 also suggests that most (414/620, 66.8%) studies were performed using multivariate modeling. In addition, we investigated the counts and percentages of modeling purposes (Figure 1) and specific models used in the 414 multivariate modeling studies in Table 2. The results show that most (375/414, 90.6%) of the multivariate modeling studies were performed for confounder adjustment. Some were conducted for clustered data modeling (69/414, 16.7%) and factor exploration (68/414, 16.4%). Two types of models were used for clustered data modeling: the generalized estimating equations (GEE) method and multilevel models. The GEE methods adjust for the clustering nature of the data and correctly estimate the SE of the estimated parameters. Multilevel models are often used with random effects to estimate the predictor effects for patients in specific clusters. Our results indicate a greater tendency to use multilevel regression (43/414, 10.4%) than GEE (26/414, 6.3%) in clustered data modeling studies. Only a few (8/414, 1.9%) studies analyzed cost-effectiveness. Regarding the specific models used in the multivariate modeling studies, logistic regression (249/414, 60.1%), Cox proportional hazards regression (87/414, 21%), and linear regression (57/414, 13.8%) were the most used.

Diseases and Outcomes

We investigated the percentage of each outcome measured for different diseases. As shown in Figure 3, most (10/14, 71%) studies on eye diseases have focused on assessing their treatment patterns. Similarly, a number of studies on mental disorders (21/38, 55%), musculoskeletal diseases (21/42, 50%), and respiratory tract diseases (11/27, 40%) have also focused on assessing treatment patterns. Among the studies on hemic and lymphatic diseases, mortality accounted for the highest percentage (10/16, 63%), whereas few studies assessed adverse events. Furthermore, mortality has not been assessed in studies of mental disorders, eye diseases, and skin and connective tissue diseases. In addition, no study has assessed hospitalization or hospital stay in musculoskeletal, eye, and skin and connective tissue diseases.

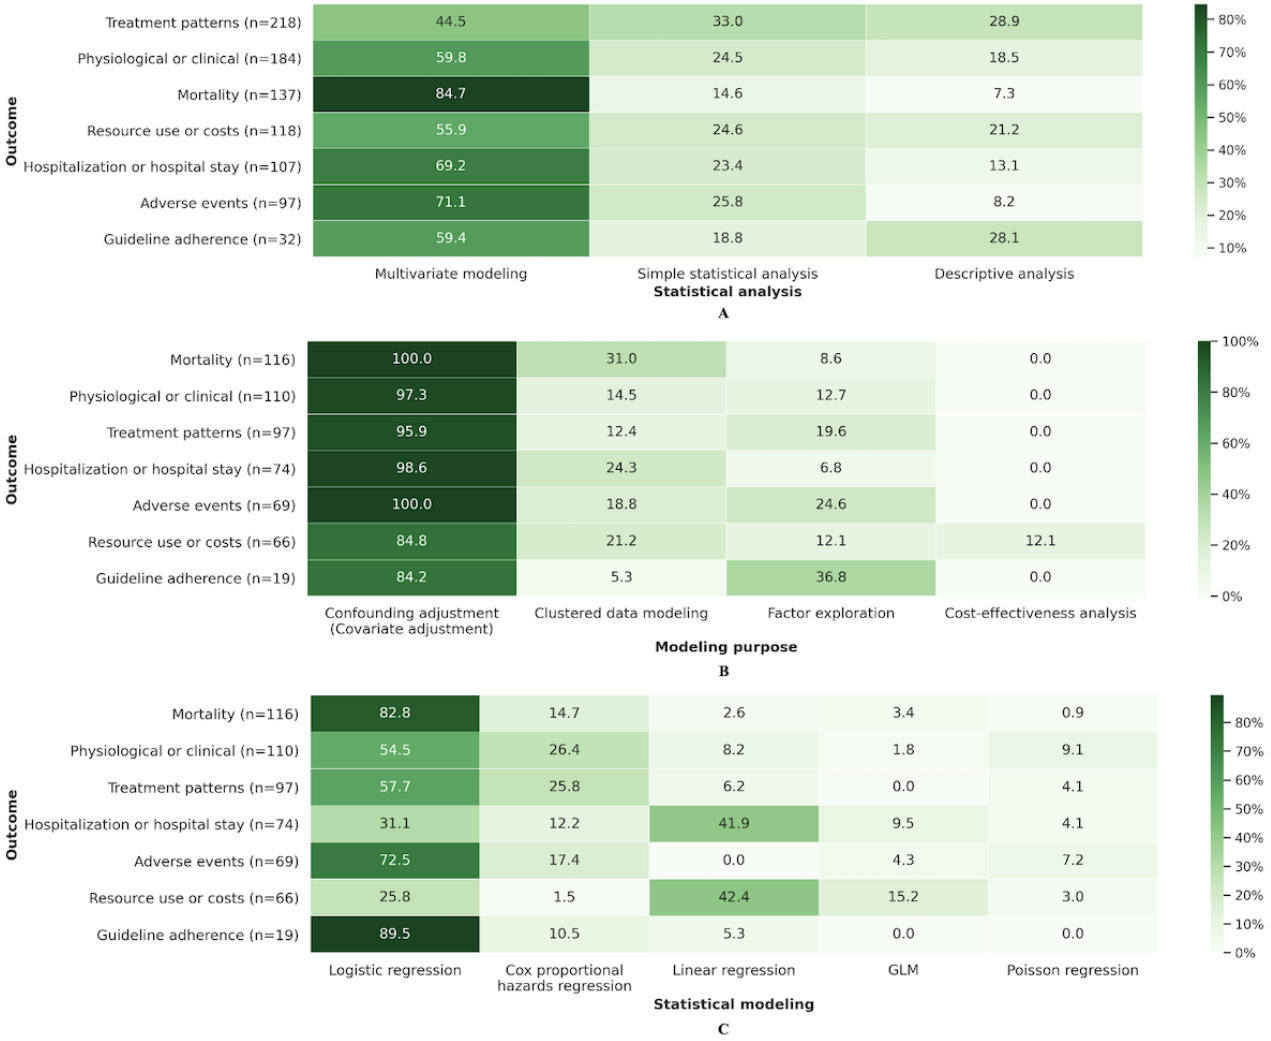
Figure 3. Percentages of outcomes in each disease.



Statistical Methods and Outcomes

We also calculated the percentages of statistical methods used to assess different outcomes. Figure 4A shows the percentages of the 3 types of statistical analyses used for each outcome; Figure 4B shows the percentages of multivariate modeling studies for different purposes for assessing these outcomes, and Figure 4C shows the percentage of each detailed multivariate model used for these outcomes. Multivariate modeling was used most frequently to assess mortality (116/137, 84.7%). Although the treatment patterns were the most assessed by the target studies (n=218), not many of them used multivariate modeling (97/218, 44.5%). Figure 4B indicates that almost all outcomes were measured with confounding adjustments. As shown in Figure 4C, logistic regression was the first choice for assessing mortality (96/116, 82.8%), physiological or clinical outcomes (60/110, 54.5%), treatment patterns (56/97, 58%), and guideline adherence (17/19, 90%). The results also suggest the use of Cox proportional hazards regression to assess these outcomes. In contrast, linear regression was the most commonly used model for assessing hospitalization or hospital stay (31/74, 42%) and resource use or costs (28/66, 42%).

Figure 4. (A) Percentages of statistical analysis types for each outcome, (B) modeling purposes for each outcome, and (C) specific models for each outcome. GLM: generalized linear model.



Discussion

Principal Findings

A comprehensive narrative literature review was conducted to understand the secondary use of nationwide claims data, EMRs data, and EHRs data in clinical epidemiology in Japan. On the basis of the search strategy and eligibility criteria, a total of 620 eligible articles were identified from PubMed between January 1, 2006, and June 30, 2021 (the date of search).

We quantified 7 categories of key information from these 620 eligible articles. The main findings were that (1) most of the research has been done by academic institutions, whereas nonacademic institutions tend to collaborate with academic institutions; (2) the cohort study was the major design that longitudinally measured outcomes of proper patients; (3) most studies used claims data; (4) the JMDC, DPC database (MHLW), MDV, and NDB were mostly used, whereas only a few studies used EMRs or EHRs from a single hospital or multiple hospitals, which do not have a large patient population; (5) the top rank of diseases studied in the current research were infections, cardiovascular diseases, neoplasms, and nutritional and metabolic diseases; (6) treatment patterns, physiological or clinical outcomes, and mortality were the most assessed in these articles; and (7) multivariate models were commonly used, during which logistic regression and linear regression were shown to be the first choice for analyzing categorical variables and continuous variables, respectively.

The findings on the percentage of outcomes for different diseases hint at the tendency of existing studies to examine different diseases. For some common, chronic, and psychiatric diseases, current studies tended to assess their treatment patterns, whereas for some sudden onset severe diseases, patient mortality and hospitalization or hospital stay were assessed more often. Existing studies have focused more on assessing treatment modalities, physiological or clinical outcomes, and mortality when targeting diseases such as infections, cardiovascular diseases, and neoplasms. Furthermore, although strong trends were detected between eye diseases and treatment patterns, hemic and lymphatic diseases versus mortality, and mental disorders versus mortality (Figure 3), it was difficult to draw any conclusions that reflect clinical importance because of the small sample size. However, these results indicated different distributions of outcomes measured in different diseases, from which we can learn the focus and shortcomings of the existing studies. In addition, the total number of studies measuring guideline adherence was relatively small (n=32). During this

period, 63% (20/32) of the studies were conducted on "cardiovascular diseases" and "nutritional and metabolic diseases." These results also revealed a relative lack of studies measuring guideline adherence in infections. We expect that RWD research on guideline adherence would receive more attention in future.

The percentage of databases used for different diseases implied the selection of databases for observing different diseases. The JMDC databases and DPC database (MHLW) showed opposite use trends in diseases, especially nutritional and metabolic diseases, musculoskeletal diseases, mental disorders, hemic and lymphatic diseases, eye diseases, and skin diseases.

According to the investigation of statistical methods used to assess different outcomes, multivariate models were the most commonly used in assessing mortality. Regardless of the outcome, multivariate modeling was accompanied by adjustments for various confounders (Figure 4B). Mortality, hospitalization or hospital stay, and resource use or costs have been analyzed using multilevel models or marginal models (eg, GEE) more than others. This implies that hospital-related outcomes tended to be assessed by models that took clustering into account. Logistic regression was the first choice for measuring many of the outcomes, with the exception of hospitalization or hospital stay and resource use or costs, for which linear regression was commonly used. Cox proportional hazards regression was suggested as the second choice when assessing mortality, physiological or clinical outcomes, and treatment patterns. Although the PS technique has been proven effective in balancing confounders between groups, it has not been widely used in existing studies. There is a relative preference for this technique in studies assessing mortality.

Comparison With Prior Work

In this subsection, we compare this review with 2 similar studies [27,28]. Hirose et al [27] conducted a narrative review of 68 studies on the secondary use of claims data in a specific database, NDB, from October 2016 to June 2019. They summarized 5 key pieces of information, including study design, research area, setting or sample, outcomes, and strengths and limitations. Subsequently, Fujinaga and Fukuoka [28] conducted a similar narrative review of 643 studies on the secondary use of claims data in 4 large-scale domestic databases: NDB, DPC database (MHLW), JMDC, and MDV, from January 2015 to October 2020, from which 3 categories of research type, design, and area were analyzed descriptively. Both studies used a classification of the journals in which the target articles were published to extract information about the research area [29]. These classifications mixed disciplinary categories, such as clinical medicine, pharmacology and pharmacy, pharmacology and toxicology, and immunology; disease categories, such as infectious diseases; and general categories, such as social sciences and public environmental health. In addition, only the primary outcomes were analyzed in these 2 studies. As a result, the distribution of articles in each category was summarized in these studies.

Because of the partial overlap in search periods, as well as the fact that PubMed was used for the search, there were some articles that were reviewed in both this study and these 2 prior studies. In contrast to these 2 studies, which used 1 or more specific claim databases without specifying a research area, our review investigated domestic epidemiological studies based on the secondary use of 3 types of RWD: claims, EMRs, and EHRs. A further difference is that we defined 7 categories for data collection to assess the status and trends of the existing studies. One of the novelties is that we classified the outcomes with reference to the paper by Abaho et al [24] paper and collected information on all the outcomes measured in the target articles. The advantage of this classification is that these outcomes are also applicable to clinical trial studies and can be automatically identified from biomedical articles [24]. Another innovative point is that we proposed a hierarchical approach to classify the statistical methods that appear in the target articles. For the results of the data collection, we summarized the distribution of the target articles in each category. Additional comparative analyses were performed for diseases versus outcomes (Figure 3), outcomes versus statistical methods (Figure 4), and diseases versus databases (Multimedia Appendix 5), which revealed trends in the assessment of outcomes across different diseases, trends of statistical methods used for different outcomes, and trends in database selection when analyzing different diseases. Moreover, our findings shed light on the focus and shortcomings of previous studies.

In addition, we identified several other review studies on the secondary use of RWD data [30-32]. The paper by Ferver et al [30] provided a narrative review of 1956 claims-based studies in 5 health care journals from 2000 to 2005 by summarizing the research types and areas. The paper by Hutchings et al [31] provided a systematic literature review of 18 studies to investigate the attitudes of relevant practitioners toward the secondary use and sharing of health administrative and clinical trial data. Schlegel et al [32] conducted a literature review of 941 studies on the secondary use of health care data in 2016 to select the best performing articles. We summarized these additional studies to understand other investigations on the secondary use of RWD data. Comparisons were not made because of the survey years or different research purposes.

Limitations

The first limitation of this review is that we only searched the literature in PubMed, which may have led to significant publication bias. Second, we only investigated studies conducted in Japan. In the future, a comparison of studies from other countries, such as the United States, will be necessary to understand the Japan-specific trends of such studies. In addition, searches of multiple electronic databases should be considered to reduce potential publication bias.

Future Directions

In this subsection, we discuss the future perspectives for the use of claims, EMRs, and EHRs in epidemiology in the Japanese context, in terms of the findings of this large narrative literature review.

Organization

Regarding collaborative aspects, with strong national promotion for RWD use and high level of interest from health care firms, collaborative research, involving multiple stakeholders and

academic researchers, is seen to be necessary to leverage academic results and accelerate clinical applications.

RWD Type

Notably, only a few studies have used EHRs. EHRs have not been widespread in Japan because of the high cost of implementation and the difficulties in bridging different EHR service vendors. With the promotion of "cloud-based EHR" development by the Japanese Ministry of Internal Affairs and Communications, EHRs are expected to become widely used in the future.

Disease

With regard to the disease trend detected in this review, we made a rough comparison with worldwide trends. As we did not find a quantitative survey of RWD research on different diseases, the worldwide trend was roughly estimated by counting the number of related publications for different diseases. We focused on the top-ranked disease areas identified in this review, including infections, cardiovascular diseases, and neoplasms. The number of publications for these diseases was obtained by searching for electronic databases, such as PubMed or PubMed Central with search keywords: combinations of "claims," "EHR," "EMR," to "infection," "cardiovascular disease," and "cancer." We retrieved 18,847 publications on cancer, 7517 publications on infections, and 6624 publications on cardiovascular diseases from PubMed. The same trend was detected in PubMed Central. According to these counts, we estimated that the worldwide trend of the disease examined in existing studies was cancer. In contrast, our results revealed a Japan-specific trend in the studies on infections.

It is important to note that the above counts may be subject to bias because we have not designed any eligibility criteria for the precise search of related publications worldwide. In the future, it will be necessary to compare relevant studies with those of other countries to clarify the Japan-specific status and challenges.

Statistical Method

On the basis of the statistical skills used in the eligible articles, we summarized the appropriate statistical methods for use under different conditions. First, to design simple statistical analyses, our findings suggest using Fisher's exact tests or chi-square test to compare categorical variables, and 2-tailed *t* test, ANOVA, and Mann-Whitney *U* test were used to compare continuous variables [33-36]. To evaluate variable change trends, the Cochran-Armitage test was used for categorical variables, whereas the Jonckheere-Terpstra test was used for continuous variables [37].

Suggestions for statistical methods to measure different outcomes are summarized in Table 3. For confounding adjustment, there are 2 methods: covariate adjustment and PS analysis. PS analysis is known to be an effective technique for balancing the patient backgrounds between the 2 groups across all putative risk factors or confounders [38-40]. However, referring to the study by Elze et al [41] that PS analysis is not necessarily superior to conventional covariate adjustment, we suggest selecting PS analysis with caution for confounder adjustment. Our findings also demonstrated that most existing studies used covariate adjustment (n=279) rather than PS analysis (n=96; Multimedia Appendix 4). In addition, hospital-based medical data are frequently clustered within medical centers or physicians. For instance, patients treated in a particular hospital may be more alike than those treated in another hospital because of differences in treatment policies. To model such clustered data, multilevel models with random effects have been suggested for use in estimating predictor effects for patients in specific clusters [42,43].

Table 3. Suggestions of statistical methods for measuring different outcomes.

Outcome	Method recommendation
Treatment patterns	Logistic regression, Cox proportional hazards regression
Physiological or clinical	Logistic regression, Cox proportional hazards regression
Mortality	Kaplan-Meier analysis, log-rank test, logistic regression, Cox proportional hazards regression
Hospitalization or hospital stay	Linear regression, GLM[a]
Adverse events	Logistic regression, Cox proportional hazards regression
Resource use or costs	Linear regression, GLM
Guideline adherence	Logistic regression
Quality indicators	Logistic regression

[a]GLM: generalized linear model.

In contrast, there were few studies on predictive machine learning models in this review (n=3; Multimedia Appendix 4). However, we roughly retrieved 2223 publications worldwide on PubMed by searching for the keywords of "claims," "EHR," "EMR," and "machine learning." Notably, we did not design any eligibility criteria for this study. The large difference in the number of articles indicates that epidemiological research based on claims, EMRs, and EHRs in Japan is backward in the use of artificial intelligence techniques.

Conclusions

This literature review provides a good understanding of the current status and trends in the use of claims, EMRs, and EHRs in clinical epidemiology in Japan. The results demonstrated appropriate statistical methods regarding different outcomes, Japan-specific trend of disease areas, and lack of use of artificial

intelligence techniques in existing studies. We hope that the results of this narrative review will provide useful information for researchers to design relevant studies. In the future, a more precise comparison of relevant domestic research with worldwide research will be conducted to clarify the Japan-specific status and challenges.

Abstract

Background: Over the past 2 decades, various desktop and mobile telemedicine systems have been developed to support communication and care coordination among distributed medical teams. However, in the hands-busy care environment, such technologies could become cumbersome because they require medical professionals to manually operate them. Smart glasses have been gaining momentum because of their advantages in enabling hands-free operation and see-what-I-see video-based consultation. Previous research has tested this novel technology in different health care settings.

Objective: The aim of this study was to review how smart glasses were designed, used, and evaluated as a telemedicine tool to support distributed care coordination and communication, as well as highlight the potential benefits and limitations regarding medical professionals' use of smart glasses in practice.

Methods: We conducted a literature search in 6 databases that cover research within both health care and computer science domains. We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology to review articles. A total of 5865 articles were retrieved and screened by 3 researchers, with 21 (0.36%) articles included for in-depth analysis.

Results: All of the reviewed articles (21/21, 100%) used off-the-shelf smart glass device and videoconferencing software, which had a high level of technology readiness for real-world use and deployment in care settings. The common system features used and evaluated in these studies included video and audio streaming, annotation, augmented reality, and hands-free interactions. These studies focused on evaluating the technical feasibility, effectiveness, and user experience of smart glasses. Although the smart glass technology has demonstrated numerous benefits and high levels of user acceptance, the reviewed studies noted a variety of barriers to successful adoption of this novel technology in actual care settings, including technical limitations, human factors and ergonomics, privacy and security issues, and organizational challenges.

Conclusions: User-centered system design, improved hardware performance, and software reliability are needed to realize the potential of smart glasses. More research is needed to examine and evaluate medical professionals' needs, preferences, and perceptions, as well as elucidate how smart glasses affect the clinical workflow in complex care environments. Our findings inform the design, implementation, and evaluation of smart glasses that will improve organizational and patient outcomes.

KEYWORDS

smart glass; care coordination; telemedicine; distributed teamwork; mobile phone

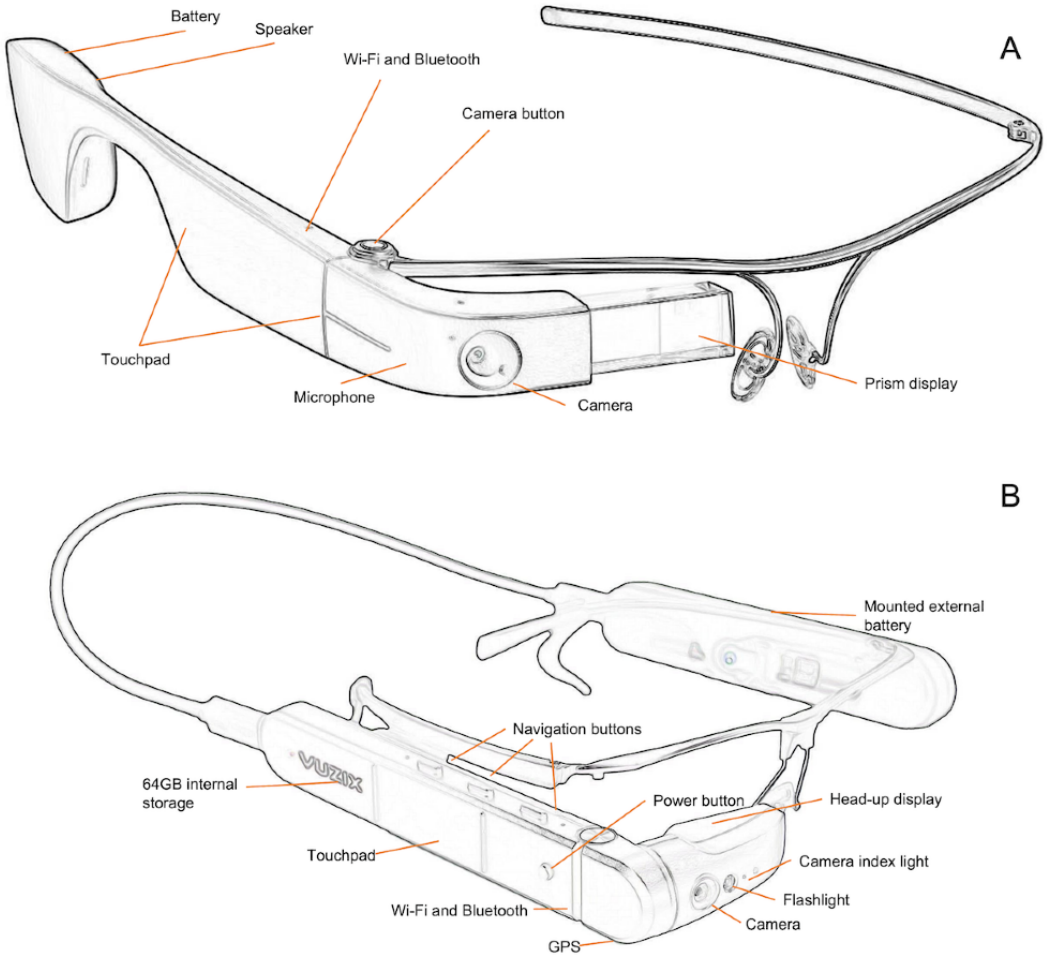
Introduction

Background

Effective and timely care coordination and communication are critical components of efficient and safe patient care [1,2]. Failure in providing coordinated care and communicating patient data is seen as one of the root causes of adverse events such as delays in patient care and deviations from standard medical procedures [3]. The challenges in maintaining effective care coordination and communication are exacerbated when care providers are distributed (eg, located in different places) [4,5]. Over the past 2 decades, many telemedicine systems have been developed to augment remote clinical consults [6-8]. During the COVID-19 pandemic, the need for such systems became more obvious. Most telemedicine systems are implemented on desktops or tablet devices [6,7]. However, these devices have practical limitations: (1) desktop systems have limited portability because they are installed in a fixed location; and (2) tablet device–based systems rely on manual input and control, which can hinder usability [9,10]. These issues could result in limited use of technology in real time, especially during complex care environments and time-critical patient scenarios because they demand the full cognitive attention and physical involvement of care providers [11].

In recent years, the use of smart glasses—a computing device worn as a conventional pair of glasses (Figure 1)—has been gaining momentum in health care because they allow for real-time visual communication in a hands-free manner [12,13]. In particular, smart glasses can present both imagery and textual information within the wearer's field of view (FOV) through a prism and enable videoconferencing for consults or second opinions via a front-facing camera. Since the introduction of smart glasses to the market, researchers have explored their applicability and usefulness in various medical settings and clinical scenarios [9], such as broadcasting surgeries to facilitate resident teaching [14], recording encounters with patients in wound care [15,16], assessing patients in mass casualty incidents [17], and supporting communication between prehospital and hospital providers [18,19].

Figure 1. Examples of smart glasses with various hardware components labeled. (A) Google Glass. (B) Vuzix M400.



Objectives

As there is a growing interest in using smart glasses to support care coordination and communication across distributed care providers [9,11,20], the aim of this study was to synthesize the knowledge and experiences in this area, understand the benefits and limitations regarding adopting smart glasses as a telemedicine tool, and inform the design of future smart glass applications to better support remote care coordination. We focused on the use of smart glasses in care coordination in various clinical settings (eg, surgical operation, emergency care,

and intensive care unit). Our specific research questions were as follows:

1. What are the general characteristics of prior research on using smart glasses for care coordination?
2. How was the system designed, used, integrated, and evaluated in supporting communication and care coordination across distributed care providers?
3. What types of challenges were identified by medical providers while they were using or testing the smart glass technology in practice?

These research questions were answered through a systematic literature review covering research within both health care and computer science fields.

Our work contributes the following to the medical informatics community: (1) an in-depth analysis and synthesis of prior research on the use of smart glasses for care coordination and communication; and (2) methodological and design implications for future research on smart glasses to improve distributed care coordination and communication.

Methods

Data Search

Our search started with discussing the search time frame and the most appropriate databases to use as well as search terms with experienced librarians. Using technology keywords such as "smart glasses" and "heads-up display," along with health care keywords such as "distributed care" and "telemedicine," a health librarian performed database searches for articles published between January 1, 2000, and March 1, 2022. We chose this time frame to capture the evolvement of this technology (ie, from early concepts such as head-worn displays [21] to smart glasses, which became a well-known concept after the introduction of Google Glass in 2013 [22]). The full list of search terms is presented in Textbox 1. We chose the following databases to cover research within both health care and computer science: ACM Digital Library, Cochrane Library, IEEE Xplore, Ovid MEDLINE, Embase, and Web of Science. A sample search strategy for Ovid MEDLINE is illustrated in Textbox 2. The database searches were set to include only studies published in peer-reviewed journals and conference proceedings in English. Literature reviews, dissertations, posters, and extended abstracts were excluded from the literature search. The retrieved citations were stored and managed using EndNote bibliographic management software (version X9; Clarivate).

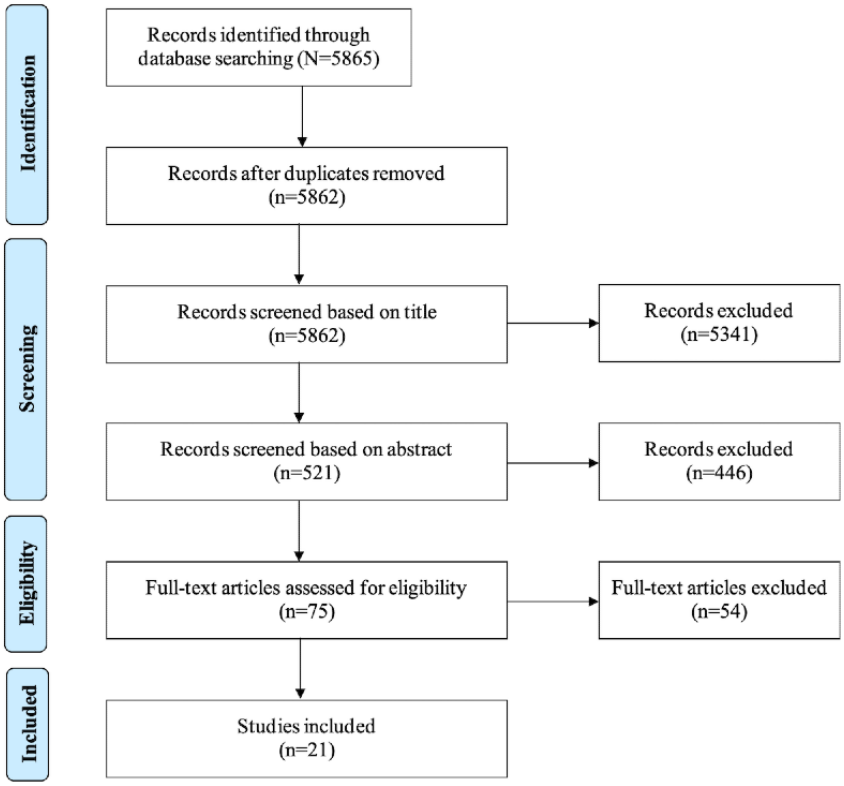
5. (training* or education* or simulation* or telephon* or teleconferenc* or television*).ti. or exp *education/ or *telephone/ or *television/
6. Step 4 not step 5

Article Screening and Selection

We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology to search and screen articles [23]. Figure 2 outlines the number of records that were identified, included, and excluded through different phases. More specifically, 5865 articles were identified through database searches, of which 5862 (99.95%) were included for screening after removing duplicates. Article titles were screened first, followed by abstract screening, to identify relevant articles. Of the 5862 articles, after screening of article titles, we excluded 5341 (91.11%); of the remaining 521 studies, 446 (85.6%), were excluded, leaving 75 (14.4%) for full-text review. After reviewing the full text of these 75 articles, we deemed 21 (28%) to be eligible for this systematic review.

Figure 2. Information source and search strategy.



Three authors (EB, KJ, and PG) independently screened all papers through the paper stack and selected relevant papers for inclusion. Two senior researchers (ZZ and MO) oversaw the whole article review and selection process. Any conflicts in selection decisions were resolved through discussion among all the authors during weekly group research meetings. The inclusion criteria were peer-reviewed articles that reported the use or testing of any smart glass technology and accompanying software in the context of communication and collaboration across distributed care providers. Articles were excluded if they only reported the use of smart glasses by an individual or in a collocated clinical setting or if they did not provide adequate supporting information, such as what clinical setting the smart glasses were used in and who used the technology.

Data Extraction, Analysis, and Synthesis

Guided by the research questions of this study, 2 authors (KJ and EB) used a Microsoft Excel spreadsheet to extract, collate, and summarize data from the included studies, such as the country where the study was conducted, study objectives and scope, clinical scenarios, system evaluation methods, technology specifics, barriers and challenges, and a summary of study findings. Textbox 3 summarizes these data fields and their brief definitions. In addition to extracting the aforementioned metadata, we also assessed the technology readiness levels (TRLs) [24] of the systems tested in the reviewed studies. There are 9 different TRLs, ranging from level 1 (scientific knowledge generated underpinning hardware and software technology) to level 9 (actual system "flight proven" through successful mission operations). Two authors (KJ and EB) followed the metrics proposed in the study by Engel et al [25] and independently assessed TRLs for each system. They then compared and discussed their TRL evaluations until they reached agreement.

Two senior researchers (ZZ and MO) reviewed all the articles and analyses as a verification step. The research team met regularly to discuss the results. We performed the data analysis iteratively (ie, we went back and forth as more knowledge was obtained), as suggested by prior work [11,26]. A meta-analysis of the study results was not considered in this work owing to the heterogeneity of the study designs and results.

In the following section, we report information that was synthesized from the reviewed articles, including characteristics of the selected studies, system architecture and features, TRLs of the reviewed systems, system evaluation methods, and care providers' perceived benefits and challenges of using and adopting smart glasses for distributed care coordination.

Textbox 3. Assessed article information and metadata.

Assessed information and brief definition

- Study objectives and scope: the objective of the research and the purpose and scope of the use and test of smart glasses in each study (eg, patient care vs medical training)
- Clinical scenarios: the clinical domain and context in which the study was conducted
- Publication details: the type (eg, journal article vs conference paper), region, and year of the publication
- System infrastructure: the hardware, software, and network setup on both local and remote sites for establishing teleconsultation
- System features: the system features used, developed, or evaluated in each study
- System evaluation: the aspects of the smart glass system that were evaluated in the study and the methods used for system evaluation
- Benefits and challenges: the reported benefits and challenges of using smart glasses in improving communication and care coordination among distributed medical teams
- Major study findings: a summary of the major findings of a study

Results

General Characteristics of the Reviewed Studies

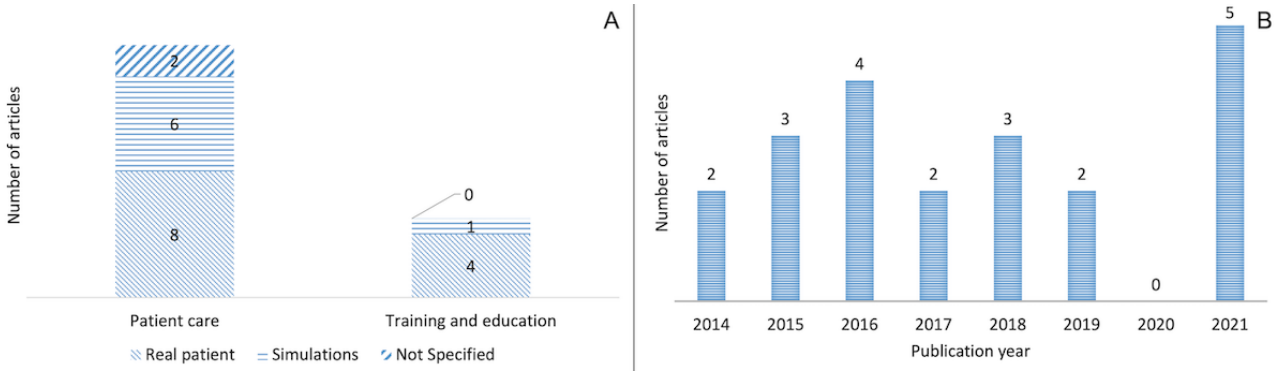
Of the 21 reviewed articles, 10 (48%) were conducted in the United States [18,19,27-34], and 2 (10%) were conducted for surgical teleproctoring between high-income countries and low- and middle-income countries (LMICs), such as between surgeons in the United States and Mozambique [35] and between experienced surgeons recruited from the United States and Germany and novice surgeons in Brazil and Paraguay [36]. The remaining studies (9/21, 43%) were conducted in different countries, such as Spain [37], China [38], Germany [39], France [40], Italy [41], Switzerland [42], Malaysia [43], South Korea [44], and Republic of the Congo [45]. The reviewed studies were conducted to assess the feasibility, effectiveness, and user experience of smart glasses in supporting remote patient evaluation and care procedure operation in a particular medical domain. The study objectives, along with major findings for each reviewed article, are presented in Multimedia Appendix 1 [18,19,27-45].

The clinical foci in these 21 papers vary: 9 (43%) focused on surgical settings [29,30,33-38,44], whereas 6 (29%) focused on the prehospital or emergency medical services domain [18,19,28,31,39,42]. The remaining studies (6/21, 29%) focused on intensive care [40,43], toxicology [27], ophthalmology [32], pediatric cardiology [41], and general medicine [45].

The scope and purpose of the use of smart glasses among these studies vary. As shown in Figure 3A, the majority of the reviewed studies (16/21, 76%) used smart glasses to enable remote patient care and evaluation [18,19,27,28,30-32,37-45]. Of these 16 studies, 8 (50%) [27,28,30,32,37,38,43,45] tested smart glasses with real patients, 6 (38%) [18,19,31,39,40,44] conducted system testing in a simulated environment, and 2 (13%) [41,42] did not specify how the device was tested. The remaining studies (5/21, 24%) [29,33-36] leveraged smart glasses for training and teleproctoring purposes; of these 5 studies, 4 (80%) [29,34-36] tested the device with real patients, whereas 1 (20%) [33] tested the device in a simulated environment.

The reviewed articles were published between 2014 and 2021 (Figure 3B). It is noticeable that almost half of the reviewed articles (9/21, 43%) were published within the first 3 years of the release of Google Glass [22]. Subsequently, the number of studies on the use of smart glasses for supporting distributed care decreased until 2021. One possible explanation for this finding is that the use of smart glasses regained momentum right after the outbreak of the COVID-19 pandemic as researchers started exploring smart glass use to enable medical personnel to participate in remote assessment and consultation, with the aim of safeguarding patients and health care providers during the pandemic.

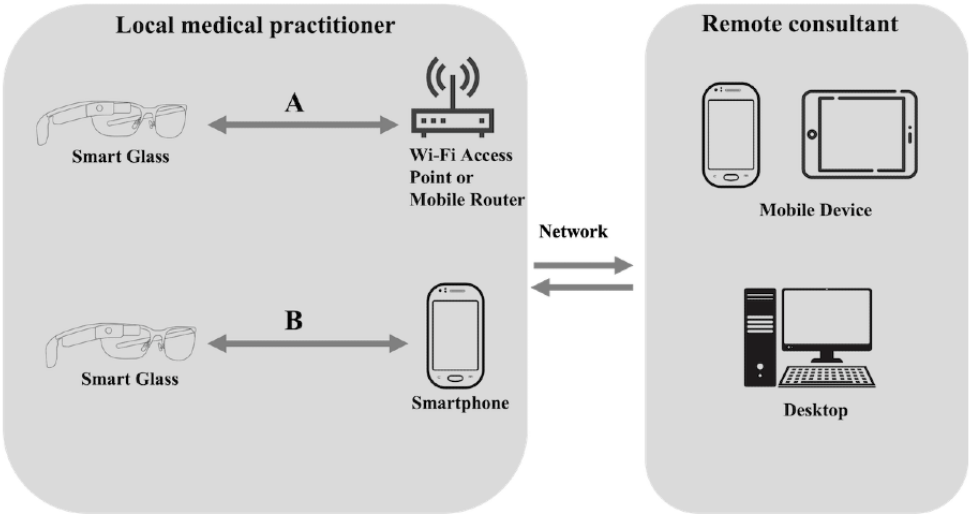
Figure 3. (A) The scope and testing environment of smart glasses in the reviewed articles. (B) The distribution of reviewed articles over the years.



System Architecture

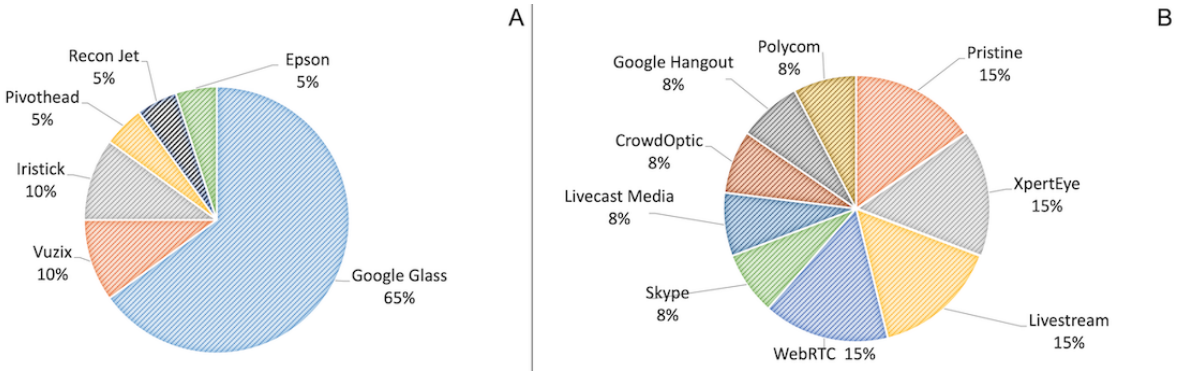
Although the system architecture implemented in each study varied, there were some similarities across the reviewed studies. Typically, there are two types of technology setups on the local site: (1) smart glasses are connected to a Wi-Fi network, a Wi-Fi hotspot, or a mobile router to directly stream the first-person point-of-view to a remote consultant (Figure 4A); or (2) smart glasses are connected to a smartphone or a laptop via Bluetooth or Wi-Fi for video streaming and audio transmission (Figure 4B). The first approach was adopted by 52% (11/21) of the studies [19,27,28,31,32,36,38,39,41,43,44], and the second approach was used in 33% (7/21) of the studies [18,29,35,37,40,42,45]; for example, in the study by Diaka et al [45], the smart glasses were designed as an extension of a smartphone, which meant that the local wearer needed to initiate the call on the smartphone. Regardless of the system implementation method on the local site, the remote experts were usually equipped with either a computer or a mobile device (eg, a tablet device) to review and access the video stream and other multimedia data shared by the local medical practitioner (Figure 4). However, it is worth mentioning that in the study by Brewer et al [33], where smart glasses were used for surgical training, the remote expert (trainer) also wore a pair of smart glasses to view the video streamed from the learner.

Figure 4. Common system architecture setups in the reviewed studies. (A) Smart glasses connected to a Wi-Fi network, a Wi-Fi hotspot, or a mobile router. (B) Smart glasses connected to a smartphone via Bluetooth or Wi-Fi.



As shown in Figure 5A, the reported brands of smart glasses in these studies included Google Glass [18,19,27-30,33-36,40,42,44], Vuzix [38,43], Iristick [37,45], Pivothead Original Series [32], Intel Recon Jet [31], and Epson Moverio BT-200 [41]. Google Glass was the most frequently used smart glass device (13/20, 65%). Another interesting observation is that all of the studies (21/21, 100%) used off-the-shelf, commercialized videoconferencing software (Figure 5B) such as Pristine Eyesight [19,27], AMA XpertEye [28,35], Livestream [18,36], WebRTC (enabled by Google) [42,44], Livecast Media [38], Skype [29], CrowdOptic [33], Google Hangout [34], and Polycom RealPresence Group 500 [32]. Most of the videoconferencing software used was compliant with the Health Insurance Portability and Accountability Act (HIPAA) rules, except in the case of the study by Cicero et al [18], where the researchers only tested the use of smart glasses in a simulated environment (real patient care was not involved).

Figure 5. (A) Smart glass brands used in the reviewed articles. (B) Videoconferencing tools used in the reviewed articles.



System Features

Although there was variation in the application scopes and domains, there were some common software features across the reviewed studies (Textbox 4). Real-time synchronous video and audio streaming from the local smart glass wearer to the remote consultant is the most common feature among the studies (19/21, 90%). In the case of the exceptions (2/21, 10%), because of technical limitations (eg, limited internet connection), the study by Gupta et al [30] first recorded patient care and evaluation

using smart glasses and then transmitted the recordings to remote experts at a later time to simulate real-time telemedicine consults, whereas in the study by Hashimoto et al [34], researchers used Google Glass and an Apple iPhone to capture videos of a surgical operation and compared the video quality and its adequacy for safe use in telementoring.

Another noteworthy feature is enabling imagery and text-based remote guidance and annotation; for example, the remote consultant can annotate images captured from the live stream and project them back onto the local glass wearer's visual field [35,37]. In 19% (4/21) of the studies [19,27,36,44], the remote consultant could use the texting feature to type messages that could be projected onto the smart glass display. These annotation features provide the remote consultant with more channels (in addition to audio and video) to direct and guide local medical practitioners to perform critical procedures.

Augmented reality (AR)—a technique that can enhance an individual's visual experience of the real world through the integration of digital visual elements—was also tested in several studies. In Ponce et al [29], for example, AR enabled a remote surgeon to insert their hands or instruments virtually into the visual field of the local surgeon who wore smart glasses for real-time guidance, training, and assistance as needed. In another study [41], a remote specialist used AR-based markers to guide the execution of an echocardiographic examination performed by a local operator. The markers were overlaid on the ultrasound device and could be seen through the screen of the local operator's smart glasses.

Other features of smart glasses reported in the studies included zooming in and out of the live stream video [35]; using voice commands [27,28,30,31] or head movements [27] to control, and interact with, the smart glass device; taking photographs [19,30,31,35]; automatically detecting the geographic location of on-site medical teams with the built-in GPS [31]; and presenting prehospital triage algorithm on the glass screen for decision support during mass casualty incidents [39].

Textbox 4. Summary of smart glass features as described in the reviewed studies.

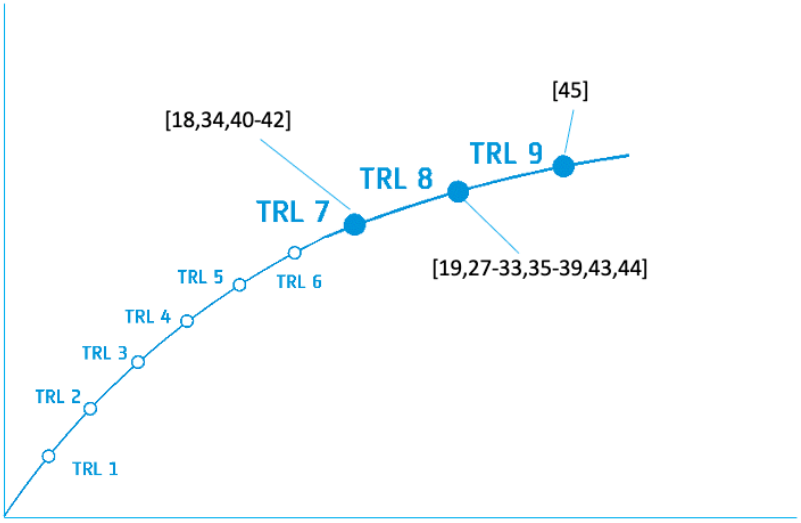
System features

- Real-time synchronous video and audio streaming [18,19,27-29,32-38,40-45]
- Record and forward video recordings [30]
- Imagery and text-based remote guidance and annotation [19,27,35-37,44]
- Augmented reality [29,41]
- Zooming in and out of the live stream video [35]
- Hands-free interaction with smart glasses [27,28,30,31]
- Taking photographs [19,30,31,35]
- GPS-based tracking of the geographic location of on-site medical teams [31]
- Presenting prehospital triage algorithm on the glass screen for decision support [39]

TRLs of the Systems Tested in the Reviewed Studies

On the basis of our analysis, we found that the TRLs of all the systems used or tested in the reviewed studies ranged between 7 and 9. Our TRL assessment for each system is visualized in Figure 6 [18,19,27-45]. The reasoning for our assessment is summarized in Multimedia Appendix 2 [18,19,27-45].

Figure 6. Diagram of technology readiness levels (TRLs) for the systems reported in the reviewed studies [18,19,27-45].



The systems in 24% (5/21) of the studies [18,34,40-42] have a TRL of 7, which indicates that the technology is in the form of a high-fidelity prototype and has all key functionality available for demonstration and test; for example, in the study by Widmer and Müller [42], the Google Glass device on the local site was set up to connect with a computer application on the remote site for teleconsultation. This integrated system was only preliminarily tested by the research team but not in a simulated or real environment (a criterion for TRL 8); thus, its TRL was set to 7. It is worth mentioning that of these 5 studies, 3 (60%) [18,40,41] tested smart glasses in simulated scenarios; however, there were several reasons for their failure to meet the criteria for TRL 8, such as using non–HIPAA-compliant videoconferencing software, testing the technology with only 1 volunteer, or not fully integrating smart glasses with the network and remote devices.

The majority of the studies (15/21, 71%) [19,27-33,35-39,43,44] tested or used systems that met the criteria for TRL 8, indicating that they are actual systems in their final configuration and have been fully developed and tested in either simulated or real operational scenarios. However, these studies provided limited information regarding some criteria for TRL 9, such as whether the system had been fully integrated with other operational hardware and software systems (eg, database and hospital IT infrastructure), whether all system documentation had been completed, whether training on system use was available, and whether engineering support team was in place. Without such information, it is difficult to assess the readiness of these systems for large-scale deployment.

In comparison, only the system in the study by Diaka et al [45] was assessed to have a TRL of 9 because the system had been successfully operated on actual missions and tasks in the operational environment for a relatively long time (ie, more than a year). Furthermore, the system was fully integrated with other operational software, hardware, and network devices, as well as care delivery services (eg, moto-ambulances to facilitate patient referrals after teleconsultation).

System Evaluations

Overview

The reviewed studies evaluated different dimensions of the smart glass system, including technical feasibility, effectiveness, and user experience. The details regarding the aspects of the smart glass system that were evaluated as well as the evaluation methods used in the reviewed studies are summarized in Table 1 and then elaborated on in the following sections.

Table 1. Summary of system evaluation details.

Evaluated dimensions	Specific evaluated aspects	Evaluation methods
Technical feasibility [27,34-36,44]	• Success rate of established video teleconsultations between local and remote medical practitioners [27,36] • Whether the quality of video and audio streaming was good enough for enabling video streaming [34-36,44]	• Researchers' observations of the successfulness of teleconsultations [27,36] • Questionnaire [27,34-36,44]
Effectiveness [18,19,27,28,30-33,36,39,40,43]	• Compared with in-person patient evaluation, whether the use of smart glasses could achieve similar performance and accuracy regarding patient evaluation and diagnosis [19,28,32,43] • Compared with either mobile phone–based or no remote patient consultation, whether the use of smart glasses could lead to changes in clinical management and remote consultant's confidence regarding diagnosis [18,27,30,39,40] • Whether the use of smart glasses could improve medical training (eg, surgical operation) [33,36]	• Comparison study between control (without smart glass support) and treatment (with smart glass support) groups [18,19,28,32,39,40,43] • Questionnaire [33] • Exit interview [36]
User experience [18,19,27,29-31,35,37-41,43-45]	• Usability of smart glasses [19] • Opinions regarding using and adopting smart glasses in practice [18,27,30,31,35,37-41,43-45]	• Survey [18,19,27,29-31,35,38-40,43,44] • Interviews and observations [18,31,35,45]

Technical Feasibility

Several studies assessed whether the smart glass technology was a practical means to support care coordination and communication in different contexts, such as teletoxicology consults [27] and remote surgical teleproctoring [34-36,44]. The main measurements included the success rate of established video teleconsultations between local and remote medical practitioners and whether the quality of video streaming was acceptable and good enough to allow for real-time, seamless guidance and assistance. The technical feasibility was primarily determined by the researchers' observations and the users' ratings via questionnaire; for example, in a study evaluating the feasibility and acceptability of Google Glass for teletoxicology consults [27], questionnaires were administered immediately after the study to elicit remote consultants' opinions regarding whether consults through smart glasses were considered successful and the technical feasibility of using smart glasses for teleconsultation.

Effectiveness

Of the 21 reviewed studies, 10 (48%) evaluated the effectiveness of smart glasses, that is, whether this novel technology could improve patient care and decision-making compared with current approaches (eg, no remote consultation, in-person patient evaluation, or consultation via telephone)

[18,19,27,28,30,32,33,39,40,43]; for example, in some settings where remote consultations were usually accomplished via telephone or radio, which typically do not support visual communications [27,30], researchers compared using such traditional communication mechanisms with using smart glasses to determine whether the use of smart glasses could lead to changes in clinical management and the remote consultant's confidence regarding diagnosis.

Of these 10 studies, 7 (70%) [18,19,28,32,39,40,43] conducted an experiment with a control group (no smart glasses and either in-person consultation or no remote consultation at all) and an intervention group (with smart glasses) to measure whether using smart glasses could increase the quality and accuracy of patient diagnosis while reducing the time needed to perform patient care; for example, in the scenario of patient triage during mass casualty incidents [19], researchers asked 2 emergency medicine (EM) physicians (control group) to make triage decisions after examining the simulated patients in person as 2 other EM physicians (intervention group) simultaneously evaluated the same group of patients via real-time point-of-view video stream from a paramedic wearing Google Glass. They then used the agreement within and among the groups of EM physicians on the need for immediate trauma evaluation to determine the effectiveness of smart glasses for supporting patient triage.

User Experience

Of the 21 studies, 15 (71%) examined end users' experience and perceptions to some extent with regard to using smart glasses in their work [18,19,27,29-31,35,37-41,43-45]. The primary methodology used for eliciting user experience was a survey, which was adopted by 80% (12/15) of these studies [18,19,27,29-31,35,38-40,43,44]; for example, in a recent study [43], a survey was sent to the participants on completion of the study to assess acceptance, satisfaction, overall impact, efficacy, and potential of adopting smart glasses as an alternative method of teleconsultation in neurosurgery. Among these 12 studies that administered a survey, 9 (75%) specifically reported the number of participants, which ranged between 2 and 276. Other methods such as interviews and observations were also used to gather more qualitative, in-depth insights from end users [18,31,35,45]. In particular, of these 4 studies, 2 (50%) [31,35] conducted interviews in conjunction with a survey.

It is also worth mentioning that of the 15 studies, 2 (13%) [19,31] specifically focused on evaluating the usability of smart glasses, that is, whether smart glass technology is perceived as easily usable by, and acceptable to, medical professionals. Another study [30] also examined patient perceptions of medical providers wearing smart glasses with recording capability. Finally, of the 15 studies, 5 (33%) [29,37,38,41,42] mentioned that they collected end users' opinions and experiences but did not specify the methods they used.

Benefits and Challenges of Using and Adopting Smart Glasses for Teleconsultation

Benefits

Our reviewed work highlights the advantages of smart glasses in improving communication and care coordination among distributed medical teams because this technology enables local medical providers to share visual information and perform teleconsultation in a hands-free manner. Regarding the effects on clinical care and patient outcome, the studies reported that smart glasses could shape clinical management and boost remote consultants' confidence in clinical care [27,30], achieve diagnostic accuracy comparable with that achieved in in-person patient examination [19,28,32,43], improve proficiency and performance of the clinical tasks [31,33,35,38-40], and lower the medical service cost and improve quality of life for people in rural areas or LMICs [36,38]. Finally, many studies reported positive user perceptions, acceptance, and satisfaction with the use of smart glasses [19,27,29-31,35,38,39,41,43,45].

Notwithstanding these reported benefits, the reviewed studies also highlight a set of challenges and user concerns regarding the adoption of smart glasses in practice. We grouped them into 4 main categories: technical challenges, human factors and ergonomics, privacy and security concerns, and organizational challenges (Textbox 5).

Textbox 5. Challenges to using and adopting smart glasses in practice.

Technical challenges

- Unstable or low-bandwidth internet connections [18,19,29,33,35,36,39,44]
- Battery drain becomes higher during video streaming [18,29,39]
- The microphone is unable to filter out background noise [18,29]
- Screen contrast and readability issues in bright or dark environments [18]
- Image distortion owing to overexposure to room light [18,29,35]
- Smart glass see-through screen is too small for easy interaction [41]
- Difficulty controlling video streaming software [18,35,38]
- Lack of a lock function to prevent the possibility of inadvertently halting the video streaming and ability to opt out of frequent software updates [18]

Human factors and ergonomics

- Compatibility issues with wearer's glasses or personal protective equipment [27,29,35,37,39-41]
- Misalignment between the direction of gaze and range of smart glass camera [29,35,37,40,41,43]
- Voice control function could be problematic [18,30]
- Added distractions for medical professionals [31]

Privacy and security concerns

- Concerns regarding violations of patient privacy and data breach [28-30,43]

Organizational challenges

- Added workload for medical professionals [39]
- Costly device and software [35]
- End users have limited experience with, and prior knowledge of, smart glasses; need extensive equipment and software training [27,37,41,43]

Technical Challenges

The reviewed studies reported a variety of technical challenges that may impede the effective use of smart glasses in teleconsultation. These challenges are mainly related to internet connections, hardware limitations, and software reliability. More specifically, because smart glasses require a high-speed network to transmit visual media (eg, video streaming, audio, and pictures), unstable or low-bandwidth internet connections were seen as a major technical barrier because this issue would compromise video and audio quality, leading to breakdowns in communication and loss of patient information [18,19,29,33,35,36,39,44]. This is more evident in low-resource or out-of-hospital settings where medical practitioners have limited access to the internet; for example, because Wi-Fi is not steadily available in the prehospital environment, the problem with internet connections was commonly reported in this domain [18,19,39]. One practical and successful solution used by a study in prehospital communication [31] was using a mobile router to provide a fault-tolerant network that ran independent of Wi-Fi and other external networks, allowing for deployment at any location.

Regarding hardware limitations, medical professionals were concerned about battery life (eg, the battery could get drained quickly during video streaming) [18,29,39], microphone sensibility (eg, not being able to filter out background noise) [18,29], screen contrast and readability (eg, hard to read the screen in extremely bright or dark environment) [18], image quality (eg, the image could be distorted because of overexposure to room light) [18,29,35], and small screen for interaction [33,41,44].

Issues regarding software were primarily related to controlling and interacting with the video streaming software; for example, 14% (3/21) of the studies [18,35,38] mentioned difficulties regarding zooming in or out during video streaming; as such, the smart glass wearer needs to bring their face close to the patient. Other software issues included the lack of a lock function to prevent the possibility of inadvertently halting the video streaming and the inability to opt out of frequent software updates [18].

Human Factors and Ergonomics

Many issues related to the interactions between users and the smart glass system were also reported. First, 38% (8/21) of the studies [27,29,33,35,37,39-41] highlighted the compatibility issue with users' spectacles or personal protective equipment. In particular, fitting the smart glass headset onto surgical loupes was problematic, interfering with the surgeon's ability to wear such devices [35]. Some users had to remove their spectacles to wear the smart glass headset or tie up their hair to prevent the glass camera from being hidden [40]. Second, the difference in line of sight—misalignment between what the glass wearer sees (eg, the direction of gaze) and what the camera captures (eg, range and angle of the camera)—was also cited as a major

barrier [29,35,37,40,41,43]. This issue was often attributed to the limited FOV of smart glasses [33,44]. This misalignment problem could be worsened owing to sudden head movements and frequent relocation of the smart glass wearer or the patient's unpredictable movements because these could cause motion blur for remote experts or consultants and make it difficult for them to identify the clinical situation [44]. Third, although the reviewed studies reported that their participants perceived that the smart glass was easy to use overall, usability issues still exist; for example, the voice control function did not work perfectly and thus required the user to remove their gloves to use the built-in touchpad or buttons to operate the device, such as starting or stopping the video call [18,30]. In another study, smart glasses were reported to be a distraction for medical practitioners [31].

Privacy and Security Concerns

Patient privacy and data security issues were perceived as important to address because smart glasses can transfer or even store sensitive patient data [28-30,43]. These studies stated that any implementation of smart glasses must not only comply with HIPAA requirements but also alleviate patient concerns about any potential privacy violation or misuse of their data [30,43].

Organizational Challenges

As medical professionals have limited prior knowledge of using the novel smart glass technology (compared with their experience of using smartphones or tablet devices), a few studies mentioned that user training is necessary to increase efficiency and reduce human errors in system operation [27,33,37,41,43]. In addition, the smart glass technology is costly; for example, as McCullough et al [35] reported, the cost of a yearly contract for a piece of wearable hardware and the videoconferencing platform is approximately US $7000. Such high costs could become a critical barrier to adopting this technology at scale, especially for those health care providers who have limited resources. Finally, integrating smart glasses into the current workflow is a prominent challenge; for example, Follmann et al [39] reported that adopting smart glasses in prehospital triage and communication added more workload to emergency care providers in the field and took markedly more time compared with not using smart glasses.

Discussion

Methodological Implications

In this work, we conducted a systematic review of studies focused on the use and application of smart glasses in supporting care coordination and communication among distributed medical teams. Of the 5862 papers included for screening, only 21 (0.36%) met our criteria, highlighting the paucity of studies examining the feasibility, effectiveness, and user experience of using smart glasses as a telemedicine tool. Furthermore, the studies were mostly conducted in the United States and a few other high-income countries (eg, Italy, Germany, and France). One possible explanation is that smart glass technology is costly, hindering its adoption in LMICs and low-resource settings. However, 14% (3/21) of the reviewed studies [35,36,45] revealed the substantial benefits that smart glasses could bring to LMICs and rural areas, such as providing remote training and mentoring and more accurate instructions to the field medical practitioners in low-resource settings who otherwise have limited access to remote experts. Given such benefits, more future work is needed to expand the research of smart glasses to LMICs.

Another interesting observation is that all the reviewed studies (21/21, 100%) only used off-the-shelf hardware and software without involving users in the system design process. Prior work has suggested that it is critical to involve users and understand user requirements in the early phase of system development to identify and address potential usability and technical issues [6,46,47]. In addition, regarding the methodology for eliciting user opinions, out of 15 studies conducted user evaluation, 33% (5/15) of them did not specify what questions they asked, how the questionnaire was developed, and what procedure was followed. Despite the user-friendliness of health care information technology being a determinant factor for user adoption and acceptance [48,49], the usability of smart glasses was neglected by most of the studies (19/21, 90%), with only the studies by Broach et al [19] and Demir et al [31] specifically examining this aspect. These facts highlight the need to adopt a *user-centered design* approach in the development of smart glass technology by placing users at the center of the system design process from inception to implementation and deployment.

A similar concern is that a few of the reviewed studies (4/21, 19%) only recruited a small number of study participants (eg, 2 health care professionals) to participate in their user studies (eg, survey or interview). In addition, some of the studies (5/21, 24%) did not report the details of their user research, including the number of participants. These findings may suggest that the important role of user research was not recognized in some of the reviewed studies (9/21, 43%), and their results might not be generalizable because of the limited number of study participants. Given these study limitations, we argue that involving human-computer interaction researchers in such type of research and establishing close collaborations between these researchers and health care domain experts are critical and much needed, as demonstrated in the study by Schlosser et al [50].

Finally, almost all of the reviewed studies (20/21, 95%) focused on evaluating the smart glass technology either from a technical perspective or a clinical perspective, while neglecting other important factors that could substantially affect the use and adoption of this technology, such as workflow, teamwork, policies, and organizational cultures. As prior work has argued [51], an ongoing challenge to the successful implementation and deployment of health IT (HIT) interventions is to operationalize their use within the workflow of a complex health care system; for example, a new technology could disrupt current clinical work, causing not only frustrations for medical providers but also patient safety issues [52-54]. When this problem occurs, not surprisingly, medical practitioners are left with no choice but to bypass the technology or adopt informal, low-tech, potentially unsafe workarounds that deviate from the formal protocol [55,56]. As such, researchers have highlighted the importance of examining the design, use, and application of HIT interventions through the lens of a sociotechnical

perspective [55-57]. This approach allows researchers and practitioners to understand the complex interrelations between various social and technical elements of systems that are equally important in determining the success of HIT adoption in a health care organization. In line with this argument, we believe that more research adopting a sociotechnical model [51,58] is needed to investigate the factors (eg, human-computer interaction, workflow and communication, internal organizational features, and external rules) that contribute to the uptake of smart glasses in routine use.

Design Implications

The reviewed studies revealed a set of challenges and barriers to adopting and using smart glasses in practice; for example, a commonly cited technical challenge is internet connection quality—smart glasses rely on a high-bandwidth internet network for streaming videos and transmitting other visual media data (eg, high-resolution pictures, texts, and augmented objects). However, this technical requirement could be challenging to fulfill, especially in low-resource or out-of-hospital settings [59]. With the rapid development of 5G technology, this technical barrier might be overcome in the near future; for example, a study [60] showed that 5G technology could not only enable safe and efficient complex surgical procedures during telementored surgery but also lead to a very high degree of surgical team satisfaction. In addition to internet connections, other technical improvements suggested by the reviewed studies include increasing the memory space of smart glasses to store more information, adding autofocus and stabilization features to the smart glass camera, and improving the camera resolution [35].

Human factors and usability issues make up another set of important considerations for smart glass designers and developers; for example, the difference in line of sight between the local medical practitioner and remote consultant impeded the remote consultant from seeing exactly what the smart glass wearer's eyes were fixed on. In addition, the limited FOV further complicated the video transmission to the remote experts. One reviewed study [44] experimented by attaching a mirror to the smart glass to increase the FOV of the local practitioner by transmitting both the wearer's front view and their hand operations below the camera to the remote experts. However, the video received on the other end by the experts was deemed confusing. Another viable solution suggested by prior work [59] is using more advanced mounting techniques to make sure that the smart glass can sit steadily on the wearer's head to align their visual field with the camera range. Another interesting issue brought out by a few of the studies (5/21, 24%) was the necessity of enhancing user interactions with the smart glass, such as offering more hands-free interaction mechanisms (eg, using head movements to control the device) [35] and enabling the user to zoom in and out during video streaming as well as pan the image [38].

Current smart glass applications are stand-alone and limit their potential. The data collected and transferred through smart glasses can best benefit patient care tasks if they can be incorporated into, and fully integrated with, other HITs such as electronic health records or clinical decision support systems. Interoperability issues (eg, standardized terminology) should be considered when deploying and integrating smart glasses into complex health care systems.

Other important design considerations that need full attention for developing and deploying the smart glass technology include (1) ensuring that the software is compliant with HIPAA requirements to protect patient privacy and data security, (2) integrating smart glasses into the workflow to minimize the disruption to medical practitioners' work, and (3) providing sufficient training to end users.

Study Limitations

Defining the search keywords was difficult. To generate a comprehensive and relevant list of keywords, we iteratively discussed and selected the keywords for the search based on suggestions from the health librarian and a review of systematic review articles regarding smart glasses. Another limitation is that we did not assess the quality or impact of the results from the included articles. A meta-analysis was not feasible because of the heterogeneity of the study designs and results.

Conclusions

Smart glasses were found to be an acceptable and feasible tool in enabling visual communication and information sharing among distributed medical teams. Despite the high potential of this novel technology, the reviewed articles pointed out a set of challenges that need to be addressed before the wide deployment of this technology in complex health care systems. Thoughtful system design involving end users from the beginning and improved hardware and software reliability are needed to improve the usefulness and usability of smart glasses for medical practitioners [11,59]. We suggest that more user-centered design and evaluation research is needed to examine and evaluate medical professionals' needs and perceptions and determine how to design smart glass technology to meet their needs. In addition, more research is required to elucidate how smart glasses affect the workflow of medical professionals in complex care environments.

Acknowledgments

The authors thank the health librarians Lilian Hoffecker and Ben Harnke at the University of Colorado for performing the literature search and documenting the search process and results. This study was supported by the National Science Foundation (grant 1948292) and the Agency for Healthcare Research and Quality (grant 1R21HS028104-01A1).

Abstract

Background: Sensors are increasingly used in health interventions to unobtrusively and continuously capture participants' physical activity in free-living conditions. The rich granularity of sensor data offers great potential for analyzing patterns and changes in physical activity behaviors. The use of specialized machine learning and data mining techniques to detect, extract, and analyze these patterns has increased, helping to better understand how participants' physical activity evolves.

Objective: The aim of this systematic review was to identify and present the various data mining techniques employed to analyze changes in physical activity behaviors from sensors-derived data in health education and health promotion intervention studies. We addressed two main research questions: (1) What are the current techniques used for mining physical activity sensor data to detect behavior changes in health education or health promotion contexts? (2) What are the challenges and opportunities in mining physical activity sensor data for detecting physical activity behavior changes?

Methods: The systematic review was performed in May 2021 using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. We queried the Association for Computing Machinery (ACM), IEEE Xplore, ProQuest, Scopus, Web of Science, Education Resources Information Center (ERIC), and Springer literature databases for peer-reviewed references related to wearable machine learning to detect physical activity changes in health education. A total of 4388 references were initially retrieved from the databases. After removing duplicates and screening titles and abstracts, 285 references were subjected to full-text review, resulting in 19 articles included for analysis.

Results: All studies used accelerometers, sometimes in combination with another sensor (37%). Data were collected over a period ranging from 4 days to 1 year (median 10 weeks) from a cohort size ranging between 10 and 11615 (median 74). Data preprocessing was mainly carried out using proprietary software, generally resulting in step counts and time spent in physical activity aggregated predominantly at the daily or minute level. The main features used as input for the data mining models were descriptive statistics of the preprocessed data. The most common data mining methods were classifiers, clusters, and decision-making algorithms, and these focused on personalization (58%) and analysis of physical activity behaviors (42%).

Conclusions: Mining sensor data offers great opportunities to analyze physical activity behavior changes, build models to better detect and interpret behavior changes, and allow for personalized feedback and support for participants, especially where larger sample sizes and longer recording times are available. Exploring different data aggregation levels can help detect subtle and sustained behavior changes. However, the literature suggests that there is still work remaining to improve the transparency, explicitness, and standardization of the data preprocessing and mining processes to establish best practices and make the detection methods easier to understand, scrutinize, and reproduce.

activity tracker; wearable electronic devices; fitness trackers; data mining; artificial intelligence; health; education; behavior change; physical activity; wearable devices; trackers; health education; sensor data

Introduction

Wearable sensors are increasingly employed in health interventions because of their ability to track participants' physical activity (PA) in an unobtrusive, continuous, and precise manner under free-living conditions [1]. In the context of health promotion, sensor data are commonly used to objectively assess interventions by monitoring PA changes and progress toward compliance with public health PA guidelines [2].

The rich data captured by activity sensors contain information about the participants' PA, potentially unlocking valuable insights into PA behaviors and patterns [3]. These insights can help to advance the understanding of how interventions affect PA behaviors and how behaviors change, thereby scaffolding the design of future interventions, and enhancing their outcomes, efficacy, and adherence.

In the last decade, a growing number of artificial intelligence and data mining models and techniques have been developed to detect and extract these latent PA patterns beyond the typical summaries of pre- and postintervention daily steps or time spent in various PA levels. In this systematic review, we aimed to describe the data mining models and techniques currently used to detect PA with a focus on behavior changes. We discuss their value, identify gaps or challenges, and highlight opportunities. The following research questions (RQs) guided this review:

RQ1: What are the current techniques used for mining PA sensor data to detect behavior changes in health education or health promotion contexts?

RQ1.1 What are the types of sensors used and what data are collected?

RQ1.2 How are data preprocessed?

RQ1.3 What features are used to detect behavior changes?

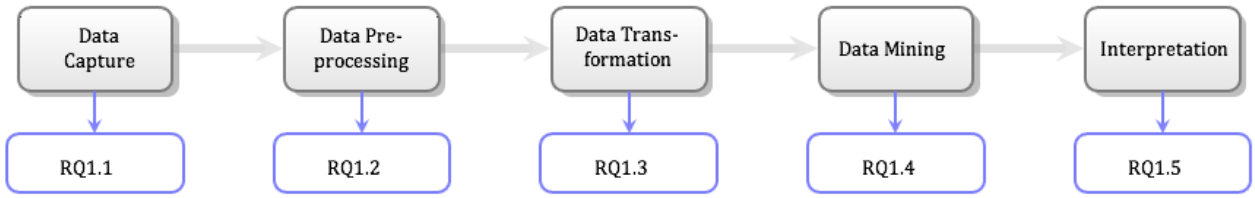
RQ1.4 What are the data mining models and techniques used to detect behavior changes?

RQ1.5 What are the interpretation of data mining models used for?

RQ2: What are the challenges and opportunities in mining PA sensor data for detecting PA behavior changes?

The RQ1 subquestions were established following the reasoning and order of the process of knowledge discovery in databases [4]. Figure 1 summarizes this process and maps each step with the relevant RQ1 subquestion.

Figure 1. Knowledge discovery in database steps (in grey) and research question 1 (RQ1) subquestions (in blue).



Methods

Design

For this systematic review, we followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [5] and used the Rayyan QCRI web application [6] to manage the review process. We identified studies by searching the Association for Computing Machinery (ACM), IEEE Xplore, ProQuest, Scopus, Web of Science, Education Resources Information Center (ERIC), and Springer digital libraries. We also searched Google Scholar to identify grey literature and extracted the first 100 results. For this scholarly reference search, we used the following query: (education OR promotion OR "behaviour change") AND ("data mining" OR "machine learning" OR "artificial intelligence") AND (sensor OR accelerometer OR tracker OR wearable) AND "physical activity" AND health. All extracted scholarly references had been added to the database at the latest on the search day (May 28, 2021). The inclusion and exclusion criteria are presented in Textbox 1.

Textbox 1. Inclusion and exclusion criteria for article selection in the review.

Inclusion criteria

- Full-length articles
- Peer-reviewed articles in journals or conference papers
- Articles that used data mining techniques for data from physical activity (PA) wearable sensors
- Articles that included PA data
- Articles on applied health education/promotion or on behavior change scenarios
- Articles that used well-known data mining techniques such as classification, regression, clustering, association, and sequence algorithms, as well as specific algorithms to model PA data

Exclusion criteria

- Use of analytics without data mining
- Studies on animals (eg, accelerometers on dogs)
- Self-quantification without a health education or health motivation component
- Dissertations and theses, due to lack of a peer review process
- Systematic reviews, reviews, and meta-analyses
- Health care applications without a health education or motivation for behavior change component
- Specific movement detection (abnormal gait, falls)
- Aid for sport training (eg, maintaining heart rate, postures, specific movements)

Search Outcome

The number of references extracted from each electronic database is summarized in Table 1.

Following the PRISMA methodology, we retrieved 4388 references from the sources listed in Table 1. We then removed 415 duplicates, leaving 3973 unique references that were screened by reading their titles and abstracts. Using the inclusion/exclusion criteria (Textbox 1), we excluded 3688 references and selected 285 publications. After full-text reading, we excluded 266 references: 33 on activity recognition, 5 on data mining, 24 on systems, 31 on rehabilitation, 39 not on behavior changes, 54 without data mining, 51 not on health education/promotion, 13 not on PA, and 16 reviews. At the end of the selection process (summarized in Figure 2), we retained 19 references for this systematic review.

Table 1. Number of references extracted from each database.

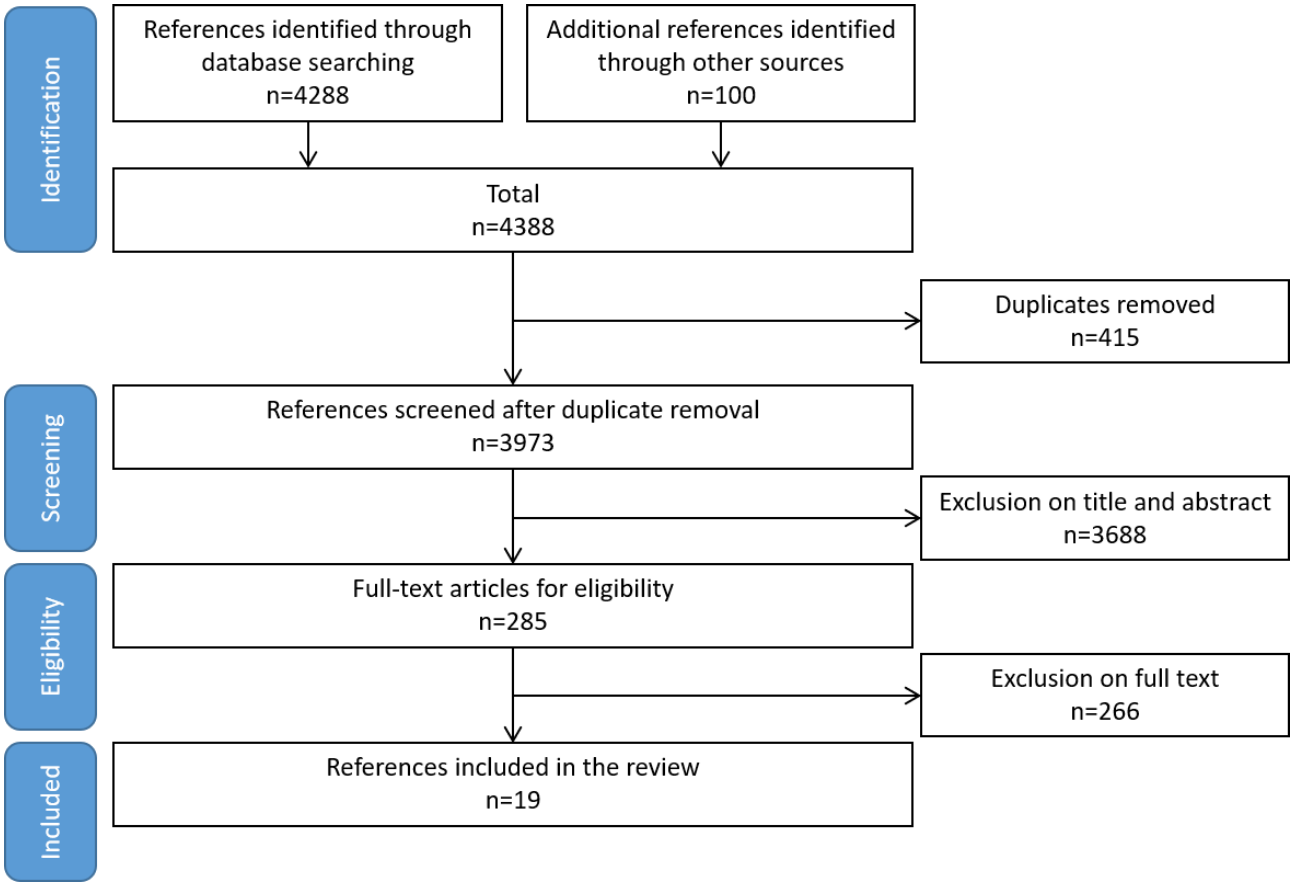
Figure 2. Study inclusion flowchart according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology.



Results

Overview

The 19 included articles were published between 2013 and 2021. Their number per year increased from 1 in 2013 to 2 in 2017 and up to 5 in 2018. Subsequently, the number of publications decreased to a mean of 3 per year.

The selected articles were published in conferences and journals focused on five different themes (Table 2): medical and public health, medical and health informatics, human-computer interactions, physical human behavior, and engineering and science. The three most popular themes were medical and health informatics, human-computer interactions, and engineering and science (15/19, 79%). Among the included articles, four were published in JMIR publications: three in JMIR mHealth and uHealth and one in JMIR Public Health and Surveillance.

Sensor Types and Data Capture

The characteristics of the sensors (eg, number and type) used to capture PA behaviors and of the collected raw data are summarized in Table 3.

The length of data recordings varied between 4 days and 1 year, with a median of 70 days. Recording lasted ≤7 days in two studies, between 3 and 5 weeks in six studies, between 10 and 16 weeks in eight studies, and ≥6 months in three studies.

The number of participants varied between 10 and 11,615, with <30 in five studies, between 30 and 299 in 10 studies, and ≥300 participants in four studies.

All included studies used accelerometer sensors. We could categorize these devices into three groups: (1) commercial wrist-worn wearable accelerometers that are consumer-grade devices with a sample rate between 30 Hz and 60 Hz, such as Fitbits [13,14,19,22,25], Samsung Gear [17], and Nokia [15]; (2) smartphone accelerometers with a sample rate usually set to 50 Hz and up to 100 Hz, in which data were collected via an app installed in the smartphone [7,9,10,16,18]; and (3) scientifically validated wearable accelerometers with a sample rate up to 100 Hz, such as ActiGraph [8], GENEActiv [11,24], and other devices developed for health care [12,20].

In 7 out of the 19 (37%) selected studies, accelerometers were used with other sensors such as GPS tracking [10,16,17], compass position tracking [17,20], heart rate trackers [17,21], and smart scales [15,19].

The recorded raw data varied in function of the sensor characteristics, including sampling frequency, accuracy, and axis number. Moreover, other sensor features such as battery duration and storage capacity affected the recording length. For instance, a long battery life and high storage capacity enable longer recording without interruptions. Table 4 summarizes the number of participants and data recording duration for the included studies.

Data Preprocessing

Raw data extracted from sensors need to be transformed into variables that will contribute to generating the input features for data mining models to detect PA behavior changes. Table 5 provides a summary of the initial transformation and the resulting preprocessed data.

The preprocessing of the raw data from sensors was carried out in two ways. The first approach was to use proprietary programs to transform the sensors' data directly into the resulting preprocessed data, without specifying whether there was an initial preprocessing stage such as that used to generate steps, metabolic equivalents (METs), calories, heart rate, or exercise characteristics (type, duration, distance, or frequency). The second approach was to produce intermediate data that were then transformed in the resulting preprocessed data using a custom preprocessing tool. For instance, to generate PA levels (PALs), raw data were first transformed into MET, activity classes, or signal vector magnitudes.

The resulting preprocessed data were mainly activity characteristics (step count, PAL, integrals of the moduli of acceleration, activity types, duration, distance travelled, and frequency) and energy expenditure (MET and calories). Step count from smartphones and commercial wrist-worn devices was the most frequent, followed by PAL from research-grade devices.

The resulting preprocessed data were aggregated at different time levels (Table 6). Day and minutes were the most frequent time levels of aggregation. Generally, PAL and MET were aggregated per minute. Calories and step counts were calculated per day.

Features Used to Detect and Extract Behavior Changes

The features of the data mining models were mostly generated from the sensors' preprocessed data and, in some cases, from other sources (nonsensor data). Table 7 provides the features categorized with respect to the function of their source: accelerometers, other sensors, and nonsensor devices.

Most of the included articles used descriptive statistics to present the preprocessed data as features, for instance total number of steps per day [9,11,14,17,25], mean number of steps per day [17], or PA count per hour [8]. Other studies created windows or segments of time to calculate PA characteristics, including segments of steps or sleep [15] and PA bouts [13,24]. Other articles used the preprocessed data to calculate the participants' step achievements such as whether they reached their step goal [9,11,19,23]. Zhu et al [13] used more complex features such as the ratio between the most active and least active period or the circadian rhythm strength.

In addition to the features derived from sensors, others were created from measurements carried out during the intervention by scientists, such as the number of days that a person participated in the intervention [19] and anthropometric [7,21] or psychological [14,16,25] characteristics. Data were collected through surveys/questionnaires or interviews with participants.

Data Mining

Algorithm Overview

Table 8 summarizes the data mining methods and specific algorithms used in the selected articles.

Clustering was the most used method, particularly the K-means algorithm. Indeed, in health interventions, the PA performed by each participant varies in duration, form, and intensity. Therefore, an algorithm that clusters PA behaviors is required to analyze them. The unsupervised K-means algorithm is suitable for this task. Indeed, due to its simplicity and ease of use, this is one of the most popular options for data mining [26]. Decision-making algorithms and classifiers were the second most used methods. Both rely on supervised algorithms that use PA characteristics as a method for predicting when and/or what information must be delivered to individual participants for increasing their PA. Other algorithms were also tested to extract PA behaviors, such as social cognitive and contagion models, PA windows permutations, and recommendation algorithms.

[a]MAB: multiarmed bandit.

Classifiers

Hermens et al [20] used a k-nearest neighbor model and a support vector machine to determine whether a specific time of the day was suitable for sending a motivational message to optimize adherence to the intervention. Dijkhuis et al [22] used a tree and tree-based ensemble algorithm classifiers to predict whether users will achieve their daily PA goal. On the basis of this prediction, a personalized PA coaching program was proposed. Forman et al [18] developed gamified personalized

feedback using a score model depending on the PA change detected from accelerometer data. Batool et al [16] predicted the likelihood that the PA level of a given patient was too low. They also predicted which patients were at higher risk of not adhering to the prescribed therapy to optimize their PA.

Clustering Techniques

Lee et al [8] grouped participants in two clusters on the basis of their step counts (one more active than the other), and analyzed them to better understand these PA patterns. Diaz et al [24] used a clustering-based approach for a more insightful analysis of the participants' PA behavior and of the nature of the PA behavior changes, if present. Galy et al [11] clustered PA levels and daily step goal achievement to assess the adherence to a health program. Fukuoka et al [12] identified PA clusters to analyze and compare sociodemographic features and cardiometabolic risks among participants belonging to these clusters. Chen et al [21] clustered the participants' PA, and then established a system to adapt the exercise program for the next week as a function of the individual PA behavior change. Gasparetti et al [15] clustered the participants' PA to generate groups of habits recommended by a system to the participants with the objective of changing their PA to obtain weight loss effects.

Decision-Making Algorithms

Rabbi et al [10] generated personalized suggestions in which users were asked to continue, avoid, or make small changes to their existing PA behaviors in order to help them reach their PA goals. Forman et al [19] developed an algorithm that could personalize and optimize the PAL during the intervention as a function of the amount of PA performed. Aguilera et al [7] generated personalized messages for participants in the intervention to increase their PA and consequently the intervention effectiveness. Zhou et al [9] adapted the step goal settings of the intervention depending on the PA behavior change. Zhu et al [14] personalized social comparison among participants to motivate them toward improving their PA behavior.

Social Cognitive Model

Mollee and Klein [25] developed a model that simulates changes in PALs over 2 to 12 weeks to optimize the participants' health outcome.

Social Contagion Model

Mollee et al [23] used a social contagion model to explain the PAL dynamics in a community.

PA Windows Permutations

Sprint et al [13] proposed a window-based algorithm to detect changes in segments of users' PA behavior to motivate progress toward their goals.

Recommendation Algorithms

Angelides et al [17] used genetic algorithms and Pareto optimality to compare the participants' and peer community's data to help participants interpret the PA data and to generate personal lifestyle improvement recommendations.

Interpretation of the Data Mining Models

Overview of Models

The resulting data mining models detecting PA behavior changes were used for several purposes, as summarized in Table 9 and below.

Table 9. Main uses of the resulting data mining models.

Main use	Reference
Personalized feedback	[7,10,15,16,18,20]
Personalized program	[9,19,21,22]
Support for self-reflection	[17]
Cohort analysis of the intervention impact on PA[a]	[8,11-13,24]
Analysis of the social component effects on PA	[14,23,25]

[a]PA: physical activity.

Personalized Feedback

The PA behavior changes extracted from participants' data were used to promote PA by creating and sending personalized messages that reported the behaviors and gave suggestions for achieving the previously established PA goals. For instance, Aguilera et al [7] built a system that detects the participants' PA behavior changes and generates personalized daily text messages with custom timing, frequency, and feedback about their step count/goal and motivational content. Hermens et al [20] built a system that chooses the best suitable time to send a message with personalized intention, content, and representation. Schäfer et al [18] created an app with gamified feedback where different avatars are awarded based on the participant's daily PA behavior. Gasparetti et al [15] suggested personalized PA patterns based on the participants' PA patterns. Batool et al [16] detected the participants' PA behavior while commuting and suggested how to increase it. Rabbi et al [10] generated personalized simple PA suggestions (continue, avoid, or make small changes).

Personalized Programs

The PA intervention program and objectives are adapted to each participant's needs. For instance, Chen et al [21] created a guided exercise prescription system that adapts as the participants' PA behavior changes. Similarly, Forman et al [19] changed the participant's exercise intensity suggestion depending on their PA behavior achievements. On the basis of

each participant's step count progress, Dijkhuis et al [22] suggested new daily step objectives. Zhou et al [9] used push notifications to deliver daily step goals.

Support for Self-Reflection

Algorithms can help participants to interpret their PA behavior changes. For example, Angelides et al [17] used an algorithm to assist in the interpretation of the participant's PA data by comparing them with those of the peer community and to generate personalized recommendations to achieve their daily goals.

Cohort Analysis of the Intervention Impact on PA

These algorithms detect PA behavior changes in participants that allow analyzing the intervention impact. For example, Fukuoka et al [12] determined PA patterns in women throughout the day that could help to develop more personalized interventions and guidelines. Diaz et al [24] analyzed the changes in PA behavior (bouts and frequency) during an intervention. Galy et al [11] tracked the participants' adherence to the international recommendations during an intervention. Lee et al [8] identified PA patterns associated with specific subgroups of people who participated in an intervention. Sprint et al [13] analyzed the participants' PA changes during an intervention by comparing multiple time windows.

Analysis of the Social Component Effect on PA

These algorithms analyze the psychosocial influences on the participants' PA. For example, Mollee et al [23] analyzed the PA dynamics in a community using a social contagion model. Mollee and Klein [25] analyzed the PA dynamics in a networked community using social cognitive theories, and Zhu et al [14] personalized social comparison during an intervention to increase the participants' PA.

The main uses can be classified in two groups. The first group, composed of 11 out of the 19 (58%) selected studies, aimed to generate personalized feedback/PA programs to scaffold and support PA behavior changes among participants. Indeed, researchers seem inclined to generate greater personalization because it increases the intervention efficiency, effectiveness, enjoyment, and reliability [27]. The second group, composed of 8 out of the 19 (42%) selected studies, sought to analyze the impact of interventions on the participants' PA. Specifically, these studies analyzed the intervention impact on PA at the cohort level to assess health education interventions, and analyzed participants' PA to show them their behaviors and help to understand them. The main objective of both groups was to explore how PA behavior patterns relate to the intervention effectiveness, which can add new evidence on how to create more effective interventions [28].

Discussion

Principal Findings

Summary

We found 19 articles about data mining models and techniques to detect PA behavior changes in health education or promotion studies, and their number has progressively increased over time. We here discuss the principal findings, identify opportunities and challenges for future research directions, and present the limitations of this systematic review. The Discussion is structured according to the RQs as a guide.

Opportunities and Challenges

Sensor Types and Data Capture

All selected studies used accelerometer sensors to capture PA behaviors. While 7 out of the 19 (37%) studies utilized accelerometers exclusively, the rest employed them with other sensors. Nonaccelerometer sensors capture additional information that may be relevant to PA (such as work/school schedule, itineraries, and sleep patterns [29]) and could yield auxiliary features for the data mining models. For instance, GPS sensors provide the number of kilometers and location of PA performed.

The median number of participants in the selected studies was 74, and participants were mainly young or middle-aged adults. This low number of participants and the skew toward adults may have generated biased data mining models that can detect and find behavior changes only in a specific population. Different population groups behave differently and should be studied independently. For instance, PA behaviors are different in children and adults [2]. Some of the studies focused on groups with specific PA behaviors, such as children [18,24], adolescents [11], and women [12]. However, some population groups with distinctive PA patterns, such as pregnant women [30] and people with health conditions or disabilities [31], may need custom detection models.

In 15 out of the 19 (79%) included studies, data were recorded for less than 3 months. Therefore, the current methods for detecting PA behavior changes have been developed mostly for capturing short-term patterns, making the conclusions valid only for short periods. To detect medium- and long-term PA behavior changes, studies with more extended recording periods are needed, such as the study by Gasparetti et al [15] based on data collected during 1 year. Moreover, new methods to detect extended (eg, annual or seasonal) PA patterns are required to study how the participants' behavior and habits change over time. An increase in the participants' number and recording length will lead to new challenges related to big data analysis, such as efficient data management and data mining processing speeds.

Data Preprocessing

Many of the selected studies used commercial accelerometers that allow only the retrieval of aggregated preprocessed data using proprietary software (ie, number of steps per minute), without being transparent on how data were preprocessed (ie, how steps were calculated from the accelerometry data). This data preprocessing black box makes it impossible to determine the quality of the captured PA data and makes the data mining results scientifically irreproducible. Conversely, in studies that used medical-grade accelerometers, the accelerometry data were explained in detail and the preprocessing steps were documented and referenced.

We found a lack of standard procedures for data preprocessing that made it challenging to compare the study results and conclusions. Indeed, if data are not preprocessed correctly, this could cause the transfer of incorrect information to the features and then to the data mining models. This could lead to the creation of inaccurate models, thus limiting the study validity. Data cleaning is a good example of this issue. Indeed, the best procedure to eliminate the nonwearing time remains unclear along with the impact on the accuracy of the resulting models. If nonwearing time is poorly removed, features can generate a PA underestimation by recognizing nonwearing time as sedentary behavior when it is not. Moreover, if sensor data concerning changes in accelerations while commuting by car or bus are not completely removed, they will be erroneously classified as steps, thereby overestimating PA in the model and in the conclusions. Similarly, sedentary activities could be overestimated if sleep time is not correctly removed.

Most of the selected studies aggregated information by day or minute. Although data aggregation is useful when comparing general features of PA behaviors, such as daily steps, this procedure may overlook subtle behavioral changes that can be crucial for detecting major PA behavior changes. For instance, if a person who walks every morning decides to change their behavior and starts to walk at night, the sum of daily steps will be the same, but this new behavior will not be detected. Conversely, it could be detected if the aggregation level is changed to the hour. To detect these and other subtle behavior changes, PA should be analyzed simultaneously at different aggregation levels, and new time frames should be created to match daily habits and behaviors, such as periods of the day (eg, morning, afternoon) or participants' office hours.

Features Used to Detect and Extract Behavior Changes

Most of the preprocessed data were transformed into features that are simple descriptive statistics, such as the total time spent at a specific PAL or the mean number of steps. These features are valuable to detect behavior changes, but they mainly capture the PA intensity and the PA presence or absence. Yet, PA has more valuable characteristics that vary during PA behavior changes and that can help to detect such behavior changes, such as the length of PAL bouts or the amount of time spent doing PA. These PA characteristics can be extracted from current sensor data. For instance, Galy et al [11] explored different moderate-to-vigorous PA bout lengths and Sprint et al [13] assessed the circadian rhythm. International PA guidelines can serve as inspiration to identify new PA features. For instance, according to World Health Organization recommendations, adults should perform muscle-strengthening activities (involving all major muscle groups) at moderate or higher intensity at least twice per week [2]. This calls for the creation of features that capture the muscle activity type, intensity, and frequency. Moreover, most of the included studies used only PA-derived features to detect behavior changes, and did not consider relevant non-PA data associated with PA changes, such as the participants' weight and quality of sleep. Some studies captured non-PA data, but they did not use them to detect PA changes. For instance, Rabbi et al [10] used only PA-derived data (PA frequency and calories burned) to detect behavior changes, although they also recorded the participants' food intake, thus excluding their caloric intake that is closely related to weight and the amount of PA participants are likely perform.

The use of simple descriptive statistics as features and the exclusion of non-PA data associated with behavior changes indicate that sensor data were underexploited and that the features used to detect PA behavior changes are still underdeveloped. Including new PA characteristics and new non-PA features could help to better understand the nature of PA changes and how these features influence PA behavior changes, ultimately increasing the model detection accuracy.

Data Mining Methods and Techniques

Most studies used off-the-shelf classifiers, clusters, and decision-making algorithms to detect PA behavior changes. We expected to find tailor-made algorithms because in health education settings, it is important to find specific PA patterns in participants of different classes who follow learning modules with different contents and with different PA goals. Moreover, we noticed that most authors did not explain how they chose the algorithms and did not specify the efficiency and accuracy of the models used for detecting PA behavior changes, raising uncertainty about how good they are at this task. This suggests that more efficient and accurate algorithms could be created and calls for more transparency in the algorithm choice process. Therefore, authors should explicitly describe the steps and methodology of new algorithms, and share their source codes to be scrutinized and to compare their detection accuracy. The creation of open accelerometry databases is also needed to enable benchmarking.

Interpretation of the Resulting Data Mining Models

The main uses of the data mining models focused on personalization, support for self-reflection, and analysis of PA behaviors. Model interpretation focused on generating personalization and support for promoting behavior changes. Personalized feedback and intervention programs were based mostly on the participants' PA data. The inclusion of additional information that may influence behavior changes (eg, contexts, schedules, social constraints, motivation, and weather) would allow for better interpretation and use of the detected behavior changes. Systems could exploit these additional data to improve the feedback delivery time and content, with positive effects on the effectiveness of health education programs and interventions. For instance, with the current models, a participant could receive an automatized personalized behavior change message that suggests taking a short walk, although it is snowing outside. This would decrease the likelihood of following the suggestion. However, if the system could be aware of the weather, the participant would receive this suggestion only after the weather conditions have improved, or a different suggestion that is more likely to trigger a behavior change at that point in time. Moreover, as the models relied mainly on PA features to model and interpret the behavior changes, only the physical dimension of the learning process in health education was incorporated in the models and their interpretation, leaving aside the knowledge dimension of the learning process. Learning management systems and intelligent tutoring systems already capture the knowledge dimension. Their integration would help to understand, in a comprehensive way, how participants learn,

and would enable the real-time monitoring of how PA behavior changes align with the intervention purpose. This would allow adapting each participant's content and learning objectives in real time, thereby improving instructions and learning, ultimately increasing the program or intervention effectiveness.

Most of the included studies generated complex output models that require detailed knowledge of how they were created to interpret the resulting patterns, making them difficult to understand for health scientists and any other scientist not familiar with machine learning. This is a common problem in interdisciplinary teams; however, an effort can be made to create more readable, intuitive, and easy-to-understand algorithms and methods, a goal that exists in related machine learning areas such as explainable artificial intelligence [32].

Limitations

Studies on wearable machine learning devices to detect changes in PA in health education have only started to be published in the last decade. As research is advancing, keywords are changing and new terms are created. Although we used a wide range of keywords in our query to include sensors, PA, and health education, we may have left some keywords out, and thus we may have missed some references. This may have also affected the initial reference screening process by title and abstract. We minimized this issue by testing several queries before starting our systematic review until we found the one we ultimately used. Another possible limitation in our search is that we might have omitted references listed only in other peer-reviewed databases (we searched only the most popular databases in engineering and computer science), such as medical databases (ie, PubMed). We mitigated this risk by including grey literature in our systematic review (see the Methods section).

Regarding the research subquestions and the review structure, we created research subquestions in line with the usual data mining process steps, but we certainly left some topics unaddressed. For instance, we did not address ethics, privacy, and security issues, or how data are filtered during preprocessing (eg, sleeping time or sensor nonuse). Although these are common substeps during the data mining process and including them would have made this systematic review more comprehensive, we preferred to limit this review only to the critical steps.

Conclusions

In the last 10 years, different methods have been developed to detect behavior changes in health education or health promotion contexts. These methods have been tested in small populations, are based on short data-recording periods, and rely mainly on accelerometry data. Incorporating information that is complementary to the participants' PA data would allow for creating more precise detection models, better interpreting these models, and understanding how participants learn and what triggers new behaviors. Exploring other data aggregation levels, in addition to days and minutes, could help to detect more subtle and long-term behavior changes. Fully describing the data preprocessing methods and the efficiency and accuracy of the behavior change detection models would help to better understand, scrutinize, and compare studies. Detection models were mainly used to generate personalized feedback and to provide support for promoting or maintaining behavior changes, but did not integrate the knowledge dimension of the learning process. Adding the knowledge dimension and creating easier-to-understand models could facilitate the interpretation of participants' behavior changes in a more comprehensive way, opening the way toward better and deeper analyses and personalization.

Abstract

Background: Common data models (CDMs) are essential tools for data harmonization, which can lead to significant improvements in the health domain. CDMs unite data from disparate sources and ease collaborations across institutions, resulting in the generation of large standardized data repositories across different entities. An overview of existing CDMs and methods used to develop these data sets may assist in the development process of future models for the health domain, such as for decision support systems.

Objective: This scoping review investigates methods used in the development of CDMs for health data. We aim to provide a broad overview of approaches and guidelines that are used in the development of CDMs (ie, common data elements or common data sets) for different health domains on an international level.

Methods: This scoping review followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. We conducted the literature search in prominent databases, namely, PubMed, Web of Science, Science Direct, and Scopus, starting from January 2000 until March 2022. We identified and screened 1309 articles. The included articles were evaluated based on the type of adopted method, which was used in the conception, users' needs collection, implementation, and evaluation phases of CDMs, and whether stakeholders (such as medical experts, patients' representatives, and IT staff) were involved during the process. Moreover, the models were grouped into iterative or linear types based on the imperativeness of the stages during development.

Results: We finally identified 59 articles that fit our eligibility criteria. Of these articles, 45 specifically focused on common medical conditions, 10 focused on rare medical conditions, and the remaining 4 focused on both conditions. The development process usually involved stakeholders but in different ways (eg, working group meetings, Delphi approaches, interviews, and questionnaires). Twenty-two models followed an iterative process.

Conclusions: The included articles showed the diversity of methods used to develop a CDM in different domains of health. We highlight the need for more specialized CDM development methods in the health domain and propose a suggestive development process that might ease the development of CDMs in the health domain in the future.

Introduction

Rationale

Integration of heterogeneous data is a ubiquitous topic in modern medicine. The arising large variety of data has the potential to provide in-depth insights about different aspects of clinical care and can lead to improvements in health care [1,2]. Yet, challenges, such as the identification and access of relevant data, the association between different data sources, and the assurance of data quality given the structural variations among data sources, still pose major barriers [3,4]. Common data models (CDMs) provide the possibility of harmonizing data from disparate sources, storing information in a standard structure by defining the syntax and semantics of data, and enabling operations on data using standard analysis methods [5]. In particular, a CDM contains a unified set of metadata, allowing data and its information content to be shared across applications and institutional borders, and thus enabling harmonized data integration and analysis on an international scale [6].

In the health domain, there are different types of CDMs (eg, CDMs for harmonization and storage of electronic health record–based patient data). An example is the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) developed by the Observational Health Data Science and Informatics (OHDSI) community, which ensures homogeneous storage of observational health care data across different databases with similar formats and terminologies [7]. There are also further CDMs for clinical data, like Sentinel CDM, Clinical Data Interchange Standards Consortium (CDISC) Study Data Tabulation Model (SDTM), and National Patient-Centered Clinical Research Network (PCORnet) [8], and data warehouse models, like Informatics for Integrating Biology and the Bedside (i2b2) [9]. Moreover, some CDMs define the data from patient cohorts and describe a medical specialty or a group of diseases. For example, there are specific CDMs for the domain of rare diseases [10,11] or radiology [12]. Overall, there is a large variety of CDMs in the literature for common, rare, and context-specific medical examinations, and each of them follows a more self-defined development process.

As described by Melles et al [13], a practical design meets the users' needs. While designing a CDM in the health domain, in addition to the developers (ie, IT staff and computer scientists), the primary stakeholders (ie, patients and clinicians) are particularly interested in the outcome. It is therefore recommended to include them in the design process as early as possible [13,14]. In addition to the stakeholders, the medical context is also quite complex and requires extensive medical and technical expertise to ensure the usefulness of the model after its development. This is why the development process of a CDM is critical and a comprehensive development method or guideline is necessary.

Studies, such as those by Gericke and Blessing [15] and Bobbe et al [16], have already tried to determine the commonalities and differences in development processes across disciplines. Bobbe et al [16] performed a comparison of design models from academic theory and professional practice, and discussed 8 types of design processes. In particular, the basic design cycle, V design process, human-centered design, hypercyclic design, Munich procedural model, double diamond model, frog model, and IDEO model were presented. Additionally, Melles et al [13] introduced categories for models, namely, whether a model is activity-based or stage-based, solution-oriented or problem-oriented, and design-focused or project-focused.

However, given the complexity of the health domain and the importance of many stakeholders taking part in the process, it might be difficult to transfer models from other disciplines. This is why we aim to derive such a process and review the available CDM instances in the domain. Exemplarily, the results of this scoping review will be integrated into the design and development of a CDM for the SATURN ("Smartes Arztportal für Betroffene mit unklarer Erkrankung" ["Smart physicians' platform for patients with unclear diseases"]) Project in the future [17]. This project aims to develop an artificial intelligence–based diagnosis support tool for primary care physicians. With the help of user-centered design, the requirements of a decision support tool, especially for noncharacteristic symptoms, will be studied. The medical focus is on the diagnosis of unclear and rare medical conditions. This is why, in this review, we focus on the similarities between the CDM development methods in rare medical conditions and common medical conditions in order to determine whether the methods for common medical conditions can be adopted for rare medical conditions as well. On a technical level, rule-based systems, machine learning, and case-based reasoning will be implemented. As part of this project, CDMs for 3 groups of rare diseases, namely, endocrinology, gastroenterology, and pneumology, will be developed.

Our review contributes to the analysis of CDM development methods in the health domain on an international scale and aims to explore the actual involvement of stakeholders, especially medical experts, in the development process. To the best of our knowledge, this is the first scoping review focusing on CDM development methods in the health domain.

Objectives and Research Questions

This scoping review has been conducted to provide an overview of the methods used for the initial and further development of CDMs in the health domain. We divided the overall development process into conception, users' needs collection (eg, collection of evidence, review of the literature, and guidelines), and implementation, as well as individual evaluations within the phases. We consider the conception phase as an initial step, where the CDM is theoretically designed along with stakeholders. Subsequently, the essential elements previously identified are gathered in the "users' needs collection" phase. The finalized process, in which the conceptualized model is implemented and ready-to-use, is termed the implementation phase.

According to the rationale and objective explained above, this scoping review examines the following questions:

1. How are CDMs methodically developed in the health domain? What requirement analysis methods, design processes, and validation methods were used?

2. How or when do stakeholders, especially medical experts, get involved in the development process?
3. How can the CDM development methods be classified based on their requirement analysis methods, design processes, validation methods, and model type?

Methods

Protocol and Registration

To ensure methodological quality, this scoping review has followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR) checklist [18]. According to this checklist, we published and registered the review protocol [19]. Out of the 22 items of the PRISMA checklist, 20 have been considered in this review (Multimedia Appendix 1).

Search Strategy

To achieve a comprehensive query, an initial search was performed in PubMed with the term "common data model." Six randomly chosen articles matching the topic were analyzed [10-12,20-22]. The keywords associated with the articles listed in Table 1 were considered and subsequently tested in the query. The combination of terms that delivered the highest number of matching articles was included in our final search string.

Some studies used the term *data set* [11], and others defined alternative data elements that can be part of a data set or data model [10]; thus, to avoid the exclusion of certain studies, we jointly used the following terms in our search string: *common data model*, *common data element*, and *common data sets*. We also added the short forms of these terms in our search string and analyzed the relevance of the results by simply looking into the resulting literature. Additionally, we added the following terms in our search string to ensure that the included CDMs were developed within the health domain: medical, medicine, health, healthcare, health care, electronic health, clinical, and disease. The search string used in PubMed is presented in Table 2. It was developed as a combination of the mentioned terms, their possible variations, and where applicable, Medical Subject Headings (MeSH) [23]. The search strings used in the other 3 databases have been provided in Multimedia Appendix 2.

The query was designed and tested by the author NA and was approved by all coauthors. The resulting articles were added to Rayyan (Rayyan Systems Inc) [24] for further screening and annotation.

Table 1. Six randomly chosen articles for the construction of the search string and their keywords.

Article title	Keywords
The EPIRARE proposal of a set of indicators and common data elements for the European platform for rare disease registration [10]	Registries, common data elements, European platform, rare diseases, patient registration, and EPIRARE
A methodology for a minimum data set for rare diseases to support national centers of excellence for healthcare and research [11]	Common data elements, interoperability, metadata, minimum data set, national health program, and rare diseases
Development and validation of the Radiology Common Data Model (R-CDM) for the international standardization of medical imaging data [12]	*Metadata*, standardization, and radiology information system
Common data model for natural language processing based on two existing standard information models: CDA+GrAF [20]	Natural language processing, medical informatics, data model, information model, HL7 clinical document architecture, and ISO graph annotation format
Genomic common data model for biomedical data in clinical practice [21]	High-throughput nucleotide sequencing, data analysis, and observational study
Towards a newborn screening common data model: The Utah Newborn Screening Data Model [22]	Newborn screening, newborn screening laboratory information management system, common data model, interoperability, electronic data exchange, NBS, LIMS, and standards

Table 2. Search strings used to identify articles from PubMed.

Search aspects	Variations	Search string[a]
Common data model	Common data model (CDM), common data element (CDE), and common data sets (CDS)	("common data model" AND CDM) OR ("common data element*" AND CDE) OR "Common Data Elements"[Mesh] OR "common dataset*" OR "common data set*"
Health care	Medical, medicine, health, healthcare, health care, electronic health, and disease	medical OR medicine OR "Medicine"[Mesh] OR health OR "Health"[Mesh] OR healthcare OR "health care" OR "electronic health" OR clinical OR disease OR "Disease"[Mesh]

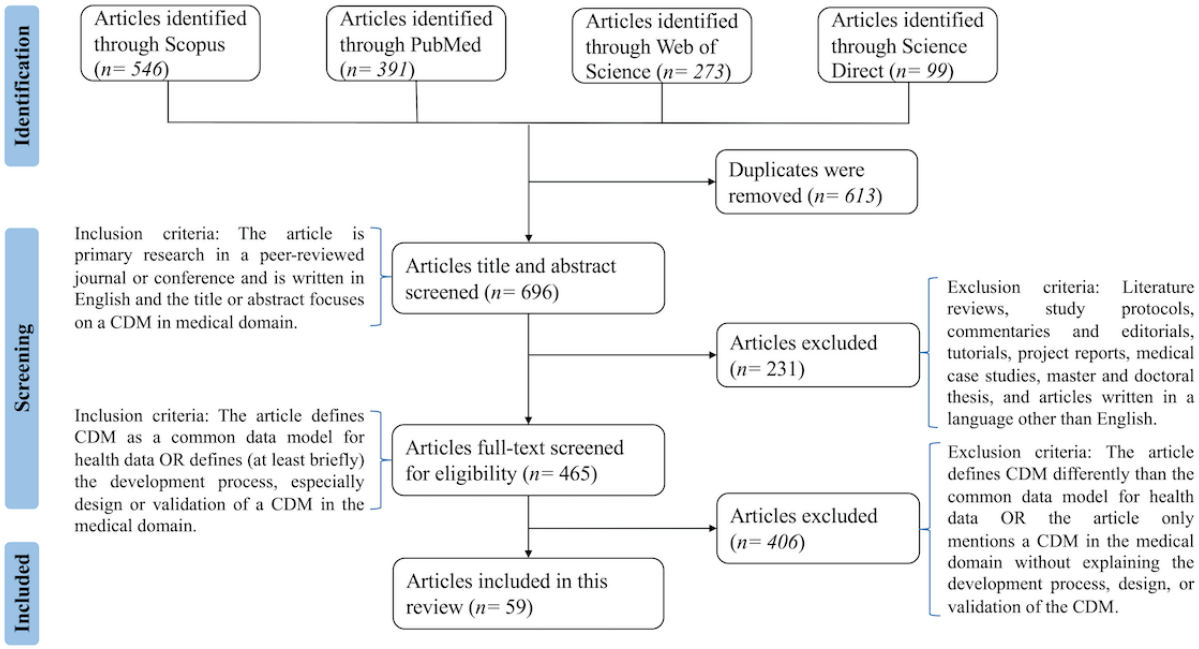
[a]The common data model and health care search terms were combined with "AND."

In particular, literature from 2000 to 2022 was considered, which is an extension of the previously published study protocol [19]. It is also noteworthy that the MeSH terms were only available in PubMed. The language of the articles was limited to English. Using the Boolean operators "AND" and "OR," the systematic search was carried out in the following electronic databases: PubMed, Web of Science, Science Direct, and Scopus. The search was performed in March 2022. The publication date tag in PubMed and Web of Science was set to January 1, 2000, to March 15, 2022, and that in Science Direct and Scopus was set to 2000 to 2022 (it is not possible to specify the month and day in Science Direct and Scopus).

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria are summarized in Multimedia Appendix 3 and are visualized along with the number of outcome articles in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart showing the paper selection process and the inclusion and exclusion criteria. CDM: common data model.



Selection and Review of Articles

Duplicates were removed using the built-in function in Rayyan [24]. The process of deletion was monitored by the author NA. After eliminating duplicates, the selection of studies was performed in 2 steps. The title and abstract screening steps were performed by the authors in groups of two. The articles were tagged as “include,” “exclude,” or “maybe.” Tagged articles were decided upon based on the tags described in Table 3. Disagreements were resolved by a third author. This process was initially carried out on 10% of the articles to confirm the accuracy of our inclusion and exclusion criteria, and clarify ambiguities. After the title and abstract screening, the full text of the included articles was screened by the authors, again in groups of two. The selected articles were included in the data extraction step.

Table 3. Description of tags used by the authors in the article screening process.

Data Charting and Extraction Process

A data charting table was developed and refined throughout the study, with several iterations. This table contained a list of items that were extracted from all included publications. All authors examined 10% of the articles for the defined data items and refined the data charting table, if necessary. The data charting table, including the extracted information from articles, is included in Multimedia Appendix 4.

For each article, we focused on 4 major aspects: (1) the meta information, such as DOI, authors, year, country, and project name, if applicable; (2) the medical condition for which the CDM was built, whether the condition is rare or common, the organ affected by the condition, and whether the condition is long term (longer than a year) or short term; (3) methodological information, such as requirement analysis, design, and validation process; whether the design process was linear or iterative; and advantages and disadvantages of the method, as stated in the respective article; and (4) information about stakeholder involvement. The extracted data elements, their categories, and their definitions are shown in Table 4.

Table 4. Data extraction sheet with specified elements, categories, and subcategories, including their definitions.

Category and subcategory	Definition
Meta information	
DOI	A link to the article
Author	First author's name
Publication year	Year of the publication date of the article
Country of study	Country of the leading author's affiliation
Project name	If applicable; when the CDM[a] study was part of a project/consortium
Medical background	
Medical condition	Name of the medical condition for which the CDM was built
Organ function	Organ affected by the medical condition
Short-term/long-term condition	Short term: less than a year; long term: longer than a year
Is the condition rare or common?	Is the medical condition considered rare or common based on its occurrence? Available answers: common medical condition, rare medical condition, and conditions that can be rare and common.
Requirement analysis method	
Literature analysis	It includes searching in a variety of literature, such as extraction of frequent CDEs[b] from real-world data, data harmonization across studies, multicenter longitudinal and observational studies, consensus documents and guidelines, primary outcome data of trials, review of instruments, and forms like report forms, users' needs collection forms, etc.
Interview/questionnaire	It includes expert interviews, focus group meetings, working group meetings, consensus meetings, workshops and discussions, and online surveys.
Delphi	Delphi or modified Delphi was used. Delphi techniques involve experts evaluating complex issues iteratively, where knowledge is incomplete or uncertain. Typically, the response from the previous questionnaire is appended to the next questionnaire [25].
Review of existing CDEs	When an existing CDE was validated/reviewed.
Design	
Creation of new CDEs	If there were no CDEs in the domain and the experts tried to come up with some CDEs using literature in the field.
Modification of existing CDEs	If existing CDEs in a disease domain were modified.
Reuse of existing CDEs (without modification)	If existing CDEs in the domain were used without any modification.
Validation	
External experts	It includes only external validation of any sort, such as public reviews on a website from experts or nonexperts in the field. Excluded are experts that were part of the conception process of the model.
Others	Any other type of validation, such as internal reviews, working group consensus, etc.
Model type	
Iterative	When at least one iterative process was performed during development of the CDM.
Linear	When there was no iteration in the process.
Stakeholder information	
Were stakeholders involved in the design process?	Yes/no
Which stakeholders were involved?	Patients' representatives, clinicians, domain experts, computer scientists, IT personnel, and registry staff
When did they get involved in the process?	In users' needs collection (when experts were involved in the preanalysis step, eg, collection of evidence, review of literature, guidelines, etc), in conception (when experts were involved in conception of the CDEs), in evaluation (when the model was evaluated via experts), and in implementation (when experts were involved in the implementation of the model).
What was the nature of stakeholder involvement?	Through expert workshops, semistructured interviews, questionnaires, etc
Pros and cons of methods as mentioned in the article	

Category and subcategory	Definition
Pros	Advantages of the method as stated in the article
Cons	Disadvantages of the method as stated in the article

[a]CDM: common data model.

[b]CDE: common data element.

Visualization and Summarization of Results

At the end of the data extraction, the data items collected in Table 4 were summarized and visualized. A flowchart according to the PRISMA-ScR guidelines was designed to show the article processing approach (Figure 1). Tables, timeline plots, histogram charts, pie plots, and scatter histograms were used to display the extracted data items. The graphics and the required analysis were performed using Python version 3.9.12 (Python Software Foundation), with matplotlib, pandas, and NumPy packages. The script used for the plots is publicly available [19,26].

First, we aimed for a broad overview of available CDMs and whether original CDMs were developed or existing CDMs were modified, as well as whether they focused on common or rare diseases and addressed a specific organ function. Second, to answer our first research question, we documented the medical domain of each article, whether the medical condition was considered as long term (more than a year) or short term (less than a year), and the affected organ as stated in the respective original article. To classify the development process of the CDMs, we documented 4 categories of data information for each article: requirement analysis, design, validation, and model type (Table 4). We categorized the methodology that was used for the requirement analysis (ie, why a CDM was needed), as well as the context to design a set of common data elements (CDEs). For validation, we distinguished between external evaluation and any other type of evaluation. The "other" category included the evaluations performed by the same clinical experts who were involved in the conception process, such as working group consensus, user evaluations, reviews performed via the members of the project, statistical tests, and pilot tests conducted within the project. Additionally, we investigated stakeholder involvement in the development stages in those studies and whether the studies followed an iterative or linear method of development. We used the advantages and disadvantages of the methods as stated in the articles (Table 4) and formulated them into a list of constraints in the area of CDM development to further highlight the need for streamlined methods. Finally, after analyzing the included CDMs, we summarized the most frequent methods used in the included literature in a suggestive development process that could be a reasonable basis to start with when developing a novel model.

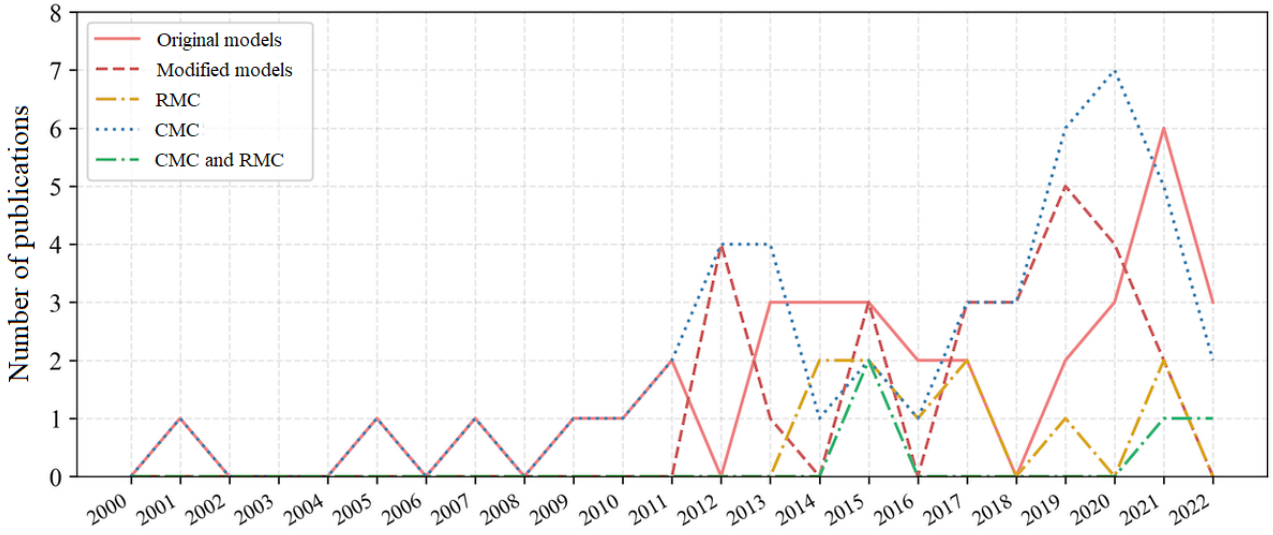
Results

Selection of Articles

In total, we identified 1309 articles from PubMed, Web of Science, Science Direct, and Scopus search engines. From the identified articles, after duplicate removal, 695 articles were included in the title and abstract screening. Finally, 465 articles underwent full-text screening, and of these, 59 matched the full-text screening criteria of this review and were finally included. We excluded articles that did not describe the development or evaluation of a CDM in the health domain. Additionally, articles that were not publicly available and those in a language other than English were excluded. The article identification process along with the inclusion and exclusion criteria are shown in Figure 1.

The selected articles defined CDMs, common data sets, or CDEs for common or rare medical conditions. All included articles were published between 2000 and 2022. As shown in Figure 2, the number of articles that focused on CDM development increased after 2011 and continued to increase in the last years.

Figure 2. The number of publications focusing on common data model (CDM) development per year from 2000 to 2022. The line chart compares the number of articles developing original CDMs (original models) with the number of articles developing CDMs via modification of existing models (modified models), and compares the number of articles developing CDMs for rare medical conditions (RMCs), the number of articles developing CDMs for common medical condition (CMCs), and the number of articles developing CDMs for both kinds of conditions (CMCs and RMCs). In addition to the increase in the number of articles from 2011 in general, we can see that CDMs for rare diseases were only developed starting from 2014.



Country of Publication

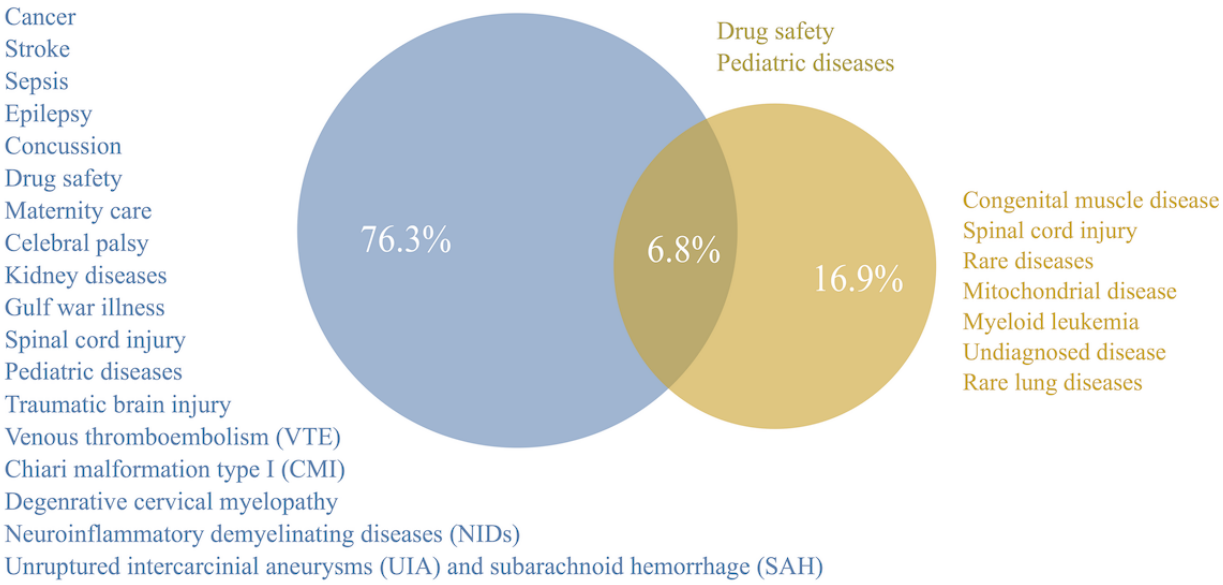
We categorized the articles into countries based on the affiliation of the first author. Among the 59 articles, 26 (44%) were published in the United States, 8 (14%) were published in Canada, and 6 (10%) were published in Germany. The number of articles according to country is as follows: Belgium, 2 [27,28]; Canada, 8 [29-36]; China, 1 [37]; Denmark, 2 [38,39]; France, 2 [11,40]; Germany, 6 [41-46]; Italy, 1 [10]; Spain, 1 [47]; Republic of Korea, 1 [48]; Norway, 3 [49-51]; Switzerland, 1 [52]; Taiwan, 1 [53]; the Netherlands, 1 [54]; United Kingdom, 3 [55-57]; and United States, 26 [58-83].

Medical Conditions and Their Domains

According to our research, CDMs were developed for a variety of medical domains in the past 22 years; however, we divided them into 3 categories, namely, rare, common, and rare and common (both). An aggregated list of the medical conditions and their domains is shown in Figure 3. A full list of the medical conditions extracted during this scoping review is shown in Multimedia Appendix 4. An organ function overview and the long- and short-term conditions are shown in Multimedia Appendix 5. Among these, 10 (17%) CDMs were designed for rare medical conditions, such as myeloid leukemia and rare lung diseases, and mitochondrial diseases [41,44-46,59]. Moreover, 1 CDM, namely, the CDM in the study by Berger et al [44], was designed for undiagnosed diseases in general.

Among the 59 articles, 45 involved the development of a CDM for common medical conditions. These included traumatic brain injury [27,28,30], spinal cord injury in children and youth [67], dental caries [68], sport-related concussion [65], cerebral palsy [29], degenerative cervical myelopathy [55], unruptured intracranial aneurysms and subarachnoid hemorrhage [32,42,55,60], Chiari malformation type I [63], breast implant [43], stroke [37], venous thromboembolism [33], pediatric epilepsy [61], pediatric critical illness [62], pregnancy drugs and treatments [49], sepsis [31], medication use in pregnancy and breastfeeding [40], degenerative cervical myelopathy [55], Gulf War illness [58], neuroinflammatory demyelinating disease [43], traumatic brain injury [27], and neurologic disorder and stroke [69]. Wandner et al [66] focused on clinical pain management, and Jaboyedoff et al [52] focused on pediatric diseases in general.

Figure 3. Characteristics of the included studies. A Venn diagram showing the proportions of identified common data models (CDMs) for common medical conditions (76.3%; blue), rare medical conditions (16.9%; golden yellow), and medical conditions that could fit into both categories (6.8%). Additionally, an aggregated list of medical conditions that CDMs were developed for in the studies is shown in 3 different colors according to their categories.



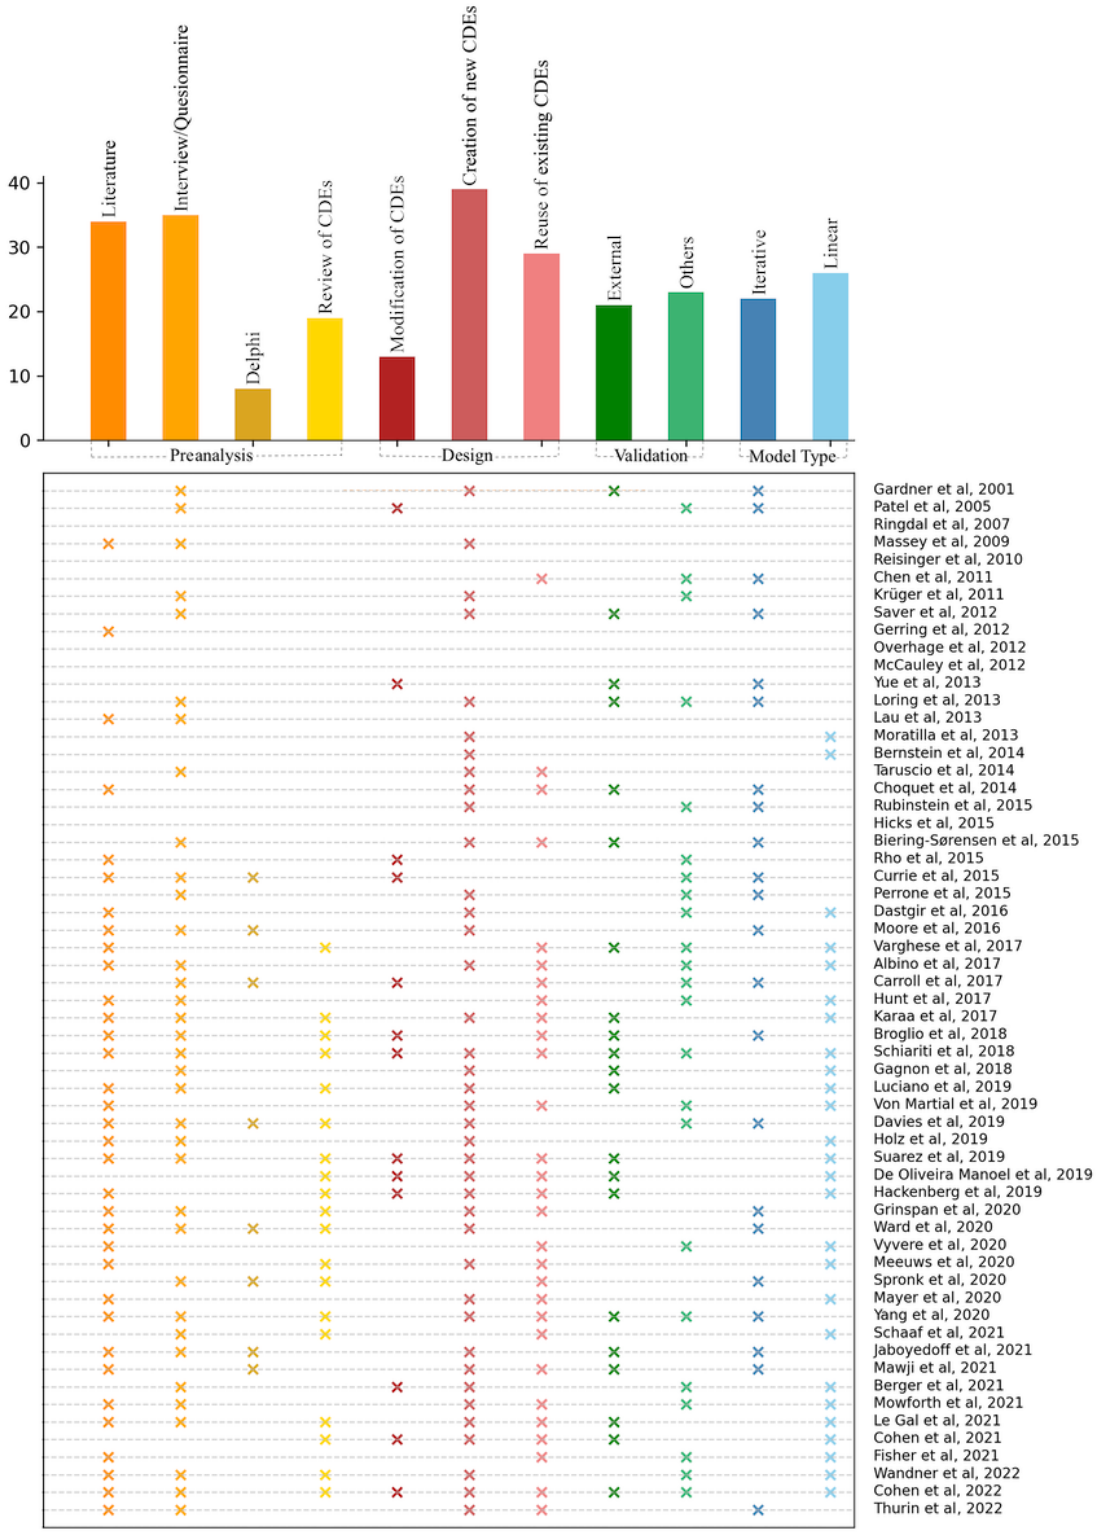
Stakeholder Involvement

To investigate the involvement of stakeholders, we summarized at which particular stage they were involved in the CDM development process. Out of the 59 included articles, 54 (92%) mentioned at least one stakeholder in the design process. Additionally, we were interested in the different types of stakeholders that were involved, how they were involved, and at what stage of the process they typically got involved. As shown in Figure S1 in Multimedia Appendix 6, stakeholders were mostly involved in the initial stage, namely, the conception phase. Domain experts and clinicians were the most common stakeholders involved in the studies (Figure S2 in Multimedia Appendix 6). Additionally, while many different methods were used to involve the stakeholders, such as expert groups, surveys, consensus meetings, interviews, teleconferences, questionnaires, and workshops, "working group" was the most frequent method used (Figure S3 in Multimedia Appendix 6).

Design Process

The methods used in the articles for designing a CDM were literature analysis, interview, Delphi, and review of existing CDEs. From our extraction table (Multimedia Appendix 4), we noted that 39 articles involved the definition of an original model/set of CDEs, 13 involved the modification of an existing set of CDEs, and 29 involved the use of an existing set of CDEs without any modifications. The external evaluation included web-based feedback, public review and comments, and feedback in a conference, among others. Finally, we found that 26 articles involved a rather linear design method and 22 others involved an iterative process. The list of articles that involved the use of each of these categories is shown in Figure 4. Detailed information is presented in Multimedia Appendix 4.

Figure 4. Methodological information on the articles [10,11,27-83]. The y-axis shows the list of articles by publication year. The x-axis shows the methodological categories. The scatter plot includes a cross mark when the Boolean is true for a specific article, for example, if the authors have used literature analysis as a preanalysis method, a cross (x) is added. The sum of cross marks in each column contributes to the bar size of the bar plot positioned on the x-axis. To improve visibility, each subcategory is shown with a different color. The subcategories of the same category are grouped via the same family of colors. CDE: common data element.

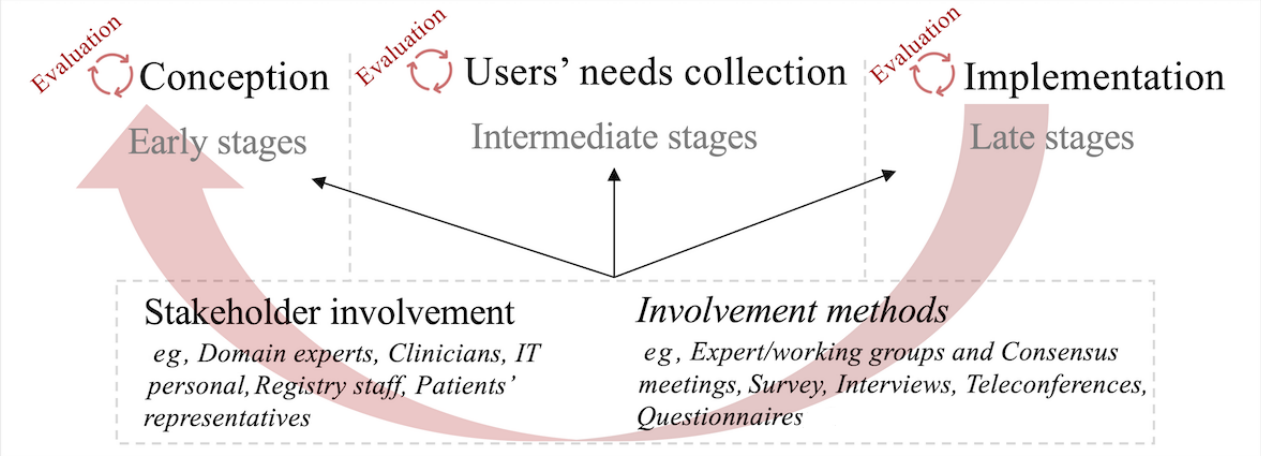


Methodological Constraints Highlighted in Previous Studies

The included articles presented a range of constraints in the development process from the methods used in the different stages of the process to the applicability of the outcome elements. For example, Thurin et al [40] performed interviews with a single data access provider per data source and mentioned that other data access providers might conceptualize the data source differently. Additionally, they tested the applicability of the developed model only on the included data sources in the project. The model might require modification to use it with

other data sources. The limited sample size used to test the developed model is a common problem in rare conditions [44] given the rarity of the disease. One of the limitations mentioned by Broglio et al [65] is that some of their developed CDEs require special expertise that might not be implementable in certain settings. Grinspan et al [61] mentioned that some subcategories of epilepsy syndrome were merged at a level higher into a single category, which might have led to reduced data resolution, although uphill mapping is often used, especially in the OMOP context [5]. Additionally, the elements considered do not cover every possible influencing element, and the source was limited to only US-based patients, which means the elements can differ once an international data level is considered. They also included CDEs that were documented as free text, and processing of such elements might require natural language processing applications. The authors also highlighted the possible bias caused by the methodology used for consensus and discussion, and the Delphi approach, focus groups, and interviews might have also influenced the outcome of the study.

Figure 5. Summary of a basic common data model development process.



Essence of the CDM Development Process

Our outcomes showed that a heterogeneous variety of methods or processes were used in CDM development in the included articles, which highlights the need for a more streamlined field-specific development method. Therefore, we summarized our analysis outcomes into a suggestive development process (Figure 5), considering the 3 development steps that have been identified from the included models in this study, namely, conception, users' needs collection, and implementation. We suggest that evaluation and validation should be integrated into every stage of development, which gives the stages an iterative nature, and feedback should be integrated into the process as much as possible. We also emphasize the involvement of stakeholders in the process as early as possible and propose continuous involvement until the end of the development process because in every phase, questions might arise that need to be answered from different perspectives.

Discussion

Overview

One of the major challenges faced by CDM developers in the health domain is the lack of a comprehensive methodology or workflow to follow, which is also reflected in this review. The general models from industrial design and even academia (eg, the model introduced by Bobbe et al [16]) do not generally translate one-to-one to the health domain. The medical context is usually complex, and the involvement of stakeholders, such as clinicians, patients' representatives, and IT staff, is of utmost importance to ensure the applicability of a to-be-developed CDM. In addition, user-friendly, adaptable, and straightforward models are preferred in health care as one can start working with them without requiring a substantial amount of time [84].

This scoping review provides a summary of the development methods for CDMs and categorizes them based on the requirement analysis method, design process, validation approach, and model type. A variety of methods were used in the requirement analysis step in the articles, starting from searching in different types of literature and medical guidelines [43,44] to interviews [29], the Delphi approach [31], and a review of existing CDEs. A full list of these articles is shown in Figure 4 and Multimedia Appendix 4.

The majority of the developed CDMs have been designed for common medical conditions, and only 10 articles involved the design of a particular CDM for rare diseases. However, we did not find a significant difference in the development process of a CDM for rare and common conditions. Interestingly, based on our analysis, we can conclude that common medical conditions were the focus of CDM studies from early 2000, whereas the first CDM for rare conditions was developed in 2014. Despite methodological similarities, every article usually mentioned following a more individualistic method of development. This may arise because rare conditions occur rarely and the number of patients included in studies is limited [44]. Moreover, finding an expert for each rare or unclear disease is a challenging task. Additionally, most of the information crucial in the diagnosis of such diseases (like symptoms or phenotypes and genotypes) is currently stored in unstructured forms (eg, clinical notes). Extraction of such information requires a lot of time and effort from technical and clinical stakeholders [41].

Thus, given the variety of studies, the methods used for common conditions might be adaptable for rare conditions. Considering that a CDM is an essential part of data harmonization (a necessity in the health domain), we see highly emphasized development models as essential. Therefore, after analyzing the included CDMs, we summarized a suggestive development process that is shown in Figure 5, which could be the starting point for conceptualizing and implementing novel CDMs.

Limitations

The findings of our study are subject to certain limitations. First, our analysis is restricted to the selected databases, namely, PubMed, Web of Science, Science Direct, and Scopus. Additionally, the scope of our investigation is confined to articles published within a specific time frame and written in English. Moreover, we did not conduct any assessment of the quality of the included articles. In addition, it may also be worth noting that the authors of this review have varying interdisciplinary backgrounds, expertise levels, and experiences in the CDM field. However, to optimize the screening and analyzing processes, we performed them in pairs and first tested the method on a subset of 10% of the articles, resulting in a minimal number of conflicts.

Conclusion

We considered 4 steps in the development of a CDM: conception, users' needs collection, implementation, and evaluation. We could identify 4 groups of methods that were most often used in the articles as part of the requirement analysis of the CDM development process. These were literature analysis, interviews, Delphi approaches, and review of existing CDEs. The articles considered in this review either developed a new CDE or made use of an existing set of CDEs with or without modification.

Most of the articles involved at least one stakeholder from among domain experts, clinicians, IT staff, registry staff, and patients' representatives, and mostly from the initial step, which was conception. The methods used to involve the stakeholders were expert groups, surveys, consensus meetings, interviews, working groups, teleconferences, questionnaires, and workshops, and among these, working groups were most often used.

We conclude that the methods used in the development of CDMs in the health domain are heterogeneous and this field is lacking solid guidelines that may ease up this process, especially in terms of the reusability and adaptability of a CDM. This is why the proposed outline (Figure 5) could be a reasonable basis to start with. In our future work, we plan to test and improve the proposed outline for developing a CDM.

Abstract

Background: With the advent of the digital economy and the aging population, the demand for diversified health care services and innovative care delivery models has been overwhelming. This trend has accelerated the urgency to implement effective and efficient data exchange and service interoperability, which underpins coordinated care services among tiered health care institutions, improves the quality of oversight of regulators, and provides vast and comprehensive data collection to support clinical medicine and health economics research, thus improving the overall service quality and patient satisfaction. To meet this demand and facilitate the interoperability of IT systems of stakeholders, after years of preparation, Health Level 7 formally introduced, in 2014, the Fast Healthcare Interoperability Resources (FHIR) standard. It has since continued to evolve. FHIR depends on the Implementation Guide (IG) to ensure feasibility and consistency while developing an interoperable health care service. The IG defines rules with associated documentation on how FHIR resources are used to tackle a particular problem. However, a gap remains between IGs and the process of building actual services because IGs are rules without specifying concrete methods, procedures, or tools. Thus, stakeholders may feel it nontrivial to participate in the ecosystem, giving rise to the need for a more actionable practice guideline (PG) for promoting FHIR's fast adoption.

Objective: This study aimed to propose a general FHIR PG to facilitate stakeholders in the health care ecosystem to understand FHIR and quickly develop interoperable health care services.

Methods: We selected a collection of FHIR-related papers about the latest studies or use cases on designing and building FHIR-based interoperable health care services and tagged each use case as belonging to 1 of the 3 dominant innovation feature groups that are also associated with practice stages, that is, data standardization, data management, and data integration. Next, we reviewed each group's detailed process and key techniques to build respective care services and collate a complete FHIR PG. Finally, as an example, we arbitrarily selected a use case outside the scope of the reviewed papers and mapped it back to the FHIR PG to demonstrate the effectiveness and generalizability of the PG.

Results: The FHIR PG includes 2 core elements: one is a practice design that defines the responsibilities of stakeholders and outlines the complete procedure from data to services, and the other is a development architecture for practice design, which lists the available tools for each practice step and provides direct and actionable recommendations.

Conclusions: The FHIR PG can bridge the gap between IGs and the process of building actual services by proposing actionable methods, procedures, and tools. It assists stakeholders in identifying participants' roles, managing the scope of responsibilities, and developing relevant modules, thus helping promote FHIR-based interoperable health care services.

Introduction

Background

The development and innovation of health care service models have accelerated the demand for data exchange and service interoperability. In the United States, the Health Information Technology for Economic and Clinical Health Act took effect in 2009, specifying health IT–based systems as an integrated part of the country's health care reform. It has spurred the electronic health record (EHR) adoption rate through reward and punishment measures [1]. In addition, the US Department of Health and Human Services established a specific agency, the Office of the National Coordinator for Health Information Technology, to accelerate the implementation of advanced medical IT standards, promote the exchange of electronic health care information, and improve the quality of health care services throughout the country. In Canada, the federal government funded an independent, not-for-profit organization called Canada Health Infoway, tasked with accelerating the adoption of digital health solutions, such as EHR, across the country. The government has set a 10-year implementation strategy for EHR in cooperation with the Canadian Institute for Health Information [2]. Japan has made great efforts to develop remote health care technology and has established a communication system among regional institutions by implementing electronic medical records (EMRs) in the form of an app or software as a service [3]. In China's state health system, major public hospitals administered by national, provincial, and local health authorities are the pioneers in reforms. Over the years, the government has issued a series of policies promoting coordinated care among health care institutions at different levels of the health system [4,5], together with many qualitative or quantitative assessment criteria that guide the establishment of high-standard EMR system, regional information interoperability, and intelligent service and management in hospitals. In summary, the demand for tiered and coordinated care delivery among health care institutions worldwide is increasing rapidly, and the requirement for health care data exchange continues unabated.

The enhancement of interoperability is required by transforming health care service models and tackling the challenges of societal problems. According to a United Nations report [6], the share of the population aged ≥65 years is expected to increase from 9.3% in 2020 to approximately 16% in 2050. The rapid aging of the population unavoidably increases the burden of chronic disease care, bringing about the requirements for people-centered and continuous care delivery built on the foundation of a robust primary health care system. Therefore, it is necessary to enhance health IT system interoperability to bridge the gap between uneven health care resource distribution, remove the barrier of isolated data islands, and comprehensively improve the quality of health care services.

