- Recommendation 19: A range of data types across different settings should be included in the databank.
- Recommendation 20: The databank should be kept up-to-date so that NLP tools are trained on current information.

Governance and oversight

- Recommendation 21: An independent oversight committee that has no stake in the NLP tools being developed should be established to monitor and review applications for data use and ensure transparency around use (eg, what the NLP tools being developed will be used for, the range and types of data included in the databank, who is using the databank, and safeguards to protect the data).
- Recommendation 22: The oversight committee should include members from a range of diverse ethnic and sociodemographic backgrounds and expertise, including data experts, data controllers, and lay representatives. Experts in specific data domains may be brought into the committee on an ad hoc basis to advise on specific applications.
- Recommendation 23: Ensure the process for applying to join the oversight committee is accessible and does overemphasize the need for previous experience on such committees.
- Recommendation 24: Lay members should be paid for their time serving on the committee.

Databank housing, management, and security

- Recommendation 25: The databank should be housed in a university or NHS trusted research environment.
- Recommendation 26: Robust technical controls should be put in place as the primary mechanism for managing data, including allowing and revoking access.
- Recommendation 27: A mechanism should be put in place to allow the use of data to be tracked in real time to see what happens to the data after they are accessed.
- Recommendation 28: Transparency around how the databank is being used to track public benefit should be ensured, for example, publishing details on a website.

Approaches to maintain participant anonymity

- Recommendation 29: Further engagement with stakeholders should be carried out to explore views around whether data should be stored in an identifiable or deidentified form in the databank and expectations around deidentification.

Comparison With Prior Work

Although the focus of this study centered on creation of the databank that has not, to the authors' knowledge, been previously explored, there were several areas where themes overlapped with previous research on attitudes toward the use of free-text data for research, which has been discussed particularly among patients and the public [16,39]. Although several benefits highlighted by participants in this study related specifically to the databank, wider benefits discussed included the potential for improving health and care leading to better outcomes for patients, which mirrored benefits identified by other UK research studies that used clinical free text [2]. Despite acknowledging a broad range of potential benefits, participants raised a number of concerns, particularly around how AI tools are developed and perform in general, the effect of possible biases, privacy risks, and reidentification. Previous research on potential harms of the use of free-text data for research has shown that the public harbors similar concerns around the use of free-text data for research generally, despite no evidence of these harms actually taking place following data breaches [40]. The issue of trust was raised several times, as was the importance of clear communication and a transparent approach to help build trust. Participants in this study felt that trust is strongly linked to the level of trust in the organizations that access the data, which echoes findings from other studies that showed that the public evaluates the trustworthiness of research organizations by assessing their competence in data handling and motivation for accessing the data [41]. A Citizens' Jury on the use of free text for research carried out in 2018 [16] found a high degree of willingness to share EHR data for public benefit among public participants who were informed about the use of free-text data, although participants expressed caution owing to concerns around the lack of transparency in the use of data and increased privacy risks. Participants in the Citizens' Jury suggested keeping patients informed about the use of their data and being transparent about ways to opt out of data sharing. These attitudes were mirrored in this study, as were views on risks related to deidentification of free text, which were in line with previous findings, including concerns around accuracy of removing patient identifiers.

Next Steps

The recommendations and advice resulting from the study are summarized in Textbox 1. The findings will be used to plan the next phase of developing the databank, including a pilot study to design the road map and communication plan and test the feasibility of donating to the databank. Next steps will involve identifying and reaching out to a broad range of stakeholders based on their diverse knowledge and skill sets to develop the vision for the databank and inform the road map and standards, including researchers, patients and public members, governance

experts, providers of NHS, data controllers, charities, government, and industry. The road map and standards could be further informed by a national web-based survey that will be co-designed with stakeholders to explore in more detail the acceptability and design considerations highlighted in this study, including understanding whether stakeholders expect data to be stored in an identifiable or deidentifiable form. Planning the next steps will draw on recommendations across relevant themes that were highlighted in a position paper on developing data governance standards for the use of free-text data in health research, including the involvement of patients and public members at identifiable data stages and opt-in consent models for the reuse of free-text data [1].

Conclusions

Improved access to clinical free-text data will help support technological innovation for developing novel and valid NLP tools to support research for public benefit. One way to leverage access is through the creation of a consented databank to develop and train NLP tools outside the NHS via the lawful basis of informed consent. This study showed strong multistakeholder support for a databank for this purpose and an urgent need to move forward to develop something quickly. Stakeholders expressed commonality around many issues such as governance, communication, and sustainability, but there were also stakeholder-specific concerns such as clinician concern around increased workload and privacy and patient-and-public concern around inaccuracies in their personal EHRs and how their data will be used. These issues should be explored in more detail and targeted among individual stakeholder groups. Findings from this study will be used to inform the next steps for adopting a partnership approach to establish a national, funded databank of free text for use by the research community.

Acknowledgments

Abstract

Background: A patient's family history (FH) information significantly influences downstream clinical care. Despite this importance, there is no standardized method to capture FH information in electronic health records and a substantial portion of FH information is frequently embedded in clinical notes. This renders FH information difficult to use in downstream data analytics or clinical decision support applications. To address this issue, a natural language processing system capable of extracting and normalizing FH information can be used.

Objective: In this study, we aimed to construct an FH lexical resource for information extraction and normalization.

Methods: We exploited a transformer-based method to construct an FH lexical resource leveraging a corpus consisting of clinical notes generated as part of primary care. The usability of the lexicon was demonstrated through the development of a rule-based FH system that extracts FH entities and relations as specified in previous FH challenges. We also experimented with a deep learning–based FH system for FH information extraction. Previous FH challenge data sets were used for evaluation.

Results: The resulting lexicon contains 33,603 lexicon entries normalized to 6408 concept unique identifiers of the Unified Medical Language System and 15,126 codes of the Systematized Nomenclature of Medicine Clinical Terms, with an average number of 5.4 variants per concept. The performance evaluation demonstrated that the rule-based FH system achieved reasonable performance. The combination of the rule-based FH system with a state-of-the-art deep learning–based FH system can improve the recall of FH information evaluated using the BioCreative/N2C2 FH challenge data set, with the F1 score varied but comparable.

Conclusions: The resulting lexicon and rule-based FH system are freely available through the Open Health Natural Language Processing GitHub.

Introduction

Family history (FH) has long been regarded as a core element in caring for patients who have varied health concerns [1], with the capability to significantly enhance the delivery of precision medicine [2]. However, FH data are underused for actionable risk assessment [1]. One barrier to using FH information is provider preference in recording the collected FH information

in an unstructured format (eg, clinical notes) [3] as opposed to within electronic health record (EHR) structured data [4]. As clinical text tends to be unstructured, the information contained within is computationally inaccessible relative to that contained in structured records. This lack of computational accessibilities poses a challenge in using FH information for downstream data analytics or clinical practice (eg, via clinical decision support). One approach to render information data computationally accessible is through the use of natural language processing (NLP), thus motivating our work to develop an NLP system that can extract and normalize FH information.

Despite the majority of clinical NLP measurement studies focusing on statistical approaches, rule-based NLP systems based on semantic lexicons and rule patterns are popular among observational studies [5] for cancer research and practice [6,7]. With the advantages of ensuring process transparency, implementability, and scientific rigor, semantic lexicons and rule patterns are interpretable and easily modifiable, conforming to the FAIR (Findable, Accessible, Interoperable, and Reusable) and RITE (Reproducible, Implementable, Transparent, and Explainable) principles [8,9] for scientific data management. In addition, semantic lexicons and rule patterns capture sublanguage characteristics of domains that can be portable and generalizable to other applications [10]. By sublanguage, we refer to domain-specific linguistic and lexical patterns that are more prominent in free text in specialized fields such as medicine.

One popular lexical resource for clinical NLP is the Unified Medical Language System (UMLS), a repository of biomedical vocabularies distributed by the US National Library of Medicine, integrating over 200 biomedical vocabularies. A source vocabulary contained within the UMLS is the Systematized Nomenclature of Medicine Clinical Terms (SNOMED-CT), which is the recommended coding system for clinical problems. As not all terms in the UMLS or SNOMED-CT are part of the FH sublanguage, in this study, we exploited a corpus-driven method with pretrained language models to build an FH semantic lexicon with the normalization feature and reasonable size and coverage.

There have been previous efforts focused on creating semantic lexicons for clinical NLP. Johnson [11] automatically constructed a semantic lexicon based on the Specialist Lexicon of the UMLS, which can assist NLP analysis of a medical narrative with the semantic preference options of selecting semantic type. Luo et al [12] created a semantic lexicon using UMLS knowledge sources by leveraging a corpus from ClinicalTrials.gov. Liu et al [13] constructed a corpus-driven semantic lexicon based on the UMLS assisted by variants mined and usage information gathered from clinical text.

Regarding deep learning–based approaches, pretrained language models such as bidirectional encoder representations from transformers (BERT) [14] can learn the structure of language (ie, the basic semantic and syntax information) through unsupervised training on a large corpus of unlabeled text [15]. Given a new task, such pretrained models can be fine-tuned with a small number of annotated samples to perform well [16].

With respect to the FH information extraction task, we hypothesized that terms in a large-scale corpus having semantic types similar to the entities labeled in the data set used for fine tuning can be detected by fine-tuned BERT models in a named entity recognition task. Additionally, we hypothesized that corpus-driven methods would enable more term variants to be discovered from real-world EHR data, from which the lexicon results could further enhance and empower FH information extraction systems. Operating under these two hypotheses, we here present an FH lexicon derived through a combination of these two approaches. To demonstrate the usability of the FH lexicon, we further developed a rule-based FH system based on the lexicon that extracts FH entities and relations specified in previous FH challenges and evaluated its performance accordingly. In terms of system development, we consider that an FH system that prioritizes recall is highly desired for NLP-assisted curation in EHR-based studies.

Methods

FH Concepts

Before assembling an FH lexicon, we defined FH concepts as those belonging to the selected UMLS semantic types within the “DISO” (disorder) semantic group (Table 1), excluding T050 (experimental model of disease) [17]. Figure 1 shows our study design. We first fine-tuned Bio_ClinicalBERT, UmlsBERT, and bert-base-uncased models, and selected the model with the best performance. We then used the selected model to extract potential disorder/finding related mentions in a large clinical corpus. Subsequently, potential FH mentions were automatically normalized, manually curated, and prepared into symbolic lexicon format compatible with the Open Health Natural Language Processing (OHNLP) Toolkit’s NLP engine MedTagger [18]. A coverage evaluation was conducted for the lexicon. To demonstrate the usability of the lexicon, a rule-based FH system was developed to extract FH information. In parallel, we also experimented with a deep learning–based FH system for FH information extraction. Previous FH challenge data sets were used for evaluation [19,20].

T191	Neoplastic process
T033	Finding
T046	Pathologic function
T184	Sign or symptom

Resources

Overview

Here, we introduce the resources used for lexicon construction and all relevant evaluations. Specifically, the 2018 BioCreative FH challenge training set and the 2012 I2B2 training set were used as the supervised data sets to fine-tune the deep learning models for lexicon preparation. Various data sets were experimented with based on a hypothesis that more data could encompass more semantic contexts of potential FH mentions. The 2018 test set was used to evaluate lexicon coverage. The 2018 and 2019 FH challenge training sets were used for training of the rule-based FH system and fine-tuning the deep learning–based FH system, and the 2018 and 2019 FH challenge test sets were used for evaluating the performance of the FH systems in extracting FH entities (task 1) and relations (task 2). A large EHR corpus was used for collecting potential FH mentions. MedLex was used to further enrich term variants of FH concepts extracted by the selected model. The UMLS was used for semantic type selection, while UMLS and SNOMED-CT were used for a comparison of size with our corpus-driven dictionary. Table 2 summarizes specific applications of the resources in the lexicon construction and all relevant evaluations. Detailed descriptions for each resource are provided below.

Synthetic FH Annotation Data Sets (A-D)

As the organizer of the BioCreative/OHNLP 2018 Family History Extraction Task [19] and 2019 NLP Clinical Challenge (N2C2)/OHNLP shared task [20], we curated deidentified annotation data sets based on synthetic clinical narratives. Data set A corresponds to data set C in the BioCreative Challenge and data set B corresponds to data set D in the N2C2 Challenge. FH was annotated as "observation" and defined as any health-related problem, including diseases, smoking, suicide, and drinking, while excluding auto accidents, surgeries, and medications [19]. Family members (FMs), observation, age, and living status were annotated as entities, and then all entities related to an FM category were linked into one chain. We further enhanced the resulting annotations in the data sets by normalizing observations to SNOMED-CT codes and correcting errors in previous annotations. The reannotated data sets are accessible based on the Data Use Agreement. Multimedia Appendix 1 shows the statistical comparison between original and enhanced annotations.

I2B2 Data Set (D)

The 2012 I2B2 NLP challenge organizers provided a fully deidentified data set with annotations for temporal relations as well as those generated from previous challenges such as the 2010 challenge of clinical concept extraction (problems, tests, treatments) [21], where problems include symptoms, complaints, diseases, and diagnoses.

EHR Raw Corpus

The raw corpus used in the study consists of 9,426,352 text segments extracted from the Family History section of clinical notes prior to 2013 of a primary care cohort (ie, the employee and community health cohort), which contains 83,000 patients at Mayo Clinic.

Dictionary Resources

MedLex is a semantic lexicon built on a large corpus of clinical documents collected at Mayo Clinic and from the UMLS (2011AA version) [13]. MedLex contains term variants from real-world EHRs, serving as a practical dictionary resource for FH lexicon expansion. We used MedLex to further enrich term variants of FH concepts extracted by the selected model. The UMLS (2021AA) and SNOMEDCT_US concepts accessible through the UMLS were restricted to only English entries. The MRCONSO table of the UMLS, which includes over 200 source vocabularies, was used for coverage evaluation, and the MRSTY table of the UMLS was used for screening semantic types for each concept unique identifier (CUI) in the MRCONSO table.

Ethical Approval

Use of the EHR raw corpus data was approved by the Mayo Clinic Institutional Review Board (17-003030) for Human Subject Research.

BERT-Based Corpus Analysis for Lexicon Construction

BERT Models for Extraction of Potential FH Mentions

BERT-base-uncased was pretrained on an unsupervised NLP data set using a masked language modeling approach [14]. Bio_ClinicalBERT was initialized from BioBERT and trained on all Medical Information Mart for Intensive Care notes [22]. UmlsBERT is a contextual embedding model that integrates domain knowledge during the pretraining process via a novel knowledge augmentation through the UMLS Metathesaurus [23]. UmlsBERT and Bio_ClinicalBERT are domains related to this study, while BERT-base-uncased could be used as a baseline comparison. We used configurations mostly consistent with the recommendations in the original release of the models. The maximum sequence length was set to 512, the batch size was set to 16, the total number of training epochs was set to 100, and the weight decay was set to 0.01. An early stopping method was used to determine the optimal number of epochs and to prevent overfitting. The train/test split was 80/20, where the "train" split was used for training and the "test" split was used for validation.

We fine-tuned these models on the BioCreative training data set, I2B2 training data set, as well as the combination of the BioCreative and I2B2 training data sets. We then selected the model with the best performance to extract any potential FH mentions in the raw corpus having coarse-grained semantic types similar to the entities labeled in the supervised data.

Normalization

The extracted FH mentions were automatically normalized through a standardization framework for clinical problems (SFCP) [24]. This framework converts free-text clinical problem descriptions into standardized forms based on the UMLS CUI corresponding to SNOMED-CT concepts and the Health Level 7 Fast Healthcare Interoperability Resources (FHIR)-based structured representations, including the codified problem and all relevant modifiers and context. The CUIs associated with the SNOMED-CT concept were used for coding. For example, for the mention "allergy-induced asthma," the framework outputs "C0440102 | Various patch test substance" and "C0155877 | Allergic asthma."

Manual Curation and Further Enrichment

We reviewed all normalized FH mentions and retained the main normalized problem concepts with semantic types corresponding to those previously selected. For example, for the mention "allergy-induced asthma," the codified problem "C0155877 | Allergic asthma" was kept and "C0440102 | Various patch test substance" was removed from the final lexicon. In some cases, one BERT-extracted mention can be normalized to several individual concepts through the automatic standardization. We then enriched the FH lexicon by keeping all individual concepts and obtaining associated variants from MedLex.

In addition, we manually mapped high-frequency mentions that occurred across at least 20 patients that were not automatically standardized to corresponding CUIs.

Rule-Based FH System

To demonstrate the capability of the FH lexicon in extracting FH relations, we further implemented a rule-based FH system by integrating rules for FM identification with the resulting lexicon. Multimedia Appendix 2 shows three degrees of consanguinity we aggregated into FM identification rules. FH relations were then extracted based on co-occurrence within a clause of one sentence or across three adjacent sentences if coreference existed, as indicated by keywords such as "he," "she," "none of them," "her," or "his," while excluding relations between FMs of spouse and FH. We implemented this as an OHNLP Toolkit module with code available on GitHub [25]. The implementation provides several output formats, including FHIR-based output, with FM and FH standardization conforming to FHIR standardization. The final output of the rule-based FH system includes entities and relations. The entity output includes file name (which links to document references with patients' ID), sentence ID, chunk ID, entity type, concept, and certainty. The relation output includes file name, FM, side of family, text of observation, and certainty. An option is also available to output this information to CSV, instead of FHIR, format. To set SNOMED-CT condition codes as the standard, a separate mapping file is required due to SNOMED-CT licensing restrictions.

Deep Learning–Based FH System

As information extraction remains a challenging task, it is preferred to investigate what is the gain from deep learning–based models. Therefore, we further implemented a deep learning–based FH system as follows. Note that we experimented with fined-tuned models for two purposes in this study. The first was to fine-tune models for identifying and collecting potential FH mentions from clinical texts to build a dictionary, as described in the previous section. Here, the second purpose was to fine-tune models for information extraction to automatically identify FH entities and relations.

The Princeton University Relation Extraction (PURE) system is an approach where the entity model builds on span-level representations and the relation model builds on contextual representations specific to a given pair of spans. As this pipelined approach has been demonstrated to be extremely effective, we implemented PURE using scibert-scivocab-uncased as the base encoder and fine-tuned it based on the BioCreative and N2C2 training data [26].

Evaluation

Overview

We conducted two evaluation studies, including (1) a coverage evaluation of the lexicon and (2) a comparison study of a lexicon-based module with a deep learning–based module for FH information extraction.

Lexicon Coverage

To the best of our knowledge, our lexicon is the first to incorporate a large number of text variants and concepts of FH. Therefore, we compared the resulting lexicon with the UMLS and SNOMED-CT in terms of the number of concepts under each semantic type. We analyzed the lexicon coverage by

calculating the number of concepts under each semantic type. In addition, we calculated the number of concepts and variants covered by the corpus-driven lexicon run against the BioCreative testing data set relative to annotated gold standards. True positive (TP) rate based on a partial match, false negative (FN) rate, and recall (TP/[TP+FN]) at the concept level and variant level were calculated.

Performance of FH Information Extraction

We evaluated the utility of the lexicon in identifying mentions of FMs and their associated attributes (side of family) using the BioCreative testing set and the N2C2 testing sets (ie, task 1 of the challenges). Precision, recall, and F1-scores were calculated as the performance metrics of the lexicon-based module, the deep learning–based module, and both.

We also evaluated the rule-based FH system's ability to identify relations between FMs, observations, and living status using the BioCreative testing set and N2C2 testing sets (ie, task 2 of the challenges). This task was different between the 2018 BioCreative and 2019 N2C2 challenges in that the latter added a certainty attribute (negated or nonnegated) into relation extraction. Three sets of precision, recall, and F1 values were separately calculated using varying setups: rule-based module only, deep learning–based module only, and a combination of both. Our evaluation scheme is the same as that applied in the 2018 BioCreative and 2019 N2C2 FH challenges. We performed a general error analysis to investigate error sources. In addition, to further investigate how much the lexicon contributes to system performance, we performed an ablation study and specific error analyses.

Results

Multimedia Appendix 3 shows the performance of the BERT-base-uncased, UmlsBERT, and Bio_clinicalBERT models fine-tuned on the BioCreative training data set, I2B2 training set, and on the combination of the BioCreative training set with the I2B2 training set. As the model fine-tuned on the combination of the two data sets outperformed other models, we selected the combined model to extract potential FH mentions from the corpus.

There were 72,518 unique entities identified by the Bio_clinicalBERT model fine-tuned on the combination data set, of which 47,250 (65.16%) were automatically normalized to 10,579 CUIs through the standardization framework for clinical problems. We manually normalized 148 entities occurring across more than 20 patients that were not automatically normalized to CUIs. For example, "typediabetes" with a frequency of 3693 was normalized to C0011854 (diabetes). Note that spellings such as "typediabetes" found in the EHRs are most likely typos due to physicians' writing, backend EHR note processing, or tokenization challenges. Therefore, manual normalization is important. After semantic type screening, manual curation, and MedLex enrichment, the final FH lexicon contained 33,351 dictionary entities normalized to 6177 CUIs and 15,126 SNOMED-CT codes, with an average of 5.4 variants for each concept. Table 3 shows the comparison of sizes of various lexicons. The corpus-driven lexicon was more light-weighted, with more variants per concept. This implies that implementation with the lexicon for NLP tasks would be easier and more efficient with the corpus-driven lexicon than with the SNOMED-CT and UMLS lexicons.

Lexicon coverage evaluation on the BioCreative testing data set showed that there are 137 TP entities corresponding to 128 concepts and there are 16 FN entities, of which 6 entities had no corresponding concepts in the FH lexicon and 10 entities had 10 corresponding concepts in the FH lexicon. Concept-level recall was 95.8% and variant-level recall was 89.5%. For the N2C2 testing set, there were 507 TP entities corresponding to 214 concepts and 62 FN entities, of which 33 entities had no corresponding concepts in the FH lexicon and 29 entities had 26 corresponding concepts in the FH lexicon. Concept-level recall was 87.9% and variant-level recall was 89.1%. Table 4 shows the comparison of numbers of semantic types of CUIs in various lexicons. It can be observed that the corpus-driven lexicon contains less concepts under each semantic type compared with the UMLS and SNOMED-CT lexicons.

Table 5 shows the performance of FH systems for subtasks 1 and 2 of the BioCreative and N2C2 challenge data sets (original and reannotated) categorized by the rule-based FH system only, deep learning–based FH system only, and a combination of the two. For task 1, the highest F1 score was 0.8766 from the deep learning–based model on the original BioCreative data set and was 0.8061 on the original N2C2 data set. For task 2, the highest F1 score was 0.6206 from the deep learning–based module on the original BioCreative dataset and was 0.5940 from the combined results on the original N2C2 data set. The rule-based FH system based on the corpus-driven lexicon produced lower F1 scores in contrast with the deep learning–based FH system for both tasks, but higher or comparable recall for task 1 and higher recall for task 2. The combined results had the highest recall compared with the rule-based FH system or the deep learning–based FH system for task 1, ranging from 0.8669 to 0.9475. The combined results also showed the highest recall (ranging from 0.7109 to 0.8370) and varied F1 scores (ranging from 0.4288 to 0.6142) for task 2.

Table 3. Comparison of the size of lexicons.

Lexicon	Concepts (CUI[a])	Variants	Average number of variants per CUI
Corpus-driven lexicon	6177	33,351	5.40
SNOMED-CT[b]	412,027	1,349,838	3.28
UMLS[c]	4,440,279	9,569,507	2.16

2019 testing	0.3309	0.8168	0.4629	0.4003	0.5292	0.4548	0.3060	0.8150	0.4288

A general error analysis showed that errors could be divided into two major sources. First, varied definitions of FH between different subtasks represented a confounding factor. FH in the gold standards was defined as any health-related problem, including diseases, smoking, suicide, and drinking, excluding auto accident, surgery, and medications [19], whereas the definition in the FH lexicon is based on semantic types (Table 1). For example, mastectomy, a procedure, was annotated as an

observation (FH) in the challenge data sets, which is not in the scope of our lexicon. Second, the intrinsic difficulty of FH relation extraction and its textual representations presented several obstacles, particularly with symbolic systems. The rule-based FH system used simple heuristic rules, and therefore it is difficult to handle complex relationships, especially when the subtask 2 of challenges includes multiple layers of relationships.

In the ablation study, for task 2 based on the original BioCreative test set, the precision, recall, and F1 score for observation only (excluding living status) were 0.5419, 0.6265, and 0.5783, respectively, representing a slight improvement compared with the corresponding values of 0.5413, 0.6000, and 0.5673 for both observation and living status. For task 2 based on the original N2C2 test set, the precision, recall, and F1 score were 0.3984, 0.7033, and 0.5449, respectively, for observation only (excluding living status); 0.4275, 0.6658, and 0.5444, respectively, for both observation and living status; and 0.3730, 0.6675, and 0.5169, respectively, for both observation and certainty. Although living status and certainty alone had little impact on the performance, the combination of observation, living status, and certainty resulted in significantly lower performance of 0.4089, 0.5571, and 0.4716 for precision, recall, and F1, respectively.

Discussion

FH has its own sublanguage. However, some terms related to FH may not actually be used in practice or may be used very rarely, such as “ancestor,” “descendant,” or “genealogy.” For this reason, these terms may not appear in the lexicon. As FH is specifically related to blood relations (consanguinity), it relates to the patient themselves. Therefore, the FM of spouse should not be considered, and FH elements relating to a spouse (rather than the patient) should consequently not be extracted. The advantage of this operation is the consistency with definitions of FM, resulting in a list of FH of the relevant FMs. The disadvantage may be missing the spouse’s relatives and associated FH information. There are some social, behavioral, and environment factors shared in the same household, which also represent critical information. However, these are social determinants of health and not part of the blood relations.

Collecting lexicon entries can be defined as a named entity recognition task, which is an important task for identifying meaningful terms and multiword phrases in free text [27]. In this study, we fine-tuned several BERT-based models for the purpose of identifying potential FH mentions from an EHR corpus, leveraging various data sets for the purpose of providing more context for fine-tuning BERT-based models. Lexicon entries were collected from a large clinical EHR corpus, mitigating the problem of missing entities caused by limited amounts of data. The dictionary coverage evaluation showed that it covers a greater range of lexical variants and focuses primarily on clinical concepts typically reported as part of FH relative to a direct lexicon generated from the UMLS and SNOMED-CT. Our corpus-driven lexicon features FH definitions based on semantic types, concept normalization to UMLS and SNOMED-CT CUIs, and manual curation, with the potential to resolve semantic ambiguity and promote interoperability among various systems. The rule-based FH system also provides standard Health Level 7 FHIR output to foster interoperability.

FH relation extraction is more relevant for downstream analysis compared with entity extraction. In previous challenges, the F1 score was regarded as the most important metric for relation extraction evaluation. The highest F1 score obtained from challenges was 0.5708 in the BioCreative challenge [19] and was 0.681 in the N2C2 challenge [20]. However, it is not our aim to compete with previous studies in terms of F1 scores. As relation extraction is still a challenging task, an FH system that prioritizes recall is highly desired for NLP-assisted curation in EHR-based studies. Our evaluation results showed that the rule-based FH system on top of the corpus-driven lexicon produced higher recall than that obtained with the deep learning–based FH system. In addition, the combined results from both the rule-based module and the deep learning–based FH system resulted in the highest recall for relation extraction, ranging from 0.7109 to 0.8370, which were higher than the recall values obtained in any previous challenge results, ranging from 0.3732 to 0.6810.

Note that we did not observe higher performance when using the reannotated data as compared to the original data. There may be two underlying reasons for this. First, reannotated data have not been used for training the rule-based system. Second, reannotated data were obtained by a professional annotator with deep domain knowledge, which makes the information extraction task harder. In addition, we observed that performance on 2019 N2C2 FH challenge data was worse than that on the 2018 BioCreative FH challenge data. This is mainly because the 2019 N2C2 FH challenge added a certainty attribute (negated or nonnegated) into the relation extraction, which made the relation extraction task harder.

Our FH synthetic data sets used for training and testing were from real clinical sentences, for which the observations, FMs, and ethnicities are shuffled among the whole corpus using a heuristic deidentification process. The granularity of the synthetic FH data sets is the same as that of real FH data. In this study, we have not exhaustedly compared all BERT-related models. Theoretically, large language models–empowered knowledge engineering is sufficient for lexicon entry collection from a clinical corpus. Our focus in this study was to provide a corpus-driven lexicon resource that leads to a rule-based FH baseline system for high-throughput analysis, while doing so in a manner that promotes interpretability and explainability for downstream applications.

We recommend that a comprehensive FH system include both a rule-based module and a deep learning–based module to obtain higher recall, which could facilitate manual curation. Although only the rule-based FH system can output normalized concepts, output from a deep learning–based FH system can be a rich source to enrich the lexicon. In the future, we will repeat the SFCP normalization for the output from the deep learning–based FH system to consistently improve the FH lexicon and the rule-based FH system. Meanwhile, we will continue to manually review the BERT-extracted entities without automatic

normalization with frequency under 20, and look into other data sources such as social media so as to expand more concepts and/or term variants for the current lexicon. In addition, we will engage the user community to continuously refine the lexicon. We also plan to update the lexicon and rule-based FH system yearly, which will be distributed through the same open-source repository on GitHub.

There are three limitations to this study. First, although a large corpus with 83,000 patients was used for collection of potential FH variants, there is still a possibility that the FH information is not well represented. In addition, as the lexicon was developed using a largely monoinstitutional data resource, the lexicon may not be generalizable in other institutions. Second, during the entity normalization, we simply adopted an existing standardization framework, as it was not a priority of this study to focus on standardization method development. Third, we arbitrarily set a frequency cutoff of 20 for entities that were not automatically normalized to include in our manual review. However, we realize that some entities with low frequency also have the potential to contribute to the lexicon entries, such as "rectal ca" with a frequency of 18 and "highcholesterol" with a frequency of 12.

In summary, we constructed a corpus-driven FH lexicon to serve as a language resource for FH information extraction. Standardization of concepts in the FH lexicon and the rule-based FH system foster interoperability. The resulting lexicon and the rule-based FH system are freely available as part of the OHNLP Toolkit ecosystem. In the future, we will continue to expand more concepts and/or term variants of the current lexicon, and will explore the incorporation of the system for data curation efforts needed in various EHR-based studies and applications.

Abstract

Background: Given the threat posed by cancer to human health, there is a rapid growth in the volume of data in the cancer field and interdisciplinary and collaborative research is becoming increasingly important for fine-grained classification. The low-resolution classifier of reported studies at the journal level fails to satisfy advanced searching demands, and a single label does not adequately characterize the literature originated from interdisciplinary research results. There is thus a need to establish a multilabel classifier with higher resolution to support literature retrieval for cancer research and reduce the burden of screening papers for clinical relevance.

Objective: The primary objective of this research was to address the low-resolution issue of cancer literature classification due to the ambiguity of the existing journal-level classifier in order to support gaining high-relevance evidence for clinical consideration and all-sided results for literature retrieval.

Methods: We trained a multilabel classifier with scalability for classifying the literature on cancer research directly at the publication level to assign proper content-derived labels based on the "Bidirectional Encoder Representation from Transformers (BERT) + X" model and obtain the best option for X. First, a corpus of 70,599 cancer publications retrieved from the Dimensions database was divided into a training and a testing set in a ratio of 7:3. Second, using the classification terminology of International Cancer Research Partnership cancer types, we compared the performance of classifiers developed using BERT and 5 classical deep learning models, such as the text recurrent neural network (TextRNN) and FastText, followed by metrics analysis.

Results: After comparing various combined deep learning models, we obtained a classifier based on the optimal combination "BERT + TextRNN," with a precision of 93.09%, a recall of 87.75%, and an F_1-score of 90.34%. Moreover, we quantified the distinctive characteristics in the text structure and multilabel distribution in order to generalize the model to other fields with similar characteristics.

Conclusions: The "BERT + TextRNN" model was trained for high-resolution classification of cancer literature at the publication level to support accurate retrieval and academic statistics. The model automatically assigns 1 or more labels to each cancer paper, as required. Quantitative comparison verified that the "BERT + TextRNN" model is the best fit for multilabel classification of cancer literature compared to other models. More data from diverse fields will be collected to testify the scalability and extensibility of the proposed model in the future.

Introduction

Background

According to the World Health Organization (WHO) reports, cancer is one of the leading causes of death worldwide, accounting for nearly 10 million deaths in 2020 [1]. With cancer emerging as the greatest threat to human life, there is a rapid growth in the volume of literature published in the cancer field. The trend of disciplinary convergence has led to publications requiring labels from multiple subjects. Consequently, there is increasingly more demand for accurate cancer literature classification for retrieval, evidence support, academic analysis, and statistical evaluation in order to support clinical research, precision medicine, and discovery of interdisciplinary cancer research [2,3] by forecasting trends and hotspot statistics.

Text classification is the process of assigning specific labels to the literature based on individual features. The current methods of classifying the literature can be divided into 3 groups: mapping based, subject information based, and machine learning based [4-6]. Recently, an increasing number of studies have experimented with deep learning to enhance the effects of text classification [4]. Most of the existing literature classification (eg, Web of Science, Scopus [7-11]) is usually carried out at the journal level, that is, all papers in a given journal get the same labeling categories as the hosted journal. However, given that interdisciplinary research is increasing in the cancer field [12], there is a need for a more precise classifier, as papers from a journal always present a diverse range of topics [13,14]. Moreover, literature classification at the journal level can no longer adapt to the dynamics of newly developing subjects and fully characterize text features.

Related Works

Development of Text Classification Technology

Text classification technology has undergone rapid development from expert systems to machine learning to finally deep learning [15]. Maron [16] published the first paper on automatic text classification in 1961. By the end of the 20th century, machine learning had matured into a fully developed field [17]. Joachims [18] established the bag-of-words model to transform text into a vector with a fixed length and then selected features using the information gain criterion to achieve dimensionality reduction, eventually training the feature vector iteratively using a support vector machine (SVM) classifier. Rasjid [19] focused on data classification using k-nearest neighbors (k-NN) and naive Bayes. Liang et al [20] improved the feature recognition of the literature using appropriate clusters and the introduction of differential latent semantics index (DLSI) spaces. In 2006, with the rapid development of deep learning, text classification research based on deep learning gradually replaced traditional machine learning methods and became the mainstream, with wide applications in numerous tasks [4].

The deep learning–based text classification method adopts word vectors (eg, GloVe [21] and word2vec [22]) for word semantic representation [23], and subsequently, various deep neural network (DNN)–based text classification methods develop. Convolutional neural networks (CNNs) [24] were originally constructed for image processing and have been broadly used for text classification [25-27]. Due to the computational complexity, deep network gradient disappearance, and short text content of a CNN, a series of optimized models were gradually derived to address these issues, including FastText [28], deep pyramid convolutional neural networks (DPCNNs) [29], knowledge pyramid convolutional neural networks (KPCNNs) [30], and text convolutional neural networks (TextCNNs) [26]. Especially, the TextCNN is a simple, shallow network and requires only a small number of hyperparameters for fine-tuning. Compared with CNNs, recurrent neural networks (RNNs) can easily implement multilayer superposition to construct a multilayer neural network [31], such as multilayer long short-term memory (LSTM) [32] or multilayer gate recurrent unit (GRU). In terms of improvements to RNNs, the text recurrent neural network (TextRNN) uses a multitask learning framework to jointly learn across multiple related tasks; a deep recurrent neural network (DRNN) [23] incorporates position invariance into an RNN, captures local features to find the optimal window size, and then achieves marked improvements over RNN and CNN models. All these models have laid the foundation for follow-up studies.

Bidirectional Encoder Representation from Transformers (BERT) has emerged as a new linguistic representation model by the introduction of attentional mechanisms, which have been broadly applied in machine translation [32], image description generation [33], machine reading comprehension [34], and text classification [35]. Being a bidirectional encoder model based on a transformer, BERT became an important advancement of natural language processing, especially text classification. For example, Shen et al [36] attempted to train a Chinese corpus–based $BERT_{base}$ model for the classification of the literature on Chinese social science and technology and also explored its application to practical production. In addition, Lu and Ni [37] developed a multilayer model for patent classification using the combination "BERT + CNN," while Liu et al [38] proposed a sentence-BERT for hierarchical clustering of literature abstracts. However, the accuracy of applying universal language models directly to the biomedical field is not sufficient, and this motivated studies to train the biomedical BERT from scratch. Typical instances are BioBERT pretrained on PubMed citations and PubMed Central (PMC) full text [39] and PubMedBERT obtained with mixed-domain pretraining using PubMed text and clinical notes [40]. Up to now, BioBERT and PubMedBERT have achieved success in named entity recognition, extraction of relationships between entities, entity normalization [41,42], *International Classification of Diseases* (ICD) autocoding [43], and its multilabel classification (MLC) [44]. These studies afford us lessons that merit attention.

Multilabel Text Classification

The deep learning model has contributed to the success of MLC due to its dynamic representation learning and end-to-end learning framework. Multilabel text classification (MLTC) is the application of MLC to the task of text classification and the assigning of a set of targeted labels to each sample [45], which has been part of the longstanding challenge in both academia and industry. In the biomedical domain, Du et al [46] proposed an end-to-end deep learning model ML-Net for biomedical text, while Glinka et al [47] focused on a mixture of feature selection methods, filter, and wrapper methods. In addition, Hughes et al [48] tried to classify medical text fragments at the sentence level based on a CNN, and Yogarajan et al [49] used a multilabel variant of medical text classification to enhance the prediction of concurrent medical codes. Automatic question-and-answer systems and auxiliary decision-making are the 2 typical applications of MLTC. For example, Wasim et al [50] proposed a classification model for multilabel problems in the flow of biomedical question-and-answer systems with factlike and listlike questions. Similarly, Baumel et al [51] presented a hierarchical attentional bidirectional gated cyclic unit that used attention weights to better understand the sentence and word with the greatest impact on the decision.

In this study, we adopted MLTC technology to classify cancer publications for better retrieval, academic analysis, and statistical evaluation. We introduced a method of multilabel classification for cancer research at the publication level based on the "BERT + X" model. BERT is a learning model that can migrate to other tasks to obtain better outcomes, which was pretrained on a large and easily accessible data set, and X is a deep learning model that can capture semantic features of text accurately. The combined model was trained on a corpus from a multilabel publication database, and then cancer publications were classified into appropriate categories directly at the publication level instead of the journal level.

Methods

Study Design

This study mainly aimed to train a deep learning–based multilabel classifier for cancer literature classification at the publication level. The overall framework of the study is illustrated in Figure 1. First, a corpus of titles and abstracts of cancer publications retrieved from the Dimensions database were divided into a training and a testing set in a ratio of 7:3 after preprocessing. Second, to capture sufficient text features for multilabel classification, the titles and abstracts were taken separately as 2 independent layers, which were called the "tuple" in this study. Finally, "BERT + X" classifiers based on 5 deep learning models were trained; X refers to "TextRNN," "TextCNN," "FastText," "DPCNN," and "DRNN." The performance of the candidate classifiers was compared quantitatively in terms of 3 conventional metrics in order to identify the optimal model for classifying cancer literature.

Data Collection and Preprocessing

Refined data with semantic and context features are the basis of deep learning model training. In this study, to train a lightweight, compatible, and high-applicability classifier for text classification, we first preprocessed cancer literature data to extract features and sequential semantic information. The classification terminology maintained by the International Cancer Research Partnership (ICRP), called cancer type (CT), was used as standard labels to characterize individual cancer studies in terms of 62 CTs. The ICRP CT has been linked to the ICD maintained by WHO [52] and is increasingly gaining rapid recognition worldwide. Moreover, the ICRP CT has been applied to several international databases for labeling cancer literature and research documents with fine granularity. A typical example is the Dimensions database (Digital Science & Research Solutions, Inc), which covers more than 135 million publications, 6.5 million grants, and 153 million patents, providing a collaborative path to enhanced scientific discovery with transparent data sources. Importantly, cancer publications with ICRP CT–classified labels from the Dimensions database provide a way to prepare annotation data for model training.

Construction of the Corpus and Balanced Sampling

A set of 70,599 publications from 2003 to 2022 was randomly sampled from the Dimensions database using the keyword "cancer," along with the ICPR CT labels for each publication. Figure 2 shows the distribution of different CTs among the corpus data. Here, to intuitively demonstrate the volume distribution in the 62 different cancer categories, we ranked the

categories in descending order of the number of corresponding publications included. Categories with sample sizes larger than 500 were listed separately, while the remaining 41 (66.13%) categories were grouped into 3 classes: CT22-CT35, n=14 (34.15%) categories; CT36-CT49, n=14 (34.15%); and CT50-CT62, n=13 (31.71%). The top 9 (14.52%) categories (breast cancer, non-site-specific cancer, colon and rectal cancer, lung cancer, prostate cancer, ovarian cancer, stomach cancer, cervical cancer, and pancreatic cancer) accounted for 76.35% (53,899/70,599) of the total corpus. Obviously, the distribution of labeling data was uneven, and the top 9 labels contained more than three-fourths of the total corpus. Once the original corpus was directly used to train the deep learning model without balanced sampling, the resulting classifier would cause overfitting due to a few categories with excessive volume and fail to be generalized in practical use.

To avoid the degradation of precision caused by overfitting, we balanced the data sampling before model training. First, we ranked the cancer categories in descending order of the number of corresponding publications. Next, a threshold (70 in our study) used for setting the sampling index was obtained after multiple testing, followed by calculation of the index using categories with more than 70 publications. The resulting mean , median, variance, standard deviation of the number of samples contained in each category were recorded as follows: mean=1127, median=282, variance=5,889,927, and standard deviation=2427. Here, the median was selected as the initial index according to the actual distribution of sampling data. Considering that 30% of the corpus was used as the testing set, the final index was set to 500 in terms of the number of publications for a competent training set. Therefore, categories whose number of publications exceeded the final index were balanced and down-sampled separately, which means that 500 publications from each category were randomly extracted for a uniform corpus.

Table 1 shows part of the balanced sampling results. It is clear that the optimized corpus contributed to a reduction in the adverse effects of overfitting and was subsequently used for keyword extraction and model training.

Figure 2. Original sample distribution of CTs. CT: cancer type.