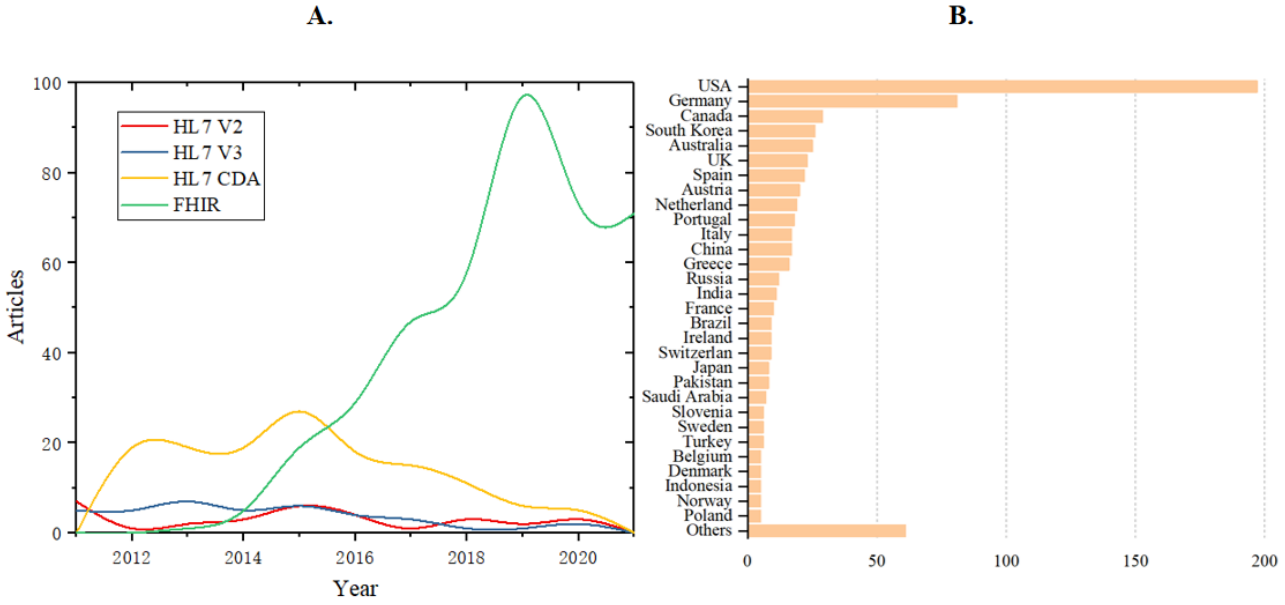
Health Level 7 Fast Healthcare Interoperability Resources

Health Level 7 (HL7), founded in 1987, is a not-for-profit, standards-developing organization dedicated to providing a comprehensive framework and related standards for the exchange, integration, sharing, and retrieval of electronic health information that supports clinical practice and the management, delivery, and evaluation of health services. It has successively released many standards, including HL7 version 2, HL7 version 3, and Clinical Document Architecture (CDA). However, with the constant evolution of the internet and the thriving of the application programming interface (API) economy, digital services or assets of health organizations tend to be exposed even more widely in the form of APIs. In this context, HL7 formally introduced Fast Healthcare Interoperability Resources (FHIR) in 2014, highlighting the core concept of resources, and thus, creating a new era for health care service interoperability. A resource is the smallest exchangeable logical unit in FHIR. Resources are independent of each other but can be linked or assembled through specific rules to meet diverse service requirements. FHIR combines web standards to support resource operations through RESTful API in XML or JavaScript Object Notation format. Compared with other alternative standards, FHIR has more advantages and potential, such as comprehensive coverage of data definitions, substantial flexibility of data exchange, explicit semantics, and many available open-source tools, among others. Therefore, it has attracted constant and favorable attention from health care stakeholders since its first release, as shown in Figure 1.

We investigated the literature from the Web of Science and plotted 2 statistical charts in Figure 1. Figure 1A shows the promotion trends of different health data standards. By using the search term "HL7 v2," "HL7 v3," "HL7 CDA," and "FHIR," we identified the corresponding papers in the Web of Science database from 2010 to 2022. The results show that the attention paid to FHIR has increased rapidly within a short time, far exceeding the HL7 version 2, HL7 version 3, and CDA standards. Figure 1B compares FHIR-relevant literature among different countries. We used the search term "FHIR" to find the corresponding papers in the Web of Science database from 2014 to 2022. By reading each paper's abstract and the corresponding author's information, we identified the country to which the work belongs. Countries that record <5 papers fall into the "others" category. The chart shows that the United States, Germany, and Canada were the top 3 countries that published the most studies on FHIR, accounting for 28.39% (197/694), 11.67% (81/694), and 4.18% (29/694), respectively.

In addition to the dissemination activities of enthusiastic researchers and pioneering health IT ecosystem players, national health policy makers also play a pivotal role in FHIR adoption, as evidenced by the actions in the United Kingdom, United States, and Canada [7]. Overall, FHIR has gradually gained worldwide recognition and acceptance, and it has the most potential for future large-scale promotion in the health care ecosystem.

Figure 1. Works of literature that focus on health data standards. (A) The attention to Fast Healthcare Interoperability Resources (FHIR) has risen rapidly within a short time of its first release, far exceeding HL7 version 2, HL7 version 3, and Clinical Document Architecture (CDA) standards. (B) The United States, Germany, and Canada are the top 3 countries that published the most literature on FHIR. HL: Health Level.



Objectives

Owing to the growing popularity of FHIR, some academic researchers have authored review papers from their perspectives in the last few years. Ayaz et al [8] searched for FHIR-related papers published between 2012 and 2019 in 6 databases (ACM, IEEE, Springer, Google Scholar, PubMed, and ScienceDirect) and selected 80 papers for review. They found that FHIR is identical in supporting intelligent technologies, such as smartphones, tablets, mobile health apps, smartwatches, and fitness trackers, which could solve numerous health care problems that were impossible for the previous standards. Lehne et al [9] searched for FHIR-related papers in 2 databases (Web of Science and PubMed) up to 2019 and selected 131 papers for review. The statistical results revealed that data model–related topics mainly focusing on constructing profiles to implement FHIR in specific scenarios were the most attractive direction. At the same time, analytics-related topics concerning data analysis, modeling, machine learning, and more were less attractive because most FHIR projects were still in the initial development phase, dealing with implementation and data definitions rather than large-scale data analysis. Barker and Johnson[10] surveyed 734 apps released up to December 2020 in 5 digital health care application libraries (hosted by Cerner, Epic, Allscripts, Athenahealth, and Substitutable Medical Applications Reusable Technologies [SMART]) and measured their support for FHIR. They found that the number of apps that support the FHIR standard had increased from 19% in 2019 to 22% in 2020.

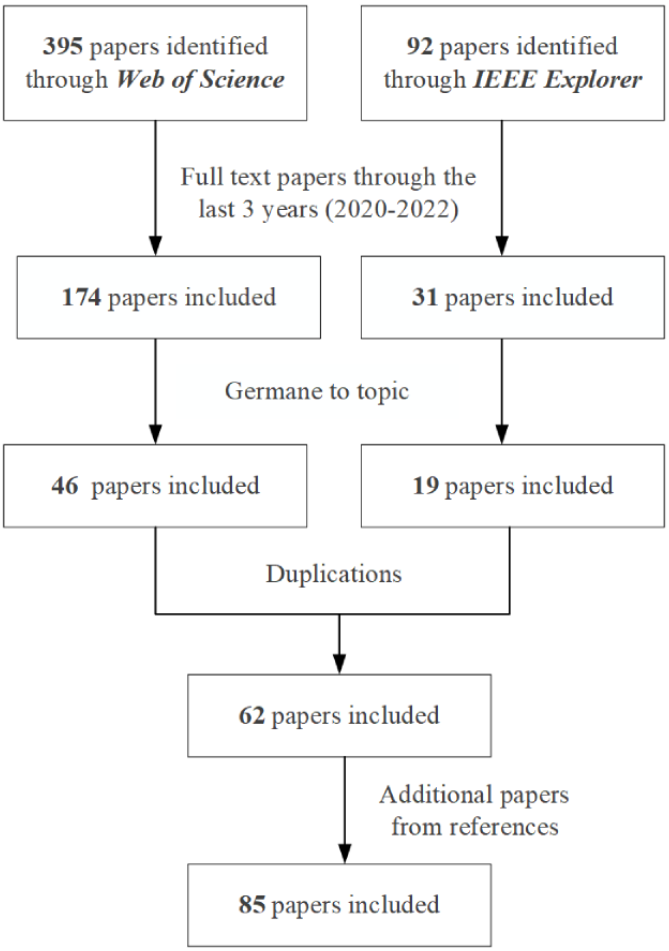
However, to our knowledge, there is a lack of systematic reviews that focus on the FHIR practice. A gap remains between the FHIR Implementation Guide (IG) and building actual services because IGs are rules specifying no methods, procedures, or tools. Thus, stakeholders may feel it nontrivial to participate in the ecosystem, giving rise to the need for a more actionable practice guideline (PG) for promoting FHIR's fast adoption. Therefore, this study proposed a general FHIR PG to facilitate stakeholders in the health care ecosystem to understand FHIR and quickly develop interoperable health care services.

Methods

Article Selection

Figure 2 presents the paper selection flowchart used in this review. Initially, we identified a total of 487 papers in the Web of Science and IEEE databases by using the search term "FHIR" or "Fast Healthcare Interoperability Resources." The time range of publications was set from January 1, 2020, to July 1, 2022, and we finalized 205 articles. After excluding those that merely mentioned the term FHIR but did not elaborate on it, 65 articles were retained. A check of duplications from this batch removed a further 3 articles. Finally, from the references of the remaining 62 articles, we found an additional 23 relevant articles, ending up with a total of 85 articles as the research materials of this study.

Figure 2. Flowchart of paper selection.



Analysis Process

By carefully analyzing and collating the recent studies on the design of FHIR-based interoperable health care services, we derived the details of the FHIR PG.

We selected 85 FHIR-related articles and found that building FHIR-based health care services contains typically 3 stages, that is, data standardization, data management, and data integration. Each stage may use different practice methods, depending on the targeted scenarios and types of services.

The way to categorize these 85 articles is as follows: if an article's main innovation feature focused on 1 of the 3 stages, we assigned it to the corresponding group. Specifically, we assigned those articles emphasizing the design process of FHIR profiles or proposing methods for migrating data from specific clinical data models (CDMs) to FHIR to the data standardization group, articles discussing the management of RESTful APIs to the data management group, and articles presenting approaches for integrating data with specific apps or platforms to the data integration group.

After categorizing the articles, we reviewed the key techniques used by each group to build their respective health care services. We compiled a general FHIR PG through this review. The workflow of the FHIR PG was derived by linking the stages, each consisting of multiple steps. It is important to note that alternative solutions might be identified for certain steps in the workflow based on different conditions. In addition, we leveraged the collective experience of our team working on health care IT projects to further refine and optimize the FHIR PG.

Finally, as an example, we arbitrarily selected a use case outside the scope of the reviewed articles and mapped it back to the FHIR PG to demonstrate the effectiveness and generalizability of the PG.

Results

Article Classification

Data Standardization

Data standardization typically involves two main steps: (1) defining profiles based on the data exchange requirements of interoperable services and (2) filling these profiles with the corresponding exchange data.

The base FHIR specification provides foundational resources applicable to various health care contexts. However, health care services often exhibit significant variability across different jurisdictions. Therefore, the base FHIR specification typically requires further adaptation, known as profile definition, to suit specific application contexts. Profile definition mainly encompasses three aspects: (1) rules about which resource elements to use and what additional elements to add to the base specification, (2) rules about which terminologies to use in

particular elements, and (3) the restricted value range and cardinality of the elements.

Table 1 lists the typical profile definitions and the corresponding FHIR foundational resources discussed in the reviewed articles. As shown, these articles cover a wide range of categories, including genomics [10-14], imaging [15-17], cancer [18-20], diabetes [21,22], COVID-19 [23,24], infections [25], electrocardiography [26], screening [27], and allergy [28].

There are typically 2 approaches to filling the profiles with exchange data. One is redesigning the database to align with the FHIR resource structure, and the other is mapping data from an existing CDM-based legacy system to the FHIR-based system. Table 2 lists relevant articles discussing the latter approach. These articles could roughly fall into 7 groups based on the types of source CDMs. The groups include informatics for integrating biology and the bedside [29,30], Observational Medical Outcomes Partnership (OMOP) [31,32], OpenEHR [33,34], HL7 version 2 [35], variant call format [36], free text or arbitrary proprietary data [37,38], and multisource [39-42]. Multisource refers to cases where multiple CDMs are involved. For example, the study by Lenert et al [40] focused on transforming data from the OMOP and Patient-Centered Outcomes Research Network to FHIR. The study by Pfaff et al [39] aimed to transform data from informatics for integrating biology and the bedside, OMOP, and Patient-Centered Outcomes Research Network to FHIR. The study by Prud'hommeaux et al [41] compared 3 methods for transforming data from various source CDMs into FHIR. The study by Kiourtis et al [42] proposed a resource description framework transformation toolkit to combine FHIR and non-FHIR data.

The studies in Table 2 indicate that the transformation from a specific CDM type to FHIR typically involves a 2-step mapping process: model mapping and element mapping. Model mapping establishes a relationship between the original data model and the FHIR resource. Element mapping comprises 2 parts, key mapping and value mapping, which define how to map the data fields from the source CDM to the corresponding fields in the FHIR resources. The mapping rules observe the consensus-mapping relationships established by domain experts. These experts analyzed the semantic and structural differences between the source CDMs and FHIR and determined the appropriate mappings to ensure accurate and meaningful data transformation. Although current data transformation approaches intend to support specific source data and target FHIR resource types, it is worth noting that ongoing research and advancements in domain-based applied artificial intelligence, including natural language processing and deep learning, hold great potential for developing more generalized data transformation algorithms.

As highlighted in previous studies, the granularity of data plays a crucial role in data standardization. When the granularity of the source data is finer than that of the target data, there is potential for information loss during the transformation process: the severity of information loss increases with the extent of the granularity gap.

[a]HL7: Health Level 7.

Data Management

Data management includes data storage and data exposure. Although FHIR defines 5 approaches for data exposure, including RESTful API, messaging, documents, services, and persistent store, recent articles predominantly chose to expose data in the form of APIs because of the rapid growth of the APIs economy. There are typically 2 methods for data management: developing a customized FHIR warehouse to store and manage FHIR data or selecting a mature third-party warehouse to handle the task.

Table 3 shows various data management choices and their corresponding targets. It reveals that developing a customized FHIR warehouse to maintain FHIR data often requires meeting some special service requirements. For instance, the customized FHIR warehouse developed by Demurjian et al [43] aimed to enable sensitivity and multilevel security controls. The one developed by Chatterjee et al [44] and Saripalle et al [45] served to integrate with specific terminology. The one developed by Ruminski et al [46], Saripalle [47], and Yu et al [48] intended to support multiple Internet of Things protocols. Finally, the one discussed in the studies by Khvastova et al [49], Dridi et al [50], Lee et al [51], Tanaka and Yamamoto [52], Cheng et al [53], Semenov et al [54], and Gruendner et al [55] was used to support data preprocess plug-ins.

On the other hand, several mature third-party platforms are available for managing FHIR data. In 2018, a total of 6 technology giants, including Amazon, Microsoft, Google, IBM, Oracle, and Salesforce, jointly announced that they would be committed to removing the barriers to adopting health care interoperability technologies, particularly those enabled through the cloud [56]. All these companies have launched FHIR data management platforms, providing FHIR data APIs for resource operations. Users of these platforms can store their data as FHIR resources and use the data APIs offered by the cloud platform for service development. For instance, the studies by Shi et al [57], Zampognaro et al [58], Ploner and Prokosch [59], and Kamel and Nagy [60] chose cloud warehouses, and the study by Mandl et al [61] chose an on-premises warehouse to rapidly deploy an FHIR development environment.

The abovementioned analysis highlights that choosing between proprietary and third-party warehouses involves trade-off considerations. Maintaining FHIR data through a proprietary warehouse offers 2 advantages: better privacy and greater flexibility for functional expansion. However, developing a proprietary warehouse requires extensive knowledge of FHIR standards and software development skills, resulting in higher costs. On the other hand, relying on third-party platforms offers the advantages of lower cost and higher implementation efficiency. However, storing sensitive data in a third-party warehouse, with the service provider not being the data owner, raises security and privacy concerns.

Table 3. Fast Healthcare Interoperability Resources (FHIR) data management methods and their corresponding targets.

Method and study, year	Target
Develop FHIR warehouse	
Demurjian et al [43], 2020	Support lattice-based access control
Chatterjee et al [44], 2022; Saripalle et al [45], 2020	Integrate with specific terminologies

[a]IoT: Internet of Things.

Data Integration

Data integration plays a vital role in health care across various domains, including service delivery, public health management, and clinical medicine or health care economics research, enabling better decision-making and improving overall health care outcomes. In service delivery, data integration is crucial for coordinating multiple IT systems, including the hospital information system (HIS), laboratory information system, picture archiving and communication system, EMR, and EHR. In public health, local governments need to collect health-related data within their jurisdictions to monitor regional health status and effectively address public health issues. In clinical medicine or health care economics research, it is essential to obtain data from diverse domains to conduct comprehensive studies and analyses.

There are 2 typical modes of FHIR data integration, as listed in Table 4.

The first mode of data integration is using an integrated service platform (ISPf). The ISPf is an orchestrating platform offering a series of API management functions such as API registration, API calling authorization, and API routing forward. Organizations wishing to exchange data through the ISPf must register their APIs on the platform. Other organizations can search for the appropriate APIs on the ISPf and make API calls. The ISPf performs API calling authorization to verify the calling rights and then routes the API calls to the respective organization to which the API belongs. This process facilitates data exchange among multiple organizations [62-75]. An example of this mode is the efficient transfer of medical records when a patient referral occurs.

The second mode of data integration is by way of interoperable apps. Different architectures can be selected for different application scenarios. In the case of apps with specific functions, such as statistics and analysis, SMART on FHIR would be a more efficient option [76-85]. In the case of apps with customized functions, such as supporting microservice architecture or blockchain architecture, customized architecture apps would be a more suitable option [86-94].

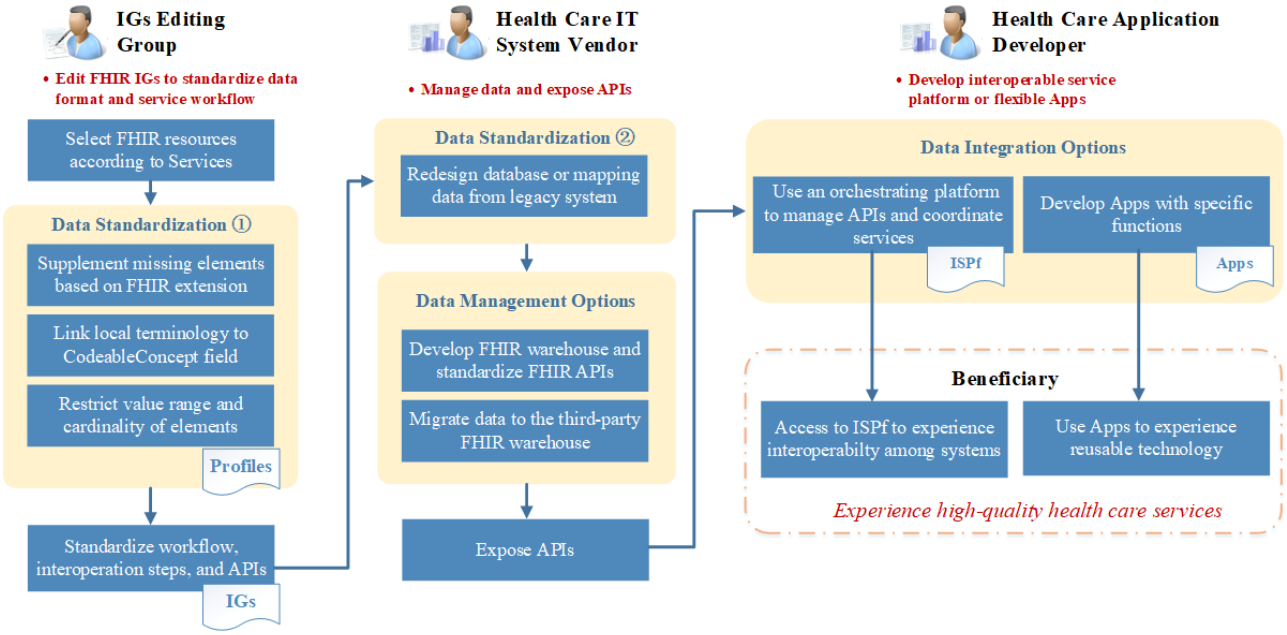
FHIR PG Design

Practice Design

We present an FHIR practice design in Figure 3, which defines the responsibilities of stakeholders and outlines the complete practice process from data to services.

Figure 3. The general Fast Healthcare Interoperability Resources (FHIR) practice guideline—practice design. API: application programming interface; IG: Implementation Guide; ISPf: integrated service platform.



IGs Editing Group

The first stakeholder involved in the process is the IGs editing group, usually coordinated by a government agency or an institution with significant influence in the ecosystem. The primary responsibility of this group is to define the data and service models and release the IGs. The detailed processes are as follows. First, select necessary FHIR resources based on the service requirements. Second, for specific requirements beyond the scope of the original FHIR resources, the group needs to customize resource structure by FHIR profile. Profile generally involves 3 aspects: extending the data field by FHIR extension, linking the local CodeSystem to the CodeableConcept field of FHIR resources, and restricting the cardinality and ValueSet of FHIR foundational resource. The customized resources created by the profile enable better alignment with the data requirements in various scenarios. After completing the data unification task, the IGs editing group moves on to the unification of services workflow, which involves specifying the implementation steps in the workflow and standardizing the corresponding APIs. Ultimately, the abovementioned data and workflow specifications are integrated to form the comprehensive FHIR IGs that health care IT system vendors can adopt.

Health Care IT System Vendor

The second type of stakeholder is the health care IT system vendor, responsible for developing and maintaining systems, such as the HIS, laboratory information system, and picture archiving and communication system. First, the vendor must implement the IGs published by the IGs editing group, which involves standardizing data by redesigning the database according to the FHIR resource structure or mapping data from existing CDM-based legacy systems to FHIR-based systems. Second, with RESTful APIs, the vendor has 2 options for data exposure: either maintaining the FHIR data and APIs themselves or selecting a mature third-party platform. FHIR APIs must be exposed to support resource-level operations regardless of the chosen option.

It is worth pointing out that in terms of data exposure, FHIR defines 5 different approaches, and each data exposure approach has a different data integration method; it would be a lengthy discussion if all approaches are considered. To make FHIR PG more compatible with current technology stacks, we chose to focus on RESTful API rather than on other approaches in this study.

Health Care Application Developer

The third stakeholder involved in this process is the health care application developer, responsible for developing interoperable services using open FHIR APIs. As described in the *Data Integration* section, there are 2 typical modes. The first is to develop an ISPf, that is, an orchestrating platform, for service interoperability. The ISPf manages open APIs registered by each organization and enforces access specifications such as IGs, profiles, and workflows. Any IT systems accessing the ISPf and exchanging data must comply with these specifications. When an IT system needs to access multiple ISPfs, it must support multiple specifications. In such cases, the IT system can deploy an adapter above its native database to comply with various specifications. When the IT system acts as a producer, it reads the corresponding specifications from the adapter to expose the data. When it acts as a consumer, it reads the corresponding specifications from the adapter to parse data. The second mode is to develop specific apps that cater to specific requirements. For example, an app built with SMART on FHIR

architecture supports a flexible and switchable application ecosystem.

Beneficiary

Beneficiaries such as hospitals, patients, public health institutions, and research institutions can benefit from high-quality FHIR-based health care services. For instance, if there is a need to exchange data through APIs to facilitate service coordination among multiple organizations, they can easily access the ISPf to fulfill this objective. Alternatively, they can choose a suitable app from the application gallery that caters to their needs and functions.

The Development Architecture for the Practice Design

Overview

We presented a 3-stage development architecture for the practice design, as shown in Figure 4. In addition, we compiled a list of commonly used tools in Table 5 to support the development process.

Figure 4. The general Fast Healthcare Interoperability Resources (FHIR) practice guideline—the development architecture for the practice design. IG: Implementation Guide; ISPf: integrated service platform; SMART: Substitutable Medical Applications Reusable Technologies.

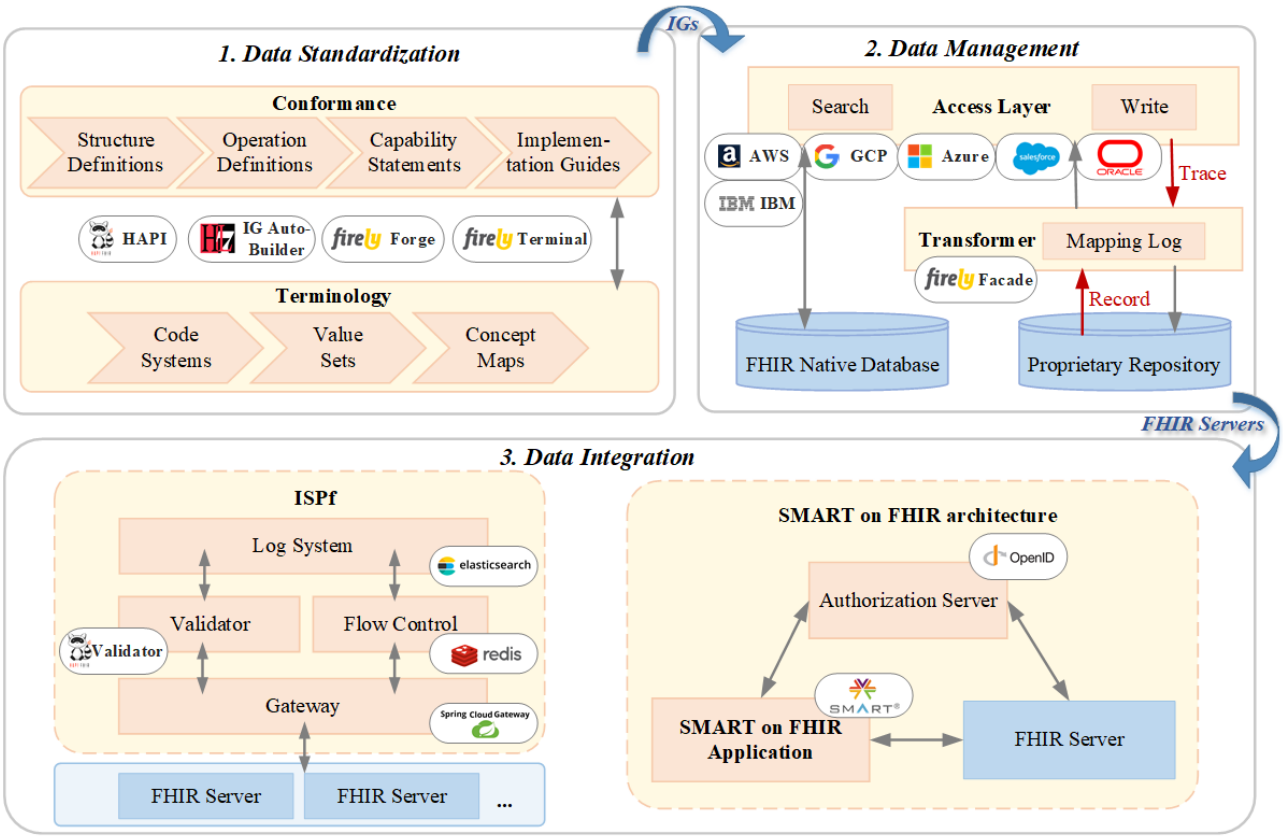


Table 5. A list of commonly used tools.

Tool and description		Availability
Data standardization		
HAPI[a] FHIR[b]	This tool provides Java API[c] for HL7[d] FHIR clients and servers	[95]
IG[e] Auto-Builder	An IG publishing tool that makes your IGs to be visible on the internet [96]	[97]
Firely Forge	The official FHIR tool for managing FHIR profiles	[98]
Firely Terminal	A cross-platform command line tool with a range of commands for working with FHIR resources and installing and publishing FHIR packages	[99]
Data management		
Firely Facade	A special type of plug-in that registers services to access the existing data repository. It speaks FHIR in the front-end and talks directly to native data in the back-end	[100]
FHIR Works on AWS[f]	A framework used to deploy an FHIR server on AWS	[101]
FHIR server for Azure	An open-source implementation of FHIR specification designed for the Microsoft cloud	[102]
GCP[g] Healthcare API	A cloud application that accelerates health care solution development with fully managed, enterprise-scale HL7 FHIR, HL7 version 2, and DICOM[h] APIs	[103]
IBM FHIR server	An open-source Java solution that supports the processing, validation, and storage of health care data according to the HL7 FHIR specification	[104]
Oracle Healthcare Data Repository	The foundation of a health care information exchange platform that makes health care data more useful by supporting the integration and operation of a full spectrum of health care applications	[105]
Health Cloud	A tool that combines clinical and nonclinical customer data to drive efficiencies in health	[106]
Data integration		
Spring Cloud Gateway	This tool provides an API Gateway built on top of the Spring Ecosystem	[107]
Redis	This tool provides access to mutable data structures via a set of commands sent using a server-client model with TCP[i] sockets and a simple protocol	[108]
Validator	The HAPI FHIR Validator API is a simple REST[j] API to validate the structure and content of an FHIR object	[109]
Elasticsearch	A distributed, RESTful search and analytics engine is at the heart of the Elastic Stack	[110]
OpenID	An open standard and decentralized authentication protocol promoted by the nonprofit OpenID Foundation	[111]
OAuth	An open protocol to allow secure authorization in a simple and standard method from web, mobile, and desktop applications	[112]
SMART[k]	Define a workflow that an application can use to securely request access to data and then receive and use that data	[113]

[k]SMART: Substitutable Medical Applications Reusable Technologies.

Data Standardization

In the data standardization development stage, several components are defined to ensure the consistent use of codes within a specific context. The terminology system comprises essential resources such as CodeSystem, ValueSet, and ConceptMaps. These resources establish a framework for determining which codes can be used. Furthermore, the

conformance system includes resources such as StructureDefinition, OperationDefinition, CapabilityStatement, and ImplementationGuide. These resources are crucial in creating profiles and IGs that adhere to a specific exchange framework. As mentioned in the *Data Standardization* section, the granularity of the data plays a crucial role in information loss. Pfaff et al [39] pointed out that information loss can be avoided by defining custom values or extensions during the data standardization stage. By incorporating custom values or extensions defined in this stage, it is possible to capture and preserve the finer-grained information that is likely to be lost during the transformation process.

During this process, developers can use various tools to facilitate efficient data standardization. The HL7 API (HAPI) FHIR offers a Java API for developing HL7 FHIR clients and servers. Forge serves as a management tool for FHIR profiles. The Firely Terminal, a cross-platform command line tool, provides a wide array of commands for working with FHIR resources and installing and publishing FHIR packages. IG Auto-Builder is another helpful tool that simplifies the creation and publication of IGs, available on the internet [96].

Ultimately, the data standardization stage would generate a set of IGs to ensure consistency and conformity in implementing higher-level services.

Data Management

Various situations can arise in the data management development stage, each bringing different challenges. These situations can fall into 3 options.

The first is to develop an FHIR-native warehouse that the health care IT system vendor manages. In this scenario, the vendor assumes responsibility for designing, implementing, and maintaining the warehouse.

The second is to select a well-established third-party warehouse, such as FHIR Works on Amazon Web Services, IBM FHIR Server, Google Cloud Platform Healthcare API, FHIR Server for Azure, Health Cloud, and Oracle Healthcare Data Repository, to store and explore the FHIR APIs. This approach allows vendors to leverage the capabilities of mature third-party warehouses for FHIR API functionality.

The third is to provide FHIR data using plug-ins. In this scenario, vendors retain their existing data infrastructure and use plug-ins to facilitate data transformation from its native format to the FHIR format. A tool called Facade is available to facilitate this mapping process.

As discussed in the *Data Standardization* section, the discrepancy in granularity between different systems can lead to potential information loss. To mitigate this issue, developers can incorporate a mapping log within the transformer component. When encountering a granularity gap during the mapping process, the mapping log captures and records the lost information, associating it with the corresponding target resource ID. This mapping log serves as a reference for any subsequent services or systems requiring detailed information about the mapping process. If the overlying services need to retrieve the lost information, they can make a request based on the resource ID recorded in the mapping log. This measure allows them to access the details lost during the initial mapping, ensuring that the required information is preserved and available for further analysis or processing.

Ultimately, the data management stage generates a series of FHIR APIs. These APIs serve as a foundation for data exploration and form the backbone of the infrastructure required for high-level services.

Data Integration

Two types of interoperable services are commonly used in the data integration development stage.

The first type is the ISPf, which enables interoperability among multiple organizations. The ISPf comprises 4 key components: gateway, validator, flow control, and log system. The gateway, built by the Spring Cloud Gateway, is responsible for API authorization and forwarding API requests between organizations. The validator ensures that the structure and content of the API data comply with the FHIR object defined in IGs. The HAPI FHIR Validator can build this functionality. The flow control component is designed to limit the number of simultaneous API calls to ensure a stable operation. Redis can effectively fulfill the flow control requirements. As ISPf manages multiple organizations and facilitates data exchange, maintaining a comprehensive log system is crucial for history tracking and auditing. Elasticsearch, a powerful search and analytics engine, can be used to develop the log system within the ISPf, enabling efficient storage and retrieval of API call records.

The second type of interoperable service is represented by apps built by the SMART on FHIR architecture [114]. This architecture consists of 3 key components: the resource server, authorization server, and the SMART on FHIR apps. The resource server is an access layer between the data management layer and the SMART on FHIR apps. The authorization server (an OpenID Connect–compliant web server) authenticates users and issues access tokens. SMART on FHIR apps is designed with specific functionalities and can be substituted based on user preferences.

Use Case

We arbitrarily selected a use case that was in addition to the reviewed articles. Portugal et al [115] designed a smart bed infrastructure with an HIS using FHIR. We mapped it back to the FHIR PG to demonstrate PG's effectiveness and generalizability.

In this case, the roles and responsibilities can be mapped to the FHIR PG–practice design. The authors and their research partners formed an IGs editing group to define IGs consisting of profiles and workflows. The profiles were derived from foundational FHIR resources such as Observation, Device, and ServiceRequest. The workflows defined the frequency at which the smart bed would collect vital signs from the smart bed. Subsequently, the authors' team, acting as a health care IT system vendor, developed a gateway that gathers raw data from sensors and converts it into FHIR for transmission. Although they did not discuss the final applications in detail, it can be

inferred that health care application developers can build a better smart bed monitor based on their infrastructure.

The development architecture described in this paper can also be mapped back to the FHIR PG–development architecture. In the data standardization stage, the authors used the HAPI FHIR for HTTP processing, parsing and serialization, and FHIR REST semantics. It provided a bare-bones structure to build the API. In the data management stage, the authors developed a fog server as a gateway between the smart bed and HIS. This fog server is responsible for collecting raw data from the HIS, transforming it into the FHIR format, and facilitating its integration into the FHIR ecosystem. Finally, in the data integration stage, the authors enabled the HIS software to monitor patient procedures and flows, accompanied by the OAuth2 protocol for secure API communication.

Discussion

Principal Findings

FHIR has shown significant advantages in facilitating interoperability among health IT systems compared with established international standards. However, there are challenges in large-scale implementation and promotion, particularly in different countries. First, countries without incentive policies to encourage FHIR research and implementation may exhibit less enthusiasm for adopting FHIR standards. Second, the lack of a suitable infrastructure to support the implementation process can result in high costs associated with FHIR adoption. Third, the foundational resources provided by FHIR may not directly align with the specific service requirements in different regions, necessitating additional customization processes.

The following steps must be taken to address these challenges. First, it is crucial to have government policies that encourage the evolution and adoption of health care data standards. These policies can stimulate the enthusiasm and investment of stakeholders in the health care ecosystem to promote FHIR implementation on a larger scale. Second, strengthening the infrastructure helps reduce the cost and complexity associated with FHIR adoption, which includes developing services such as FHIR data storage, data standard quality control, and managed services for data operations. Third, FHIR profiles and workflows should be defined to address the specific requirements and characteristics of local health systems. By tailoring FHIR IGs to match the needs of different regions, the gap between FHIR foundational resources and specific service requirements can be bridged.

FHIR holds significant potential in standardizing health care data and promoting service interoperability among health care institutions. Its adoption can drive the transformation of the health care service model and enhance the overall quality of health care services. With the growing recognition of the benefits of FHIR and its demonstrated impact on health care interoperability, more stakeholders are expected to actively participate in enriching its implementation. This collective effort would lead to the emergence of extensive health care service innovations, further enhancing the delivery of high-quality health care services.

Limitations

There are a few current limitations when applying the FHIR PG: (1) PG is derived from the waterfall model that follows a sequential and linear approach. Each step must be completed before proceeding to the next step. Therefore, it is time-consuming and costly to return and modify the previous steps if changes are necessary during the development process. (2) Although PG emphasizes the achievement of interoperability, it leaves out the security discussion. Developers must incorporate additional security mechanisms into PG–development architecture to ensure secure interoperation among multiple organizations.

Conclusions

Owing to the unique characteristics of FHIR, including comprehensive coverage of data definitions, substantial flexibility of data exchange, explicit semantics, and many available open-source tools, FHIR-based services have attracted strong interest from stakeholders in the health care ecosystem. Current studies reveal that many institutions, such as hospitals, regulators, and researchers, have already begun collaborations in actively building FHIR foundational frameworks or application use cases. After conducting the latest literature review, we proposed a general FHIR PG to bridge the gap between FHIR IGs and the practice of building usable services. This PG helps stakeholders identify their participant roles, manage the scope of responsibilities, and develop relevant modules, which we believe would effectively facilitate the application and promotion of HL7 FHIR standards across the health care ecosystem.

Abstract

Background: Recent advances in natural language processing (NLP) have heightened the interest of the medical community in its application to health care in general, in particular to stroke, a medical emergency of great impact. In this rapidly evolving context, it is necessary to learn and understand the experience already accumulated by the medical and scientific community.

Objective: The aim of this scoping review was to explore the studies conducted in the last 10 years using NLP to assist the management of stroke emergencies so as to gain insight on the state of the art, its main contexts of application, and the software tools that are used.

Methods: Data were extracted from Scopus and Medline through PubMed, using the keywords “natural language processing” and “stroke.” Primary research questions were related to the phases, contexts, and types of textual data used in the studies. Secondary research questions were related to the numerical and statistical methods and the software used to process the data. The extracted data were structured in tables and their relative frequencies were calculated. The relationships between categories were analyzed through multiple correspondence analysis.

Results: Twenty-nine papers were included in the review, with the majority being cohort studies of ischemic stroke published in the last 2 years. The majority of papers focused on the use of NLP to assist in the diagnostic phase, followed by the outcome prognosis, using text data from diagnostic reports and in many cases annotations on medical images. The most frequent approach was based on general machine learning techniques applied to the results of relatively simple NLP methods with the support of ontologies and standard vocabularies. Although smaller in number, there has been an increasing body of studies using deep learning techniques on numerical and vectorized representations of the texts obtained with more sophisticated NLP tools.

Conclusions: Studies focused on NLP applied to stroke show specific trends that can be compared to the more general application of artificial intelligence to stroke. The purpose of using NLP is often to improve processes in a clinical context rather than to assist in the rehabilitation process. The state of the art in NLP is represented by deep learning architectures, among which Bidirectional Encoder Representations from Transformers has been found to be especially widely used in the medical field in general, and for stroke in particular, with an increasing focus on the processing of annotations on medical images.

Introduction

Stroke, also called "brain attack," is a medical emergency that occurs when blood flow to a part of the brain is disrupted caused by a clot blocking an artery or by a cerebral hemorrhage due to a ruptured artery. Stroke can result in a range of symptoms and complications depending on the area of the brain that is affected, having impacts on perception, motor control (typically weakness or paralysis on one side of the body, dizziness or difficulty with balance), or behavior (difficulty in speaking or understanding speech), which is a life-threatening emergency that requires immediate medical attention. Although mortality from stroke is decreasing in developed, high-income countries, it remains one of the leading causes of mortality and disability along with ischemic heart disease, and the prevalence of people living with the effects of stroke is increasing due to the growing and aging population [1].

Therefore, the economic and social costs related to the hospitalization, treatment, and recovery of stroke patients are increasing, and there is a growing demand for advanced technologies that can assist in clinical diagnosis, treatment, predictions of clinical events, intervention recommendations, rehabilitation programs, and related factors [2]. For instance, a quick diagnosis and treatment of stroke is crucial as it leads to improved outcomes and prognosis among patients treated within the so-called "golden hour" [3].

In this context, novel approaches that complement and go beyond evidence-based medicine are required. Tools based on artificial intelligence (AI), with their ability to process large amounts of data, have been widely discussed in recent years as one of the proposed approaches to improve the care of stroke, assisting in diagnosis, prognosis, treatment, and prevention [3,4].

AI is an interdisciplinary science with multiple approaches, which in recent years has experienced a significant growth in the fields of machine learning (ML) and deep learning (DL). ML and DL algorithms can learn from data and improve their performance over time without being explicitly programmed, and these methods can deal with very large and complex data sets. DL is considered a recent specialization of ML, which uses artificial neural networks to extract complex representations and features from data. Throughout the manuscript, a distinction is made between DL, used for algorithms based on multilayered neural networks, and traditional ML based on other techniques.

The application of AI to the management of stroke is a topic that has gained a lot of traction in the general field of health informatics [5], partly owing to the remarkable impact of stroke in public health and the subsequent high demand for effective and efficient tools to diagnose and treat stroke. Moreover, the complexity and variety of stroke casuistry make it a good target for AI solutions, which are especially suited to process large amounts of data from a wide range of sources, identify patterns and trends in large data sets, and learn and adapt to new data.

A domain where those advances have produced particularly good results is natural language processing (NLP), which is a promising tool for medicine to unlock the full potential of electronic health records (EHRs), since it might be used to automatically transform clinical text into structured clinical data that can guide clinical decisions [6,7]. The potential of NLP in the analysis of EHR data is particularly appealing given the great quantity of data contained in these records. Notwithstanding their importance, such data are intractable with conventional mathematical methods, since they are recorded in clinical reports, prescriptions, annotations on medical images, and generally unstructured texts [8].

NLP can assist in the identification of patterns and trends in large data sets, which can improve the understanding of factors that contribute to the development of diseases and can in turn help to define more effective prevention and treatment strategies. NLP can also be used in the analysis of particular cases to guide decisions and potentially delay or prevent the onset of the disease. NLP can also be used to develop intelligent systems to find relevant information in the medical literature [9].

Nevertheless, NLP poses particular challenges, including the protection of privacy in the extraction of data, since personal information is often mixed with other data; the variety of the quality and format of EHR data, which depend on the source and software used to collect them; and the difficulty of annotating data samples for training [10]. Therefore, to unlock the potential of NLP in the exploitation of EHRs, researchers and developers need to combine different advanced ML techniques, apply careful data management, and gain a deep understanding of the clinical domain. There is, however, a paucity of guidance on selecting appropriate methods tailored to the health care industry [11].

This scoping review aimed to gather the knowledge that might help in that guidance by investigating how NLP is used to deliver a smarter health care in different phases of stroke disorders (prevention, diagnosis, treatment, and prognosis). The primary questions that served as a guide for the review are: (1) In which phases or contexts of stroke management is NLP used (prevention, diagnosis, treatment, and/or prognosis)? (2) Which are the main benefits of applying NLP to stroke management, related to clinical, social, and economic factors? and (3) What types of clinical data are collected and used by NLP in stroke management (ie, demographic data, medical notes, physical and functional examination, reports of laboratory or medical devices)?

This review also focused on the following secondary questions: (1) What NLP methods, AI algorithms, and tools are used in stroke studies? (2) Which AI techniques or frameworks are used to process and analyze the data? (3) Are there algorithms and NLP software specifically tuned for stroke? and (4) Which tools have the best performance and how do they compare to others?

Methods

Design

The unregistered protocol for this review was created following the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) guidelines [12] and the JBI Manual for Scoping Reviews [13].

Inclusion Criteria

The target patient population of this scoping review included adults that had suffered stroke and people at risk of stroke due to a history of predisposing vascular background or other conditions that increase the risk of developing stroke, including mental illness or heart diseases such as a reduced ejection fraction.

The main concept of interest was the use of NLP in stroke management in public or private health care systems, including use cases and the data and technologies involved in those applications. We considered both the application of NLP for monitoring and decision-making of individual patients as well as for the planification of care resources in the management of stroke cases.

We were interested in any context where prevention, treatment, or rehabilitation of stroke might take place, ranging from early detection outside or inside clinical settings, diagnosis and evaluation of cases, clinical decision-making, administration and monitoring of rehabilitation, and postrehabilitation management.

The types of evidence sources taken into account included articles from peer-reviewed journals, books, and conference papers, considering both primary research studies and systematic or scoping reviews, as well as reports from scientific, medical, or government institutions.

Search Strategy

The search was performed in the electronic databases of Scopus and Medline through PubMed, using the keywords “natural language processing” and “stroke,” restricted to articles published in the last 10 years, between 2013 and 2022.

Selection Process

The results of the search were imported into the Zotero Reference Manager software (Corporation for Digital Scholarship, Virginia), which was used to filter out duplicate records. Titles and abstracts of the filtered list were screened independently by two reviewers to ascertain their eligibility according to the inclusion criteria. Disagreements were resolved in a discussion session between the reviewers to obtain a consensus.

The full text of the papers was read by two independent reviewers to extract the relevant data as described below. An internal cross-validation by three other experts on the topic was also considered. Works whose content did not meet the eligibility criteria or did not contain sufficient information to answer the primary questions were excluded and those that reported the same results from the same study were treated as duplicates. The record of rejected works was shared by the reviewers to confirm the decisions of either part.

Data Extraction and Presentation of Results

The reviewers filled out a table with the following data from each work included in the final selection: type of study, primary diagnosis, related diseases that were used either as inclusion criteria or as predictors in the data analysis, sample size (if suitable), and qualitative responses to the primary and secondary questions.

Works were classified depending on whether or not they reported experimental studies, and those that did were further subclassified as clinical trials or different types of observational studies: cross-sectional, retrospective or prospective, and cohort or case-control studies.

A dictionary of terms was defined for the tabulated records of the primary and secondary questions and their relative frequencies were calculated. In addition, the relationships between answers were analyzed in two different multiple correspondence analyses (MCAs), which can be employed to detect and represent underlying structures in categorical data sets (ie, frequent co-occurrence of specific categories in two or more variables) [14]. One of the MCAs focused on the primary questions, seeking relationships between the context of application (eg, classification of diagnostics, prognosis of outcomes) and the types of data that were processed. The other MCA focused on the secondary questions, seeking relationships between NLP methods and software tools. In both analyses, the type of AI models (general ML, DL, or rule-based algorithms) was also included as a variable. The analysis was performed in R [15], using the packages *factoMineR* [16] and *factoextra* [17] for MCA and its graphical representation.

Results

General Description of the Studies

A total of 115 unique papers were identified out of 223 records obtained in the search; 29 studies were eventually included for data extraction and analysis after screening by title and abstract and reading of the full text (see the flow diagram in Figure 1).

The general characteristics of the 29 reviewed studies (year, type of study, target diseases, and sample size), together with the items extracted from the primary and secondary questions are respectively presented in Tables 1, 2, and 3.

Figure 1. Flow diagram of the review process. NLP: natural language processing.

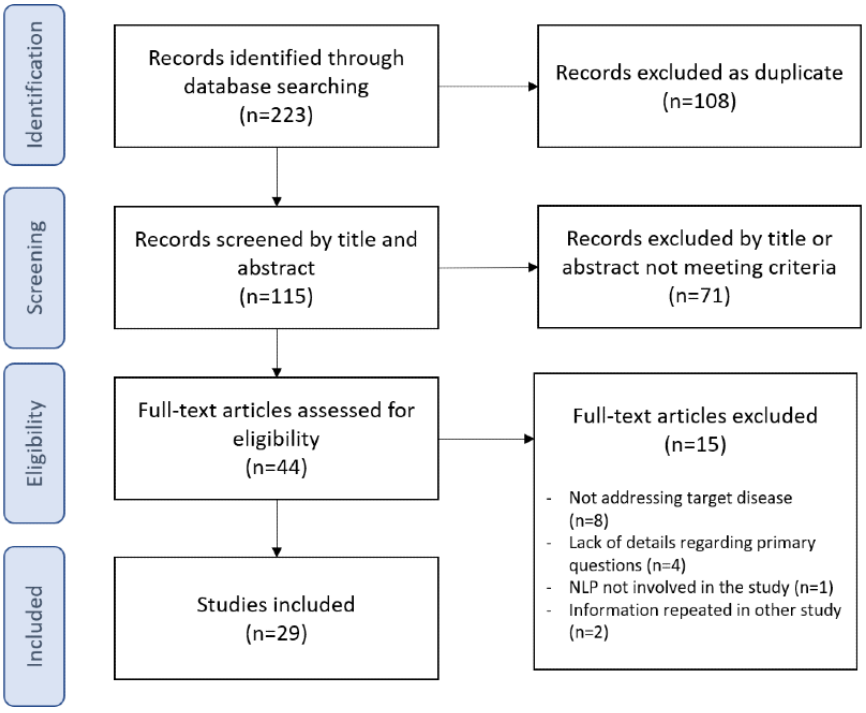

Table 1. Summary of the included studies: study type, sample size, type of stroke, and other diseases or conditions taken into account.

Reference	Year	Type of study	Sample size[a]	Type of stroke	Other conditions
Zhao et al [18]	2021	Cohort study	4914	Transient ischemic attack, hemorrhagic stroke	AF[b]
Zanotto et al [19]	2021	Retrospective cross-sectional cohort study	188	Ischemic stroke	AF, CAD[c], DM[d], dyslipidemia, hypertension, smoking, other[e]
Sung et al [20]	2022	Retrospective cohort study	3847	Acute ischemic stroke	AF, CHF[f], DM, cancer, hyperlipidemia, hypertension
Sung et al [21]	2021	Retrospective cohort study	3847	Acute ischemic stroke	AF, CHF, DM, cancer, hyperlipidemia, hypertension
Miller et al [22]	2022	Retrospective cohort study	918	Ischemic stroke	Other
Mayampurath et al [23]	2021	Cohort study	965	Acute ischemic stroke, hemorrhagic stroke	Other
Lineback et al [24]	2021	Retrospective cohort study	2855	Ischemic stroke, hemorrhagic stroke	AF, CAD, CHF, DM, cancer, hyperlipidemia, hypertension, other
Kogan et al [25]	2020	Retrospective cohort study	7149	Ischemic stroke, hemorrhagic stroke, transient ischemic attack	None
Heo et al [26]	2020	Retrospective cohort study	1810	Acute ischemic stroke	DM, dyslipidemia, hyperglycemia, hypertension, smoking, other
Deng et al [27]	2022	Feasibility study	1000 (simulated)	Hemorrhagic stroke	DM, hypertension
Bacchi et al [28]	2019	Cohort study	2201	Transient ischemic attack	None
Yu et al [29]	2021	Cohort study	1320	Ischemic stroke, hemorrhagic stroke	None
Wheater et al [30]	2019	Cohort study	2160	Ischemic stroke, hemorrhagic stroke	None
Sung et al [31]	2020	Cohort study	4640	Acute ischemic stroke	None
Sung et al [32]	2018	Feasibility study	90	Acute ischemic stroke	Hyperglycemia, other
Shek et al [33]	2021	Cohort study	2327	Stroke comorbidities	AF, CHF, DM, hypertension
Rannikmäe et al [34]	2021	Cohort study	207	Intracerebral hemorrhage, subarachnoid hemorrhage, and ischemic stroke	None
Ong et al [35]	2020	Cohort study	721	Acute ischemic stroke	None
Mowery et al [36]	2016	Cohort study	498	Ischemic stroke	CAD, CHF, DM, hypertension
Li et al [37]	2021	Cohort study	3971	Acute or subacute ischemic stroke	None
Leung et al [38]	2021	Cohort study	182	Not applicable	Other
Kim et al [39]	2019	Cohort study	3204	Acute ischemic stroke	None
Kent et al [40]	2021	Retrospective cohort study	261,960	Ischemic stroke	AF, CAD, CHF, DM, hyperlipidemia, hypertension, other
Lin et al [41]	2021	Retrospective cohort study	1700	Acute ischemic stroke	Other
Guan et al [42]	2021	Cohort study	1598	Ischemic stroke	CHF, other
Garg et al [43]	2019	Cohort study	1091	Ischemic stroke	AF, CAD, DM, hyperlipidemia, hypertension
Farran et al [44]	2022	Retrospective cohort study	16,916	Not applicable	AF
Elkin et al [45]	2021	Cohort study	96,681	Not applicable	AF
Bacchi et al [46]	2022	Cohort study	438	Ischemic stroke, hemorrhagic stroke	None

[a]Number of patients involved.

[b]AF: atrial fibrillation.

[c]CAD: coronary artery disease.

[d]DM: diabetes mellitus.

[e]Other refers to conditions that are not already listed in the table.

[f]CHF: coronary heart failure.

The vast majority were cohort studies that analyzed clinical aspects, along with societal or economic aspects of the disease in some cases, at the moment of data gathering. Approximately one third of the papers (n=10) also included a retrospective analysis and 2 of them were limited to feasibility studies. Although the search included a time span of 10 years, only one of the studies included in the review was older than 5 years [36] and most studies (n=19) had been published in the last 2 years (2021 or 2022).

Most studies (n=24) focused on ischemic stroke (either acute, subacute, or transient); the second most frequent type of stroke was hemorrhagic stroke (n=9), which in the majority of cases was in addition to and not excluding ischemic stroke (only 2 papers dealt exclusively with hemorrhagic stroke). Many studies considered other clinical conditions that were used to select the patients or were included as information taken into account by the models. The most common conditions were atrial fibrillation, diabetes mellitus, and hypertension; each of them was considered in one third of the reviewed papers (n=10). Other diseases that were considered with smaller frequency were hyper- or dyslipidemia, hyperglycemia, hypercholesterolemia, coronary heart failure, smoking, or cancer.

The sample size of the cohort studies was highly varied, ranging between 182 patients [38] and more than 260,000 patients [40], with a median sample size of 2160 patients. The two feasibility studies were conducted either with simulated cases [27] or with a smaller sample of 90 patients [32].

Table 4 shows the frequency of each category used to classify the answers to the primary and secondary questions, except for the question about the specificity of algorithms and NLP tools for stroke, since there was little variability in those answers.

Table 2. Summary of the answers to the primary questions.

Reference	Context for NLP[a] use	Expected benefits	Types of clinical data[b]
Zhao et al [18]	Prevention and diagnosis (classification)	CLINICAL: improved triage	Demographic data, laboratory test results, medical history, medication

[i]NPV: negative predictive value.

[j]ROC: receiver operating characteristic.

[k]AUC: area under the curve.

[l]NRI: Net Reclassification Index.

[m]IDI: integrated discrimination index.

The most frequent context of stroke in which the studies were applied was the diagnostic phase, followed by the prognosis of outcomes. The potential benefit of the results on clinical processes (eg, improving the triage of patients depending on the type or severity of stroke, more efficient management of care information) was the main focus of all studies but one [41], which chiefly focused on the societal aspect of supporting research studies, similar to two other studies that also evaluated that aspect along with clinical applications. Five of the 29 studies (17%) also considered the potential economic benefit of NLP, in terms of reducing the costs of stroke for the public health sector.

The most frequent source of data for NLP models was diagnostic reports (n=24), followed in many cases by annotations on medical images such as radiographs and scans (n=15). General ML models were used more frequently than DL or rule-based algorithms to process the data (n=15 for ML vs n=10 papers for either DL or rule-based techniques). NLP tools, other statistical methods, and the software packages that were used to implement them highly varied across papers, although there were some associations with the AI technique and other variables (see the next subsection).

In nearly all studies, the AI architectures and algorithms had been adapted to deal with stroke-related data, except for one study that used an ML model for patients with severe mental illness at risk of stroke [44]. One of the studies actually used a software tool that was specifically designed for stroke [41], StrokeBERT, which is a language representation model based on Google's Bidirectional Encoder Representations from Transformers (BERT) [47]. Other studies used models that were adapted to broader medical terminology, including ClinicalBERT [52], BioClinicalBERT [53], and BioWordVec [54], or models tuned with standard medical vocabularies such as Systematized Nomenclature of Medicine (SNOMED) [55] or Unified Medical Language System (UMLS) [56].

The methods used to compare the performance of the models were also highly varied, although in the greatest majority of cases (n=23) they were metrics based on the ratios of true/false-positive or -negative values (positive predictive value, negative predictive value, sensitivity, specificity, F1 score, or accuracy), and many were based on the receiver operating characteristic curve (n=14); a few studies (n=2) also used measures of classification improvements such as the net reclassification index and the integrated discrimination index [48], and only one study used other statistics such as correlation coefficients or the root mean squared error [25].

Owing to the variety of methods and tools used in the studies, there were few coincidences in the selection of the best ones. The only methods that were chosen as the best performing in more than one study were random forest (n=3), convolutional neural network (n=2), and BERT (n=2).

Multiple Correspondence Analysis

Figures 2 and 3 show the proximity of the categories that exhibited the closest relationships in the two first dimensions obtained in the MCA.

The common variable used in the analysis (AI technique) was clearly distinguished in the first two dimensions of the MCA plot, which on the one hand separated rule-based techniques from ML and DL and on the other hand separated general ML from DL.

In the first MCA (Figure 2), it could be observed that the studies focusing on the classification of diagnostics (often used for the triage of patients) and prospects of recurrent stroke were often those that also used ML techniques with demographic data and information on treatments. Although the other categories were less tightly related, the text associated with clinical tests and the annotations on images were related more closely to prognostics of outcomes than to other contexts of application, with annotated images also being used to ascertain details of the stroke episode. Both types of studies were frequently approached by DL and sometimes by rule-based techniques.

In the other MCA (Figure 3), AI techniques were separated between ML, DL, and rule-based methods in the two main dimensions of the projected space, although only general ML and DL were closely related to other items.

Figure 2. Projection of the scores of the categories in the first two dimensions of the multiple correspondence analysis plot involving context of application, data sources, and artificial intelligence technique. DL: deep learning; ML: machine learning.

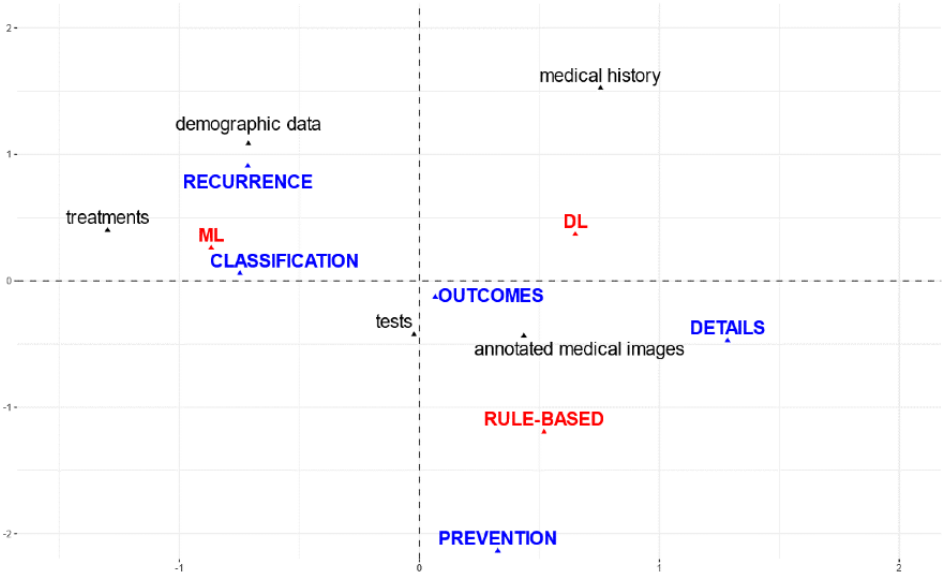

Figure 3. Projection of the scores of the categories in the first two dimensions of the multiple correspondence analysis plot involving natural language processing methods, software, and artificial intelligence techniques. See brief descriptions of the methods and software in Multimedia Appendix 2. BERT: Bidirectional Encoder Representations from Transformers; BOW: Bag-of-words; BRAT: Browser-based Rapid Annotation Tool; DL: deep learning; ML: machine learning; NEGEX: Negation extraction; NLTK: Natural Language Processing toolkit for Python; REG-EXPR; regular expressions; TF-IDF; term frequency-inverse document frequency; XGBoost: extreme gradient boosting.

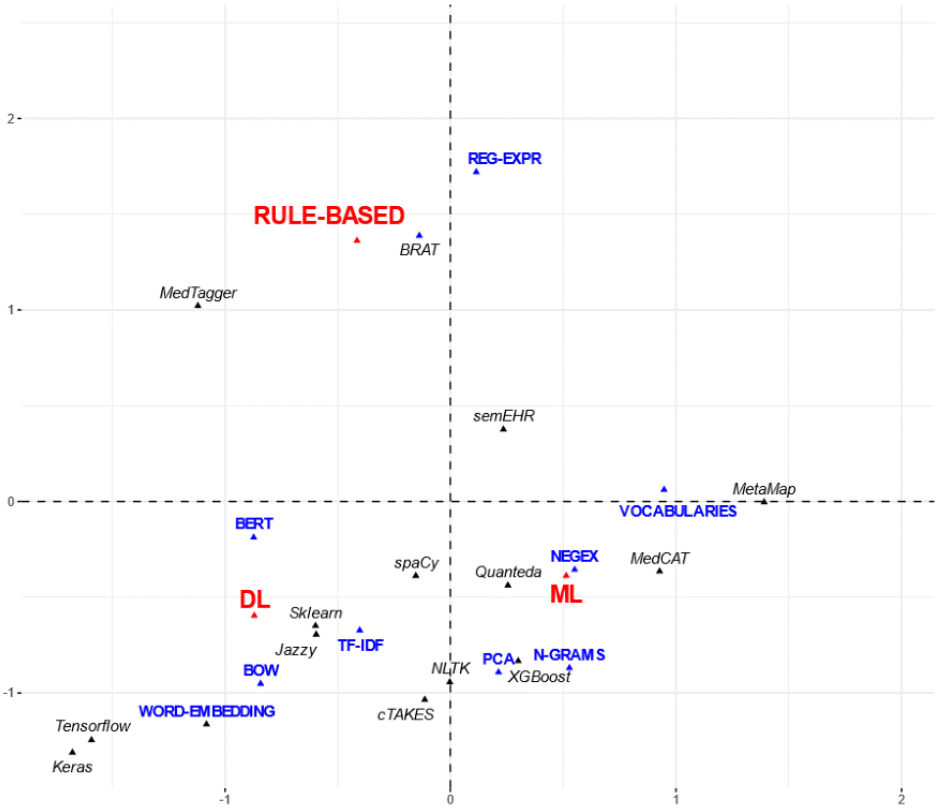

ML was related to NLP methods that are used in the first steps of the processing pipeline, such as the extraction of text tokens in the form of *n*-grams, detection of negated terms, and use of standard vocabularies. This was mostly performed with software tools such as MetaMap, MedCAT, Quanteda, and extreme gradient boosting.

Conversely, DL was more associated with the usage of BERT, a language representation model based on transformers [47], and NLP methods applied to numerical and vectorized representations of the language tokens, such as the "bag-of-words," term frequency-inverse document frequency word embeddings, and other word embeddings. This was chiefly performed with software packages such as Tensorflow through Keras and scikit-learn. Other software packages that are often used for NLP, such as Natural Language Processing toolkit for Python, were observed in the middle of the primary axis of the MCA plot, halfway between the general ML and DL architectures.

Discussion

The research on AI for stroke management has gained greater interest and impact in the last few years [5], and the growing rate of publications found in this scoping review reveals that the same trend is occurring in research on NLP, which is a particular field of AI, applied to the same clinical condition. However, in other aspects, the studies focused on NLP show their own specific trends.

Although the search for this scoping review was very broad, and did not limit the type and phase of stroke to be studied, the vast majority of studies were focused on ischemic stroke in its acute, subacute, or transient stage, and the purpose of using NLP was to improve processes in a clinical context. This focus on clinical contexts is related to the relevance that is attributed to the unstructured information contained in EHRs, (ie, in notes, reports, and annotated images) as predictors of outcomes and complications, which are crucial for proper decision-making, together with the difficulty of processing that information automatically with traditional tools. The deployment of NLP models integrated in the pipelines of an EHR, programmed to automatically ingest and process incoming records [57], or even the patients' commentaries in emergency through voice-to-text [58], may be used to identify patients at high risk and requiring prompt access to specific treatments; find signs to anticipate impending stroke; or evaluate its severity, type, and risks of complications.

Efficient triage of patients in emergency and early consultations, more accurate diagnostics, or prognostics of outcomes and recurrence were the main intended applications of NLP models in the reviewed studies. Accordingly, the main sources of information exploited by NLP algorithms were clinical data of the patients obtained from their history, especially the diagnostic reports of the current stroke episode. Administration and monitoring of rehabilitation, or postrehabilitation management, were not dealt with in the final selection of studies that were the object of the review.

NLP is itself a broad concept, which involves many types of computational techniques. In its more general sense, NLP comprises all methods and tools that can be used to analyze texts in order to represent human languages, based either on theory of language constructs, semantic mappings, or emulation of linguistic processes occurring in the human brain [59]. The relationships between these tools, types of statistical and ML models, data sources, and applications found by the MCA help to understand how each subset of techniques can be used to solve different problems, and can also help to interpret some trends in the evolution of this technology applied to the clinical management of stroke.

Some of these methods rely on text-processing algorithms that use predefined rules and vocabularies, such as the tokenization of long texts into smaller items, categorization of those items in parts of speech, and construction of syntactic structures, and they have been widely used since long before the recent revolution of big data and DL fields. What this revolution has provided to the field of NLP is the maturity of more complex representations of language data, such as the word embeddings into large-dimensional numeric vectors and their effective processing through deep neural networks, as well as the exploitation of huge databases of texts, such as the Common Crawl data set that includes petabytes of text data, crawled monthly from dozens of billions of web pages [60].

In this context, the state of the art in NLP is represented by DL architectures such as GPT, XLNet, or BERT [61]. Among these, BERT has been found to be particularly widely used in the medical field in general, and for stroke in particular, along with specialized versions fitted to these applications that improve their performance [22,41]. More basic ML algorithms and hybrid approaches with rule-based techniques are still more present than advanced DL networks in the recent research on NLP for stroke, and in some cases, tailored rule-based systems outperformed BERT and its derivatives [19,22]. Support vector machine methods were also found to perform better than BERT in one study [19], although random forest was reported to have the best performance more frequently than any other ML method in the set of reviewed studies [18,42,46]. Some of these results may seem unexpected, given the remarkable performance of DL in general, and particularly large language models (LLMs), in other areas. However, the computational complexity and large data sets needed to train LLMs can limit their current scalability, not outperforming other ML methods that work better on limited training data such as the data sets of the mentioned studies.

The prevalence of studies based on traditional ML methods over those that use DL neural networks may be partly due to the recency of the more complex DL architectures, as well as to the need of larger sets of data to train those models, which raises the bar to conduct studies with that approach. However, it is also interesting to observe that the choice of the AI technique also relates to the type of data that are processed and the context of application of NLP, such that DL is more closely related to studies that involve medical imaging with annotations to prognosticate the outcomes of stroke.

Taking into account these pieces of evidence, and considering the future of NLP in stroke, further development of LLMs in the biomedical field may be expected. LLMs emerged in 2018 as a class of language models that use neural networks with billions of parameters trained on huge amounts of unlabeled text data through self-supervised learning. LLMs are often based on transformers, a self-attention mechanism to compute contextual relationships between the input tokens [62]. However, innovation in the NLP field will come from the development of these models for medical specialties such as stroke. These biomedical LLMs can be trained not only with data sources from EHRs but also from scientific and clinical publications and social network posts from specialized fields. The particularity is that these models need to be trained on much larger databases than those used by classical ML algorithms to achieve adequate performance metrics. This involves combining computational resources and very large data sources, an option that is not always available for the existing resources in research.

Acknowledgments

This review was conducted within the framework of the IBERUS project Technological Network of Biomedical Engineering Applied to Degenerative Pathologies of the Neuromusculoskeletal System in Clinical and Outpatient Settings (CER-20211003) and the CERVERA Network financed by the Ministry of Science and Innovation through the Center for Industrial Technological Development (CDTI), charged to the General State Budgets 2021 and the Recovery, Transformation, and Resilience Plan.

Abstract

Background: Transformer-based models are gaining popularity in medical imaging and cancer imaging applications. Many recent studies have demonstrated the use of transformer-based models for brain cancer imaging applications such as diagnosis and tumor segmentation.

Objective: This study aims to review how different vision transformers (ViTs) contributed to advancing brain cancer diagnosis and tumor segmentation using brain image data. This study examines the different architectures developed for enhancing the task of brain tumor segmentation. Furthermore, it explores how the ViT-based models augmented the performance of convolutional neural networks for brain cancer imaging.

Methods: This review performed the study search and study selection following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines. The search comprised 4 popular scientific databases: PubMed, Scopus, IEEE Xplore, and Google Scholar. The search terms were formulated to cover the interventions (ie, ViTs) and the target application (ie, brain cancer imaging). The title and abstract for study selection were performed by 2 reviewers independently and validated by a third reviewer. Data extraction was performed by 2 reviewers and validated by a third reviewer. Finally, the data were synthesized using a narrative approach.

Results: Of the 736 retrieved studies, 22 (3%) were included in this review. These studies were published in 2021 and 2022. The most commonly addressed task in these studies was tumor segmentation using ViTs. No study reported early detection of brain cancer. Among the different ViT architectures, Shifted Window transformer–based architectures have recently become the most popular choice of the research community. Among the included architectures, UNet transformer and TransUNet had the highest number of parameters and thus needed a cluster of as many as 8 graphics processing units for model training. The brain tumor segmentation challenge data set was the most popular data set used in the included studies. ViT was used in different combinations with convolutional neural networks to capture both the global and local context of the input brain imaging data.

Conclusions: It can be argued that the computational complexity of transformer architectures is a bottleneck in advancing the field and enabling clinical transformations. This review provides the current state of knowledge on the topic, and the findings of this review will be helpful for researchers in the field of medical artificial intelligence and its applications in brain cancer.

KEYWORDS

artificial intelligence; AI; brain cancer; brain tumor; medical imaging; segmentation; vision transformers

Introduction

Background

Brain cancer is typically characterized by a brain tumor. A brain tumor is a mass or development of aberrant brain cells. The signs and symptoms of a brain tumor vary widely and are determined by the size, location, and rate of growth of the brain tumor. Brain tumors can originate in the brain (primary brain tumors) or move from other body regions to the brain (secondary or metastatic brain tumors). In general, studying brain cancer is challenging given the highly complex anatomy of the human brain, where several sections are responsible for various nervous system processes [1].

Medical imaging technologies for studying the brain are rapidly advancing. Therefore, it is critical to provide tools to extract information from brain image data such that they may aid in automatic or semiautomatic computer-aided diagnosis of brain cancer. Artificial intelligence (AI) techniques based on modern machine learning and deep learning models enable computers to make data-driven predictions using massive amounts of data. These techniques have a wide range of applications, many of which can be customized to extract useful information from medical images [2-6].

Among AI techniques developed for brain cancer applications, architectures based on convolutional neural networks (CNNs) have dominated the research on brain cancer diagnosis and classification. For example, UNet (an encoder-decoder CNN architecture) and its variants [7,8] are popular for brain tumor segmentation tasks. However, CNNs are known to be effective in extracting only local dependencies in the input image data, which is mainly attributed to the localized receptive field. Compared with CNNs, attention-based transformer models (transformers) [9] are good at capturing long-range dependencies. Given their ability to learn long-range dependencies, transformers form the backbone of most state-of-the-art models in the natural language processing domain [10].

For image classification tasks, Dosovitskiy et al [11] proposed the computer vision variants of the transformer architecture, typically known as vision transformer (ViT). The concept of attention was applied to images by representing them as a sequential combination of 16×16-pixel patches. The image patches were processed in a way similar to tokens (words) in natural language processing [11]. The sections (with positional embeddings) are ordered. The embeddings are vectors that can be learned. Each piece is organized in a straight line and multiplied by the embedding matrix. The position embedding result is passed to the transformer encoder.

Given the potential demonstrated by transformer-based approaches for computer vision tasks, transformers have quickly penetrated the field of medical imaging. For example, some studies [12-15] have used them on computed tomography scans and x-ray images of the lungs to classify COVID-19 and pneumonia. Similarly, Zhang and Zhang [16] and Xie et al [17] used ViT for medical image segmentation, and He et al [18] used ViT for brain age estimation. With the recent developments of ViTs in computer vision applications, there has been a growing interest in developing ViT-based architectures for cancer imaging applications. ViT can also aid in the diagnosis and prognosis of other types of cancers. For example, Chen et al [19] showed the scaling of ViTs to large whole-slide imaging for 33 different cancer types. The benchmarking results demonstrate that the transformer-based architecture with hierarchical pretraining outperforms the existing cancer subtyping and survival prediction methods, indicating its effectiveness in capturing the hierarchical phenotypic structure in tumor microenvironments.

Accordingly, many recent efforts have been reported on the developments of ViT architectures to make progress in brain cancer applications. With the growing interest in developing ViT-based methods for brain cancer imaging, there is a dire need to review the recent developments and identify the key challenges. To the best of our knowledge, no study (review) has reported the different ViT architectures for brain cancer imaging and analyzed how ViT complements CNNs in brain cancer diagnosis, classification, grading, and brain tumor segmentation.

A few review and survey articles that are relevant to our work are by Parvaiz et al [20], Magadza and Viriri [21], Akinyelu et al [22], He et al [23], and Biratu et al [24]. Among these, Magadza and Viriri [21] and Biratu et al [24] have surveyed the articles that used deep learning and machine learning methods for brain tumor segmentation. In addition, they covered papers until mid-2021 only and did not cover studies on ViT. Similarly, the survey by Akinyelu et al [22] has a broad scope, as it covered different methods including CNNs, capsule networks, and ViT used for brain tumor segmentation. In addition, it included only 5 studies on ViT, of which 4 were from 2022. Reviews by Parvaiz et al [20], He et al [23], and Shamshad et al [25] covered the applications of ViT in medical imaging; however, the scope of all these reviews is broad, as they included different medical imaging applications. In addition, they conducted a descriptive study of ViT for various medical imaging modalities. Similarly, many relevant recent studies on ViT-based architectures have been left out, as both the reviews [20,25] were released in early 2022. Nevertheless, the aforementioned reviews could be of interest to the readers. Table 1 compares our review with the previously published review articles.

Compared with other existing reviews on ViTs and medical imaging, our study is specific to brain cancer applications and covers the most recent developments. This review provides quantitative insights into the computational complexity and the required computational resources to implement ViT architectures for brain cancer imaging. Such insights will be helpful for the researchers to choose hardware resources and graphics processing units (GPUs). This review identifies the research challenges that are specific to ViT-based approaches in brain cancer imaging applications. These discussions will raise awareness for the related research directions. This review identifies the available public data sets and highlights the need for additional data to motivate the community to develop more publicly available data sets for brain cancer research. Furthermore, this review follows a narrative synthesis approach that would help the readers follow the text quickly.

Table 1. Comparison with similar review articles.

Review title	Month and year	Scope and coverage	Comparison with our review
Vision transformers in Medical Computer Vision—A Contemplative Retrospection [20]	March 2022	• The title is specific to ViT[a]; however, the full text has a very broad scope with discussions on deep learning, CNNs[b], and ViT. • It covers different applications in medical computer vision, including the classification of disease, segmentation of tissues, registration tasks in medical images, and image-to-text applications. • It does not provide much text on brain cancer applications of ViT. • Many recent studies of 2022 are left out as the preprint was released in March 2022. • It does not provide a comparative study on the computational complexity of ViT-based models.	• Our review is also specific to ViT. • Our review is specific to brain cancer applications. • Our review includes more recent studies on ViT. • Our review provides a comparative study of the computational complexity of the ViT-based models.
Transformers in medical imaging: A survey [25]	January 2022	• It is specific to ViT. • It has a broad scope as different medical imaging applications are included. • It does not include many recent studies on ViT for brain cancer imaging (as the preprint was released in January 2022).	• Our review is also specific to ViT. • Our review is specific to brain cancer applications. • Our review includes more recent studies on ViT.
Transformers in Medical Image Analysis: A Review [23]	August 2022	• It is specific to ViT. • It has broad scope as different medical imaging applications are included. • It provides a descriptive review of ViT techniques for different medical imaging modalities. • It does not provide a quantitative analysis of the computational complexity of ViT-based methods.	• Our review is also specific to ViT. • Our review is specific to brain cancer applications. • Our review provides a comparative study of the computational complexity of the ViT-based models.
Brain Tumor Diagnosis Using Machine Learning, Convolutional Neural Networks, Capsule Neural Networks and Vision Transformers, Applied to MRI[c]: A Survey [22]	July 2022	• It covers applications specific to brain tumor segmentation. • It has a broad scope, as it includes studies on CNNs, capsule networks, and ViT. • It includes only 5 studies on ViT. • Many recent studies are left out as it covers only 4 studies from 2022. • It provides no quantitative analysis of computational complexity.	• Our review is also specific to brain cancer and brain tumor. • Our review covers more recent studies. • Our review includes 22 studies on ViT for brain cancer application. • Our review provides a comparative study of the computational complexity of the ViT-based models.
A survey of brain tumor segmentation and classification algorithms [24]	September 2021	• It has a very broad scope as it covers traditional machine learning and deep learning methods. • It covers studies until early 2021 only.	• Our review is specific to ViT. • Our review covers more recent studies.
Deep learning for brain tumor segmentation: a survey of state-of-the-art [21]	January 2021	• It has a broad scope as it covers different deep learning methods. • Many recent studies are left out.	• Our review is specific to ViT. • Our review covers more recent studies.

Research Problem

The popularity of transformer-based approaches for medical imaging has been increasing. Many recent studies have developed new transformer-based methods for brain cancer application. Hence, there is a need to review the recent studies on how transformer-based approaches have contributed to brain cancer diagnosis, grading, and tumor segmentation. In this study,

we present a review of the advancements in ViTs for brain cancer imaging applications. We present the recent ViT architectures for brain cancer diagnosis and classification, identify the key pipelines for combining ViT with CNNs, and highlight the key challenges and issues in developing ViT-based AI techniques for brain cancer imaging. More specifically, this review aims to identify the common techniques that were developed to use ViT for brain tumor segmentation and whether ViTs were effective in enhancing the segmentation performance. This review also identifies the common modality of brain imaging data used for training ViT for brain tumor segmentation. Moreover, this review identifies the commonly used data sets for the brain tumor that contributed to developing ViT-based models. Finally, this review presents the key challenges that the researchers faced in developing ViT-based approaches for brain tumor segmentation. We believe that this review will help researchers in deep learning and medical imaging interdisciplinary fields to understand the recent developments on the topic. Furthermore, it will appeal students and researchers interested to know about the advancements in brain cancer imaging.

Methods

Overview

We performed a literature search in famous scientific databases and conducted a scoping review following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [26]. Multimedia Appendix 1 provides the PRISMA-ScR checklist. The literature search and the study selection were performed using the steps described in the following subsections.

Search Strategy

Search Sources

We searched for relevant literature in 4 databases: PubMed, Scopus, IEEE Xplore, and Google Scholar. The search was performed between July 31 and August 1, 2022. For Google Scholar, we retained the first 300 results, as the results beyond 300 lacked relevance to the topic of this review. We also screened the reference lists of the included studies to retrieve any additional studies that fulfilled the inclusion criteria.

Search Terms

We defined the key terms for the search by referring to the available literature and by a discussion with domain experts. The search terms comprised the terms corresponding to the intervention (ie, transformers) and the target application (ie, cancer and tumor). The search strings are provided in Multimedia Appendix 2.

Search Eligibility Criteria

Our search focused on studies that reported developing ViT-based architectures for brain tumor segmentation, brain cancer diagnosis, or prognosis. We considered studies conducted between January 2017 and July 2022. We included studies that used ViT with or without combining other deep learning architectures, such as CNN, and excluded studies that used only CNN. We excluded studies that reported the diagnosis of other cancer types, such as lung cancer or colorectal cancer, and did not report the use of the model for any form of brain cancer. We included studies that used any type of brain cancer data, including brain magnetic resonance imaging (MRI) and histopathology image data. We included studies published as peer-reviewed articles or conference proceedings and excluded nonpeer-reviewed articles (preprints), short notes, editorial reviews, abstracts, and letters to the editor. We excluded survey and review articles. We did not impose any additional restrictions on the country of publication and the performance or accuracy of the ViT used in the studies. Finally, for practical reasons, we included studies published only in English.

Study Selection

Two reviewers, HA and RQ, independently screened the titles and abstracts of the studies retrieved in the search process. In abstract screening, the reviewers excluded the studies that did not fulfill the inclusion criteria. The studies retained after the title and abstract were included for full-text reading. At this stage, disagreements between the 2 reviewers (HA and RQ) were analyzed and resolved through mutual discussion. Finally, the study selection was verified by a third reviewer.

Data Extraction

We designed a custom-built data extraction sheet. Multimedia Appendix 3 presents the different fields of information in the data extraction sheet. Initially, we pilot-tested the fields in the extraction sheet by extracting data from 7 relevant studies. Two reviewers (HA and RQ) extracted the data from the included studies. The critical information extracted was the application of ViT, the architectures of ViT, the complexity of the architectures used, the pipeline for combining ViT and CNNs, the data sets and their relevant features, and the open research questions identified in the studies. The 2 reviewers resolved disagreements through mutual discussions and revisiting the full text of the relevant study where needed.

Data Synthesis

We followed a narrative approach to synthesize the data after data extraction. We categorized the included studies based on applications, such as tumor segmentation, grading, or prognosis. We also organized the studies based on data type, such as public versus private data and 2D versus 3D data. We also identified the modality of the data used in the included studies, such as MRI or pathology images. Next, we identified the most frequently used architectures of ViT and the key pipelines for incorporating ViT in cascade or parallel connections with CNN models. We also classified the included studies based on the metrics used to evaluate the performances. Finally, if available, we identified the public code repositories for the model implementation as reported in the included studies.

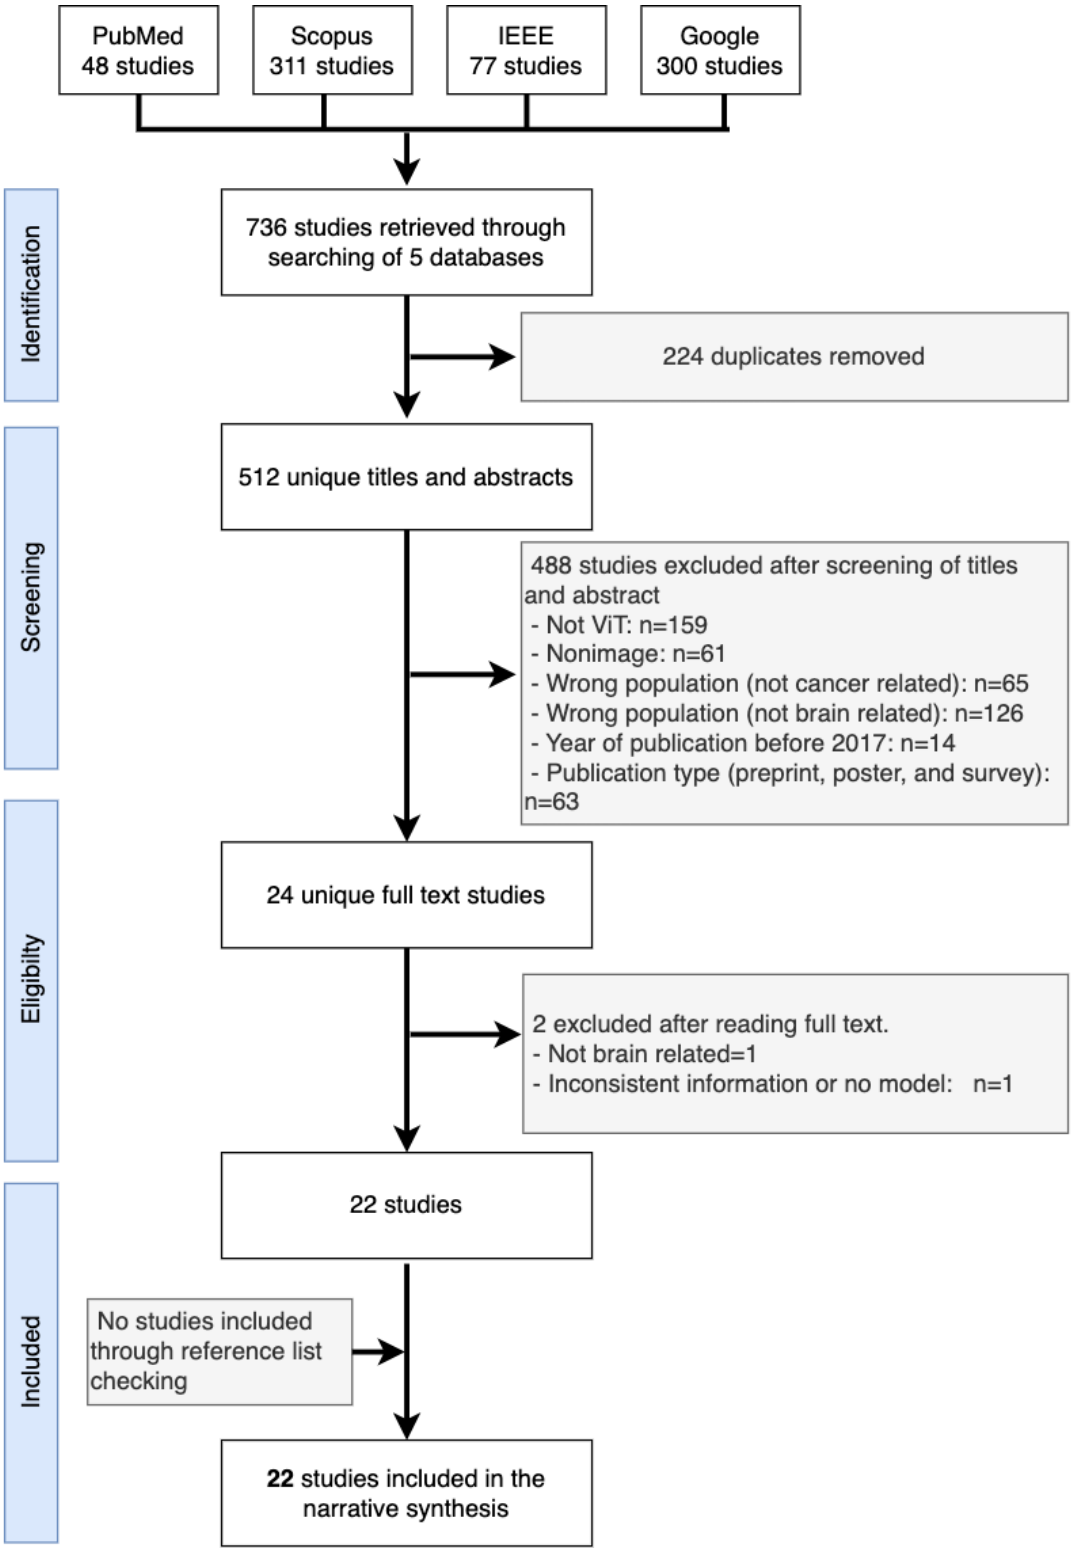
Results

Search Results

A total of 736 studies were retrieved. Of these, we removed 224 duplicates. After the title, abstract, and metadata screening, we removed 488 studies that did not fulfill the inclusion criteria and retained 24 studies. In the full-text screening, we removed

2 studies. Overall, 22 studies were included in this review. We did not find any additional studies by forward and backward reference checking. Figure 1 shows the flowchart for the study selection process. Multimedia Appendix 4 shows a list of all the included studies.

Figure 1. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flowchart for the selection of the included studies. ViT: vision transformer.



Demographics of the Included Studies

Among the 22 included studies, 9 (41%) were published in peer-reviewed journals, whereas 13 (59%) were published as conference or workshop proceedings. Of the 22 studies, 19 (86%) were published in 2022, whereas only 3 (14%) were published in 2021. No studies published before 2021 were found. Among the studies published in 2022, one-third (6/22, 27%) were published in July. The included studies were published by authors from 6 different countries (based on first-author

affiliation). Among the 22 studies, almost half (n=10, 45%) were published by authors from China and 5 (23%) were published by authors from the United States. Authors from the United Kingdom and India published 3 and 2 studies, respectively, whereas both South Korea and Vietnam published 1 study each. Multimedia Appendix 5 shows a summary of the year-wise and month-wise studies. Multimedia Appendix 6 shows a summary of the country-wise demographics of the included studies. Table 2 summarizes the demographics of the included studies. Figure 2 shows a visualization for the mapping of the included studies with year, month, and country of publication.

Main Tasks Addressed in the Studies

Among the included studies, 19 (86%) of the 22 studies addressed the task of segmentation [27-45], and 1 study [46] reported survival prediction. One study [47] reported the detection of lesions. One study [48] performed grading of the tumor. In addition, 1 study [43] performed the diagnosis of multiple sclerosis, and 1 study [45] performed reconstruction of fast MRI. One study [44] also performed isocitrate dehydrogenase (IDH) genotyping in addition to segmentation. Table 3 shows a summary of the key characteristics and tasks addressed in the included studies.

Table 3. Summary of key characteristics of the included studies.

[a]MRI: magnetic resonance imaging.

[b]SWIN: Shifted Window.

[c]UNETR: UNet Transformer.

[d]SP: survival prediction.

Key Architectures of the ViT for Brain Tumor Segmentation

In the included studies, ViTs were combined with different variants of a CNN to improve the overall performance of brain tumor segmentation. Shifted Window (SWIN) transformer [49] has recently become a popular choice for image-based classification tasks. Therefore, the most recent studies [27-29,34,39,45] reported using SWIN transformers in their models. Some of the studies [28,29,36,38,40,41] incorporated the transformers module within the encoder or decoder or both modules of the UNet-like architectures. Some studies [30-33,35,37,44] used the transformer module as a bottleneck between the encoder and decoder modules of UNet-like architectures. One study [41] explored both cascade and parallel combinations of the transformer module with CNNs. One study [48] used the transformer module in parallel combination with a residual network (a CNN). One study [42] implemented the training of transformers using federated learning over distributed data for 22 institutions.

Complexity of the Models Used in the Studies

The included studies presented transformer-based models with different computational complexity. Of these, Fidon et al [35] used the TransUNet model, which has 116.7 million parameters, whereas the UNETR model proposed by Hatamizadeh et al [38] has 92.58 million parameters. The SegTran model proposed by Li et al [33] has 93.1 million parameters. Compared with the UNETR [38], the recent variant, that is, SWIN UNETR [34], has 61.98 million parameters. The Segtransvae [31] has 44.7 million parameters. The BTSWIN-UNet model [28] has 35.6 million parameters that are higher than other SWIN transformer–based models but much smaller than the UNETR. For example, the SWIN transformer–based models Trans-BTS and SWIN-UNet have 30.6 million and 27.1 million parameters, respectively, on the same data, but UNETR has 102.8 million

parameters on the same data. The TransConver proposed by Liang et al [27] has 9 million parameters. The SWINMR [45] has 11.40 million parameters for reconstruction. Other studies [28,30,32,36,37,39-44,46-48] did not provide details regarding the computational complexity of the models. Some studies have reported a different number of parameters for other models used on their data. We believe that these minor differences occur because of the resolution of the input images, which may not be the same in different studies.

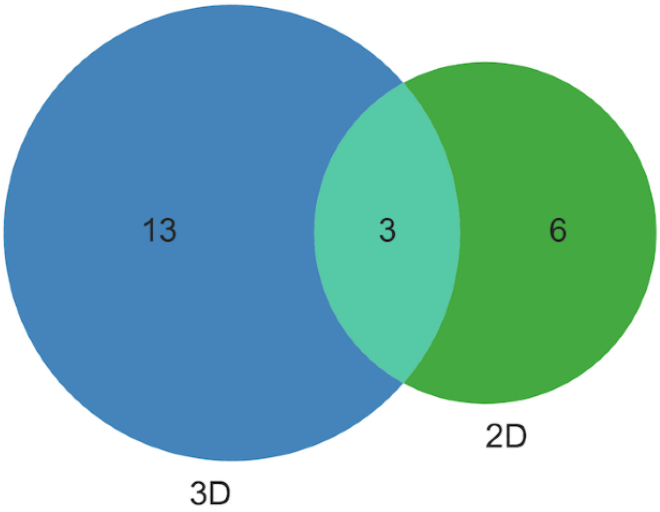
Hardware Use

Wang et al [32] used 8 NVIDIA Titan RTX GPUs for training their model. Similarly, Hatamizadeh et al [34] and Hatamizadeh et al [38] trained their models on a DGX-1 cluster with 8 NVIDIA V100 GPUs. Jia and Shu [37] used 4 NVIDIA RTX 8000 GPUs for training the model, whereas Zhou et al [48] used 4 GeForce RTX 2080 Ti GPUs. Liang et al [27] and Liang et al [29] trained their models on 2 parallel NVIDIA GeForce 2080Ti GPUs. Similarly, Huang et al [45] trained the model on 2 NVIDIA RTX 3090 GPUs with 24 GB GPU memory, and Cheng et al [44] used 2 NVIDIA V100 GPUs. Zhang et al [30] and Li et al [47] trained their models on a single NVIDIA Tesla V100 GPU, Li et al [33] trained the model on a single 24 GB Titan RTX GPU, Luu and Park [36] used a single NVIDIA RTX 3090 GPU for training the model, Liu et al [39] trained the model using NVIDIA GTX 3080, and Dhamija et al [41] used Tesla P-100 GPU.

Types of Data Used in the Studies

All the included studies (except 1 [48]) used MRI data for brain tumor segmentation. Zhou et al [48] used histopathology images. In 16 studies, volumetric MRI data were used, whereas in 9 studies, the models were developed for 2D image data. Three studies [27,33,43] reported experiments on both volumetric data and image data. Figure 3 shows the Venn diagram for the number of studies using 3D versus 2D data.

Figure 3. Venn diagrams showing the number of studies that used 3D versus 2D data.



Data Sets Used in the Studies

Three studies [42,47,48] reported using privately developed data sets or did not provide public access to the data. One study [42] used both publicly available and privately developed data. The Brain Tumor Segmentation (BraTS) challenge data set of brain MRI has been the most popular data used in 17 (77%) of the 22 studies. More specifically, 6 studies used BraTS 2021 data [28,31,34-37], 5 used BraTS 2020 data [28,32,42,44,46], 7 used BraTS 2019 data [27-29,32,33,39,40], 3 used BraTS 2018 data [27,29,43], and 1 used BraTS 2017 data [45]. Some of these studies also used >1 data set, either independently or by combining them. Other data used in the included studies were MRI data from the Medical Decathlon used by Hatamizadeh et al [38], the Cancer Imaging Archive data used by Dhamija at [41], the UK Biobank data used by Pinaya et al [43], data from the University Hospital of Ljubljana used by Pinaya et al [43], the Calgary-Campinas Magnetic Resonance reconstruction data used by Huang et al [45], data from the University Hospital of Patras Greece used by Zhou et al [48], and data from the Cancer Hospital and Shenzhen Hospital used by Li et al [47]. One study [30] did not specify the data. Table 4 summarizes the data sets used in the included studies and provides the public access links for each data set. Figure 4 shows the Venn diagram for the number of studies using public versus private data.

Evaluation Metrics

The Dice score and the Hausdorff distance measurements are popular metrics commonly used to evaluate segmentation performance on the BraTS MRI data sets. Hence, in the included studies, the Dice score and Hausdorff distance were the most common metrics used to assess the results of brain tumor segmentation. In summary, 19 studies [27-45] reported the use of the Dice score, whereas 15 studies [27-32,34-40,42,44] used both the Dice score and Hausdorff distance. Two studies [41,45] reported intersection-over-union. One study [42] reported the focal score and Tversky score for the federated learning framework evaluation in addition to the Dice score and Hausdorff distance for the segmentation evaluation. One study [45] reported peak signal:noise ratio, structural similarity index, and Fréchet Inception Distance in the assessment of the reconstructed MRI in addition to Intersection over Union and Dice scores for segmentation evaluation. One study [46] used

the concordance index and hazard ratio to evaluate the performance of survival analysis. One study [47] reported sensitivity and precision, and 1 study [48] reported precision and recall.

Discussion

Principal Findings

In this study, we reviewed the studies that used ViT to aid in brain cancer imaging applications. We found that most studies (19/22, 86%) were published in 2022, and almost one-third of these studies (6/19, 32%) were published in the second quarter of 2022. As ViT was first proposed in 2020 for natural images, it has only recently been explored in brain MRI and cancer imaging. Almost half of the studies (10/22, 45%) were published by authors from China. Furthermore, the authors from China published twice the number of studies published by authors from the United States. Other countries published approximately one-third of the studies (7/22, 32%).

Motivation of Using Transformers for Segmentation

The transformer module works on the self-attention concept, that is, calculating pairwise interactions between all input units. Thus, transformers are good at learning contextualized features. Although this learning of the contextualization by a transformer can be related to the upsampling path in a UNet encoder-decoder architecture, the transformer overcomes the limitation of the receptive field, and hence, it works better to capture long-range correlations [34]. In a UNet architecture, one may enlarge the receptive fields by adding more downsampling layers or by introducing larger stride sizes in the convolution operations of the downsampling path. However, the former increases the number of parameters and may lead to overfitting, whereas the latter sacrifices the spatial precision of the feature maps [34]. Nevertheless, the initial attempts to introduce transformers for brain tumor segmentation used the transformer block in the encoder or decoder or the bottleneck stage of the UNet-like architectures. These approaches were mainly driven by the success of UNet-based architectures for segmentation, such as nnUNet's success on the BraTS2020 challenge [59]. In addition, until 2020, CNN-based models were the best performers for brain tumor segmentation. Therefore, nnUNet [59] was the winning entry for the BraTS2020 challenge. With improved strategies and architectures, attention-based models performed competitively in recent years. Wang et al [32] presented the TransBTS model, which was the first attempt to incorporate transformers into a 3D CNN for brain tumor segmentation. Although Hatamizadeh et al [34] reported SWIN UNETR for brain tumor segmentation, and it was the first transformer-based model that performed competitively for the BraTS 2021 segmentation task. The TransBTS model was trained and tested on the BraTS2018 and BraTS2019 data sets, whereas the SWIN UNETR has been evaluated on the BraTS 2021 data set. However, for the BraTS 2021 data set, the winning entry was an extension of the nnUNet model [59] presented by Luu and Park [36] who proposed introducing attention in the decoder of the nnUNet to perform the tumor segmentation. As identified by Jia and Shu [37], the UNETR removed convolutional blocks in the encoder, which may result in insufficient extraction of local context information when applied to volumetric MRI data. Overall, these approaches of combining transformers and CNNs are driven by the motivation to use the best of both worlds. These studies suggested that the best-of-both-worlds approach can be effective in improving brain tumor segmentation by combining CNNs with transformers. In theory, there are many possibilities for how we approach combining the advantages offered by the 2 different architectures.

Applications Covered in the Studies

Most of the studies included are those that either designed an attention-based architecture or used existing ViT architectures to achieve the task of tumor segmentation. In the brain segmentation tasks, the key focus is the segmentation of gliomas, which is the most common brain tumor. As most of these studies used 1 of the variants of the BraTS data set where the MRI data are annotated for 4 regions, these studies reported segmentation of the whole tumor, tumor core, enhancing tumor, and background. Some studies also reported using attention-based models for other applications related to brain cancer, such as survival prediction, MRI reconstruction, grading of brain cancer, and IDH genotyping.

Discussion Related to the Architectures

Among the studies that used the ViT module after a 3D CNN features extraction, the TransBTS [32] was the first architecture (released in September 2021) and served as inspiration for many other architectures. The TransBTS architecture was motivated by the idea of incorporating global context into the volumetric spatial features of brain tumors. Furthermore, the work highlighted the need to use an attention module on image patches instead of flattened images, unlike previous efforts. Essentially, the flattening of high-resolution images makes the implementation impractical, as transformers have a quadratic computational complexity with respect to the number of tokens (ie, the dimension of the flattened image). The TranBTS architecture has downsampling and upsampling layers linked through skip connections; however, in the bottom part of the architecture, there are transformer layers that help with the global context capturing. These transformer layers are in addition to a linear projection layer and a patch embedding layer to transfer the image to sequence representation. So, in a way, the ViT serves as the bottleneck layer to capture long-range dependencies. Later, Jia and Shu [37] presented a modification in the TransBTS architecture [32] using 2 ViT blocks after the encoder part instead of 1 transformer block in the TransBTS. Specifically, the outputs of the fourth and fifth downsampling layers pass through a feature embedding of a feature representation layer, transformer layers, and a feature mapping layer and then pass through the corresponding upsampling 3D CNN layers. Compared with the TransBTS architecture, where the transformer was used at the end of the encoder and features representation was obtained after the fourth layer, Jia and Shu [37], increased the depth to 5 layers and used the transformer in both the fourth and fifth layers. Therefore, after the fourth layer, the transformer effectively builds a skip connection with the corresponding layer of the decoder block.

Similarly, Zhang et al [30] used a multihead self-attention–based transcoder module embedded after the encoder of a 3D UNet.

However, they replaced the residual blocks of the 3D UNet with a self-attention layer that operated on a 3D feature map, followed by progressive upsampling via a 3D CNN decoder module. Pham et al [31] also used transformer layers after a 3D CNN module and used a variational encoder to reconstruct the volumetric images. Li et al [33] presented the SegTran architecture, which is again based on using the transformer modules after the features extraction with CNN, thus capturing the global context. Here, the authors suggested combining the CNN features with positional encodings of the pixel coordinates and flattening them into a sequence of local feature vectors.

Fidon et al [35] used the TransUNet architecture [60] as the backbone of their model and used the test time augmentation strategy to improve inference. Finally, Cheng et al [44] presented the MTTUNet architecture, which is a UNet-like encoder-decoder architecture for multitasking. They used the CNN layers to extract spatial features, which were then processed by the bottleneck transformer block. Subsequently, the decoder network performed the segmentation task. In addition, the authors also used the transformer output to perform IDH genotyping, thus making it a multitask architecture.

Hatamizadeh et al [38] presented the UNETR architecture that redefined the task of 3D segmentation as a 1D sequence-to-sequence classification that can be used with a transformer to learn contextual information. Therefore, the transformer block in the UNETR operates on the embedded representation of the 3D MRI input data. In effect, the transformer is incorporated within the encoder part of a UNet architecture. Compared with other architectures such as BTSWIN-UNet [30], TransBTS [32], SegTran [33,35], and BiTr-UNet [37], which use the transformer as a bottleneck layer of the encoder-decoder architectures, the UNETR directly connects the encoded representation from the encoder with the decoder part. Compared with other methods where the encoder part uses 3D CNN blocks, such as TransBTS [32] and BiTr-UNet [37], the UNETR does not use a convolutional block in the encoder. Instead, the UNETR obtains a 2D representation for the 3D volumes and then uses the 2D ViT architecture that works on the 2D patches of the images. Each patch is treated as 1 token for the attention operation. UNETR does not rely on a backbone CNN for generating the input sequences and directly uses the tokenized patches.

Luu and Park [36] introduced an attention mechanism in the decoder of the nnUNet [59] to perform the tumor segmentation. They extended the nnUNet and modified it by using axial attention in the decoder of the 3D UNet. Furthermore, they doubled the number of filters in the encoder while retaining the same number in the decoder. Sagar [40] presented the Vision Transformer for Biomedical Image Segmentation architecture, which used transformer blocks in the encoder and decoder of a UNet architecture. The architecture introduced multiscale convolutions for feature extraction that were used as input to the transformer block.

Dhamija et al [41] explored the sequential and parallel stacks of transformer-based blocks using a UNet block. In principle, they used a transformer-based encoder and a CNN-based decoder connected in parallel with a UNet-based encoder and then in cascade with a UNet-based encoder. Apparently, the parallel combination (USegTransformer-P) outperformed the cascade combination by some margin. Zhou et al [48] designed a parallel dual-branch network of a CNN (the ResNet architecture) and ViT and used it to grade brain cancer from pathology images. The dual-branch network established a duplex communication between the ResNet and ViT blocks that sends global information from the ViT to ResNet and local information from ResNet to the ViT.

Many similar architectures were probably released concurrently by different research groups or released very close in time to each other. For example, Li et al [33] found that segmentation transformer [61] and TransUNet [60] were released concurrently with their own model. Therefore, it is not surprising that there are a few similarities between the approaches adopted by these studies.

Discussion Related to SWIN Transformers

In general, transformers are notoriously popular for the computational complexity of the order O (n^2). For example, as identified by Jia and Shu [37], UNETR stacks transformer layers and keeps the sequence data dimension unchanged during the entire process, which results in expensive computation for high-resolution 3D images. SWIN transformers helped overcome the computational complexity. Hence, it became a popular backbone architecture for many recent studies [27-29,32,39,45] to overcome the computational complexity of transformer-based models. For example, Liang et al [27] reported the use of a 2D SWIN transformer [49] and a 3D SWIN transformer [62] to replace the traditional architecture of ViT to overcome the computational complexity. Jiang et al [28] used a SWIN transformer as the encoder and decoder rather than as the attention layer. Furthermore, they extended the 2D SWIN transformer to a 3D variant that provided a base module. Similarly, Liang et al [29] used a 3D SWIN transformer block in the encoder and decoder of a 3D UNet-like architecture. The architecture was inspired by the SWIN transformer and the SWIN-UNet model; however, they replaced the patchify stem with a convolutional stem to stabilize the model training. Furthermore, they used overlapping patch embedding and downsampling, which helped to enhance the locality of the segmentation network.

Hatamizadeh et al [34] extended the UNETR architecture to the SWIN-UNet transformer (SWIN UNETR), which incorporated a SWIN transformer in the encoder part of the 3D UNet. The decoder part still used a CNN architecture to upsample the features to the segmentation masks. As reported previously, the SWIN UNETR was the first transformer architecture that performed competitively on the BraTS 2021 segmentation challenge. Liu et al [39] presented a transition net architecture that combined a 2D SWIN transformer with a 3D transition decoder. The transition block transforms the 3D volumetric data into a 2D representation, which is then provided as an input to the SWIN transformer. Subsequently, in the decoder part, the transition block transforms the multiscale feature maps into a 3D representation to obtain the segmentation results. Huang et al [45] used a cascade of residual SWIN transformers to build

a feature extraction module, followed by a 2D CNN network. This architecture was designed for MRI reconstruction.

Discussion Related to Model Complexity

In general, transformer architectures have a high computational complexity. The number of parameters for the architectures for the models, such as UNETR and TransUNet, are as large as 92 million and 116 million, respectively. The SWIN transformer-based architecture has a relatively smaller number of parameters (of the order of 30-45 million). For models with a higher number of parameters, the researchers had to rely on high-end GPU resources. Therefore, the computational setup reported in some of the included studies was built with as many as 8 GPUs. However, few studies also reported training the models on a single GPU with memory sizes ranging from 12 GB to 24 GB.

Discussion Related to 3D Data

Our categorization of a model designed for 3D or 2D data was either based on direct extraction of the information from the studies or the description of the model architecture in the included studies. Therefore, if a study did not specify whether it used the volumetric data directly or transformed the data into 2D images but provided a 2D model architecture, we placed the study in the 2D data category. Many modern deep learning methods for medical imaging, including transformers, rely on pretrained models as their backbones. These backbones can generalize well, making them good candidates for use in other related tasks, as they provide generalization, better convergence, and improved segmentation performance [39]. However, Liu et al [39] argued that such backbone architectures are, in general, difficult to be migrated to 3D brain tumor segmentation. First, there is a general lack of 3D data, and most publicly available data sets provide 2D data. Second, medical images such as MRI vary in their distribution and style compared with natural images. These variations hinder the direct transformation of the 2D pretrained models for 3D volumetric data. Hence, they recommended transforming the 3D data into a 2D representation to enable its use with 2D transformers. However, numerous other studies have developed and used 3D models directly on volumetric data.

The most commonly used data in the included studies were the brain MRI of the BraTS data set. The BraTS data set has been phenomenal in facilitating the research on brain glioma segmentation. The BraTS challenge has served as a dedicated venue for the last 11 years and has established itself as a foundation data set in helping the community push the state-of-the-art in brain tumor segmentation. The BraTS data set has 4 MRI modalities, namely, T1-weighted, postcontrast T1-weighted, T2-weighted, and T2 fluid-attenuated inversion recovery. Furthermore, the data set provides baseline segmentation annotation from physicians.

Discussion Related to Evaluation Metrics

The Dice score and Hausdorff distance measurements have been more commonly reported, as these metrics are widely used to evaluate segmentation performance on the BraTS MRI data sets. In the included studies, the Dice score and Hausdorff distance were the most common metrics used to assess the results of brain tumor segmentation.

Strengths and Limitations

Strengths

Although there has been a surge in studies on the use of ViTs in medical imaging, only a few reviews have been reported on ViTs in medical imaging [20,23,25]; however, their scopes are too broad. In comparison, to the best of our knowledge, this is the first review of the applications and potential of ViTs to enhance the performance of brain tumor segmentation. This review covers all the studies that used ViTs for brain cancer imaging; thus, this is the most comprehensive review. This review is helpful for the community interested in knowing the different architectures of ViTs that can help in brain tumor segmentation. Unlike other reviews [20,23,25] that cover many different medical imaging applications, this review focuses on studies that have only developed ViTs for brain tumor segmentation. In this review, we followed the PRISMA-ScR guidelines [26]. We retrieved articles from the popular web-based libraries of medical science and computing to include as many relevant studies as possible. We avoided bias in study selection through an independent selection of studies by 2 reviewers and through validation of the selected studies and data extraction by the third reviewer. This review provides a comprehensive discussion on the different pipelines to combine ViTs with CNNs. Hence, this review will be very useful for the community to learn about the different pipelines and their working for brain tumor segmentation. In addition, we identify the computational complexity of the various pipelines to help the readers understand the associated computational cost of ViTs for brain tumor segmentation. We provide a comprehensive list of available data sets for brain MRI and hope that it will provide a good reference point for researchers to identify suitable data sets for developing models for BraTS. We maintain an active web-based repository that will be populated with relevant studies in the future.

Limitations

In this review, we included studies from 4 major databases. Despite our best efforts to retrieve as many studies as possible, the possibility that some relevant studies may be missed cannot be ruled out. Moreover, the number of publications on the applications of ViTs in medical imaging is increasing at an unprecedented rate; hence, recent studies may be published while we draft this work. For practical reasons, we only included studies in English. Therefore, non-English text might be excluded even if it were relevant. Not all studies reported on the computational complexity and the required training time. Hence, we provide the computational complexity only for the studies in which this information was available; thus, the comparison might not be exhaustive. This review did not analyze the claims on the performance of the different architectures, as such an assessment is beyond the scope of this work. We did not attempt to reproduce the results reported in the studies, as such an execution of the computer code is beyond the scope of the review. We included studies that reported working with any imaging modality for brain cancer and did not evaluate the use of physiological signals, although understanding physiological

signals can also play a significant role in brain cancer studies. We did not evaluate the bias in the training data used in the included studies; therefore, the performance reported for ViTs in brain cancer imaging could be occasionally overestimated.

Open Questions and Challenges

Research efforts on developing transformer-based methods for brain cancer applications are progressing rapidly. Some of the challenges are highlighted in the following text.

In the included studies, we did not find any study that addresses the challenge of early detection of brain cancer. Similarly, the number of studies related to prognosis and tumor growth in the brain is also minimal. Early detection and prognosis are applications of great interest where the potential of ViTs can be explored. One approach is to combine ViT with the sequential representation of time-based data for tumor growth in the brain.

ViTs lack scale invariance, rotation invariance, and inductive bias capabilities. Consequently, they do not perform well at capturing local information and cannot be trained well with a small amount of data [48]. One way to overcome this limitation is to provide a larger training data set. Therefore, the development of large public data sets is encouraged. Another widely used method in the included studies is combining ViTs with CNNs.

In general, models pretrained on a large-scale data set (ImageNet) are known to perform well on many other data sets. However, using the pretrained transformer-based models and fine-tuning them for brain cancer imaging did not improve the performance, as reported by Hatamizadeh et al [38]. Similarly, Pinaya et al [43] reported that the model trained on 3D data from the UK Biobank could perform well on the test set. However, the performance degraded when the model was evaluated on subsets of other data sets. Therefore, the generalization of the models is still a challenge.

Combining CNN with ViTs can be achieved through serial (cascade), parallel connections, or a combination of both. In serial combination of CNNs and ViTs, the arrangement may cause training ambiguities in terms of fusing local and global features. If the learning eventually loses local and global dependencies in the image data [48,63,64], optimal performance may not be achieved. In contrast, for parallel combinations, there will be undesired redundant information captured by the 2 models [33].

The BraTS challenge completed its 10 years in 2021 and has been a dedicated venue for facilitating the state-of-the-art developments of methods for glioma segmentation [37]. As the data set is publicly available, almost all the included studies have used it. However, there seems to be a very limited effort in developing other data sets that are publicly available. It would be interesting to have additional data sets for brain cancer imaging that can facilitate advancing the research on AI models for brain cancer diagnosis and prognosis.

The included studies reported advancements in transformer-based architectures for brain cancer imaging. However, these studies commonly lack the explanability and interpretability of the model behavior. Future research should focus on new methods to address this issue.

ViT-based architectures, as of now, may not always be the best for brain tumor segmentation. For example, the TransBTS model (a ViT-based model) had suboptimal performance owing to its inherently inefficient architecture, where the ViT is only used in the bottleneck as a stand-alone attention module and does not have a connection to the decoder at different scales (as identified by Hatamizadeh et al [34]). In contrast, architectures based on UNet (eg, nnUNet and SegResNet) have achieved competitive benchmarks on the BraTS challenge.

As identified by Huang et al [45], one can argue that the heavy computations in transformers are the main bottleneck in development, and the performance improvements of transformers for brain cancer imaging come at the cost of computational complexity. Therefore, lightweight implementations of transformer architectures for brain cancer imaging are a topic of great interest for future research. Furthermore, the transformer architectures that transform image data into sequential representation (such as in UNETR) may not be the best choice. First, the removal of convolutional blocks in the encoder does not guarantee the capture of context information in volumetric MRI data. Second, keeping a fixed sequence during the entire processing of data leads to expensive computation when the input data are a batch of high-resolution 3D images [37]. Models such as UNETR and TransBTS for brain tumor segmentation lack cross-plane contextual information; hence, the 3D spatial context is not fully captured by these models [29].

Conclusions

In this work, we performed a scoping review of 22 studies that reported ViT-based AI models for brain cancer imaging. We identified the key applications of ViTs in developing AI models for tumor segmentation and grading. ViTs have enabled researchers to push the state-of-the-art in brain tumor segmentation, although such an improvement has resulted in a trade-off between model complexity and performance. We also summarized the different vision architectures and the pipelines with ViTs as the backbone architecture. We also identified the commonly used data sets brain tumor segmentation tasks. Finally, we provided insights into the key challenges in advancing brain cancer diagnosis or prognosis using ViT-based architectures. Although ViT-based architectures have great potential in advancing AI methods for brain cancer, clinical transformations can be challenging, as these models are computationally complex and have limited or no explainability. We believe that the findings of this review will be beneficial to the researchers studying AI and cancer.

Authors' Contributions

HA contributed to the conception, design, literature search, data selection, data synthesis, data extraction, and drafting. RQ contributed to the data synthesis, data extraction, and drafting. ZS contributed to the drafting and critical revision of the manuscript. All authors gave their final approval and accepted accountability for all aspects of this work.

Abstract

Background: Machine learning (ML) models provide more choices to patients with diabetes mellitus (DM) to more properly manage blood glucose (BG) levels. However, because of numerous types of ML algorithms, choosing an appropriate model is vitally important.

Objective: In a systematic review and network meta-analysis, this study aimed to comprehensively assess the performance of ML models in predicting BG levels. In addition, we assessed ML models used to detect and predict adverse BG (hypoglycemia) events by calculating pooled estimates of sensitivity and specificity.

Methods: PubMed, Embase, Web of Science, and Institute of Electrical and Electronics Engineers Explore databases were systematically searched for studies on predicting BG levels and predicting or detecting adverse BG events using ML models, from inception to November 2022. Studies that assessed the performance of different ML models in predicting or detecting BG levels or adverse BG events of patients with DM were included. Studies with no derivation or performance metrics of ML models were excluded. The Quality Assessment of Diagnostic Accuracy Studies tool was applied to assess the quality of included studies. Primary outcomes were the relative ranking of ML models for predicting BG levels in different prediction horizons (PHs) and pooled estimates of the sensitivity and specificity of ML models in detecting or predicting adverse BG events.

Results: In total, 46 eligible studies were included for meta-analysis. Regarding ML models for predicting BG levels, the means of the absolute root mean square error (RMSE) in a PH of 15, 30, 45, and 60 minutes were 18.88 (SD 19.71), 21.40 (SD 12.56), 21.27 (SD 5.17), and 30.01 (SD 7.23) mg/dL, respectively. The neural network model (NNM) showed the highest relative performance in different PHs. Furthermore, the pooled estimates of the positive likelihood ratio and the negative likelihood ratio of ML models were 8.3 (95% CI 5.7-12.0) and 0.31 (95% CI 0.22-0.44), respectively, for predicting hypoglycemia and 2.4 (95% CI 1.6-3.7) and 0.37 (95% CI 0.29-0.46), respectively, for detecting hypoglycemia.

Conclusions: Statistically significant high heterogeneity was detected in all subgroups, with different sources of heterogeneity. For predicting precise BG levels, the RMSE increases with a rise in the PH, and the NNM shows the highest relative performance among all the ML models. Meanwhile, current ML models have sufficient ability to predict adverse BG events, while their ability to detect adverse BG events needs to be enhanced.

KEYWORDS

machine learning; diabetes; hypoglycemia; blood glucose; blood glucose management

Introduction

Diabetes mellitus (DM) has become one of the most serious health problems worldwide [1], with more than 463 million (9.3%) patients in 2019; this number is predicted to reach 700 million (10.9%) in 2045 [2], which has resulted in growing concerns about the negative impacts on patients' lives and the increasing burden on the health care system [3]. Furthermore, previous studies have shown that without appropriate medical care, DM can lead to multiple long-term complications in blood vessels, eyes, kidneys, feet (ulcers), and nerves [4-7]. Adverse blood glucose (BG) events are one of the most common short-term complications, including hypoglycemia with BG<70 mg/dL and hyperglycemia with BG>180 mg/dL. Hyperglycemia in patients with DM may lead to lower limb occlusions and extremity nerve damage, further leading to decay, necrosis, and local or whole-foot gangrene, even requiring amputation [8,9]. Hypoglycemia can cause serious symptoms, including anxiety, palpitation, and confusion in a mild scenario and seizures, coma, and even death in a severe scenario [10,11]. Thus, there is an imminent need for preventing adverse BG events.

Machine learning (ML) models use statistical techniques to provide computers with the ability to complete assignments by training themselves without being explicitly programmed [12]. However, ML models for managing BG requires huge amounts of BG data, which cannot be satisfied by the multiple data points generated by the traditional finger-stick glucose meter [13]. With the introduction of the continuous glucose monitoring (CGM) device, which typically produces a BG reading every 5 minutes all day long, the size of the data set of BG readings is sufficient to be used in ML models [14].

Recently, there has been an immense surge in using ML technologies for predicting DM complications. Regarding BG management, previous studies have developed different types of ML models, including random forest (RF) models, support vector machines (SVMs), neural network models (NNMs), and autoregression models (ARMs), using CGM data, electronic health records (EHRs), electrocardiograph (ECG), electroencephalograph (EEG), and other information (ie, biochemical indicators, insulin intake, exercise, and meals) [10,15-20]. However, the performance of different models in these studies was not quite consistent. For instance, in terms of BG level prediction, Prendin et al [21] showed that the SVM achieved a lower root mean square error (RMSE) than the ARM, while Zhu et al [22] showed a different result.

Therefore, this meta-analysis aimed to comprehensively assess the performance of ML models in BG management in patients with DM.

Methods

Search Strategy and Study Selection

The study protocol has been registered in the international prospective register of systematic reviews (PROSPERO; registration ID: CRD42022375250). Studies on BG levels or adverse BG event prediction or detection using ML models were eligible, with no restrictions on language, investigation design, or publication status. PubMed, Embase, Web of Science, and Institute of Electrical and Electronics Engineers (IEEE) Explore databases were systematically searched from inception to November 2022. Keywords used for study repository searches were ("machine learning" OR "artificial intelligence" OR "logistic model" OR "support vector machine" OR "decision tree" OR "cluster analysis" OR "deep learning" OR "random forest") AND ("hypoglycemia" OR "hyperglycemia" OR "adverse glycemic events") AND ("prediction" OR "detection"). Details regarding the search strategies are summarized in Multimedia Appendix 1. Manual searches were added to review reference lists in relevant studies.

Selection Criteria

Inclusion criteria were as follows: (1) participants in the studies were diagnosed with DM; (2) study endpoints were hypoglycemia, hyperglycemia, or BG levels; (3) the studies established at least 2 or more types of ML models for prediction of BG levels and 1 or more types of ML models for prediction or detection of adverse BG events; (4) the studies reported the performance of ML models with statistical or clinical metrics; (5) the studies contained the development and validation of ML models; and (6) study outcomes were means (SDs) of performance metrics of test data for prediction of BG levels and sensitivity and specificity of test data for prediction or detection of adverse BG events.

Exclusion criteria were as follows: (1) studies did not report on the derivation of ML models, (2) studies were based only on physiological or control-oriented ML models, (3) studies could not reproduce true positives, true positives, false negatives, and false positives for prediction or detection of adverse BG events, (4) studies were reviews, systematic reviews, animal studies, or irretrievable and repetitive papers, and (5) studies had unavailable full text or outcome metrics.

Authors KL and LYL screened and selected studies independently based on the criteria mentioned before. Authors KL and YM extracted and recorded the data from the selected studies. Conflicts were resolved by reaching a consensus. The study strictly followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) statement (Multimedia Appendix 2) [23-25].

Data Extraction and Management

Two reviewers independently carried out data extraction and quality assessment. If a single study included more than 1 extractable test results for the same ML model, the best result was extracted. If a single study included 2 or more models, the performance metrics of each model were extracted. For studies predicting BG levels, RMSEs based on different prediction horizons (PHs) were extracted. For studies predicting or detecting adverse BG events, the sensitivity, specificity, and

precision of reproducing the 2×2 contingency table were extracted.

Specifically, the following information was extracted:

- General characteristics: first author, publication year, country, data source, and study purpose (ie, predicting or detecting hypoglycemia)
- Experimental information: participants (type of DM, type 1 or 2), sample size (patients, data points, and hypoglycemia), demographic information, models, study place and time, model parameters (ie, input and PHs), model performance metrics, threshold of BG levels for hypoglycemia, and reference (ie, finger-stick)

Methodological Quality Assessment of Included Reviews

The Quality Assessment of Diagnostic Accuracy Studies (QUADAS-2) tool was applied to assess the quality of included studies based on patient selection (5 items), index test (3 items), reference standard (4 items), and flow and timing (4 items). All 4 domains were used for assessing the risk of bias, and the first 3 domains were used to assess the consensus of applicability. Each domain has 1 query in relation to the risk of bias or applicability consisting of 7 questions [26].

Data Synthesis and Statistical Analysis

The performance metrics of ML models used to predict BG levels, predict adverse BG events, and detect adverse BG events were assessed independently. The performance metrics were the RMSE of ML models in predicting BG levels and the sensitivity and specificity of ML models in predicting or detecting adverse BG events. A network meta-analysis was conducted for BG level–based studies to assess the global and local inconsistency between studies and plotted the surface under the cumulative ranking (SUCRA) curve of every model to calculate relative ranks. For event-based studies, pooled sensitivity, specificity, the positive likelihood ratio (PLR), and the negative likelihood ratio (NLR) with 95% CIs were calculated. Study heterogeneity was assessed by calculating I^2 values based on multivariate random-effects meta-regression that considered within- and between-study correlation and classifying them into quartiles (0% to <25% for low, 25% to <50% for low-to-moderate, 50% to <75% for moderate-to-high, and >75% for high heterogeneity) [27,28]. Furthermore, meta-regression was used to evaluate the source of heterogeneity for both BG level–based and adverse event–based studies. The summary receiver operating characteristic (SROC) curve of every model was also used to evaluate the overall sensitivity and specificity. Publication bias was assessed using the Deek funnel plot asymmetry test.

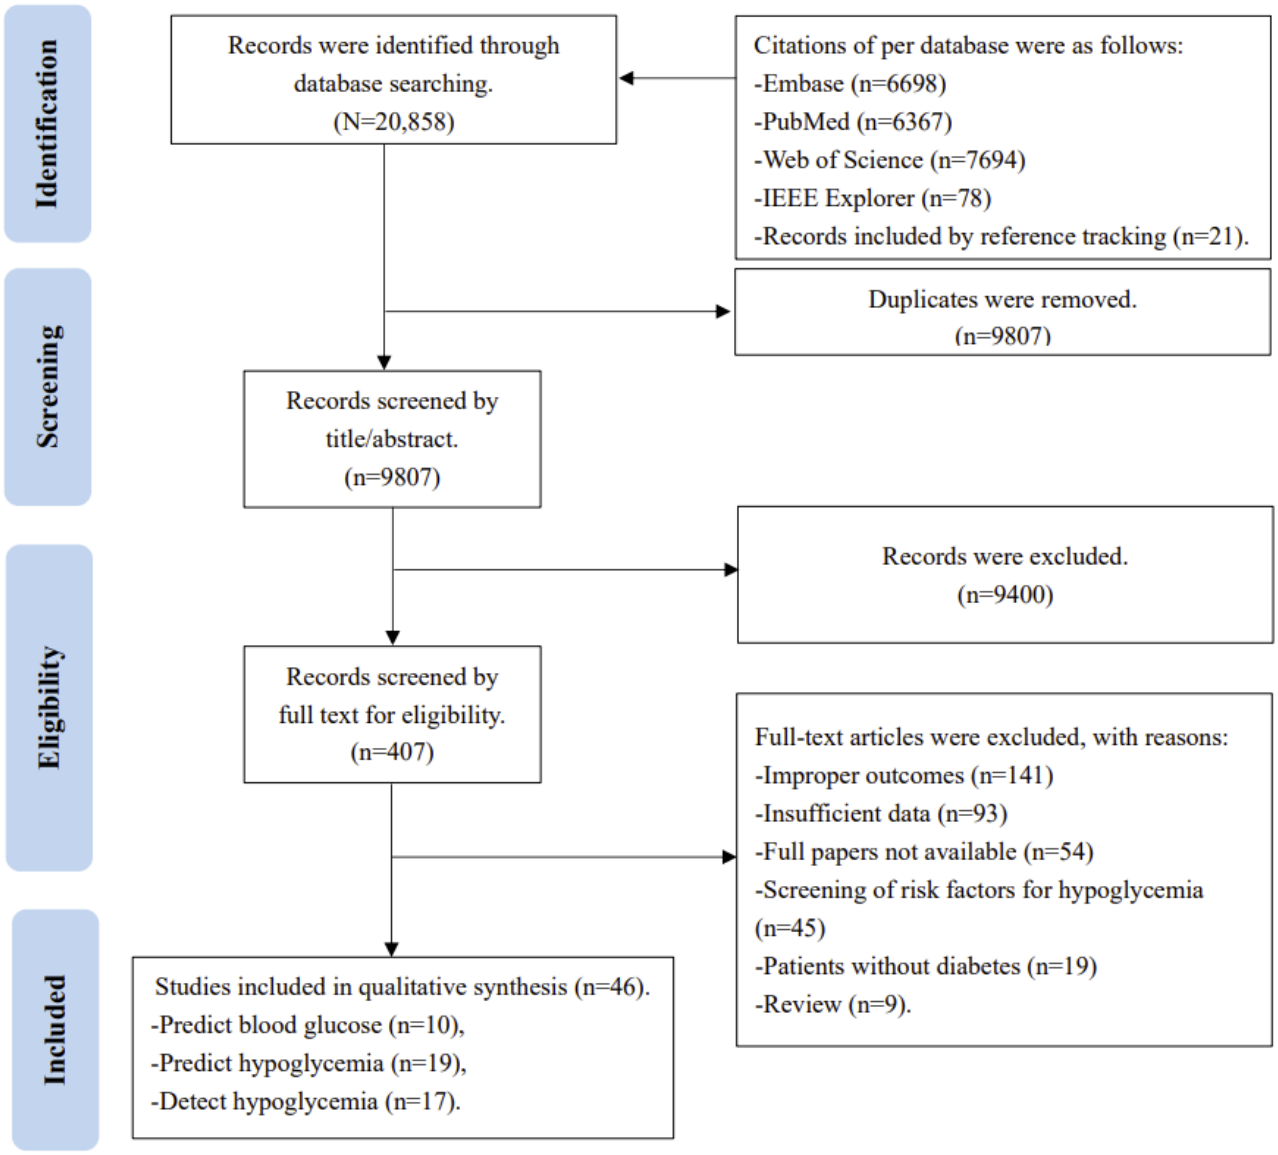
Furthermore, BG level–based studies were divided into 4 subgroups based on different PHs (15, 30, 45, 60 minutes), and adverse event–based studies were analyzed using different types of models (ie, NNM, RF, and SVM). A 2-sided *P* value of <.05 was considered statistically significant. All statistical analyses were performed using Stata 17 (Stata Corp) and Review Manager (RevMan; Cochrane) version 5.3.

Results

Search Results

A total of 20,837 studies were identified through systematically searching the predefined electronic databases; these also included 21 studies found using reference tracking [10,29-48]. Of the 20,837 studies, 9807 (47.06%) were retained after removing duplicates. After screening titles and abstracts, 9400 (95.85%) studies were excluded owing to reporting irrelevant topics or no predefined outcomes. The remaining 407 (4.15%) studies were retrieved for full-text evaluation. Of these, 361 (88.7%) studies were excluded for various reasons, and therefore 46 (11.3%) studies were included in the final meta-analysis (Figure 1).

Figure 1. Flow diagram of identifying and including studies. IEEE: Institute of Electrical and Electronics Engineers.



Description of Included Studies

As studies on hyperglycemia were insufficient for analysis, we selected studies on hypoglycemia to assess the ability of ML models to predict adverse BG events. In total, the 46 studies included 28,775 participants: n=428（1.49%）for predicting BG levels, n=28,138 (97.79%) for predicting adverse BG events, and n=209 (0.72%) for detecting adverse BG events. Of the 46 studies, 10 (21.7%) [20-22,49-55] predicted BG levels (Table 1), 19 (41.3%) [15,29-39,47,48,56-60] predicted adverse BG events (Table 2), and the remaining 17 (37%) [10,16,40-46,61-68] detected adverse BG events (Table 3).

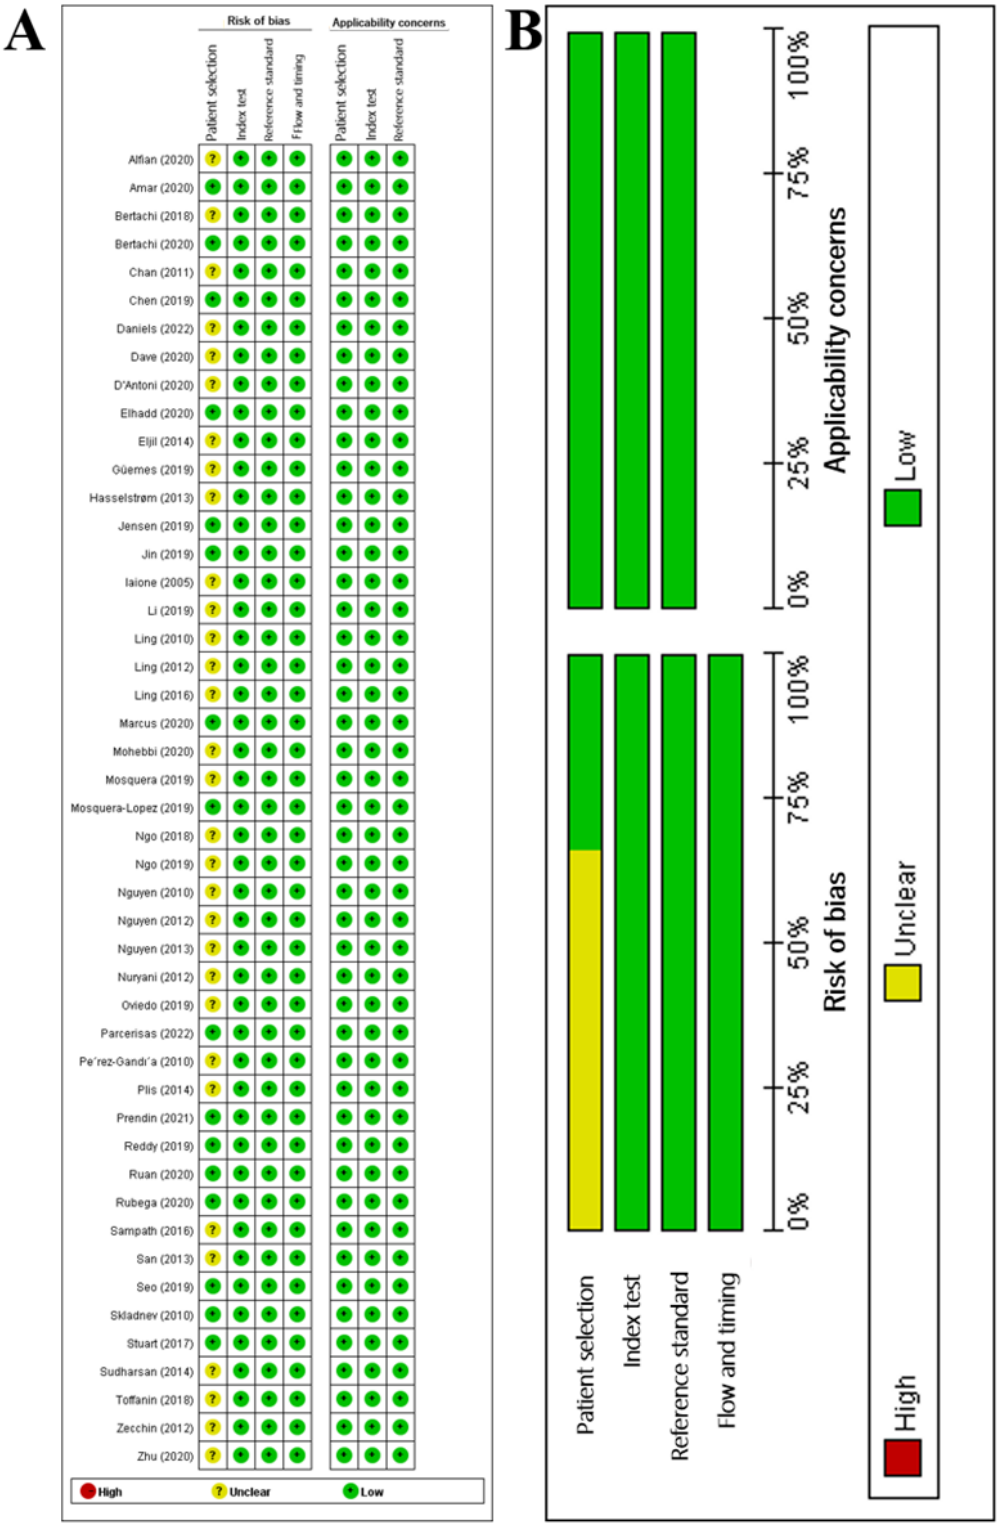
As shown in Tables 1-3, 40 (87%) studies [10,16,20-22,29,31,33-42,44-59,62-68] included participants with type 1 diabetes mellitus (T1DM), 2 (4.3%) studies [32,60] included participants with type 2 diabetes mellitus (T2DM), and the remaining 4 (8.7%) studies [15,30,43,61] did not specify the type of DM. Regarding the data source of ML models, CGM devices were involved in 22 (47.8%) studies [15,20,21,29,31,33,35-40,44,45,47,48,50,52,54-57], EEG signals were used in 8 (17.4%) studies [16,41-43,46,65-67], ECG signals were involved in 5 (10.9%) studies [61-64,68], EHRs were used in 3 (6.5%) studies [10,30,34], data generated by the UVA/Padova T1D simulator were used in 3 (6.5%) studies [22,51,52], the Ohio T1DM data set was used in 2 (4.3%) studies [22,49], and 4 (8.7%) studies [32,58-60] did not report the source of data. Regarding the setting of data collection, 24 (52.2%) studies [15,20-22,29,31-33,35-39,47-49,51,52,54,56-60] were conducted in an out-of-hospital setting, 13 (28.3%) studies [10,16,34,43,50,53,61-67] were conducted in an in-hospital setting, 6 (13%) studies [40-42,44,46,68] were conducted in an experimental setting, and the remaining 1 (2.2%) study [55] did not specify the environment. Regarding when adverse BG events occurred in the 36 (78.3%) adverse event–based studies, 15 (41.7%) [29,31,33,35,36,40,41,45,47,59,63,64,66-68] reported nocturnal hypoglycemia, 16 (44.4%) [10,16,30,32,34,38,39,42-44,48,56,57,60-62] were not specific about the time of day, 2 (5.6%) [15,37] reported postprandial hypoglycemia, 1 (2.8%) [46] reported morning hypoglycemia, and the remaining 2 (5.6%) [58,65] did not report the time setting. To carry out the network meta-analysis of BG level–based studies, we chose the RMSE as the outcome to be compared.

Quality Assessment of Included Studies

The quality assessment results using the QUADAS-2 tool showed that more than half of all included studies did not report the patient selection criteria in detail, which led to low-quality patient selection (Figure 2). Furthermore, the diagnosis of hypoglycemia using blood or the CGM device was considered high quality in the reference test in our study.

Figure 2. Quality assessment of included studies. Risk of bias and applicability concerns graph (A) and risk of bias and applicability concerns summary (B).



Statistical Analysis

Machine Learning Models for Predicting Blood Glucose Levels

Network meta-analysis was conducted to evaluate the performance of different ML models. For PH=30 minutes, 10 (21.7%) studies [20-22,49-55] with 32 different ML models were included, and the network map is shown in Figure 3A. The mean RMSE was 21.40 (SD 12.56) mg/dL. Statistically significant inconsistency was detected using the inconsistency test(^{2}=87.11, *P*<.001), as shown in the forest plot in Multimedia Appendix 1. Meta-regression indicated that I^2 for the RMSE was 60.75%, and the source of heterogeneity analysis showed that place and validation type were statistically significant (*P*<.001). The maximum SUCRA value was 99.1 for the dilated recurrent neural network (DRNN) model with a mean RMSE

of 7.80 (SD 0.60) mg/dL [22], whereas the minimum SUCRA value was 0.4 for 1 symbolic model with a mean RMSE of 71.4 (SD 21.9) mg/dL [49]. The relative ranks of the ML models are shown in Table 4, and the SUCRA curves are shown in Figure 4A. Publication bias was tested using the Egger test (P=.503), indicating no significant publication bias.

For PH=60 minutes, 4 (8.7%) studies [50,51,55] with 17 different ML models were included, and the network map is shown in Figure 3B. The mean RMSE was 30.01 (SD 7.23) mg/dL. Statistically significant inconsistency was detected using the inconsistency test (^{2}=8.82, P=.012), as shown in the forest plot in Multimedia Appendix 3. Meta-regression indicated that none of the sample size, reference, place, validation type, and model type was a source of heterogeneity. The maximum SUCRA value was 97.8 for the GluNet model with a mean RMSE of 19.90 (SD 3.17) mg/dL [51], while the minimum SUCRA value was 4.5 for the decision tree (DT) model with a mean RMSE of 32.86 (SD 8.81) mg/dL [55]. The relative ranks of the ML models are shown in Table 5, and the SUCRA curves are shown in Figure 4B. No significant publication bias was detected using the Egger test (P=.626).

For PH=15 minutes, 3 (6.5%) studies [20,49,55] with 14 different ML models were included, and the network map is shown in Figure 3C. The mean RMSE was 18.88 (SD 19.71) mg/dL. Statistically significant inconsistency was detected using the inconsistency test (^{2}=28.29, P<.001), as shown in the forest plot in Multimedia Appendix 4. Meta-regression showed that I^2 was 41.28%, and the model type and sample size both were the source of heterogeneity, with P=.002 and .037, respectively. The maximum SUCRA value was 99.1 for the ARTiDe jump neural network (ARJNN) model with a mean RMSE of 9.50 (SD 1.90) mg/dL [49], while the minimum SUCRA value was 0.3 for the SVM with a mean RMSE of 13.13 (SD 17.30) mg/dL [55]. The relative ranks of the ML models are shown in Table 6, and SUCRA curves are shown in Figure 4C. Statistically significant publication bias was detected using the Egger test (P=.003).

For PH=45 minutes, only 2 (4.3%) studies [54,55] with 11 different ML models were included, and the network map is shown in Figure 3D. The mean RMSE was 21.27 (SD 5.17) mg/dL. Statistically significant inconsistency was detected using the inconsistency test (^{2}=6.92, P=.009), as shown in the forest plot in Multimedia Appendix 5. Meta-regression indicated significant heterogeneity from the model type (P=.006). The maximum SUCRA value was 99.4 for the NNM with a mean RMSE of 10.65 (SD 3.87) mg/dL [55], while the minimum SUCRA value was 26.3 for the DT model with a mean RMSE of 23.35 (6.36) mg/dL [55]. The relative ranks of the ML models are shown in Table 7, and SUCRA curves are shown in Figure 4D. Statistically significant publication bias was detected using the Egger test (P<.001).

Machine Learning Models for Predicting Hypoglycemia

ML models for predicting hypoglycemia (adverse BG events) involved 19 (41.3%) studies [15,29-39,47,48,56-60], with pooled estimates of 0.71 (95% CI 0.61-0.80) for sensitivity, 0.91 (95% CI 0.87-0.94) for specificity, 8.3 (95% CI 5.7-12.0) for the PLR, and 0.31 (95% CI 0.22-0.44) for the NLR. The heterogeneity between different ML models in these studies is shown in the forest plot in Figure 5, which was high for both sensitivity (I^2=100%, 95% CI 100%-100%) and specificity (I^2=100%, 95% CI 100%-100%). The SROC curve is shown in Figure 6A, with an area under the curve (AUC) of 0.91 (95% CI 0.88-0.93). According to the meta-regression results, the type of DM and time were statistically significant sources of heterogeneity for sensitivity while the type of DM, reference, data source, setting, and threshold were statistically significant sources of heterogeneity for specificity (Multimedia Appendix 6). No statistically significant publication bias was detected (*P*=.09). In addition to integral analysis for the hypoglycemia prediction model, we also carried out analysis of 4 subgroups based on the characteristics of the included studies, including the NNM, the RF, the SVM, and ensemble learning (RF, Extreme Gradient Boosting [XGBoost], bagging).

For the NNM, 3 (6.5%) studies [15,34,47] were included, with pooled estimates of 0.50 (95% CI 0.16-0.84) for sensitivity, 0.91 (95% CI 0.84-0.96) for specificity, 5.9 (95% CI 3.2-10.8) for the PLR, and 0.54 (95% CI 0.24-1.21) for the NLR. As shown in the forest plot in Figure 7A, I^2 values were 99.59% (95% CI 99.46%-99.71%) and 97.82% (95% CI 96.68%-98.86%) for sensitivity and specificity, respectively. The SROC curve is shown in Figure 6B, with an AUC of 0.90 (95% CI 0.87-0.92). Meta-regression results revealed that statistically significant heterogeneity was detected in all the factors between these studies (type of DM, reference, time, data source, setting, threshold) for sensitivity and 4 factors (reference, data source, setting, threshold) for specificity (Multimedia Appendix 7). No statistically significant publication bias was detected (*P*=.86).

For the RF, 5 (10.9%) studies [15,34,56,58,60] were included, with pooled estimates of 0.87 (95% CI 0.79-0.93) for sensitivity, 0.94 (95% CI 0.91-0.96) for specificity, 13.9 (95% CI 10.1-18.9) for the PLR, and 0.14 (95% CI 0.08-0.22) for the NLR. The forest plot in Figure 7B shows that statistically significant heterogeneity was detected in both sensitivity (I^2=98.32%, 95% CI 97.61%-99.02%) and specificity (I^2=99.41%, 95% CI 99.24%-99.58%). The SROC curve is shown in Figure 6C, with an AUC of 0.97 (95% CI 0.95-0.98). Meta-regression failed to run due to data instability or asymmetry. No statistically significant publication bias was detected (*P*=.21).

Figure 5. Sensitivity and specificity forest plots of ML models for predicting adverse BG events. The horizontal lines indicate 95% CIs. The square markers represent the effect value of a single study, and the diamond marker represents the combined results of all studies. The vertical line shows the line of no effects. BG: blood glucose; ML: machine learning.

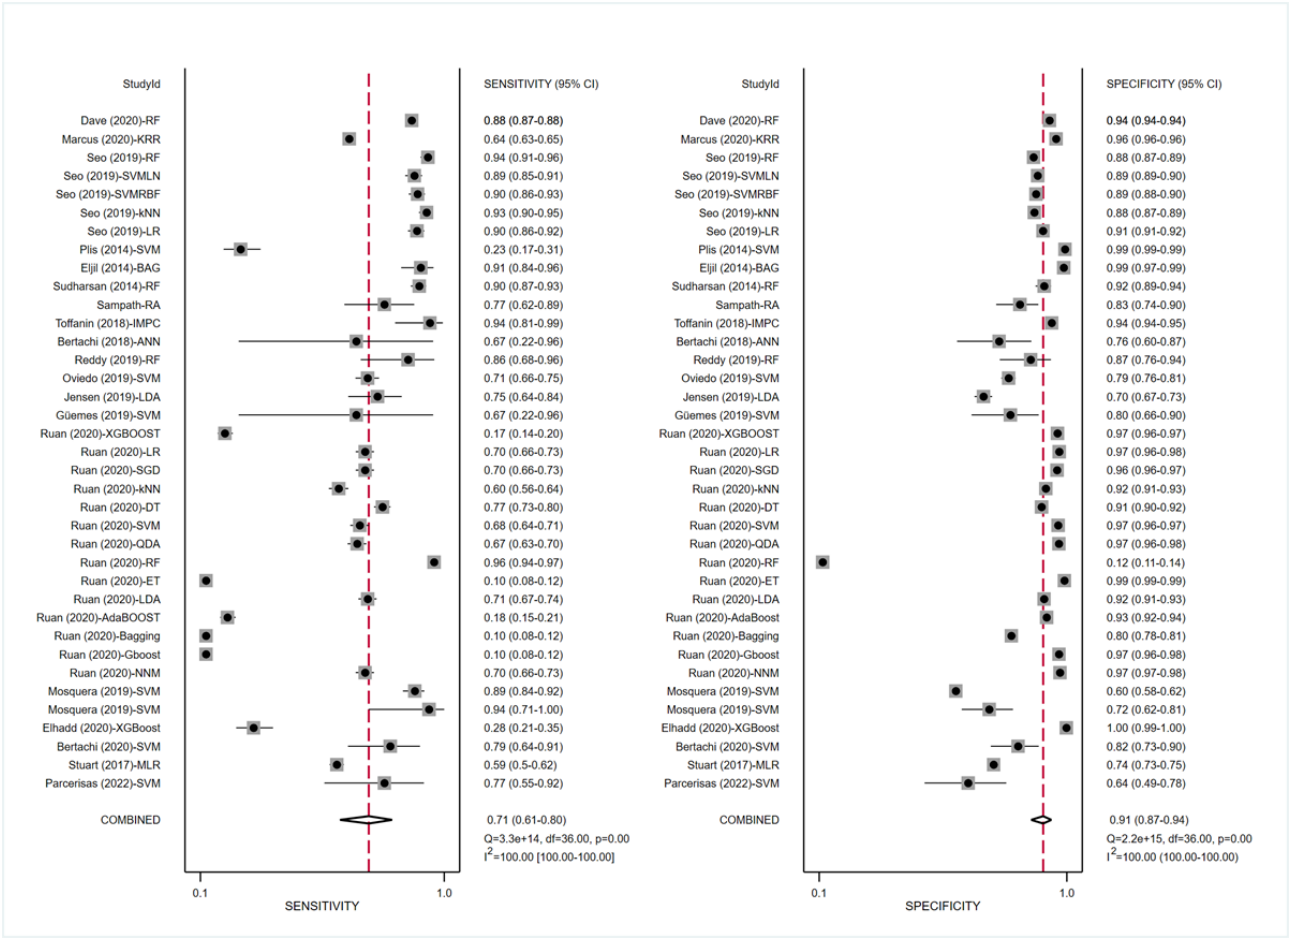

Figure 6. SROC curves of all ML algorithms (A), NNM algorithms (B), RF algorithms (C), SVM algorithms (D), and ensemble learning algorithms (E) for predicting adverse BG events. The hollow circles represent results of all studies, and the red diamonds represent the summary result of all studies. AUC: area under the curve; BG: blood glucose; ML: machine learning; NNM: neural network model; RF: random forest; SROC: summary receiver operating characteristic; SVM: support vector machine.

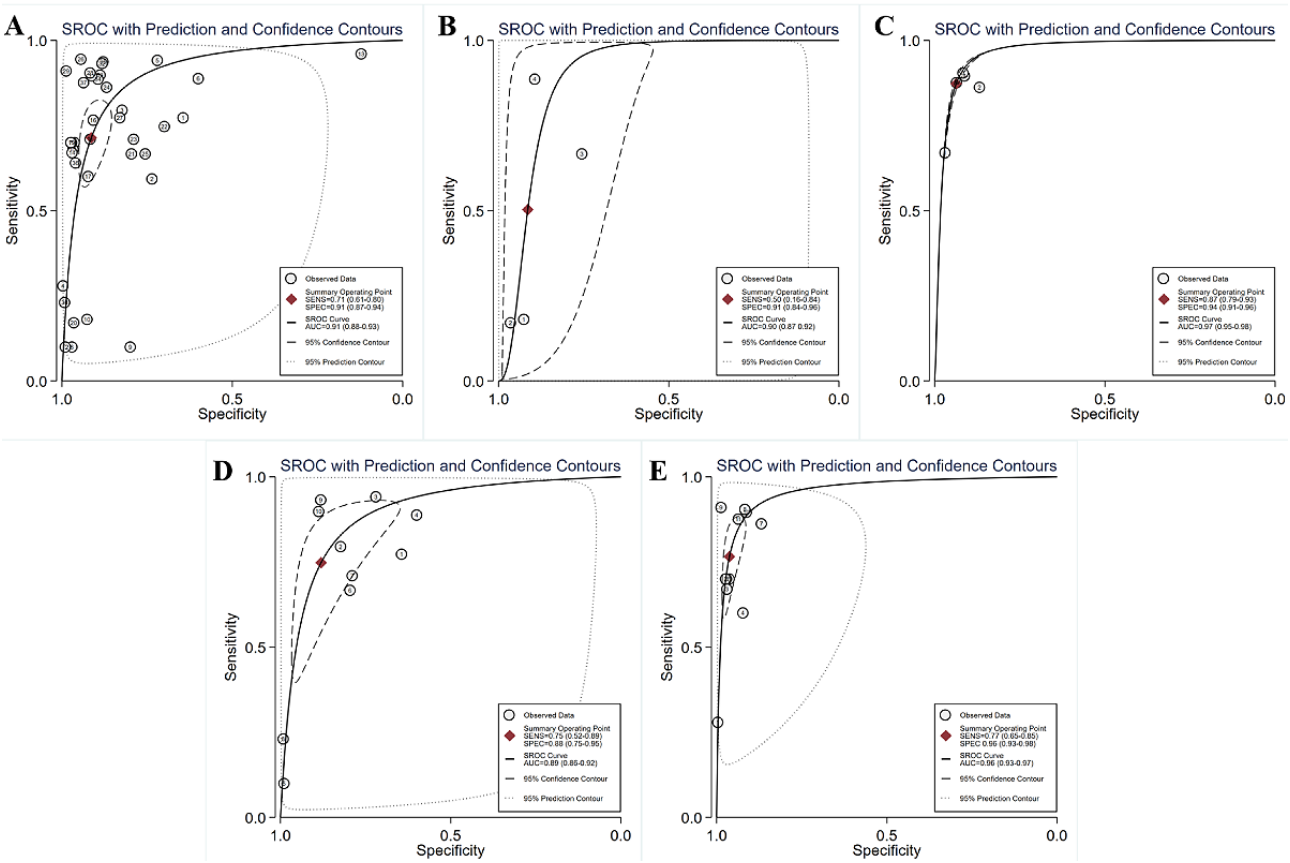

Figure 7. Sensitivity and specificity forest plots of NNM algorithms (A), RF models (B), SVM algorithms (C), and ensemble learning algorithms (D) for predicting adverse BG events. The horizontal lines indicate 95% CIs. The square markers represent the effect value of a single study, and the diamond marker represents the combined results of all studies. The vertical line shows the line of no effects. BG: blood glucose; NNM: neural network model; RF: random forest; SROC: summary receiver operating characteristic; SVM: support vector machine.

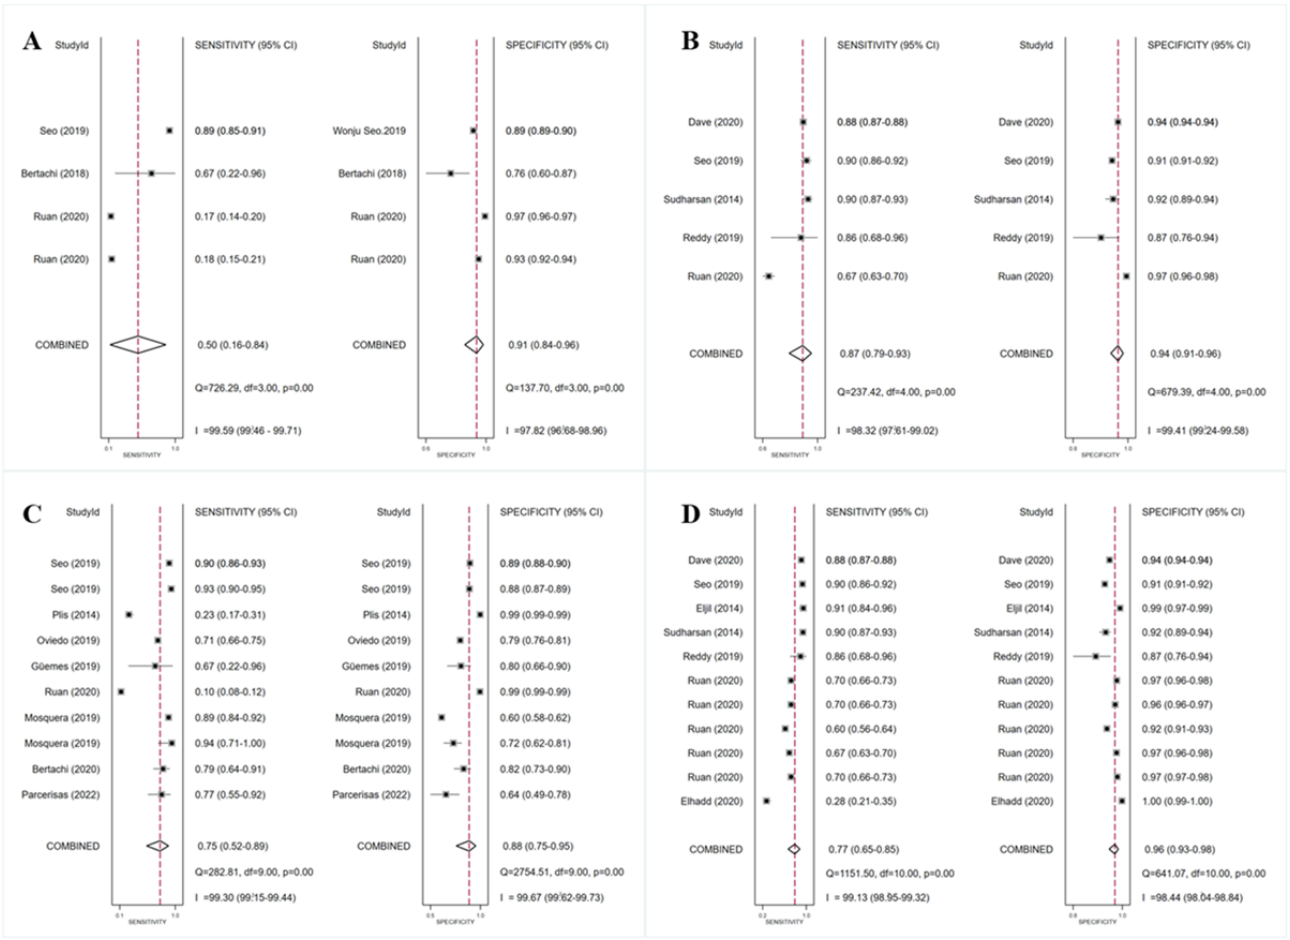

For the SVM, 8 (17.4%) studies [15,29,33-35,37,39,47] were involved, with pooled estimates of 0.75 (95% CI 0.52-0.89) for sensitivity, 0.88 (95% CI 0.75-0.95) for specificity, 6.3 (95% CI 3.4-11.7) for the PLR, and 0.29 (95% CI 0.15-0.55) for the NLR. Statistically significant heterogeneity was detected for both sensitivity (I^2=99.30%, 95% CI 99.15%-99.44%) and specificity (I^2=99.67%, 95% CI 99.62%-99.73%), as shown in Figure 7C. The SROC curve is shown in Figure 6D, with an AUC of 0.89 (95% CI 0.86-0.92). Meta-regression results showed that reference, time, data source, setting, and threshold were sources of heterogeneity for sensitivity, while reference, data source, setting, and threshold were sources of heterogeneity for specificity (Multimedia Appendix 8). Publication bias was not statistically significant (*P*=.83).

For ensemble learning models (RF, XGBoost, bagging), 7 (15.2%) studies [15,32,34,48,56,58,60] were involved, with pooled estimates of 0.77 (95% CI 0.65-0.85) for sensitivity, 0.96 (95% CI 0.93-0.98) for specificity, 20.4 (95% CI 12.5-33.3) for the PLR, and 0.24 (95% CI 0.16-0.37) for the NLR. Statistically significant heterogeneity was detected for both sensitivity (I^2=99.13%, 95% CI 98.95%-99.32%) and specificity (I^2=98.44%, 95% CI 98.04%-98.84%), as shown in Figure 7D. The SROC curve is shown in Figure 6E, with an AUC of 0.96 (95% CI 0.93-0.97). Meta-regression results showed that there was no source of heterogeneity for sensitivity, while the type of DM, setting, and threshold were sources of heterogeneity for specificity (Multimedia Appendix 9). No statistically significant publication bias was detected (*P*=.50).

Machine Learning Models for Detecting Hypoglycemia

ML models for detecting hypoglycemia (adverse BG events) involved 17 (37%) studies [10,16,40-46,61-68], with pooled estimates of 0.74 (95% CI 0.70-0.78) for sensitivity, 0.70 (95% CI 0.56-0.81) for specificity, 2.4 (95% CI 1.6-3.7) for the PLR, and 0.37 (95% CI 0.29-0.46) for the NLR. The heterogeneity between different models in these studies is shown in the forest plots in Figure 8 and was high for both sensitivity (I^2=92.80%, 95% CI 91.10%-94.49%) and specificity (I^2=99.04%, 95% CI 98.82%-99.16%). The SROC curve is shown in Figure 9A, with an AUC of 0.77 (95% CI 0.73-0.81). Based on the meta-regression results, reference, time, data source, setting, and threshold were statistically significant sources of heterogeneity for sensitivity, while reference, data source, and threshold were statistically significant sources of heterogeneity for specificity (Multimedia Appendix 9). Statistically significant publication bias was detected (*P*<.001). In addition to integral analysis for the hypoglycemia detection model, we also carried out analysis of 2 subgroups based on the characteristics of the included studies, including the NNM and the SVM.

For the NNM, 11 (23.9%) studies [40-42,45,46,62-67] were involved, with pooled estimates of 0.76 (95% CI 0.70-0.80) for sensitivity, 0.67 (95% CI 0.49-0.82) for specificity, 2.3 (95% CI 1.4-3.9) for the PLR, and 0.36 (95% CI 0.27-0.48) for the NLR. The heterogeneity between different studies is shown in the forest plot in Figure 10A and was high for both sensitivity (I^2=97.30%, 95% CI 96.62%-97.99%) and specificity (I^2=98.23%, 95% CI 97.83%-98.62%). The SROC curve is shown in Figure 9B, with an AUC of 0.78 (95% CI 0.74-0.81). Based on the of meta-regression results, reference, time, data source, setting, and threshold were statistically significant sources of heterogeneity for sensitivity, while reference and setting were statistically significant sources of heterogeneity for specificity (Multimedia Appendix 10). Statistically significant publication bias was detected (P<.001).

For the SVM, 4 (8.7%) studies [10,44,61,62] were included, with pooled estimates of 0.80 (95% CI 0.73-0.86) for sensitivity, 0.65 (95% CI 0.41-0.83) for specificity, 2.3 (95% CI 1.2-4.4) for the PLR, and 0.31 (95% CI 0.18-0.51) for the NLR. The heterogeneity between different studies is shown in the forest plot in Figure 10B and was high for both sensitivity (I^2=55.86%, 95% CI 11.96%-99.76%) and specificity (I^2=99.02%, 95% CI 98.68%-99.36%). The SROC curve is shown in Figure 9C, with an AUC of 0.81 (95% CI 0.78-0.85). Meta-regression results indicated that reference, time, data source, setting, and threshold were statistically significant sources of heterogeneity for sensitivity, while reference, data source, setting, and threshold statistically significant sources of heterogeneity for specificity (Multimedia Appendix 11). No statistically significant publication bias was detected (P=.31).

Figure 8. Sensitivity and specificity forest plots of ML models for detecting adverse BG events. The horizontal lines indicate 95% CIs. The square markers represent the effect value of a single study, and the diamond marker represents the combined results of all studies. The vertical line shows the line of no effects. BG: blood glucose; ML: machine learning.

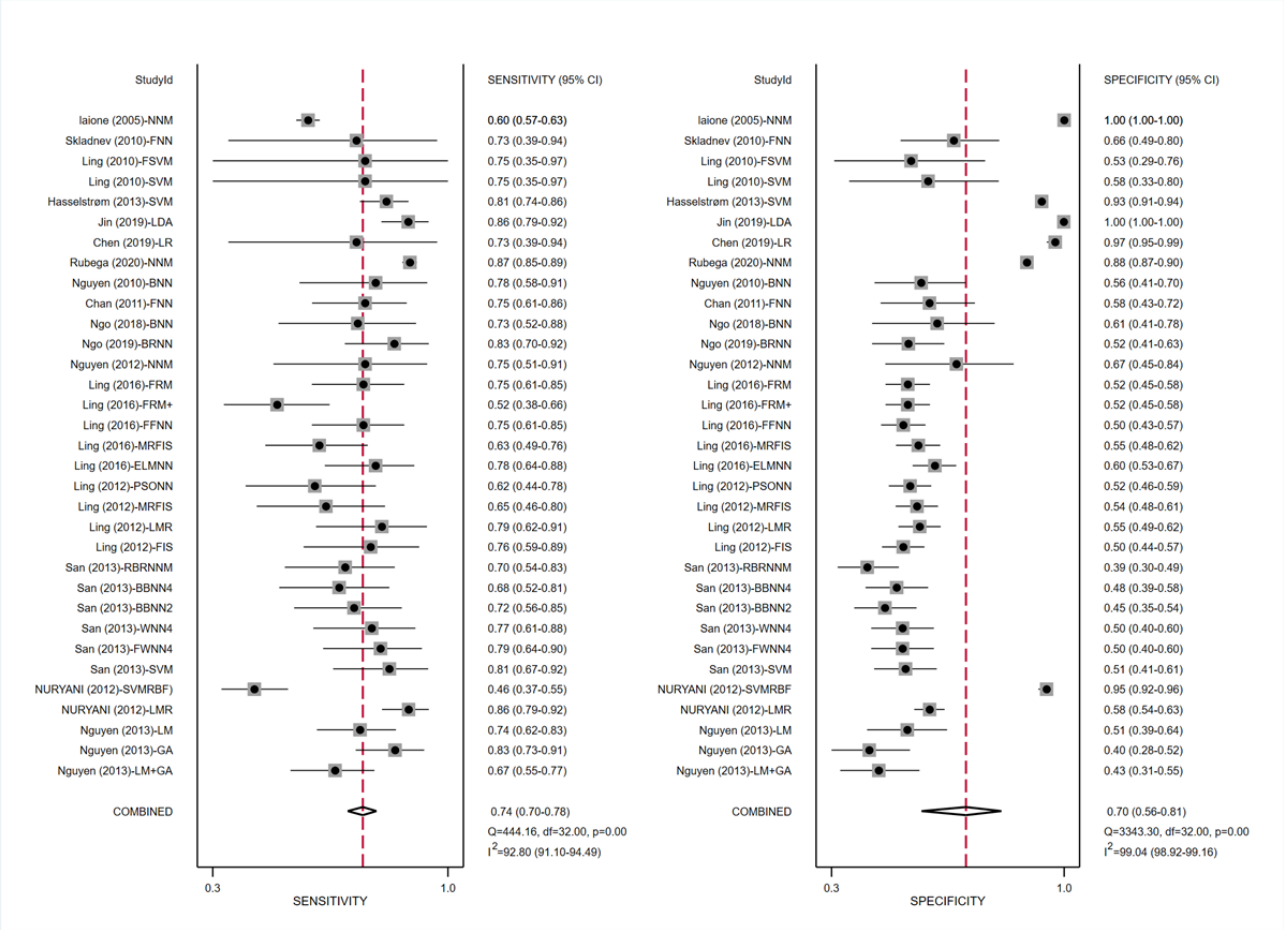

Figure 9. SROC curves of all ML algorithms (A), NNM algorithms (B), and SVM algorithms (C) for detecting adverse BG events. The hollow circles represent results of all studies, and the red diamonds represent the summary result of all studies. AUC: area under the curve; BG: blood glucose; ML: machine learning; NNM: neural network model; SROC: summary receiver operating characteristic; SVM: support vector machine.

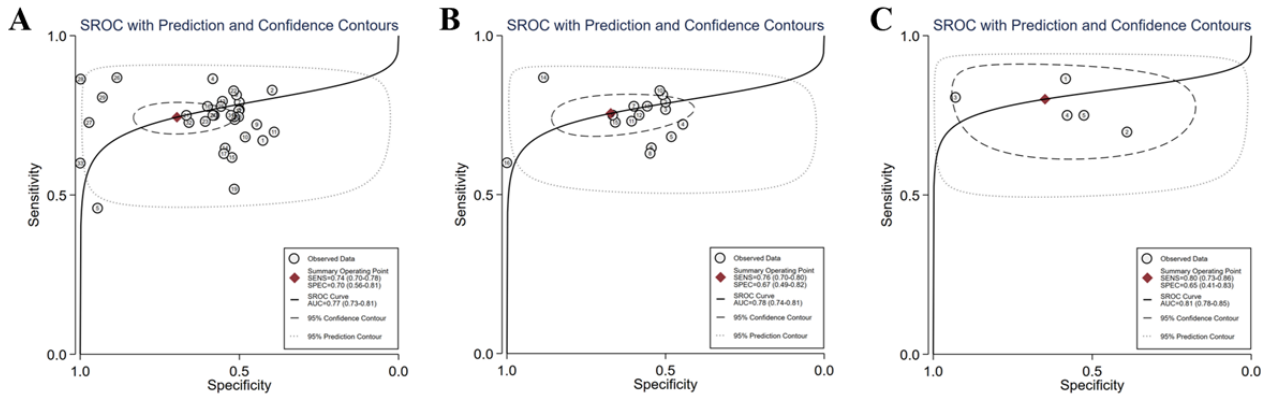

Figure 10. Sensitivity and specificity forest plots of NNM algorithms (A) and SVM algorithms (B) for detecting adverse BG events. The horizontal lines indicate 95% CIs. The square markers represent the effect value of a single study, and the diamond marker represents the combined results of all studies. The vertical line shows the line of no effects. BG: blood glucose; NNM: neural network model; SVM: support vector machine.

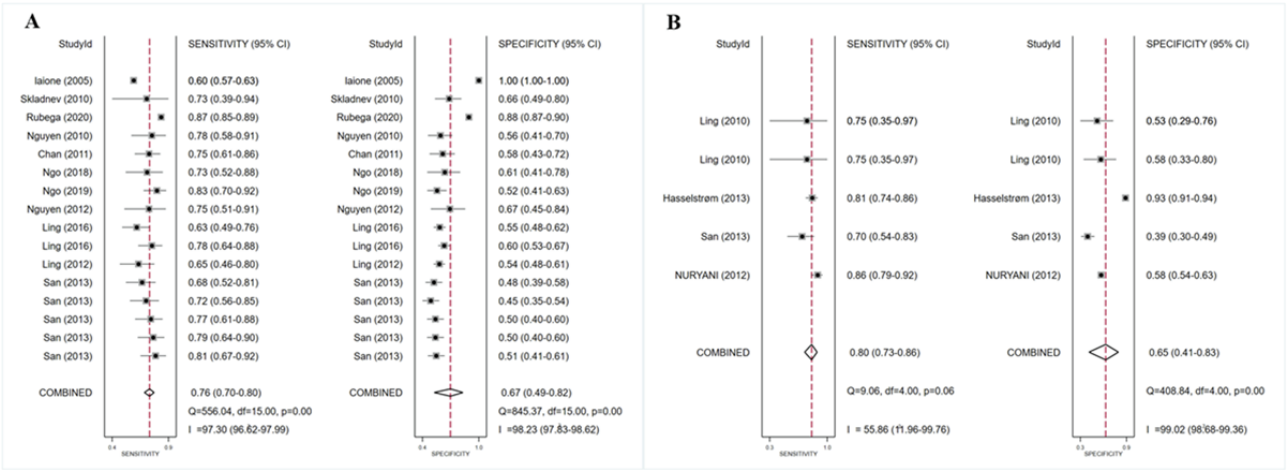

Discussion

Principal Findings

This meta-analysis systematically assessed the performance of different ML models in enhancing BG management in patients with DM based on 46 eligible studies. Comprehensive evidence obtained via exhaustive searching allowed us to assess the overall ability of the ML models in different scenarios, including predicting BG levels, predicting adverse BG events, and detecting adverse BG events.

Comparison to Prior Work

Obviously, the RMSE of ML models for predicting BG levels increased as the PH increased from 15 to 60 minutes, which indicates that the longer the PH, the larger the prediction error. Based on the results of relative ranking, among all the ML models for predicting BG levels, neural network–based models, including the DRNN, GluNet, ARJNN, and NNM, achieved the minimum RMSE and the maximum SUCRA in different PHs, indicting the highest relative performance. In contrast, the DT achieved the maximum RMSE and the minimum SUCRA in a PH of 60 and 45 minutes, indicating that lowest relative performance. Thus, for predicting BG levels, neural network–based algorithms might be an appropriate choice. We found that time domain features combined with historical BG levels as input can further improve the performance of NNM algorithms [49,55]. However, the quality of training data for NNMs needs to be high; therefore, the requirements during data collection and preprocessing of raw data are high [22,51].

Regarding ML models for predicting adverse BG events, the pooled sensitivity, specificity, PLR, and NLR were 0.71 (95% CI 0.61-0.80), 0.91 (95% CI 0.87-0.94), 8.3 (95% CI 5.7-12.0), and 0.31 (95% CI 0.22-0.44), respectively. According to the *Users' Guide to Medical Literature*, with regard to diagnostic tests [69], a PLR of 5-10 should be able to moderately increase the probability of persons having or developing a disease and an NLR of 0.1-0.2 should be able to moderately decrease the probability of having or developing a disease after taking the index test. Hence, current ML models have relatively sufficient ability to predict the occurrence of hypoglycemia, especially RF algorithms with a PLR of 13.9 (95% CI 10.1-18.9) and an NLR of 0.14 (95% CI 0.08-0.22). On the contrary, although the PLR of NNM algorithms was 5.9 (95% CI 3.2-10.8), their sensitivity and NLR were 0.50 (95% CI 0.16-0.84) and 0.54 (95% CI 0.24-1.21), respectively, which is far from satisfactory. Although RF algorithms seem to be able to capture the complex, nonlinear patterns affecting hypoglycemia [56], it was still not enough to determine which algorithm shows the best

performance, as the test scenarios were quite different and there was high heterogeneity between studies.

Regarding ML models for detecting hypoglycemia, the pooled sensitivity, specificity, PLR, and NLR were 0.74 (95% CI 0.70-0.78), 0.70 (0.56-0.81), 2.4 (1.6-3.7), and 0.37 (0.29-0.46), respectively, which indicates that the algorithms generate small changes in probability [69]. Nevertheless, it does not mean that ML models combined with ECG or EEG monitoring, which we found in 13 of 17 studies, should not be further investigated. Considering patients with both DM and cardiovascular risk, or patients under intensive care and in a coma, combined ML models and ECG or EEG signals might be able to avoid deficits in physical and cognitive function and death caused by hypoglycemia [70].

Strengths and Limitations

The study has several limitations. First, although we developed a comprehensive search strategy, there was still a possibility of potential missing studies. To further increase the rate of literature retrieval, we included the main medical databases with a feasible search strategy, including PubMed, Embase, Web of Science, and IEEE Explore, and references from relevant studies were also screened for eligibility to avoid omissions. Second, statistically significant high heterogeneity was detected in all subgroups, with different sources of heterogeneity, including different types of DM, ML models, data sources, reference index, time and setting of data collection, and threshold of hypoglycemia, among studies. To address this issue, hierarchical analysis and meta-regression analysis were carried out in different subgroups to explore the possible sources of heterogeneity. Furthermore, for several studies that provided no required outcome measures or had inconsistent outcome measures, relevant estimation methods were used to calculate the indicators, which might have led to a certain amount of estimation error. However, the estimation error was small enough to be accepted owing to an appropriate estimation method, and the results of this study were further enriched. However, future studies are required to report all relevant outcome measures for further evaluation.

Future Directions

In future, more accurate ML models will be used for BG management, which will certainly improve the quality of life of patients with DM and reduce the burden of adverse BG events. First, as mentioned before, current ML models have relatively sufficient ability to predict BG levels and hypoglycemia, and the fact that an extended PH is more beneficial for increasing the time available for patients and clinicians to respond still needs to be emphasized [15]. Hence, future studies should focus on enhancing the performance of ML models in longer PHs (ie, 60 minutes). Second, most of the raw data from CGM devices are highly imbalanced due to the low incidence of adverse BG events, which may lead to several performance distortions. Previous studies have reported several approaches to reduce the data imbalance, including oversampling [71] and cost-based learning [15]. However, to the best of our knowledge, few studies have investigated the effectiveness of those approaches in BG management models, which needs to be further studied in the future. Furthermore, the high variability of BG levels in the human body due to several factors, such as meal intake, high-intensity exercise, and insulin dosage, creates challenges for ML models; thus, future works need to integrate these factors with existing models to further enhance their accuracy [22,51]. It is also necessary to consider the computational complexity and convenience of use for patients and physicians. Moreover, several studies have implied that a combination of ML models and features extracted from CGM profiles can achieve better predictability compared to an ML model alone [15,56]. Recently, studies have focused on more novel deep learning models, such as transformers, which have also been proved clinically useful [72]. Therefore, further studies that focus on optimizing the structure of an ensemble method are needed to explore more models with a new structure. Lastly, it should be mentioned that although several studies have achieved high performance using relatively small data set [29,31,32,35,39,47,57], which can reduce the difficulty in model development, it also creates a concern about whether this will decrease the generalization ability of the models. Most of the models were developed and tested with a certain data set, and few of them have been prospectively validated in a clinical setting. Therefore, they need to be applied in clinical practice and be updated, as needed, to provide real-time feedback for the automatic collection of BG levels and generate a basis for prompt medical intervention [73].

Conclusion

In summary, in predicting precise BG levels, the RMSE increases with an increase in the PH, and the NNM shows the relatively highest performance among all the ML models. Meanwhile, according to the PLR and NLR, current ML models have sufficient ability to predict adverse BG (hypoglycemia) events, while their ability to detect adverse BG events needs to be enhanced. Future studies are required to focus on improving the performance and using ML models in clinical practice [70,73].

Acknowledgments

The study was funded by the National Natural Science Foundation of China (grant no. 82073663) and the Shaanxi Provincial Research and Development Program Foundation (grant nos. 2017JM7008 and 2022SF-245).

Data Availability

The data sets used and analyzed during the study are available from the corresponding author upon reasonable request.

Authors' Contributions

YW and CC conceived and designed the study. KL and LL undertook the literature review and extracted data. KL, LL, and JJ interpreted the data. KL, YM, and SL wrote the first draft of the manuscript, with revision by YW, ZL, CP, and ZY. All authors have read and approved the final version of the manuscript and had final responsibility for submitting it for publication.

Abstract

Background: Clinical trials are a crucial element in advancing medical knowledge and developing new treatments by establishing the evidence base for safety and therapeutic efficacy. However, the success of these trials depends on various factors, including trial design, project planning, research staff training, and adequate sample size. It is also crucial to recruit participants efficiently and retain them throughout the trial to ensure timely completion.

Objective: There is an increasing interest in using electronic health records (EHRs)—a widely adopted tool in clinical practice—for clinical trials. This scoping review aims to understand the use of EHR in supporting the conduct of clinical trials in low- and middle-income countries (LMICs) and to identify its strengths and limitations.

Methods: A comprehensive search was performed using 5 databases: MEDLINE, Embase, Scopus, Cochrane Library, and the Cumulative Index to Nursing and Allied Health Literature. We followed the latest version of the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guideline to conduct this review. We included clinical trials that used EHR at any step, conducted a narrative synthesis of the included studies, and mapped the roles of EHRs into the life cycle of a clinical trial.

Results: A total of 30 studies met the inclusion criteria: 13 were randomized controlled trials, 3 were cluster randomized controlled trials, 12 were quasi-experimental studies, and 2 were feasibility pilot studies. Most of the studies addressed infectious diseases (15/30, 50%), with 80% (12/15) of them about HIV or AIDS and another 40% (12/30) focused on noncommunicable diseases. Our synthesis divided the roles of EHRs into 7 major categories: participant identification and recruitment (12/30, 40%), baseline information collection (6/30, 20%), intervention (8/30, 27%), fidelity assessment (2/30, 7%), primary outcome assessment (24/30, 80%), nonprimary outcome assessment (13/30, 43%), and extended follow-up (2/30, 7%). None of the studies used EHR for participant consent and randomization.

Conclusions: Despite the enormous potential of EHRs to increase the effectiveness and efficiency of conducting clinical trials in LMICs, challenges remain. Continued exploration of the appropriate uses of EHRs by navigating their strengths and limitations to ensure fitness for use is necessary to better understand the most optimal uses of EHRs for conducting clinical trials in LMICs.

KEYWORDS

electronic health records; clinical trials; low- and middle-income countries

Introduction

Clinical trials are a crucial element in advancing medical knowledge and developing new treatments by establishing the evidence base for safety and therapeutic efficacy [1]. However, the success of these trials depends on various factors, including trial design, project planning, research staff training, and adequate sample size [2]. It is also crucial to recruit participants efficiently and retain them throughout the trial to ensure timely completion [3].

Randomized controlled trials (RCTs) are considered the gold standard for evaluating the benefits and risks of health care treatments. Despite their high level of evidence, RCTs are often time consuming and expensive and may be limited by strictly standardized research settings that can hinder the generalizability of their results [4]. One promising solution to this challenge is the use of electronic health records (EHRs) to conduct large and pragmatic trials [5]. However, the gap in health care resources between high-income countries (HICs) and low- and middle-income countries (LMICs) varies greatly [6,7]. Although HICs have made significant progress in using EHR for clinical trials [8-10], little is known about the effectiveness of similar applications in LMICs [11,12]. Understanding the progress made in LMICs and how EHR has been applied to clinical trials can provide valuable insights for promoting and improving population health [13]. Conducting clinical trials in LMICs can also provide a comprehensive evaluation of interventions in different settings beyond HICs [14].

This scoping review aims to comprehensively understand the roles of EHRs in the life cycle of clinical trials, determine how EHRs were implemented in clinical research settings, and further describe specifically how this technology should be used to support different types of clinical trials in an LMIC context.

Methods

This scoping review followed the latest version of the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guideline for the entire review process [15].

Data Sources and Search Strategy

A comprehensive search was performed using 5 databases for articles published until the end of 2021: PubMed or MEDLINE, Embase, Scopus, Cochrane Library, and the Cumulative Index to Nursing and Allied Health Literature. We prepared the search terms using the patients, problem, or population; issue of interest or intervention; comparison, control, or comparator; outcome; and study type (PICOS) approach. As the search aimed to be as comprehensive as possible and correspond to the research questions, 3 domains including EHRs, clinical trials, and LMICs (based on the list on the World Bank definition) were used to develop the search strategy [16]. A combination of keywords and controlled vocabulary terms related to the target concepts was used. The search strategy was designed and developed by 2 authors (JY and SX) independently and confirmed with an experienced librarian. Multimedia Appendix 1 presents the search strategy.

Study Selection

Studies were included in this review if they met the following criteria: (1) clear indication of clinical trials; (2) EHR was involved in the trial conduct, including identification, recruitment, informed consent collection, implementation, outcome adjudication, and outcome verification; (3) the study was conducted in an LMIC; (4) the study was published until December 31, 2021; and (5) no language restrictions. The exclusion criteria were as follows: (1) absence of a clinical trial focus; (2) the primary research question was nonclinical (ie, cost analysis study); (3) not available in full text; (4) conference abstracts or posters; (5) nonresearch articles (ie, perspectives, commentaries, letters, and reviews); and (6) retrospective secondary data analysis in a clinical trial, for example, studies that used retrospective data for 2 groups of patients who received different treatments and compared their outcomes.

First, duplicate articles were eliminated from the retrieved articles. Then, 4 reviewers (JY, SX, TW, and YY) independently screened articles based on titles and abstracts to identify the studies that could potentially fit the research question and meet the eligibility criteria. Records were excluded if they were marked as irrelevant by 2 reviewers. For records that were kept or were difficult to decide based on the title or abstract, the full text was scrutinized. When disagreements regarding study inclusion occurred between the 2 reviewers, a third or fourth reviewer was involved in the discussion until consensus was reached.

Data Extraction

A data extraction form was developed for data extraction. For each included study, we first extracted the studies' basic information, including the first author's name, publication year, country, trial setting, trial design, target population, intervention, and outcome. Of note, for trial designs, we considered individual RCT, cluster RCT, quasi-experimental studies, and feasibility pilot studies. To determine how the studies used EHR in conducting the trials, we extracted information on the roles that EHR played at any step in each of the included studies.

Data Synthesis and Analysis

We conducted a descriptive analysis on the basic information of each included paper and conducted qualitative synthesis to analyze the roles that EHR played in conducting the trials and to identify their associated implications. In the qualitative synthesis process, we referred to an established framework from a publication in 2019 [11]. The study reviewed the current and prospective uses of EHR in clinical trials worldwide and outlined five steps in which EHR could be used: (1) patient identification

and recruitment, (2) participant consent and randomization, (3) intervention, (4) outcome assessment, and (5) extended follow-up [11]. On the basis of this framework, we first attempted to map our identified roles of EHR in clinical trials into these 5 steps, and then, we performed modifications by adding our identified new roles of EHR from the included studies. The identifications and articulations of new roles were based on research team discussions until consensus was reached (JY, SX, and YY). In addition, when available, we further synthesized text information about implications of using EHR in conducting clinical trials, by summarizing them as "strengths" and "limitations" under each role of EHR.

Quality Assessment

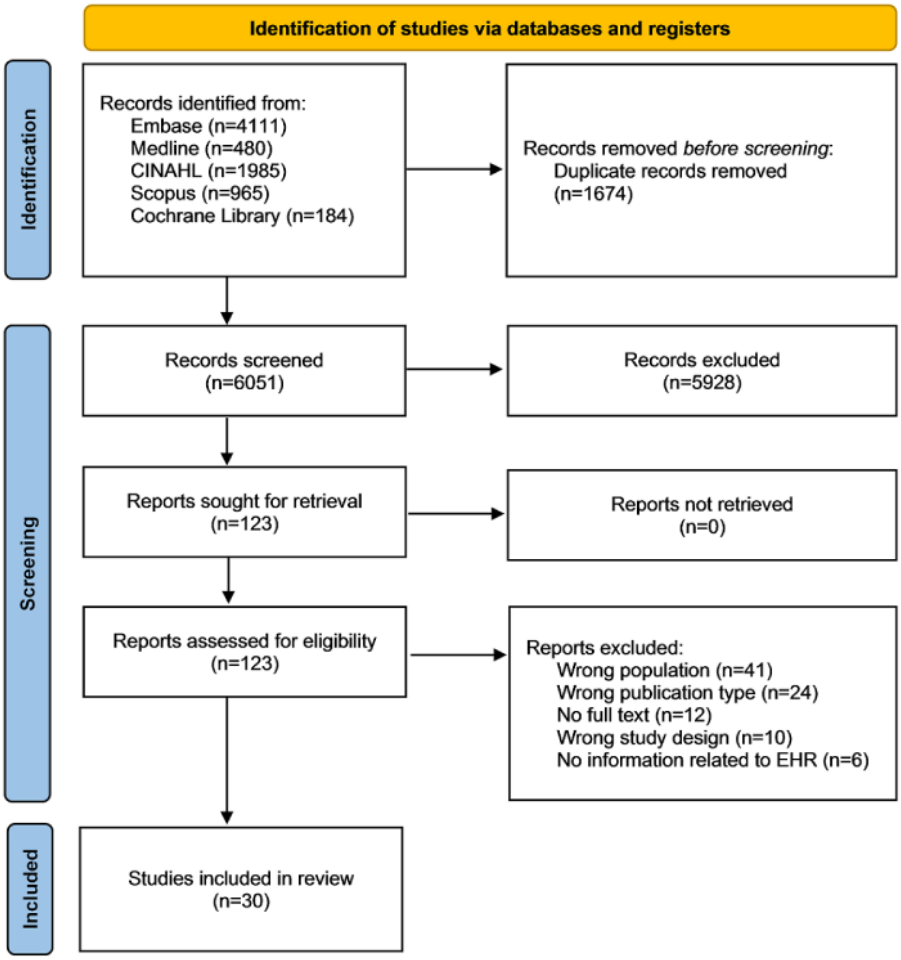
We followed the National Heart, Lung, and Blood Institute's Study Quality Assessment Tools for the quality assessment of the included studies [17]. For studies with control groups, a total of 14 questions were considered, including the adequacy of randomization, blinding of treatment assignment and outcome assessment, use of intention-to-treat analysis, and sufficiency of the sample size. For the quasi-experimental studies without independent control groups (eg, pre-post studies), a total of 12 questions were considered, including clarity in study objectives, participant eligibility criteria, prespecification of outcomes and subgroups, and sample size sufficiency. We marked studies that met ≥80% of applicable criteria as "good quality," 60% to 80% as "fair quality," and <60% as "poor quality."

Results

Selected Characteristics of the Included Studies

Figure 1 displays the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for article selection. The initial search from the 5 databases yielded a total of 7725 references. After removal of duplicates, the first round of screening excluded 6051 references for ineligibility, leaving 123 references for full-text screening. A total of 93 references were then further excluded, primarily for wrong populations (ie, studies conducted exclusively in HICs) and wrong study types (ie, study types other than clinical trials). Finally, 30 studies were included in the data charting and analysis.

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the included studies in the review. EHR: electronic health record.



As shown in Table 1, the 30 studies were conducted in 15 LMICs, with China being the most represented (n=7, 23%), followed by Kenya (n=5, 17%). Zambia, South Africa, and Malaysia were all included in an equal number of studies, with each country being part of 3 (10%; 3 for each) studies. Of note, 27 (90%) of the 30 studies were conducted in a single LMIC, and 3 (10%) were conducted in multiple LMICs [18-20]. Table 2 presents the summaries of the characteristics of included studies. Most of the reported trials were conducted after 2010 (29/30, 97%), with the majority published in 2018 (5/30, 17%),

2019 (5/30, 17%), and 2020 (7/30, 23%). The oldest study was conducted in 2004 (1/30, 3%), whereas the most recent studies were conducted in 2021 (3/30, 10%). For study types, most included studies were RCTs (13/30, 43%), followed by quasi-experimental studies (12/30, 40%), cluster RCTs (3/30, 10%), and feasibility pilot studies (2/30, 7%). Of note, 9 quasi-experimental studies adopted a retrospective design using past data from the EHR systems. Regarding disease types, most studies addressed infectious diseases (15/30, 50%), with 40% (12/30) of them addressing HIV or AIDS. Another 12 studies focused on noncommunicable diseases, such as hypertension, diabetes, cancer, and mental illness. Three studies focused on injuries, such as hip fracture and brain injury.

Table 1. Characteristics of the included studies.

Study, year	Country	Trial design	Disease areas	Summary of interventions	Outcomes
Figar et al [21], 2004	Argentina	Quasi-experimental study	Hypertension	A complex antihypertensive intervention program for physicians of the older adults	• Systolic and diastolic blood pressure and the proportion of patients who were well controlled
Lakkis et al [22], 2011	Lebanon	Randomized controlled trial	Cancer	An informative SMS text remainder about mammogram tests	• Performance of (whether or not performed) the mammogram test
Were et al [23], 2013	Kenya	Randomized controlled trial	AIDS	A CDSS[a] with clinician-targeted computer-generated reminders	• The number of clinical visits before the completion of overdue tasks, including HIV testing, laboratory monitoring, initiating antiretroviral therapy, and making referrals
Li et al [24], 2014	China	Quasi-experimental study, using retrospective data	Cardiovascular disease	Salvianolate injection treatment over 14 days	• Indexes of liver and kidney function, including alanine aminotransferase, aspartate aminotransferase, creatinine, and blood urea nitrogen
Zhang et al [25], 2014	China	Quasi-experimental study, using retrospective data	Urologic diseases	Pharmacist interventions that included real-time monitoring of medical records and controlling the prescription of prophylactic antibiotics	• Rational use of antibiotic prophylaxis, including frequency of prophylactic antibiotic use, indications for and rate of prophylactic antibiotic use, medical cost/patient, inappropriate prophylactic antibiotic use, rate of correct antibiotic administration, and cost-benefit
Ghadieh et al [26], 2015	Lebanon	Randomized controlled trial	Bacterial infection	A set of reminders to invite participants to get the PPSV23[b] vaccine	• The vaccine administration rate in the clinics
Ali et al [18], 2016	India and Pakistan	Randomized controlled trial	Diabetes	A multicomponent quality improvement strategy	• Primary: the proportion that achieves multiple care targets • Secondary: achieving individual risk factor targets, mean risk factor changes, and patient reported outcomes (eg, health-related quality of life and treatment satisfaction scores)
Oluoch et al [27], 2015	Kenya	Cluster randomized controlled trial	AIDS	A CDSS with pop-up information and reminder whenever action is needed for an individual patient, and an alert when a patient had immunological treatment failure	• Primary: the difference between groups in the proportion of patients who experienced immunological treatment failure • Secondary: the effect of CDSS on time from detection of immunological treatment failure to clinical action and time from antiretroviral treatment initiation to first CD4[c] cell measurement
Wang et al [28], 2016	China	Quasi-experimental study, using retrospective data	Hypertension	A guideline for hypertension management	• The incidence of stroke
Al-Hashar et al [29], 2018	Oman	Randomized controlled trial	Chronic disease	Medication reconciliation on admission and discharge, medication review, bedside medication counseling, and take-home medication list	• Primary: percentage of preventable adverse drug events • Secondary: rates of readmission, rates of emergency department visits, rates of unplanned visits to hospitals or health centers, and the 3 combined

Study, year	Country	Trial design	Disease areas	Summary of interventions	Outcomes
George et al [30], 2018	Kenya	Randomized controlled trial	AIDS	A SMS intervention promoting the availability of oral self-administered HIV self-testing kits	• HIV testing rates
Mody et al [31], 2018	Zambia	Quasi-experimental study, using retrospective data	AIDS	A new HIV treatment guideline	• Timely antivirus treatment initiation, retention in care at 6 mo, and being retained and on antiretroviral treatment at 6 mo
Bachmann et al [32], 2019	Brazil	Cluster randomized controlled trial	Asthma or chronic obstructive pulmonary disease	A guide and training program for doctors and nurses	• Primary: composite scores of treatment changes, spirometry, and new asthma and COPD[d] diagnosis rates • Secondary: the disaggregated treatment and spirometry components of asthma and COPD scores, prescriptions (eg, support tobacco cessation, depression), diseases diagnosed for the first time (eg, cardiovascular disease and diabetes mellitus), and cardiovascular risk assessed
Engelbrecht et al [33], 2018	South Africa	Quasi-experimental study, using retrospective data	Mental illness	A mental health therapy in an occupational therapy-led day treatment center	• Hospitalization days, frequency of attendance and admissions to hospital, frequency of attendance and number of days spent in hospital, and attendance rate at day treatment center
Ismail et al [34], 2019	Saudi Arabia	Quasi-experimental study	Renal disease	A patient-centered pharmacist care in the hemodialysis unit, using comprehensive medication review through medication therapy management and motivational interviewing	• Primary: changes in serum phosphate levels and differences in number of medications • Secondary: systolic blood pressure, serum low-density lipoprotein levels, glycosylated hemoglobin levels, the prevalence and types of medication-related problems, and the rates of therapeutic interventions acceptances or rejections
Kelvin et al [35], 2018	Kenya	Randomized controlled trial	AIDS	An intervention consisting of sending a text message and offering a brief demonstration of the self-testing kit on the site	• HIV testing rates
Lima et al [36], 2018	Brazil	Quasi-experimental study, using retrospective data	Cancer	A guideline for hemodynamic and depth of anesthesia monitoring	• Postoperative outcomes including the use of cardiac output, central venous oxygen saturation, depth of anesthesia monitoring, intraoperative total fluid volume and colloid volumes, number of patients receiving colloids and received inotropes, rates of postoperative delirium and urinary tract infection, postoperative morbidity, and length of hospital stay
Phillips et al [37], 2020	South Africa	Randomized controlled trial	AIDS	A maternal and child health service in the antenatal clinic through cessation of breastfeeding	

Study, year	Country	Trial design	Disease areas	Summary of interventions	Outcomes
					• Primary: a composite of female participants' retention in HIV care and viral suppression preceding the long-term adherence and care engagement study visit • Secondary: current use of family planning, pregnancies since the trial, maternal hospitalizations and tuberculosis diagnoses in the past year
Tay et al [38], 2019	Malaysia	Quasi-experimental study	Bacterial infection	An education program for both physicians and patients on the rational use of antibiotics for upper respiratory infection and acute diarrhea	• Antibiotic prescription rate and rates of reattendance or hospital admission
Wu et al [39], 2019	China	Quasi-experimental study, using retrospective data	Hip fracture	A comanagement program involving both orthopedic surgeons and geriatricians embedding in a pathway of care spanning emergency department presentation to discharge from hospital	• Primary: the proportion of patients who received surgery within 48 h of admission to a ward • Secondary: the proportion of patients who were admitted to a ward within 4 h of presentation to emergency department, who developed a pressure ulcer, who received geriatrician care, and who received osteoporosis and falls prevention assessment
Ali et al [40], 2020	India	Randomized controlled trial	Depression and diabetes	A multicomponent quality improvement strategy with nonphysician care coordinators and decision support EHRs[e]	• Primary: between-group difference in Symptom Checklist Depression Scale scores and a reduction in glycosylated hemoglobin, systolic blood pressure, or low-density lipoprotein • Secondary: percentage of patients who met treatment targets or had improvements in individual outcomes; percentage of patients who met all glycosylated hemoglobin, systolic blood pressure, or low-density lipoprotein targets; and mean reductions in Symptom Checklist Depression Scale scores and Patient Health Questionnaire-9 scores
Yang et al [41], 2020	China	Randomized controlled trial	Orthognathic disease	A hydroactive dressing on the nasal ala of patients undergoing orthognathic surgery	• The incidence of nasal ala pressure injury associated with nasotracheal intubation
Puttkammer et al [42], 2020	Haiti	Feasibility pilot study	AIDS	An EHR-based alert for adherence intervention	• HIV viral load status, antiretroviral treatment adherence, and proportion of patients who were never >7 d late for an antiretroviral treatment refill pickup
Roy et al [43], 2020	Zambia	Cluster randomized controlled trial	AIDS	Adherence club group intervention to improve on-time drug pickup and retention in HIV care through off-hours facility access and pharmacist-led group drug distribution	• Primary: time to first late drug pickup • Secondary: medication possession ratio, implementation outcomes (adoption, acceptability, appropriateness, feasibility, and fidelity), and viral load suppression at 12 mo

Study, year	Country	Trial design	Disease areas	Summary of interventions	Outcomes
Seth Kalichman et al [44], 2020	South Africa	Randomized controlled trial	Sexually transmitted infections	Two counseling sessions for brief risk reduction sexual behavior change and brief enhanced partner notification	• Primary: return sexually transmitted infection visits after counseling and rate of scale representing the percentage of times condoms were used • Secondary: sexually transmitted infection risk and prevention-related knowledge assessed by 4 heterogeneous items, HIV stigma assessed by the HIV Stigma Scale, and prevention skills self-efficacy
Mahmood et al [19], 2020	United Kingdom and Malaysia	Randomized controlled trial	Traumatic brain injury	A tranexamic acid treatment	• Primary: the volume of intraparenchymal hemorrhage after randomization • Secondary: presence of progressive intracranial hemorrhage, new intracranial hemorrhage, presence of cerebral infarction, composite poor outcome, and intracranial hemorrhage volume
Mody et al [45], 2021	Zambia	Quasi-experimental study, using retrospective data	AIDS	A new national HIV treatment	• Primary: rates of both antiretroviral treatment initiation and retention on antiretroviral treatment across subgroups in 3 timestamps, antiretroviral treatment initiation within 1 mo of enrollment, and retention in care on antiretroviral treatment at 12 mo
Semeere et al [20], 2021	Uganda and Kenya	Feasibility pilot study	AIDS	A rapid case ascertainment measurement shortly after diagnosis	• Performance of (whether or not performed) rapid case ascertainment
Xu et al [46], 2021	China	Quasi-experimental study, using retrospective data	Bacterial infection	A pharmacist-led intravenous to oral antibiotic conversion practice with computerized reminders	• Primary: the proportion of patients who converted to oral therapy on the day patients were eligible for the conversion • Secondary: length of IV[f] antibiotic therapy days, total length of antibiotic therapy days, and length of hospital stays
Abdulrahman et al [47], 2017	Malaysia	Randomized controlled trial	AIDS	Mobile phone reminders based on SMS, telephone call, and peer counseling	• Primary: improved scheduled clinic attendance and medication adherence self-report • Secondary: immunological, virological, and clinical measurements

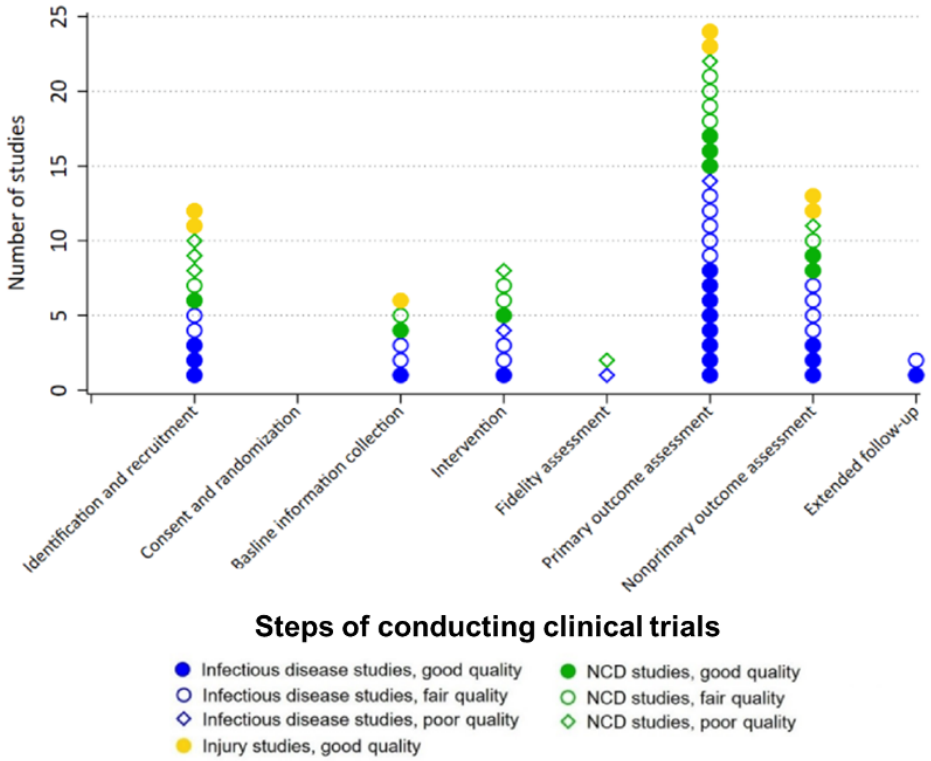
Interventions and Outcomes in Included Trials

The included clinical trials covered various types of interventions, ranging from single behavioral interventions such as informative SMSs for clinical appointments or vaccinations and clinical therapies such as tranexamic acid treatment or Salvianolate injection to complex multifaceted intervention packages for service quality improvements or education programs [28,31,36,45]. Corresponding to the diversity of interventions, the included studies also focused on a wide range of outcomes, including individual clinical outcomes such as blood pressure and incidence of stroke, individual behavioral outcomes such as medication use and retention in antiretroviral care, and facility-level administration data such as the number of hospital visits and vaccine administration rates [48,49].

Of the 8 steps of conducting clinical trials (Figure 2), we identified 7 in which EHR was used in the 30 included studies, with the only exception for "participant consent and randomizations." The role of EHR in primary outcome assessment (24/30, 80%) was the most commonly documented, followed by the use of EHR to assess nonprimary outcomes (13/30, 43%). For example, 1 study focused on the effects of adherence club groups on the on-time antiretroviral drug pickup among people with HIV or AIDS, whose primary outcome was "time to first late drug pickup," and secondary outcome was "the proportion of time that a patient has antiretroviral drug in their possession over 12 months," and both of them were ascertained using EHR data [43]. One study used EHR to obtain safety outcomes as a nonprimary outcome, which was the adverse change in participants' bioindicators after the intervention [24]. We summarized that there were 3 main types of information collected from the EHR: people's clinical information (eg, systolic and diastolic blood pressure), behavioral information (eg, medication use), and health facility administration data (eg, frequency of hospital visits).

Figure 2. The roles of electronic medical records in the different steps of conducting clinical trials among the included studies. NCD: noncommunicable disease.



Roles of EHRs in Trial Steps

Table 3 demonstrates the roles of electronic medical records in the different steps of conducting clinical trials among included studies. A total of 12 trials used EHR to identify and recruit study participants based on automatically or manually extracted data. These studies queried a series of data entries of clinical information from the databases to identify their target populations and retrieved the contact information to approach the potential patient participants. For example, Bachmann et al [32] identified eligible participants with asthma or chronic obstructive pulmonary disease using the International Classification of Disease diagnostic codes in a consolidated municipal EHR database in Brazil. Lakkis et al [22] used EHR to extract cell phone numbers of female participants who were recommended to undergo a screening mammogram for breast cancer.

Table 3. The roles of electronic medical records in the different steps of conducting clinical trials among included studies.

Roles of EHR[a] (number of studies)	Descriptions	Implications	References
Participant identification and Recruitment (n=12)	People's demographic, clinical, and contact information from the EHR systems was either automatically or manually extracted to help researchers identify and then recruit trial participants.	• Strength: EHR enabled researchers to access participants that were otherwise unfeasible to access. • Strength: EHR enabled researchers to identify and include all eligible patients whose interaction with health systems were electronically recorded, which increased generalizability and sample size at minimal cost. • Limitation: some eligible participants may not be documented in the EHR systems. • Limitation: artifacts, errors, and misclassifications in EHR may cause inclusion of ineligible participants or exclusion of eligible ones.	[19,21,22,24-28,30,32,35,39]
Baseline information collection (n=6)	For people who were enrolled, many trials used EHR systems to collect their baseline basic characteristics, including demographical and socioeconomical information, which were used as covariates in later analyses.	• Not mentioned.	[31,32,34,41,43,45]
Intervention (n=8)	Many trials incorporated EHR systems in the intervention packages, including three scenarios: (1) electronic reminders or alerts to health providers based on EHR data, (2) clinical decision support systems built in the EHR system, and (3) monitoring of EHR data by health providers to make clinical decisions.	• Strength: EHR could integrate different intervention components of complex interventions. • Strength: the EHR-based data review by health providers allowed real-time monitoring of patients' health. • Limitation: lack of complete and high-quality data in EHR systems would prohibit relevant, timely, and accurate clinical decision support. • Limitation: technical glitches such as server breakdown compromised the continuity of EHR-based interventions.	[18,21,23,25,40,42,46]
Fidelity (n=2)	Some trials used EHR systems to assess the fidelity of trial conduct according to predefined protocols, such as providers' adherence to study protocols and patients' adherence to lifestyle changes.	• Not mentioned.	[21,42]
Primary outcome assessment (n=24)	Most included trials used EHR systems to assess studies' primary outcomes, including clinical data (eg, blood pressure), behavioral data (eg, medication use), and service use data (frequency of hospital visits).	• Strength: using EHR for data extraction is time saving compared with conventional individual chart review. • Limitation: EHR's data quality could be questionable, subject to inaccuracy, misclassification, and incompleteness. • Limitation: some relevant information was not available in the EHR systems. • Limitation: lack of integration across or linkage with different EHR systems might cause missing information or underdetection of events. • Limitation: EHR was not able to provide information for individuals who moved out of the region in the middle of the trial. • Limitation: some data might be missing or omitted in the transformation from handwritten medical records to EHR.	[19,23-27,29-40,42-45,47,50]

Roles of EHR[a] (number of studies)	Descriptions	Implications	References
Nonprimary outcome assessment (n=13)	Many trials used EHR systems to assess studies' nonprimary outcomes, including clinical, behavioral, and service use data. In addition, 1 study used EHR to assess safety outcomes (eg, the occurrence of adverse events).	• Strength: using EHR for data extraction is time saving compared with conventional individual chart review. • Limitation: some relevant information was not available in the EHR systems, which might omit potential confounders.	[19,23,24,27,35,37-44]
Extended follow-up (n=2)	A few trials used EHR systems to follow-up with participants beyond the study time frame to determine the sustainability of effects.	• Not mentioned.	[23,37]

[a]EHR: electronic health record.

We found 8 studies that incorporated EHR into their intervention packages. There were 3 types of interventions that used EHR. First, 3 studies used electronic reminders or alerts to health care providers based on EHR data [21,42,46]. For example, Puttkammer et al [42] used the EHR systems to alert physicians of patients at elevated risk of treatment failure through automated calculations of patients' risk score based on their past EHR data. Second, 4 studies incorporated clinical decision support systems into the EHR systems [18,23,27,40]. Third, 2 studies involved manual monitoring and review of EHR data by health care providers [25,40]. For example, Ali et al [40] included both an EHR-based clinical decision support system and manual monitoring of EHR data. Their EHR-based clinical decision support system integrated patient characteristics, depressive symptom scores, and laboratory data to provide evidence-based guidelines to physicians based on treatment guidelines, and the study team also manually monitored and reviewed the EHR data and developed consensus recommendations for patients with severe symptoms.

A total of 6 studies used EHR to collect baseline information, which mainly included individual demographic, socioeconomic, and clinical information to determine the basic characteristics of the participants. For example, 1 study collected baseline information through EHRs, including age, sex, pregnancy status, HIV clinic enrollment date, and antiretroviral treatment initiation date among people with HIV or AIDS in Zambia [45].

Only 2 studies used EHR for fidelity assessment of the trial. Puttkammer et al [42] used EHR to determine health workers' "engagement" with the EHR-based computerized alert, which was defined as the frequency of the health workers' clicking on the alert to bring up the "pop up" window. Figar et al [21] used EHR to determine adherence to lifestyle changes in older patients with hypertension [21]. Both studies were feasibility studies and both lacked randomization.

Two studies used EHR to follow-up with participants beyond the study timeframe to determine the sustainability of the effects [23,37]. Phillips et al [37] used EHR to follow-up with female participants who attended a past trial on HIV or AIDS to determine the continued effects of the interventions on female participants' retention in HIV care and viral suppression. Were et al [23] queried the EHR data 3 months after the study closure to capture the study's sustained effects on the quality of pediatric HIV care in a resource-limited setting in Kenya.

Some studies discussed the strengths and limitations of using EHR in conducting clinical trials. For participant identification and recruitment, Semeere et al [20] reported that EHR enabled researchers to access participants who were otherwise unfeasible to access, and Bachmann et al [32] mentioned that EHR enabled researchers to identify and include all eligible patients whose interactions with health systems were electronically recorded, which increased generalizability and sample size at minimal cost. However, a few studies shared concerns about the inclusion of ineligible participants or exclusion of eligible participants owing to artifacts, errors, and misclassifications in EHR [22,32,35].

For studies that incorporated EHR in their interventions, Ali et al [40] mentioned the advantage of EHR to "integrate different intervention components of complex interventions," and Zhang et al [25] mentioned that EHR systems enabled real-time monitoring and reviewing of patients' health data by health providers. For limitations, by contrast, Were et al [23] argued that the lack of complete and high-quality data in EHR systems prohibits relevant, timely, and accurate clinical decision support. The server breakdown in the study by Puttkammer et al [42] represented a general concern about potential technical glitches of EHR, which could lead to risks of discontinuity of interventions.

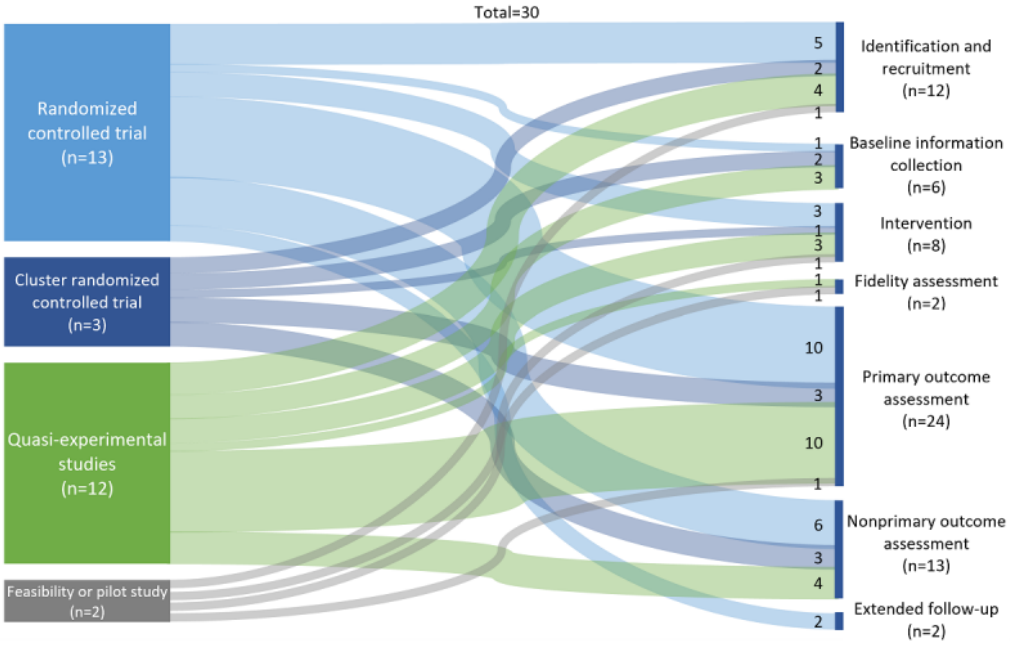
For studies that used EHR for outcome assessment, an important strength was that it was more time saving than conventional outcome research approaches, for which databases and patient registries are often fragmented and limited in the number of patients [26]. However, numerous limitations were documented, particularly concerning data quality. These limitations included inaccuracies, misclassifications, and incompleteness, which were evident in various aspects, including the use of EHR for participant identification, recruitment, baseline information collection, and interventions [35,37,45]. Data quality issues were emphasized in the study by Oluoch [26], which observed a loss of information in the transformation process from handwritten records to EHR. However, 1 study argued that these intrinsic flaws in EHR data represented the situation of real-world care delivery and was thus valuable in its own way [45]. Four studies mentioned that not all relevant information

was available in EHR systems, which could prohibit suboptimal data analysis such as underadjustment for study confounders [36,37,42,45]. Finally, some studies mentioned that the lack of integrated EHR systems across different health facilities might cause missing information or underdetected events [37,44,46].

Roles of EHRs in Trial Designs

We further found that the roles of EHR in conducting clinical trials differed by different trial designs (Figure 3). Of the 4 types of trials, RCT covered the most steps of conducting trials that used EHR and was the only type that used EHR for "extended follow-up" [23,37]. Other than that, RCTs, cluster RCTs, and quasi-experimental studies covered the same 5 steps of conducting trials using EHR: participant identification and recruitment, baseline information collection, intervention, primary and nonprimary outcome assessment. Notably, a controlled trial without randomization [21] and a feasibility study [42] were the only 2 studies that used EHR to assess the fidelity of conducting their interventions.

Figure 3. The roles of electronic health records in conducting clinical trials by different trial designs.



Quality Assessment

The quality assessment results are presented in Multimedia Appendices 2 and 3. Less than half of the included studies were found to be of good quality (14/30, 47%), 40% (12/30) of fair quality, and 13% (4/30) of poor quality. For the 20 studies that had control groups (ie, all the RCTs, cluster RCTs, non-RCTs, some quasi-experimental studies, and 1 of the feasibility pilot studies), the most common factors that compromised the quality of the studies was the lack of prespecification of outcomes and subgroups (9/30, 30%), followed by the lack of similar baseline characteristics between groups (8/30, 27%), lack of blinding in treatment assignment (7/30, 23%) and outcome assessment (7/30, 23%), and nonreport of calculations for sufficient sample size (7/30, 23%). Of the 10 studies that did not have control groups, 7 (70%) did not have interrupted time series design, 6 (60%) did not report sufficient sample size, and 5 (50%) had suboptimal representativeness of the participants to the target population.

Discussion

Summary of Principal Findings

We synthesized our findings on the use of EHR for conducting clinical trials in LMICs into a framework that depicts the typical life cycle of a clinical trial. The EHRs were primarily used for eligible participant identification or recruitment, trial outcome assessment, and intervention implementation in LMICs. The limited use of EHR was documented for participant consent, randomization, and fidelity assessment. An encouraging observation was the diversity of disease types covered in the selected studies, highlighting that EHRs have a wide appeal across various medical domains. Notably, a wide range of outcomes were assessed using EHRs in these trials, including clinical outcomes [51,52], behavioral outcomes [53,54], and health service outcomes [55].

Characteristics of EHR-Supported Trials in LMICs

The identified EHR-supported trials in LMICs were heterogeneous in terms of their targeted populations and outcomes. LMICs include, by nature, a diverse group of regions with varying population characteristics including health conditions and socioeconomic status. In general, many LMICs reportedly face challenges in terms of technological infrastructure [56], data quality, and interoperability of EHR systems, which can impact the feasibility and reliability of EHR-based trials [57]. Moreover, regulatory frameworks and guidelines for EHR-supported clinical trials have been poorly defined in some LMICs, especially for data use and security in these settings [58].

In our review, although there was a clear use of EHR in conducting clinical trials in LMICs, few of them focused on

medication. One possible explanation is that the focus of the medication-related trials is more explanatory (ie, understanding whether an intervention or medication is efficacious in an ideal setting) rather than pragmatic (ie, determining the effectiveness of interventions in real-world settings). As EHRs are usually routine health information systems rather than tools specialized for clinical trials, they are naturally more suitable for studies focusing on real-world effectiveness and implementation of an intervention but not necessarily for those focusing on intervention efficacy under strictly controlled conditions. In addition, the reported data quality issues and lack of population coverage in EHRs may also have limited their usability in efficacious studies. However, EHR can still be used to inform planning, participant recruitment, baseline statistics, and outcome extraction in medication-related trials [43]. Given that current medication development studies are primarily conducted in HICs [59], future uses of EHR may have the potential to enable more medication-related trials to be conducted in LMICs, thus increasing the representation of LMICs in study populations and geographic settings at a relatively low cost [60,61].

Challenges of Using EHRs in Clinical Trials in LMICs

There are 2 potential challenges to using EHRs in clinical trials. The first relates to possible barriers, including difficulties in accessing relevant data, linking different data sources, high financial costs, and limited familiarity with such systems [62]. The second pertains to the underreporting or exclusion of EHR information. For example, researchers may neglect the inclusion of EHR data owing to time constraints or competing priorities [63] or selectively report the EHR data that aligns with their hypotheses or desired outcomes, potentially introducing bias into the results [64]. Integrating EHR data into a clinical trial can be technically complex and time consuming [65]. Researchers may lack the resources or technical expertise to effectively integrate EHR data with the clinical trials' data set, leading to the decision to exclude or underreport it [12,66].

Another prominent observation was that almost all the included articles expressed challenges with using EHR, with some being explicit experiences and lessons. Common challenges were typically related to data availability, data quality, data interoperability, and missing data. For data availability, it meant that some relevant components to define a clinical entity were absent [37]. For data quality, the most common concern was data missingness, such as missing laboratory values in an EHR system; data artifacts were also a main concern, especially when the data were manually entered into the EHR [24]. Ultimately, the specifics of these challenges can be potentially beneficial for developing guidance on optimal EHR uses [67]. Specific to the LMICs, a tailed framework for using EHRs in clinical trials may be useful to assess the fitness of EHR for the trials [68]; using the insights from these identified challenges may be useful in ensuring the EHR selected best fits the desired need [69,70].

None of the selected studies used EHRs to collect participants' consent information and conduct randomization, which has been successfully performed in HICs. For example, the *Join Us* initiative in Australia uses the linkage of the routinely collected data including EHRs to recruit residents and collect their consent to enroll in potential clinical trials [71]. To do this in LMICs, it may be necessary to establish an updated regulatory framework for research ethics, such as the consent process for using and sharing routinely collected data and for intervention implementation. Nevertheless, obtaining informed consent for automated trials conducted using EHRs may be difficult [5]. For example, there is still debate on whether informed consent needs to be acquired when only variations of usual care are explored [72]. There are also disconnections between clinical trials that use EHRs and regulation guidelines created for traditional RCTs without the involvement of EHRs (eg, the lack of standardized requirements of institutional review boards for the use of EHRs in trials). With more examples of EHR-supported trials emerging, further research and constructive dialogues among all stakeholders are needed to alter and align the ethical norms and regulatory processes to enable more successful and accountable uses of EHRs in clinical trials in LMICs.

Notably, the quality assessment of the included trials indicated that a substantial portion of the studies did not meet the criteria for good quality. The lack of prespecification of outcomes and subgroups, for example, emerged as a notable issue, which may lead to outcome reporting bias and ambiguity in result interpretation. Other major issues included the absence of comparable baseline characteristics between the treatment and control groups, inadequate blinding, lack of considerations for sample size sufficiency, and lack of control groups. On the one hand, these commonly identified shortcomings revealed the exploratory nature of many of the included EHR-supported trials in LMICs, which needs to be addressed in future efforts to enhance rigor and credibility. On the other hand, they also implied that quasi-experimental designs, such as interrupted time series and self-controlled studies, might be the "comfort zone" for using EHRs to support future clinical trials.

Limitations

This scoping review has some limitations. First, we only focused on EHRs in clinical trials in the context of LMICs, rather than comparing the results between HICs and LMICs. Different LMICs follow different data schemas and regulatory structures, which may lead to challenges when considering generalizability. Second, we required the mention or self-tagging of EHR within the articles. This requirement likely led to a swath of missed potential articles. However, we included a wide range of synonyms of EHR in the search syntax, which should have helped address this limitation. Third, we did not test any hypothesis regarding the effect of using EHR in clinical trials, and we did not we assess the impact of using EHRs on health outcomes. Although we extracted a few characteristics that could point to the methodological quality of the studies, including the evaluation of risk of bias, we did not evaluate the intervention effects reported in the trials but merely offered a description of EHRs' roles in the trial conduct.

Conclusions

We mapped the roles of EHRs in clinical trials from the selected studies to the life cycle of clinical trials and identified opportunities to enhance the use of EHRs for clinical trials in LMICs. Specifically, the most commonly documented use was the incorporation of EHRs into clinical trials for outcome

assessment, whereas the use of EHR in collecting participant consent and conducting randomization was scarce. Efforts should be made to improve the curation of EHR data to improve data quality, explore the integration of automated processes in EHR to obtain people's consent for data use in research, and standardize regulatory frameworks for using EHR for research. Future research and practices are recommended to navigate the strengths of EHRs, such as time sensitivity and low costs, and mitigate the current challenges, such as suboptimal data quality and limited population coverage, to ensure better use of EHR in future clinical trials in LMICs. With the ongoing digitization of health information systems globally, researchers, practitioners, and policy makers are recommended to maintain continued evaluations of the availability and quality of EHRs to better understand their optimal use and unlock the full potential of EHRs for health care services and research purposes.

Acknowledgments

MT and YY are co-corresponding authors on this article. This study was financially supported by the Startup Fund for Young Faculty at Shanghai Jiao Tong University (grant BJ1-3000-22-0066), and the Science and Technology Committee of Shanghai Municipality (grant 23ZR1436400 to YY). Abstract

Background: Information overflow, a common problem in the present clinical environment, can be mitigated by summarizing clinical data. Although there are several solutions for clinical summarization, there is a lack of a complete overview of the research relevant to this field.

Objective: This study aims to identify state-of-the-art solutions for clinical summarization, to analyze their capabilities, and to identify their properties.

Methods: A scoping review of articles published between 2005 and 2022 was conducted. With a clinical focus, PubMed and Web of Science were queried to find an initial set of reports, later extended by articles found through a chain of citations. The included reports were analyzed to answer the questions of where, what, and how medical information is summarized; whether summarization conserves temporality, uncertainty, and medical pertinence; and how the propositions are evaluated and deployed. To answer how information is summarized, methods were compared through a new framework "collect—synthesize—communicate" referring to information gathering from data, its synthesis, and communication to the end user.

Results: Overall, 128 articles were included, representing various medical fields. Exclusively structured data were used as input in 46.1% (59/128) of papers, text in 41.4% (53/128) of articles, and both in 10.2% (13/128) of papers. Using the proposed framework, 42.2% (54/128) of the records contributed to information collection, 27.3% (35/128) contributed to information synthesis, and 46.1% (59/128) presented solutions for summary communication. Numerous summarization approaches have been presented, including extractive (n=13) and abstractive summarization (n=19); topic modeling (n=5); summary specification (n=11); concept and relation extraction (n=30); visual design considerations (n=59); and complete pipelines (n=7) using information extraction, synthesis, and communication. Graphical displays (n=53), short texts (n=41), static reports (n=7), and problem-oriented views (n=7) were the most common types in terms of summary communication. Although temporality and uncertainty information were usually not conserved in most studies (74/128, 57.8% and 113/128, 88.3%, respectively), some studies presented solutions to treat this information. Overall, 115 (89.8%) articles showed results of an evaluation, and methods included evaluations with human participants (median 15, IQR 24 participants): measurements in experiments with human participants (n=31), real situations (n=8), and usability studies (n=28). Methods without human involvement included intrinsic evaluation (n=24), performance on a proxy (n=10), or domain-specific tasks (n=11). Overall, 11 (8.6%) reports described a system deployed in clinical settings.

Conclusions: The scientific literature contains many propositions for summarizing patient information but reports very few comparisons of these proposals. This work proposes to compare these algorithms through how they conserve essential aspects of clinical information and through the "collect—synthesize—communicate" framework. We found that current propositions usually address these 3 steps only partially. Moreover, they conserve and use temporality, uncertainty, and pertinent medical aspects to varying extents, and solutions are often preliminary.

KEYWORDS

summarization; electronic health records; EHR; medical record; visualization; dashboard; natural language processing

Introduction

Background

Summarization is an essential element of human cognition and consists of taking a set of information and retaining the pertinent elements to take action [1]. Feblowitz et al [2] defined information summarization in the health care context as "the act of collecting, distilling, and synthesizing patient information for the purpose of facilitating any of a wide range of clinical tasks." This definition translates as simplifying the presented information so that health care professionals (HCPs) can act more smoothly and efficiently in different clinical situations.

Automatic summarization of information in electronic health records (EHRs) can serve as a solution for information overload [3], a widespread problem in health care when the presented data are too much to be efficiently processed in a care situation. Information overload can have detrimental effects on patient care in the form of professional stress, fatigue, delays, and medical errors [4]. Although the phenomenon is not novel, it is increasingly present owing to an aging population with an exponentially increasing presence of chronic diseases, increased administrative burden, overabundance, and suboptimal storage of medical data [5,6]. Furthermore, current EHR systems present information in a fragmented manner [7] with widespread repetition, copy-pasting [8], and details not relevant to clinical care [9].

Despite the need for automatic patient information summarization, there is no widely accepted theory or methodology. This report aimed to synthesize the contributions of patient information summarization scattered in the literature. Scoping review is the chosen form with the aim of mapping ideas, mapping concepts related to the question, and identifying knowledge gaps.

The review is not unprecedented: in their narrative review, Pivovarov and Elhadad [10] already summarized the most important contributions to clinical summarization in 2015. Moreover, there have been several published studies surveying the literature in related fields, including the summarization of biomedical literature [11,12], the summarization from medical documents [13], neural natural language processing (NLP) in EHRs [14], named entity recognition, a type of information extraction and NLP technique, free-text clinical notes [15], automatic clinical documentation [16], the visualization of medical information in the clinical context [17-20], the visualization of intensive care unit (ICU) data [21], and the visualization of trends in medical data [22]. The latter reviews, although exhaustive in their specific scope, do not permit the identification of state-of-the-art summarization methods for HCPs. For example, it is difficult to state the current state of research for the management of uncertainty and time in clinical summarization. Moreover, they did not provide any informed guidelines for clinical summarization.

Objective

This review, building on a broader scope of articles than the combination of all the previous studies, systematically evaluates where, what, and how medical information is summarized; whether summarization conserves temporality, uncertainty, and medical pertinence; and how the propositions are evaluated and deployed.

On the basis of cognitive science literature, this review also proposes a novel "collect—synthesize—communicate" framework to compare studies on how they contribute to clinical summarization.

Methods

Overview

The methodology was designed to process a broad scope of articles; hence, different search strategies were combined to diversify the sources. Two reviewers agreed on the selection method: 2 databases with a clinical focus were searched with similar queries and the retrieved articles were filtered by one of the reviewers according to their titles and abstracts. The same reviewer read the remaining reports in the full text and selected them according to the inclusion and exclusion criteria. The same filtering was then carried out on citations within these articles and the citations of these articles. The reporting was done using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [23], and a checklist is provided in Multimedia Appendix 1.

The 2 databases searched in this review were the Web of Science Core Collection and PubMed as they contain a broad scope of articles in the medical field and are less inclusive of other articles in computer science, not related to the medical or scientific domain.

The search query for Web of Science was designed as a combination of 2 parts: capturing the summarization process and capturing the health care content. An iterative process was used to define the exact search term, where the gain of adding a keyword was examined by determining whether the first 5% (sorted by relevance defined by Web of Science) of the results from a query containing the new word but excluding the previous words shows any relevant article. This led to the following query: "ALL=((‘ehr’ OR ‘emr’ OR ‘health’ OR ‘patient’ OR ‘medical’ OR ‘hospital’ OR ‘healthcare’) AND (‘summarization’ OR ‘summarisation’ OR ‘summarizing’))" searching in the title, abstract, and metadata of the articles in the database, including the "keyword plus" field containing terms frequently appearing in the body of an article but not mentioned in the title or abstract.

The query in PubMed was "(‘her’ OR 'emr' OR ‘health’ OR ‘patient’ OR ‘medical’ OR ‘hospital’ OR ‘health care’ OR ‘medical record’[(MeSH Terms])) AND (‘summarization’ OR ‘summarisation’ OR ‘summarizing’)." This query was almost identical to the search made in Web of Science except that

PubMed does not have a "keyword plus" field like Web of Science to search in. Instead, preindexed articles with the Medical Subject Headings term "medical records" were included in the search.

All results of the queries were imported into the Rayyan app [24], helping to organize the citations for a review article. After duplicates were removed, the abstracts and titles were scanned in this application to filter records that were obviously irrelevant to patient information summarization. The app enables highlighting specific words in the abstract with 2 distinct colors, speeding up the review process. After this filtering step, the remaining articles were read in the full text for inclusion using the inclusion and exclusion criteria detailed in the following section.

After identifying the relevant works, the list of references in the selected articles and the list of citing papers retrieved by Google Scholar were manually reviewed for titles related to the topic. These potentially relevant titles were manually added to the citation manager and further filtered by reading their abstract and eventually reading them in the full text (as with the original results). If these articles contained further (previously unseen) relevant references or citations toward them, they were also processed.

Inclusion and Exclusion Criteria

According to the inclusion criteria, all records mentioning the summarization of clinical or health data as a general goal in their abstract, proposing solutions for information overflow, or claiming to make steps for these general goals were included.

All records were excluded where the corresponding article was not available in the full text for the authors (ie, at the University of Geneva campus), as the analysis could not be conducted on these records.

As several articles do not mention the source of the data in their abstracts, an exclusion criterion excludes articles about summarizing non-EHR data (eg, summarizing research articles; not EHR). Similarly, articles developing summarization for users other than HCPs *(not for HCP)* or for contexts other than clinical applications *(not clinical)* were excluded.

As many different methods can be labeled as "summarization," only records presenting a type of overview of a patient's current or past status are aimed to be included, therefore articles proposing alerts (eg, risk scores and cues) or similar simple parameters to summarize the state of a disease or patient *(alert)* and articles proposing other remedies for information overflow than automatic summarization for information overflow *(not automatic)* were excluded.

As previous reviews analyzed articles using different aspects, a broad timeframe was aimed at the review. However, as early EHR systems were very different from current systems, and hence the concept of summarization is largely different in these systems, articles before 2005 were excluded (*<2005*). The cutoff year is somewhat of an arbitrary (but round) threshold, although contributions before this year are sporadic.

Finally, articles presenting summarization solutions only for nontextual and nonstructured data (eg, video or signal summarization; *Other data)* and review papers *(Review)* were also excluded.

Articles found relevant to the review were evaluated by one of the reviewers for several criteria chosen to answer the following questions:

1. Where is summarization performed?
2. What is summarized? How?
3. How crucial aspects of clinical information are conserved and used?
4. How are the algorithms evaluated?

Textbox 1 presents the detailed criteria. Some of these criteria were defined a priori, whereas others were shaped during the analysis process. For 1 aspect, the input data type for summarization, the analysis was carried out on a broader scope, and reports excluded by the "other data" criterion were also analyzed for this information.

Textbox 1. Criteria according to which articles are evaluated in the analysis part of this review. For some of the criteria, categories are defined a priori. For others, they are shaped during the analysis process (the ones defined a posteriori are marked with an asterisk).

General aspects

- Type of the study
  - Prototype: articles describing a summarization system or algorithm that can be evaluated. The evaluation might be present or absent from the article.
  - Evaluation study: articles evaluating summarization systems, algorithms, or current summarization processes in health care without presenting a new automatic summarization solution.
  - Recommendations: articles with theoretical contributions not being implemented.

Where are summaries needed?

- Field of application*: the medical or clinical domain where the summarization is applied. The categories are discovered during the review process.

What should be summarized?

- Source of information:
  - Single encounter
  - Multiple encounters
  - This information cannot be inferred from the text.
- Input for the summarization:
  - Structural data: a combination of numerical and categorical data
  - Textual data: free-text patient information present in electronic health record systems

How to summarize?

- The summarization method*: the categories of summarization methods are shaped during the review process.
- Presentation*: how the summary is presented to the end user. The types of presentations are shaped during the review process.
- View on the summarization problem:
  - The top-down group represents records where summarization consists of eliminating “disturbances” from all available information, that is, hiding information deemed to be unnecessary.
  - Bottom-up methods see summarization as a process of finding the most salient information available and building a summary from it.

Aspects to be conserved during summarization

- Temporality*: if and how temporal information is conserved and used during summarization. The categories are shaped by the discoveries in the scoping review.
- Uncertainty*: if and how the uncertainty of information is represented during summarization. The categories are shaped by the discoveries in the scoping review.
- Medical knowledge*: if any medical knowledge is included in the design of the summarization system or during summarization. The categories are shaped during the review process.

What is a good summary? Evaluation and deployment

- Evaluation*: the method of evaluation. The types are shaped according to the discoveries from the review process.
- Deployment: if the summarization system was deployed in real clinical settings

Collect—Synthesize—Communicate Framework

During the analysis, we developed a new framework to compare methods of how they summarize clinical information. Following the definition presented in the introduction [2], the model divides the summarization process into an ideally sequential process of information collection, information synthesis, and summary communication. Information collection refers to the extraction of information from raw data, synthesis describes the selection and eventual transformation of the retrieved information, and communication refers to the representation of the synthesized information in a human-digestible format.

This view was consistent with that of several sources of cognitive psychology. For example, Johnson [25] describes summarization as a sequence of prerequisites for summarization (including comprehending individual propositions of a story,

establishing connections, identifying the consistent structure of the story, and remembering the information), information selection, and formulating a concise summary. This is also similar to the view presented by Hidi and Anderson [26], who discussed selection, condensation, and transformation.

Nevertheless, the few theoretical studies on clinical summarization have slightly different views on the process. Feblowitz et al [2] described clinical summarization as a process of aggregation, organization, reduction, transformation, interpretation, and synthesis. Jones [27,28] describes textual summarization as a process of interpretation, transformation, and text generation. Although these theories mention seemingly different steps for summary creation, they can be mapped to the proposed simpler and more general 3-step framework. Table 1 presents the mapping to the present framework of these theories and some of the most commonly used summarization methods.

Table 1. Summary of how existing theoretical frameworks and most abundant summarization methods relate to the collect—synthesize—communicate framework.

Theory or method	Collection	Synthesis	Communication
Feblowitz et al [2]	Aggregation, organization, and interpretation	Reduction, transformation, and synthesis	Organization and synthesis
Jones [27,28]	Interpretation	Transformation	Text generation
Extractive summarization (eg, Liang et al [29])	N/A[a] (not covered)	Sentence selection	N/A (not covered)
Abstractive summarization (eg, Gundogdu et al [30])	Encoding	Attention mechanism	N/A (not covered)
Topic modeling (eg, Botsis et al [5])	Topic extraction	N/A (not covered)	N/A (not covered)

[a]N/A: not applicable.

Results

Overview

As shown in Multimedia Appendix 2 [31], a total of 7925 titles were retrieved from PubMed and 3641 articles were retrieved from Web of Science. After removing duplicates, 9166 records were screened by their title and abstract for inclusion criteria and 380 records were chosen for full-text reading. From these, 1 could not be accessed by the authors and 328 were excluded based on the exclusion criteria.

From the 52 articles included in the analysis, 612 records were identified as potentially relevant by their title and 175 titles were chosen to be read in the full text after screening the abstracts. From these 175 titles, 2 could not be accessed, 97 records were excluded according to the exclusion criteria, and 76 titles were included in the analysis.

Among the 128 articles remaining in the analysis, 102 titles were categorized as a prototype, 20 were categorized as evaluation studies, and 6 were categorized as "recommendations."

Fields of Application

This review identified diverse fields of application for which summarization methods have been developed. A grouping of these fields is as follows:

1. ICU (27/128, 21.1%), where recent events and vital parameters are summarized
2. *Surgery* (1/128, 0.8%) and *related anesthesiology* (5/128, 3.9%), requiring all the information related to surgery to be summarized
3. *Diagnostics*, showing findings from one or several diagnostic sessions and including radiology (19/128, 14.8%), out of which 5.5% (7/128) were presented as a solution in the MEDIQA 2021 summarization task [32], ultrasound (2/128, 1.6%), prostatectomy (1/128, 0.8%), and laboratory data management in a clinical context (1/128, 0.8%)
4. Hospital care (9/128, 7%), where information related to a hospital stay requires efficient summarization
5. Chronic disease monitoring including diabetes (4/128, 3.1%), HIV (1/128, 0.8%), chronic obstructive pulmonary disease care (1/128, 0.8%), cardiology (2/128, 1.6%), nephrology (1/128, 0.8%), and monitoring of multiple chronic diseases (4/128, 3.1%), where salient events and information during a complex and long-lasting disease are required
6. Oncology (5/128, 3.9%), where the main events and elements of complex treatment are summarized
7. Drug prescription (3/128, 2.3%), where pharmaceutical history is summarized
8. Other medical environments included psychotherapy (3/128, 2.3%), opioid misuse treatment (1/128, 0.8%), general practice (2/128, 1.6%), emergency room (2/128, 1.6%), older adult care (2/128, 1.6%), and maternal care (1/128, 0.8%).

In addition, 25% (32/128) of articles did not specify their field of application or were meant to be usable in multiple types of medical environments and domains.

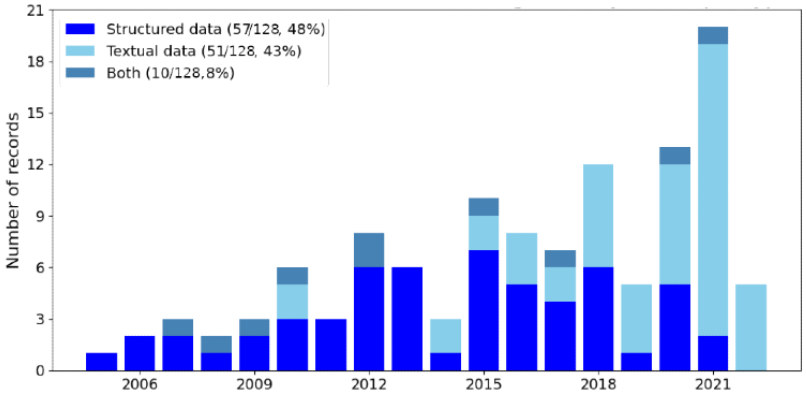
Input for Summarization

Regarding the source of information, 62.5% (80/128) of reports talk about systems summarizing single patient encounters, 27.3% (35/128) of reports explicitly talk about summarizing multiple encounters, 6.3% (8/128) of reports implicitly describe multiple encounter summarization, and 3.9% (5/128) of reports did not specify the cardinality of encounters.

Among the 128 articles in the review, 3 (2.3%) reports *do not specify the input* type for the summary, 59 (46.1%) worked only with *structured data*, 53 (41.4%) worked only with *textual data*, and 13 (10.2%) worked with *both types*. The trends in the number of articles with different input types are shown in Figure

1. Although more records use only structured data as the input type, the number of articles using textual information has shown a rapidly increasing trend in recent years. Textual information is usually assumed to be in English [33,34] and presents solutions for Finish and German languages [35,36].

Figure 1. The number of records by year of publication and the input type used in the summarization system or method presented or evaluated. Each column corresponds to a year, the different input types are aggregated into this column, their proportion for the given year is visible on the figure. ICU: intensive care unit.



A rapid analysis of the excluded articles using other types of clinical data identified the following:

1. Overall, 37 video and image sequence visualization tools in the clinical domain, mainly keyframe extraction [37,38] or motif discovery [39] methods in various fields of medicine, including older adult care, endoscopy [40], hysteroscopy [40,41], laparoscopy [42], magnetic resonance image [39,43], and ultrasound [44]
2. Overall, 20 sensory data simplification techniques using time-series analysis, motif discovery [45], and classification [46] methods for electrocardiogram or other types of signals
3. Overall, 117 articles about summarizing genomic data [47]

How Data Can Be Summarized? Summarization Methods

Common summarization methods used in the analyzed studies include (a report might use several of these) the following:

1. *Visual design* (59/128, 46.1%) organizes the information visually to help HCPs understand it within a short timeframe.
2. *Concept and relation extraction* (30/128, 23.4%): extracts semantic information from textual information
3. *Abstractive summarization* (19/128, 14.8%) [30,48-52] shortens texts by reformulating them using different wording to describe the content of a document [10].
4. *Extractive summarization* (13/128, 10.2%) [29,53] shortens texts by omitting a part of it, that is, composing a short text (a summary) from extracts of the original document.
5. *Summary specification* (11/128, 8.6%) describes the content to be presented for a summary.
6. *Pipeline extracting* information and *synthesizing and communicating* it with natural language generation tools (7/128, 5.5%)
7. *Topic modeling* (5/128, 3.9%) [54-57] categorizes documents according to their content and labels them with a list of representative words [58]
8. *Time-series analysis* (6/128, 4.7%) identifies characteristic properties in a temporal data series, including motif discovery, identifying meaningful patterns in temporal data (used in the study by Jane et al [59]), trend detection [60], or change detection [61].
9. *Dimensionality reduction* (3/128, 2.3%) treats patient data as a long vector encoding all patient information (ie, a row in a table with many columns), and reduces this information to a shorter vector (ie, a row with a much smaller number of columns) without losing too much information.

Some of these methods are intrinsic to the input data type and work only with a particular data type. For example, time-series analysis (including motif discovery), risk scores, and dimensionality reduction are intrinsic methods for structured data. Although a large number of articles using these methodologies are not included in this review as they are used by non-HCPs (eg, machine learning algorithms), some of the titles propose this approach as the first step to clinical summarization [62-64].

The most common intrinsic methods for textual data are extraction, abstractive summarization, and topic modeling.

Some of these summarization methods can apply machine learning techniques. An overview of the applied machine learning methods is presented in Table 2. The table lists all records obtained using machine learning and categorizes the records according to the summarization method and the type of machine learning method they use. Machine learning methods can be categorized into traditional machine learning methods, deep neural networks, and transformers. Traditional methods include support vector machines, random forests, and conditional random field methods; deep neural networks include deep neural networks, recurrent neural networks, and convolutional neural networks; transformers contain BART [65], BERT [66], Pegasus-based [67] methods, and pointer-generator models. In addition, Reunamo et al [34] used an interpretable machine learning technique (Local Interpretable Model-Agnostic Explanations, LIME [68]). N/A indicates that a machine learning method is not used for a given type of summarization method.

Table 2. Summary of records applying machine learning methods for clinical summarization[a].

[a]Machine learning methods are categorized into traditional machine learning methods, deep neural networks, and transformers.

[b]SVM: support vector machine.

[c]CRF: conditional random field.

[d]CNN: convolutional neural network.

[e]RNN: recurrent neural network.

[f]BERT: Bidirectional Encoder Representation from Transformers.

[g]N/A: not applicable.

[h]BART: Bidirectional Autoregressive Transformer.

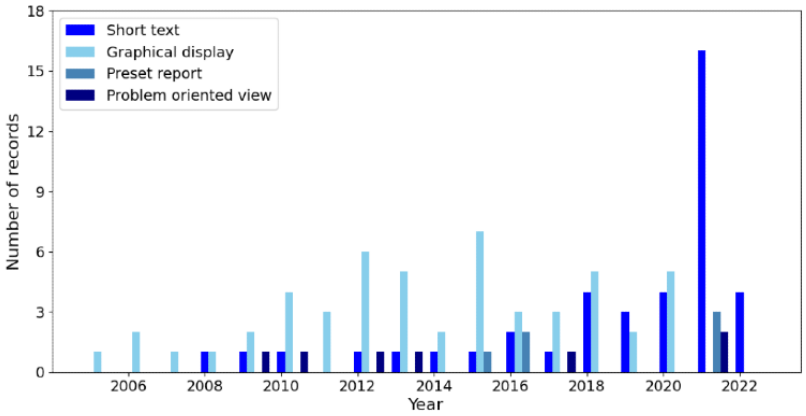
[i]GPT-2: Generative Pre-trained Transformer 2.

Summarization methods can also be categorized based on their outputs. The review identified several ways in which the summarized information is presented to the end user:

- A graphical display (53/128, 41.4%) is a specific way (interactive or not) to present information on the computer screen.
- A short textual summary (41/128, 32%) describes information in an ordinary language (eg, English).
- A preset static report: including its content designed to include specific medical information (6/128, 4.7%) or chosen statistical distributions representative of the patient (1/128, 0.8%)
- Problem-oriented view: a view grouping findings according to the problems the patient may present (7/128, 5.5%).
- Low-dimensional vector (4/128, 3.1%): encoding information n numbers (where n is the dimension) where each number represents the state of the patient from a particular aspect.
- List of words representing a topic (5/128, 3.9%), problem list (2/128, 1.6%), list of medical concepts found in the document (2/128, 1.6%), or label (2/128, 1.6%)
- A table (1/128, 0.8%) with rows and columns or a directed graph or concept map representing information in a graph-structured data model (2/128, 1.6%)
- No presentation: the articles in the "recommendation" group (5/128, 3.9%) did not present the results to the end user.

Figure 2 depicts the evolution (by the time of publication of records) of the most abundant formats for communicating the summarization results.

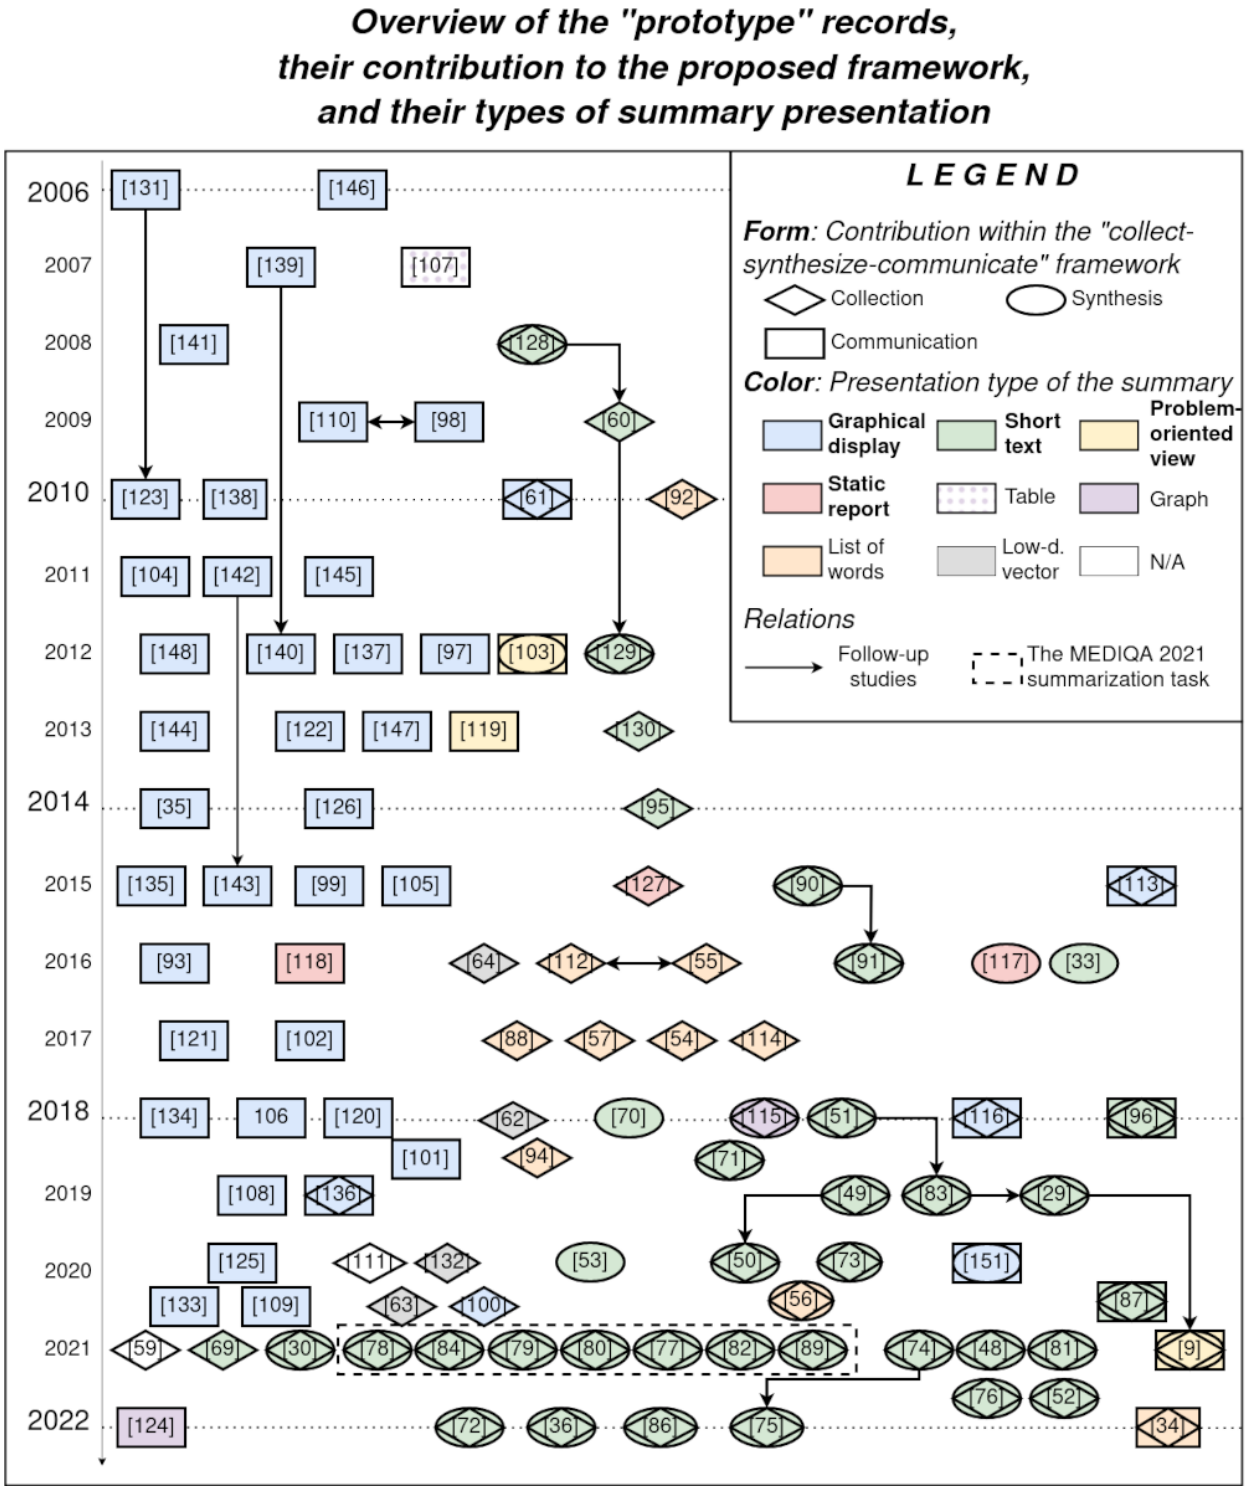
Figure 2. The number of records by year of publication and the most common ways of summary presentation used in the summarization method presented or evaluated in the report.



Concerning their view on summarization, 32.8% (42/128) of the records regarded summarization as a *bottom-up* approach and 64.8% (83/128) used the *top-down* view, whereas 1.6% (2/128) of records *do not show a clear opinion* on summarization.

Using the proposed framework, 42.2% (54/128) of the records contributed to *information collection*, 33.6% (43/128) recorded *information synthesis*, and 46.1% (59/128) presented solutions for *summary communication*. Figure 3 [9,29,30,33-36,48-57,59-64,69-84,86-149] visualizes all the analyzed prototype articles and how they fall into these categories (ie, which step of the framework is addressed within the corresponding work). The records' year of publication, presentation of summaries, and relationship between records are also displayed. The diagram has a vertical axis showing the year of publication, and all the "prototype" records (presented as a reference) published in that year appear in a line (or in 2 lines if the number of publications for a given year is very high). The order within a line has no significance, although the records were grouped within a line to show their contributions. The shape or shapes surrounding a reference symbolizes the steps that the record addresses in the "collect—synthesize—-communicate" framework. The reference to the study by Liang et al [9] is surrounded by all 3 shapes, indicating that the study addresses all the 3 steps. The records also have a color representing in which format the summaries are presented to the HCPs. Closer relationships (ie, follow-up studies) are also presented. The studies submitted to the MEDIQA-2021 challenge [21] are also marked in the diagram.

Figure 3. Diagram showing references to all analyzed "prototype" records and how they contribute to the "collect—synthesize—communicate" framework (ie, which step of the framework is addressed within the corresponding work). The records' year of publication, the presentation of summaries, and the relation between records are also displayed [9,29,30,33-36,48-57,59-64,69-84,86-149].



Regarding information collection, concept and relation extraction (50/54, 56%), time-series analysis (6/54, 11%), encoding (22/54, 41%), temporal abstraction (6/54, 11%), and topic extraction (5/54, 9%) were proposed as solutions. Medical concepts are extracted from textual data either using publicly available solutions (eg, cTAKES [164] in the study by Goff and Loehfelm [94]) or tools developed by the authors (eg, [113,114,157]). The retrieved list of concepts can be used for simpler tasks, such as problem list generation [88], or some records present systems that take a step further extracting the context [115], syntactic structure [94], or approximate semantic structure of a sentence [116] as well.

With regard to information synthesis, sentence selection by scoring (13/43, 30%), knowledge-based rules (18/43, 42%), and attention mechanism (19/43, 44%) were possible solutions.

Proposals for summary visualizations are usually features on a graphical screen; they are listed and compared in Table 3. For

unprocessed textual data, the solutions included highlighting important concepts (3/5, 60%) and creating graphs that visualize the semantic structure of the textual data (2/5, 40%).

Table 3. The number of records presenting various features for visualizations in works with graphical displays. A record can use several features.

Feature	Occurrence (out of 58), n

Variability of parameters	1

Aspects to Be Conserved and Used

In total, 58.6% (75/128) of the titles did not conserve temporal information, whereas 2.3% (3/128) of titles were agnostic to temporal information (they conserve but do not use it). The remaining articles used a variety of approaches:

- *Timeline visualization*: plotting information along a horizontal or vertical temporal axis (34/128, 26.6%).
- *Other visualizations*: showing only the trend of parameters (1/128, 0.8%) or providing a complex visualization framework in which temporal information can be displayed and analyzed (1/128, 0.8%).
- *Information extraction from the temporal domain* by analyzing how the parameters change during the patient journey. This group included a time-series analysis (6/128, 4.7%), pattern recognition (2/128, 1.6%), and change detection (1/128, 0.8%). Time-series analysis (applied in several studies) [59,60,125-127,150] extracts statistical information from the temporal evolution of one or several variables. Pattern recognition [117,128] attempts to identify meaningful patterns in temporal data. Change detection [61] seeks important events that manifest in the trends and patterns of temporal variables. Some studies have revealed the relationship between these events.
- A *theoretical model of temporal events*, which can either describe more complex interactions between temporal events (6/128, 4.7%) or be very simple (eg, creating an order: 1/128, 0.8% or describing events with a single time [n=1]).

It is worth noting that timeline visualization was applied in 3 articles in the temporal information extraction and in 1 article in the complex model of the temporality group as well.

Regarding information uncertainty, 89.1% (114/128) of the articles did not consider the uncertainty of information. Others have proposed the following solutions:

- Statistical methods were used to treat *uncertainty in data*. These methods included correcting detectable errors (3/128, 2.3% [60,79,150]) and optimizing the statistical description of the data using robust statistics (1/128, 0.8% [62]).
- *Uncertainty of temporal events*was described (2/128, 1.6%).
- *Uncertainty of statements* was described by assigning them to uncertainty categories (3/128, 2.3% [71,74,75]) or using existing ontology (3/128, 2.3%).

Medical pertinence was not conserved in 34.4%, (44/128) of the studies (ie, they had no requirements that the summary had any relation to medical concepts or knowledge). A total of 35.9% (46/128) of records used medical knowledge to specify the information to be included in the summary and with what design. Other propositions included the following:

- Using ontologies to find and relate concepts within textual notes (20/128, 15.6% [87,92,93]), the use of Unified Medical Language System (UMLS) extraction tools (6/128, 4.7%) to extract them (eg, [94-96]), or improving the performance of abstractive summarization (2/128, 1.6% [76])
- Use of risk scores to create visualizations (3/128, 2.3% [97-99]) or the application of guidelines to assess risks (2/128, 1.6% [100,101])

- The use of medically salient rules to constrain summarization (3/128, 2.3% [29,61,102])
- Evaluation of the factual correctness of the created summaries integrated into reinforcement learning (2/128, 1.6% [79,83])
- Application of medical knowledge to select pertinent information (2/128, 1.6% [103,151])
- The use of medical knowledge to construct evaluation metrics (2/128, 1.6% [81,152])

What Is a Good Summary? Evaluation and Deployment

Several types of evaluation methods and metrics are presented in the publications:

- Quantitative measurements in experiments with human participants (31/128, 24.2%)
- Quantitative measurements when summarization was performed in a real clinical environment (8/128, 6.3%)
- Interviews (7/128, 5.5%), focus groups (2/128, 1.6%), or surveys (19/128, 14.8%) asking the opinions of the users after exposure to the summarization system
- Intrinsic evaluation (25/128, 19.5%) of measuring quality by comparing the results to a ground truth
- Performance on a proxy task (ie, disease prediction; 10/128, 7.8%)
- Performance in identifying human-annotated concepts (9/128, 7%) or topics (2/128, 1.6%)

The distribution of the number of human evaluators is shown in Multimedia Appendix 3. Two records [119,173] used significantly more evaluators than other solutions, which are represented as 2 distinct groups at the tail of the histogram. One of these records [173] is a large-scale survey, whereas the other [119] is a pilot study measuring user performance.

Although some records present several evaluation techniques, in 9.4% (12/128) of the articles, no evaluation is presented; in 1.6% (2/128) of articles, the evaluation is not detailed; and in 4.7% (6/128) of records, the evaluation consists of a subjective evaluation carried out by the authors of the article.

The metrics used in the evaluations are as follows:

- *Performance metrics* (eg, precision, recall, and *F* score) on a *prediction/classification task* measuring the "goodness" (validity) of predictions or classifications (used both in usability experiments and formative evaluations; 11/128, 8.6%)
- *Performance metrics* (eg, accuracy) of human participants (ie, the validity of their decisions) on an *experimental task* (24/128, 18.8%)
- *Time savings* due to summarization systems: *time to completion* (*ie, the time needed to perform a predefined task*) in experiments (21/128, 16.4%) or time saved during patient visits (1/128, 0.8%) in deployed systems
- *Patient outcome metrics* (6/128, 4.7%) included mortality and hospital readmission rates.
- The *NASA-TLX score* describes the workload of the user (5/128, 3.9%) and the relationship between the NASA-TLX score and error count (1/128, 0.8%).
- *Number of interactions* (eg, click and screen change) in usability studies (3/128, 2.3%)
- *Grades* given by human evaluators measuring the utility and usability of a system (13/128, 10.2%) or trust in it (1/128, 0.8%).
- Scores comparing textual summaries with properties of the input text. These scores included *Recall-Orientated Understudy for Gisting Evaluation (ROUGE)* [153] (20/128, 15.6%), *bilingual evaluation understudy* [154] (2/128, 1.6%), and *comparison between* input and output *distributions*(2/128, 1.6%).
- *Other properties of the output textual summaries* including *readability/fluency* (10/128, 7.8%), *accuracy* or *factual correctness* (5/128, 3.9%), *completeness* (7/128, 5.5%), and *overall quality* (7/128, 5.5%) in qualitative evaluations of textual outputs. Two (N=128, 1.6%) records distinguished between ontological and nonontological correctness.
- *Proxy measures for the faithfulness* of textual summarization (6/128, 4.7%)
- *Heuristics* derived from requirement specification (5/128, 3.9%)

The evaluation metrics used in quantitative evaluations usually depend on the method of summarization; for dimensionality reduction, it is often a performance metric to predict diseases; for extractive and abstractive summarizations, the ROUGE score [153] is the most commonly used metric, as it is considered the most reliable [32], and for topic modeling, it is its empirical likelihood [174].

For text summarization, evaluations with human participants are often carried out by annotators subjectively grading each produced summary along some metrics, including readability, factual correctness, and completeness. For other summarization methods, this task is usually approximated by either usability tests [134-139] or experiments [140-147] where performance and workload are measured. The few systems deployed in clinical settings are often evaluated by measuring patient outcomes or clinical indicators.

Reviewing the results of each report, some records compared the results with summarization methods in the general domain [48], and 6 (5%) [30,32,50,75,78,144] presented a comparison of clinical summarization methods. The distribution of cross-citations between articles, that is, the number of other publications appearing in the review cited by each report, is represented in Multimedia Appendix 4. Furthermore, 80% of the records cited fewer than 3 other articles analyzed in this review.

Among the 128 records analyzed, 4 (3.1%) talked about a method deployed on a large scale, 7 (5.5%) described deployment in a pilot study, and 1 (0.7%) disclosed the code alongside the publication.

Discussion

Principal Findings

Where Are Summaries Needed in Health Care?

Publications on clinical summarization are tied to several different medical and clinical fields, mainly where quick decision-making is crucial (eg, ICU) or where a large amount of information is routinely produced (eg, oncology, chronic disease management, and hospital care).

However, some fields requiring quick decision-making (eg, emergency room environments) have seen less progress. In contrast, others where quick decision-making is less critical (eg, radiology) are covered by a relatively large number of records. This discrepancy suggests that clinical summarization can be beneficial in almost all medical fields, although the idea may not have reached all domains at the same pace. Although the previous drivers are easily identifiable, we speculate that the presence of other solutions proposed to handle information overload (eg, the study by Xu et al [85]; see the study by Hall and Walton [4] for review) can decelerate, whereas a shortage of personnel in a field (eg, radiology [155]) can accelerate adaptation.

What Should Be Summarized?

The increasing trend in both single-encounter and multiencounter summarizations suggests that both types are salient and should be used depending on the care situation.

Regarding the input for summarization, several experiments show that HCPs can act at least as accurately and in a timely manner with summarized structured [104-110,156] data or textual data [60,157] or with most information coded in these types of data [158] than using complete documentation. Therefore, the focus should be on summarizing textual and structured data when creating summaries for HCPs.

The increasing trend of using textual data for summarization might be attributed to the improvement of NLP, the improved computing power required for some NLP tasks, and the results published by Van Vleck et al [158], who claimed that a significant portion of patient information lies in clinical notes. In contrast, Hsu et al [111] challenged this hypothesis by presenting experiments to predict some clinical measures (eg, hospital readmission and mortality) using textual and structured patient information sources. They concluded that textual sources have little predictive power for the outcomes. However, their analysis might be biased by their methodology, as they use only simple syntactic metrics to describe textual information, whereas semantic information is not included in their model.

How Data Can Be Summarized?

The records analyzed in this review show myriad techniques for summarizing clinical data. Some are intrinsic to the input data type and work only with a particular data type, whereas others are not dependent on the input data type.

For textual data, the review reveals more works about abstractive summarization than extractive summarization or topic modeling combined, whereas in the general domain, topic modeling and extractive summarization techniques are the most researched [58,159]. This discrepancy suggests that despite abstractive summarization techniques being immature [160], general problems with extractive summarization, such as redundancy [161], lack of coherence [162,163], and lengthiness [163], can be problematic for clinical applications. The verdict about topic modeling is unclear. Arnold et al [112] argue that clinicians are good at interpreting topic model results, but other records using this technique do not present evaluations with human participants.

An alternative (and natural) way of organizing summarization methods is to assess how they contribute to the summarization process. Motivated by the lack of a widely accepted theory of the summarization process, this review proposes a 3-step (collect—synthesize—communicate) framework to describe the summarization process, where each step should ideally be addressed by all summarization methods.

For the information collection step, many studies assume an easily queriable information source or propose medical concept extraction from textual data as a solution. More complex information (context, syntactic, or semantic structure of statements) is extracted in only a few studies, and some works propose extracting specific aspects as information.

Concerning information synthesis, a common approach is to precisely define the content of the summary (eg, [118,165,166]) or at least its format [167]. However, these studies do not evaluate the quality of their proposition (except the study by Ham et al [119]). In contrast, some records carried out experiments on the information needs of physicians [158,168]; however, the results were not integrated into any of the reviewed systems.

Concerning summary visualizations, there is no clear opinion on whether textual or graphical summaries are preferable in the medical context. Although there is a slight dominance of graphical displays among the analyzed records, some works [169,170] argue that textual summaries lead to more accurate decisions. However, a general pattern of these works is that they compare a specific graphical display with a particular textual display, limiting generalizability. These contradictory results suggest that both formats are helpful for clinical summarization, if relevant features are present. Problem-oriented views presented in some records (eg, [120]) can include both types of display and might have other advantages, as they group all available information about patient-specific problems [171].

Concerning the view on summarization, both top-down and bottom-up approaches are justifiable in a clinical setting. However, several bottom-up approaches have been inspired by studies that use top-down approaches. One example is the recent development of techniques for identifying salient concepts in source documents for abstractive summarization. This phenomenon may be due to the natural need for accountability and interpretability, which can be achieved more easily with a bottom-up approach closer to human cognition. The need for bottom-up approaches also suggests that there is a need that summarization techniques address all 3 steps of the proposed "collect—synthesize—communicate" framework, including information collection, synthesis, and visualization.

How Are the Temporal, Uncertain Aspects of Information and Its Medical Persistence Conserved and Used?

The temporal nature of clinical data is an essential aspect of clinical reasoning [172], and a relatively large portion of analyzed records presents solutions to use this aspect of information. However, in most of these studies, this aspect was only represented as a visualization feature. Most visualizations are timeline visualizations, plotting information along a horizontal or vertical temporal axis following Plaisant et al [175], although some alternative methods exist [121-124]. Alternatively, some studies have revealed the relationship between events by analyzing how variables change during the patient journey.

Although temporality in clinical settings is believed to be more complex [172] than a series of punctual events, current solutions to clinical summarization hardly reflect this complexity. Very few studies have attempted to incorporate more temporal information by using more complex models of temporality (eg, events lasting during an interval). Complex temporal information is usually not directly available in patient records and must be deduced from the context and knowledge-based rules. This process is called temporal abstraction and was applied in previous studies [90,91,129-132,176]. Hunter et al [129,130] considered the uncertainty of temporal information by defining the beginning and end of each time interval as an interval.

Although several levels of uncertainty exist in clinical care [177], the majority of the analyzed reports do not present solutions to conserve or handle any information uncertainty.

To a lesser extent, the pertinence of medical knowledge has been overlooked by many summarization approaches. Many records do not consider medical pertinence or use it only for some design considerations. However, the few records that handle this aspect of medical data provide a relatively wide range of solutions to constrain the resulting summaries. In most cases, these constraints are relatively weak; for example, concepts are assumed to be part of a specific medical ontology. This is obviously the case for concept extraction tools, but the records using reinforcement learning approximate factual correctness using this approach as well.

Deeper integration of medical knowledge is only present in works using medical rules to select salient information and in the 2 works using medical rules to create summaries. Liang et al [9] used medical knowledge to create components of their proposed NLP pipeline, whereas Shi et al [102] used medical knowledge–based rules to visualize abnormalities in the human body.

How to Identify a Good Summary?

Using the definition of clinical summarization (ie, simplifying and presenting information so that HCPs can act more smoothly and efficiently in different clinical situations), the ultimate purpose of an evaluation might be to determine whether using the proposed summarization systems would improve the efficiency of HCPs.

However, such an evaluation is often unfeasible owing to the high costs and ethical issues associated with potential medical errors.

This is supported by the results, as many of the proposed evaluations are approximative solutions, and there is quasi-uniform agreement that evaluating summarization is challenging and suboptimal [168]. The spectrum of these evaluations is broad, but a common trend is to carry out a qualitative evaluation using an easily calculable evaluation metric describing either the quality of the summary or its "usefulness" to perform a proxy task (ie, disease prediction).

These qualitative analyses are suboptimal. For example, one of the most common qualitative metrics, the ROUGE score, assumes a human-annotated "gold standard" summary to which to compare, but this standard may not exist given the high cost of annotation or because there are disagreements between people about what would be a "gold standard summary" [70,168]. To tackle this problem, some records [72,178] present a comparison between the semantic distribution of the input and the summary, whereas others [133,150,179] use heuristics to evaluate the results. Another problem with the ROUGE score is that even with a high ROUGE score, a summary can be very inaccurate [168]; therefore, there have been attempts to measure the "faithfulness" of summaries either by the number of medical concepts retrieved [81] or with a more complex faithfulness measure defined by Zhang et al [83].

Evaluations with human participants often complement the qualitative evaluations. Human evaluations have mainly positive outcomes (except in the study by van Amsterdam et al [148]); however, most of the evaluations are carried out on a small scale. This can explain why very few long-lasting implementations in health care have been presented in the literature.

It is also important to mention that there is very little comparison between summarization methods, and citations between records are scarce. This suggests that the research in this domain is fragmented.

These shortcomings suggest that evaluation is a weak point in clinical summarization proposals, and the lack of widely accepted evaluation metrics and methodology might be a main obstacle for research in the field.

Limitations

Methodological biases are present in selection, synthesis, and reporting. First, the number of reviewers was limited both in the selection and analysis of records, resulting in selection and synthesis bias.

Selection bias also comes from the fact that the review was carried out on works published in a scientific paper or in the gray literature, and the initial search was carried out on 2 databases that are more specific to medicine. However, several unpublished summarization solutions have been applied to current EHR systems.

Moreover, publishing bias also adds to selection bias, as there is a clear dominance of positive results in scientific publishing.

Furthermore, the applied research queries and the selection of the database are also a source of bias. Using other data sources (eg, IEEE Xplore and Scopus) might have introduced further bias to the analysis. However, including the citations and references in the review process might have reduced this bias significantly. Moreover, the queries are formulated in English; therefore, results not in English and containing non-English terms might be missed if their abstract was not translated or if they do not appear in the citation list or references in the retrieved articles. Finally, there were potentially relevant records [149,180,181], where the full text could not be read and analyzed as it was not available at the time of writing the manuscript.

Conclusions

Clinical summarization has not reached all domains at the same pace, although it is potentially beneficial in most medical fields. Two aspects, the requirement for quick decision-making and the overabundance of data, were identified as the main drivers for the development of automatic summarization methods. However, other less-evident drivers might also play a role in adaptation.

Despite this need, very few [113,119,182] scientific publications are presenting adaptation in real clinical settings, suggesting a low success rate in clinical environments.

Despite the large number and variety of propositions, hardly any comparisons exist between the solutions. This low rate is due to the difficulty in comparing the summarization methods. From a cognitive psychological perspective and to measure how the summarization methods align with the definition of summarization, this review proposes to compare these algorithms through a "collect—synthesis—communicate" framework referring to information gathering from data, its synthesis, and communication to the end user.

Only a small proportion of the current propositions address all 3 steps, and none of the most abundant methods (ie, abstractive, extractive summarization, and visual design) address them completely.

Beyond the lack of alignment of the dimensions of summarization, propositions conserve and use crucial aspects of information (temporality, uncertainty, and medical pertinence) to varying extents.

Although uncertainty is rarely considered, temporality and some medical pertinence are conserved during some presentations, but the solutions are often preliminary or lack depth in these aspects. Further research is necessary to address these issues.

Nevertheless, the main shortcoming of the current automatic summarization methods is the lack of consistent evaluation. Although there are some new proposals to evaluate the quality of summarizations more rigorously [83], further research is required to relate these metrics to human perceptions.

Acknowledgments

This work has been supported by "The Fondation privée des HUG" and the University Hospitals of Geneva. The authors would like to thank the reviewers for their valuable comments, which helped them improve the quality of the manuscript.

Conflicts of Interest

CL is the editor-in-chief of the JMI Journal, but was not involved in the process of reviewing/accepting this paper. The author have no further interests to declare.

Abstract

Background: In recent years, health data collected during the clinical care process have been often repurposed for secondary use through clinical data warehouses (CDWs), which interconnect disparate data from different sources. A large amount of information of high clinical value is stored in unstructured text format. Natural language processing (NLP), which implements algorithms that can operate on massive unstructured textual data, has the potential to structure the data and make clinical information more accessible.

Objective: The aim of this review was to provide an overview of studies applying NLP to textual data from CDWs. It focuses on identifying the (1) NLP tasks applied to data from CDWs and (2) NLP methods used to tackle these tasks.

Methods: This review was performed according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. We searched for relevant articles in 3 bibliographic databases: PubMed, Google Scholar, and ACL Anthology. We reviewed the titles and abstracts and included articles according to the following inclusion criteria: (1) focus on NLP applied to textual data from CDWs, (2) articles published between 1995 and 2021, and (3) written in English.

Results: We identified 1353 articles, of which 194 (14.34%) met the inclusion criteria. Among all identified NLP tasks in the included papers, information extraction from clinical text (112/194, 57.7%) and the identification of patients (51/194, 26.3%) were the most frequent tasks. To address the various tasks, symbolic methods were the most common NLP methods (124/232, 53.4%), showing that some tasks can be partially achieved with classical NLP techniques, such as regular expressions or pattern matching that exploit specialized lexica, such as drug lists and terminologies. Machine learning (70/232, 30.2%) and deep learning (38/232, 16.4%) have been increasingly used in recent years, including the most recent approaches based on transformers. NLP methods were mostly applied to English language data (153/194, 78.9%).

Conclusions: CDWs are central to the secondary use of clinical texts for research purposes. Although the use of NLP on data from CDWs is growing, there remain challenges in this field, especially with regard to languages other than English. Clinical NLP is an effective strategy for accessing, extracting, and transforming data from CDWs. Information retrieved with NLP can assist in clinical research and have an impact on clinical practice.

natural language processing; data warehousing; clinical data warehouse; artificial intelligence; AI

Introduction

Background

For >20 years, health data from patient care have been systematically archived in the form of electronic health records (EHRs) [1,2]. Databases have been created to gather both structured data (eg, vital signs and clinical-biological characteristics and demographics) and unstructured data (eg, textual reports of hospitalizations or visits). These large amounts of data involve multiple contributors: patients, for whom data are collected during hospitalizations or visits; caregivers, who care for the patients and collect the data; and health care institutions, which organize all operational and financial logistics involving the care and related data [3]. The first purpose of collecting these data is to broadly deliver high-quality care to patients, even if the data may be repurposed for secondary use, such as reduction in health care costs, population health management, and clinical research [1]. Human data in clinical research are intended for research purposes and limited in terms of sample size, scope, and longitudinal follow-up (ie, clinical trials or disease registries). The secondary use of EHRs allows to increase patient recruitment in trials [4] and enables access to a larger variety of clinical information for clinical research [5,6].

The rapid increase in digital data production prompted the construction of clinical data warehouses (CDWs), also known as health data warehouses or biomedical data warehouses, for the secondary use of EHRs [2]. *CDW* refers to the interconnection of disparate data from different sources, which are restructured into a common format and indexed using standard vocabularies. CDWs collect data from millions of patients treated in hospitals and can be accessed by stakeholders to analyze care situations and make critical decisions [7]. Unlike in the fields of logistics, marketing, and sales, the health care field has been slow to fully integrate data warehouses. CDWs require managing security and privacy constraints related to medical data [7]. Depending on which country houses the CDW, medical data–related policies can vary and potentially slow the construction process [8]. Data warehouses have been part of the health care landscape for decades [9], especially in the United States, where the first CDWs appeared in the 1990s. In some countries, such as France, CDWs have only been constructed more recently owing to policy constraints. At the institutional level, the use of CDWs underscores that organizations recognize the transformative potential and value of the data generated by their activity. This secondary use of data is facilitated by technological advances in artificial intelligence [10]. Among many types of data, textual data reinforce the popularity of a subgroup of artificial intelligence methods, natural language processing (NLP), which implements algorithms that can operate on massive unstructured textual data [11]. The majority of clinical information is stored in unstructured text format, and NLP allows accessing this information [12,13].

Objectives

This review aims at providing an overview of studies applying clinical NLP to textual data from CDWs. The focus of this review is to identify the (1) NLP tasks applied to data from CDWs and (2) NLP methods used for each task.

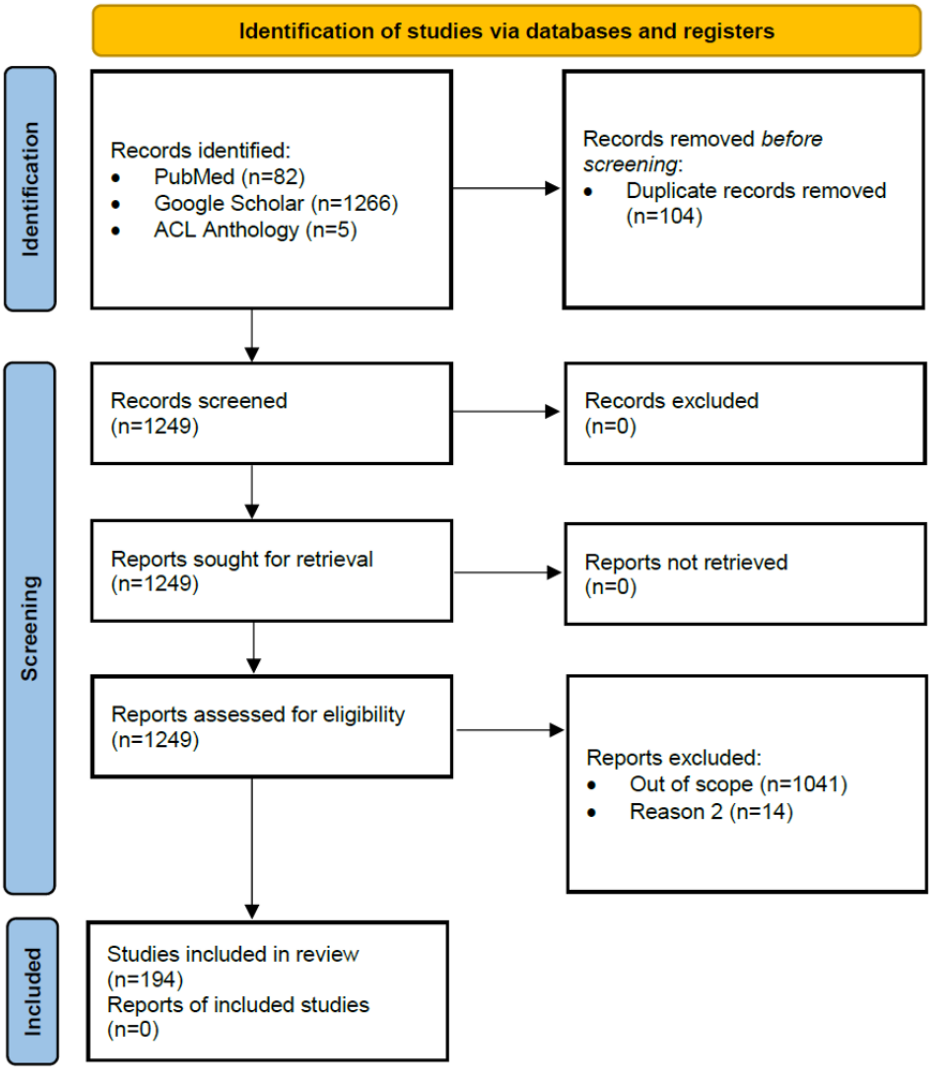
Methods

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines were followed for reporting this review (Multimedia Appendix 1).

Review Method and Selection Criteria

Articles identified from the queries were manually included on the basis of the following inclusion criteria: articles (1) mentioning the use of NLP on data from CDWs, (2) published between 1995 and 2021, and (3) written in English. The inclusion was carried out by reading titles and abstracts or by searching the article for the keywords used in the queries to determine whether it was relevant. Details of the article selection steps are described in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) article selection flowchart.



Bibliographic Databases

We searched for relevant articles in 3 bibliographic databases: PubMed, ACL Anthology, and Google Scholar. PubMed is specialized in biomedical literature; its query builder allows searchers to construct queries based on both Medical Subject Headings terms and natural language. ACL Anthology covers the literature published in conferences related to computational linguistics and NLP. Google Scholar does not have a dedicated area of specialty for the papers it references and covers a wide range of the literature.

Search Strategy

Identifying papers with NLP applied to data from CDWs involved combining multiple designations: the term *data warehouse* is sometimes referred to as a *database* or a *repository*. In addition, the source of the data used in clinical studies may only be listed in the main manuscript. Data collection requires using multiple queries to aim at both high specificity and high sensitivity.

To retrieve a representative selection of papers, we used queries based on specific keywords for each topic of interest, that is, (1) CDWs and (2) NLP:

- CDWs: “clinical data warehouse,” “biomedical data warehouse,” and “health data warehouse.” The selected keywords representing this topic correspond to the most commonly used terms for CDWs.
- NLP: “natural language processing,” “NLP,” and “text mining.” The keyword “text mining” complements the concept of the “natural language processing” keyword. Text mining stands out as the most frequently used NLP application in the medical field. As a result, the term “natural language processing” can sometimes be eclipsed by “text mining.”

Several queries were made using the selected keywords in each bibliographic database. The details of each query are available in Multimedia Appendix 2.

All queries were run on February 23, 2022. PubMed and ACL Anthology papers were retrieved by manually executing queries on the respective websites of these bibliographic databases. Google Scholar papers were collected using free software [14]. The results of the queries were merged, and duplicates were removed.

The queries are not exhaustive but rather aim to provide a limited and representative selection of papers covering the topics

of interest. Synonyms for *warehouse*, such as *database* or *repository*, were not used in the queries to avoid the collection of a significant number of irrelevant articles to review. Furthermore, some papers may also apply NLP to data from CDWs without mentioning the CDW and could be missed by the queries.

Data Collection

The following data were manually collected from the included articles: (1) NLP tasks addressed in the original paper (the NLP task classification is based on the one provided by Névéol et al [13]), (2) NLP methods used to address the tasks, (3) the CDW that is the source of the data, and (4) the language of the data used in the paper.

Results

Overview

A total of 1353 articles (PubMed: n=82, 6.06%; Google Scholar: n=1266, 93.57%; and ACL Anthology: n=5, 0.37%) were identified with the initial search strategy. After reviewing the title and abstract of each article, of the 1353 articles, 1159 (85.66%) were excluded owing to duplication (n=104, 8.97%), language issues (n=14, 1.21%), and for being out of the scope of this review (n=1041, 89.82%). Overall, of the initially identified 1353 articles, 194 (14.34%) met the inclusion criteria. These 194 articles were published between 2002 and 2021, which means that articles published between 1995 and 2001 did not meet the inclusion criteria.

This section gathers the topics covered in published research on NLP applied to data from CDWs. The results of the reviewed articles are presented by the NLP task mentioned in the articles. Although many articles address the same NLP task, we decided to not directly compare the performances of the methods used in the articles in this review. Methods have been evaluated with different data in different languages and with different metrics. Hence, we concluded that it was not relevant to perform this comparison.

Table 1 gives the count of studies based on the NLP task for 2 periods of time: 2002-2015 and 2016-2021. The 2 time periods were chosen owing to the transition in the NLP paradigm, shifting from knowledge-based to machine learning methods. This transition coincided with the emergence of new tasks, including language modeling.

Table 1. Natural language processing (NLP) tasks reported in the retrieved publications (n=194).

Information Extraction

Information extraction is one of the most studied tasks in NLP within the clinical field. In the included articles, named entity recognition (NER) primarily focuses on identifying entities such as protected health information (PHI) to deidentify clinical documents [206,207], as well as various clinical concepts. These concepts encompass diseases [20,25,40,41,45,47,49]; findings and symptoms [49,52,116-119,121]; and medication names [49,52,93-95,99,100,102,106,107,112,113,115], along with their associated details such as dose, frequency, and duration [52,93-95,112,113,115] as well as potential adverse events [96-98,100,101,106-110,114]. These medical concepts can be mapped to terminologies or ontologies such as the Unified Medical Language System (UMLS) [23,24,30,37-39,41,46,97], Systematized Nomenclature of Medicine–Clinical Terms (SNOMED-CT) [27,28,30], or International Classification of Diseases, Ninth Revision (ICD-9) [21].

Several popular NLP systems have been extensively used for extracting, structuring, and encoding clinical information from narrative patient reports in English. Numerous studies detail the application of the Medical Language Extraction and Encoding System (MedLEE) for clinical concepts [24,27-29,32-36,50,51,121] or medication [103,104,111] extraction, as well as UMLS coding. The extraction and mapping of clinical information from clinical notes to UMLS has also been accomplished using the clinical Text Analysis and Knowledge Extraction System (cTAKES) [16,17,20,22,100,129,134,168], MetaMap [31,37,38,47], MedTagger [44,45,67,78,86,105], and the National Center for Biomedical Ontology (NCBO) Annotator

[97,99,106,107,109,114]. Extracted concepts can be mapped to other standard ontologies and terminologies, such as SNOMED-CT [27]. Caliskan et al [95] evaluated the Averbis Health Discovery NLP system on a medication extraction task on German clinical notes.

Other systems addressing NER or information extraction were customized to specific use cases. Rule-based methods encoded dictionaries and terminologies to match terms and concepts in clinical texts [40-42,49,102,108,112,113]. Machine learning methods take advantage of the clinical knowledge in the large amount of data in CDWs. According to the time period, methods that were used reflect the trend of using NLP state-of-the-art methods and language models. Conditional random fields (CRFs) were used to extract clinical concepts [23,46] or PHI for the deidentification of clinical documents [207]. Hierarchically supervised latent Dirichlet allocation was applied to hospital discharge summaries to predict ICD-9 codes [21]. Deep learning approaches such as bidirectional long short-term memory–CRF (BiLSTM-CRF) [93,113,115] and recurrent neural network grammars [93] performed medical entity extraction in French clinical texts. Chokshi et al [119] compared a bag-of-words model with support vector machine (SVM) and 2 neural network models: a convolutional neural network (CNN) and a neural attention model, both with Word2Vec embedding as input. The accuracies of the CNN and neural attention model models were relatively equal, but they were higher than the accuracy of the SVM model. Lerner et al [49] compared 3 systems for clinical NER: a terminology-based system built on UMLS and SNOMED-CT, a bidirectional gated recurrent unit–CRF system, and a hybrid system using the prediction of the terminology-based system as a feature for the bidirectional gated recurrent unit–CRF system. Yang et al [206] identified PHI from free text with a long short-term memory (LSTM)–CRF model.

Recent state-of-the-art models based on transformer neural architectures [209] were also applied to extract medical concepts. Neuraz et al [52] used a BiLSTM-CRF layer on top of a vector representation of tokens computed by Bidirectional Encoder Representations from Transformers (BERT) in French. BERT and Robustly Optimized BERT Pretraining Approach were examined to extract social and behavioral determinants of health concepts from clinical narratives [15]. Some of the studies paired a neural language model with simple pattern matching techniques; for example, Jouffroy et al [115] proposed a hybrid approach for the extraction of medication information from French clinical text that combined regular expressions to preannotate the text with contextual word embeddings (embeddings from language models [ELMo]) that are fed into a deep recurrent neural network (BiLSTM-CRF).