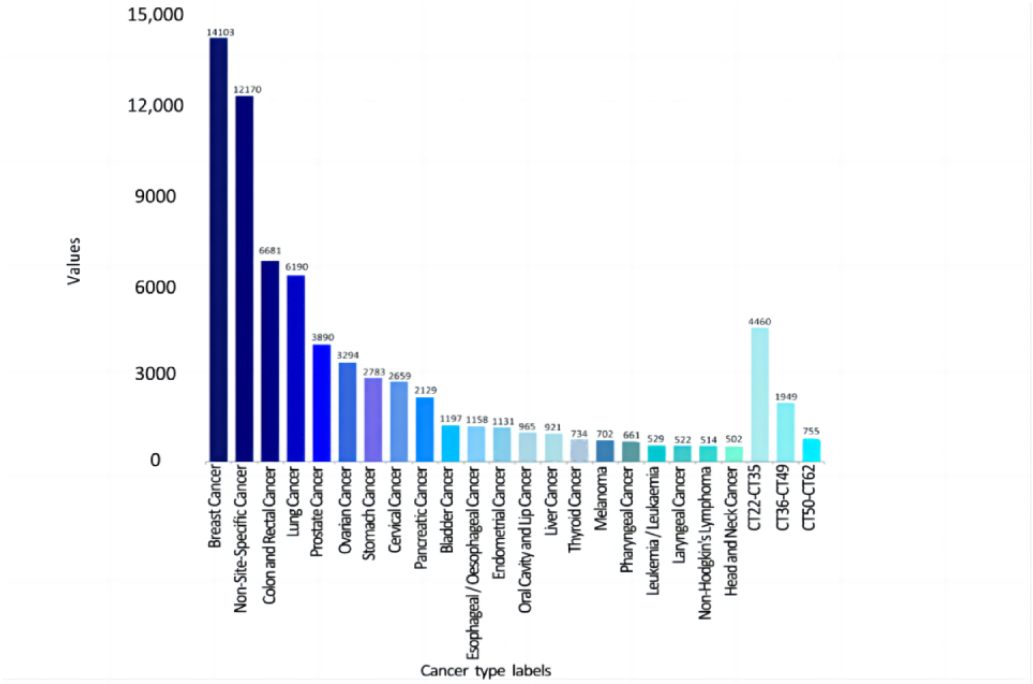

Table 1. Example of balanced sampling of top 21 categories (N=70,599 publications).

Sequence number	ICRP CT[a]	ICRP code[b]	ICD-10[c] code	Original sample[d], n (%)	Balanced sample[e], n (%)
1	Breast cancer	7	C50	14,103 (19.98)	500 (3.55)

12	Endometrial cancer	11	C54	1131 (1.60)	500 (44.21)
13	Oral cavity and lip cancer	36	C00, C01, C02, C03, C04, C05, C06, C09	965 (1.37)	500 (51.81)
14	Liver cancer	23	C22	921 (1.30)	500 (54.29)
15	Thyroid cancer	54	C73	734 (1.04)	500 (68.12)
16	Melanoma	29	C43	702 (0.99)	500 (71.23)
17	Pharyngeal cancer	61	C14.0	661 (0.94)	500 (75.64)
18	Leukemia/leukaemia	27	C91, C92, C93, C94, C95	529 (0.75)	500 (94.52)
19	Laryngeal cancer	26	C32	522 (0.74)	500 (95.79)
20	Non-Hodgkin's lymphoma	35	C82, C83, C84, C85, C96.3	514 (0.73)	500 (97.28)
21	Head and neck cancer	21	C76.0	502 (0.71)	500 (99.60)

[a]ICRP CT: International Cancer Research Partnership Cancer Type; here, "ICRP CT" denotes the label.

[b]"ICRP code" refers to the label code.

[c]ICD-10: International Classification of Diseases, Tenth Revision; this is the ICD code linked to the appropriate ICPR CT.

[d]"Original sample" represents the number of publications obtained directly from the Dimensions database.

[e]"Balanced sample" means the number of publications after balanced sampling.

[f]N/A: not applicable.

Construction of a Tuple Consisting of a Title and an Abstract

The corpus of cancer publications consisted of titles and abstracts in English, while the title and abstract of each publication was saved separately for ease of use. Generally, the title is a short sentence of a confined length to express an independent meaning, which has a high rate of conformity regarding the content. Comparatively, an abstract is also valuable, since it clearly and accurately summarizes the main content of the publication by expressing its purpose, methods, results, and conclusions. In this study, both title and abstract were independently used to train a 2-layer classifier based on their semantic and context features, called a tuple for simplicity.

Keyword Extraction From the Abstracts of Cancer Publications

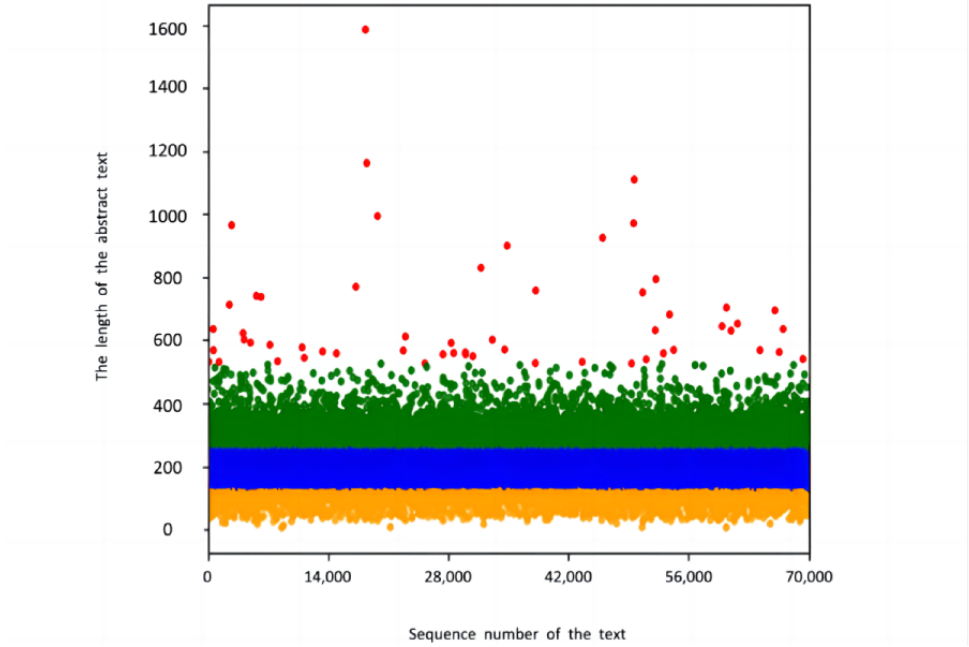
In this study, in contrast to the abstract layer, the operation of the title layer mainly focused on keyword training. However, the number of valid keywords contained in titles is quite limited. To improve feature representation and model performance, more keywords were extracted from the abstracts and merged with the title layer. The TextRank algorithm [53] was adopted for keyword extraction from the abstracts, taking advantage of the co-occurring semantics information between words from the given sentences.

A lightweight classifier was desired in this study, so the length of the abstracts needed to be controlled to keep a balance between the running speed, effectiveness, and volume occupied. To ascertain the most appropriate abstract length, we analyzed the scatter plot of the abstract length distribution, as shown in Figure 3. Here, the horizontal axis represents the serial number of publications, the vertical axis represents the length of the publication abstracts, and the red (length>512), green (256<length≤512), blue (128<length≤256), and orange (length≤128) colors represent different abstract lengths separately. Among them, the blue zone was evenly distributed

and had a high proportion, the red zone had the least proportion, and the green and orange zones were comparable.

After statistical analysis, the maximum length of the abstracts was set to 256 characters mainly for 3 reasons. First, 256 is the 8th power of 2, which facilitates machine understanding after tuning [53]. Second, we wanted to collect the most valid information as much as possible, while reducing sparsity. Third, we wanted to avoid the learning of shallow networks, which are equivalent to follow-up layers when training (ie, gradient disappearance).

Figure 3. Scatter plot of distribution of abstract length.



Training a Model for MLCT

Upstream Pretrained Language Models

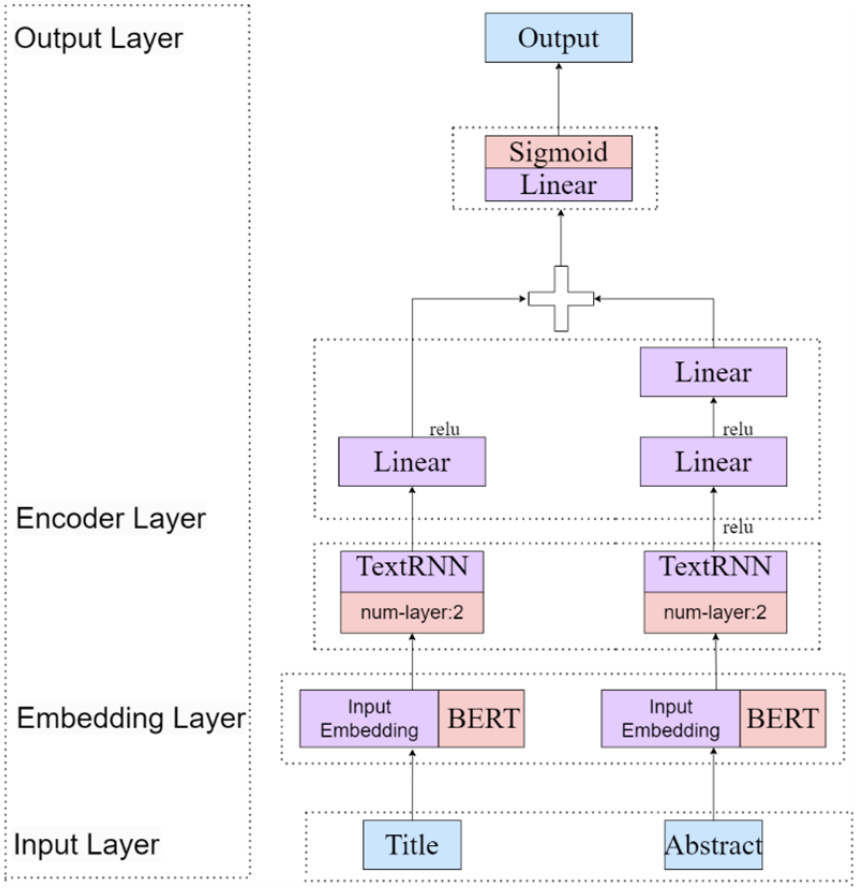
Pretraining generally refers to putting a large amount of low-cost collected training data together, learning the commonalities of the data, and then tuning the model that has the commonalities with a small amount of labeled data of a specific domain. Therefore, pretrained language models start from the commonalities and learn the special parts of the specific task. BERT is a successful model pretrained on Wikipedia and a book corpus via self-supervision tasks, and fine-tuning benefits downstream tasks. Being a pretrained language model based on the bidirectional transformer encoder architecture, BERT uses sentence-level negative sampling to obtain sentence representation/sentence pair relationships. In addition, BERT takes advantage of the transformer model instead of LSTM for expressive and temporal efficiency, as well as the masked language model to extract contextual features. We used BERT to handle specific natural language processing tasks downstream to produce word vectors in the pretraining stage. During the fine-tuning, we then completed data training for the pretrained BERT through the output layer based on cancer publications in order to save time and improve accuracy.

Downstream Classification Model Training

To complete the actual task of downstream natural language processing based on the fine-tuned upstream procedure, we tried to train several preliminary language models and then chose one as the optimal model for our classifier according to its all-round performance. The “BERT + X” pattern was adopted for the classifier to determine the optimum option for X and the best way to combine BERT and X. According to the actual scenario and expert consultations, including the length, tightness of context, and multidisciplinarity, 5 models suitable for cancer publications were compared for the classification model: TextCNN, TextRNN, FastText, DPCNN, and DRNN. Eventually, the definitive combined classifier would come out dependent on the comprehensive performance analysis of these 5 models.

The structure of the classification model is shown in Figure 4, where the TextRNN is selected as a representation of the 5 models, for example. Here, the title and abstract were input into the title layer and the abstract layer, respectively, while the word vectors were converted by BERT and passed to the encoder layer. The word vectors output from the title and abstract layers were stitched together and then transferred to the fully connected layer for normalization, while the final output of multilabel classification was generated by the sigmoid layer with the activation function.

Figure 4. Structure of the classification model. BERT: Bidirectional Encoder Representation from Transformers; TextRNN: text recurrent neural network.



Testing and Verification

To evaluate the performance of the trained classifier, a subset of the testing sample was selected from the corpus, which covered all 62 classification labels defined in the ICRP CT. We applied 3 frequently used indexes, namely precision, recall, and the F_1-score, to verify the classification results of the 5 models. Here, the F_1-score is the harmonic mean of precision and recall; the larger the F_1-score, the better the performance of the classification model. The quantitative indexes of the 5 "BERT + X" models were compared numerically and independently to choose X.

Results

Quantitative Analysis of the Performance of Classification Models

The test results of the combined classification downstream models are shown in Table 2, where we compared performance on 3 aspects (precision, recall, F_1-score) of 5 classification models (BERT + TextRNN, BERT + TextCNN, BERT + FastText, BERT + DPCNN, and BERT + DRNN). All metrics of BERT + TextRNN were consistently at a high level, with a precision of 93.09%, a recall of 87.75%, and an F_1-score of 90.34%. Here, BERT was directly used for fine-tuning training, combined with the TextRNN for multilabel classification. After adjusting and testing the parameters several times, the best parameters were obtained and are shown in Table 3.

Table 2. Performance comparison of 5 different "BERT[a] + X" models.

Model	Precision (%)	Recall (%)	F_1-score (%)
BERT + TextRNN[b]	93.09	87.75	90.34
BERT + TextCNN[c]	84.19	79.69	81.88
BERT + FastText	93.05	75.73	83.50

Supplementary Analysis of the Model Structure

The proposed classification model takes the title and abstract of a publication as independent input, namely a tuple, as mentioned in the "Methods" section. To verify the effectiveness of the tuple input of the trained model, we conducted a set of comparison experiments based on "BERT + TextRNN." Especially, "2 tuples and 2 levels" represents the model that took the title and abstract as 2 levels of the training model separately, "1 unit and 1 level" represents the model that combined the title and abstract as whole-text input for training, and "the title alone" and "the abstract alone" represent the models that took the title or the abstract alone as input, respectively. Table 4 records the performance of different models from supplementary experiments, where the "2 tuples and 2 levels" model was superior, with a precision of 93.09%, a recall of 87.75%, and an F_1-score of 90.34%. The reason is that when applying the title or abstract alone to train the classification model, feature reduction occurs, which further leads to inferior performance of classification. In addition, compared with the "1 unit and 1 level" model taking the title and abstract as a 1-part text input, the "tuple and 2 levels" model enhanced the specificity of feature extraction. Notice that the title and abstract make different contributions to the subject of publication, and the classification model will lose the sufficient feature of the abstract if it is not trained separately. Eventually, the classification of the tuple input was elected for the proposed classification model. This is also identical to most of the subject-based literature processing, which take the title and abstract as independent text, such as subject indexing.

In addition, the proposed classification model used the TextRank algorithm to extract keywords from the abstract and supplement the title layer with them. To demonstrate the necessity and effectiveness of this step, Figure 5 shows the numerical indexes of the classification model with and without keyword extraction and supplementation. Here, the performance of the model with TextRank keyword extraction is shown in blue, and the results with direct training using titles and abstracts separately are plotted in green. It is obvious that the model without keyword

supplementation had a lower performance in recall, precision, and the F_1-score, which confirms the efficiency and effectiveness of the proposed classification model from a different perspective.

Table 4. Comparison of different types of input.

Input	Precision (%)	Recall (%)	F_1-score (%)
2 tuples and 2 levels	93.09	87.75	90.34
1 unit and 1 level	82.32	79.78	81.04
The title alone	44.37	31.54	36.88
The abstract alone	85.50	79.79	82.55

Comprehensive Analysis of the Multilabel Classification

To explore whether there was a particular regularity in the distribution of multiple labels among different categories, the proportion of multilabel publications was statistically analyzed for classifier training. In total, 15,296 (21.67%) of the 70,599 publications had 2 or more labels, that is, more than one-fifth of the publications were multilabel ones. In addition, the categories were counted based on the characteristics of the number of labels (Figure 6) to visualize multilabel distributions. Here, we listed the top 20 categories by the volume of the publications included. The blue color refers to the total number of samples collected under a specific category, the green color is the number of samples with multiple labels under that category, and the yellow color denotes those with at least 3 labels. The categories with fewer samples had a higher ratio of multiple labels, and multiple labels had different characteristics among different categories. Analysis for a deeper relationship between multiple labels is necessary.

There are principally 2 roles of comprehensive analysis of multilabel publications. First, it highlighted the process of balanced sampling. Since part of the publications belonged to multiple categories and some of the categories had a high co-occurrence frequency compared to other categories, direct model training on the original corpus would lead to overfitting due to uneven distribution of samples. This is why we selected multilabel papers instead of those with a single label in order to obtain a balanced sample for classifier training. Second, the multilabel publications revealed the potential semantic correlation of texts, which provided a direction for the analysis of data characteristics. Based on the co-occurrence correlation and distribution between different categories, the semantic features were further characterized and the proposed classification model extended to other data with the same characteristics.

To explore the inherent correlation between multiple labels, we selected 2500 multilabel publications from the corpus for characteristics analysis. Specifically, samples with 2 labels accounted for 59.04% (1476/2500) and samples with at least 3 labels accounted for 40.96% (1024/2500) of all publications. Table 5 lists part of the analysis results. For instance, different CTs often co-occurred for statistical surveys in the literature review with a weak association.

The correlation strength of multiple labels of cancer publications were independently reviewed and assessed by 3 biocurators with relevant knowledge. Concretely, a publication with 2 labels and a clear semantic correlation within the corresponding subject classification labels was interpreted as “1,” while a publication

with 3 or more labels and more than two-third of the labels holding an obvious semantic association were also considered as "1". Once the 2 biocurators reached the same results, that specific publication was passed into the "review completed" data set. When they had different opinions, the corresponding publication was annotated as "pending review." After the first round of reviewing, the "pending review" data set was discussed together for the second time, and a third biocurator was invited for confirmation and agreement.

Figure 7 shows specific numbers of labeled publications with interlabel correlation, where the "strong association" zone consists of publications whose co-occurrence labels had explicit links between semantics, the "low association" zone consists of publications whose co-occurrence labels did not have clearly semantic links, and the "independent examples" zone consists of publications whose cancer labels were taken as single entities or independent examples for observation without intrinsic correlations. Of the 1476 publications with 2 labels, 1201 (81.37%) had a strong association, while 572/1024 (55.86%) publications with at least 3 labels had a low association. Among the publications with lowly correlated labels, 718/1024 (70.12%) took the different categories of cancers as a single entity or independent examples for observation without intrinsic correlations. We noticed some possible influence on the association distributions for training. In addition, the relationship between 2 labels in a publication was stronger than that among 3 or more labels, which justifies the demand to classify publications by subject at the publication level. Therefore, the strength of interlabel association could achieve the effect of assisting decision-making after multilabel classification to further support clinical diagnosis and treatment. In the future, we will carry out knowledge mining based on the existing interlabel semantic network and strengthen the training of interlabel association to improve the performance of the proposed classification model.

Figure 6. Comparison of samples with multilabels.

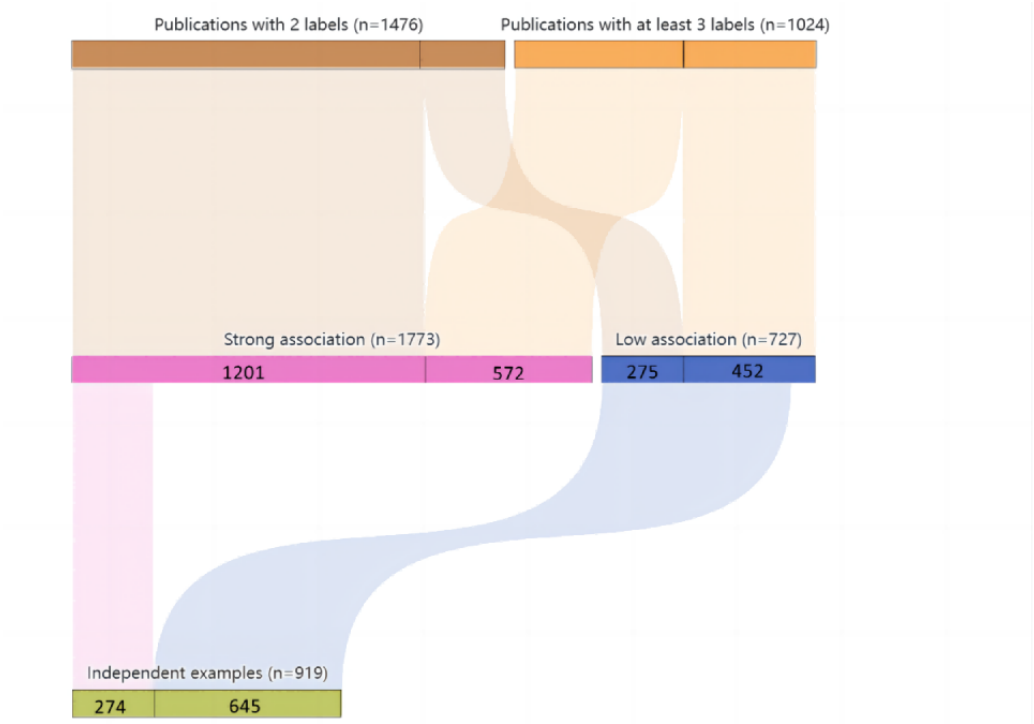
[a]In the last column, “1” refers to a strong correlation, which means 2 labels of a given publication are semantically or syntactically linked to each other, such as relaying, concurrency, and coupling effects. Conversely, “0” indicates a weak association between multiple labels of a specific publication, and there is no obvious semantic or syntactic correlation.

Figure 7. Relational mapping of multilabel publication distributions.



Discussion

Principal Findings

There are several reasons for the "BERT + TextRNN" model to show optimal performance in cancer publication classification. First, cancer publications usually consist of long texts (eg, titles and abstracts) containing specialty terms and intensive contextual semantic correlations, which are quite suitable for the TextRNN model, which is good at processing sequential information with strong correlation and a high degree of uniformity. Moreover, comprehensive analysis of multilabel classification reflects that cancer publications are characterized by a high multilabel rate in areas with low research intensity due to the interdisciplinary and cooperative working, which enhances the contextual correlation to a certain extent. The "BERT + TextRNN" model is more likely to be efficient in such fields because it can effectively capture contextual semantics.

Compared with the TextRNN, the other models were insufficient and could be further improvement. The TextCNN might not be able to capture sufficient features, since it is not highly interpretable and well suited to address the fixed-length horizon issue. Although the DRNN is an enhanced version of the RNN with low computational speed, it fails to consider any upcoming input to the current state. Therefore, the DRNN is much less effective than the TextRNN. Being a long-linear model, FastText hardly handles the recognition of the long text of cancer publications and needs further optimization due to a limited recall rate.

Limitations

The proposed classifier based on the "BERT + TextRNN" model has 2 issues. On the one hand, the performance of the classifier may be reduced due to the accumulation of errors caused by keyword extraction, which will be enhanced by adjusting the model parameters and adding a self-testing function. On the other hand, the tuple input of titles and abstracts was integrated to train the multilabel classifier, which proved to be better than the input of titles or abstracts alone. Therefore, cancer publications with both title and abstract are desired for the proposed classifier. However, for the few cancer publications papers without abstracts, the classifier we trained will still be usable and has a slight performance cost.

Major Applications of the Proposed Classifier

We trained a classifier based on the "BERT + TextRNN" model for classifying the cancer literature at the publication level, which could directly assign multiple labels to each publication. The proposed classifier has at least 2 major applications. First, the desired model can achieve efficient and effective multilabel classification of cancer publications more granularly, not only for cancer publications in English, but also for full-text literature in other language whose titles and abstracts have English versions. Since the trained classifier is based on cancer publications with titles and abstracts, it should be suitable for any papers whose titles and abstracts are written in English (eg, Chinese medical publications). Another significant application is the fine-grained classification of scientific data on cancer research. Given that valuable data are accompanied by a brief description in English, the proposed model will classify them into the groups with appropriate CTs. Therefore, a content-based label in terms of CTs will be assigned to scientific data and literature, which provides a way to construct a full spectrum of data foundation for precision medicine.

Conclusion

Given that existing classification methods are at the journal level and there is an urgent need for subject classification due to the proliferation of cancer research, a multilabel classifier

was trained based on deep learning models, specifically "BERT + TextRNN." Moreover, the proposed high-resolution classification model was evaluated as being efficient and effective for cancer publications in terms of quantitative comparison and feature analysis.

The innovative exploration in this study is as follows:

- The "BERT + TextRNN" classification model was trained for classifying cancer literature at the publication level, which shows promise in automatically assigning each publication at least 1 label to which it belongs.
- The proposed model achieves high-quality multilabel classification at the publication level, which could reflect the features of cancer publications more accurately with multiple labels compared to the existing method that annotates papers with a single label at the journal level.
- By comprehensive analysis of the correlation between multiple labels, as well as the data characteristics of multilabel cancer publications, the proposed model was verified to be suitable for the literature with features such as high specialization, uniform entity nouns, and standardized long texts.

In the future, the classification model will be extended to classify medical literature on cardiovascular disease and diabetes, where a great number of highly specialized publications have accumulated and are attracting increasing research attention, in order to improve health conditions worldwide.

Abstract

Background: In molecular tumor boards (MTBs), patients with rare or advanced cancers are discussed by a multidisciplinary team of health care professionals. Software support for MTBs is lacking; in particular, tools for preparing and documenting MTB therapy recommendations need to be developed.

Objective: We aimed to implement an extension to cBioPortal to provide a tool for the documentation of therapy recommendations from MTB sessions in a secure and standardized manner. The developed extension should be embedded in the patient view of cBioPortal to enable easy documentation during MTB sessions. The resulting architecture for storing therapy recommendations should be integrable into various hospital information systems.

Methods: On the basis of a requirements analysis and technology analysis for authentication techniques, a prototype was developed and iteratively refined through a user-centered development process. In conclusion, the tool was evaluated via a usability evaluation, including interviews, structured questionnaires, and the System Usability Scale.

Results: The patient view of cBioPortal was extended with a new tab that enables users to document MTB sessions and therapy recommendations. The role-based access control was expanded to allow for a finer distinction among the rights to view, edit, and delete data. The usability evaluation showed overall good usability and a System Usability Scale score of 83.57.

Conclusions: This study demonstrates how cBioPortal can be extended to not only visualize MTB patient data but also be used as a documentation platform for therapy recommendations.

Introduction

Background

In molecular tumor boards (MTBs), clinical and molecular genetic data from patients with cancer, with a focus on those who lack standard treatment options or have rare tumors, are analyzed and discussed by oncologists, pathologists, and bioinformaticians regarding similarities, abnormalities, and possible new findings. The main goal is both to use advanced molecular genetic diagnostics and clinical assessment to provide therapy recommendations and to gather new insights and potential indications for highly personalized and genome-based therapy recommendations. Such MTBs combine research with patient care and are thus increasingly being implemented by oncologists around the world, as initial studies have shown a benefit for overall patient survival [1-3].

Despite the promising opportunities offered by MTBs, they still face various challenges that need to be addressed. These include the structured documentation of molecular data alongside clinical data and the resulting therapy recommendation in accordance with internal hospital guidelines and patient protection guidelines [4]. However, these data protection guidelines are yet to be uniformly designed and thus handled differently in each hospital [5], requiring local implementation of interfaces to patient records and laboratory systems. Although the transition from paper-based solutions to structured tools such as the electronic health record (EHR) is well advanced, patient-specific MTB therapy recommendations are still often designed as unstructured, free-text fields [5]. Hospitals use either self-programmed software solutions or a combination of various text editors and prefabricated forms, as shown by Hinderer et al [5] in 5 German hospitals. In these hospitals, the genomic data are recorded and communicated electronically or via paper, but in all cases, they are documented as free text without a coordinated data structure. However, this unstructured and nonstandardized state leads to the poor traceability of treatment evidence and decisions, making retrospective or follow-up studies, data sharing, and research projects difficult or even impossible.

Therefore, it is of utmost importance to document MTB recommendations and decisions based on molecular diagnostics in a structured and digital manner to standardize therapy recommendations and medical outcomes across clinics and sites with uniform data formats and reporting rules with the aim to improve patient care, as implied by Buechner et al [6].

Within the Medical Informatics in Research and Care in University Medicine (MIRACUM) consortium [7], the open-source platform cBioPortal [8,9], originally designed as a research platform for storing, analyzing, and visualizing omics data, is used to support MTBs.

To reach this goal, the platform is being adapted, extended, and integrated into university hospital networks so that data can be exchanged among the EHR, the laboratory systems, and the extended cBioPortal [10]. To promote structured therapy recommendations, we developed a therapy recommendation documentation module in cBioPortal, which is suitable for web-based use during MTB sessions as well as for preparation for upcoming MTB sessions.

Therapy recommendations are stored using Health Level Seven Fast Healthcare Interoperability Resources (FHIR) in compliance with the implementation guide “Genomics Reporting” and its German counterpart “Molekulargenetischer Befundbericht” by an FHIR-capable service running alongside cBioPortal [11]. This enables interoperability with the hospital information system (HIS). The standard cBioPortal data model is used for the storage of clinical and molecular patient data. During the development of the module, in addition to developing a standardized way to input the data, the focus was particularly on assuring high usability of the interface for the actual users, as this is a crucial point for the acceptance of a new tool and can even impact the operator’s therapeutic decisions, as shown by Bates et al [12]. To enable secure and compliant use of the data in the hospital network, IT security was taken into account from the beginning of the project. This means that the development was based on best practices regarding the chosen protocols and used interfaces. However, the developments in the area of IT security mainly focus on enabling a connection among the newly created user interface, the HIS, and external backends to the authentication mechanism already existing in the open-source platform and introducing role-based access rights to the backends compatible with commonly used identity providers (IdP). Other security-related aspects, such as enforcing encrypted communication in the network, identifying existing attack vectors, and following all legal and organizational guidelines, must be addressed by the responsible parties during integration into the target network of the respective partner sites.

Objectives

The cBioPortal research platform was expanded with a module that (1) is linked to EHRs and HISs, facilitates the digital documentation of therapy recommendations in MTB sessions in a structured manner, and (2) enables digital accessibility for all persons and partner sites involved in research projects. This allows the standardization of documentation processes across partner sites and supports subsequent collaboration between research and patient care. Therefore, the extension had to be compliant with IT security standards to protect patient data. Furthermore, the solution should be largely independent of the specifics of the HIS in use by providing portable interfaces, which ensures that it can be put into operation at additional sites without major migration effort and thus contribute to an expansion of the research network.

The first objective was to demonstrate the extent to which the solution can harmonize the currently used documentation processes for MTBs across sites. The second objective was to engage future users in a user-centered design approach by

applying an iterative feedback process [13-15] to ensure the quality of the module's use and user satisfaction during the MTB workflow. Finally, to further involve users in the development process and to test the success of this approach, a usability evaluation of the module's web interface was conducted.

Methods

User-Centered Design Approach

During the development of the application, a user-centered design approach was used, which consisted of a requirements analysis together with an iterative feedback process including all partner sites, to improve the usability and, thereby, the clinical applicability of the resulting tool. A total of 12 experts from 6 of the 10 partner sites were involved in this process. They covered a wide variety of backgrounds, including oncology, systems medicine, bioinformatics, and IT, and all of them belonged to the circle of future users. Although the exact processes and roles of an MTB vary from site to site, the use scenario of the documentation platform can be roughly divided into 2 roles. First, there is a preprocessing and postprocessing team, which takes care of data maintenance and documentation. Second, there is a specialist team, which looks at the data and discusses the cases in the MTB. However, both roles can sometimes be performed by the same people, depending on the responsibilities in the site. It was ensured that people from both roles were involved in the user-centered design approach. The selection of additional technologies and frameworks required for authentication and ensuring IT security was elaborated by means of a technology analysis and compared with widespread standards and best practices.

In the first step, the experts specified the required data elements and types from a medical perspective. Subsequently, this information was converted into a data structure applicable to therapy recommendations to be used in the prototype implementation for a high-fidelity mock-up of the documentation module. The resulting mock-up was then iteratively refined in 3 feedback sessions with the help of future users. Each session consisted of a short evaluation with the users, in which they reported feedback or problems via unstructured free text. This feedback was converted into change requests, documented in a quality management system, and integrated into the mock-up before the next feedback session commenced.

Prototype

After the completion of the extended user interface, the module was integrated into the front-end codebase of cBioPortal as a new tab in the patient view. For persisting the entered data, it was connected via a representational state transfer (REST) interface to a FhirSpark server that was used as a tightly coupled, secondary backend [11], resulting in the first fully functional prototype of the module. During the development of the front-end application as well as the backend connections and integrations, an agile approach was used, which was largely based on the adaptive software development concept [16]. The state of the prototype was extended in iterative steps, with the developers meeting at regular intervals with the project team and domain experts to evaluate the recent implementations and discuss the priorities and next features to be implemented from the design phase.

To provide a standardized and simplified way to install the whole setup, cBioPortal and the corresponding services were packaged as Docker containers [17] to make the solution independent of the operating system and use the easy deployment and distribution process of these containers. In the first step, the deployment workflow was tested at the University Hospital Erlangen, including the integration of the components with the HIS. In the second step, the tool was distributed to all 9 consortium sites of MIRACUM and 2 external partner sites to demonstrate that connection to the various systems in the hospital network can be established without major effort and is almost independent of the specific HIS in use. This test was accompanied by structured feedback questionnaires to evaluate whether the general installation was successful, the test data could be imported, and the various tools and annotation services were working as expected. The questionnaire was sent to the partner sites together with the documentation and was meant to be completed by the person responsible for setting up the system together with a key user of the application. This feedback was intended to show whether the planned goals for integrating external sites and distributing the modules can be achieved [10].

Usability Evaluation

Finally, a usability evaluation was conducted using the MIRACUM-cBioPortal (version 2021q1 [18]). This evaluation aimed less at evaluating the resulting application in comparison with other existing tools and more at evaluating the application's general usability in contrast to the previously unstructured approach, as a sufficient level of usability, which leads to users' acceptance, is the basis for a later successful adoption into the clinical workflow. The evaluation was set up as a combination of a task analysis with the thinking-aloud technique, as this approach focuses on the user needs and behaviors while they perform the tasks and can facilitate and accelerate further usability enhancements. In addition to the qualitative evaluation, several quantifiable metrics regarding the time and effort users spent on interacting with the system while completing the tasks were established to determine the extent to which the resulting web interface could meet the self-imposed requirements for improving the documentation process. During the test, users were guided through a series of 8 specific tasks designed to evaluate the system's usability and functionality while articulating their intentions and thoughts as they interacted with the web interface. These tasks encompassed actions such as logging in, creating a new MTB entry for a test patient, manually and automatically generating therapy recommendations, adjusting therapy priorities, and securely logging out. The tasks were formulated to closely mimic a typical workflow and test the essential features of the MTB software system. The users' performance on each task, that is, the time it took them to complete the task and the number of errors they made, as well as their verbally articulated insights, was derived into metrics that allow conclusions about the difficulty of the task itself as well as the amount of time the users spent physically interacting and cognitively engaging with the web interface while working on the given task. After the tasks were completed by the

prospective users, their perceived acceptance of and satisfaction with the module and workflow were measured by interviewing them using a structured questionnaire and the widely used System Usability Scale (SUS) [19] to obtain qualitative feedback as well. In these questionnaires, the users were asked about their level of agreement with preformulated statements about the platform (Multimedia Appendix 1) and performed tasks using a 5-level Likert scale, which ranged from "strongly agree" to "strongly disagree," allowing the derivation of an average satisfaction rate. Finally, the users were given the opportunity to share their opinions and additional subjective remarks to obtain further feedback about their acceptance of the developed module. This feedback was used to assess possible areas of improvement in the interface that could further increase the perceived usability.

Ethical Considerations

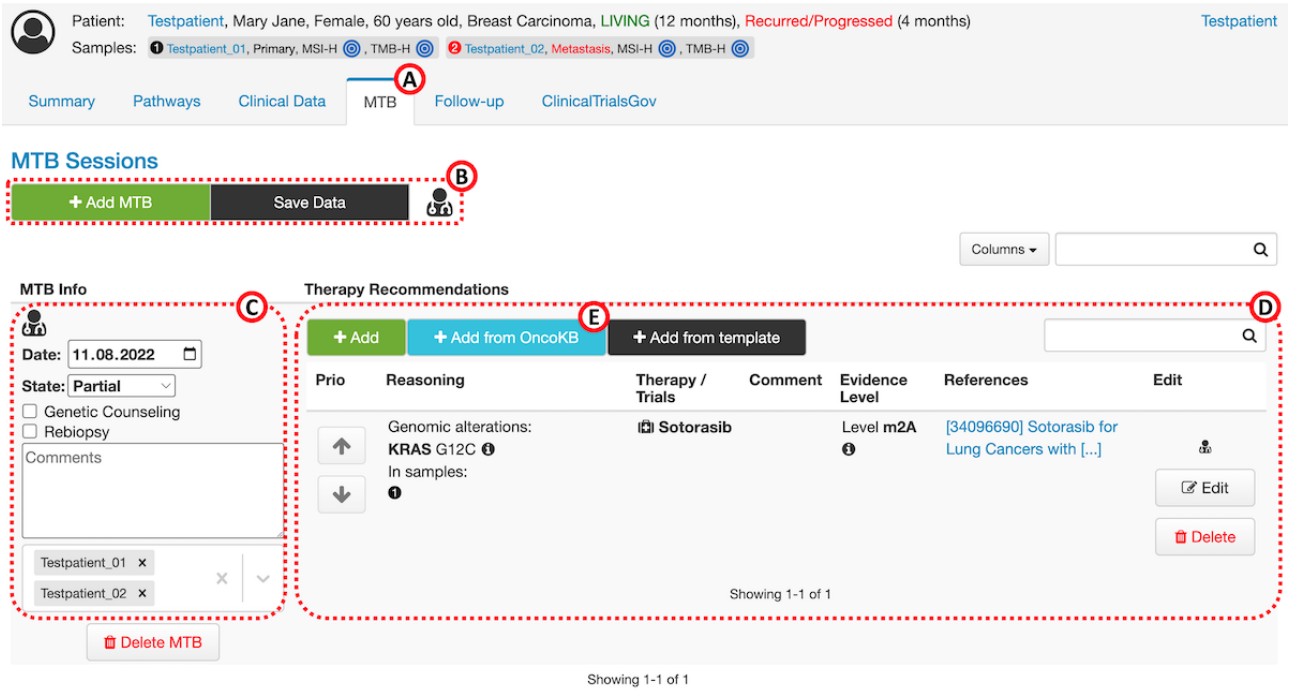
The project was performed in compliance with the World Medical Association Declaration of Helsinki on Ethical Principles for Medical Research Involving Human Subjects. Ethical approval was not required.

Results

User-Centered Design Approach Results

The harmonized data structure of the documentation module in the front end was developed using the iterative approach described earlier. The results showed that in addition to the general and organizational information about the MTB session and the medical data of the discussed patient, further therapy-related characteristics are required. Therefore, the data should include information such as the active substance or substances recommended for therapy, genetic alteration or alterations, complex biomarkers, and clinical data on which the recommendation is based, as well as the level of evidence (defined by the Zentren für Personalisierte Medizin). The clinical and genomic data of the respective patient are already stored in cBioPortal, whereas data about the active substances recommended and level of evidence had to be added and be selectable via a drop-down menu to avoid typing errors and inconsistencies during entry. To substantiate the evidence level, case reports and medical articles listed in the PubMed database [20] can be indicated by their ID, and a field for comments should be available for entering free text. In addition, the knowledge database OncoKB [21], which contains treatment implications of cancer gene alterations, was integrated. A separate button can be used to search for predefined treatment entries in this database and adopt them directly (Figure 1). The mapping of the entries derived from the external database into the module's corresponding input fields is automated, and only the evidence level must be defined manually owing to the use of different evaluation scales. Finally, the design of the web interface was defined, as shown in Figure 1.

Figure 1. Overview of the extended cBioPortal patient view. (A) Newly created tab "MTB" for documenting therapy recommendations. (B) User interface for adding molecular tumor boards (MTBs), saving data, and user management. (C) General information of the MTB session. (D) Detailed documentation of the recommended therapies or trials. (E) Button for adopting matching OncoKB entries as therapy recommendations.



Authentication Enhancement Results

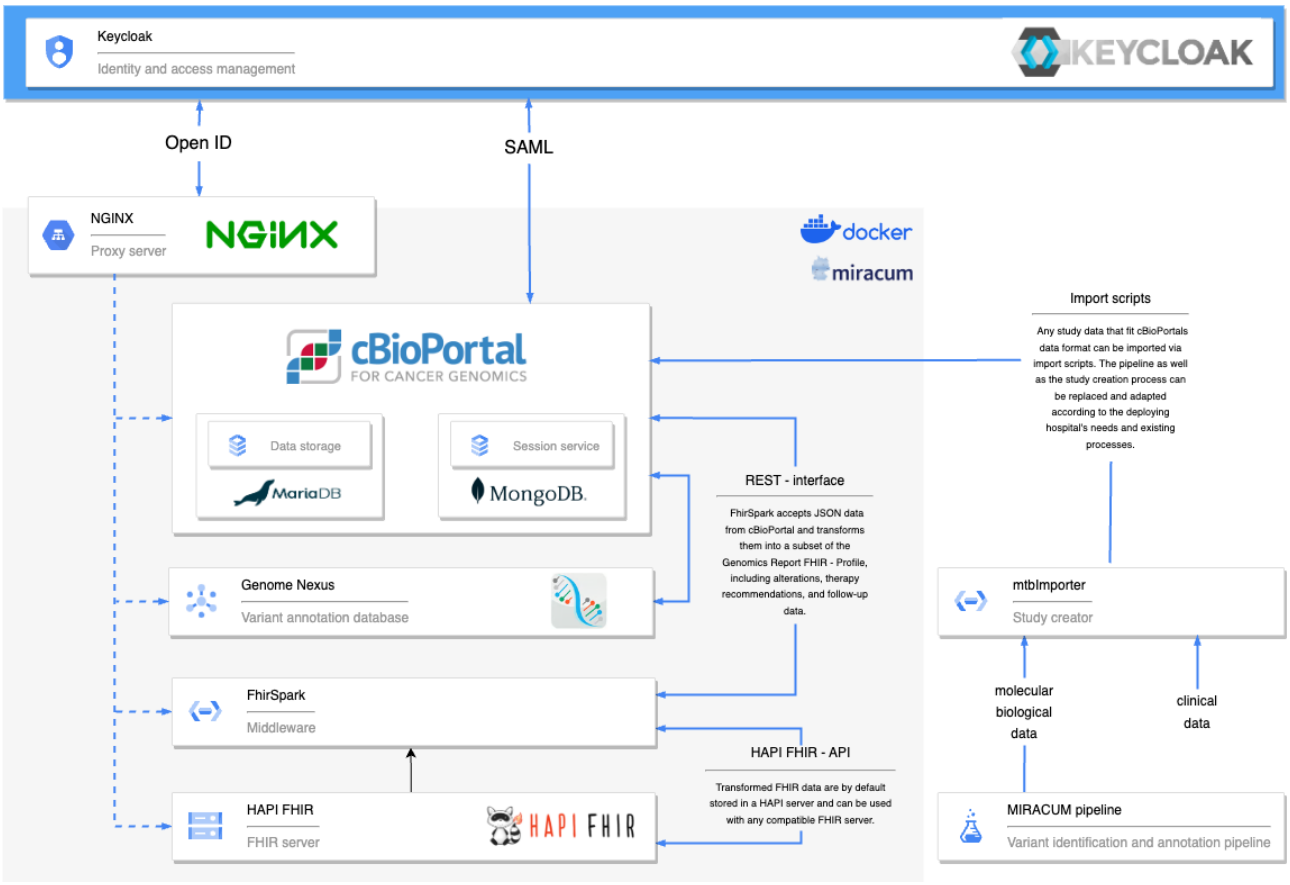
To integrate the module into the HIS and, thereby, comply with the applicable regulations and guidelines for the later planned productive operation, further measures for authentication and authorization had to be implemented in addition to the security features already provided by cBioPortal. Unauthorized access to the data stored in the secondary backend had to be prevented, and a finer distinction between read and write permissions for the data sets had to be enabled.

By default, it is already possible to connect cBioPortal to an external IdP using the Security Assertion Markup Language (SAML) framework [22] to establish a secure connection between the systems and enable individual user log-in sessions. In this process, users can be authorized individually via the IdP for each of the imported studies. For this purpose, the widely used open-source software Keycloak (JBoss) [23] is used, which is supported by Red Hat (Red Hat, Inc) and was already in use at the hospital's network. Keycloak is connected to the corresponding user databases via Lightweight Directory Access Protocol [24], whereby user information can be automatically imported to Keycloak and users can be granted access to cBioPortal, depending on their preassigned roles. However, the therapy documentation module requires the possibility of individually restricting access to patient data as well as a further differentiation of the rights for accessing, editing, and deleting the data. Therefore, it was necessary to set up an additional way of role-based access control for protecting the entered data and to generally restrict access to the FhirSpark backend server. For this purpose, with the lua-resty-openidc module [25], another open-source software was chosen. This module protects the backend by running directly on the nginx proxy server (Nginx, Inc) and can be configured to act as a relying party within the OpenID-Connect [26] authentication layer. For each incoming request, it verifies whether the caller is authenticated by Keycloak and, if so, forwards the user roles attached to the request so that the backend application server can process or deny the request according to the defined logic. Although this architecture uses 2 different protocols, the users are not negatively affected because they only have to log in once via Keycloak. When accessing individual resources, the IdP automatically takes care of the log-in and user role forwarding in the background via single sign-on (SSO). The advantage of outsourcing the access restriction to the nginx proxy server is that with this setup, additional backends can easily be integrated into the SSO realm without them having to deal with authentication protocols, as this is already taken care of by the proxy server.

Prototype Results

For the evaluation of the tool across partner sites, the dockerized workflow was made available via GitHub (GitHub, Inc) [18]. This project combines the extended cBioPortal front end and backend as well as the FhirSpark server, additional annotation services, and further modules for authenticating and authorizing users through a preconfigured nginx proxy server. A detailed system overview is depicted in Figure 2. The tool was deployed and evaluated at 11 partner sites, including the integration of local authentication and authorization services. The study by Reimer et al [10] provides a detailed overview of the evaluation results. Configuring and testing the authentication setup and the subsequent transmission of therapy recommendations to the FhirSpark backend were successful at 4 (36%) of the 11 sites. At the remaining sites (n=7; 64%), the setup was not tested because either a decision was made not to use an authentication service or configuration problems had already occurred at an earlier step, because of which a connection to the secondary backend could not be established. Feedback suggested that the documentation and setup instructions should be extended and adapted to the errors that arose. For example, in addition to listing the minimum hardware requirements and the recommended software versions to rule out errors due to insufficient server configuration, the documentation should be expanded to include an even more detailed description of the Keycloak integration.

Figure 2. Detailed system overview of the extended cBioPortal and the associated services that together form the software platform for supporting molecular tumor boards. API: application programming interface; FHIR: Fast Healthcare Interoperability Resources; HAPI: HL7 Application Programming Interface; MIRACUM: Medical Informatics in Research and Care in University Medicine; REST: representational state transfer; SAML: Security Assertion Markup Language.



Usability Evaluation Results

Among the 12 experts who participated in the user-centered design approach, 7 (58%), all of whom were working in the fields of molecular biology, oncology, and systems medicine and belonging to the group of potential future users, participated in the subsequent usability evaluation conducted to review the extended front-end module. The evaluation showed that, on average, the test users were 89% (SD 19.7%) confident that the enhanced platform can support them with their specific documentation tasks and 71% (SD 36.6%) confident that it can also support the general approach to conducting MTB sessions. With regard to the usability of the web interface itself and the input dialogs, an average satisfaction of 75% (SD 25%) was indicated in terms of the perceived comprehensibility and clarity of the user interface. In addition, the authentication features in particular were rated as satisfactory, with 82% (SD 18.9%) satisfaction in terms of user-friendliness, meaning that the users predominantly did not perceive authentication as disrupting their workflow. The mean score on the administered SUS was 83.6 (SD 14.3). On the basis of the results of the qualitative questionnaire, there is general comprehensibility of the web interface, although in some cases, the correct assignment of clinical data to the designated input fields was rated as not clear enough. For example, some participants attempted to enter relevant biomarkers such as the tumor mutational burden (TMB) value directly into the field for single genomic alterations, possibly thinking that the TMB should be directly assigned to the respective alteration. However, a separate field is provided for this purpose, as values such as the TMB refer not to an alteration but to a specific sample. Apart from providing minor assistance with entering free text so that it gets automatically applied when typing, allowing formatted comments, and more intuitive labeling of the log-in button, no major changes to the user interface were requested. Furthermore, the test users recommended that actual users be given a brief introduction to all the available functionalities at the beginning of productive operation.

For the quantitative evaluation of the task analysis, the proportions of time spent thinking and idling, with thinking and idling combined as cognitive processes, and time spent physically interacting with the web interface while executing the tasks in relation to the total time needed as well as the proportions of time spent for log-in and logout activities were collected. The results are depicted in Figures 3 and 4 and reveal that the actual physical tasks of interacting with the interface and entering new data accounted for the largest share of time spent at 56% (mean 190, SD 70 seconds) of the total time needed, followed by the cognitive processes at 39% (mean 267, SD 101 seconds). A total of 5% of the time was spent making corrections to previously entered data. The process of logging in and out of the platform, as well as verifying the authentication status, accounted for an average of 16% of the total interaction time.

Figure 3. Temporal distribution of the user interaction processes.

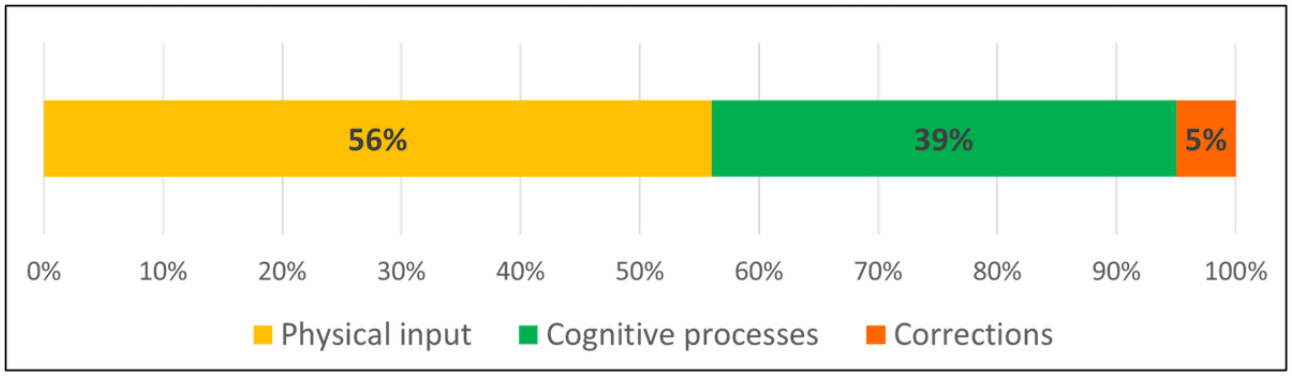


Figure 4. Temporal distribution of the authentication process.

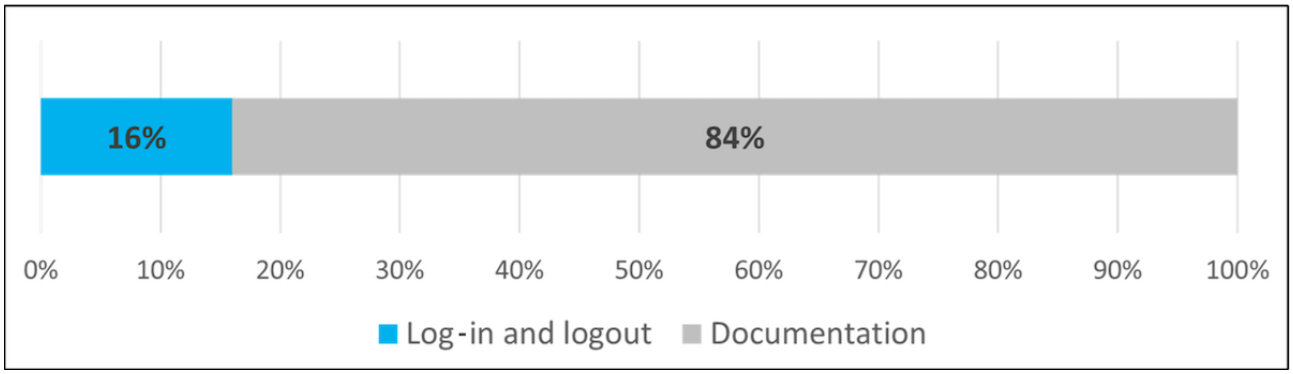

Discussion

User-Centered Design Approach Discussion

A new therapy documentation module for structured therapy recommendations in cBioPortal has been developed using a user-centered design approach and was tested with regard to its functionality and usability. As this was only a prototype implementation, there is still potential for additional enhancements and improvements in usability. The iterative development process revealed its importance through the users' identification of additional requirements at different stages of the prototype. It was found that maximizing the number of feedback rounds with the users provided valuable insights, although the frequency of these rounds was constrained by user availability and the development timeline. Comprehensive documentation was emphasized as crucial for facilitating the deployment phase, allowing for easier adoption and integration of the tool into existing workflows.

Authentication Discussion

To ensure compliance with information security goals, with the SAML framework, a standardized authentication technology is used to protect the connection between the software and the IdP of the hospital. cBioPortal already supports SAML by default; however, no practicable way could be identified to use SAML with the externally developed FhirSpark server, so OpenID-Connect was chosen instead as the security technology for connections to this application. As both protocols are widely used and most IdPs support them, it is possible to flexibly switch from Keycloak to another IdP while maintaining the existing setup and configuration without the need for major adjustments. The use of a proxy server in front of the different backends that takes care of the authentication protocols and forwards the user roles promotes subsequent adaptability to different network environments and the possibility to easily connect additional applications to the same role-based access control system. Furthermore, it is possible within the IdP to enable an SSO session between both protocols and across the several connected backends. With this SSO session, the IdP takes care of the authentication and authorization flow in such a way that users need to log in only once, but their user session is automatically authenticated at all the backends connected via the protocols without losing the advantages and flexibility that come from having 2 security mechanisms in place, with each one suited for its specific purpose. Evidently, certain applications can be excluded from the SSO, and the user permissions can be revoked as necessary. Another possible expansion of the functional scope and, at the same time, a broader differentiation of user permissions for the therapy recommendation module would be the introduction of explicit rights for the deletion of data, which would split up the previously existing editing rights into 2 separate scopes. This would enable the realization of further distinction possibilities between these operations, as there may be use cases where a user has the permission to create or edit entries but not to delete an entire MTB session for traceability and other security reasons. This possible introduction of different rights for the editing and deletion of data was specifically requested by the users; however, in the backend server, there are logging mechanisms that enable the traceability of data records and user actions.

Prototype Feedback

The decision to use a secondary backend for data persistence in the prototype implementation instead of using the existing

internal cBioPortal database is based on the fact that the cBioPortal database is primarily intended as a repository with read-only access to patient data without frequent changes. By contrast, the FhirSpark module is specially designed for changing data sets and provides support for traceability and version control. Furthermore, with each new release of the official cBioPortal backend, the differing database structures would have to be reviewed and potentially merged, which would require an additional maintenance effort. In addition, the proprietary backend offers a higher potential for interface customization and access control, allowing additional external applications to be connected to the database as needed with little effort.

By distributing the prototype implementation to several locations and receiving feedback on the installation and first practical tests, it was determined that the distribution of the application as Docker containers is a suitable method for deploying the software at all partner sites almost independently of the operating systems used and, thereby, accelerating the installation process [10]. This also facilitates the subsequent updates of new versions and changes to individual components. The successful setup and deployment of the platform's basic functionalities were confirmed by all sites, and the newly added components for IT security were successfully connected to the existing solutions and tested at several sites. However, at some sites, problems were encountered at various points in the configuration process, indicating that the documentation needs to be more detailed to cover all the edge cases and specifics of the different IT infrastructures used. To reduce the complexity of the installation process while testing, integrating the tool into the HIS with authentication services was highly recommended but only optional. Although this led to a significant adoption of the tool in general, little feedback was obtained on additional features such as authentication and connection to other systems. Some sites have not implemented these features because of time constraints; others used systems different from Keycloak for identity management, for which configuration instructions were not provided, although integration would be possible. Overall, the feedback provided several indications on how to improve the documentation for future releases as well as further suggestions for minor usability improvements to the user interfaces.

Qualitative Usability Evaluation

Regarding the functionalities offered by the enhanced web interface and the user satisfaction achieved while documenting the therapy recommendation, both indicators were rated as fundamentally positive and satisfactory by the users who participated in the usability evaluation. This shows that the future users are convinced that the module has the potential to digitalize the current processes and documentation data in a structured form and fulfills the general requirements for supporting the existing documentation processes and the expectations of the users. The somewhat lower assessment of the perceived overall support potential for MTB meetings (71%), in contrast to the assessment of the individual functionalities, can be explained by the fact that many sites already use locally established documentation processes, such as their own proprietary implementations or prefabricated text-based document templates. Therefore, converting all workflows to the integrated infrastructure is considered too costly and accepted by stakeholders only with reservations. Another issue is that some users mistakenly related the purpose of the evaluation not only to documentation tasks but also to the whole process of an MTB, starting with case preparation and data analysis. Therefore, the questions were answered from different perspectives. Nevertheless, further feedback should be sought on how to further increase the perceived potential among users. Altogether, the achieved SUS score of 83.6 is above average and can be rated as "excellent" [27] or graded as "A" [28], depending on the evaluation standard applied. Thus, the SUS confirms the results of the structured feedback questionnaire on user satisfaction with and support in using the module. It should be mentioned that the concrete SUS score should not be overinterpreted and can only show a tendency.

Quantitative Usability Evaluation

As the temporal distribution of the processes shows, the users spent most of their time physically entering the data. This is expected because the module is primarily a documentation tool. On the contrary, a predominant share of mental processes would be an alarm sign that the structure of the interface is too complicated. At 39%, the mental processes are nevertheless at a relatively high level, which is due to the fact that most users were using the platform for the first time ever at the time of the evaluation and, therefore, had to first familiarize themselves with the design of the site. In addition, the molecular biology background plays an important role, as the validity of the entries must also be checked during the documentation process and compared with the patient data to avoid errors. The amount of time required to complete the authentication tasks is relatively high (16%). However, this can be explained by the fact that, as part of the tasks, the users had to explicitly check whether the log-in and logout processes were successful and whether they had been granted the correct user rights. After logging out, they also had to actively check whether the therapy recommendations could no longer be modified as part of the test. In the routine workflow, these steps are omitted, and the log-in process needs to be performed only once per session. This will significantly reduce the time spent on authentication tasks. This is also supported by the qualitative feedback from the test users, as the authentication function was subjectively rated as not hindering the workflow and overall perceived as positive.

Furthermore, it can be stated that the participants basically coped well with the operation of the platform but that a short introduction to all the functionalities, user dialogs, and submenus and further test runs before the integration of the platform into the daily clinic routine are considered helpful for quick familiarization. Major changes to the design are not necessary, but the minor suggestions for improving usability that were most frequently mentioned in the feedback, such as the instant adoption of typed text and the sorting of the entered MTB sessions, should be addressed to further improve the quality of use.

Comparison With Other Systems

Although several projects aim to provide an MTB platform and focus on different use cases, none of them yet provide a

standardized means of documenting MTB recommendations and decisions. The Molecular Tumor Board Portal of Tamborero et al [29] offers a clinical decision support platform to analyze Variant Call Format files and generate HTML reports with annotated and interpreted variants. An internal and further expanded version is used by 7 comprehensive cancer centers to analyze sequencing data harmonized with respect to data privacy, state of research, and technological implementation. The platform can be used for joint case discussions, but the documentation thereof is not supported by the portal.

The "VITU – Virtuelles Tumorboard" tool [30] aims to support and digitize MTBs by serving as an information and communication platform. In addition to facilitating MTBs with a videoconferencing tool integrated into the platform and a digitized, process-based case review option, further solutions for integrating external experts will be offered, according to their website. It also contains a module for structured documentation in combination with an FHIR interface for accessing the data. Although there is a demo version of the software available for web-based testing and the source code is available on GitHub, it is not yet conceivable how the software would perform in productive operations, as it still seems to be in the development phase, and updates seem to have slowed down since version 2019.3 [31].

A similar purpose in terms of supporting and promoting MTBs is pursued by Alteration Annotations for Molecular Tumor Boards [32]. This is an R shiny–based web application developed by researchers at the University Hospital in Ulm and consists of multiple modules that, in addition to the visualization and annotation of mutations, offer the possibility of displaying the evidence for possible therapeutic drug targets. Thereby, the identified mutations can be evaluated, discussed, and processed in various formats so that the findings can be exported to external clinical systems. Therefore, the public databases GDKD, CIViC, and TARGET [33-35] can be connected, which are used as a knowledge basis for variant annotations by linking together various information sources. Overall, the application, which is based on the R programming language, is primarily designed for the preparation and visualization of data but also includes functions for highly automated data integration and the standardized documentation of results. However, the capability to share data across sites, specifically for research purposes, appears to be limited.

Schapranow et al [36] have created an advanced software tool designed specifically for multidisciplinary tumor boards. Their approach involved a thorough requirements analysis and followed a user-centered development process. The software allows a dedicated person to note down therapy recommendations, clinical trials, and additional remarks live and transparently on a presentation screen visible to the attendees. The software then automatically generates a report upon the completion of the structured documentation, which is provided to the treating physician. In addition, the software integrates external data sources in a modular manner, focusing on the specific requirements of multidisciplinary tumor boards, and builds the technical foundation of a multisite database of participating hospitals. Although the software is still in the prototype phase, its modular design should enable easy integration with existing clinical documentation.

Comparing the functional scope of cBioPortal in combination with the newly created module with that of similar, already existing systems, it becomes apparent that the integration of a standardized documentation tool for the cross-site harmonization of findings and therapy approaches can create an added value that is not yet fully exploited by other solutions. The possibility of integrating the tool into the clinic's internal workflow and additionally connecting other external systems and data sources to it holds great potential, particularly with regard to the exchange of research data for the transfer of knowledge and the promotion of innovation between clinic alliances and research networks that this makes possible. Thus, there are many more use cases that can be addressed beyond just data visualization and storage, such as fostering collaboration between research and patient care and facilitating the selection and inclusion of appropriate data sets and patients for studies and research projects. That this is a contemporary application field with great potential is demonstrated by the National Network of Genomic Medicine, in which personalized therapy for patients with lung cancer is supported through the provision of a common database and facilitated by the use of a central study registry [37].

Finally, the question of whether the developed solution might be used for similar applications, especially organ tumor boards, arises. Although there is a significant overlap in the general requirements, as well as some overlap in the underlying data model, cBioPortal is primarily tailored to molecular biological data and their visualization. Therefore, it is not an adequate software basis for other tumor board applications without significant alterations. That said, the general approach to design and development is replicable and may be adapted to develop solutions for related problems. One of the key points of this study that can be generalized to the field of medical informatics is that it is crucial to develop tools that adhere to established standards, especially using FHIR and harmonized implementation guides. This ensures seamless integration. In addition, consistently prioritizing user requirements is essential for effective and efficient support for health care delivery.

Outlook

Using the feedback from the usability evaluation, the tool will be refined and adapted to provide users with a comprehensive documentation platform for MTBs. Subsequently, an additional tab will be developed to enable the documentation of follow-up data based on the recommended therapies to further expand the documentation capabilities of cBioPortal. This also paves the way for building a standardized and multisite pool of MTB data, which can later be used for the annotation of new patients and as input for machine learning techniques to generate new insights about MTB treatment and outcomes. An important aspect of extending the tool is compliance with the Medical Device Regulation and In Vitro Diagnostic Device Regulation. As the software currently supports (in the context of Medical Device Coordination Group 2019-11 [38]) only simple functionalities, such as storage, archiving, communication, and simple search, it does not fall within these regulations.

Conclusions

In summary, a custom module for the cBioPortal platform was implemented to enhance the platform with functionalities for documenting therapy recommendations in a harmonized manner across collaborating hospitals and research sites, and an interface for enhanced authentication and authorization purposes was added to comply with security regulations and ensure the protection of patients' data. The findings of the hands-on tests and the usability evaluation suggest that the resulting solution for the documentation of therapy recommendations can be deployed successfully at various sites independently of the HIS in use without much effort. The usability evaluation leads to the assumption that the module and user interface will be widely accepted by the future users and thus can be successfully integrated into their workflow. Therefore, the newly introduced functionalities have the potential to improve the existing documentation processes by providing a structured and harmonized digital template for documentation data. Thus, these functionalities could not only lead to a significant benefit by directly supporting the preparation and conduct of MTBs but also promote the development of further applications, leveraging the implemented harmonized data structure to reuse the collected data. Fields of possible applications are the postprocessing of MTBs and case preparation using the follow-up data of previous patients in future MTBs. In addition, opportunities for interdisciplinary exchange may arise through the transfer of innovation among different research groups to discover new medical relationships based on the accessibility and sharing of data among partner sites.

Abstract

Background: Computerized clinical decision support systems (CDSSs) are increasingly adopted in health care to optimize resources and streamline patient flow. However, they often lack scientific validation against standard medical care.

Objective: The purpose of this study was to assess the performance, safety, and usability of a CDSS in a university hospital emergency department setting in Kuopio, Finland.

Methods: Patients entering the emergency department were asked to voluntarily participate in this study. Patients aged 17 years or younger, patients with cognitive impairments, and patients who entered the unit in an ambulance or with the need for immediate care were excluded. Patients completed the CDSS web-based form and usability questionnaire when waiting for the triage nurse's evaluation. The CDSS data were anonymized and did not affect the patients' usual evaluation or treatment. Retrospectively, 2 medical doctors evaluated the urgency of each patient's condition by using the triage nurse's information, and urgent and nonurgent groups were created. The *International Statistical Classification of Diseases, Tenth Revision* diagnoses were collected from the electronic health records. Usability was assessed by using a positive version of the System Usability Scale questionnaire.

Results: In total, our analyses included 248 patients. Regarding urgency, the mean sensitivities were 85% and 19%, respectively, for urgent and nonurgent cases when assessing the performance of CDSS evaluations in comparison to that of physicians. The mean sensitivities were 85% and 35%, respectively, when comparing the evaluations between the two physicians. Our CDSS did not miss any cases that were evaluated to be emergencies by physicians; thus, all emergency cases evaluated by physicians were evaluated as either urgent cases or emergency cases by the CDSS. In differential diagnosis, the CDSS had an exact match accuracy of 45.5% (97/213). The usability was good, with a mean System Usability Scale score of 78.2 (SD 16.8).

Conclusions: In a university hospital emergency department setting with a large real-world population, our CDSS was found to be equally as sensitive in urgent patient cases as physicians and was found to have an acceptable differential diagnosis accuracy, with good usability. These results suggest that this CDSS can be safely assessed further in a real-world setting. A CDSS could accelerate triage by providing patient-provided data in advance of patients' initial consultations and categorize patient cases as urgent and nonurgent cases upon patients' arrival to the emergency department.

Introduction

Digital health technology is increasingly being developed to support health care systems around the world. Digital health technology includes solutions that assess the urgency and the differential diagnosis of the patient's symptoms with the help of artificial intelligence. These solutions are frequently called *clinical decision support systems* (CDSSs) or *computerized diagnostic decision support programs* [1,2].

These systems can either aid health care professionals in their decision-making or give information on symptoms, conditions, and possible recommendations for future actions to the patient. However, patient-provided data solutions are rarely scientifically validated [3,4]. There are very few studies that have assessed

solution performances in real-world settings, and these are rarely performed using a patient sample with a broad range of conditions [3,5-8].

Work in triage and emergency departments is highly demanding, with substantial time pressure. There is a risk of human errors when operating with high patient volumes, acute conditions, and severe stress. Physicians have been estimated to have a 5% diagnostic error rate [9], with half of these errors being potentially harmful [10]. In an emergency department setting, a CDSS based on patient-provided data that are shared prior to patients entering the emergency department could have the potential to significantly help in allocating optimal resources for the patients who need more prompt assessments and complex care.

The extensive need for the validation of any CDSS with patient-provided data has been acknowledged widely [2,4,5,7]. Studies that evaluate the accuracy or diagnostic performance of a CDSS with patient-provided data in a wide and diverse set of patients are rare and have mainly used clinical vignettes rather than actual patients in a real-life setting [3,4]. A clinical vignette study can describe the experimental accuracy and performance of a system algorithm, but it (1) omits the complex diversities and randomness among patients in real life, (2) typically concentrates only on textbook cases, and (3) omits the usability of the system. Combined clinical vignette studies mainly describe the theoretical performance of an algorithm and do not validate the performance of the CDSS in actual use. Hence, a CDSS with patient-provided data should always take usability into consideration. High usability is one of the key factors that allow a system to make correct interpretations when dealing with patient-provided data. The system needs to be widely easy to use and effective (ie, usable) [11]. One of the most popular questionnaires for assessing system usability is the System Usability Scale (SUS) questionnaire [12-14]. A positive version of the SUS questionnaire has, in addition, been developed [13].

The aim of this study was to analyze the performance of a particular CDSS (Klinik Access [Klinik Healthcare Solutions Oy]) with patient-provided data in a real-world university hospital emergency department setting. The main aims were to (1) evaluate the performance of the system in detecting the clinical urgency of a patient's condition and (2) evaluate diagnostic performance by using the actual *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*) diagnoses assigned at the emergency department. Our third aim was to assess the usability of the system in a real-world setting with real patients. Our hypotheses were that the CDSS has acceptable safety margins and sensitivity in clinically urgent cases, diagnostic performance correlates well with actual medical diagnoses, and the usability of the system is good or better.

Methods

Study Population

The study population consisted of patients who entered the emergency department of Kuopio University Hospital, Finland, during a 3-week period in September 2020. The patients were recruited by the research assistants in the emergency department waiting room while waiting for a triage nurse's assessment. Participation in this study was fully voluntary. The following patients were excluded from this study: patients aged 17 years or younger, patients with cognitive impairments, and patients who entered the unit in an ambulance or with the need for immediate care. The patients were informed about this study, including the information that this study would not affect their emergency department visit or received treatment in any way. To verify their acceptance to participate in this study, the patients provided written informed consent.

Ethics Approval

This prospective study has been reported in ClinicalTrials.gov (NCT04577079), and this study was approved by the research ethics committee of the Northern Savo Hospital District (347/2020), Finland.

Data Collection, Urgency Evaluation, and Diagnosis

After consenting to study participation, patients completed the CDSS (Klinik Access) web-based form independently, using tablet computers that were provided by the research assistants. The form was used to obtain information, including demographics, history, and symptom-related factors. The data provided by the patients were not used by the emergency department personnel. After the data collection phase, 2 independent physicians (KH, MD [15 y of experience]; MI, MD [7 y of experience]) assessed the patient data from the electronic health records. The assessing physicians did not have any access to or knowledge of the CDSS data.

First, the physicians assessed the urgency of each patient case, using only written information provided by the triage nurse—the identical information on which urgency is based in the emergency department. Urgency was mapped to the same four categories that the CDSS software used (Table 1). After evaluating the urgency, the assessing physicians reviewed the visits in the electronic health records and checked that the correct *ICD-10* diagnoses were provided by the emergency department clinicians.

Table . Evaluation of the urgency of a patient's condition and clinical examples of related conditions.

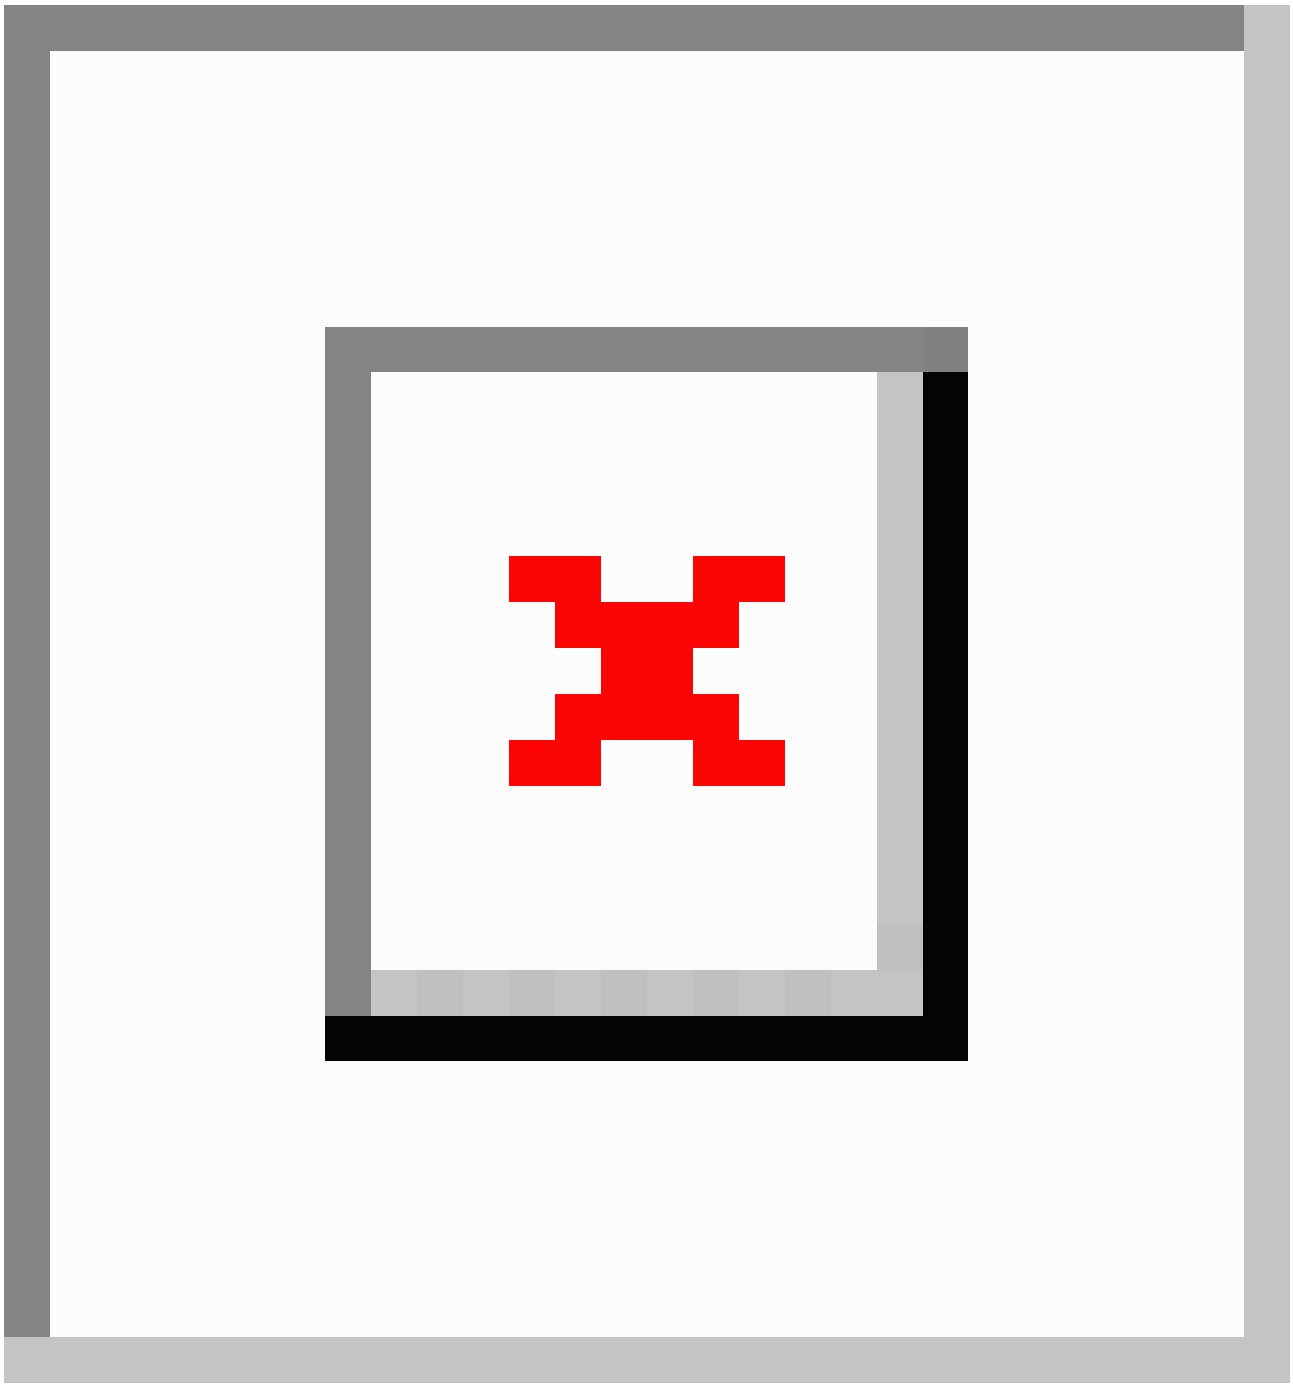
Urgency	Definition	Clinical example (symptom or condition)
Self-care	Benign condition that could primarily be self-treated by the patient (ie, no real need for assessment by a clinician)	• Mild viral infection • Hives (urticaria)
Nonurgent	Condition that requires nonurgent evaluation by a clinician (ie, patient should primarily receive a nonurgent [general practitioner] appointment)	• Prolonged cough in an otherwise healthy young patient • Symptomatic knee arthrosis without significant disability
Urgent	Condition that requires evaluation by a clinician within the next few days, preferably during the same day	• Ear pain with only temporary relief via analgesics • Severe shoulder pain from an injury
Emergency	Condition that should be evaluated by a clinician within 2 hours or as soon as possible	• Chest pain • Breathing difficulty

The CDSS

The CDSS used in this study was Klinik Access (version 1.1). The system intends to support primary care health care organizations by receiving service inquiries from patients, automatically preanalyzing the included clinical information, and supporting health care professionals in managing the triage demand effectively. It has already been implemented in over 400 primary care and dental facilities in the Nordics, the United Kingdom, and the Netherlands. Klinik Access evaluates patient symptoms and potential conditions by using the situational data provided by the patients (Figure 1). It consists of an interface for receiving the patient inputs, a back end for generating the computational dynamic questionnaire and other business logic, and a professional interface for the management of the patient inquiries by health care staff. It was originally developed for general primary care use, including children and adolescent care use. Although it properly recognizes various urgent and emergency situations, it has not yet been optimized for use solely in an emergency department context. As such, the clinical context in this study was intended to be partially experimental.

The Klinik Access system uses a medical gold standard Bayesian methodology [15,16] for inferring the effect of clinical features on the probabilities of the differential diagnosis conditions. The severity and the urgency of a condition were inferred, in addition to the differential diagnosis, by using specific severity symptoms and by setting a threshold (15%) for the probabilities of relevant conditions in the differential. The purpose of this study was to analyze the performance of the algorithm and the patient usability of the CDSS. As such, only the system output data were analyzed after data collection, and the professional interface was not used or assessed in this study.

Figure 1. The system process of our computerized clinical decision support system (Klinik Access). In this study, "finish form information" was the request to complete the positive version of the System Usability Scale questionnaire, after which the patients were directed to wait for the triage nurse to call them in. Customer PRO UI was not used in this study, and case information was only archived for the study purposes. AI: artificial intelligence; Customer PRO UI: Customer Professional Interface.



Usability

Usability was evaluated by using the positive version of the SUS questionnaire [13]. The questionnaire has 10 items that are rated on a 5-point Likert scale. The difference between the original and positive versions of the questionnaire is that the positive version has only positive statements about usability, whereas in the original one, every other statement is negative [13]. The positive version of the SUS questionnaire was used, as respondents and researchers are less likely to make mistakes when filling in and analyzing the questionnaire, respectively [13]. After completing the web-based CDSS form, the patients filled in the positive version of the SUS questionnaire, and they had the opportunity to give free-text feedback by using the web-based form.

Statistical Analysis

The estimated required sample size for this study (estimated via a power analysis) was a minimum of 246 patients (confidence level=95%; margin of error=5%; study population proportion=80%). A patient was excluded from the analyses if they had intentionally ignored filling in the majority of the web-based form, misused the form, or stated that they were not willing to participate in this study in the free-text field. The

sensitivity and positive predictive values, with 95% CIs, were calculated for the urgency evaluations between the CDSS and the two assessing physicians, and the mean of these results was used to report the performance of the CDSS in comparison to that of the assessing physicians' evaluations. When evaluating the performance of the assessing physicians, the sensitivity was calculated for both assessors, and the mean was used to report the performance of the assessors.

The urgency of the patients' needs was evaluated, using 4 categories, by the CDSS and the assessors. However, as the patients were practically grouped only into 2 groups (nonurgent and urgent) in the emergency department, we dichotomized the urgency as nonurgent (blue=0; green=1) and urgent (yellow=2; red=3) cases for the analyses.

The diagnostic accuracy of the CDSS was evaluated, using the differential diagnosis proposed by the system. A condition had to exceed the fixed probability threshold of 15% to be included in the differential diagnosis list. The diagnostic match was evaluated as "exact" if the actual *ICD-10* diagnosis from electronic health records was included in the differential diagnosis list proposed by the CDSS. The diagnostic match was evaluated as "close" if the condition proposed by the CDSS in the differential diagnosis list was a close match to the actual *ICD-10*–coded diagnosis (Table 2). The statistical software IBM SPSS Statistics version 25 (IBM Corporation) and Microsoft Excel 2022 (Microsoft Corporation) were used.

Table . The prevalence of the most frequent *International Statistical Classification of Diseases, Tenth Revision* diagnoses from the electronic health records of the whole study population and the prevalence of the most frequent diagnoses with exact and close matches to those produced by the clinical decision support system (CDSS).

Diagnosis		Frequency
Diagnoses from electronic health records, n (%)		
	A46 Erysipelas	8 (3.8)
	M54.5 Low back pain	7 (3.3)
	M54.4 Lumbago with sciatica	6 (2.8)
	M79.6 Pain in limb, hand, foot, fingers, and toes	6 (2.8)
	R10.3 Pain localized to other parts of lower abdomen	6 (2.8)
	R10.4 Other and unspecified abdominal pain	6 (2.8)
	K35.9 Acute appendicitis, unspecified	5 (2.3)
	T81.4 Infection following a procedure	5 (2.3)
	R07.4 Chest pain, unspecified	4 (1.9)
	S61.0 Open wound of finger(s) without damage to nail	4 (1.9)
	H16.9 Keratitis, unspecified	3 (1.4)
	I49.9 Cardiac arrhythmia, unspecified	3 (1.4)
	J06.9 Acute upper respiratory infection, unspecified	3 (1.4)
	R06.0 Dyspnea	3 (1.4)
	R10.1 Pain localized to upper abdomen	3 (1.4)
	S52.5 Fracture of lower end of radius	3 (1.4)
	S93.4 Sprain and strain of ankle	3 (1.4)
	T15.0 Foreign body in cornea	3 (1.4)
Diagnoses with exact matches to the CDSS, n		
	R10.3 Pain localized to other parts of lower abdomen	6
	A46 Erysipelas	5
	M54.5 Low back pain	5
	R10.4 Other and unspecified abdominal pain	5
	M79.6 Pain in limb, hand, foot, fingers, and toes	4
	S61.0 Open wound of finger(s) without damage to nail	4
	H16.9 Keratitis, unspecified	3
Diagnoses with close matches to the CDSS, n		
	M54.4 Lumbago with sciatica	3

Results

Study Population Characteristics

There were 259 patients who had completed the CDSS form and had comparable information in the electronic health records. Of these patients, 11 were excluded (4 patients were aged younger than 18 y, 5 patients had an emergency department visit that was solely associated with an earlier emergency department or control visit, and 2 patients had an inadequately filled form). Thus, there were 248 patients in total, with 122 (49.2%) female patients and 126 (50.8%) male patients, and the mean age was 46 (range 18-82) years. The median number of symptoms provided by patients to the CDSS form was 5 (range 1-20).

Urgency

Physician A evaluated all 248 patient cases. However, physician B missed 12 patient cases due to difficulties in accessing appropriate electronic health record data, thus leaving 236 comparable patient cases in total (Tables 3-6). The mean sensitivities were 85% for urgent cases and 19% for nonurgent

cases when assessing the performance of the CDSS evaluations in comparison to those of the physicians. The corresponding mean sensitivities were 85% and 35%, respectively, when comparing the evaluations of the assessing physicians. The CDSS did not miss any cases that were evaluated to be emergencies by physicians, that is, all emergency cases evaluated by the physicians were evaluated as either urgent cases or emergency cases by the CDSS (Tables 3-6).