Some of the studies (31/194, 16%) addressed specific clinical information extracted from clinical texts. These included bone density [59], breast cancer gene 1 or 2 mentions [86], the predictors and timing of lifestyle modification for patients with hypertension [60], the determination of positivity at imaging presentation in radiology reports [66], Banff classification [69], surgical site infection [70], Breast Imaging Reporting and Database System category 3 [71,72], chemotherapy toxicities [76], vital signs [79], transurethral resection of bladder tumors [80], statin use [57], human leukocyte antigen genotypes [82], unplanned episodes of care [83], smoking status [65,84], monoclonal gammopathy [90], skeletal site-specific fractures [85], and social determinants of health [66]. Methods used to extract this information were rule based [67,69-72,76,79,80,82-85], statistical [59,60], or a combination of both [86,90].

Multiple pieces of information about patients were extracted from clinical texts for application in retrospective studies [56]. Ansoborlo et al [89] extracted 52 pieces of bioclinical information from French multidisciplinary team meeting reports concerning lung cancer by applying regular expressions and then compared this approach with a Bayesian classifier method.

Extracting information from clinical text was also carried out as a prediction task. Predicted data cover length of hospital stay [73], the likelihood of neuroscience intensive care unit admission [64], the risk of 30-day readmission in patients with heart failure [55], or quality metrics for the assessment of pretreatment digital rectal examination documentation [62]. Risk assessments of diseases or pathologies, including HIV [61,81], pancreatic cancer [75], pressure ulcer [91], chronic kidney disease [63], and breast cancer [54], have also been studied as prediction tasks. Predicting this clinical information can be achieved with rule-based methods [73,81], machine learning techniques such as latent Dirichlet allocation [63,73], or a combination of both [75,91].

Context Analysis

Linguistic occurrences are particularly relevant where medical information is concerned, such as negation, temporality, uncertainty, or experiencer (ie, determine whether the identified information is related to the patient or a third party, such as a family member). In the included studies, rule-based methods were often used to detect contextual information in clinical text [178,180,182]. Although these methods offer good results (with an approximate F_1-measure value of 0.90), they rely on handmade resources, such as terminologies and regular expressions, and customization is often needed for specific use cases. Temporality patterns have been studied by Liu et al [92] to discern adverse drug events from indications in clinical text. Zhou et al [179] describe a temporal constraint structure constructed from temporal expressions in discharge summaries to model these expressions. In the clinical domain, many temporal expressions have unique characteristics, and this structure provides comprehensive coverage in encoding these expressions. Abbreviations are widely used in medicine and have been studied in French [183] and English [184] clinical texts to better handle medical abbreviations. Recent embedding-based methods such as BERT have made it easier to study negation detection [181] and text similarity [173,174]. Text similarity has also been studied to identify semantically similar concepts [175], similar patients [177], or to detect redundancy in clinical texts [172,176].

Classification

Identifying patients is a key component in clinical research for constructing population studies. NLP can improve the querying and indexing of patients and their data in CDWs. Zhu et al [161]

addressed query expansion based on a large in-domain clinical corpus to solve problems of polysemy, synonymy, and hyponymy in clinical text to improve patient identification. Query expansion was also studied through 3 methods: synonym expansion strategy, topic modeling, and a predicate-based strategy derived from MEDLINE abstracts [165]. An automated electronic search algorithm for identifying postoperative complications was evaluated by Tien et al [162]. A semantic health data warehouse was designed to assist health professionals in prescreening eligible patients in clinical trials [163,164]. A combination of structured and unstructured German data was used by Scheurwegs et al [160] to assign clinical codes to patient stays.

Downstream of the query of CDWs, NLP can be applied to identify patients or documents of interest when the classification methods offered by CDWs are not precise enough. Patient identification can be carried out using methods such as rule-based approaches, which involve using terms related to eligible criteria [127,137,140-150,153,170], or learning-based approaches [126,131,133], or a combination of both [152,155-157,169]. Li et al [166] and Chen et al [167] applied latent Dirichlet allocation in clinical notes for topic modeling. Agarwal et al [154] detailed a logistic regression model of phenotypes learned on noisy labeled data. Some of the studies (4/194, 2.1%) relied on Dr Warehouse, a biomedical data warehouse oriented toward clinical narrative reports, developed at Necker Children's Hospital in Paris, France. This data warehouse was used to explore, using the frequency and term frequency–inverse document frequency (TF-IDF), the association between clinical phenotypes and rare diseases such as the potassium voltage-gated channel subfamily A member 2 variant in neurodevelopmental syndromes [138], Dravet syndrome [125], ciliopathy [139], and other rare diseases [136].

Language Modeling

Recent word embedding–based methods take advantage of the large amount of data stored in CDWs to learn effective semantic representations of clinical texts. In the included articles, these methods allowed to make calculations on words to find, for example, similar terms in the embedding space [88,130]. Among these methods, transformer-based models, such as BERT, were fine-tuned for multiple tasks, including text classification to map document titles to Logical Observation Identifiers Names and Codes Document Ontology [159] and sequence labeling to detect and estimate the location of abnormalities in whole-body scans [53]. Similarly, clinical text was structured with the classification of ICD-9 codes based on vectorization methods [190,191].

Some of the studies evaluated the effectiveness of word embedding models on multiple tasks. Lee et al [135] evaluated Node2Vec, singular value decomposition, Language Identification for Named Entities, Word2Vec, and global vectors for word representation (GloVe) in retrieving relevant medical features for phenotyping tasks. The authors demonstrated that GloVe, when trained on EHR data, outperforms other embedding methods. GloVe and Word2Vec were used in conjunction with LSTM and gated recurrent unit and evaluated across multiple tasks, with gated recurrent unit outperforming LSTM [192]. Similarly, Dynomant et al [193] compared on multiple tasks 3 embedding methods (Word2Vec, GloVe, and fastText) trained on a French corpus. The 3 methods were evaluated on 4 tasks, and Word2Vec with the skip-gram architecture had the highest score on 3 (75%) of the 4 tasks. Peng et al [185] evaluated 2 transformer-based models, BERT and ELMo, on 10 benchmark data sets and found that the BERT model achieved the best results. BERT was also evaluated on sentence similarity, relation extraction, inference, and NER tasks on data sets from clinical domains [186]. The study by Neuraz et al [188] comparing fastText and ELMo showed that models learned on clinical data performed better than models learned on data from the general domain. The study by Tawfik and Spruit [187] described a toolkit to evaluate the effectiveness of sentence representation learning models.

Text representation models are commonly used as embedding layers in neural network models developed for specific tasks. Word2Vec has been used in numerous studies for various purposes, including assessing bone scan use among patients with prostate cancer with a CNN [151], screening and diagnosing of breast cancer with a deep learning architecture [123], extracting features used for risk prediction of liver transplantation for hepatocellular cancer with a capsule neural network [124], and using a CNN to learn the clinical trial criteria eligibility status of patients for participation in cohort studies [171]. Lee et al [194] proposed a unified graph representation learning framework based on graph convolutional networks and LSTM to construct an EHR graph representation of medical entities. Dligach et al [189] developed a clinical text encoder for specific phenotypes. Experiments were conducted with a deep averaging network and a CNN to construct this text encoder.

Resource Development and Shared Tasks

Many NLP methods rely on clinically specific resources to be developed. In the included articles, data from CDWs, combined with clinical expert knowledge, allowed the development of resources such as annotation guidelines and schemes [195,196,198], lexica [200], ontologies [199], or frameworks to validate the outputs of NLP systems [197].

International community efforts have been demonstrated through shared tasks involving clinical notes from CDWs. In the included articles, the Informatics for Integrating Biology and the Bedside (i2b2) obesity challenge focused on obesity and its 15 most common comorbidities through a multiclass multilabel classification task [204,205]. Another i2b2 challenge held in 2009 concerned extracting medication information from clinical text [202,210]. Three tasks were proposed in the fourth i2b2 or Department of Veterans Affairs shared-task and workshop challenge: extraction of medical problems, tests, and treatments; classification of assertions made on medical problems; and classification of a relationship between a pair of concepts that appear in the same sentence where at least 1 concept is a medical problem [202]. These i2b2 shared tasks relied on deidentified discharge summaries from the Partners HealthCare research patient data repository. The 2018 National NLP Clinical Challenges (n2c2) shared-task workshop presented a cohort selection task for clinical trials [203].

Previously presented NLP tasks and methods were applied to medical data in different languages, with the majority being in English (153/194, 78.9%; Table 2).

Multimedia Appendix 3 presents the CDWs used in the publications presented in this review. Overall, the oldest CDWs, such as the Columbia University Irving Medical Center CDW, Mayo Clinic, and the Partners HealthCare research patient data repository, are the ones that reuse the most textual data and contribute the most to developing the application of NLP on EHR data.

Discussion

Principal Findings

As CDWs become more prevalent and are adopted in many countries, they open up opportunities for clinical NLP to flourish. This review shows that the use of NLP on data from CDWs is primarily focused on extracting information from clinical texts and identifying patients. Depending on the task, various methods can be used, from symbolic methods to machine learning and deep learning techniques. The oldest CDWs are associated with the most numerous publications. This shows that the use of NLP is not a 1-time event but is intended to be established in the long term. It contributes to the continuous quality improvement of data made available in CDWs.

Symbolic and linguistics methods have still been widely used in recent years, despite the preponderance of deep learning approaches that have shown excellent results across a majority of tasks. This shows that some tasks can be partially achieved with classical NLP techniques, such as regular expressions and pattern matching that exploit specialized lexica such as drug lists and terminologies. Existing information extraction tools such as cTAKES, MedLEE, and MetaMap offer easy handling and satisfactory results. As a result, they are often used for processing English language clinical text.

Interestingly, the number of data languages presented in our review is quite low—only 5 languages: English, French, German, Korean, and Japanese. This can be explained by three factors: (1) CDWs are not cited as data sources in articles, resulting in a bias related to queries; (2) CDWs are operational in another country, but NLP has not yet been used on these data; and (3) CDWs have not yet been adopted in every country.

Opportunities and Challenges

Although NLP methods are becoming increasingly popular, there remain challenges within the clinical field. This review demonstrates that the use of NLP in CDWs is becoming more frequent over time. However, CDWs still rarely provide open access for NLP research owing to medical data confidentiality. A first step to partially overcome the privacy constraints could involve working on deidentified or anonymized data from CDWs, as has been done in some recent shared tasks [202,204,205,210]. These shared tasks, crucial for making advances in medical NLP research, are too scarce, particularly for languages other than English [9]. Providing an appropriate measure to respect patient privacy should encourage collaboration among hospital and NLP research teams and facilitate access to clinical data.

The global movement is toward the structuring and interoperability of clinical data; yet, the finer points of medical reasoning are always expressed in textual reports, and such information cannot always be structured. The increase in NLP approaches applied to clinical data could lead to major advances in clinical research, both to identify the populations of interest and to retrieve relevant information of these patients for clinical research. NLP could also have a positive impact on the daily life of caregivers by speeding up access to information contained in patient EHRs using automated tools for the summarization of patient history. Indeed, caregivers invest a significant amount of time recording information gathered during care delivery in textual reports. Surprisingly, they also dedicate an equivalent amount of time sifting through numerous documents to retrieve this information when needed.

Structured or semistructured data stored in CDWs provide information about patient follow-up and can serve as a valuable resource for developing or enhancing NLP systems. Indeed, temporal data can offer guidance on where the information is most relevant in the text. In addition, other data such as PHI, including names, surnames, and addresses, can be used as a starting point in NLP systems.

Clinical data are a use case for NLP research. They possess the advantage of being accessible in multiple languages owing to the global nature of medical care. This accessibility enhances research efforts focused on multilingualism. Such data are available in abundance, facilitating the acquisition of effective clinical text representations that can be applied in deep neural networks to learn relevant concept models. Clinical data fall within the category of specialized domains or languages

designed for specific purposes. They share certain properties, such as specific knowledge, uses, and discourse. This also entails undertaking specific tasks such as deidentification or anonymization.

The analysis of the literature conducted here highlights the need for further development of CDWs, with a stronger integration of NLP applications throughout the entire data value chain.

Limitations

The NLP tasks identified in this review cover only a small part of all existing NLP tasks in the general domain. These tasks globally reflect the primary needs in clinical research, such as identifying the study population and extracting clinical information for a defined population. Other tasks, such as context analysis and language modeling, have been widely studied in the general domain NLP but are less prevalent in the clinical domain. In recent years, transformer-based approaches have emerged as the state-of-the-art methods for most NLP tasks. However, this review indicates that these methods have not fully spread to the clinical domain. This demonstrates a gap between methods that are well established in the general domain NLP and their adoption in specific domains such as the clinical domain.

This review focuses on 2 very specific subjects from different emerging domains: clinical NLP and CDWs. This combination of subjects implies the use of multiple bibliographic databases and the aggregation of multiple queries to ensure good coverage of the literature. Some bibliographic databases cover a wider range of articles and include articles already present in other more specialized sources. To avoid having a surfeit of duplicate articles, we prioritized the use of the most encompassing bibliographic databases: Google Scholar and PubMed. This introduces a bias of completeness because relevant articles could be missing from the selected bibliographic databases and be present in others we did not use in this review, such as Scopus, Web of Science, and Embase.

There is another bias of completeness related to the search by keywords in the bibliographic databases. A given concept can be expressed in various ways in natural language, using different keywords. The choice of keywords is crucial to aim at both high specificity and high sensitivity, even if the selected keywords are searched in the whole paper. In this review, we used very broad keywords to have the highest sensitivity but at the expense of specificity (n=194, 14.34% relevant articles among 1353 articles identified from the queries).

Conclusions

CDWs are central to the secondary use of clinical texts for research purposes. Our review highlights the growing interest in computerized health data, particularly in clinical texts, where NLP is used to address various clinical tasks. These tasks include patient identification and information extraction, as well as clinical NLP tasks such as language modeling, context analysis, and EHR deidentification. The broad spectrum of NLP approaches has been effectively leveraged, ranging from symbolic methods to machine learning and deep learning methods. Despite the prevalence of pretrained language models in the broader NLP domain, symbolic and linguistics methods have continued to be used in recent years. In the realm of clinical NLP for CDWs, the trends align with global NLP patterns, where resources and methods are predominantly developed for the English language. The development of NLP in the medical field will require cooperation between health care and NLP experts.

A Call to Reconsider a Nationwide Electronic Health Record System: Correcting the Failures of the National Program for IT

Abstract

The National Programme for IT (NPfIT) was launched in 2005 to implement 7 nationwide IT services across the National Health Service (NHS). Despite the success of many of these designated "deliverables," the establishment of a single nationwide electronic health record (EHR) system never fully materialized. As a result, NHS medical records are now stored using a diverse array of alternate EHR systems, which frequently restricts health care practitioners from accessing extensive portions of their patients' notes. This not only limits their ability to make well-informed clinical decisions but also impacts the quality of care they are able to provide. This article assesses the medical, economic, and bureaucratic implications of an NHS-wide EHR system. Additionally, it explores how the shortcomings of the NPfIT should be addressed when attempting to introduce such a system in the future.

"The Biggest IT Failure Ever Seen" [1]

In April 2005, the NHS Connecting for Health Agency (CFH) was established to implement the National Programme for IT (NPfIT). Its goal was to propel NHS England into the 21st century by creating 7 nationwide IT services, including a secure NHSmail system and an electronic prescription service. Although many of these services have now been incorporated into everyday practice, the program's primary objective was never realized: to establish a single nationwide database of electronic health records (EHRs). Reluctance from several trusts to transition from paper-based records, along with concerns regarding delayed financial returns and data privacy, led to the NPfIT being branded as "the biggest IT failure ever seen" [1], and it was ultimately discontinued. Now, on the decennary of the program's dissolution, it is increasingly apparent that a nationwide EHR service could represent the panacea for the inexcusable inefficiencies within today's NHS.

The Status Quo

Instead of a single nationwide EHR system, NHS trusts currently have the option to choose from 40 different approved suppliers [2]. Due to economic competition, these suppliers offer limited cross-compatibility. NHS staff are well aware of the restrictions this places on the quality of health care. Oftentimes, we cannot access notes from previous admissions due to their being recorded using an alternate EHR system, nor do we have the luxury of previous laboratory results and radiographs with which to compare recent investigations. During the 12 months following April 2017, 3.9 million patients in NHS England attended more than one trust as either an inpatient or outpatient, or in accident and emergency department [3]. On over 11 million occasions, patients sought care at a trust that used a different EHR system than their previous attendance, implying that for 9.1% of all acute presentations [3], clinicians were left uninformed about their patient's recent medical history.

Following a hospital admission, general practitioners (GPs) are left with little more than a brief discharge summary from which they assimilate weeks' worth of inpatient notes. To access the results of inpatient investigations, they must first overcome administrative hurdles, and even then, detailed notes are seldom made available to GPs. Although notes can be transferred, most often via GP2GP [4] when switching primary care providers, data are notoriously "lost in translation" between different EHR systems. Furthermore, administrative delays completely preclude the transfer of EHR data in acute health care settings. Such obstacles quickly leave NHS staff feeling not unlike the protagonist of Kafka's 1926 novel, "The Castle" [5]: so disillusioned by the excessive complexity of bureaucracy that

they settle for the status quo, ceasing to seek the information they presume to be unattainable.

Creating a single national database would not only improve the quality of care for contemporary patients but also benefit generations to come. Clinical research would achieve unprecedented statistical power if physicians were granted access to the full cohort of patients registered with NHS GPs—comprising over 62 million people in England alone [6]. Although national research databases are available through the Data Access Request Service, they provide incomplete information of limited applicability and are are hindered by a thick layer of bureaucratic red tape.

Finally, the burden of manually reporting notifiable diseases and maternal deaths could be entirely avoided by automating the process within a nationwide EHR system, thereby improving both the efficiency and fidelity of MBRRACE-UK (Mothers and Babies: Reducing Risk through Audit and Confidential Enquiries) and UKHSA (United Kingdom Health Security Agency) data.

Lessons From NPfIT

The status quo of NHS record-keeping is indisputably Kafkaesque, but if we are to successfully establish a nationwide database the second time around, we must first address the NPfIT's shortcomings. The Committee of Public Accounts published a damning report outlining the reasons for the program's failure; of these, poor financial returns received the lion's share of the blame. The £9.8 billion investment had yielded just £3.7 billion out of a forecasted £10.7 billion by March 2012 [7] (£1.00 GBP = $1.27 USD at the time of writing); however, this was largely due to the reluctancy of many NHS trusts to switch to the nationwide system, with only 22 of 220 trusts joining the integrated network. Without full participation, the government not only had a weak position in negotiating licensing costs [7], but it was also unable to reap the aforementioned benefits to efficiency and service quality that come with a fully unified system. Therefore, the reported £3.7 billion is likely to represent but a fraction of the potential savings under the final system. The licensing costs for 5 years were originally quoted at £3.1 million per trust [7] (then, £682 million in total), suggesting that the majority of the costs up until the program's dissolution were one-time investments in establishing the new EHR system, in addition to the £31.5 million squandered on prematurely terminating existing contracts with Fujitsu [7]. The costs quoted are, therefore, likely to diminish alongside exponentially increasing benefits as the system is implemented throughout the NHS.

There have been concerns that granting a single provider with a monopoly on EHRs in the NHS could result in drastic price hikes and limit service quality, with critics quoting the old adage that "competition breeds innovation." This is true, but only with regard to innovations that maximize profits. By incentivizing co-operation rather than competition between developers (for example, through establishing open source software development), beneficial features would be accreted rather than credentialed as intellectual property, which Carson aptly criticizes as a "toll on the free transfer of information" [8]. In addition, there is evidence to suggest that countries with stricter market entry regulations, and thus, restricted economic competition, do not suffer from reduced quality in public or private goods and services [9].

To motivate universal participation throughout the NHS, the concerns of its employees must also be addressed; namely, the unintuitive user interface and limited functionality of all EHR systems during the early days of their development. This caused many trusts to stick with paper-based records and, as of May 2022, 27 NHS trusts had still not transitioned to digital records [10]. Although the most popular EHR systems are still considered to have suboptimal usability [11], the principal barrier today will be convincing trusts to switch from one EHR to the nationwide system, rather than phasing out paper-based systems, as was the original issue. Parenthetically, EHR system usability varies significantly between different developers [11], and as such, implementing a single nationwide system should also help to curtail geographical health care inequalities by providing a more uniform service.

The NPfIT was further criticized for failing to provide training for NHS staff on how to use the novel EHR systems, which did not initially allow clinicians to view laboratory results and other investigations within the same interface. The former issue is easily resolved by offering training to staff who are unfamiliar with the new EHR system using a platform like e-Learning for Healthcare. Conversely, the latter emphasizes the need for the nationwide EHR system to be a "one-stop shop" for all patient data. The interface should combine both primary and secondary care notes, along with investigations and imaging within a single interface, a concept which, in primary care settings, has already been demonstrated to improve cost-effectiveness, efficiency, and patient satisfaction [12].

Using a single platform to store the comprehensive medical records of an entire population does, nonetheless, bring with it a risk of massive data breaches. Accordingly, the NPfIT and its predecessors were heavily criticized for failing to establish adequate safeguards against such a scenario in which patient data would be vulnerable to surveillance by governmental and clandestine organisations. The unsettling imagery this provokes—that of an Orwellian panopticon endlessly monitoring the public's medical records—led Privacy International to present the NPfIT with a Big Brother Award for the "most appalling project" of 2004. Since then, the public has grown far more supportive of a nationwide system, with only 9.6% of participants from a 2013 study [13], and 12% of participants from a 2015 study [14], opposing the nationwide EHR system. This shift in attitudes has coincided with increasing safeguards as well as the introduction of mandatory annual training on data protection for all NHS staff. Nevertheless, a unified system should still demand further safeguards, such as limiting the access of the most sensitive sections of the record, for example, genitourinary medicine, fertility, and psychiatry, to those health care professionals directly involved in a given patient's care.

Looking to the Future

Switching to a single nationwide system will, of course, demand a massive investment of time and resources; however, should

it be attempted, it has the potential to slash NHS expenditure for decades to come. Policymakers will have to garner the support of most, if not all, 215 NHS trusts, if the system is to prove financially viable and avoid falling victim to the same shortcomings as its predecessor. Once a contract is negotiated, a firm date should be set, by which time all NHS trusts are required to phase out their current EHR system in favor of the nationwide network. Such a date should lie beyond the expiry of all contemporary contracts to circumvent the expenses associated with their premature termination, an oversight which ultimately contributed to the downfall of the NPfIT. Fortuitously, the majority of the concerns raised against the program, both by clinicians and the general public, have since been overcome. Nonetheless, e-learning modules should be introduced during the interregnum to allow health care staff to familiarize themselves with the new platform and to emphasize the importance of high-quality data entry prior to its formal introduction. The EHR system itself will have to be refined at regular intervals if it is to continue meeting the ever-evolving needs of its various stakeholders. It is essential, therefore, that a public health body be established to represent the needs of each NHS trust and to continuously re-evaluate them as part of the NHS commissioning cycle. When these are no longer being met, such an organization should present these shortcomings to developers and advocate for specific enhancements to be made to the software.

By providing NHS physicians and approved researchers with a cradle-to-grave record of all NHS patients, the nationwide EHR system would allow clinical decisions to become far better informed and, as a result, the quality of health care should also drastically improve. With consideration for the myriad benefits outlined hitherto, the Department of Health and Social Care is urged not to abandon the nationwide EHR system as Kafka did "The Castle" [5], but to see it through until clinicians and patients alike may reap these benefits for years to come.

Acknowledgments

I would like to thank my close personal friend, Pauline Gronczewska, for our engaging debates regarding the inherent inefficiencies of NHS EHR systems and, ultimately, the inspiration for this manuscript.

Abstract

Telehealth is an effective combination of medical service and intelligent technology. It can improve the problem of remote access to medical care. However, an imbalance in the allocation of health resources still occurs. People spend more time and money to access higher-quality services, which results in inequitable access to primary health care (PHC). At the same time, patients' usage of telehealth services is limited by the equipment and their own knowledge, and the PHC service suffers from low usage efficiency and lack of service supply. Therefore, improving PHC accessibility is crucial to narrowing the global health care coverage gap and maintaining health equity. In recent years, China has explored several new approaches to improve PHC accessibility. One such approach is the capsule clinic, an emerging institution that represents an upgraded version of the internet hospital. In coordination with the United Nations, the Yinzhou district of Ningbo city in Zhejiang, China, has been testing this new model since 2020. As of October 2022, the number of applications in Ningbo was 15, and the number of users reached 12,219. Unlike internet hospitals, the entire process—from diagnosis to prescription services—can be completed at the capsule clinic. The 24-hour telehealth service could also solve transportation problems and save time for users. Big data analysis can accurately identify regional populations' PHC service needs and improve efficiency in health resource allocation. The user-friendly, low-cost, and easily accessible telehealth model is of great significance. Installation of capsule clinics would improve PHC accessibility and resolve the uneven distribution of health resources to promote health equity.

Background

Combining intelligent technology with health care has become increasingly popular [1,2]. Telehealth is the remote provision of clinical health care and health administration services via information and telecommunication technologies [3]. In exploring suitable methods to meet people's increasing demands, countries are establishing intelligent medical models in telehealth to provide convenient health services [4] and solve geographical, temporal, and economic problems of accessibility to health care. Doctors use telehealth to transmit digital imaging, conduct video consultations, and make medical diagnoses. Telehealth began in the 20th century [5], with the advent of television, and has developed rapidly in the 21st century along with advancements in technology. Most people currently have access to basic devices, such as mobile phones and computers, which can be used to obtain telehealth services. With improved accessibility of health care through telehealth, individuals in rural areas and busy urban areas can often connect more easily with a provider. In the United States and the United Kingdom

[6], telehealth is a popular trend. According to the National Health Service Long Term Plan in the United Kingdom, "digitally enabled care will go mainstream" [7].

Compared with other countries, China is a late starter in the field of telehealth. In recent years, China has been committed to applying internet technology to medical services. The internet hospital is a rapidly developing, new telehealth model that is gaining wide popularity [8]. The establishment of internet hospitals could help some citizens overcome temporal and geographical barriers to accessing traditional medical services [9]. However, the issue of accessibility to primary health care (PHC) services has not been completely resolved. Owing to urban-rural differences and unbalanced allocation of regional health human resources [10], the phenomenon of inequality in health resource allocation still exists [11]. Furthermore, as the population continues to age [12] and the number of chronic diseases grows [13], the demand for health services increases every year. Researchers have found that accessibility of PHC services has been challenged by insufficient funds [14], limited-service locations [15], poverty-stricken areas, and inconvenient transportation [16-18]. The use of PHC is inefficient because people rely on doctors in higher-tier hospitals [19]. Although the internet hospital is a promising public health tool because it could significantly increase access to health care for medically underserved populations, some obstacles remain. For example, people with low digital information literacy, especially older people and children, cannot easily use internet health care. Low digital literacy remains the key barrier to accessing intelligent health systems [20,21]. In order to use telehealth, such as internet hospitals, mobile devices have high requirements [22,23]. Inadequate communication facilities hinder telehealth services [24,25] for many people in remote areas, and many older people experience barriers to using smartphones. Internet hospitals must improve applications for older adults. In addition, patients also face the problem of waiting for drug delivery after receiving remote consultation services via the internet hospital, which could cause a loss of time [26,27]. Moreover, big data is not being used well in the allocation of drug resources; the advantages of big data analysis of population characteristics and rational allocation of drug resources cannot be realized in internet hospitals.

In many cases, although internet hospitals address the problem of unbalanced distribution of health resources, the shortcomings mentioned above must be addressed to provide access to PHC services. In the near future, the application of telehealth will not only increase convenience and access to health care but also reduce costs. Telehealth services should also be more user-friendly and implement low-cost devices to facilitate remote health care services. Intelligent medical service systems should be better integrated with the traditional medical models, and internet hospitals must be upgraded to meet the needs of all members of society.

Capsule Clinics in China

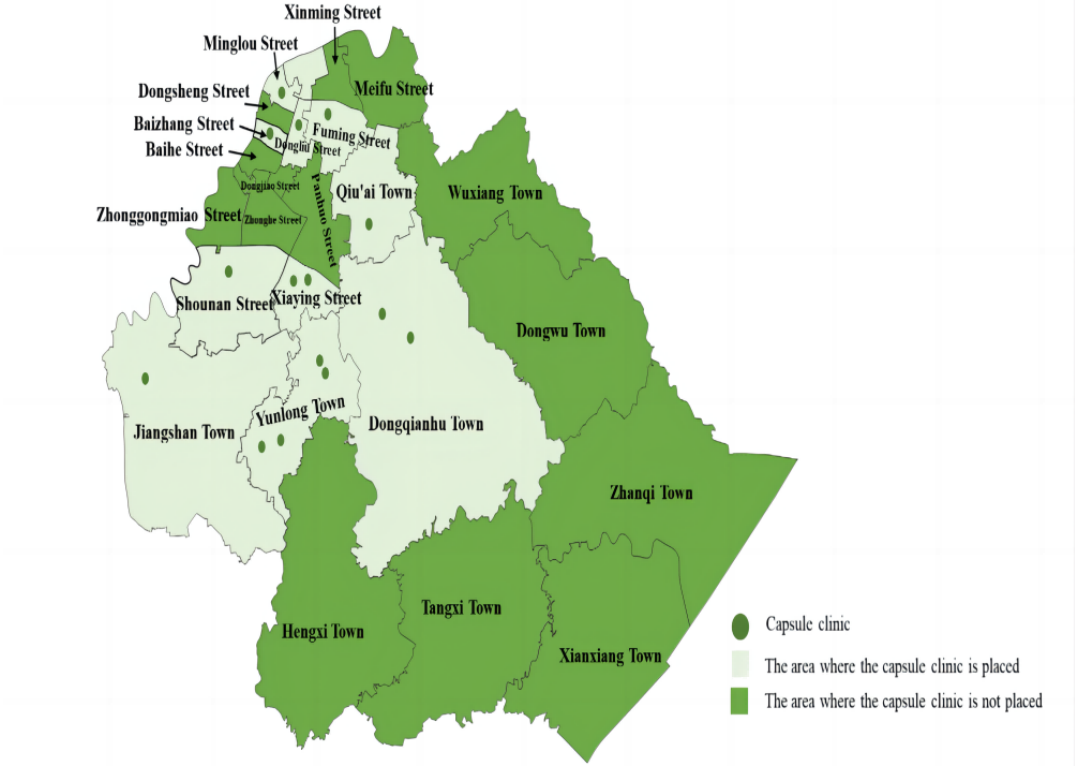
The accessibility of PHC services in China is usually considered in terms of geographical accessibility [28-30], economic accessibility, and temporal accessibility [31,32]. To that end, we propose the development of the Internet Hospital 2.0 in the era of big data, in the context of Ningbo, a city in China with an estimated population of over 9 million individuals [33]. Ningbo residents face challenges in accessing PHC services. They remain disappointed with the inconvenient primary care model and are anxious about the time and economic costs of daily medical visits, particularly during the COVID-19 pandemic. Ningbo is a coastal city that includes many islands and other remote areas. People living in remote villages or islands experience greater challenges in accessing and paying for PHC services.

In an attempt to combine the use of available public health data with the provision of easy access to health care, and toward the achievement of universal health coverage, the World Health Organization implemented a pilot project for developing a higher-quality and efficient medical and health service e-system. The Yinzhou district in Ningbo is one of the pilot locations. Yinzhou has created a specialized health service model in the Chinese context—the capsule clinic, an upgraded version of the internet hospital. The capsule clinic (20 m^2 in area) is a novel type of health service facility that began operating in 2020. It incorporates traditional medical models, including diagnosis and prescription. Capsule clinic services comprise 3 parts: health examination, consultation, and an intelligent pharmacy.

The special clinic, which relies on Zhejiang province's excellence in digital reform and Yinzhou's superior health care resources, is an emerging form of medical treatment facility that can provide residents with more convenient PHC services than those currently available. One advantage of advanced intelligent technology–based models is that they increase geographical accessibility to PHC. Capsule clinics are placed within communities to enable residents' convenient access to PHC without leaving the community. The capsule clinic offers some important advantages, such as 24-hour services, comprehensive medical services that include the entire process from diagnosis to prescription services, and efficient allocation of health resource services. The capsule clinic overcomes some of the administrative shortcomings of the internet hospital.

In recent years, Zhejiang has attached great importance to the combination of intelligent technology and medical services, allowing grassroots residents to enjoy higher-quality and inclusive PHC services. Figure 1 shows that as of October 2022, there were 15 applications for capsule clinics in Yinzhou (Figure 1). According to China's "one village, one health care room" principle, Yinzhou plans to establish over 190 capsule clinics across communities or villages and expand throughout China.

Figure 1. Distribution of capsule clinics in Yinzhou.



The Function of the Capsule Clinic

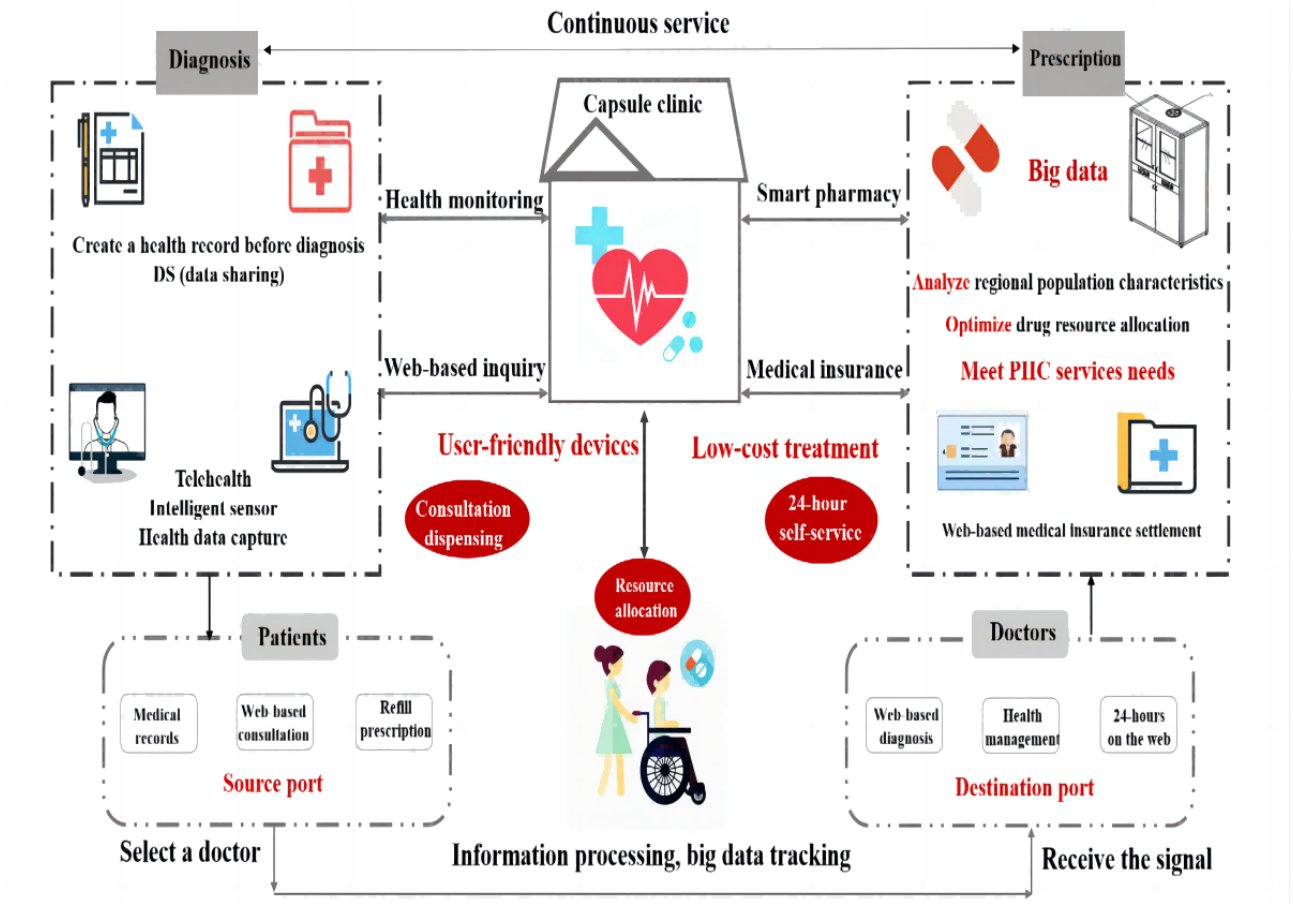
Figure 2 shows that several critical hardware and software components are included in the capsule clinic to ensure the necessary functions to meet the medical demands of residents living nearby. The capsule clinic has continuous medical services, including diagnosis and prescription, which fit the traditional medical model. Doctors can communicate with patients for remote health care consultations around the clock. Patients can access services on their own any time they need them and even gain access to essential medicine. In addition, patients can use the telehealth service of capsule clinics to consult doctors from higher-tier hospitals; this feature provides an opportunity for PHC service resources to be equitably deployed, especially for people in remote areas.

The capsule clinic, a product of the digital reform, has developed rapidly and is devoted to improving geographic accessibility to PHC. For each community, the capsule clinic will be conveniently located within 15 minutes of the community's health service center, which is responsible for the full scope of the capsule clinic. At nearby capsule clinics, people located in remote areas (mountainous areas and islands) can access health resources equal to those available to urban residents. This measure is intended to benefit the public and solve issues of not only geographic accessibility but also temporal accessibility; with the capsule clinic, people do not have to miss work or travel long distances for medical appointments.

Although some internet hospitals and telehealth centers are also available 24 hours a day, capsule clinics are more helpful to residents because they provide comprehensive services. In the past, patients received their medications within a few days after receiving a web-based diagnosis. The capsule clinic takes advantage of intelligent technology to help residents save time in receiving their medications. After completing a remote consultation with the doctor, patients can easily access the capsule clinic's intelligent pharmacy to pick up their medication. They can also refill prescriptions from offline doctors. Moreover, if further examination or tests are needed, patients can visit the higher-tier hospitals within the period determined by the capsule clinic doctors. If hospitalization is required, treatment can be transferred to the hospital, as determined by the capsule clinic doctors. The capsule system embodies the advantages of an integrated health care delivery system. It facilitates convenient access to health care and makes good use of PHC resources.

Big data analysis and artificial intelligence can assist doctors in a variety of ways, such as by detecting lesions and improving diagnostic efficiency. They also play a role in improving medical services and easing constraints on medical resources. With the deep integration of digital technology and medical measures, as well as comprehensive improvements in patients' health literacy, diversified medical and health service models can provide convenience for doctors and patients, thus improving the efficiency of diagnosis and treatment. Big data allows for systematic analysis of the relevant characteristics and medical needs of people in each region and the subsequent reasonable allocation of drug resources. For instance, in a community with a wide distribution of older or chronic patient populations, the capsule clinic would be equipped with more drugs to treat geriatric issues and chronic diseases. One benefit of a big data–based system is the reduction in medical processing time and distance, which significantly improves the efficiency and quality of the medical care provided and facilitates optimum resource allocation.

Figure 2. Main functions of the capsule clinic. PHC: primary health care.



Comparing the Capsule Clinic With the Traditional Hospital and Internet Hospital

Overview

The capsule clinic has the physical appearance and essential equipment of a traditional medical institution. It also includes 24-hour remote consultation, integrated consultation and pharmacy services, optimal health resource allocation, and health management functions. The clinic has the strong support and oversight of a traditional hospital, and offers web-based services for relatively simple problems that do not necessitate a visit to the hospital.

Digital technology will soon be deeply integrated with medical treatment and will provide important support for medical professionals' diagnosis and treatment decisions. However, the internet hospital model [34,35] still has much room for improvement, for example, in terms of medical insurance and the allocation of medical resources. With the support of big data technology, capsule clinics analyze the regional group characteristics, realize the reasonable allocation of essential drug resources, and meet the health needs of different populations. Even more importantly, capsule clinics may alleviate shortages in human resources chronically faced by primary-level medical institutions. The capsule clinic allows community residents to conveniently purchase medication 24 hours a day, taking pressure off in-person facilities. Remote consultation can also reduce pressures on grassroots medical staff and, thus, improve work efficiency. Figure 3 provides comparison of 3 medical models.

In order to understand the user experience of the capsule clinic during the implementation process, we conducted the research during November and December 2021. The research team visited communities and villages where capsule clinics were established, such as Haichuang Community, Lijia Village in Yunlong Town, and Dongfu Community in Qianhu Street, to conduct qualitative interviews with users (Table 1). Qualitative interviews collected basic user characteristics, home addresses, user acceptance of the capsule clinic, and feelings about using it. The interviews revealed that internet hospitals are different from capsule clinics, which have physical clinics and equipment, and rely on medical resources from offline hospitals. Users can not only experience the same diagnosis and prescription services in capsule clinics as in offline hospitals, but also use intelligent equipment that improves the accessibility of PHC services. As capsule clinics are physical entities, patients view them as more reliable than intangible internet hospitals. Moreover, this physicality makes them more user-friendly and greatly reduces use disparities caused by the digital divide [36-38].

Figure 3. Comparison of the 3 medical models. PHC: primary health care.

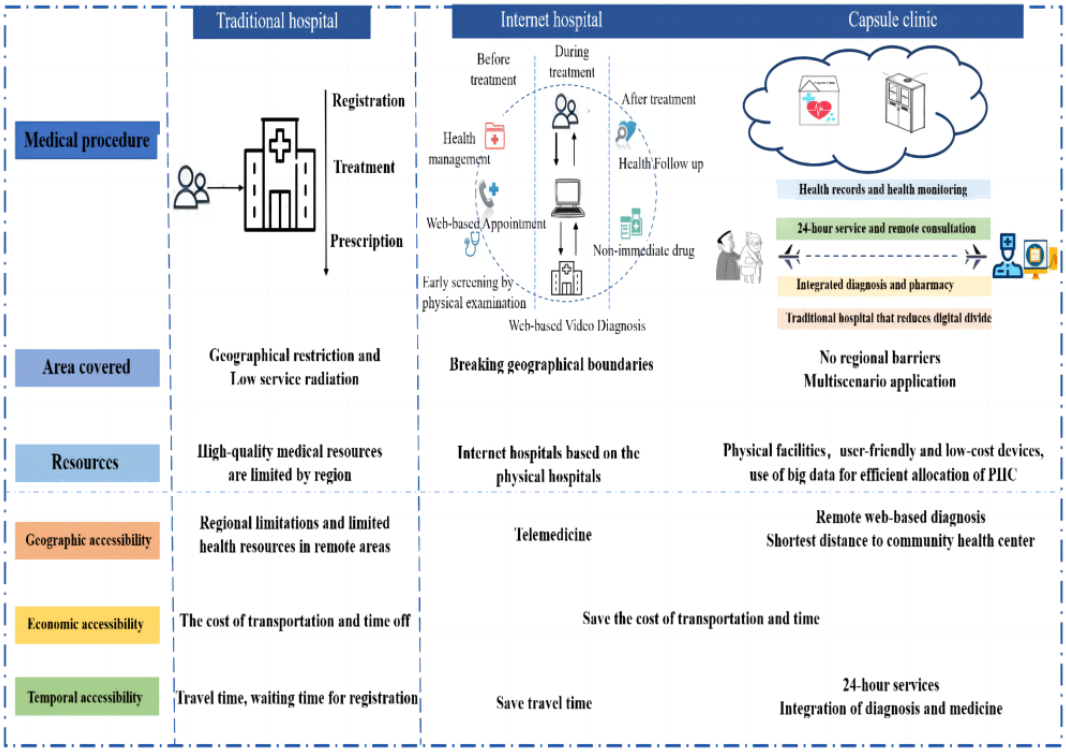


Table 1. Qualitative interviews of the user experience of capsule clinics.

Interviewee	Personal information				Interview content
	Age (years)	Gender	Address of capsule clinic	Job	
Interviewee 1	45	Female	Haichuang Community Health Service Station, Yinzhou District, Ningbo	Employee of a state-owned enterprise	“It is time-saving for me to go to the clinic after work. It is the same as the local community hospital and I can find a doctor remotely through the capsule clinic whenever I need.”
Interviewee 2	28	Male	Hefeng Community Health Service Station, Hefeng Creative Plaza, Yinzhou District, Ningbo	Employee of a foreign company	“I've used capsule clinics accessible by walking. Compared with the Internet hospital, the capsule clinic can give me the feeling of being treated in a physical hospital. I could complete the procedure of diagnosis and treatment and did not have to wait for drugs.”
Interviewee 3	50	Male	Shanglijia Village Committee, Yunlong Town, Yinzhou District, Ningbo	Factory worker	“The capsule clinic is in our village, it's like a convenience store, and I can go in and take my blood pressure when I'm walking by. I come here to take my blood pressure and use the screening program every day.”
Interviewee 4	68	Female	Zhongxing Community Health Service Station, Dongliu Street, Yinzhou District, Ningbo	Retiree	“I haven't been to the capsule clinic but I've heard about it because I'm too old to use these smart devices.”
Interviewee 5	38	Female	Party Mass Service Center of Junrui Community, Xiaying Street, Yinzhou District, Ningbo	Full-time housewife	“The capsule clinic is closer, which is more convenient than the community hospital. The common drugs that my children and older adults need can be dispensed here under the consultation of the doctor.”
Interviewee 6	35	Male	Guanying Village Committee, Yunlong Town, Yinzhou District, Ningbo	Private entrepreneur	“I like the 24-hour service of the capsule clinic, which is convenient and fast.”

Operation Process of the Capsule Clinic

The patient arrives at the capsule clinic and enters. They scan their identification or insurance card to gain access to the web-based site, where they can review their medical records, refill prescriptions, and schedule a remote appointment with a doctor. Figure 4 illustrates this flowchart of capsule clinic health care services for patients. After receiving the signal that a patient needs a consultation, a doctor from a higher-tier medical institution provides web-based medical services, including face-to-face consultation via a remote video system. Figure 5 illustrates this flowchart of capsule clinic health care services for doctors. As noted, patient prescriptions are generally filled immediately after the web-based consultation. The big data system collects the characteristics of the population in the area where the capsule clinic is located, along with past medication habits. It configures the drug resources in the intelligent pharmacy in accordance with the provided information and the doctor's advice. The available drug resources are configured to meet the needs of more than 90% of the population. Patient prescriptions are provided by an intelligent pharmacy that focuses on the community residents' demands and their physical conditions. Furthermore, if residents only want to refill medications at the capsule clinic, they can receive the same prescription with the help of web-based doctors.

Unlike the internet hospital, the capsule clinic not only provides consultation services but also supports patients' medication needs with the intelligent medicine cabinet under the approval of the offline physical clinic. This measure provides great convenience for patients with long-term drug demands due to chronic diseases. When patients complete a physical hospital visit and have qualified for web-based prescription refills, they can pick up their next refill at the capsule clinic. If patients are identified as needing further examination or hospitalization during the remote consultation, the doctor will schedule an appointment for them at the parent hospital.

The number of capsule clinic users reached 12,219 by October 2022 (Table 2). Since 2020, the number of users has shown a gradual upward trend. Most of these patients are aged between 18 and 60 years; older adults have problems using the capsule clinics owing to the digital divide. Regarding the choice of drug purchased at the capsule clinic, 94.09% of patients buy Rx (Receptor X) medication, whereas only 4.49% choose over-the-counter medication, and 1.42% visit the capsule clinic simply to use the health monitoring program. This shows that most patients use both diagnosis and treatment and medicine dispensing functions in capsule clinics. In terms of the total cost of related drugs, more than 80% of patients spent less than 300 Chinese Yuan (US $43.20) per visit. Perhaps most of the PHC needs of nearby residents can be met by the capsule clinics, where people can avail of basic diagnostic services and buy essential medicines.

Various data from the past 3 years show that the number of capsule clinics in use is increasing year by year. Residents who live nearby are curious about the new medical institutions and may try the health monitoring program when walking past. Users are very interested in the 24-hour service provided by the clinic. In addition, the low number of users may have resulted from inadequate publicity; therefore, many people, especially older adults, are afraid to try this novel medical model. Although older adults still experience obstacles to using the new intelligent medical model, the use of capsule clinics is on the rise owing to the rapid development of internet technology, the expansion of internet access facility coverage, and the facilitation of using facilities. The gap between patients' "willingness to use" and "ability to use" capsule clinics may influence the digital divide.

Thus far, based on the geographical distribution mentioned above, the capsule clinics are distributed in each residential location, which satisfies the residents' desire to avail of PHC services close to home and at any time. Compared with the distance that the residents previously had to travel to reach community hospitals, the geographic accessibility of PHC services has been largely addressed by the capsule clinics. Furthermore, the issue of economic accessibility has also been addressed as people with jobs can avoid the cost of absence for medical treatment and the cost of transportation. With the help of big data, the capsule clinic's smart pharmacy could estimate and allocate drugs in accordance with residents' medication characteristics, meet residents' medication needs, and achieve good coverage of PHC services.

Figure 4. Flowchart of capsule clinic health care services for patients.

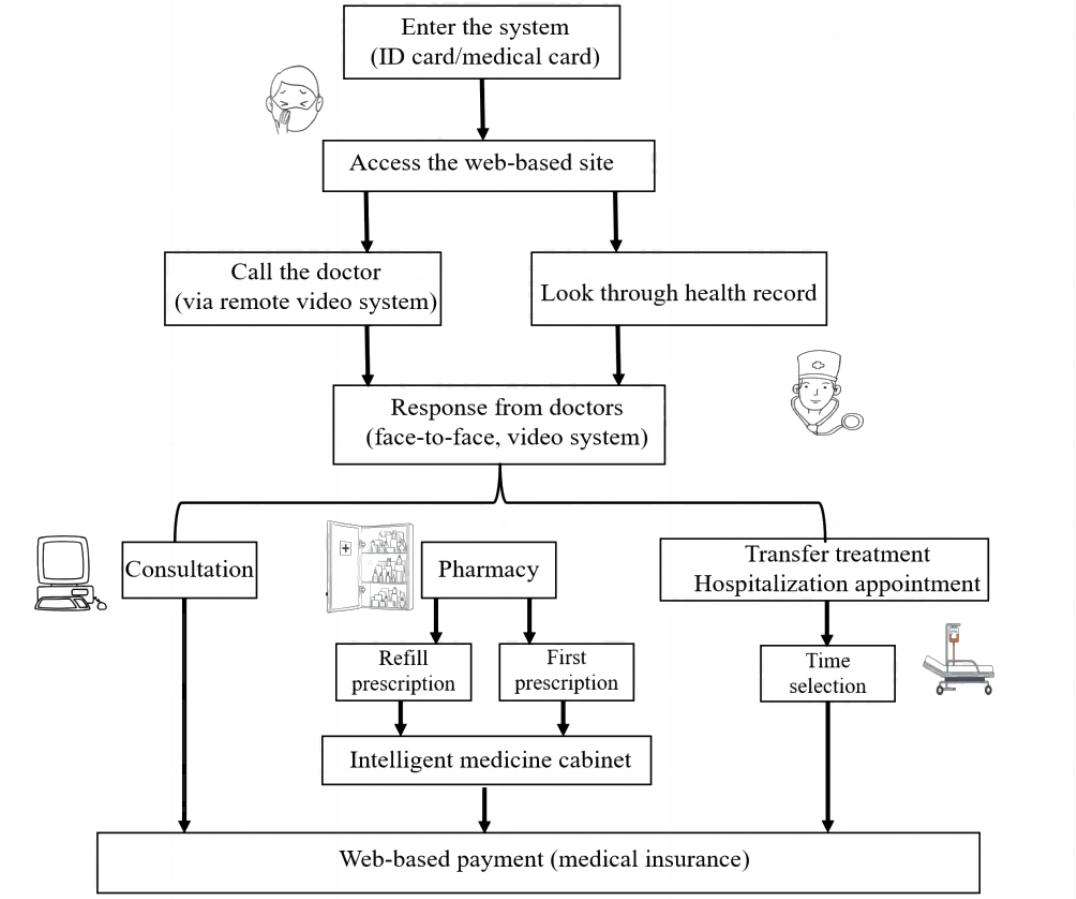

Figure 5. Flowchart of capsule clinic health care services for doctors.

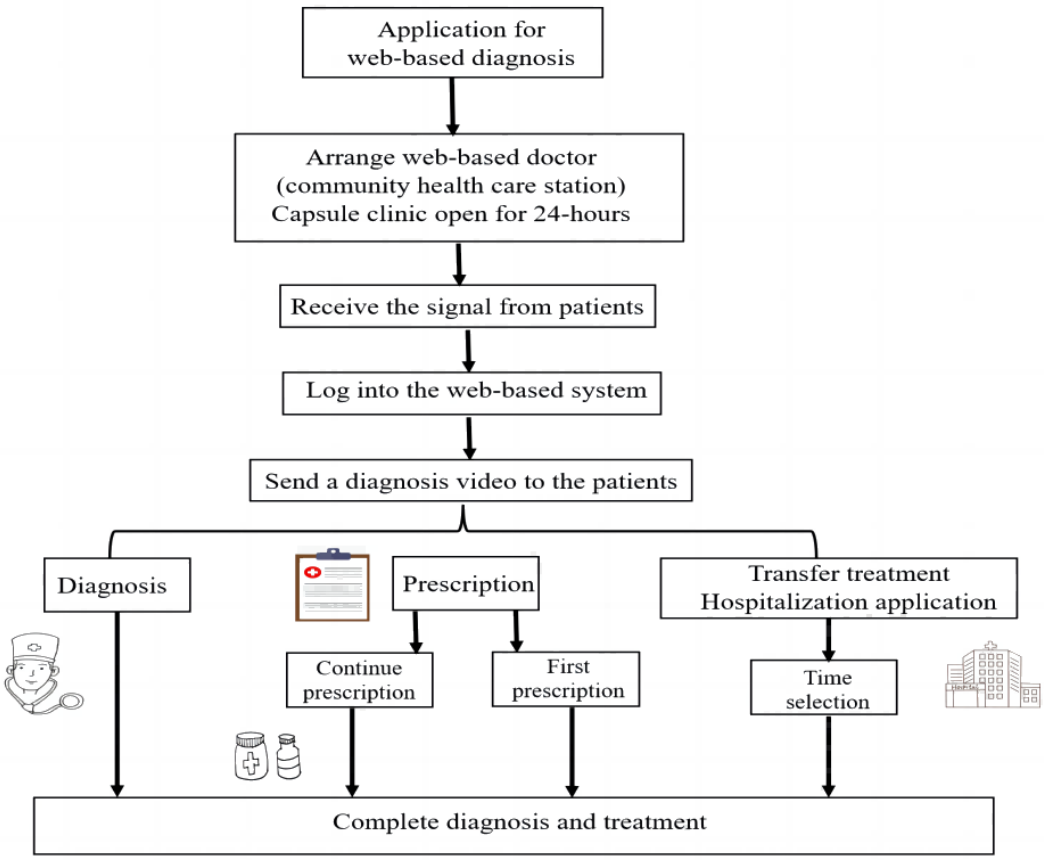

Table 2. Characteristics of patients of capsule clinics from 2020 to 2022.

Characteristics	Patients, n (%)			
	2020	2021	2022	Total
Total users	2392 (19.58)	4595 (37.60)	5232 (42.82)	12,219 (100)
Age (years)				
≤18	430 (17.98)	879 (19.13)	925 (17.68)	2234 (18.28)
18-40	874 (36.54)	1923 (41.85)	1740 (33.25)	4537 (37.13)
40-60	739 (30.89)	1168 (25.42)	1650 (31.54)	3557 (29.11)

[a]Rx: Receptor X.

[b]OTC: over the counter.

[c]No medicine: patients do not obtain medicine from the capsule clinic and only use the health monitoring system services, such as measuring blood pressure, height, weight, and other basic items.

[d]1 Chinese Yuan=US $0.14.

Routine Management and Operation

In the context of the United Nations (UN) pilot program, since the capsule clinic concept will be implemented throughout China, its routine management should be considered. The physical medical institutions (community health care stations) that have obtained the "Medical Institution Practicing License" can apply to establish a capsule clinic. The institution and application report should be submitted together to the local health administration department. Doctors from the parent institution provide remote consultations for the associated capsule clinic. Additionally, traditional hospitals (community health care centers), doctors, and the local health administration department are jointly responsible for the routine management. It is important to encourage video surveillance at capsule clinics and to incorporate procedures that ensure the traceability of drugs dispensed automatically. The physical health care center is primarily responsible for not only the unified management of capsule clinics set up by subordinate branches but also the safety of the medical services provided and the quality of the drugs dispensed at the capsule clinic. Drugs dispensed by the intelligent medicine cabinet at the capsule clinic should adhere to the wholesale drug distribution enterprises' unified procurement guidelines.

Conclusions and Limitations

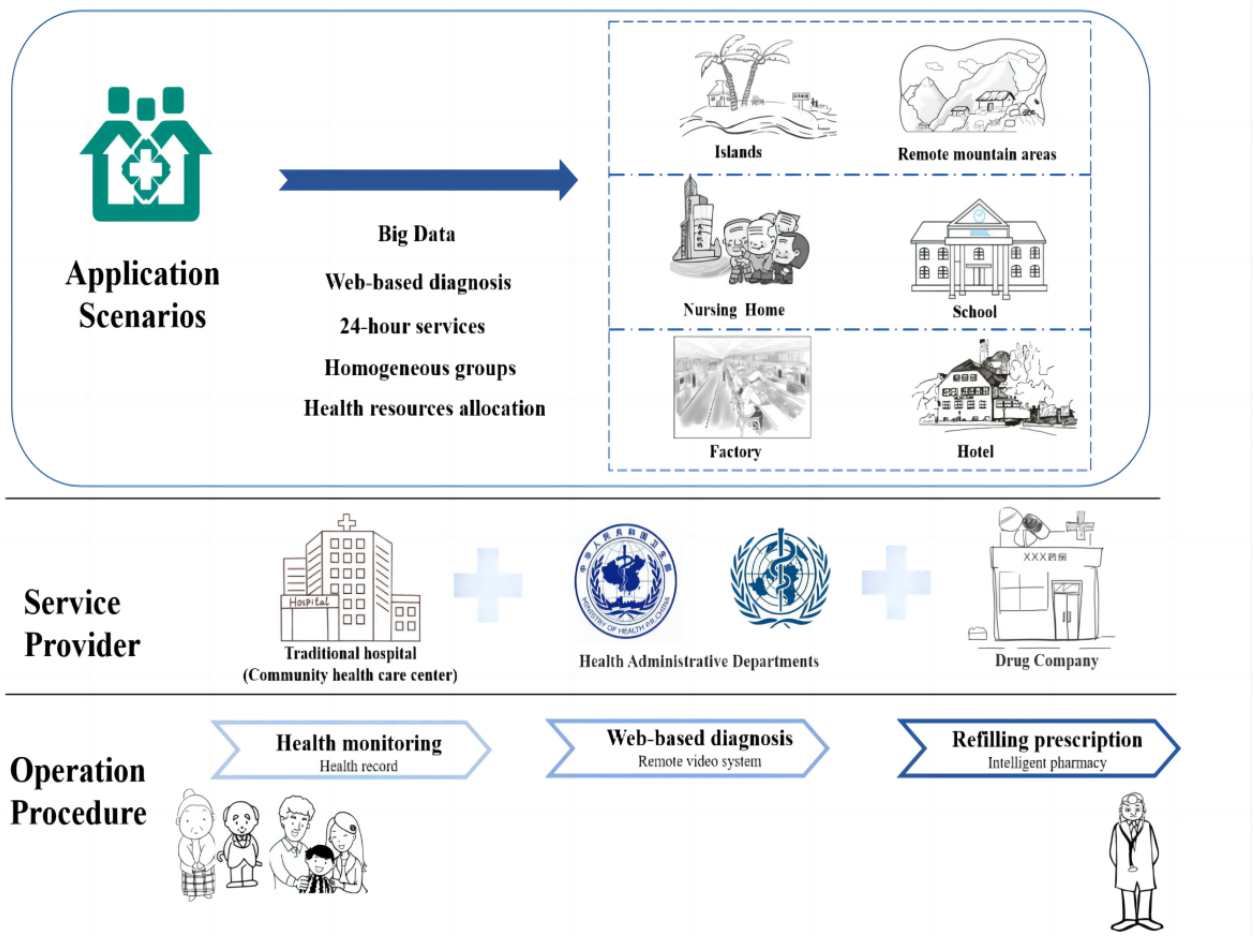
With the emergence of capsule clinics, China has a new medical model that can alleviate PHC accessibility problems. Capsule clinics are currently being promoted in every township, village, and community in Ningbo, with the goal of ensuring that every community resident has access to PHC services at their doorstep. The clinics make it convenient for people in remote areas to achieve higher-quality and equitable health resources. In the future, the UN and China will reach consensus on promoting capsule clinics nationwide and become the global template for PHC service delivery. Capsule clinics in remote areas can improve the geographic accessibility for people who lack PHC resources. Capsules can also work well in cities through the use of big data. In many cases and situations, capsule clinics can provide people with the timely PHC services they need, thus reducing financial losses.

Capsule clinics are aimed at people with both common diseases and chronic diseases, and they provide web-based follow-up services, medication disbursement, web-based medical insurance settlement, and more. With the goal of enhanced PHC accessibility, the UN and China intend to place capsule clinics in schools, nursing homes, suburbs, islands, remote mountain

areas, and other modern communities. Establishing capsules in these areas can have important effects on many populations. Figure 6 shows that the capsule clinics can be used in the future as follows:

1. Capsule clinics can be placed in remote mountainous areas and islands to increase residents' access to PHC services. In many cases, low geographic accessibility is a barrier to residents' access to effective health resources. The capsule clinic can help solve the problem. People in remote areas can receive basic health care services through telehealth. The advantages of capsule clinics, especially in terms of access to essential medicines, are greatly highlighted for these populations.
2. Capsule clinics can use big data to effectively allocate resources, accurately identify regional population characteristics, allocate appropriate PHC resources, and increase investments in the resources needed to meet the various needs of the people. As such, capsule clinics can be placed in homogeneous, crowded places such as schools and nursing homes. As a special place in the community, the school takes the safety of students very seriously, and an on-site capsule clinic can help ensure it.
3. Communities should take advantage of capsule clinics' 24-hour services. Capsule clinics could be installed in crowded locations with nighttime activity to prevent accidents and, at the same time, offer people timely treatment or access to medication. For example, factories and hotels are key places where things go wrong; an on-site capsule would allow people to seek timely medical help. Doctors are always available digitally to provide reliable advice for seekers.

Figure 6. Future application scenarios planned.



Of course, the capsule clinic has some limitations. First, data security supervision and drug use safety must be strengthened. Second, the publicity for capsule clinics is not sufficient. People seem to be unaware of this new model or have a wait-and-see attitude. Influenced by traditional health care concepts, numerous patients are more likely to use physical hospitals and are unwilling to use the capsule clinic; consequently, capsule clinic usage is still low. Third, capsule clinics in China are currently limited to urban communities in Ningbo; the single location application and scenario reflect the lack of promotion efforts.

Although the capsule clinic still has some challenges and limitations, it is meaningful in terms of developing convenient and less costly intelligent PHC treatments. People who live in remote areas such as villages and poor mountainous areas far from health care centers face barriers to accessing PHC. Telehealth needs to be enhanced in terms of user experience, and the equipment should be more user-friendly and universal. People are more likely to use smart medical treatment to improve the quality of health services on the basis of the familiar medical treatment mode. Many patients are likely to be driven into poverty by the indirect economic burden of disease. Meanwhile, with higher living standards and enhanced

conceptions of health, more and more people are demanding better health products and higher-quality health services. If we are to reach our goal of improving universal health coverage, we must commit to investing in and scaling up proven solutions. Thus, promoting capsule clinics is highly relevant. The intelligent medical industry is still in its infancy, and there is great room for improvement and sufficient potential demand. In the future, the capsule clinic may help solve fundamental imbalances in the distribution of medical resources and contradictions among the growing health care needs of the population.

Countries need to make more and smarter investments in foundational health systems, with an emphasis on PHC, essential services, and marginalized populations. We must make great efforts to ensure equal access to public health services for all.

Acknowledgments

We would like to thank Yinzhou District Health Bureau, Ningbo, for their assistance and support in the field research. This study was sponsored by The National Natural Science Foundation of China (72274141); the Zhejiang Provincial Natural Science Foundation (LY22G030006); the World Health Organization, which collaborated on a pilot project to build a high-quality and efficient health service system (GJ2-2021- WHOPO-C2); and the General Research Project of Education Department (Y202147813). The sponsors were not involved in the design and conduct of the study; the collection, management, analysis, and interpretation of data; or the preparation, review, and approval of the manuscript.

Authors' Contributions

DLL, RJZ, CC, MH, and LMS conceived and designed the study. YYH, XYW, XYZ, and QRY participated in field research. CC, RJZ, YYH, and XBZ wrote the original draft. DLL, RJZ, LMS, and XYZ substantively revised the manuscript. All authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Smart cities and digital public health are closely related. Managing digital transformation in urbanization and living spaces is challenging. It is critical to prioritize the emotional and physical health and well-being of humans and their animals in the dynamic and ever-changing environment they share. Human-animal bonds are continuous as they live together or share urban spaces and have a mutual impact on each other's health as well as the surrounding environment. In addition, sensors embedded in the Internet of Things are everywhere in smart cities. They monitor events and provide appropriate responses. In this regard, accident and emergency informatics (A&EI) offers tools to identify and manage overtime hazards and disruptive events. Such manifold focuses fit with One Digital Health (ODH), which aims to transform health ecosystems with digital technology by proposing a comprehensive framework to manage data and support health-oriented policies. We showed and discussed how, by developing the concept of ODH intervention, the ODH framework can support the comprehensive monitoring and analysis of daily life events of humans and animals in technologically integrated environments such as smart homes and smart cities. We developed an ODH intervention use case in which A&EI mechanisms run in the background. The ODH framework structures the related data collection and analysis to enhance the understanding of human, animal, and environment interactions and associated outcomes. The use case looks at the daily journey of Tracy, a healthy woman aged 27 years, and her dog Mego. Using medical Internet of Things, their activities are continuously monitored and analyzed to prevent or manage any kind of health-related abnormality. We reported and commented on an ODH intervention as an example of a real-life ODH implementation. We gave the reader examples of a "how-to" analysis of Tracy and Mego's daily life activities as part of a timely implementation of the ODH framework. For each activity, relationships to the ODH dimensions were scored, and relevant technical fields were evaluated in light of the Findable, Accessible, Interoperable, and Reusable principles. This "how-to" can be used as a template for further analyses. An ODH intervention is based on Findable, Accessible, Interoperable, and Reusable data and real-time processing for global health monitoring, emergency management, and research. The data should be collected and analyzed continuously in a spatial-temporal domain to detect changes in behavior, trends, and emergencies. The information periodically gathered should serve human, animal, and environmental health interventions by providing professionals and caregivers with inputs and "how-to's" to improve health, welfare, and risk prevention at the individual and population levels. Thus, ODH complementarily combined with A&EI is meant to enhance policies and systems and modernize emergency management.

(JMIR Med Inform 2023;11:e43871) doi:10.2196/43871

Introduction

Background

The current data-driven society pushes people to seek and ask for an always-increasing number of highly personalized services [1]. Citizens of smart cities use ubiquitous and mobile technologies and expect to obtain what they need before asking for it. Thus, smart cities are models of urbanization development wherein technologies are actively deployed to enhance the quality of life (QoL) of both humans and animals [2].

Accordingly, personal data such as location, interests (eg, queries on search engines, reads on social media, answers to surveys, and purchases), contacts (eg, calls and social media connections), and activities (eg, neighborhood meetings and personal announcements) are shared continuously [3]. Concerning health-related issues, citizens, as patients, demand proactive suggestions from a modern and evolving public health sector to improve self-care and lower the number of critical events. To this end, their digitized health records encompass the entire process, from the physician's consultation (in person or remote) to purchasing prescribed drugs (in person or on the web). People use web-based services to check their laboratory tests or reports of certified physical training. Furthermore, they may use applications for sleep monitoring that are provided by a health care management organization [4-8].

Smart cities and (digital) public health share aspects related to a healthy lifestyle. The Internet of Things (IoT; we will use *IoT* as an encompassing term including the Internet of Medical Things [IoMT] and the Internet of Animal Health Things [IoAHT]) monitors several subtopics of public health: environmental conditions, electromagnetic radiation, health conditions, fitness activities, food quality, emotions, and accidents [9-11]. Therefore, we need signals, data, and information produced by sensors in wearables or mobile apps or existing on social media networks to run health interventions [10] and cope with emergencies [12]. Accordingly, this has been called to expand the capabilities of health records. In smart cities, IoT devices also trace and track animals. Such applications reflect social and cultural norms, the safety and wellness of animals (eg, pet activity and feeding trackers [13]), and the collective composed of humans and animals [14]. In such communities, large amounts of data are produced continuously and exchanged wirelessly [15]. Its purposes range from home automation to trip management and QoL. These sensors range from microelectromechanical systems to advanced medical devices.

It is worth noting that, during the first waves of the COVID-19 pandemic, an increasing rate of shared information was observed. The need arose to timely deliver health care for both humans and animals as specific clusters of customers belonging to the same ecosystem [5,9]. Valid data collection was needed [16,17] that fit the essential elements of smart (healthy) cities [18,19]. For instance, McConnell et al [20] analyzed the influence of owning animals on stress. Other work has assessed the impact of the surrounding ecosystem on humans' and animals' QoL [21,22].

A practical setup for the entire data management process comprises aspects of generation, collection, transmission, storage, extraction, analysis, reporting, and decision-making as codified according to the principles of accident and emergency informatics (A&EI), with the dual purpose of preventing harm and supporting decisions [23]. Furthermore, aspects such as education, citizen engagement, and the large vision of human nature are notable elements of the One Digital Health (ODH) framework.

The ODH Framework to Set Up an ODH Intervention

The *ODH framework* develops around 2 so-called keys [24]. On the one hand, One Health looks at monitoring and assessing environmental hazard interactions and their impacts on health and biodiversity [25]. In contrast, Digital Health stands as the mature deployment of currently available technology to improve individuals' health and care [26]. The framework also includes 3 perspectives, 5 dimensions, and a technological ring.

As ODH proposes a new holistic, data-driven approach encompassing human, animal, and environmental health and welfare, a solid common ground with this working scenario emerges. Table 1 adjusts the common aspects of smart cities and digital public health using the ODH framework.

Health professionals traditionally define an intervention as the whole process, starting by defining a protocol; implementing it; systematically evaluating its effects; and then using the results to define, for example, a new therapeutic strategy or a new policy. According to the Digital Health perspective, we refer to *ODH Intervention* as the use of digital and mobile technologies for specific initiatives addressing human, animal, and environmental system needs. In other words, an ODH intervention is a real-world implementation of the theoretical ODH framework, which relies on Findable, Accessible, Interoperable, and Reusable (FAIR) data [27-29]. In this regard, we recognize an appropriate alignment with the *Classification of Digital Health Interventions v1.0* proposed by the World Health Organization (WHO), which deals with the principles of implementing and delivering formal or informal care using electronic health services [10,30].

Table 1. Relationships between smart cities, digital public health, and One Digital Health (ODH).

Topics in common between (digital) public health and smart cities	ODH dimensions				
	Citizen engagement	Education	Human and veterinary health care	Industry 4.0	Surrounding environment
Surveillance					
Accidents and emergencies				✓	
Environmental conditions					✓
Electromagnetic radiation					✓
Health condition of older adults		✓	✓		
Emotions	✓				
Epidemics			✓		✓
Fitness activities	✓	✓	✓		
Food quality			✓	✓	✓
Healthy lifestyle promotion	✓	✓	✓		

Our main objective was to show and discuss how the ODH framework—combined with A&EI—can dynamically support the comprehensive monitoring and analysis of the daily life events of humans and animals in technologically integrated environments such as a smart home and a smart city.

The paper is structured as follows. After the introduction, we present and analyze a timely use case from a smart healthy city context [31]. We then describe the planning of an ODH intervention to deal with the use case features. Therefore, we remodel and update the original use case as an actual outcome of an ODH intervention. In the end, we introduce a part of the generic evaluation process of an ODH intervention and discuss its implementation potential. We conclude by pointing out the strengths and limitations of this use case, such as future developments of the ODH framework jointly with A&EI.

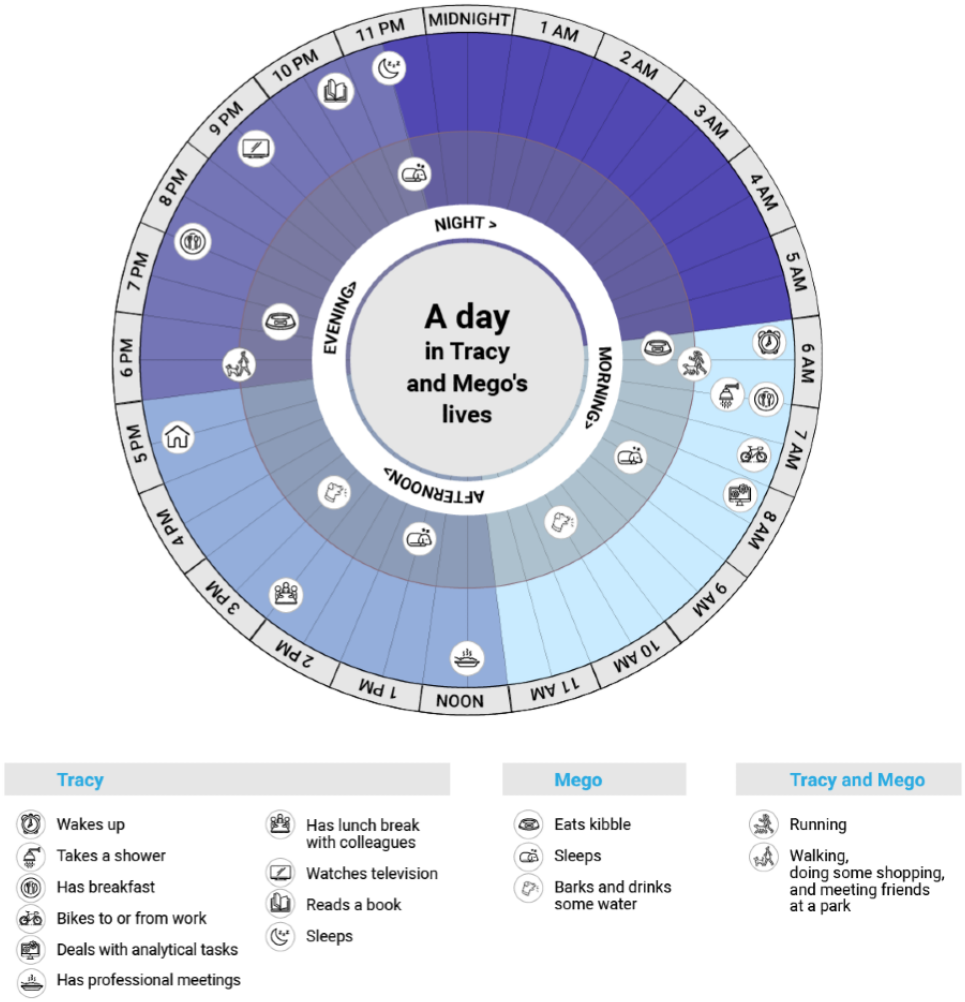
Use Case

Overview

A smart and healthy city well acknowledges several core ODH challenges. Our use case describes the sequence of steps needed to set up an ODH intervention around a user-centered demand and measure several parameters continuously, comprehensively, and reliably for effective multipurpose and integrative welfare monitoring. In this use case, we deal with human and animal health and welfare monitoring, continuously measuring physiological and behavioral parameters during their different activities—alone or together.

Tracy is a healthy single woman aged 27 years who shares her apartment in a metropolitan area with her dog Mego. Tracy is a junior finance analyst (ie, a tertiary position with responsibilities that might cause stress). During working weekdays, Tracy follows some typical activities of daily living. Mego is a healthy midsized male Shiba Inu dog aged 5 years. Mego lives with his owner Tracy. Most of Mego's time is spent at home (Figure 1).

Figure 1. A day in Tracy and Mego's lives.



A Regular Day in Tracy and Mego's Lives

At 6 AM, Tracy usually wakes up and checks that Mego's smart pet feeder delivered kibble and water. She then goes for a 30-minute run with Mego. Returning at 6:50 AM, Tracy takes a shower and has breakfast while briefly checking emails, social media, and the news. At 7:30 AM, she goes to the office by car or bicycle depending on the weather. Tracy works from 8 AM to 5:30 PM. She starts by planning and reviewing professional emails and then tackles high-priority tasks before handling analytical tasks. She takes a 1-hour lunch break with colleagues approximately at noon. The afternoon is organized around meetings and administrative tasks.

To return home, if Tracy used the bicycle on her way to work and there are issues on the way back, she may choose to take it on the bus or train. During this time, Mego, similar to other dogs, rests for a large part of the day and occasionally wakes up and barks to react to surrounding noises, plays with his toys, or drinks some water [13].

At around 6 PM, Mego warmly welcomes Tracy as he is excited to go out. If the weather, unexpected events, and mood conditions allow, they spend approximately 1 hour on a walk. During this time, Tracy does some shopping and meets friends in a park [32]. By 7:15 PM, they return home, and Mego receives his evening food ration. Tracy cooks dinner, watches television, reads a book, and prepares her plans for the next day. At 11:30 PM, Tracy goes to sleep.

Figure 1 shows a 24-slice clock in which the main activities of Tracy and Mego are reported depending on the moment of the day. In particular, an inner circle is recognizable that reports Mego's activities (eg, sleeping or eating kibble). An external circle features Tracy's activities (eg, moving to or from work or reading a book). Activities involving both of them are instead reported on the partition line between the aforementioned circles.

Some Important Spatial-Temporal Facts in Tracy and Mego's Daily Lives

Activity

Tracy spends most of her time indoors at home, her working place, shopping centers, restaurants, and the gym. Outdoor activities include running, working, hanging out with friends in parks and other open spaces, and using public transportation [33-35].

Tracy uses different means of transportation, such as walking, bicycle, car, and public vehicles. From home to work and back, she takes approximately 1 hour of biking—a considerable physical activity. Tracy's smartwatch informs her of caloric consumption, pulse, and oxygen saturation. The last physiological measurements are regularly stored in the cloud,

allowing Tracy to follow and share her physical activities [8]. Mego's sensor-endowed collar (an IoT device) connects to Tracy's smartwatch so that she can also monitor his activity and vitals. Most of the day, Mego rests (60% of the time; 14.5 hours a day). However, he has moderate activity (30% of the time; 7 hours a day), such as reacting to environmental stimuli (eg, welcoming Tracy when she returns home or barking at external noises). Mego has an intense physical activity (10% of the time; 2.5 hours a day) when he goes out for a walk or run with Tracy, plays with other dogs in the park, or is at home with his toys either alone or with Tracy [13].

Sleep and Rest

When going to bed, Tracy takes off her smartwatch for charging. This is also to prevent this device from disrupting her sleep quality. Tracy turns on her smart home speakers for relaxing music. She also bought a pair of blue light–blocking glasses to guarantee high-quality naps [36]. Mego rests most of the time [13] on a dog bed in Tracy's room.

Nutrition

Tracy has breakfast and dinner at home. Her smart fridge provides potential recipes with the available products [37,38]. She eats catering food at work, such as crudités, cooked legumes, and other protein sources. The cashier's receipt comprises all the related nutritional intakes [39-41].

Following the recommendation of the veterinary physician, Mego eats kibble. Tracy owns a sensor-endowed feeding station for effective feeding control and regulation [42]. In case of a product recall, Tracy receives a message on her mobile phone explaining the relevant "what to do's" [43].

A Particular Day in Tracy's Life—Example of a Health-Related Disruptive Event

One day, during a busier and more stressful period than regular at work, Tracy took her bicycle to work, but because of the weather, she took the train back home. Afterward, when walking in the park with Mego, Tracy suddenly collapsed. Unfortunately, she had not met her friends yet, nor had anyone happened to be around. Mego noticed the problem and started barking. After a while, some people came along, and finally, the ambulance arrived. Tracy stayed a few days in the hospital and another week at home to recover. During this time, Tracy's friends had been taking care of Mego, hosting him and trying to preserve his routine to reduce the negative impact of Tracy's absence (ie, during hospitalization) or unavailability to take care of him on her own (ie, during recovery).

Methods

Planning an ODH Intervention

An ODH intervention can be seen as the implementation of a set of digital functionalities, or digitalities [24], designed and deployed to (1) support specific initiatives that address human, animal, and environmental system needs and challenges; (2) assess and study these systems' expected and unexpected outcomes and effects and collect related data; and (3) select timely metrics for the outcomes of multicriteria decision analyses.

An ODH intervention is implemented to (1) *address One Health–related challenges*; (2) *achieve One Health–related* important and strategic *outcomes* for clinical follow-up and practice, such as for technology improvements needed; and (3) *achieve* FAIR uses of *digital technologies* [30,44].

In our case, this translates to (1) *a challenge* aiming to enhance aspects of healthy lifestyle promotion and surveillance; (2) *an outcome* consisting of performing effective monitoring of human and animal welfare within the context of a smart city, where health is a pivotal component; and (3) sensors for monitoring as *digital technologies* through which the intervention is implemented.

Effective monitoring of humans and animals in a smart environment must cover all relevant locations (indoors and outdoors) and define the critical parameters of health care and QoL [45]. Table 2 reports the 9 major types of interactions between the intervention recipients considering the extant strict interconnectedness between them [46]. Each cell reports instances of how one actor (row) positively or negatively affects another (column).

Table 2. Examples of interactions between the 3 One Health components.

	Human	Animal	Environment
Human	• Face to face [6] • Interactive (technology-based; eg, via social media) [8,47]	• Food, habitat provision, emotional bond, and health and well-being control [48] • Population follow-up and birth control [49,50] • Environment destruction [51]	• Compliance and sustainability for a technological environment at home, on a bicycle, in the steering wheel of a car, in the fridge handle, and more [52] • Urbanization [53-55] • Climate change, pollution, and regulation [51]
Animal	• Emotional and physical bond; health, well-being, and safety feelings (eg, dog) [56] • Disease vectors (zoonoses) [57]	• Food chain [58,59] • Natural regulation of populations [60]	• Soil fertilization [61,62] • Natural hazard (invasive species) [63-66]
Environment	• Food chain [58,59] • Natural hazards and disasters [67] • Space for well-being development [68-70]	• Availability of survival resources (food and shelter) [71] • Chemicals' influence on animal reproduction [72]	• Wildfire impacts on slope stability triggering in mountain areas [73] • Natural hazards and disasters [67]

Therefore, all the collected physiological, behavioral, and environmental data must (1) comprise indoor and outdoor locations where subjects are active and in contact [74,75], (2) be continuously time stamped, and (3) be shareable in a FAIR way [27].

Adverse Health Events

The ODH framework delivers a variety of observations for continuous health monitoring. It aims at analyzing health data on environmental, behavioral, physiological, and psychological domains, which is in line with the WHO QoL definition [76]. Continuous health monitoring allows continuous data analytics and even subtle trends to become recognizable at the early stages. This then opens many options for preventive medicine, hindering adverse health events (AHEs) [77]. However, AHEs will still occur but maybe not as frequently as without continuous monitoring. In such an event, the measurements taken from the subject are helpful. As of today, smart homes, smart cars, smart wearables, and smart clothes send out emergency calls, but so far, useful information—although available at the site—is not transferred because of lacking protocols and communication standards. This is addressed by A&EI [23]—in an emergency, whether an accident or a health-related adverse event, every second in fact counts as it carries data correlated with the individual involved. In a temporal-spatial continuous monitoring supported by the dynamic point of perception, the subject's associated data are distributed in each measuring smart environment and device. Upon the occurrence of an event, such isolated data silos have to concatenate to build the complete informative understanding of the latest health status of the subject. The International Standard Accident Number (ISAN) takes over the role, aiming at (1) standardizing an event by associating a unique number (token) composed of time and location of the event and ID number, (2) automatically collecting the corresponding isolated data slices of the individual from the alerting system (ie, smart environments and wearables), (3) automatically generating the alert and transferring it to the responding system (ie, emergency service), and (4) simultaneously transferring the vital and nonvital data to the curing system (ie, hospital) for informing the medical personnel before the subject is delivered to the hospital [78,79].

ODH Intervention Steps

Overview

We deconstruct the ODH intervention into single independent events and steps (globally called "activities") as items to be organized in tabular form, called the ODH intervention table (see Multimedia Appendix 1). For each activity, a number of fields must be identified, which relate to, for example, ODH domains and dimensions considered, digitalities involved, and their eventual mutual linkages (FAIRness levels).

Activity Identification

Each activity is assigned to a single row. The field "Activity UID" indicates the unique numerical identifier of the activity within the ODH intervention. The "Activity name" describes the single ODH intervention step. If the activity is broken down into subtasks, each one of them will be evaluated individually (ie, as a single row).

ODH Dimension Scores

An ODH dimension score assesses the dimensions of the ODH framework that directly relate to the activity. Each dimension obtains a specific importance value (increasing integer from 1 to 5) that indicates its connection rate to the corresponding activity of the intervention. The dimensions are reported as follows: C (*citizen engagement*), E (*education*), H (*human and veterinary health care*), I (*health care Industry 4.0* as health care services and technologies involving, eg, robots, 3D printing, cutting-edge ITs, and artificial intelligence [24,80]), and S (*surrounding environment*).

Main Digitality Domain

The field refers to 1 of the 3 areas of digital functionalities (humanities, animalities, and environmentalities) encompassed by the technology ring within the ODH steering wheel [24]. This field is divided into 2 subfields.

The first one, named "*Speciality*," reports the digitality explicitly deployed in the corresponding activity. Each speciality is assigned to a single row. This means that each single activity is operationalized by one or more specialities and is characterized by the marking letter of the domain it refers to: H (human), A (animal), or S (surrounding environment). Accordingly, H(Si) denotes the *i*th speciality that operationalizes the general digital functionality from the human domain, which delivers the corresponding activity.

The second subfield, named "*Technology*," refers instead to one or more technological solutions through which the speciality is deployed. Each technology is assigned a single row as well.

FAIR Data and Data FAIRness

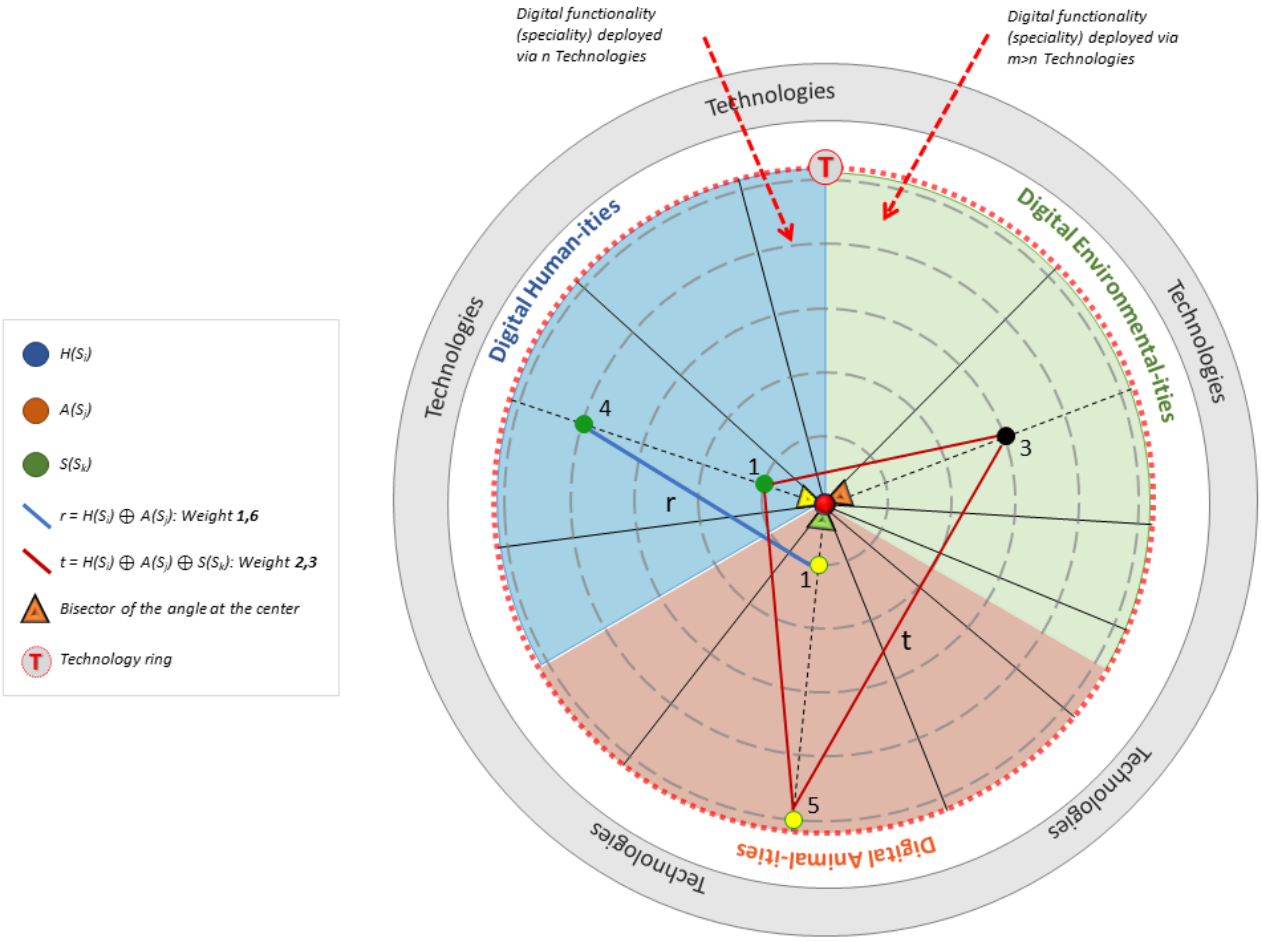
Assessing an ODH intervention's FAIRness is a basic requirement to correctly process the entire management cycle and stewardship of the data collected and shared during the intervention itself. Thus, the design and deployment steps of an ODH intervention need for its data to be FAIR. In this context, it means that the data must be (1) "Findable" by allowing for their discovery and sharing continuously between different monitoring, analyzing, and alerting systems; (2) "Accessible" by allowing the relevant and approved individuals and connected systems (ie, on behalf of accredited organizations) to deal with data and information when, where, and how needed to manage regular and disruptive events; (3) "Interoperable" by involving health-related communication, data exchanges, and processing standard protocols offered in a secured technological framework; and (4) "Reusable" to allow for a systematic, continuous, and intelligent integration of big multidimensional data for primary (eg, real-time clinical and environment monitoring) and secondary (eg, clinical and epidemiological follow-up) uses [29].

More specifically, a FAIR data assessment is conducted for every technology singled out so that an overall score is extracted for the speciality that the technologies refer to [29]. We mark satisfying, good, and total versus inadequate FAIRness of an individual technology with the symbols + or −, respectively.

Related Digitality Domain

This points out 1 of the other 2 areas of the technology ring (Figure 2) involved in the same activity as the main one. Similar to the main digitality domain, we divide related digitalities into the subfields *speciality* and *technology* and assess their level of FAIRness.

Figure 2. Example of a graphical representation of digitalities involved in a One Digital Health intervention.



Data Linkage

In total, 2 digitalities from 2 different domains form a relationship. If 3 digitalities—one from each of the 3 domains—connect with each other, we refer to it as a *triality*, and the field is duplicated. The **"**Data Linkage" field relates to the relationship or triality between the specialities described in the previous subsections. Equation 1 describes an example of a relationship between 2 specialities:

$$r_{HA} = H(S_i) \oplus A(S_j) \quad \textbf{(1)}$$

where r_{HA} is the relationship between specialities, $H(S_i)$ is the *i*th speciality related to a digital functionality in the human domain, $A(S_j)$ is the *j*th speciality related to a digital functionality in the animal domain, and ⊕ denotes a special defined operation similar to addition. It implies a possible confrontation between different specific deployments (in different domains) of the same kind of digital functionality.

In the absence of a relationship between one speciality from one domain and another speciality from another domain, the symbolism of equation 1 becomes as follows:

$$r_{H\emptyset} = H(S_i) \oplus \emptyset \quad \textbf{(2)}$$

where ø is the null element (there is no speciality connecting with S_i) and $r_{H\emptyset}$ is the absence of a relationship (the second member is null). Consequently, we represent a triality as:

$$t = r_{HAS} = H(S_i) \oplus A(S_j) \oplus S(S_k) \quad \textbf{(3)}$$

where $t = r_{HAS}$ is the triality (the specialities relate to all 3 domains) and $S(S_k)$ is the *k*th speciality related to a digital functionality in the environment domain.

Technology Ring

The technology ring serves as a catalyst among all the digital functionalities that the ODH framework relies on [24]. Accordingly, an ODH intervention takes place ideally within it through a series of steps described as follows. Each of the 3 domains is divided into as many circular sectors as digitalities are involved in the ODH intervention (Figure 2).

The width of each circular sector is directly proportional to the number of technologies deployed by the single speciality. Then, the bisector of the angle at the center is identified for each sector and represented by a dashed line. A dot is located along the bisector to represent the rate of involvement of the referring digitality within the ODH intervention.

The position of each dot is the output of the overall assessment of the FAIRness of the digitality considered, which involves all the possible technologies related at once; the lesser the output of the assessment, the farther the dot is from the center, and the higher the associated score (decreasing importance from 1 to 5; integer values) of the digitality.

We define the harmonic average of the associated mentioned scores as the weight of a relationship between 2 digitalities:

where M_g=M_g(S_i) is the harmonic average, N=2 is the number of digitalities related to each other, and S_i is the score associated with each of the specialities that operationalize the digital functionalities involved in the relationship.

We use a harmonic average as it is based on all observations, gives larger weights to smaller observations, and is thus more robust to strong observations and fluctuations of samples. Moreover, it can cope with variable time factors—in our case, the same speciality deployed via different technologies in different domains and in different time settings.

For a triality, we calculate the M_g value for each of the 3 single relationships and then their arithmetic average. M_g is a function of the scores associated with the 2 related dots. The higher the output of the FAIRness assessment of the digitalities, the closer the corresponding dot is to the center of the technology ring, the lower the ranking of the relationship (decreasing importance from 1 to 5), and the more effective that portion of the ODH intervention is. From a graphical point of view, the dots and relationships shall tend toward the center of the ring. For an optimal ODH intervention, its ODHness (ie, an overall evaluation of how well the ODH intervention is delivered) has to tend to 0 [24].

Eventually, the weight associated with the dimensions involved in the ODH intervention is a corrective factor that improves the scores obtained in the previous steps. Accordingly, the greater the number of dimensions involved in the ODH intervention, the more effective the corrective factor is supposed to be.

Ethical Considerations

Our research is not an observational study and does not produce or analyze any data taken from humans. Rather, we present a viewpoint and a use case as a potential scenario for an ODH intervention. Accordingly, a review by an ethics committee is not required.

However, planning an ODH intervention must cope with data privacy and security. In our opinion, confidentiality protection is a sensitive issue. In this use case, we do not focus specifically on this aspect. Nevertheless, in a real-world operationalization, it will be critical to have a dedicated data protection framework that allows us to deal when needed with data anonymization and deidentification.

In addition, anyone interested in running (primary use) or using data collected (secondary and tertiary uses) during an ODH intervention in real-world conditions must, according to the relevant local rules, obtain the approval of the relevant research ethics and data protection committees.

Results

Use Case (Updated): A Day in Tracy's Life in a Smart Healthy City

To picture this vision, we flashback to our use case with Tracy and Mego. This time, we tell the same story but set in a smart city using smart devices.

Tracy wakes up while her smart home processes the physiological measurements acquired overnight with IoT devices: a radar sensor on top of the bed monitors the respiratory rate, and the bed is equipped with a capacitive electrocardiograph in the mattress. Tracy also uses ballistocardiography and seismocardiography mounted on the bed frame for cardiorespiratory measurements and sleep assessment. When Tracy opens a door or presses a switch, her body temperature, electrodermal activity (EDA), and photoplethysmography (PPG) are taken, which deliver heart and respiratory rates upon touching the smart door handle or smart switch, respectively. In addition, passive infrared sensors gather activity data for both Tracy and Mego. In the bathroom, the smart toilet analyzes her urine and measures the pH value and density of excrements. In front of the mirror, Tracy's body temperature is measured by an infrared thermal sensor, whereas the weight scale integrated into records PPG and EDA. When watching television, Tracy's electrocardiogram (ECG) chair records her heart and respiratory rates.

Before Tracy leaves her apartment, she checks for Mego's general health status, provided by his smart dog collar, on her app. Upon Tracy's exit, her smart home transfers the health monitoring to her wearable sensors: Tracy's smart clothes are equipped with an embedded ECG. During all her outdoor activities, Tracy's wearable device performs the measurement, and data on the air quality are recorded [17,45].

Today, Tracy uses her car to drive to work. Opening the smart car door activates the measuring system, including body temperature, EDA, and ECG from the steering wheel as well as heart and respiratory rates from image-based PPG computed from the smart car's indoor camera. It is worth mentioning as well that Tracy's bicycle is equipped with a smart handlebar that also delivers health data.

A Particular Day in Tracy's Life (Updated)

Some days ago, the continuous health monitoring system reported to Tracy that she should consult a physician—the sequence and length of atrial fibrillation periods had slightly increased, a well-known harbinger of stroke. However, because of time conflicts, the physician's appointment was still outstanding when Tracy collapsed during her evening walk in the park with Mego. Instantaneously, Tracy's smartwatch detected the AHE and asked Tracy to release the alert return. While the countdown had not yet ended, Mego's collar reported Mego's extraordinary excitement to Tracy's smartwatch, which immediately generated the ISAN and sent an emergency alert. Using the ISAN, the rescue team requested access to the

smartwatch so as to check previous and ongoing measurements and, therefore, be well prepared when arriving at Tracy's location. This made it possible to perform the right intervention at the earliest point in time. Tracy recovered soon without staying in the hospital overnight.

Analyzing the ODH Intervention

Multimedia Appendix 1 showcases examples of "how-to" analysis of several "activities" (2 in regular time and 1 during a health-related disruptive event) as part of a wider ODH intervention. For each one of them, the rates of involvement of the ODH dimensions are scored, and the relevant technical fields are evaluated in light of the FAIR principles prism. Eventually, for each activity, the data linkage formula is also reported.

The first example relates to the monitoring of Tracy's respiratory rate via a radar sensor on top of her bed. From the A&EI viewpoint, this activity allows for the detection of respiratory abnormalities to be reported, if needed, in real time to an emergency medical service or be collected for future investigation.

The second example relates to the possibility for Tracy to check on the activity of the wearable devices she and Mego use. This may allow Tracy to know that, "in case of emergency" (eg, fever and muscular pain detected in Mego [before] and Tracy [after] may be signs of a zoonotic phenomenon, such as a bacterial infection known as leptospirosis), the system will be able to send relevant data from each of them to their own medical records [81].

In both cases, the industrial- and health care–related dimensions of the ODH framework appear to be highly involved. The surrounding environment is only slightly affected, whereas no notable involvement emerges for the human-related dimensions.

The last example involves all the ODH dimensions. In this case, using a smartwatch to send an alert message reflects some kind of citizen engagement (C) in sharing data with health care providers (M) that need to be trained (E) to use advanced technologies based on industrial standards (I) that can be used in different environments (S).

Discussion

Overview

In this viewpoint and use case, our main objective was to show and discuss how the ODH framework will support 24/7/365 technology-based health and environment monitoring to provide the right answer to the right event (related to a human, animal, or place) in the right place at the right time and with the right means. The central challenge in applying ODH in real-world conditions is the integration of digital development and technologies into 1 health concept. This comes with their use to achieve One Health goals rather than redefining and reconceptualizing One Health in the face of technological advancements [10,11,24,29]. In this regard, planning an ODH intervention is critical for taking forward the integration of the 3 main One Health domains (human, animal, and ecosystem) in light of their digital and computational components. The analyzed use case emerges from the combination of smart cities and digital public health. It suggests an around-the-clock scenario of sensor-based welfare monitoring for a human and a pet in a smart environment context—a large part of Tracy and Mego's lives involves technological measuring and monitoring systems related to IoMT or IoAHT [8,12]. To enhance the understanding of the impact of an ODH intervention and the subsequent assessment of its ODHness, we proposed a way to analyze human and animal activities in different environments by quantifying their relationships with the ODH framework features [24] and their links to technical fields by considering the assessment of the FAIR guiding principles for the 3 areas identified and included within the ODH technology ring [29,76].

Principal Findings

In the use case supporting our viewpoint, as in real life, the large amount of data generated by IoT sensors and technologies allows for an effective analysis of behaviors, habits, pattern extraction, and medical conditions of different types of subjects in the mid- and long term. In addition to the initial aim of health condition prediction, prevention, and early alert perspective—usually reported in the existing literature for single contexts such as home [82], hospital [83], or even veterinary epidemiology [84] and that ODH already addresses in a unified way—a growing importance has arisen for disruptive events and punctual abnormalities.

For Tracy, this could be related, for instance, to a medical emergency, such as dyspnea or cardiac arrest during sleep or a physical activity, detected by physiological sensors. It can be, as another example, a bicycle accident detected by physiological sensors, accelerometers, and automatic alerts to emergency services. An additional example relates to contact tracing via an app for highly contagious diseases such as COVID-19, which can alert Tracy and support her in making timely decisions according to the public health authorities' recommendations.

For Mego, a disruptive event can be a veterinary emergency in case of an accident, as seen for Tracy, or a change in the hydration frequency that can suggest a food-based intoxication.

Moreover, a disruptive and dangerous event can involve both Tracy and Mego, such as a fire, with Tracy's physiological parameters dramatically changing within a couple of minutes overnight and Mego's similarly agitated behavior.

Such aspects of emergency management demand a continuous follow-up of humans', animals', and surrounding environments' health care in a P5 medicine approach [85-88] that combines (1) prediction, acquiring data and building relevant models supporting emergency and disaster preparedness [8]; (2) prevention, detecting (weak) signals of abnormalities and treating them before strong deviations (eg, preventive confinement to avoid an epidemic); (3) participation, involving the handling of human, animal, or environmental issues (eg, engaging in vaccination campaigns [89-91]); (4) personalization, proposing the use of the adapted solutions to a detected issue (a drug-based treatment for a human or an animal or the development of a repopulation program for a hurt vegetable ecosystem); and (5) precision, delivering the right intervention at the right time (as much as possible in real time) by the right

individual on the right ecosystem components to get to, for example, efficient and dedicated evacuation plans [92,93].

In addition, a specific interpretation is also delivered for what concerns (1) citizen engagement and education aimed at information development and large-scale information gathering (so-called citizen science [94]) for first aid, basic health-related technologies, and sustainability using, for example, mobile apps to increase their penetration rate in the grand public and (2) interoperability from an industrial perspective to facilitate the interconnection and communication between the different IoT systems and alert systems to enhance end-to-end accident and disaster management [78,79].

As shown, singling out the activities that the ODH intervention in a "smart city meets public health" scenario would be made up of and working the technology ring out accordingly (also) to define its ODHness aimed to commence the dialogue with topics from different perspectives dealing with health communication (eg, health promotion based on engagement and education [6,95]) and surveillance (eg, monitoring health conditions and physical activity, detecting and preparing the health care system for disruptive and long-term events, and behavior or environmental changes) [9].

A&EI discipline showed its contributions to the use case regarding the short-term and abrupt event and abnormality detection as well as long-term prediction and prevention. The use-case analysis indicated that A&EI aims to (1) turn smart private spaces into diagnostic spaces unobtrusively (eg, home and car) [96], (2) build continuous measurement and monitoring via dynamic points of perception, and (3) achieve interconnectivity and communication of the means of measurement. The field focuses on the data linkage and interconnectivity of medical and nonmedical sensors and devices in smart environments to construct and support the onboard and distributed data processing and analysis in hierarchical levels of abstracts [12]. The integration of ODH and A&EI in this use case contributes to the development of educational projects and programs, allowing health, environment, engineering, design, and business students and trainees to develop their creative and critical abilities by proposing new concepts and systems [42,95,97]. These education projects could be used in future smart cities wherein One Health and disaster (ie, accidents and emergencies) prevention and preparedness will be daily life pillars [98,99]. This aspect fits with the United Nations 2030 Agenda for Sustainable Development, which points out that young people should be educated in such a way that smart health monitoring is not only for unhealthy humans and older adults [100,101]. For example, analyzing walking steps is a default functionality of mobile devices and is used by young and healthy people to measure their physical activity in real time. Moreover, from an A&EI perspective, preventing complications of a potential medical emergency is something that smartwatches have yet to achieve by detecting and alerting their owners of the first signs of a cardiac event [102].

What emerges is that the very act of planning an ODH intervention placed particular emphasis on aspects of emergency management, which in this context refers directly back to A&EI. This is actually a way to deal with the same dimensions as ODH. Therefore, it is plausible to say that the ODH framework can be enriched with a new layer-like cross-sectional element so that an infinitely recurring loop is created between the 2 models.

In summary, ODH and A&EI as a whole contribute to enhancing (1) the overall QoL of the smart city inhabitants (both humans and animals); (2) the public (digital) health policies and processes frame, such as the entire smart city ecosystem development and management, that is, architecture (eg, accessibility for people with disabilities and reduction of energy consumption) and urbanization (eg, communication systems, transportation networks, malls, education, and health care center locations); and (3) the communication between the different health care system actors involved, such as clinicians, engineers, regulators, and administrators and, more generally, the 3 domains that the ODH framework is made of. The existing Medical Informatics and Digital Health Multilingual Ontology could be expanded and adapted to this end [103,104].

Viewpoint Constraints

A correct development of the "smart city meets digital public health" field is currently still hindered by a number of factors, as briefly discussed in the following sections.

Governance

The control and governance of environmental sustainability can be best approached by assessing ecosystem services that are capable of quantifying and valuing all the goods and services that are generated within the ecosystems themselves. Recently, such networks have been increasingly endowed with digital technologies such as (1) environmental management and monitoring information systems; (2) automated and scalable approaches for collecting, digitalizing, and assembling geocoded big data; and (3) information-fusion algorithms and artificial intelligence that use multiple data streams and clinical decision support algorithms that integrate population-based, public health–focused perspectives into outbreak detection–focused management systems [45,105,106].

Data Security and Privacy

However, it is necessary to consider that using electronic and computational systems to collect, store, and analyze data and react and deliver an appropriate response induces at least 2 challenges. Dealing with health care customer data requires dealing with their security and privacy from an ethical viewpoint to ensure patient rights [107] and prevent data theft that can induce, for example, health-related device hijacking with dramatic consequences [108]. Moreover, the health-related data acquisition and monitoring systems used in smart cities demand seamless and secured bidirectional communication, supporting high-speed, large-bandwidth, and low-latency internet infrastructures materialized by the fifth and sixth generation of wireless network technology (respectively known as 5G and 6G) and future versions. Moreover, the use of cloud-based storage and computational resources is essential to allow (near) real-time data collection and analysis.

Sustainability

Accordingly, from a sustainability perspective, as smart cities are electric power–based and digital green, digital health green

infrastructures must be developed to reduce the environmental fingerprint [109,110].

Therefore, from an industrial perspective, reducing power consumption, electronic waste, and biodegradable health care–related materials is a global challenge [111,112].

Interoperability

Furthermore, in smart cities, the heterogeneity of IoT devices, and specifically those related to the health care industry, must benefit from improved interoperability standards and procedures and device compatibility. This last point must critically affect the health service providers' and customers' acceptance and use of mobile and ubiquitous technologies [113].

Health Communication and Disparity

Nevertheless, a limitation of having a generalized use of IoT devices or, more globally, a healthy smart city lies on health communication and disparity. Indeed, using IoT may be challenging for different groups such as older adults as well as individuals with communication disabilities or limited abilities. Accordingly, even though IoT is taking health care to the next stage worldwide, it could paradoxically exclude some people who need it [6,114]. Therefore, a similar threat may affect the veterinary sector, whose development rate is still quite lagging behind that of human medicine.

Ethical and Cultural Limitations

In addition, collecting continuous data on anyone and anything may entail ethical and cultural limitations both related to privacy. In a smart city, data collection and processing are performed such that the customers of health care services are not (fully) aware of the sharing of personal data [115]. Moreover, developing a smart city wherein health monitoring is a pillar requires a high technology acceptance level when we consider that technologies are everywhere. Just to mention another critical sector such as transportation safety, the development of IoT-based vehicle accident detection is important, but privacy limitations exist regarding the fact that any driving event can be recorded even if it is not related to an accident [116,117].

In the use case presented, the use of the different activity trackers points out that the technology is accepted by our persona (Tracy), yet it is an open question whether she was fully aware of "giving up" part of her privacy rights [4,118].

Limitations of the Study

Some limitations of this work arise from the way the use case for the ODH intervention was determined. First, the "Animal" domain was only represented by a pet. The presence or role of other kinds of animals—such as nonconventional pets (eg, rabbits and reptiles), herds (eg, cows and goats), or wildlife (eg, wolves and boars)—was not addressed. In addition, the "Environment" domain was not properly included in the use case, whereas in a smart and healthy city, the management of environmental resources, made itself smart via IoT and information and communications technologies, is a critical element toward actual e-governance policy planning [119].

Furthermore, a major focus was on the general category of IoT that, although an all-encompassing type of technology, is currently dealing with peculiar declinations for what concerns the general (human) health care sector with IoMT and, in more recent times, animals' health and well-being status with IoAHT [120].

Another findable limitation is that the proposed use case only describes a single day in Tracy and Mego's lives. Although Tracy's working days are characterized by many routine activities, the analysis of a longer period would have likely involved many more things to be discussed.

Future Perspectives

Tracy's daily occupations and activities presented in this fictional use case are applicable to a large part of the population living in similar contexts.

One of the potential and expected implications of ODH interventions lies on supporting digital health literacy, from children to older adults, to engage with personal health, public health, and environmental monitoring systems to increase awareness. Improvement in this aspect is likely to lead to better health outcomes and a more proactive approach to medical practice, thus reducing both the digital divide and health inequalities [6,121].

On the basis of these assumptions, the development of policies regarding health data management and sharing for secondary use [122-126] is expected to be facilitated and perhaps automated. A timely and FAIR deployment of ODH- and A&EI-based data collection modalities would lead to the establishment of more comprehensive guidelines and decision support systems for what concerns the many (interrelated) features of health care and to a better understanding of user expectations.

The combination of health literacy, human expectations, and data collection—or, rather, the logical flow through these points—yields scenarios where information is stored in electronic health records in a timely manner and available in health care management organizations' repositories and allows for the implementation of personalized medicine processes considering environmental measurements and human [127] or animal [120,128,129] behaviors. In a broader, holistic view, it looks at a proactive medical practice that no longer addresses patients but humans outside the human-centered health care systems whose improved awareness even steps beyond the concept of "empowerment" [130,131]. This means that electronic health record data shall be processed with other data such as lifestyle habit data, for example, patient-generated health data (ie, not reported to health care professionals) and environmental data (eg, pet owning [42] and hobbies). An integrative understanding of the human way of life and human needs and expectations will help efficiently and effectively enhance health communication–targeted campaigns to improve disease prevention, detection, and follow-up at a large scale [6].

Conclusions

Our vision for the future sees smart cities as an emerging paradigm involving a large set of technologies (eg, IoT and, thus, digital health, telehealth, mobile health, and web-based social networks of patients and caregivers) and behavior-changing tools to refine education, engagement, the consumption of food, physical activity, and the use of technology. The main aim is to improve QoL and life expectancy. This has shifted health care focus from treatment after diagnosis to prediction and prevention and from a health care professional–centered (so-called paternalistic [132]) approach to a health care service user–centered follow-up management. Thus, health care is no longer limited to the walls of the health care centers (eg, clinics and hospitals) and the "homespitals" (also known as hospital at home) but is ubiquitous and based on continuous, comprehensive, and reliable measurement of several physiological and behavioral parameters. The integration of the ODH and A&EI viewpoints will allow for the reduction of disparities and loss of time in managing disruptive health-related events and for looking at health as a whole, wherein human and animal well-being in a secure and proactive environment. ODH and A&EI are triggers for developing and implementing precision public health, currently defined as imaginary, by dealing with the entire data management process from end to end [11].

Acknowledgments

The authors are grateful to Mrs Orly Seligmann (Bachelor of Design), visual communication designer at the Holon Institute of Technology, for her assistance.

Data Availability

Data sharing is not applicable to this paper as no data sets were generated or analyzed during this study.

Abstract

Personalized health care can be optimized by including patient-reported outcomes. Standardized and disease-specific questionnaires have been developed and are routinely used. These patient-reported outcome questionnaires can be simple paper forms given to the patient to fill out with a pen or embedded in digital devices. Regardless of the format used, they provide a snapshot of the patient's feelings and indicate when therapies need to be adjusted. The advantage of digitizing these questionnaires is that they can be automatically analyzed, and patients can be monitored independently of doctor visits. Although the questions of most clinical patient-reported outcome questionnaires follow defined standards and are evaluated by clinical trials, these standards do not exist for data processing. Interoperable data formats and structures would benefit multilingual and cross-study data exchange. Linking questionnaires to standardized terminologies such as the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) and Logical Observation Identifiers, Names, and Codes (LOINC) would improve this interoperability. However, linking clinically validated patient-reported outcome questionnaires to clinical terms available in SNOMED CT or LOINC is not as straightforward as it sounds. Here, we report our approach to link patient-reported outcomes from health applications to SNOMED CT or LOINC codes. We highlight current difficulties in this process and outline ways to minimize them.

Introduction

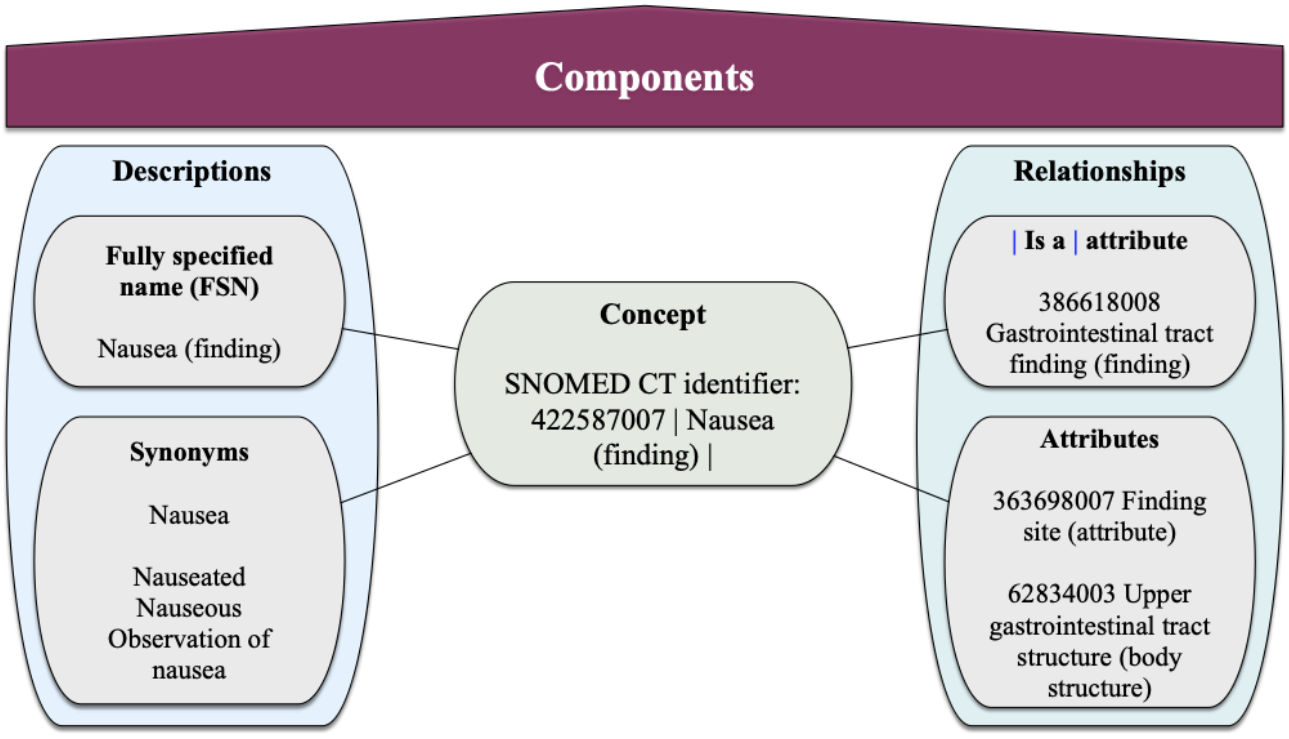
The recording of symptoms and laboratory tests is of paramount importance in clinical practice. In addition to objective, measurable parameters, the patient-reported symptoms and their quality of life have come into focus in modern medicine [1,2]. In this context, patient-reported outcome (PRO) questionnaires have become a standard tool to capture patients' perspectives on their health status. Depending on the underlying disease, PROs cover topics such as quality of life [1], adverse events [3,4], or stress [5], among others. Although in the past, PROs were typically reported using paper-and-pencil methods, electronic PROs (ePROs) are increasingly used and preferred by patients [6]. Because physician and patient perceptions of symptoms can be discrepant [7], PROs are essential for identifying conditions requiring a therapy adjustment [3]. In addition, ePROs can automate their analysis, and they can be used as an outpatient triage tool to identify those in a cohort who need therapy adjustment or closer support [8]. PRO questionnaires can be constructed for different topics and can be more general or tailored to specific diseases [9]. In addition, questions can have different recall time resolutions (eg, today or last week) or differ in their detailed description of symptoms [3]. Thus, the questions and the corresponding answers can be very specific. As a result, minor adjustments in wording can affect the final result [9]. The same is valid for alternative translations. To address these issues, the European Organization for Research and Treatment of Cancer (EORTC), among others, has developed standardized quality-of-life PRO questionnaires

[1]. These questionnaires were initially developed in 1986 and have been refined, translated into several languages, and validated [10,11]. Moreover, the consortium provides a detailed analysis plan to enable comparable results between clinical trials regardless of the geographical region or linguistic and cultural population [10].

Like the underlying questionnaires, the outgoing ePRO data should be accurate, standardized, and interoperable to enable sharing, reuse, and international data comparison. Unfortunately, what seems obvious at first glance is far from reality [12]. The Fast Healthcare Interoperability Resources (FHIR) specification, developed by Health Level Seven International, is the most widely accepted standard for communicating health care data [12]. It aims to provide a comprehensive framework and related standards for exchanging, integrating, sharing, and retrieving electronic health information [13]. The FHIR elements required for PRO questionnaires are Questionnaire and QuestionnaireResponse. A Questionnaire defines a structured set of questions to guide the collection of answers. In addition to the questions, it also defines the answer types and possible answers. It provides detailed control over order, presentation, phraseology, and grouping for consistent data collection. Each Questionnaire requires a QuestionnaireResponse as its counterpart for retrieving and organizing the answers. The QuestionnaireResponse provides a structured set of answers for a specific Questionnaire and must match the definitions of the Questionnaire. Terminologies are integrated as CodeSystems by providing a base URL and the term code. This combines the syntactic interoperability (structure and data format) enabled by standards such as FHIR with the semantic interoperability enabled by health terminologies. The Systematized Nomenclature of Medical Clinical Terms (SNOMED CT) is currently the most appropriate and comprehensive clinical health terminology with natural language properties [14,15]. It includes terminologies for medical concepts, descriptions, and relationships, forming a unique component with a specific identifier [15,16] (Figure 1). Another common medical terminology is the Logical Observation Identifiers Names and Codes (LOINC) [12,14]. A LOINC term is defined as the combination of the LOINC code, a unique identifier, and the fully specified name (FSN), which consists of 5 to 6 parts, including the component or analyte, the observed property, the time of the measurement, the type of system, and the scale of the measurement. Where relevant, the measurement method is included as part 6 [17] (Figure 2). Although SNOMED CT seems appropriate as a reference terminology for multilingual semantic interoperability in health care [18], LOINC has the advantage of also providing “display text” that can be used to link questions (“SURVEY_QUEST_TEXT”) [17]. For these reasons, it may be appropriate to supplement SNOMED CT terminology with LOINC, and several approaches for their mapping have been proposed [19,20].

To improve the international reuse and comparison of PROs in clinical trials, we tested the mapping of standardized and validated questionnaires with their corresponding queries to the SNOMED CT and LOINC terminologies. In the following sections, we introduce these PROs, report on our experience mapping them to SNOMED CT and LOINC, highlight current difficulties, and outline some suggestions for minimizing them.

Figure 1. Exemplary composition of SNOMED CT components for nausea. SNOMED CT content consists of concepts, descriptions, and relationships. Each concept is associated with a set of textual descriptions. The descriptions can be grouped into an FSN, which is unique, and several accepted synonyms, allowing users to apply their preferred terms. In addition to the preferred FSN, a synonym can be selected by a language refset. Relationships link concepts within hierarchies. The |Is a| relationship connects concepts within the same hierarchy, whereas the attribute relationship connects relationships in different hierarchies such as finding site, procedure site, or method. SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.



Patient-Reported Outcome Questionnaires

Content of Patient-Reported Outcome Questionnaires

Various questionnaires focus either on the quality of life and its impact on the underlying disease or on disease- or treatment-related adverse events. Recent approaches have identified conceptual differences between these PRO measures (PROMs) [21]. On the basis of these findings, we have limited our approach to a few clinically relevant and widely accepted questionnaires that differ in their representation of the domains assessed. Thus, our content analysis included the following PROMs, which can be accessed at

- EORTC Quality of Life of Cancer Patients Questionnaire (QLQ-C30) [22]
- EORTC Quality of Life of Breast Cancer Patients Questionnaire (QLQ-BR23) [22]
- Patient-Reported Outcomes Measurement Information System (PROMIS-29) [23]
- Common Terminology Criteria for Adverse Events (CTCAE) [24].

In the following, we describe the analyzed PROMs in more detail.

EORTC QLQ-C30

The EORTC QLQ-C30 is one of the core validated questionnaires of the EORTC Quality of Life Group. It has been optimized in several revisions since its initial release in 1987 and assesses general aspects and symptoms of patients with cancer based on 30 core items [1]. As there is a wide range of tumor diseases, the questionnaire is not considered to be too disease specific. Five questions of the QLQ-C30 do not consider a recall time interval, whereas the remaining questions refer to the recall time interval *last week*. Two different value scales are used for the answers. Most of the questions can be answered with the text *not at all*, *a little*, *quite a bit*, and *very much*, combined with the numerical values 1 to 4. The others have only text for the first and last values (*very poor* and *excellent*), and the numerical values range from 1 to 7. To score the QLQ-C30, the questions are divided into groups to assess functional scales, symptom-related scales, and global health status, using the Likert method of summing scales [10]. The QLQ-C30 is currently available in version 3.0 and is recommended for use in any new study [10]. The QLQ-C30 core questionnaire can be supplemented by modules containing questions about specific tumor sites, symptoms, or treatments [10,25]. All EORTC questionnaires are available in several languages, but the initial version is in English [10,26]. Special care has been taken in their development to ensure that they are universally understandable, regardless of the level of education or cultural background. To ensure these quality standards, each questionnaire undergoes several rounds of revision, including testing with patients from several countries [26]. The current versions of all EORTC questionnaires and their development status can be requested at the website in [22].

EORTC QLQ-BR23

The EORTC QLQ-BR23 questionnaire is the validated add-on module to the QLQ-C30 core questionnaire for patients with breast cancer. It is recommended for general use, but its updated version (QLQ-BR45) has already completed phase IV testing [10], and a new version will soon be available for newly initiated studies. The QLQ-BR23 questionnaire consists of 23 items that address dealing with symptoms, treatment adverse events, body image, sexual functioning, and future outlook [10]. Similar to the QLQ-C30, the items of the QLQ-BR23 can be grouped for scoring based on the available scoring scheme [10]. This time, however, all questions can be answered with the text *not at all*, *a little*, *quite a bit*, and *very much* combined with the numerical values 1 to 4, and the questions cover a recall time interval of either the last week or the last 4 weeks.

PROMIS-29

The PROMIS is an item bank for constructing patient-reported questionnaires in the context of chronic diseases and conditions. It covers the domains of physical, mental, and social health, which are further subdivided into more precise symptom item banks such as physical function (124 items), pain behavior (39 items), or fatigue (95 items), among others, tailored to a broad population of chronic diseases. This allows comparisons between diseases. The system enables exchanging items or minimizing the number of items within a questionnaire without compromising the reliability [27].

Because of the many possible PROMIS questionnaires, we limited our approach to the PROMIS-29 questionnaire available at the website in [23]. It contains 29 questions derived from the 7 PROMIS categories of physical function, anxiety, depression, fatigue, sleep disturbance, ability to participate in social roles and activities, and pain interference, each measured by 4 questions. It also includes a numeric pain intensity scale ranging from 0 (no pain) to 10 (worst pain imaginable). In addition to the pain intensity scale, all other items have a 5-point response scale (eg, 1=never, 2=rarely, 3=sometimes, 4=often, and 5=always). Except for the questions on physical function and ability to participate in social roles and activities, where the time interval is not specified, the requested recall period is the past 7 days.

CTCAE

The CTCAE is the classic scoring system physicians use to classify side effects during cancer treatment. It is used to grade patient-reported symptoms and those observed by clinicians or from laboratory tests [7,28]. Unlike the EORTC and PROMIS questionnaires, the CTCAE questions were not originally designed in a pen-and-paper format to be given to patients. Therefore, clinicians do not rate each question. It is a descriptive terminology for adverse events coupled with a descriptive grading of the event that occurred [24]. The CTCAE presents scores from 1 to 5 with the associated grading (*mild*, *moderate*, *severe*, *life-threatening*, or *dead*). Each grade has a unique textual clinical description to help to assess the correct grading. Because not all adverse events can be classified into 5 classes, some described adverse events have fewer than 5 grades [24]. The current CTCAE scoring (version 5.0) and previous versions

are available at the website in [29]. We have limited our approach to the current CTCAE version 5.0. However, a CTCAE version 6.0 is already in preparation. Following the idea of the CTCAE, the National Cancer Institute (NCI) has developed a Patient-Reported Outcomes Version of the CTCAE (PRO-CTCAE) scoring system. It contains 78 adverse events from the classic CTCAE, which can be queried based on 124 individual questions [2,30]. The PRO-CTCAE scoring system records adverse events according to attributes such as severity (*none*, *mild*, *moderate*, *severe*, *very severe*), frequency (*never*, *rarely*, *occasionally*, *frequently*, *almost constantly*), or interference (*not at all*, *a little bit*, *somewhat*, *quite a bit*, *very much*) and has a general recall time of the last 7 days [30]. Thus, it lacks the detailed textual descriptions of the symptoms that occurred. In contrast, the health application NEMO (German, Nebenwirkungs-Management Onkologie) tried to combine PRO questions with the classic CTCAE scoring descriptions for daily use [3].

Workflow—Finding SNOMED CT and LOINC Codes for PRO Questionnaires

Limitations

SNOMED CT and LOINC are both optimized for health care and laboratory terminologies. Thus, several approaches have been proposed to map SNOMED CT and LOINC codes [19,20] due to their close knowledge representation formalisms (see Figures 1 and 2). However, even applying this mapping to data for which both terminologies are specialized resulted in incomplete results and required significant human effort to complete the task [19,20].

Therefore, we also manually mapped the questionnaires with their associated questions and response options to assign them SNOMED CT and LOINC codes. The questionnaires analyzed in our study were obtained from [22-24]. The workflow used is shown in Figure 3 and is described in more detail below. The results of the manual mapping can be found in Tables S1-S4 in Multimedia Appendix 1.

We did not consider the relationship between questions and responses in our analyses of term availability. However, we want to inform the reader that the context between questions and possible responses must also be considered and marked in our workflow for actual use cases.

Figure 2. Exemplary composition of a LOINC term for nausea. A LOINC term is defined as the combination of the LOINC code, a unique identifier, and the FSN, which consists of 5-6 parts, including the component or analyte, the observed property, the time of the measurement, the type of system, the scale of the measurement, and sometimes also the method used. The FSN parts are listed sequentially, separated by ":". "Nausea [Presence]" is one of the additional names, a long common name, which must be unique. LOINC: Logical Observation Identifiers, Names, and Codes.

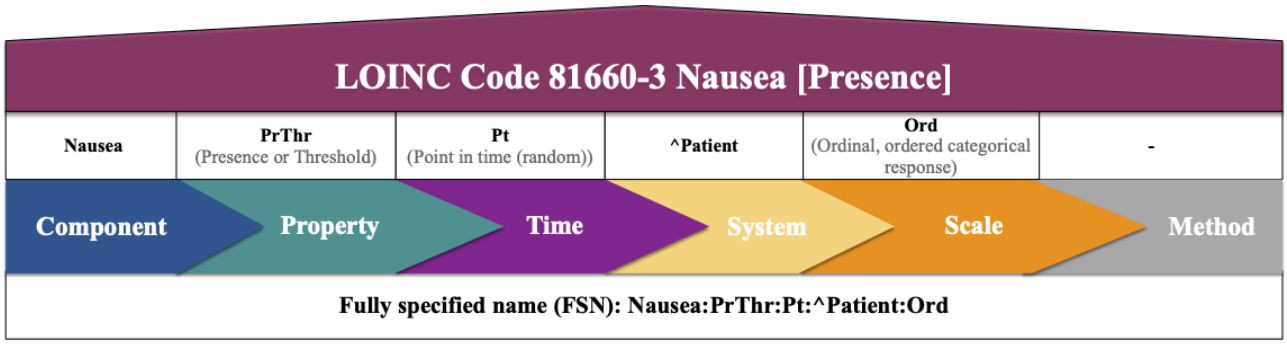


Figure 3. Workflow. Depicted is our workflow to match patient-reported outcome questionnaires with the standardized terminologies LOINC and SNOMET CT to enable semantic interoperability. The workflow marked in black depicts the procedure to analyze the current status of terms included in both terminologies. If a term still needs to be included, we suggest the blue workflow to extend the terminologies. The empty box indicates the end of the procedure. LOINC: Logical Observation Identifiers, Names, and Codes; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

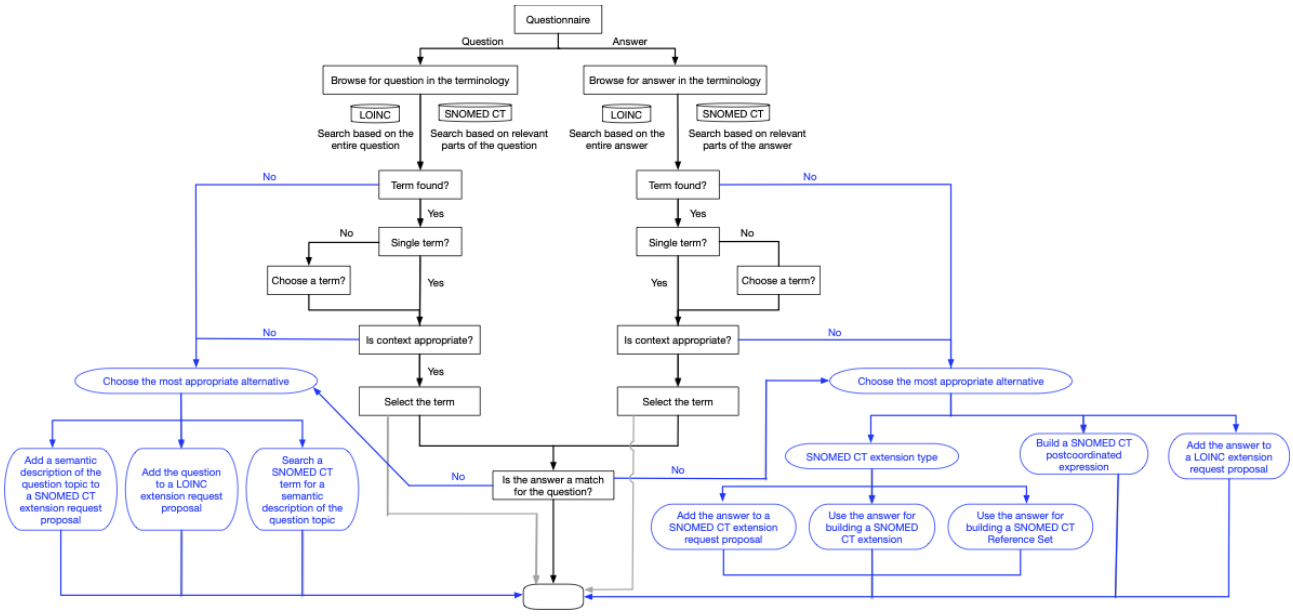

LOINC

After free registration at the website in [31], keywords from our PRO questions and possible answers were queried. If only 1 term was found, it was evaluated if it was a "perfect match." If multiple terms were found, the most appropriate term was selected and considered a perfect match. If this evaluation resulted in a perfect match, the term was chosen as the terminology term. However, if the match was negative or no term was found, the item was treated as "not found." For example, for the question *Have you felt nauseated?* there was no match, and a search for the term *nausea* alone returned 12 results, which are listed as follows:

- *67232-9 | How often did you have nausea in the past 7 days [PhenX]*
- *64713-1 | In which months of the pregnancy did you have frequent nausea or vomiting [PhnX]*
- *81660-3 | Nausea [Presence]*
- *70406-4 | I have nausea in the past 7 days [FACIT]*
- *77711-0 | Patient has anorexia, nausea or vomiting in the past week [UPDRS]*
- *42848-2 | Nausea [CCC]*
- *77510-6 | Can pronounce nausea [AmNART]*
- *28391-1 | Nausea [HIV-SSC]*
- *69711-0 | Did you have nausea or an upset stomach, or the feeling that you were going to have diarrhea [Reported.PHQ]*
- *69682-3 | Bothered by nausea, gas, or indigestion in last 4 weeks [Reported.PHQ]*
- *67231-1 | How often did you have pain in the center of the upper stomach in the past 7 days [PhenX]*
- *96839-6 | Nauseous or had stomach problems when I thought about or was exposed to information about the coronavirus in past 2 weeks*

All of these are not a perfect match to the original question. Therefore, we considered the term not an ideal match.

SNOMED CT

To find SNOMED CT components and the corresponding identifier, we used the SNOMED CT Browser [32] and entered keywords from our PRO questions and possible answers into the search field.

Because full text cannot be entered into SNOMED CT, we searched for relevant parts of the question or answer. For example, for the question *Have you felt nauseated?* the search term *nauseated* or *nausea* returned the following result, which we interpret as a perfect match:

- *422587007 | Nausea (finding) |*

Here, we were interested in a general proof of principle of whether PRO questionnaires can be mapped to semantic terminologies. Therefore, we stopped our analysis after querying the PRO questionnaire terms. However, if the goal is to extend the terminologies, we recommend the following alternatives (marked in blue in Figure 3), which we discuss in more detail below.

In the case of LOINC, the missing term can either be requested to be added by an extension request proposal, or a semantic description of the term can be searched in the SNOMED CT terminology. The specificity of the term description can be further increased by building a postcoordinated expression.

In the following sections, we report on the challenges of term mapping to semantic terminologies.

Challenges in Terminology Binding

Our attempts to complete the exemplary questionnaires' terminology binding revealed the following challenges.

Language

Although the PRO questionnaires are translated into different languages while preserving the original meaning [11], the terminology databases SNOMED CT and LOINC are only available for a limited number of languages [18]. This is counterproductive to the goal of digitization and medical terminologies to improve interoperability, especially if automatic mapping is the ultimate goal. In addition to the international edition of SNOMED CT, there are currently 18 other country-specific editions that cover, at least in part, 10 additional languages: Danish, Dutch, Estonian, Finnish, French, German, Māori, Norwegian, Spanish, and Swedish [32]. However, several European languages are not yet included [18]. On the positive side, at least the same identifiers are used for different languages. However, this should be the case to ensure interoperability. LOINC currently has 20 linguistic variants covering 14 additional languages: Chinese, Dutch, Estonian, French, German, Greek, Italian, Korean, Polish, Portuguese, Russian, Spanish, Turkish, and Ukrainian [33]. Because of the various language alternatives, we limited our mapping to the English versions of the PRO questionnaires and terminology databases, as has been done by others [34]. The language barrier could be reduced by putting more effort into translating the terminologies into more languages. As mentioned above, FHIR, a standard for health data exchange, enables syntactic interoperability [13]. To ensure a correct transition to semantic interoperability, mapping validators, such as the open-source FHIR Validator framework [35], check whether the exported textual questionnaire and the specified identifier match. If the language of the PRO questionnaire and, thus, the survey text from the FHIR export differs from the language of the associated terminology, the program generates a warning. However, the fact that it only generates a warning may allow existing tools to continue to be used.

Concept Availability and Term Selection

The SNOMED CT and LOINC terminologies are comprehensive, but questionnaire questions are often use-case-specific. We limited our approach to searching for general term matches in the terminologies to provide a proof of concept. However, we recognize and want to emphasize that terminology mapping of PRO questionnaires is more than just finding a match for applied use case scenarios. In addition to the term itself, the context must also match. For example, in SNOMED CT, the term *nausea* is a finding that expects a *yes* or *no* response. In contrast, in LOINC, the code *81660-3 | Nausea [Presence]* expects responses such as follows:

- *LA137-2 | None*
- *LA6752-5 | Mild*
- *LA6751-7 | Moderate*
- *LA6750-9 | Severe*
- *LA9041-0 | Resolved*

Therefore, the question and the response must be addressed in the correct context for a proper representation using encoding systems. This also includes the evaluation of multiple isosemantic representations.

In addition to the context, precise wording is paramount for PROs [25]. Mapping the PROMIS-29 questionnaire to LOINC version 2.71 was relatively straightforward because it has its own LOINC profile (*62337-1 | PROMIS item bank - 29 profile*), including codes for questions and response scores. However, caution is still required. Although the LOINC code for the PROMIS-29 panel has basic attributes, including first released and last updated, these version numbers do not match the version number of the underlying questionnaire. The PROMIS-29 questionnaire is available in versions 1.0, 2.0, and 2.1 [36], with changes to the *abilities to participate in social roles and activities* items in versions 2.0 and later. The available LOINC panel, instead, contains only the 1.0 version items. However, the 4 questions that have changed between these versions can also be found in another LOINC panel (*76731-9 | PROMIS short form - ability to participate in social roles and activities 8a - version 2.0*).

In contrast to LOINC, none of the complete PROMIS-29 statements could be mapped to SNOMED CT identifiers. Sometimes, the requested symptom finding could be matched, but without having the full statement (eg, SNOMED CT code: *307077003 | feeling hopeless (finding)*| for the PROMIS-29 statement *In the past seven days I felt hopeless*). However, not all descriptive symptoms (eg, *In the past seven days I felt worthless*) could be found in SNOMED CT. The best SNOMED CT match for the PROMIS-29 response options was obtained with the following:

- The parent concept: *1157335009 | Numeric grade on a scale of 1 to 5 (qualifier)*|
- Its child concept: *1157337001 | Grade 1 on a scale of 1 to 5 (qualifier value)*|
- Up to its child concept: *1157341002 | Grade 5 on a scale of 1 to 5 (qualifier value)*|
- The parent concept: *1157336005 | Numeric grade on a scale of 0 to 10 (qualifier value)*|

Another difficulty is that not all answer options in the PROMIS-29 questionnaire are associated with an ascending scale from 1 to 5. Nevertheless, this scale is sometimes reversed, even though the same text has been assigned. This demonstrates the disadvantage of using only numerical scales alone as terminological concepts for PRO comparison. Instead, it is essential to couple the numerical scales with a semantic representation of their meaning.

For the EORTC QLQ-C30 and QLQ-BR23 questionnaires, finding LOINC terms that semantically matched the questions was difficult. If at all, we could only find phrases formulated as statements that appeared in questions on the EORTC questionnaires, were taken from other questionnaires, and approximated the flow of words. For example, the QLQ-C30 question *Did you need to rest?* has similarities to the LOINC code

- *70815-6 | I need to rest during the day*

from the Functional Assessment of Chronic Illness Therapy (FACIT) Measurement System questionnaire, which is included in LOINC. Sometimes, we also identified multiple LOINC codes that partially matched the searched item from the EORTC

questionnaire. For example, the question *Do you have any trouble taking a long walk?* could be matched to the LOINC code

- *61609-4 | Are you able to go for a walk of at least 15 minutes [PROMIS]* or
- *79006-3 | Are you able to walk more than a mile [PROMIS]*

Overall, we could not match 2 of 30 questions (7%) from the QLQ-C30 questionnaire and 9 of 23 (39%) from the QLQ-BR23 questionnaire. Similar to LOINC, we did not find a single question in the EORTC PROs that exactly matched the SNOMED CT terminology, but we did find at least 1 or more concepts that described the requested symptoms. For example, the QLQ-C30 question *Have you felt nauseated?* could be mapped to the SNOMED CT concept:

- *422587007 | Nausea (finding)|*

Overall, 29 of 30 questions (96%) of the QLQ-C30 and 18 of 23 (78%) of the QLQ-BR23 could be mapped to SNOMED CT terminologies. However, finding appropriate terminologies for response options in SNOMED CT and LOINC has been difficult. The EORTC Quality of Life Group explicitly states that the coupling of textual descriptions and numerical scores is paramount for using their PRO questionnaire concepts [25]. Thus, the simple use of numerical scales such as

- *1157272001 | Numeric grade on a scale of 1 to 4 (qualifier value)|* or

general adjectival modifiers such as

- *89292003 | Rare (qualifier value)|*

would not be sufficient to match the response options. Although the LOINC terminology includes response list codes that include textual descriptions and numerical scores (eg, *LL5215-0*), we could not find a list that correctly matched all scores and associated text.

Adverse events associated with CTCAE-scored drugs have been reported using terminologies such as the Medical Dictionary for Regulatory Activities (MedDRA) [37]. Thus, the CTCAE scoring incorporates certain elements of the MedDRA terminology [24]. In general, there is a mapping between MedDRA and SNOMED CT [37], which can also be used for our purposes. However, this mapping is not freely available. A manual test to find corresponding SNOMED CT identifiers for the first 50 CTCAE terms resulted in 6 missing terms. For the CTCAE response options, the parent concept and its child concepts exist in SNOMED CT:

- Parent concept: *273141005 | Severities (qualifier value)|*
- Child concept: *255604002 | Mild (qualifier value)|*
- Child concept: *6736007 | Moderate (severity modifier) (qualifier value)|*
- Child concept: *2448400 | Severe (severity modifier) (qualifier value)|*
- Child concept: *442452003 | Life threatening severity (qualifier value)|*

However, the last class *dead* of the CTCAE scores is not included in this severity scoring, and there is no direct relationship to adverse events or the meaning of each score for a specific symptom. We have mainly used the European version of SNOMED CT. Nevertheless, we would like to mention that the US version of SNOMED CT has fully equivalent concepts for the CTCAE scores:

- *46411000124101 | Common terminology criteria for adverse events grade 1 (finding)|*
- *446421000124109 | Common terminology criteria for adverse events grade 2 (finding)|*
- *446431000124107 | Common terminology criteria for adverse events grade 3 (finding)|*

However, even with this CTCAE-related scoring, definitions and symptom descriptions are needed for each CTCAE term.

In summary, it is generally challenging to map the exact wording of questions derived from PRO questionnaires to LOINC or SNOMED CT codes if the specific questionnaire is not included in the terminology. However, linking the response options when text is transformed into numeric scales is easier. However, questionnaires like those of the EORTC consortium declare that more is needed to represent numeric response options with the category descriptions [25]. When comparing the 2 ontologies, LOINC was better suited to map PRO questionnaires and their associated response options than SNOMED CT due to its text representation options.