Table . The urgency evaluations of the computerized decision support system (CDSS) and physician A (cases: n=248).[a]

		Physician A cases, n			
		Self-care	Nonurgent	Urgent	Emergency
CDSS cases, n					
	Self-care	3	4	5	0
	Nonurgent	2	4	23	0
	Urgent	2	32	97	4
	Emergency	0	14	54	4

[a]The positive predictive values for nonurgent and emergency cases were 32% (95% CI 20%-46%) and 77% (95% CI 74%-79%), respectively. The sensitivity values for nonurgent and emergency cases were 21% (95% CI 12%-34%) and 85% (95% CI 79%-90%), respectively.

Table . The urgency evaluations of the computerized decision support system (CDSS) and physician B (cases: n=236).[a]

		Physician B cases, n			
		Self-care	Nonurgent	Urgent	Emergency
CDSS cases, n					
	Self-care	0	4	8	0
	Nonurgent	0	1	25	0
	Urgent	0	17	107	5
	Emergency	0	18	55	6

[a]The positive predictive values for nonurgent and emergency cases were 13% (95% CI 6%-26%) and 87% (95% CI 85%-89%), respectively. The sensitivity values for nonurgent and emergency cases were 17% (95% CI 6%-35%) and 84% (95% CI 78%-89%), respectively.

Table . The urgency evaluations of physician A and physician B (cases: n=236; physician A vs physician B).[a]

		Physician B cases, n			
		Self-care	Nonurgent	Urgent	Emergency
Physician A cases, n					
	Self-care	0	4	3	0
	Nonurgent	0	10	42	0
	Urgent	0	16	147	6
	Emergency	0	0	3	5

[a]The sensitivity values for nonurgent and emergency cases were 47% (95% CI 28%-66%) and 78% (95% CI 72%-84%), respectively.

Table . The urgency evaluations of physician A and physician B (cases: n=236; physician B vs physician A).[a]

		Physician A cases, n			
		Self-care	Nonurgent	Urgent	Emergency
Physician B cases, n					
	Self-care	0	0	0	0
	Nonurgent	4	10	16	0
	Urgent	3	42	147	3
	Emergency	0	0	6	5

[a]The sensitivity values for nonurgent and emergency cases were 24% (95% CI 14%-37%) and 91% (95% CI 86%-95%), respectively.

Differential Diagnosis

Of 248 patients, 35 had to be excluded from the differential diagnosis analyses due to the absence of an *ICD-10* diagnosis in the electronic health records or for having a code denoting a Z-diagnosis (factors influencing health status or contact with health services). Thus, 213 cases in total were included in the differential diagnosis analyses. The results of the differential diagnoses of the CDSS are shown in Table 7. The CDSS had an exact match accuracy of 45.5% (97/213), with an additional close match in 12.7% (27/213) of patients. The most frequent actual diagnoses from the electronic health records, including exact- and close-match diagnoses, are presented in Table 2. Other close-match diagnosis examples are H43.8 (other disorders of the vitreous body; CDSS suggestion: visual disturbances), K64.0 (first-degree hemorrhoids; CDSS suggestion: bleeding from anus), and H16.0 (corneal ulcer; CDSS suggestion: foreign object in the eye). The median number of diagnoses (ie, conditions) within the differentials provided by our CDSS was 5 (range 0-21).

Table . The results of the differential diagnostics of the clinical decision support system (CDSS), including possible explanatory factors for missed diagnoses.

Differential diagnosis		CDSS accuracy (diagnoses: N=213), n (%)
Exact match		97 (45.5)
Close match		27 (12.7)
Missed diagnoses		89 (41.8)
	False location	9 (4.2)
	Inadequate response	25 (11.7)
	No identified diagnosis[a]	16 (7.5)
	Other miss	39 (18.3)

[a]The exact *International Statistical Classification of Diseases, Tenth Revision* diagnosis was not included in the CDSS differential diagnostics selection.

Usability

A positive version of the SUS questionnaire was answered by 95.4% (247/259) of the whole study population. The mean SUS score for the CDSS was 78.2 (SD 16.8). A total of 31 patients had given feedback on the CDSS, of whom 12 gave positive feedback, 14 had some critiques or suggested certain changes, and 5 gave neutral feedback. The most frequent free-text feedback for improving the CDSS addressed possible challenges for older patients (n=5) and the need for guidance to fill in the form (n=3).

Discussion

Overview

To the authors' knowledge, this is the first real-world study that uses a large population with a wide age range to extensively evaluate the performance and usability of a CDSS for urgency evaluation and differential diagnosis in a patient setting. The CDSS was found to be equally as sensitive as the assessing physicians in terms of urgent patient evaluation, but the CDSS underperformed in nonurgent patient cases. The CDSS was considered to be safe, as none of the emergency cases evaluated by physicians were evaluated as nonurgent cases by the CDSS. The diagnostic performance of the CDSS was good, with a 45.5% (97/213) exact match accuracy and 12.7% (27/213) close match accuracy for differential diagnosis in a real-world setting, and it included a vast range of possible diagnoses. The usability of the CDSS was considered to be impressive, with a mean SUS score of 78.2 (SD 16.8).

Digital health technologies and CDSSs have the potential to optimize health care resources and enable patients to manage their conditions themselves more effectively [4]. In addition, CDSS technologies have been suggested to have a significant role in helping with both patient management and triage [17]. Digital health technologies, including CDSSs, are however often lacking an evidence base [18]. Both the importance and the lack of validation for digital health technologies have been acknowledged widely [2,19].

With web-based CDSS access, patients can complete their inquiries at home or prior to their emergency department arrival. Health care and triage personnel would then have comprehensive written information on the patient's symptoms, demographics, and history data available when the patient enters the emergency department. This can help to speed up the work in triage considerably. A CDSS could also categorize patient cases as urgent and nonurgent cases when patients enter the emergency department. This would improve the waiting times for patients with urgent conditions and thus improve treatment outcomes [1].

Even though any CDSS should not be too risk averse [4], it is of utmost importance that the CDSS is safe enough to avoid missing any emergency cases. Considering the high resource demands and massive time pressures within the emergency department, directing even every fifth patient safely to nonurgent care would be very beneficial. This is a significant factor to consider for the patient population who would, in any case, enter the emergency department, regardless of possible overtriaging. Eventually, the purpose of a CDSS in the emergency department is to relieve the health care personnel's burden, so that time and effort can be optimally allocated [20,21]. Additionally, to fully gain the benefits of a CDSS, it is important that the CDSS is properly implemented in health care professionals' everyday work and workflow [22].

Urgency Evaluation

In this study, the CDSS was found to be as sensitive as physicians in identifying urgent patient cases. For nonurgent patient cases, the CDSS was oversensitive. This is logical when considering the nature of artificial intelligence–driven digital health technology in the health care field, where safety is of utmost importance. As described previously, there is a great need to validate every CDSS in real-world clinical settings [4,7].

The original purpose of this study was to assess the triage nurses' assessments, using the Emergency Severity Index (ESI) [23]. However, the distribution of the ESI scores was greatly skewed; no patients had an ESI score of 1, and only 2% (5/248) of patients had an ESI score of 2, which substantially limited data analysis. Therefore, the physicians were considered to be the most suited to assessing the urgency of the patients' conditions by using the triage nurse's information.

There is a lack of studies assessing CDSSs for urgency evaluation in a real-world setting with a broad range of possible conditions [7,8]. Cotte et al [24] assessed the triage performance of a CDSS (Ada) in a real-world emergency department setting with 344 patients. They found overtriage in 57% of cases and undertriage in 9% of cases when the CDSS was compared to physicians' evaluations. Yu et al [25] assessed 2 CDSSs (ie, symptom checkers) retrospectively for 100 real-world patients that entered the emergency department, and they found a sensitivity of 58%; however, this study was performed retrospectively by researchers and thus lacked an acute emergency department setting and patient usability evaluation. Schmieding et al [26] assessed the performance of 22 CDSS technologies in 2015 and 2020 and discovered no improvement in triage performance over the 5-year period. However, to conclude, studies assessing CDSS performance underline the importance of real-world data. This is because clinical vignettes have been found to have considerable inherent limitations when used to assess diagnostic accuracy or triage safety, in comparison to real-world data [5]. Just recently, Fraser et al [8] evaluated the performance and usability of a CDSS (Ada; ie, in a similar setting to ours) in an emergency department. In terms of urgency, among 37 patient cases, 22% and 14% were considered unsafe and too risky by at least one or two out of three physicians, respectively [8].

Differential Diagnosis

When assessing the CDSS's diagnostic performance with *ICD-10* diagnoses set by physicians in the patients' electronic health records, an exact diagnostic match was found in 45.5% (97/213) of cases, and missed diagnoses were found in 41.8% (89/213) of cases. Given the real-world, acute emergency department study setting, this can be considered a good performance. As described previously, studies assessing the performance of a CDSS usually use vignettes without real patient data, which makes it difficult to draw any clinical conclusions [4,5]. In a review by Wallace et al [7], there were only a few studies that assessed diagnostic accuracy by using real patient data, and this was done only in specific subspecialties. Despite these facts, the accuracy of the primary diagnosis was found to be low, with a range of 19% to 38% [7]. In a recent emergency department study that used another CDSS, the sensitivity of the differential diagnosis was far higher (70%) [8].

This study assessed the exact and close diagnostic matches between our CDSS and electronic health record diagnoses. Through this, we wanted to highlight the challenges faced when using real-world data. Even though the CDSS evaluated in this study contained over 500 medical conditions, patients may experience rare conditions that are difficult and often futile to include within CDSS differential diagnostic algorithms. Among 213 patients, there were 16 patients (7.5%) who had an *ICD-10* diagnosis that was not included in the CDSS differential diagnostics, such as myelodysplastic syndrome (D46.9). As described previously, there are numerous diagnoses that may not be necessary to include in CDSS differential diagnostics. This is because some diagnoses may be too niche for emergency department triage or are only relevant for certain specialist clinical settings, such as tertiary subspecialty care.

The main objective of any CDSS is to provide support for triage evaluation, as setting an accurate diagnosis often requires specific tests, such as blood sample and imaging tests [7]. Therefore, it is impractical to aim for the perfect diagnostic performance of a CDSS. Nevertheless, a CDSS could optimally guide health care professionals to consider a patient's relevant differential diagnosis.

Unlike several CDSSs, the one used in this study (Klinik Access) proposed a differential diagnostic list by setting a threshold (15%) for the probabilities of relevant conditions. This mimics the testing threshold design in a physician's clinical decision-making, during which all of the relevant and possible conditions are considered [27,28].

With regard to practical issues, there are multiple factors that affect a unique patient case in real life and are complicated to include in theoretical studies with clinical vignettes. For instance, in this study, some patients were referred to the emergency department by the general practitioner, which affected the answers of the CDSS questionnaire. Further, as in real life, some diagnoses were not accurately recorded within the electronic health records by the physicians in the emergency department, although cases with empty diagnoses and cases with a code denoting a Z-diagnosis were excluded.

Usability

Usability and user interaction have been noted as key elements for evaluating a CDSS [2,29]. In this study, the CDSS (Klinik Access) achieved a mean SUS score of 78.2 (SD 16.8), which indicates good usability and is in the highest quartile when evaluating the SUS [30]. There is a lack of studies that have evaluated the usability of a CDSS in a real-world setting with a diverse patient sample that actually used the CDSS themselves. In addition, our study population of 247 patients is fairly large when compared to other study populations, considering the real-world setting of our study. Fraser et al [8] showed the acceptable usability of a CDSS that used the Technology Acceptance Model among 40 emergency department patients. Additionally, in a study consisting of 49 psychotherapy outpatients, the CDSS (Ada) achieved a mean SUS score of

81.5 [6]. However, this study was performed in a narrow patient context with a more limited study population.

With regard to gathered usability feedback, the fact that the patients with an acute ongoing condition used the CDSS while waiting for a triage nurse in the emergency department is an important detail to consider, and this activity could have negatively impacted the results. Patients filled in the CDSS web-based form at the emergency department waiting room while experiencing an acute ongoing condition and not, for example, at home without distractions, as in the typical primary care setting process. Although participation was voluntary, according to a few answers, some patients had low motivation to fill in the form, most likely as they were aware that the CDSS would not have affected their actual care in any way. Additionally, some answers in the CDSS questionnaire were clearly inadequate. Certain patients had difficulties with choosing the right location for their symptoms and conditions. Some patients also omitted some of their symptoms in the selection phase but reported those symptoms in the free-text field instead, which left the algorithm with insufficient information. These factors are partly inevitable when evaluating patients in an emergency department setting. However, motivation issues could have affected the results due to the study design, in which the CDSS was separate from the actual care. These limitations underline again the challenges of CDSS studies in a real-world setting compared to those of studies using clinical vignettes.

As the positive version of the SUS questionnaire was added solely for the research purposes, it was collected by using a separate web-based form after patients completed the CDSS form, and it did not include the medical information of the patients. Therefore, we could not evaluate the usability among different user categories, such as age groups or gender. Nevertheless, the mean SUS score describes well the results of the whole study population, as 95.4% (247/259) of the study population completed the SUS questionnaire.

There has been no reported statistical difference between the original and positive versions of the SUS [31]. This study was performed in the emergency department; thus, the ease of answering the questionnaire is relevant for the patients [13]. In addition, the positive version of the SUS has been suggested for users with cognitive load or stress, which is typical in an emergency department setting [31].

Strengths and Limitations of This Study

There are clear strengths in this study. We want to underline the fact that, unlike the majority of the previous studies that explored CDSSs and symptom checkers (with data provided by the patients themselves), the population sample in this study consisted of real patients who entered the emergency department of a university hospital, and patient CDSS data were entered via the internet by the patients themselves [4,7]. To the authors' knowledge, this is the first study to assess the diagnostic performance and triage sensitivity of a CDSS in a broad clinical setting, using patient-submitted data. The patient sample is representative of the normal adult patient population entering the emergency department in Finland and is presumably unbiased by demographic variance, which strengthens the findings of this study [20].

This study also has some limitations. Even though this study included a broad set of patients, it excluded children, adolescents, and patients with cognitive impairments. This was due to the fact that these patient groups may need another person to fill in the web-based CDSS form, which would have likely affected the study results. In fact, unlike the majority of CDSS technologies, the CDSS assessed in this study (Klinik Access) does include children and adolescents, and a study is in progress to assess the diagnostic and triage performance of the CDSS for children and adolescents aged <18 years in a university hospital setting. Further, the patient selection could have been biased, as the patients were voluntarily participating in this study. We also excluded patients who arrived to the emergency department via prehospital emergency care (ambulance). Additionally, 49.2% (122/248) of patients were female and 50.8% (126/248) were male in this study, and the mean age was 46 (range 18-82) years. Therefore, the patient population in this study reflects the typical patient sample in a university hospital emergency department. The fact that the evaluations of the assessing physicians were reliant on the recordings of a triage nurse can also be considered as a limitation. One assessing physician experienced challenges in accessing the appropriate electronic health record data for 12 patients, which were due to the access permissions used within the electronic health records of the emergency department.

The patients were informed that this study would not affect their normal assessment or the care of their condition. This could have lowered patients' motivation to complete the web-based CDSS form, which in turn could have resulted in inadequacies in answers. If true, this would directly diminish the study results. These issues are unavoidable when dealing with real-world patient data and, again, underline the challenges of CDSS studies using real-world data compared to those of vignette studies. To tackle these limitations, further studies should assess health care professionals' practical use of a CDSS to show the performance and possible benefits of the CDSS.

Conclusions

This study is the first to validate a CDSS with a large, real-world patient population within a university hospital emergency department. The CDSS was found to be safe to use, with no missed urgent cases, and was equally as sensitive as emergency physicians' judgments in urgent patient cases. It provided acceptable differential diagnoses and good patient usability, as evaluated via a positive version of the SUS questionnaire. The CDSS should further be evaluated for its practical use (eg, studies in which health care professionals can use the CDSS and its output in real time). This would likely further demonstrate the practical benefits and effectiveness of CDSS technologies in emergency medicine.

Acknowledgments

The authors thank Maarit Kumpulainen (Kuopio University Hospital Living Lab) for contributing to the design and practical arrangements of this study. This work was supported by Klinik Healthcare Solutions Oy (provided tablets and salary to research assistants who recruited the study population).

Conflicts of Interest

JM, RL, NH, and PH are employed by Klinik Healthcare Solutions Oy, the creator of the clinical decision support system (CDSS). JM, RL, and PH have stock ownership in Klinik Healthcare Solutions Oy. The independent emergency care physicians who evaluated patients alongside our CDSS were not employed by Klinik Healthcare Solutions Oy.

Abstract

Background: Inappropriate medication in older patients with multimorbidity results in a greater risk of adverse drug events. Clinical decision support systems (CDSSs) are intended to improve medication appropriateness. One approach to improving CDSSs is to use ontologies instead of relational databases. Previously, we developed OntoPharma—an ontology-based CDSS for reducing medication prescribing errors.

Objective: The primary aim was to model a domain for improving medication appropriateness in older patients (chronic patient domain). The secondary aim was to implement the version of OntoPharma containing the chronic patient domain in a hospital setting.

Methods: A 4-step process was proposed. The first step was defining the domain scope. The chronic patient domain focused on improving medication appropriateness in older patients. A group of experts selected the following three use cases: medication regimen complexity, anticholinergic and sedative drug burden, and the presence of triggers for identifying possible adverse events. The second step was domain model representation. The implementation was conducted by medical informatics specialists and clinical pharmacists using Protégé-OWL (Stanford Center for Biomedical Informatics Research). The third step was OntoPharma-driven alert module adaptation. We reused the existing framework based on SPARQL to query ontologies. The fourth step was implementing the version of OntoPharma containing the chronic patient domain in a hospital setting. Alerts generated from July to September 2022 were analyzed.

Results: We proposed 6 new classes and 5 new properties, introducing the necessary changes in the ontologies previously created. An alert is shown if the Medication Regimen Complexity Index is ≥40, if the Drug Burden Index is ≥1, or if there is a trigger based on an abnormal laboratory value. A total of 364 alerts were generated for 107 patients; 154 (42.3%) alerts were accepted.

Conclusions: We proposed an ontology-based approach to provide support for improving medication appropriateness in older patients with multimorbidity in a scalable, sustainable, and reusable way. The chronic patient domain was built based on our previous research, reusing the existing framework. OntoPharma has been implemented in clinical practice and generates alerts, considering the following use cases: medication regimen complexity, anticholinergic and sedative drug burden, and the presence of triggers for identifying possible adverse events.

Introduction

Medical advances have resulted in a rise of life expectancy. The prevalence of multimorbidity, which is defined as the coexistence of 2 or more chronic conditions, tends to be higher among older people [1]. As a result, the use of multiple medicines, which is commonly referred to as *polypharmacy*, has become a common phenomenon in this population [2,3].

Polypharmacy increases the risk of inappropriate medication [4,5], leading to a greater risk of adverse drug events (ADEs) [6]. ADEs are associated with hospital admissions, higher mortality rates, and increased health care expenditures [7-10]; therefore, improving medication appropriateness in older patients with multimorbidity is a priority [11].

One approach to improving medication appropriateness is to use clinical decision support systems (CDSSs) for assistance during the prescription process. CDSSs are intended to improve health care delivery by enhancing medical decisions with targeted clinical knowledge and patient information [12,13]. Relational databases are the predominant choice when it comes to designing a CDSS. However, due to the main challenges of CDSSs, such as the lack of interoperability or alert fatigue [14-16], there is increasing interest in using ontology-based CDSSs to overcome these challenges. An ontology is an explicit conceptualization of the entities of a domain [17,18]. Because ontologies add semantics to models, they enhance the reusability of data and are more efficient in dealing with changing requirements and maintenance requirements [19-21].

Previously, we used Protégé-OWL (Stanford Center for Biomedical Informatics Research) to develop OntoPharma—an ontology-based CDSS for reducing medication prescribing errors [22]. The domains addressed by OntoPharma include the identification and technical data of medicinal products, as well as data on drug appropriateness for ensuring the safe use of medicines. These domains were addressed in the following four use cases: maximum dosage alerts, a drug-drug interaction checker, renal failure adjustment, and a drug allergy checker. OntoPharma is currently implemented in a tertiary referral hospital.

Alerts generated by OntoPharma are, nowadays, commonly available. To leverage the ease of using ontologies to represent rich and complex knowledge, the modeling of drug knowledge that is absent in usual commercial databases is needed.

For this reason and on the basis of our previous research, the primary aim of this study was to model a domain for improving medication appropriateness in older patients with multimorbidity (hereinafter called the *chronic patient domain*). The secondary aim was to implement the version of OntoPharma containing the chronic patient domain in a hospital setting.

Methods

This study was conducted between 2020 and 2022 at a 710-bed tertiary hospital in Spain, which was equipped with computerized physician order entry (CPOE) and an electronic health record (EHR) system provided by SAP SE. The following 4-step development process was designed: defining the domain scope, representing the domain in the model, adapting the OntoPharma-driven alert module, and implementing the version of OntoPharma containing the chronic patient domain in a hospital setting.

Ethics Approval

This study was approved by the ethics committee of the Hospital Clínic of Barcelona (reference number HCB/2019/0735).

Defining the Domain Scope

Overview of the Domain Scope

The chronic patient domain focused on improving medication appropriateness in older patients with multimorbidity. Given the dimension of the domain, we decided to establish an expert advisory panel to limit the scope of the domain. The group of experts included geriatricians and clinical pharmacists, of whom all were members of the C3RG (Central Catalonia Chronicity Research Group) and had expertise in ensuring medication appropriateness in older patients with multimorbidity. Focus group sessions yielded consensus on the importance of the following three use cases: medication regimen complexity, anticholinergic and sedative drug burden, and the presence of triggers for identifying possible adverse events.

Medication Regimen Complexity

Complex medication regimens are challenging for patients, which may impact medication adherence and safety [23,24]. The Medication Regimen Complexity Index (MRCI), which was developed by George et al [25], is currently the most widely used scale for assessing medication regimen complexity. Medication complexity considers more factors than a simple medication count. The MRCI consists of 65 items, including weighted scores for types of prescribed dosage forms (section A), dosing frequency (section B), and additional administration instructions (section C). The sum of the scores of the three sections provides a total score, with higher scores indicating greater regimen complexity.

The MRCI has been translated and validated for other languages, including Spanish (Spanish MRCI [MRCI-E]) [26]. We used the MRCI-E as a source of information.

Section A provides weights for 32 dosage form and administration route combinations. For example, an oral tablet medication is given a weight of 1. More complex combinations result in higher weights.

Section B provides weights for 23 dosing frequencies (“scheduled” or “as needed”). The “once daily” frequency is used as the baseline (weight of 1), on which the other weightings are built.

Section C provides weights for 10 additional instructions that a patient may need to follow in adhering to a prescribed regimen. Additional administration instructions are related to taking medication at specific times, taking medication in relation to food, taking multiple units at one time, and needing to break or crush a tablet or needing to taper or increase a dose.

Anticholinergic and Sedative Drug Burden

Anticholinergic burden is defined as the cumulative effect of taking 1 or more drugs that are capable of causing anticholinergic adverse effects, and the load increases with the number of medications prescribed [27]. Anticholinergic toxicity is a common problem in older people. Anticholinergic effects are associated with peripheral manifestations (urinary retention, constipation, decreased secretions, etc) and central manifestations (delirium, cognitive disorders, and functional disorders) [27,28].

Several tools have been developed to estimate anticholinergic burden by giving a score to drugs according to their anticholinergic potential [29]. The Drug Burden Index (DBI) is the only scale that accounts for a patient's dose [30]. In addition, the DBI considers not only anticholinergic effects but also sedative effects. The total DBI exposure is calculated as the sum of exposure to any DBI medication, according to the following formula:

(1)

where "D" is the daily dose taken and "δ" is the minimum effective daily dose for that drug.

Byrne et al [31] provided a master DBI list containing a final list of DBI medications and their minimum effective daily doses. The master DBI list included 156 entries. Each entry consisted of the following fields: drug description (ingredient), World Health Organization Anatomical Therapeutic Classification codes, anticholinergic and sedative effects, and minimum effective daily dose (expressed as mg) by route of administration (parenteral, sublingual, buccal, transdermal, rectal, and inhalation).

Triggers

A trigger is defined as a flag, occurrence, or prompt that alerts reviewers to initiate further in-depth investigations regarding a patient's record to determine the presence or absence of an adverse event [32]. An example of a trigger is a potassium level of <2.9 mEq/L in a patient with loop diuretics. Triggers are based on the assumption that any new condition may be due to the use of a drug. Multiple sets of triggers have been developed. Guzmán et al [33] identified the most appropriate triggers for detecting ADEs in older patients with multiple chronic conditions.

The trigger set developed by Guzmán et al [33] included a total of 51 entries. Each entry consisted of the following fields: high-alert medications for patients with chronic illnesses (therapeutic class or ingredient) and triggers for detecting potential ADEs (11 care module triggers, 9 antidote- and treatment-based triggers, 11 medication concentration–based triggers, 18 triggers based on abnormal laboratory values, and 1 emergency department trigger).

Domain Model Representation

Data sets were not organized in a predefined format. Prior to modeling the chronic patient domain through ontologies, we processed all of the information in a relational database to clean the data, detect redundancies, and detect relationships between different concepts.

To add this new domain to OntoPharma, we built on our previous research by using the existing framework, which was composed of 3 ontologies (*Drugs*, *Decision support system* [*DSS*], and *Local pharmacy*) [22]. The *Drugs* ontology was designed to represent the identification and technical data of medicinal products. The *DSS* ontology provides data on drug appropriateness. The *Local pharmacy* ontology was designed to represent local concepts from EHRs and CPOE in order to ensure interoperability.

The design, development, and maintenance of the chronic patient domain was driven by medical informatics specialists and clinical pharmacists. The information was represented in the Web Ontology Language (OWL) [34]. For encoding the OWL ontologies, we used the Protégé 3.5 editor tool [35]. The concepts of the chronic patient domain were organized hierarchically, following a top-down approach, as we did with all previous domains of OntoPharma. The development of the class hierarchy, the defining of properties, and the slotting of concepts were carried out at the same time. Finally, we defined individual instances of the classes represented.

OntoPharma-Driven Alert Module Adaptation

We reused the OntoPharma-driven alert module that was proposed in our previous research [22]. The integration between the CPOE system and the ontologies was performed through a REST API. A REST API call was published (in JSON format) each time a clinician added a new medication in the CPOE system, modified an existing one, or requested on-demand CDSS information. The request contained patient-specific clinical data. SPARQL (Apache Jena Fuseki server) was used to query ontologies [36]. After applying the queries, a returning REST API, with the results, was published.

It was necessary to update the content of the REST API published each time OntoPharma was triggered. We specifically had to add more laboratory parameters (to date, the only one considered was glomerular filtration rate). New local concepts were manually mapped with existing concepts in the ontologies. In addition, we created new SPARQL queries to ensure the safe use of medicines in older patients.

Alerts were shown in the CPOE system in cases of high medication regimen complexity, in cases of high anticholinergic and sedative drug burden, or in cases where triggers for detecting ADEs in older patients were present. In addition, patients were required to be older than 65 years.

In accordance with the recommendations of end users, the user interface proposed in the previous paper [22] was slightly modified to ensure usability and minimal interference with the clinician's workflow.

Formal testing was performed to demonstrate that the new version of the ontology-driven alert module met functional requirements. In addition, clinical pharmacists performed manual testing in a control environment (the SAP quality assurance server) to evaluate whether the alert module functioned properly when generating the prescribing alerts.

Implementation of the Version of OntoPharma Containing the Chronic Patient Domain in a Hospital Setting

In July 2022, the version of OntoPharma containing the chronic patient domain was implemented at one ward of the internal medicine unit, which had capacity for 20 admissions. Informatics staff and clinical pharmacists were responsible for the diffusion and for providing support.

A retrospective analysis of the alerts generated was performed. We included patients who were admitted to the internal medicine ward from July to September 2022. The following patient data were collected: gender, age, duration of hospital stay, and number of medications during hospital stay. We further examined the alerts, including the number of alerts, the types of alerts, clinical relevance, and the acceptance rates.

Quantitative variables were expressed as means and SDs for variables with a normal distribution or as medians and IQRs for variables with a skewed distribution. Qualitative variables were expressed as percentages. Data analysis was carried out by using SPSS 20.0 (IBM Corp).

Results

Knowledge Representation Using Ontologies

Overview of Ontologies

For modeling the chronic patient domain, we proposed new classes and properties, introducing the necessary changes in the ontologies previously created (*Drugs*, *DSS*, and *Local pharmacy*). The three ontologies are interconnected. The import schema of ontologies is shown in Figure 1.

Figures 2-4 provide diagrams showing the relationships between classes for defining the chronic patient domain in the *Drugs* ontology, *DSS* ontology, and *Local pharmacy* ontology, respectively.

Multimedia Appendix 1 contains a list of the medication knowledge concepts and their definitions, which were used to define the chronic patient domain. Multimedia Appendix 2 contains a list of properties and their facets, which were also used to define the chronic patient domain.

Figure 1. Import schema of the ontologies used in OntoPharma. For modeling drug-related knowledge, 3 ontologies have been developed (*Drugs*, *DSS*, and *Local pharmacy*). Each ontology has been divided into 2 parts. The first part provides concepts and classes (also known as *T-Box*), and the second provides the instances of these concepts (also known as *A-Box*). The three ontologies are interconnected, as shown in Figure 1. DSS: Decision support system.

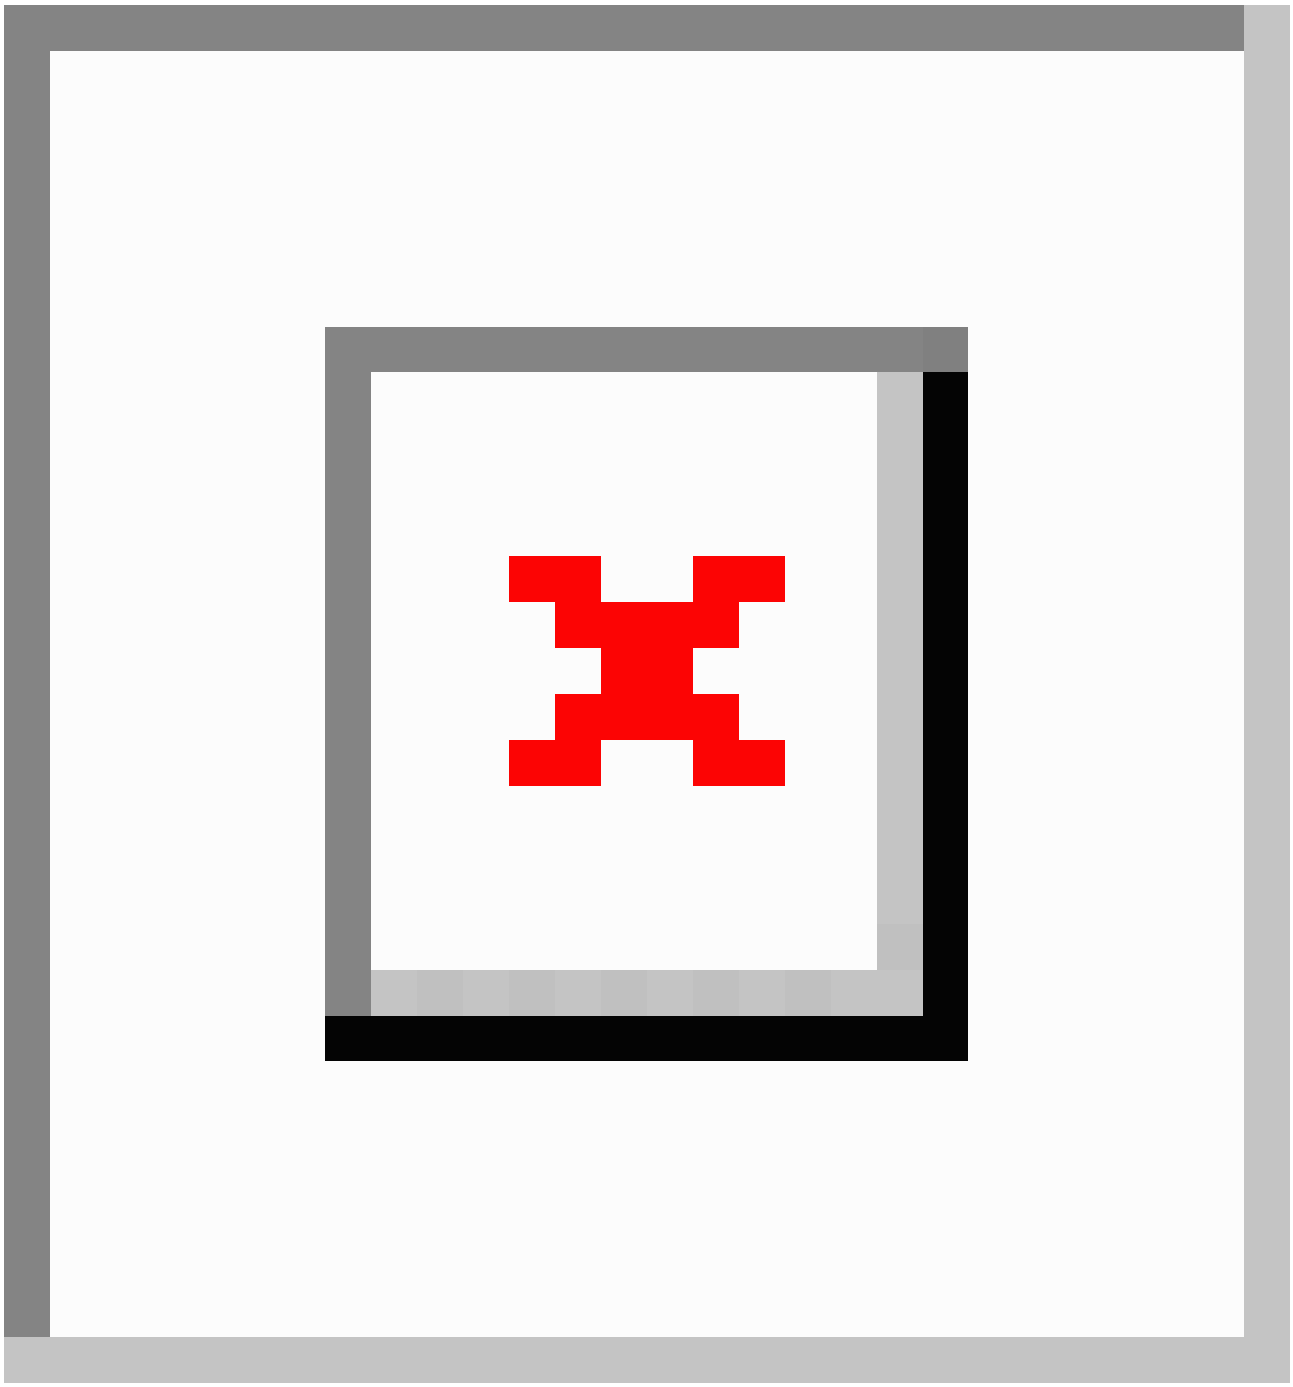

Figure 2. Diagram showing the relationships between classes in the *Drugs* ontology for defining the chronic patient domain. The *Drugs* ontology was designed to represent the identification and technical data of medicinal products.

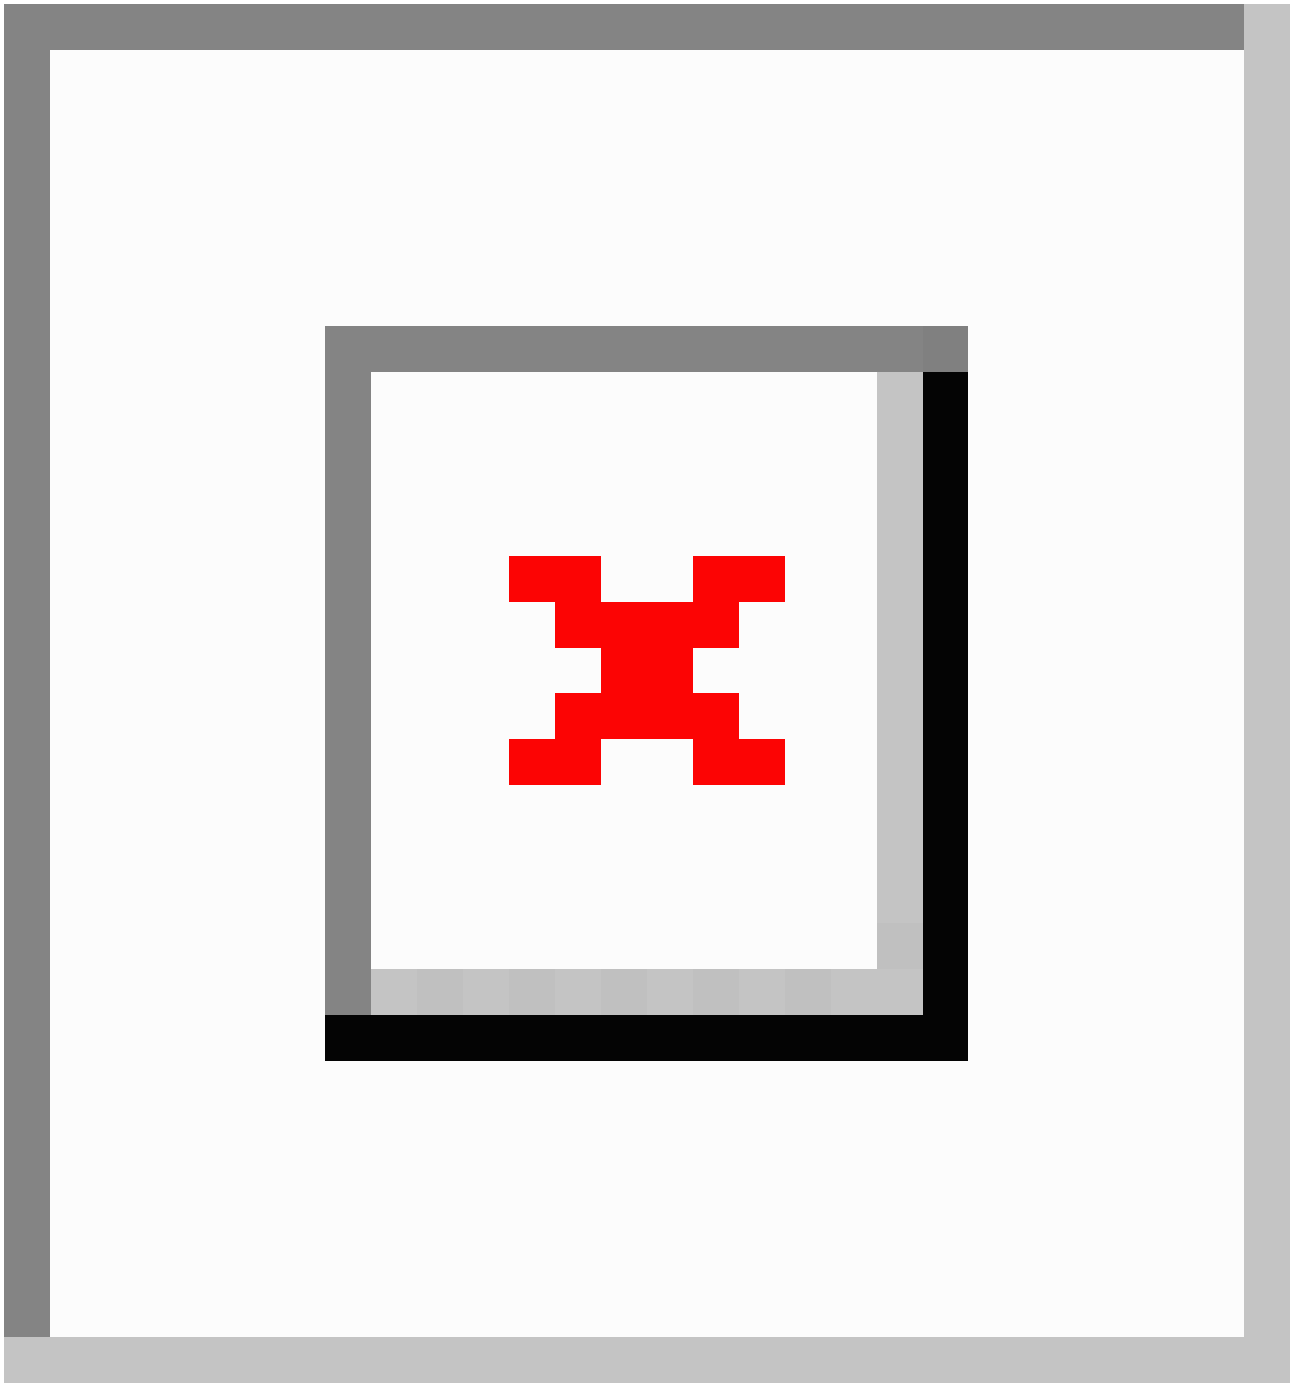

Figure 3. Diagram showing the relationships between classes in the *DSS* ontology for defining the chronic patient domain. The DSS ontology provides data on drug appropriateness. Concepts that were specifically created to define the chronic patient domain are highlighted in yellow. DBI: Drug Burden Index; DSS: Decision support system; MRCI: Medication Regimen Complexity Index.