Questionnaire Licenses

Standardized questionnaires are often licensed, for example, from EORTC, and can only be used for patient surveys after obtaining permission. For commercial purposes, permission usually requires payment of a fee. This may prevent their questions and response options from being included in the SNOMED CT or LOINC terminologies. However, even if a licensed version is available, it should be noted that this does not mean that it is freely available for use. For example, LOINC indicates the copyright for terms for which copyright licenses must be considered. Thus, some licensed PRO questionnaires can be found in LOINC, such as the FACIT PRO questionnaire [38] with its 7 panels, including copyright and reference information. This is possible because the English version of FACIT is freely available [38] and can be included in terminology databases. Including at least 1 language version of the PROs in terminology databases would increase the international data exchange and its reusability.

In recent years, there has been a general movement toward “open access” and “open data,” and Creative Commons licenses as an extension of copyright law are seen as a way to protect the origin of data while making it available [39]. In this context, Ehrnsperger and Tietze [40] provide a broad collection of applied cases for patent pledges and open IP. These concepts may also be considered for licensed questionnaires in the future. Furthermore, initiatives such as the Medical Data-Models portal attempt to establish an open metadata repository to overcome the licensing problem [41].

Because standardized questionnaires, such as those of the EORTC Quality of Group, are designed to be culturally independent and have been tested for language comparability [26], linking the data processing to another language would not change the meaning of the data. Instead, the comparability of

the data supports the original intent of the consortia that created each PRO. This reconciliation of different languages would require human effort, but it would be a first step in improving the reusability and comparability of PRO results across studies.

Terminology Changes

Terminologies are not static. LOINC is currently updated twice a year. SNOMED CT International Edition will be updated monthly beginning in 2022. As a result, terms and concepts may become inactive, and definitions may change. Although the meaning of an identifier should be stable, we found LOINC codes assigned to FSNs with several different parts when comparing the 2.64 and 2.75 releases. For example, the LOINC code *18682-5* is mapped to the

- FSN *Ambulance claims attachment:Cmplx:Enctr:^Patient:Set* in the 2.64 release and to the
- FSN *Note:Find:Pt:Ambulance:Doc:Emergency medicine* in the 2.75 release.

So, in the 2.64 release, it was defined as 5 parts. In the current 2.75, it is defined as 6 parts. No part is identical to another.

Time Resolution

Many PRO questionnaires have a general recall period of 7 days [27,42]. However, only some questions in the questionnaire are associated with this period. Some questions do not specify the exact recall period; others include it at the top of a panel but do not specify it for each question. Thus, a semantic matching of the PRO text may not correctly match a textual description that includes the time span, even though both may refer to the same thing. Because the recall time can dilute the remembered details [3], it is essential to include the period in the semantic terminology or at least include it in one of its compositional parts.

Another issue is the semantic representation of time. An example is the textual description of the general PRO recall time, which can be *past week* or *past seven days*. This semantic variation could be resolved using relationships that indicate the same meaning. Notably, some LOINC terms also include the time resolution. Thus, another way to address the issue of including time is to extend the questionnaire FHIR specification in combination with omitting the time range from some LOINC terms. LOINC extension requests could also help to enable full terminology binding of a questionnaire. As a workaround, SNOMED CT concepts could be used to describe the subject of questions semantically.

Opportunities for Improvement

Extension of Terminologies

The interoperability requirement aligns with the original idea of standardized PRO questionnaires that can be used in trials worldwide. However, considering their year of origin, it is evident that digitization aspects were not considered in their development, and most versions were designed in the classical pen-and-paper format. To overcome this limitation, the EORTC Quality of Life Group has developed guidelines for coupling available EORTC instruments with electronic devices [25]. A desirable next step would be to adapt the existing copyright of the PROs to allow at least 1 language version in the terminology databases, as is the case for the FACIT PRO [38].

If licensing issues are not the limiting problem, new codes can be proposed to extend the current databases. In the case of LOINC, the proposal may include new terms for the entire questionnaire, or if some content matches existing terms, they may be included in the submission form and sent to the Regenstrief Institute [17]. Like LOINC, SNOMED CT is also open to requests for additional concepts, coordinated through its members' National Release Centers [16]. Because both terminologies, SNOMED CT and LOINC, are curated databases, it should be expected that not all extension requests will be accepted. In addition, there is a time lag between submitting an extension request and the final release. Special circumstances call for special measures. LOINC allows for advance release of terms for emergency situations (eg, pandemics or new technologies).

However, these prereleases will be reviewed for the next version release and may disappear again. For SNOMED CT, there are 2 other ways to provide additional data: extensions and reference sets [16]. Extensions can be created to support national, local, or organizational needs that may not have international relevance. Instead, reference sets can be made to customize and extend the content for specific needs. However, in addition to the fact that these extensions have limited availability, a disadvantage of these reference sets is that they must be maintained in the future to adapt to new international SNOMED CT releases, which requires more effort than requesting new identifiers.

Combining LOINC and SNOMED CT

Manual mapping of PRO questions has shown a better match using question text from LOINC. If the requested terminology extension is denied or there is too much time between the request and the release, another way to handle questions without matching LOINC terms might be to find SNOMED CT concepts that at least describe the topic of the underlying question. This will not be as specific as a matching question, but it will at least semantically describe the topic of the question. SNOMED CT provides so-called postcoordinated expressions to logically combine multiple identifiers logically to represent a clinical idea at a higher level of detail [16]. A postcoordinated expression can increase the specificity of the topic description for a question. For example, the question *During the past week, have you vomited?* corresponding to the main concept *300359004 | finding of vomiting* is extended by the attribute *Temporal relationship* and the value *per week*, resulting in the following code:

- *300359004 |Finding of vomiting| : 260863009 |Temporal relationship| : 259038000 |per week|*

In the future, it will be possible to use postcoordinated expressions with concrete values such as integer and decimal numbers as attribute values, which are already included in the compositional grammar specification but are not yet available in the International Edition.

Distinction From Other International Medical Terminologies

Here, we have focused on the general applicability of semantic terminologies for PRO questionnaires in the 2 comprehensive terminology systems for clinical settings, SNOMED CT and LOINC, from an international perspective.

However, we would also like to point out some other interesting terminologies that allow PRO mapping, such as the NCI Thesaurus or the MedDRA. While NCI Thesaurus mainly focuses on cancer and thus includes cross-links to CTCAE [43], MedDRA contains a lexicon for adverse events common in clinical trials [34].

A recent study attempted to map free text entries to MedDRA terms manually and found a match for 68% of the terms [34]. However, similar to our findings, the authors encountered the problem that the textual description of adverse events could fit several different terminology codes, but they were mutually exclusive.

Next, we would like to make a small excursion into the general use of these terminologies in the health care sector, where medical documentation is undergoing a paradigm shift. The structured documentation of health data should now facilitate the exchange of patient data and not only be used for statistical and administrative purposes such as billing [44]. This puts the patient at the center of attention [45]. The International Classification of Disease and Related Health Problems (ICD) code is a globally recognized system of medical terminology that provides uniform names for medical diagnoses [46]. Although the semantic terminologies such as SNOMED CT or LOINC are much more fine grained and could, therefore, replace established data collections such as the ICD in health care, they will certainly only be used in the near future in addition to the ICD codes, as the use of ICD codes is legally required [44]. This also requires additional SNOMED CT or LOINC codes that map to the currently accepted ICD code versions ICD-10 or, soon, ICD-11. Because the aim of this viewpoint was to find a reasonably accurate mapping of the PRO questionnaires analyzed, we did not map the PROs studied to the latest ICD-11 code. However, automatic mappings have been proposed for this task [47].

Discussion

Principal Findings

In general, using semantic terminologies is possible to improve the interoperability and reusability of PRO questionnaires and their associated response options. However, this task cannot be automated and requires human effort. In particular, the limited number of available languages limits the general idea of barrier-free interoperability. We have limited our mapping to the English versions of SNOMED CT and LOINC for these reasons. Although this is a limitation of our approach, we believe that this is the most comprehensive version [17,18] and that our results would be even lower for other languages. In addition, the exact mapping of the phrasing needs to be revised. Although the PRO questionnaires examined in SNOMED CT could only be mapped by symptom descriptions, some PRO questions with exact wording could be found in LOINC. Recognizing that we analyzed a limited number of PRO questionnaires, we would also like to highlight the positive development that some have already been entered into LOINC. One reason for not including PRO questionnaires is primarily due to licensing and copyright issues, which currently prohibit the inclusion of the PRO questions in terminologies. Including at least 1 language version of a licensed PRO is desirable. In this context, initiatives such as the MDM-Portal should be mentioned again, which try to provide open formats [41]. Although SNOMED CT offers a wide range of possible numeric response scales, none of the available scales combine numeric scores with textual descriptions required for PROs. Although such a coupling of scores and text is available in LOINC, none of the available scales perfectly matched the response options of the PROs analyzed. In addition, some questions within a questionnaire may have inverted scales, so care must be taken.

Conclusions

In this study, we manually mapped the PRO questionnaires EORTC QLQ-C30 and QLQ-BR23 as well as the PROMIS-29 and a CTCAE-based questionnaire to the 2 widely used standardized terminologies in health care settings, SNOMED CT and LOINC. We showed that among the PRO questionnaires analyzed, only the PROMIS-29 is fully available in LOINC, whereas for the others, between 60.9% and 93.3% of PRO questions could be linked to the LOINC terminology. Although the PROMIS questionnaire is unavailable in SNOMED CT, the American version includes the CTCAE questions, and 78.3%-96.7% of the EORTC questions could be linked to SNOMED CT. Even more critical were our findings concerning the response options. Except for the PROMIS-29 response options in LOINC, which included a score coupled with displayed text, these responses were not available for other questionnaires in any of the terminologies.

It would be desirable to allow at least 1 language version per licensed questionnaire to be included in the terminologies or to use the open formats for future trials. Moreover, special attention should be paid to linking scores and displayed text in the terminologies, as strongly recommended by the original questionnaire settings.

On the basis of our analysis, we recommend LOINC for the future inclusion of additional PRO questionnaires due to its ability to include displayed text.

Acknowledgments

We thank the “Zentrum für Innovative Versorgung” for the fruitful discussion on mapping the analyzed patient-reported outcome questionnaires. HAK acknowledges funding provided by the Ministry of Science and Art Baden-Württemberg (Zentrum für Innovative Versorgung); the German Federal Ministry of Education and Research, as part of the DIFUTURE project (Medical

Informatics Initiative, grant 01ZZ1804I); and the Ministry of Social Affairs and Integration Baden-Württemberg as part of the project feelBack (networked, digital, patient-related psycho-oncology feedback).

Data Availability

All data generated or analyzed during this study will be included in the published article (and its supplementary information files).

Abstract

Background: Clinical decision support (CDS) tools in electronic health records (EHRs) are often used as core strategies to support quality improvement programs in the clinical setting. Monitoring the impact (intended and unintended) of these tools is crucial for program evaluation and adaptation. Existing approaches for monitoring typically rely on health care providers' self-reports or direct observation of clinical workflows, which require substantial data collection efforts and are prone to reporting bias.

Objective: This study aims to develop a novel monitoring method leveraging EHR activity data and demonstrate its use in monitoring the CDS tools implemented by a tobacco cessation program sponsored by the National Cancer Institute's Cancer Center Cessation Initiative (C3I).

Methods: We developed EHR-based metrics to monitor the implementation of two CDS tools: (1) a screening alert reminding clinic staff to complete the smoking assessment and (2) a support alert prompting health care providers to discuss support and treatment options, including referral to a cessation clinic. Using EHR activity data, we measured the completion (encounter-level alert completion rate) and burden (the number of times an alert was fired before completion and time spent handling the alert) of the CDS tools. We report metrics tracked for 12 months post implementation, comparing 7 cancer clinics (2 clinics implemented the screening alert and 5 implemented both alerts) within a C3I center, and identify areas to improve alert design and adoption.

Results: The screening alert fired in 5121 encounters during the 12 months post implementation. The encounter-level alert completion rate (clinic staff acknowledged completion of screening in EHR: 0.55; clinic staff completed EHR documentation of screening results: 0.32) remained stable over time but varied considerably across clinics. The support alert fired in 1074 encounters during the 12 months. Providers acted upon (ie, not postponed) the support alert in 87.3% (n=938) of encounters, identified a

patient ready to quit in 12% (n=129) of encounters, and ordered a referral to the cessation clinic in 2% (n=22) of encounters. With respect to alert burden, on average, both alerts fired over 2 times (screening alert: 2.7; support alert: 2.1) before completion; time spent postponing the screening alert was similar to completing (52 vs 53 seconds) the alert, and time spent postponing the support alert was more than completing (67 vs 50 seconds) the alert per encounter. These findings inform four areas where the alert design and use can be improved: (1) improving alert adoption and completion through local adaptation, (2) improving support alert efficacy by additional strategies including training in provider-patient communication, (3) improving the accuracy of tracking for alert completion, and (4) balancing alert efficacy with the burden.

Conclusions: EHR activity metrics were able to monitor the success and burden of tobacco cessation alerts, allowing for a more nuanced understanding of potential trade-offs associated with alert implementation. These metrics can be used to guide implementation adaptation and are scalable across diverse settings.

Introduction

Background

Provider-facing computerized clinical decision support (CDS) tools in electronic health records (EHRs) are common digital health interventions supporting health care quality improvement programs [1-6]. Monitoring (ie, continual evaluation) of the impact of these tools is important for program evaluation and may ultimately contribute to implementation success [7,8]. Approaches for evaluating CDS tools largely rely on surveys, qualitative interviews, and data collected through direct observation or audio/video recording [9-12]. These approaches require substantial human effort (from implementation staff and clinical teams) for data collection. Automated methods leveraging EHR activity data offer a promising solution to reduce the data collection burden, but research on these methods is still in the earliest stage.

This study aimed to develop automatic metrics to monitor the implementation of EHR-embedded CDS tools and demonstrate their use within the context of a smoking cessation program sponsored by a National Cancer Institute (NCI)–designated cancer center.

Tobacco Control Programs in NCI Cancer Centers

Tobacco use increases the risk of cancer and leads to poor prognosis after cancer diagnosis [13-16]. Clinical practice guidelines recommend routine screening for tobacco use and referral to evidence-based cessation interventions in patients with cancer [17,18], but this practice is underused [19]. To address this practice gap, the NCI's Beau Biden Cancer Moonshot program launched the Cancer Center Cessation Initiative (C3I) in 2017 to provide funding to NCI-designated cancer centers to implement or enhance their tobacco treatment services [20].

Electronic alerts (e-alerts) are common CDS tools in EHRs, promoting adherence to practice guidelines [2-5,21,22], including tobacco screening and treatment at the point of care [23-25]. This strategy has been adopted by some C3I-funded cancer centers [26,27]. However, effective implementation of alerts into the clinical workflow is nontrivial [28-32]. Monitoring of provider responses to newly implemented alerts can identify barriers to adoption and the burden imposed by the alerts.

Study Objectives

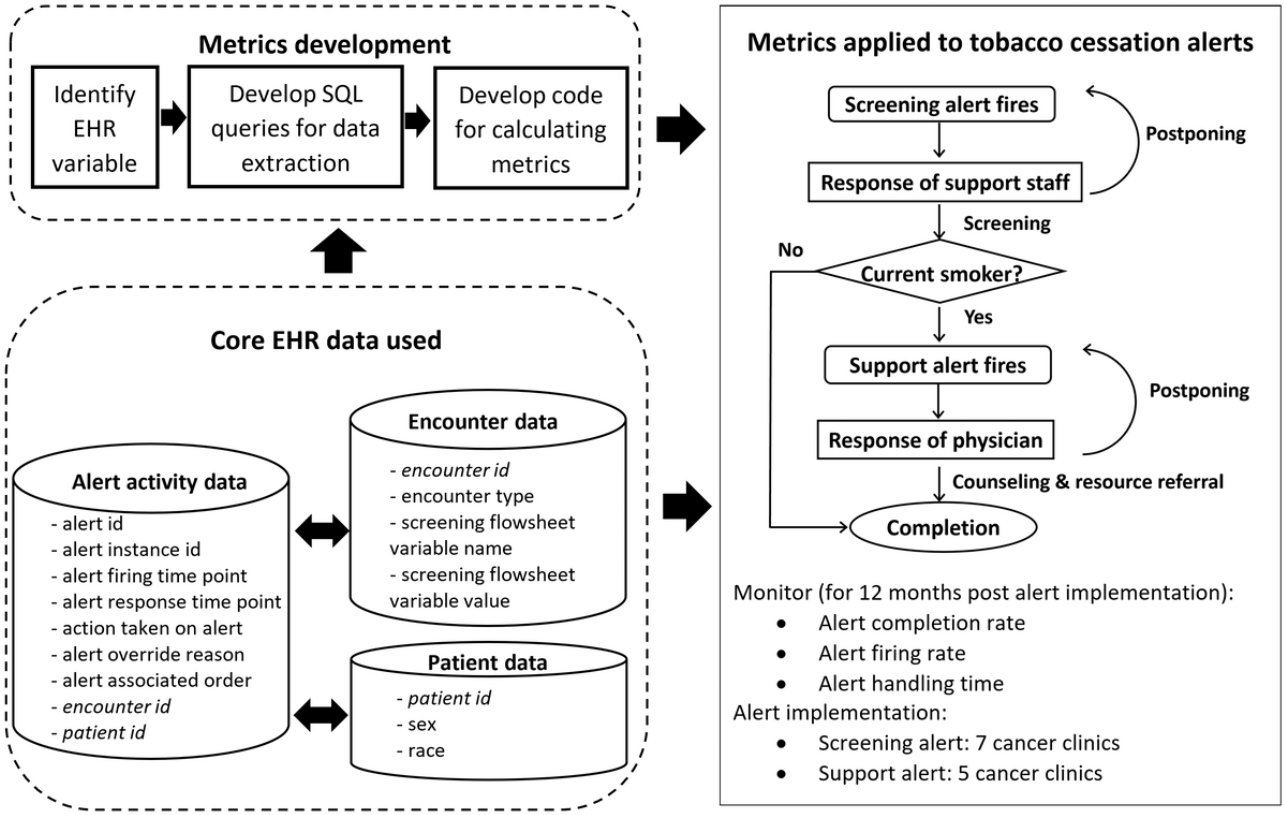
We developed and applied EHR activity metrics to answer three questions. (1) Did the alert completion rate change over time or vary across clinics? (2) What was the burden introduced by the alerts? (3) What factors were associated with variation in alert completion? Our research questions were motivated by three factors. First, sustainability (eg, sustained use and completion of the alerts) is a key construct of implementation outcomes [8] and should be monitored over time. Second, monitoring variations in alert completion across clinics can support the adaptation of alert implementation to the local context. Third, alerts could add a "burden" on providers [30-33], which should be evaluated.

Methods

Study Design

We developed and applied new EHR activity metrics to monitor the tobacco cessation tools (two Best Practice Advisory [BPA] alerts) implemented in cancer clinics for 12 months (Figure 1).

Figure 1. Study overview. The support alert would fire only if the screening result was positive (ie, patient being a current smoker) and answers to both Smoking Screener questions (Q1: "When did you last smoke (even 1 or 2 puffs)?"; Q2: "Quitting smoking could help improve your health. Are you interested in quitting?") were documented (see Multimedia Appendix 1, step B1). EHR: electronic health record.



Ethics Approval

The study was approved by the Wake Forest School of Medicine Institutional Review Board (IRB00066841). Deidentified EHR data were used, with informed consent for data access waved by the institutional review board.

Digital Health Intervention

The CDS tools were two conditional sequential alerts integrated into the Epic EHR, a commercial cloud-based EHR system (Figure 1; detailed in Multimedia Appendix 1): (1) a screening alert to remind clinic staff to complete tobacco screening, triggered if "current smoker" or "unknown smoking status" was previously documented in the EHR, and (2) a support alert to prompt the clinical provider to discuss support and referral to a tobacco cessation clinic, triggered if the screening result was positive and answers to both Smoking Screener questions were answered (see note for Figure 1). Each alert had two modalities: (1) interruptive (triggered when the patient chart was opened; if postponed, presenting again after 10 minutes or when the patient chart was reopened) and (2) noninterruptive (in the general BPA section of the EHR).

Implementation Context

The Tobacco Control Center of Excellence (TCCOE) at the Wake Forest Baptist Comprehensive Cancer Center implemented the alerts in the Epic EHR system used by 7 cancer clinics (medical oncology: n=3; radiation oncology: n=3; cancer survivorship: n=1) in the Atrium Health Wake Forest Baptist Comprehensive Cancer Center in 2019 and 2020. The alerts were integrated into the Epic EHR as BPAs, a form of CDS in the EHR that reminds providers to attend to important tasks [4]. The implementation team from the TCCOE worked with the hospital information technology team on implementing the alerts. The alerts were customized by using rule-based logic (eg, rules on who will receive the alerts and when to fire the alerts; detailed in Multimedia Appendix 1). All 7 clinics implemented the screening alert; 5 implemented the support alert. Training was provided to clinic staff and providers (1-month weekly before or in the first month of implementation and monthly check-in after alert implementation). Some clinics used extensive support from patient navigators and tobacco treatment specialists to complete screening documentation and referral to the cessation clinic.

Evaluation

Metrics Development and Automation

Metrics development took three steps: (1) identifying relevant EHR variables, (2) developing SQL queries to extract variables from the EHR database, and (3) developing computer code to calculate the metrics. We used EHR data associated with 2 clinics to develop and test the metrics. A team of experts in health informatics and implementation science, EHR specialists, and physicians participated in the metrics development.

Using the computer code we developed, EHR data extraction takes about 10 minutes, and the calculation of each metric takes tens of seconds. This speed is adequate for monitoring CDS tools used by implementation programs. Full automation of these metrics is possible after their integration into the EHR.

EHR Variables Used to Derive the Metrics

We extracted alert activity data from event log files of the Epic EHR system. The variables used to develop the metrics included *alert id*, *alert instance id*, *alert name* (eg, a tobacco screening alert), timestamps corresponding to alert firing and provider responding (called *alert firing time point* and *alert response time point* for convenience), *alert triggering condition* (eg, triggered by opening the patient chart), *subsequent actions taken* (eg, acknowledge/override warning), *alert override reason*, and *alert-associated signed orders*.

Each *alert id* is associated with a unique *encounter id* and a *patient id*. An *alert id* corresponds to multiple *alert instance ids* if the alert is fired again after being postponed. *Alert triggering condition* was used to distinguish interruptive alerts from noninterruptive ones.

We used *subsequent actions taken*, *alert override reason*, and *alert-associated signed orders* to identify providers' actions on the alerts. When the clinic staff completed or postponed the screening alert, *subsequent actions taken* recorded a value "acknowledge/override warning," and *alert overridereason* recorded whether the staff acknowledged screening completion (ie, hit the button "Documented in Flowsheet," step A in Figure A1-1, Multimedia Appendix 1), postponed the alert (hit "Defer"), or determined that the patient was inappropriate for screening (hit "Not appropriate"). For the support alert, *subsequent actions taken* recorded a value "acknowledge/override warning" when the provider hit the buttons under "acknowledge reason," and *alert override reason* recorded the provider's actions (eg, discussed or not discussed with patients) and patient's readiness to quit (Figure A1-2, Multimedia Appendix 1). *Alert-associated signed orders* recorded whether the provider placed an order for a referral to the cessation clinic.

In addition, we used two encounter-level variables, *flowsheet name* and *flowsheet value*, to determine whether the clinic staff documented screening results (ie, answers to Q1-Q3 in step B1 in Figure A1-1, Multimedia Appendix 1) in the EHR.

Metrics

We defined three metrics to measure alert completion and burden (Multimedia Appendix 2).

The *alert completion rate* was defined as the number of encounters where a provider completed alert-prompted actions divided by the number of encounters where the alert fired. We defined screening alert completion by either staff's acknowledging completion of screening or completion of EHR documentation of screening results. We defined support alert completion at two levels: (1) discussing with patients and assessing patient readiness to quit ("discussion") or (2) referring patients to the on-site tobacco cessation clinic ("referral").

We measured the burden of interruptive alerts by two metrics: *alert firing rate* and *alert handling time*. We focused on interruptive alerts because they were more likely to add a "burden" on providers [30-33]. We defined *alert firing rate* as the number of times the alert fired during a specific period divided by the number of times the alert was completed during that period. We calculated the average time providers spent completing an alert per encounter, using encounters in which the alert was completed; similarly, we calculated the average time spent postponing alerts per encounter using encounters in which the alert was postponed at least once.

Data Collection

For each clinic, we collected EHR data about clinic characteristics, patient characteristics, and EHR activities related to tobacco cessation alerts. We collected EHR alert activity data as described previously. Each instance of an alert was linked to a specific patient encounter and the patient's demographic information (sex and race), using encounter and patient IDs.

Data Analysis

We summarized clinic and patient characteristics for each clinic. We then used EHR activity metrics to address the research questions related to alert completion and burden. Statistical analyses were conducted using STATA/MP 15.1 (StataCorp LLC) [34].

We measured the overall and per-clinic alert completion rates for the screening alert during every 3-month period across 12 months post alert implementation. The 12-month postimplementation period was specified for each clinic. We measured the support alert completion rate at two levels: "discussion" and "referral."

We measured the alert firing rate and handling time of interruptive screening alerts and support alerts to assess the burden of interruptive alerts.

Factors Associated With Alert Completion

As a secondary analysis, we examined the distribution of alert completion over patients' demographics (sex and race) and encounter types.

Three physicians reviewed all encounter types and selected "relevant encounter" types as those in which screening for smoking status was an appropriate part of routine care (Multimedia Appendix 3).

Results

Clinic Characteristics

The clinics varied in the number of encounters (from n=1464 to n=110,553) and patients (from n=328 to n=9410) during 12 months post alert implementation (Table 1). The typical structure of these clinics was for nurses to support multiple providers across multiple days.

Table 1. Clinic and patient characteristics during the 12 months after implementing tobacco cessation alerts.

[a]M1-M3: medical oncology clinics 1-3.

[b]R1-R3: radiation oncology clinics 1-3.

[c]S: cancer survivorship clinic.

[d]M1 and R1 implemented only the screening alert.

[e]The approximate number of clinic team members (physicians, advanced practice practitioners, nurses, and other clinical staff) in a clinic. The number is not precise due to staff turnover and the hiring of temporary staff.

[f]Some clinics have a small percentage of patients missing information on sex (0.03% missing for R3; complete for other clinics), race (complete for M2; less than 0.3% missing for other clinics), and ethnicity (1% missing for M1, 0.6% missing for R1, 0.2% missing for M3 and R3; complete for other clinics).

[g]Other: American Indian or Alaska Native, Asian, Native Hawaiian or Other Pacific Islander, Latin American or Hispanic, and other.

[h]The percent of patients who were active smokers during 12 months post alert implementation. The denominator is the number of patients who had their smoking status documented in the electronic health record.

Patient Characteristics

The patients seen by the cancer survivorship clinic were 5-8 years older than patients seen by other clinics (mean age for each clinic 59-67; Table 1). Most patients were non-Hispanic White and were beneficiaries of Medicare. The smoking rate ranged between 8.9% (n=45 among 506 patients who had smoking status documented in the EHR; cancer survivorship clinic) and 17.8% (58/325; radiology oncology clinic 2).

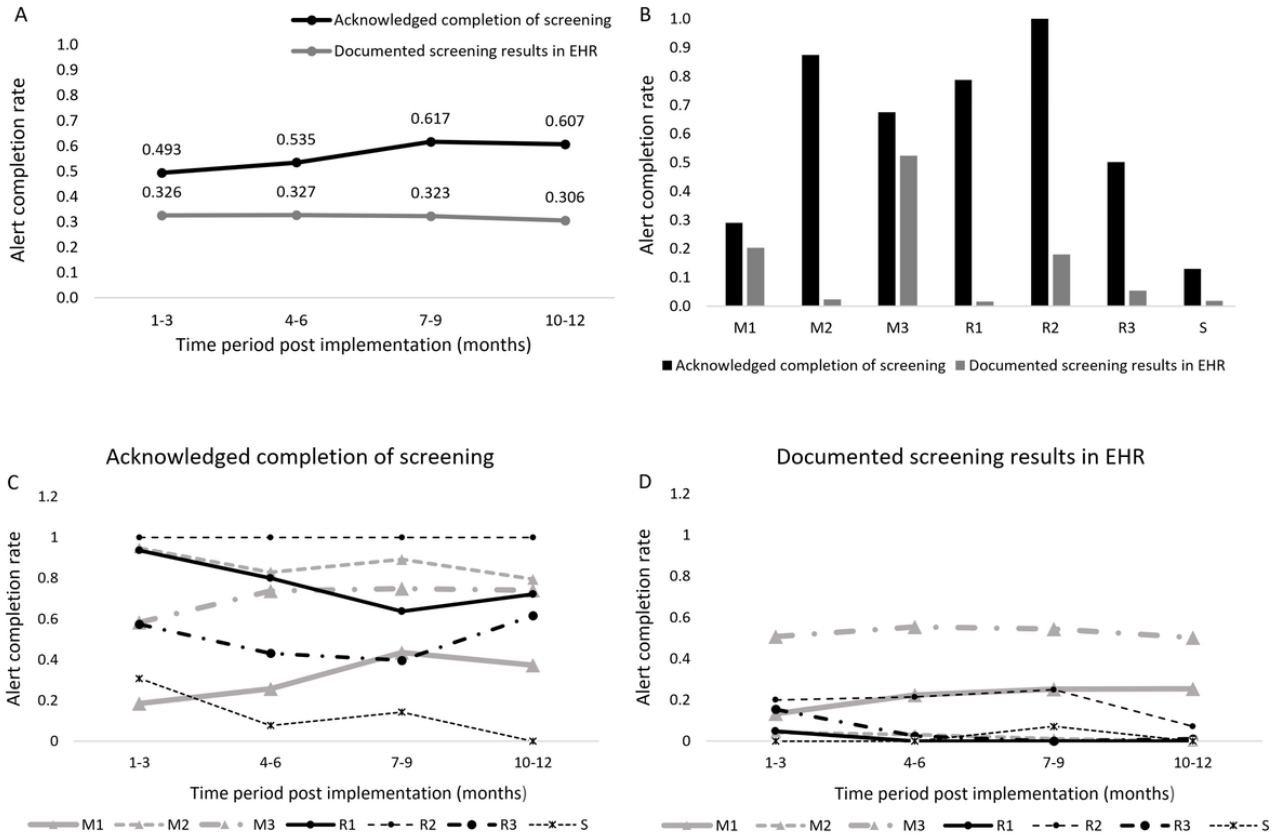
Alert Completion Rate

The screening alert fired in 5121 (2.8% of 180,647) encounters 12 months post implementation. The alert completion rate was 0.55 (2817/5121) based on the staff's acknowledgment of screening completion in EHRs and 0.32 (1647/5121) based on the completion of EHR documentation of screening results. Both alert completion rates remained stable over time (Figure 2A) but varied considerably across clinics (Figure 2B-D).

Among the 2817 encounters where the staff acknowledged completion of screening, 84.7% completed interruptive alerts and 15.4% completed noninterruptive ones.

The support alert was implemented for 5 clinics (medical oncology clinic 2 and 3, radiation oncology clinic 2 and 3, and cancer survivorship clinic) and fired in 1074 encounters. Providers responded without postponing (n=938, 87.3%), discussed tobacco use treatment options (n=640, 59.6%), identified patients who were ready to quit (n=129, 12%), and placed referrals to the cessation clinic (n=22, 2%).

Figure 2. Completion rate of tobacco screening alert for (A) all clinics and (B-D) individual clinics. Clinics in (C) and (D) were categorized into three levels based on the number of encounters in which a screening alert was fired during 12 months post alert implementation. Level 1: >1000; level 2: >100 and ≤1000; level 3: ≤100. Line thickness was used to represent these three levels. EHR: electronic health record. M1-M3: medical oncology clinics 1-3. R1-R3: radiation oncology clinics 1-3. S: cancer survivorship clinic.



The Burden of Interruptive Alerts

On average, the number of times a screening alert was fired before completion was 2.7 (range 1.0-12.7 for individual clinics; Table 2); the average number of times a support alert was fired before completion was 2.1 (range 1.8-3.3 for individual clinics; Table 2).

Table 2. Alert firing rate of the screening alert and the support alert by clinics.

	Medical oncology[a]			Radiation oncology[b]			Cancer survivorship (S[c])
	M1[d]	M2	M3	R1[d]	R2	R3	
Screening alert	4.9[e]	1.3	2.2	2.1	1.0	4.0	12.7
Support alert	N/A[f]	1.8	3.3	N/A	2.3	3.0	3.0

[a]M1-M3: medical oncology clinics 1-3.

[b]R1-R3: radiation oncology clinics 1-3.

[c]S: cancer survivorship clinic.

[d]M1 and R1 implemented only the screening alert.

[e]We defined the alert firing rate as the number of times the alert fired during 12 months post alert implementation divided by the number of times the alert was completed during the same period. We did not calculate the alert firing rate at the encounter level because it was undefined (ie, division by 0) for encounters that did not complete the alert.

[f]N/A: not applicable.

On average, time spent completing the screening alert per encounter was 53 seconds (50 seconds for support alert); time spent postponing screening alerts per encounter was 52 seconds (67 seconds for support alerts).

Factors Associated With Alert Completion

Completion rates of the screening alert and the support alert were balanced across patient subgroups (sex, race, and their interaction).

Among 5121 encounters for which the screening alert was fired, 4425 (86.4%) were "relevant" and 696 (13.6%) were "less relevant" to routine tobacco screening. The alert completion rate for "relevant" encounters was higher than that for "less relevant" ones (2793/4425, 63.1% vs 24/696, 3.5%; $P<.001$).

Discussion

Principal Results

We developed and applied EHR activity metrics to monitor two tobacco cessation CDS alerts implemented in 7 cancer clinics. Our metrics were able to capture variation in alert completion across clinics, monitor alert efficacy, identify discrepancies between staff-acknowledged screening completion and screening documentation, and provide insights into the balance between alert efficacy and imposed burden. These findings inform four areas where CDS tool design or use can be improved (Table 3), which we discuss below.

Table 3. Key findings from the application of the electronic health record (EHR) activity metrics and implications for clinical decision support (CDS) tool design and use.

Key findings from the application of EHR activity metrics	Implications for CDS tools
Variation in alert completion	Potential for improving alert adoption/completion through local adaptation
• The screening alert completion rates varied substantially across the clinics.	Strategies to support use: • Use clinic-specific strategies to support CDS tool adoption
• The screening alert completion rate was higher for encounters perceived as relevant to routine tobacco screening by physicians.	Strategies to support use: • Consider this factor when promoting the use of tobacco cessation CDS tools among health providers
Limited alert efficacy	Potential for improving support alert efficacy
• Providers responded to most support alerts, but few patients were ready to quit, and referral to the tobacco cessation clinic was rare.	Strategies to support use: • Use additional strategies (eg, patient education, provider training in patient-provider communication) to increase the impact of the CDS tools
Inconsistencies between the acknowledgment of alert completion and documented screening	Potential for improving the accuracy of tracking for alert completion
• EHR documentation of screening results was rare for some clinics, even though their clinic staff acknowledged completion of screening for most encounters.	Design: • Improve CDS tool design to allow accurate tracking of screening completion at the alert level Strategies to support use: • Use metrics that can accurately track screening completion, such as metrics calculated based on the completion of EHR documentation of screening results
Interruptive alerts received more responses but also added burden to providers	Importance of balancing alert efficacy with the burden
• Providers were more responsive to interruptive alerts than noninterruptive ones. • Postponing the interruptive alert did not save providers time compared with completing the alert.	Design: • Increase the time interval between postponing and refiring an interruptive alert • Set a threshold to limit the total number of firing of tobacco cessation alerts during a single encounter

Improving Alert Adoption and Completion Through Local Adaptation

Clinics varied substantially in completing the alert, calling for clinic-specific strategies to improve alert adoption. We also identified a modifiable factor (ie, the alert encounter relevance) that affects alert completion. Our physician coauthors considered certain encounter types (eg, initial consultation and office visit) to be relevant for routine tobacco use screening, while others (eg, lab visit and radiation oncology treatment visit) were deemed less relevant. While existing guidelines recommend repeating the smoking assessment at every encounter [17,18], we found that the completion rate of the screening alert was much lower for "less relevant" encounters, which may appear

to be guideline noncompliance. This finding could be informative for committees that develop tobacco screening and treatment guidelines. Implementation teams that want to enforce the "screening at every encounter" rule may need additional strategies. These could include using provider orientation and local champions to influence the culture surrounding tobacco screening [35].

Improving Support Alert Efficacy

Although providers responded to support alerts frequently, referral to the tobacco cessation clinic was rare. One reason was that few patients were ready to quit at the point of care. Future programs may incorporate additional strategies, such as patient education, provider training in patient-provider communication, and addressing patient-level barriers (eg, barriers associated with health beliefs and socioeconomic factors) [36,37]. Note that the 2% referral rate may underestimate the effect of the support alert because it was calculated based on referrals directly linked to the alert. If tobacco treatment specialists contacted the patients interested in quitting after the patient visits, these follow-up activities would be documented elsewhere without a link to the alert, or if a patient chose other treatment methods (eg, quitline or medications), the alert-driven referral would not happen.

Improving Accuracy of Tracking for Alert Completion

The completion rates of the EHR documentation of screening results were lower for some clinics, even though their clinic staff acknowledged screening completion for most encounters. Through discussion with the team coordinating the tobacco cessation program, we identified one major reason for this gap. In clinics using support from patient navigators to complete screening documentation, the clinic staff were likely to bypass the screening but still acknowledged completion. Therefore, measuring EHR documentation is important for the accurate tracking of alert success. We used encounter-level data for this measurement. Alert-level tracking may be necessary for the future development of targeted strategies (eg, provider-specific training) to improve alert adoption. The alert design can be improved to allow this, for example, by disabling the button for acknowledging the completion of screening until the EHR documentation is completed.

Balancing Alert Efficacy With Burden

Although commonly used, effective integration of e-alerts into the clinical workflow has proven difficult [29-33,38,39]. Medication alerts were frequently overridden by health care providers [29,30,33,40], and providers experienced alert-related burden and fatigue [9,29,31,41]. Our study found that postponing the interruptive alert did not save providers time compared with completing the alert. This was partly due to the refiring of postponed alerts. An overabundance of interruptive alerts in EHRs may lead to frequent "postpone" or "override" actions and user dissatisfaction [31-33]. However, our findings do not support disabling the interruptive alerts, as we found that providers were much more responsive to interruptive alerts than noninterruptive ones. One way to alleviate the alert burden is increasing the time interval between postponing and refiring or setting the maximum number of times (eg, 2 or 3) to fire a tobacco cessation alert during each encounter.

Contribution to Implementation Science Methods

New methods are needed for monitoring implementation, including automated approaches that reduce the data collection burden [7,42]. We contributed to this literature by developing automatic EHR activity metrics for monitoring the implementation of CDS tools. Our approach has three merits. First, automatic metrics are suitable for rapid periodic evaluation of implementation programs. These metrics can identify deviations and variations of CDS use at clinic and provider levels, which may inform the selection of key informants for interviews to identify causes of deviation and variation, and the development of strategies to improve CDS design and use. Second, EHR activity data work "behind the scenes" to capture EHR use behavior without interruptions [43-45]. Metrics built on this data can reduce reporting bias and may minimize Hawthorne effects (ie, participants' engagement with an intervention changes when they are aware of attention from observers) [46]. Third, EHRs have been adopted by most US hospitals [47], and EHR-embedded CDS tools are frequently used to support health care quality improvement [1-6]. The ubiquity of EHRs contributes to the generalizability of our approach.

Our work relates to studies using EHR audit logs (one type of EHR activity data) but is different in methodology. The metrics described in these studies measure EHR use and associated burden (eg, total time on EHR, time spent using the EHR after hours, time spent on chart review per patient per day) [48-52] nonspecific to CDS tools. Using EHR audit logs to measure providers' response to a specific EHR tool is challenging, typically involving manual mapping of low-level actions recorded in the log files to EHR use activities [39,50,53]. We used alert activity data generated by Epic's built-in functions to eliminate manual mapping.

Prior studies on alert burden focused on medication alerts and used alert override rate and alert volume as markers for burden in the context of de-implementation [30-33,40]. To our knowledge, this study is the first to systematically measure the burden of preventive care alerts. Our findings did not support a simple de-implementation approach but call for better local adaptation to balance alert efficacy and burden.

Limitations

This study has several limitations. First, the EHR data we analyzed only contained alert-linked referrals to the tobacco cessation clinic. Our analysis may underestimate the actual effect of the support alert. Second, EHR activity data only capture provider interaction with the EHR and lack information about other clinical activities (eg, discussion with patients, pager ringing) during an encounter. In-depth investigations on clinical workflows and their impact on alert response are needed to better understand the variation of alert completion across clinics.

Conclusions

This study developed EHR activity metrics and demonstrated their use in monitoring the impact of CDS tools implemented

by a C3I-funded implementation program that promotes tobacco cessation in patients with cancer. These metrics can be used to guide implementation adaptation and are scalable and adaptable to other settings that use e-alerts to promote adherence to health practice guidelines.

Acknowledgments

The tobacco cessation alerts were implemented by the Tobacco Control Center of Excellence for clinics at the Wake Forest Baptist Comprehensive Cancer Center. The Wake Forest Baptist Comprehensive Cancer Center was renamed Atrium Health Wake Forest Baptist Comprehensive Cancer Center in 2021.

This work was supported by the National Cancer Institute of the US National Institutes of Health (grants P50CA244693 and P30 CA012197, and CRDF award 66590 through the Cancer Center Cessation Initiative Coordinating Center contract) and the National Heart, Lung, and Blood Institute of the US National Institutes of Health (grant K12HL138049 to JC through the Massachusetts Consortium for Cardiopulmonary Implementation Science Scholars K12 Training Program). The study funder had no role in the design of the study; the collection, analysis, and interpretation of the data; and the decision to submit for publication.

Data Availability

Data supporting the study reported in this paper can be made available in deidentified form subject to establishing a data use agreement with the Wake Forest University School of Medicine. The code supporting this study can be accessed on GitHub [54].

Authors' Contributions

All authors take responsibility for the manuscript content, made critical revisions or contributed important intellectual content, and took the decision to submit the final manuscript. KLF, TKH, SLC, JC, ECD, and ELS obtained funding for this study. JC, TKH, and SLC conceptualized the study. JC designed and developed the electronic health record metrics, with advice from TKH and input from all coauthors. AB, AM, BO, SCB, and ERH obtained or provided data. JC, TKH, SLC, and AD analyzed data. JC and TKH visualized and interpreted the results. SLC, AD, SCB, KLF, ECD, and ELS provided critical feedback on metrics design and result interpretation. JC, TKH, SLC, and KLF wrote the first draft of the manuscript. JC, TKH, SLC, AD, SCB, KLF, BO, ERH, AB, AM, ECD, and ELS contributed to the manuscript revision.

Conflicts of Interest

AD serves as an EHR Consultant for the AAMC CORE program. AD is a co-inventor of WHIRL, which is licensed to IllumiCare, Inc. They have an ownership interest in the WHIRL application. AD is also a co-inventor of mPATH. They have equity in Digital Health Navigation (DHN) Solutions, which has licensed mPATH. None of these potential COIs overlap in any way with the content of the current study.

Abstract

Background: While high-quality primary health care services can meet 80%-90% of health needs over a person's lifetime, this potential is severely hindered in many low-resource countries by a constrained health care system. There is a growing consensus that effectively designed, resourced, and managed community health worker programs are a critical component of a well-functioning primary health system, and digital technology is recognized as an important enabler of health systems transformation.

Objective: In this implementation report, we describe the design and rollout of Zanzibar's national, digitally enabled community health program–Jamii ni Afya.

Methods: Since 2010, D-tree International has partnered with the Ministry of Health Zanzibar to pilot and generate evidence for a digitally enabled community health program, which was formally adopted and scaled nationally by the government in 2018. Community health workers use a mobile app that guides service delivery and data collection for home-based health services, resulting in comprehensive service delivery, access to real-time data, efficient management of resources, and continuous quality improvement.

Results: The Zanzibar government has documented increases in the delivery of health facilities among pregnant women and reductions in stunting among children younger than 5 years since the community health program has scaled. Key success factors included starting with the health challenge and local context rather than the technology, usage of data for decision-making, and extensive collaboration with local and global partners and funders. Lessons learned include the significant time it takes to scale and institutionalize a digital health systems innovation due to the time to generate evidence, change opinions, and build capacity.

Conclusions: Jamii ni Afya represents one of the world's first examples of a nationally scaled digitally enabled community health program. This implementation report outlines key successes and lessons learned, which may have applicability to other governments and partners working to sustainably strengthen primary health systems.

Introduction

Background

The World Health Organization estimates that high-quality primary health care services can meet 80%-90% of health needs over a person's lifetime [1]. However, in many low-resource countries, this potential is severely hindered by a constrained health care system tackling significant shortages of health workers and the stock of lifesaving medical supplies, all of which limit progress toward universal health coverage (UHC) and damage trust among users [2,3]. There is a growing consensus that effectively designed and managed community health worker (CHW) programs are a critical component of a well-functioning primary health system [4-6]. CHWs have significant potential to extend health services to people's homes, build relationships and meet individual health needs, improve access to services, and improve health system performance [7]. In addition, CHW programs have been shown to deliver a 10:1 return on investment due to increased productivity from a healthier population [8]. Despite this potential, scale-up and management of CHW programs has been slow and often underprioritized by governments [9].

Digital technology has been increasingly recognized as a critical tool to improve both access to health care and the quality of health care delivery, even for CHW programs [10]. Mobile apps, which are designed to fit the local context and are based on program guidelines, can support CHWs to register households and individuals in their communities, thus guiding CHWs through home-based visits following government guidelines. These tools, when integrated into broader digital and public health systems, can improve supervision, coordination, and program monitoring through access to real-time client-level data.

Zanzibar's Community Health Context

The islands of Zanzibar are a semiautonomous region of Tanzania with a population of 1.9 million people. One in 33 women in Zanzibar are estimated to die of maternal complications in her lifetime [11], 20% of children are stunted [12], and Zanzibaris face a high burden of noncommunicable diseases [13]. There is a significant human resource shortage that exacerbates health system challenges; currently, Zanzibar is lacking more than 3900 health workers, which implies a 35% shortage. A key priority for the Ministry of Health Zanzibar is to strengthen its primary health system, including community health [14].

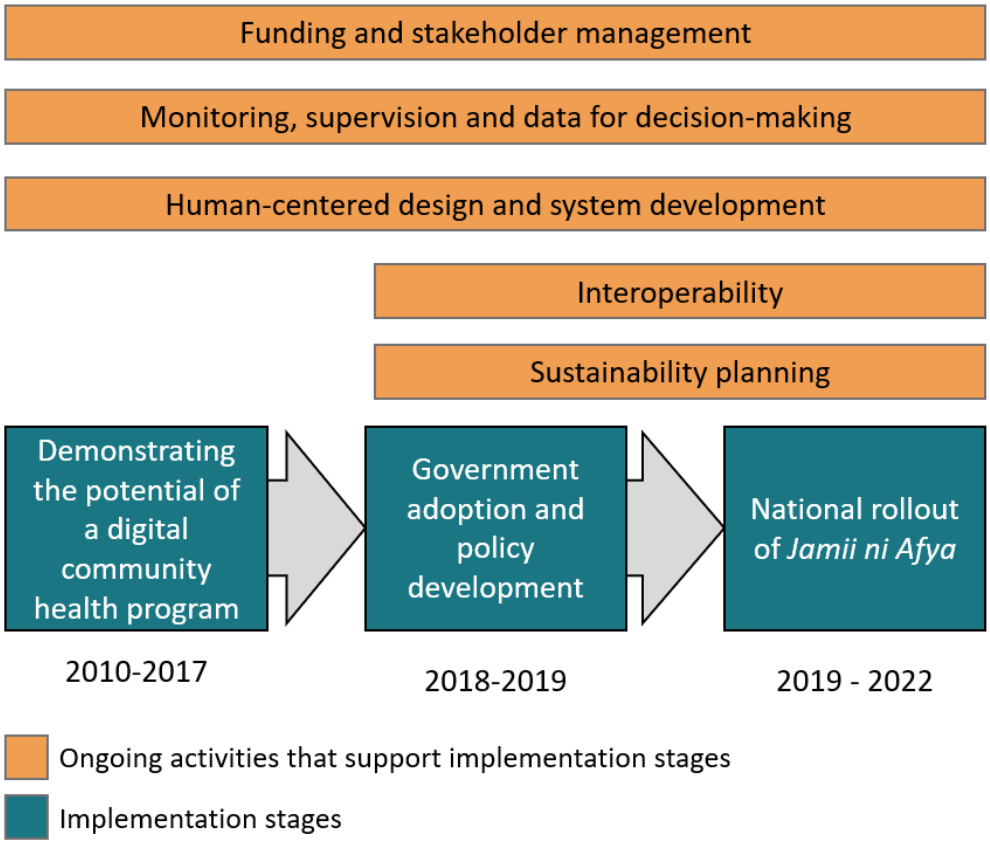
Until recently, community health programs in Zanzibar were traditionally siloed by vertical health programs, funded by donors, and implemented by nongovernmental organizations (NGOs) with programs ending based on donor funding cycles and thematic areas of interest. This resulted in lack of coordination, duplication of efforts, and hindered long-term sustainability. In 2018, the Revolutionary Government of Zanzibar (RGoZ) took the pivotal step of formalizing a government-led community health program, bringing together all previously siloed, donor-funded programs under a single national program, making the pivotal decision to digitize the community health workforce from the start.

In this implementation report, we describe the design and rollout of Zanzibar's national digitally enabled community health program. Our aim is to share lessons learned, drivers for success, and best practices to help other countries succeed in designing, scaling, and sustaining digitally enabled community health programs. This implementation report follows the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) [15].

Methods

In this section, we present the stages of the evolution of Zanzibar's community health program, which are summarized in Figure 1.

Figure 1. Stages of the evolution of Zanzibar's community health program.



Demonstrating the Potential of a Digital Community Health Program

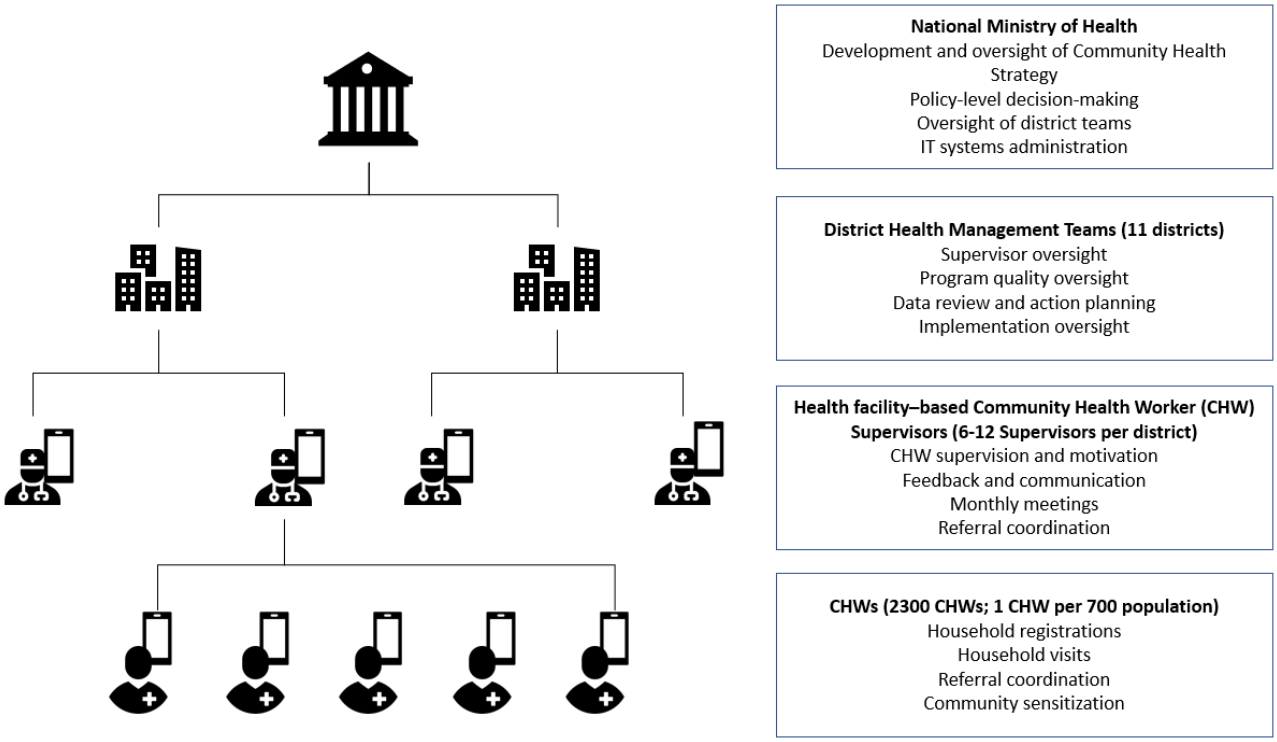
D-tree International, a digital health NGO, began working with the RGoZ in 2010 on Safer Deliveries—a digitally enabled maternal and newborn community health pilot project aimed at increasing facility deliveries and improving postpartum care. This project has been described elsewhere [16,17]. Briefly, CHWs were trained, supervised, and equipped with a mobile app to enable them to register pregnant women, provide health education, screen them for danger signs and refer them to a health facility, and link them with locally available transportation. From 2012 to 2018, this project supported 400 CHWs to care for over 80,000 pregnant women and their newborns and demonstrated an increase in pregnant women delivering at health facilities from 50% to 75% (a 50% increase), led to increases in facility-based postpartum care visits from 20% to 80%, and increased the completion of community facility referrals from 27% to 90% [16]. Clients reported receiving personalized, responsive, and compassionate care. They were empowered to provide direct feedback about the quality of facility-based services, which district health teams used to monitor and improve service quality. Health facility staff and District Health Management Teams were involved in the program design to ensure that health facilities—especially primary health care facilities—were prepared for increased demand for maternal health services.

Government Adoption and Policy Development

Based on the success of the Safer Deliveries project and the recognition that a digitally enabled, government-owned community health system was critical to sustainably improve health in general in Zanzibar, the RGoZ adopted this digital CHW program as part of the formal health system at the national level, unifying all community health programs through this single initiative named "Jamii ni Afya" (Swahili for "Community is Health"). In order to formalize this program as a government initiative, the RGoZ updated its community health strategy to make Jamii ni Afya a central pillar of community health. This strategy serves as a formal government document outlining how community health volunteers fit into the larger Zanzibar health system and specifying their roles, responsibilities, training, and required qualifications. Figure 2 summarizes the structure of the community health program. In particular, the revised community health strategy specifies that CHWs will be supported with a digital health platform, as the Ministry of Health Zanzibar recognized the benefits of technology in the pursuit of its vision for a healthy population.

The program uses the term "community health volunteers" to emphasize engagement on a volunteer basis; however, in line with prior literature, we will henceforth refer to them as CHWs.

Figure 2. Structure of the Zanzibar community health program. CHW: community health worker.



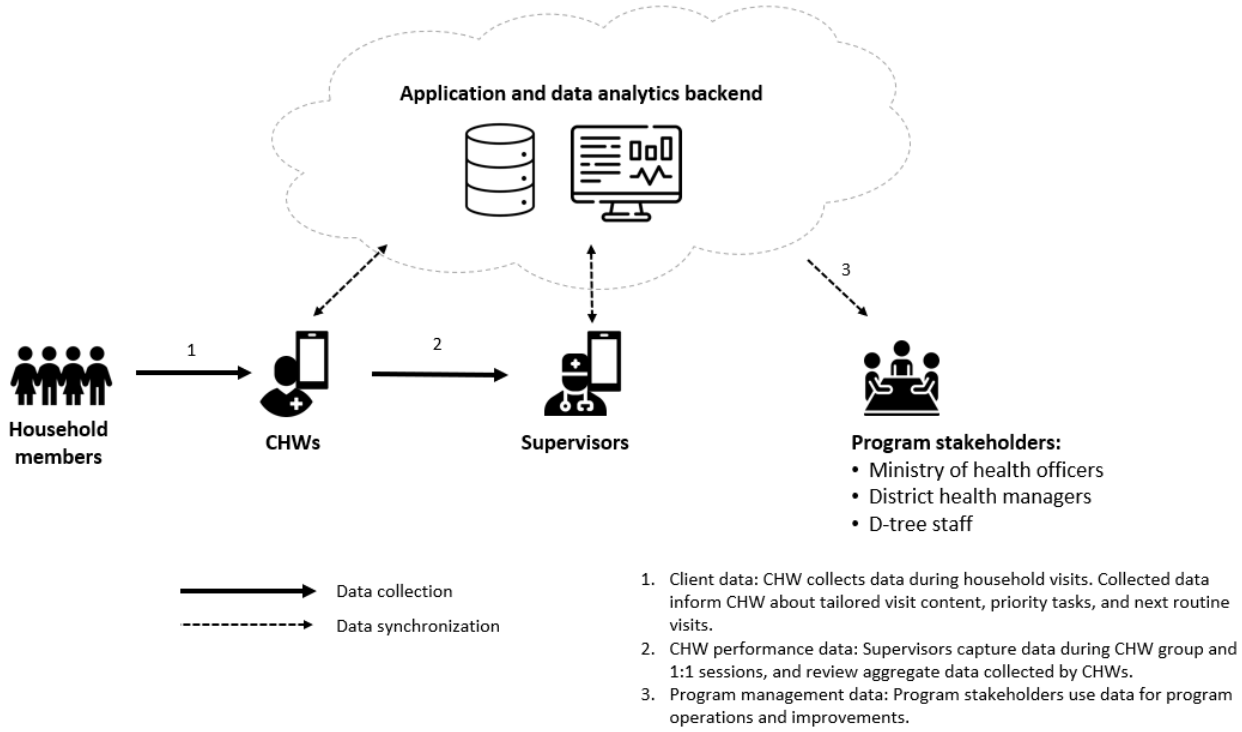
Human-Centered Design and Development

From January to June 2019, the Ministry of Health Zanzibar, D-tree International, and other community health stakeholders participated in a human-centered design process to cocreate both the programmatic and technical aspects of the Jamii ni Afya app. The approach was to fully define the health problem and local context first and then select the technology that is best suited to solve that problem. Thus, the program and technology design processes were conducted simultaneously, where program requirements—including health objectives, CHW workflows, supervisory systems, and long-term government management capacity—informed technology design choices. Community health stakeholders included community members, political and religious village leaders, CHWs, CHW supervisors, and District Health Management Teams. Input was initially gathered through sensitization meetings with all abovementioned community stakeholders and then periodically with district managers. Supervisors also had WhatsApp groups to discuss program questions. During app design and development, CHWs were involved in early prototype testing. Further feedback was gathered during CHW training sessions by observing how well CHWs were able to conduct practical exercises on a training app. After implementation, feedback was gathered during field observations. All activities considered the local context, including gathering buy-in from political village leaders; conducting activities with larger groups and broad participation given the communal culture; and understanding basic digital literacy, resulting in involving CHWs in later app design stages.

The Principles for Digital Development [18] were used throughout the design process, specifically “design with the user,” “understand the existing ecosystem,” “design for scale,” and “reuse and improve” to ensure that the resulting system was locally relevant, user-friendly, cost-effective, and sustainable.

Jamii ni Afya leverages government guidelines and global best practices to guide CHWs using digital technology in delivering high-quality health education and counseling services in maternal and child health, nutrition, water, sanitation and hygiene, and early childhood development. The data generated from these interactions are used to further personalize health services by tailoring health messages based on the personal circumstances of the client, improving supervision, and supporting programmatic and policy decision-making at the community, district, and national levels. For example, if a pregnant woman has specific risk factors (based on government guidelines), the app flags that she should plan to deliver at a hospital rather than a primary health facility, and subsequent counseling within the app supports the woman to develop a birth plan for delivery at the nearest hospital. If a CHW indicates that a child has developmental delays (based on observing the child and caregivers at home), the app suggests specific play activities that the caregivers can undertake to support the child’s development. Figure 3 illustrates the data flow for the program.

Figure 3. Flow of data within Jamii ni Afya. CHW: community health worker.



Interoperability

The Jamii ni Afya mobile app is built on the Community Health Toolkit (CHT), an open-source global goods platform developed to support community health workers globally. This platform was selected by the Zanzibar government due to the following reasons: it is open-source and uses well-known components and frameworks, it has a growing community that can be leveraged for support, it can be hosted in a local data center, the skills required to configure health worker tools are found among Ministry of Information, Communications and Technology staff, and it is easily available in the local market. In addition, CHT runs on low-end Android smartphones and has offline functionality, which is critical in Zanzibar where network connectivity is not guaranteed. Developers from D-tree International and the Ministry of Health Zanzibar led the mobile app development process, including system requirements and specifications. The system was designed to ensure interoperability with the broader digital health ecosystem in Zanzibar. The CHT is integrated with the government's health management information system (District Health Information System [DHIS2]) and provides data for the community health information system. Jamii ni Afya is referenced in the RGoZ's first-ever digital health strategy, which works to coordinate and optimize government resources for digital health in Zanzibar. It is integrated with the Zanzibar Health Interoperability Layer (based on OpenHIM) and can thus integrate with an up and coming electronic medical records system. There are plans to integrate with the future client registry system and a health care worker registry. To date, interoperability has been achieved at the level of data exchange, which is a foundational level focusing on sending and receiving information without interpreting it. Interpretation occurs at the receiving end in accordance with separately defined specifications. For example, when integrating with DHIS2, the submitted data payload was formatted in accordance with DHIS2 requirements, and the meaning of the data payload was agreed on by the involved technical teams. The OpenHIM-based interoperability layer enables higher levels of interoperability, including interoperability of data structures, meaning of data, process, organizational rules, etc. This affords the interpretation of data and information without a system having to understand the DHIS2 or CHT, and makes interoperability with additional systems and platforms easier. However, the technical teams agreed that OpenHIM would initially only pass through payloads—that is, it would not use the higher-level interoperability options—to speed up implementation. For new integrations and for updated integrations, it is planned to leverage terminology and other data standards, which will be consistent with the planned electronic medical record system, but the specific standards are still under discussion.

National Rollout

Jamii ni Afya was introduced in phases from July 2019 to August 2021 to all of Zanzibar's 11 districts. Throughout the rollout, the Ministry of Health Zanzibar played a central role, from recruiting and training CHWs and supervisors, raising awareness in communities, and coordinating supportive supervision for health workers. The standard implementation approach used to scale up the project included community sensitization, recruitment and selection of CHWs and health facility–based supervisors, 10 days of training on the overall program and mobile app, and intensive mentorship for a 3-week period, followed by ongoing monthly supervision and semiannual refresher trainings.

Monitoring, Supervision, and Data-Driven Decision-Making

As a by-product of program implementation, Jamii ni Afya collects extensive data on enrollment, health care usage, and health outcomes. These data are made available on program dashboards that are used by district health management teams to monitor program progress and CHW performance, track health trends, and identify challenges. Supervisors have a mobile app that displays data on the CHWs they supervise, enabling tailored and prompt follow-up and support. We leverage these data in 3 important ways. First, we continuously evaluate the process of program rollout and scale-up to identify successes and areas for improvement [17]. Second, we evaluate the impact of specific components of our program on key outcomes. For example, we found that the number and timing of CHW visits increases the likelihood of health facility delivery [19]. Third, we develop and embed prediction models built using machine learning to tailor our program to individuals and communities [20].

Insights from monitoring and evaluation are used to inform ongoing quality improvement. In 2017, district health managers used the program dashboard to identify that 37% of women were paying for antenatal services, even though they are supposed to be free of charge. The district health team learned that facilities were chronically out of stock for the reagents for tests performed at antenatal visits, and needed to charge clients for services so they could procure these reagents from local pharmacies. With this information, the district health team met with the District Commissioner and presented the data and findings. They were able to obtain a commitment to increase the district health budget to cover the cost of these reagents. Prior to the digital program, district managers knew women were paying for health services but could not back this up with data and were, therefore, never able to advocate for increased funding. Due to this action by the district health team, payments for antenatal care decreased immediately from 37% to 1%.

With Jamii ni Afya established as a fully scaled national government program, there is also increasing interest to leverage the resulting data for other purposes. For example, the RGoZ is exploring how Jamii ni Afya can collect household socioeconomic data during routine visits, which can inform subsidies for the upcoming Universal Health Insurance program.

Sustainability Planning

RGoZ's leadership has been critical to Jamii ni Afya's success and instilled trust in the population for the long-term sustainability of the program. By establishing Jamii ni Afya as part of a national strategy, the government has been able to formally assign oversight and implementation responsibility to government staff so that running the program becomes part of their job description and regular responsibility. The government directly pays the salaries of Jamii ni Afya CHW supervisors (210 individuals), who are health care providers working at health facilities and are 100% dedicated to community health. In addition, 1 person in each of Zanzibar's 11 districts acts as a District Health Promotion Focal Person for Jamii ni Afya. These government employees are responsible for district-level coordination of the program, which has been critical for program oversight, government commitment, and ownership.

The Zanzibar Community Health Strategy Costed Operational Plan developed by the Ministry of Health Zanzibar in 2022 found that the annual operating cost for Jamii ni Afya is TZS 6.4 billion (approximately US $2.73 million), which is equivalent to US $1.70 per capita. Currently, the government is spending US $0.30 per capita on Jamii ni Afya salaries. The remaining costs are covered by donor funds, which funds equipment and working tools, CHW stipends, training, meetings, technology, and hosting costs. The RGoZ has committed to increasing their funding commitments by 25% each year for the next 4 years, until they are fully funding the program by the end of 2026. Of note, the cost per capita is the cost of the entire community health program, which includes the digital health system. We have not isolated the digital system costs since technology is fully integrated in the community health program and cannot be viewed as a stand-alone cost.

Funding and Stakeholder Management

Since the program's inception in 2010, a variety of funders have contributed to the development, piloting, and scale of Jamii ni Afya. From 2010 to 2014, the pilot project was funded by the Bill & Melinda Gates Foundation through their Grand Challenges initiative, which enabled early evidence generation. From 2014 to 2018, the project was funded by the Saving Lives at Birth Grand Challenges Transition to Scale grant, which allowed the program to scale to all districts in Zanzibar and further generate evidence. In 2018, when the program was formally adopted by the RGoZ, funders included Fondation Botnar and the Human Development Innovation Fund. Since 2019, the program also received cofunding from the James Percy Foundation, UNICEF (United Nations Children's Fund), the Conrad N. Hilton Foundation, Google AI for Social Good, the Patrick J. McGovern Foundation, and Jhpiego.

Implementation (Results)

Since August 2021, Jamii ni Afya has been operating on a full national scale. In total, 2300 CHWs and 210 supervisors have been trained to support every household in Zanzibar. As of March 2023, more than 1.5 million people had been registered to the system, representing nearly 80% of Zanzibar's population, and over 320,000 pregnant women and children younger than 5 years have received health visits.

Both the current Jamii ni Afya and prior Safer Deliveries programs focus on education and promotion of health-seeking behavior for maternal and child health and have played a role in positive trends in key health outcomes. The percentage of women delivering at a health facility increased from a baseline of 64% [11] in 2015 to 85% among women registered in the program in 2022, implying a 33% increase. In addition, rates of stunting reduced from 30.4% in 2015 to 17.6% in 2022 [11,21]. While we cannot attribute these reductions to Jamii ni Afya, we are confident that the program's focus on education and promotion of health-seeking behavior for maternal and child health played a role in these significant changes. To directly quantify the Jamii ni Afya's impact on early childhood

development outcomes, our team implemented a nationally representative baseline survey in 2018 with a postimplementation survey planned for late 2023 [22].

There were many factors that led to the success of Jamii ni Afya as a nationally scaled, digital community health program. Briefly, a key element was designing the program by starting with the health challenge and local context rather than the technology. Only when the health challenge was defined and a clear vision for what was possible was conceptualized did we bring in technology, which enabled us to focus on the need, rather than the technology solution. In addition, we leveraged the Principles for Digital Development to guide the technology design process. We also heavily focused on the use of data for decision-making, which amplified the value of the program beyond service delivery, and demonstrated how population-level data could add tremendous value to planning, budgeting, and policy-making at the local, district, and national levels. Finally, extensive collaboration with local and global partners was critical to the success of Jamii ni Afya. The project team engaged with global technology partners, health experts, evaluators, data scientists, and data governance coalitions. Within Zanzibar, collaboration with health experts, universities, political strategists, and communication experts helped to shape the program and support its sustainability. Collaboration with long-term and flexible funders was also key to Jamii ni Afya's success, enabling the project to adapt on the basis of evolving needs and understanding throughout various stages of maturity.

While there were many success factors, there are also a number of challenges and lessons learned. In general, a key lesson is that scaling and sustaining a national digital health program is time-consuming. When we began implementing in 2010, digital health was not a key priority for the RGoZ. It took years to demonstrate the value of the system and get key leaders on board. In addition, it is challenging to successfully scale a digital health intervention when a country has low maturity in foundational aspects of digital health overall (such as digital health leadership and governance, digital health infrastructure, standards and interoperability, and health workforce capacity in digital health). Over the course of the last 13 years, we have been supporting the RGoZ to advance its digital health capacity, which is critical to sustain the Jamii ni Afya program. However, this takes time and significant investment. In addition, managing competing stakeholder interest is a challenge. Often, funders and implementing organizations push for their own interests to be prioritized, which may not be aligned with government priorities. We have been working closely with the Ministry of Health Zanzibar to develop processes and guidelines to manage stakeholder demands in a way that enables continued investment but also ensures that development of the program is aligned with government interest and need. Finally, government capacity and long-term sustainable financing is a challenge, which we are addressing through a formal transition plan, and describe further in the *Discussion* section.

The current focus on Jamii ni Afya is full transition to the RGoZ. Working with partners, the government has developed a transition plan that outlines the financial, technological, and operational aspects of the program that will be fully absorbed by the government by 2026. D-tree International and partners are supporting skills transfer and systems development to enable this transition, recognizing that financing and management of a nationally scaled digitally enabled community health program is a major undertaking, and strong accompaniment from nongovernmental organizations is critical to the effective handover of such a system.

Discussion

This implementation report outlines the evolution of Zanzibar's national, digitally enabled community health program. Since 2010, the program grew from a small pilot to a nationally scaled, government-owned initiative that is set to be fully institutionalized within the national health system. During this time, we have learned many lessons and best practices that may be relevant to governments and practitioners designing, scaling, and institutionalizing digitally enabled community health programs.

Community health programs have traditionally been driven by vertical health programs (ie, HIV/AIDS, family planning, or maternal health) and focus on specific health service delivery [9,23]. With Jamii ni Afya, we focused on designing a strong community health system, independent of the types of services being delivered, which serves as a strong foundation on which to add service delivery areas. The Zanzibar Community Health Strategy is a critical document that not only formalizes Jamii ni Afya as a government initiative, but also outlines critical systems-level criteria to guide the program. This includes defining the supervision structure, selection criteria, and training and stipend payments, which is aligned with the World Health Organization's guidelines for community health [10].

Just as it is important to invest in building strong foundations in the community health system, it is critical to design digital health initiatives that are integrated and harmonized with the broader digital health ecosystem. A recent article by Karamagi et al [24] describes the alarming lack of coordination, integration, scalability, and sustainability of digital health interventions in sub-Saharan Africa. Through the design of Jamii ni Afya, we were intentional in ensuring that the digital system was interoperable with other digital health systems such as DHIS2 in order to enable the transfer of data between systems. The Jamii ni Afya team was also closely involved in the development of the Zanzibar Digital Health Strategy, which features Jamii ni Afya as a core digital health intervention. Jamii ni Afya was among the first systems to adopt the Zanzibar Health Interoperability Layer, which lays the foundation for seamless data exchange across systems. These intentional design decisions, coupled with integrating the program into government policy, have set the stage to ensure long-term coordination and synergy with the evolving digital health landscape in Zanzibar.

Having the right leadership is recognized as a critical lever to accelerate the institutionalization of a product or service [25]. Strong leadership, ranging from the highest levels of government to local community leaders, may be the single-most important success factor for Jamii ni Afya. Extensive work was carried out early on to establish buy-in and trust at the community level. Community sensitization was built into the national rollout plan, leveraging shehas (ward leaders) to champion the initiative

within their communities. Sensitization activities were led by district- and national-level government staff who introduced the program as a government-led initiative, and CHWs have official government-issued identification cards that provide increased credibility. These initiatives were critical in building public trust and ownership of Jamii ni Afya from the beginning, resulting in 90% of the population being registered in the program. We also focused on high-level political support to champion this initiative and set the stage for full government ownership and sustainable financing. In February 2023, the Minister of Health Zanzibar presented Jamii ni Afya to the Zanzibar President who pledged his commitment to champion the institutionalization of this initiative. While this support is encouraging, one lesson learned is the importance of high-level political engagement early on. The Jamii ni Afya team initially focused on community, district, and departmental support within the Ministry of Health Zanzibar in order to build buy-in and support, and only after the program was established, began lobbying higher levels of government for their support. Earlier engagement with these higher levels may have expedited the institutionalization process.

The evolution of Jamii ni Afya has lasted nearly 13 years and is now in a strong position to be institutionalized within Zanzibar's health system. Each stage of the project—beginning with a small pilot to demonstrate the potential of this model, gaining consensus for government adoption, and integrating the program into government policies—was critical to build demand and formalize Jamii ni Afya as a government initiative. Often, donors expect that health systems strengthening initiative, including digital health, should be conceptualized, piloted, scaled, and institutionalized within a short period of a few years. However, our experience is consistent with that of other studies and shows that significant digital health systems transformations take time and require funding and partnerships to accompany governments on their journey to scale [26].

One of the most significant challenges for Jamii ni Afya's institutionalization is sustainable financing, which is a common challenge for community health programs across many low- and middle-income countries [27]. The RGoZ has committed to full institutionalization of Jamii ni Afya by 2026, which is an ambitious target and will require substantial political commitment and innovative solutions. The Jamii ni Afya program's team is currently working on a number of strategies to support the government to fully finance the program within 4 years. One way is to increase demand for the program outside of the health sector. Jamii ni Afya champions are in discussion with the Ministry of Finance Zanzibar, Ministry of Social Welfare, Ministry of Agriculture, and Ministry of Education to discuss how existing or new data from Jamii ni Afya could be valuable to them, or the potential of expanding the package of services delivered by CHWs. By extending the value of the program outside of the Ministry of Health Zanzibar, additional government entities can contribute toward operating costs, thus reducing the burden on any one particular ministry and reducing duplication of efforts. We are also in the process of integrating Jamii ni Afya into the government's upcoming Universal Health Insurance scheme, which will be rolled out in the next 1-2 years. The Jamii ni Afya digital platform can be leveraged to collect data on household economic status and feedback on health facility quality, and CHWs can support registration of households into the program. In turn, the community health program can be partially financed by revenue generated through the Universal Health Insurance scheme. It has been reported that many national health insurance schemes fail to adequately engage the informal sector [28]. Leveraging CHWs to support these efforts in Zanzibar could both increase participation in the informal sector and support operational costs for the community health program. There is also increasing support from multilateral donors who are increasingly investing in digitally enabled community health systems and provide funding directly to governments to decrease financial reliance on nongovernmental partners. This multipronged financing approach is aligned with a recent review that found that an adaptive mix of health financing mechanisms is necessary for low- and middle-income countries [29].

In conclusion, Jamii ni Afya represents one of the world's first examples of a nationally scaled digitally enabled community health program. This implementation report outlines the evolution of this program, from the pilot to the national scale and institutionalization. While Zanzibar has a relatively small population and is geographically isolated, the challenges they face are similar to many other settings. Indeed, based on the experience in Zanzibar, D-tree International is replicating this approach by supporting government-led digital community health initiatives in Mainland Tanzania and Zambia. However, drawing on work from Greenhalgh et al [30], we also recognize that the spread and scale-up of innovations is a combination of technical, ecological, and social aspects and require social science approaches to understand and facilitate change based on local contextual factors and incentives [30]. The authors hope that the experiences and lessons learned described in this implementation report will be helpful to others working to implement digitally enabled community health systems at scale. In addition, given the maturity of Jamii ni Afya, the relatively small size of Zanzibar's population, and the significant health need, there is an opportunity for Zanzibar to become a digital health implementation research hub in order to test new and promising innovations, research various implementation models, and develop best practices that can be applicable in other settings.

Authors' Contributions

EL made substantial contributions to the conception and design, drafted the manuscript, revised it critically, and granted final approval for the version submitted. SS, IM, and AWAM revised the manuscript critically and granted final approval for the version submitted. GVRB made substantial contributions to the conception and design, revised the manuscript critically, and granted final approval of the version submitted. Abstract

Background: Yaoundé Central Hospital (YCH), located in the capital of Cameroon, is one of the leading referral hospitals in Cameroon. The hospital has several departments, including the Department of Gynecology-Obstetrics (hereinafter referred to as "the Maternity"). This clinical department has faced numerous problems with clinical information management, including the lack of high-quality and reliable clinical information, lack of access to this information, and poor use of this information.

Objective: We aim to improve the management of clinical information generated at the Maternity at YCH and to describe the challenges, success factors, and lessons learned during its implementation and use.

Methods: Based on an open-source hospital information system (HIS), this intervention implemented a clinical information system (CIS) at the Maternity at YCH and was carried out using the HERMES model—the first part aimed to cover outpatient consultations, billing, and cash management of the Maternity. Geneva University Hospitals supported this project, and several outcomes were measured at the end. The following outcomes were assessed: project management, technical and organizational aspects, leadership, change management, user training, and system use.

Implementation (Results): The first part of the project was completed, and the CIS was deployed in the Maternity at YCH. The main technical activities were adapting the open-source HIS to manage outpatient consultations and develop integrated billing and cash management software. In addition to technical aspects, we implemented several other activities. They consisted of the implementation of appropriate project governance or management, improvement of the organizational processes at the Maternity, promotion of the local digital health leadership and performance of change management, and implementation of the training and support of users. Despite barriers encountered during the project, the 6-month evaluation showed that the CIS was effectively used during the first 6 months.

Conclusions: Implementation of the HIS or CIS is feasible in a resource-limited setting such as Cameroon. The CIS was implemented based on good practices at the Maternity at YCH. This project had successes but also many challenges. Beyond project management and technical and financial aspects, the other main problems of implementing health information systems or HISs in Africa lie in digital health leadership, governance, and change management. This digital health leadership, governance, and change management should prioritize data as a tool for improving productivity and managing health institutions, and promote a data culture among health professionals to support a change in mindset and the acquisition of information management skills. Moreover, in countries with a highly centralized political system like ours, a high-level strategic and political anchor for such projects is often necessary to guarantee their success.

implementation report; challenges; success factors; Sub-Saharan Africa; Cameroon; healthcare; health care; clinical information; information management; clinical information systems; hospital information systems; data governance

Introduction

Cameroon is a transitional country located in Central Africa. As a resource-limited country, its health system faces many challenges and barriers [1,2]; these include inadequate quality of care, human resources, health infrastructure, poor drug supply, poor health financing, and poor health information management. Yaoundé Central Hospital (YCH) is located in Cameroon's capital city; it is one of the country's leading national referral hospitals. YCH has several departments, including the Department of Gynecology-Obstetrics, also known as (and hereinafter referred to as) "the Maternity." The management of clinical information at the Maternity has multiple limitations including those identified by the World Health Organization's classification of digital health interventions: lack of high-quality and reliable clinical information (issues with data completeness, integrity, and confidentiality), lack of access to the information, and its insufficient use for management and decision-making [3]. This poorly managed clinical information prevents clinicians from accessing information regarding diagnoses, treatments, prescriptions, and previous care [4]. This results in fragmented processes, reduced quality and safety of care, and increased cost of care. Implementing and strengthening robust hospital information systems (HISs) or clinical information systems (CISs) is one of the solutions to these problems [5-8]. The MatLook Project was initiated between the Geneva University Hospitals (HUG) and the YCH to implement an electronic CIS to strengthen the HIS in the Maternity at YCH. This implementation report follows the Guidelines and Checklist for the Reporting on Digital Health Implementations (iCHECK-DH) [9].

Methods

Objectives

The general objective of the MatLook Project was to improve the management of clinical information generated at the Maternity at YCH. This implementation report describes the results of the implementation and the associated challenges, success factors, and lessons learned. The primary outcome of this implementation was the completion of the parameterization of MediBoard [10] and services developed, and determination of the level of the deployment of the solution. Secondary outcomes were the development of a procedure manual and determination of the level of its implementation, implementation of training sessions for users, determination of the level of implementation of change management support for users, determination of the level of use of the solution, establishment of project governance or management, development of local leadership to promote the use of the solution, and use of this information for the management of the Maternity or the hospital.

Technical Design

The objectives of this project were aligned with YCH's strategy, one of its goals being to use ICT to improve YCH's productivity. This project corresponds to categories H and K (electronic medical record and facility management information system, respectively) of World Health Organization's classification of digital health interventions [3]. At the time this project was implemented, Cameroon did not have a national digital health strategy.

The project was conducted using the HERMES method [11]. This project management method is used in IT, service or product development, and organizational adaptation. It consists of 4 phases: initialization, design, implementation, and deployment. Each step comprises tasks or activities to be performed by roles to achieve the expected results. Each stage leads to a decision or milestone that enables the project to proceed to the next phase. In addition to these phases, plans were developed for risk management, marketing and communication (web portals, newsletters, and information sessions), project quality assurance, and solution testing.

The project was organized into 2 parts. The first part aimed to cover outpatient consultations, billing, and maternity cash management. Billing and cash management were to be handled through the additional development of billing and cash management software that interoperates with this CIS. This first part, including all the 4 phases of the HERMES model, cross-functional project management activities, and users' training, lasted approximately 15 months. The second part aimed to cover other care processes, such as hospitalization management, delivery management, surgery management, etc.

From a technical point of view, the project consisted in adapting and parameterizing an existing open-source hospital information system called MediBoard [10]. The choice of this solution was based on a comparative study of several HISs with the advantage of being open-source with a dynamic community, the existence of a French version, the fact that several functionalities cover the needs of a hospital located in a resource-limited setting such as Cameroon, and the possibility of making the necessary adaptations relatively quickly [12]. It was also based on the experience of a successful implementation in Mali [6]. MediBoard is an open-source HIS developed in a modular and multilayer web architecture, using Apache, PHP, MySQL, XML, XHTML, JavaScript, CSS, Prototype.js, Smarty, and PEAR. It contains several functionalities such as management of administrative, medical, and nursing patient files; prescription management; consultation appointment management; hospitalization management; billing and accounting management (this service was not adapted to the processes in place, where, for example, people pay before they receive treatment); stock management; human resources management; meal management; quality assurance; incident management; etc.

Target

The Maternity at YCH was chosen as the pilot unit to implement the solution. It is the second largest maternity unit in Yaoundé after the Yaoundé Gynaecology, Obstetrics and Pediatrics Hospital, which specializes in mother and child care (detailed data not available). This clinical department registers approximately 20,000 patients per year (65% of which are registered through outpatient consultations), 3500 deliveries, and 1000 surgical interventions (63% of which are caesarean deliveries, the remaining 37% of them being ectopic pregnancies, uterine revisions, hysterectomies, myomectomies, cystectomies, etc).

The targets of this intervention were the staff at the Maternity at YCH, including the managers and administrators, health professionals, the team responsible for billing and cash management, and the patients.

Data

Cameroon has a law (n° 2010/012, December 21, 2010) on cybersecurity and cybercrime, which protects and ensures respect for the privacy of individuals and punishes offences related to the use of information and communication technologies in Cameroon.

Data were collected using computers in consultation rooms, doctors' offices, and treatment rooms. The data were processed and stored at the YCH (data owner) on a data server acquired for this project. The data were disseminated through the intranet network implemented for this project. Several security measures were implemented to ensure data security: physical security (secure rooms dedicated to the server and switches) and computer security and confidentiality (access to the wired intranet network via a dynamic host configuration protocol, implementation of firewalls, management of user profiles, and control of access rights—authentication and authorization—via logins and passwords). Based on their level of confidentiality, the people who had access to these data were reception and triage nurses, doctors, nurses, administrative and financial staff, and patients.

Interoperability

MediBoard integrates technical interoperability standards such as HL7 (Health Level 7; technical specifications for computerized exchange of clinical, financial, and administrative data between HISs) and HPRIM (harmoniser et promouvoir l'informatique médicale [English: harmonizing and promoting medical informatics] for transmitting information regarding biological examinations in France). It also integrates semantic interoperability standards such as *ICD-10* (*10th revision of the International Classification of Diseases*) and CCAM (Classification Commune des Actes Médicaux [English: Common Classification of Medical Procedures]), which lists all medical procedures to be performed by doctors, midwives, and dental surgeons.

Participating Entities

At the national level, this project was supported exclusively by the direction of the YCH through the signing of an authorization by the director to carry out a feasibility study and the signing of a decision authorizing the implementation of the project in this hospital. This local institutional support, the needs and requests formulated by the beneficiaries, the potential of the YCH in terms of equipment and human resources, the existence of local expertise in the field of digital health, the individuals in charge of operational management of the project, and the financial guarantees enabled us to implement the project. The project was implemented within the framework of existing cooperation agreements between the YCH, which committed to financing one-third of the budget, and the HUG, which committed to funding two-thirds of the budget. The government was not directly involved because the framework was the existing cooperation agreement between these 2 hospitals.

Budget Planning

This project was estimated at CHF 60,000 (US $65,144.64): CHF 8000 (US $8685.95) for the adaptation of the MediBoard software; CHF 33,000 (US $35,829.55) for investments (intranet network, servers, computers, switches, etc), communication, and marketing of the project; CHF 14,000 (US $15,200.42) for operations (project management, change management, management of steering, and working meetings with the Maternity user group); CHF 2000 (US $2171.49) for training and support of users; and finally CHF 3000 (US $3257.23) for the evaluation of the solution by an external evaluator of the project. This budget was intended to cover the first and second parts of the project.

Sustainability

To ensure the sustainability of this project, several actions have been taken, including the alignment of the project's objectives with those of YCH and its implementation with the agreement of the director of YCH; the commitment of the director to fund one-third of the budget; the establishment of a steering committee including all YCH stakeholders; the integration of the YCH IT manager as the deputy project manager; the creation of a user group to assist the project group in the design and the implementation of the project; the designation of local champions to promote the use of the CIS; and finally, the official launch (supported by a document signed by the director) of this CIS at the Maternity.

Ethical Considerations

The study does not require ethical approval since it focuses on the implementation of a clinical information system based on an open-source hospital information system. No individual patient data was collected as part of this project.

Implementation (Results)

Coverage

The first part of the project covered the Maternity's outpatient consultations and billing and cash management. The processes covered were the administrative and financial management of patients (administrative data, billing, and payments); management of appointments and clinical information (clinical observations, requests for laboratory and radiological tests, management of the results of these tests, prescriptions for medical consumables, drugs, and medical procedures). The second part did not take place due to nonpayment of one-third of the funding from the YCH.

Outcomes

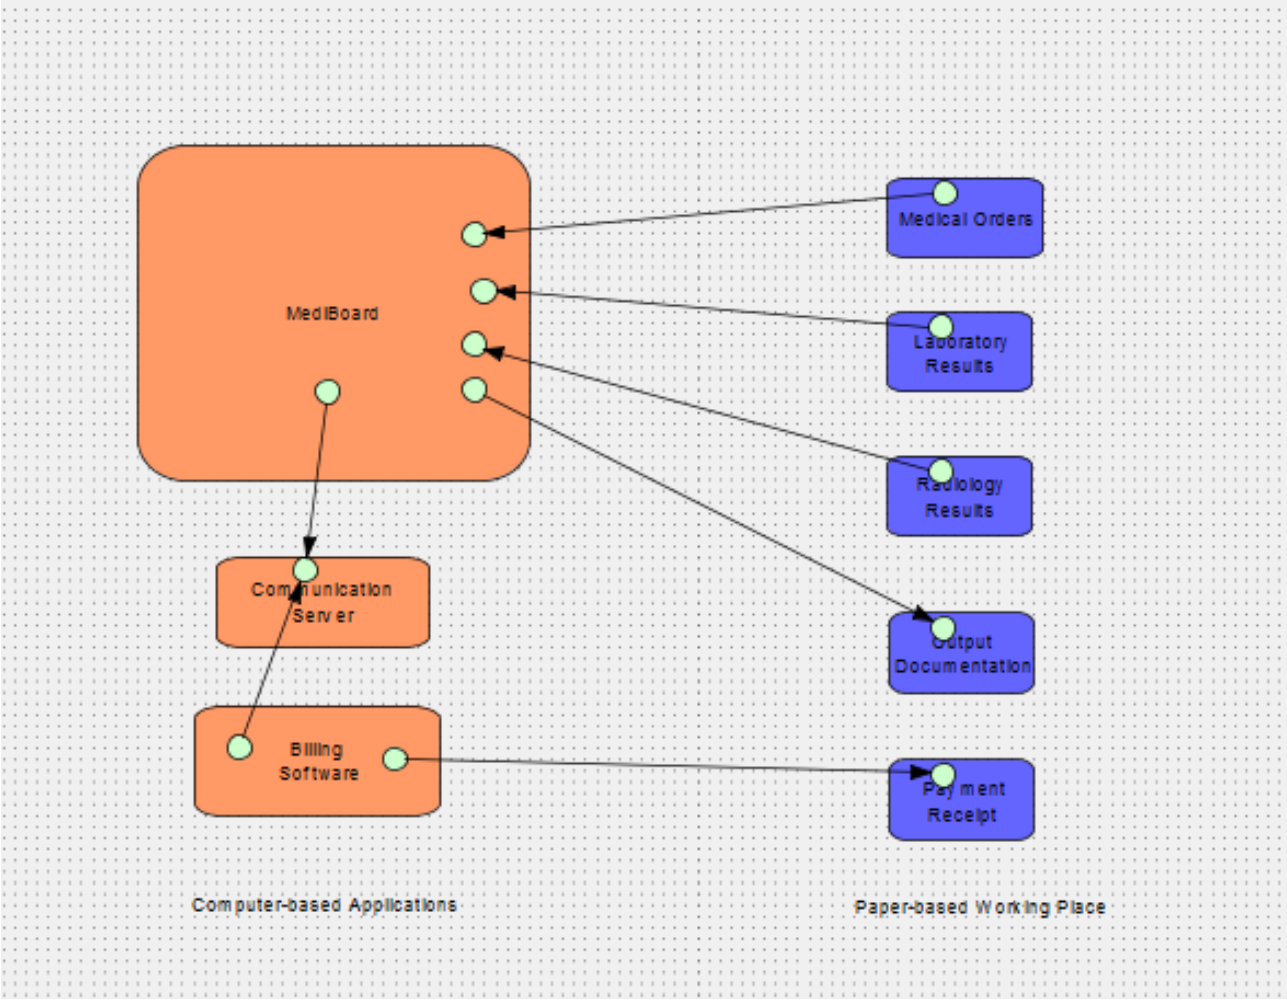
The MediBoard software was adapted to manage outpatient consultations. The software parameterization activities included filling in the YCH metadata; adapting forms for entering administrative and sociodemographic data of patients, clinical observations, laboratory and radiology test requests, collection of test result data, medical consumables, and prescription for drugs and medical procedure; defining user profiles (doctor-head of department, gynecologist, resident, reception nurse, student, and secretary) and creating user accounts for maternity health care professionals.

A complementary billing and cash management module, integrating local coding of medical procedures was developed, validated ad hoc, and integrated into the MediBoard HIS (Figure 1) [13]. This software had several functionalities, namely invoice management (creation, modification, and possibility to pay all or part of the invoice); invoice quote management (creation, modification, and transformation of invoice quotes); medical procedure management (editing of medical procedures carried out or the tariffs of these medical procedures); and cash and accounting management (statements of financial entries by the cashier by medical procedure, service, practitioner, period, etc). These services have been deployed at the Maternity at YCH.

An intranet network with a capacity of 40 computers was implemented, and equipment (1 server and 20 laptops) was provided. Security was ensured by physical measures (restriction of access to servers, switches, and consultation rooms) and information and communication technology (ICT) measures (restriction of access to the local network and access to the user account via logins and passwords).

The solution was deployed to cover the Maternity's outpatient consultations and billing and cash management and was used over 6 months.

Figure 1. The architecture of the clinical information system of the Department of Gynecology-Obstetrics at Yaoundé Central Hospital (logical level based on the 3LGM^2 model).



To ensure proper functioning of the solution, a user guide and a procedure manual specifying required organizational architecture, processes covered, rules, roles and privileges, and options for entering medical data during the consultation were developed. This procedure manual made it possible, for example, to redefine the workflow for the patient coming for an outpatient consultation.

Users (the staff involved) were regularly trained (before the start of the use of the system and at each staff turnover; this was due to high staff turnover) on the new organizational processes and for proper use of the CIS. This training was provided by a dedicated staff explicitly recruited in the project for this task.

In total, 80 people were trained, including senior gynecologists, gynecology residents, medical students, nurses in charge of reception and recording patients' parameters, and administrative and financial staff. This was a 100% increase on the initial target of people who could benefit from the training during this stage of the project (part 1).

Support staff was recruited to provide specific support to users of the CIS. Computer maintenance was shared between the project team and the YCH IT staff.

An evaluation of the use of this system carried out 6 months after the use of the CIS revealed 113 users, 1278 patient records,

and 960 medical consultations recorded, corresponding to a financial income of approximately CHF 8000 (US $8685).

In terms of project governance or management, the project was organized as follows: a steering committee comprising the hospital's administrative, business, and financial managers to steer the project; a project team comprising external and internal skills in medical informatics, informatics, and project management to implement the project; and a user group comprising health professionals at the Maternity (1 department head physician; 2 gynecologists; 1 anesthesiologist; 4 care coordinators for the outpatient consultations, delivery room, hospitalization, and operating room; 1 nurse; and 1 midwife) to monitor the project activities and to verify that they meet the users' needs. A marketing and risk management plan for the project has been drawn up. A communication based on the distribution of posters presenting the advantages of the new solution was carried out for the health care professionals and the patients.

Regarding leadership, the 2 heads of department for maternity units A and B were involved as local champions (health professionals of the Maternity who have adopted IT and are ready to provide leadership for their integration in health care in motherhood) to promote the use of the CIS.

Due to the short evaluation period, we could not objectify using the dashboard indicators in the management of the Maternity or the hospital.

Lessons Learned

Success Factors

Several factors contributed positively to the progress of the project—these include the feasibility and implementation agreements of the MatLook project issued by the YCH management; the implementation of a project organization integrating the steering committee, the project group, and the user group; the management of the project based on a robust methodology (HERMES model); the involvement of local champions to ensure leadership and to promote the use of this system; the success of software parameterization and development activities; the realization of several communication and marketing activities for the project and the ongoing training and support of users; and the feasibility and implementation agreements of the MatLook project issued by the YCH management.

Challenges

Throughout the project, several challenges or barriers were encountered. These included a change of director of the YCH (3 months after the official launch of the project); lack of leadership from local champions; lack of standard care procedures or protocols; resistance to change; insufficient ICT skills among maternity staff; lack of staff to enter data into the electronic CIS; high staff turnover leading to an increase in the frequency of training sessions on the use of the CIS; poor promotion and valorization of this project within the institution; and an increase in workload due to the diversity of supports to be completed (paper-based service registers coupled with the electronic CIS).

Finally, another challenge was about the reliability and confidentiality of the data collected and the level of responsibility of residents and students for these data. Due to a lack of ICT skills, senior gynecologists gave their logins and passwords to residents or students to document patients' case files in the electronic CIS on their behalf. This last problem, relating to the exchange of logins and passwords among gynecologists, residents, and students, was identified as soon as the CIS was introduced. To mitigate this, we carried out an awareness-raising campaign among users, demonstrating the risks of this practice and urging them to stop. In addition, we held a meeting with the user group to find more sustainable solutions. The solutions proposed were organizing workshops to strengthen gynecologists' data entry skills; making consultation notebooks with tracers so that stubs could be used for data entry after patients' encounters; and recruiting medical secretaries dedicated to this data entry activity. Unfortunately, none of these measures could be implemented due to a lack of resources.

Budget Report

Of the expected CHF 60,000 (US $65,144.64), the project received CHF 40,000 (US $43,360.52; two-thirds of the expected funding) from HUG. These funds were allocated as follows: CHF 8000 (US $8685.95) for the adaptation of the MediBoard software (part 1), CHF 18,500 (US $20,054.24) for the investments (intranet network, computer equipment, and communication and marketing of the project), CHF 9000 (US $9756.12) for operations (project management, change management, management of steering and working meetings, and incentives for health professionals to document cases), CHF 3000 (US $3257.23) for training and support of users, and finally, CHF 1500 (US $1626.02) for the transport of some equipment (servers and computers) from Geneva to Yaoundé and bank account fees. The CHF 20,000 (US $21,680.26; one-third) that was to be paid by the YCH was not paid. This money was to be used as follows: CHF 4000 (US $4336.05) for the adaptation of the MediBoard software (part 2), CHF 4000 (US $4336.05) for the investments (computer equipment, communication, and marketing of the project), CHF 6000 (US $6504.08) for operations (project management, change management, management of steering and working meetings, and incentives for health professionals to document cases), CHF 3000 (US $3252.04) for training and support of users, and finally, CHF 3000 (US $3252.04) for the evaluation of the solution.

Unintended Consequences

During this project and after implementing some approaches for change management (setting up a user group, identifying local champions, training users, implementing new processes based on the procedure manual, and setting up user support), we experienced an unintended or unexpected event—staff reluctance to use the system after implementation. The reason was the lack of financial motivation. This situation required the project management team to implement a special documentation gratification (per diem introduced to encourage staff to enter patient information into the system). At the end of this documentation gratification fund (approximately 6 months after

the beginning of the use of the CIS), users stopped entering data. In addition, due to the lack of funding from the YCH, part 2 of the project could not be continued, which raises the issue of trust and institutional continuity in sub-Saharan Africa.

Discussion

Implementing HIS or CIS is feasible in a resource-limited country such as Cameroon. The management of this process is complex and critical to the success of the project.

The implementation of this CIS at the Maternity at YCH was carried out following the defined and approved institutional framework (feasibility and implementation agreements issued by the YCH management, mobilization, and cofunding of the HUG partner) and by relying on a methodology (HERMES phase model) adapted to the implementation of such projects. This project enabled the deployment of a functional CIS at the Maternity at YCH covering (in part 1) outpatient consultations and billing and cash management.

As with any project of this type in our setting, where the implementation of HIS or CIS is still at the embryonic stage, this project registered successes but also many challenges, which have been described in detail in the *Implementation (Results)* section.

Publications describing such implementations in Africa have highlighted similar difficulties: low staff involvement, lack of project management skills, insufficient ICT skills among users, lack of political and administrative support for the project, lack of an interoperability framework, low funding, and lack of logistical support and system maintenance [8,14-18].

In addition, a study evaluating the main factors of failure in implementing HISs in several African hospitals showed that the main difficulties encountered were not technical [8]. They were mainly human, cultural, social, administrative, and environmental, such as skepticism, resistance to change, insufficient ICT skills, poor organization (operating in silos), unrealistic implementation deadlines, insufficient technical support, and lack of support for users after implementation [8,17].

On the other hand, factors strongly associated with success were adequate allocation of resources (infrastructure, human, and financial), good communication, good planning and project management, ability to reorganize the institution to adapt to new processes, local buy-in from stakeholders, implementation based on a holistic approach (integration of all services), highlighting successes to motivate users and reduce mistrust, adequate technical support, perceived usefulness and user satisfaction [6,16,19,20]. To increase the chances of success, in addition to technical aspects (software and equipment) and human resources, good planning, stakeholder commitment, and in-depth change management were required [7]. It is also essential to prioritize design: “enhancing consultations during the intervention design, better consideration of implementation challenges during the design and better recognition of relations between different influences” [21].

By taking into account lessons learned from previous CIS or HIS implementations, including those conducted in resource-limited settings and in addition to technical aspects, we emphasized the management, organizational, leadership, and change management aspects during the project’s implementation. This concerned the representation of all entities (steering committee, project team, and user group), phase-based project management, marketing of the project, management of communication with all stakeholders, drafting and implementation of a procedure manual, use of local champions, change management activities (user awareness–raising activities and allocation of dedicated human resources for responsive users’ support), and finally, the training of users. We also sent a letter and had a meeting with the director of the YCH about the project and raised awareness among health care professionals, managers, and decision makers about the importance of an HIS or CIS in a hospital through scientific conferences and the general public media, etc.

Despite all these approaches, and as shown by our results, beyond the project management, technical, and financial aspects, the other main problems of implementing health or hospital information systems in sub-Saharan Africa lies in digital health leadership, governance, and change management. This digital health leadership, governance, and change management should prioritize data as a tool for improving productivity and managing health care institutions, promote a data culture among health care professionals to support the change of mindset, and the acquisition of information management skills (collection, processing, discussion, and use).

However, the use of good practice in managing a digital health project for setting up a new system by incorporating a good grasp of the project management, technical, organizational, leadership and cultural aspects does not always guarantee its success [18]. In countries with a highly centralized political system such as ours, it is very often necessary for such projects to have a high-level strategic and political anchor (for example, at the level of the ministries responsible for public health or telecommunications or even higher authorities such as the prime minister or the president of the republic). The government has a critical role in developing a vision and creating the foundation upon which innovation activities will be developed [22]. In Mali, for example, the success of the implementation of the HIS at the CHU Mère-Enfant Le Luxembourg was partially based on the support received by the country's first lady. Furthermore, a decision by the minister of health in 2011, with the advent of health insurance in Mali, enabled this tool to be deployed in 72 hospitals nationwide. In the case of our project, at the time of its implementation, Cameroon did not yet have a vision or strategy for digital health. The strategy was adopted in January 2020 and contains 7 strategic objectives covering governance and leadership, legal and regulatory framework, human resources, funding and investment, services and applications, ICT infrastructure, and standards and interoperability [23]. Even if it is still in its embryonic stages, we note that since the adoption of this strategy and following the outbreak of the COVID-19 pandemic, the State of Cameroon is gradually pushing for the adoption and integration of digital health tools

into our health system. An operational plan linked to this strategic plan is currently being designed and validated.

Acknowledgments

This project was implemented with the agreement of both partners Yaoundé Central Hospital and Geneva University Hospitals.

Abstract

Background: Clinical decision support (CDS) has the potential to improve clinical decision-making consistent with evidence-based care. CDS can be designed to save health care providers time and help them provide safe and personalized analgesic prescribing.

Objective: The aim of this report is to describe the development of a CDS system designed to provide dentists with personalized pain management recommendations to reduce opioid prescribing following extractions. The use of CDS is also examined.

Methods: This study was conducted in HealthPartners, which uses an electronic health record (EHR) system that integrates both medical and dental information upon which the CDS application was developed based on SMART (Substitutable Medical Applications and Reusable Technologies) on FHIR (Fast Healthcare Interoperability Resources). The various tools used to bring relevant medical conditions, medications, patient history, and other relevant data into the CDS interface are described. The CDS application runs a drug interaction algorithm developed by our organization and provides patient-specific recommendations. The CDS included access to the state Prescription Monitoring Program database.

Implementation (Results): The pain management CDS was implemented as part of a study examining opioid prescribing among patients undergoing dental extraction procedures from February 17, 2020, to May 14, 2021. Provider-level use of CDS at extraction encounters ranged from 0% to 87.4% with 12.1% of providers opening the CDS for no encounters, 39.4% opening the CDS for 1%-20% of encounters, 36.4% opening it for 21%-50% of encounters, and 12.1% opening it for 51%-87% of encounters.

Conclusions: The pain management CDS is an EHR-embedded, provider-facing tool to help dentists make personalized pain management recommendations following dental extractions. The SMART on FHIR–based pain management CDS adapted well to the point-of-care dental setting and led to the design of a scalable CDS tool that is EHR vendor agnostic.

Trial Registration: ClinicalTrials.gov NCT03584789; https://clinicaltrials.gov/study/NCT03584789

Introduction

The United States has experienced an epidemic of opioid overdose deaths, with deaths associated with prescription pain relievers of particular concern [1]. Inappropriate prescribing of opioids, heroin use, and the increase in the use of illicitly manufactured fentanyl and its analogues have driven this unprecedented opioid epidemic. Opioid analgesics are among the most frequently prescribed drugs by dentists [2]. An estimated 5 million people undergo third-molar extractions in the United States each year [3]. Evidence shows that exposure to opioid analgesic prescriptions following dental extractions and other procedures is widespread in the United States [4]. Combining a nonsteroidal anti-inflammatory drug with acetaminophen provides a viable and evidence-based pain management alternative to prescription opioids when better pain control is needed [5].

Electronic health records (EHRs) may contain much of the relevant medical history information needed to make appropriate decisions without navigation of multiple screens required to locate desired information. Unfortunately, dental EHR systems are generally not part of the medical EHRs; therefore, dentists rely on the patients to complete a medical history questionnaire. Currently, the information exchange between dentistry and medicine is hampered by a lack of data standards and interoperability between medical and dental EHR systems [6].

Clinical decision support (CDS) has the potential to improve clinical decision-making consistent with evidence-based care [7-9]. CDS can be designed to save providers time and help them provide safe, personalized analgesic prescribing by bringing together relevant medical conditions, current medications, a prior history of substance use, and additional prescribing information from the state prescription drug monitoring program. The problem with integrating siloed yet important health information [6] and the proposed solution of using CDS to integrate this information into one interface serves as the premise for this research study [10].

The objective of this study was to test the efficacy of two interventions (CDS with and without patient education), compared to the treatment-as-usual approach to decrease opioid prescribing for dental extractions. This manuscript adheres to the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) [11]. The National Institute of Dental and Craniofacial Research of the National Institutes of Health (NIH) funded this project using a cooperative agreement where they provided oversight, coordination, and facilitation. This paper describes the development of a CDS system using HL7 (Health Level 7) FHIR (Fast Healthcare Interoperability Resources) and the SMART (Substitutable Medical Applications and Reusable Technologies) on FHIR framework.

Methods

Development of the CDS

The project overview is presented in Multimedia Appendix 1.

The CDS is built on secure, scalable, and EHR-agnostic core design principles using health care systems' critical IT infrastructure. Point-of-care, real-time patient medical information extraction is key to the CDS system. This allows for accurate personalized recommendations and integration with the EHR in a manner that fits into the clinical workflow without deviating from the standard-of-care process, facilitating improved CDS use with low or no burden on the health care provider. The CDS system used the industry-standard EHR interoperability method, HL7 FHIR, for data formats and the application programming interface (API) for data exchanges and health care IT. The EHR-agnostic third-party application integration method, the "SMART on FHIR" framework, provides secure authentication and authorization management to the application through a valid existing EHR session. The SMART on FHIR framework built on OAuth 2.0 [12] authorization framework provides secure token and code exchanges to establish access to the FHIR resource server for patient medical record data extraction and presents clinical recommendations in a dental provider interface.

The DIODE ("De-Implementing Opioid Use and Implementing Optimal Pain Management Following Dental Extractions" study) CDS tool follows the EHR data governance model to protect the data privacy and data security of patients. The backend database system for the DIODE CDS tool follows the highest industry standards and enterprise access control policies, limiting data access to only authorized IT personnel who are designated for maintaining the systems. The SMART on FHIR–based DIODE CDS application design approach follows EHR access control policies and privacy settings, allowing only authorized individuals with valid HER-authenticated user sessions to access patient records.

Translating Local Data Into FHIR-Compliant Data

Data access is limited to specific FHIR resources (Table 1) through the OAuth 2.0 authorization scope, and API access expires in a short time for improved data privacy and security. The pain management CDS is only launched from a valid EHR session on specific patient records, based on context provided by the dentist in a secure manner, enabling the pain management CDS as a single sign-on and saving time for the provider.

Since different versions of HL7 FHIR specification have been developed and implemented by EHR vendors, the pain management CDS selected the HL7 FHIR DSTU2 version, which is supported by multiple leading EHR systems.

Table 1. FHIR (Fast Healthcare Interoperability Resources) resource and use.

Source	FHIR resource	Pain management CDS[a] use
1	AllergyIntolerance.Search (DSTU2)	Relevant allergies.
2	Condition.Search (DSTU2)	Relevant medical conditions from the active problem list and diagnosis.
3	MedicationStatement.Search (DSTU2)	Current medications with potential interactions with pain medications commonly prescribed by dentists.
4	Observation.Search (DSTU2)	Nonprescription substances used by the patient.
5	Patient.Read (DSTU2)	Relevant patient demographic information.

[a]CDS: clinical decision support.

Pain Medication Recommendations (Algorithm Development)

Pertinent patient medical information is extracted from the EHR as FHIR resources. The pain management CDS uses an algorithm developed by our team to identify patient-specific contraindications for pain medications, including opioid medications, nonsteroidal anti-inflammatory drugs, and acetaminophen. It also identifies patient allergies and conditions potentially impacted by these analgesics.

RxNorm API

RxNav is a service of the National Library of Medicine, which is part of the NIH, an agency of the US Department of Health and Human Services [13]. RxNav is a browser for several drug information sources, including RxNorm, RxTerms, and Medication Reference Terminology (MED-RT). We relied on the RxNorm code system to translate the system-specific drug or medication names into standardized names. These codes are further used to get ingredient-level information using the RxNav API web service [14]. The ingredient-level information is used in a custom-defined algorithm to find the drug-level interactions.

Medication ingredient-level information is incorporated into the RxNorm web service API to convert brand name or generic name drugs from the EHR to normalized RxNorm code details. The medication ingredient-level information is used in an in-house custom-defined algorithm to identify drug-level interactions. The pain management CDS application uses these drug-level interactions to display patient-level personalized pain management recommendations.

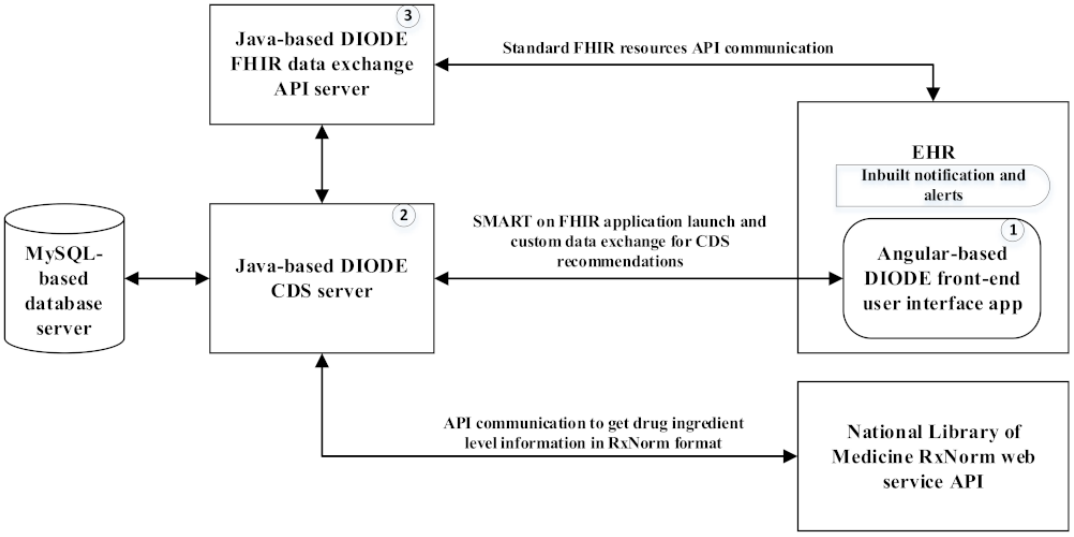
EHR Integration

The CDS is designed as a software component-based, reusable subsystem to perform various functions and data flow support. Angular was used as the framework for the user interface, which was embedded into the EHR for integrated workflow support. The Java-based DIODE CDS server is the heart of the system, which performs algorithm processing, data storage, and retrieval from the database server and provides personalized clinical recommendations. The Java-based DIODE FHIR data exchange server facilitates FHIR resource exchanges with the EHR FHIR resource server and provides collected data to the DIODE CDS server. Figure 1 explains the application architecture.

The Angular-based DIODE front-end application was developed for presenting CDS personalized recommendations to an intuitive user interface with subsections for (1) drug interactions, (2) condition considerations, as well as (3) allergies or intolerances and relevant action items. The front-end application is launched from the EHR and communicates with the DIODE CDS server to get the required data to generate the user interface and education materials.

The CDS server is the core of the pain management CDS, which connects to other software components for data extraction and processing, including the management of OAuth 2.0 communication with the EHR authorization server. The CDS server connects to the backend database server for storing patient data extracted from the EHR, which includes personalized recommendation information generated by CDS algorithms. It also retrieves data from the database server to generate the user interface. The FHIR exchange API server communicates with the EHR FHIR resource server to extract patient medical record information in JavaScript Object Notation standard text-based format. The HER's inbuilt Notification and Alert functionality highlights the CDS prompt in the record when an appropriate clinical condition is met, such as the addition of a tooth extraction procedure to the patient's chart. By default, the dentist has access to the pain management CDS from the patient header section, and only eligible patient records show the highlighted link to the CDS. A MySQL database server is used to store the CDS data, which includes extracted patient clinical data from the EHR, algorithm mapping data, and generated personalized CDS recommendations.

Figure 1. The pain management clinical decision support system (CDS) application architecture. API: application programming; CDS: clinical decision support; DIODE: De-Implementing Opioid Use and Implementing Optimal Pain Management Following Dental Extractions; FHIR: Fast Healthcare Interoperability Resources interface; SMART: Substitutable Medical Applications and Reusable Technologies.



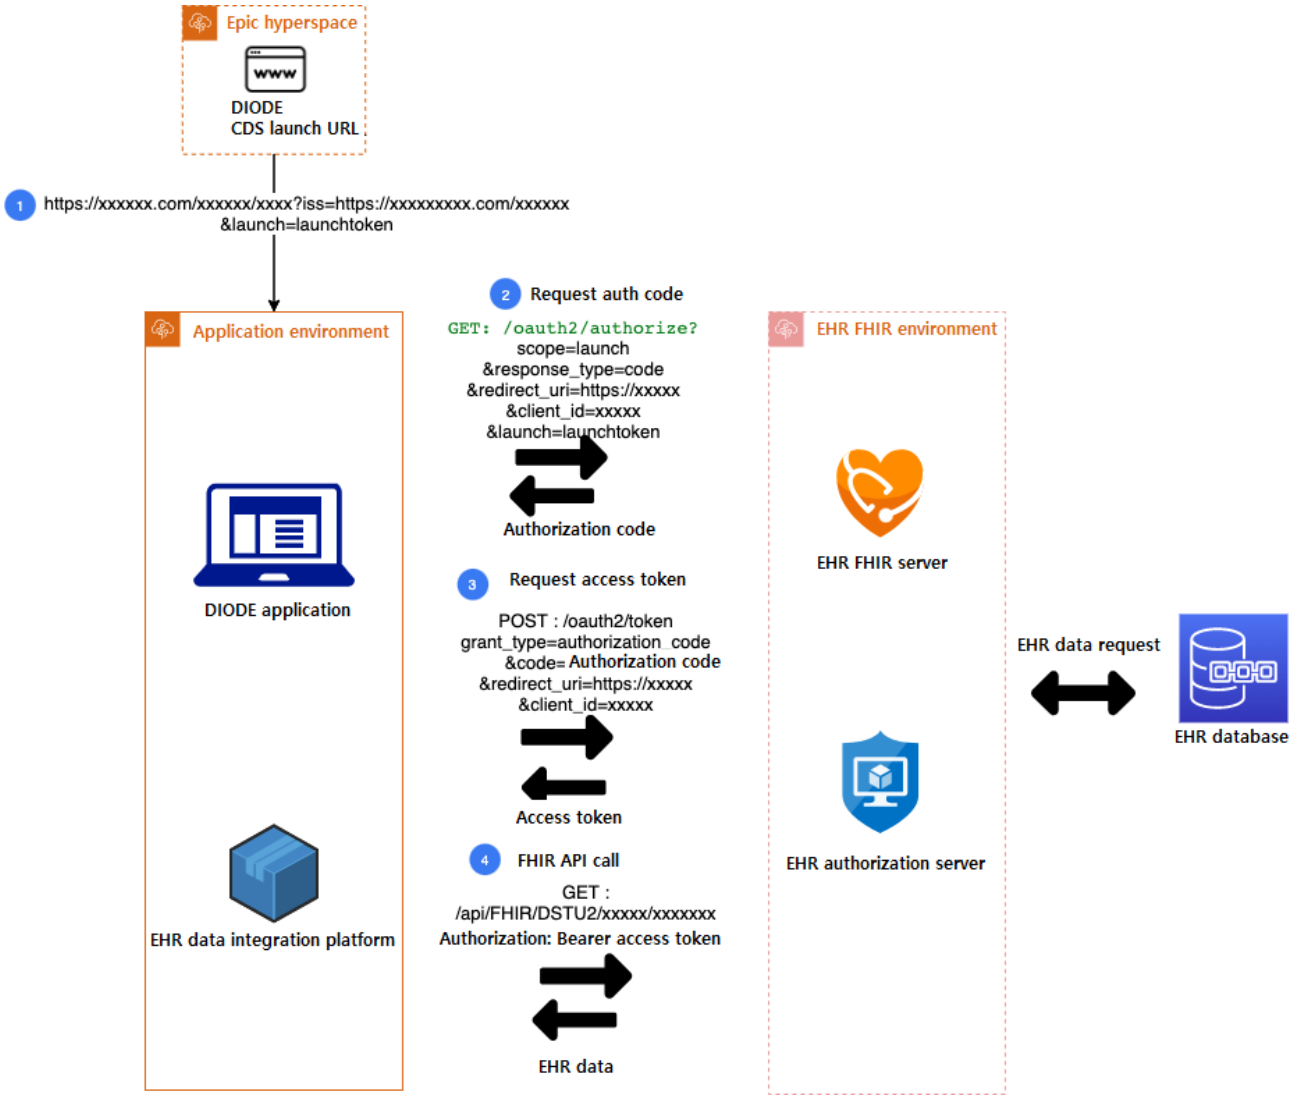
Access to the Minnesota Prescription Monitoring Program

The CDS provides a hyperlink to the Minnesota Prescription Monitoring Program for providers to view controlled substance prescriptions from the state-level prescription monitoring database.

Launching the CDS Application

Since the CDS is embedded in the EHR, the application can be launched, when needed, using a navigation link integrated within the EHR. In the initial launch, the application receives a launch token, which provides a valid EHR user session context and a URL; the URL helps to identify EHR FHIR server information, including EHR authorization server and resource server URL end points. The application receives the authorization code after a successful request along with a launch token. The authorization code prompts an access token, which is used subsequently in multiple FHIR resource API call requests to get the required patient information for CDS use. In the EHR, a header alert is highlighted when patient eligibility criteria are met. The CDS can be launched with 1 click, simplifying navigation to the CDS. Additionally, an HER-specific navigational link was created to access the pain management CDS from any patient chart context. Figure 2 [12] explains the data extraction flow.

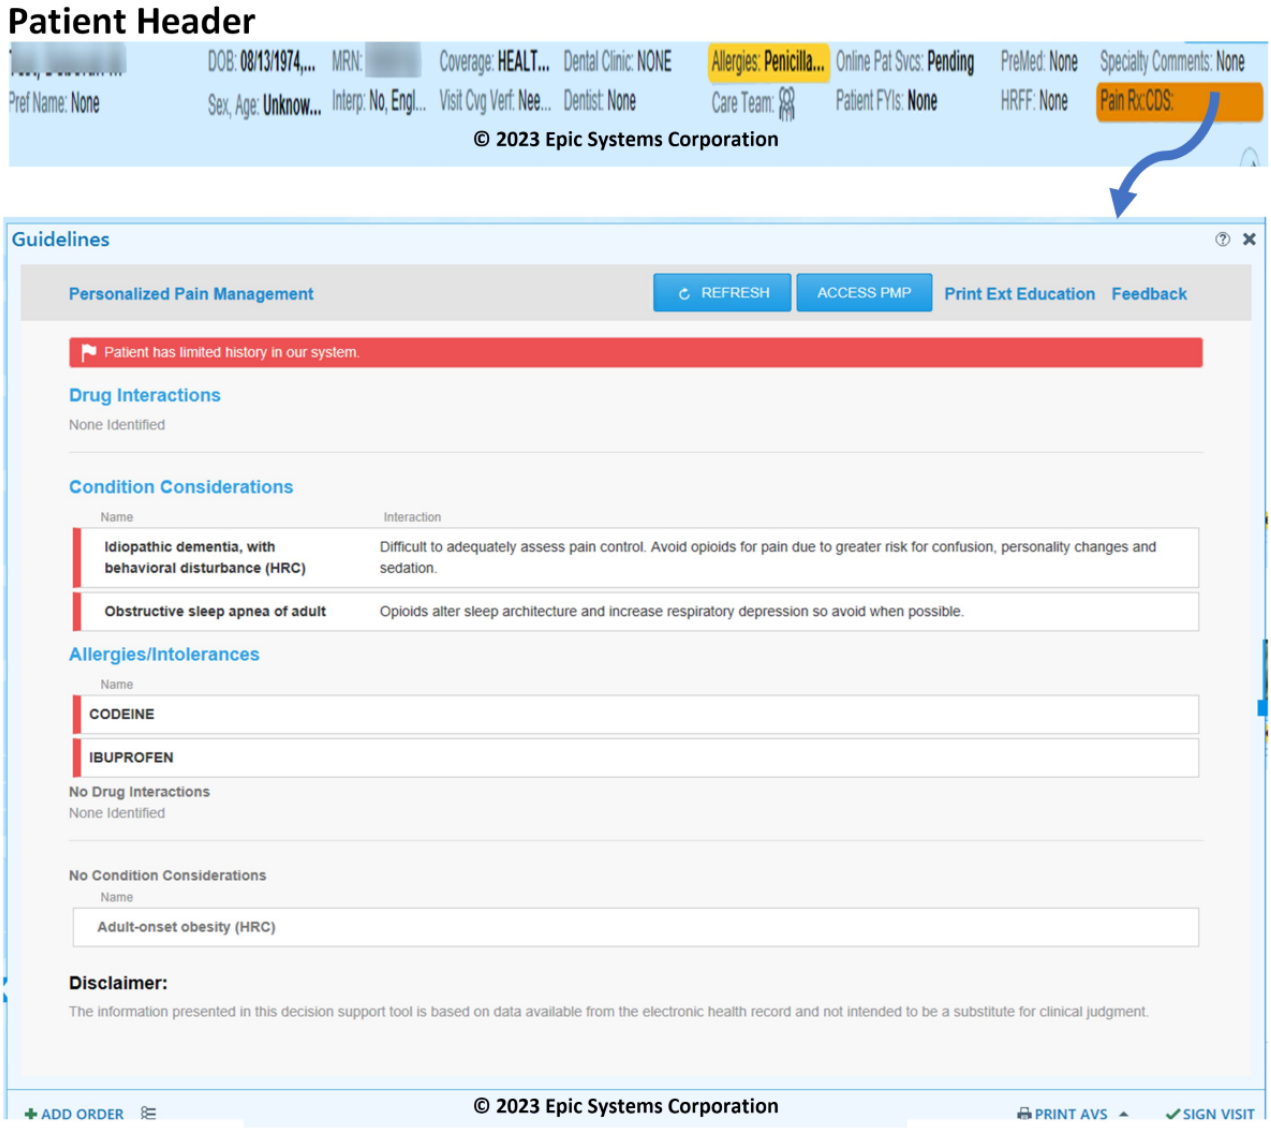
Figure 2. The pain management—OAuth2.0 [12] and the HL7 (Health Level 7) FHIR (Fast Healthcare Interoperability Resources) resource data extraction dataflow diagram. CDS: clinical decision support. DIODE: De-Implementing Opioid Use and Implementing Optimal Pain Management Following Dental Extractions; EHR: electronic health record; FHIR: Fast Healthcare Interoperability Resources.



Pain Management CDS Application Interface

The CDS interface provides a simple summary (Figure 3) of the relevant information that should be considered in deciding about the most appropriate pain management strategy, including the most appropriate analgesic to prescribe or recommend for an individual patient. Relevant information was highlighted in red.

Figure 3. Clinical decision support (CDS) system screen example.



Addressing Missing HL7 FHIR Resources

The CDS extracts data from the EHR using the HL7 FHIR DSTU2 standard data model, which was lacking a few data items at the time of the CDS design. A few custom data elements were added, such as (1) Patient Pregnancy Status, (2) Patient Breastfeeding Status, and (3) Substance Use Status. These data were extracted using custom functionality provided by the EHR system (Epic Extensions) and sent as part of the SMART on FHIR access token response, which is an extension of standard OAuth 2.0 token response after successful authorization validation.

Addressing Other Technical Requirements

AngularJS is a JavaScript-based open-source front-end web framework for developing single-page applications. It is maintained mainly by Google and a community of individuals and corporations. It aims to simplify both the development and the testing of such applications by providing a framework for client-side model–view–controller and model–view–view–model architectures, along with components commonly used in web applications and progressive web applications. AngularJS implements the model–view–controller pattern to separate presentation, data, and logic components [15]. Using dependency injection, Angular brings traditionally server-side services, such as view-dependent controllers, to client-side web applications. Consequently, much of the burden on the server can be reduced. AngularJS brings value when dealing with non-Epic systems.

Statistical Analysis of CDS Use

The CDS was highlighted to alert the dental provider when an extraction was planned but did not open automatically. Therefore, this design offered an opportunity to measure when a clinician opened the CDS, which was an important outcome of CDS use.

Dental provider attributes and the frequency of CDS use are described with counts, percentages, and means (SDs). Differences in CDS use by provider attributes, including provider sex, provider age (<40 vs >40 years), and number of extraction encounters (<100 vs >100) are tested in a generalized linear mixed model (with a logit link and binomial error distribution) containing fixed effects for the provider attributes

and a random intercept for the provider to accommodate the clustering of patient encounters within providers. Model-derived percentages and *P* values are presented.

Implementation (Results)

Among 20 clinics with providers assigned to the intervention arms, 95.0% (19/20) of clinics had at least 1 extraction encounter with the CDS opened. Among 3 oral surgeons assigned to the active intervention arms, 2 opened the CDS for 0.5% (10/1874) of tooth extraction encounters. Among 30 dentists assigned to the active intervention arms, 27 opened the CDS for 24.3% (501/2059) of tooth extraction encounters. Provider-level use of the CDS at extraction encounters ranged from 0% to 87.4%, with 12.1% of providers never opening the CDS (0% of encounters), 39.4% opening the CDS for 1%-20% of encounters, 36.4% opening it for 21%-50% of encounters, and 12.1% opening it for 51%-87% of encounters.

Among 2059 encounters linked to 30 dentists in the active intervention arms, the CDS was opened at similar levels by dentists aged 40 years and younger compared to dentists older than 40 years (27.0% vs 22.5%; *P*=.62). Male and female dentists opened the CDS at similar levels (24.0% vs 26.0%; *P*=.83). Dental providers with 100 or more extraction encounters opened the CDS at similar levels as those with fewer than 100 extraction encounters (26.1% vs 21.5%; *P*=.62).

Among 1061 extraction encounters in the two intervention arms in which an opioid was prescribed, the CDS was opened for 5.4% (57/1061) of encounters. Among 2872 extraction encounters in the two intervention arms in which an opioid was not prescribed, the CDS was opened for 15.8% (454/2872) of encounters.

Ethical Considerations

The study was approved by the HealthPartners Institutional Review Board (#A17-013). The project was part of a broader quality improvement initiative approved by the HealthPartners Dental Group and did not alter the standard of care for dental extractions; approval by the Dental Group for this minimal risk study was acceptable as an alternative to written informed consent documentation for dentists. Patients on the research exclusion list were not included in the study.

Discussion

Principal Findings

This study used a programming interface and integration platform that combines with existing EHRs, patient portals, personal health records, and data warehouses. The 3 key aspects of SMART on FHIR are as follows: (1) a data access layer based on FHIR, combined with a set of constraining profiles that lock down optionality and align vocabularies with Meaningful Use requirements; (2) a security layer that provides narrowly scoped authorization to specific portions of a patient's record via OAuth 2.0; and (3) a single-sign-on layer using OpenID Connect, which can either integrate with an existing EHR or patient portal session, conveying the current patient, encounter, and other host environment details, or launch independently, such as on a mobile phone or device [12,16,17].

The HL7 FHIR standards are constantly improved, and new data items are added to FHIR resources data model with each new version [18]. Since the custom data extraction varies for each EHR vendor, some data items from the patient's medical record may not be part of the standard FHIR resources. The custom data elements are sent as part of Access Token Response after successful Authorization providing streamlined data flow without comprising IT security.

The CDS application link is built into the patient header section in the EHR as a clickable link, which can be launched anytime as a SMART on FHIR application by a dentist. The clickable link is highlighted in a yellow background color to get the provider's attention when an eligible criterion (ie, a tooth extraction procedure) is added to the patient's chart. This approach is different from the HL7 CDS Hooks approach, which sends the information to the CDS server system on a specific event in the patient's chart, such as chart open or order entry, and provides a response to show actionable CDS card information.

Overall, results showed that health care providers' use of the pain management CDS was low and consistent with CDS use in other studies [19]. Postintervention interviews with providers indicated that the app worked exactly as developed and that those who used it regularly found the synthesized health information to be very beneficial, informative, and time saving. Providers who did not use it more than once or twice identified several reasons for not using it consistently. These reasons included the following: forgetting about the CDS, which is plausible, as it was not triggered unless an extraction was treatment planned; some dental providers not modifying their workflow to include checking the CDS; and some finding the visual representation (highlighting in the EHR) to be subtle and easily overlooked in a busy EHR dashboard. Early attempts at opening the CDS that resulted in either problems with functionality or providers determining that the type of information they expected to see was not included also negatively impacted its continued use.

CDS strategies to deimplement opioid prescribing for dental extractions did not lead to reduced opioid prescribing compared to standard practice in the main trial. We found that opioid prescribing declined significantly over time in all conditions. A comprehensive description and results of this clinical trial have been published [20]. HealthPartners [21] was already paying close attention to opioids and undertaking several actions to reduce opioid prescribing by providers while the study was being implemented. In the context of a downward trend in opioid prescribing, dental providers identified several factors that led to reduced reliance on opioids, including governmental and health system opioid prescribing policy changes and the COVID-19 pandemic [22].

We trained providers to open the CDS for all extraction procedures so they could receive a summary of relevant information about potential drug interactions and medical conditions relevant to analgesic prescribing. In qualitative interviews conducted at the end of the study, dentists often described the CDS as something they perceived as useful only if they were considering prescribing an opioid. If another

analgesic option was planned or the patient did not have any medical conditions or few current medications, the providers did not see a reason to open the CDS [22]. These findings suggest that the appropriate use of CDS needs to be tailored to more complex or high-risk patient groups. In addition, the training information was sent in an email communication that included training slides and continuing education credit for viewing the slides. We provided contact information for a study team member if there were any questions. CDS was likely negatively impacted by a passive approach to email communication. A more robust in-person or web-based training session for the providers to attend could improve CDS use.

CDS application using the SMART on FHIR framework improves health care interoperability similar to standards applied to other industries [23]. Most EHR databases use a proprietary API. Without tools like SMART on FHIR, it becomes necessary to build a custom connection to each database to access medical data. This is costly, hindering the ability of health care providers and patients to access their data with their preferred technology [24]. SMART on FHIR provides a standard, universal API for accessing the EHR database they use. We estimate that 20% of the budget was used to build and integrate various data elements into the CDS tool. This research project was budgeted at US $500,000 a year and funded for 5 years without an option for additional funding.

Conclusions

Development of the provider-facing, point-of-care CDS using SMART on FHIR supported the study goals of providing dental practitioners with context-dependent pain management alternatives and enabling patient-centered shared decision-making for pain management. However, CDS use was limited. Strategies to improve its use need to be considered for CDS tools to realize their potential. Future opportunities for CDS use and tools such as SMART on FHIR include clinical topics where provider behavior needs to align with current evidence and would benefit from integrating medical data. Table 2 summarizes key insights and recommendations. This report follows the Implementation Reporting Guidelines.

Table 2. Insights and recommendations.

Insight	Recommendation
Well-designed CDS[a] does not insure utilization.	Engage providers in the design and provide robust training.
Linking data from an EHR[b] into a CDS does not require the use of tools such as SMART[c] on FHIR[d].	SMART on FHIR tools allow for interoperability.
Not all well-intended provider-focused CDS use results in improved care.	Test the CDS to determine if it achieves the desired change.

Acknowledgments

Research reported in this publication was supported by the National Institute of Dental and Craniofacial Research of the National Institutes of Health (NIH) under (Award U01DE027441). The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.

Authors' Contributions

All authors were involved in conducting the study. DPP and VT were responsible for building the SMART on FHIR application. DPP, VT, ART, SEA, and DBR were involved in drafting the manuscript. SMK had full access to all the data in the study. SEA worked with SMK to ensure data accuracy and was responsible for data analysis. All authors critically reviewed and approved the manuscript. SGM and DBR were the study’s principal investigators.

Conflicts of Interest

Unrelated to this study, JG is an investigator on an NIH-funded study that has received free medication from Indivior and Alkermes, has received research funding from Indivior (paid to his institution and including project-related salary support) and has part of the ownership of COG Analytics. The other authors have no potential conflicts of interest to report.

Abstract

Background: Causal structure learning refers to a process of identifying causal structures from observational data, and it can have multiple applications in biomedicine and health care.

Objective: This paper provides a practical review and tutorial on scalable causal structure learning models with examples of real-world data to help health care audiences understand and apply them.

Methods: We reviewed traditional (combinatorial and score-based) methods for causal structure discovery and machine learning–based schemes. Various traditional approaches have been studied to tackle this problem, the most important among these being the *Peter* Spirtes and *Clark* Glymour algorithms. This was followed by analyzing the literature on score-based methods, which are computationally faster. Owing to the continuous constraint on acyclicity, there are new deep learning approaches to the problem in addition to traditional and score-based methods. Such methods can also offer scalability, particularly when there is a large amount of data involving multiple variables. Using our own evaluation metrics and experiments on linear, nonlinear, and benchmark Sachs data, we aimed to highlight the various advantages and disadvantages associated with these methods for the health care community. We also highlighted recent developments in biomedicine where causal structure learning can be applied to discover structures such as gene networks, brain connectivity networks, and those in cancer epidemiology.

Results: We also compared the performance of traditional and machine learning–based algorithms for causal discovery over some benchmark data sets. Directed Acyclic Graph-Graph Neural Network has the lowest structural hamming distance (19) and false positive rate (0.13) based on the Sachs data set, whereas Greedy Equivalence Search and Max-Min Hill Climbing have the best false discovery rate (0.68) and true positive rate (0.56), respectively.

Conclusions: Machine learning–based approaches, including deep learning, have many advantages over traditional approaches, such as scalability, including a greater number of variables, and potentially being applied in a wide range of biomedical applications, such as genetics, if sufficient data are available. Furthermore, these models are more flexible than traditional models and are poised to positively affect many applications in the future.

Introduction

Background

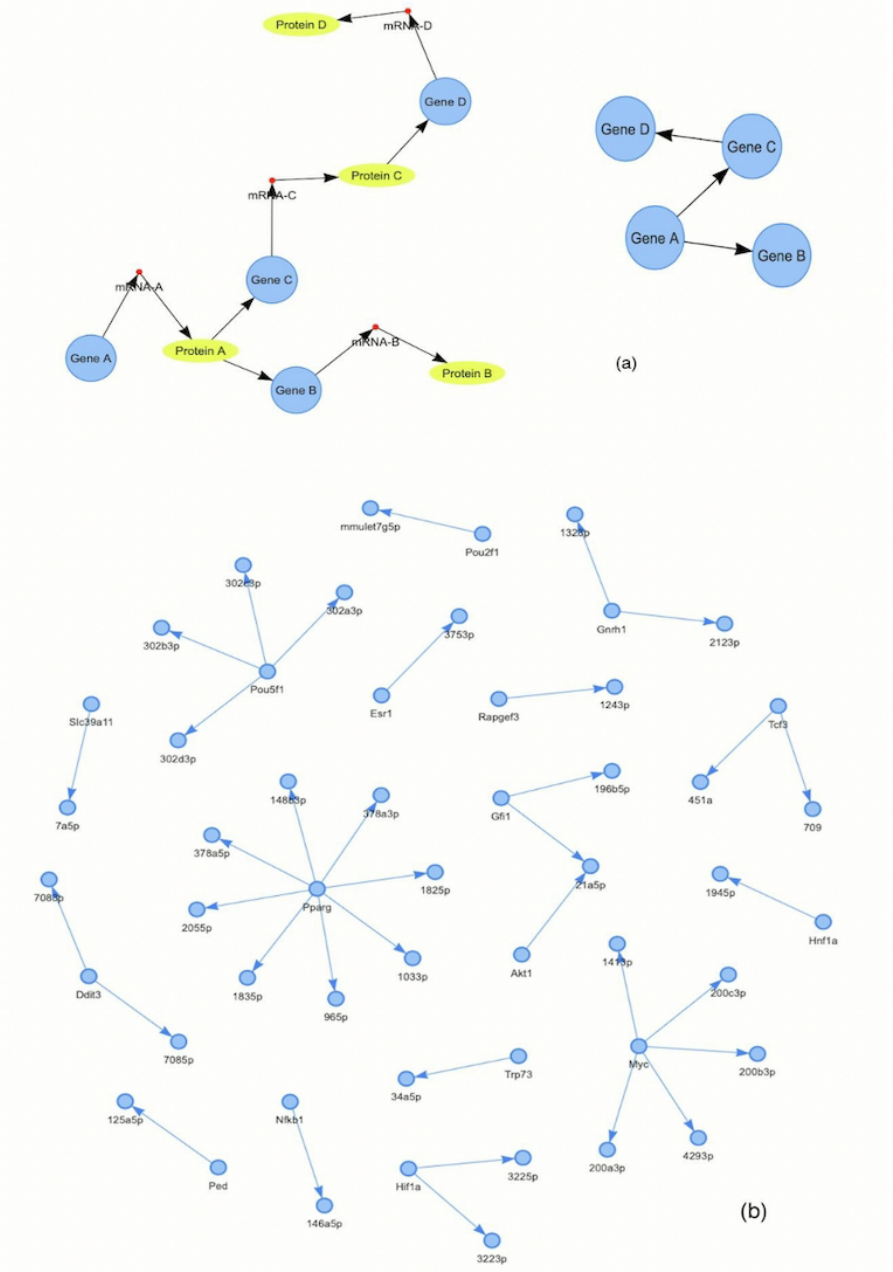
Many applications in biomedicine require the knowledge of the underlying causal relationship between various factors beyond association or correlation. Randomized controlled trials are widely used to uncover causality, but these experiments can be prohibitively expensive or unethical in many cases. Therefore, it has sparked an enormous amount of interest in identifying causal effects from observational data [1-3].

In this paper, we discuss causal structure learning; that is, learning causal relationships that are represented as directed graph structures between different factors and its application to biomedicine. The causal structure is represented by a causal graph (also called a causal Bayesian network), which is a directed acyclic graph (DAG), in which the nodes represent variables and edges represent causation (Figure 1). An edge is drawn from a variable that represents the cause to a variable that represents the effect of that cause. Based on a variety of methodologies, causal structure learning identifies which causal models represented by DAGs accurately represent the observed data.

For example, consider the example of a gene regulatory network [4-7], which is an abstract representation of the gene regulation processes as shown in Figure 1. By observing the data of multiple variables such as gene expression profiles, causal structure learning attempts to discover causal relationships among the genes. For example, if a gene A regulates another gene B, it is represented by an arrow between gene A and gene B.

Many researchers in the biomedical field are interested in causality and not just correlation (eg, whether a particular treatment affects a particular outcome). Unlike association- or correlation-based studies that simply indicate that any 2 variables are correlated, this approach seeks to determine the directional relationship between any 2 variables (eg, between a treatment variable and an outcome variable). In biomedicine, causal structure learning can be applied in a variety of applications.

Figure 1. Example of the causal structure. (A) A gene regulatory network is an abstracted structure (given by the directed graph on the right) of the complex biophysical process shown on the left. (B) A gene regulatory structure from the transmiR database for mice [6].



Examples

Gene Regulatory Networks

A gene regulatory network is a network in which molecular regulators and genes are the nodes, and the directed edges denote the interactions among them [5]. This is in contrast to association-based methods such as finding correlation or mutual information among the genes (finding Pearson, Kendall, Spearman correlation coefficients, etc) that do not have any directional information [8]. Such methods can only be accurate to a certain extent when it comes to deducing extensive gene regulatory structures from data sets with a large set of observations. Correlational studies can only indicate gene-gene association and not the direction of regulation. A gene regulatory network is an example of a causal structure that can be used to develop interventions to control gene expression.

Causal structure learning algorithms have been used to jointly deduce the phenotype network structure and directional genetic architecture [9]. It uses a difference causal inference method and compares it with another causal structure learning algorithm (difference-based Greedy Equivalence Search [GES]) as a baseline. Another study proposed a hybrid algorithm that combines Simulated Annealing with Greedy Algorithm to predict intergene transcriptional regulatory relationships [10], which are also directional in nature. In cancer, somatic genome alterations and differentially expressed genes have causal relationships. A correlational study cannot provide directional information in any of these applications.

The tumor-specific causal inference algorithm proposed by Xue et al [11] uses a Bayesian causal learning framework to find those relationships. Unlike association-based studies, this study is based on a causal structure learning framework across the

whole genome where Ha et al [12] found gene signatures that were the causes of clinical outcomes and were not merely correlated to them. Apart from these examples, there are also networks such as those represented in the Sachs data set [13] that simultaneously incorporates measurements of 11 phosphorylated proteins and phospholipids to find causal pathways linking them. This is different from association-based correlation studies because protein signaling pathways are directional.

In our comparative analysis of the performance of this data set, we found that machine learning models can also be effective at finding causal structures (details are available in the *Results* section). In the case of more complicated protein signaling networks with many nodes, machine learning–based methods might be particularly effective.

Brain Connectivity Networks

Different regions of the brain have distinct functions. Previous studies have used correlation-based methods [14] to find nondirectional functional connectivity among cortical regions. Spatial localization of brain functions has been studied using methods such as functional magnetic resonance imaging [15]. Regions within the brain are the nodes, and a directed edge between regions represents some functional connection (see Figure 2 in the paper by Brovelli et al [16] for the difference between coherence and causality graphs). Such connections are directional, can have different strengths (weights), and can be both inhibitory or excitatory [17]. Scalable causal structure learning models can also model such connection strengths in addition to directionality, which makes them more expressive than an association. In addition, brains have large-scale structural cortical networks that are directional with respect to information flow and can only be captured by causal structure instead of correlation.

Epidemiology

Causal structure learning has also been used in epidemiology with patients' medical records. Many complex diseases are multifactorial in which a combination of these factors contributes to disease predisposition. Causal structure learning considers multiple confounders to determine causal effects solely from one factor of interest to another. For example, causal structure has been used to disentangle psychological factors that predispose adolescents to smartphone addiction [18]. Incorporating a large set of medical claim records, a recent study used a scalable causal structure learning to elucidate the clinical pathways from comorbid illnesses to Alzheimer disease [19].

Challenges

However, there are a few challenges. The general approach to solving this problem of learning a DAG from data, which has been studied for a long time [20], has a time complexity that scales exponentially with the number of observed variables. This is because the problem is generally nondeterministic polynomial-time complete [21]. In practice, if the number of variables is greater than a few hundred, the problem becomes intractable to solve optimally.