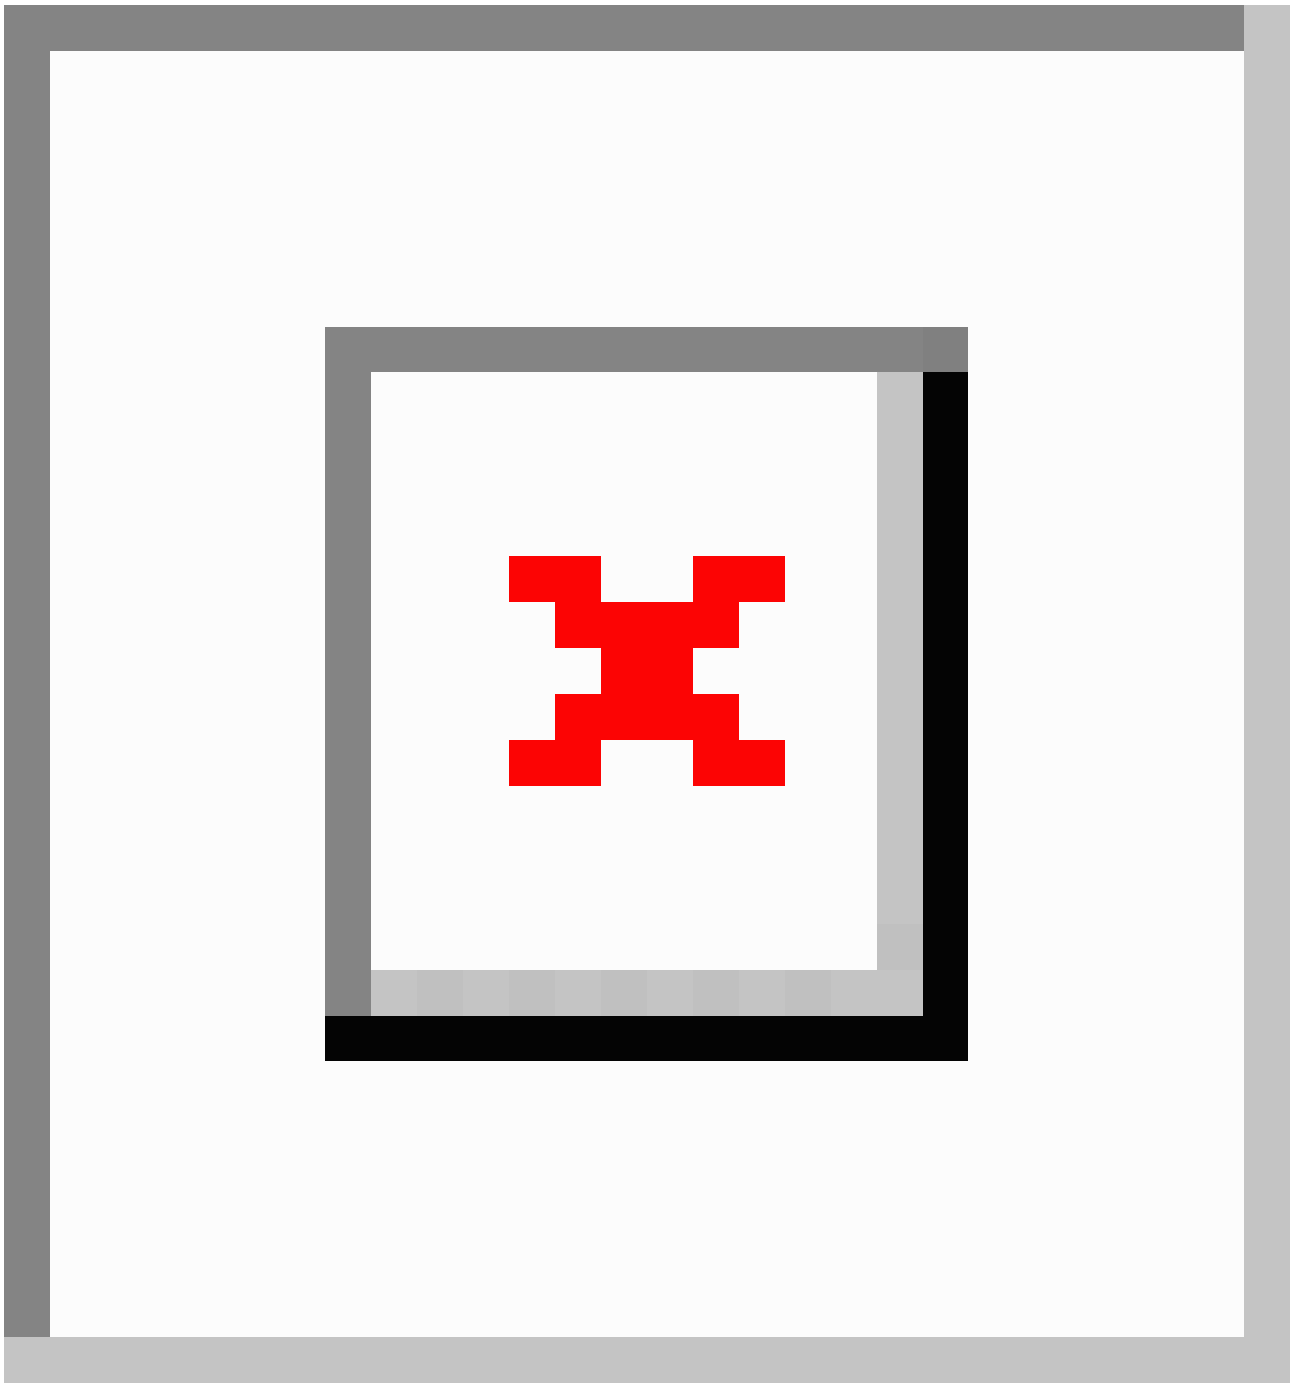

Figure 4. Diagram showing the relationships between classes in the *Local pharmacy* ontology for defining the chronic patient domain. The *Local pharmacy* ontology was designed to represent local concepts from electronic health records and computerized physician order entry. Each local concept is mapped to the corresponding OntoPharma concept.

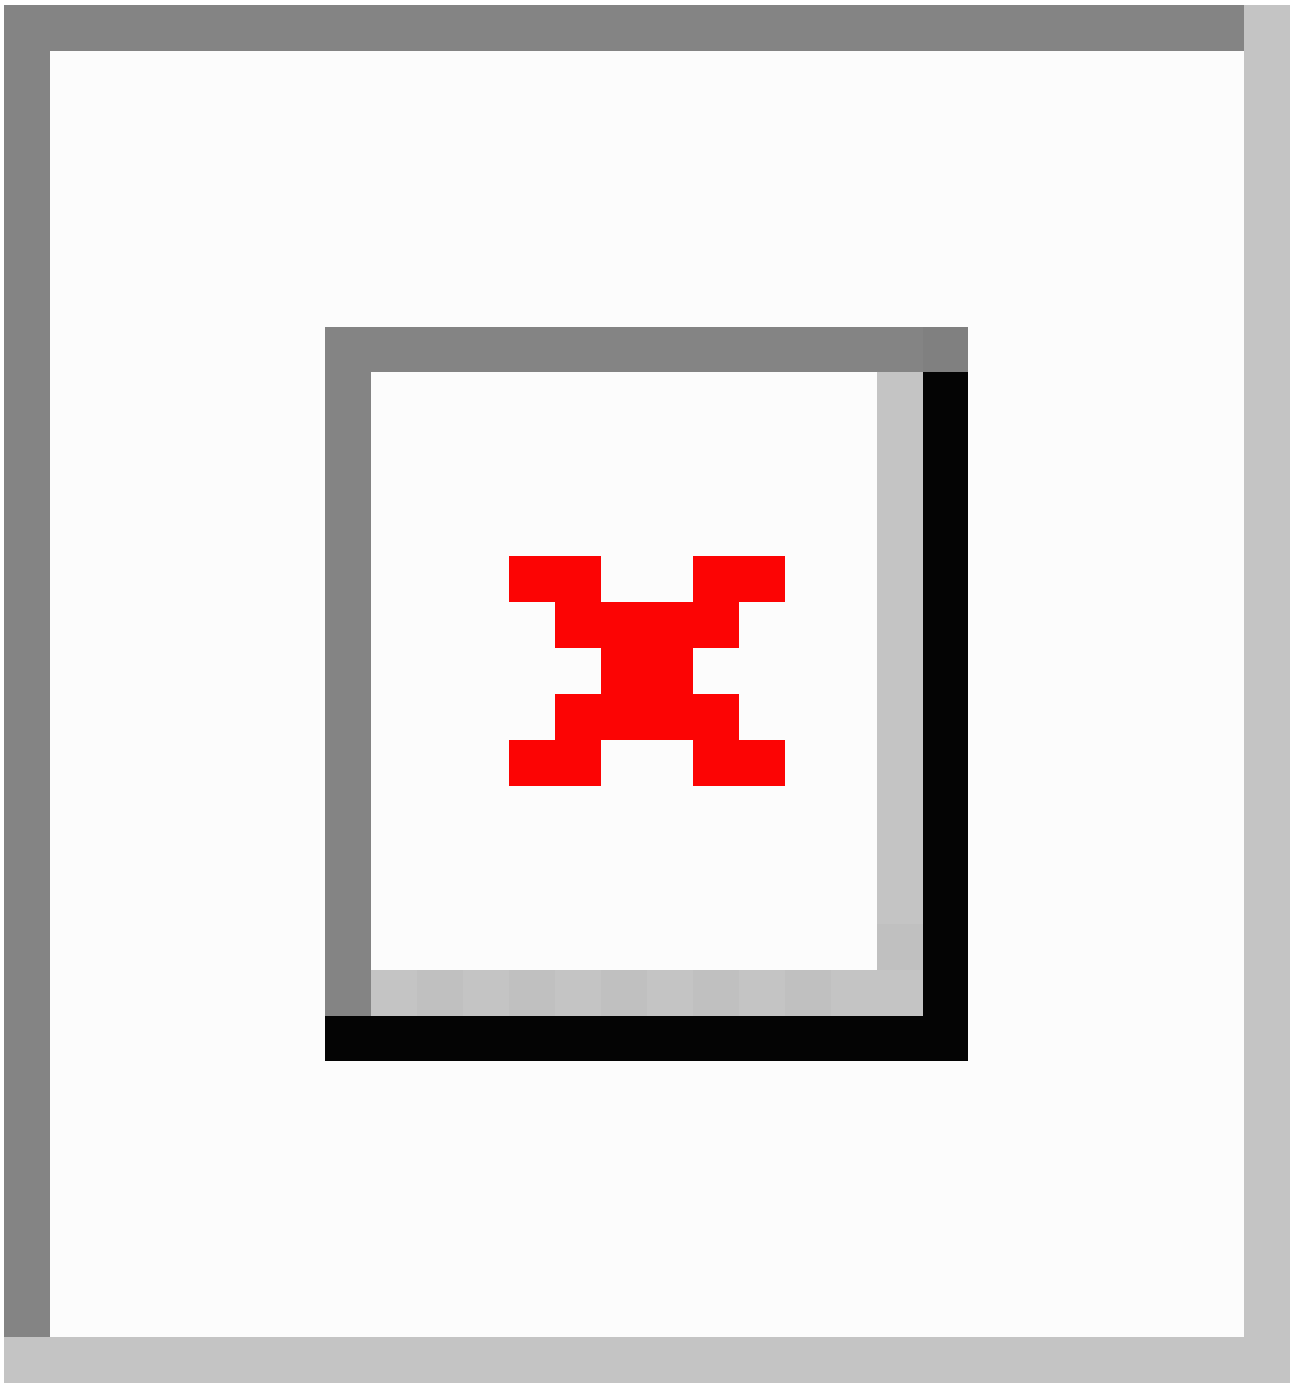


Medication Regimen Complexity

The MRCI quantifies drug regimen complexity based on dosage form, dosage frequency, and additional instructions.

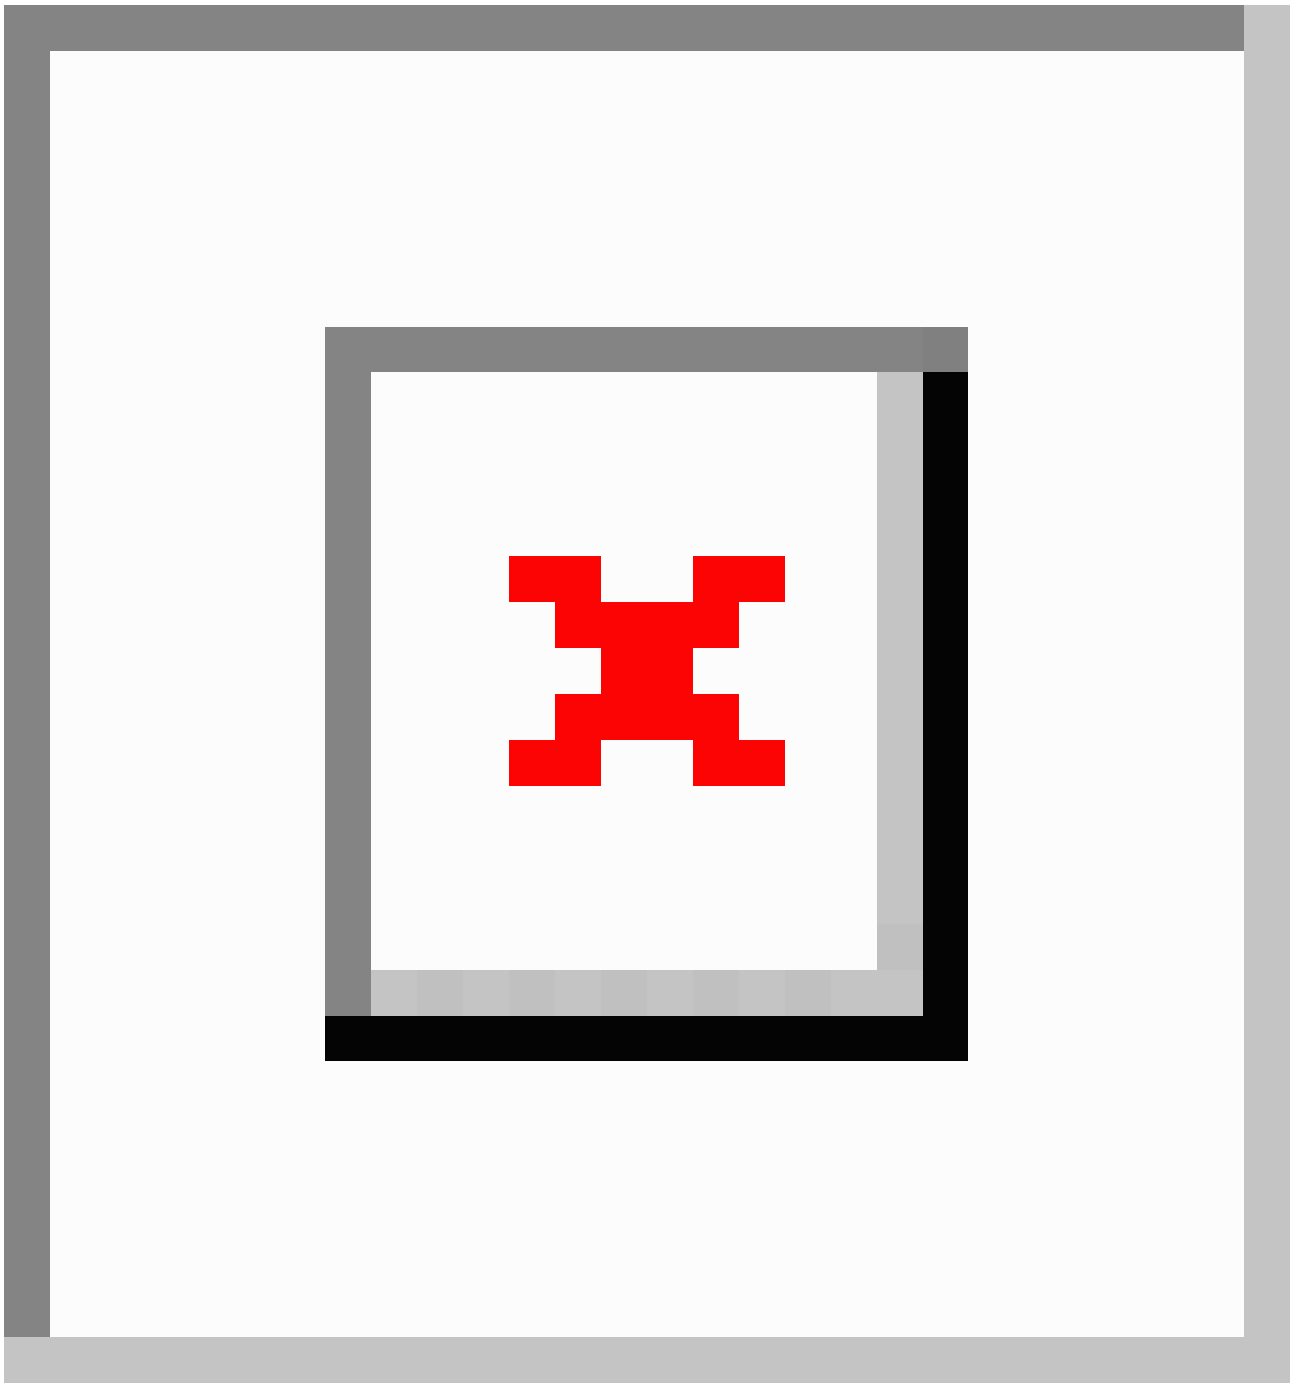
To represent the weighted scores for types of prescribed dosage forms (section A), we first created the concept "MRCI A form" (*DSS* ontology), which comprises 30 subclasses for identifying the possible dosage form and route of administration combinations. To provide the weight for each dosage form and route of administration combination, we introduced the property "mrci A weight."

To represent the weighted scores for dosage frequency (section B), we introduced the following two attached properties within the class "Local frequency" (*Local pharmacy* ontology): "mrci B," which provides weights for "scheduled" dosing frequencies, and "mrci B PRN," which provides weights for "as needed" dosing frequencies.

We identified 231 distinct frequency combinations. Frequency weights were assigned, considering that frequency data also contained indicators that qualify for component C scoring, such as indicators to take medication less often than once per day (eg, once every 48 hours) or indicators to take medication at specific times (before a meal, at bedtime, etc).

To represent the weighted scores for additional administration instructions (section C) related to taking medication with or without food, we introduced 1 attached property ("mrci C") within the class "Virtual medicinal product (VMP)" (*Drugs* ontology). A virtual medicinal product is an abstract representation of an active medicinal ingredient associated with strength information and a route of administration (eg, "omeprazole 20mg capsule"). We assigned a total of 6257 weights. Figure 5 provides a class diagram to model medication regimen complexity, which is explained with an example.

Figure 5. Class diagram to model medication regimen complexity. Circles represent the classes needed to quantify drug regimen complexity. Squares represent the attached properties (object or data) within each class. An example is given in brackets. MRCI: Medication Regimen Complexity Index; VMP: virtual medicinal product.



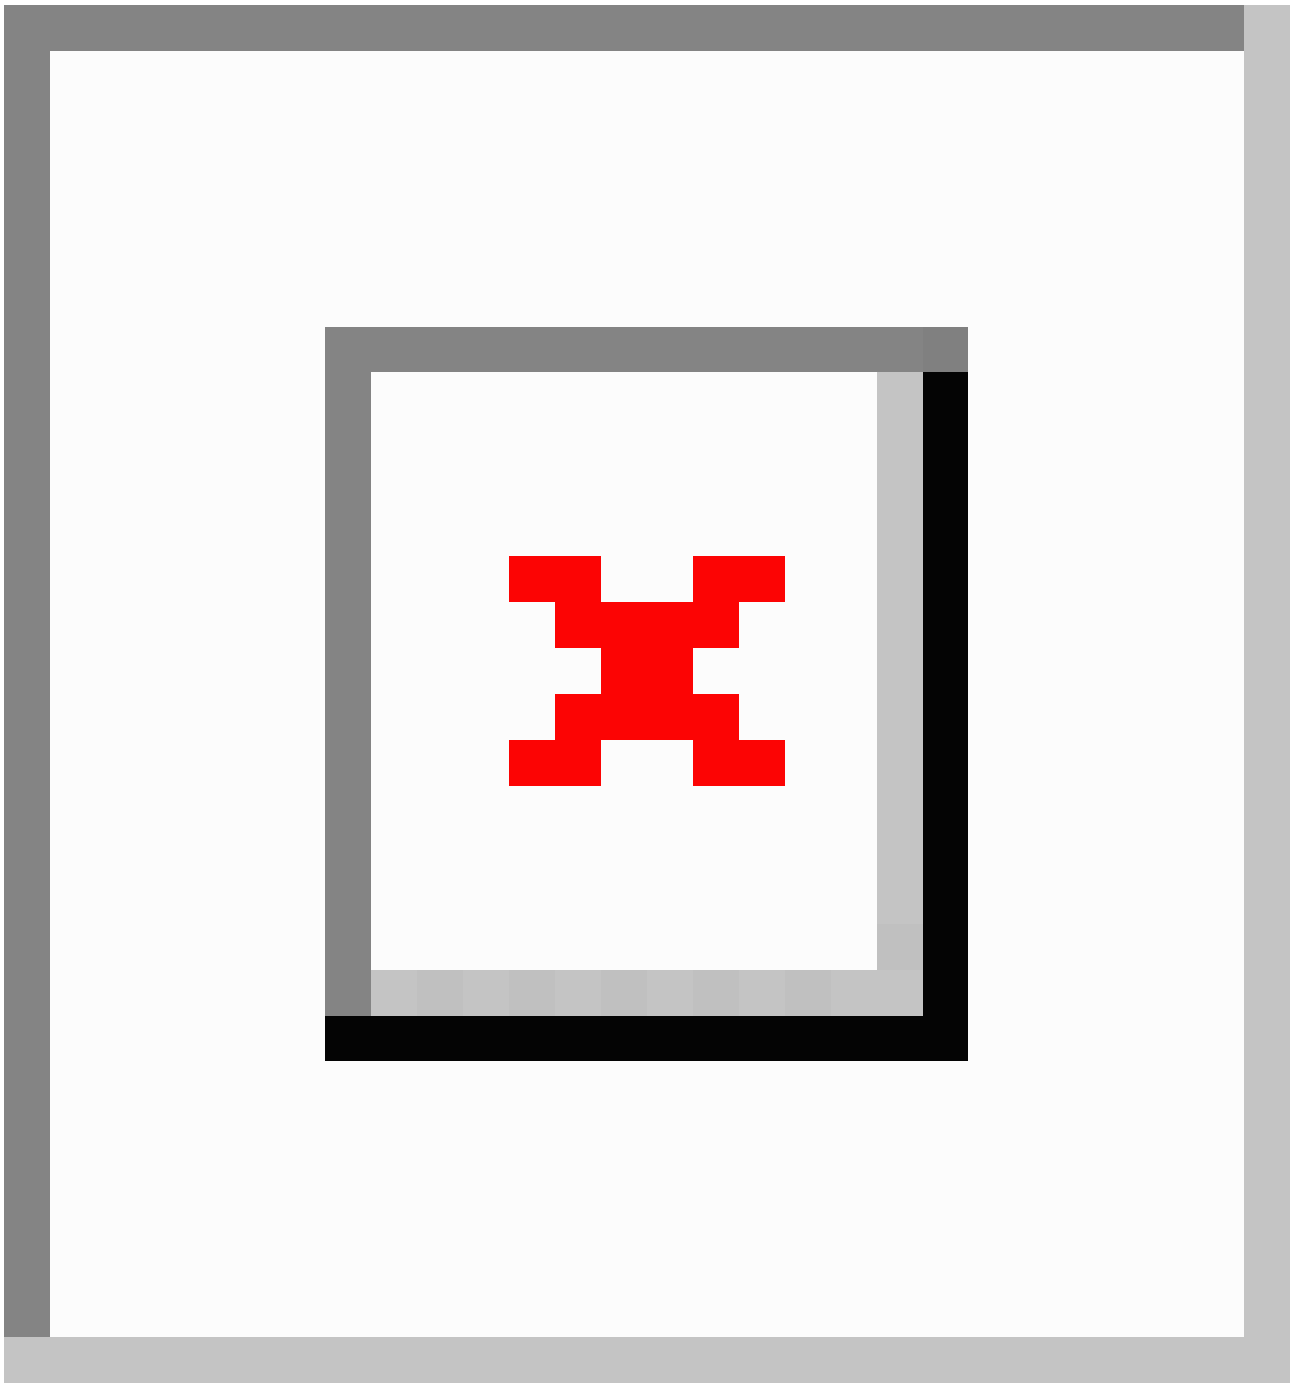
Anticholinergic and Sedative Drug Burden

The OWL concept that was used to enter the data on anticholinergic and sedative drug burden was "DBI" (*DSS* ontology), in reference to the scale used for its calculation. Because the DBI is a dose‐related measure of anticholinergic and sedative drug exposure, we created the "DBI" concept as a subclass of the "Dose appropriateness" concept. To provide enough information to calculate the DBI, we introduced the property "medd," which describes the minimum effective daily dose of each drug.

The "DBI" class contains 164 individuals. Each individual contains the following knowledge: ingredient (eg, alprazolam),

route of administration (eg, oral), age range (eg, 65-999 years), minimum effective daily dose (eg, 0.5), unit (eg, mg), base unit (eg, every 24 hours), and alert-related data. Figure 6 provides a class diagram to model anticholinergic and sedative drug burden, which is explained with an example.

Figure 6. Class diagram to model anticholinergic and sedative drug burden. Circles represent the classes needed to quantify anticholinergic and sedative drug burden. Squares represent the attached properties (object or data) within each class. An example is given in brackets. DBI: Drug Burden Index.

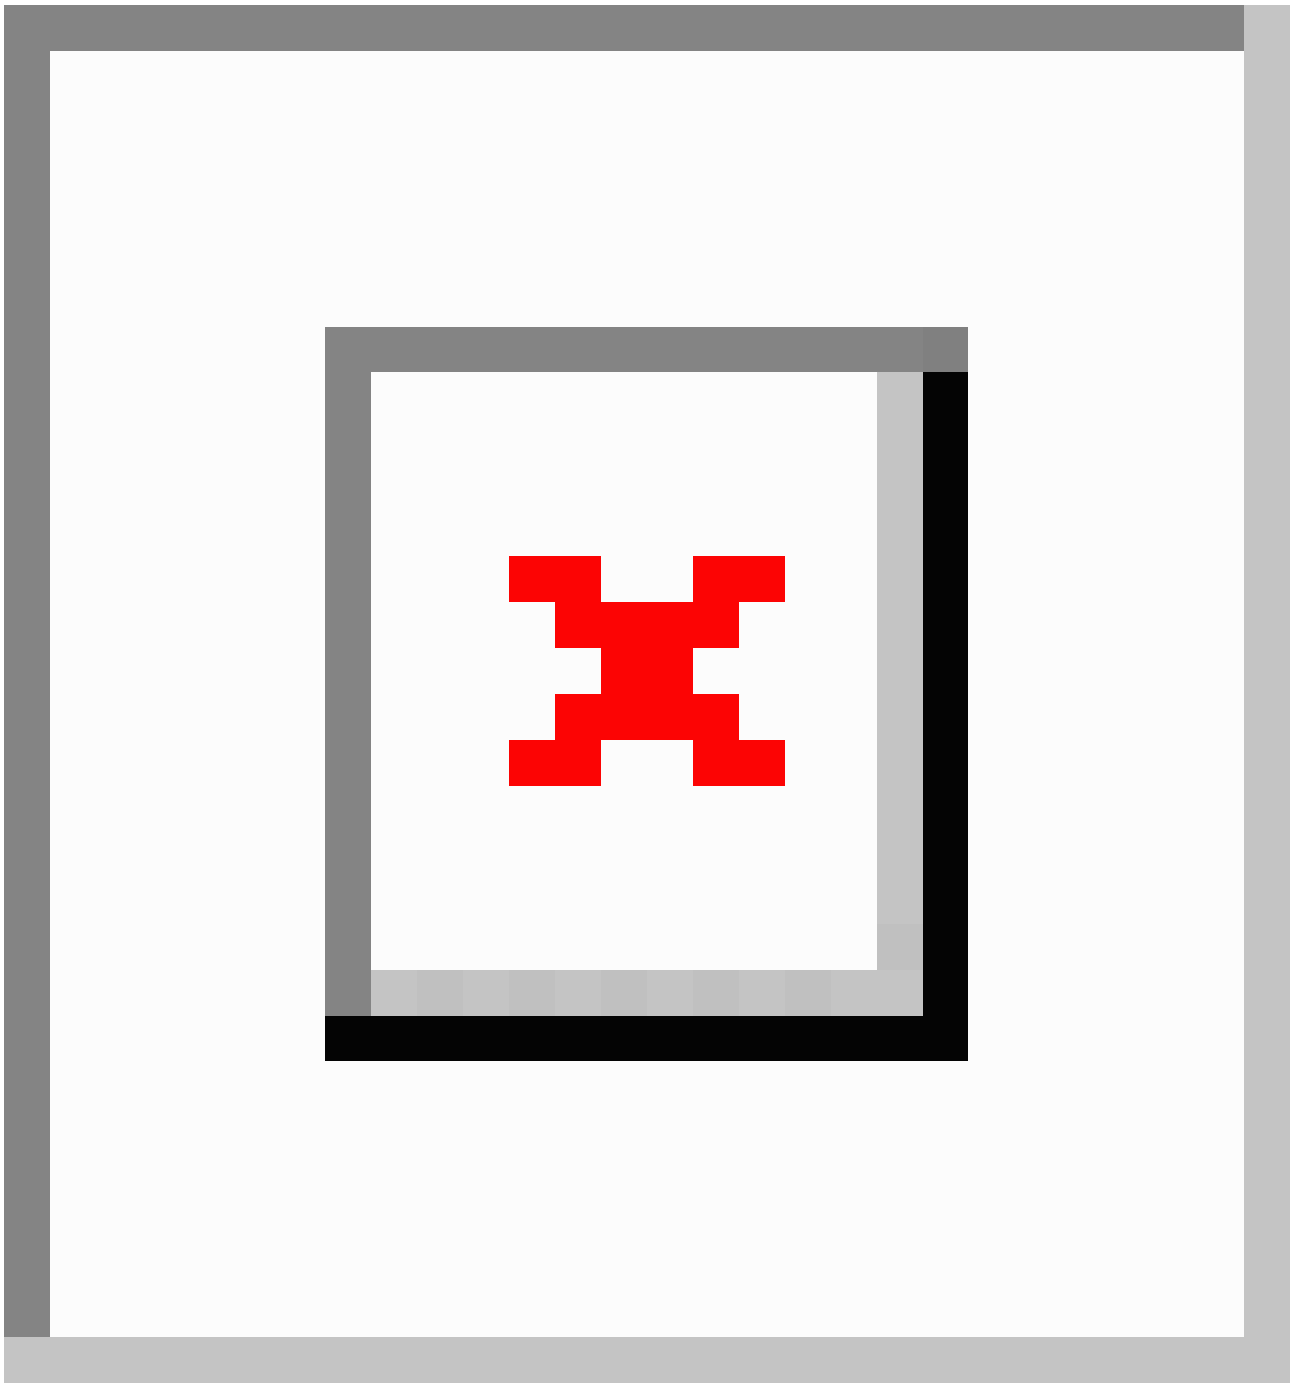


Triggers

The OWL concept that was used to enter the triggers for detecting ADEs in older patients with multiple chronic conditions was "Trigger tool" (*DSS* ontology). We created the "Trigger tool" concept as a subclass of the "Appropriateness lab test" concept because we only included triggers based on abnormal laboratory values. Introducing new properties was not required.

The "Trigger tool" class contains 821 individuals. Each individual contains the following knowledge: ingredient (eg, furosemide), route of administration (eg, parenteral), age range (eg, 65-999 years), lab test (eg, serum glucose), lab test unit (eg, mg/dL), low value (eg, 0), high value (eg, 110), and alert-related data. Figure 7 provides a class diagram to model triggers for detecting ADEs in patients with multimorbidity, which are explained with an example.

Figure 7. Class diagram to model triggers for detecting adverse drug events in patients with multimorbidity. Circles represent the classes needed to identify triggers of a possible adverse drug event. Squares represent the attached properties (object or data) within each class. An example is given in brackets.



Alerts

In addition to the abovementioned actions, we made changes related to the "Alert" class (*DSS* ontology). The "Alert" class included the information that was displayed when appropriateness criteria were not met. The following fields related to the "Alert" class remained unchanged: alert description, alert recommendation, alert source, alert date (the date when the alert was last updated), and related information (supporting documentation). In addition to the existing instances of the "Alert level" class ("not recommended," "contraindicated," or "unallowed prescription"), we created a new one called "risk minimization." We also introduced a new class—the "Drug intervention" subclass of the "Alert" class (*DSS* ontology). We defined the following two types of drug intervention: "global drug" intervention for when a complete treatment revision is required (eg, high MRCI) and "specific drug" intervention for when a partial treatment revision is required (eg, high DBI).

Knowledge Not Represented Using Ontologies

With regard to medication regimen complexity, we did not represent complexity based on the additional instructions related to taking multiple units at one time or needing to break or crush a tablet.

The triggers used to identify ADEs can be abnormal laboratory values, the use of certain medications or antidotes, or changes in clinical status that may indicate a possible medication-related harm. We only represented triggers based on abnormal laboratory values.

OntoPharma-Driven Alert Module Adaptation

The OntoPharma-driven alert module works the same as it did in our previous study [22]. Once the patient-specific clinical data are sent from the CPOE system and EHR to the ontologies, local concepts are matched to their equivalent OntoPharma concepts. With regard to the chronic patient domain, we defined the following decision rules.

The MRCI is obtained by summing the scores of the three sections.

The section A score is estimated by considering the dosage form and route of administration combination. Because administering the same dosage form more than once is easier than administering different dosage forms, each dosage form and route of administration combination is counted only once within a regimen. For example, if a patient's regimen consists of taking 3 tablets orally, their component A score is 1, not 3.

Section B and C scores are estimated by considering the dosage frequency and the virtual medicinal product prescribed, respectively. The cutoff point selected for triggering an alert (MRCI≥40) was determined by the expert advisory panel, in accordance with the literature.

The total DBI is calculated with the equation  , where "D" is the daily dose taken by the individual patient and "δ" is the minimum effective daily dose for that drug. The daily dose taken for each DBI medication is estimated by considering the dose, dose unit, and frequency. We have defined conversion factors for cases where the drug dose unit prescribed is different from the unit dose defined in the ontologies. The minimum effective daily dose is represented in the *DSS* ontology for each ingredient and route of administration combination. The cutoff point selected for triggering an alert (DBI≥1) was determined by the advisory panel, in accordance with the literature.

To evaluate the presence of triggers for identifying ADEs, we consider the ingredient regardless of the dosage. If a patient has several laboratory values, we consider the most recent values. An alert is triggered when a value is outside of the defined range [33].

Medications prescribed "as needed" were not considered in previous cases.

With regard to the interface, alerts are shown in different colors (red, orange, and yellow) according to their clinical relevance (contraindicated, moderate relevance, and low relevance). We added a new label (blue) to identify alerts aimed at risk minimization. To date, the advisory text contains the generic drug name, a short description of the possible concern, and a recommendation for improving medication appropriateness. The generic drug name is still displayed if the alert requires "specific drug" intervention. In cases where the alert requires "global drug" intervention, the text "Review total treatment" is displayed. We also included a hyperlink to relevant literature.

Alerts related to the chronic patient domain were defined, such as soft-stop alerts, so that the clinician can decide whether to ignore or accept the alert. To avoid alert fatigue, if an alert is ignored once, it will not be displayed again.

The interface that displays the alerts also includes a link to a user guide and an activity registry that serves as traceability system.

Despite the addition of new use cases, the results show that the response time for generating decision support remains short (within milliseconds), with minimal impact on the user's workflow.

Implementation of the Version of OntoPharma Containing the Chronic Patient Domain in a Hospital Setting

A total of 107 patients were included. The median age was 86 (IQR 80-90) years, and the majority of patients were women (n=63, 58.9%). The median length of hospital stay was 8 (IQR 5-13) days. Patients had a median of 15 (IQR 11-19) medications.

Of the 107 patients, 96 (89.7%) received at least one alert. OntoPharma generated 364 alerts (mean 3.9, SD 5.3 alerts per patient). Of these, 296 (81.3%) alerts were considered of low relevance, and 68 (18.7%) aimed at risk minimization. Further, 154 (42.3%) alerts were accepted.

Details of the types of alerts and the acceptance rates are included in Table 1. The most frequent alerts were alerts due to high anticholinergic and sedative drug burden (231/364, 63.5%), followed by alerts due to high medication regimen complexity (68/364, 18.7%) and alerts due to the presence of triggers (65/364, 17.8%).

Table . Description of the types of alerts generated by OntoPharma and the acceptance rates.

Type of alert	Frequency (N=364), n (%)	Acceptance rate, n (%[a])
Medication regimen complexity	68 (18.7)	40 (58.8)
Anticholinergic and sedative drug burden	231 (63.5)	84 (36.4)
Triggers	65 (17.8)	30 (46.2)

[a]Percentages were calculated by using the numbers in the "Frequency" column as denominators.

Discussion

Principal Results

This paper presents a modeling approach, which was formalized in ontological terms, for defining the chronic patient domain that provides support for improving medication appropriateness in older patients with multimorbidity. The chronic patient domain was built on OntoPharma—an ontology-based CDSS for reducing medication prescribing errors that has already been implemented in a tertiary referral hospital [22].

There are already ontology-based CDSSs that address medication management in patients with chronic conditions [37]. However, to the best of our knowledge, this is the first ontology-based approach that models medication regimen complexity, anticholinergic and sedative drug burden, and triggers for identifying possible adverse events. Farrish and Grando [38] built an ontology to assist with the management of polypharmacy prescriptions for patients with multiple chronic conditions to reduce the overall treatment complexity. Recently, Román-Villarán et al [39] developed an ontology-based CDSS for patients with complex chronic conditions. However, the knowledge sources used were different from ours, including clinical practice guidelines, the LESS-CHRON (List of Evidence-Based Deprescribing for Chronic Patients) criteria, and the STOPP/START (Screening Tool of Older Persons' Prescriptions and Screening Tool to Alert to Right Treatment) criteria, among others. These ontology approaches for patients with chronic conditions have been validated with patient data from databases. However, it is important to note that they are not implemented in a real environment, unlike our ontology approach. OntoPharma provides rapid and real-time support to improve medication appropriateness in older patients with multimorbidity.

Using ontologies instead of relational databases, which are the predominant choice in current commercial CDSSs, has distinct advantages [40,41]. First, the semantic approach and the use of OWL enable a convenient infrastructure for reuse. Hence, we reused the existing OntoPharma framework, without having to start from scratch. In addition, ontologies are more flexible and efficient in dealing with changes; thus, it was possible to add a new domain to OntoPharma without major complications. We were able to model a complex domain, creating only 6 new classes and 5 new properties. This was possible because the three ontologies (*Drugs*, *DSS*, and *Local pharmacy*) are interconnected (Figure 1), and classes are linked between them through object properties.

To ensure flexibility, scalability, and sustainability, we operated on the most appropriate level of abstraction. To define anticholinergic drug burden and triggers, we considered the ingredient. However, to define weighted scores for additional administration instructions (MRCI section C), we considered the class "Virtual medicinal product (VMP)."

To integrate structured clinical data with clinical knowledge, we reused the mappings previously established in the ontology *Local pharmacy*. It was only necessary to add some new mappings related to laboratory parameters.

End users participated throughout the development of the chronic patient domain in order to ensure usability and gain user acceptance [42,43]. As a result, we introduced some changes in the user interface, such as new clinical relevance levels and a hyperlink to relevant literature. Some proposals for improvement, such as showing the laboratory values next to the alert, have not been implemented yet. Usability may also be influenced by the response time for generating decision support. However, response time has not been modified, showing that OntoPharma is scalable.

Limitations

In terms of evaluation, we have not identified a database-based system for direct comparison with OntoPharma. van der Sijs et al [44] conducted a systematic review, concluding that drug safety alerts are overridden by clinicians in 49% to 96% of cases. Our acceptance rate (154/364, 42.3%) was expected to be better, considering that an expert advisory panel selected the most useful information to improve medication appropriateness in older patients. This may be partly explained by the following limitations. First, appropriateness criteria were evaluated if patients were older than 65 years. Considering that the older population is heterogeneous, we should also have considered frailty—a known factor indicative of vulnerability to medication-related problems [45]. Second, the alerts with a lower acceptance rate (84/231, 36.4%) were related to the DBI. Interventions for reducing the DBI commonly involve progressive medication deprescribing, which is difficult to realize in a tertiary hospital and would be easier in intermediate care [46]. On the other hand, poor adherence is one of the major consequences of high MRCI scores [23]. In hospitals, the administration of medications is primarily the nurses' responsibility; therefore, clinicians may have not given sufficient importance to MRCI alerts. Acceptance rates might improve in outpatient care. Our research focused primarily on clinician decision-making. The variables analyzed allowed us to identify the scale of potentially inappropriate medications and the usefulness of OntoPharma. However, evaluating OntoPharma's influence on health outcomes is a challenge that we should take up in future.

As mentioned in our previous paper on OntoPharma [22], one limitation of this study is maintaining the evidence and keeping it relevant and up to date [47]. To create individual instances, we extracted the information from papers. Since this was not done via automatic extraction, it was a time-consuming process. With regard to the maintenance, we must assign a complexity weight if there is a new dose form or dosing frequency; these data are not updated frequently. In addition, we must check if new medications have additional administration instructions, are capable of causing anticholinergic adverse effects, or are included in the set of triggers for detecting ADEs in older patients.

Of note, although mapping in this study did not take excessive time, we are aware that manual mapping is a resource-intensive and ongoing process.

We have not represented all of the knowledge from the sources of information. OntoPharma relies on structured data; therefore, we have prioritized representing data that are structured in text

format within the EHR. As a result, medication regimen complexity may be underestimated because special instructions are underrepresented. In addition, there are triggers that are different from abnormal laboratory values that are not represented in ontologies. Even though there exist large amounts of health care data, the main challenge to improving results of CDSSs is converting free-text data into structured fields computationally [48].

In future implementations, we will continue to represent complex drug knowledge that is absent in commercial databases. We are currently modeling knowledge for supporting the neonatal population and populations at risk for hepatitis B virus reactivation. To capture clinicians' reasoning processes, we must place a high priority on increasing structured patient data within EHRs.

Other areas for future work are mentioned in our previous OntoPharma paper [22], such as developing a more complex CDSS that can be applied across the entire treatment process and is not only restricted to the medication prescription process. Finally, we must continue working on customized alerts to avoid alert fatigue [49].

Despite the limitations, we believe that our methods have been successful in modeling knowledge related to the chronic patient domain and that the proposed version of OntoPharma is an enhancement of the previous one. Although optimizing care in older patients is a context-dependent, complex process, we believe that developing an ontology to support the chronic patient domain constitutes a major step toward improving medication appropriateness in a generalizable and reusable way.

Conclusions

Polypharmacy in the older population poses challenges to the delivery of medical care because of the increased difficulties in guaranteeing appropriate prescription. We proposed an ontology-based approach to provide support for improving medication appropriateness in older patients with multimorbidity in a scalable, sustainable, and reusable way. OntoPharma has been implemented in clinical practice and generates alerts, considering the following use cases: medication regimen complexity, anticholinergic and sedative drug burden, and the presence of triggers for identifying possible adverse events.

Acknowledgments

We thank Central Catalonia Chronicity Research Group (C3RG)-Line of research "Person-Centred Prescription" for providing advice in the conceptualization of the use cases. We especially thank Joan Espaulella-Panicot, Daniel Sevilla-Sánchez, and Núria Molist-Brunet.

Abstract

Background: Dermoscopy is commonly used for the evaluation of pigmented lesions, but agreement between experts for identification of dermoscopic structures is known to be relatively poor. Expert labeling of medical data is a bottleneck in the development of machine learning (ML) tools, and crowdsourcing has been demonstrated as a cost- and time-efficient method for the annotation of medical images.

Objective: The aim of this study is to demonstrate that crowdsourcing can be used to label basic dermoscopic structures from images of pigmented lesions with similar reliability to a group of experts.

Methods: First, we obtained labels of 248 images of melanocytic lesions with 31 dermoscopic "subfeatures" labeled by 20 dermoscopy experts. These were then collapsed into 6 dermoscopic "superfeatures" based on structural similarity, due to low interrater reliability (IRR): dots, globules, lines, network structures, regression structures, and vessels. These images were then used as the gold standard for the crowd study. The commercial platform DiagnosUs was used to obtain annotations from a nonexpert crowd for the presence or absence of the 6 superfeatures in each of the 248 images. We replicated this methodology with a group of 7 dermatologists to allow direct comparison with the nonexpert crowd. The Cohen κ value was used to measure agreement across raters.

Results: In total, we obtained 139,731 ratings of the 6 dermoscopic superfeatures from the crowd. There was relatively lower agreement for the identification of dots and globules (the median κ values were 0.526 and 0.395, respectively), whereas network structures and vessels showed the highest agreement (the median κ values were 0.581 and 0.798, respectively). This pattern was also seen among the expert raters, who had median κ values of 0.483 and 0.517 for dots and globules, respectively, and 0.758 and 0.790 for network structures and vessels. The median κ values between nonexperts and thresholded average–expert readers were 0.709 for dots, 0.719 for globules, 0.714 for lines, 0.838 for network structures, 0.818 for regression structures, and 0.728 for vessels.

Conclusions: This study confirmed that IRR for different dermoscopic features varied among a group of experts; a similar pattern was observed in a nonexpert crowd. There was good or excellent agreement for each of the 6 superfeatures between the

crowd and the experts, highlighting the similar reliability of the crowd for labeling dermoscopic images. This confirms the feasibility and dependability of using crowdsourcing as a scalable solution to annotate large sets of dermoscopic images, with several potential clinical and educational applications, including the development of novel, explainable ML tools.

Introduction

The use of dermoscopy, a low-cost, noninvasive diagnostic technique based on a hand-held device with a light source and magnifying lens, is routine practice for the evaluation of pigmented skin lesions and has been shown to increase sensitivity for early melanoma detection [1,2]. Dermoscopy allows examination of morphological features below the stratum corneum that would not be visible by visual inspection alone [3]. Diagnosis of melanoma using dermoscopy relies on assessment of lesion morphology and identification of dermoscopic features. A number of diagnostic criteria and algorithms have been developed for this purpose, including pattern analysis [4], the ABCD (asymmetry, border, color, diameter) rule [5], the Menzies method [6], the 7-point checklist [7], and the CASH (color, architecture, symmetry, homogeneity) score [8].

As use of dermoscopy has expanded, so too has dermoscopic vocabulary, resulting in a vast number of published feature definitions and 2 competing terminologies: metaphoric and descriptive. In recent years, efforts have been made to harmonize nomenclature, and the 2016 International Dermoscopy Society terminology consensus proposed 31 specific “subfeatures” of melanocytic lesions, falling into 9 “superfeatures” based on structural similarities (Textbox 1) [9].

However, interrater reliability (IRR) for identifying melanoma-specific dermoscopic structures has been shown to be poor [10]. Our research group recently performed the EASY (Expert Agreement on the Presence and Spatial Location of Melanocytic Features in Dermoscopy) study, which found that agreement was highly variable when 20 dermoscopy experts were asked to identify the 31 dermoscopic subfeatures in an image set specifically curated for this purpose. IRR across 248 images was poor to moderate for all but 7 features. We demonstrated that when individual subfeatures were collapsed into 9 superfeatures, increased agreement was observed, ranging from a pairwise Fleiss κ of 0.14 for the detection of dots to 1.0 for the detection of a pigment network structure.

Machine learning (ML) methods have recently been investigated in the field of dermatology, and the majority of developed algorithms are diagnostic binary classifiers [11,12]. A number of studies have evaluated the performance of algorithms developed to detect specific dermoscopic features, including pigment network structures, vessels, and blue-white veil; however, many algorithms were trained and tested on relatively small data sets and have achieved only moderate accuracy [13-21].

Due to the vast dimensionality of medical images, classifier algorithms are typically of an uninterpretable “black box” nature, a term that describes the phenomenon whereby functions that connect input pixel data to output labels cannot be understood by the human brain. There has been a push by medical regulators and the artificial intelligence community to develop explainable algorithms; however, it has been acknowledged that this may come at the cost of decreased accuracy [22]. Incorporating detection of dermoscopic features into melanoma classifier algorithms may allow for better explainability and therefore greater acceptance into clinical practice by clinicians and regulatory bodies [23,24].

The International Skin Imaging Collaboration (ISIC) archive provides an open-access data set comprising almost 70,000 publicly available dermoscopic images at the time of writing, including 5598 melanomas and 27,878 nevi. As well as hosting the regular ISIC Grand Challenge to promote the development of ML for melanoma detection, the archive has been extensively utilized to train independent ML algorithms and acts as a comprehensive educational resource for dermatologists via the Dermoscopedia platform [25,26]. Most public images in the archive have labels serving as a diagnostic ground truth for supervised learning. However, accurate feature annotations are thus far lacking. As part of the 2018 ISIC Challenge, 2595 images were annotated for 5 dermoscopic patterns (pigment network structures, negative network structures, streaks, milia-like cysts, and dots/globules) [27]. However, the ground truth labels were provided by only 1 clinician and the performance of the 23 submitted algorithms was acknowledged to be exceptionally low, likely as a result of this [27].

As medical data sets continue to rapidly expand and computing power increases, it is widely recognized that one of the major limiting factors for the development of robust and generalizable ML in dermatology is the need for large, comprehensively labeled data sets [28,29]. Obtaining annotations of medical images by medical experts is both time-consuming and expensive, creating a bottleneck in the development pipeline and making it challenging to obtain annotations at scale [30].

Crowdsourcing provides a potential solution to these problems. Crowdsourcing involves the recruitment of groups of individuals of varying levels of knowledge, heterogeneity, and number who voluntarily complete an online task, often with financial incentives [31,32]. Monetary compensation is typically less than US $0.10 per annotation, and tasks can be distributed to a

large number of workers in parallel, aggregating the crowd's knowledge to complete the task in a cost- and time-effective manner [33,34]. One study reported that it took 6 months to obtain expert labels comprising 340 sentences from radiology reports written by 2 radiologists, whereas the authors obtained crowdsourced annotations of 717 sentences in under 2 days at a cost of less than $600. A classification algorithm trained using these crowdsourced annotations outperformed an algorithm trained using the expert-labeled data as a result of the increased volume of available training examples [32].

Given the heterogeneity of biomedical data, the utility of crowdsourcing may decrease with the complexity of the task. For example, the 14 million images contained in the ImageNet archive were easily annotated by the untrained public, whereas the ability to classify and segment radiological images may require many years of specialist training [28,30,35]. Nevertheless, crowdsourcing has proven effective in a wide range of applications for biomedical imaging, most commonly histopathology or retinal imaging [34].

Feng et al [36] reported that a crowd of South Korean students were able to reach similar diagnostic accuracy as experts for diagnosing malaria-infected red blood cells after only 3 hours of training, allowing the authors to build a gold standard library of malaria-infection labels for erythrocytes. The authors used a game-based tool that made the task easy to complete by including points and a leaderboard on the platform. This method of so-called gamification is frequently used by crowdsourcing platforms and has been shown to increase the engagement of the crowd and improve the quality of the crowdsourced work [37]. Bittel et al [38] used a hybrid crowd-ML approach to create the largest publicly available data set of annotated endoscopic images. Heim et al [28] found that a crowd was able to segment abdominal organs in computed tomography (CT) images with comparable quality to a radiologist, but at a rate up to 350 times faster.

There are few studies published to date evaluating crowdsourcing in the field of dermatology, and to the best of the authors' knowledge, there are no published studies on the utility of crowdsourcing for the annotation of features present in dermoscopic images [39,40].

The aim of this study is to demonstrate that crowdsourcing can be employed to label dermoscopic subfeatures of melanocytic lesions with equivalent reliability to a small group of dermatologists. This will allow for efficient annotation of a large repository of dermoscopic images to aid the development of novel ML algorithms [32]. Incorporating detection of dermoscopic features into diagnostic algorithms will result in explainable outputs and may therefore improve the acceptability of these outputs to the medical community.

Textbox 1. List of superfeatures (in bold) and corresponding subfeatures seen in melanocytic lesions [9].

Dots

Irregular, regular

Globules

Cobblestone pattern, irregular, regular, rim of brown globules

Lines

Branched streaks, pseudopods, radial streaming, starburst

Network structures

Atypical pigment network, broadened pigment network, delicate pigment network, negative pigment network, typical pigment network

Regression structures

Peppering/granularity, scarlike depigmentation

Shiny white structures

Patterns

Angulated lines, polygons, zigzags

Structureless areas

Irregular blotches, regular blotches, blue-whitish veil, milky red areas, structureless brown areas, and homogenous (not otherwise specified)

Vessels

Comma, corkscrew, dotted vessel, linear irregular vessel, polymorphous vessel, milky red globules

Methods

Ethics Approval

This study was conducted as part of the umbrella ISIC research protocol and was approved by the Memorial Sloan Kettering Cancer Center Institutional Review Board (16-974). All images were deidentified and do not contain any protected health information as per the terms of use agreement for the ISIC archive.

Materials

This study was performed in 3 separate experiments, each using the same set of 248 lesion images used in the EASY study. Briefly summarized, clinical experts contributed 964 lesion images showing 1 of 31 preselected subfeatures, as described

by Kittler et al [9]. Clinicians were asked to submit images of "excellent quality showing the exemplar feature in focus." Three experts chose 248 of these images, roughly balancing benign and malignant lesions and ensuring image quality. Each of the 31 features was the exemplar in 8 of the lesion images submitted. However, each image could, and typically did, show multiple features.

Subfeatures and Superfeatures

As described earlier, low to moderate IRR was observed for the majority of subfeatures. Hence, we used only the superfeature terms for our scalability investigation. While each of the subfeatures had 8 exemplar images, collapsing the labels into superfeatures created some imbalance. The full list of subfeatures is shown in Textbox 1. The 9 superfeatures (dots, globules, lines, network structures, patterns, regression structures, shiny white structures, structureless areas, and vessels; shown in Multimedia Appendix 1, Table S1) were presented to participants during the tutorial on the DiagnosUs smartphone app, adapted from Marghoob and Braun [41].

Agreement Measure

To measure agreement across raters, we employed the Cohen κ [42], which has a value of 0 for completely random choices, increasing toward a maximum value of 1.0 with improved IRR. Measures of agreement are interpreted as poor (0-0.4), fair to good (≥0.4-0.75), and excellent (≥0.75-1.0) [43]. This measure was primarily chosen to accommodate the nature of the 3 separate studies (see below), allowing for partial data between pairs of raters using the binary choice of "feature present" or "feature absent." Throughout this paper, we use the term "median κ" to refer to the median of κ values across the set of pairwise comparisons as a measure of central tendency, given the nonnormal distribution of κ values.

Initial Expert Annotations (Study 1)

For the first study, we used a custom programmed annotation platform built for the ISIC archive. We asked a total of 20 dermoscopy experts to each annotate 62 images (2 per exemplar feature) in 4 substudies of nonoverlapping image sets. Experts for study 1 were clinicians with ≥10 years of dermoscopy experience who had made significant contributions to dermoscopy research or teaching dermoscopy of pigmented lesions. For each image, 5 experts were asked to provide benign/malignant status and then to self-select which of the 31 available subfeatures they perceived as present in the image. Full data and results of the EASY study will be published separately.

Gold Standard for the Crowd Study

After collapsing the subfeatures into the 9 abovementioned superfeatures, we found that 3 had very poor agreement and too few exemplars to allow reliable evaluation by the crowd: patterns, shiny white structures, and structureless areas. For the remaining 6 superfeatures (dots, globules, lines, network structures, regression structures, and vessels), images in which at least 3 of 5 experts in study 1 had selected ≥1 of the subfeatures within the same superfeature as present were used as the gold standard for "superfeature present." Images in which none of the 5 experts had identified any of the subfeatures within the same superfeature as present were used as the gold standard for "superfeature absent."

Nonexpert Crowd Annotations (Study 2)

To collect nonexpert image annotations, we used the commercially available platform DiagnosUs (Centaur Labs) [44] through a collaboration agreement. Users can sign up to the app and participate in competitions, which increases engagement and improves accuracy [37]. Users are recruited via a referral system or advertisements on social media. To ensure that only users somewhat skilled at a task computed average detection values, gold standard images were used for both training and validation. This left the remaining images, for which either 1 or 2 expert raters annotated a subfeature within the same superfeature as being present, as true test images. If a user did not reach at least 83% correctness for the validation items, that user's choices were not used in the subsequent analysis. Each of the 6 superfeatures was presented as a separate task. In addition to the binary choice of presence or absence of a superfeature, we also collected reaction times to assess decision difficulty [45].

Expert Crowd Annotations (Study 3)

As study 1 allowed experts to select from the 31 subfeatures, we replicated the methodology of study 2 to allow direct comparison with the nonexpert crowd. Experts in study 2 were dermatologists with ≥5 years of experience. We recruited 7 experts to use the DiagnosUs platform and annotate the same 248 images from studies 1 and 2 for the presence of the 6 superfeatures. For each of the features, we selected the first 5 dermatologists who completed annotation of the image set.

Reaction Times

For each of the tasks in studies 2 and 3, we computed the per-item averaged logged reaction times as the log of (1 + reaction time) to approximate a normal distribution of measurement errors. These averaged logged reaction times were then regressed against the average responses and a quadratic term, allowing for an inverted-U–shaped response function, which peaked roughly at the (across-readers) point of indecision.

Results

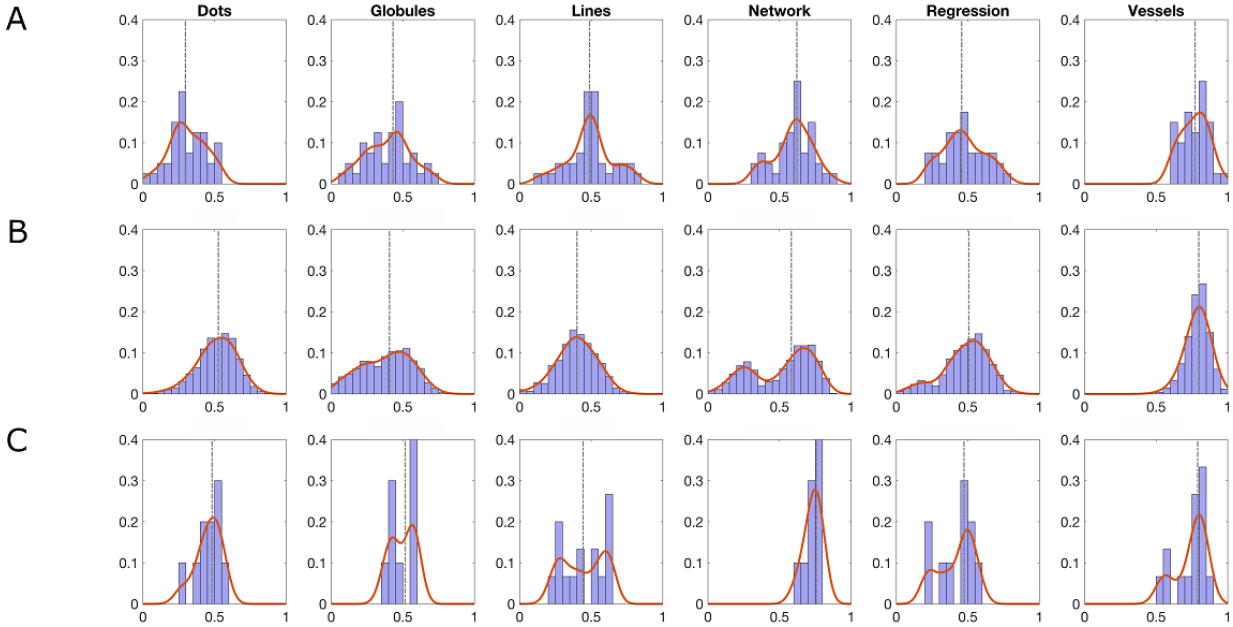
Initial Expert Annotations (Study 1)

In study 1, we found that dots showed poor agreement (median κ=0.298), whereas vessels showed excellent agreement (median κ=0.768). All other superfeatures showed fair to good agreement (Table 1). The resulting distributions of pairwise Cohen κ values are shown in Figure 1A. The number of resulting gold-standard images for each of the 6 superfeatures was as follows (0 readers/at least 3 readers, respectively): dots (93/61), globules (57/92), lines (129/60), network structures (63/140), regression structures (113/59), and vessels (152/66).

Table 1. Median Cohen κ values for pairwise readers. For study 2, pairs of readers were considered only if both readers saw at least 62 of the same images.

Feature	Study 1 (experts), median κ	Study 2 (nonexpert crowd), median κ	Study 3 (expert crowd), median κ
Dots	0.2977	0.5264	0.4829
Globules	0.4075	0.3945	0.5166
Lines	0.5205	0.3983	0.4433
Network structures	0.6175	0.5810	0.7575
Regression structures	0.4643	0.5066	0.4730
Vessels	0.7683	0.7977	0.7903

Figure 1. Pair-wise Cohen κ values for study 1 (A), study 2 (B), and study 3 (C).



Nonexpert Crowd Annotations (Study 2)

Providing demographic data pertaining to the users' jobs and their reasons for using the DiagnosUs platform was optional; these data were collected from 190 users. Of these, 23 (12.1%) were physicians (2 dermatologists, 21 other specialties), 72 (37.9%) were medical students, 11 (5.8%) were nurse practitioners, 8 (4.2%) were physician assistants, and 76 (40%) were "other" or "other healthcare student." The most common reason for using DiagnosUs was "improve my skills" (134/190, 70.5%), followed by "earn money" (37/190, 19.5%) and "compete with others" (19/190, 10%).

The number of users that engaged with each of the features varied for dots (92 users), globules (111 users), lines (82 users), network structures (97 users), regression structures (79 users), and vessels (95 users). Equally, the median number of ratings made per user per task varied for dots (160 images rated per user), globules (131 images), lines (177 images), network structures (91 images), regression structures (124 images), and vessels (104 images). The total number of crowd base ratings obtained in this study was 139,731, including 25,466 total ratings for dots, 40,853 for globules, 21,074 for lines, 17,114 for network structures, 17,020 for regression structures, and 18,204 for vessels.

The pattern we found in study 1 was largely replicated by the nonexperts. To ensure that there was sufficient and comparable overlap for images between pairs of readers, only pairs in which both readers saw at least 62 of the same images were evaluated. Dots and globules showed relatively lower agreement (with median κ values of 0.526 and 0.395, respectively), whereas network structures and vessels showed the highest agreement (with median κ values of 0.581 and 0.798, respectively). To allow a direct comparison between studies 1 and 2, we have compiled the 6 superfeatures into a panel figure (Figure 1A and 1B).

Expert Crowd Annotations (Study 3)

Again, the patterns found in studies 1 and 2 were replicated, such that dots and globules showed relatively lower agreement (median κ values were 0.483 and 0.517, respectively), whereas network structures and vessels showed the highest agreement (median κ values were 0.758 and 0.790, respectively; Figure 1C).

We computed κ values for each nonexpert reader from study 2 compared to a single simulated expert by thresholding the responses in study 3 from 3 of 5 experts into a binary variable. The median κ values between nonexperts and the thresholded average expert reader were as follows: for dots, 0.709; for

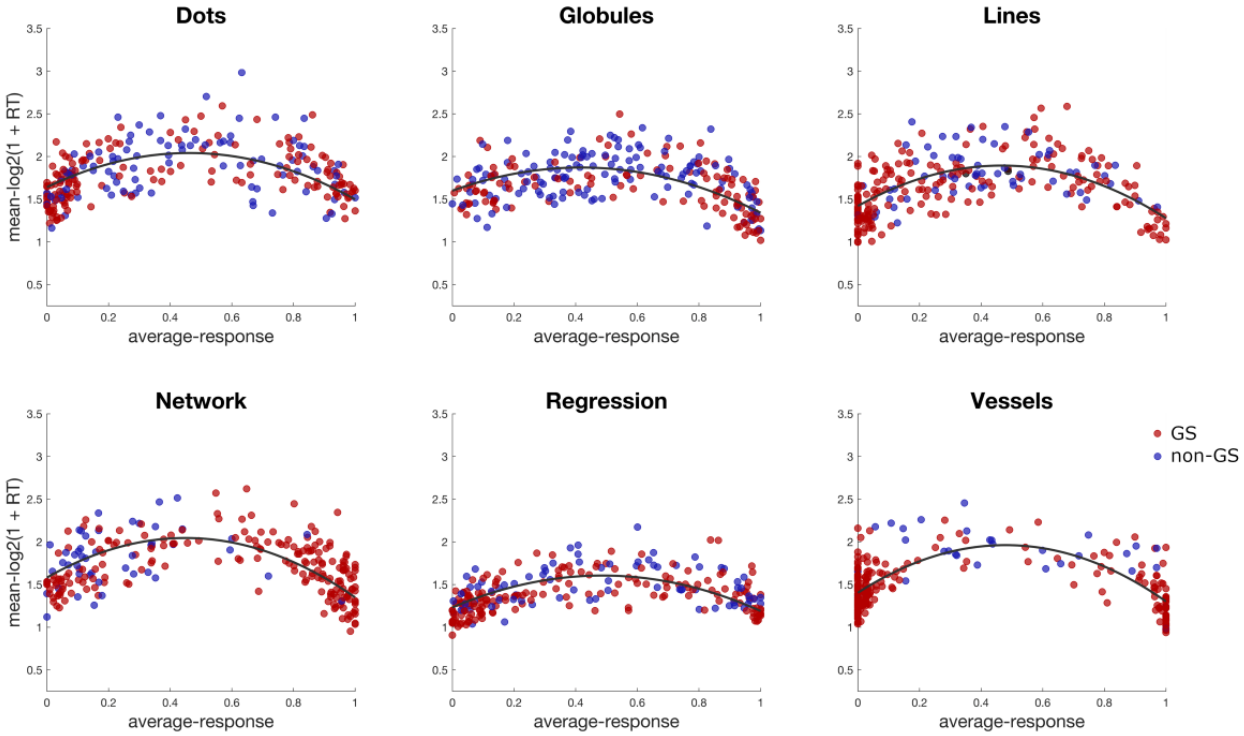
globules, 0.719; for lines, 0.714; for network structures, 0.838; for regression structures, 0.818; and for vessels, 0.728.

Reaction Times

Irrespective of task, the reaction time varied by user (the median IQR for reaction time across users was 2.5 seconds to 4.3 seconds) and across images (the median IQR for the difference in reaction time per user was –0.93 seconds to +1.5 seconds), suggesting that the variability within users was somewhat greater than the variability across users.

For both the nonexperts and experts, the quadratic term accounting for the inverted-U–shaped response in averaged logged reaction times reached statistical significance across all tasks. Among the nonexperts, the *t* values (calculated with a 2-tailed *t* test) ranged from t_{244}=–14.3 (for dots) to t_{244}=–20.09 (for vessels). Among the experts, probably due to higher noise, the *t* values ranged from t_{244}=–7.63 (for regression structures) to t_{244}=–10.62 (for vessels). All *t* values were highly significant (*P*<.001). In all tasks and for both sets of readers, the linear term had a negative sign and was also significant (at lower levels), meaning that in all cases readers were faster to respond when a feature was present compared to when it was absent (Figure 2).

Figure 2. Log reaction times for gold standard images (shown by the red dots) and non–gold standard images (shown by the blue dots) of nonexperts regressed against their average responses and showing the estimated quadratic term for each superfeature. RT: reaction time; GS: gold standard.



Discussion

Principal Findings

The main findings of this study confirmed the variable, and sometimes low, IRR between experts for identifying dermoscopic superfeatures on images of melanocytic lesions. The patterns of repeatability were mirrored in all 3 studies, highlighting that some features are more challenging to identify regardless of experience level. We found that the IRR between the untrained crowd and expert crowd was good to excellent for all superfeatures, suggesting that crowdsourced labels can be reliably used for future research. Reaction times were slower for lesions that would be considered more challenging in both cohorts, and therefore may be used as a proxy for decision difficulty.

Initial Expert Annotations (Study 1)

In Study 1, the lowest level of agreement was observed for dots and globules, and the highest agreement was observed for network structures and vessels. This is in keeping with the findings of previous studies evaluating IRR for the identification of dermoscopic patterns among a group of experienced dermoscopists [10,46]. It has been suggested that poor agreement on criteria such as structureless areas, streaks, and dots or globules may be the result of lack of standardization in dermoscopy education [46,47].

Furthermore, the definition of dermoscopic structures may evolve over time. Whereas vascular structures and pigment network structures are easily recognizable, and their definitions have been consistent in the literature to date, dots and globules may be less easy to categorize. Tiny, numerous gray dots may be categorized as regression structures, and red dots may be defined as vascular structures [48-50]. Globules are defined as measuring >0.1 mm, which may be challenging to identify in dermoscopic images without a unit of measurement as a reference point. Going forward, it may be more feasible to consider dots and globules as a single criterion to eliminate the

challenges encountered when attempting to differentiate them based on size.

Nonexpert Crowd Annotations (Study 2)

A similar pattern of results was seen in study 2, suggesting that the gridlike pattern of a pigment network structure and the distinctive red color of vascular structures may be more repeatably identified by an untrained crowd. In keeping with the results of study 1, dots and globules were identified with poor repeatability. Again, this may be as a result of the ambiguity in distinguishing between the two on the basis of their diameter.

Prior studies have shown that dermoscopy by novice clinicians is no more accurate than visual inspection alone, and so an untrained crowd would not be expected to identify complex dermoscopic patterns, particularly when agreement between a group of world experts is known to be low, such as in our EASY study. To obtain reliable crowdsourced labels for complex medical images, an easier set of images may be used or participants may receive extended training; the study must also be designed to accommodate a large number of redundant labels [28]. In a study evaluating crowdsourcing as a method of identifying colonic polyps in CT colonoscopy images, McKenna et al [51] found that the crowd performance deteriorated with increasing difficulty, as well as with increasing reaction time. By collapsing the 31 subfeatures into 6 superfeatures, we created a more achievable task for a crowd with no prior experience of dermoscopy.

Expert Crowd Annotations (Study 3)

The results from study 3 showed that agreement between experts was higher for dots, globules, and network structures when compared to study 1, in which annotations for subfeatures were aggregated into superfeature categories. It is known that there is a greater potential for disagreement with an increased number of categories and that the Cohen κ is typically observed to be lower in this circumstance [52]. Thus, if experts has been asked to choose from 6 superfeatures rather than 31 subfeatures, there would have been less potential for disagreement.

When comparing the median κ across all 3 studies, we found that repeatability for identifying all 6 superfeatures was similar across the experts and nonexperts. When comparing the median nonexpert annotations in study 2 to the thresholded expert annotations in study 3 for the same task, we saw that agreement was excellent for network structures and regression structures and good for the 4 remaining superfeatures. This suggests that the crowd was able to both repeatably and reliably identify dermoscopic superfeatures. Interestingly, agreement for vessels was higher within groups than between groups; thus, crowd annotations, although repeatable, were less accurate than expert annotations, suggesting that the crowd may be less reliable when annotating vessels. Vessels had the highest number of subfeatures (6) with distinct morphologies, several of which were not presented to the crowd during training on the DiagnosUs platform. Redesigning the tutorial may result in better accuracy for crowd annotations of vessels.

Reaction Times

For both experts and nonexperts, there were 2 common patterns of response time (ie, the time it took a participant to feel confident enough to log a response varied as a function of estimated difficulty). For images for which the crowd showed low agreement (the average response was approximately 0.5 seconds), the response times were significantly slower than for images for which the crowd showed high agreement. For gold standard images (those for which ≥3 of 5 experts in study 1 agreed on the presence or absence of a feature) reaction times were faster than those for images of lesions upon which only 1 or 2 experts agreed, highlighting the challenging nature of these images. Furthermore, images where the feature was present had faster reaction times than those where the feature was absent, regardless of level of agreement. Overall, experts took longer to respond to images than nonexperts, suggesting that they exerted more effort to ensure a correct response. In addition, there was no financial reward for experts in this study; thus, they were less motivated to annotate as many lesions as possible within a designated timeframe.

Limitations

One of the fundamental limitations of this study and future implications that can be drawn from it is the potentially low dependability of crowdsourced annotations. Although we found high repeatability and reliability of labels in study 3, this was for a relatively small set of images that had been carefully curated to have high-quality examples of a limited number of superfeatures.

There are a number of proposed methods to improve the quality of crowdsourced data. Crowd performance has been shown to improve with increased time spent training for the task, and participants that complete more readings have been observed to perform better [36,53]. Therefore, we may be able to improve performance of the crowd by providing additional training, as well as by increasing participant engagement, such as with greater financial rewards. This may, however, come at the cost of increased time and a smaller number of participants. Although crowdsourced annotations may be marginally less accurate than those provided by experts, the increased number of available labels for training ML algorithms has been shown to make them more robust to noisy data [54].

In this study, we validated the participants' performance against gold standard images to ensure the quality of labels, and poorly performing participants were not included. In the absence of an expert-labeled image, DiagnosUs allows a ground truth to emerge with an unlabeled competition design in which images that show internal consistency across raters become the initial gold standard. Filtering of individuals may also be achieved by evaluating participants based on previously performed tasks or providing a pretask test [34]. Aggregating results via majority voting is another commonly used method of preprocessing to improve annotation quality. Annotations may also be evaluated by using them to train a ML model and using the model's performance as a proxy for crowd performance [34].

It is essential that some level of quality assurance take place for crowdsourced annotations in the absence of expert labeling for

comparison, as would be the case in future studies. Although agreement is traditionally considered an indicator of data reliability, it has been suggested that participants' competence and confidence should be taken into account [55]. This can be achieved by filtering participants with poor accuracy on gold standard images, aggregating annotations, and using reaction time as a proxy for decision confidence. Images that give rise to long reaction times and a low level of agreement may then be transferred to an expert for annotation.

Many of the lesions in the archive are complex and have multiple dermoscopic patterns, which we observed created challenges for the experts to reliably identify, let alone the untrained crowd. Obtaining annotations for only 6 superfeatures may limit the diagnostic value of an ML tool. Crowdsourced labeling of the ISIC archive may be limited by its size; at the time this study was conducted, approximately 10,000 superfeature annotations were collected per day. However, engagement with the DiagnosUs platform continues to grow exponentially, and it currently receives in excess of 1 million crowd opinions daily across multiple tasks. Therefore, it may be entirely achievable to annotate the ISIC archive with crowdsourced labels within a timeframe of weeks to months.

Although the images in this study were subject to a manual quality assurance process, they were not standardized. For example, some images contained a unit of measure, which may have introduced bias when differentiating between dots and globules, as mentioned earlier in the discussion.

Insufficient demographic data were collected by the DiagnosUs platform to allow meaningful subanalyses; however, disparities in experience level between users were highlighted. Importantly, 2 physicians specializing in dermatology participated in the crowd, and it therefore cannot be truly considered untrained. Due to the nature of the platform, it appeals to medical professionals as a learning tool with the aim of driving innovation in medical artificial intelligence, and the platform provides meaningful labels at scale regardless of the background of its users.

Future Work

Given the sheer size of the ISIC archive, it would be infeasible to obtain annotations by expert dermoscopists for all images. We have shown the feasibility of obtaining crowdsourced annotations; this method can be used in several ways. First, it will allow hierarchical organization of the archive, allowing users to filter lesions based on dermoscopic patterns. Second, it may act as a teaching tool, allowing novice dermoscopists to learn patterns and corresponding diagnoses. And third, these annotated data may be used to develop novel ML tools. Even if only a small proportion of images are labeled by the crowd, a pattern classification or segmentation algorithm could be used to annotate additional images in the archive though a weakly supervised technique [56]. A hybrid crowd-algorithm approach has been successfully developed by several groups for the purpose of segmenting large databases of medical images [28,38,54,57].

The issues regarding "black box" algorithms have been raised as a barrier to implementation of these tools in clinical practice. Given the complexity of medical imaging data, a fully explainable algorithm would be unlikely to have adequate performance; however, use of interpretable outputs may go some way to assuage hesitancy in uptake. A classification tool that is also able to detect dermoscopic patterns that have influenced its decision would allow dermatologists to make more informed decisions when evaluating the output of the algorithm [22]. Furthermore, a multidimensional algorithm that is trained on both diagnoses and dermoscopic features may have increased accuracy when compared to those trained on diagnoses alone.

The next steps in exploring the applications of crowdsourced data are to expand labeling to a larger sample of images with a robust quality assurance process and incorporate the labels into a pattern-detection algorithm to be evaluated in a study of readers. Should this algorithm display acceptable performance measures, it may be deployed to label further images and be incorporated into a classification algorithm to improve its explainability.

Abstract

Background: Prevention of binge eating through just-in-time mobile interventions requires the prediction of respective high-risk times, for example, through preceding affective states or associated contexts. However, these factors and states are highly idiographic; thus, prediction models based on averages across individuals often fail.

Objective: We developed an idiographic, within-individual binge-eating prediction approach based on ecological momentary assessment (EMA) data.

Methods: We first derived a novel EMA-item set that covers a broad set of potential idiographic binge-eating antecedents from literature and an eating disorder focus group (n=11). The final EMA-item set (6 prompts per day for 14 days) was assessed in female patients with bulimia nervosa or binge-eating disorder. We used a correlation-based machine learning approach (Best Items Scale that is Cross-validated, Unit-weighted, Informative, and Transparent) to select parsimonious, idiographic item subsets and predict binge-eating occurrence from EMA data (32 items assessing antecedent contextual and affective states and 12 time-derived predictors).

Results: On average 67.3 (SD 13.4; range 43-84) EMA observations were analyzed within participants (n=13). The derived item subsets predicted binge-eating episodes with high accuracy on average (mean area under the curve 0.80, SD 0.15; mean 95% CI 0.63-0.95; mean specificity 0.87, SD 0.08; mean sensitivity 0.79, SD 0.19; mean maximum reliability of r_D 0.40, SD 0.13; and mean r_{CV} 0.13, SD 0.31). Across patients, highly heterogeneous predictor sets of varying sizes (mean 7.31, SD 1.49; range 5-9 predictors) were chosen for the respective best prediction models.

Conclusions: Predicting binge-eating episodes from psychological and contextual states seems feasible and accurate, but the predictor sets are highly idiographic. This has practical implications for mobile health and just-in-time adaptive interventions. Furthermore, current theories around binge eating need to account for this high between-person variability and broaden the scope of potential antecedent factors. Ultimately, a radical shift from purely nomothetic models to idiographic prediction models and theories is required.

Introduction

Binge Eating

Binge eating (objectively excessive food intake accompanied by feelings of loss of control) represents a core symptom of bulimia nervosa (BN), binge-eating disorder (BED), and the binge-purge subtype of anorexia nervosa. It is also the most debilitating symptom in most eating disorders (alongside the associated compensatory behavior in BN and binge-purge subtype of anorexia nervosa), accounting for gastrointestinal comorbidities, along with psychological consequences (eg, shame, secrecy, and social isolation [1]). Thus, interventions have focused on binge eating to ameliorate psychological consequences and subsequent purging behavior, which further contributes to oral and dental harms. However, treatment as usual–cognitive behavioral therapy for eating disorders (EDs) is effective for only about 65% of individuals with an ED [2] and has high relapse rates (26.8% across EDs) [3].

Nomothetic Binge-Eating Models

To predict binge eating, researchers typically rely on *nomothetic theories*—theories that are based on the average characteristics of multiple individuals in groups. Some nomothetic findings hold that individuals with BN and BED overeat in response to negative emotions, whereas healthy controls do not [4]. However, although particular efforts have been directed at predicting high-risk states for binge eating based on a variety of measures (eg, negative emotions or irregular eating patterns) [5,6], nomothetic binge-eating models often fail to translate to an idiographic–*individual*–level [7-10]. To illustrate, nomothetic theories claiming that emotional eating underlies binge eating [11] imply that emotion regulation interventions provide causative help [12,13]. However, this reasoning might not be applicable to patients who are prone to binge eating when impulsive, after extensive fasting periods, or experiencing dissociative states [6,13,14]. Correspondingly, various nomothetic theories of binge eating have proliferated. They differ substantially in the assumed causal mechanisms, which include, but are not limited to, emotional eating, impulsivity, restrained eating, food addiction, ego depletion, associative learning, and emotion-regulation or coping with emotions [4,15-21].

Idiographic Binge-Eating Models and Interventions

As binge eating can be highly impulsive, automatic, and difficult to resist, interventions that target binge eating based on its antecedents are promising as they attempt to stop the process as soon as possible, before the binge-eating pressure builds up. As such states can fluctuate quickly, they need to be assessed and evaluated with a high timely resolution to inform about the appropriate timing for interventions for high-risk states. Recently, the methodologies of just-in-time adaptive interventions (JITAIs) [22] and high-frequency ecological momentary assessment (EMA) have merged into a methodological framework that can be applied to binge-eating prediction and prevention. JITAIs have been shown to enhance cognitive behavioral therapy in BED and BN [23] and have been successfully implemented in other domains of eating behavior (eg, in weight loss) [24].

In the "OnTrack" weight-loss intervention, Forman et al [24] sampled emotions and stress, next to eating history and context conditions such as watching television or alcohol consumption. By investigating a wide range of antecedents for dietary lapses, they go well beyond what emotional-eating theory suggests as predictors (eg, negative emotions). Similarly, with their "Think Slim" app, Spanakis et al [25] showed that a sample of participants with normal weight and overweight can be clustered into multiple groups according to the different momentary states in which they tend to eat unhealthily. Therefore, applying a single nomothetic binge-eating theory might be insufficient to identify a broad spectrum of individually varying antecedents and would yield inaccurate predictions of binge eating in most individuals [26]. Instead, to cover all relevant antecedents for many patients, a broad set of EMA items is required. Notably, items that serve this purpose in weight disorders (eg, "OnTrack" JITAI-enhanced weight-loss intervention by Forman et al [24]) may not cover all antecedent states that arise in patients with clinical binge eating. Furthermore, despite being often disregarded within nomothetic frameworks, protective factors (eg, positive emotions or healthy coping [27,28]) have the potential to improve prediction accuracies in idiographic machine learning frameworks because of their negative associations with binge-eating likelihood. However, to balance participant burden with broad sampling, a baseline phase with the full item set could be followed by a phase with a reduced EMA-item set, based on a prediction model that identifies the ideographic subset of items that best predict binge eating for a given individual.

Aims and Hypothesis

This study examined the feasibility of the first part of this approach, that is, whether subsets of items could be found with good prediction accuracies for binge eating.

Furthermore, 2 studies were conducted to establish a conceptual and empirical foundation for JITAIs on binge eating. In study 1, we collected a comprehensive set of binge-eating antecedents in the form of EMA items. We combined a literature review with qualitative and quantitative interviews (focus group with 11 inpatients) following Soyster and Fisher [29]. In study 2, an algorithm was used to select idiographic subsets of binge-eating predictors based on Elleman et al [30], Kaiser et al [10], and Soyster et al [31]. We hypothesized that these idiographic binge-eating antecedents would predict binge eating with high

accuracy. This selection and prediction were tested in 13 patients with BN or BED.

Methods

Ethics Approval

All participants signed an informed consent form (stating which data were stored, where and for how long, who the investigator was, and the purpose of the study) approved by the ethics committee of the University of Salzburg (EK-GZ: 37/2018).

Study 1—Development of the EMA-Item Set

Literature Research

A PhD-level researcher systematically searched Google Scholar, PsycINFO, and PubMed databases for articles with the word "binge" in their title and the terms "ecological momentary" or "experience sampling" to find risk state descriptors with relevance to binge eating in the literature. The search resulted in 509 articles that were deduplicated and scanned for relevance. Only empirical articles reporting the results of EMA studies on binge eating were retained. A total of 262 articles were subsequently analyzed (see Multimedia Appendix 1, Figure S1 for an attrition diagram).

Text Analysis Using Word Embedding

Abstracts of all articles in the literature were retrieved. The R package *text2vec* [32] was used to perform global vector word-embedding analysis on these abstracts. Word embedding is an "unsupervised" learning algorithm that maps words to a vector space based on their similarity. It is unsupervised as no labeling of training data is needed because training is performed on aggregated global word-word cooccurrence statistics from a corpus. A matrix is calculated where each element X_{ij} represents how often word$_i$ appears in the context of word$_j$ (ie, in the same sentence). Thus, words can be represented numerically and their similarities can be compared [32].

The following parameters were set for training the word vectors (vector dimensions=100, window size=15, and minimum word count to be included in the model=5). The English stop words were removed. Single words (eg, "sadness"), as well as combinations of 2 words (eg, "negative affect"), were allowed in the model. The cosine similarity between word vectors was used to quantify the similarity between word embeddings. This metric computes the angle between 2 vectors to quantify the similarity in the vector space they inhabit. The interpretation of cosine similarity resembles that of the correlation coefficients. Perfectly similar word vectors have a cosine similarity of 1, whereas perfectly dissimilar vectors have a similarity of −1. We calculated the cosine similarity of all retained words with the words "binge" or "binges" retaining only words that had at least a cosine similarity of +.10 or −.10 (resembling a small effect according to the criteria of Cohen [33] for the interpretation of correlation coefficients). In this way, we intended to find words that were conceptually similar to "binge eating" while covering a wide range of binge-eating antecedents.

Integration Into a Preliminary Item List

In the next step, 2 authors independently rated whether a given retained word was quantifiable with a psychometric item (ie, the words "dissociation" or "dissociative" were rated as quantifiable with the item "I feel detached from myself." [0=*not at all* to *very much*=100]) and in terms of usefulness for an EMA survey. Items were only retained if they were rated as quantifiable and useful by both authors. Overlapping constructs were organized into categories to reduce redundancy. Finally, a preliminary list of 47 items was compiled from the empirical and theoretical constructs and complemented by constructs derived from previous EMA studies (Multimedia Appendix 2, Table S1).