Several approaches have been used to solve this problem of intractable time complexity. Traditionally, constraint-based and score-based methods, which search for the optimal graph from a discrete space of candidate graphs, have been used to learn the DAG from data. Constraint-based methods such as the *Peter* Spirtes and *Clark* Glymour (PC) and Fast Causal Inference

(FCI) algorithms (which will be discussed in detail in the *Discrete Space Algorithms* section) rely on statistical tests to estimate the correct causal structure. However, biological data usually involve hundreds to thousands of variables, and the complexity of algorithms increases exponentially as the number of variables increases. For example, typical human RNA sequence data contain at least 20,000 genes. Therefore, the complexity of the PC algorithm is proportional to 2^{20000}, which is infeasible within a reasonable amount of time.

Hence, researchers have investigated various score-based methods that assign scores based on the data to each DAG and select the one with the best score. Although score-based methods scale better than constraint-based methods, they do not scale well for several thousand variables. On the other hand, patient medical records in electronic health records or claim data raise severe scalability concerns, because they include up to 144,000 International Classification of Diseases-Ninth Revision or 69,823 International Classification of Diseases-Tenth Revision diagnosis codes, >2000 US Food and Drug Administration–approved drugs, and >10,000 Current Procedural Terminology procedures or laboratory test codes.

To overcome the limited scalability of traditional methods, recent advances in machine learning algorithms have relaxed the problem of finding an optimal DAG into a continuous optimization problem with smooth acyclicity constraints. This enables the use of nonheuristic machine learning (including deep learning) algorithms to determine the optimal causal structure. This is a promising development in the field of biomedicine. In this study, we focus on scalable algorithms. Table 1 summarizes the algorithms discussed in this study. The tools available for some of these algorithms are listed in Multimedia Appendix 1. A list of ground truth causal structures can be found in the *bnlearn* repository [22].

There are 2 distinct approaches in the context of treatment effect evaluation: the structural approach and potential outcome framework approach [23]. In this study, we consider the first approach, in which there are 2 distinct types of algorithms for finding the causal DAG structure. In all of these examples, the goal is to learn a DAG that shows the directional relationship among variables from observational data.

Table 1. Summary of various algorithms for causal structure learning.

Algorithm	DS[a]	CS[b]	Summary	Remarks	Scalability
PC[c]	✓	✗	A partially directed acyclic graph (CPDAG[d]) is produced by iteratively checking the conditional independence conditions of adjacent nodes, conditioned on an all-size subset of neighbors.	Outputs usually converge to the same equivalence class; high FPR[e] on experimental data	+[f]
IC[g]	✓	✗	Returns the equivalent class of the DAG[h] based on the estimated probability distribution of random variables and an underlying DAG structure.	Outputs usually converge to the same equivalence class.	+
FCI[i]	✓	✗	Modified PC algorithm to detect unknown confounding variables and produces asymptotically correct results.	Faster than PC with similar TPR[j]; converges to the same asymptotic result; high experimental FPR	++
GES[k]	✓	✗	Starts with an empty graph and iteratively adds and deletes edges in the graph by optimizing a score function.	Faster than PC with higher TPR; stable result for the same score function	++
Fast GES	✓	✗	Improved and parallelized version of GES	Faster than GES; same TPR; stable result for the same score function	++
K2	✓	✗	Performs a greedy heuristic search for each nodes' parents.	Greedy searches might return very suboptimal solutions.	++
MMHC[l]	✓	✗	MMHC to find the skeleton of the network and constrained greedy search for edge orientation.	Greedy searches might return suboptimal solutions.	+
LiNGAM[m]	✓	✗	Transfer the linear structure model  to the form of  , and optimize for matrix B.	Works very well on linear data but not on nonlinear data.	++
NOTEARS	✗	✓	Uses smooth function $h(A)$, whose value characterizes the "DAG-ness" of the graph with adjacency matrix A—that is, $h(A)=0$ for DAG—and optimizes using continuous optimization.	Might converge to many different DAGs; GPUs[n] can speed up the process.	+++
NOBEARS	✗	✓	Proposed a new acyclicity constraint that allows for faster optimization and scalability, and a polynomial regression loss to infer gene regulatory networks from nonlinear gene expressions.	Might converge to many different DAGs; GPUs can speed up the process.	+++
DAG-GNN[o]	✗	✓	Uses an autoencoder framework and deep learning to train it and infer the causal structure from the weights of the trained network and is more scalable than NOTEARS.	Might converge to many different DAGs; GPUs can speed up the process.	++++
NOFEARS	✗	✓	Modify NOTEARS so the scoring function remains convex to ensure local minima.	Might converge to many different DAGs; GPUs can speed up the process.	++++
GAE[p]	✗	✓	Scalable graph autoencoder framework (GAE) whose training time increases linearly with the number of variable nodes.	Good accuracy; might converge to many different DAGs; GPUs can speed up the process.	++++
GRAN-DAG[q]	✗	✓	Extends the NOTEARS algorithm for nonlinear relationships.	Works on nonlinear data; better accuracy than NOTEARS; might converge to many different DAGs; GPUs can speed up the process.	++++
CGNN[r]	✗	✓	Generative model of the joint distribution of variables reducing MMD[s] between the graph and data.	Does not always converge to a single class of equivalent DAGs; GPUs can speed up the process.	++++
SAM[t]	✗	✓	Structurally agnostic model for causal discovery and penalized adversarial learning.	Does not always converge to a single class of equivalent DAGs; GPUs can speed up the process.	++++
RL-BIC[u]	✗	✓	Reinforcement learning-based algorithm that uses both the acyclicity constraint and the BIC[v] score.	Very good accuracy; does not always converge to a single class of equivalent DAGs; GPUs can speed up the process.	++++

Paper Structure

This study attempts to provide a comparative study of various scalable algorithms that are used to discover causal structures from observational data to the biomedicine community. Some of these traditional and score-based methods have been extensively studied [24], but many of the algorithms discussed here focus on scalable causal structure learning. Although we do not list all possible approaches as Vowels et al [25], we sample a few important algorithms and evaluate their performance on synthetic data sets and the Sachs data set [13].

This tutorial paper presents algorithms for causal structure identification in biomedical informatics. In the *Methods* section, we discuss the methodology and examine the traditional algorithms that determine the optimal causal graph in a discrete space. We also discuss algorithms that use continuous space optimization to discover causal relationships. We compare the performance of these algorithms in the *Results* section. Finally, we present the discussion and conclusions. A brief overview of the methods and results is presented in Figure 2.

Methods

Overview

In this section, we discuss 2 paradigms of algorithms for causal structure learning. First, we consider algorithms that search for the optimal DAG in the discrete space of all possible DAGs (space of all possible discrete DAGs for a given number of variable nodes) or *discrete space algorithms*. Second, we consider scalable algorithms that use continuous optimization methods to find the optimal DAG (ie, algorithms that search the continuous space of all possible weighted DAGs to find the optimal one), known as *continuous space algorithms*.

Discrete Space Algorithms

Overview

The first type that we discuss in this section is discrete space algorithms for causal discovery; that is, algorithms that search for the optimal DAG in the discrete space of candidate causal graphs. This is in contrast to continuous space algorithms (discussed in the *Continuous Space Algorithms* section) that search for the optimal DAG from the continuous space of weighted candidate graphs.

The discrete space algorithms can be divided into the following 4 types: combinatorial constraint-based models, score-based models, hybrid models, and functional models. In combinatorial constrained-based methods, we consider methods that check the conditional independence relations of 2 adjacent nodes conditioned on all subsets of their neighbors. Such methods can be useful when the number of variables is up to a few hundred. Score-based methods perform optimization by considering a score representing the goodness of fit and can handle more variables than constraint-based methods. Hybrid methods combine constraint- and score-based algorithms. Functional models find structural equations to describe the causal relationship and are useful mostly when the variables can be assumed to be expressed by some linear or nonlinear equations.

Combinatorial Methods

We now focus on combinatorial optimization methods, where conditional independence relationships in the data are used for finding the optimal DAG.

PC and Its Variants

The PC algorithm was proposed by *PC* and is named after them [26]. This algorithm produces a completed partially DAG (CPDAG) by iteratively checking the conditional independence relations of 2 adjacent nodes conditioned on all-size subsets of

their neighbors. Three assumptions underlie the algorithm: no confounder variable, the causal Markov condition, and faithfulness. Under these conditions, this algorithm generates a partially directed causal graph that is proven to be asymptotically correct.

The PC algorithm is order-dependent; that is, the output of the algorithm can depend on the order in which the variables are provided to the algorithm. To address this problem, Colombo and Maathuis [27] developed a PC-stable algorithm in which the deletion of an edge takes place at the end of each stage (considering any 2 nodes' relations within a predetermined neighborhood). Thus, any ordering of vertices will result in the same edge deletions, resulting in the same stable output. The PCMCI and PCMCI+ [27-29] are 2 extensions of the PC algorithm proposed to handle large-scale time-series data sets.

Inductive Causation Algorithm and Its Variants

The inductive causation (IC) algorithm uses the estimated probability distribution of random variables with an underlying DAG structure and outputs the equivalent class of the DAG. In contrast, PC provides a schematic search method and is thus considered a refinement of the IC.

The IC* algorithm [30,31] is an extension of the IC algorithm, which searches for causal relations using observations of a set of variables, even when they appear as latent variables. The output of the IC algorithm is a CPDAG that only has directed edges (identified causation) and undirected edges (undetermined causation). The output of the IC* algorithm is an embedded pattern; that is, a hybrid graph containing ≥2 types of edges.

FCI and Its Variants

The FCI is a modification of the PC algorithm [30,32] that detects unknown confounding variables and produces asymptotically correct results. FCI improves the PC algorithm by adopting 2 rounds of phases of the PC algorithm. The algorithm first uses PC-phase I to find an initial skeleton, then uses the separation set to orient all v-structure triples (a->c<-b) and outputs a CPDAG; then performs another round of skeleton searching based on the CPDAG and repeats the orientation for unshielded triples. The really fast causal inference algorithm [33,34] skips the second step, which is the most time-consuming part of the task, and therefore significantly accelerates the FCI procedure. A set of 10 rules was added to the algorithm to orient the edges of the skeleton.

Score-Based Methods

Overview

In addition to traditional combinatorial methods such as PC and FCI, score-based methods have also been used to uncover causal structures. In these methods, algorithms determine the optimal DAG by optimizing a particular score.

A typical score function is the Bayesian information criterion (BIC) score. The GES algorithm uses different score functions for different data types as follows: the BIC score (for continuous data), likelihood-equivalence Bayesian Dirichlet uniform joint distribution score (for discrete data), and Conditional Gaussian score (for continuous or discrete mixture data).

where  is the maximized likelihood function of the model, n is the number of observational data points, and k is the degree of freedom. The definition of the Bayesian Dirichlet uniform joint distribution scoring function was found in a study by Buntine [35]. The conditional Gaussian score is defined on the ratios of joint distributions, and Andrews et al [36] have proved that the Conditional Gaussian score is *score equivalent*; that is, a scoring function that scores all DAGs in the same Markov Equivalence Class equally.

Score-based methods include the GES algorithm, the fast GES algorithm, and the K2 algorithm.

GES Algorithm

The GES algorithm was proposed by Chickering [37], and its underlying principles were obtained from Meek [37,38]. The algorithm starts with an empty graph and iteratively adds and deletes the edges in the graph by optimizing a score function. During the forward phase, the algorithm searches iteratively from the space of the DAGs created by one edge addition on the current DAG and selects the edge with the best score. The forward phase ends when the score is no longer increasing. In the second phase, the algorithm repeats the above step but deletes one edge at a time and selects the edge that improves the score the most. The algorithm stops as soon as there are no more edges to be deleted.

Fast GES Algorithm

Fast GES is an improved and parallelized version of the GES. Significant speedup was achieved by storing the score information during the GES algorithm [39]. In addition, several insights regarding parallelization were offered in the paper. First, the precalculation of covariances can be parallelized by variables. Second, it is possible to parallelize the process of calculating the edge scores when an edge addition is being performed on the graph. A greater speedup can be achieved for sparse graphs.

K2 Algorithm

The main idea of the K2 algorithm [40] is to perform a greedy heuristic search of the parents of each node. For each node, the algorithm iteratively determines the parents. When visiting node X_i, the algorithm searches for all possible parents of X_i (X_j such that j has a lower ordering of i). The algorithm greedily adds X_j to the parent set of X_i if it could increase a predefined score function. The iteration for node X_i stops when the number of parent nodes reaches the (preset) maximum or when adding an X_j does not increase the score anymore. The entire algorithm finishes after completing the iteration for all X_i.

Hybrid Algorithms

Hybrid algorithms use a combination of score-based and combinatorial constraint-based optimization methods to determine the optimal DAG. An example is the Max-Min Hill Climbing (MMHC) algorithm**.** The MMHC algorithm is a combination of constraint- and score-based algorithms [41]. It uses the Max-Min Parents and Children algorithm. A detailed

description is provided in [41,42] to find the skeleton of the Bayesian network and then perform the constrained greedy search to orient the edges.

Algorithms for Functional Causal Models

Overview

Functional causal models or structural equation models (SEMs) assume structural equations that define the causal relationships. Such structural equations may describe the linear and nonlinear relationships among variables. In addition to the discrete methods discussed here, SEMs are also an important assumption in many machine learning–based methods that use the continuous optimization techniques in the *Continuous Space Algorithms* section.

Linear Non-Gaussian Acyclic Model

The linear non-Gaussian acyclic model (LiNGAM) was originally proposed by Shimizu [43] to learn linear non-Gaussian acyclic causal graphs from continuous-valued data. The LiNGAM transfers  to the form of  , and the causal structure problem becomes an optimization problem for matrix *B*. There are several extensions of the LiNGAM model using different estimation methods, including independent component analysis–based LiNGAM [43,44], DirectLiNGAM [45], and Pairwise LiNGAM [46].

Additive Noise Models

A nonlinear additive noise model is proposed in [47]. The model assumes that the observed data are generated according to the following equation:

where f_i is an arbitrary function, $x_{pa(i)}$ denotes the ancestor nodes of node x_i in the true causal graph, and n_i is the noise variable of an arbitrary probability density function. This study proves the basic identifiability principle for the 2 variables case and generalizes the results to multiple variables.

Continuous Space Algorithms

Overview

Traditional causal discovery algorithms attempt to discover a causal graph, which is usually a DAG, while searching for an optimal graph in the space of candidate graphs. The score-based optimization problem of DAG learning (discussed in the *Score-Based Methods* section) is mathematically given by the following equation:

Here,  is the set of all DAGs with *d* nodes, and  is the cost or score function. The problem of searching for all DAGs is usually intractable and superexponential in the number of nodes in the graph.

An alternative approach would be to model the problem as a continuous space optimization problem, which would then allow the application of various learning techniques. Recently, several publications have explored continuous optimization methods that learn DAGs by adding an acyclicity constraint. In these approaches, the discrete acyclicity constraint  is replaced by  , where $h(A)$ is a smooth function that ensures acyclicity of $G(A)$.

The hard constraints on acyclicity can be relaxed and incorporated into the loss function to be optimized. This smooth continuous constraint allows the use of machine learning–based tools, which in turn can make the algorithms scalable in the presence of substantial amounts of data. These algorithms are based on SEMs.

NOBEARS Algorithm

Several other improvements such as the NOBEARS algorithm [48] have improved the scalability of the NOTEARS algorithm. A fast approximation of a new constraint is proposed, and a polynomial regression loss model is proposed to account for nonlinearity in gene expression to infer gene regulatory networks.

NOTEARS Algorithm

This algorithm considers the acyclicity constraint and comes up with the constraint.

Here,  is the element-wise product. $h(A)$ equals 0 if and only if $G(A)$ is acyclic, and more severe deviations from acyclicity would increase the value of the function. This study assumes a linear SEM:

Here, X_i is a d-dimensional sample vector of the joint distribution of d variables and Z_i is a d-dimensional noise vector. We denote n such samples by matrix X, and the loss function (with l_1-regularization) is given as follows:

The constraint is given by $h(A)=0$ and is used in the final Lagrangian formulation of the loss function. The paper on learning sparse nonparametric DAGs is an extension of NOTEARS, which tries to define a “surrogate” of the matrix above for general nonparametric models to optimize [49].

Directed Acyclic Graph-Graph Neural Network Algorithm

A Directed Acyclic Graph-Graph Neural Network (DAG-GNN) [50] generalizes the NOTEARS algorithm by considering the nonlinearity in the SEMs. It can be modeled with a variational autoencoder neural network with a special structure, with an encoder  , and a decoder  and where g_1,g_2 are parameterized functions that can be assumed to serve as the inverse of f_1,f_2, respectively.

This variational framework considers Z to be a latent vector (instead of viewing it as noise in linear SEMs), which can have dimensions other than d. The decoder then attempts to

reconstruct the data from this latent variable. The encoder and decoder can be trained together from *n* samples of  such that the loss function:

is minimized, where *KLD* is the Kullback-Liebler Divergence. The constraint in this optimization process to ensure the acyclicity of matrix *A* is slightly modified to:

where α is an arbitrary parameter. This constraint can be implemented more easily in graphical processing unit-based deep learning libraries owing to the algorithm's parallelizability and scalability of the algorithm.

NOFEARS Algorithm

Wei et al [51] demonstrated that the NOTEARS algorithm fails to satisfy the Karush-Kuhn-Tucker regularity conditions. Therefore, they reformulated the problem to ensure that the convexity of the scoring function can still ensure local minima even when the constraints are nonconvex. This new algorithm called the NOFEARS algorithm has the following acyclicity constraint.

Graph Autoencoder

Ng et al [52] propose another graph autoencoder (GAE) framework for causal structure learning, which improves the training speed and performance over DAG-GNN for both linear and nonlinear synthetic data sets.

Some other similar machine learning–based continuous learning algorithms include gradient-based neural DAG [53], Causal Generative Neural Network [54], and structurally agnostic model [55].

Reinforcement Learning-Based Methods

Reinforcement learning-based methods have been proposed recently that consider both the acyclicity constraint and BIC score in the reward function and attempt to learn the DAG [56]. They used an actor-critic model, where the actor is an encoder-decoder framework that takes data as input and outputs the graph. The critic uses the reward function for this graph and updates the proposed graph.

Results

This section provides the results to compare the effectiveness of some causal structure learning algorithms on synthetic and real data.

Benchmark Methods

The synthetic data were generated in the same manner as in the DAG-GNN paper [50]. An Erdos-Renyi model with an expected node degree of 3 was used to generate the random graph, and the adjacency matrix was formed by assigning weights to the edges from a uniform distribution. The samples were generated using the following structural equation:

Here, *Z* is random Gaussian noise. We consider 2 functions for *g*(*X*). The first is a (linear) identity function:

and the second is a nonlinear function

We considered 5 data sets for both linear and nonlinear functions. For each data set, we generated n=5000 independent samples according to the above equations. We used 6 algorithms, 4 of which are discrete space algorithms. PC and Greedy Fast Causal Interface (GFCI) are constraint-based methods, GES is a score-based method, and MMHC is a hybrid method. We also considered 2 continuous space methods, DAG-GNN and GAE.

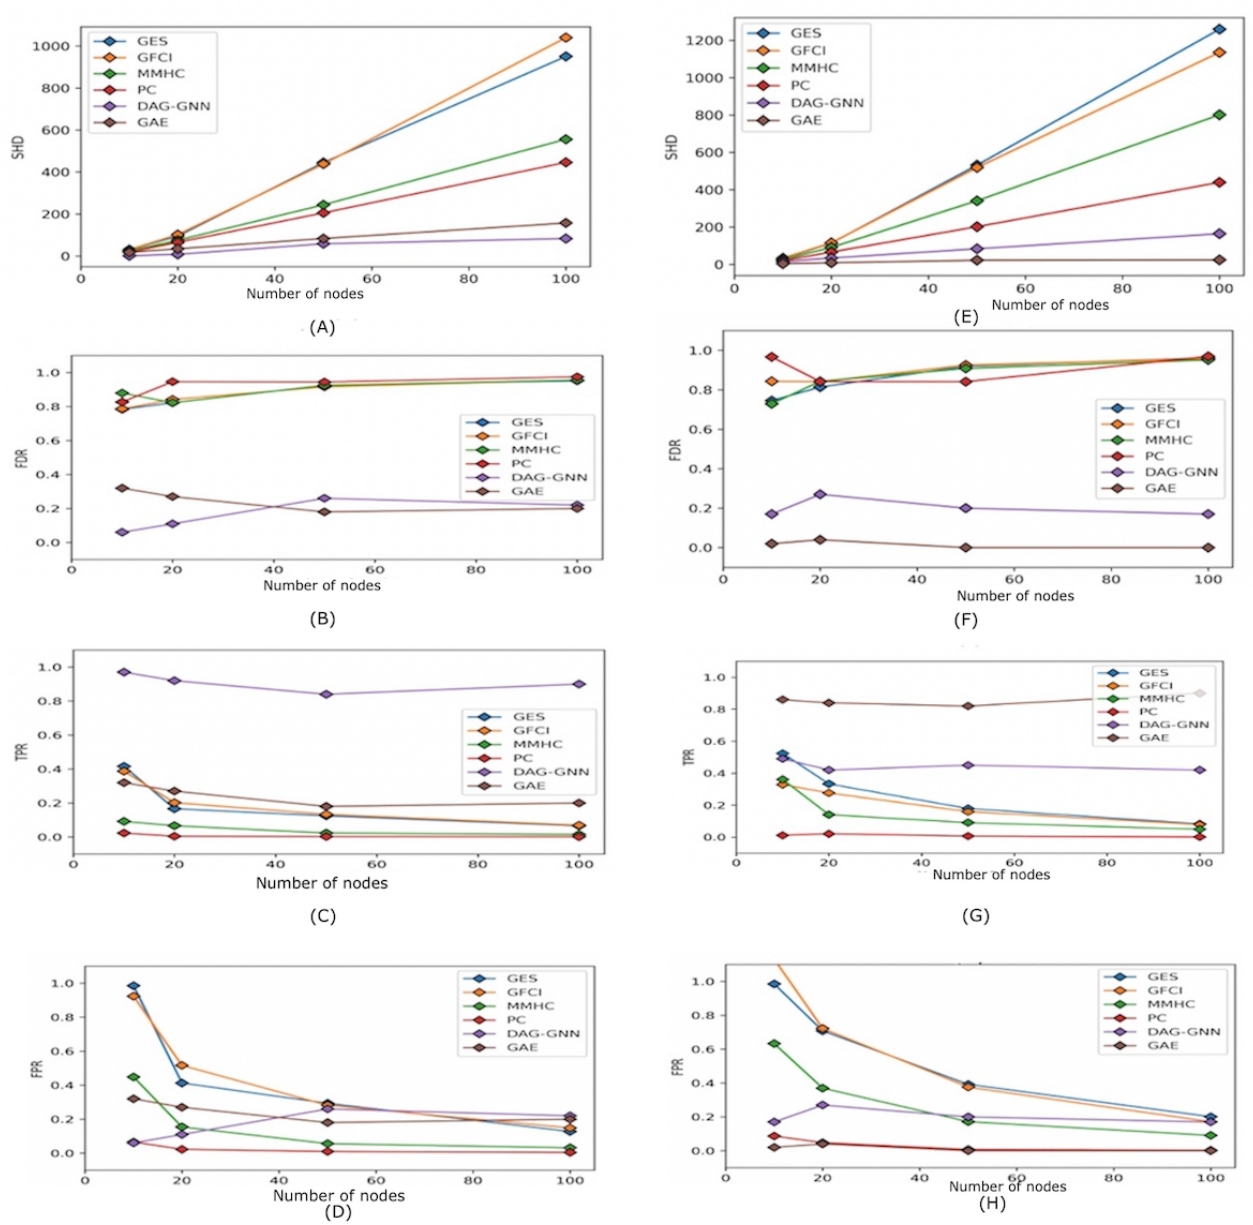
We also evaluated these algorithms on the publicly available Sachs data set [13] using the above 4 metrics and showed the results are shown in Table 2. For other data sets that have the ground truth but are not covered in our experiments, please refer to the *bnlearn* repository [22]. The algorithms were implemented in Python for machine learning–based continuous space methods and R for discrete space algorithms.

Table 2. Benchmark experiments on the Sachs data set. We evaluated 6 algorithms— Peter Spirtes and Clark Glymour (PC), Greedy Equivalence Search (GES), Greedy Fast Causal Interface (GFCI), Max-Min Hill Climbing (MMHC), Directed Acrylic Graph-Graph Neural Network (DAG-GNN), and graph auto encoder (GAE), on 4 metrics—structural hamming distance (SHD), true positive rate (TPR), false positive rate (FPR), and false discovery rate (FDR)—and show their results in Figure 3. In all these evaluations, we consider any edge whose direction is reversed as half discovered.

Metric	PC	GES	GFCI	MMHC	DAG-GNN	GAE
SHD (↓)	24.50	26.50	29.50	22.00	*19.00* [a]	22.00
FDR (↓)	0.77	0.72	0.79	*0.68*	0.71	0.89
TPR (↑)	0.32	*0.56*	0.44	0.47	0.11	0.05
FPR (↓)	0.49	0.64	0.72	0.45	*0.13*	0.21

[a]Italicized values represent the best results for each metric.

Figure 3. Accuracy comparison. We evaluated 6 algorithms: Peter Spirtes and Clark Glymour (PC), Greedy Equivalence Search (GES), Greedy Fast Causal Interface (GFCI), Max-Min Hill Climbing (MMHC), Directed Acrylic Graph-Graph Neural Network (DAG-GNN), and graph auto encoder (GAE) on 4 metrics, structural hamming distance (SHD↓), true positive rate (TPR↑), false positive rate (FPR↓), and false discovery rate (FDR↓). In all these evaluations, we considered any bidirectional edges as half discovered. In experiments (A-D), first column, the data are drawn from a distribution according to the underlying causal graph where relationships between nodes are linear, and experiments (E-H), second column, is for the nonlinear case. In all experiments, the number of nodes of the graph ranges from 10, 20, 50, to 100. For each graph size, we drew 5 different data sets from the graph structure with a sample size of 1000 and calculated 4 evaluation metrics and obtained the average.



Observations

All algorithms were tested on both linear and nonlinear data. The accuracies of some of these algorithms are shown in Figure 3. We used the following 4 evaluation measures: structural hamming distance (SHD), true positive rate (TPR), false positive rate (FPR), and false discovery rate (FDR). SHD refers to the number of edge insertions, deletions, and reversals. In our case, we used a modified SHD, where a reversal contributes half of the SHD score instead of 1. The TPR is the ratio of the algorithm's correctly discovered edges to the number of edges in the ground truth graph. FPR is the ratio of the algorithm's falsely discovered edges to the number of nonedges in the ground truth graph. FDR is the ratio of the algorithm's falsely discovered edges to the total number of discovered edges. We also evaluated these algorithms on the Sachs data set using the above 4 metrics, and the results are shown in Table 2.

Time Complexity

The relative scalability of different algorithms is presented in Table 1. The worst-case time complexity of the PC, GES, and GFCI algorithms was $O(m^k)$, where m is the number of variables (nodes in the DAG). For the GES, the best-case time complexity was $O(m)$. For the GAE and DAG-GNN, the time complexity of the algorithm is $O(m^2+k)$, where k is the number of iterations. The time complexity for MMHC is $O(mV)$, where V is the set of

variables, *S* is the largest set of parents and children, and *l* is a parameter of the algorithm that denotes the size of the largest conditioned subset [41].

In our experiments, we observed that in the worst-case scenario, the running time for a maximum of 100 variables was of the order of hours for MMHC and of the order of minutes for the other algorithms. However, as the number of variables increases to a few thousand, machine learning–based methods such as DAG-GNN and GAE can provide solutions in a reasonable time. The trade-off between complexity (number of iterations) and accuracy can provide a choice between a method that is less accurate but faster or vice versa.

Discussion

Interpretation of Results

It is clear from the results that the algorithms have different advantages and disadvantages. Although the PC algorithm performs well across both linear and nonlinear data, it has a low TPR and is computationally intensive. The GES, GFCI, and MMHC algorithms show a very high FPR, but their TPR is higher than that of the PC algorithm. The SHD of the 2 machine learning–based methods—DAG-GNN and GAE—was also considerably lower for both data sets.

Continuous constraint-based algorithms generally exhibit a very low FDR, except for the benchmark Sachs data set. This is generally because both linear and nonlinear models are based on SEMs with the same causal relationship function at every node, which is an algorithm assumption when they learn the causal structure, but one cannot guarantee the same for Sachs data [13], because such constraints cannot be defined a priori.

This is corroborated by recent results from Zhu et al [56] where such gradient-based methods performed poorly on data generated by a nonlinear model, in which every causal relationship (node function) was sampled from a Gaussian distribution. However, this is a growing research area. In general, in areas such as gene regulatory networks and brain connectivity networks where the number of variables is large, machine learning–based methods can provide comparable results to traditional methods with a much more efficient time complexity and scalability.

Challenges

Machine learning for causal structure learning is not without its limitations, which may present several challenges. First, in many applications, there is no ground truth about causal structure, which makes it difficult to evaluate the performance of these algorithms. Furthermore, many scalable methods use stochastic gradient descent; thus, the final output graph is not always deterministic. When the number of data samples or variables is low, traditional or score-based methods are a better choice, especially when the application requires fewer false positives. For the PC, GES, and GFCI algorithms, we observed that these algorithms require considerable running time, as the number of variables is more than 100 [57].

However, when it comes to large samples of data (eg, more than 100,000 samples) or hundreds of variables (eg, in many gene networks), machine learning methods can provide a reasonable solution, because other methods fail owing to scalability issues. As machine learning algorithms are highly parallelizable, the solutions can be computed much faster, particularly through the use of a graphical processing unit. These algorithms are potentially useful for many applications related to genetics and biomedicine, especially those with an abundance of observational data.

The continuous space machine learning models are more scalable and might be useful in the era of big data. Traditional methods might have complexities that grow exponentially with the number of attributes. Despite the nonconvexity of the optimization proposed by Zheng et al [58], optimization and learning strategies can be used to help find the optimal solution. Several methods have been used to solve this problem using augmented Lagrangian approaches [50,52].

The NOBEARS algorithm reduces the computing complexity of NOTEARS from cubic to quadratic in terms of the number of attributes [48], allowing for smooth implementation in data sets that have more than 4000 attributes. The algorithms are also highly parallelizable, and most of the algorithms use deep learning libraries such as Tensorflow [59] and PyTorch [60].

Machine learning techniques for causal discovery, which use continuous space optimization, are an emerging area of research, which can lead to more efficient causal discovery, particularly in applications where directed graphs are used to specify causal relations more clearly. With sufficient data, machine learning models can be robust to certain discrepancies such as sample bias, missing data, and erroneous measurements. Many of these applications have also focused on weaker concepts of causality such as pairwise directionality during the analysis of gene networks and brain connectivity networks [61,62].

It is noteworthy that machine learning methods are usually black box methods, which might provide lesser insight into the process of derivability of the causal structures. For higher interpretability, an option that has been explored is to develop parallel versions of these algorithms, such as PC [63]. In the future, options such as ensemble learning can be explored for the same.

Some other challenges can be found in finding causal structure from data. In the case of learning causal structure from electronic health record data, they might have several problems, such as missing values or noise in the data, which are very common [64]. If the number of missing values or the amount of noise is significant, the application of causal discovery methods might yield unreliable results.

Furthermore, most causal discovery methods assume that the distribution of data is stationary, which may not be true in certain medical applications [65]. Hence, it is very important to consider the aforementioned problems as well as issues related to selection bias before causal structure learning methods are applied. Glymour et al [24] discuss some general guidelines to avoid such problems in causal structure learning. These generalized learning algorithms are ineffective in many biomedical applications, such as in learning biological or gene networks, because they do not consider specific network

constraints. These constraints can be incorporated into causal structure learning methods for greater efficiency.

Conclusions

In this paper, we have discussed the motivation for causal structure discovery in biomedicine as well as some interesting applications. Two paradigms of causal discovery algorithms have been reviewed. Combinatorial or score-based algorithms are used in the first paradigm for optimizing discrete spaces of candidate causal graphs, whereas machine learning algorithms are used in the second paradigm to solve continuous optimization problems with acyclicity constraints. In addition to listing these methods, we have also included resources that readers can use to find appropriate applications. Furthermore, we tested several algorithms against synthetic benchmark data sets and against the Sachs real-world data set and evaluated their relative performances. We have also discussed their theoretical time complexity. Our discussion of the limitations and challenges of various algorithms is intended to offer readers a guide for choosing an algorithm from among the many available options. Finally, we highlight several challenges associated with finding causal structure from real-world data (eg, missing values, nonstationarity, noise, and sampling bias).

Acknowledgments

XJ is a Cancer Prevention and Research Institute of Texas scholar in cancer research (RR180012) and was supported in part by the Christopher Sarofim Family Professorship, University of Texas Stars award, University of Texas Health Science Center startup, and the National Institutes of Health under award numbers R01AG066749 and U01TR002062.

Authors' Contributions

The survey and experiments on deep learning–based methods and the survey on potential applications were conducted by PU. The survey and experiments on traditional methods were conducted by KZ and CL. XJ and YK conceived the study and provided useful inputs for the potential applications of scalable structure learning.

Abstract

Background: In emergency departments (EDs), early diagnosis and timely rescue, which are supported by prediction modes using ED data, can increase patients' chances of survival. Unfortunately, ED data usually contain missing, imbalanced, and sparse features, which makes it challenging to build early identification models for diseases.

Objective: This study aims to propose a systematic approach to deal with the problems of missing, imbalanced, and sparse features for developing sudden-death prediction models using emergency medicine (or ED) data.

Methods: We proposed a 3-step approach to deal with data quality issues: a random forest (RF) for missing values, k-means for imbalanced data, and principal component analysis (PCA) for sparse features. For continuous and discrete variables, the decision coefficient R^2 and the κ coefficient were used to evaluate performance, respectively. The area under the receiver operating characteristic curve (AUROC) and the area under the precision-recall curve (AUPRC) were used to estimate the model's performance. To further evaluate the proposed approach, we carried out a case study using an ED data set obtained from the Hainan Hospital of Chinese PLA General Hospital. A logistic regression (LR) prediction model for patient condition worsening was built.

Results: A total of 1085 patients with rescue records and 17,959 patients without rescue records were selected and significantly imbalanced. We extracted 275, 402, and 891 variables from laboratory tests, medications, and diagnosis, respectively. After data preprocessing, the median R^2 of the RF continuous variable interpolation was 0.623 (IQR 0.647), and the median of the κ coefficient for discrete variable interpolation was 0.444 (IQR 0.285). The LR model constructed using the initial diagnostic data showed poor performance and variable separation, which was reflected in the abnormally high odds ratio (OR) values of the 2 variables of cardiac arrest and respiratory arrest (201568034532 and 1211118945, respectively) and an abnormal 95% CI. Using processed data, the recall of the model reached 0.746, the F_1-score was 0.73, and the AUROC was 0.708.

Conclusions: The proposed systematic approach is valid for building a prediction model for emergency patients.

Introduction

In the emergency department (ED), early identification of high-risk patients can improve clinical decisions, avoid waste of resources, and lead to better patient prognosis [1,2]. A prospective study showed that the incidence of adverse events due to improper emergency care is about 5%-10%, of which half can be prevented through early detection [3]. However, early identification is difficult as these patients often show little obvious signs before rapid deterioration [4].

Prediction models for high-risk patients in EDs can greatly support caregivers [5]. Electronic medical record (EMR) data, which fully capture patients' status, are an important source for developing disease risk prediction models [6]. As a typical high-risk disease in EDs, sudden death is a major public health problem worldwide, accounting for 15%-20% of all deaths [7,8]. A previous study showed that cardiogenic diseases, potassium, mean platelet volume, creatinine, chloride, and sodium are important variables to predict the risk of death in patients [5]. A survey showed that age, male, hypertension, diabetes, hypercholesterolemia, and a family history of coronary heart disease are all associated with increased risk of sudden death [9]. A study evaluating the relationship between the variables of laboratory tests and the occurrence of acute death in patients found that serum sodium, glucose, and the leukocyte count show a U-shaped relationship with mortality [10]. In addition, total bilirubin, creatine kinase, the international normalized ratio, aspartate aminotransferase, and lactate dehydrogenase are all risk factors associated with acute death in patients [11-13]. However, the data quality of EMRs limits their effective use for developing prediction models [6,14]. Prediction of sudden death needs a variety of clinical data, which are frequently missing, imbalanced, and having sparse features.

Missing values, imbalanced data, and sparse features are 3 common problems of EMR data. Missing values indicate not enough data collected due to improper use of the hospital information system or other reasons [14]. Imbalanced data refer to the imbalanced distribution of negative and positive samples. This leads to more features of negative samples in the learning model, which is not suitable for the prediction of arbitrary patients [15,16]. Sparse features are zero features that are much larger than nonzero features and increase computing memory and reduce generalization ability [17,18]. Especially in small samples, a large amount of noise in sparse features makes model training impossible to converge. Therefore, tackling these quality issues of EMR data is an essential step to improve the predictive performance of machine learning (ML) models.

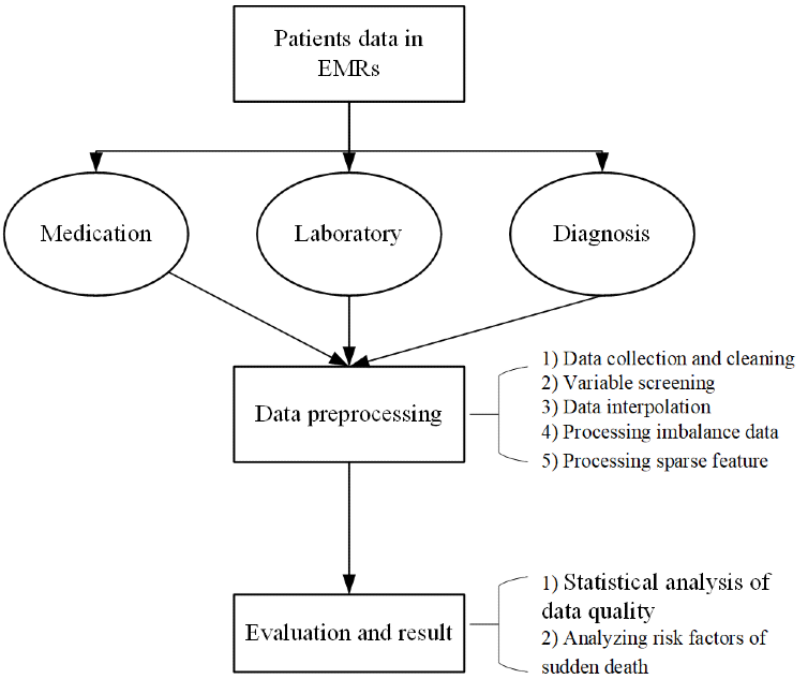
To solve the aforementioned 3 problems, we propose a series of ML approaches to increase fitting ability and generalization ability. Using the approach, we developed a sudden-death predication model. The risk factors related to sudden death obtained through logistic regression (LR) model were consistent with the results reported in the earlier literature on the analysis of risk factors of in-hospital death. These results show that our data-preprocessing approach can effectively maintain the rich information contained in emergency data and provide a reliable data source for the development of a sudden-death prediction model.

Methods

Study Design

Our methods of data preprocessing consisted of 5 steps, as shown in Figure 1. The last 3 steps tackle 3 low-quality issues: missing values, imbalanced data, and sparse features. Finally, postprocessing data quality is evaluated by a sudden-death prediction model case study.

Figure 1. Workflow of ED data preprocessing and evaluation. ED: emergency department; EMR: electronic medical record.



Data Collection and Cleaning

Data for ED patient prediction model development are summarized in Table 1.

Close investigation of each data table is required so as to know the location of our content of interest. For instance, data regarding a patient's basic information are stored in the emg_visit table. Lab test items and results are stored in the lab_result and lab_master tables. The clinical record field in the emg_order table can be used to determine whether a sudden-death event occurred. One lab test (eg, blood test) can be performed multiple times to observe the patient status closely. Based on clinical experts' opinions, only the last one is meaningful.

Table 1. Description of the data table involved in the query process.

Table name	Data description
emg_drug detail	The patient's medication record, including the prescription number, drug name, dosage, drug specification, administration time, and administration route during the treatment period
emg_drug_master	Master record form of patient medication recording patient ID and prescription number
emg_order	Doctor's order record form used to record the medication, inspection, diagnosis, treatment, and other doctor's orders of the patient during treatment
emg_visit	Patient visit information table, including the patient's basic personal information, diagnosis of the current visit, triage, and other information
lab_test_master	Patient's laboratory test master record form recording the patient's age and gender information, laboratory test items made during the visit, and the corresponding doctor's order ID
lab_result	Laboratory test results of patients, including test results of patients

Variable Screening

The number of variables obtained from the data collection was large, so screening of important variables facilitated final analysis. Two approaches can be adopted. One is based on statistical significance. The other is based on the specific research objective, opinions of medical experts, or authoritative literature [5,12,13]. In our study, the first approach was taken. Variables with many missing values were filtered out using the threshold. For example, Alvarez et al [19] set the threshold to 2%, while Seki et al [20] set it to 25%. In this study, we set the threshold to 80%. This means that when 80% of the values of 1 variable are missing, that variable should be filtered out.

Data Interpolation for Missing Values

Missing values affect the effectiveness of ML models. Data missing show 3 different patterns: missing completely at random (MCAR), missing at random deletion (MAR), and not missing at random (MNAR). MCAR means that the missing of data is completely random and does not depend on observed or unobserved values [21]. In this case, any interpolation method will not cause deviation. However, the assumption of MCAR in actual data is difficult to satisfy [22,23]. MNAR and MAR mean that the missing of data depends on the unobserved value and does not depend on the unobserved value, respectively [24]. However, it is impossible to infer whether the missing pattern belongs to MNAR or MAR through the existing data containing the missing pattern, and the assumption based on MAR is more consistent with the actual data situation [22,25]. MAR allows us to estimate missing values using existing observation data in the data set [24].

The goal of all kinds of interpolation methods is to reasonably estimate missing values and improve the quality of data. Interpolation methods are mainly divided into single interpolation and multiple interpolation. Multiple interpolation is a commonly used and better performance interpolation method. It generates multiple possible estimates for missing data and uses statistical inference to interpolate the final value. This method can reflect the randomness of missing data, and the interpolation error is smaller [21]. In a single interpolation, interpolation methods, such as constants (ie, specific identifications), mean, median, and data distribution, can be used. However, such methods usually cause greater deviation [26,27]. The single interpolation method based on ML has attracted increasingly more attention [23], such as interpolation based on a clustering algorithm [28], an ensemble model [29], and Bayesian theory [30]. Although multiple imputation can bring smaller deviation, when the frequency of missing data is high and the sample size is small, multiple imputation should be considered [31]. However, its implementation is relatively complex, and it needs to involve the selection of an interpolation model and the number of interpolation data created [32]. When the data are sufficient and the variability of the estimated value does not need to be considered, it is feasible to choose multiple imputation or single imputation [31]. Considering that our sample size was relatively sufficient, to build a simpler interpolation method, we used a random forest (RF) [33,34] as the interpolation algorithm to realize the interpolation of missing data in the form of a single interpolation.

Altogether, the followed steps are proposed.

- For variable "i," 1 set of patient samples without missing values work as training samples and the other set of patient samples with missing values work as test samples.
- If other variables in the 2 samples are missing, the mean (continuous variable) or mode (discrete variable) is temporarily interpolated to form a complete sample.
- Use training samples to train RF models, the model is applied to test samples to predict missing values.
- For the next variable, steps 1, 2, and 3 are repeated until all variables of the whole sample are interpolated.

Processing Imbalanced Data

Imbalanced data refer to the imbalanced distribution of negative and positive samples. For example, in the classification of rare diseases and credit predictions, there could be more negative samples than positive ones. Because most ML algorithms assume that categories (eg, positive or negative) of samples are evenly distributed, classifying models trained with imbalanced data are more likely to classify a new sample into the majority category [15].

Basic solutions for imbalanced data are to use under- or oversampling to make the data balanced, such as random oversampling [35], random undersampling, the synthetic minority oversampling technique (SMOTE) [36], and the adaptive synthetic sampling method (ADASYN) [15]. Although both undersampling and oversampling approaches can achieve data balance, the oversampling approach adds many sample copies to overfit the model. Wang and Japkowicz [16] and Chawla et al [36] also argued that undersampling is more favorable than oversampling in extreme imbalance situations. However, randomly discarding undersampling may also lose some representative samples. Segura-Bedmar et al [37] and Lin et al [38] proposed a clustering method to tackle this problem. The k-means considers the similarity between samples and uses the sample closest to the centroid of the cluster to approximate all the sample characteristics within the cluster, and the obtained samples are representative. The advantage of the clustering method over random undersampling is that all samples are used in the clustering process. This ensures that the information about all samples can be used to determine the sampling results and some important samples are not randomly discarded. In addition, we can adjust the number of clusters in k-means according to the actual data imbalance so as to achieve different undersampling ratios without other complex adjustments.

To avoid the loss of important samples, we adopted k-means based on the Euclidean distance to cluster samples. New samples were generated though clustering, which had similar characteristics in the same cluster and were distinguished in the different clusters. The centroid of a cluster represents the overall characteristics of the whole cluster. In this way, important features are not discarded. Since the centroid of the cluster is calculated based on the average of the samples in the cluster, the centroid is not necessarily a real sample. So, we took the real samples with the smallest distance from the centroid.

Processing Sparse Features

Sparse features means that the feature index is much larger than the actual number of nonzero features. In total, there were 891 different types of diagnosis in our data set. However, for a single patient, the number of diagnoses was quite few. This formed sparse-feature phenomena.

When sparse features occur, the sample is prone to having the problem of variable separation and multicollinearity. That is, a single variable or a linear combination of multiple variables can perfectly predict outcome events. However, this only works for small-size samples. It also leads to the situation in which the model gives an abnormally large weight to the variables and the results are unreliable [17,18,39]. Although there are many methods to optimize weights, such as gradient descent, a large number of zeros in features make the gradient tend to 0, and the parameters cannot be fully trained.

The processing of sparse features can be considered from both the model and the data themselves. From the point of view of the model, the parameter estimation bias of high-dimensional sparse data can be reduced through the optimization of the algorithm. For example, Firth regression [40] is used. The basic idea is to add a penalty term to the score function so as to reduce the deviation of the maximum-likelihood estimate of the parameter. This can solve the problem of variable separation and multicollinearity caused by sparse features to a large extent. From the point of view of the data themselves, it is necessary to transform the data to be processed into nonsparse data, and this transformation should retain the amount of information contained in the original data as much as possible. Considering the theme of our paper, our goal is to improve the quality of data rather than optimize the model algorithm. Therefore, we solved the problem of sparse features from the perspective of data. At present, there are many dimensionality reduction methods for high-dimensional sparse features, such as principal component analysis (PCA) [39], singular value decomposition (SVD) [41], and linear discriminant analysis (LDA) [42]. The essence of these methods is to map the original data to a low-dimensional space through a specific transformation form to solve the problem of data sparsity. Among these methods, LDA needs to reduce dimensionality based on sample labels. Considering that the actual data may not be able to carry labels, and the difference in label definitions will greatly affect the dimensionality reduction results, this supervised dimensionality reduction method is not conducive to being extended to other data scenarios [43]. Therefore, we considered using unsupervised dimensionality reduction methods, such as PCA, to transform our data.

PCA has been widely used in analysis with high-dimensional sparse features [44-46]. PCA essentially transforms the feature space of the original sample so that the new feature is a linear combination of the original features. The basic principle of principal component (PC) selection is to keep the maximum variance, and all PCs are orthogonal to one another. Thus, the phenomenon of multicollinearity is avoided. Therefore, new samples no longer have sparse features, which makes the ML model better fit the parameters.

In detail, new data can replace the original data as the input source for regression or classification models. Suppose  where each column represents a feature and each row is a sample. Assuming that the sample has been decentralized,  represents the covariance of matrix X. Let the transformed matrix Y = XV be D, which is derived as:

As C is a real symmetric matrix, according to the properties of the real symmetric matrix, its order m must have m unit orthogonal eigenvectors. That is,  is a matrix that can make the original covariance matrix similar to diagonalization.

Therefore, by solving m eigenvalues and eigenvectors of . By sorting the eigenvalues from large to small, we got $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_m)$. There are the following relationships:

Take the first k columns of V as the basis for transforming m-dimensional features into k-dimensional features and record it as the transformed sample matrix is Y = XP.

First, we manually merged similar diagnostic nouns according to prior knowledge, from 891 to 405. However, the data were obviously separated and sparse. For instance, none of the negative samples had a sudden cardiac arrest or sudden respiratory arrest diagnosis. Next, we only kept the diagnosis that appeared in more than 5% population. Finally, PCA was proposed for the remaining variables. The first 17 PCs that could explain 98.2% variance of the original sample were selected. Regression analysis was carried out on the samples after dimensionality reduction. The explanation of variables was achieved by counting the weight of the original variables on each PC.

Ethical Considerations

After preliminary review, the project was found to be in line with relevant medical ethics requirements. If it is funded by the Hainan Major Science and Technology Program in 2020, the Hainan Medical Ethics Committee will perform its duties and strictly abide by relevant regulations and requirements for medical ethics and informed consent of patients to ensure ethical supervision and review during the implementation of the project (reference number: 00824482406).

Results

Data Preprocessing and Model Building

A comprehensive evaluation was carried out on the ED data set of the Hainan Hospital of Chinese PLA General Hospital. We developed a set of Python programs to implement our methods. Specifically, the program was developed in Microsoft Windows 10 (Intel (R) core (TM) i5-9500 CPU, 3GHz). All data preprocessing and model building were completed in Python (Python 3.8 Anaconda) using multiple Python data science libraries, mainly including Numpy, Pandas, Matplotlib, and Scikit-learn. In addition, codes on data interpolation, imbalance correction, and PC regression are currently available on GitHub [47].

Data Collection and Cleaning

We collected the data of patients who went to the ED of the Hainan Hospital of Chinese PLA General Hospital from July 27, 2017, to May 6, 2021. In the sudden-death group, the data of 1085 patients were collected. In the non-sudden-death group, the data of 17,959 patients were collected. For the analysis of laboratory test data, we excluded patients who did not have any laboratory test records before sudden death. A total of 108 (10%) patients were excluded, and 977 (90%) patients with sudden death were used for the analysis of laboratory test data. For diagnostic data, we excluded patients who were missing diagnostic data from the visit. Finally, there were 1083 patients with sudden death and 615 patients with nonsudden death. We developed statistics on the baseline data of all patients, as shown in Supplementary Table S1 in Multimedia Appendix 1. Distributions of age and gender are visualized in Figures 2-5.

In the first group, there were 741 males (68.4%) and 342 females (31.6%), and 2 (0.2%) patients lacked gender information (Figure 2). The age varied between 45 and 80 years. The mean age was 56.4 years (SD 11.2). The quartile, median, and mode were 44, 59, and 68, respectively. In the second group, there were 9403 (52.4%) males and 8556 (47.6%) females. The age distribution is shown in Figures 4 and 5. The mean age was 41.6 years (SD 13.6). The quartile, median, and mode were 29, 42, and 48, respectively. For both groups, their distributions of age were akin to the normal distribution, which is consistent with a real-life situation.

Figure 2. Distribution of the gender of patients with sudden death.

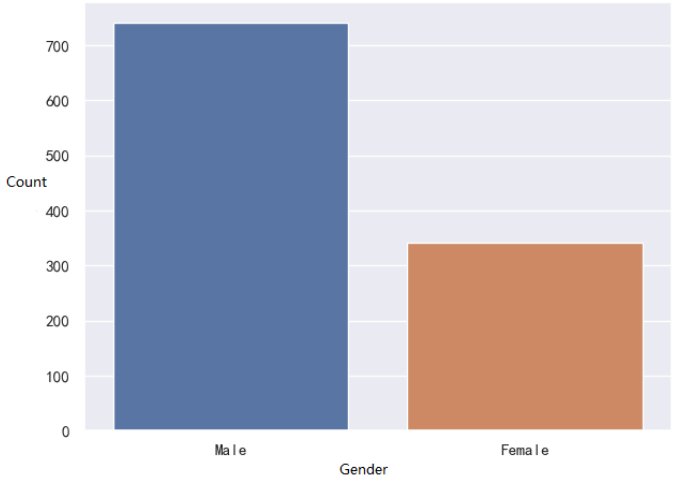


Figure 3. Distribution of the gender of patients without sudden death.

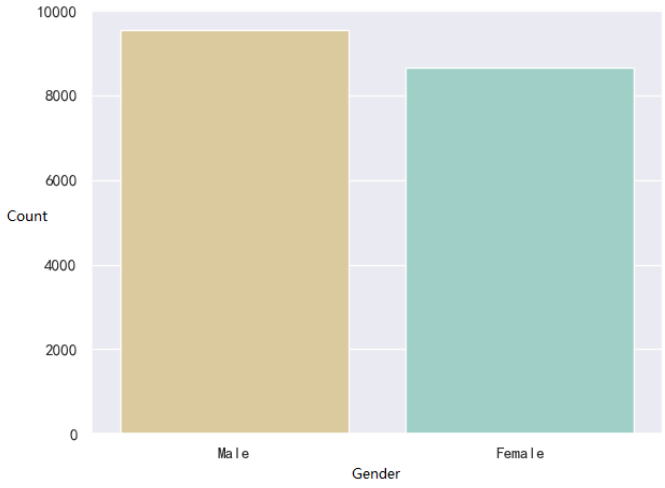

Figure 4. Distribution of age of patients with sudden death.

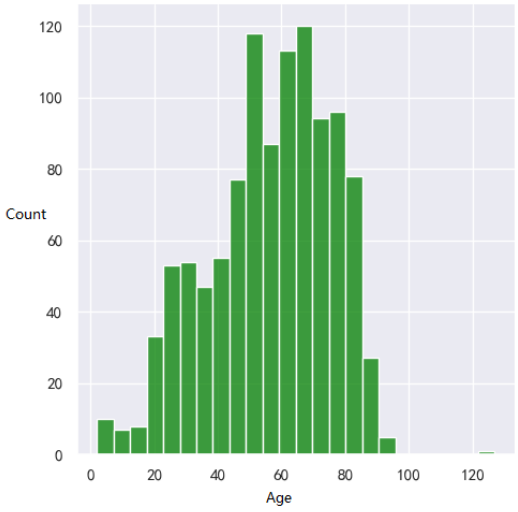

Figure 5. Distribution of patients of age with nonsudden death.

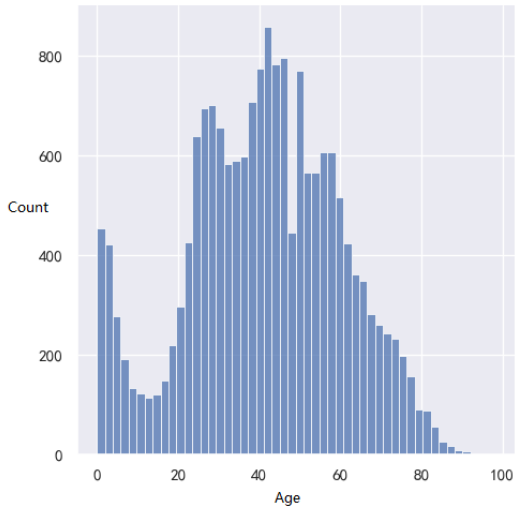

Variable Screening

To perform variable screening, that is, filtering out insignificant variables, we counted the total number of appearance and missing times. The second row of Table 2 shows the number of patients who had no corresponding data in the individual category. Moreover, we investigated the reasons missing data exist in all the 3 categories. For instance, there were 108 (10%) patients having no laboratory test. Among them, we could not find lab test data for 33 (30.6%) patients. For the remaining 75 (69.4%) patients, their lab tests appeared after the sudden-death event. There were 287 (26.4%) patients having no medication data. Sudden death had occurred before the medication was given, and the medication was in the doctor's order record, such as an epinephrine injection, but was not recorded in the patient's medication table.

There were 275 variables in the lab test category. For a given variable, not every patient (sample) had the value, namely a missing value. The missing ratio of a variable could be obtained by the number of cases having a missing value of that variable being divided by the total number of patients. The average ratio was 79.8%, as shown in the third row of Table 2. So, we set an 80% threshold to screen nonstatistically significant variables. Finally, 72 variables were kept in this category. These were patient age, gender, glucose, creatine kinase, inorganic phosphorus, total cholesterol, triglycerides, potassium, sodium, and calcium.

For diagnosis, 891 different types of diagnosis were obtained after the initial data collection. Because the diagnosis is recorded in the form of free text, 1 diagnosis item could have several different synonyms. By merging these texts into a unified name via manual review, we obtained 405 variables. The number of confirmed patients of each diagnostic variable was counted. Instead of an 80% threshold, 5% was considered. Considering both positive and negative samples, 18 diagnostic variables were kept. Among them, 11 (61.1%) variables were shared by both. These were myocardial infarction, chest distress, sudden cardiac arrest, fever, rib fracture, renal dysfunction, chest pain, diabetes, abdominal pain, pulmonary infection, respiratory arrest, trauma, atrial fibrillation, disturbance of consciousness, cerebral hemorrhage, cerebral infarction, coronary heart disease, and hypertension.

Table 2. Missing value ratios of variables of patients with sudden death.

	Laboratory tests (275 variables)	Medications (402 variables)	Diagnosis (891 variables)
Patients without data, n (%)	108 (10%)	287 (26.4%)	2 (0.18%)
Average ratio of missing values	79.8% (866/1085)	72.4% (786/1085)	99% (1080/1085)
Maximum ratio of missing values	90% (977/1085)	73.5% (797/1085)	100% (1085/1085)
Minimum ratio of missing values	25.8% (280/1085)	48.5% (526/1085)	58.4% (634/1085)

Data Interpolation, Processing Imbalanced Data, and Sparse Features

In addition to age and gender, we used an RF to interpolate the missing values for each of the remaining variables. Nonmissing patient data were used as a training set to train the model to interpolate missing values. The training set was further split into training data (80%) and validation data (20%). The coefficient of determination R^2 and the κ coefficient were used to test the consistency of the imputation results of continuous variables and categorical variables. In the interpolation process, the median of R^2 was 0.623 (IQR 0.647) and the median of the κ coefficient was 0.444 (IQR 0.285).

Due to the extreme imbalance of our original data, the number of patients with sudden death only accounted for 5% (977/18,936) of the total sample size. We generated 4 different data ratios (1:10, 1:5, 1:2, and 1:1) through k-means to achieve undersampling. These data were used with the original ratio to evaluate models of different data ratios and then to verify the rationality of our sampling method.

Validation by a Sudden-Death Case Study

Analyzing Risk Factors of Sudden Death

We constructed an LR model to analyze the patients' laboratory test variables using a data set with a data ratio of 1:1 as the data source to filter variables. To reflect the degree of correlation between variables, continuous variables were treated as ordinal categorical variables. Taking the normal index range of the variables as a reference point, the test results of the patients were mapped into 3 categories: L (index is lower than the normal value), N (index is normal), and H (index is higher than the normal value). To determine the significant factors affecting the sudden death of patients and avoid a negative effect on the final analysis results, we first performed the chi-square test to filter out the variables and then excluded variables when $P>.10$. Next, LR univariate analysis was performed to filter out variables with $P>.05$. Tables 3 and 4, respectively, show the variables excluded by the chi-square test and the LR univariate analysis, and their P values. We reintroduced some of the excluded variables into the final candidate variable set according to the literature review and the advice of consulting medical experts, including urine specific gravity, chloride, hematocrit, sodium, magnesium, lactate dehydrogenase, urine ketone body test, red blood cell count, and serum albumin. These variables have no significant statistical significance but are clinically related to sudden death. Finally, we selected 4 subgroups from the set of variables with significant statistical significance. In addition, variables not statistically significant but related to outcome events were also grouped separately. The final 5 groups were subjected to LR multivariate analysis, and the groups were as follows:

- Group 1: qualitative test of creatinine, serum uric acid, urine protein
- Group 2: γ-glutamyl transferase, alanine aminotransferase, total bilirubin

- Group 3: international normalized ratio, platelet count, plasma prothrombin time
- Group 4: potassium, creatine kinase
- Group 5: urine specific gravity, chloride, hematocrit, sodium, magnesium, lactate dehydrogenase, urine ketone body test, red blood cell count, serum albumin

For each group, 500-fold bootstrapping was used for model training and evaluation [48]. Each bootstrap randomly split 70% of the data into the training set and 30% of the data into the test set. Finally, the mean values of AUROC, recall, and F_1-score for 500 training sessions in each group were reported, and the AUROC also reported the 95% CI. Table 5 illustrates the model evaluation results of the 5 groups of variables. The performance parameters of group 2 were the best among the 5 groups of variables. In the recognition of patients with sudden death, a recall rate of 0.801 was obtained, the F_1-score was 0.835, and the model's AUROC was 0.843 (95% CI 0.842-0.844). The results showed that this set of variables can better identify patients with sudden death. Therefore, other group variables based on the group 2 variables were added successively, and AUROC was taken as the evaluation index. The added variables would be included in the final model if AUROC could be improved. In the end, 13 laboratory test risk variables related to sudden death events were determined, and the patient's gender variable was retained as a demographic feature. In general, the final variables used included γ-glutamyl transferase, alanine aminotransferase, total bilirubin, creatinine, serum uric acid, the international standardized ratio, creatine kinase, the platelet count, potassium, sex, sodium, magnesium, chloride, and serum albumin. These variables were used to build the final LR model. Table 6 shows the results of LR multivariate analysis.

After determining the patient features for analysis, we split the original scale data into a training set (70%) and a test set (30%). For the training set, 4 different categories of data sets (1:1, 1:2, 1:5, 1:10) were formed by undersampling to train the model. Finally, the performance of the model was evaluated on the test set. The mean and 95% CI (500-fold bootstrapping) of the final AUROC, AUPRC, F_1-score, and recall are shown in Supplementary Table S2 in Multimedia Appendix 1. In addition, we further used Brier scores to evaluate the calibration ability of models trained with different data ratios.

In general, as the data ratio tended to balance, the performance of the model gradually improved. Figures 6 and 7 show the model receiver operating characteristic (ROC) curve (Figure 6) and the precision-recall (PR) curve (Figure 7) of the 4 data ratios. In recognizing patients with sudden death, the best model obtained a recall rate of 0.863 (95% CI 0.862-0.865), the F_1-score was 0.84 (95% CI 0.839-0.842), the AUROC of the model was 0.895 (95% CI 0.894-0.896), and the AUPRC was 0.897 (95% CI 0.896-0.899). The original scale data model performed the worst, with an AUROC of 0.812 (95% CI 0.811-0.813) and an AUPRC of 0.407 (95% CI 0.404-0.409). We plotted the reliability curves of 5 training sets with different data ratios on the same test set and calculated Brier scores (Supplementary Figure S1 in Multimedia Appendix 1). Consistent with the viewpoint mentioned by Geeven et al [49], imbalance correction actually weakened the clinical application value of the model, which was mainly manifested in the poor calibration ability of the model. With the increase in sampling, the calibration of the model was worse and the Brier score was 0.16 and 0.108 in the data ratio of 1:1 and the original data ratio, respectively. Imbalance correction can balance the sensitivity and specificity of the model to a greater extent and avoid biased errors in the model. Undersampling optimizes the AUROC, F_1-score, and AUPRC of the model trained by the proportion of the original data. Although the Brier score in calibration improved, the gap was not large. To observe the risk factors of sudden death in patients more intuitively, we visualized the regression coefficients of the best model after performing LR(Figure 8) to observe the relationship between variables and sudden-death events.

Table 3. Statistics of variables filtered by the chi-square test.

Variable	χ^2 (*df*)	*P* value
Monocytes	5.433 (6)	.49
Basophil	0.705 (4)	.95
Eosinophils	0.977 (4)	.91
Urine specific gravity determination	0 (2)	.99
Urine tube type	1.25 (4)	.87
Urine tube type (microscopic examination)	6.863 (8)	.98
Qualitative test of urinary bilirubin	13.185 (4)	.21
Mean erythrocyte hemoglobin concentration	7.828 (6)	.25
Chloride	4.649 (6)	.59
Erythrocyte volume distribution width measurement coefficient of variation (CV)	1.148 (4)	.89
Hematocrit assay	4.982 (6)	.55
Sodium	7.915 (6)	.24
Magnesium	10.22 (6)	.12

Table 4. Statistics of variables screened by LR[a] univariate analysis.

Variable	Reference range	OR[b] (95% CI)	*P* value
Lactate dehydrogenase	50.0-150.0 U/L	1.029 (0.94-1.127)	.53
Urine ketone body test	N/A[c]	0.912 (0.769-1.081)	.29
Red blood cell count	3.5-5.9 1012/L	0.827 (0.642-1.065)	.14
Serum albumin	35.0-50.0 g/L	0.893 (0.689-1.157)	.39
High-density lipoprotein cholesterol	1.0-1.6 mmol/L	0.961 (0.749-1.232)	.75

Development of Other ML Models

We use interpolated and undersampled data (data ratio 1:1) to train several other ML models and evaluate their performance. The training models included an RF [50], a gradient boosting machine (GBM) [51], a support vector machine (SVM) [52], and least absolute shrinkage and selection operator (LASSO) [53], which are also often used to develop medical prediction models [49,54]. We use 500-fold bootstrapping for internal validation. Each bootstrap used 70% data for training and the remaining 30% data for performance evaluation. The area under the curve (AUC), AUPRC, recall, and F_1-score and their 95% CI values were reported. Before model training, a grid search was conducted to tune the best hyperparameter of each model through 5-fold cross-validation. The hyperparameter settings of each model are shown in Supplementary Table S7 in Multimedia Appendix 1. The ROC curve and PR curve of the models are shown in Supplementary Figures S2 and S3 in Multimedia Appendix 1, respectively, and the performance evaluation results are shown in Supplementary Table S8 in Multimedia Appendix 1. In general, the performance of the RF and GBM with an integrated scheme was the best, with an AUC of 0.936 (95% CI 0.934-0.937) and 0.931 (95% CI 0.93-0.932),respectively, and an F_1-score of 0.857 (95% CI 0.856-0.858) and 0.821 (95% CI 0.82-0.823), respectively. This can benefit from the generalization and the ability to deal with complex feature relationships of the integrated model. The comprehensive decision results of multiple base learners are more stable than the single-model prediction results, and the performance is better. The SVM also performed better than the LR and LASSO, which are linear models, with an AUC of 0.913 (95% CI 0.912-0.914). This shows that there are some nonlinear features we used that made the linear model insufficient to recognize the relationship between these features.

Diagnostic Data Analysis Results

The final sample included 1083 patients with sudden death and 615 patients with nonsudden death. Table 7 shows the number of confirmed patients with 18 variables. The final diagnostic variables used included hypertension, myocardial infarction, cerebral hemorrhage, cardiac arrest, absolute pain, atmospheric fabric, fever, trauma, respiratory arrest, diabetes, corporate heart disease, and cerebral infarction.

We used 500-fold bootstrapping for internal validation of the model. For each bootstrap, 70% of the samples were randomly selected as the training set and 30% as the test set to evaluate the model. The final reported model performance was the mean and 95% CI of 500 results [48].

The first 17 PCs that could explain 98.2% of the variance of the original sample were selected as new variables for analysis. To observe the role of PCA, we compared the 2 schemes: the LR model using the original data and the LR model after dimensionality reduction using PCA. The LR model trained with the original data obtained a recall rate of 0.445 (95% CI 0.443-0.448), an F_1-score of 0.562 95% CI 0.56-0.564), and an AUROC of 0.602 (95% CI 0.6-0.603). After PCA dimensionality reduction of the original data, the PC variable was used as the data source to train the LR model, and a recall rate of 0.746 (95% CI 0.731-0.76) was obtained, the F_1-score was 0.73 (95% CI 0.721-0.738), and the AUROC of the model was 0.708 (95% CI 0.707-0.71). Figure 9 shows the ROC curves of the 2 models. The LR model using the original data had the phenomenon of variable separation, which is reflected in the abnormally high OR values of cardiac arrest and respiratory arrest (201568034532 and 1211118945) and an abnormal 95% CI, which makes the results unreliable. In addition, the performance of the model was poor, and only a recall rate of 0.445 was obtained in the identification of patients with sudden death, which means that the identification ability of the model for patients with sudden death is not strong. After PCA dimensionality reduction, the data were no longer sparse, the model parameters were better fitted, and the model performance improved to a certain extent. In addition, data conversion also eliminated the problems of variable separation and multicollinearity.

To determine the impact of various diagnostic variables on the sudden death of emergency patients, we statistically analyzed the results of multivariate analysis on 17 PCs input into the LR model. The OR of PC4, PC5, and PC6 was 3.044, 2.859, and 3.931, respectively, showing a significant correlation with sudden-death events (Table 8). In each PC, the magnitude of the loading, the elements in the PC, reflected the importance of the original variable in the PC (Supplementary Table S3 in Multimedia Appendix 1). The loadings of all components showed that cerebral infarction, hypertension, and pulmonary infection were the top 3 variables in PC4. In PC5 and PC6, the top 3 variables were consciousness disorder, diabetes, and fever. Based on the results of the 3 PCs, we believe that the 6 diagnoses of cerebral infarction, hypertension, pulmonary infection, consciousness disorder, diabetes, and fever are significantly associated with sudden death in emergency patients.

Table 7. Statistics of people diagnosed.

Variable	People with sudden death diagnosed, n (%)/people with nonsudden death diagnosed, n (%)
Myocardial infarction	57 (5.26)/23 (3.74)
Chest tightness	8 (0.74)/35 (5.69)
Cardiac arrest	120 (11.08)/0
Fever	50 (4.62)/43 (6.99)
Rib fracture	58 (5.36)/3 (0.49)
Abnormal renal function	42 (3.88)/35 (5.69)
Chest pain	18 (1.66)/38 (6.18)
Diabetes	65 (6.00)/66 (10.73)
Abdominal pain	30 (2.77)/45 (7.32)
Pulmonary infection	85 (7.85)/64 (10.41)
Respiratory arrest	106 (9.79)/0
Trauma	58 (5.36)/16 (2.60)
Atrial fibrillation	39 (3.60)/33 (5.37)
Disturbance of consciousness	82 (7.57)/17 (2.76)
Cerebral hemorrhage	77 (7.11)/26 (4.23)
Cerebral infarction	75 (6.93)/71 (11.54)
Coronary heart disease	29 (2.68)/39 (6.34)
Hypertension	65 (6.00)/106 (17.24)

Discussion

Principal Findings

In this paper, 3 ML schemes were proposed to deal with missing, imbalanced, and sparse features in the process of developing sudden-death prediction models using emergency medicine data, which improves the performance of the developed model. To solve the problem of missing data, we propose an RF method to use real data to interpolate missing data. In the interpolation process, the consistency of the interpolation results is checked by determining the coefficient R^2 and the κ coefficient. From the interpolation results, the method shows the ability to correctly interpolate missing data. Imbalanced data are not conducive to obtaining accurate analysis results, and the model will be more inclined to predict new samples as patients with nonsudden death [15]. In view of this phenomenon, we used the k-means algorithm to generate multiple data sets with different proportions of different categories by undersampling to evaluate the model. The method based on k-means can better preserve the patient's characteristic information. This method will not lose some representative patient samples due to random discarding, thus reducing the bias caused by sampling. The results show that the comprehensive performance of the model gradually improves as the data tend to balance (Figures 3-5). However, imbalance correction will weaken the calibration ability of the model and increase the calibration error. Data sparsity is also not conducive to modeling and analysis. When the samples are too sparse, the results of the classifier based on maximum-likelihood estimation will become unreliable, because there may be variable separation and multicollinearity [18,55]. PC regression analysis is a method that uses PCA to extract the PC information about the original samples and uses PCs to replace the original variables for regression modeling [39]. In our diagnostic data, the LR model using the original data showed the phenomenon of variable separation, which led to unreliable results and poor performance. The performance of the PC regression model has been improved. In addition, we can analyze the diagnosis significantly related to the sudden death of emergency patients from the results of PC regression. These diagnoses are consistent with previous findings [9].

At present, there are many studies on the prediction of sudden death. Yu et al [54] constructed an ML model to predict sudden cardiac death (SCD) in 15,661 patients with atherosclerosis. The results showed that the ML model performs better than the standard Poisson regression model and the AUROC of the ML model was 0.89. Karen et al [56] trained an ML-based early warning model for identifying sudden infant death syndrome using the public data set “Lipidomic in sudden infant death syndrome.” The RF algorithm achieved an AUROC of 0.9 and a recall of 0.8. Ye et al [5] selected a variety of ML algorithms to build an early real-time early warning system (EWS) to predict the death risk of emergency patients and carried out prospective validation. The results showed that the EWS could give an early warning within 40 hours before sudden death, and the AUROC reached 0.884. Bhattacharya et al [57] used the electronic health records of 711 patients with hypertrophic myocardial cake and established an LR and naive Bayesian model with 22 variables, including statins, a family history of

SCD, and left ventricular ejection fraction, to predict the risk of sudden death (ventricular fibrillation) in these patients. The sensitivity and specificity of the optimal model were 0.73 and 0.76, respectively, and the AUROC was 0.83. For our model, in the LR model constructed by using laboratory test data, the AUROC reached 0.895. After imbalance correction, the recall rate and AUPRC improved, reaching 0.863 and 0.897, respectively. Compared to the existing sudden-death prediction model based on ML, the performance of our model can achieve a similar effect, further indicating that our data-preprocessing methods can preserve the patient's characteristic information and improve the availability of emergency care.

Limitations

This work also has some limitations. On the one hand, we only considered a single ML algorithm for data interpolation and did not discuss and compare the application of other possible ML algorithms in interpolation. It is possible that we overlooked the better performance of other methods. For example, for our data, due to the large proportion of missing and seriously imbalanced categorical variables, although we tried to adjust the relatively balanced data set to train the model, the κ coefficient improved to a certain extent but the effect was still poor. Therefore, a further discussion of ML methods that can handle a large number of missing and unbalanced categories or more reasonable feature processing may achieve better imputation results. Although imbalance correction can improve the sensitivity and specificity of the model, it can avoid biased errors of the model. However, this correction will also weaken the clinical application value of the model, lowering the calibration ability of the model and making it unable to accurately estimate the risk probability of patients. For the prediction model, the calibration ability of the model was not high, even on the original scale data set. Model calibration is another important characteristic of evaluating the clinical significance of prediction models. A well-calibrated model can provide more useful information for clinical decisions [58,59]. We can further consider using isotonic regression [60] to calibrate the model to improve its clinical application value. In addition, although the solution to deal with missing, imbalanced, and sparse features proposed by us is not the latest method, it is sufficient to solve the main data quality problems encountered in the development of prediction models for sudden death, which is reflected in the improvement of model performance and the consistency of the risk factors of sudden death obtained with the earlier literature results. In the future, we need to further explore the latest methods to solve these 3 data quality problems so as to extend the data-processing process to other data sets and provide a more reliable data source for prediction models. With regard to the construction of risk factor prediction models for patients with sudden death, we have a broad definition of sudden death, including patients who have undergone rescue or death events. These patients may include some nonemergency death cases, which may have a confusing effect on the final model. In addition, our feature selection was completely based on data, and only the remaining variables were trained in groups during the model training stage. This form can reduce the complexity of manually selecting features and also explore some potential risk variables. However, some clinically significant variables will also be discarded. Therefore, whether the model has clinical guiding significance remains to be further investigated. As a case study, we used LR as the main prediction model, which facilitated us to develop and analyze the risk factors of sudden death. However, the processing capacity of the LR model for nonlinear predictors is insufficient, resulting in insufficient performance of the developed model [17]. This can be seen from the results of other ML models we additionally developed (the RF and GBM had the best performance, with an AUC of 0.936 and 0.931, respectively, which are better than LR models). Therefore, in the future, we will further optimize the data-preprocessing process and try to develop ML models with better performance to improve the clinical usability.

Conclusion

Our work proposes to use ML methods to deal with data quality issues, such as missing data, data imbalance, and sparse features in emergency data, so as to improve data availability. In addition, the risk factors of sudden death in emergency patients are obtained from our model analysis. As a preliminary analysis result, this result is also the basis for the later use of ML algorithms to build the feature selection and data analysis of the prediction model of sudden death in emergency patients.

Acknowledgments

The authors would like to show their appreciation to the engineers working in the Information Centre (ICT) department of the Hainan Hospital of Chinese PLA General Hospital for their help with data preparation.

Abstract

Background: People with long-term conditions frequently transition between care settings that require information about a patient's medicines to be transferred or translated between systems. This process is currently error prone and associated with unintentional changes to medications and miscommunication, which can lead to serious patient consequences. One study estimated that approximately 250,000 serious medication errors occur in England when a patient transitions from hospital to home. Digital tools can equip health care professionals with the right information at the right time and place to support practice.

Objective: This study aimed to answer the following questions: what systems are being used to transfer information across interfaces of care within a region of England? and what are the challenges and potential opportunities for more effective cross-sector working to support medicines optimization?

Methods: A team of researchers at Newcastle University conducted a qualitative study by performing in-depth semistructured interviews with 23 key stakeholders in medicines optimization and IT between January and March 2022. The interviews lasted for approximately 1 hour. The interviews and field notes were transcribed and analyzed using the framework approach. The themes were discussed, refined, and applied systematically to the data set. Member checking was also performed.

Results: This study revealed themes and subthemes pertaining to 3 key areas: transfer of care issues, challenges of digital tools, and future hopes and opportunities. We identified a major complexity in terms of the number of different medicine management systems used throughout the region. There were also important challenges owing to incomplete patient records. We also highlighted the barriers related to using multiple systems and their subsequent impact on user workflow, a lack of interoperability between systems, gaps in the availability of digital data, and poor IT and change management. Finally, participants described their hopes and opportunities for the future provision of medicines optimization services, and there was a clear need for a patient-centered consolidated integrated health record for use by all health and care professionals across different sectors, bridging those working in primary, secondary, and social care.

Conclusions: The effectiveness and utility of shared records depend on the data within; therefore, health care and digital leaders must support and strongly encourage the adoption of established and approved digital information standards. Specific priorities regarding understanding of the vision for pharmacy services and supporting this with appropriate funding arrangements and strategic planning of the workforce were also described. In addition, the following were identified as key enablers to harness the benefits of digital tools to support future medicines optimization: development of minimal system requirements; enhanced IT system management to reduce unnecessary repetition; and importantly, meaningful and continued collaboration with clinical and IT stakeholders to optimize systems and share good practices across care sectors.

health information exchange; patient safety; medicines optimization; transfer of care; health informatics; qualitative

Introduction

Background

Medicines are the most common therapeutic intervention in the United Kingdom's National Health Service (NHS). However, it is estimated that between 30% and 50% of medicines prescribed for long-term conditions are not taken as intended [1]. More than a quarter of the adult population in England live with ≥2 conditions [2], and approximately 15% of people in England take ≥5 medicines a day, with 7% taking ≥8 medicines per day [3]. Furthermore, the prevalence of multimorbidity is estimated to increase substantially, with the proportion of those with >4 diseases almost doubling to 17% by 2035 [4]. Therefore, it is important that individuals receive the maximum benefit from their medicines while minimizing harm. Effective medicines optimization contributes to improved health outcomes, patient care, safety and satisfaction, improved efficiency and use of resources, better use of professional skills, and effective clinical governance [5,6].

Transfer of Care

People with long-term health conditions frequently transition between care settings; consequently, information about a patient's medicines is regularly transferred or translated between systems. However, the point at which patients transfer across different interfaces of care is high risk and is associated with unintentional changes to medications, errors, and miscommunication [7]. This can have consequences for patients, health care professionals, and the health system as a whole [8]. For example, each interaction with a health care professional may result in medication or treatment changes. Problematic polypharmacy may then occur, whereby multiple medicines are prescribed inappropriately or in which the intended benefits of the prescribed medications are not realized [3].

The Department of Health and Social Care's report, *Good for you, good for us, good for everybody*, highlighted that to reduce overprescribing, there is a need for better shared decision-making with patients; better guidance and support for clinicians; more alternatives to medicines, such as physical and social activities and talking therapies; and more structured medication reviews for those with long-term health conditions [3]. However, these goals and initiatives must be supported by effective digital systems that are interoperable and must equip health care professionals with the right information to optimize a patient's medications [9]. A systematic review of 13 publications found that the use of IT applications such as electronic health records (EHRs), electronic decision support tools, and electronic communication applications had a positive impact on financial and health outcomes [10]. However, contemporaneous and accurate information is often not available, with substantial local variation in practice, which can result in increased workload, duplication of tasks, and errors [11,12]. Currently, there is a complex network of different systems that contain patient health record data in distinct silos throughout a patient's journey. There is also a range of services available to support medicines optimization activities in the United Kingdom, including those that target transitions in care. For example, the Discharge Medicines Service, New Medicines Service, and NHS Community Pharmacist Consultation Service [6,13,14]. Plans also exist to roll out the electronic prescription service to secondary care and other care settings and to develop a patient-centered consolidated medication record that can be used by health care professionals working in different settings [15]. Such records may be associated with a range of benefits including improved safety, greater flexibility, enhanced ability to respond to patient queries, reduced duplication, and lower costs [16-18]. However, their use is still at an early stage, and challenges have been identified in some studies, including problems with system reliability, technical issues, and patient concerns regarding inaccuracies and the governance around sharing data [17,19]. The government recognizes the need for information to be collected once and then shared among providers to meet an individual's needs. Interoperability is defined as "the ability of two or more systems or components to exchange information and to use the information that has been exchanged" [20]. Nationally, a range of work is underway to enhance interoperability within health and social care settings and is a clear priority for the United Kingdom [21]. A recent policy paper, *Data saves lives: reshaping health and social care with data*, highlights commitments to introducing clear and open standards to make it easier to share data safely and efficiently across care settings [22].

Objectives

When considering how services might be delivered in the future and the necessary digital transformation, it is important to understand the current landscape of systems including their benefits, challenges, and opportunities. In this study, we aimed to address the following questions: *what systems are being used to transfer information across interfaces of care? and what are the challenges and potential opportunities for more effective cross-sector working to support medicines optimization?*

Methods

Overview

The aim of this study was to engage with key stakeholders in medicines optimization and IT across the North East and North Cumbria (NENC) integrated care system (ICS) to scope out current systems related to the transfer of information across interfaces of care. ICSs were established across regions of England on July 1, 2022, and have been described as *partnerships of organizations that come together to plan and deliver joined up health and care services.* Digital solutions will be central to supporting the function and role of ICSs. In addition, we sought to identify the challenges and potential

opportunities for a more effective cross-sector working to support medicines optimization and inform future priorities.

A qualitative methodology was selected to ensure gathering of a detailed understanding of participants' experiences and perspectives. A constructivist and interpretivist approach was taken [23] together with the framework approach, which is a method developed for use in applied policy research in which there is a need to address a clear set of aims and objectives, while following an inductive approach that allows theories to develop "bottom-up" [24].

Key stakeholders in medicines optimization and digital health were invited to participate in a semistructured interview to gather their perspectives on the current medicines optimization services provided and the digital tools used to support these activities. In addition, stakeholders were asked to provide their opinions on the barriers and potential opportunities for more effective medicines optimization across sectors.

Eligibility Criteria

We included all clinicians, managers, commissioners, and stakeholders who were or had been involved in commissioning, developing, and delivering medicines optimization–related activities and who had expertise in IT, clinical informatics, and digital health solutions used within the NHS.

Recruitment

We used a snowball sampling approach to identify suitable key participants [25]. In the first instance, the researcher was introduced to an initial set of contacts by the senior medicines optimization pharmacist based at the NENC Academic Health Science Network and the digital transformation director for the NENC Academic Health Science Network. The researcher emailed potential participants and invited them to participate in a semistructured interview. This email also included attachments to a participant information leaflet and a consent form. The participants were required to provide consent via a web-based consent form before participating in the study. We proactively aimed to engage with individuals from a range of professional backgrounds and levels of experience to ensure that the data gathered were rich and representative. Data were collected until thematic saturation was reached, and we used an inductive approach to look for the nonemergence of new themes as interviews and analysis were conducted [25,26].

Data Collection

Semistructured interviews were conducted by 1 researcher (CT) between January and March 2022 to explore stakeholders' perspectives on the current medicines optimization services provided in the region and the digital tools used to support these activities, including details regarding the flow of health information exchange and interoperability reached. In addition, stakeholders were asked to provide their opinions on the barriers and potential opportunities for more effective medicines optimization across sectors. A flexible topic guide was developed that incorporated open-ended questions and prompts. The guide was shared with a team of researchers and clinicians to review and refine the data before use, and the guide was developed iteratively throughout data collection [27]. Interviews lasted for approximately 1 hour and were conducted via video call by a researcher with clinical and postgraduate level of qualitative data collection experience, at a mutually convenient time for each participant. All interviews were recorded, transcribed verbatim together with accompanying field notes, and anonymized.

Analysis (Interviews)

Qualitative data collection and analysis were iterative, allowing themes to be generated, interpreted, explored, and disconfirming evidence identified [28]. Different data sources, for example, interviews with a range of participants, facilitated triangulation to identify where and how different data converged and diverged. The main themes and subthemes were identified using a constant comparative analysis [28]. For this purpose, data were constantly compared among interviewees to explore similarities and differences between groups and to uncover explanations for why these differences existed. Field notes contributed to the analysis by providing valuable context, for example, in which the participants used their voice to stress points or in which humor was used. Field notes were also used by the interviewer to note their own reflections and consider questions for future exploration [29]. The framework approach was used, which is a 5-staged approach to thematic analysis, enabling previous theories and insights identified through literature review or experience, to inform the development of the thematic framework, while allowing theme generation based on the data and was, therefore, open to discovering unexpected concepts based on the participants' experiences. This was used as a complementary method along with the constant comparative analysis. Themes were discussed among team members and continually refined and applied systematically to the whole data set using the computerized software N-Vivo (QSR International). All data were analyzed by qualified members of the research staff. "Member checking" was also performed, whereby a draft of the key findings was shared with all participants, who were given a minimum of 2 weeks to provide feedback on the interpretations made and contribute any additional insight [26].

Ethics Approval

This study was approved by the Research, Policy, Intelligence, and Ethics team at Newcastle University (reference: 17851-2021).

Results

Overview

A total of 22 interviews were conducted with 23 participants lasting between 38 and 75 minutes (Table 1). Two participants (a community pharmacist and general practitioner [GP]) were unable to take part in an interview, owing to clinical commitments and availability. "Member checking" resulted in 1 correction to the results (clarification regarding work underway to create a patient medication records) and provided further information regarding national initiatives currently underway to support development of shared care records, which was incorporated into the discussion and recommendations in the *Addressing Digital Gaps* section.

This study revealed a range of different systems that are used across a region to support medicines optimization activities. From the interviews, a range of themes and subthemes pertaining to three key areas were identified: (1) transfer of care issues, (2) challenges of digital tools, and (3) future hopes and opportunities.

Table 1. Table of participants (N=23).

Profession and Sector	Participants, n (%)
Pharmacists (n=21)	
Community	4 (17)
Hospital	5 (22)
Primary care (GP[a] practice, primary care network, and CCG[b])	5 (22)
North East Ambulance Service	2[c] (9)
NHS[d] England and NHS Improvement	5 (22)
GPs	2 (9)

[a]GP: general practitioner.

[b]CCG: clinical commissioning group.

[c]One interview conducted with both participants.

[d]NHS: National Health Service.

Medicines Optimization Systems

Informed by participant interviews and relevant literature, a simplified overview of the key systems related to medicines across primary, secondary, tertiary, and social care across the NENC was developed (Multimedia Appendix 1 [30-32]). This was not intended to provide a comprehensive overview of all systems used throughout the region but instead to illustrate the complexity of how data are stored and moved between settings. Several patient health record systems have been used in general practice and primary care. A range of different community pharmacy patient medication record systems was also identified, which lacked the ability to directly transfer information with GP systems. At the time of data collection, some hospital trusts in the region used paper-based health records and prescriptions. The transfer of information between different systems and care settings was largely facilitated through bespoke solutions delivered by third-party companies in response to a particular problem, for example, a digital referral as part of the Discharge Medicines Service from 1 hospital to a community pharmacy was typically either sent using NHS mail or a website or integrated web platform such as PharmOutcomes or Cegedim. The information flow between the systems was found to be typically unidirectional.

Transfer of Care Issues

All participants highlighted problems owing to incomplete patient records. Data were described as being held in separate silos by the GP, secondary care providers, or a community pharmacy, with ineffective data flow among them, resulting in reduced efficiency and safety. For example, participants described discrepancies between the allergy status recorded in different clinical systems (eg, missing documented allergies) and omissions owing to poor communication and clinical handover. Incomplete records also made it difficult to proactively provide care by identifying patterns of behavior that would warrant further investigation or management, for example, “if someone’s getting emergency contraception on a regular basis [from a community pharmacy], actually that should be flagging up a risk” (GP 006). A GP recalled a “significant incident where the GP hadn’t put down [methotrexate] or- on the GP record was not methotrexate, and they [the patient] ended up in an ITU in Wales and [the staff] didn’t know that the patient was on methotrexate and had actually accidentally overdosed” (GP 006), but the staff were unaware that the patient was even prescribed this medication.

Challenges of Digital Tools

Participants raised concerns on specific challenges associated with the digital tools used to optimize medications. These included the use of multiple systems and workflow, interoperability, digital gaps, IT systems management, and change management.

Multiple Systems and Workflow

Participants working across all settings described the need to interact with multiple IT systems as a part of their day-to-day role. Those working in general practice, for example, would access a core EHR system alongside other systems for viewing additional information, such as hospital notes, appointment letters, or blood tests. Community pharmacists described navigating between a growing number of different systems to fulfill different tasks and purposes (refer to the quote below) and felt that exposure to “more interfaces, [presented] [...] more opportunities [...] for information to have to be re-transcribed [and] [...] actually alert tasks to get dropped, because the right people can’t see [what needs to be done]” (Pharmacist 010). They emphasized how “the more you’re having to step out of your day-to-day workflows and go, ‘Oh my goodness, I really must remember to send a DMS [Discharge Medicines Service] referral for this thing’. You’re just not going to do it” (Pharmacist 010):

> *On a Sunday, I do a COVID clinic, so I've got Q-Flow open, which is the appointments booking system [...] I’ve got PharmOutcomes open for CPCS referrals*

> *via 111. I've got PharmOutcomes open for other things, any other bits and pieces that might come. I've got Outcomes4Health, which is the sister platform. That's open for recording the COVID vaccinations. Then we've got the...What else is there? There are half a dozen different things there. Of course, in the pharmacy clinical system, we [they] use Positive Solutions Analyst, but we'd have that open as well.* [Pharmacist 007]

Interoperability and Safety

A GP described how community nurse practitioners do not have access to the full EHR of certain patients in their care. This occurred because the community nurses were employed by the local hospital rather than by the GP practice, and the 2 organizations used different IT systems, which did not share data in real time. Consequently, automated checks such as drug-laboratory checks or drug-interaction checks are not reliable. There was the risk that if community nurses "don't have the blood results in their system [so] they will not get that [computerised] warning, so they may merrily go ahead and prescribe that [medication]. Then conversely, if they've prescribed a drug, I [the GP] don't know that the interactions are there now" (GP 012).

Digital Gaps

The participants revealed important gaps in the availability of health data that could not be easily shared or used by health care professionals, for example, paper-based hospital notes. A locally shared health record for people living in NENC known as the "Great North Care Record" (GNCR) is currently in development, with the aim of providing health and care workers access to current medical information. However, 1 GP highlighted how their local acute hospital trust only imported some "very, very, primitive data" into the GNCR and so was not "hugely valuable" (GP 012). In addition, data from social care, for example, care homes, were not imported into the GNCR, which meant that "any changes that are made there are not displayed" (GP 006). In contrast, however, more digitally advanced hospitals transferred a greater quantity of information from their EHR into the GNCR, which was "more useful" (GP 012). This raised the possibility of inequalities among health care providers because organizations "that are [digitally] further behind are the ones that...The Great North Care Record doesn't help" (GP 012).

Some professional sectors, such as community pharmacy, were also unable to access the GNCR, which made it "really difficult" to maximize use of that workforce and "shift patients away from some of those higher acuity services" (Pharmacist 003). Furthermore, information governance arrangements for accessing multiple systems were considered problematic. For example, 1 pharmacist suggested that the current consent model whereby community pharmacists must obtain consent before accessing information within the summary care record was inappropriate because "if you've got a patient's prescription it should almost imply by informed consent, they've given you their script" (Pharmacist 005).

Participants also revealed a low adoption of standardized digital codes for documenting clinical data within health systems. There are "a lot of trusts [that]don't use dm+d" (Pharmacist 002), and many hospitals are "not using SNOMED at the moment" (GP 006); without adoption of the standards, large initiatives such as shared patient medication records are "not going to work" (Pharmacist 002). Dictionary of medicines and devices is a dictionary of descriptions and codes, which represent medicines and devices used across the NHS. Systematized Nomenclature of Medicine Clinical Terms is a structured clinical vocabulary for use in EHRs and covers diagnoses, procedures, etc.

Finally, the participants noted how certain services were being rolled out without a supportive digital infrastructure. For example, the national hypertension case finding service in community pharmacies lacked "a national system for reporting it [blood pressure] [and reporting] between the two [pharmacy to GP]" (Pharmacist 011). Consequently, a range of different communication techniques, including email, letter, or pilot digital platforms, were being used, depending on local arrangements, and as data were not collected in a standardized digital format, it could not be transferred between care settings in an interoperable way.

IT Systems Management

Participants suggested that a lack of minimum standards or mandating how services are technically delivered is problematic and contributes to low adoption and delays in rolling out clinical services and digital solutions:

> *So pharmacy DMS transmissions, we launched the DMS service but pharmacies [are] not seeing many of them because yes you can do it by snail mail and NHS Mail, but that's not good enough. We shouldn't launch a service without a platform to deliver it on. So every hospital should be told, "You can have your own, but we're launching this new service and you must be able to provide a digital solution that's integrated."* [Pharmacist 005]

A need was identified to rationalize the number of digital systems used, create clear expectations for suppliers, and develop standards and frameworks that outline how services should be digitally enabled. This would reduce waste from "reinventing the wheel every single time" (Pharmacist 020). A new service or digital tool was developed to limit duplication and unnecessary costs. Another pharmacist added the following:

> *I think there needs to be a suite of expectations that everybody needs to have and it's the same with hospitals, you can't have a hospital system that doesn't do these 10 things [...] every system needs to do that by a certain deadline.* [Pharmacist 005]

Change Management

Change management was seen as important for managing the future development of digital medicines optimization services. For instance, although the clinical terminology standards have now been defined in the Systematized Nomenclature of Medicine (SNOMED) and dictionary of medicines and devices (dm+d), "the hard bit is to come, which is the adoption and more importantly the transformation around that. There's also

a Hearts and Minds piece" (Pharmacist 002). Similarly, participants described concerns regarding data sharing, for instance:

> *If you suggest [data sharing] to some general practices, they'll say: "No chance. Nobody should have access to that data." But once you get over that barrier, and there's a bit of trust built into it, then you can start adding to it.* [Pharmacist 003]

Instead, all health care professionals need to work together to "best serve the needs of the patients" (Pharmacist 019).

Future Hopes and Opportunities

Consolidated Integrated Care Record

Participants revealed several ambitions for the future of digital medicines optimization services, although the need for a single shared consolidated medication record, giving all health and care professionals access to data, was a clear priority and reflected those working across care sectors:

> *One record across all organizations, that's the blue-sky thinking. The data would sit in a data repository that would be coded and accessible, via APIs, via front-end systems that could be customised to be targeted to how GPs work, targeted too how secondary care clinicians work, targeted for acute and outpatient mental health. Fundamentally, all the data would be held in one central repository for that patient and all of the systems can pull in all that data. A patient, for example from a prescribing basis, would have one prescribing record. That prescribing record would continue out of hospital, into hospital.* [GP 012]

This would "open up a number of opportunities [...] for optimisation and proper management of patients and overprescribing" (Pharmacist 002). Furthermore, by identifying and using common digital architectures and standards, such records may be linked in the future.

Some participants were worried that increased access to information could be problematic in some situations, for example, community pharmacists could have "too much information, to make a decision on" because "you could spend hours and hours and hours trailing back through communications and stuff that gets put onto records, [which] it's probably completely inappropriate to the query" (Pharmacist 018). Consequently, several participants suggested involving end users in the development of shared records and posed that for "a sector and a workforce like community pharmacy, I think it's big enough to warrant having a bespoke solution developed for it" (Pharmacist 001). A change in funding arrangements was also discussed as vital to support and incentivize community pharmacists to deliver clinical services at scale and to justify the need for access to shared care records in the first instance.

Uses of Data

There were hopes that the enhanced availability of medication data could improve workflows across care settings and population health management. Improved efficiency may be realized, for example, by sending a coded list of a patient's medications from one system to another, so that a clinician only has to "go click, click, click, and it populates the prescribing system" (Pharmacist 010). In addition, to support better interprofessional working and better continuity of care, participants thought it would be good if they could send a "request, where you've got specific things that you want following up" (Pharmacist 010) alongside any information and context about a patient's medication, directly between systems.

Participants also discussed how the development of a comprehensive shared patient record could serve as a "population health platform" (Pharmacist 002). It would then be possible to "start interrogating the information at a patient level, but [also] at a population level" (Pharmacist 002) and target public health challenges such as "overprescribing, opiate prescribing, valproate [prescribing in pregnancy]" (Pharmacist 002). Digital tools could also support better clinical prioritization, for example:

> *If you've got 100 Primary Care Network pharmacists delivering a structured medication review every year or so, that's 1,000 reviews a week. How do you know which 1,000 patients put in for those slots? How do you caseload? That's really important.* [Pharmacist 016]

Comprehensive patient data repositories could enable clinicians to develop robust strategies to identify patients more efficiently, to avoid "each practice pharmacist going out and trying to design their own searches" (Pharmacist 013). It was clear that there are major opportunities arising from more effective data sharing, and as 1 pharmacist remarked, there are likely innovations that health care professionals have not even started to dream about.

Discussion

Principal Findings

This research has identified several challenges and potential opportunities related to the use of digital tools for delivering medicines optimization, which are categorized under 3 key concepts: transfer of care issues, challenges of digital tools, and future hopes and opportunities. There is substantial complexity in the number of various medicines management systems used throughout the region and the challenges associated with incomplete patient records. The use of multiple systems also affects the user workflow. There was a lack of intrasystem and intersystem interoperability and important gaps in digital data in some settings (eg, social care and in some areas where hospital prescribing was paper based). Several problems related to IT systems management and change management have also been described. Participants described a clear need for a patient-centered consolidated integrated health record for use by all health and care professionals across different sectors, bridging those working in primary, secondary, and social care.

We also identified a series of recommendations relevant to health service managers, policy makers, and clinical staff, which are discussed in Table 2.

Table 2. Summary table: stakeholder recommendations and objectives.

Recommendations and specific objectives	Key stakeholder group
Identify the future vision for pharmacy services and support with appropriate funding plan	
Support realization of the vision through appropriate strategic planning and funding arrangements, for example, community pharmacy contractual framework	Policy makers and service managers
Development of a patient-centered consolidated integrated health record for use by health and care professionals	
Support digitization of social care, for example, implementation of electronic prescribing and medication administration in care homes	Researchers and service managers
Creation of local multistakeholder working groups to ensure cocreation of digital solutions and facilitate effective teamwork and "buy-in"	Service managers
In-depth exploration of concerns around data sharing and governance considerations with key clinical and IT stakeholders and patients and members of the public	Policy makers, service managers, researchers, clinical staff, and public
Explore need for tailored views for health professional groups to shared care records	Service managers and researchers
Support adoption of digital solutions across NENC[a] region's hospitals with a pledge to end paper records and prescribing	Policy makers, service managers, and clinical staff
Adoption of medication standards across NHS[b] (ie, dm+d[c] and SNOMED CT[d])	
Identify what is the level of dm+d adoption across the region	Policy makers and service managers (this is in progress via NHS Digital)
Explore the local facilitators and barriers to adoption of standards	Policy makers, service managers, and researchers
Prioritize communication around the need to adopt standards locally	Policy makers, service managers, and clinical staff
Support sites through the transformation process, using tools from NHS England or FCI[e]	Service managers
Rationalizing number of systems and services to reduce unnecessary repetition	
Mapping process to identify services provided across sectors and highlight duplication and gaps	Service managers and clinical staff
Identify clinical services that would benefit from digitization in the community pharmacy sector and to support service provision and service management or audit	Service managers and researchers
Development of frameworks and minimum standards outlining how services should be delivered using digital means at a local and national level	
Monitor guidance and toolkits from NHS organizations (eg, NHS Transformation Directorate) and publish updates, publish bulletins, and organize workshops to increase awareness of an organization's responsibilities and share lessons across the region	Policy makers, service managers, researchers, and clinical staff
Use and promote the use of forums for communication across all sectors and levels from manager to frontline staff	Service managers and clinical staff
Cross-sector communication around approaches to digital medicines optimization	
Development or use of established forums and groups to proactively collate and communicate examples of good practices between different clinical and IT stakeholders	Policy makers, service managers, and researchers
Working with suppliers to develop integrated solutions to avoid unnecessary development of bespoke solutions	
Share lessons across organizations about successful collaborations with suppliers on innovation projects	Service managers, researchers, and clinical staff
Harness insight from existing projects to support scale-up of innovations	Service managers and researchers

Addressing Digital Gaps

The provision of health services in the United Kingdom needs to substantially change to meet the needs of an aging population, with a key focus on more integrated care across health and care settings to local needs [33]. This requires better collaboration between different professionals working across care sectors who have the right information to inform decision-making, with

digital developments recognized as key to the transformation [33,34]. To enable this, participants emphasized the need for a single consolidated electronic patient record where all health and care professionals can read and write into and share information across traditional boundaries to deliver acute care, manage long-term conditions, and ensure patients receive the right care at the right time and place. For example, most community pharmacists in the United Kingdom do not have access to an up-to-date and comprehensive list of a patient's medications or medical records, which hinders their ability to support individuals. However, pilot projects such as the Somerset shared care record case study (SIDeR) are underway with some promising feedback, although there is a need for further evaluation to fully understand the benefits and any unintended consequences or challenges [35]. There is a strong relationship between the maturity of digital health and comprehensive evaluation methods; therefore, this should be included as part of future locally shared care strategies to support learning and facilitate the development and adoption of systems [36]. In addition, as Cresswell et al [37] noted, there are several socio-organizational dimensions of change that must be considered to support a digitally enabled shared care agenda. They summarize key areas, such as structural and organizational complexity; variations in data management and expectations; poorly defined current shared care pathways; and issues associated with reluctance to data sharing, managing "data overload," and configuring systems appropriately. In terms of technological dimensions, existing infrastructures and legacy systems may hinder data sharing across new technological junctions, while it may also be difficult to connect incompatible data structures and overcome supplier resistance to make distinct systems interoperable [37]. In their report, they advocated the need to map potential architectural components and designs for shared care solutions with careful consideration of their potential benefits and limitations [37].

In our study, participants highlighted that the need to undertake the process of developing shared records *with* end users to ensure the design and functionality is "fit for purpose." Specifically, participants raised the question of developing tailored solutions, that is, a bespoke community pharmacy view of a patient's health record, to enhance the usability and utility of such systems. Research has shown how the design of EHRs can influence behavior and prescribing safety [38,39]; therefore, further work is needed to explore how to create usable health records for a range of different end users working across sectors.

Participants also expressed specific ways in which data could be used to better support the transfer of care, for instance, sending digital referrals or requests for follow-up directly between existing clinical systems, further demonstrating the need for continued engagement and collaboration with end users involved in the delivery of frontline services to optimize and enhance systems over time [40].

To fully harness the benefits of a comprehensive and consolidated shared patient record, there is a need to address digital gaps within organizations across the health and social care sector. The effectiveness and utility of the tool depends on the data within. First, organizations must prioritize the use of established and approved digital information standards related to medicines and clinical information within NHS digital systems. Notably, all NHS care providers who are involved in prescribing, dispensing, or administering medicines must transfer medication information using the newest UK version of fast health care interoperability resources, use approved dose syntax to transfer the amount of medication per dose as a simple coded quantity, and use SNOMED and dm+d codes for allergy or intolerance information by March 31, 2023 [41]. However, barriers to the adoption of such standards have been identified, including a lack of cohesive national-scale digital health system; funding and support for standards; knowledge and infrastructure related, such as the impact on preexisting workflows; and lack of use of a consistent patient ID [42,43]. Therefore, local ICSs must explore how they can address such challenges and support the implementation of the standards across the region. This underscores the importance of effective clinical leadership and understanding the personal factors that influence health IT uptake [44,45]. The adoption of digitized health records, electronic prescriptions, and medication administration across primary, secondary, and social care is vital. As is embedding digital technologies across social care, particularly as estimates suggest that less than half of social care providers have any form of digital care records in England [46]. Furthermore, research has shown that a large proportion of medication errors occur in care homes [47]; therefore, tools to support the digitization of the sector to support medicines optimization and enhance the safety, quality, and efficiency are urgently needed. Our findings echo those of a recently published report by the Royal Pharmaceutical Society Scotland, *Pharmacy 2030: a professional vision document*, which outlines the changes to and enhanced roles of pharmacy professionals and key enablers, including data to inform decision-making, harnessing digital technology, developing the workforce, and increasing emphasis on multidisciplinary work [34]. A further report and policy review from the Royal Pharmaceutical Society and The King's Fund that will inform the development of vision for pharmacy was published at the end of 2022.

To support the delivery of enhanced medicines optimization activities across care settings, there will be an increased emphasis on pharmacists and pharmacy staff undertaking clinical roles in all sectors. Community pharmacies, for example, will have a far greater role in providing enhanced clinical services and supporting the holistic prevention of ill health in a community [48,49]. The supply of medicines will be facilitated by accuracy checking technology, such as dispensing robots, or possibly through hub-and-spoke model dispensing [50]. To support this, the participants in this study highlighted the need for changes in how services are funded through the community pharmacy contractual framework. Although the demand for community pharmacies has risen since the outbreak of the Covid-19 pandemic, staff shortages are a growing concern; 1 survey reported that 91% (estimated from responses from 418 representatives of 5000 pharmacy premises) of pharmacies have experienced staff shortages [51]. There are also huge concerns around staffing shortages more widely across the NHS, which has an impact on patient care, while awaiting the results and recommendations of the NHS long-term workforce strategy [52]. This is important because changes resulting from the implementation of new digital tools, particularly systems with

poor usability, can contribute to clinician burnout and consequently reduce job satisfaction, quality and safety of care, and costs [53]. Any digital transformation relating to how medicines optimization is delivered should, therefore, be mindful of the working environment and additional stressors present, and improving the working life of health and social care providers should be a goal and actively monitored [54]. In addition, IT systems management is needed to closely monitor the number of digital systems used across an ICS footprint and rationalize how services are delivered to reduce unnecessary duplication and streamline services. This may be supported by forums and established groups with a key objective of proactively collating and communicating examples of good practices between different clinical and IT stakeholders.

Limitations

We acknowledge some limitations of this study; semistructured interviews were conducted via web-based videocall platforms, which enabled participants across a large geographical area to participate; however, we did encounter some technical issues, which may have impacted the flow and nature of discussions. We only included 2 GPs in this study; however, 5 primary care and clinical commissioning group pharmacists who provided in-depth detail about the experiences of medicines optimization of health care professionals working within GP practices were recruited, and data were collected until thematic saturation was reached. Further work may specifically explore the challenges experienced within different sectors and enhanced by using observational data collection approaches. Furthermore, the interviewer was professionally known to a small number of participants before the study, and her experience as a practicing pharmacist and academic researcher enabled her to build rapport and relationships with the participants. Throughout data collection and analysis, notes were recorded on any personal reactions or reflections to support consideration of the intersubjective reflexivity between herself and the participants [55]. This was used during the analysis stage to provide context and allowed the researcher to honestly and critically reflect on their role in interpreting the data. It also prompted further exploration of ideas and themes during the data collection stage [55]. We collected data from a range of participants across different sectors; however, this was limited to the NENC regions and so may not be representative of other parts of the United Kingdom. Finally, although the analysis and results were discussed with the research team and member checking was performed with the participants, only 1 researcher coded the data collection transcripts, which could have further decreased the rigor and replicability of our work.

Conclusions

The findings from this qualitative study of 23 clinical and IT stakeholders identified major complexity in terms of the number of different systems used throughout the NENC region and identified several important challenges in the transfer of care issues, focusing on having access to incomplete patient records. We also highlighted important barriers related to the use of digital tools, such as multiple systems and workflow, interoperability, digital gaps, IT systems management, and change management. Finally, participants discussed their future hopes and opportunities for the provision of medicines optimization services in the future, and there was a clear need for a patient-centered consolidated integrated health record for use by health and care professionals across different sectors, which would be fundamental to delivering effective and safe patient care. Further specific priorities were around understanding the vision for pharmacy services and supporting it with appropriate funding arrangements and strategic planning of the workforce, adoption of digital information standards, and development of minimal system requirements and frameworks. In addition, IT system management to reduce unnecessary repetition and, importantly, meaningful and continued collaboration with stakeholders and system suppliers to optimize systems and share good practices across care sectors were important key enablers.

Acknowledgments

This study was supported by the Academic Health Science Network and the National Health Service England Digital Primary Care First program. The funder had no input in the study design and data collection, analysis, or interpretation. The authors would like to thank the participants for their time and valuable contributions to this work.

Authors' Contributions

All the authors were responsible for the conception and study design. CT performed data collection and liaised with all authors on the analysis. CT led the writing of this manuscript, with all authors commenting on drafts. All authors have read and approved the final manuscript for submission.

Abstract

Background: With the advent of electronic storage of medical records and the internet, patients can access web-based medical records. This has facilitated doctor-patient communication and built trust between them. However, many patients avoid using web-based medical records despite their greater availability and readability.

Objective: On the basis of demographic and individual behavioral characteristics, this study explores the predictors of web-based medical record nonuse among patients.

Methods: Data were collected from the National Cancer Institute 2019 to 2020 Health Information National Trends Survey. First, based on the data-rich environment, the chi-square test (categorical variables) and 2-tailed *t* tests (continuous variables) were performed on the response variables and the variables in the questionnaire. According to the test results, the variables were initially screened, and those that passed the test were selected for subsequent analysis. Second, participants were excluded from the study if any of the initially screened variables were missing. Third, the data obtained were modeled using 5 machine learning algorithms, namely, logistic regression, automatic generalized linear model, automatic random forest, automatic deep neural network, and automatic gradient boosting machine, to identify and investigate factors affecting web-based medical record nonuse. The aforementioned automatic machine learning algorithms were based on the R interface (R Foundation for Statistical Computing) of the *H2O* (H2O.ai) scalable machine learning platform. Finally, 5-fold cross-validation was adopted for 80% of the data set, which was used as the training data to determine hyperparameters of 5 algorithms, and 20% of the data set was used as the test data for model comparison.

Results: Among the 9072 respondents, 5409 (59.62%) had no experience using web-based medical records. Using the 5 algorithms, 29 variables were identified as crucial predictors of nonuse of web-based medical records. These 29 variables comprised 6 (21%) sociodemographic variables (age, BMI, race, marital status, education, and income) and 23 (79%) variables related to individual lifestyles and behavioral habits (such as electronic and internet use, individuals' health status and their level of health concern, etc). H2O's automatic machine learning methods have a high model accuracy. On the basis of the performance of the validation data set, the optimal model was the automatic random forest with the highest area under the curve in the validation set (88.52%) and the test set (82.87%).

Conclusions: When monitoring web-based medical record use trends, research should focus on social factors such as age, education, BMI, and marital status, as well as personal lifestyle and behavioral habits, including smoking, use of electronic devices and the internet, patients' personal health status, and their level of health concern. The use of electronic medical records can be targeted to specific patient groups, allowing more people to benefit from their usefulness.

Introduction

Background

Regular review of self–medical records by patients can enhance patient-doctor communication and facilitate disease treatment. Effective communication can increase patient satisfaction, acceptance, adherence, and co-operation with the medical team. It can also improve a patient's physiological and functional status [1]. Conversely, poor communication between doctors and patients can lead to poor quality and continuity of care [2]. Therefore, ensuring good communication by recording, processing, and sharing health information with patients is a necessary and integral part of the health care process. Encouraging patients to use medical records can reduce unnecessary duplication of testing and treatment [3].

Before the advent of electronic medical records, traditional paper-based medical records written in technical language and comprising raw data were provided to health care professionals. However, such medical records can be worrying and confusing for patients. Consequently, clinical trials that provided written records to patients at the time reported that the use of medical records by patients had little success in enhancing communication and facilitating disease treatment [4-7]. However, with the advent of electronic storage of medical records and the internet, patients can be provided with web-based access to their medical records. Internet-accessible medical records may be particularly helpful to patients compared with centrally stored paper-based medical records. Patients can review web-based medical records repeatedly at their convenience. The readability optimization of web-based cases and the increasing popularity of internet medical information have made understanding web-based medical records easier for patients. Moreover, with the current COVID-19 pandemic, the use of web-based medical records may become more prevalent.

Studies have shown that providing patients with internet-accessible medical records may lead to modest benefits. For example, overall adherence to medical advice improved among patients using web-based medical records. A trend of improvement in satisfaction with doctor-patient communication has also been observed [8]. However, many patients avoid using web-based medical records despite their greater availability and readability. Historically, this was possibly because patients had little access to web-based medical records. For example, in 2013, only 3 in 10 patients gained access to medical records, and almost half of those who gained access viewed their web-based records at least once [9]. What factors influence the use of web-based medical records in the current population? This study explored the factors that influence people's nonuse of web-based medical records.

Some studies have applied traditional statistical methods to explore the relationship between certain factors and web-based medical record nonuse. For example, using univariable and multivariable regression models, Gerber et al [10] analyzed the use of MyChart (a personal health record portal for electronic medical record systems) among patients attending a National Cancer Institute–designated cancer center and predictors of MyChart use. Using data from the Health Information National Trends Survey (HINTS) cycle 3, Elkefi et al [9] applied descriptive statistics and chi-square tests to explore why patients tended to avoid using web-based medical records and compared patients' perceptions of web-based medical records based on demographics and cancer diagnoses. On the basis of 2017 to 2018 HINTS data, Patel and Johnson [11] used descriptive statistics and hypothesis testing to assess individuals' access, viewing, and use of their web-based medical records and the use of smartphone health apps and other electronic devices in 2017 and 2018. Trivedi et al [12] used multivariable logistic regression (LR) analyses to examine the association between sociodemographic and health care–related factors on being offered access to web-based medical records and accessing web-based medical records and cited reasons for not accessing web-based medical records. These studies used traditional and relatively simple statistical methods, and the selection of predictors has certain limitations. As in the research by Elkefi et al [9], predictors relate only to demographic variables and cancer diagnoses. Screening of predictors based on a data-rich environment can be optimized.

With the rapid development of artificial intelligence, machine learning methods have received increasing attention. Machine learning algorithms are used in a wide variety of applications, such as in medicine and health care, where it is difficult or unfeasible to develop conventional algorithms for necessary tasks [13]. Compared with traditional regression-based statistical methods, machine learning is data-driven and has the advantage of not assuming the distribution and relationship of predictors, and machine learning algorithms are good at handling data that are multidimensional and multivariety. Deep learning is a step forward, which makes feature engineering part of the learning task, reducing the algorithm's dependence on feature engineering. However, the parameters of the machine learning method greatly influence model accuracy. Incorrect parameter selection and a small sample size can both lead to reduced model performance. Some parameters (such as the number of trees, learning rate, and number of leaf nodes in the random forest

method) determine the structure and training method of the model, which affects prediction performance. To take full advantage of the relevant machine learning algorithms, an appropriate strategy must be developed to determine the parameters.

Objectives

In this study, explanatory variables were chosen based on a data-rich environment. Data for this study were collected from the National Cancer Institute 2019 to 2020 HINTS. The HINTS regularly collects nationally representative data about the American public's knowledge of, attitudes toward, and use of cancer- and health-related information; therefore, this study is based on the relevant background in the United States. We used almost all the questions in the questionnaire as possible predictors, thus avoiding the subjectivity of manual screening. To resolve the parameter selection problem of machine learning algorithms, this study adopted the current popular *H2O* (H2O.ai) automatic machine learning algorithms to realize the automation of the entire process, from construction to the application of the machine learning model. At the same time, we also used the traditional statistical method of LR. To the best of our knowledge, this is the first study that applied a range of H2O's automatic machine learning algorithms to such a large representative sample based on a data-rich environment. We implemented a combination of H2O's automatic machine learning methods and a data-rich environment. Predictors of web-based medical record nonuse were identified based on the results of the H2O automatic machine learning methods.

Methods

Data Source

Data for this study were collected from the National Cancer Institute 2019 to 2020 HINTS. The HINTS regularly collects nationally representative data about the American public's knowledge of, attitudes toward, and use of cancer- and health-related information. Survey researchers use the data to understand how adults (aged ≥18 years) use different communication channels, including the internet, to obtain vital health information for themselves and their loved ones. This study analyzed merged data from cycles 3 to 4. Data from cycle 3 were collected between January 2019 and May 2019, and those from cycle 4 were collected from February 2019 to June 2019. We screened the respondents based on the target-dependent variable (ie, web-based medical record nonuse), leaving respondents with no missing values in the target-dependent variable. Finally, 9072 respondents were screened.

Ethical Considerations

The HINTS administration was approved by the institutional review board at Westat Inc and deemed exempt by the National Institutes of Health Office of Human Subjects Research. This exemption also extends to this study. HINTS data are available for public use. Additional information on the survey design is available on the HINTS website.

Statistical Analysis

Explanatory variables were selected in this study based on a data-rich environment, and all questions in the questionnaire that could be answered by all participants were selected (P_0=141; variables that could only be answered by a specific group were not considered, such as questions only for females, eg, whether they had been screened for cervical cancer). The sociodemographic characteristics and other relevant variables of individuals who had or had not used web-based medical records were compared using chi-square tests for categorical variables and 2-tailed *t* tests for continuous variables. According to the results of the aforementioned statistical tests, significant variables were selected. Preliminary screening of variables was completed (P_1=49; some variables were merged and answers were regrouped; refer to Multimedia Appendix 1 for details). Samples with missing values for the preliminary screened variables were excluded, and accordingly, a total of 4827 samples were obtained. On the basis of these samples, 5 algorithms were used for modeling: LR, automatic generalized linear model (auto-GLM), automatic random forest, automatic deep neural network (auto–deep learning), and automatic gradient boosting machine (auto-GBM). Of them, LR is a traditional statistical method, and the last 4 are automated machine learning algorithms based on the R interface (R Foundation for Statistical Computing) of the H2O extensible machine learning platform.

We divided the data set as follows: 80% of the data were used as the training set, and 20% of the data were used as the test set. We used the method of 5-fold cross-validation on the training data to determine hyperparameters and used the selected optimal hyperparameters to fit the model using all training data and make predictions on the test set. To evaluate the predictive accuracy of the models, we reported the accuracy, precision, recall, F_1-score, and area under the curve (AUC) of the validation set (validation set results for 5-fold cross-validation in the training set) and test set. The LR model selected predictors through backward selection and stepwise regression. The relative effects of the predictors in the LR model were measured based on crude odds ratios (ORs), whereas the variability and significance were assessed based on CIs and the corresponding P values. Variable importance values were used in the other 4 H2O automatic machine learning classification algorithms to identify predictors (variables with higher importance indexes were screened as predictors, and a 5-fold cross-validation method was used to select important variables by using all data). All statistical analyses were performed using the R software (version 4.1.2). In this study, P<.05 was considered statistically significant.

Measures

Nonuse of Web-Based Medical Records

Web-based medical records are used to organize processes in clinical and outpatient settings and forge doctor-patient communication that establishes mutual understanding and trust. The variable "nonuse of web-based medical records" in this study was calculated based on the following question in the HINTS: "How many times did you access your web-based

medical record in the last 12 months?" We used this question to identify users and nonusers of web-based medical records. The respondents who reported accessing their web-based medical records at least once were coded as users, and those who reported accessing their records 0 times were coded as nonusers.

Demographic and Other Related Variables

Demographic variables of interest (dichotomized for analysis) included sex (male and female), race and ethnicity (non-Hispanic White and racial and ethnic minority group), education (high school or lower and more than high school), income ranges (<US $20,000 and ≥US $20,000), area (nonmetropolitan and metropolitan), and marital status (married and not married), as well as numerical demographic variables, including age (continuous years) and BMI.

For further analysis, we selected as many variables as possible from the HINTS database to identify their relationship with the use of web-based medical records. Statistical tests were performed on almost all variables in the questionnaire, including chi-square tests for categorical variables and 2-tailed *t* tests for continuous variables. The variables that passed the significance test were used as potential predictors, as follows (consistent with the question blocks in the questionnaire): 6 variables, such as *Confidence in access to health information*, in part A (looking for health information); 6 variables, such as *Internet use*, in part B (using the internet to find information); 2 variables, such as *Have regular health providers*, in part C (your health care); 3 variables, such as *Health provider maintain MR (medical record)*, in part D (medical records); *Care for someone* in part E (caregiving); 7 variables, such as *General health*, in part F (your overall health); 2 variables, such as *Notice calorie information*, in part G (health and nutrition); 2 variables, such as *Exercise days per week*, in part H (physical activity and exercise); 3 variables, such as *Smoke*, in part K (tobacco products; this part of the questionnaire was about the respondents' consumption of tobacco products); 3 variables, such as *Ever tested colon cancer*, in part L (cancer screening and awareness); *Ever had cancer* in part M (your cancer history); 4 variables, such as *Everything cause cancer*, in part N (beliefs about cancer); and 1 numerical variable, *Sitting time per day*.

Specific variables and their descriptive statistics are shown in Multimedia Appendix 2, and Multimedia Appendix 1 lists details of some of the aforementioned variables, including demographic variables and variables adjusted for research needs with the readjustment information.

Machine Learning Methods

LR Model

LR is a generalized linear regression analysis model that is part of supervised learning in machine learning. LR usually uses numerical or categorical independent variables x_1, x_2,...,x_n to predict the value of the categorical dependent variable y to determine the probability that y belongs to a particular category [14].

$$p(y = 1 \mid x_1, x_2,...,x_n) = (e^{\beta_0 + \beta_1 x_1 + ... + \beta_n x_n})/(1 + e^{\beta_0 + \beta_1 x_1 + ... + \beta_n x_n}) \quad \textbf{(1)}$$

The OR expresses the ratio between the probability p that the dependent variable y is 1 and the probability $1 - p$ that the dependent variable y is 0. The OR is related to the interpretability of LR. When x_i is increased by 1, the odds become the original $e^{\beta i}$ times.

$$logit(p) = \ln(p/1-p) = \beta_0 + \beta_1 x_1 + ... + \beta_n x_n \quad \textbf{(2)}$$

In the aforementioned formula, β_1, β_2,..., β_n are the coefficients that measure the contribution of the independent variables x_1, x_2,...,x_n to y. If the coefficient β is positive, $e^{\beta}>1$ and the factor have a direct correlation with y, whereas if β is negative, e^{β} is between 0 and 1.

H2O's Auto-GLM

Generalized linear models (GLMs) were proposed and published by Nelder and Wedderburn [15] in 1972. It is a modeling method that can solve the problem that ordinary linear regression models cannot handle discrete dependent variables. GLM is an extension of the linear model and establishes the relationship between the mathematical expectation of the response variable and the linear combination of predictor variables through a link function. In this study, 5-fold cross-validation was adopted on the data set to select the hyperparameters of the model, and the selection range of the regularization parameter was (0, 1). Ridge regression (α=0) was used in the regression of the GLM for the variable selection and final classification. The importance of the variable was judged according to the "absolute value of the normalization coefficient" indicator; the larger the value, the greater the importance of the variable. This study used the "h2o.glm" function in the "h2o" package to build a GLM for the classification of web-based medical record use.

H2O is an open-source, in-memory, distributed, fast, and scalable machine learning and predictive analytics platform that allows users to build machine learning models on data and avoid the tedious process of manual hyperparameter tuning. H2O supports traditional (or "Cartesian") grid searches. In a Cartesian grid search, users specify a set of values for each hyperparameter that they want to search, and H2O trains a model for every combination of the hyperparameter values. This means that, if we have 3 hyperparameters and specify 5, 10, and 2 values for each, the grid will contain a total of 5 × 10 × 2 = 100 models. After the grid search is complete, the user can query the grid object and sort the models by a specific performance metric (eg, "AUC") and select the locally best model within the specified parameter range.

H2O's Automatic Random Forest

The random forest is a multivariate statistical technique that considers an ensemble (forest) of trees for efficiency and predictive power [16]. Random forest uses a bagging technique (bootstrap aggregation) to select resamples randomly and choose a random sample of variables at each tree node as the training data set for model calibration. As the random selection of the training data set may affect the model's results, a large set of trees is applied to guarantee model stability. In this study, the

selection range of the number of trees was between 100 and 500, the selection range of the number of variables in the variable selection set at the node of the tree was approximately $p^{0.5}$ (p is the total number of variables), and the maximum tree depth was selected from 10 to 30. When selecting variables, the parameters of the final model selected under 5-fold cross-validation were as follows: the number of trees was 150, the number of variables contained in the variable selection set at the node of the tree was 7, and the maximum depth of the tree was 10. The importance of the variable was judged according to the "mean decrease gini" indicator, where the larger the value, the greater the importance of the variable. When fitting the model, the final parameters were as follows: the number of trees was 300, the number of variables included in the variable selection set at the node of the tree was 2, and the maximum depth of the tree was 10. Model-fitting processes were implemented using the "h2o.randomForest" function in the "h2o" package. Parameter tuning was implemented using the "h2o.grid" function in the "h2o" package by grid searching for parameters.

H2O's Auto–Deep Learning

The concept of deep learning originates from the study of artificial neural networks, and a multilayer perceptron with multiple hidden layers is a basic deep learning structure. Deep learning algorithms try to identify potential relationships in a data set by mimicking human brain functions. Similar to the human brain structure, deep learning models consist of neurons in complex and nonlinear forms. Deep learning models have 3 basic types of layers: input, hidden, and output layers. Each neuron in the current layer is connected to the input signal of each neuron in the previous layer. In each connection process, the signal from the previous layer is multiplied by a weight, and a bias is added and then passed through a nonlinear activation function through multiple composites of simple nonlinear functions to achieve a complex input space–to–output space map. In this study, the input values were observations of 49 variables, and the output value was the probability of the use of web-based medical records. When training the model, the number of hidden layers was 2 to 3; the number of nodes in the first layer was between 100 and 200; the number of nodes in the second layer was between 50 and 100; and the number of nodes in the third layer was 5, if any. The activation function was selected from the rectifier and rectifier with dropout; dropout ratio defaults to 0.5. The deep learning model chosen using 5-fold cross-validation to be applied for selecting variables contained 3 hidden layers, each with 100, 50, and 5 nodes. When training the model, a 50% random dropout of the nodes was set to prevent overfitting. The variable importance of the model was measured using the combination of absolute values of the coefficients. The final model for classification contained 3 hidden layers, each with 200, 50, and 5 nodes with 50% random dropout, which provided the highest mean AUC in the test set of the model in 5-fold cross-validation. In this study, we used the "h2o.deeplearning" function in the "h2o" package to realize the deep learning algorithm.

H2O's Auto-GBM

The gradient boosting machine (GBM) algorithm is a type of boosting algorithm. GBM is a model that trains decision trees sequentially. Each decision tree is based on the errors of the previous tree. The core idea is to generate various weak learners in series, and the goal of each weak learner is to fit the negative gradient of the loss function of the previous accumulated model. After adding the weak learner, it enables the accumulated model loss to decrease along the negative gradient direction. It uses different weights to linearly combine the basic learners to ensure that learners with greater performance can obtain larger weights. The most commonly used base learners are tree models. Variable importance is determined by calculating the relative influence of each variable: whether that variable is selected to split during the tree-building process and how much the squared error improves or decreases as a result. We used 5-fold cross-validation in both the variable selection and classification model-fitting procedures, which would provide indicators for the selection of optimal hyperparameters. In the process of using a grid search for hyperparameter optimization, it is necessary to train the models under different hyperparameter specifications and evaluate the goodness of fit of the models under these specifications through 5-fold cross-validation. The number of trees ranged from 100 to 500, and the final parameter was set to 300 in both the variable selection and classification model-fitting procedures, which promises a balance in the training and test set errors in 5-fold cross-validation. In addition, the selection of the learning rate ranged from 0.01 to 0.10, and the final parameter was set to 0.01. The maximum depth was between 10 and 30, and the final parameter was set to 10 in both the variable selection and classification model-fitting procedures, which implements a trade-off between model bias and model variance. This study used the "h2o.gbm" function in the "h2o" package to build a GBM for the use of web-based medical record classification problems. Parameter tuning was implemented using the "h2o.grid" function in the "h2o" package by grid searching for parameters.

Results

Descriptive Statistics

The merged data sets from HINTS cycles 3 and 4 yielded a sample of 9072 respondents, including 5409 (59.62%) nonusers and 3663 (40.38%) users of web-based medical records. Multimedia Appendix 2 presents the frequencies and proportions of the variables. The chi-square test of categorical variables and the 2-tailed t test of continuous variables showed significant differences in some variables between nonusers and users of web-based medical records (P<.05). Among the categorical variables, respondents who chose the following options comprised a significantly higher proportion (P<.05) of the group not using web-based medical records: "male," "trust information about health or medical topics from religious organizations and leaders," "have no drink," and "smoke more." For example, in this group, male individuals accounted for 45.23% (2196/4855) of the respondents, whereas in the group using web-based medical records, the percentage decreased to 38.65% (1331/3444). The same was true for the other aforementioned variables: "trust information about health or medical topics from

religious organizations and leaders" (1501/4934, 30.42% vs 824/3573, 23.06%), "have no drink" (2623/4692, 55.9% vs 1575/3421, 46.04%), and "smoke more" (824/3573, 39.38% vs 1264/3630, 34.82%). However, those choosing "Non-Hispanic White" (3492/4885, 71.48% vs 2686/3488, 77.01%), "have higher education level" (3471/5212, 66.6% vs 3160/3598, 87.83%), "have higher income level" (3569/4741, 75.28% vs 3042/3349, 90.83%), "in marriage" (2481/5198, 47.73% vs 2252/3600, 62.56%), "ever looked for information about cancer" (2378/5344, 44.50% vs 2429/3646, 66.62%), "use Internet" (3841/5379, 71.41% vs 3501/3650, 95.92%), "use electronic" (3752/5346, 70.18% vs 3572/3642, 98.08%), "use Internet for health use" (3337/5289, 63.09% vs 3111/3636, 85.56%), "have regular healthcare provider" (3285/5293, 62.06% vs 2930/3625, 80.83%), "caring someone" (723/5216, 13.86% vs 656 /3604, 18.20%), "general health relative good" (4343/5331, 81.47% vs 3169/3625, 87.42%), "high confidence in ability to take good care of own health" (5036/5337, 94.36% vs 3503/3632, 96.45%), and others were significantly higher (P<.05) in the group using web-based medical records. Among the numeric variables, mean values of age were significantly higher (P<.05) in the group not using web-based medical records, whereas time spent sitting was significantly higher (P<.05) in the group using web-based medical records. The 2-tailed t test of continuous variables also showed no significant difference (P>.05) in some variables between individuals who had and had not used web-based medical records. In other words, the proportions of these variables were similar between the 2 groups. As for BMI, the average value in both groups was approximately 28.5 (SD 0.1).

Machine Learning Model Results

As shown in Tables 1 and Table 2, a total of 29 predictors of nonuse of web-based medical records variables (*Age, Sitting time per day, BMI, Confidence in access to health information, education, Electronic means use, Ever tested colon cancer, Everything cause cancer, Number of visits to health provider, Have electronic device, income, Obesity affects cancer onset, Social media use, Little interest, Marital status, Offered access to MR by health provider, Offered access to MR by health insurer, Health provider maintain MR, race, Have regular health providers, Seek cancer information, Shared health information, Smoke, Exercise days per week, Strength training days per week, Trust doctor, Trust religious organizations, Internet use, and Electronic wearable device use*) were selected in all the 5 algorithms, and 7 variables (*Age, Electronic means use, Number of visits to health provider, Offered access to MR by health provider, Offered access to MR by health insurer, Health provider maintain MR, and Internet use*) were selected simultaneously in the 5 algorithms.

Table 1. Predictors of nonuse of web-based medical records (MRs) using the logistic regression algorithm.

Predictor	OR[a] (95% CI)
Race (reference: non-Hispanic White)	1.04 (0.90-1.19)
Education (reference: high school or lower)	0.32 (0.27-0.37)
Income (reference: <US $20,000)	0.35 (0.29-0.43)
Marital status (reference: not married)	0.60 (0.54-0.68)
Trust doctor[b] (reference: low_level)	0.73 (0.53-0.99)
Trust religious organization[b] (reference: low_level)	1.31 (1.15-1.50)
Internet use (reference: no)	0.12 (0.09-0.16)
Electronic means use (reference: no)	0.05 (0.03-0.07)
Electronic wearable device use (reference: no)	0.40 (0.35-0.45)
Shared health information (reference: N/A[c])	
No	0.71 (0.58-0.87)
Yes	0.26 (0.20-0.33)
Social media use (reference: no)	0.37 (0.32-0.43)
Have regular health providers[d] (reference: no)	0.36 (0.32-0.42)
Number of visits to health provider[e] (reference: none)	
1 time	0.24 (0.18-0.33)
2 times	0.19 (0.15-0.26)
3 times	0.15 (0.12-0.21)
4 times	0.14 (0.11-0.19)
5-9 times	0.10 (0.08-0.14)
≥10 times	0.10 (0.08-0.14)
Health provider maintain MR (reference: no)	
Yes	0.11 (0.06-0.22)
Don’t know	1.14 (0.56-2.30)
Offered access to MR by health provider[f] (reference: no)	
Yes	0.03 (0.03-0.04)
Don’t know	0.83 (0.57-1.22)
Offered access to MR by health insurer[f] (reference: no)

4-7 days per week	0.84 (0.70-1.01)
Ever tested colon cancer (reference: no)	0.74 (0.66-0.83)
Age	1.01 (1.00-1.01)
BMI	0.99 (0.99-1.00)

[a]OR: odds ratio.

[b]In general, how much would you trust information about cancer from a doctor/government health agencies/charitable organizations/religious organizations and leaders? (Supplement to the variable-related questions in the survey).

[c]N/A: not applicable.

[d]Not including psychiatrists and other mental health professionals, is there a particular doctor, nurse, or other health professional that you see most often? (Supplement to the variable-related questions in the survey).

[e]In the past 12 months, not counting times you went to an emergency room, how many times did you go to a doctor, nurse, or other health professional to get care for yourself? (Supplement to the variable-related questions in the survey).

[f]Have you ever been offered online access to your medical records by your health care provider/health insurer? (Supplement to the variable-related questions in the survey).

Table 1 shows significant predictors of nonuse of web-based medical records in LR (P<.05). The variables in LR were screened using 2 methods: backward selection and stepwise regression. The results obtained using the 2 variable selection methods were consistent, and 20 significant variables were finally selected.

The results of LR showed that sociodemographic indicators, such as age, BMI, education, marital status, income, and race, significantly affected the nonuse of web-based medical records, whereas sex and area had no significant effect on the prediction of nonuse of web-based medical records. On the basis of sociodemographic variables, people who were relatively older (OR 1.01, 95% CI 1.00-1.01), had a relatively lower BMI (OR 0.99, 95% CI 0.99-1.00), had relatively lower education (higher education OR 0.32, 95% CI 0.27-0.37), were not married (married OR 0.60, 95% CI 0.54-0.68), had a lower income (higher income OR 0.35, 95% CI 0.29-0.43), and belonged to racial and ethnic minority groups (OR 1.04, 95% CI 0.9-1.19) were more likely to not use web-based medical records. People who did not often access the internet or send and receive emails (OR 0.12, 95% CI 0.09-0.16), had not used a computer or smartphone to inquire about medical information in the past 12 months (OR 0.05, 95% CI 0.03-0.07), did not often use a wearable device to track health (OR 0.40, 95% CI 0.35-0.45), did not share health information from an electronic monitoring device or smartphone with a health professional in the previous 12 months, and people who had not used social media in the last 12 months (OR 0.37, 95% CI 0.32-0.43) were more inclined not to use web-based medical records. Moreover, those who were less concerned about their own health were more likely to not use web-based medical records. People who were more likely to not use web-based medical records tended to be those who did not see a particular doctor or health care professional frequently (OR 0.36, 95% CI 0.32-0.42); had not gone to a doctor, nurse, or other health professional to receive care in the last 12 months; did not have doctors or other health care providers maintain their medical records in a computerized system (OR 0.11, 95% CI 0.06-0.22); were not offered web-based access to their medical records by the health care provider (OR 0.03, 95% CI 0.03-0.04); were not offered web-based access to their medical records by the health insurer (OR 0.21, 95% CI 0.19-0.25); and did not perform leisure-time physical activities specifically designed to strengthen muscles. People who strongly trusted information about health or medical topics from religious organizations and leaders (OR 1.31, 95% CI 1.15-1.50), trusted information about health or medical topics from a doctor only a little (OR 0.73, 95% CI 0.53-0.99), and did not check for colon cancer (OR 0.74, 95% CI 0.66-0.83) were more inclined to not use web-based medical records.

Table 2. Predictors of web-based medical record (MR) nonuse built using automatic generalized linear model (auto-GLM), automatic random forest, auto–deep learning, and automatic gradient boosting machine (auto-GBM).

Model and predictor	Importance scores
Auto-GLM	
Offered access to MR by health provider[a]	100
Electronic means use	47.41
Health provider maintain MR	22.72
Number of visits to health provider[b]	21.63
Age	17.11
Offered access to MR by health insurer[a]	14.94
Electronic wearable device use	13.91
Have regular health providers[c]	13.10
Shared health information	12.06
Internet use	10.97
Ever tested colon cancer	9.64
Social media use	9.30
Income	6.45

Offered access to MR by health provider	100
Electronic means use	19.15
Offered access to MR by health insurer	19.02
Health provider maintain MR	16.03
Number of visits to health provider	10.20
Internet use	6.88
Have regular health providers	5.97
Age	5.43
Shared health information	4.71
Electronic wearable device use	4.58
Sitting time per day	4.29
BMI	4.15
Have electronic device	4.13
Education	2.96
Sitting time per day	2.83
Auto–deep learning	
Offered access to MR by health provider	100
Electronic means use	51.18
Health provider maintain MR	40.19
Internet use	34.94
Offered access to MR by health insurer	34.41
Number of visits to health provider	33.24
Little interest[d]	33.02

Model and predictor	Importance scores
Social media use	32.59
Smoke	32.22
Confidence in access to health information	31.86
Race	31.80
Sitting time per day	31.71
Age	31.62
Obesity affects cancer onset	30.91
Have electronic device	30.78
Auto-GBM	
Offered access to MR by health provider	100
Electronic means use	15.87
Number of visits to health provider	6.84
Age	3.97
Offered access to MR by health insurer	3.95
Sitting time per day	3.08
Electronic wearable device use	2.48
Shared health information	2.08
Internet use	1.80
BMI	1.49
Health provider maintain medical records	1.46
Have electronic device	1.28
Have regular health providers	1.23
Exercise days per week	1.13
Everything cause cancer	0.97

[a]Have you ever been offered online access to your medical records by your health care provider/health insurer? (Supplement to the variable-related questions in the survey).

[b]In the past 12 months, not counting times you went to an emergency room, how many times did you go to a doctor, nurse, or other health professional to get care for yourself? (Supplement to the variable-related questions in the survey).

[c]Not including psychiatrists and other mental health professionals, is there a particular doctor, nurse, or other health professional that you see most often? (Supplement to the variable-related questions in the survey).

[d]Over the past 2 weeks, how often have you been bothered by little interest or pleasure in doing things? (Supplement to the variable-related questions in the survey).

The essence of this study is a binary classification problem of judging whether individuals have used web-based medical records based on a set of inputs, such as education and income. Therefore, we evaluated the 5 methods using a series of evaluation metrics commonly used for classification algorithms. Table 3 presents the accuracy, precision, recall, F_1-score, and AUC values for the 5 machine learning methods on the validation and test sets. Accuracy is a metric of a classification model that measures the percentage of correct classification accounts for the total number of classifications. Precision is the proportion of correctly predicted positives to all predicted positives, whereas recall is the proportion of correctly predicted positives to all actual positives. The F_1-score is the harmonic mean of precision and recall. From the results of the verification set, LR had 3 indicators that performed best, with an accuracy of 83.35%, a recall of 88.97%, and an F_1-score of 83.59%. However, the performance of LR on the test set was inferior to that of machine learning methods. In the test set, auto-GLM had the highest accuracy (82.49%), auto-GBM had the highest precision (79.73%), and automatic random forest had the highest recall (87.15%) and AUC (82.87%). AUC is not affected by the classification threshold and data distribution and, thus, reflects the overall classification power of the model. Automatic random forest had the highest AUC in both the validation (88.52%) and test (82.87%) sets. Therefore, in general, we were more inclined to choose the automatic random forest as the optimal model for predicting web-based medical record nonuse. Equations 3 to 6 provide the evaluation formulas for the machine learning models.

$$Accuracy = (TP\ [True\ Positive] + TN\ [True\ Negative])/(TP + TN + FP\ [False\ Positive] + FN\ [False\ Negative]) \quad (3)$$

$$Precision = TP/(TP + FP) \quad (4)$$

$$Recall = TP/(TP + FN) \quad (5)$$

$$F1\text{-}score = 2 \times (Recall \times Precision)/(Recall + Precision) \quad (6)$$

Table 3. Correct classification metrics for each machine learning method.

Criterion	LR[a]		Auto-GLM[b]		Automatic random forest		Auto–deep learning		Auto-GBM[c]	
	Validation	Test	Validation	Test	Validation	Test	Validation	Test	Validation	Test
Accuracy, %	83.35	81.47	82.17	82.49	82.48	82.38	82.57	80.93	81.32	79.69
Precision, %	78.86	76.26	85.09	77.73	86.1	76.43	89.52	74.3	85.38	79.73
Recall, %	88.97	86.7	79.76	84.81	79.04	87.15	75.01	87.15	77.78	76.96
F_1-score, %	83.59	82.01	82.34	81.11	82.3	81.44	81.57	80.22	81.31	78.32
AUC[d], %	82.29	81.8	88.46	82.72	88.52	82.87	87.54	81.56	87.68	79.57

[a]LR: logistic regression.

[b]Auto-GLM: automatic generalized linear model.

[c]Auto-GBM: automatic gradient boosting machine.

[d]AUC: area under the curve.

Discussion

Principal Findings

Effective communication is key for delivering high-quality health care services [1]. Ensuring good communication by recording, processing, and sharing health information with patients is integral to the health care process. At present, the development of information and communications technology has allowed for the realization of web-based medical records, but because of some situations, web-based medical records are still not fully popular among patients. On the basis of demographic and individual behavioral characteristics, this study explored the predictors of web-based medical record nonuse.

We conducted a comprehensive assessment of the effects of individual sociodemographic characteristics, lifestyle, and behavioral habits on nonuse of web-based medical records. Although generalizing the factors that influence individuals' nonuse of web-based medical records was difficult, based on the survey data, this study conducted in a data-rich variable selection environment demonstrated that an individual's nonuse of web-based medical records is related to their sociodemographic characteristics, such as age, lifestyle, behavioral habits, and attention to health problems.

To date, numerous studies on the use of web-based medical records by patients have been based on surveys wherein data were gathered using a semistructured interview approach [17]. Using data from the National Cancer Institute 2019 to 2020 HINTS database, we applied the following question—"How many times did you access your web-based medical record in the last 12 months?"—to determine whether a person used web-based medical records. Our analysis showed that 59.62% (5409/9072) of the population in the survey samples had no experience using web-based medical records.