Patient Focus Group

A focus group of inpatients (11 female adolescents and young adults in treatment for regular binge-eating episodes at the Schoen Clinic Roseneck, Germany) complemented this literature-based approach. It was conducted to tap into antecedents that nomothetic EMA research might have overlooked so far. After an individual written brainstorming session on "triggers and circumstances associated with binge eating," the inpatients rated the preliminary list of EMA items on relevance to their binge-eating episodes ("happens before/during/after binge eating…": 1=*[almost] never*, 3=*might or might not*, 5=*[almost] always*). A moderated discussion of the brainstormed and provided items concluded the sessions.

Next, 2 researchers analyzed the rating data and integrated patient-generated items. This led to the following changes: several constructs missing in the preliminary item list were identified and items were added to cover these gaps (eg, eating based on internal opposed to external motivation: "Did you eat on your own accord?"; (not) following a regular meal structure: "How much did you follow a regular meal structure today?"; and restricting specific foods: "Are you restricting on certain foods right now?").

The focus group participants further rated 27 of the provided items as positively associated with their binge-eating episodes (mean >3.5), 11 items as negatively associated (mean <2.5), and 9 items as unrelated to their binge-eating episodes (mean 2.5-3.5; Multimedia Appendix 2, Table S1). Some items were scored as unrelated (eg, "Right now I feel: tired" and "I engaged in increased levels of sport."), and items with large SDs (SD >1.00; eg, "Right now I feel: relived," "Right now I am shopping for groceries." and "I acted upon my plans regarding my eating behavior.") were disregarded, merged (eg, "I am in company." with "I am on my own."), or exchanged (eg, "I feel strained due to...work / university / school; close social network; wider social network; everyday stressors" with "Do you feel like you can handle all upcoming tasks and problems?"). As the patients expressed concerns over the redundancy of emotional states, 4 more items were disregarded ("Right now I feel: calm/ashamed/guilty/frustrated"). Finally, 4 items regarding eating behaviors such as "resistance to food craving" or "restriction" were rephrased to map more accurately on constructs introduced by the focus group (see Multimedia Appendix 3, Figure S1 for all item iterations)

Feedback of Clinicians

Finally, clinicians with experience in ED treatment (n=4) provided feedback on the gaps in the included constructs. This feedback was integrated by adding concepts such as accessibility to tasty food, day structure (ie, regular sleep and eating patterns), self-regulation intentions, and eating alone. This feedback further led us to include the autoregressive effect of binge-eating episodes on subsequent binge-eating risk in our models [34].

First Pilot

The EMA items were then piloted by 2 authors and 1 female patient with BN (consistent with the Diagnostic Statistical Manual-5 [DSM-5] [1]) to evaluate content, coverage, wording, and participant burden. Piloting revealed that some items needed further changes to map more accurately on the intended constructs: 1 item about adaptive coping strategies was added ("How much did you try to distract yourself from a possible urge to overeat by *healthy* strategies [e.g., relaxation, social activity, mindfulness, etc.]?") to complement the items on dysfunctional coping and distraction strategies, which were merged into one item ("how much did you try to distract yourself from a possible urge to overeat by unhealthy strategies [eg, alcohol, cigarettes, drugs, self-harm, etc]?"). Two items were rephrased, and 1 item assessing food craving was split up and rephrased to differentiate *food craving*, *overeating*, and *objective binge-eating episodes* (food craving: "how strong is your craving for certain foods right now?"; overeating: "how strong is your urge to overeat right now?"; and binge-eating episodes: "how high would you rate your risk for a binge-eating episode right now?").

The highly compliant participant with BN (all 84 EMA signals answered) reported that the participant burden was too high. Thus, 6 more items were disregarded to shorten the extensive list of items assessing different forms of self-licensing [35,36] and restrictions. Finally, the authors integrated the information gathered in the previous steps (ie, literature review, feedback of the focus group, feedback from clinicians, and feedback of the pilot patient) to make final iterations to the EMA-item set (see Multimedia Appendix 3, Figure S1 for all item iterations, and Multimedia Appendix 4, Tables S1 and S2 for the final EMA-item set).

Study 2—Idiographic Predictor Selection and Prediction of Binge Eating From EMA Data

Participants

Female patients with current BN (n=12) or BED (n=1) were recruited via mail from the waiting list for inpatient treatment of the Schoen Clinic Roseneck, Germany (n=10), and from web-based forums on eating disorders and psychology (n=3; see Multimedia Appendix 5, Figure S1 for a CONSORT [Consolidated Standards of Reporting Trials] flowchart). This study was advertised as a pilot study for a smartphone-based binge-eating intervention. The data were collected between April 2020 and April 2021.

Procedure

All participants completed the following study protocol. First, the BN and BED research diagnoses according to DSM-5 [1] were determined via telephone using the Eating Disorder Examination interview [37] and the Structured Clinical Interview for DSM-IV [38]. Both interviews were adapted to the diagnostic criteria of the DSM-5 (eg, 1 binge-eating episode per week for 3 months instead of 2 binges per week for 3 months).

The participants were then introduced to the EMA items and logged into the customized smartphone app *SmartEater*. SmartEater was used during the subsequent EMA phase, in which signal-based EMA questionnaires were inquired up to 84 times per participant (6 signal-contingent prompts per day, in intervals of 2.5 hours for 2 weeks; questionnaires expired 1 hour after the initial prompt). In addition, an event-contingent EMA questionnaire on overeating, loss of control, and binge-eating episodes was accessible. Participants were instructed to fill in this event-contingent questionnaire whenever they felt like they overate or felt a sense of loss of control over food intake or both. The event-contingent questionnaire included questions to differentiate between subjective and objective binge eating and objective overeating (Multimedia Appendix 4, Table S2). EMA items assessing emotions were presented in a randomized order. However, the other items were presented in a fixed order to prevent carryover effects. The participants were able to review and change their answers through a "back" button. Answering all items (except branched items) was mandatory for submission of the questionnaires.

After the EMA phase of 2 weeks, a JITAI phase of 2 weeks started, in which the participants received short intervention suggestions from the app to prevent binge-eating episodes at ideographically predicted high-risk times. Every study stage was accompanied by web-based questionnaires that assessed current eating behavior pathology, demographic data, perceived acceptability, feasibility, and so on. Data from the intervention phase were not covered in the present article. For reimbursement, the participants received €30 (US $32.80) and personalized feedback on their EMA data and psychometric web-based questionnaires.

Data Preparation and Measures

To avoid the violation of the assumption of equally spaced time series [39], empty rows were inserted in the data set after every last signal for a given day. This prevented the prediction algorithm from regressing on data from the previous day.

Binge-Eating Episodes–Criterion

Objective binge-eating episodes, characterized by (1) "feelings of loss of control over eating behavior" and (2) "consumption of objectively large, inappropriate amounts of food" [1,37,40], were identified from eating episodes reported over the signal-based (1 item: "Was your meal a main meal**,** snack, or binge?") and event-based EMA questionnaires (2 items: "Would other people rate the amount of food as excessive under similar circumstances?" and "Did you feel like you are losing control of your eating behavior?"). The signal-based and the 2 event-based items were recoded into a binary variable indicating the occurrence of an objective binge-eating episode (binge-eating episode reported=1, no binge-eating episode reported=0). As the algorithm was supposed to predict future

binge-eating episodes, this variable was shifted backward in time by one signal (approximately 2.5 hour).

EMA Predictors

An unshifted version of the binge-eating variable was included as a possible predictor of the autoregressive effects of binge eating. Furthermore, additional EMA items (n=31) were used to model possible binge-eating antecedents. Thus, only items that were assessed with every signal-based questionnaire were included (aside from the binge-eating classifier), as each variable needed to have a sufficient percentage of data points within a person (see Multimedia Appendix 4, Table S1 for the wording of each item).

Time Predictors

Time variables, especially in the form of circles and distinct times of day, have been shown to be highly predictive in everyday life [41]. EMA studies have even found peak times for certain binge-eating antecedents (ie, food cravings or hunger; [42]) and binge eating itself [43-45]. Thus, as temporal data are passively collected in the EMA setting via timestamps, without additional participant input, we decided to include different temporal predictors that could detect a single high-risk time per day (24-hour oscillation) or several times per day (sub-24 hour oscillation).

Variables representing 8-, 12- and 24-hour sinusoidal and cosinusoidal cycles were computed based on the cumulative sum of time differences between assessments (eg, 10:30 AM-8 AM, 1 PM-10:30 AM=2.5, 5, 7.5...). For example, a 24-hour sinusoid cycle was calculated using the following formula: $sin24h = sin(2\pi : 24 * \Delta_t)$, where Δ_t is the difference between assessment points in hours (here: 2.5). Finally, dummy-coded variables representing the time of day were calculated for each signal (morning, late morning, early afternoon, afternoon, evening, and late evening). This allows for identifying a daytime when binge eating is particularly likely for a given participant (eg, when returning from work) that could not be well captured by the cyclical predictors.

Application of the Best Items Scale that is Cross-validated, Unit-weighted, Informative, and Transparent Algorithm to EMA Data (for Idiographic Predictor Selection and Prediction of Binge Eating)

The machine learning algorithm Best Item Scales that are Cross-validated, Unit-weighted, Informative and Transparent (BISCUIT) [30] of the *bestScales* function from the R package *psych* [46] was applied separately to the EMA data of each patient to select the best idiographic predictors of binge-eating episodes. This method was chosen because of its (1) robustness to missing data; (2) use of unit-weighted scoring of predictors, which was found to be more generalizable, especially in the context of prediction; and (3) tendency to select more parsimonious predictor sets compared with other approaches such as Elastic Net regression [30,47,48]. BISCUIT is a simple algorithm that correlates a set of predictors (here all EMA and time variables) with a criterion (here, the binary time-shifted binge-eating variable at t+1) and retains the predictors with the highest correlation to form a unit-weighted scale [10,30,46]. This scale was then used to estimate the out-of-sample predictive performance using 10-fold cross-validation. The average correlation of the scale with the criterion across 10 cross-validation splits was then computed, and the set of items with the highest cross-validated correlation was retained [30,46]. The output of BISCUIT is the selection of items showing maximum predictive validity, as the cutoff values that lead to the highest combination of sensitivity and specificity are retained [30,46].

Thus, multiple Rs (pairwise Pearson correlations) of all predictors with time-shifted binge-eating episodes (at t+1) were calculated for each participant separately to select the idiographic predictor sets. Furthermore, the area under the curve (AUC) with a bootstrapped 95% CI, specificity, sensitivity, and within- and out-of-sample reliability were calculated as prediction accuracy measures of the idiographic predictor sets and their prediction of binge eating in the next 2.5 hours (t+1).

Results

Study 1—EMA-Item Set

The final signal-contingent EMA questionnaire included 36 EMA items (momentary emotions, stress, exhaustion, and context; eg, being alone, social interactions, dissociations, eating behavior, resistance to food craving, distraction, and coping), which were designed to be assessed 6 times per day. In addition, an optional event-contingent EMA questionnaire on overeating, loss-of-control eating, and binge eating was self-initialized and included 20 items. See Multimedia Appendix 4, Tables S1 and S2 for all interval- and event-contingent items and their wording. A flowchart of all iterations applied to the EMA-item set can be found in Multimedia Appendix 3, Figure S1).

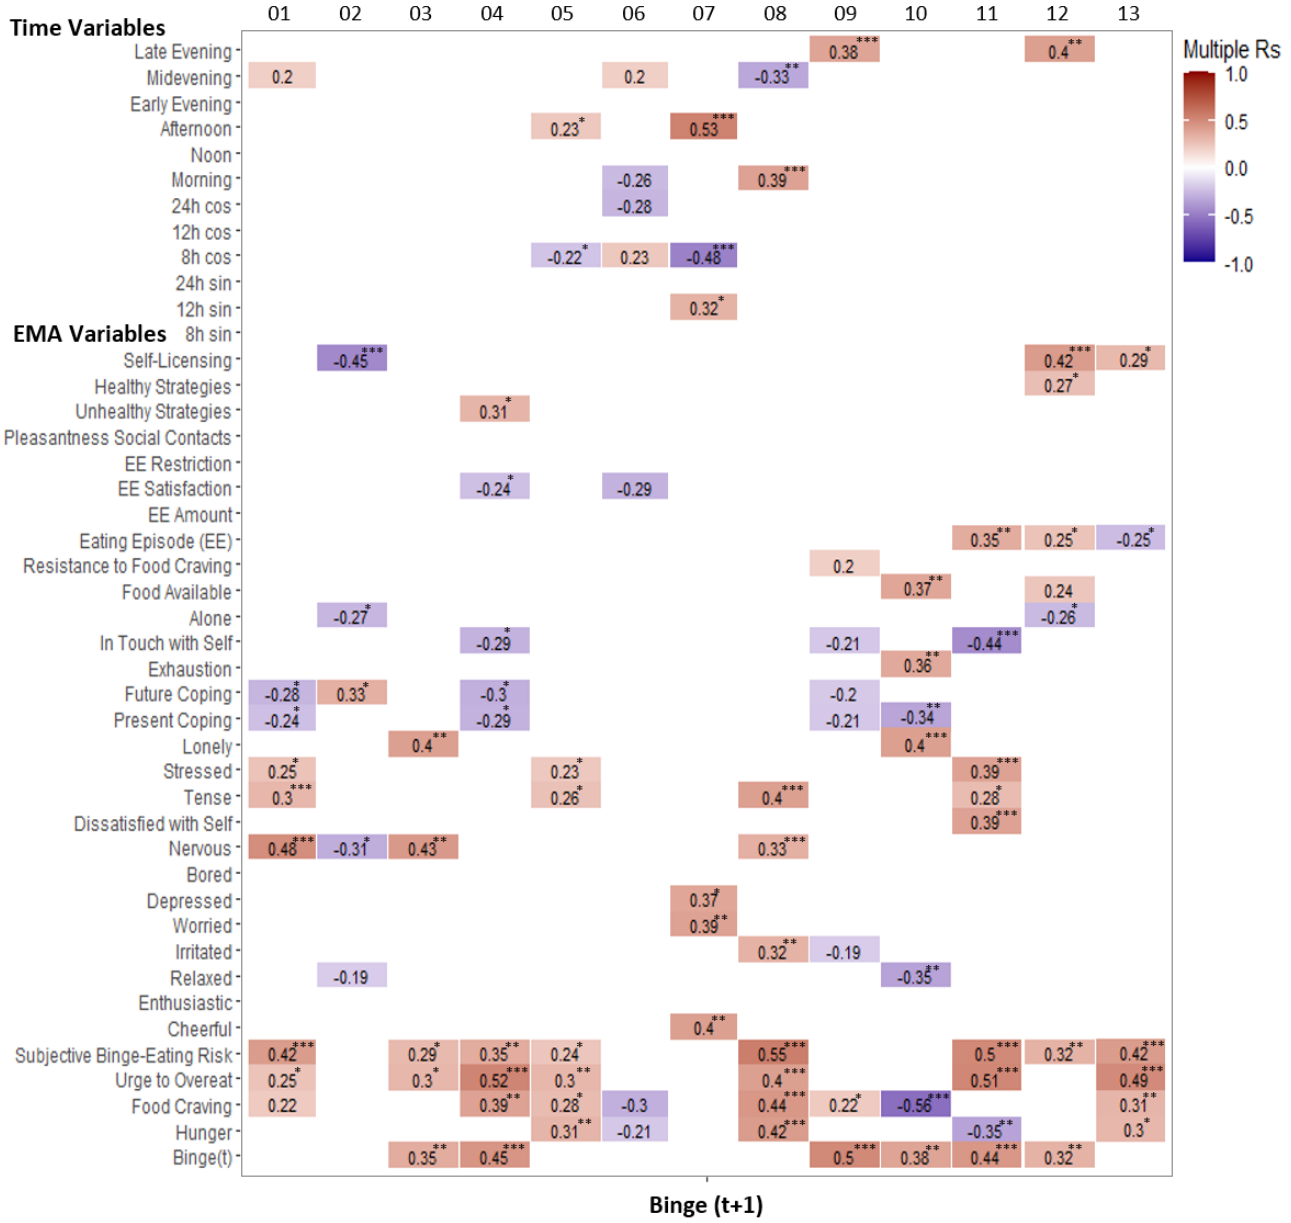
Study 2—Idiographic Predictor Selection and Prediction of Binge Eating From EMA Data (by Application of the BISCUIT Algorithm)

Selection of Idiographic Predictor Subsets

The patients (n=13) answered on an average 67.3 out of 84 EMA prompts (SD 13.4; range 43-84; see Multimedia Appendix 6, Table S1 for EMA compliance and occurrences of binge-eating episodes per patient). Across participants, the algorithm selected highly heterogeneous predictor sets of varying sizes (mean 7.31, SD 1.49; range 5-9 predictors) for the prediction of binge-eating episodes.

Figure 1 shows the idiographic predictor selection that showed maximum predictive validity for each participant. Thus, the predictors (at t) with the highest multiple Rs (pairwise Pearson correlations) with time-shifted binge-eating episodes (at t+1) were selected. All listed items were selected as idiographic predictors of binge eating, independent of their significance. However, we additionally calculated the significance of the correlations for the context. The exact *P* values, codes, and data can be found in the corresponding project in the Open Science Framework [49]. Note that the results might vary slightly, as the R function *set.seed* does not apply to the cross tables.

Figure 1. Idiographic predictor subsets for binge eating with Pairwise Pearson Correlations (Multiple Rs) of each selected predictor of binge eating in the next 2.5 hours (t+1). *, **, and *** indicate that the correlations are significant at a level of .05, .01, and .001, respectively; 2-tailed. EMA: ecologic momentary assessment.



Prediction of Binge Eating by Idiographic Predictor Subsets

The selection of idiographic predictor sets resulted in good average prediction accuracy (mean AUC 0.80, SD 0.15; mean 95% CI 0.63-0.95; mean specificity 0.87, SD 0.08; mean sensitivity 0.79, SD 0.19; mean maximum reliability of r_D 0.40, SD 0.13; mean r_{CV} 0.13, SD 0.31). The mean AUC of 0.80 indicates that there is on average an 80% chance that the idiographic models predict binge and nonbinge episodes accurately. The mean specificity of 0.87 indicates that the idiographic models mistakenly classified 13 of 100 episodes as binge-eating episodes. The mean sensitivity of 0.79 indicates that the idiographic models mistakenly classified 21 out of 100 binge-eating episodes as nonbinge episodes. Table 1 shows the prediction accuracies of the idiographic predictor subsets for binge-eating episodes per participant. R code and data are available from the Open Science Framework [49].

Table 1. Model fit indices for prediction of binge eating in the next 2.5 hours from idiographic predictors, selected by the Best Items Scale that is Cross-validated, Unit-weighted, Informative, and Transparent (BISCUIT) algorithm, separately for each participant.

[a]AUC: area under the curve.

[b]CI: bootstrapped 95% CI of the AUC.

[c]r_D: multiple *R* of the unit-weighted scale in the derivation step.

[d]*r*: pairwise Pearson correlation of the item with time-shifted binge-eating episodes (at t+1).

[e]r_{CV}: average cross-validated multiple *R* of the derived scale.

Discussion

Principal Findings

Study 1—EMA-Item Set

This study used a mixed methods approach to develop a conceptual and statistical basis for an idiographic JITAI for binge eating. The EMA-item development in study 1 followed a replicable procedure similar to Soyster and Fisher [29] while considering nomothetic theories on binge-eating antecedents (ie, emotional eating) and underwent several qualitative (literature research and focus group brainstorming and discussion) and quantitative (focus group ratings) iterations and piloting.

This resulted in a broad EMA-item set (Multimedia Appendix 4), including several constructs underrepresented in the nomothetic literature (eg, “I feel detached from myself.”, and “specific” restrictions “did you restrict yourself [eg, by eating less, avoiding certain foods]?” [12,50,51]). This approach also helped us shorten the extensive lists of emotional states (eg, “right now I feel...calm/relived/ashamed/guilty/frustrated.”) because within-person ratings for similar emotions were often identical, and concerns about redundancy were expressed during the moderated discussion. Furthermore, we did not only incorporate risk factors into the EMA-item set but also protective factors that could potentially decrease the likelihood of binge eating (ie, healthy coping strategies to keep oneself from binge eating or positive emotions [27,28]). The role of protective factors is often overlooked in nomothetic binge-eating theories but is crucial to idiographic binge-eating prediction and intervention models.

Study 2—Prediction Based on Idiographic Predictor Subsets

Regularly completing extensive EMA-item sets (such as the present one with 36 interval-contingent and 20 event-contingent items) becomes increasingly burdensome over prolonged study periods. Thus, we applied a machine learning algorithm to the EMA data of patients with BN and BED to select parsimonious idiographic subsets of EMA items. This data-driven selection optimizes the predictive power within participants and decreases potential researcher bias.

The idiographic item subsets predicted binge-eating episodes with a high average accuracy (mean AUC 0.80) across 13 patients. Notably, the sensitivity approached 100% (successful prediction of every reported binge) in several patients, without forfeiting much specificity (predicting no binge when none occurred). This is noteworthy as outcome frequency was not extremely high (mean 10.4, SD 7.4; range 2-28 binge-eating episodes; see also Multimedia Appendix 6, Table S1 “Number of binge-eating episodes and total data points per participant”).

Secondary Findings

Regarding the composition of the selected item sets, a high selection rate of items with high proximity to the binge-eating construct was evident (ie, hunger, food craving, urge to overeat, subjective binge-eating risk, and preceding binge-eating episodes). This suggests that some patients may accurately predict upcoming binge-eating episodes. This reveals a relatively high level of insight into the temporal evolution of the symptoms in some patients. Surprisingly, hunger and food craving were negatively correlated with binge eating in 3 patients. One could speculate that the negative correlations between hunger and binge eating in patients 06 and 11 point to disinhibition, that is,

because of the temporary abandonment of rigid diet rules after eating in the absence of hunger [52,53].

In addition to items with conceptual similarity to binge eating, emotional items were selected in 9 patients. This supports the relevance of emotional eating in binge-eating predictions [4,11,19]. However, the selected emotion sets were highly heterogeneous across the 9 patients. In fact, no single emotion item (or specific set of emotion items) was consistently selected across all patients. This speaks against a singular and generalizable emotional eating theory of binge eating. Similarly, because no other nonemotion–related predictor was consistently selected across all patients, our pilot data provide no evidence for other generalizable nomothetic theories of binge eating. Thus, several nomothetic theories are needed to explain present heterogeneity, which may in turn explain the multitude of competing nomothetic binge-eating theories. Clearly, nomothetic theories must model individual differences more explicitly to account for these findings. These findings also support the use of a broad EMA-item set that covers a large range of possible binge-eating antecedents in the context of idiographic prediction [4-6,14-21].

Interestingly, time-derived predictors were selected only in 7 patients. In 6 of these patients, discrete time predictors were chosen that were consistent with the literature on the timing of binge-eating peaks (ie, afternoon to late evening) [43-45]. Time cycles were only selected in 3 patients. This is surprising given the observation of cyclic symptoms (eg, in depression [41]). However, time-based predictors may be more powerful if EMA items with conceptual similarity to binge eating are omitted. In the case of binge eating, time cycles could represent a rising and falling urge to overeat (eg, due to prolonged restriction between meals) [41,54]. Discrete time variables could represent the time of the day where a patient usually binges (eg, due to contexts such as being alone at home every afternoon) [41]. Assessing such time-derived variables does not require user input and thus does not contribute to the participant burden. This makes them valuable for the predictions in the JITAI framework.

Limitations and Strengths

Compared with the high average within-sample performance (mean r_D 0.40), the average out-of-sample performance (mean r_{CV} 0.13) was lower, suggesting limited out-of-sample generalizability. This might be because of 10-fold cross-validation, which does not account for the serial correlation and potential nonstationarity of time-series data [55]. Future studies could resort to alternative time-series–specific techniques (ie, roll forward cross-validation and out-of-sample evaluation) that ensure that training data always precede test data. However, X-fold cross-validation has been shown to outperform these techniques [55]. Furthermore, the number of observations was limited (max 84 per participant), leading to relatively small splits in the 10-fold cross-validation. Thus, there was a high possibility of randomly drawn training sets that were unrepresentative of the data set. The results from the validation step might also vary slightly, as the R function *set.seed* does not apply to the cross tables.

Another general drawback of the BISCUIT algorithm is that nonlinear trends and interaction effects among predictors are not considered. In addition, when applied under optimal conditions (ie, big data sets and no missing data), gold standard machine learning approaches, such as random forests [56] and XGBoost [57] in combination with super learners [58], calibrate better to the data. However, for typical EMA data sets, the conditions are rarely optimal for these algorithms. Missing data and a limited number of observations are typical features of high-burden EMA sampling schemes. However, BISCUIT was created to handle these problematic properties. BISCUIT outperformed random forest and elastic net approaches in other studies with smaller idiographic data sets and more missing data (Beck et al [59]: mean 57.4, SD 16.3; range 40-109 EMA observations; present data: mean 67.3, SD 13.4; range 43-84 EMA observations).

Finally, the idiographic approach used in this study precludes mechanistic and theoretical inferences about binge eating. Generally, machine learning algorithms are silent about the underlying mechanisms; instead, they tailor models are as close as possible to the given data and conditions. Thus, the present results are highly specific, for example, to the used “prediction interval” of 2.5 hours between predictors and outcome. This could be problematic as it has been shown that emotions and eating can influence each other at different time intervals [60].

Implications and Future Directions

In addition to emphasizing the importance of a broad predictor set, the results have a direct implication for the JITAI and EMA methodology: participant burden in longer EMA sampling periods precludes the use of large EMA-item sets. Thus, such EMA studies might prune their large EMA-item sets after a “calibration period” by applying the described predictor-selection approach. Therefore, the participant burden is reduced, whereas accurate idiographic binge-eating predictions are retained. Such predictions can then be used to trigger JITAIs, as done by Forman et al [24,61] in a JITAI on dietary lapses.

Future studies may transfer the present work to a range of disordered and maladaptive eating behaviors (eg, purging behaviors or food restrictions) to develop low-threshold JITAIs. EMA-item–based prediction should be compared with predictions generated from passive data sources (ie, smartphone sensors, use data, and wearable data) that do not inflict much user burden [10,62-64]. In the long term, acceptance, dropout rates, and effectiveness of JITAI protocols on binge eating need to be tested in microrandomized trials [65] and classic randomized controlled trials against nonadaptive, non–real-time interventions before the ultimate recommendation as the gold standard.

Finally, feeding back personal binge-eating predictors can serve as a psychoeducational intervention and raise awareness of personal risk and protective factors. Such personal binge-eating predictors can also inform conventional face-to-face psychotherapy. Patients with a clear dominance of emotion-related predictors might profit from emotion-focused interventions [66] more than patients with a dominance of

impulsive or craving-related predictors, who might profit more from impulse control intervention [67].

Acknowledgments

This project received funding from the European Research Council under the European Union's Horizon 2020 Research and Innovation Program (ERCStG-2014 639445 NewEat) and the Austrian Science Fund (KLI 762). Publishing open access was supported by the Paris Lodron University of Salzburg and Austrian Science Fund. The funding bodies were not involved in the study design, assessment and analysis of data, interpretation of results, or writing of the manuscript.

Authors' Contributions

AKA, TK, BP, JR, and JB conceptualized the studies; AKA conducted the studies; AKA, TK, and BP analyzed the data; AKA, TK, and JB wrote the paper; and BP, JR, SN, and UV contributed to the interpretation of the studies and critically revised the work for important intellectual content. All authors have read and approved the final manuscript.

Abstract

Background: The clinical narrative in electronic health records (EHRs) carries valuable information for predictive analytics; however, its free-text form is difficult to mine and analyze for clinical decision support (CDS). Large-scale clinical natural language processing (NLP) pipelines have focused on data warehouse applications for retrospective research efforts. There remains a paucity of evidence for implementing NLP pipelines at the bedside for health care delivery.

Objective: We aimed to detail a hospital-wide, operational pipeline to implement a real-time NLP-driven CDS tool and describe a protocol for an implementation framework with a user-centered design of the CDS tool.

Methods: The pipeline integrated a previously trained open-source convolutional neural network model for screening opioid misuse that leveraged EHR notes mapped to standardized medical vocabularies in the Unified Medical Language System. A sample of 100 adult encounters were reviewed by a physician informaticist for silent testing of the deep learning algorithm before deployment. An end user interview survey was developed to examine the user acceptability of a best practice alert (BPA) to provide the screening results with recommendations. The planned implementation also included a human-centered design with user feedback on the BPA, an implementation framework with cost-effectiveness, and a noninferiority patient outcome analysis plan.

Results: The pipeline was a reproducible workflow with a shared pseudocode for a cloud service to ingest, process, and store clinical notes as Health Level 7 messages from a major EHR vendor in an elastic cloud computing environment. Feature engineering of the notes used an open-source NLP engine, and the features were fed into the deep learning algorithm, with the results returned as a BPA in the EHR. On-site silent testing of the deep learning algorithm demonstrated a sensitivity of 93% (95% CI 66%-99%) and specificity of 92% (95% CI 84%-96%), similar to published validation studies. Before deployment, approvals were received across hospital committees for inpatient operations. Five interviews were conducted; they informed the development of an educational flyer and further modified the BPA to exclude certain patients and allow the refusal of recommendations. The longest delay in pipeline development was because of cybersecurity approvals, especially because of the exchange of protected health information between the Microsoft (Microsoft Corp) and Epic (Epic Systems Corp) cloud vendors. In silent testing, the resultant pipeline provided a BPA to the bedside within minutes of a provider entering a note in the EHR.

Conclusions: The components of the real-time NLP pipeline were detailed with open-source tools and pseudocode for other health systems to benchmark. The deployment of medical artificial intelligence systems in routine clinical care presents an important yet unfulfilled opportunity, and our protocol aimed to close the gap in the implementation of artificial intelligence–driven CDS.

Introduction

Background

As of 2017, >95% of the hospitals in the United States adopted an electronic health record (EHR), and >80% are collecting electronic clinical notes [1]. Clinical decision support (CDS) and intelligent data-driven alerts are part of federal incentive programs for Meaningful Use [2,3]. With the increasing capacity of EHR data and financial incentives to improve quality care, hospitals are increasingly well equipped to leverage computational resources to improve case identification and care throughput [4].

The unstructured narrative of EHRs provides a rich source of information on patients' conditions that may serve as CDS tools. Detailed medical information is routinely recorded in providers' intake notes. However, this information is neither organized nor prioritized during routine care for augmented intelligence at the bedside. Moreover, clinical notes' free-text format hinders efforts to perform analytics and leverage the large domain of data. The computational methods of natural language processing (NLP) can derive meaning from clinical notes, from which machine learning algorithms can screen for conditions such as opioid misuse.

In 2020, overdose deaths from opioid misuse soared to an all-time high, with a record 93,000 deaths nationwide during the pandemic year [5]. Substance misuse ranks second among the principal diagnoses for unplanned 7-day hospital readmission rates [6]. Screening for patients at risk for opioid use disorders is not part of the admission routine at many hospitals, and many hospitalized patients in need are never offered opioid treatment. The high prevalence rate of substance use disorders in hospitalized adults exceeds the rates in the general population or outpatient setting and reveals the magnitude of this lost opportunity [7]. We previously trained a convolutional neural network (CNN) that outperformed a rule-based approach and other machine learning methods for screening opioid misuse in hospitalized patients. The CNN substance misuse classifier had >80% sensitivity and specificity and demonstrated that clinical notes captured during hospitalization may be used to screen for opioid misuse [8].

There remains a paucity of evidence on the implementation of clinical NLP models in an interoperable and standardized CDS system for health operations and patient care [9]. The interactions among an artificial intelligence (AI) system, its users, its implementation, and the environment influence the AI intervention's overall potential effectiveness. Few health systems have been able to accommodate the complexities of an NLP deep learning model integrated into an existing operational ecosystem and EHR [10]. Much of the literature on NLP-driven CDS has described retrospective studies [11,12] outside the clinical workflow or simulated clinical environments [13,14]. Others have used NLP for information extraction efforts aimed at quality improvement without direct integration into the clinical workflow and operations [15,16]. Few provide a real-time NLP system but do not share an implementation framework or pipeline details to ensure fidelity and reproducibility [17]. Although the field of AI-driven CDS is growing, sharing knowledge in development and operations for health care delivery is lacking in best practices for processes and technologies in application planning, development, delivery, and operations.

This Study

This protocol describes a cloud service designed to ingest, process, and store clinical notes as standardized and interoperable messages from a major EHR vendor in an elastic cloud computing environment. We subsequently demonstrate the use of multiple open-source tools, including an open-source NLP engine for processing EHR notes and feeding them into a deep learning algorithm for screening for opioid misuse. Our resultant NLP and deep learning pipeline can process clinical notes and provide decision support to the bedside within minutes of a provider entering a note into the EHR.

To our knowledge, this is the first protocol for a bedside implementation of an NLP-driven CDS tool. We expect that our protocol will serve as a guide for other health systems to leverage open-source tools across interoperable data standards and ontologies. We provide an implementation framework and a cost-effectiveness analysis of a tool developed for the automated screening of hospitalized adults for opioid misuse. We aimed to describe a hospital-wide protocol and computing architecture for implementing a real-time NLP-driven CDS tool.

Methods

Hospital Setting and Study Period

The NLP CDS tool was implemented at the University of Wisconsin (UW) Hospital across the surgical and medical hospital inpatient wards. The EHR system used at the UW Health is Epic (Epic Systems Corp). The tool was designed for hospitalized adults (aged ≥18 years) and was assessed using a

pre-post quasi-experimental study design over 30 months (24 months of usual care and 6 months for the implementation of automated screening). The study was a quality improvement initiative by the health system to provide an automated hospital-wide screening system for opioid misuse and was registered on ClinicalTrials.gov (NCT05745480).

Preintervention Period: Usual Care With Ad Hoc Addiction Consultations

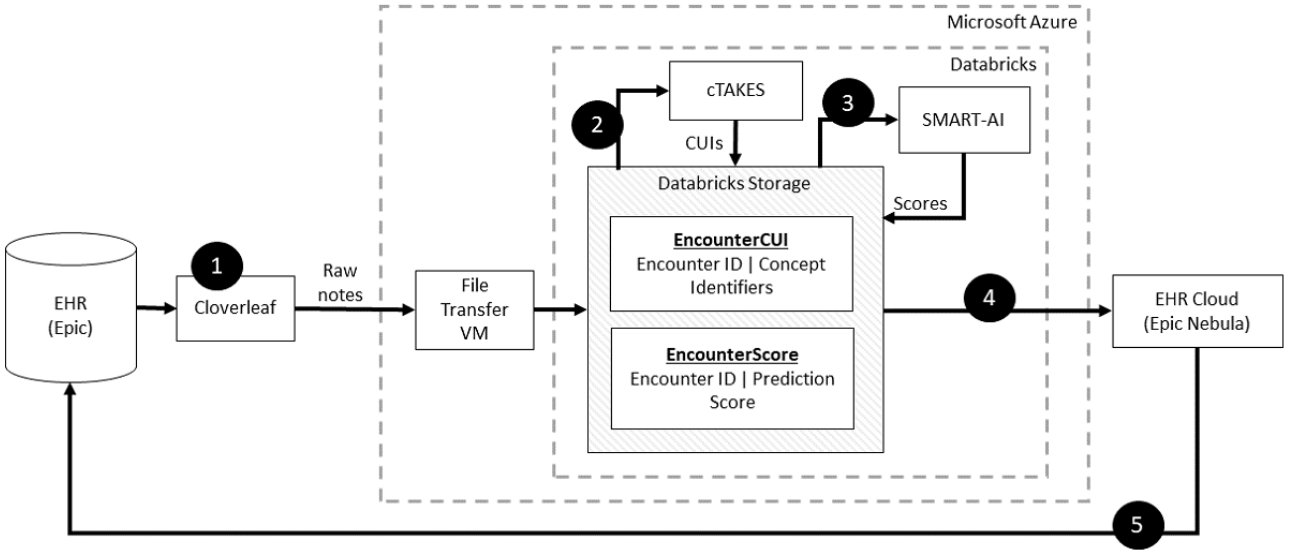
The UW Hospital launched an Addiction Medicine inpatient consult service in 1991 to address the high prevalence of substance use disorders among hospitalized adults. A screening, brief intervention, and referral to treatment program [18] was instituted for alcohol misuse. Screening, intervention flow sheets, and consult order sets were built into EHR-driven workflows for inpatient nurses and social workers for alcohol screening using the Alcohol Use Disorders Identification Test–Concise [19], a best practice alert (BPA) for patients at risk of alcohol use disorder, and order sets for withdrawal treatment. For other drugs, a single screening item queries "marijuana or other recreational drug use," but no formal screening process was in place specifically targeting opioid misuse. For patients at risk of an opioid use disorder, the practice was ad hoc consultations at the discretion of the primary provider.

Postintervention Period: Computing Architecture and Real-time Implementation

Overview

The technical architecture that enabled the real-time NLP CDS tool incorporated industry-leading and emerging technological capabilities. Figure 1 details the overall NLP CDS infrastructure that exported the notes from the EHR, organized them, and fed them into an NLP pipeline; input the processed text features into the opioid screener deep learning model; and delivered the resultant scores back to the bedside EHR as a BPA. The final architecture was a real-time NLP CDS tool, and the 6 components of the architecture are further detailed in the subsequent sections.

Figure 1. Step-by-step implementation of clinical natural language processing (NLP) pipeline. Step 1 ran a scheduled program to ingest notes from the EHR for each patient organized the notes, and relayed them via an HL7 data feed (Cloverleaf) into the cloud computing environment and data lake (Microsoft Azure and Databricks) onto a VM (Step 2). The NLP engine (cTAKES) processed the text stored on the VM and mapped them to medical concepts from the National Library of Medicine's metathesaurus (CUIs). The machine learning model received the CUIs as inputs and stored the results in DataBricks. At regular intervals, a custom Python script in Databricks performed the text extraction and linguistic feature engineering via cTAKES and stored CUIs with the appended data of patient identifiers. The CUIs served as the input to the machine learning model (SMART-AI) at the encounter level. The output of prediction probabilities and classification was stored in a Databricks table (Step 3). An API call from the EHR cloud is made to determine whether the cutpoint threshold from the machine learning model was met to trigger a BPA. In Step 4, the EHR cloud made an HTTP call to Databricks to request the score. The score was returned to the EHR cloud and subsequently delivered as a BPA when the provider opened the patient's chart in our on-premise instance of the EHR (Step 5). API: application programming interface; BPA: best practice alert; cTAKES: Clinical Text Analysis and Knowledge Extraction System; CUI: concept unique identifier; EHR electronic health record; HL7: Health Level 7; SMART-AI: Substance Misuse Algorithm for Referral to Treatment Using Artificial Intelligence; VM: virtual machine.



Component 1: Transferring Clinical Notes From the EHR to Cloud Computing

Health Level 7 (HL7) refers to the standards for transferring health care data between data sources. Cloverleaf (Infor Cloverleaf Integration Suite) was the UW's vendor solution that served as an application programming interface (API) gateway for accessing the clinical narratives in the EHR using HL7 version 2. To initialize the data feed, a UW Health interface analyst created a new entry in the Cloverleaf vendor software detailing the desired record information, which included clinical note text and identifiers. The analyst then "activated" the data feed, which began a continuous Transmission Control Protocol message–generating process. The Transmission Control Protocol messages were communicated using the HL7 application protocol to the Azure Virtual Machine (version 2022; Microsoft Corp) host at a port designated by the data science engineering team. This port was reserved by a NET program (the "TCP listener"), which wrote the message to the cloud file system and replied to the Cloverleaf server with acknowledgment messages,

conforming to the HL7 version 2 specification. Ultimately, the API extracted clinical notes from Epic and transferred them to a Microsoft Azure cloud computing environment that was under a business associate agreement with the UW. On-premise relays with the File Transfer Protocol were used to transfer the clinical notes to a specified location in the Azure cloud environment.

Component 2: Cloud Analytic Computing Platform

In the Microsoft Azure framework [8], the UW Health invoked the Databricks (Databricks Inc) analytic resources and services for scalable computing, data storage, and querying. The open-source tools from the NLP engine and our trained, publicly available machine learning model were hosted in Databricks. The machine learning model life cycle management (MLFlow) tool in Databricks supported the data flow for the deep learning model. MLFlow created and scored models when clinical notes were received and subsequently reported the results upon request. The final infrastructure was a scalable and failure-resistant environment for analytic computations.

Component 3: NLP Pipeline

The Clinical Text Analysis and Knowledge Extraction System (cTAKES; Apache Software Foundation) was built on multiple open-source Apache projects and incorporated technologies with the Unstructured Information Management Architecture framework and the Apache OpenNLP NLP toolkit [20]. This configuration contained several engines for sentence detection, tokenization, part-of-speech tagging, concept detection, and normalization to extract information from the clinical narrative in the EHR. We did not use the negation module because it was not used in the current use case; however, this can be turned on for other use cases. cTAKES is one of the most ubiquitous NLP engines used in the clinical domain [21]. cTAKES provided named entities from the free text that were mapped from the National Library of Medicine's Unified Medical Language System (UMLS), which is a repository of groups of words with relevant clinical contexts (eg, drugs, diseases, symptoms, anatomical sites, and procedures). Each named entity was mapped to a concept unique identifier (CUI) using the UMLS Systemized Nomenclature of Medicine–Clinical Terms and medical prescription normalized ontologies. For instance, "heroin misuse" from the text was assigned C0600241 as its CUI, which was different from the CUI assigned to "history of heroin misuse," C3266350. For generalizability, we used the default cTAKES pipeline [22].

As clinical notes were entered into the EHR for an individual patient, Cloverleaf relayed the notes via HL7 from the Epic EHR and used the Azure File Transfer Protocol server running on a virtual machine to place them at a known location within the Azure cloud environment. In 15-minute intervals, Databricks triggered a custom Python script to extract the text and fed it into the cTAKES pipeline to map and extract the CUIs. The CUIs were stored in the Azure Data Lake with appended data, including patient ID, encounter ID, and note time stamp, and were ready to be fed into any machine learning model. The code executed for the pipeline consisted of several services that operated independently and communicated through data stores. These services were "always on," but each had a trigger condition that initiated the code execution. The pseudocode for these services is provided in Multimedia Appendix 1.