This study used 5 algorithms—LR, auto-GLM, automatic random forest, auto–deep learning, and auto-GBM—to identify and investigate factors affecting individuals' nonuse of web-based medical records. Of them, LR is a traditional statistical method, and the latter 4 algorithms are part of H2O's automatic parameterization methods. A total of 29 influencing variables concerning the use of web-based medical records were selected based on coefficient significance in the LR model and the variable importance indicators in the other 4 methods. Many well-established determinants were also identified as proof of concept for our analytical approach, such as sociodemographic characteristics [9]. Although nonlinear and ensemble algorithms exhibit better predictive performance than traditional parametric models, they are less interpretable [18]. Therefore, predictors determined by such algorithms should be evaluated in conjunction with relevant research evidence.

This study showed that sociodemographic indicators, such as age, BMI, race, marital status, education, and income, significantly affected the nonuse of web-based medical records, whereas sex and area did not significantly affect the prediction of the nonuse of web-based medical records. In addition, predictors involving personal lifestyle and behavioral habits, such as smoking, electronic device use, and internet use, also played essential roles in predicting the nonuse of web-based medical records. Finally, individuals' health status and their level of health concern were also associated with the nonuse of web-based medical records. Of course, some regions or units do not provide web-based access to medical records, or these are not maintained by health care providers, which may directly limit the use of web-based medical records.

On the basis of some of the conclusions of this study, recommendations can be made to promote the widespread use of web-based medical records. The use of electronic equipment is also a factor affecting the use of web-based medical records. People who are not accustomed to using electronic devices, such as mobile phones and computers, generally do not access their web-based medical records. The reason for avoiding web-based medical records may not be the disadvantage of web-based medical records itself but the resistance to electronic products, which is more common in older adults. However, older adults are more likely to become sick, so web-based medical records for this group are also a direction that needs special attention and development, such as building an interface

that is friendly to the older adult population and keeping the internet-accessible interface simple and clear. Web-based medical records are often used by people with more related health problems. A study by the Office of the National Coordinator of Health Information Technology found that individuals may not realize the value of accessing their web-based medical records until they have a medical need. Given that the patient record request process can be time consuming, it may be more beneficial to have access to a person's data in advance of an urgent health need. Therefore, popularizing health knowledge to the public and increasing the public's attention to health information can increase the public's demand for health-related information to a certain extent, thereby promoting the use of web-based medical records.

This research can provide a theoretical basis for predicting individual web-based medical record use. On the basis of the predictors of people not using web-based medical records selected by machine learning algorithms, individuals who do not use such records can be identified in advance, and use of web-based medical records can be promoted among them. Thus, this would provide more effective doctor-patient communication and better health care services.

Limitations

This study has some limitations. First, this study explored the influencing factors of nonuse of web-based medical records and discussed the correlation between each influencing factor and the target variable but did not involve the study of the influence path and influence mechanism. We considered conducting a causal analysis, but the cross-sectional survey design of the HINTS prevented us from making or testing causal claims. Second, the relationships between the selected variables were not studied further, and the screened important predictors may have certain collinearity. Third, the data were obtained using a self-report questionnaire. Therefore, we did not obtain detailed information on the nonuse of web-based medical records, and self-report bias may have affected the results. Finally, patient access to web-based medical records varies from country to country, and cultural background also has a strong impact on medical services. This study used HINTS data from the United States, and the conclusions may not be generalizable to other countries.

Comparison With Prior Work

The use of web-based medical records can enhance patient participation and co-operation in disease treatment and enhance doctor-patient communication to promote disease treatment. This is evidenced in the study by Stewart et al [19], whose research took patients with diabetes as the research object and found that patient portals support engagement by facilitating patient access to their health information and facilitating patient-provider communication. With the advancement of internet technology and the popularization of electronic products, the use of web-based medical records has become more convenient, but its penetration rate is still not high. Therefore, it has become a research hot spot to explore the characteristics and differences between users and nonusers of web-based medical records and identify the influencing factors of low use rate.

There are many studies based on HINTS data, such as that by Anthony et al [20], who used data from the 2017 HINTS to estimate 2 separate multivariable LR models to predict the factors associated with not having been offered access and those associated with not using a portal. On the basis of the 2017 to 2018 HINTS data, Patel and Johnson [11] used descriptive statistics and hypothesis testing to assess individuals' access, viewing, and use of their web-based medical records and the use of smartphone health apps and other electronic devices. Trivedi et al [12] used multivariable LR analyses to examine the association between sociodemographic and health care–related factors on being offered access to web-based medical records and accessing web-based medical records and cited reasons for not accessing web-based medical records. Hong et al [21] used LR to investigate the trend of patient portal use in the general population and the barriers to adoption. The aforementioned studies are all based on traditional statistical methods such as LR [12,20,21] and hypothesis testing related to association analysis [11], and the selection of influencing factors and the conclusions drawn only involve demographic variables and some variables of interest, whereas our research combines traditional statistical methods and machine learning methods to find predictors of web-based medical record use based on variable-rich environments. Furthermore, the results of machine learning methods also provide variable importance scores and rankings, which have also not been covered in previous studies. To the best of our knowledge, this is the first study to apply a range of H2O's automatic machine learning algorithms to a nationally representative sample for optimizing the classification of web-based medical record nonuse. Compared with previous studies, we found that personal lifestyle and behavioral habits as well as individuals' health status and their level of health concern significantly affect web-based medical record nonuse.

Conclusions

Using data from the National Cancer Institute 2019 to 2020 HINTS database, this study applied 5 machine learning algorithms—LR (linear), auto-GLM, automatic random forest, auto–deep learning, and auto-GBM—to identify and investigate the factors that affect whether individuals use web-based medical records. Using these 5 models, 29 variables were identified as crucial predictors of nonuse of web-based medical records. When monitoring web-based medical record use trends, research should consider social factors such as age, education, BMI, and marital status, as well as personal lifestyle and behavioral habits, including smoking, use of electronic devices and the internet, patients' personal health status, and their level of health concern. The use of electronic medical records can be targeted to specific patient groups, allowing more people to benefit from their usefulness.

The main contributions of this study are as follows: (1) using authoritative data, potential predictors were selected based on a data-rich environment, involving more comprehensive variables and avoiding unnecessary subjectivity, and (2) the key parameters of the machine learning methods considerably influenced the accuracy of the model. In this study, H2O's automatic parameter selection methods were introduced to optimize the key parameters of the model. Compared with

traditional machine learning algorithms, the H2O automatic machine learning methods effectively improved model performance.

Abstract

Background: In the context of a syphilis outbreak in neighboring states, a multifaceted systems change to increase testing for sexually transmitted infections (STIs) among young Aboriginal people aged 15 to 29 years was implemented at an Aboriginal Community Controlled Health Service (ACCHS) in New South Wales, Australia. The components included electronic medical record prompts and automated pathology test sets to increase STI testing in annual routine health assessments, the credentialing of nurses and Aboriginal health practitioners to conduct STI tests independently, pathology request forms presigned by a physician, and improved data reporting.

Objective: We aimed to determine whether the systems change increased the integration of STI testing into routine health assessments by clinicians between April 2019 and March 2020, the inclusion of syphilis tests in STI testing, and STI testing uptake overall. We also explored the understandings of factors contributing to the acceptability and normalization of the systems change among staff.

Methods: We used a mixed methods design to evaluate the effectiveness and acceptability of the systems change implemented in 2019. We calculated the annual proportion of health assessments that included tests for chlamydia, gonorrhea, and syphilis, as well as an internal control (blood glucose level). We conducted an interrupted time series analysis of quarterly proportions 24 months before and 12 months after the systems change and in-depth semistructured interviews with ACCHS staff using normalization process theory.

Results: Among 2461 patients, the annual proportion of health assessments that included any STI test increased from 16% (38/237) in the first year of the study period to 42.9% (94/219) after the implementation of the systems change. There was an immediate and large increase when the systems change occurred (coefficient=0.22; *P*=.003) with no decline for 12 months thereafter. The increase was greater for male individuals, with no change for the internal control. Qualitative data indicated that nurse- and Aboriginal health practitioner–led testing and presigned pathology forms proved more difficult to normalize than electronic prompts and shortcuts. The interviews identified that staff understood the modifications to have encouraged cultural change around the role of sexual health care in routine practice.

Conclusions: This study provides evidence for the first time that optimizing health assessments electronically is an effective and acceptable strategy to increase and sustain clinician integration and the completeness of STI testing among young Aboriginal people attending an ACCHS. Future strategies should focus on increasing the uptake of health assessments and promote whole-of-service engagement and accountability.

Introduction

Background

Aboriginal and Torres Strait Islander people in Australia can access sexually transmitted infection (STI) testing at primary health care services, including Aboriginal Community Controlled Health Services (ACCHSs) and mainstream general practice or government sexual health services [1]. The first ACCHS was established in 1971; now, there are >150 ACCHSs nationwide [2]. As in other countries with a history of colonization similar to that of Australia, culturally competent primary health care services run by and for Aboriginal communities play a vital role in ensuring equitable and culturally safe access to sexual and reproductive health care [3-5]. Reflecting this, previous research has identified that ACCHSs are more likely to provide health care that is free of racism than mainstream services [6]. ACCHSs are well situated to embed screening for STIs into routine clinical practice to more regularly identify asymptomatic infections [7].

In Australia, the highest rates of notified STIs (chlamydia, gonorrhea, and syphilis) are among young people aged 15 to 29 years, higher in young Aboriginal and Torres Strait Islander people than in young non-Indigenous people, and the highest in remote areas [8]. *Chlamydia trachomatis* (CT) is the most commonly reported STI among young Aboriginal people, followed by *Neisseria gonorrhea* (NG) and *Treponema pallidum* (syphilis) [9]. CT and NG are easily cured with antibiotics but can be asymptomatic and lead to complications if not treated, such as pelvic inflammatory disease, ectopic pregnancy, and infertility [10-13]. Syphilis is of major concern in Australia, with an expanding epidemic over the last decade beginning in northern Australia and extending to southern Australia, including New South Wales (NSW) and Victoria. Nationally, the notification rate (defined as the rate of notifiable diagnoses per 100,000 person years) is 6 times higher for Aboriginal and Torres Strait Islander people and up to 50 times higher in very remote areas of northern Australia [8]. If left untreated, syphilis can have particularly serious consequences, including miscarriage, stillbirth, and fetal abnormalities [11]. Modeling suggests that the STI prevalence in remote Aboriginal and Torres Strait Islander communities could be considerably reduced if screening was increased to 60% coverage and sustained for 10 years [14], and increasing STI screening rates for young Aboriginal people is a priority target in state and national public health strategies [15,16].

Most ACCHS patients present for reasons other than seeking an STI test; therefore, the mechanisms proposed to increase STI testing in this cohort include integration into other routine primary care visits, such as the Medicare Benefits Schedule item 715 annual health assessment (hereinafter referred to as *health assessment*) [17]. This is a structured preventive health assessment that can be provided annually to Aboriginal and Torres Strait Islander people in primary care settings, including ACCHSs. Australia's universal health insurance system, Medicare, provides a rebate per individual health assessment, and additional practice-level incentives are attached for eligible practices managing patients with chronic disease [18]. The *National guide to a preventive health assessment for Aboriginal and Torres Strait Islander people* [19] recommends the inclusion of STI screening for sexually active young people, along with an assessment of lifestyle factors; social and emotional well-being; vaccination status; and blood lipids, renal function, and blood glucose levels. Approximately one-quarter of young Aboriginal and Torres Strait Islander people participate in a health assessment each year [20]. This is a national figure, and local uptake is highly variable among regions and services [17]. The uptake of health assessments more than tripled in the decade preceding the COVID-19 pandemic, which resulted in a slight decrease of 2% over 2 years [20]. The pandemic also resulted in many health services temporarily deprioritizing the routine STI screening of asymptomatic patients in a context of significant disruption to clinical services [21].

Health assessments involve completing an electronic template in the patient electronic medical record (EMR), which can be customized at the practice level or by the software vendor [22]. The potential of EMR customization to improve the completeness and consistency of health assessments has been anticipated since ACCHSs first began to implement computerized health assessment templates >10 years ago [23]. Electronic prompts have been found to be more effective at increasing STI test requests made by clinicians in other settings than nonelectronic reminders, such as reminder stickers on paper medical records or pathology result forms [24]. The implementation of electronic prompts and automated pathology sets in both the mainstream general practice setting and at government-funded sexual health clinics has been found to increase comprehensive STI testing in line with clinical guidelines and the resulting detection of STIs for patients considered to be at higher risk, such as gay and bisexual men [25-27]. To our knowledge, the use of electronic prompts or

automated pathology sets to increase STI testing in the context of a health assessment at ACCHSs has not been evaluated.

The implementation and integration of complex health care interventions into routine clinical practice relies on action and interaction by and among individuals—the "work" of normalizing and embedding change [28]. In this paper, normalization is defined as per May et al [29] as the work of actors when engaging with new or changed activities by which the new activities become routinely embedded into existing knowledge and practices. Through this lens, implementation is characterized as an inherently social process involving collective action from human actors within dynamic contexts [30]. This provides a framework to analyze the factors that encourage or inhibit the incorporation of health care interventions into routine clinical practice [31].

Objectives

This mixed methods evaluation examined whether the systems change implemented at an NSW ACCHS increased the integration of STI testing into health assessments in young people, with a particular focus on concurrent syphilis testing, and explored the understandings of the acceptability and normalization of the systems change among ACCHS staff.

Methods

Setting

This study was conducted in partnership with a western NSW ACCHS caring for a large Aboriginal population [32] of between 8.4% in the main town center and 61.2% in smaller satellite towns (compared with 2.9% for NSW as a whole) [33,34]. This ACCHS provides 53,000 occasions of service to an average of 3500 patients per year, 80% of whom are Aboriginal patients. This figure accounts for all separate interactions with patients and includes face-to-face visits and telephone calls, both clinical and administrative. As the Torres Strait Islander population is low, we will hereinafter respectfully use the term *Aboriginal* when referring to this setting. Although NSW is home to the largest Aboriginal population in Australia, there is little quantitative sexual health research conducted with Aboriginal populations in NSW [35], although some qualitative studies have been published in recent years [36,37].

The Systems Change

We collaboratively developed a multifaceted systems change with ACCHS staff in March 2019. ACCHS clinical, managerial, and administrative staff who had been identified as potential sexual health champions cocreated the systems change at a workshop facilitated by 2 members of the research team (HM and CB). The workshop aimed to identify strategies to improve syphilis testing rates and STI testing rates more broadly among the patient population within the existing range of services, activities, and staff skills available. A core component was the addition to the EMR of an electronic prompt and an automated pathology set. The prompt was attached to the health assessment template completed by general practitioners (GPs) and triggered for all patients in the target age range, advising the GP to query sexual activity since the patient's last test because guidelines recommend STI screening after a change in partner or otherwise annually [38]. An affirmative indication updated the health assessment template in the EMR and autopopulated a pathology request for a comprehensive STI test (chlamydia, gonorrhea, and syphilis). The automated pathology set replaced the manual completion of pathology requests for individual STI tests with a single-click button that autopopulated a pathology request for a comprehensive STI test. The prompt aimed to increase the integration of STI tests into the health assessment, and the automated pathology test set aimed to increase the inclusion of syphilis tests when STI tests were requested, both within and outside of the health assessment.

Three other operational components completed the package: credentialing registered nurses (RNs) and Aboriginal health practitioners (AHPs) to undertake STI screening, pathology request forms presigned by a GP to authorize tests conducted by RNs and AHPs [39], and the enhanced internal reporting of STI screening targets to staff via standing agenda items at staff meetings for detailed data reports. Credentialing RNs and AHPs aimed to create opportunities for STI testing in clinical encounters that did not involve a GP, whereas having pathology forms presigned by a GP allowed these tests to receive Medicare funding under the signing GP's provider number. Enhanced data reporting has been shown to be an important component of continuous quality improvement (CQI) systems implemented at ACCHSs [40,41]. These 3 components aimed to increase STI testing outside of the health assessment.

Strengths-Based Approach

Our evaluation explicitly adopted a strengths-based approach. This project centers the strengths, assets, and capabilities of ACCHSs and ACCHS staff [42], rather than deficit-focused epidemiological framing that can act as a barrier to improving health outcomes [43]. As such, both the qualitative and quantitative analyses focused on factors associated with positive health outcomes for Aboriginal people rather than measuring ill health against a non-Indigenous baseline [44], and the integration of findings in the discussion foregrounded the strengths and enablers of success rather than barriers and deficiencies.

Mixed Methods Approach

Our mixed methods evaluation used an explanatory sequential design as defined by Creswell and Clark [45], with quantitative data collected first and then used to inform qualitative data collection and analysis. This design supported the use of in-depth qualitative analysis to more closely examine potential explanations for the quantitative findings, which provides greater insight into the performance of the systems change than quantitative analysis alone [45]. The interview guide for the qualitative component was informed by preliminary findings from the quantitative component, with the qualitative interviews then exploring how staff understood the implementation and outcomes of the systems change. Our qualitative analysis allowed the researchers to explore how and why the components of the systems change had or had not been successfully normalized into staff experiences of routine practice, building on our quantitative analysis to provide a more whole and complex picture of the success of the systems change. The

quantitative and qualitative findings have been narratively integrated and explored together in the *Discussion* section.

Quantitative Methods

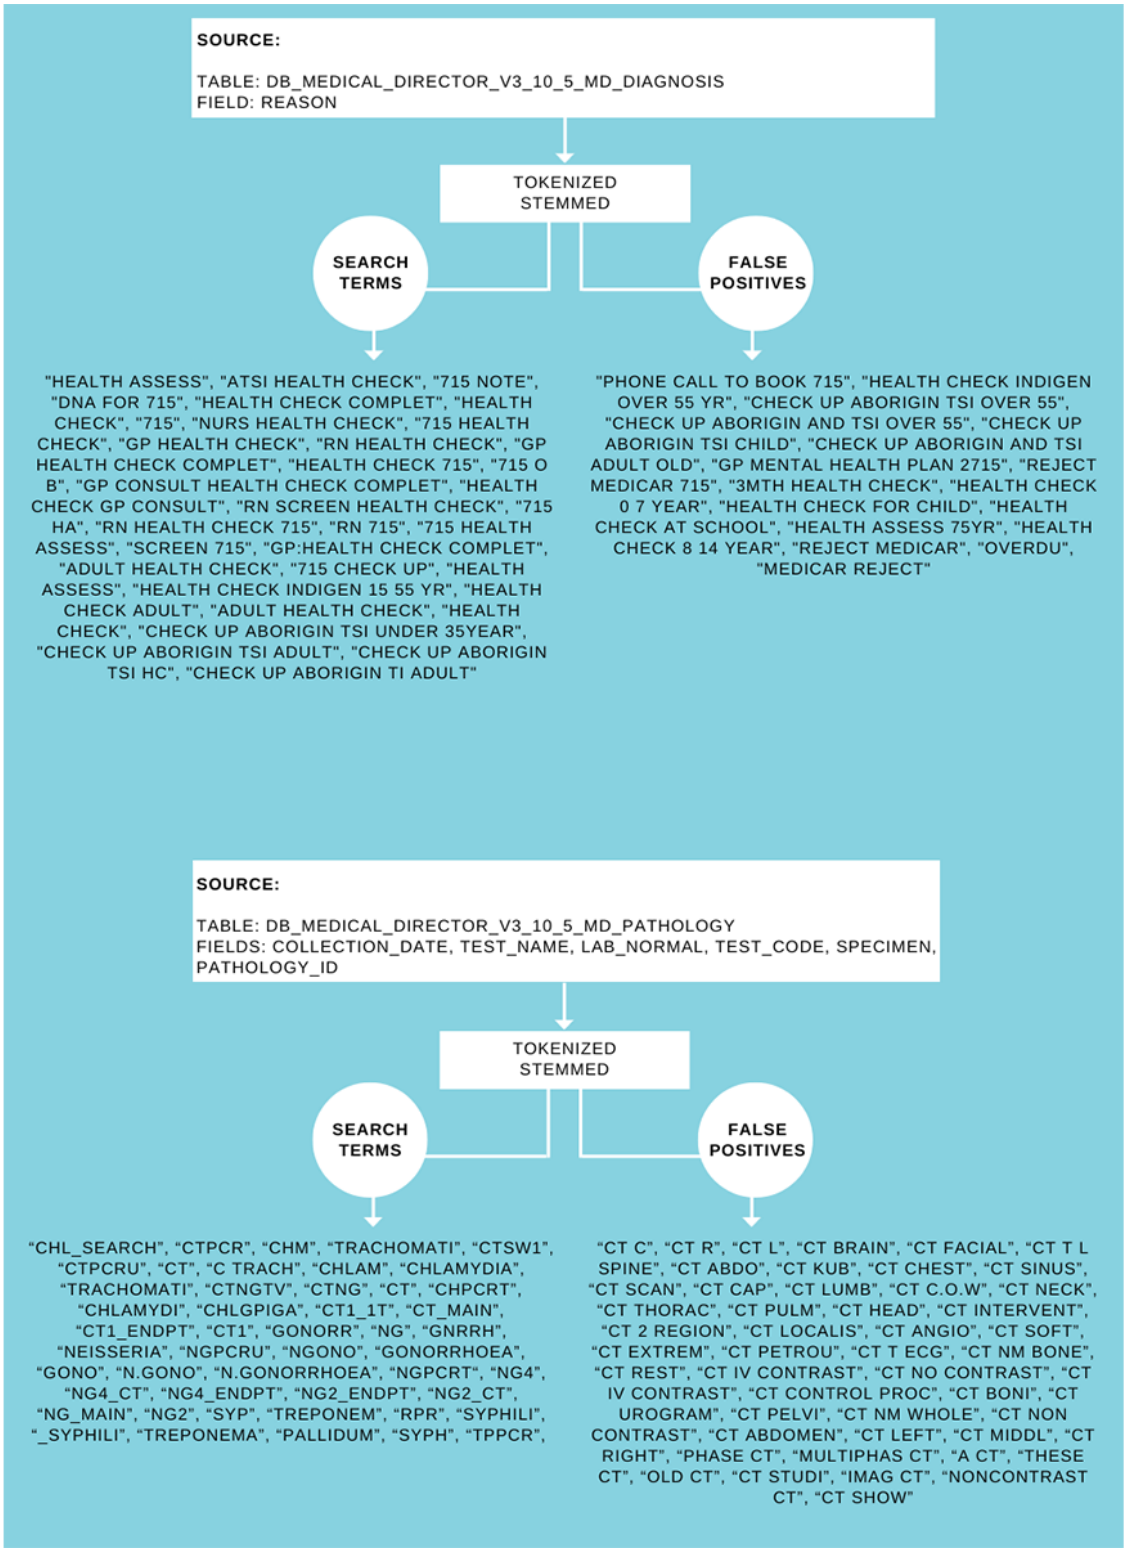
Our analysis was based on an annually deduplicated data set of unique Aboriginal patients aged 15 to 29 years who attended the NSW ACCHS in the 24 months before implementation and in the 12 months after implementation (April 2017-March 2020). Using the exact probabilities of the binominal distribution, we determined that a sample size of ≥2000 patients would be sufficient to detect a difference of 5% to 7% in the proportion of those who had an STI test between the intervention and control periods, assuming that STI testing coverage was 10% to 20%, with 80% power.

The primary outcome for the quantitative component of this study was the proportion of health assessments that included a test for any STI (chlamydia, gonorrhea, or syphilis). The secondary outcomes were the proportion of health assessments that included all 3 STI tests, the proportion of health assessments inclusive of a chlamydia and gonorrhea test that also included a syphilis test (concurrent testing), the proportion of the total study population that received a test for any STI (chlamydia, gonorrhea, or syphilis), and the proportion of the total study population that received a health assessment. The control outcome was the proportion of health assessments that included a random blood glucose level test, a recommended inclusion in the health assessment unaffected by the systems change.

Under strict confidentiality and privacy protocols, deidentified routinely collected clinical data for all young Aboriginal people aged 15 to 29 years who attended the ACCHS in the study period (April 2017-March 2020) were extracted from the EMR using software called GRHANITE (Generic Health Network Information Technology for the Enterprise) [46] via the enrolment of the service in the ATLAS sentinel surveillance network, which has been described elsewhere [47]. We estimated the average number of clinical interactions per person and their 95% CIs using Poisson regression. Demographic variables included age, sex, and Aboriginal status. Testing variables collected via ATLAS included the test performed (chlamydia, gonorrhea, or syphilis) and the date the test was conducted. A further testing variable (random blood glucose level test) was collected manually by the in-house ACCHS statistician because it was outside the scope of ATLAS. ATLAS data collected via natural language processing and keyword search was validated with the help of ACCHS clinical staff. The ATLAS keywords are shown in Figure 1. As tests were conducted at the time of consultation at an in-house pathology service, the date of the test request is not reported separately. Attendance and visit variables included the date of consultation and Medicare Benefits Schedule item for health assessment.

Annual changes in each outcome were examined by age group and sex. An interrupted time series (ITS) regression model (also known as segmented regression) was used to estimate the changes in the proportion of any STI test conducted among those who had a health assessment over time. Regression coefficients with 95% CIs were presented for comparing the before and after periods. An ITS is a technique used for evaluating what are sometimes referred to as natural experiments by estimating the consequence of specific changes in a real-world setting and adjusting for individual- and community-level factors via multilevel regression models to account for covariates [48]. The ITS analysis was then stratified by sex for the primary outcome and the control outcome.

Figure 1. Health assessment and sexually transmitted infection test request data extract coding.



Qualitative Methods

The staff of the NSW ACCHS were the population for the qualitative component of this study. Stratified purposeful sampling [49] was used to recruit staff, who were informed of the project at an in-service information program delivered by members of the research team (HM and CB) and then invited to participate via email, with key staff members also contacted by telephone. Recruitment remained open until the sample contained representation from each of the 3 inclusion categories of clinical staff (GPs, RNs, and AHPs). Because of the impacts of the COVID-19 pandemic, interviews were not completed until the year after the implementation of the systems change. Each participant completed a semistructured interview lasting approximately 1 hour that followed an interview guide informed by normalization process theory (NPT) [28,30,50]. Previous sexual health research has drawn on NPT to examine provider-initiated HIV testing and counseling in South Africa

[51] and annual STI screening in remote ACCHSs in the Northern Territory, Australia [52,53]. As well as open-ended questions on topics such as how the systems change affected work practices, the factors that made the components of the systems change easier or more difficult to implement, perceived impacts on the service, and suggestions for future modifications, the interviews included questions informed by the quantitative findings. Participants were asked whether they thought that STI testing rates had increased after the systems change, then presented with preliminary quantitative data and asked for their opinions on how the components of the systems change had contributed to these findings.

The interviews were transcribed and analyzed thematically by the first author (HM) as per Braun and Clarke [54] and later works [55,56] using NVivo software (Lumivero). HM is an Aboriginal woman from NSW with expertise in sexual health. She was supported throughout the analysis by CN, a non-Indigenous researcher with substantial experience in qualitative approaches to sexual health research. Codes were informed by NPT [31,50], focusing on the 4 main constructs of coherence, cognitive participation, collective action, and reflexive monitoring. Component definitions within each construct were informed by the study conducted by Hengel et al [53], which used NPT to assess the integration into routine practice of an ACCHS CQI program. Textbox 1 (adapted from Hengel et al [53] and Murray et al [31]) outlines NPT constructs and components.

Textbox 1. Normalization process theory constructs and components.

Construct, component, and definition of component

- Coherence
  - Differentiation: perceived difference from existing practice
  - Communal specification: shared understanding of the aims of the systems change
  - Individual specification: individual understanding of the aims of the systems change
  - Internalization: perceived importance and value of the systems change
- Cognitive participation
  - Initiation: willingness to drive the systems change forward
  - Enrolment: collaborative work to make the systems change succeed
  - Legitimation: perceptions of the worthiness of time and effort
  - Activation: likelihood of participants sustaining the changes to work practice
- Collective action
  - Interactional workability: effect of the systems change on shared work
  - Relational integration: accountability built on knowledge
  - Skill set workability: appropriateness of the systems change to participant skill sets
  - Contextual integration: compatibility with existing policies, practices, and environmental context
- Reflexive monitoring
  - Systematization: effectiveness of the systems change in daily practice
  - Communal appraisal: group evaluation of the systems change
  - Individual appraisal: personal relationship with the systems change
  - Reconfiguration: opportunities for participant experience to inform modifications to systems change

HM developed a thematic map and undertook a reread of the raw data to recode any data that were missed in the earlier stages of analysis. Codes, themes, and the analytic framework were discussed by all authors throughout the coding and analysis process to make sense of shared understandings and to interrogate assumptions and interpretations.

Ethical Considerations

The evaluation was overseen by a research governance committee with representation from the medical staff, nursing staff, public health staff, and primary health care management staff of the ACCHS. An ACCHS staff member also contributed to the research team. This study received ethics approval through the ethics committee of the Aboriginal Health & Medical Research Council of NSW (HREC 1700/20). Participants were informed both at the in-service program and before each interview that their participation was voluntary and provided with a participation information sheet and consent form, the contents of which were read aloud at the commencement of the interview. Informed voluntary consent was obtained before the collection of any personal information. The research team includes 2 researchers with an existing relationship with the

health service with no authoritative influence over prospective interview participants.

Results

Quantitative Results

During the study period (April 2017-March 2020), a total of 54,299 patient interactions were recorded in the EMR; after excluding interactions recorded with non-Indigenous patients (n=6317, 11.63%) and deduplication, 2461 (4.53%) unique Aboriginal patients who attended the ACCHS for a clinical interaction at least once, with an average of 19 interactions (SE 0.09; 95% CI 19.32-19.68) recorded in the EMR per patient, were included in the analysis. The recorded interactions per patient may have occurred at a single visit or across multiple visits. Among these 2461 unique Aboriginal patients, 644 (26.17%) had at least 1 episode of a health assessment annually recorded as a clinical interaction in the EMR. Of the 2461 unique Aboriginal patients, 45.43% (n=1118) were men, and 54.57% (n=1343) were women, with a median age of 22 (IQR 18-26) years. The study population is shown in Figure 2.

Overall, 27.2% (175/644) of the health assessments included any STI test, 23.6% (152/644) included a CT/NG test, and 18.5% (119/644) included a syphilis test. Combined CT/NG and syphilis testing occurred in 14.9% (96/644) of the health assessments.

Compared with the 24 months before implementation, the annual proportion of health assessments that integrated any STI test (CT/NG and syphilis) increased in the postintervention period (year 1: 38/237, 16%; year 2: 43/188, 22.9%; and intervention period: 94/219, 42.9%). Greater increases were observed in those aged 20 to 24 years and 25 to 29 years than in those aged 15 to 19 years. The increase by age group was similar for all study outcomes. The changes in the integration of a CT/NG test into a health assessment were similar for both male individuals and female individuals, although male individuals had a higher baseline value. However, the increase in concurrent syphilis testing with CT/NG testing was more substantial for male individuals than for female individuals. Similar results by patient sex were observed for the integration of any STI test and the integration of both a CT/NG test and a syphilis test (Table 1).

Of the health assessments that included a CT/NG test, 63.2% (96/152) overall also included a concurrent syphilis test.

[a]STI: sexually transmitted infection.

The annual proportion of health assessments inclusive of a CT/NG test that also included a syphilis test increased in all age groups, although those aged 25 to 29 years had higher baseline values than those aged 15 to 19 years or 20 to 24 years (Table 2). The inclusion of a syphilis test in health assessments with a CT/NG test increased for male individuals to 88% (18/32) but remained relatively stable for female individuals.

The annual proportion of young people who received a health assessment fluctuated slightly, with uptake slightly higher in male individuals than in female individuals and in those aged 15 to 19 years than in older young people throughout the study period. Among unique young Aboriginal people attending the service each year, there was a small increase in the proportion tested for CT/NG (from 195/800, 24.4% to 243/823, 29.5%) and a greater increase in the proportion tested for syphilis (from 103/800, 12.9% to 225/823, 27.3%), with increases greater for male individuals than for female individuals for both as well as the outcome: receiving all STI tests (Table 3).

The ITS model shown in Figure 3 shows a significant increase in the quarterly proportion of health assessments completed with young Aboriginal people that included an STI test immediately after implementation (coefficient=0.22; *P*=.003), greater among male individuals (coefficient=0.28; *P*=.01) than among female individuals (coefficient=0.15; *P*=.005; Table 4; Figures 4 and 5). There was no trend in the quarterly intervals in the postintervention period for either male or female individuals.

When the ITS analysis was repeated with the final quarter excluded (January-March 2020, the beginning of the COVID-19 pandemic), an increasing trend was observed (*P*=.006, data not shown).

There was no immediate change in the quarterly proportion of health assessments that included a random blood glucose level test (Table 5), overall (Figure 6) and for male individuals (Figure 7) and female individuals (Figure 8). In the postintervention period, no trend was detected overall (*P*=.90) or in male individuals (*P*=.20) and female individuals (*P*=.20).

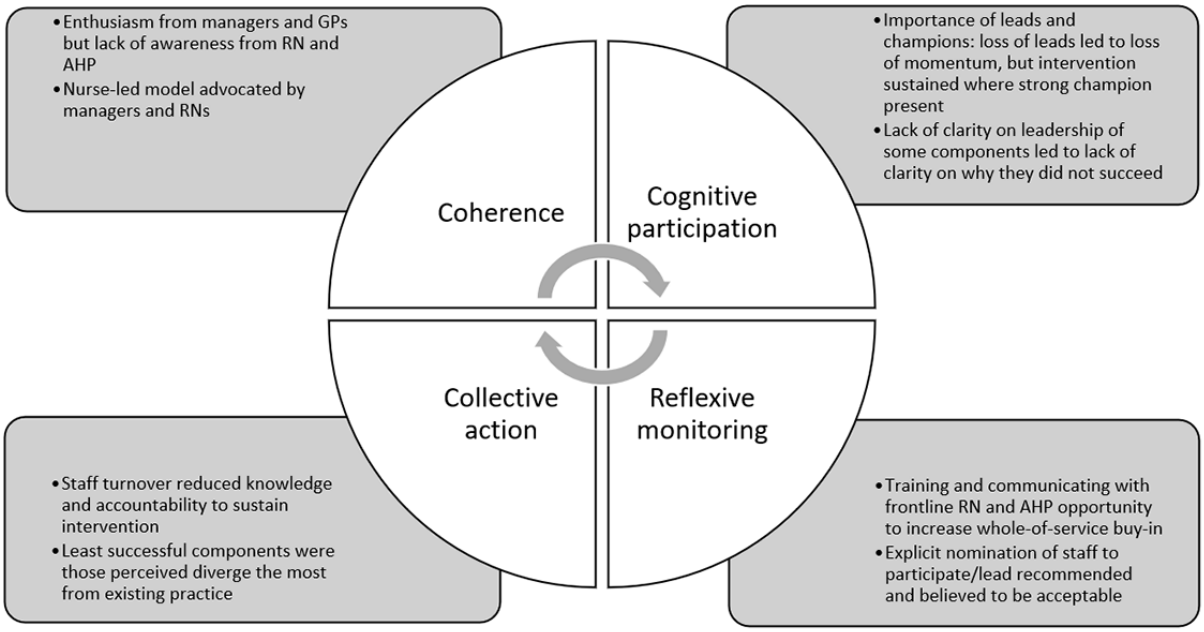
Qualitative Results

Overview

A total of 6 ACCHS staff members participated in an interview: managers (n=2, 33%), GPs (n=2, 33%), an RN (n=1, 17%), and an AHP (n=1, 17%), representing a little more than half of the staff members who had maintained continuous employment from before the implementation until after the end of the postintervention period. The qualitative interviews explored potential explanations for the quantitative findings through seeking to understand how ACCHS staff had experienced and perceived the implementation of the systems change and its impact both on the STI testing rates examined in the quantitative

analysis and on everyday work practice. This allowed the research team to tease out which components of the systems change had or had not been successfully normalized, what factors had contributed to normalization, and how the successful or unsuccessful normalization of different components of the systems change explained key findings from the quantitative analysis. The coding framework consists of 4 NPT constructs: coherence (how participants make sense of the change), cognitive participation (engagement by participants), collective action (the participants' work that has contributed to the intervention functioning), and reflexive monitoring (participant assessment of benefits and costs). Figure 9 captures the key insights from the qualitative data of relevance to each of the 4 NPT constructs.

Figure 9. Thematic map of qualitative analysis informed by normalization process theory. AHP: Aboriginal health practitioner; GP: general practitioner; RN: registered nurse.



Coherence

Managers and GPs displayed enthusiasm about the electronic prompts and automated pathology sets, but the RN and the AHP, whose roles did not require them to use the prompts and test sets, demonstrated low awareness. Communication to frontline staff about the systems change seemed to have been inadequate to instill a shared understanding of its importance and value. However, participants who demonstrated a high awareness of the systems change identified that the systematized incorporation of age-based STI testing into the health assessment had had a broader impact on organizational norms around sexual health in routine practice, with several participants identifying this as a potential explanation for the observed increase in STI testing:

> *Previously it was an individual clinician who may or may not have decided this patient should be tested. Like there was no organizational-wide policy or...expectation that clinicians would be doing that.... Our [health assessments] were changed to include the sexual health testing for people in the targeted age range. So that lifted sexual health screening from sort of some nebulous thing that people may or may not do...to something that was very much at the forefront and was discussed at clinical meetings. It really gained a life of its own which it had never had previously.* [Participant 1, manager]

Participants expressed appreciation for RNs and AHPs, but the RN and AHP participants felt that non-GP clinical roles were not leveraged to their full potential and that this had limited the successful implementation of the systems change. All participants recognized the importance of the "soft" skill sets of RNs and AHPs in patient engagement. Adding to this with enhanced clinical autonomy and a nurse-led model of care via credentialing RNs and AHPs to complete STI screens independently was broadly supported by staff at all levels. Participants considered the nurse credentialing component of the package and the presigned pathology forms component to be strongly interlinked. However, whereas participants reported strong support for the credentialing component, the pathology forms met resistance among the GP workforce, although the RN participant was supportive of the component:

> *One thing I encounter when I was working here is things like, just ordering pathology form, like STI check, for example, if they can allow the nurses to do that, you know. Because sometimes people just come in.... They are asymptomatic.... But they don't want to see the doctor...if I'm given the autonomy to practice, I could just give the, print out a pathology form and order it.... If the nurses are allowed to do, to order things like that, STI check, then it may improve the STI screening.* [Participant 6, RN]

The underuse of the non-GP personnel was also apparent in participant discussions of data reporting. An increased

transparency of data was perceived positively, and several participants described an increased awareness of trends in practice data as motivating for the workforce. However, GPs and managers again had much greater awareness of the changes that had been made than the RN and AHP participants, although the RN and AHP participants felt that strengthening communication with frontline staff would increase whole-of-service commitment to improving outcomes. Participants did not identify any linkages between the improvements made to data analysis capacity and the quantitative findings.

Cognitive Participation

All participants perceived leads and champions as vital to moving the systems change forward, which was most evident in relation to the electronic prompts and automated pathology sets. Strong leadership encouraged early adoption among the GP workforce, but the departure of people in key lead or champion roles led to this action being deprioritized among some newer GPs. It was sustained consistently among GPs who had been present before the development of the package, but only implemented ad hoc for newer GPs after the departure of a key GP champion partway through the study period. Participants perceived staff turnover as a barrier to normalizing this component and felt that the positive impact seen on STI testing rates within the health assessment was the result of the commitment of longer-term staff to this component of the systems change.

Participants were unclear who held responsibility for the credentialing of RNs and AHPs. Some RNs completed training, but this lack of clarity impeded the necessary systemic change to routine practice. The presigned pathology forms were successfully sustained in the prenatal setting owing to a strong GP champion, and there was interest from RNs service-wide, but outside of the prenatal setting, no individual GP had self-nominated as the signatory. The lack of GP commitment to this component also prevented the implementation of the credentialing component because RNs who had completed credentialing could not order tests without presigned forms. As the aim of these components was to enable RN- and AHP-led testing outside of GP consultations, this explains the lower increase in STI testing outside of the health assessment:

> *I think a GP champion and I'm gonna say the sexual health physician that should be full time in that sexual health area.... Apart from the fact we have an inexperienced, untrained person in the job, there's just not enough time left over to give it, to actually do all that; you know, that working one-on-one with people and following up, and talking to the GPs, and...yeah. So that's what I'd say. A GP champion and a full-time sexual health RN or health worker.* [Participant 1, manager]

However, participants did not always expect champions to be senior clinicians or managers. The standardization of the health assessment was perceived to provide systemic support for AHPs to champion the inclusion of routine STI testing to GPs who may otherwise use their discretion to not include it, which further supports the systems change as the driver of increased testing within the health assessment. Participants expressed that this normalization of practice had partially addressed the concern regarding some newer or locum GPs not having implemented the EMR modifications:

> *If we've got good-quality, well-trained health workers, I think that's a really big plus and a really good way for it to go forward, 'cause it doesn't depend on the GP who might be a locum for 2 weeks: it depends on that health worker going, "Part of our [health assessment] is that we always do this comprehensive STI screen.*" [Participant 4, GP]

Although participants supported improvements in data reporting in principle, they almost universally perceived it as something that they were recipients of, rather than participants in. The interviews depicted an understanding of data reporting as a contribution to the service made by an unidentified other that would then inform participants' work, rather than a reflection of the outcomes of their work that could meaningfully contribute to quality improvement. This perhaps explains why participants did not perceive a strong relationship between this component and the quantitative findings.

Collective Action

Considerable staff turnover and limited follow-up from the project team owing to travel restrictions imposed at the onset of the COVID-19 pandemic reduced knowledge of the systems change among service staff. This contributed to a reduction in the shared accountability required to sustain the components of the systems change that had not already been successfully normalized. The electronic prompts also required moderate digital literacy on the part of individual GPs, and frequent staffing changes and low numbers of long-term ongoing GPs prevented technological upskilling of the GP workforce as a whole:

> *'Cause we have so many doctors coming and going, we do have a couple of local GPs as well. GPs that have been here for years. You know, they're here for 4 weeks, they're away 4 weeks, back for 4 weeks. And then obviously, you know, we have locums which come and go, you know. They're here for 2 weeks. They're gone. And then you get the next one. So, I think it's just basically having so many staff coming and going, and having the availability I guess to, to train them or to go over all that sort of stuff.* [Participant 5, AHP]

Of the 4 components, the presigned pathology forms component was perceived to diverge the most from existing practice, requiring cultural as well as process change. This finding was of interest to us because it did not reflect the outcomes of the initial collaborative development of the systems change. During the planning process, this component had been perceived by service staff as an "easy win," but retrospectively it was seen by participants as a significant and extremely challenging change.

The enhanced data reporting was initially implemented successfully and sustained during the study period but was not sustained during the COVID-19 pandemic. However, participants perceived benefits to reinstating this component in

a post–COVID-19 context. Participants recognized the normalization of STI testing as an ongoing investment in community health and continued to view this as an important priority even in the context of a recent and ongoing crisis that disrupted previously normalized practice.

Reflexive Monitoring

The electronic prompts and automated pathology sets had been proposed by staff as a strategy with high potential to reduce friction and minimize provider-end barriers to increasing comprehensive STI testing. However, although participants felt that the component had realized some of its potential among both existing staff of the service and some newcomers, and the quantitative findings indicate that it had successfully increased STI testing within the health assessment, the capacity for universal normalization was limited by EMR functionality requiring separate configuration for each individual GP user. Participants identified an opportunity to reconfigure the component so that it is implemented from the level of either the software vendor or the pathology level rather than on the practice level and believed that this greater systematization would enable the replicability and sustainability of the observed increase in STI testing:

> *Putting the prompt there, it's easier to one-click for the GPs, to select it, and we will get all the tests that we need, and make sure that it gets reported correctly from the path lab. So we'll add the STI testing, you know, thinking we'll just go for chlamydia, get the urine. But having it on the [autopopulated] panel it says "syphilis," so, therefore, it goes back to either the pathology collector or the nurse, or health worker; they'll immediately draw the blood...I think that's worthwhile.* [Participant 2, manager]

The credentialing component was not integrated into regular practice, explaining our finding of limited increase in overall testing across all consultation types. Participants identified value in introducing a defined clinical educator role to support the training of RNs and the alignment of clinical care with policy. Managers reported that the lack of support from GPs for the presigned pathology forms component dampened the enthusiasm of RNs but believed that the explicit delegation of a GP by management to presign forms would be acceptable to the GP workforce.

Participants perceived a link between the data component and existing and prospective internal communications mechanisms, which they identified as an opportunity to strengthen and sustain the systems change. Recommendations included incorporating data reporting into existing meeting agendas and building on existing channels to streamline communication between management and frontline staff (eg, via a staff newsletter).

Discussion

Principal Findings

This study provides evidence for the first time that optimizing the health assessment is an effective strategy to increase STI testing in the ACCHS setting. It also contributes to the evidence base on the use of electronic prompts and automated pathology sets to increase STI testing, demonstrating that these are effective in the ACCHS setting and acceptable to ACCHS staff. Our qualitative data show that across all 4 components of the systems change, the electronic prompts and automated pathology sets had the highest level of integration and normalization into routine practice, resulting in a substantial and sustained increase in STI testing within the health assessment seen in our quantitative data.

In our evaluation, we observed an increase in overall STI testing integrated into the health assessment in the period when the electronic prompts and automated pathology sets were introduced, from 16% (38/237) in year 1 to 42.9% (94/219) in the intervention period. Although an increase in syphilis testing was observed both within and outside of the health assessment, this was not accompanied by an increase in CT/NG tests outside of the health assessment. As no effect was observed for the internal control, and the intervention coincided with an immediate increase in STI testing, we can conclude that the increases are likely to have been the result of the electronic prompts and automated pathology test sets implemented as part of the systems change. The increase in STI testing generally was primarily seen within health assessment consultations, and the electronic prompt was the only component of the systems change to focus directly on the health assessment, with other components focusing on other consultation types. The increase in syphilis testing outside of the health assessment occurred independently of an increase in tests for other STIs, indicating that this effect represents the inclusion of syphilis tests in existing STI test requests. This suggests that the electronic prompts and automated pathology test sets and their resulting normalization into routine practice were the components of the systems change responsible for the increase in STI testing observed within health assessment consultations and the increase in syphilis testing specifically.

The successful adoption of STI testing into the health assessment by providers and patients is likely to be due to the perceived acceptability and cultural safety of the strategy [57]. Age-based STI screening in routine medical consultations is perceived as acceptable by both GPs and their male and female patients [58-60], which may have contributed to strong support for this strategy among our interview participants. However, the electronic component of the systems change could have achieved greater reach if more health assessments had been conducted among young people. We found that only a quarter of the young people received a health assessment in both the pre- and postintervention periods, consistent with another study in the same context [17]. This meant that despite the increases in STI testing within the health assessment, we only saw a modest increase in STI testing overall, consistent with a previous CQI program involving enhanced data reporting and incentives that increased STI testing among young Aboriginal people within health assessments but not in routine medical consultations outside of the health assessment [61]. Fully realizing the potential of the electronic optimization of the health assessment to increase STI testing will require investment in strategies to increase the uptake of the health assessment itself. This will require investment in both provider-end systems change and better resourcing of health promotion to increase patient demand

[62]. Currently, the health service participates in a health promotion program called Deadly Choices that provides nonfinancial incentives to patients for participating in a health assessment. The role of nonfinancial incentives in increasing health assessment uptake is the focus of a future paper.

Our interview participants valued the work done by champions to push the systems change forward and consistently advocated further investment in dedicated champions to advance project goals. However, the qualitative data also provided evidence of the vulnerabilities created when systems change relies on individuals rather than a sustained, collective, whole-of-service approach. Two components that aimed to increase STI testing outside of the health assessment—the credentialing of RNs and AHPs as well as the presigning of pathology request forms—were not successfully implemented, which explains why STI testing increased substantially within the health assessment but only modestly outside of it. In the primary care setting, RNs tend not to hold positions of equal power to GPs or engage in shared decision-making, and in the Australian context specifically, the inability of RNs to claim reimbursement from Medicare for clinical services has been identified as a significant barrier to increasing shared care [63]. Previous research examining RN-led cervical screening using a model similar to the one discussed in this paper identified medicolegal implications in GPs using their provider number to authorize tests ordered by RNs because there is no way to identify the clinician responsible for requesting an individual test [64]. Our interview participants attributed the unsuccessful normalization of these 2 components primarily to the loss of momentum caused by the departure of key champions. The value of champions in driving forward innovations has been recognized in ACCHS and other primary care settings [65,66], and Aboriginal leadership, in particular, remains an often untapped resource [67]. However, the *National Framework for Continuous Quality Improvement in Primary Health Care for Aboriginal and Torres Strait Islander People 2018-2023* [68] advocates for systems change to be championed at the organizational level rather than by individual staff and recommends that leadership encourage a culture of "CQI is everyone's business."

We also found that a higher proportion of health assessments conducted with men included an STI test in both the pre- and postintervention periods, compared with women, and the increase in the proportion of health assessments that included an STI test in the postintervention period was greater for men than for women. In addition, the proportion of health assessments inclusive of a chlamydia test that had a concurrent syphilis test increased more substantially in the postintervention period for men than for women. Although other studies have instead found that the uptake of STI testing overall is higher in young Aboriginal women [1,17,69-73], our previous work has identified gender parity in STI testing in the context of the health assessment [74]. One potential explanation for this identified in the qualitative data was the impact of standardization resulting in routine tests being offered during the health assessment that clinicians may have previously used their discretion to skip. Qualitative research with Aboriginal men has identified not only a reluctance to proactively access health care [75] but also strongly held values for being a responsible sexual partner [76], highlighting the importance of health assessment in providing routine, comprehensive STI testing to young Aboriginal men who may not otherwise seek out testing.

Normalizing STI testing into routine practice is the cumulative product of multiple small and interrelated changes [77], and our qualitative findings support the value of this model for promoting changes in clinical practice related to STI testing owing to the varied and individual needs of clinicians targeted by systems change [78]. Collaboratively designing this systems change ensured high acceptability even of those components that were not successfully implemented or sustained. Previous literature has found that RN-led testing increases STI testing in primary care, while also noting difficulty in sustaining the required changes to the supporting infrastructure and processes [77]. Although some RNs perceive GPs' reluctance to share care to be a barrier to implementing RN-led testing [39], related research has found that GPs support RN-led testing and believe that it is suitable for their skill set [79]. Our findings suggest potential for more successful future implementation of these components of the systems change, with appropriate investment in ongoing engagement of staff at all levels. Future work using NPT may benefit from examining the elements of collaboration associated with successful systems change and identifying what may satisfy expectations to achieve normalization.

Our evaluation has a few limitations to consider when interpreting the findings. First, the qualitative data were collected over a longer period than was planned after the conclusion of the postintervention period owing to the impacts of the COVID-19 pandemic on the participating ACCHS. Although it is also a standard expectation that qualitative findings be recognized as nongeneralizable owing to the small samples typical in qualitative research, the qualitative sample size represented more than half of the staff who had continued employment throughout the study period, which supports the value of incorporating these findings into the analysis as a whole. Second, our quantitative analysis used a before-and-after design to evaluate the effectiveness of the intervention, which may be subject to temporal biases but was strengthened using an ITS analysis with a 2-year before period (12 time points) and an internal control. Third, we were unable to evaluate which GPs installed the prompts and automated pathology sets or how frequently they were activated. Finally, the strategy was evaluated at 1 health service; therefore, the findings may not be generalizable to all NSW ACCHSs. The use of the NPT framework is a strength of this study because a systematic review has identified that NPT strengthens analysis of implementation processes [28].

Conclusions

We have shown that the introduction to the EMR of an electronic prompt to encourage GPs to offer age-based STI testing and a shortcut to autopopulate a pathology request for a comprehensive STI test is an effective and acceptable strategy to increase both integration of STI tests into the health assessment and the inclusion of syphilis testing in STI tests completed within the health assessment in the ACCHS setting. Future systems change should also incorporate strategies to increase the uptake of the health assessment among the target

population and work to better promote whole-of-service engagement and accountability to increase normalization. Future work exploring the suitability of related interventions for other sites should continue collaboration with ACCHS staff to develop locally customized solutions.

Abstract

Background: Personal recovery is of particular value in bipolar disorder, where symptoms often persist despite treatment. We previously defined the POETIC (Purpose and Meaning, Optimism and Hope, Empowerment, Tensions, Identity, Connectedness) framework for personal recovery in bipolar disorder. So far, personal recovery has only been studied in researcher-constructed environments (eg, interviews and focus groups). Support forum posts can serve as a complementary naturalistic data resource to understand the lived experience of personal recovery.

Objective: This study aimed to answer the question "What can online support forum posts reveal about the experience of personal recovery in bipolar disorder in relation to the POETIC framework?"

Methods: By integrating natural language processing, corpus linguistics, and health research methods, this study analyzed public, bipolar disorder support forum posts relevant to the lived experience of personal recovery. By comparing 4462 personal recovery–relevant posts by 1982 users to 25,197 posts not relevant to personal recovery, we identified 130 significantly overused key lemmas. Key lemmas were coded according to the POETIC framework.

Results: Personal recovery–related discussions primarily focused on 3 domains: "Purpose and meaning" (particularly reproductive decisions and work), "Connectedness" (romantic relationships and social support), and "Empowerment" (self-management and personal responsibility). This study confirmed the validity of the POETIC framework to capture personal recovery experiences shared on the web and highlighted new aspects beyond previous studies using interviews and focus groups.

Conclusions: This study is the first to analyze naturalistic data on personal recovery in bipolar disorder. By indicating the key areas that people focus on in personal recovery when posting freely and the language they use, this study provides helpful starting points for formal and informal carers to understand the concerns of people diagnosed with a bipolar disorder and to consider how to best offer support.

KEYWORDS

bipolar disorder; personal recovery; peer online support forums; natural language processing; corpus linguistics; social media; online support; recovery

Introduction

Bipolar disorder (BD) is a severe mental health (MH) problem characterized by recurring episodes of depressed and elevated mood [1]. Its lifetime prevalence ranges from 0.1% to 2.6% internationally [2]. BD is associated with lower quality of life [3] and high suicide risk [4]. Therefore, fostering recovery and living well with BD are important societal tasks.

MH care agendas increasingly focus on enhancing personal recovery (PR), defined as "a way of living a satisfying, hopeful life even with the limitations caused by the illness" [5]. This contrasts with a previously narrower focus on reducing symptoms (clinical recovery). PR might be of particular value in BD [6], where symptoms often persist despite treatment, but has been underresearched to date [7]. Jagfeld et al [8] (hereafter the POETIC review) recently synthesized 12 qualitative studies to develop the first conceptual framework for PR in BD. The POETIC (Purpose and Meaning, Optimism and Hope, Empowerment, Tensions, Identity, Connectedness) framework, based on the CHIME (Connectedness, Hope and Optimism, Identity, Meaning and Purpose, Empowerment) framework [9], comprises the following processes: "Purpose and meaning,"

"Optimism and hope," "Empowerment," "Tensions," "Identity," and "Connectedness" (see Table 1).

Table . The POETIC[a] framework [8]: lived experience of personal recovery in bipolar disorder.

First-level domains	Second-level categories
Purpose and meaning	• Meaning of mental illness experiences • Paid or voluntary work • Quality of life • Meaningful life and social roles
Optimism and hope	• Belief in possibility of recovery • Positive thinking and valuing success • Hope-inspiring relationships • Having dreams and aspirations
Empowerment	• Self-management and personal responsibility • Controversial role of medication • Control over life
Tensions	• Balancing acceptance with ambitions • Openness enables support but also stigmatization • Ambivalence around (hypo)mania
Identity	• Rebuilding positive sense of self • Overcoming stigma • Dimensions of identity
Connectedness	• Support from others • Relationships • Peer support and support groups • Being part of the community

[a]POETIC: Purpose and Meaning, Optimism and Hope, Empowerment, Tensions, Identify, Connectedness.

Current research on PR in BD has several limitations. First, it is mainly based on qualitative studies with few participants [10] and expert opinions, lacking quantitative evidence from larger samples [11]. Second, data collection is limited to structured settings (semistructured interviews, focus groups, and structured measures), which are not naturalistic and are subject to either interviewer bias [12] or constrained responses in structured measures. Third, recruitment is biased toward people who want to talk about PR and are in contact with services or researchers [8].

Naturalistic data collection, where "participants are not aware that they are being studied" [13], overcomes many of these limitations. Online forum posts are a source of naturalistic data, which can offer potential insights into "an experience as it is lived rather than as it is enacted in the researcher constructed environment" [14]. Some natural language processing (NLP) studies have analyzed large numbers of BD online forum posts via automatic quantitative methods such as content analysis [15] or emotion analysis [16,17] to identify forum topics or language differences between people with different or no MH diagnoses. Qualitative studies have applied conversation analysis [18], thematic analysis [19], grounded theory [20], and content analysis [21] to BD online forum posts. Such studies offer rich nuanced accounts of web-based discussions on BD but include only few, often handpicked, posts.

Corpus linguistics [22] provides a mix of quantitative and qualitative methods informed by linguistic theory for analyzing large amounts of text data with depth and richness that can overcome some of the shortcomings of previous NLP and qualitative studies. Semino et al [23] analyzed interviews and online forum posts of patients with cancer and their carers to learn about their lived experience and the metaphors they use for dealing with cancer. Hunt and Brookes [24] applied a combination of corpus linguistics and discourse analysis [25] to MH forum posts. Two corpus-linguistics studies have focused on BD specifically: Abdo et al [26] studied linguistic types of judgments, and McDonald and Woodward-Kron [27] studied forum users' roles and identities.

A systematic review strongly recommended considering web-based content from individuals with lived experience in PR research [10], which has not yet been done. Therefore, the main aim of this paper was to gain further insights into the experience of PR in BD from online forum posts via a combination of NLP, corpus linguistics, and qualitative health research methods. Furthermore, the POETIC framework, synthesized from data collected via interviews or focus groups, has not been applied to new data yet. Hence, the secondary aim of this paper was to validate the framework by exploring to what extent it captures experiences shared on the web. The research question covering both aims is "What can online

support forum posts reveal about the experience of PR in BD in relation to the POETIC framework?"

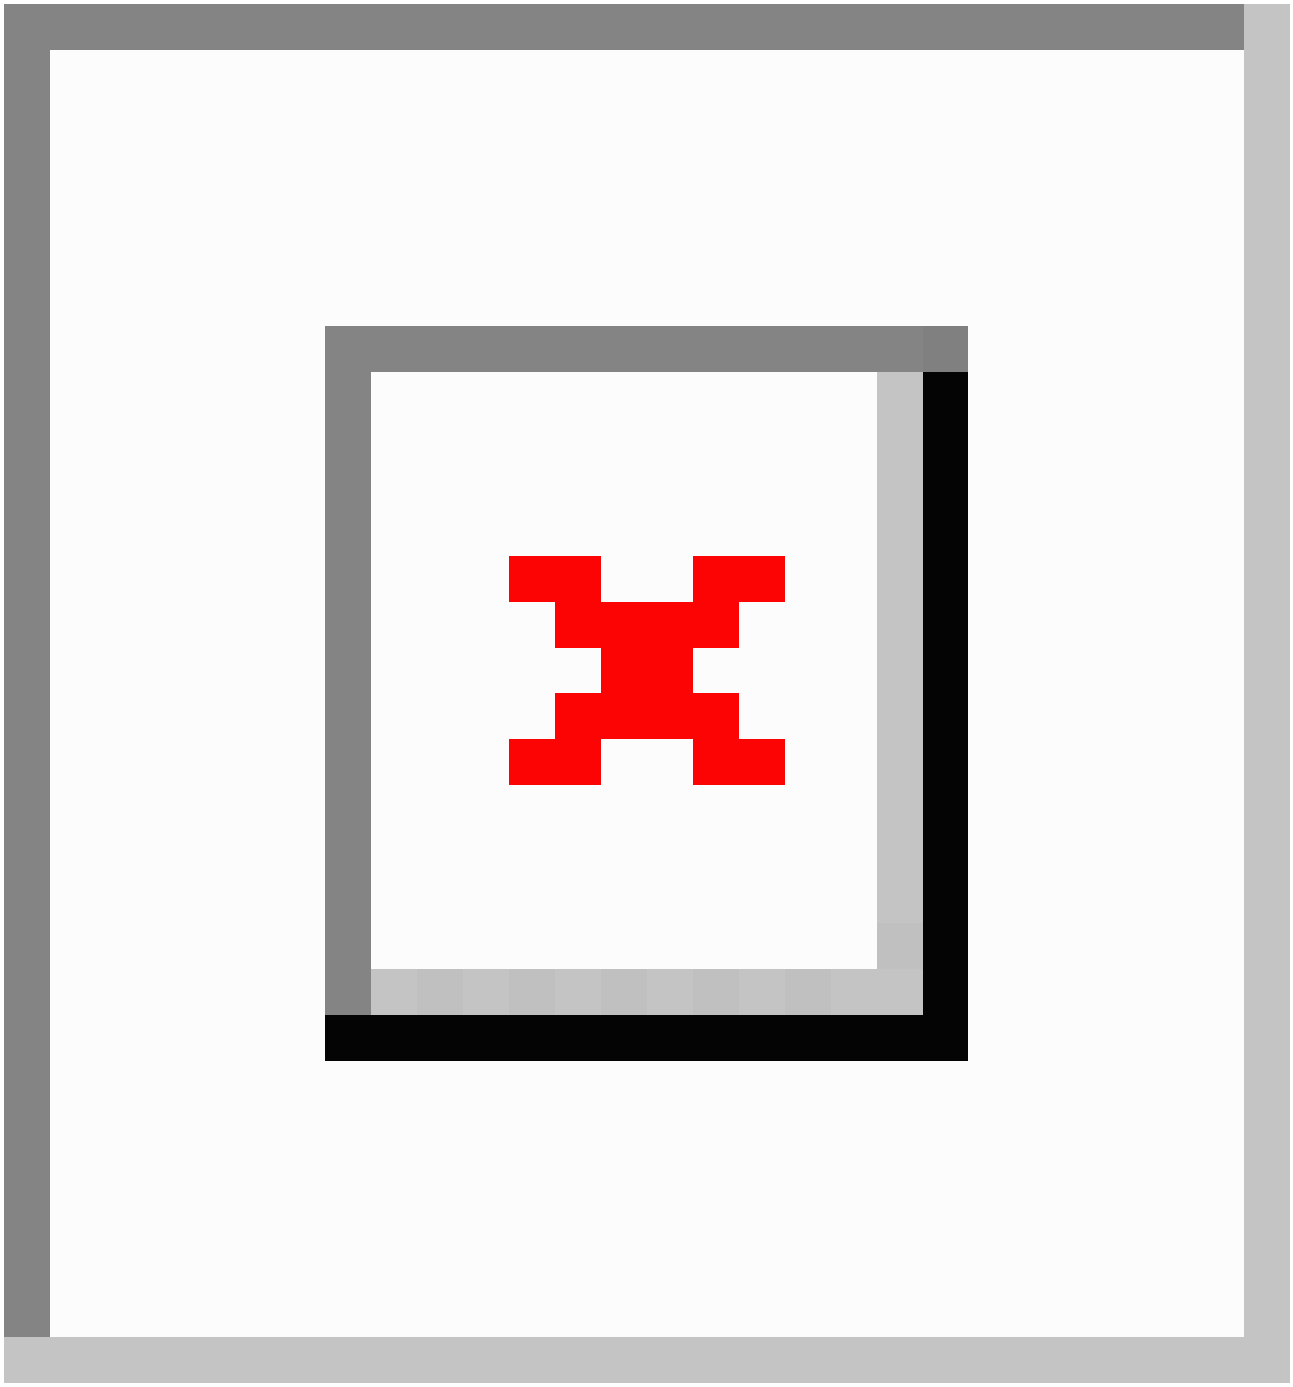
Methods

Data Source

This study analyzed posts from the international web-based discussion platform Reddit [28], which hosts subforums (subreddits) for various topics, including BD. Several reasons motivated the choice of this site: Reddit is one of the most visited internet sites worldwide with an international user base [29]; in contrast to other online support communities, everyone can read all public posts without a user account; and Reddit allows data analysis by third parties.

Reddit users with a self-reported BD diagnosis (S-BiDD) were automatically identified by matching phrases such as "I was diagnosed with bipolar" in all posts between January 2005 (the inception of Reddit) and March 2019 (see Jagfeld et al [30]). All posts of the identified users form the S-BiDD data set. Naturalistic data collection required subsequent filtering for content relevant for PR in BD, as an exploratory study revealed that the posts in the S-BiDD data set covered many other topics (see Report S1 in Multimedia Appendix 1). Figure 1 displays a flow chart for construction of the PR-BD corpus. In linguistics, a corpus is a sampled collection of texts representing a particular language variety [31]. The basis for the corpus was only posts in BD subreddits [32] (fourth level="bipolar"), because a second exploratory study found that references to "recovery" and associated word forms were almost exclusively in relation to BD in BD subreddits (see Report S2 in Multimedia Appendix 1). Furthermore, only posts mentioning BD [33] were selected because only two-thirds (66%) of MH-related "recovery" mentions in BD subreddits referred to BD.

Figure 1. Flowchart of the 4 steps to create the PR-BD corpus and reference corpus. BD: bipolar disorder; MH: mental health; PR: personal recovery; S-BiDD: self-reported bipolar disorder diagnosis.



To select PR-relevant posts, a list of PR terms (comprising both single words and multiword phrases; n=562) [34] was compiled using corpus-linguistics methods (Document S2 in Multimedia Appendix 1). BD subreddit posts that mentioned BD were ranked according to their similarity with the PR terms list via term frequency–inverse document frequency–weighted cosine similarity, a standard information retrieval approach [35,36] (see Document S3 in Multimedia Appendix 1). To determine the cosine similarity cutoff, GJ coded whether 90 posts pertained to PR in BD using a preliminary codebook based on the second exploratory study and the POETIC codebook. SHJ audited the coding. To select the 90 posts, 10 posts were randomly sampled from every 10% quantile of the cosine similarity scores, taking only 10 posts from the first 2 quantiles that all scored 0. Following this, a minimum length of 94 words was set, as 5 posts shorter than this length lacked context to decide on their PR relevance (see Figure S5 in Multimedia Appendix 1). The codebook was refined to its final version (Document S4 in Multimedia Appendix 1). GJ and CH blindly coded 120 additional posts, again randomly sampled from each quantile of the cosine scores.

Ethical Considerations

The Lancaster University Faculty of Health and Medicine research ethics committee approved this research in May 2019 (reference FHMREC18066), which follows ethics guidelines for internet-mediated research [37]. It was infeasible to seek

individual informed consent from the large number of included forum users, but quotes were paraphrased to protect users' anonymity (see Document S5 in Multimedia Appendix 1). We recognize that some people may object to the use of web-based posts as research data without individual consent (eg, [38]). Users generally post to share information or seek support and do not directly provide their content for research. However, we believe that on balance, the benefits of this research to better understand PR makes it worthwhile while acknowledging these potential objections.

The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008.

Involvement of People With Lived Experience

In all, 4 volunteers with lived experience of BD, who use online forums, and were recruited via People in Research [39] provided input on the study design, results, and subsequent plans in individual web-based meetings. All 4 volunteers—1 man and 3 women—were UK-based and in their 30s to 40s; additionally, 3 (75%) reported a bipolar II disorder diagnosis, 1 (25%) did not further specify their BD diagnosis, and at least 2 (50%) had a migrant background. Importantly, all volunteers were very supportive of the project, and none raised ethical concerns. After study completion, the volunteers were reinvited to provide feedback on our interpretations of the results.

Reflexivity

Reflexivity is important to highlight how subjectivity may have impacted on research findings [40]. The research team embraces a PR approach in BD. GJ, FL, and SHJ previously developed the POETIC framework for PR in BD. They anticipated that it would capture many aspects shared on the web, but data analysis would reveal new aspects and deeper insights into the experience of PR in everyday life.

Corpus Framework Analysis

Data analysis drew on methods from corpus linguistics [22] and qualitative framework analysis [41], which we call corpus framework analysis. Quantitative corpus-linguistics methods derive frequency lists of the words in the corpus; identify keywords that occur statistically significantly more frequently in the corpus compared to other language samples; and find collocations, that is, words a target word co-occurs with more frequently than by chance. The main qualitative method is to analyze the context of specific words or phrases in so called concordances. Key lemmas in the PR-BD corpus were identified by comparing it to a reference corpus of posts with low similarity to the PR terms list via #LancsBox (version 6.0; Lancaster University) [42]. A lemma is the dictionary form of a word; for example, "recovering" and "recovered" are word forms of the lemma "recover." To focus on the most salient topics of the PR-BD corpus, key lemmas overused at least twice at a significance level of $P<.0001$ [43] and used by at least 5% of users were analyzed. See Document S6 in Multimedia Appendix 1 for methodological details.

The key lemmas were coded into the POETIC framework via concordance analysis. First, overall impressions of all concordances were noted after sorting them according to the lemma, left, and right context (20 words each) in #LancsBox. Subsequently, 30 randomly sampled concordances for each key lemma were coded into the second-level POETIC categories (see the codebook in Appendix B of Jagfeld et al [8]). The coders read the full post if the 40 words did not provide enough context and noted impressions for every key lemma again. Finally, concordances that did not fit into an existing POETIC category were coded inductively. GJ coded all key lemmas, and SHJ and FL audited 6 key lemmas each.

Finally, new key lemmas that were not in the PR terms list and absent PR terms [44] were analyzed. Absence was defined as 0 frequency in the PR-BD corpus or a lower relative frequency than in the reference corpus. Additionally, collocations were analyzed via the #LancsBox *GraphColl* tool for some key lemmas. To do so, content words (noun, verb, adjective, and adverb) within a context of 5 words left and right of the target term and a minimum collocation frequency of 5 were ranked according to cubed mutual information [24].

Results

The S-BiDD data set [45] contains 21,407,595 posts by 19,685 users (available for noncommercial research after signing a data usage agreement). The programming code is publicly available [46].

Coding the PR Relevance of Posts and Constructing the PR-BD Corpus

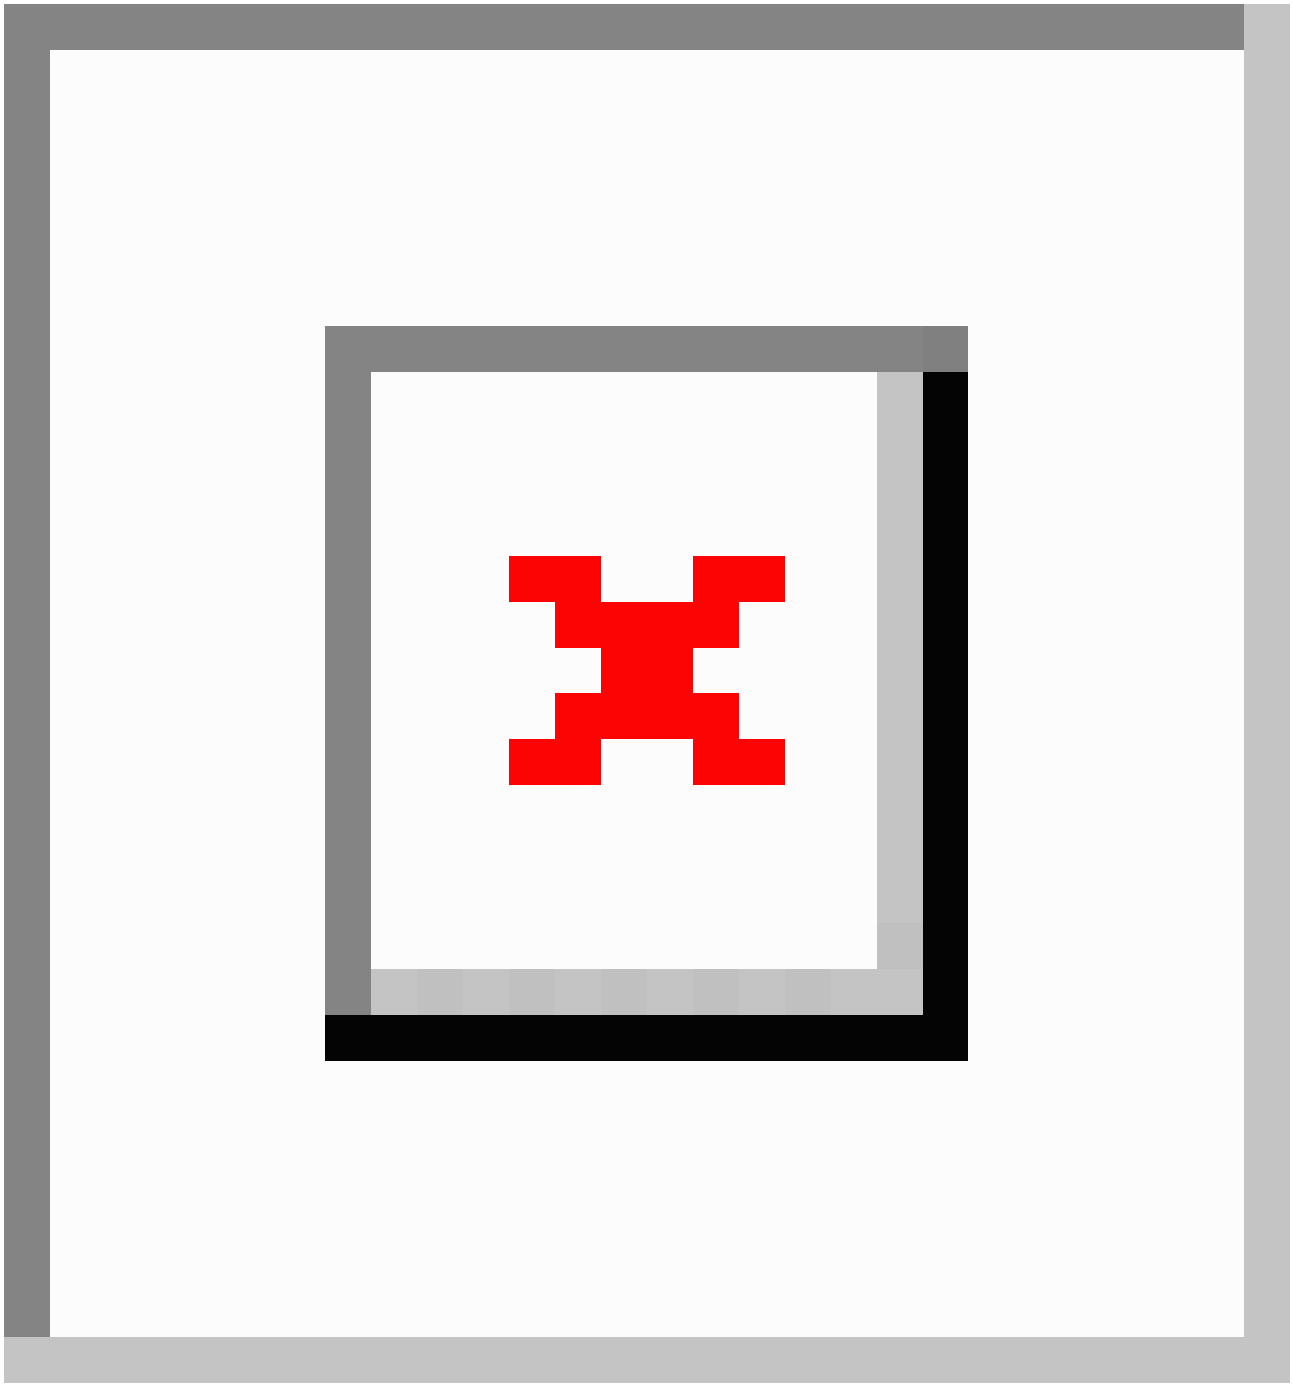
Following a blind trial of coding the PR relevance of 20 posts and a subsequent discussion, GJ and CH achieved moderate agreement (Cohen κ=0.51; 77/100, 77% observed agreement) in coding the remaining 100 posts (see Table S20 in Multimedia Appendix 1). The team resolved all disagreements. In total, 66 (31%) of the 210 posts were coded as PR relevant (see Table S21 in Multimedia Appendix 1). Based on this, the PR-BD corpus comprises posts with a PR score above 0.025 to balance precision in selecting PR-relevant posts and corpus size (see Table S22 in Multimedia Appendix 1). The PR-BD corpus has 4462 posts with 1,337,080 words by 1982 users. The reference corpus of posts with a PR score below 0.013 (see Table S23 in Multimedia Appendix 1) comprises 25,197 posts with 4,700,834 words by 6075 users.

Concordance Analysis With the POETIC Framework

In all, 130 lemmas met the prespecified keyness criteria. Figure 2 shows the domain and category frequencies, extrapolated from the 30 concordance lines coded for each key lemma and color coded according to Tol's [47] light scheme for color-blindness accessibility. Table S28 in Multimedia Appendix 1 lists the key lemmas coded into each category, and Table S29 in Multimedia Appendix 1 lists the categories that each key lemma was coded into. Overall, the POETIC framework captured the experiences in the PR-BD corpus very well: there was evidence for all categories. Only 16% (9303/59,199) of key lemma instances fell into the new "Not POETIC" domain rather than the existing framework. The text below briefly reviews each domain with

key lemmas in italics, highlighting the differences between the original framework and the web-based data. Tables S30 and S31 in Multimedia Appendix 1 provide illustrative quotes for all categories.

Figure 2. Frequency of POETIC domains and categories and new categories. MH: mental health; POETIC: Purpose and Meaning, Optimism and Hope, Empowerment, Tensions, Identity, Connectedness.



Purpose and Meaning

"Purpose and meaning" was the most frequent domain and contained the most salient topic differences between the POETIC review and web-based data. Although participants in the POETIC review mainly discussed the meaningful life and social role of being a *parent*, web-based discussions focused on reproductive decisions. Participants discussed perceived *risks* they might be *responsible* for, for example, the *possibility* for their *child* to *develop* MH issues that affected their *decision* or *choice* to *bear* and *raise kids*. In the "Work" category, extended to include formal education, many discussions focused on *struggles* around *studying* and *graduating college*. No participant in the POETIC review reported financial or housing issues, whereas several web-based users complained about a low *quality* of *life* due to *money* problems, causing homelessness or inability to afford treatment. Spirituality was discussed more frequently and richer than in the POETIC review. Users often wondered whether to regard their experiences as truly spiritual or rather as (hypo)manic symptoms.

Optimism and Hope

Reddit users differed in their "Belief" in the possibility of *recovery*. The mainstream opinion on Reddit was that BD is a "chronic condition that cannot be *cured*, only *managed*." Users questioned whether feeling fully *recovered* was not just a temporary experience caused by (hypo)mania. In the "*Positive* thinking and valuing *success*" category, many users were *grateful* for aspects of their BD experiences; for example, *challenges* provide *opportunities* for *growth* and demonstrating *strength*.

Empowerment

As in the POETIC review, "Self-management and personal *responsibility*" was the most frequent and richest category. Forum users generally considered (taking *steps* towards) *maintaining* a *healthy lifestyle* (including *routines* or *schedules*, *diet*, *exercise*, and *coping skills*) as an individual's *responsibility* to reach *recovery*. In contrast, experiencing MH symptoms or feeling stuck in their recovery was regarded outside of someone's responsibility if they followed professional or mainstream forum advice. The "Controversial role of medication" category included concerns about drug effects on the *baby* during pregnancy or nursing and alternative non–evidence-based treatments such as the keto *diet* or cannabis, which were not present in the POETIC review.

Tensions

Experiences coded in the "Tensions" domain were similar to the POETIC review. Several participants shared feeling more comfortable to discuss "Ambivalence" around (hypo)mania on the web. Some asked if there was a *possibility* to *enjoy* increased *motivation* and *confidence* to make *progress* in their goals without the hypomania getting out of control.

Identity

Some participants shared rich *success* stories in the "Rebuilding positive sense of self" category, in which they moved away from *shame* and *guilt* by *forgiving* themselves for past behaviors and toward *accepting* themselves, whereas others were struggling with this process. *Shame* associated with *stigma* in the *society* was another focus of discussions, and some participants shared creative ways for overcoming stigma.

Connectedness

Regarding "Connectedness," users mainly discussed relationships and *support* from others. Although there were positive accounts, participants often discussed *struggles* with romantic *relationships* or *marriage* and *friendships* and complained about issues with *professional* and *family support*, similar to the POETIC review. However, the web-based accounts, particularly those of relationship and family problems, appeared more candid, for example, with them also discussing *sexual* issues, *trauma*, and *shame*.

Not POETIC

Inductive coding of the 645 concordance lines that did not fit into the POETIC framework revealed that they were unrelated to individuals' PR or lived experience. Most quotes discussed other MH issues without PR relevance (symptoms, genetics and heredity, treatment, diagnosis, societal issues, and scientific research), followed by storytelling of their own or others' situation without PR relevance; direct interactions between forum users, for example, giving advice or congratulating; and discussions of non-MH issues.

New PR Terms

Although 99 (76%) of 130 key lemmas were PR terms, 31 (24%) key lemmas were new. Of these 31 lemmas, 15 (48%) conveyed similar meanings to PR terms; for example, *brother* likened other family members in the PR terms list such as son or nephew. Another 7 (23%) new key lemmas introduced aspects not covered by PR terms. For example, *baby*, *raise*, and *bear* were related to reproductive decision-making; *childhood* was related to making sense of MH issues via early traumatic experiences; and *environment* was related to a focus on structural or societal circumstances rather than the individual (see Table S32 in Multimedia Appendix 1).

Absent PR Terms

Only 13% (n=54) of the 416 unique PR terms (after removing spelling and phraseological variants) were absent: 46 (11%) did not appear in the PR-BD corpus and 8 (2%) were underused compared to the reference corpus. The underused PR terms referred to symptoms (*high mood*, *mania*, *manic*, and *sleep*) or medical MH professionals (*doctor*, *pdoc* [psychiatrist], and *psychiatrist*; see Table S33 in Multimedia Appendix 1). These terms were relevant for some PR domains but also were strongly associated with clinical recovery. All PR terms missing in the PR-BD corpus were also missing in the reference corpus. They were mostly complex phrases, for example, *brush yourself off*, and none indicated aspects that were not covered by other key lemmas (see Table S34 in Multimedia Appendix 1).

Feedback From People With Lived Experience

Two volunteers who had commented on the first exploratory study provided feedback on the main study results. Overall, they valued the results and agreed with our findings but indicated limitations of the data, as reflected in the *Discussion* section. One volunteer argued that categorizations of experiences can be problematic for masking individual differences. Conversely, the other volunteer had found it particularly helpful to align some of her behaviors with CHIME categories because this gave her a sense of being on the right track.

Discussion

This study analyzed Reddit posts of people with a BD diagnosis via corpus framework analysis to learn about the lived experience of PR in BD and validate the POETIC framework.

Key Findings in Relationship to Previous Work

The primary study aim was to provide new insights on PR in BD. Indeed, the web-based data contained candid, in-the-moment experiences that traditional qualitative data collection is unlikely to retrieve. For example, 1 user posted about their experiences in a current manic episode on 2 subsequent days: "Yesterday I posted here about the realization that I've entered a manic episode." Other users shared things on the web that they had not shared elsewhere: 'Talking about

this part of my inner world to a psychiatrist would require a lot of trust for me." The users had different interpretations of elated mood as signs of recovery, spiritual experiences, helpful motivational boosts, or dangerous MH symptoms to avoid. Quantitative [48,49] and qualitative [50,51] evidence shows that web-based anonymity affords personal self-disclosures and discussions of sensitive and stigmatized issues.

The results show that 3 POETIC domains were featured the most in Reddit discussions: "Purpose and meaning" (particularly reproductive decision making, work, and formal education), "Connectedness" (romantic relationships and social support), and "Empowerment" (self-management and personal responsibility). In line with a recent quantitative review [52], the concerns raised on Reddit pointed to a wide range of social and occupational functioning among people with a BD diagnosis: some were not working or leaving their house and therefore sought support on the web, whereas others asked for specific advice to further improve their already functional lifestyle. The popularity of the "Self-management and personal responsibility" category agrees with recent quantitative findings. A review by Mezes et al [53] found positive associations between PR and psychological characteristics focusing on control and personal agency, and a longitudinal study identified positive impacts of adaptive coping and balanced risk-taking on PR [54].

Importantly, the analysis highlighted PR issues that exclusively or more frequently came up on the web. This might be due to differences in sample demographics and data collection methods between this study and those included in the POETIC review. Users in the S-BiDD data set were younger than those in the studies included in the POETIC review: the S-BiDD data set users had a mean age of 32 years versus 45 years in the POETIC review, 30% (5866/19,685) versus 17% (18/163) of participants were aged between 18-29 years, and 7% (1299/19,685) versus 34% (36/163) were aged between 50-64 years [8,30]. This might explain why perspectives on transitioning into adulthood with BD, challenges of college education, and reproductive decision-making exclusively surfaced in the web-based data. Sahota and Sankar [20] summarized their qualitative analysis of discussions of genetic risk and reproductive decision-making in 2 BD subreddits as centering around the manageability of parenting a child for people with a BD diagnosis, which aligns well with the experiences found in this study.

Moreover, users in the S-BiDD data set were overwhelmingly from the United States [30], whereas all POETIC review studies stemmed from countries that provide at least a basic level of free public MH care and social security (the United Kingdom, Norway, Australia, Canada, China, Spain, and Turkey). This may explain why existential financial issues such as (threat of) homelessness and the inability to afford treatment surfaced only in the web-based data. Since health insurance in the United States (except for Medicare for those aged 65+ y) is either employer provided or privately paid, individuals who cannot work due to their MH issues lose their insurance and in turn access to professional support, often causing MH issues to exacerbate, for example, by abruptly stopping medication. One Reddit user described this as a "vicious cycle." It also appears plausible that Reddit users stem from a different socioeconomic group than the participants recruited into the POETIC review studies.

The secondary aim of this study was to validate the POETIC framework. Results confirmed that the framework usefully captured PR experiences shared on the web. Web-based users discussed all second-level POETIC categories, and only 645 of the 3900 analyzed concordance lines could not be accommodated in the framework, demonstrating its comprehensiveness.

Strengths and Limitations

Three aspects of this study constitute both strengths and limitations. First, using online forums as a data source provided rich, candid, and in-the moment experiences. However, there is limited background and demographic information on the online forum users (but see Jagfeld et al [30] for an analysis of these properties in the users in the S-BiDD data set), and they are not representative of the general population with a BD diagnosis. One user in the PR-BD corpus posted "My hunch is that r/bipolarreddit overrepresents those who are struggling, who, understandably, may be more pessimistic about everything." One volunteer shared his experience that discussions on Reddit MH forums mainly followed a mainstream opinion and that deviant opinions were ignored or suppressed. McDonald and Woodward-Kron [27] support this with corpus-linguistics evidence that BD forum users over time shifted from advice seeking to giving and used more medicalized language. Similarly, Vayreda and Antaki [18] showed that established BD forum users urged new members to seek a formal diagnosis and reinforced a biomedical view of BD. Our Reddit study provides one lens on the lived experience of some people that can complement studies of other MH forums and other sources, such as one-on-one interviews.

Second, the list of PR terms facilitated focusing on the concept of interest among the wealth of data, yet it arguably biased the data selection. Nevertheless, 52% (16/31) of the key lemmas that were not PR terms contributed new PR aspects. Moreover, explicitly stating our expectations of PR aspects via the terms list enabled us to identify absent aspects in the data.

Third, corpus-linguistics methods, particularly the coding of key lemmas, allowed the analysis of more data than traditional qualitative methods. However, single words probably more readily capture topic-like (eg, "Relationships") rather than theme-like (eg, "Balancing acceptance with ambitions") categories. Therefore, the relative category frequencies should be interpreted with some caution.

Research Implications

This study has at least 4 research implications. First, it demonstrates the usefulness of analyzing online forum posts to tap into authentic and candid accounts of lived experience of MH issues. Second, this study serves as the first validation of the POETIC framework. Ideally, this encourages other researchers to apply it in their research. Third, the combination of corpus linguistics and qualitative framework analysis allowed the analysis of large amounts of data. Hence, corpus framework analysis may also be useful for future studies of text data, such as therapy transcripts (eg, [55]). Lastly, the S-BiDD data set

and derived corpora are available for future research, for example, on other aspects of the lived experience of BD.

Clinical Implications

This study identifies the key issues relevant to PR in BD shared by people with lived experience on the web and extends previous knowledge from interviews and focus groups. These findings, including the quotes in Tables S30 and S31 in Multimedia Appendix 1, are a rich resource for understanding more about the experience of PR in BD for individuals living with BD, their loved ones and informal carers, and MH professionals. This is also relevant for recent initiatives to educate MH professionals on the lived experience of severe MH issues, such as the current "Understanding psychosis and BD" training for the UK National Health Service [56]. Subsequently, issues identified in this study may provide helpful starting points for therapists to collaboratively consider them with their clients, for example, in recovery-focused therapy [57,58].

Individuals discussed issues on the web that they considered contentious and personal and were not comfortable sharing offline, such as sexuality, spirituality, and (hypo)mania. Recovery-focused therapies that are free to work with whatever model the clients bring for their BD experiences [58] may be particularly suitable to create a therapeutic environment where clients feel comfortable to discuss such sensitive issues. Moreover, Jones et al [59] showed that recovery-focused therapy reduces the positive self-appraisal of hypomanic experiences.

Reproductive decision-making surfaced as a major issue for young adults living with BD, and dedicated counseling on this topic may be advisable. Although understanding genetic vulnerability and risk data in MH is challenging, there is evidence that genetic counseling can offer effective support [60].

Conclusions

This study analyzed 4462 Reddit posts by 1982 people with an S-BiDD within the POETIC framework [8] for PR in BD. It is the first to analyze online forum data on PR. This study confirmed the validity of the POETIC framework to also capture PR experiences shared on the web and highlighted new aspects in PR that did not come up in previous studies using interviews and focus groups. It also demonstrated the utility of integrating corpus linguistics and qualitative framework analysis to identify key themes within large text data sets. By indicating the key areas that people focus on when posting freely, this study provides rich insights into the lived experience of PR in BD for formal and informal carers of people with a BD diagnosis.

Acknowledgments

The authors wish to thank the volunteers with lived experience who provided helpful insights for conducting and writing up this research. GJ is grateful to Enrica Troiano for insightful discussions on designing and evaluating the coding for personal recovery relevance. She would also like to thank Gavin Brookes and the participants of the 6th Corpora & Discourse International Conference for helpful comments on the corpus construction and analysis. The authors also thank Matthew Coole for testing the code release. This study was completed as part of a PhD studentship for GJ, which was funded by the Faculty of Health and Medicine at Lancaster University, United Kingdom.

Authors' Contributions

GJ led on the study design, supported by SHJ, FL, and PR. GJ collected the data, conducted the analyses, and drafted the manuscript. SHJ and FL audited the analyses (personal recovery relevance of posts and framework analysis of concordance lines). CH double coded the personal recovery relevance of posts and reviewed the paraphrasing of selected quotes. All coauthors discussed and agreed on the results, commented on the draft manuscript, and approved the final version. SHJ, FL, and PR obtained the funding for this study.

Conflicts of Interest

None declared.

Abstract

Background: Assessing patients' suicide risk is challenging, especially among those who deny suicidal ideation. Primary care providers have poor agreement in screening suicide risk. Patients' speech may provide more objective, language-based clues about their underlying suicidal ideation. Text analysis to detect suicide risk in depression is lacking in the literature.

Objective: This study aimed to determine whether suicidal ideation can be detected via language features in clinical interviews for depression using natural language processing (NLP) and machine learning (ML).

Methods: This cross-sectional study recruited 305 participants between October 2020 and May 2022 (mean age 53.0, SD 11.77 years; female: n=176, 57%), of which 197 had lifetime depression and 108 were healthy. This study was part of ongoing research on characterizing depression with a case-control design. In this study, 236 participants were nonsuicidal, while 56 and 13 had low and high suicide risks, respectively. The structured interview guide for the Hamilton Depression Rating Scale (HAMD) was adopted to assess suicide risk and depression severity. Suicide risk was clinician rated based on a suicide-related question (H11). The interviews were transcribed and the words in participants' verbal responses were translated into psychologically meaningful categories using Linguistic Inquiry and Word Count (LIWC).

Results: Ordinal logistic regression revealed significant suicide-related language features in participants' responses to the HAMD questions. Increased use of anger words when talking about work and activities posed the highest suicide risk (odds ratio [OR] 2.91, 95% CI 1.22-8.55; *P*=.02). Random forest models demonstrated that text analysis of the direct responses to H11 was effective in identifying individuals with high suicide risk (AUC 0.76-0.89; *P*<.001) and detecting suicide risk in general, including both low and high suicide risk (AUC 0.83-0.92; *P*<.001). More importantly, suicide risk can be detected with satisfactory performance even without patients' disclosure of suicidal ideation. Based on the response to the question on hypochondriasis, ML models were trained to identify individuals with high suicide risk (AUC 0.76; *P*<.001).

Conclusions: This study examined the perspective of using NLP and ML to analyze the texts from clinical interviews for suicidality detection, which has the potential to provide more accurate and specific markers for suicidal ideation detection. The findings may pave the way for developing high-performance assessment of suicide risk for automated detection, including online chatbot-based interviews for universal screening.

KEYWORDS

depression; suicidal ideation; clinical interview; machine learning; natural language processing; automated detection

Introduction

Up to 77% of individuals who died by suicide had contact with their primary care provider within 12 months prior to their death [1]. Suicidal ideation is a significant risk factor for suicidal death and is an important clinical concern [2-4]. Screening for suicidal ideation is a standard practice in health care settings. However, a past study reported poor agreement in rating suicide

risk among primary care providers [5]. Assessing patients' suicide risk is challenging, especially among those who deny suicidal ideation and perceive suicide as taboo to talk about [6-8]. In recent years, researchers have attempted to screen suicide risk unobtrusively based on implicit language-based clues in patients' speech [9,10]. A study applied a naive Bayes classifier to patients' verbal responses in clinical interviews to detect suicide risk with an area under the curve (AUC) of 0.63 [9]. This line of research is supported by recent behavioral and neuroimaging studies that demonstrated a close relationship between language use and social-emotional processing [11].

A systematic review has suggested that first-person singular pronouns and negative emotion words are language features of people who are suicidal [12]. However, first-person singular pronouns and negative emotion words are also found among those who are prone to depression [13,14], and first-person singular pronoun use has been proposed as a specific language marker of depression in a meta-analysis [15]. This result is concordant with the idea of depressive self-focus and rumination on past events, particularly on negative memories in depression. Given the overlapping language features among patients with depression and those with suicide risk, there is a need to look for language features that are specific in predicting suicide among patients with depression. Previous studies reported other linguistic features (eg, prepositions and verbs) for predicting suicide risk [12,16]. Another study differentiating suicide notes from depression notes and neutral blog posts found adverbs, cognitive processing words, and death words as the most significant language features of suicidality [17].

Natural language processing (NLP) and machine learning (ML) have been used to detect suicide risk [18,19]. Previous studies have incorporated NLP and ML into suicide detection for universal screening on social media [20-22]. Researchers have identified explicit suicide expressions (eg, suicide notes) [23] and texts written by suicidal individuals (eg, songs, poems, diaries) [24], but these have mostly been searched for in social media posts and other personal documents [25]. Few studies have evaluated the techniques in clinical settings [18,19,26]. This study used a text analysis approach using NLP and ML techniques for suicidal ideation detection from the words spoken by participants in clinical interviews for depression. It is hypothesized that (1) language features extracted from responses to interview questions are associated with suicidal ideation; (2) there is a difference in language features between suicidal ideation and depression; and (3) the model can contribute to more accurate suicidal ideation detection, especially among patients with depression.

Methods

Recruitment

This cross-sectional study was part of an ongoing digital phenotyping research project in characterizing depression with a case-control design [27]. Patients with lifetime major depressive disorder (MDD) were recruited from outpatient clinics in a local university-affiliated hospital. The diagnosis of any psychiatric disorder was made by the attending psychiatrist. Controls were recruited from the community. The Mini-International Neuropsychiatric Interview, version 5.0, was used to check if they had any *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, diagnosis [28]. We found that 8% (9/117) of the community sample had lifetime MDD, and these individuals were considered as cases. The diagnostic criteria for MDD included having (1) 5 or more depressive symptoms for ≥2 weeks, (2) either depressed mood or loss of interest and pleasure, (3) symptoms causing significant distress or impairment, and (4) no manic or hypomanic behavior. Participants who, at some point in their lives, had ever received a diagnosis were classified as cases of lifetime MDD. Inclusion criteria for participation were (1) being a native Cantonese speaker and (2) being a Chinese adult aged 18 to 65 years. Participants (1) with any voice, speech, and language problems; (2) with any history of psychiatric disorder other than MDD; and (3) who were incompetent to give written informed consent were excluded. The data collection was conducted between October 2020 and May 2022. This study included 197 cases and 108 controls (n=305).

Ethical Considerations

Ethical approval was obtained from the Joint Chinese University of Hong Kong–New Territories East Cluster clinical research ethics committee (2020.492).

Clinical Measurements

The structured interview guide for the Hamilton Depression Rating Scale (HAMD) was adopted [29]. The HAMD-17 shows high interrater reliability [30]. The interviews were conducted by the second author (JC), who holds an MD and a PhD. Each interview took 15 to 30 minutes. We sequentially probed 14 questions on the HAMD-17 (H1 to H14) to assess depression symptoms (we rated questions H15 to H17 based on observation during the interview). Depression severity was classified as no depression (score 0-7), mild depression (8-16), and moderate to severe depression (≥17) [29].

H11, which was used to assess suicide risk, asks "Since last week, have you had any thoughts that life is not worth living?" Suicide risk was rated in five progressive levels: (1) having no suicidal thoughts; (2) feeling life is not worth living; (3) having wishes to be dead, or any thoughts of possible death of self; (4) having suicidal ideation or gestures; and (5) having attempts at suicide. JC and TMHL rated H11 with high interrater reliability (κ=0.92). Discrepancies in ratings were discussed until a consensus was reached. A total of 236 of 305 participants (77%) who did not report any suicidal thoughts were classified as the nonsuicidal group. The severity of suicidal ideation ranged from passive ideation (ie, having wishes to be dead) to active ideation (ie, having suicidal thoughts and behaviors); persons with active ideation are more prone to suicide attempts and deaths than those with passive ideation [3]. Thus, 33 and 23 participants who felt life was not worth living and had wished to be dead, respectively, were classified as the low-suicide-risk group (18%); 12 participants and 1 participant who had suicidal thoughts and acting out behavior, respectively, were classified as the high-suicide-risk group (4%). Multimedia Appendix 1 includes verbatim quotations of the verbal responses to H11.

Feature Extraction

The interviews were recorded and transcribed by a research assistant with a psychology background. The transcripts were checked by the first author (TMHL). As interword spacing is absent in Chinese texts (eg, "I want to kill myself" in Chinese would become "Iwanttokillmyself"), Chinese word segmentation was needed to separate words. For Chinese word segmentation, the study used a deep learning–based Chinese word segmentation engine, fastHan, which included local text samples for training and testing its segmentation model, achieving over 90% agreement with human segmentation [31].

Words were translated into psychologically meaningful categories using Linguistic Inquiry and Word Count (LIWC) [32]. There are 71 categories in the Chinese version of LIWC [33]. To investigate if a language feature f existed within a verbal response, we calculated the proportion of words r_i in the response that matched with any of the words c_j listed in an LIWC category using the following formula:

where $R=\{r_1, r_2, \ldots\}$ and $C=\{c_1, c_2, \ldots\}$ denotes the collection of words in the response and the LIWC category, respectively, while $m(r, c)$ represents checking for an exact match between r and c (which returns 1=matched or 0=not matched), and $|R|$ denotes the number of words in the response. All the features were calculated by the proportion of words of each category relative to text length (as a percentage). Using the relative frequency minimized the confounding factor of text length in interview responses.

Statistical Analysis

All analyses were conducted using R (version 4.2.0; R Foundation for Statistical Computing). A P value <.05 was considered statistically significant. Descriptive statistics for continuous variables are shown as means and SDs, while categorical variables are presented as numbers and percentages. Age and the number of words in interview responses were compared among the nonsuicidal, low-suicide-risk, and high-suicide-risk groups using a 1-way ANOVA, while gender and depression severity were compared with the chi-square test among the groups. The Cramér V was used to measure the associations of clinician ratings of the HAMD questions with suicide risk.

Ordinal logistic regression was performed to model the relationship between language features (predictors) and suicide risk (the outcome)—ordered in three progressive levels from (1) nonsuicidal, (2) low suicide risk, to (3) high suicide risk [34]. The analysis was conducted for the responses to H11 (a suicide-related question) and the responses to other questions (content without suicide disclosure). The regression models were adjusted for age, gender, and depression severity. Adjusted odds ratios (ORs) with 95% CIs were calculated as a measure of the strength of association. The ORs were standardized across the HAMD questions and visualized using a heatmap. Euclidean distance was used as the similarity measure for clustering the questions with similar language features associated with suicide risk. Bonferroni correction for multiple testing was applied.

Random forest, an ML classification technique [35], was used to detect participants with suicide risk, including (1) high suicide risk and (2) any suicide risk (both low and high risk) among (1) all participants, (2) participants with lifetime MDD, (3) participants with lifetime MDD and unremitted depression (HAMD-17 score ≥8), (4) participants with lifetime MDD and remitted depression, and (5) control participants, based on language features extracted from their interview responses. All classification results were evaluated by leave-one-out cross-validation. Receiver operating characteristic curve analysis was used for analyzing the accuracy of classification results. Statistics included the AUC and 95% CI, sensitivity, and specificity of the ML classifiers. For each classifier, sensitivity and specificity at the optimal cutoff were computed.

Results

Characteristics of the Participants

Table 1 shows the characteristics of the 3 groups, namely the nonsuicidal, low-suicide-risk, and high-suicide-risk groups. No significant age or gender differences were found among the 3 groups. Suicide risk was correlated with depression severity (V=0.45, 95% CI 0.36-0.52; P<.001). All participants in the high-suicide-risk group were depressed, of which the majority (8/13, 62%) were moderately to severely depressed. In the low-suicide-risk group, 86% (48/56) had depression. The majority (28/56, 50%) were experiencing mild depression. Only 23% (54/236) of nonsuicidal participants had depression, most of whom (46/236, 20%) had mild depression. Participants, on average, generated 387.93 (SD 349.19) words in response to all 14 interview questions. There were significant differences among the 3 groups in terms of the number of words in their interview responses. The low-suicide-risk group generated longer responses than the nonsuicidal group (P<.001) and high-suicide-risk group (P=.02). The high-suicide-risk group also uttered marginally more words compared to the nonsuicidal group (P=.05).

Table . Characteristics of the participants (N=305).

Characteristics		Nonsuicidal (n=236)	Low suicide risk (n=56)	High suicide risk (n=13)	*P* value
Age (years), mean (SD)		52.63 (11.57)	54.46 (11.88)	51.69 (15.42)	.27
Gender, n (%)					.37
	Female	132 (56)	37 (66)	7 (54)	
	Male	104 (44)	19 (34)	6 (46)	
Lifetime major depressive disorder, n (%)					<.001

[a]Severity ranges for the Hamilton Depression Rating Scale–17: no depression (0-7); mild depression (8-16); moderate to severe depression (≥17).

[b]H11: Hamilton Depression Rating Scale question 11.

Table 2 shows the associations of clinician ratings of the HAMD questions with suicide risk. All the ratings were associated with suicide risk (*V*=0.14-0.40). The clinician rating of H12 (on anxiety psychic) had the strongest association with suicide risk, whereas the rating of H8 (on insomnia late) had the weakest association with suicide risk.

Table . Associations of clinician ratings of the Hamilton Depression Rating Scale (HAMD) questions with suicide risk (based on H11).

HAMD item	Question type	Cramér *V* (95% CI)	*P* value
H1	Depressed mood	0.36 (0.26-0.42)	<.001
H2	Work and activities	0.36 (0.27-0.43)	<.001
H3	Genital symptoms	0.21 (0.12-0.28)	<.001
H4	Somatic symptoms gastrointestinal	0.30 (0.21-0.37)	<.001
H5	Loss of weight	0.18 (0.08-0.25)	.005
H6	Insomnia early	0.23 (0.13-0.30)	<.001

H12	Anxiety psychic	0.40 (0.30-0.46)	<.001
H13	Anxiety somatic	0.31 (0.22-0.38)	<.001
H14	Hypochondriasis	0.28 (0.18-0.34)	<.001

Associations of Suicide Risk With Language Features in H11

Suicide risk was assessed by clinicians based on H11 (a suicide-related question). Table 3 shows the significant associations of suicide risk with language features in verbal responses to H11. Suicide risk was positively associated with linguistic (ie, function words, verbs, adverbs, prepositions, and numbers), psychological (ie, social, cognitive, and biological process words, relativity words, death words, and fillers), and Chinese-specific categories (ie, postpositions, quantity units, multifunction words, and tense markers). After adjusting the analyses for depression severity, 11 language features remained significant. Among the 11 features, increased use of past tense markers posed the highest suicide risk. For every 1% increase in past tense markers, the odds of being more likely to have

higher suicide risk (low or high suicide risk vs nonsuicidal) were multiplied 1.24 times (OR 1.24, 95% CI 1.09-1.43; *P*=.002).

Table . Significant associations of suicide risk with language features in verbal responses to H11 (Hamilton Depression Rating Scale question 11) using ordinal logistic regression.

LIWC[a] category	Nonsuicidal (n=236), mean (SD)	Low suicide risk (n=56), mean (SD)	High suicide risk (n=13), mean (SD)	Odds ratio (95% CI)[b]	*P* value	Odds ratio (95% CI)[c]	*P* value

[b]Adjusted for age and gender.

[c]Adjusted for age, gender, and depression severity.

Associations of Suicide Risk With Language Features Across Other HAMD Questions

Suicide-related language features varied across other HAMD questions (see Multimedia Appendix 2). Among the language features, increased use of anger words in H2 posed the highest suicide risk. For every 1% increase in anger words, the odds of being more likely to have suicide risk were multiplied 2.91 times (OR 2.91, 95% CI 1.22-8.55; *P*=.02). Some language features, on the other hand, were negatively associated with suicide risk. For example, increased use of feeling words (OR 0.36, 95% CI 0.12-0.82; *P*=.04), future tense markers (OR 0.50, 95% CI 0.23-0.84; *P*=.03), and anxiety words (OR 0.57, 95% CI 0.29-0.88; *P*=.04) when responding to H2, H8, and H13, respectively, reduced suicide risk. Overall, six language features—namely function words, auxiliary verbs, prepositions,

multifunction words, cognitive process words, and discrepancy words—were found to be associated with suicide risk in 3 or more questions; these are illustrated in Figure 1.

Figure 1. Significant suicide-related features of language vary across the Hamilton Depression Rating Scale questions H1-14. Six language features (namely function words, auxiliary verbs, prepositions, multifunction words, cognitive process words, and discrepancy words) were found to be associated with suicide risk in 3 or more questions. LIWC: Linguistic Inquiry and Word Count. *P<.05; **P<.01; ***P<.001.

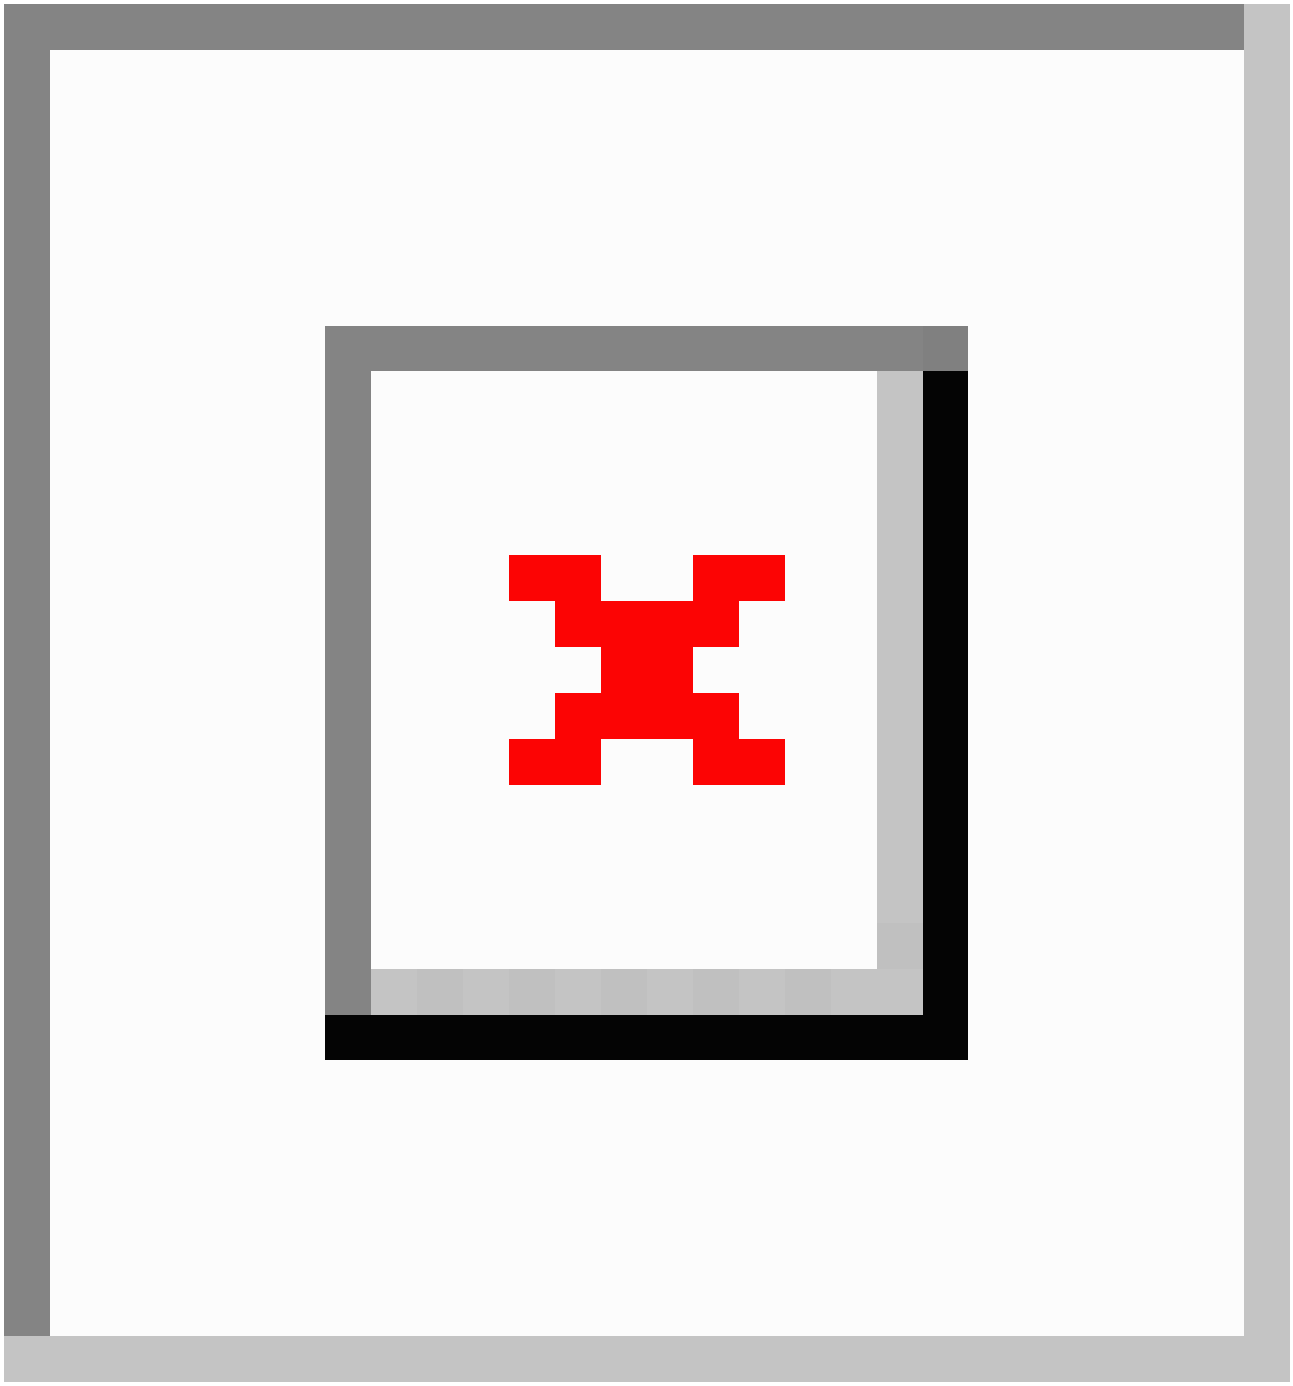

Figure 2 illustrates the hierarchical relationship between the HAMD questions based on the association of language features with suicide risk. Questions with similar suicide-related language features are closer and joined as clusters in the dendrogram. For instance, H10 (asking about feelings of guilt) joined together with H11 (a suicide-related question) as a cluster. While the heights reflect the similarity between the clusters, the largest difference between clusters is between the clusters of H10 and H11 vs the clusters of the other questions. Some possible clusters were observed in the dendrogram, including (1) the suicide-related cluster: H10 and H11; (2) the mood cluster: H2, H8, H1, and H12; (3) the appetite cluster: H5, H4, and H13; (4) the somatic symptom cluster: H7, H9, and H14; and (5) the sexual activity cluster: H3 and H6.

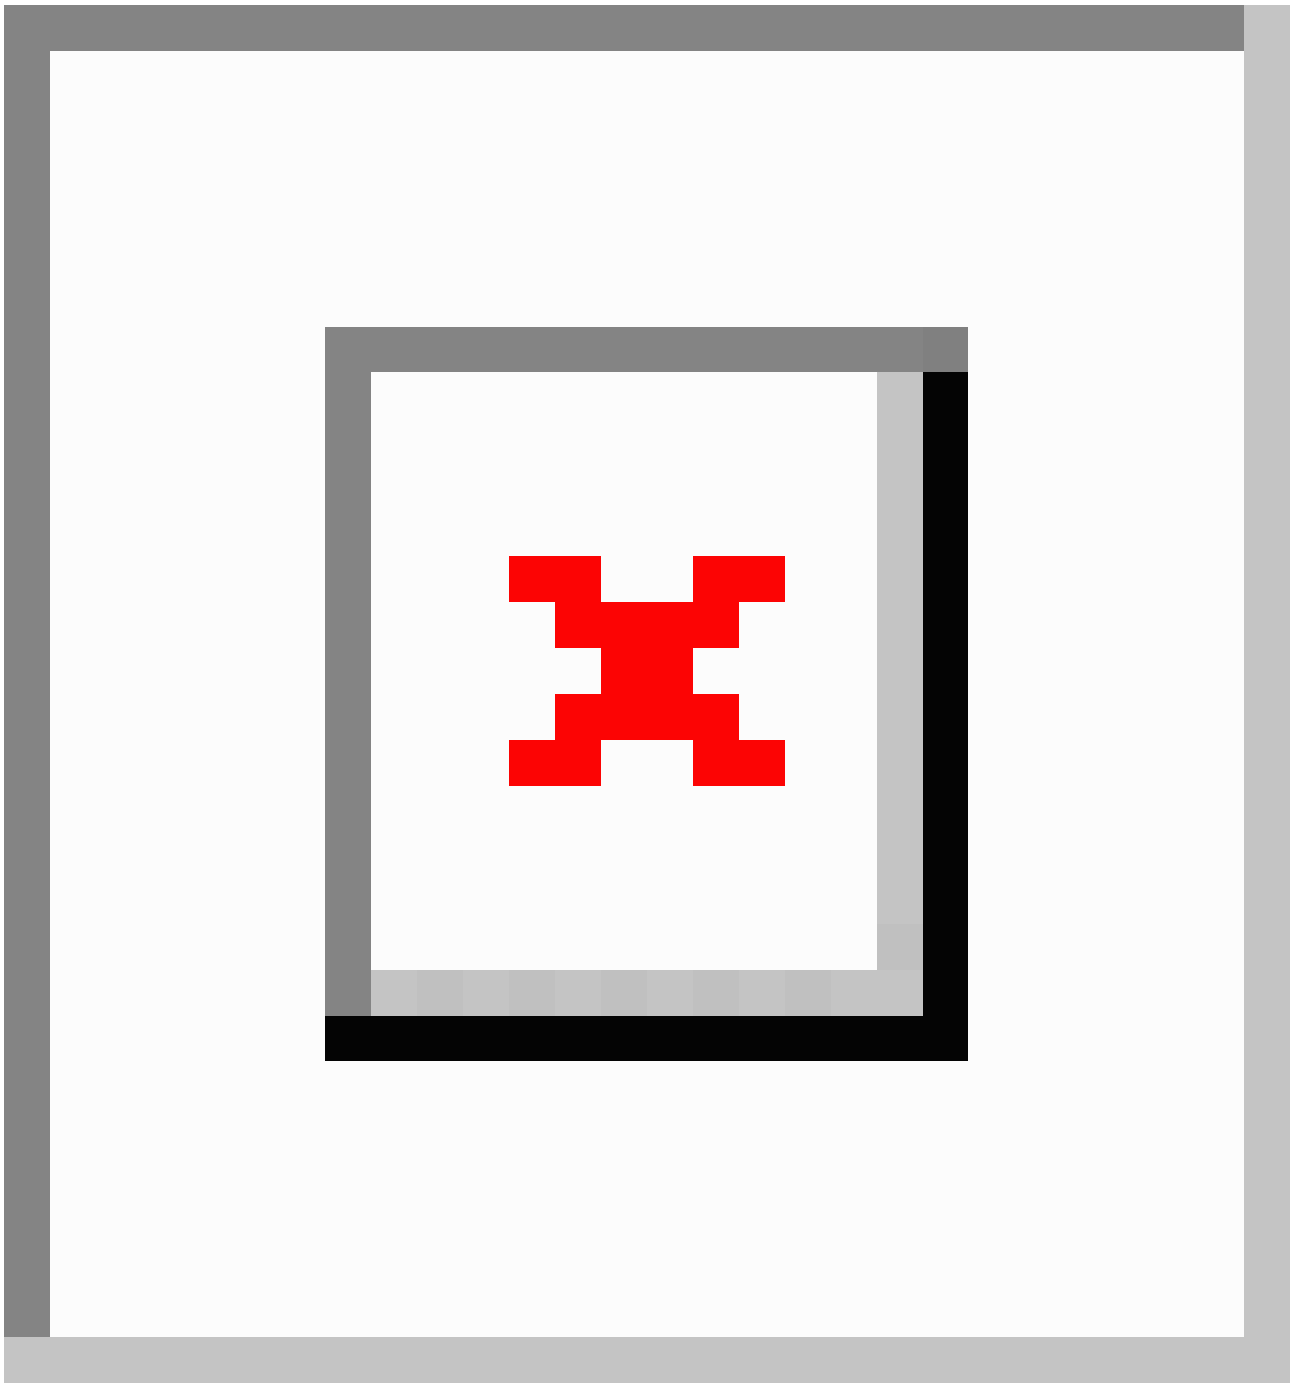
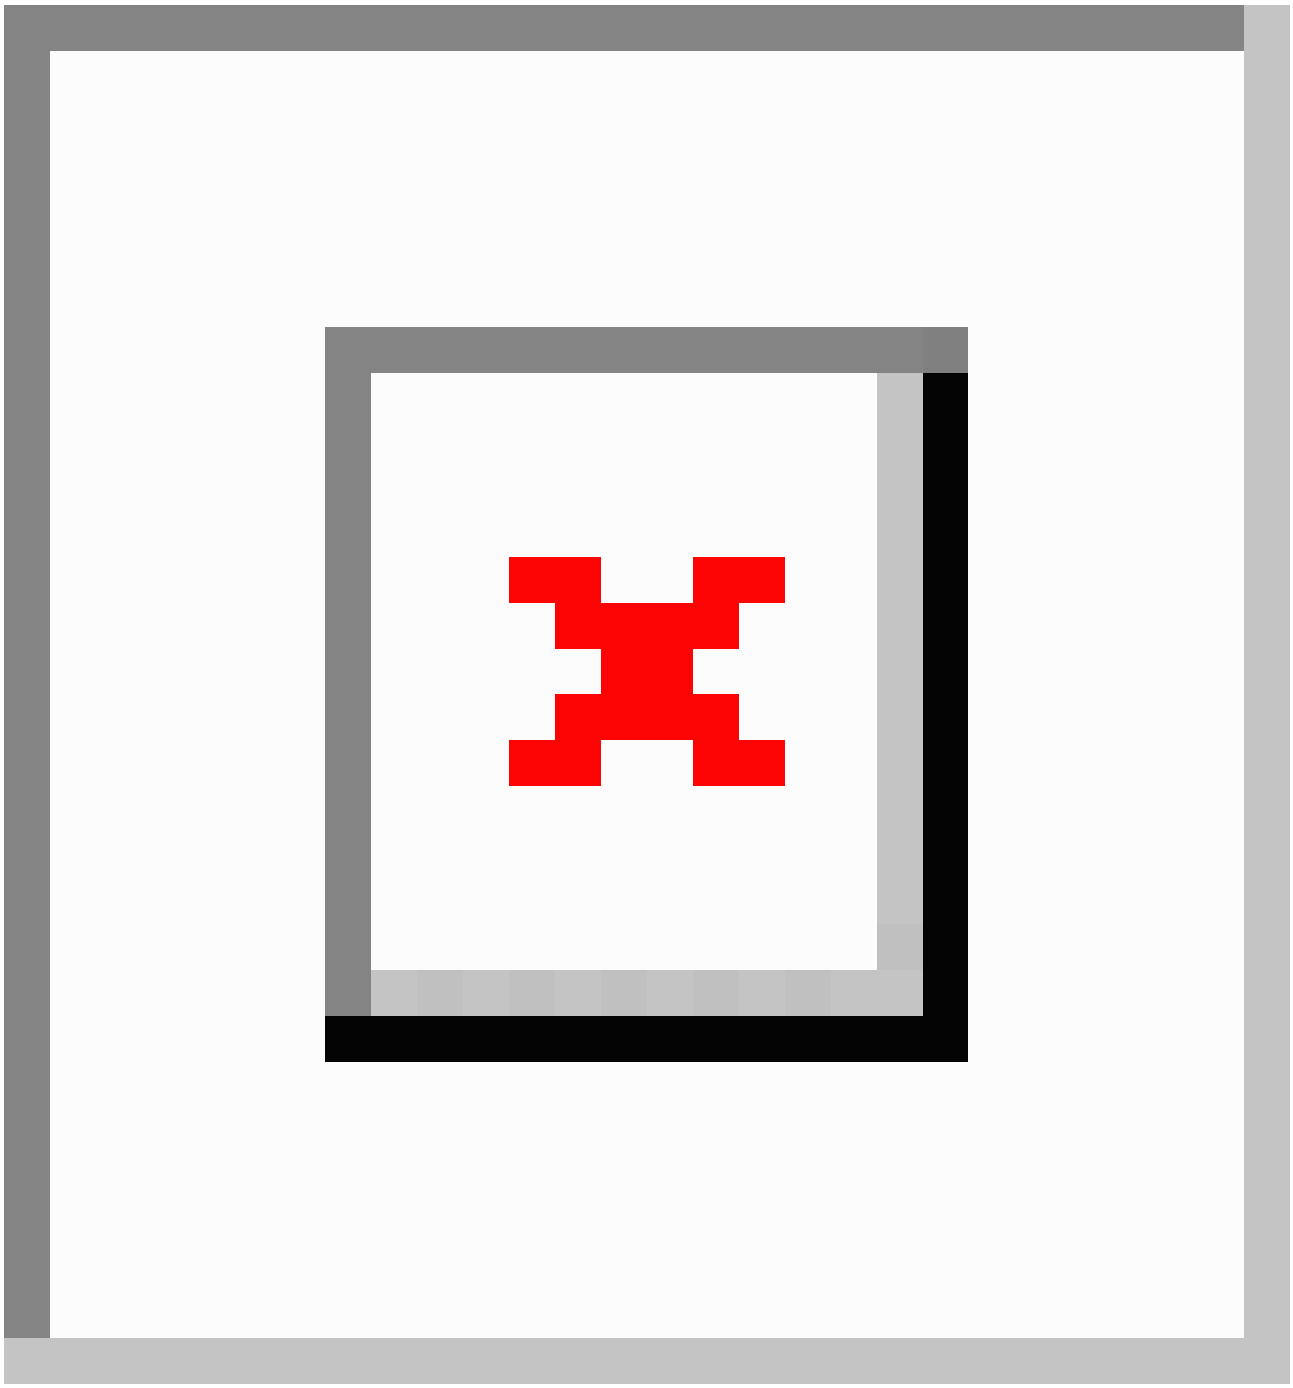
Figure 2. Heatmap of associations between language features and suicide risk across the Hamilton Depression Rating Scale (HAMD) questions (H1-14, where H11 asks about suicidal ideation) in all participants (n=305). The heatmap shows the standardized odds ratios (darker colors represent greater associations with suicide risk) obtained from ordinal logistic regression models adjusted for age, gender, and depression severity. Euclidean distance was used as the similarity measure for clustering the HAMD questions with similar language features associated with suicide risk shown in the dendrogram. LIWC: Linguistic Inquiry and Word Count.



The Performance of Suicide Risk Detection

Figure 3 depicts the performance for detecting suicide risk based on verbal responses to the HAMD questions in the ML analysis. Based on the responses to H11 (the outcome measure), ML models were trained to identify individuals with high risk in (Figure 3A) all participants, (Figure 3B) those with lifetime MDD, and (Figure 3C) those with lifetime MDD and unremitted depression (AUC 0.76-0.89; *P*<.001; sensitivity=0.69-0.85; specificity=0.73-0.84; Multimedia Appendix 3). H11 could also be used to detect suicide risk in general (including both high and low suicide risk) in (Figure 3D) all participants, (Figure 3E) those with lifetime MDD, and (Figure 3F) those with lifetime MDD and unremitted depression (AUC 0.83-0.92; *P*<.001; sensitivity=0.77-0.84; specificity=0.78-0.84). None of the control participants (without lifetime MDD) had high suicide risk, while 3 healthy controls reported low suicide risk. Using only H11, suicide risk could be detected among control participants (AUC 0.70; *P*=.04; sensitivity=0.80; specificity=0.71).

Figure 3. The performance, in terms of area under the curve (AUC), for detecting (A-C) active and (D-F) active and passive suicidal ideation based on participants' verbal responses to the Hamilton Depression Rating Scale (HAMD) questions H1 to H14 (where H11 asks about suicidal ideation) using random forest with leave-one-out cross-validation. Participants with active ideation (n=13) were detected among (A) all participants (n=305), (B) those with lifetime major depressive disorder (MDD; n=197), and (C) those with lifetime MDD and HAMD-17 score ≥8 (n=109). Participants with active or passive ideation were detected (n=69, 64, and 60, respectively) among (D) all participants, (E) those with lifetime MDD, and (F) those with lifetime MDD and HAMD-17 score ≥8. The error bars represent the 95% CI for AUC. *P<.05; **P<.01; ***P<.001.



Based on the responses to H14 (on hypochondriasis), ML models were trained to identify individuals with high suicide risk in (Figure 3A) all participants (AUC 0.76; P<.001; sensitivity=0.69; specificity=0.70), (Figure 3B) those with lifetime MDD (AUC 0.76; P<.001; sensitivity=0.77; specificity=0.77), and (Figure 3C) those with lifetime MDD and unremitted depression (AUC 0.75; P=.003; sensitivity=0.69; specificity=0.69). H4, H6, H8, and H10 could also be used to detect high suicide risk. Except for H7 and H8, other questions could be used to detect suicide risk in general (including both high and low suicide risk) in (Figure 3D) all participants. Based on the responses to H1, H4, H5, H9, H10, and H12, ML models identified individuals with suicide risk in (Figure 3E) those with lifetime MDD.

Discussion

Overview

This study aimed to provide a novel perspective on suicidal ideation detection by analyzing texts in clinician-administered,

structured interviews with NLP and ML. LIWC extracts human-understandable language features without knowing the interview content and can preserve patient privacy in clinical research. The study complements previous research with social media data (over 80% of the related studies were conducted using social media texts [19]) by (1) incorporating clinician-rated measures as the outcome, (2) investigating texts generated for specific purposes (ie, responding to the HAMD questions), and (3) exploring the added value of text analysis to clinical practice. The findings show that significant language features extracted from verbal responses to interview questions are associated with clinician-rated suicide risk. There is a difference in language features between suicidal ideation and depression. The ML models demonstrate that using direct responses to H11 is effective in identifying participants with suicide risk. More importantly, suicide risk can also be detected with satisfactory performance even without patients' disclosure of suicidal ideation.

Principal Results

The study distinguished suicidal ideation from its major confounding effect, depression, with an aim to investigate solely suicide-related language features. The use of past tense markers, verbs, and prepositions in response to a suicide-related question posed a higher risk than other language features. This finding on past tense markers is coherent with previous studies in which rumination occurred in suicidal individuals or past suicide attempts were described [12,15]. An increase in verbs is also found in previous research, which implies an aggravated suicide risk when suicidal intentions and thoughts become actions [14,16]. Prepositions are a relatively new language feature finding. This is consistent with a systematic review that analyzed 75 studies, only one of which reported increased use of prepositions of suicidal thoughts and behaviors [12]. In the modern Chinese language, neuroscience evidence suggests that prepositions are probably not a separate word class from verbs (the action words in a sentence) [36], which are also more frequently used by suicidal people. Another explanation for prepositions as connectors of words is that they demand and convey information about location, time, or direction [37]. An increase in prepositions use by suicidal people when responding to a suicide-related question may highlight the existence of concrete suicide plans.

Many previous depression and suicide detection studies were conducted on social media rather than clinical interviews [18,19]. Social media texts freely generated by users are often nonspecific to suicide or depression [22]. This study analyzed participants' responses to the HAMD questions, specifically focusing on a series of depressive symptomatologies. Results were mixed for suicide-related language features in responses to different questions. Previous studies reported a significant difference in the use of first-person singular pronouns and negative emotion words between suicidal and nonsuicidal groups [12,24]. This study consistently found these patterns posed a higher suicide risk: increased use of anger words on the work and activities question (H2), negative emotion words on the middle insomnia question (H7), and sadness words on the somatic symptoms question (H9). However, the increased use of first-person singular pronouns and anxiety words when responding to H5 (on the loss of weight) and H13 (on anxiety somatic), respectively, were intriguingly found to reduce suicide risk, which seems contradictory to previous studies that found these 2 categories were major language features of suicidal ideation [12]. It is speculated that rather than being generic, suicide-related language features appear to be more topic specific. The use of first-person singular pronouns to describe feelings and daily activities could reflect self-focus, a low level of social integration, and even suicidal rumination [12]. Paying more attention to oneself in the context of body weight management (in H5), on the other hand, may indicate positive self-concept and self-compassion [38]. Using more anxiety words (in H13) to describe the relationship between somatic symptoms and anxiety may signify a good understanding of one's own condition.

ML on the response to H11 (the outcome measure) is, understandably, highly effective in identifying both clinical and control participants with suicide risk, which is consistent with positive findings from previous studies detecting suicide-related social media posts labeled using human annotation [21,23]. With AUCs up to 92%, automatic detection of suicidal ideation in clinical settings, especially among busy and primary care clinics, seems possible. Real-time feedback from the ML models during clinical interviews can potentially facilitate early detection of suicidal ideation [8]. The ML models can be developed with other automated techniques, including chatbot-based interviews for future screening [10]. Furthermore, suicide risk can be detected with satisfactory performance without participants' disclosure of suicidal ideation or attempts (eg, in H10 on feelings of guilt and H14 on hypochondriasis), which provides new evidence on the association of language use with suicidality. In particular, while the clinician rating of H14 is not the strongest predictor for suicide risk, the responses to H14, surprisingly, generate the most powerful language clues to identify high suicide risk in the ML analysis. Verbal responses tend to provide subtle yet more objective language-based information about underlying suicidal ideation, which transcends depressive symptomatologies. The findings suggest that the investigation of suicide-related language features should be an important research topic apart from studying the clinical correlates of suicidality. The evidence strengthens the use of NLP and ML for suicidal ideation detection using implicit language-based clues, especially when health care personnel cannot identify patients' suicide risk upon a direct suicide-related question, or when patients refuse to answer a suicide-related question.

Limitations

First, although we had a relatively large sample size of patients, there were few high-suicide-risk participants. The sample size of at-risk groups will be increased for a more balanced sample. Second, this study focused on a cross-sectional time frame to investigate the discriminating power of language features for suicide detection. A longitudinal study could contribute to a longer time-frame exploration of the temporal association of language use with suicidal thoughts and behaviors. Third, although the HAMD-17 showed high interrater reliability [30] and high intermethod reliability [39], and JC and TMHL rated H11 with high interrater reliability (κ=0.92), the reliability of

the interview ratings of the rest of the HAMD questions in the current study was not assessed. H11 was used to determine whether the participants had suicide risk, while the text analysis was also conducted on the patient's verbal responses in the interview. It is also difficult to avoid errors arising from participants' willful denial of suicidal ideation or participants' belief that talking about suicide is taboo. Future research may need a more comprehensive measure for the outcome of suicidality that is based on more objective benchmarks (eg, actual suicidal behaviors or history). Fourth, the current study did not compare various machine learning algorithms (eg, support vector machines, naive Bayes classifiers, and neural networks), model parameters, and feature sets to achieve the best results. The performance of suicidal ideation detection might be an underestimate. The paper also proposes future directions to use deep learning–based models, such as Bidirectional Encoder Representations from Transformers (BERT), MentalBERT, and other large language models [40] to conduct comparative experiments. Finally, the language and cultural differences between the Chinese and English languages, which could create deviations among the studies, should be investigated. Chinese people seem more conservative in expressing emotions, and topics like suicide may receive media airtime but not be present in their personal lives [6,7]. Only rarely do Chinese or, more broadly, Asian people express personal feelings and suicidal ideation, as they commonly see these as signs of a weak personality (eg, irresponsible, fragile, impulsive, and attention-seeking), which culminates and intertwines with the social stigma of mental disorders in the general population [41].

Conclusions

The study investigated a novel perspective of using NLP and ML to analyze the texts from clinical interviews for suicidal ideation detection, which has the potential to provide more accurate and specific markers for suicide detection. Suicide risk detection is crucial groundwork for precrisis management to respond to safety concerns in automated screening and assessment. Other media such as chatbots and text-based detection have been used in many mental health applications. We hope that the enhanced suicide detection described in this study will augment and strengthen the performance of screening and assessment in the future.

Abstract

Background: Lower back pain is a common weakening condition that affects a large population. It is a leading cause of disability and lost productivity, and the associated medical costs and lost wages place a substantial burden on individuals and society. Recent advances in artificial intelligence and natural language processing have opened new opportunities for the identification and management of risk factors for lower back pain. In this paper, we propose and train a deep learning model on a data set of clinical notes that have been annotated with relevant risk factors, and we evaluate the model's performance in identifying risk factors in new clinical notes.

Objective: The primary objective is to develop a novel deep learning approach to detect risk factors for underlying disease in patients presenting with lower back pain in clinical encounter notes. The secondary objective is to propose solutions to potential challenges of using deep learning and natural language processing techniques for identifying risk factors in electronic medical record free text and make practical recommendations for future research in this area.

Methods: We manually annotated clinical notes for the presence of six risk factors for severe underlying disease in patients presenting with lower back pain. Data were highly imbalanced, with only 12% (n=296) of the annotated notes having at least one risk factor. To address imbalanced data, a combination of semantic textual similarity and regular expressions was used to further capture notes for annotation. Further analysis was conducted to study the impact of downsampling, binary formulation of multi-label classification, and unsupervised pretraining on classification performance.

Results: Of 2749 labeled clinical notes, 347 exhibited at least one risk factor, while 2402 exhibited none. The initial analysis shows that downsampling the training set to equalize the ratio of clinical notes with and without risk factors improved the macro–area under the receiver operating characteristic curve (AUROC) by 2%. The Bidirectional Encoder Representations from Transformers (BERT) model improved the macro-AUROC by 15% over the traditional machine learning baseline. In experiment 2, the proposed BERT–convolutional neural network (CNN) model for longer texts improved (4% macro-AUROC) over the BERT baseline, and the multitask models are more stable for minority classes. In experiment 3, domain adaptation of BERTCNN using masked language modeling improved the macro-AUROC by 2%.

Conclusions: Primary care clinical notes are likely to require manipulation to perform meaningful free-text analysis. The application of BERT models for multi-label classification on downsampled annotated clinical notes is useful in detecting risk factors suggesting an indication for imaging for patients with lower back pain.

Introduction

Lower back pain (LBP) is recognized as a common disability worldwide [1-3]. While there is no agreed-upon definition of LBP, in a systematic review, it was primarily defined through routinely collected electronic health data, which include *International Classification of Diseases, Ninth Revision* (*ICD-9*) and *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*) codes [4]. One estimate of the burden of LBP is that 13% of adults in the United States live with LBP, while in Canada, among those living with chronic pain, 50.9% identified the location of their pain in the upper or lower back

[2,3]. In a systematic review [4], the mean prevalence of LBP among the studies collected ranged between 1.4% and 15.6%.

While the burden of LBP remains high, it is important to understand the indicators for possible serious underlying causes that require imaging, also known as "risk factors" [5]. According to Choosing Wisely Canada, risk factors may include [6]:

- A history of cancer
- Unexplained weight loss
- A recent infection
- Fever
- Loss of bowel or bladder control
- Abnormal reflexes or the loss of muscle power in the legs

Radiological (diagnostic) imaging includes procedures such as x-rays, computed tomography scans, or magnetic resonance imaging scans. Recommendations from clinical practice guidelines state that, unless risk factors are present, radiological imaging is not needed for patients with LBP [5,7]. Moreover, ordering radiological imaging when it is unnecessary puts the patient at risk for radiation exposure and other negative consequences [5,6]. Despite these recommendations, patients with LBP are frequently subjected to unnecessary imaging [8].

The data for this study in clinical practice uses electronic medical records (EMRs). The widespread use of this IT has introduced the feasibility of analyzing large numbers of clinical notes without having to manually access paper charts and perform the analyses using automated approaches such as natural language processing (NLP) [9]. The Canadian Primary Care Sentinel Surveillance Network [10] routinely extracts clinical information such as clinical encounter notes, note type, and the date of the notes from primary care clinical practices with the permission of the providers. Applying NLP methods to EMR data makes it possible to detect LBP risk factors and understand the use of imaging in this common clinical presentation.

Since the introduction of transformers in 2019 [11], which are large language models that can be fine-tuned for specific tasks, deep language models have achieved a significant milestone in natural language understanding. The transfer learning paradigm of unsupervised pretraining and fine-tuning [12] using Bidirectional Encoder Representations from Transformers (BERT) has reduced the requirement for large labeled data sets to achieve state-of-the-art analytic performance. Previous research [13] has explored the use of topic models and deep neural networks to automatically distinguish acute LBP episodes using free-text clinical notes.

Methods

The following steps were undertaken to achieve our goal: preparation of EMR data, EMR annotation process, addressing imbalanced data, and application of the proposed model.

Preparation of EMR Data

We accessed a random sample of deidentified EMR data, and using the regular expressions created in SAS (SAS Institute), we identified a cohort of patients with any indication of LBP. Notes were further filtered by note type to only include provider-generated clinical notes. The data were then split randomly into three files. Ethics approval for the study was provided by the University of Manitoba Health Research Ethics Board and the Health Information Privacy Committee.

EMR Annotation Process

Six medical students reviewed the EMR notes to identify the six LBP risk factors in accordance to Choosing Wisely Canada. They worked in teams of two to validate the application of the inclusion and exclusion criteria, each note being annotated by two students. The inclusion criteria listed in Textbox 1 were the presence of specific clinical notes suggestive of at least one of the six risk factors indicating the need for imaging. The exclusion criteria were the presence of clinical conditions that could lead to symptoms that may be confused with any of the underlying conditions represented by the six risk factors and clinical notes that do not represent relevant visits.

Textbox 1. Inclusion and exclusion criteria for risk factors.

Inclusion criteria

- Lower extremities for loss of muscle function
- Positive straight leg test
- Nerve impingement
- Sciatica, but need to confirm radiculopathy
- Incontinence related to a nerve issue
- If back pain has improved
- Follow-up discussions of imaging results
- Saddle anesthesia
- Notes that do not specify upper vs lower back pain

Exclusion criteria

- HIV is not a relevant infection (regardless of viral load and strain/location)
- Urinary symptoms other than incontinence are neither risk factors nor symptoms of relevant infection
- Shingles as an infection if it is a lumbar dermatome
- Nocturnal enuresis
- Degenerative diseases or osteoarthritis with an indication of back pain
- Copy/pasted imaging results onto the electronic medical record note
- Notes that mention previous or resolved back pain
- Well child/adolescent visit

An experienced clinician (AK) arbitrated any disagreements between student annotators. This supported the inclusion of correctly labeled records in the classification model. For the annotation process, we used Microsoft Forms (Microsoft Corporation), which enabled us to collect the relevant data in a systematic and organized manner. Specifically, the output from Microsoft Forms was linked to a secure CSV file containing the clinical notes, using a unique identifier to facilitate data merging and subsequent analysis.

Addressing Imbalanced Data

Our data collection process consisted of two rounds. In the first round, we established the initial distribution of risk factors. Analysis of this round revealed an imbalanced distribution of labels, a well-known factor that can impact the performance of deep learning methods [14,15]. Specifically, we observed an imbalance in both the infrequent occurrence of individual risk factors and the high frequency of the "null class," which denotes the absence of risk factors.

To address this imbalance, we adopted a 2-pronged approach. First, we collected additional clinical notes specifically targeting minority risk factors. Second, we downsampled the majority of notes with "null class." Notably, the initial data set lacked any clinical notes for unexplained weight loss. Table 1 depicts the distribution of risk factors after the first labeling round, revealing that only 12% (n=296) of the 2487 annotated notes exhibited any risk factors.

Table . Risk factor distribution after the first labeling round. Zero notes exhibit the unexplained weight loss risk factor.

Risk factors	Annotations (round 1), n
Cancer	26
Weight[a]	0
Fever	8
Infection	8
Bowel	9
Abreflex	233

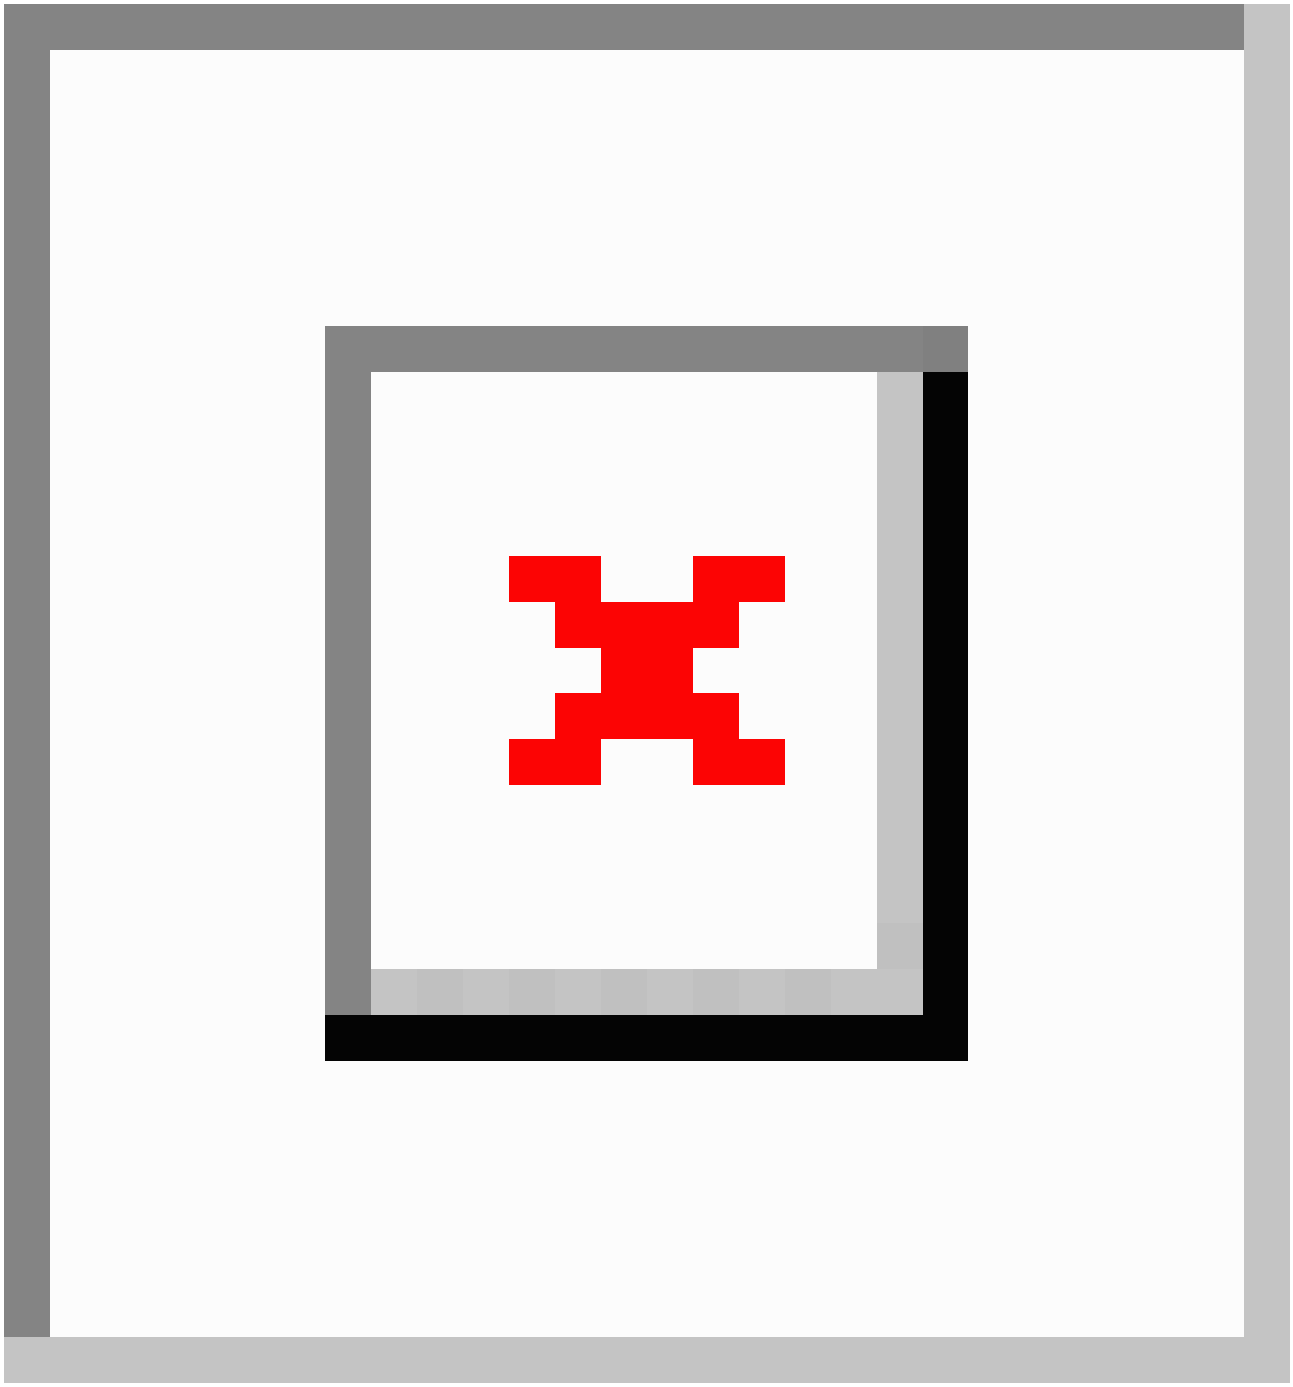
[a]Zero notes exhibit the unexplained weight loss risk factor.

Acquiring More Notes to Annotate

Prior studies have explored methods for addressing the challenge of obtaining sufficient data for training [16]. To acquire clinical notes for labeling that are more likely to exhibit a minority risk factor, we used unsupervised semantic textual similarity (STS). It is a ranking task where given a text query and a list of clinical notes, the STS model ranks the clinical notes that are semantically like the query. We trained two unsupervised STS models, Transformers and Sequential Denoising Auto-Encoder (TSDAE) [17] and Simple Contrastive Learning of Sentence Embeddings (SimCSE) [18], implemented using the SentenceTransformer Python library [19]. To rank the unlabeled clinical notes (ie, 55,000 notes with any LBP indication), we formed the queries using rationales, collected as part of the first labeling round. Here, we refer to "rationale" as an extracted snippet or text from the clinical note the annotators highlighted as evidence for a risk factor.

Figure 1 illustrates the STS sampling process with numbered steps. First, we group the clinical notes based on the exhibited risk factors. We then concatenate the rationales for each group of clinical notes to form queries and rank the unlabeled clinical notes using the unsupervised STS models. If the rationales were unavailable from the first labeling round (eg, "weight loss"), we used risk factor definition or custom text as the query. We selected the top K notes from the ranked clinical notes, where "K" is set within the 10-50 range. We further filtered noisy outputs using phrases such as "has fever," "has back pain," and "lost weight." Finally, we iterated the process for each risk factor and provided the selected notes for the second labeling round.

Figure 1. Semantic textual similarity sampling process, followed for the second labeling round. STS: semantic textual similarity.



This approach helped maximize annotations for clinical notes that exhibited risk factors. Table 2 depicts the complete distribution of risk factors after both rounds of labeling. Of the 262 annotated clinical notes in the second round, 19.5% (n=51) of the clinical notes exhibited risk factors, in contrast to 12% (n=296) in the first round.

Table . Risk factor distribution after both rounds of labeling.[a]

Risk factors	Annotations (round 1 + 2), n
Cancer	53
Weight	32
Fever	17
Infection	9
Bowel	9
Abreflex	236

[a]This includes 2487 notes from the first round and 262 notes from the second round. In the second labeling round, we collected 32 clinical notes for the unexplained weight loss risk factor.

Treating Class Imbalance With Downsampling

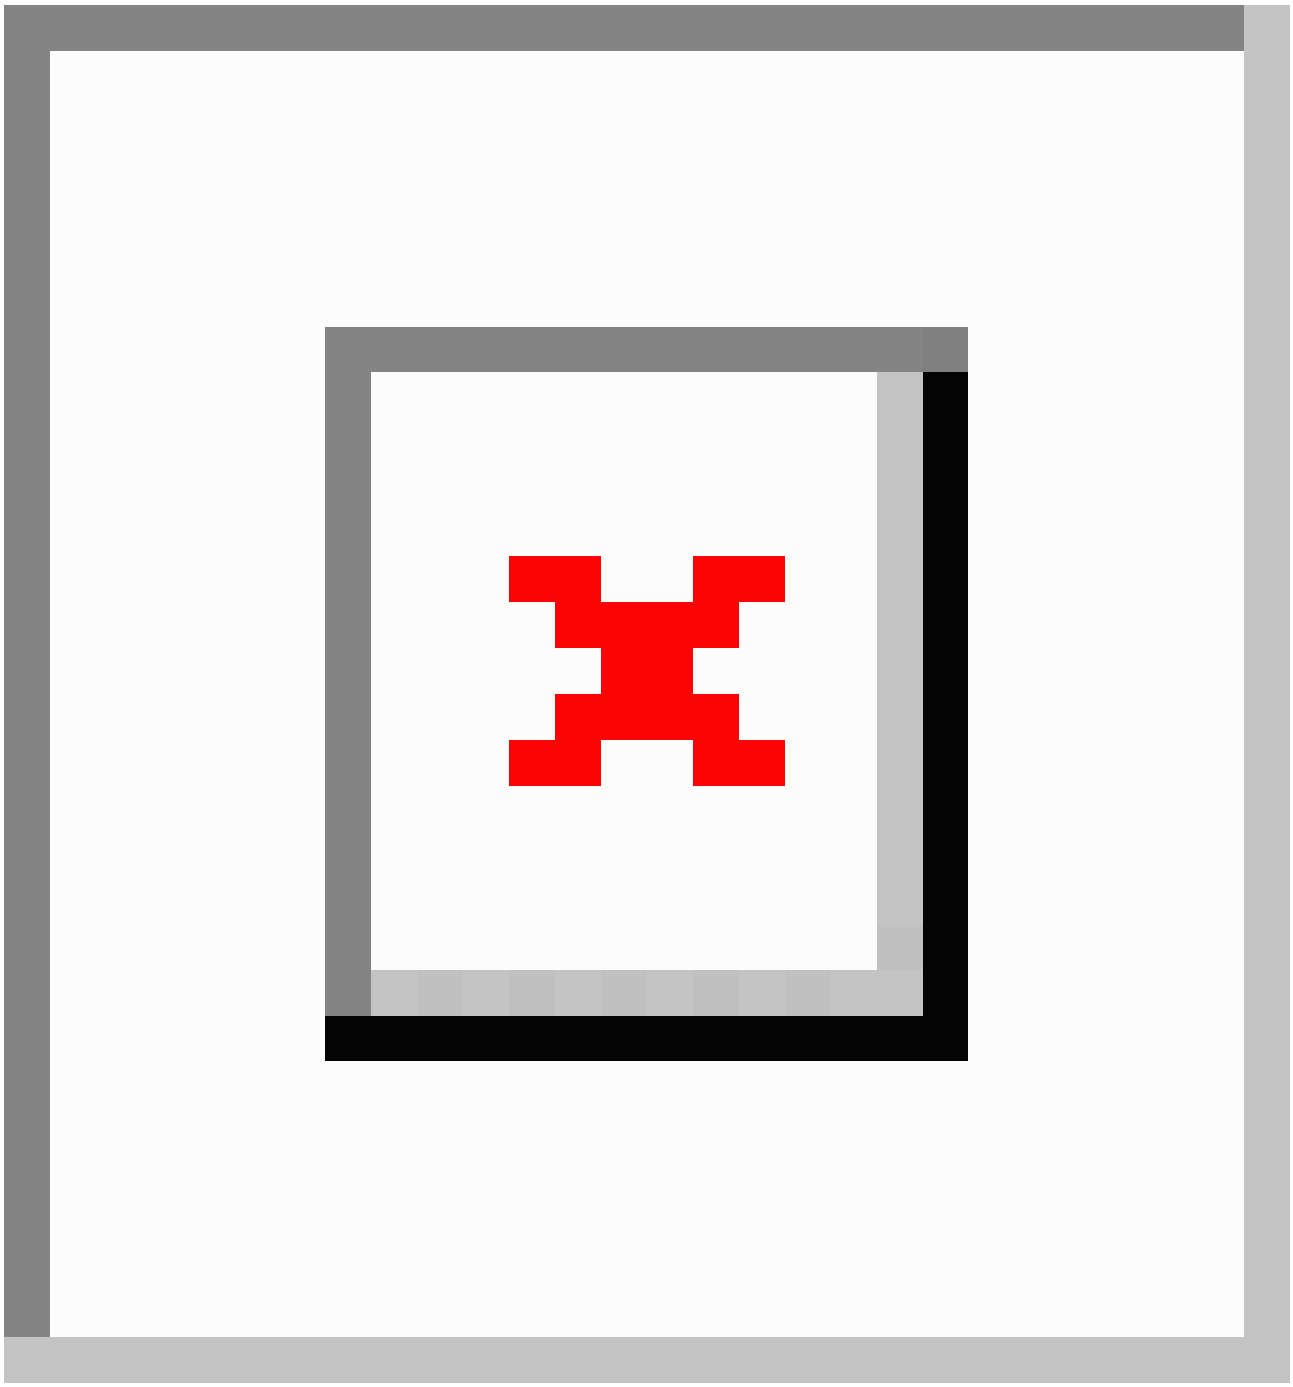
Following the second round of labeling, a significant class imbalance was observed in the resulting distribution of labels. Specifically, out of the total 2749 annotated clinical notes, only 347 were labeled as having one or more risk factors, while the remaining 2402 notes were labeled with no risk factor. To mitigate this issue, two common approaches are oversampling the minority class or downsampling the majority class. In a multi-label data set, each instance can be assigned to one or more classes. For instance, in the case of clinical notes, they may have one or more risk factors, making it challenging to oversample the minority class. This is because generating synthetic instances requires randomly selecting a minority clinical note that may have a combination of labels rather than a single label. However, this approach may bias the model toward the minority class and lead to overfitting. Consequently, we opted for downsampling the majority class to balance the class distribution and prevent the model from being biased toward the majority class.

Specifically, a subset of the clinical notes with "no risk factors" was randomly selected to match the number of clinical notes with "any risk factor." This approach aimed to balance the class distribution and enable the model to learn from both positive and negative examples. To assess the effectiveness of the downsampling strategy, we conducted a comparative analysis of the model's performance with and without downsampling.

Application of Proposed Model

Transformer-based BERT [11] models can be fine-tuned for detecting risk factors in clinical notes using a small labeled data set. The requirement for large labeled data sets is eased with models that are pretrained on large clinical text. In this work, we used BlueBERT [20] as our back-end model that is pretrained on PubMed abstracts and clinical notes from the Medical Information Mart for Intensive Care (MIMIC-III) data set [21]. However, BERT models are limited to a maximum input length of 512 tokens. The length of clinical notes in our data set ranges from 7 to 1400 tokens with 8% (n=221) of the notes having more than 512 tokens. To overcome this limitation, we propose a novel architecture called BERT–convolutional neural network (CNN) that chunks the inputs and processes them using convolution layers. The proposed chunking method is illustrated in Figure 2.

Figure 2. BERT input chunking: a clinical note is first separated into chunks of 512 tokens. Each chunk is then independently processed by the BERT-based back-end model. The chunk embedding is obtained by averaging the token embeddings from the last five layers of BERT. Finally, all the chunk embeddings are concatenated and processed using convolution layers, as defined by Kim [22]. Note: The sample clinical note does not belong to the real data set. BERT: Bidirectional Encoder Representations from Transformers.



Experimental Setup

The study used a repeated 2-fold cross-validation approach with two repetitions to improve the estimated performance of the machine learning models. As the data set was multi-label, we adopted the iterative stratification method [23,24] provided by the scikit-multilearn library [25] to generate stratified splits for the folds. This ensured that every split had a similar distribution of risk factors. The 2-fold cross-validation was repeated twice, resulting in a total of four runs. Wherever applicable, we implemented the downsampling technique (as described earlier) on the training set. Our results are reported in terms of the area under the receiver operating characteristic curve (AUROC) of individual risk factors and their macroaverage across the folds. Table 3 reports the frequency of positive risk factors in each split of the folds.

Table . Frequency of positive risk factors in train-test splits. We report the approximate counts of each risk factor across folds. Note: the counts do not include the clinical notes with no risk factors, which are approximately 1198 and 1195 for the train and test split, respectively.

Positive risk factors	Train split (n=1374 notes), n	Test split (n=1375 notes), n
Cancer	26	27
Weight	16	16
Fever	8	9
Infection	4	5
Bowel	4	5
Abreflex	118	118

Ethics Approval

The study received ethics approval from the Health Research Ethics Board of the University of Manitoba (study number HS20263; review number H2016:408).

Results

Overview

In this section, we report the analysis of the data collection and classification performance of the transformer-based models with different configurations, including traditional machine learning and BERT-based baselines. The transformer-based models were trained for 10 epochs each, with a learning rate ranging from 5e-05 to 6e-5. Unless specified otherwise, all the BERT-based models use BlueBERT [20] as the back end.

Data Collection Analysis

Each annotation was added to the clinical note level independently. These notes are associated with patient- and site-level information, allowing for further analysis based on the patient and site as the unit of analysis. Table 4 presents an analysis of the LBP characteristics reported in the collected data, using notes, patient, and site ID as the units of analysis. This enables a multilevel analysis of the reported characteristics, providing a detailed understanding of their distribution across various units of analysis.

Table . Lower back pain characteristics gathered from collected data, with notes, patient, and site ID each serving as the units of analysis.

Unit of analysis		Values, n (%)
Notes (N=2749)		
	History of cancer	53 (1.9)
	Signs of fever	17 (0.6)
	Unexplained weight loss	32 (1.2)
	Recent infection	9 (0.3)
	Loss of bowel or bladder control	9 (0.3)
	Abnormal reflexes	236 (8.6)
Patients (N=1943)		
	History of cancer	40 (2.1)
	Signs of fever	17 (0.9)
	Unexplained weight loss	32 (1.6)
	Recent infection	9 (0.5)
	Loss of bowel or bladder control	8 (0.4)
	Abnormal reflexes	201 (10.3)
Site ID (N=22)		
	History of cancer	12 (55)
	Signs of fever	11 (50)
	Unexplained weight loss	12 (55)
	Recent infection	5 (23)
	Loss of bowel or bladder control	7 (32)
	Abnormal reflexes	13 (59)

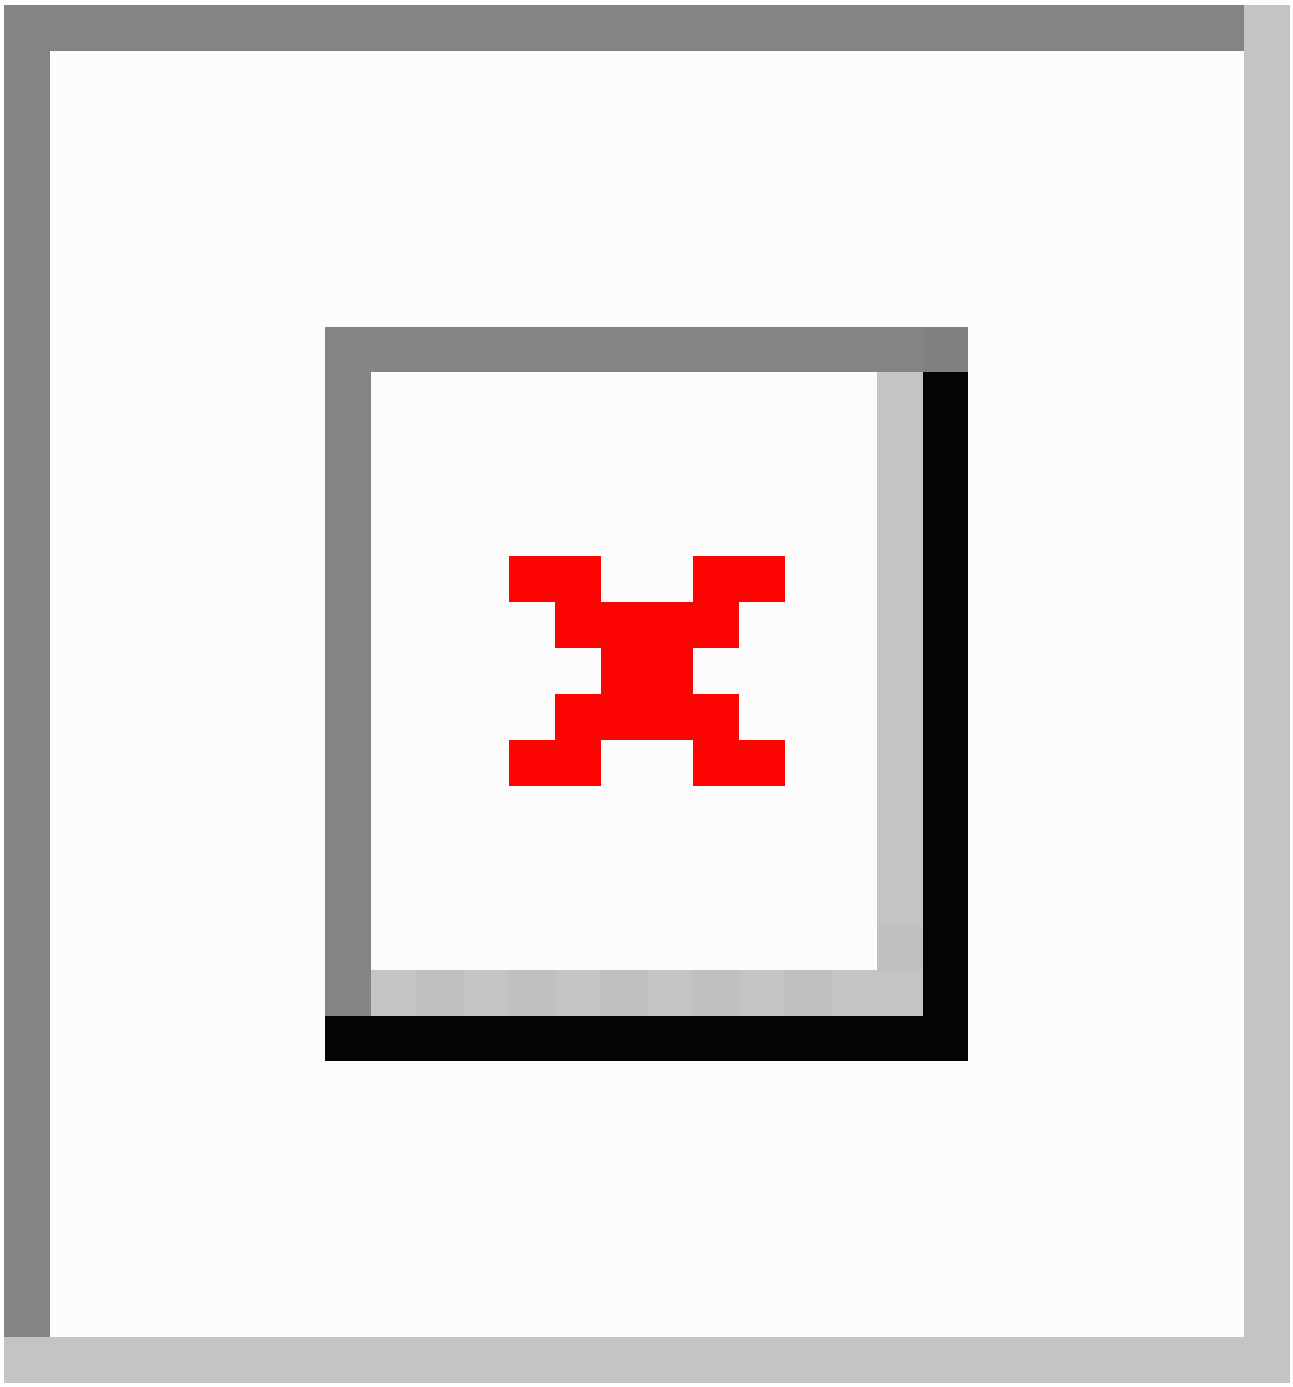
A total of 2749 clinical notes were annotated to collect information on risk factors for LBP. The most reported risk factor was "abnormal reflexes," with 236 annotations, followed by "history of cancer" with 53 annotations. Out of the 1943 patients covered by the annotation process, only 40 were labeled with a "history of cancer," accounting for 2.1% (n=40) of the total patients. More than 10% of patients were reported with "abnormal reflexes," while "recent infection" and "loss of bowel control" were reported in only 9 and 8 patients, respectively.

The analysis of clinical sites associated with the clinical notes revealed that 12 of 22 sites reported at least two risk factors, with "recent infection" and "loss of bowel or bladder control" being the least commonly reported risk factors, mentioned in only 5 and 7 clinical sites, respectively. These findings indicate that "abnormal reflexes" is the most reported characteristic of LBP across all units of analysis, with "history of cancer," "unexplained weight loss," and "signs of fever" being reported less frequently. The frequency of "loss of bowel or bladder control" and "recent infection" was relatively low across all units of analysis, indicating that these characteristics may not be as common as others in cases of LBP. The distribution of these characteristics varies across different units of analysis, which highlights the importance of examining LBP characteristics at multiple levels.

Performance With and Without Downsampling

In our initial analysis, we compared the impact of downsampling the training set, as described earlier, on the average and label-wise performance of the models. Figure 3 displays the results of this comparison. We also included a tf-idf (term frequency–inverse document frequency) + logistic regression model trained with a multi-output classifier [26] as a baseline, which was the best-performing baseline (among 7 candidates, including k-nearest neighbors, naive Bayes, random forest, and models from the scikit-multilearn Library [25]). On average, the BERT models performed 15% better than the baseline. Downsampling the training set improved performance by 2% for BERT-Multi models and reduced the SD as reflected by the error bars for minority labels (eg, "bowel" and "fever"). Downsampling of the majority class (ie, "No Risk factor notes") also helped stabilize the performance of the models, as indicated by the smaller error bars. We used the downsampled training set for further analysis.

Figure 3. Comparison of BERT-Multitask models trained on complete and downsampled data. A tf-idf + logistic regression model trained with a multi-output classifier is included as a baseline. The AUROC for each risk factor and their macroaverage are reported, with the SDs reflected in the error bars. AUROC: area under the receiver operating characteristic curve; BERT: Bidirectional Encoder Representations from Transformers; tf-idf: term frequency–inverse document frequency.

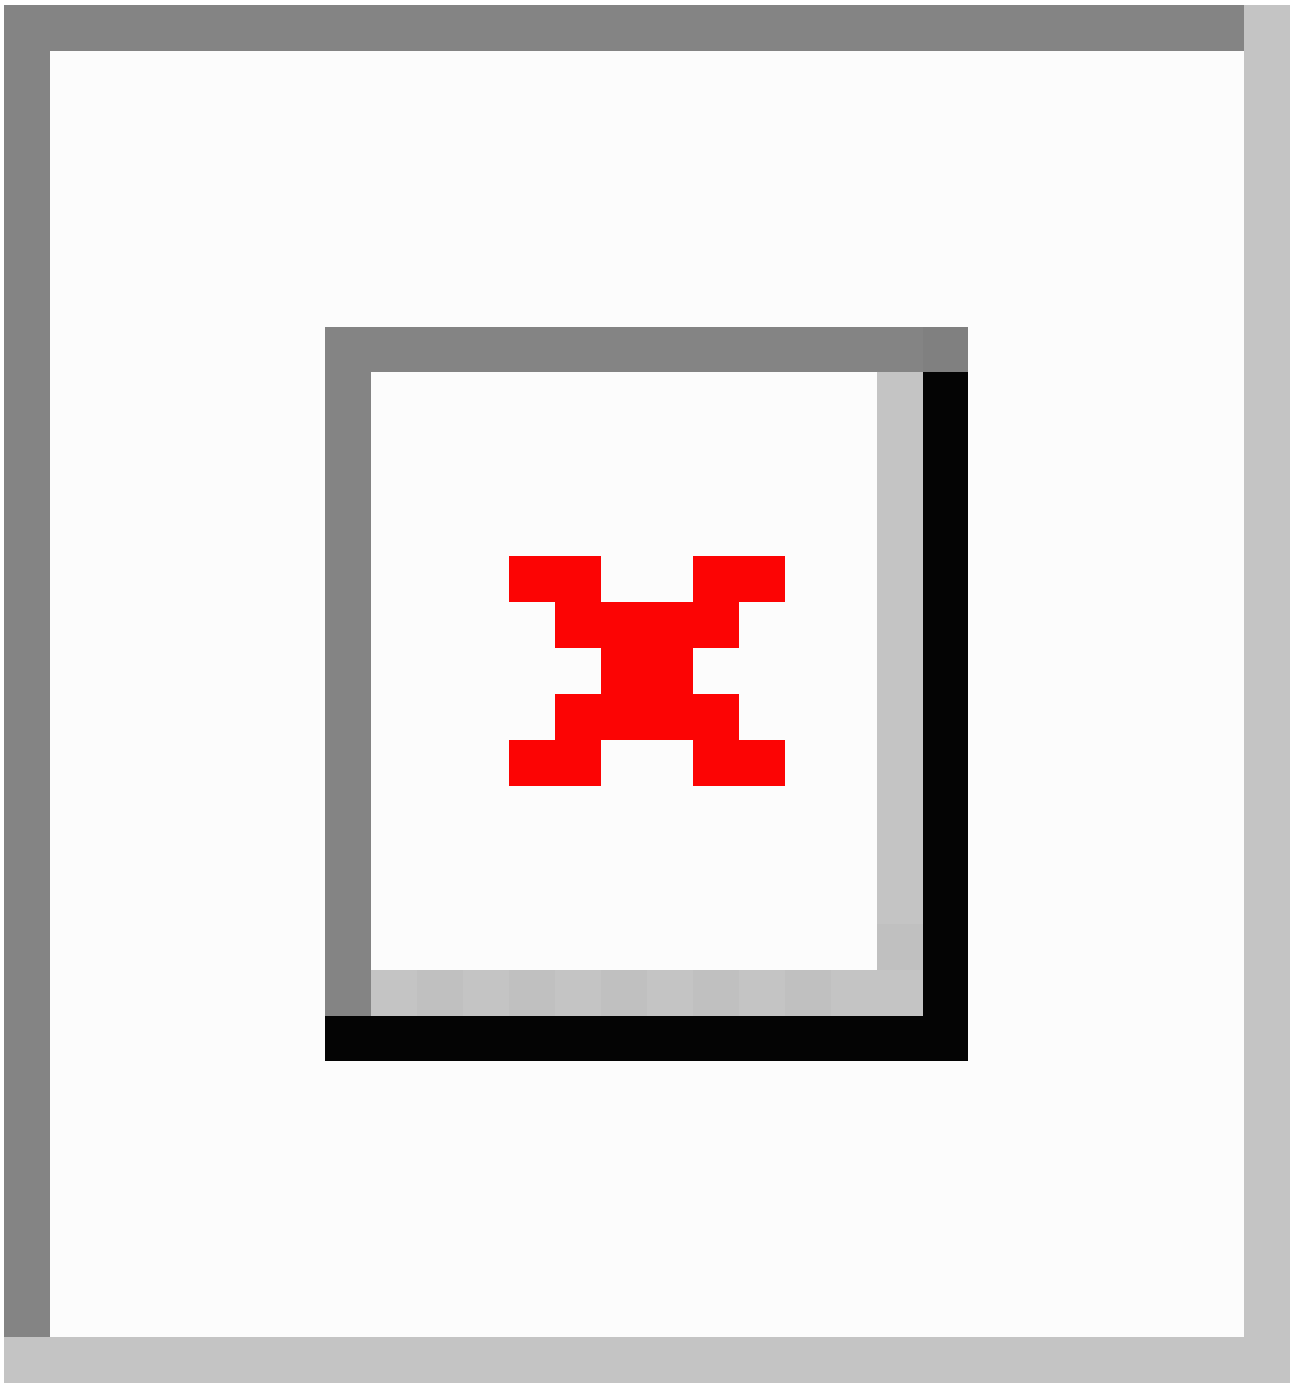


Performance With BERTCNN and Independent Binary Classifiers

Using the downsampled training set for all the models, we compared the performance of four different models chosen by architecture (BERT, BERTCNN) and task formulation (multitask learning, binary classification). Figure 4 shows the results. The comparison of BERT and BERTCNN highlights the importance of not truncating longer inputs. The comparison of the proposed model (BERTCNN) with their binary variants helps in understanding the trade-off between parameter efficiency and performance. The average AUROC of all the models are comparable, with BERTCNN-Multi performing 4% better than BERT-Multi. The multitask BERT and BERTCNN models match the performance of their binary alternative with six times fewer parameters. When sufficient positive samples are present for a risk factor (eg, abreflex), all the models perform comparably with a low SD. When the samples are insufficient (eg, “infection” and “bowel”), the binary models have high SD (indicated by the error bars), as few-samples BERT fine-tuning is known to be unstable [27]. In such cases, the multitask models generally produce more stable results, with the BERTCNN-Multi performing 9% better than BERT-Multi. In general, the BERTCNN model can benefit from the extra context

found in the complete clinical note to improve prediction performance.

Figure 4. BERT-Multi, BERT-Binary, BERTCNN-Multi, and BERTCNN-Binary trained on the downsampled training data. The AUROC for each risk factor and their macroaverage are reported, with the SDs reflected in the error bars. AUROC: area under the receiver operating characteristic curve; BERT: Bidirectional Encoder Representations from Transformers; BERTCNN: Bidirectional Encoder Representations from Transformers–convolutional neural network.

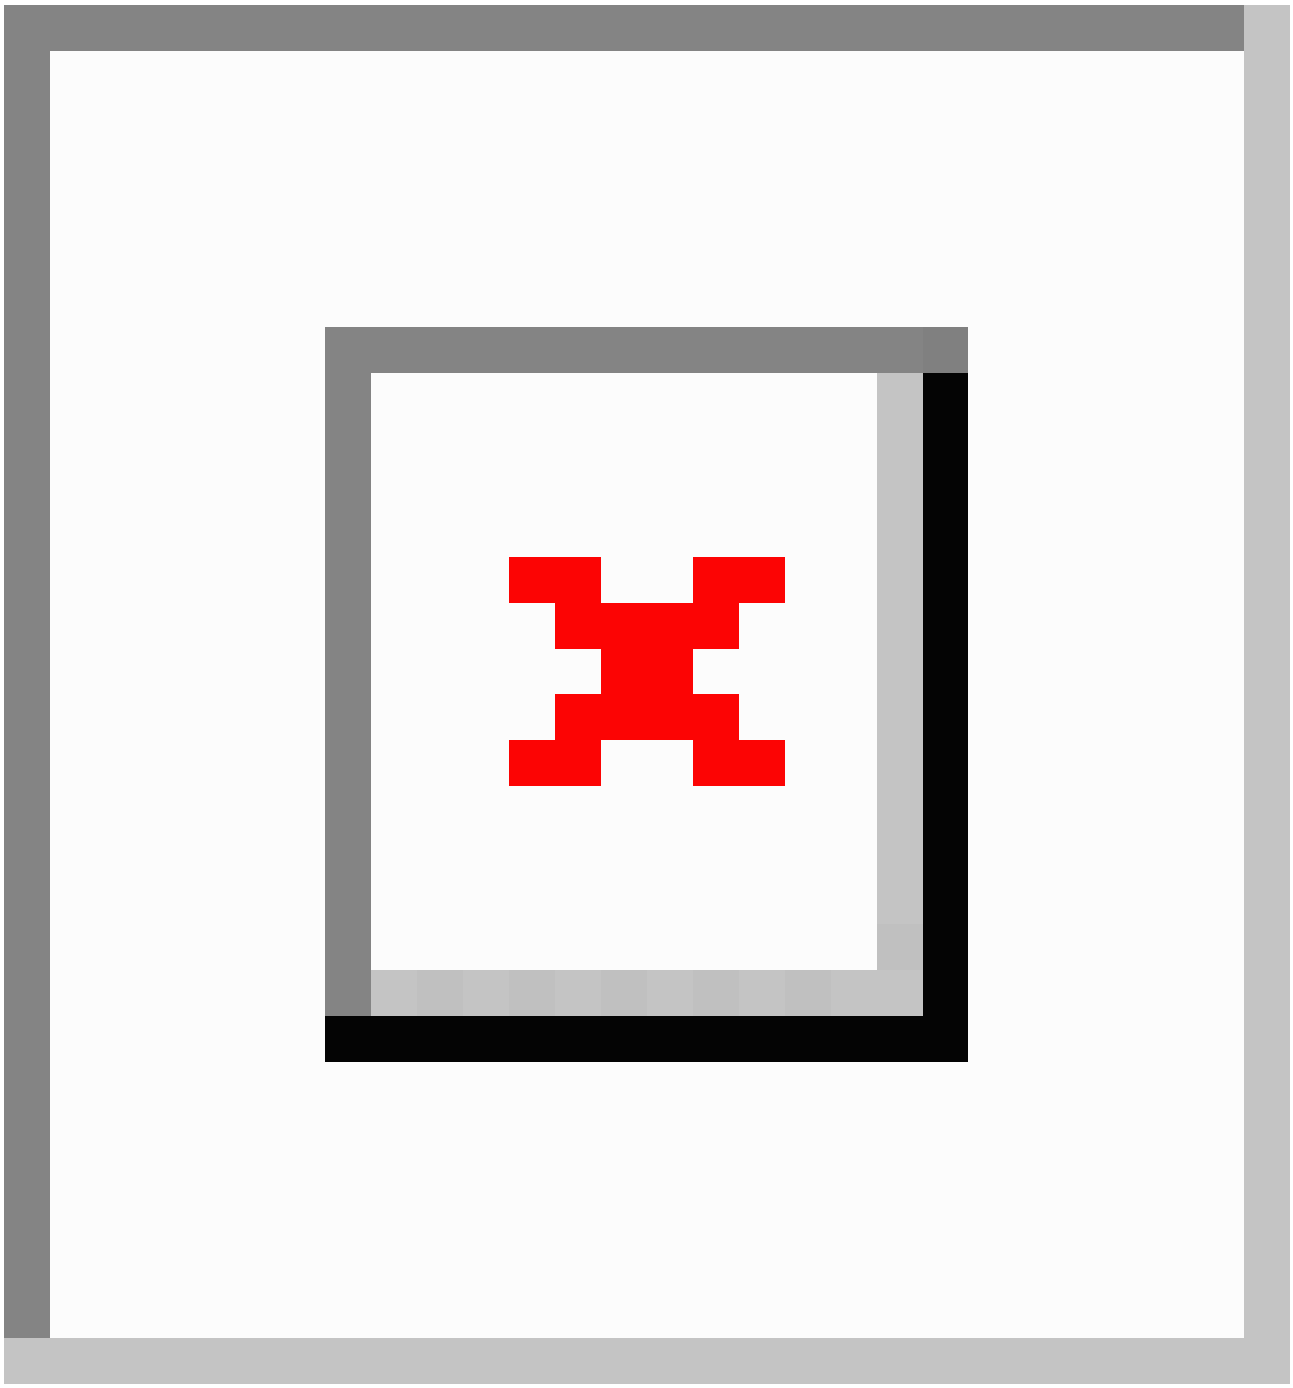


Performance With Domain Adaptation Using Unsupervised Training

The best-performing model can further benefit from pretraining [28] the underlying transformer model using the clinical notes. In this analysis, we investigate the effect of domain adaptation using pretraining on classification performance. We used BERTCNN and further pretrained the back-end model (BlueBERT [20]) with the complete corpus of relevant clinical notes (N=57,000) for 3 epochs. Two choices for pretraining the BERT architecture were considered: masked language modeling (MLM; BERTCNN-MLM-Multi) [12] and causal language modeling (CLM; BERTCNN-CLM-Multi) [29]. In addition, we also report results of the recent transformers-based model for long text in the clinical domain, called clinical-longformer [30,31], which was pretrained on clinical notes from the MIMIC-III data set [21]. Our results, shown in Figure 5, indicate that the MLM method performed 2% better than no domain adaptation and improved the performance for “cancer” by 5%. The longformer model further improves performance over MLM

by 2%. It is worth noting that while the performance improvement of domain adaptation using MLM [32] is not significant, it is comparable to that of the already pretrained BlueBERT [20] and clinical-longformer [30,31], which were pretrained on a much larger corpus of over 2 million notes.

Figure 5. Effect of domain adaptation using MLM, CLM, and comparison with the clinical-longformer model. The AUROC for each risk factor and their macroaverage are reported, with the SDs reflected in the error bars. AUROC: area under the receiver operating characteristic curve; BERTCNN: Bidirectional Encoder Representations from Transformers–convolutional neural network; CLM: causal language modeling; MLM: masked language modeling.



Discussion

The analysis of electronic clinical notes using machine learning techniques provides the opportunity to explore and evaluate clinical care, previously not possible when clinical experts had to read each clinical record. NLP of clinical records is still a relatively new research endeavor that is rapidly evolving. This study encountered and addressed several challenges that are likely to be common in the analysis of clinical notes. For example, the initially collected data were imbalanced, with most clinical notes having no risk factors for cancer, suggesting the need for further investigation of LBP. By sampling additional clinical notes from the unlabeled pool using unsupervised semantic matching techniques for a limited second round of labeling, we captured 7.5% more clinical notes with at least one risk factor. Strategic resampling can decrease bias in multi-label

data sets, which substantially helps in classification performance. The analysis comparing multitask learning and binary classification suggests we can match the performance of independent binary classifiers and produce more stable results while using a fraction of the learned parameters required for binary classifiers. This study demonstrates the value of domain adaptation as an additional technique to improve the classification results of transformer-based models and improve clinical free-text classification using unsupervised methods.

A strength of this study is the comparison of different models and approaches using a random sample of real clinical notes. We compared the BERT-based model, which does not truncate longer clinical notes and uses the complete context to make predictions, to the more commonly used truncated note model. The extensive empirical analysis on the impact of different modeling choices, including comparisons of multitask and single-task learning, resampling of data, and domain adaptation using unsupervised methods for the detection of LBP risk factors in clinical notes, provides guidance for future analysis of clinical text data.

While the low number of samples for certain risk factors in the test set is a limitation, this was addressed in reporting the AUROC for each individual risk factor, including their macroaverage for each model, and using the repeated k-fold cross-validation approach for better estimation of performance.

Future research will involve linking the outcomes of imaging studies to the identification of risk factors in this data set. It is anticipated that patients without risk factors would have normal imaging, while those with risk factors should be more likely to have abnormal imaging suggestive of disease requiring further treatment. Those analyses will need to address the imbalance in the data, as a minority of patients have undergone imaging.

Deep learning models, specifically BERT-based models, are suitable for capturing and detecting risk factors for LBP in clinical notes. Semantic matching techniques are effective during data collection in providing minority samples for labeling and improving data set distribution. The proposed method BERTCNN can be successfully applied for clinical notes that may be longer than the input limit of BERT-based models. Detecting risk factors in clinical notes is better formulated as multitask learning, which is more efficient and provides stable results. Furthermore, transformer-based models are successfully adopted for clinical text using transfer learning and MLM.

Acknowledgments

Abstract

Background: Management of abdominal aortic aneurysms (AAAs) requires serial imaging surveillance to evaluate the aneurysm dimension. Natural language processing (NLP) has been previously developed to retrospectively identify patients with AAA from electronic health records (EHRs). However, there are no reported studies that use NLP to identify patients with AAA in near real-time from radiology reports.

Objective: This study aims to develop and validate a rule-based NLP algorithm for near real-time automatic extraction of AAA diagnosis from radiology reports for case identification.

Methods: The AAA-NLP algorithm was developed and deployed to an EHR big data infrastructure for near real-time processing of radiology reports from May 1, 2019, to September 2020. NLP extracted named entities for AAA case identification and classified subjects as cases and controls. The reference standard to assess algorithm performance was a manual review of processed radiology reports by trained physicians following standardized criteria. Reviewers were blinded to the diagnosis of each subject. The AAA-NLP algorithm was refined in 3 successive iterations. For each iteration, the AAA-NLP algorithm was modified based on performance compared to the reference standard.

Results: A total of 360 reports were reviewed, of which 120 radiology reports were randomly selected for each iteration. At each iteration, the AAA-NLP algorithm performance improved. The algorithm identified AAA cases in near real-time with high positive predictive value (0.98), sensitivity (0.95), specificity (0.98), F1 score (0.97), and accuracy (0.97).

Conclusions: Implementation of NLP for accurate identification of AAA cases from radiology reports with high performance in near real time is feasible. This NLP technique will support automated input for patient care and clinical decision support tools for the management of patients with AAA.

Introduction

Worldwide prevalence rates of abdominal aortic aneurysms (AAAs) range from 1.6% to 3.3% for men older than 60 years [1]. Assessment of AAA may be performed by a variety of imaging tests, including ultrasound (US), computerized tomography (CT), and magnetic resonance imaging (MRI). In the United States, the prevalence of AAA has been reported as 2.8% among 9457 individuals screened by US [2]. Moreover, screening for early identification decreases the risk of aneurysm-related death and morbidity [1,3]. A prior study has shown that 4.5 ruptured AAA per 10,000 person-years were likely to have been prevented by screening, with an estimated 54 life-years gained per year of screening in a population of 23,000 men at risk [4].

The interpretation of imaging examinations is routinely reported in radiology reports as narrative text in electronic health records (EHRs) [5]. The automated extraction of information from narrative text can be accomplished by natural language processing (NLP) [6-8]. Prior studies have demonstrated high accuracy, sensitivity, specificity, and positive predictive value (PPV) of NLP for extraction of clinical concepts from narrative text in radiology reports [9-12]. Moreover, NLP is useful in cohort ascertainment for epidemiologic studies, query-based case retrieval, clinical decision support (CDS), quality assessment of radiologic practices, and diagnostic surveillance [5].

A previous retrospective cohort study from our institution developed a rule-based NLP algorithm for retrospective retrieval of AAA cases from radiology reports, which performed with high accuracy [12]. However, to the best of our knowledge, no prior study has demonstrated the use of NLP to identify AAA cases from radiology reports processed in near real-time. Hence, we tested the hypothesis that a rule-based NLP algorithm will extract AAA diagnosis from radiology reports in near real-time with high accuracy.

Methods

Study Settings

This study used Mayo Clinic radiology reports from May 1, 2019, to September 30, 2020.

Study Design

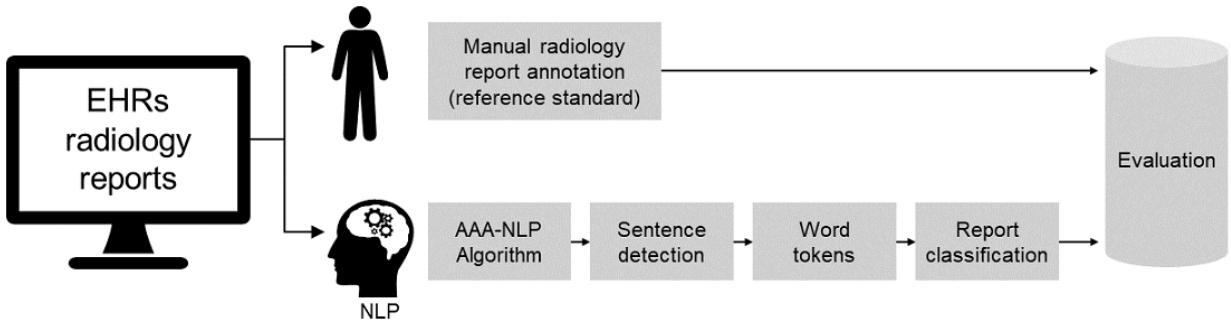
A rule-based AAA-NLP algorithm was developed for information extraction of AAA diagnosis automatically from radiology reports, including CT abdomen pelvis without intravenous (IV) contrast, CT chest abdomen pelvis angiogram with IV contrast, US abdomen complete, US aorta iliac arteries bilateral with doppler, MRI abdomen with and without IV contrast, and MRI pelvis with and without IV contrast. The rule-based NLP algorithm was developed using MedTagger and deployed in the institutional near real-time big data infrastructure to process relevant radiology reports. MedTagger is an open-source NLP tool that has been previously used in various clinical NLP applications [13]. MedTagger enables section identification, extraction of concepts, sentences, and word tokenization [14,15]. The AAA-NLP algorithm had 2 main components composed of text processing and report classification. AAA-relevant concepts were used to classify all reports (Figure 1).

A custom lexicon for AAA was identified by the study team through a manual review of radiology reports. Subsequently, this lexicon was mapped to corresponding concepts and their synonyms in the Unified Medical Language System Metathesaurus. The lexicon used for AAA identification included aorta abdominal aneurysm, aortic aneurysm abdominal, AAA, aneurysm abdominal aorta, and infrarenal aortic aneurysm. Each radiology report was then processed in near real-time by NLP. The AAA-NLP algorithm extracted both the lexicon and the contextual information of assertions, including negations or confirmations, from each radiology report. Textbox 1 displays the rules used by the NLP algorithm. The AAA-NLP algorithm classified subjects as AAA cases and controls without AAA.

To enable validation, the NLP output generated by near real-time processing of radiology reports was retrieved from the digital infrastructure by the information technology team and converted to a human-readable format for annotation. This annotation was performed by 2 trained physicians following written guidelines for standardization. The annotators were blinded to the diagnosis of each subject and to the results of the other annotator. In the written guidelines, AAA was defined as an aortic aneurysm diameter ≥3 cm by imaging as recommended by clinical practice guidelines [16].

The annotators reviewed the output from 120 processed radiology reports in 3 different training sets for iterative validation cycles to refine the algorithm. A total of 360 reports were reviewed. After abstracting and classifying the radiology reports, the information was entered and stored in a digital data set. Reports with a diagnosis of AAA were categorized as “case”; if there was no evidence of AAA or if an alternate diagnosis other than AAA was reported, the report was categorized as “control.” A board-certified cardiologist verified the information and resolved discrepancies in patient classification.

Figure 1. Study design. AAA: abdominal aortic aneurysm; EHR: electronic health record; NLP: natural language processing.



Textbox 1. Abdominal aortic aneurysm (AAA)–natural language processing rule and examples of text span.

Rule (any token + keyword for AAA + any token)

Examples of confirmatory assertions

- Suprarenal *aortic abdominal aneurysm* which measures up to 5.2 cm
- Fusiform *infrarenal abdominal aortic aneurysm* terminating proximal to the aortobiiliac bifurcation, 56 mm, previously 56 mm
- There is a 5.7×5.1 cm *infrarenal aortic aneurysm* measured on image 175 of series 4

Examples of negated assertions

- *Negative* for *abdominal aortic aneurysm* or dissection
- *Abdominal aortic aneurysm* is *absent*
- *Negative* for thoracic or *abdominal aortic aneurysm*, dissection, penetrating atherosclerotic ulcer or intramural hematoma

Statistical Analysis

The information extracted by the AAA-NLP algorithm from radiology reports in near real-time was compared to the reference standard manual review of radiology reports following written guidelines for standardization to calculate PPV, sensitivity, specificity, and F1 score. The formula to calculate F1 score was given as follows: 2 × ((PPV×sensitivity) / (PPV+sensitivity)) [5].

Ethics Approval

This project was approved by the Mayo Clinic Institutional Review Board (approval number 21-006950).

Results

Reports of 295 patients were validated in 3 different iterations. The data set for each iteration contained 120 reports, but 46 (16%) patients had more than one report. The reasons for more than one report for the same patient were imaging tests performed before and after repair procedures or surveillance for serial assessment of AAA (Table 1). There were no discrepancies regarding AAA diagnosis between 2 or more imaging reports from the same patient. Table 1 shows the distribution of demographic characteristics across AAA cases and controls. Cases and controls had similar ages in each of the iterative validation cycles, and most patients were Caucasian. AAA cases were more likely to have a history of smoking.

For evaluation of the AAA-NLP algorithm performance, 120 processed reports from each iteration were randomly selected. A total of 360 processed reports were reviewed by 2 physicians blinded to AAA diagnosis. There was 100% agreement for interactions 1 and 3. For interaction 2, the annotators disagreed on 1 report yielding a kappa coefficient of 92%. The disagreement was resolved by a board-certified cardiologist, creating the reference standard for comparison. The number of reports classified by the reference standard as true positives, false positives, true negatives, and false negatives in each iteration is shown in Table 2.

Table 1. Clinical characteristics and radiology report information.

Characteristic	Iteration 1		Iteration 2		Iteration 3	
	Case (n=31)	Control (n=52)	Case (n=44)	Control (n=59)	Case (n=59)	Control (n=50)

[b]PAD: peripheral artery disease.

[c]CAD: coronary artery disease.

[d]AAA: abdominal aortic aneurysm.

[e]N/A: not applicable.

Table 2. Classification of abdominal aortic aneurysm from radiology reports during iterative validation.

	Iteration 1			Iteration 2			Iteration 3		
	Predicted case	Predicted control	Total	Predicted case	Predicted control	Total	Predicted case	Predicted control	Total
Actual case	TP[a] 59	FN[b] 6	65	TP 56	FN 2	58	TP 59	FN 3	62
Actual control	FP[c] 1	TN[d] 54	55	FP 4	TN 58	62	FP 1	TN 57	58
Total	60	60	120	60	60	120	60	60	120

[a]TP: true positive.

[b]FN: false negative.

[c]FP: false positive.

[d]TN: true negative.

Radiology reports are composed of multiple sections. Figure 2 shows an example of a deidentified radiology report with all sections.

During the first iteration implementation, section ID number was used and section detection was challenging. For the second iteration, the algorithm was revised to include section header names for the filter criteria and solve sentence boundary issues. For the third iteration, section detection was implemented based on section names from our complete corpus using the frequency of normalized text with the tool lexical variant generation of the National Library of Medicine [17]. In a separate experiment, 203 additional radiology reports were reviewed by the annotators for evaluation of report section extraction, which resulted in accuracy of 0.96.

During this iterative refinement process, the report sections termed “reason for exam,” “referral diagnosis,” “exam type,” and “signed by” (Figure 2) were excluded, resulting in enhanced NLP algorithm performance. The report sections selected for processing were findings and impressions. During each iteration, the algorithm performance further improved. The performance metrics of the iterations are summarized in Table 3.

During the last iteration, 3 false negatives and 1 false positive contributed to the error analysis. False negatives were due to the complex nature of narrative text in these reports (ie, *no* significant interval changes in appearances of a partially

thrombosed infrarenal AAA measuring 42×40 mm, extending to the level of aortic bifurcation and proximal common iliac arteries; *no* signs of rupture or impending rupture of the known infrarenal AAA; and *no* slightly increased size of fusiform infrarenal AAA). Additionally, the false positive was due to a typographical error, which was the report of a patient with an aorta diameter of 2.7 cm labeled as AAA, which does not meet the criteria for AAA (≥3.0 cm).

Figure 2. Example of deidentified radiology report with all sections. In this figure, section names are displayed in blue font. AAA: abdominal aortic aneurysm.

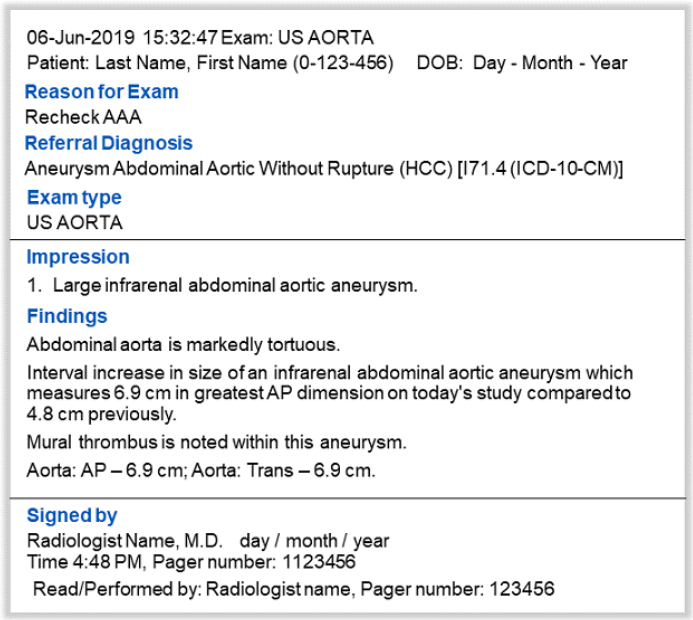

Table 3. Algorithm performance of each iteration.

Performance metric	Iteration 1 (n=120)	Iteration 2 (n=120)	Iteration 3 (n=120)
Sensitivity	0.91	0.97	0.95
PPV[a]	0.98	0.93	0.98
Specificity	0.98	0.94	0.98
F1 score	0.94	0.95	0.97
Accuracy	0.94	0.95	0.97

[a]PPV: positive predictive value.

Discussion

Overview

In this study, a novel rule-based NLP algorithm was developed for the extraction of AAA diagnosis from radiology reports and prospectively deployed in the institutional big data infrastructure for near real-time processing. Compared to the reference standard of manual review of radiology reports, the AAA-NLP algorithm extracted AAA diagnosis in near real time with high sensitivity, PPV, F1 score, specificity, and accuracy.

To the best of our knowledge, this study is the first to describe the use of NLP algorithms prospectively to extract AAA diagnosis in near real time from radiology reports. Clinicians, information technologists, and informaticians collaborated to refine the algorithm to improve performance. In previous studies, billing codes were used to find AAA cases [18,19]. However, in those studies, the cohorts were limited to patients with AAA who underwent procedures for aneurysm repair or had a history of ruptured AAA [18,19]. No prior studies using billing codes algorithms retrieved a broader spectrum of AAA diagnosis while also including patients presenting with uncomplicated AAA (ie, patients who did not undergo prior repair or who had not previously presented with ruptured AAA). In contrast, in this study, NLP automatically extracted AAA diagnosis from radiology reports prospectively and regardless of prior repair or rupture, thereby expanding the scope of computational approaches to include the detection of AAA cases prior to rupture or repair.

A radiology report consists of free text, organized into standard sections [5]. The American College of Radiology has published guidelines with recommendations for the use of sections for narrative (free text) entry in radiology reports [20]. NLP techniques enable the automatic extraction of information from narrative text [6-8]. Moreover, information extracted by NLP can be used to populate CDS systems automatically without the need for manual data entry and be better aligned with existing workflows such that radiologists can spend time interpreting images rather than filling out forms.

NLP is a computational methodology used for electronic phenotyping to extract meaningful clinical information from text fields [6,7,21]. In this study, we used NLP to process radiology text reports. The previous NLP algorithm used to find cases of AAA from radiology reports [12] was designed for retrospective cohort identification, whereas this report describes the prospective implementation of an NLP algorithm for input to a patient-specific CDS system for near real-time processing of radiology reports. Near real-time processing requires <3 milliseconds to process a document after a radiologist releases a report to the EHR [22]. The AAA-NLP implementation described in this study was developed within the existing digital infrastructure and can be used in clinical practice immediately without the need to retrain the algorithm. Additionally, the previously described algorithm [12] did not identify document sections in the radiology reports. By selecting specific sections for NLP information extraction, improvement in NLP performance was observed, as shown in the Results section. In the future, transformer-based NLP models [23,24] may be trained to interpret nuanced language, and ablation experiments [25] could be used to further evaluate these models.

The use of NLP algorithms has advantages compared to other methods. In comparison, the use of check box forms in radiology reports may require the development of new workflows [26,27]. The use of check box forms also requires the radiologist to direct attention away from the imaging interpretation process [26,27]. Manual entry of summaries of radiology findings in a check box can increase reporting time with decreased radiologist productivity [26,27]. Check box use could also result in the loss of important and clinically relevant descriptive information available only in the radiology narrative reports.

The rule-based AAA-NLP algorithm described in this study shows accurate detection of a broad spectrum of AAA cases prospectively in near real time from radiology reports, regardless of the presence of prior rupture or repair. This methodology will also potentially generate input for CDS to assist providers in managing patients with AAA by displaying the relevant information automatically at the point of care and in near real time for CDS tools. It will also support the automatic identification of cohorts for research purposes (eg, cohorts for clinical trials) and quality projects, and will support a learning health care system. NLP has been previously used for the identification of peripheral arterial disease and critical limb ischemia from narrative clinical notes of EHRs [21,28]. Therefore, it will also be possible to develop NLP algorithms for the identification of AAA cases from clinical notes in near real time.

In efforts to develop a learning health care system, Mayo Clinic has developed a robust big data–empowered clinical NLP infrastructure that enables near real-time NLP processing for the delivery of relevant information to the point of care via CDS [22]. Accordingly, we have deployed the AAA-NLP algorithm described herein to this digital infrastructure for translation to clinical practice. Importantly, the near real-time identification of patients with AAA by NLP responds to the American Heart Association scientific statement, which recommends the implementation of technologies to extract clinical information in real time that will promptly provide synopses of the information extracted [29].

Limitations

This NLP algorithm was developed, tested, and implemented in a single tertiary medical center. Future studies should evaluate this algorithm at other institutions to demonstrate portability. A robust institutional digital infrastructure is required for the execution of near real-time processing of radiology reports [22]. Hence, the absence of adequate digital infrastructure may limit porting of this algorithm. For implementation, the analysis of radiology report architecture to enable the selection of document types and document sections may also be necessary for portability. Another potential challenge for porting this algorithm to other EHRs is differences in lexicons used for the extraction of the AAA concept across institutions. In mitigation, for this NLP algorithm, each lexicon was mapped to corresponding concepts and synonyms in the publicly available Unified Medical Language System Metathesaurus for standardization.

The algorithm was developed for the extraction of AAA diagnosis but not for the extraction of iliac artery or thoracic aortic aneurysms. Future studies should create and validate NLP algorithms for the extraction of thoracic and iliac artery aneurysms. The clinical criteria for AAA diagnosis involve a minimum diameter, but this NLP algorithm did not interpret the reported diameter. This is an area for future improvement in the algorithm, as clinical criteria for AAA may change over time. In this study, most patients were Caucasian. This was likely related to the ethnic distribution of communities in the Midwest, where this study was conducted [30,31]. Additionally, prior studies have reported a higher prevalence of AAA among Caucasians compared to other races [31,32]. There were differences in comorbidities of patients included in the 3 iterations. However, the NLP was developed for the extraction of the diagnosis of AAA and not developed for the extraction of associated patient comorbidities. The differences in patient comorbidities did not influence NLP performance for the extraction of AAA from radiology reports.

Conclusions

Implementation of NLP for prospective identification of AAA cases from radiology reports in near real time with high performance is feasible. This near real-time NLP technique described will potentially be helpful for the generation of automated input for CDS tools to assist clinicians in the management of patients with AAA, quality improvement projects, and research (automated identification of cohorts).

Abstract

Background: Negation and speculation unrelated to abnormal findings can lead to false-positive alarms for automatic radiology report highlighting or flagging by laboratory information systems.

Objective: This internal validation study evaluated the performance of natural language processing methods (NegEx, NegBio, NegBERT, and transformers).

Methods: We annotated all negative and speculative statements unrelated to abnormal findings in reports. In experiment 1, we fine-tuned several transformer models (ALBERT [A Lite Bidirectional Encoder Representations from Transformers], BERT [Bidirectional Encoder Representations from Transformers], DeBERTa [Decoding-Enhanced BERT With Disentangled Attention], DistilBERT [Distilled version of BERT], ELECTRA [Efficiently Learning an Encoder That Classifies Token Replacements Accurately], ERNIE [Enhanced Representation through Knowledge Integration], RoBERTa [Robustly Optimized BERT Pretraining Approach], SpanBERT, and XLNet) and compared their performance using precision, recall, accuracy, and F_1-scores. In experiment 2, we compared the best model from experiment 1 with 3 established negation and speculation-detection algorithms (NegEx, NegBio, and NegBERT).

Results: Our study collected 6000 radiology reports from 3 branches of the Chi Mei Hospital, covering multiple imaging modalities and body parts. A total of 15.01% (105,755/704,512) of words and 39.45% (4529/11,480) of important diagnostic keywords occurred in negative or speculative statements unrelated to abnormal findings. In experiment 1, all models achieved an accuracy of >0.98 and F_1-score of >0.90 on the test data set. ALBERT exhibited the best performance (accuracy=0.991; F_1-score=0.958). In experiment 2, ALBERT outperformed the optimized NegEx, NegBio, and NegBERT methods in terms of overall performance (accuracy=0.996; F_1-score=0.991), in the prediction of whether diagnostic keywords occur in speculative statements unrelated to abnormal findings, and in the improvement of the performance of keyword extraction (accuracy=0.996; F_1-score=0.997).

Conclusions: The ALBERT deep learning method showed the best performance. Our results represent a significant advancement in the clinical applications of computer-aided notification systems.

Introduction

Background

Timely and effective communication of test results is essential in modern medicine. To promptly address patients' problems, hospitals must ensure that the test results are completed without delay and that clinicians are aware of substantial abnormal findings. Delayed or failed communication of important findings by the department performing the test and the clinical team can increase the risk of adverse patient events and result in medical malpractice and compensation, especially for potentially life-threatening and important diagnoses [1].

Although radiology reports are the primary method of communication between radiology and clinical departments, the fact that a radiologist produces a report does not necessarily mean that the clinician reads it entirely. Ignácio et al [2] showed that only 55.7% of clinicians read the entire report thoroughly. Reda et al [3] showed that >40% of clinicians read only the conclusions or only read the conclusions in detail. More than 30% of clinicians have made preventable medical errors because they did not read radiology reports carefully. Even if the radiologist has made the correct diagnosis in the report, the clinician may still miss it.

To address these communication issues, current radiology guidelines [4] now require radiologists to go beyond report completion and use additional communication methods for reports with significant findings, including flagging or alerting the report, e-mailing, or direct verbal communication via telephone. Natural language processing can also automatically extract data from radiology reports, for example, automatically extracting important diagnoses, follow-up data, or management recommendations or automatically identifying reports that require specific action [5]. These methods can help to identify important information in radiology reports or reports that need to be read in detail to alert clinicians.

In addition, the laboratory information system (LIS) used in hospitals today can automatically highlight abnormalities found in tests and display them differently to ensure that clinicians do not miss important findings, such as using different colors or special symbols [6]. For example, in our hospital, if a patient has undergone a routine blood test and some of the blood cell counts are abnormal, the LIS will automatically display the results on the computer screen in a unique color for the abnormal values and a typical color for the others. The LIS also displays important keywords (eg, nodules) within radiology reports in different colors.

However, because most radiology reports are freely typed by radiologists in an unstructured manner, both techniques encounter challenges. Negative and speculative statements are significant problems.

Radiologists can use negative statements to communicate the absence of specific diagnoses and provide a clearer picture of the patient's condition. For example, the statement "No definite CT evidence of aortic dissection" informs the clinician that the patient's condition is not related to aortic dissection.

The diagnoses in the speculative statements may or may not be related to the actual abnormal findings. The radiology report may contain speculative statements in the presence of an imaging finding of uncertain significance that requires further investigation, for example, "RUL lung nodule. Lung cancer should be suspected." In such cases, the diagnoses (lung cancer) in the speculative statements are related to abnormal findings. Even if the radiologist finds no problems with the study, the radiology report may still contain speculative statements to prevent potential medicolegal issues. Disclaimer (eg, "10%-15% of cases of breast cancer are missed on mammograms" [7]) or statement of limitations (eg, "non-enhanced images, small lesion may be obscured") are common examples. In such cases, the diagnoses (breast cancer or lesion) in the speculative statements are unrelated to the actual diagnoses.

A notification system that does not distinguish whether diagnostic Information is contained in negative or speculative statements unrelated to abnormal findings and annotates or extracts all of them to "alert" the clinician may generate excessive false alarms. Excessive false alarms can overload the clinician's senses and lead to the "cry wolf" phenomenon, causing alarm fatigue. Consequently, clinicians may delay detection or even ignore truly valuable alerts, posing a risk to patients, especially if the percentage of false alarms is high [8].

This study aimed to address the potential analytical inaccuracies resulting from negative and speculative statements in radiology reports and to facilitate the use of unstructured reports by hospital information systems.

Prior Work

Current studies have adopted various approaches to detect negation and speculation, including rule-based, machine learning–based, and deep learning–based approaches [9-17].

The rule-based approach relies on experts to define the rules that are understandable to humans. NegEx, proposed by Chapman et al [18]; NegFinder, proposed by Mutalik et al [19]; NegHunter, proposed by Gindl et al [20]; and NegExpander, proposed by Aronow et al [21], are regular expression-based approaches. Regular expression-based methods have limitations, such as the inability to capture the syntactic structure and the possibility of misinterpreting the scope of the negative and speculative statements. For example, "No change of tumor" may be misinterpreted as both "No change" and "No tumor."

Methods such as DEEPEN (Dependency Parser Negation), proposed by Mehrabi et al [22], and NegBio, proposed by Peng et al [23], analyze the syntactic structure based on grammar. These methods are more accurate than regular expression-based approaches in limiting the scope of negative and speculative statements and reducing false positives because these methods consider the dependency relationship between words. However,

these methods have certain limitations. For example, errors in the analysis may occur if the grammar of the text deviates from typical norms, such as the presence of long noun phrases [23]. When analyzing text, most of these methods [18-20,22,23] split the text into sentences that are analyzed independently. The algorithms and expert-defined rules only consider a single sentence at once and do not consider both the preceding and following contexts.

With the advancement of artificial intelligence, machine learning techniques have been applied to detect negation and speculation. For example, Medlock et al [24] proposed a weakly supervised learning–based approach to predict the labels of training samples for machine learning training and used the trained models to detect speculation in biomedical texts. Rokach et al [25] compared several machine learning approaches, including the Hidden Markov Model, Conditional Random Field (CRF), decision tree, and AdaBoost, cascaded decision tree classifiers with and without the Longest Common Sequence. They found that the cascaded decision tree with the Longest Common Sequence performed best. Morante et al proposed k-nearest neighbor algorithm–based [26] and meta-learning–based approaches [27]. Ou et al [28] compared rule-based and support vector machine–based machine learning methods and obtained better performance of machine learning methods.

Later studies began investigating deep learning–based approaches and achieved better results than previous non–deep learning approaches. Qian et al [17] were the first to propose a deep learning method for negation and speculation detection using a convolutional neural network–based model by using the relative position of tokens and path features from syntactic trees as features.

By contrast, recurrent neural networks and their derivatives, such as Long Short-Term Memory (LSTM), are suitable for processing sequential data. These architectures can incorporate dependencies on preceding and following elements, making them particularly useful for natural language processing tasks, and have achieved good results in recognizing negations and speculations. For example, in a study by Fancellu et al [14], a Bidirectional LSTM (BiLSTM)–based model was applied, and it demonstrated better performance than other methods on the Sherlock data set. Lazib et al [9] compared methods, including LSTM, BiLSTM, Gated Recurrent Unit, and CRF, and showed that the recurrent neural network–based architecture performed the best. Gautam et al [15] compared several LSTM-based models and obtained the best performance using 2-layer encoders and decoders with dropouts. Taylor et al [10] applied the BiLSTM-based model to the analysis of negation in electroencephalography reports. Sergeeva et al [11] proposed an LSTM-based approach and investigated the effect of expert-provided negation cues on the detection performance of the negation scopes. Sykes et al [12] compared the methods based on BiLSTM and feedforward neural networks and rule-based methods, including pyConText, NegBio, and EdIE-R, for negation detection in radiology reports. The BiLSTM-based approach outperformed other approaches.

BERT (Bidirectional Encoder Representations from Transformers) [29], proposed by Google in 2018, is a pretrained, transformer-based model that is effective for negation detection. Khandelwal et al [16] developed NegBERT and, in another study [13], used a multitasking approach with BERT, XLNet, and RoBERTa (Robustly Optimized BERT Pretraining Approach) for negation and speculation detection, with improved results on BioScope and Simon Fraser University review data sets compared with the control methods. Zavala et al [30] proposed a system based on BiLSTM with CRF and fine-tuned BERT; evaluated the methods on English and Spanish clinical, biomedical, and review text; and showed improved performance compared with previous methods. They also found that pretrained word embedding, especially contextualized embedding, helped to understand the biomedical text.

Numerous variants of BERT have been developed to improve performance and simplify the model. ALBERT (A Lite BERT) [31] reduces the model parameters and improves the performance through parameter sharing and matrix decomposition. DistilBERT (Distilled version of BERT) [32] uses knowledge distillation to reduce the size and improve the inference speed while retaining most of the language understanding. XLNet [33] implements autoregressive training while preserving the advantages of autoencoding models and outperforms BERT on 20 tasks. RoBERTa [34] improves the training method to outperform BERT and XLNet. ERNIE (Enhanced Representation through Knowledge Integration) [35] uses an alternative masking method to outperform BERT in Chinese tasks. SpanBERT [36] extends BERT with span-based masking and an additional training objective, resulting in a better performance on span-based tasks. DeBERTa (Decoding-Enhanced BERT With Disentangled Attention) [37] improves BERT and RoBERTa with decoupled attention, improved mask encoder, and virtual adversarial training and outperforms RoBERTa-Large on the Multigenre Natural Language Inference, Stanford Question Answering Data set, and Reading Comprehension data set from examinations tasks and humans on the SuperGLUE task. ELECTRA (Efficiently Learning an Encoder That Classifies Token Replacements Accurately) [38] outperforms BERT with a new pretraining task, Replaced Token Detection, and performs similarly to RoBERTa and XLNet with one-fourth the computation.

Contribution of This Work

This study has implications for optimizing the performance of hospital information systems in managing unstructured electronic medical records. The key findings and results of this study are as follows.

First, we found that fine-tuned general-purpose transformer models could outperform NegEx, NegBio, and NegBERT, which are explicitly designed for negation and speculation detection. We identified sources of error in the latter 3 methods and suggested potential improvements.

Second, we found that transformer, unlike NegEx and NegBio, demonstrated the ability to perform multisentence contextual analysis and further granular classification of speculative statements as related or unrelated to abnormal findings. This capability can improve information filtering in hospital information systems to eliminate nondiagnostically relevant information.

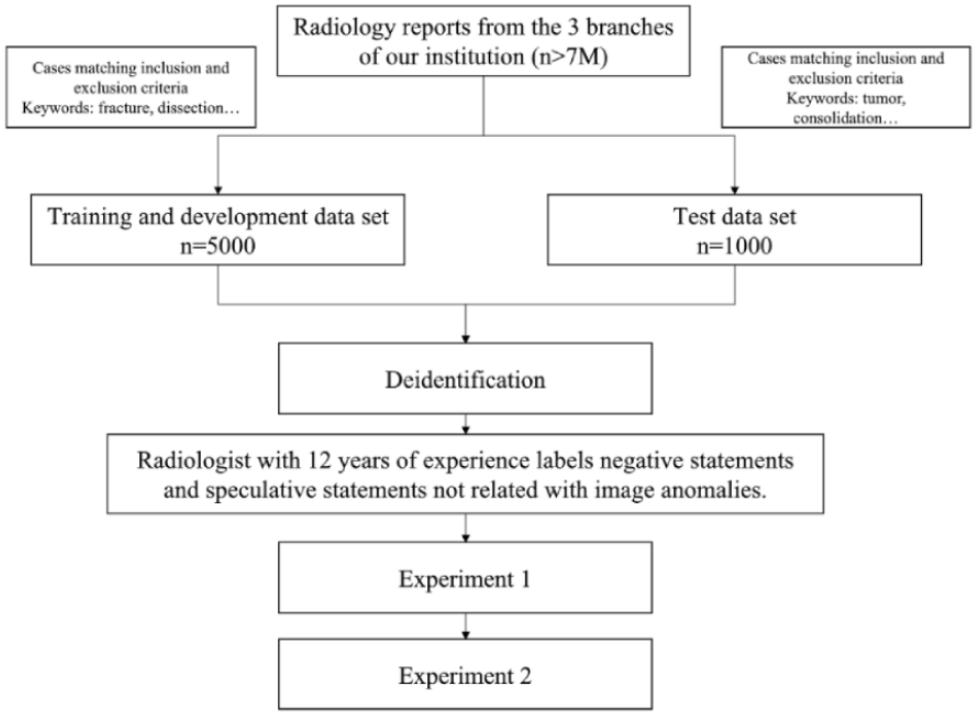
Finally, in contrast to other studies using BERT [16,39], we found that using a lightweight transformer model and learning the cues and scopes of negative and speculative sentences in a single step can perform well.

Methods

Ethics Approval

The Chi Mei Hospital Institutional Review Board reviewed and approved this study (11105-J02). This study is a retrospective analysis study using deidentified electronic medical records, thus obviating the requirement for obtaining informed consent from the individuals. Figure 1 shows the flow diagram of the study.

Figure 1. Research flow. n: number of reports.



Inclusion and Exclusion Criteria

The inclusion criteria for this study were radiological examinations performed in the 3 branches of our institution between 2012 and 2022, with the reports being written in English language and the type of examination being x-ray, special radiology, computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound. We included cases that met all criteria. The exclusion criteria were Chinese reports and patients aged <20 years at the time of examination. We excluded cases that met any of the exclusion criteria. Samples were collected using 2 independent keyword searches in a search engine targeting radiology reports that met the inclusion criteria but not the exclusion criteria.

Data

Overview

The training and development data set consisted of 5000 radiology reports randomly selected from a keyword search using the terms “fracture,” “dissection,” “infarct,” “pneumothorax,” “extravasation,” “thrombosis,” or “pneumoperitoneum.” The test data set consisted of 1000 reports selected from a keyword search using the terms “tumor,” “consolidation,” “pulmonary TB,” “metastasis,” or “bleeding.” Keywords were selected from our institution’s list of important keywords and randomly assigned to the data sets. These keywords are referred to as “important keywords” in the study. The samples in the training and development and test data sets were mutually exclusive with no overlap.

The training and development data set was automatically partitioned into training and development data sets in a 9:1 ratio for model training. The training, development, and test data sets ratio was 9:1:2, with 4500, 500, and 1000 radiology reports, respectively.

In this study, each word or token was assigned to one of the 2 categories, as shown in Table 1: “Positive statements, or speculative statements potentially related to abnormal findings” (category 0) and “negative statements, or speculative statements not related to abnormal findings” (category 1). We combined speculative statements unrelated to abnormal findings with negative statements as a single class because of their limited representation. The rationale for category 1 is that the information conveyed is not relevant to abnormal findings and should not trigger highlights or alerts. A token is the minimum output unit of the transformer-based model’s tokenizer.

All radiology reports included in the study were deidentified by removing identifying information such as medical record

number, application number, examination date, ordering department, and examination time. A radiologist with 12 years of experience (KHW) reviewed the reports and annotated all negative and speculative statements unrelated to abnormal findings using the open-source Doccano [40] software. The annotation served as the gold standard for subsequent analysis.

Table 1. Classification of words and tokens in this study.

Type[a] and subtype	Example	Category[b]
Negative	Liver laceration at S6 *without active contrast extravasation*	1
Speculative		
Unrelated to abnormal findings	No CT[c] evidence of large infarct. *Suggest MRI[d] to exclude hyperacute infarct if indicated*	1
Potentially related to abnormal findings	*Rt[e] cerebellum acute infarct cannot be ruled out.*	0
Positive	*Rt cerebellum acute infarct*	0

[a]Type refers to the type of statement.

[b]Token category in the italicized text if italicization is used. All texts without italics were classified as category 0. Category 0: positive statements or speculative statements potentially related to abnormal findings. Category 1: negative statements or speculative statements not related to abnormal findings.

[c]CT: computed tomography.

[d]MRI: magnetic resonance imaging.

[e]Rt: right.

Included Negations

This study included all statements in which the radiologist explicitly denied a diagnosis or a finding. Our data included morphological negation and sentential negation, which are common forms of negative statements in English text [22]. Morphological negation involves using prefixes, such as “un-” or “ir-,” to modify certain words to express negation. Sentential negation involves using negative words, such as “no” or “without,” to negate part of the statement. In addition, radiologists at the authors’ hospital often use unique symbols or abbreviations, such as “(−)” or “[−].”

Included Speculations

In cases where the imaging study is inconclusive but there is still the possibility of a significant abnormality, the information system should notify the clinician and allow the clinician to make the final decision. Therefore, for the task of speculation detection, our focus was limited to speculative statements that were unrelated to abnormal findings. Meanwhile, we treated speculative statements that may correlate with actual abnormal findings as equivalent to positive statements.

After reviewing the samples, we identified 2 scenarios in which speculative statements could be confidently determined to be unrelated to abnormal findings. First, the radiologist explicitly stated that there was no relevant abnormality. Second, the radiologist stated that certain diagnoses could not be evaluated owing to study limitations. In all the other scenarios, speculative statements may be associated with abnormal findings.

In the following 3 examples, we classify the diagnoses or findings written in italics as speculative statements unrelated to abnormal findings. The actual test results were normal or unrelated to these diagnoses or findings.

1. No CT evidence of pulmonary embolism. Suggest V/Q scan to exclude *small branch embolism* if indicated.
2. No CT evidence of large infarct. Suggest MRI to exclude *hyperacute infarct* if indicated.
3. *Liver tumor* cannot be excluded by noncontrast CT.

In the following 2 examples, the diagnoses or findings written in italics are speculative statements considered potentially related to actual abnormal findings:

1. Equivocal filling defect in RLL segmental pulmonary artery. Suggest V/Q scan to exclude *small branch embolism* if indicated.
2. Rt cerebellum *acute infarct* cannot be ruled out.

Design of the Experiments

We conducted 2 experiments to evaluate the ability of general all-purpose pretrained deep learning models and existing negation and speculation-detection algorithms to identify negation and speculation in real-world radiology reports.

In experiment 1 (Figure 2), we fine-tuned several transformer-based models using our training and validation data sets. We performed token category prediction (category 0 or 1) for all tokens in the training, validation, and test data sets.

In experiment 2 (Figure 3), we compared 3 negation and speculation-detection algorithms that performed well on public data sets with the best model from experiment 1. The algorithms evaluated were NegEx, NegBio, which has predefined expert rules and open-source implementation, and NegBERT, whose training code is available. We then performed category prediction (category 0 or 1) for all words that matched a given “important keyword” in the test data set. We also analyzed the sources of errors. In addition, we compared the performance of keyword extraction in positive and speculative statements potentially related to abnormal findings before and after applying various algorithms.

Figure 2. Experiment 1. X: the original text, ŷ: class predicted by the model; y: the gold standard. Category 0: positive statements or speculative statements potentially related to abnormal findings; category 1: negative statements or speculative statements unrelated to abnormal findings. Figure 3. Experiment 2 Note. X: the original text; ŷ: class predicted by the model; y: the gold standard; category 0: positive statements or speculative statements potentially related to abnormal findings; category 1: negative statements or speculative statements unrelated to abnormal findings; bold text: word matching a designated “important keyword.” Exp: experiment.

Modeling in Experiments

The deep learning models used in experiment 1 were ALBERT, BERT, DeBERTa, DistilBERT, ELECTRA, ERNIE, RoBERTa, SpanBERT, and XLNet. All models were fine-tuned based on the pretrained models from Hugging Face.

We used early stopping and used the F_1-score as the model evaluation metric. We used the Adam optimizer with a batch size of 16 and weight decay of 0.01. Table 2 lists the parameters of other models. We set all other unspecified parameters to the default values provided by the open-source PyTorch framework. We segmented the texts into blocks of no more than 510 characters before entering the model to avoid truncation.

We adopted a sequence-to-sequence approach for the training. The training program input the report text in the training and development data set into the model using the corresponding tokenizer and trained the model. The models predicted the token categories using the radiologist-annotated data as the gold standard. The test data set was not included in the training process.

For the NegEx algorithm, we used the negspaCy pipeline component of the open-source Spacy software [41]. The specific named entity recognition model used was "en_ner_bc5cdr_md." In addition, we extended the recognizable entities in Spacy to include all the important keywords defined in our experiment.

We used the previously published training parameters of NegBERT, including a batch size of 8, maximum training epochs of 60, an initial learning rate of 3×10^{-5}, and an early stopping patience of 6. We applied NegBERT for cue detection using the model "bert-base-uncased" and scope detection using the model "xlnet-base-cased." Furthermore, we validated that the trained NegBERT showed a comparable level of performance to that reported in the original publication on the data set specified in the original study.

In addition to the configuration mentioned earlier, we made only minimal modifications to NegBio and NegBERT, such as specifying the dependent software versions, adding the necessary files to the installation, and configuring file paths to ensure the proper execution of the software.

In experiment 2, we optimized the performance of the NegEx, NegBio, and NegBERT methods. This optimization was achieved by modifying the expert-defined rules of NegEx and NegBio and using our training and development data set, as well as the negation and speculation cues we identified, to train NegBERT without using the data set from the original study.

Table 2. Deep learning model and training parameters used in this study.

Model	Learning rate	Warm-up steps	Adam beta1	Adam beta2	Adam epsilon	FP16[a]
ALBERT[b]	1×10^{-5}	10,000	0.9	0.999	1×10^{-8}	False
BERT[c]	1×10^{-4}	10,000	0.9	0.999	1×10^{-8}	False
DeBERTa[d]	1×10^{-4}	10,000	0.9	0.999	1×10^{-6}	True
DistilBERT[e]	2×10^{-5}	0	0.9	0.999	1×10^{-8}	False
ELECTRA[f]	1×10^{-4}	10,000	0.9	0.999	1×10^{-6}	False
ERNIE[g]	5×10^{-5}	4000	0.9	0.98	1×10^{-8}	False
RoBERTa[h]	1×10^{-4}	10,000	0.9	0.999	1×10^{-8}	False
SpanBERT	5×10^{-5}	10,000	0.9	0.999	1×10^{-8}	False
XLNet	2×10^{-5}	10,000	0.9	0.999	1×10^{-6}	False

Results

Demographics

The data set included in this study consisted of 6000 radiology reports, including plain radiography reports (2538/6000, 42.3%), CT reports (2163/6000, 36.05%), MRI reports (668/6000, 11.13%), ultrasound reports (483/6000, 8.05%), angiography reports (97/6000, 1.62%), and reports from other types of studies (51/6000, 0.85%). The report was completed by 78 radiology residents and their attending physicians. The training, validation and test data sets were mutually exclusive with no overlap in the samples.

The data set used in this study consisted of 78,901 sentences and 704,512 words. A total of 15.01% (105,755/704,512) of all

the words in the data set, were identified as negative and speculative statements unrelated to abnormal findings. Table 3 presents examples and frequencies of these statements. In this study, we defined a "word" as a contiguous sequence of one or more non–white space characters of maximum length. For example, "(−) metastasis" contains 2 words.

Of all the 16,374 cases of sentential negations identified, 15,568 (95.1%) used "no," "without," "not," or "none" as the first word of the negative statement. Furthermore, of all the 2763 cases of negation using symbols or abbreviations, we observed that 2411 (87.2%) used (−), (_), ( ), or [−] at the beginning, end, or middle of the negated clause.

Table 4 presents the frequency and number of occurrences of important keywords, as defined in this study, within negative or speculative statements unrelated to abnormal findings and the total number of occurrences in the study.

Table 3. Types and numbers of negative and the speculative sentences unrelated to abnormal findings included in this study (N=19,467).

Type	Example	Findings, n (%)
Sentential negation	• No evidence of aortic dissection	16,374 (84.11)
Symbols or abbreviations	• Metastasis (−) • Thrombosis: No • DM[a]- HTN[b]- • Anti-HCV[c] [Negative] • - lung - bone	2762 (14.19)
Speculative statements not related to abnormal findings	• No CT[d] evidence of pulmonary embolism. Suggest V/Q[e] scan to exclude small branch embolism if indicated • Metallic artifacts, lesion may be obscured	196 (1.01)
Morphological negation	• This coronary CT scan is nondiagnostic.	135 (0.69)

[a]DM: diabetes mellitus.

[b]HTN: hypertension.

[c]HCV: hepatitis C virus.

[d]CT: computed tomography.

[e]V/Q: ventilation and perfusion.

Table 4. Occurrence and frequency of important keywords defined in this study within negative or the speculative statements unrelated to abnormal findings.

Keywords and their overall occurrences (n=11,480)	Occurrences (N+S)[a], n (%)
Pneumothorax, n=1288 (11.22%)	976 (75.78)
Extravasation, n=182 (1.58%)	84 (46.2)
Fracture, n=2161 (18.82%)	992 (45.90)
Tumor, n=2698 (23.5%)	1025 (37.99)
Infarct, n=1364 (11.88%)	514 (37.68)
Consolidation, n=428 (3.73%)	152 (35.5)
Pneumoperitoneum, n=63 (0.55%)	19 (30)
Thrombosis, n=614 (5.35%)	143 (23.3)
Dissection, n=673 (5.86%)	147 (21.8)
Metastasis, n=1876 (16.34%)	450 (23.98)
Bleeding, n=118 (1.03%)	27 (22.9)
Pulmonary TB[b], n=15 (0.13%)	0 (0)

[a]Number of occurrences within negative or speculative statements unrelated to abnormal findings.

[b]TB: tuberculosis.

Result of Experiment 1

Table 5 presents the results of experiment 1. The accuracy of all transformer-based models included in this experiment was greater than 0.98 for both the training, validation, and test data sets, with macro F_1-scores >0.90. The best-performing model, ALBERT, was selected for inclusion in experiment 2.

Table 5. Comparison of deep learning prediction performance.

Result of Experiment 2

Before optimization, the performance of NegBio and NegBERT was suboptimal. The F_1-scores for NegEx, NegBio, and NegBERT were 0.889, 0.587, and 0.393, respectively. Our optimization significantly improved the performance of NegBio and NegBERT by increasing their F_1-scores by 0.239 and 0.588, respectively.

Table 6 shows the performance of ALBERT and optimized NegEx, NegBio, and NegBERT. The precision, recall, and F_1-score of our fine-tuned transformer-based model (ALBERT) were better than those of the optimized NegEx, NegBio, and NegBERT.

Table 7 shows the performance evaluation of keyword extraction before and after applying the different negation and speculation-detection algorithms. The ALBERT method resulted in the most significant performance improvement in extracting keywords from positive and speculative statements potentially associated with abnormal findings.

Table 6. Comparison of performance of A Lite Bidirectional Encoder Representations From Transformers (ALBERT) and optimized NegEx, NegBio, and NegBERT in the test data set.

	Precision	Recall	F_1	Accuracy
ALBERT	*0.991*[a]	*0.992*[a]	*0.991*[a]	*0.996*[a]
NegEx	0.886	0.958	0.921	0.959
NegBio	0.860	0.794	0.826	0.917
NegBERT	0.992	0.970	0.981	0.991

[a]Italics highlight that the performance of ALBERT is the best comparing to the control method (NegEx, NegBio, NegBERT) across various performance metrics.

Table 7. Comparison of the performance of keyword extraction in the test data set both before and after applying A Lite Bidirectional Encoder Representations From Transformers (ALBERT) and optimized NegEx, NegBio, and NegBERT.

	Precision	Recall	F_1	Accuracy
ALBERT	*0.998*[a]	*0.997*[a]	*0.997*[a]	*0.996*[a]

NegBio	0.934	0.958	0.945	0.917
NegBERT	0.99	0.998	0.994	0.991
Baseline[b]	0.752	1.00	0.859	0.752

[a]Italics highlight that the performance of ALBERT is the best comparing to the control method (NegEx, NegBio, NegBERT) and baseline (no negation or speculation detection were performed) across various performance metrics.

[b]All named entities considered "positive." No negation or speculation-detection algorithm was applied.

Sources of Errors

Overview

We analyzed the sources of the errors (Table 8). Despite changes in the rules defined by the experts, errors persisted in NegEx and NegBio. We identified the following causes:

Table 8. Analysis of the causes of errors in different methods (after optimization).

Method and cause of the wrong prediction[a]	Counts, n (%)
NegBio (n=177)	
Errors in the extraction of named entities	58 (32.8)
Symbol-related errors	49 (27.7)
Tokenization error	21 (11.9)
Errors in the prediction of speculative statements	14 (7.9)
NegEx (n=87)	
False-positive prediction related to speculative statements	37 (42)
Trigger word not triggered	21 (24)
Incorrect scope resolution	16 (18)
Symbol-related errors	6 (6)
NegBERT (n=20)	
All false-negative predictions	16 (80)
All false-positive predictions	4 (20)
False-positive predictions related to speculative statements unrelated to abnormal findings	0 (0)
ALBERT[b] (n=9)	
All false-positive predictions	5 (55)
False-positive predictions related to speculative statements unrelated to abnormal findings	0 (0)

[a]The table only list the most important causes of identifiable error.

[b]ALBERT: A Lite Bidirectional Encoder Representations From Transformers.

Findings of NegEx

First, we found many errors owing to incompatibility between the NegEx method for identifying speculative statements and the study requirements. NegEx made identical predictions for all keywords in the identified speculative statements regardless of their relevance to abnormal findings. However, our study categorized keywords in speculative sentences differently based on their relevance to abnormal findings, leading to discrepancies with NegEx's results.

Second, the trigger word would only sometimes trigger. For example, in the phrase "1.No evidence of tumor," the trigger word "No" would not be recognized because it was concatenated with the character "1." without any intervening space.

Third, errors also occurred owing to the misinterpretation of the scope of negation and speculation, such as misinterpreting "No improvement of the tumor" as "No tumor."

Fourth, errors occurred in the presence of symbols in radiology reports; for example, the use of special symbols by radiologists that are undefined in the trigger word or the confusion caused by the co-occurrence of special symbols that express a positive and a negative statement: (−) fatty liver and (+) portal vein thrombosis.

Findings of NegBio

We identified the following errors when using NegBio:

First, errors occurred in named entity extraction. The named entities in NegBio's output file might be missing target keywords or had incorrect positions, resulting in incorrect future analyses.

Second, errors occurred when the radiology report contained negations using symbols or abbreviations, such as "metastasis (−)." Our analysis showed that these symbols could lead to unpredictable results in syntactic structure analysis and subsequent analyses.

Third, combining words with numerals or punctuation marks leads to errors in tokenization and subsequent analysis. For example, "1.No" in "1.No obvious acute infarct or brain metastasis" was not correctly parsed as "No."

Fourth, many errors occurred because NegBio made identical predictions for diagnostic keywords in all speculative sentences, regardless of their relevance to abnormal findings. This behavior was inconsistent with the labeling of this experiment.

Findings of NegBERT and ALBERT

We observed the suboptimal performance of NegBERT when applied to corpora from different domains and tasks. The performance of NegBERT trained on the Simon Fraser University review corpus was suboptimal when evaluated on our corpus and task. Retraining NegBERT with our data significantly improved its performance, indicating that the poor performance was primarily due to differences in the training data and labeling.

Our error analysis showed that retrained NegBERT and ALBERT made fewer errors than the other methods in predicting whether words occurred in speculative statements unrelated to abnormal findings. The number of all false-positive predictions by NegBERT and ALBERT was 4 and 5, respectively. Both were lower than the number of false-positive predictions made by NegEx and NegBio for this prediction task, indicating higher specificity. However, because we grouped all negative and speculative statements not related to abnormal findings into the same category, we could not calculate the exact value of specificity. Both models showed 100% sensitivity in identifying important diagnostic keywords in speculative statements unrelated to abnormal findings, with no false-negative predictions.

Owing to the complexity of BERT, we could not further analyze the causes of other errors.

Discussion

Principal Findings

Overview

This study found that 39.45% (4529/11,480) of the important diagnostic keywords occurred in negative or speculative statements unrelated to abnormal findings, posing a challenge for automatic labeling by LISs and information extraction techniques.

Our study proposes a deep learning method that accurately distinguishes whether diagnostic keywords are in negative or speculative statements unrelated to abnormal findings. Our research has revealed the shortcomings of existing methods, including NegEx, NegBio, and NegBERT, while highlighting the advantages of our proposed approach over these methods.

Limitation of NegEx and NegBio

We observed common errors in Spacy's NegEx and NegBio that the expert rule adjustment could not resolve.

First, several vital errors in NegEx and NegBio, including errors related to trigger words in NegEx, tokenization errors in NegBio, and symbol-related errors in NegEx and NegBio, were attributed to interference from punctuation and numerals. For example, in the radiology reports in our sample, English sentences were often combined with numbers and punctuation marks and written as numbered or bulleted lists, such as "1.No evidence of aortic dissection" In addition, using symbols or abbreviations in the form of checklists was also common. For example, "Metastasis (−)" or "Anti-HCV [Negative]" were frequently used. Our results showed that NegEx and NegBio could not handle this issue correctly.

Second, NegEx and NegBio also caused many errors in the analyses where the simultaneous observation of multiple sentences is required. Our data showed that it is often necessary to examine multiple sentences simultaneously to determine whether speculative statements are associated with abnormal findings. For example, in "No CT evidence of large infarct. Suggest MRI to exclude hyperacute infarct if indicated," without considering the first sentence, which denies the finding of infarct evidence, it cannot be determined that the "hyperacute infarct" in the second sentence is unrelated to the actual findings. NegEx and NegBio, which are designed to analyze sentences in isolation without considering contextual information, cannot meet this requirement.

Our results regarding NegEx are consistent with previous research of Wu et al [42], highlighting the importance of tuning algorithms such as NegEx to achieve optimal performance in different corpora. Our results also confirm that NegEx produces incorrect results owing to improper negation scope resolution [22].

We found that NegBio requires modifying expert-defined rules to improve its performance. Our study is the first to report NegBio's limited generalizability in real-world radiology reports across all body parts. We also observed problems with the implementation of NegBio.

Limitation of NegBERT

Our experiment showed a significant improvement in NegBERT's performance after retraining on our hospital data set. The difference in the training data and annotations is likely the reason for the initial poor performance of NegBERT.

This observation is consistent with previous findings that deep learning models such as BERT tend to perform poorly on out-of-domain corpora. For example, a study by Miller et al [39] using RoBERTa for negation detection on both in-domain and out-of-domain corpora observed F_1-scores of 0.95 and 0.583, respectively. Our experiment supports this result and shows that the drop in F_1-scores can be even worse depending on the corpus and task.

Advantages of ALBERT and BERT Transformer

We performed a comparison between the ALBERT and NegBERT methods and made the following key observations.

First, learning the negation cue and scope in 2 steps provides a limited performance improvement. Our method takes a different approach from NegBERT and traditional negation recognition studies in that our model learn the entire part of the sentence containing both the cue and scope in the same step without explicitly telling the model which word is the "cue" of the negation or speculation. However, the performance was still better than that of the retrained NegBERT. The study by Sergeeva et al [11] based on LSTM suggests that the deep learning method can learn negation cue information to some extent automatically, with performance comparable with that of automatic cue prediction algorithms. Our results show that BERT might have a similar capability. Our results suggest that providing additional cue information through expert annotation may not significantly improve performance compared with other factors, such as model selection, hyperparameter optimization, and training techniques.

Second, our results show that the model size and complexity do not necessarily correlate with improved performance. In our study, the fine-tuned ALBERT model outperformed larger and more complex models, including BERT and XLNet used by NegBERT, as well as RoBERTa used in the study by Miller et al [39]. The use of lightweight models, such as ALBERT, may have practical advantages, including reduced computational resource requirements and training time, compared with BERT [31].

In our study, ALBERT and retrained NegBERT outperformed NegEx and NegBio in terms of the number of false-positive predictions and specificity while maintaining 100% sensitivity in predicting whether keywords occurred in speculative sentences unrelated to abnormal findings. This task required multisentence context analysis of our data set, and our results suggest that BERT can look at multiple sentences simultaneously. The attention mechanism is a reasonable explanation for this phenomenon.

Comparison With Prior Work

Our study fine-tuned the ALBERT model using a more comprehensive data set that included a broader range of imaging modalities and subspecialties than previous studies. Table 9 shows the best performances and corresponding data sets used in previous studies that detected whether named entities occurred in negation and speculation in radiology reports. The range of imaging modalities and subspecialties represented in the radiology reports in these studies was limited, such as chest x-ray reports only in the study by Peng et al [23] or brain CT and MRI reports only in the studies by Grivas et al [43] and Sykes et al [12]. We hypothesized that including a more diverse set of examination and imaging subspecialties in the data results in a more representative sample of the report content and improves the model's generalizability. Our results support this hypothesis, as the ALBERT model showed only a 0.034 decrease in its F_1-score on an unseen test data set with different disease types and inputs from different physicians.

Our experiments also address a more difficult speculation-detection task than previous studies; however, ALBERT still demonstrates good performance. This distinction requires the ability of the algorithm to consider multiple sentences simultaneously in our data set. To the best of our knowledge, our study is the first to propose a distinction between speculative sentences related and unrelated to abnormal findings based on the application scenario to facilitate more precise filtering and the first study to highlight the impact of the lack of multisentence analysis in negation detection algorithms.

Table 9. Comparison of best performances between studies distinguishing whether named entities occurred in negation or speculation.

Study	Algorithm	P[a]	R[b]	F_1	Best[c]	N[d]	Task[e]	Type[f]

Implication in Clinical Practice

We found problems with NegEx and NegBio in that modifying expert-defined rules could not be solved, including difficulties with numbers and punctuation, implementation-specific challenges, and the design constraint of observing only a single sentence at a time; thus, NegEx and NegBio should be used cautiously or avoided in such situations to prevent errors. On the basis of our data, we also found that NegBio and NegBERT have limitations in generalizability, making them inappropriate for use without training or modeling.

Our results indicate that BERT is more suitable than NegEx and NegBio for tasks involving multisentence context analysis, similar to the experiment conducted in this study. NegEx and NegBio were designed for single-sentence analysis because they segmented the text into independent sentences. This approach limits the ability to incorporate contextual information from other sentences into the analysis. While NegEx and NegBio can perform binary classification of words in sentences as speculative or not, they lack the capacity for further granular differentiation based on contextual information.

We found that the training process of the transformers did not require 2 separate learning phases for cue and scope. Our findings could reduce the workload of expert annotation in clinical applications, as the explicit annotation of cues in a separate step requires additional work. This hypothesis needs further testing in future studies.

Our results show that deep learning models outperform non–deep learning methods, and lightweight models such as ALBERT can achieve superior performance and outperform other transformer-based models. However, fine-tuning based on the specific domain corpus and task is still essential regardless of the model used.

Limitations

The data were obtained from 3 internal branches of a single institution and not from publicly available data sets. In addition, the speculation-detection task differed from previous studies in this area. The comparability of the performance with that of previous studies may be limited. If open data using the same annotation methodology become available, subsequent research could verify our findings by implementing the same model on the open data set.

Our study optimized the control methods (NegEx and NegBio), but we cannot exclude the possibility of further performance improvement by modifying or adding expert rules. However, this highlights the limitations of an expert rule–based approach, which requires experts not only to detect negations and speculations but also to summarize and modify rules manually. Moreover, expert rules cannot resolve the algorithmic design or implementation constraints.

To prevent the deep learning model from training failure, we combined negative statements with speculative statements unrelated to abnormal findings in the same category because of the low proportion of the latter. As a result, we cannot separately evaluate the model's performance on negative and speculative sentences unrelated to abnormal findings or accurately quantify the latter's performance. Nevertheless, metrics such as the number of false-positive predictions can still be used to compare the performance between methods.

Conclusions

Manual free-text reporting remains the norm in radiology worldwide, hampering the ability to perform computer-assisted

analyses. The presence of information irrelevant to the actual findings poses a significant challenge to the implementation of automatic radiology report highlighting, flagging, or information extraction.

Previous research on negation and speculation detection in radiology has aimed to identify all instances. Our study advances this by targeting only speculative statements unrelated to abnormal findings and improving the discrimination of relevant information using BERT's multisentence contextual analysis capabilities.

Lightweight transformer models, such as ALBERT, can outperform NegEx, NegBio, and NegBERT on more complex and diverse real-world radiology reports. Despite achieving good results on public data sets, NegBio and NegBERT demonstrated different performances on more complicated real-world radiology reports.

Our research has potential applications in academia and clinical practice. Future studies may consider including lightweight models such as ALBERT. In clinical practice, our method achieved high performance. It can help algorithms such as keyword highlighting in hospital information systems to identify passages of potentially important information without false alarms, improving physician efficiency and health care quality. Our results also apply to radiology report information retrieval, such as search engines, in which negative and speculative statements unrelated to abnormalities can lead to incorrect results.

Acknowledgments

This research received no specific grants from any funding agency in the public, commercial, or not-for-profit sectors.

Authors' Contributions

KHW proposed the research topic and experimental design and completed the recruitment, data analysis, computer programming, and writing of the entire paper.

Abstract

Background: Information stored within electronic health records is often recorded as unstructured text. Special computerized natural language processing (NLP) tools are needed to process this text; however, complex governance arrangements make such data in the National Health Service hard to access, and therefore, it is difficult to use for research in improving NLP methods. The creation of a donated databank of clinical free text could provide an important opportunity for researchers to develop NLP methods and tools and may circumvent delays in accessing the data needed to train the models. However, to date, there has been little or no engagement with stakeholders on the acceptability and design considerations of establishing a free-text databank for this purpose.

Objective: This study aimed to ascertain stakeholder views around the creation of a consented, donated databank of clinical free text to help create, train, and evaluate NLP for clinical research and to inform the potential next steps for adopting a partner-led approach to establish a national, funded databank of free text for use by the research community.

Methods: Web-based in-depth focus group interviews were conducted with 4 stakeholder groups (patients and members of the public, clinicians, information governance leads and research ethics members, and NLP researchers).

Results: All stakeholder groups were strongly in favor of the databank and saw great value in creating an environment where NLP tools can be tested and trained to improve their accuracy. Participants highlighted a range of complex issues for consideration as the databank is developed, including communicating the intended purpose, the approach to access and safeguarding the data, who should have access, and how to fund the databank. Participants recommended that a small-scale, gradual approach be adopted to start to gather donations and encouraged further engagement with stakeholders to develop a road map and set of standards for the databank.

Conclusions: These findings provide a clear mandate to begin developing the databank and a framework for stakeholder expectations, which we would aim to meet with the databank delivery.

KEYWORDS

consent; databank; electronic health records; free text; governance; natural language processing; public involvement; unstructured text

Introduction

Background

Electronic health records (EHRs) contain a rich narrative of the patient journey and have huge potential for research [1]. However, research using EHRs is typically limited to the structured data (such as numerical values and diagnoses coded using a controlled vocabulary), despite a large proportion of the information in EHRs being in the form of unstructured (free) text. The analysis of free text at scale requires specialized tools and methods (natural language processing [NLP]) to "read," process, and structure the information before it can be used at scale for research purposes.

NLP of clinical text has many potential benefits, both for individual care and improving health services [2]. These include (1) to facilitate the process of clinical coding [3], which is the process by which clinical coding staff in hospitals assign codes from a specific terminology (eg, International Classification of Diseases, 10th revision [ICD-10]) [4] to patient episodes for reimbursement; (2) to facilitate structured recording of diagnoses in clinical care using Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) [5], which is currently not done consistently [6]; and (3) to enable research using information in EHRs, which are currently not coded. Compared with manual review of free text, automated analysis is much faster and enables a much larger amount of text to be analyzed, enabling larger and more representative patient samples to be used for research.

The Challenge

Tools and platforms for text access and analysis such as CogStack (developed by a consortia of scientists at King's College London, King's College Hospital, South London and the Maudsley, Guy's and St Thomas's hospital, University College London, and University College London Hospitals National Health Service [NHS] Foundation Trust and some members of the CogStack open-source community) [7] have been developed and installed at some NHS sites with great success, but overall, access to free text for researchers is still currently difficult. Ideally, free text needs to be brought out of the NHS environment so expert computer scientists working in university research or other non-NHS environments can use the data to train their computer algorithms to extract the important clinical information. In the United Kingdom, the application of NLP for health care text research is largely limited to within large NHS hospital trusts with academic affiliations and in-house NLP expertise owing to complex governance requirements arising from increased concerns around the potential risk of reidentifying patients. In Scotland, a successful model adopted by groups including the Health Informatics Centre at the University of Dundee [8], DataLoch [9], and the national electronic Data Research and Innovation Service [10] in collaboration with the University of Edinburgh Clinical NLP Research Group [11] involves the provision of data for research through secure trusted research environments outside NHS or university settings. Nind et al [12] describe an approach for extracting, linking, deidentifying, and hosting clinical imaging data within a controlled secure environment as a resource for national and international research. This model provides a potential alternative approach to hosting the databank outside of an NHS or university setting and allows for timely and secure access to data; however, the governance framework is complex. In the United Kingdom, before medical data can be shared outside of the NHS environment, identifiers such as names of patients, family members, and health care professionals; addresses; and dates of birth, which can occur anywhere in the text, first need to be removed—a process known as "deidentification" [13]. Even when deidentified, there remains a risk that some identifiable information may have been missed, third parties might be identified, or the narrative may be too revealing.

Routinely collected health data are legally accessed for secondary purposes such as research by 2 lawful bases under UK data protection law: one is the principle of informed consent from the patient and the other is "task in the public interest" [14]. For processing under the lawful basis of "task in the public interest," health care data needs to be deidentified or anonymized before it can be shared outside the clinical environment under the General Data Protection Regulation principle of data minimization [15]. This is where governance becomes difficult, as deidentifying free-text clinic notes, letters, and reports is complex and a rapidly evolving field, and the accuracy of the process is hard to assess [2]. Technology exists to automatically redact identifying information so that only deidentified documents are presented to computer scientists to develop NLP [1]. However, the reidentification risk from automatically deidentified text remains unknown. Many independent health research ethics committees (RECs) do not have the specialized technical knowledge needed to evaluate the risks posed to patients by this type of research, and indeed, many researchers and data custodians are not sure of the scrutiny and approvals needed to legally process free text for research. As a consequence, a conservative approach is usually taken, resulting in heavy restrictions on data access [16]. Therefore, there are currently very few health care free-text data sets available to NLP researchers to develop and evaluate their algorithms; 1 example is the Medical Information Mart for Intensive Care (MIMIC) database [17,18] in the United States. MIMIC is based on a selected patient population (critical care patients) from 1 US center and contains structured and unstructured (eg, diagnostic reports and physician notes) deidentified data linked to hospital EHR and mortality data. Data that will contribute to the databank remain to be decided and will follow further consultation with stakeholders, but at the very minimum, it will include unstructured text from primary care and hospital records for a defined population of patients in the United Kingdom.

The Solution

One possibility for breaking down barriers to access to free-text data is to enable access to clinical text via the lawful basis of informed consent. Creating a "donated" databank of clinical free text in which each patient represented has given informed and explicit consent for their data to be used in this way could provide an important and timely opportunity for NLP researchers to develop and train NLP algorithms to process the free text, which can then be used on other data sets in the NHS to conduct clinical research. NLP researchers in universities or other non-NHS settings only need to access a sample of patient free-text data to develop and train the NLP algorithms on the databank, which could then be run on unseen patient free text housed within the NHS for research, avoiding the important privacy issues laid out above.

To test early thinking on the databank, we carried out a series of in-depth focus groups among 4 key stakeholder groups to find out what key stakeholders think about a consented, donated databank of clinical free text to help create, train, and evaluate NLP for clinical research.

Methods

Participant Selection and Inclusion Criteria

Four stakeholder groups were identified based on their potential interest and investment in the databank as follows: (1) patients and members of the public, (2) clinicians (NHS general practitioners [GPs], hospital doctors, and doctors in training), (3) NHS Trust information governance (IG) leads and REC members, and (4) NLP researchers based in universities or NHS hospitals. Participants lived in the United Kingdom and were aged ≥18 years. Patients and members of the public were based in the community and had to have some previous knowledge or understanding of the use of free-text health data for research; for example, they may have attended events or workshops on this topic or had experience participating in advisory committees on the use of free text.

Participant Recruitment

Patients and members of the public were recruited via an advert posted by existing networks, including Health Data Research United Kingdom [19] and the National Institute for Health Research People in Research network [20]. Other stakeholders were identified via existing national networks, contacts, and organizations and were approached directly by email by the research team. In addition, IG leads were identified via the Office of the National Data Guardian [21] and by searching the websites of NHS Trusts and Health Boards. NHS Research Ethics Service committee members were identified by searching the NHS Health Research Authority website [22], and academic NLP researchers were identified via professional networks including the UK health care text analytics network known as Healtex [23].

Potential participants were invited by the research team by email to participate in 1 of the 4 relevant stakeholder focus groups. Before deciding whether to take part, participants were asked to read a study information sheet and return a completed expression of interest form recording basic demographic information including age category (deciles), gender identity, and ethnicity. To understand participants' views before taking part in the study, they were also asked to indicate how comfortable they might feel about donating their health data for the purposes of the databank outlined in the participant information sheet from 1 of the following categories: very comfortable, somewhat comfortable, not sure, somewhat uncomfortable, or very uncomfortable. Invitees were then sent a consent form by email, which they were asked to complete and sign. Patient and public members were offered a modest financial incentive for participating in the study in line with National Institute for Health Research guidance for recognizing public participation in research [24].

Focus Groups

Focus groups were conducted on the web on Zoom between March 24 and 31, 2022, and lasted for 90 minutes. A deliberative approach was used where focus groups began with a short presentation on the donated databank by a member of the research team, tailored to each stakeholder group, followed by a question-and-answer session so discussions could be fully informed. The proposed model presented to participants in the prediscussion presentations was of an opt-in approach where people would consent to donate their data to the databank. The facilitator did not direct discussions to confirm whether donated data would be identified or not so that participants could freely share their views around both scenarios.

The team employed a third-party organization with considerable experience in conducting focus groups on the topic of health data to facilitate the groups. Discussions were framed around 4 key questions: (1) Is having a donated free-text databank a good idea? (2) How best could the risks of holding donated, consented potentially identifiable data be managed? (3) What do you think about consent, and how it could be managed? and (4) Who should be allowed access, how should a databank be housed, and for what purposes? Multimedia Appendix 1 presents the questions asked of each stakeholder group.

Discussions were audio recorded, transcribed, and analyzed using thematic analysis.

Ethics Approval

The study was approved by the University College London REC (0976/002) and complies with the COREQ (Consolidated Criteria for Reporting Qualitative Research) [25] checklist for reporting qualitative studies.

Results

Overview

A total of 61 participants took part in the focus groups including patients and members of the public (24 participants), clinicians (10 participants), NHS Trust IG leads and REC members (14 participants), and NLP researchers (13 participants).

In total, 75% (46/61) of the participants recorded their demographic information on their expression of interest form. Of those, 54% (25/46) were female, 52% (24/46) were aged between 31 and 50 years, and 73% (33/45) were White. Overall, most participants (30/46, 66%) were either very comfortable or

somewhat comfortable donating their data to the databank, 28% (13/46) were not sure whether they would be willing to donate their data, and only 6% (3/46) of all participants felt either very or somewhat uncomfortable donating their data, all of whom were patients and public members, although the numbers were small (3 patients and public members out of 17; Table 1).

Key findings of the study are summarized in Multimedia Appendix 2.

Table 1. Participant demographic information and views around sharing their own data captured before participating in the focus groups.

I would feel very uncomfortable donating my data	1 (2)	1 (6)	0 (0)	0 (0)	0 (0)

[a]Data are based on 75% (46/61) of the participants who returned this information. Within stakeholder groups, data were returned as follows: patients or public members, 71% (17/24); clinicians, 100% (10/10); information governance leads or research ethics committee members, 100% (14/14); and natural language processing researchers, 38% (5/13).

Is Having a Donated Free-Text Databank a Good Idea?

Perceived Benefits and Challenges

Participants were very enthusiastic about the databank and its intended purpose and saw great value in establishing a platform for development and testing NLP tools to improve their accuracy. Many participants across groups articulated the benefits of producing trustworthy tools to unlock the rich data available in free text, which extended beyond improving NLP methods, including expediting access to, and use of, NHS data by speeding up permissions; accelerating development of NLP tools; and improving health and care leading to better outcomes for patients. The NLP researcher group highlighted its potential value as a training resource to teach and onboard researchers and help familiarize them with free-text data. NLP researchers and clinician groups both welcomed the opportunity to access free-text data for a UK-based population, which would be more appropriate for developing NLP tools on UK health care data sources, moving away from a reliance on US-based data such as MIMIC III or the recently released MIMIC IV [17,18]:

> *I'd love to see it come to fruition. I think it would be an absolute gold mine.* [IG lead and REC member]

> *Don't let this racehorse designed by [a] committee become a camel, just get something out. I think*

> *anything is better than what's currently offered, which is nothing.* [NLP researcher]

Several participants in the patient and public group felt that increased access to patient data as a result of the databank may prompt clinicians to improve the quality of their free-text data entry, as they will be more conscious of its wider use:

> *Very much a great idea. So, the MIMIC dataset I've worked with a lot has been really transformative for clinical NLP research in the US. But the MIMIC dataset has some serious issues, in terms of the kinds of data that are included, the representativeness of the sample, and so on, and so forth. So having something that can be created, as a research-specific resource like this, and created with more intentionality, and more design, as to what should be going into it, I think is a really, really incredibly valuable thing to do.* [NLP researcher]

Despite strong support, participants in all groups advised that clarity around the purpose of the databank; how it will be used; and by whom, both now and in the future, will be essential to its success. Patient and public participants felt this should be made clear in the consent process. Many participants, but patients or public members in particular, expressed concerns around how inaccurate recording, the lack of up-to-date data, or subjective data based on a physician's own impressions may threaten the aims of the databank, citing frequent instances of errors in their own health records. IG leads and REC members and patients or public participants felt that the accuracy of data must be improved before people trust the outcomes of the databank, and patients or public participants were keen for easier access to their own EHR so they can amend inaccuracies or missing information. However, other participants did not feel data accuracy would be a key factor in the success of the databank, and NLP researchers suggested the databank could provide a unique opportunity for investigating the effect of inaccurate or subjective training data on NLP research findings.

Biases owing to missing data or the lack of generalizability was a considerable concern among all groups. Many felt that donations will be more likely to come from White, middle-class populations and less likely to include people with rare diseases or whose records contain sensitive information. This was seen as most likely to affect data in mental health and social care settings:

> *There may be intrinsic biases in the actual data that's getting selected because certain classes of patients, whether it's by demographics, such as race or income, have more trust in what this is trying to achieve and, therefore, people with less trust won't actually consent to their data being used and we know, for instance, that that can be quite heavily in race, in the UK, on health data, for instance, and health services and the provision of health services. So, that may introduce biases in the data set.* [NLP researcher]

> *I'm not saying it would be necessarily unprofessional, but there could be things that may have been written 10 years ago and that maybe wouldn't be written now. Is that going to affect your data sets? So, I guess it's really about the bias that might be there within the unstructured data and whether you're proliferating that bias by collecting them and then training algorithms.* [NLP researcher]

Many participants saw artificial intelligence (AI) as playing a key role in health care in the future but were concerned about how AI tools are developed and perform in general. These concerns, which included questions around how tools "decide" which words to analyze, the possibility of scan reports being misread or missing key data, and the accuracy of annotation, are key to feeding into the communication plans for the databank.

Data Privacy and Use

Fears around data privacy for both patients and clinicians were raised. Participants discussed complexities in relation to free text, which might act as a barrier to data donation, and how clinicians may be uncomfortable that their identity and views are shared with researchers, for example, where GPs' personal views around a patient's health are recorded. Participants advised that such fears might be mitigated to some extent by ensuring robust data security, governance, and transparency around the "data pipeline"—that is, what the databank will be used for and by whom, for example, whether there is any commercial benefit. IG leads and REC members and patients or public participants in particular discussed challenges in articulating how tools may be used in the future and by whom, as technology evolves and society's views around acceptable and ethical use of their data may change over time. Participants thought that building scenarios for future use into the consent process is therefore important:

> *My only worry or concerns would be the way that technology develops way into the future and therefore, algorithms, as a result. And it could be ethical now but maybe it would be less ethical in the future.* [Patient or public member]

Types of Data to Include in the Databank and Data Linkages

All participants felt that it is very important that the databank benefit from the inclusion of data from a range of sources to reflect the whole systems approach of the health service and a more integrated care system of the future.

> *I don't see how, at this stage, you can start to select what you want to look at because you don't know what you want to look at. If the purpose of this is to develop algorithms for extracting useful, contextual information then you want the original data, which is being used to train the algorithm, to be as broad as possible.* [IG lead and REC member]

> *We are talking about a holistic approach, so that vision should be, I totally agree, whole patient records. And if we are going to use the computers, and train the algorithm, the whole purpose is looking at the wider picture, and bringing it together.* [Clinician]

Along with primary and secondary care data, some saw value in training NLP tools based on sources that are less commonly used for research, including social services and housing data, to encourage more research in these fields. Perceived advantages of including a broad range of data include introducing a more holistic view of a person's health needs and including training data based on the different styles of free-text data held in different settings. Some participants discussed the advantages of introducing the databank in phases to ensure timely access and build trust, for example, by starting with 1 health condition such as diabetes or mental health or geographical location.

Such phasing would need to be carefully considered. If condition-specific phasing were to be used, then the imperfections of the diagnostic codes used to select data for a phase would need to be addressed. Solutions might be to use existing NLP applications to identify conditions, accepting that this would have its own limitations, or choosing broader categories of data such as data from specific medical specialties or units:

> *Our health is based in our experience, and what starts in primary, might end up in secondary. You can't divide them into two separate things.* [Patient or public member]

There were mixed views around linking free-text data to other forms of data. NLP researchers particularly valued the opportunity to link the data to other sources, especially mental health data where rich narrative adds important additional detail for research, and some felt that the inclusion of coded data could help verify the accuracy of the free-text data more efficiently. However, some questioned the value of such linkages to train NLP tools and felt linkages, for example, to administrative data, may increase the risk of reidentification and would be resource intensive to manage:

> *In psychiatry, it tends to be that a lot of the information is locked behind this clinical free text, and they tend to be, by comparison to other medical specialties, a bit more verbose, a bit more narrative, in nature. And so, the ability to incorporate that, and the metadata that's required to have that, needs to be built in, I think, from the very, very start this has to be extensible, because I'd love to, for example, be able to look at GP notes, and see how they translate over into secondary care, but there are decisions about how this may be structured, early on, that could make that more difficult. So I think that's something that we need to build in from the start.* [NLP researcher]

IG leads and REC participants discussed the potential for linkages resulting in "scope drift," which could lead to the use of data outside of its original purpose. If this occurs, the databank should clearly communicate its wider remit. Scope drift was also a concern for linkages to patient-generated data such as wearable and monitoring devices. Some questioned the accuracy of these data sets and whether this may lead to the development of inaccurate NLP tools, although potential advantages including signaling support for greater use of patient data and "future-proofing" development of NLP tools by including these data, given the inevitable advancement and incorporation of these devices in health care, were also discussed:

> *This is where, as an IG person, I always start getting nervous and we're having conversations in our population health because everybody starts saying, "The police, it would be really good if we can put an algorithm together to identify individuals that might start being people that will cause domestic harm." So, that's an area that is always a bit nervous to say, "Well, what is that trying to establish," especially with this project. Because what's the purpose of having a linked dataset and then trying to do modelling on trying to extract free-text data? I'm not quite sure of the purpose of those two things together.* [IG lead and REC member]

Managing Risks of Holding Donated, Consented Identifiable Data

Data Privacy and Deidentification

The groups did not discuss a preference for whether data should be left in an identifiable form or should be deidentified; rather, discussions focused broadly on the issue of how to minimize the risk of reidentification, indicating that participants expected data to be deidentified. In particular, the patient or public group highlighted the importance of deidentification alongside data security, including robust data storage and management practices to mitigate risks to data privacy. All participants recognized that eliminating risk completely is unrealistic, but introducing steps to reduce the likelihood of reidentification by using birth year, partial postcode, or a sample of the notes rather than the whole record was discussed. Some clinician participants were conscious of potential legal implications for themselves and supported the removal of clinician details as well. Participants were mindful that the process of deidentification should be carried out on a case-by-case basis. NLP researcher members suggested involving data controllers in agreeing with the approach to deidentification, given their expert knowledge of the data and availability of resources such as data dictionaries to aid the deidentification process. Although rare diseases were regarded as posing a particular risk to reidentification, patients or public participants who themselves have been diagnosed with a rare condition were keen that this should not act as a barrier to the much-needed research and proposed that clear explanations about how data would be used, by whom, and what the data protection issues are might offset concerns. Alongside deidentification, it was felt that following the UK Caldicott Principles, which helps ensure confidential and appropriate use of people's data [26], adopting strong data security measures to protect against hacks and ensuring that only legitimate, vetted people have access to only the data they need were viewed as key to managing privacy concerns. Patients or public group members in particular voiced the importance of articulating these safeguards to reassure potential donors, and IG leads and REC members suggested that because deidentification is both difficult to define and achieve, there should be an emphasis on defining the purpose of accessing the data and the methods of safeguarding the data:

> *Is it a pseudonym? Is it a number? Is it aggregated? What level of anonymity is there when we're discussing this? What's proposed, or are there different levels (to de-id)?* [Patient or public member]

> *If you're doing a decent level of de-identification so you're getting masking rates of 90% or something, the risk is going to be very minimal, particularly if you're providing samples of notes rather than an entire record level. So if you're looking at medication as your concept for annotation, then you don't need stuff that doesn't contain that data, or is unlikely to. So you can start to pick how you pull your sample notes from a record. I think there's quite a lot you can do to continue to reduce and reduce and reduce that risk, but you won't eliminate it.* [IG lead and REC member]

Raising Awareness of the Databank

Future consultation with stakeholders, including clinicians, was viewed as essential by all groups, who were keen that engagement be continued to help develop the scope, consent model, and communication plan for the databank. Several participants advised careful planning on how to explain the databank. Patients or public participants expressed the importance of terminology when communicating plans, for example, to clarify what is meant by free text and what is in a health care record that might help allay people's fears around what they are agreeing to donate:

> *I want some power. I don't want to be a passive recipient of this whole data process, which is what's happened to a lot of us regarding data so far.* [Patient or public member]

Participants suggested that a targeted, small-scale approach be adopted in the early stages of raising awareness of the databank and starting to gather donations, working with trusted organizations who use health data for research. The involvement of GP practice staff in communicating the databank was seen as important, but clinician participants in particular were skeptical, saying that this was both impractical given their already stretched resources and unnecessary given patients already have the right to agree to their health records being shared. One alternative discussed was to recruit GPs or practice staff who were willing to take on this role. Some ideas for how to reach potential donors included making posters and leaflets available in GP surgeries with a QR code linked to a website about the databank, working with trusted organizations that support the use of health data for research such as *HealthWise* [27] and *use MY data* [28], and identifying community-based "public champions" to advocate the benefits and safety of the databank:

> *I would share it with patients but I'm constantly limited by time—something else to include in the consultation, so it has to be done through a different delivery mechanism than face to face.* [Clinician]

Managing Consent and Offering Choice

Participants expressed the importance of working with trusted NHS and research organizations and providing accessible consent including web-based consent, the availability of audio consent for people with low literacy levels, and translation into multiple languages. The information sheet should clearly set out the intended purpose of the databank and focus on providing reassurance regarding use and data security. If the approach was to include deidentified data, participants wanted this made clear in the supporting materials, possibly aided by including examples of "dummy" data to show what types of data are excluded in the deidentification process. Patients or public members thought that offering people the opportunity to view the databank before consenting might help them understand what information would be included:

> *People should know what they're getting involved in. Maybe seeing the database before they opt-in, and also, how far back will the data be taken from...* [Patient or public member]

> *Having an actual example of a fake letter or fake clinical notes with a lot of identifiable data and what, actually, will go to the databank in front of you so you see that they did remove all information about you talking about your kids or how your neighbour is annoying you because she is very noisy, all that kind of thing. Maybe, they would see it, that would make a lot of reassurance.* [NLP researcher]

Patients or public participants felt that offering choice over which data to donate and which type of organization can access the databank might increase donation rates, but others thought this may be complex and resource intensive to achieve and may encourage withholding of sensitive information. The IG leads and REC members group felt that offering choice with a promise to withhold sensitive information is likely to be unachievable and, therefore, undermine trust.

Who Should Be Allowed Access, How Should a Databank Be Housed, and for What Purposes?

Overview

Participants were in favor of access to the databank by both university- and NHS-based NLP researchers. Establishing a "road map" of the types of organizations with which the databank will work was suggested as helpful. Many participants favored a defined approach to access in the early stages of developing the databank, whereby access should be limited to NHS and university-based NLP researchers, and developing a set of standards could ensure that the use of the databank remains in line with its intended purpose. However, the IG leads and REC members group felt that it may be more appropriate to define the types of organizations that can access the databank based on a "compliance" model in which users should show that they can meet a defined level of capability and accountability. Standards should include an assessment of the applicant organization's motivation for using the databank and their reputation, although the road map should include a well-thought out vetting process to include applicants such as start-ups who may not have a proven track record in trustworthy access to data:

> *If there were particular requirements around use of the data, commitments to not attempt to re-identify,*

> *similar things like that, I think in my view both academic organisations, research students and also research organisations, with the right safeguards, even start-ups, I feel if they can meet a certain level of capability and accountability, then I feel that should be the bar rather than defining the type of organisation.* [IG lead and REC member]

Participants had mixed views on the use of the databank by commercial organizations including technology and pharmaceutical companies. Patients or public members were generally against the use of their data by these organizations for the purposes of the databank, although other groups felt that these partnerships may be beneficial owing to commercial organizations' considerable expertise and resources and that they should be allowed access if they could show that they meet the databank's standards. The primary consideration of commercial access was to ensure adequate return and public benefit. Participants discussed the need for assurances around how tools will be fed back into the public sector, for example, whether the NHS would have discounted access to any tools that were developed as a result of the databank. Access by charities was viewed as potentially problematic, as charities are less regulated and often have a campaign focus, which may result in data use being less scrutinized or controlled and the creation of NLP tools biased toward certain outcomes. Government organizations, insurance companies, and lawyers were deemed unsuitable.

Several participants agreed that existing models of good practice about access such as the Secure Anonymised Information Linkage (SAIL) Databank [29] in Wales should be incorporated and that learning from the Centre for Data Ethics and Innovation Public Attitudes Survey on Data and AI [30] about who is trusted with data and in what circumstances should inform the road map.

Fee-Based Model for Use of the Databank

Clinician and NLP researcher groups were asked about how the databank should be funded. Both groups welcomed government funding to help develop the databank, but a fee-based model was viewed as more sustainable in terms of supporting the management of access and oversight, ensuring data quality, and allowing data to be updated over time. Charging a not-for-profit fee was viewed as realistic, and participants favored the development of a tiered costing model with different levels of access and cost depending on the user, their reason for access, and the volume of data requested. Suggestions for tiered access included providing an institute-wide membership fee to enable access for anyone working within the organization and discounted rates or free access for those who contribute to data donation, maintenance of the databank, or data cleaning or other data quality control. It was suggested that the development of the cost model should be informed by existing approaches such as the Linguistic Data Consortium [31], which supports NLP research by creating and sharing resources, and the UK Data Service [32], a large repository of economic, social, and health data sets for research and teaching.

Data Gathering, Management, and Housing

Participants felt that with health care services under notable pressure, a robust and sustainable costing plan to support the transfer of data into the databank is essential. For example, GP practices may expect to be paid to carry out data extraction for the databank; therefore, costs should be factored into the costing model.

> *Services are already stretched and I know in some of my practices if you come to them and ask them for data, whether patient's consented or not, they're going to tell you to go take a high jump. I'm not going to spend my time extracting that for you or printing that off and sending it to you because I haven't got the time or capacity.* [Clinician]

The participants articulated 5 considerations that should be built into the way the databank is managed. The considerations were that the databank should be (1) accessible: access should be easier than the current process of applying for and accessing data from data providers; (2) up-to-date: the databank should be supplemented with new data so NLP tools are trained on current information; (3) controlled: robust technical controls should be put in place as the primary mechanism for managing data, including allowing and revoking access; (4) tracked: a mechanism should be in place to allow the use of data to be tracked in real time to see what happens to the data after they are accessed; and (5) transparent: transparency around how the databank is being used to track public benefit, for example, publishing details on a website, was seen as essential.

There was no clear consensus on the best approach to housing the databank. The options discussed included housing it within the NHS (perceived benefits were trustworthiness and existing robust policies around data breaches or data misuse; disadvantages were possible lack of technical infrastructure or resources to be able to manage it effectively) or a university setting. Different models considered included adopting a partnership approach in which the databank could be housed within a university but be governed by the NHS. Storing data within a secure environment such as a trusted research environment where data cannot be removed was felt to be appropriate, and existing models of good practice should be drawn upon, for example, Genomics England [33] and Health Data Research United Kingdom [19].

Oversight and Management

The integrity of the databank was closely linked to the approach to oversight and clear communication of how gatekeeping will take place. Most participants favored the establishment of an oversight committee to consider the range and types of data collected, review applications for access and use, ensure transparency around use including what the NLP tools being developed will be used for, and monitor and review data safeguarding. The committee should be independent and consist of people with diverse demographics, backgrounds, and expertise, including experts in the use of data, data controllers, and lay representatives. Patients or public participants discussed the importance of ensuring that the application process to join the oversight committee was accessible and did not put off

potential new applicants by overemphasizing a requirement for previous experience, as is often the case.

Discussion

Principal Findings

This study set out to test early stakeholder thinking around the acceptability and design considerations for the creation of a consented donated databank of clinical free text to develop and test NLP methods and tools. Understanding the details to inform establishment of such a databank was highlighted as a key recommendation in a recent position paper on the development of data governance standards for using clinical free-text data in health research [1]. All stakeholder groups voiced strong support and a pressing need for a free-text databank for the purposes set out to them. Participants highlighted a range of complex issues for consideration as the databank is developed, but there was a plea, particularly among the NLP researcher group, to move with haste to design something that works without becoming overburdened with the many complexities. One suggested approach was to develop the databank in phases, with the initial phase focusing on a specific health condition or type of health data, to test out whether people are willing to donate their data for this purpose and how it would work. Although not raised by any of the groups, a sensible starting point for the databank may be to exploit existing cohorts such as Generation Scotland or the UK Biobank where participants have already consented to share their data for research and can be easily contacted to invite them to donate their data to the databank. Participants stressed the importance of ongoing engagement and involvement with stakeholder communities in the development and operation of the databank. This position encapsulates the widely held view of the importance of transparency to increase the general lack of awareness about how patient data are used, by whom, and for what purposes [16].

Future proofing the databank at an early stage was viewed as important to take into account how uses of the databank and advances in technology might change over time. Participants also highlighted the importance of ensuring that plans for the provision and maintenance of the databank are sustainable in the future. There was a general agreement among stakeholder groups that the databank should draw upon a range of data sources to ensure that NLP tools reflect an integrated care system in the future, although there were mixed views about the benefits of linking to other data sources. The types of data to be included in the databank (eg, structured data in the GP or hospital record that may improve the performance of existing models owing to the inclusion of text-based features [34,35] or linkage to other data outside the NHS EHR, eg, national registry, mortality, or administrative data) should reflect stakeholder views on acceptability and practicalities, including cost, especially at the start. These issues should be explored in more detail in the next phase of the study. Participants agreed that the way the databank is created will be crucial to its success. The importance of communicating the intended purpose and approach to accessing the databank and the proposed mechanisms for safeguarding the data came up at numerous points during discussions with all groups. Learning from existing examples of good practice around access to data, data security, and how to fund the databank was also deemed crucial.

During the discussions, participants were not directed by the facilitator as to whether data stored in the databank would remain identifiable or not to encourage a broad conversation around anonymity in relation to the databank. Although it was made clear that donations would be based on explicit donor consent, issues of trust and maintaining patient confidentiality featured strongly in the discussions, particularly among the patient and public and IG and REC groups who were aware that public awareness of the risk of reidentification might act as a barrier to data donation, particularly among people with rare diseases who may be easier to identify. Interestingly, only patients and public participants expressed concern about sharing their own data with a databank (Table 1), although the numbers were small, with only 18% (3/17) of the patients or public members declaring that they would be very or somewhat uncomfortable donating their data. This finding is likely to reflect both a clearer understanding of the potential benefits of the databank among other stakeholder groups, given their expertise in this area, and the complexity of what is required to manage and mitigate the risks of data breaches and uphold privacy, which other stakeholder groups may understand more clearly. More work is needed to engage with patients and public members in this area to develop strategies for clear and widespread articulation of the benefits of the donated databank. Given the nature of the data and the challenges of removing personal identifiers, a realistic approach to deidentification will need to be adopted and made transparent and should be supported by robust processes to protect against risks. The deidentification approach may need to be dynamic, depending on the type of data and health condition, as some identifying data might be essential to the research study, for example, if the databank will be used to develop and test deidentification tools. It will also be worth exploring options to replace identifiers with random replacement identifiers to enable this type of work and remain mindful of the advances in generating synthetic data. Further exploration of stakeholder views to understand if stakeholders expect data to be stored in an identifiable form or if they want it to be deidentified is warranted. Although stringent steps will be adopted to minimize the risk of reidentification of patients by deidentifying the data and ensuring strict controls over who can access the data and how data will be made available, for example, within a trusted research environment, risk cannot be eliminated completely. The model for the databank should balance strong governance and security measures to ensure that access is not unnecessarily burdensome or complex. Learning from existing models will be the focus of the next phase of the development of the databank.

Another clear theme throughout the discussions was the need to develop a carefully planned and strong communication plan to build trust. It was suggested that distinct key messages be prepared depending on the stakeholders' interests in the databank. For example, there should be targeted communication with clinicians regarding their data privacy and with data controllers regarding data security. Communication should

incorporate relevant background information (eg, to counter the lack of awareness of what data are contained within EHRs) and address the context for the databank, which drives donations and the involvement of GP practices and other data providers.

Ideally, linguistic features in NLP should be representative of the entire population to ensure that the findings are not biased and are representative across patient groups. However, it is also important that the databank reflects what happens in the real world, despite the potential limitations owing to bias. The participants discussed the potential for bias and its impact on the databank ("garbage in, garbage out") in 2 areas: first, potential biases in the data because of inaccuracies or missing data, and second, potential biases in the data because of donations that lacked demographic variation. Biases in the annotation process [36] and other potential biases have not been discussed. Further in-depth consideration of how to avoid biases and the potential consequences for the trained models is needed when developing the databank and should be addressed clearly in the communication plan.

Participants expressed mixed views about the impact of training NLP models on inaccurate or missing data or data that are not up-to-date. Patients or public participants were concerned that the quality of data would affect the quality of the algorithms that will be developed. Patients or public participants were able to highlight numerous examples of inaccurate or missing data in their own health records which they found concerning and they expressed concern around how the potential lack of accurate or up-to-date data might impact on trust in the databank. Additional engagement with stakeholders, in particular patients and public participants, should be carried out to tease out and address major questions or lack of understanding about the impact of accuracy, subjectivity, and representativeness of data when training NLP tools so that people have a better understanding of what the databank can achieve. Communication should include efforts to make clear that NLP development is not interested in whether data are accurate or true, as it is simply trying to learn the linguistic properties of the data and how they relate to target concepts defined by NLP researchers and annotators.

Notably, participants were acutely aware of, and made reference throughout the discussions to, the important role AI will play in health care in the future but raised concerns about how AI tools are developed and perform and what might be ethical in the future. Embedding ethical approaches in developing data-driven technologies for AI and understanding public trust is high on the UK governments', researchers', and other stakeholders' agendas. For example, the NHS England Accelerated Access Collaborative [37] is committed to working with patients to ensure that AI innovations reflect the priorities of the end users and support innovators to embed public involvement in the development of AI technologies. The Centre for Data Ethics and Innovation, which is responsible for monitoring public attitudes toward data and AI over time, recently published findings from its second "Public Attitudes to Data and AI (PADAI) Tracker Survey" [30]. Findings from our study reflect similar views to those identified in this survey: for example, data security and privacy remain major concerns, people expect strong governance overseen by experts, and trust is strongly linked to the level of trust in the organizations that are accessing the data. Adhering to best practices around ethical AI principles and frameworks and anchoring public involvement in the development of the databank should be a priority to build trust, and developers of the databank should engage with leaders in the field to ensure this is embedded in plans for the databank, for example, the NHS England AI Ethics Initiative [38]. To keep up with the research and development in AI applied to clinical settings that is happening in the United States (made possible by data sets such as MIMIC III and IV), the UK government should channel resources into funding such a databank to harness rapid advances of AI technology and support long-term investment in the AI ecosystem in the future.

Limitations

This study has limitations. The sample size was relatively small, and there was a lack of diversity, particularly from younger and older participants and people of color. Therefore, the participants' views are unlikely to be representative of the UK general population. Engagement with more diverse groups and stakeholders who were not included in this work, for example, data controllers, is essential when planning next steps for the databank in the future. Thematic analysis does not allow views to be quantified, so we were unable to report how many participants felt a particular way. Furthermore, the aim of the focus groups was not to produce a specific set of recommendations. Rather, our findings provide useful insights into initial thinking, and the recommendations presented in this study (Textbox 1) therefore reflect a set of potential suggestions and advice based on the views of participants generally. Web-based discussions were limited to 90 minutes to ensure that the length of the focus groups was manageable for participants, which meant some topics could not be explored in depth. The research team therefore agreed in advance how to limit questions to ensure topics deemed the most relevant to particular stakeholders were covered within the time frame. Opportunities to explore topics in more detail will be sought in the next phase of the study.

Textbox 1. Proposed recommendations and suggestions for setting up the databank.

General approach

- Recommendation 1: Stakeholders should be involved throughout the development, implementation, and maintenance of the databank, including development of the scope, consent model, and communication plan.
- Recommendation 2: The databank should draw on the existing successful examples that can offer helpful models for consent, governance, data housing, and data security and be governed by an oversight committee.

Scope and phasing of the databank

- Recommendation 3: The databank should have a clearly defined purpose and take into account how natural language processing (NLP) researchers may wish to use it in the future.
- Recommendation 4: Development of the databank should be based on a small-scale, gradual approach to starting to gather donations to establish proof of concept and interest in donating to the databank. This might involve gathering data for 1 health condition (eg, diabetes) or location (eg, a mental health National Health Service [NHS] Trust) before moving to include others.

Channels to reach potential donors

- Recommendation 5: Reaching potential donors and publicizing the databank should include trusted individuals, networks, and organizations that support research using health data.
- Recommendation 6: Innovative ways to reach out to minority groups such as identifying public community champions who can advise and reassure others about the benefits and safety of the databank should be explored.

Consent

- Recommendation 7: Ensure the consent process is simple and accessible. Consent should be collected electronically, and information should link to a relevant NHS research ethics committee website and be offered in multiple formats and languages.
- Recommendation 8: The focus of the consent information sheet should be to provide reassurance around use; data security; and, if appropriate, deidentification. It should clearly define the purpose of the databank, provide a clear explanation of what data people are being asked to donate, and describe examples of scenarios for future use.
- Recommendation 9: Opportunities for showing potential participants their own personal health record before consenting should be explored.

Communication

- Recommendation 10: A clear and comprehensive communication plan should be carefully planned and developed with targeted messages for the different stakeholders (eg, clinicians regarding their data privacy and data controllers regarding data security).
- Recommendation 11: Communication should cover the following key elements clearly to build trust in the databank: predonation involvement (eg, possibility for participants to see their personal data and amend errors before donating); general aspects around data (what is free text? and what data are in a health care record?); content (what data are to be donated?); purpose (what the free-text data will be used for and by whom?); different contexts that NLP tools will be used in (eg, will data be used largely for commercial benefit?); and, crucially, the public benefit that NLP tools trained on the data could bring.

Pathways to databank access

- Recommendation 12: The foremost consideration for access should be to ensure public benefit and that benefits of data use are shared equitably.
- Recommendation 13: A “road map” should be developed to include the types of organizations the databank will work with, based on a compliance model where users should show they can meet a defined level of capability and accountability. The road map should include a set of standards and approach to “due diligence” to ensure databank use is in line with its intended purpose. Access could be granted based on an organization’s ability to meet, and commitment to comply with, the standards and an assessment of the applicant organization’s reputation and motivation for using the databank, rather than limiting which types of organization should be allowed access. The road map should incorporate recent learning on who is trusted with data and in what circumstances.
- Recommendation 14: Although development of the databank is in its infancy, it may be prudent to limit access to a small group such as NLP researchers linked to the NHS and UK universities.
- Recommendation 15: Access should be easier than the current process of applying for and accessing data from data providers.

Cost model for the databank

- Recommendation 16: A clear, transparent, and not-for-profit fee-based model should be developed that ensures sustainability of the databank over time. Fees should be used to maintain the database, support and manage access and standards, support oversight, ensure quality of data, and support updating the databank with new data over time.
- Recommendation 17: A tiered access model should include different levels of fees depending on the user, reason for use, and volume of data required (eg, access to a portion of the data set or all of it). Discounted or free access should be considered, for example, discounted access for organizations that contribute to data donation or where the databank would be used for teaching purposes. “In kind” arrangements could be considered for organizations that collaborate on improving quality of data (eg, cleaning data for access).

- Recommendation 18: Data provider costs to extract the data for the databank should be factored into the model.

Range and types of data to include in the databank