Component 4: Text Feed From the NLP Pipeline Into the Deep Learning Model

We previously published a substance misuse screening algorithm using CUIs fed into a CNN called the Substance Misuse Algorithm for Referral to Treatment Using Artificial Intelligence (SMART-AI) [8]. SMART-AI was trained on the first 24 hours of all clinical notes entered into the EHR, starting from the patient's arrival time. This approach provided sufficient time not only for robust training but also for the addiction consult service to intervene before hospital discharge. For ease of implementation, the model was not trained on any specific note type and followed a time stamp approach for all notes filed within 24 hours of arrival at the hospital. SMART-AI is a supervised model with target labels that were derived from the manual screening data of over 50,000 patients who self-reported on the validated Drug Abuse Screening Test [23] and answered follow-up questions about opioid use. SMART-AI is publicly available to run the trained model [24], and more details about the model architecture and development can be found in the original development and validation publication [8]. The model's development and validation followed guideline recommendations [25].

Temporal validation of the classifier (trained on data between 2017 and 2019 and tested on data from 2020) at an outside hospital demonstrated an area under the precision-recall curve of 0.87 (95% CI 0.84-0.91) for screening for opioid misuse. Similar results were derived in an external validation at a second independent health system [8]. Multiple cutoff points were examined for the optimal threshold selection for the BPA, including the point on the area under the receiver operating curve that minimized the difference between sensitivity and specificity. During validation on the full cohort of hospitalized patients, the optimal cutoff point for screening for opioid misuse was 0.05. At that cutoff, the sensitivity was 0.87 (95% CI 0.84-0.90), specificity was 0.99 (95% CI 0·99-0·99), negative predictive value was 0.99 (95% CI 0.99-0.99), and positive predictive value was 0.76 (95% CI 0.72-0.88). The number needed to evaluate was 1.4, which translates to 26 alerts per 1000 hospitalized patients [8]. This was deemed an acceptable workload for consultation requests in live production for the UW Addiction Medicine clinicians. Additional silent testing was performed at the UW Health to examine sensitivity and specificity with 95% CI in our practice setting.

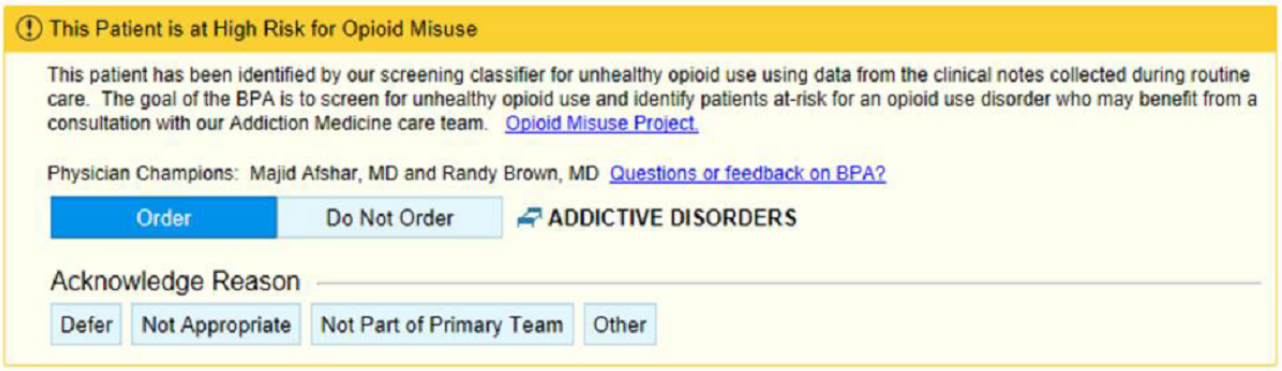
All notes from the first 24 hours of arrival at the UW Hospital were combined into a single document per patient encounter and converted into sequences of vector representations (eg, embeddings). The CUI embeddings defined the input layer to the SMART-AI model at the encounter level. The model provided prediction probabilities for opioid misuse and stored them in a Databricks table with the predefined cutoff point for screen positives.

Component 5: Real-time Delivery of the Prediction Results

The Nebula Cloud Platform was Epic's Software as a service platform for integrating new technology and specifically supported clinical prediction modeling. Nebula capabilities included the deployment of machine learning models, including a library of Epic-curated models for health care and custom algorithms. Our solution leveraged the latter to facilitate triggers from Epic to call out to the Databricks environment and provided the predictions for BPAs.

In the case of SMART-AI, we designed a BPA (Figure 2) to trigger once a clinician opened a patient chart in the EHR. Epic called its Nebula component to determine whether a BPA should be generated. Nebula made an HTTP call to Databricks to request the score. The RESTful HTTP API provided the SMART-AI model score that was serviced using MLFlow. The parameters included UMLS dictionaries, model results, patient identifiers, and other attributes necessary for individual-level predictions. The score was returned to Nebula, which was used to trigger a BPA if SMART-AI met the cutoff score for opioid misuse. For screen positives, the alert recommended the clinician to consult with the UW's Addiction Medicine consult service. The following were internal targets to meet the real-time needs of the end user at the bedside: (1) a throughput of 1000 notes per minute (<60 ms each); (2) three-nines (99.9%) availability—equivalent of <9 hours of downtime annually; and (3) an established error rate threshold.

Figure 2. In an iterative design with feedback from end users, a final BPA was implemented for bedside care. The BPA triggers upon opening a chart for a patient that meets the cutpoint predicted probability for opioid misuse from the NLP and deep learning model (SMART-AI). BPA: best practice alert; NLP: natural language processing; SMART-AI: Substance Misuse Algorithm for Referral to Treatment Using Artificial Intelligence.



Component 6: Cybersecurity

Two principles of security were applied: (1) defense in depth and (2) zero trust. The zero-trust architecture was outlined in the National Institute of Standards and Technology Special Publication 800 to 207 [26]. To secure access between Azure Databricks MLFlow and Epic's Nebula, we used an authentication token and IP range restriction (Databricks admin utility). The authentication token was issued via Databricks standard authentication. As a security best practice, we used the Databricks service principal and its Databricks access token to provide automated tool and system access to Databricks resources.

Implementation Framework

The Consolidated Framework for Implementation Research informed the development of the preimplementation assessments and will be used during the rapid Plan-Do-Study-Act (PDSA) cycles after deployment [27]. Key stakeholder interviews were planned to better understand the context and identify the barriers to and facilitators of the implementation of the BPA tool. Selected implementation strategies from the Expert Recommendations for Implementing Change were chosen to overcome barriers [28]. For pilot implementation, a regular cadence of meetings was planned with the implementation team to process, reflect, and evaluate the barriers to the implementation and use of the BPA. Process evaluation would incorporate interviews with providers and addiction specialists to understand what barriers still existed to using and acting on the BPA. During pilot implementation, we will collect and summarize clinical performance data during PDSA cycles to guide clinicians and administrators in monitoring, evaluating, and modifying provider behavior. Using the Consolidated Framework for Implementation Research–Expert Recommendations for Implementing Change matching tool [29], we will tailor relevant implementation strategies to enhance provider uptake and use of the tool. In addition, during the pilot phase, we will interview providers on the hospital units beyond the pilot units to identify and explore their determinants for the use of the BPA. After a pilot implementation period of 3 months, we will optimize provider training, enhance educational materials, and institute quality monitoring preparatory to a hospital-wide rollout.

Patient Outcome Analysis and Power Calculation

The SMART-AI study intervention sample consisted of all hospitalized patients who were screened positive for opioid misuse through the NLP CDS tool. The primary effectiveness measure was the percentage of hospitalized patients in the NLP CDS intervention sample who screened positive for opioid misuse and received an intervention by the inpatient addiction consult service. A control sample was derived by retrospectively applying the NLP CDS tool to all inpatient EHR records from the 2 years before this study's initiation in March 2023. Hospitalized patients who were screened positive retrospectively through the NLP CDS tool will form the usual care control group.

The primary outcome was the percentage of inpatients who were screened positive (or would have screened positive)

through the NLP CDS tool and who received an addiction consult with any of the following interventions: (1) receipt of opioid use intervention or motivational interviewing (MI), (2) receipt of medication-assisted treatment (MAT), or (3) referral to substance use disorder treatment. The primary outcome will be reported as a percentage in the preintervention and postintervention periods and will be measured through substance use screening and treatment service engagement for hospitalized patients screened for opioid misuse. The secondary outcomes included the 30-day unplanned hospital readmission rate. The criteria for unplanned hospital readmissions were adopted from the Centers for Medicare and Medicaid Services [30].

Hypothesis testing for intervention effects will be conducted using independent tests of the difference in the proportion of patients receiving MI, MAT, or referral to substance use disorder treatment. The null hypothesis was that the proportion of patients who screened positive and received any of the aforementioned interventions was lower (inferior) in the postintervention period than in the preintervention period, that is, H_0: $p_1 - p_2 \geq M$, where M denotes the noninferiority (eg, equivalence) margin, p_1 denotes the preperiod proportion, and p_2 denotes the postperiod proportion. The alternative 1-tailed test for noninferiority, that is, H_1: $p_1 - p_2 < M$, will be tested using the *Z* statistic. The noninferiority design was adopted to demonstrate that comprehensive screening may be as effective as manual screening but less costly via automated solutions. Our use case was an example of an AI system intended to improve efficiency and throughput within a reasonable timeframe for hospital operations. In these cases, statistically superior performance on outcomes may not be expected or required for prospective implementation, and interventions may be desirable if they are both substantially equivalent (noninferior) on clinical outcomes and cost-effective, given the high cost of building IT infrastructure, hiring vendors, and obtaining licensing and software support.

In hospital-wide screening, we expected a prevalence of 3% of adult inpatients with opioid misuse based on prior findings of hospital-wide analyses. A total sample size of 12,500 patients, with 10,000 in the preintervention 2-year period and 2500 in the postintervention 6-month period, had 85% power to detect a difference of +0.75% in the postintervention period (3.75%) compared with the preintervention period (3%), with a noninferiority difference of −0.5% using a 1-sided *Z* test with a significance level of 0.025.

Cost-effectiveness Analysis

Overview

Cost-effectiveness analysis will estimate the incremental costs of the SMART-AI intervention for the 6 months after the implementation compared with the 6 months before the implementation (ie, the added costs of the SMART-AI tool in reference to usual care) relative to the incremental effectiveness for the primary and secondary outcomes. The health economic evaluation would determine incremental intervention costs by examining the following: (1) the opportunity start-up costs of implementing the SMART-AI tool, (2) the incremental medical costs resulting from usual care for hospitalized patients with opioid misuse versus SMART-AI automated screening–supported care costs, and (3) the ongoing costs of administering and maintaining the SMART-AI tool.

The start-up costs of establishing SMART-AI substance use screening care would include the costs associated with developing and implementing the NLP CDS tool: (1) the cost of supporting the NLP and machine learning components and building the BPA in the EHR and (2) the cost of training the health professionals on tool use. The incremental costs between usual care and SMART-AI automated screening care were determined by calculating medical care costs before and after the implementation of SMART-AI. Medical costs associated with the hospitalization stay and all subsequent medical costs for the 30 days following hospital admission for the pre– and post–SMART-AI intervention periods were derived from hospital billing records and presented from the single-payer (a health system) perspective.

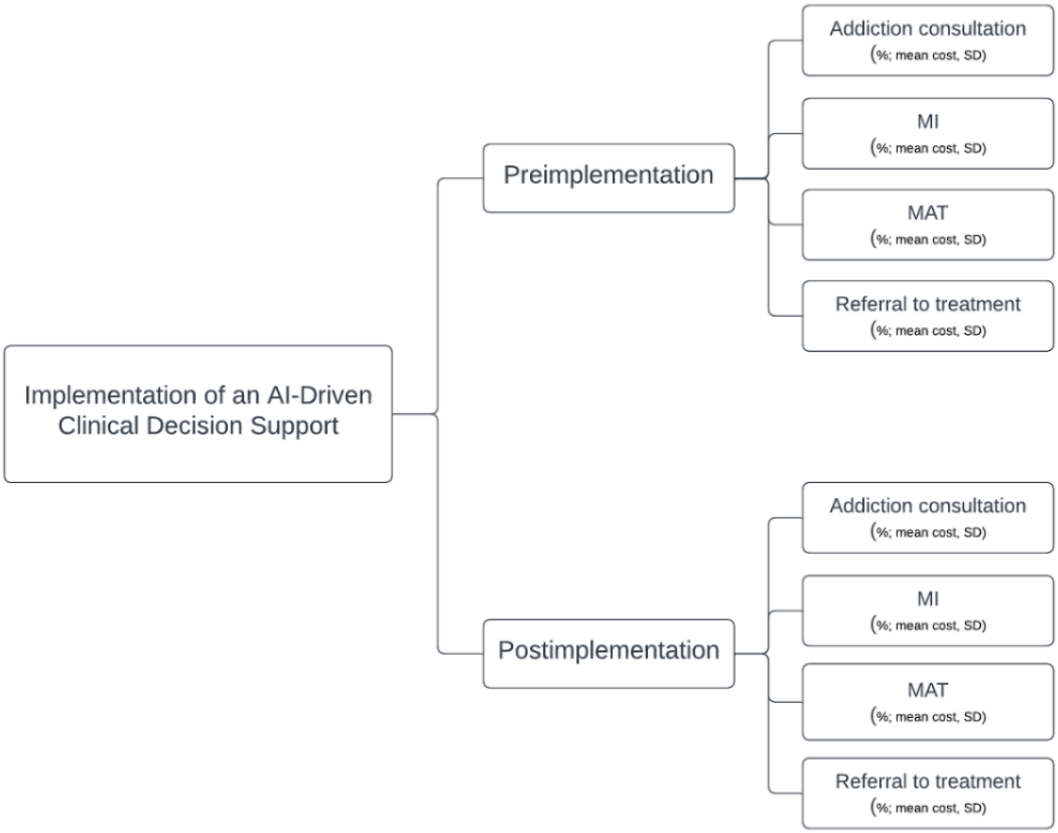
The following 3-pronged approach will be applied to identify the administration and maintenance costs associated with SMART-AI screening workflow changes introduced by the NLP CDS tool: (1) conducting in-depth interviews with hospital administrators, (2) performing activity-based observations of health care personnel who use SMART-AI, and (3) querying the clinician messaging system in the EHR. Average hospital compensation rates were used for valuing health care personnel time costs. Research-related costs were excluded.

Analytical Approach to Cost-effectiveness Analysis

The cost-effectiveness analysis was reported in terms of the incremental cost-effectiveness ratio (ICER) per additional patient who received substance use treatment. For this study, the ICER was calculated as the difference between preimplementation and postimplementation intervention costs divided by the difference between preimplementation and postimplementation intervention effectiveness as measured by the rates of patient engagement with substance use treatment services (ie, primary outcome) and 30-day hospital readmission (ie, secondary outcome).

The usual care control group and SMART-AI intervention group were characterized by the pathway probabilities of receiving substance use treatment and meeting the primary outcome. The pathway probabilities of patients' engagement with inpatient substance use consult, brief intervention or MI, MAT, and referral to substance use treatment for both study groups would result in 8 treatment combinations, which are displayed in Figure 3.

Figure 3. Cost-effectiveness decision tree. AI: artificial intelligence; MAT: medication-assisted treatment; MI: motivational interviewing.



The differential costs pre– and post–SMART-AI intervention were determined as the difference in the weighted sum of the individual pathway costs, using the pathway probabilities as weights for the intervention and control groups. Effectiveness was determined as the difference in the rates of hospitalized patients engaging with substance use disorder treatment before and after the implementation of SMART-AI for the intervention and control groups. The ICER was calculated as follows:

Sensitivity analyses will introduce uncertainty in substance use treatment receipt rates and costs for the intervention and control groups. The Monte Carlo–based simulation estimation used the rates of substance use treatment service uptake observed in the intervention and control groups as a reference to simulate a cohort of postimplementation hospitalized patients and a cohort of usual care hospitalized patients. The ICER per additional individual who received an inpatient substance use consult, brief intervention, MI, MAT, or referral to substance use treatment was calculated by drawing a random sample with replacement from the observed distributions for health care costs (μ_{COSTi}) and substance use treatment services (μ_{TRTi}) for the intervention and control groups. This process was repeated (n=1000) to produce bootstrap estimates of the 95% CI for the ICER per additional individual who received an inpatient substance use consult, brief intervention, MI, MAT, or referral to substance use treatment. These probabilistic sensitivity analyses estimated the elasticity of the differential cost per patient relative to the differential substance use treatment service rates for the intervention and control groups.

Ethics Approval

This clinical study was reviewed by the UW Institutional Review Board (ID 2022-0384). The study was part of a larger quality improvement initiative at the UW Health and met the exemption status for human participant research according to the UW Institutional Review Board. The study was secondary research with the collection of existing EHR data that met category 4 exemption. The study met the requirements for a waiver of consent, and all study results were anonymized or deidentified. No compensation was provided in the human participant research.

Results

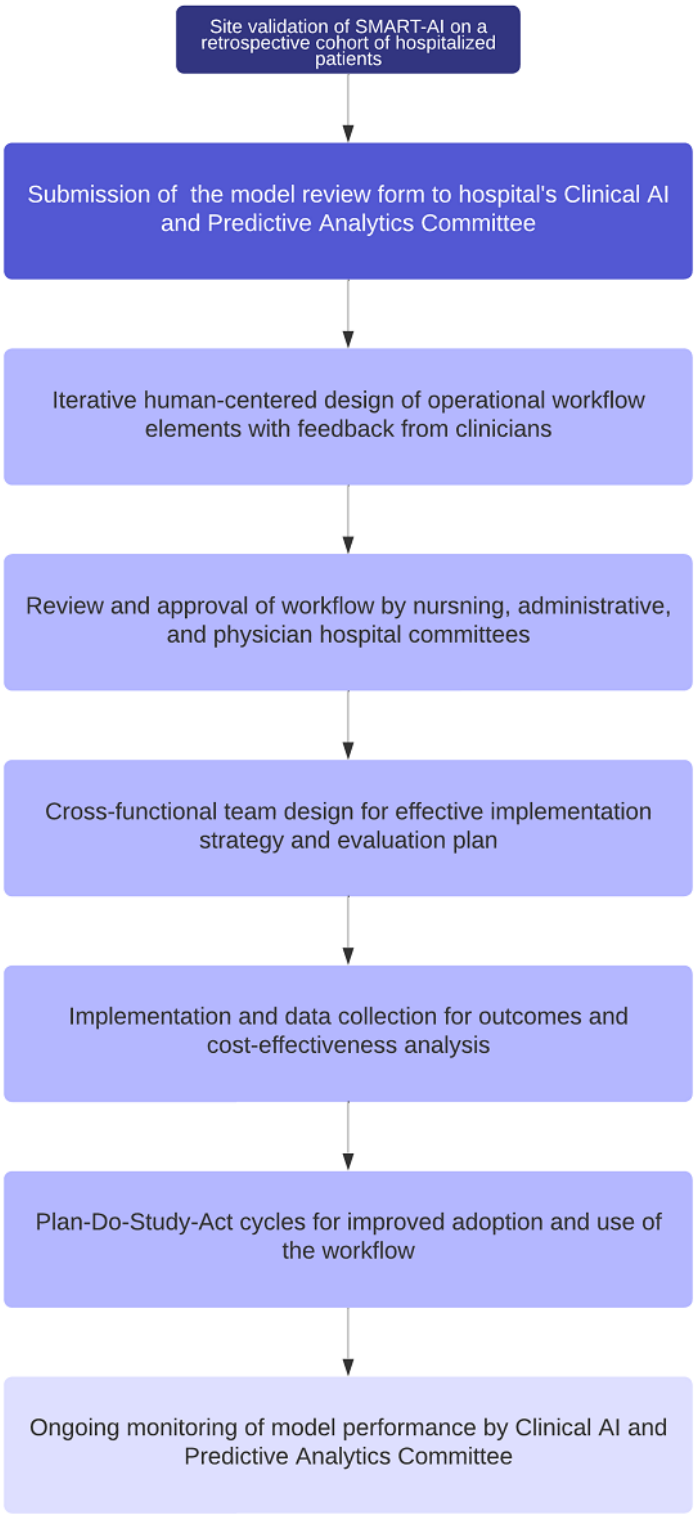
Preimplementation Testing and Approvals

Early-stage investigations were performed to assess the AI system's predictive performance in a retrospective setting and evaluate the human factors surrounding the BPA before initiating the quasi-experimental clinical study. During the silent testing of SMART-AI at the UW Health, a random sample of 100 adult patient encounters (with an oversampling of patients with the International Classification of Diseases codes for substance use) in 2021 were extracted and reviewed by an inpatient physician and a clinical informatics expert. SMART-AI performed similarly to previously published reports for screening for opioid misuse, with a sensitivity of 93% (95% CI 66%-99%) and specificity of 92% (95% CI 84%-96%).

Before the deployment of SMART-AI, approvals were received across hospital committees for inpatient operations, EHR super users, CDS, and nursing documentation. The proposal protocol

was also reviewed by the Center for Clinical Knowledge Management to confirm that there were no competing interests or roles with existing protocols for screening for substance use conditions in the health system. In addition, SMART-AI was reviewed by the UW's Clinical AI and Predictive Analytics Committee. A model review form providing details on the clinical problem, model value proposition, model description, proposed workflow integration, internal validation, and monitoring strategy (including fairness and equity) was reviewed and approved by a multidisciplinary committee of clinicians, informaticians, bioethicists, executive leadership, and data scientists. The planned workflow from introduction to implementation is shown in Figure 4.

Figure 4. Flow diagram for the process to bedside implementation and evaluation. AI: artificial intelligence; SMART-AI: Substance Misuse Algorithm for Referral to Treatment Using Artificial Intelligence.



Implementation Framework

An end-user interview guide and survey were developed to examine the user acceptability of the BPA. Open-ended questions were asked about the barriers to and facilitators of the use of the BPA. A total of 5 interviews were conducted (with 3 nurse practitioners, 1 family medicine resident, and 1 surgical attendant), and the responses led the production team to create an educational flyer, modify the BPA with more details and options for consultation refusal, and modify when and where the BPA would trigger. Figure 2 shows the final production version of the BPA for deployment. Dissemination efforts included Grand Round presentations to the Addiction Medicine Division, Department of Family Medicine, and notification via the hospital's weekly electronic newsletter.

The longest delay in operational workflow and architecture was for receiving cybersecurity approvals, especially for the exchange of protected health information between the Microsoft and Epic cloud vendors. An additional 6 months of delay occurred for achieving acceptable security monitors and checks. The go-live of SMART-AI in the EHR was scheduled for January 2023.

Discussion

Principal Findings

We offer one of the first protocols that detailed the components of a real-time NLP-driven CDS system for health care delivery at the bedside. We further detailed an implementation framework with human-centered design principles and a planned iterative process to evaluate the cost-effectiveness and health outcomes of screening for opioid misuse. We shared the components and pseudocode with open-source technologies involved in the implementation of an end-to-end NLP pipeline that processed the notes entered by the provider and returned a BPA within minutes for patients at risk of an opioid use disorder. Interviews and user-centered design as well as educational efforts for improving adherence led to changes in the BPA. Finally, we shared an experimental design with a rapid PDSA cycle and cost-effectiveness setup with a noninferiority design to evaluate the screening system for continued implementation or deimplementation.

The digital era in medicine continues to grow exponentially in terms of both the quantity of unstructured data collected in the EHR and the number of prediction models developed for detection and diagnostic, prognostic, and therapeutic guidance. In parallel, the clinical NLP field has grown in its capabilities with the advent of transformer architectures and more affordable and efficient cognitive computing of big data [31]. However, a major bottleneck remains in the successful implementation of NLP and deep learning models in clinical practice. Much of the progress in NLP has focused on information retrieval and extraction [32]; however, the application of these methods at scale with a combination of software developers and operations remains challenging at health care institutions. The role of NLP in BPAs has been limited to date, and prior BPAs have used existing technologies embedded into the EHR [33]. Similar to prior motivations for BPAs delivered to bedside clinicians [34], our intention was to support and enhance decision-making at the beside with a recommendation for an Addiction Medicine consult in patients who may otherwise not receive it or have it delayed, similar to another NLP-driven BPA [17]. However, given the lack of capacity of many EHR vendors to incorporate custom NLP models, we offer an interoperable pipeline to integrate external AI tools with existing EHRs.

Applied clinical NLP has predominantly remained a rule-based approach, but statistical machine learning models are now the leading method in the research literature [21]. Few vendors who provide NLP services rely entirely on machine learning, and a gap remains in effectively applying NLP models to EHRs that go beyond disease detection, which is limited to explicit keyword mentions [35]. Several barriers exist with neural language models, including the need to remove protected health information so that the trained models may be shared and the computational requirements to run complex deep learning models in a production environment [9]. We offer solutions for both barriers using a feature engineering approach to map free text to coded vocabulary and describe a large computing infrastructure with a connection between a data science cloud platform and the EHR to support direct data feeds into any machine learning model. The NLP CDS pipeline accomplishes efficiency in data standardization and scalability [36] for successful implementation and is extensible to other NLP engines. The benefit of augmented intelligence remains unknown and its identification using our health care outcomes and cost-effectiveness analysis is the next step in a clinical study.

Our implementation framework is largely guided by a team of implementation scientists supported by the UW's Clinical and Translational Science Award. We leveraged our Clinical and Translational Science Award's Dissemination and Implementation Launchpad to help bridge the gap between evidence-based research and practice [37]. The Dissemination and Implementation Launchpad serves to accelerate the pace of disseminating research findings and increase the adoption and implementation of effective interventions, leading to sustainable practice and policy changes. It uses strategies from implementation science, design thinking, and human-centered engineering for the better integration of AI technologies into health systems. As part of the preimplementation phase, we assessed contextual factors that may impact implementation by engaging both adopters, who are the decision-makers, and end users, who are the main implementers, of the tool [38]. We conducted qualitative interviews with end users to evaluate the need for the tool and BPA design. We involved adopters early in the process to inform the intervention or implementation process through consultations during the design, feasibility testing, and implementation phases. An iterative process ensued to address the constraints and contextual factors that affect the adoption and implementation of the tool in our health system.

During the preimplementation phase, the project team clarified roles with the project management, with the readiness of the clinical workflow approved through hospital committee meetings and individual interviews with end users. Our health system is an early adopter of AI governance with a review process similar to that of other health systems [39]. The Clinical AI and Predictive Analytics Committee follows the Minimum

Information About Clinical AI Modeling checklist [40]. The offline validation of our model incorporated principles from multiple reporting guidelines on prediction models, bias, fairness, and validation [41]. Clinical evaluation after the go-live of SMART-AI will follow the reporting guideline for the early-stage clinical evaluation of decision support systems driven by AI (Developmental and Exploratory Clinical Investigations of Decision Support Systems Driven by AI) [42].

The build of an enterprise-wide AI infrastructure for data-driven CDS is an important feature of a data-driven learning health system. At the UW, learning health system activities dating back to 2013 established an evidence-based framework with a series of organizational-level quality improvement interventions [43]. In 2020, the UW Health reaffirmed its strategic plan for embedding discovery and innovation as well as diversity, equity, and inclusion in clinical care. Successful implementation included coaching staff and administrative leaders for working in PDSA with lean management to get the problem, analysis, corrective actions, and action plan down on a single sheet of large (A3) paper, also known as “A3” thinking [44]. A rapid PDSA cycle is important in the advent of AI-driven interventions that require rigorous evaluation for implementation or deimplementation. Furthermore, the pipeline developed for the opioid screener use case is applicable to other CDS tools that use machine learning and NLP. We designed our architecture to ingest different modalities of data and provide a computing environment that is flexible to different data modalities and machine learning algorithms.

Several limitations exist in the deployment and sustainability of our NLP-driven CDS tool. First, calibration drift is a real concern with changes in medical practice, evidence, and demographic shifts over time that may affect model performance [45]. During implementation, reviews by the Clinical AI and Predictive Analytics Committee will include quarterly evaluations of the sustained effectiveness of the tool, an audit of the fairness of the tool across parity groups, and examination for alert fatigue. Others have shown benefits in recalibration approaches and domain adaptation with additional training data to update the models over time [46]. Furthermore, the start-up costs of the pipeline may be cost-prohibitive for small health systems. Our proposed cost-effectiveness analysis will provide a perspective on both the start-up costs of implementing the NLP tool and the ongoing incremental costs. The start-up costs are more of a burden to a small health system than the incremental costs, but we expect that our results will be informative in terms of both these costs.

Conclusions

The deployment of medical AI systems in routine clinical care presents an important yet unfulfilled opportunity [47], and our protocol aims to close the gap in the implementation of AI-driven CDS. Our protocol implementation for an enterprise-wide production environment of an AI opioid misuse screener provides a model for other health systems to use to bring NLP models into practice for CDS. We highlight opportunities to leverage the expertise of our applied data science team to use the open-source tools for feature engineering and model development inside a larger infrastructure with vendor support for hardware and software dependencies. Given the sensitive nature of health care data, the biggest challenges are ensuring high standards for cybersecurity and meeting the privacy requirements for protecting patient data.

Acknowledgments

The authors acknowledge support from the University of Wisconsin Institute for Clinical and Translational Research, which, in turn, is supported by the Clinical and Translational Science Award program through the National Institutes of Health National Center for Advancing Translational Sciences grant (2UL1TR002373). The research was also supported by the National Institute on Drug Abuse of the National Institutes of Health (R01DA051464; CJ, DD, MA, and RB), National Library of Medicine Temporal Histories of Your Medical Event (THYME) project (R01LM010090; DD), and National Institute of Diabetes and Digestive and Kidney Diseases R01DK126933). The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health or the other funding sources listed in this section.

Data Availability

The raw electronic health record data are not available because of regulatory and legal restrictions imposed by the University of Wisconsin-Madison Institutional Review Board. The original data were derived from the institution’s electronic health record and contain patients’ protected health information. Data are available from the University of Wisconsin Health Systems for researchers who meet the criteria for access to confidential data and have a data use agreement with the health system. Only the final trained model that is fully deidentified with a vocabulary of mapped concept unique identifiers is open source and available [38]. Our deidentification approach has been previously described [39].

Authors' Contributions

MA, FL, BWP, SA, FR, CJ, MPM, DD, and MMC led the conception and design of the study and supervised the study. MA, FL, MPM, TA, GJW, and MC had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. CJ, B Sharma, and DD could not access the original data directly because of limitations in the data use agreement but take responsibility for the accuracy of the data analysis and did have access to all the data presented in the manuscript. MA, SA, MPM, ML, TA, GJW, B Schnapp, MC, CJ, B Sharma, ESB, FR, JM, DD, BWP, MMC, and FL performed

the analysis or interpretation of data. Administrative, technical, and material support were provided by MA, BWP, SA, JL, TA, GJW, B Schnapp, and FL. All authors reviewed the manuscript and provided edits and revisions. All authors take responsibility for the integrity of the work as a whole, from inception to the finished article, and all authors approved the final version submitted. MA was responsible for the decision to submit the manuscript.

Conflicts of Interest

Research conducted by RB is supported by grants to the University of Wisconsin by the Heffter Research Institute, Usona Institute, Revive Therapeutics, and the Etheridge Foundation. MMC is a named inventor on a patent for a risk stratification algorithm for hospitalized patients (US patent #11,410,777).

Abstract

Background: The medical teams in intensive care units (ICUs) spend increasing amounts of time at computer systems for data processing, input, and interpretation purposes. As each patient creates about 1000 data points per hour, the available information is abundant, making the interpretation difficult and time-consuming. This data flood leads to a decrease in time for evidence-based, patient-centered care. Information systems, such as patient data management systems (PDMSs), are increasingly used at ICUs. However, they often create new challenges arising from the increasing documentation burden.

Objective: New concepts, such as artificial intelligence (AI)–based assistant systems, are hence introduced to the workflow to cope with these challenges. However, there is a lack of standardized, published metrics in order to compare the various data input and management systems in the ICU setting. The objective of this study is to compare established documentation and retrieval processes with newer methods, such as PDMSs and voice information and documentation systems (VIDSs).

Methods: In this crossover study, we compare traditional, paper-based documentation systems with PDMSs and newer AI-based VIDSs in terms of performance (required time), accuracy, mental workload, and user experience in an intensive care setting. Performance is assessed on a set of 6 standardized, typical ICU tasks, ranging from documentation to medical interpretation.

Results: A total of 60 ICU-experienced medical professionals participated in the study. The VIDS showed a statistically significant advantage compared to the other 2 systems. The tasks were completed significantly faster with the VIDS than with the PDMS (1-tailed t_{59}=12.48; Cohen d=1.61; P<.001) or paper documentation (t_{59}=20.41; Cohen d=2.63; P<.001). Significantly fewer errors were made with VIDS than with the PDMS (t_{59}=3.45; Cohen d=0.45; P=.03) and paper-based documentation (t_{59}=11.2; Cohen d=1.45; P<.001). The analysis of the mental workload of VIDS and PDMS showed no statistically significant difference (P=.06). However, the analysis of subjective user perception showed a statistically significant perceived benefit of the VIDS compared to the PDMS (P<.001) and paper documentation (P<.001).

Conclusions: The results of this study show that the VIDS reduced error rate, documentation time, and mental workload regarding the set of 6 standardized typical ICU tasks. In conclusion, this indicates that AI-based systems such as the VIDS tested in this study have the potential to reduce this workload and improve evidence-based and safe patient care.

Introduction

Overview

Intensive care medicine is the interdisciplinary treatment of patients with critical illnesses in specialized wards called intensive care units (ICUs) [1,2]. Patients admitted to ICUs have complex courses of disease and related treatments. However, ensuring adequate and safe measures in the ICU is often difficult due to a combination of short stays among patients, a high cognitive workload, and a limited number of rotating staff members [3]. The staff's time distribution is crucial for patient care and treatment. The direct contact between doctors and patients plays a crucial role in patient and family satisfaction as well as physicians' work satisfaction [4].

Patient contact, including treatment and communication, only makes up about one-fifth of the doctors' work time, while about one-third of their time is spent on documentation and data interpretation [5]. The documentation for patients with critical illnesses is complex and therefore labor-intensive [2]. This leads to an abundance of information with a high density of data arising from different bedside devices, consequently making their interpretation difficult and time-intensive [3]. Thus, documentation and evaluation tasks make up an increasing part of the physician's work time and become a major part of work on ICUs [6].

Physicians report that, due to rising requirements in documentation, they are under constant time pressure and complain about lacking time for patient-centered care [7]. This increasing burden is one of the crucial driving forces for burnout syndrome in physicians [8-10]. Similarly, a central part of the nurses' work on ICUs is the collection and documentation of massive, however critical, amounts of data and information about their patients [11]. This information overload and the redundancy in documentation can impair the ability to recognize the development of critical situations early on [3,12]. In response to this increasing workload, an improved documentation system is needed to enable the ICU staff to focus on their patients and decrease the time spent on documentation.

Workload in ICUs

Several aspects contribute to the workload in ICUs. First, medical knowledge in general is growing exponentially [13]. Medical guidelines and treatments increase in dynamicity and complexity as medical decisions and treatments at the patient's bed need to follow the current state of scientific evidence [14]. Additionally, the amount of generated health data doubles every 3 years [15]. Currently, an ICU patient produces more than 1000 data points per hour [15]. Thus, complex patient monitoring often leads to an information overload with unstructured and context-free data [3].

This makes it difficult to extract the most significant (and thus decision-relevant) aspects of a patient's history and the course of the disease [7,16]. The 2011 study by Ahmed et al [17] proves that the way in which the large amount of data generated in ICUs are presented has an impact on the viewer's ability to put it into the correct context. The more data are presented to the viewer, the higher the associated error rate. The phenomenon is even aggravated by the introduction of electronic health records and patient data management systems (PDMSs), especially when they present complete, unfiltered data sets [17]. Often, these systems therefore draw the immediate attention of the treating staff, resulting in less focus on the actual patient treatment [18].

These phenomena even have an imminent impact on the staff's occupational and mental health. It has been demonstrated that the more time physicians spend on less satisfying tasks (such as documentation), the higher the risk for burnout syndrome will become [19]. Shanafelt et al [19] showed in their 2009 analysis that the most important factor for burnout in physicians was to spend less than 20% of their time on the most meaningful activity (odds ratio 2.75, 95% CI 1.13-4.6; $P<.001$). The association between a physician's subjective work experience and the quality of patient care was already underlined in a 1985 study by Grol et al [20]. A similar finding for nursing staff was made in 2019 by Manomenidis et al [21]. They proved that, connected to burnout syndrome, the hand hygiene compliance in nursing staff was decreasing significantly, leading to reduced patient safety.

Documentation Systems in ICUs

Documentation facilitates interdisciplinary information flow and enhances continuity in patient care [22]. There are different forms of documentation systems available for this purpose in an ICU setting, such as traditionally used paper-based documentation, electronic health records with PDMSs, and new software developments that make use of speech recognition and artificial intelligence (AI).

Paper documentation has the advantage of being cost-efficient and simple to use, as no IT infrastructure has to be implemented [23]. However, disadvantages include the lack of on-site documentation, the lack of simultaneous access, and redundancy and ineffectiveness in documentation [24]. PDMS solutions have been developed to replace paper files, coordinate records from bedside equipment and laboratories, and thus reduce the ICU team's workload [25].

Many studies have investigated the pros and cons of PDMS implementation and show heterogeneous outcomes. Some studies underline that electronic health records lead to time savings, uniformity, and readability of the documentation. Ubiquitous and parallel availability of the patient's files reduces idle time and minimizes interruptions in documentation and data assessment [26,27]. Hence, information flow can be increased while the error rate can be decreased [3]. On the contrary, other studies show that PDMS generates a large amount of data, which, depending on the presentation, can make it difficult to identify relevant data and increase error rates, thus leading to a higher workload [7,17,28,29].

Currently, as many studies have proven, there is an imbalance between the time spent on completing documentation tasks and direct patient care [4,5,7,11,30]. Several studies show that the steady increase in time spent on documentation can be traced back to the introduction of electronic health records [7,25,27,31].

Speech recognition, a technique mainly driven by AI, can support the completion of documentation tasks. It is commonly used in consumer hardware devices and has been proven to increase productivity while reducing costs in the medical domain [28,32]. The use of computerized voice recognition in the medical domain is currently being investigated [33]. Several studies showed a reduction in documentation time with the use of speech recognition [29,33-36]. The reports produced offered greater word variety and more detailed and longer texts [34]. Additionally, an accelerated information flow and an improved subjective efficiency were proven [32,36].

Nevertheless, speech recognition is not well-established; thus, several studies examining the aforementioned technology showed a high error rate with significantly more critical clinical errors [28,35]. The main reasons for the errors in speech recognition are the use of nonnative speakers, difficulties in recognizing medical terms, and the ambient noise common in an ICU setting [33,34].

Speech recognition technologies have the potential to reduce the workload, especially regarding documentation tasks. However, it is necessary to develop a system that addresses the issues currently found in the use of speech recognition in order to establish the technology in clinical settings. This study investigates the use of an AI-based voice recognition technology for typical ICU tasks.

The development and introduction of a new documentation system must be based on the challenges in current technologies. A new system has to be intuitive and easy to understand, especially as the introduction period is often perceived as an addition burden since increased time has to be spent on the same tasks [27,36].

In addition, a new system should autonomously record and summarize patient data [11,37]. Thus, the vast amount of data produced by an ICU patient should be recorded, saved, and organized in the new system automatically, without the work of the medical team, in order to reduce workload. Flohr et al [3] confirm in their study that the automated collection of all patient data—the ability to view it in summarized form, identify trends, and have clear patient lists—can facilitate decisions and reduce workload and error rates [3].

While on the one hand, speech recognition can possibly reduce the documentational burden, on the other hand, AI can enable a well-structured, relevance-oriented patient presentation and clinical decision support [30,38].

Although of high importance for clinical outcomes, limited studies have been performed to compare new AI-based, voice-controlled documentation and information software with established documentation systems for ICUs (eg, paper documentation and classical PDMS computerized input) [32,34]. In this crossover study, we compare performance, mental workload, documentation accuracy, and user experience between methods. The objective of this study is to compare established documentation and retrieval processes with newer methods, such as PDMSs and voice information and documentation systems (VIDSs). This study compares performance, documentation accuracy, mental workload, and user experience associated with 6 tasks typical of the ICU as they are completed using 3 different approaches (paper-based, PDMS, and VIDS).

Methods

Study Design

Material

The study design includes 3 different ICU documentation tools.

An Established PDMS (IntelliSpace Critical Care and Anesthesia, Version J.01.00; Koninklijke Philips N.V.)

IntelliSpace Critical Care and Anesthesia is a clinical documentation and decision support system that includes a flowsheet, calculations engine, clinical advisories, device interfacing, orders, microbiology and pathology results, dietary and nursing orders, order management, infusion management, and numerous other functionalities [39]. We generated a fictitious patient using medical data mimicking a typical intensive care patient, including laboratory values, findings, demographic data, and other clinically relevant aspects. The validity of the data was confirmed by 2 independent trained intensivists.

Paper-Based, Conventional Documentation on Patient Curves (MEDLINQ Curve, Version 03.17)

In order to reflect the complexity of an intensive care patient, the participants received paper-based documentation (“patient curve”) of the same fictitious patient. This record included laboratory values, care reports, an anesthesia protocol, microbiology requests, a document concerning the patient’s belongings, and the patient curve. The curve consisted of 4 pages used to document the patient status for 1 day. The curve was completed for the patient until 6 AM, which was the time the participants were asked to complete the tasks. The biggest emphasis was placed on the fact that the paper-based sheet contained the same clinical information as was included in the other arms.

VIDS (Mona, Version P1.2; Clinomic GmbH)

In order to equalize potential differences between the study arms as much as possible, the AI-based software was installed on a portable system-on-chip computer (NVIDIA AGX Xavier) so that all study assessments could be performed in the same location. The system was based on adapted, proprietary software (“Mona”). For the purpose of the study, an adapted version of the Mona system was used, containing the following components: (1) voice handling capabilities: natural language understanding and processing; (2) data processing and preparation algorithms; (3) user interface components; and (4) voice synthesis components. The system was running on a Linux-based operation system and was further equipped with a directional microphone (Bose VideoMic NTG microphone) in order to create optimal voice recording circumstances (Figure 1) [40]. The VIDS interacted with an electronic health record

for each patient. The system was able to extract and display information from the patient data, enter patient care–related tasks, and navigate through charts. The user activated the system by saying, "Hey Mona." The system then played a short sound to reflect that voice recognition was activated. Throughout the interaction between the system and the user, the conversation was displayed for the user to read. The system would ask the user for any missing information to complete a task or answer a question. The patient information was shown in the form of tables and abstracts from the flow sheets. After a task was completed or a question was answered, the user had to reactivate the voice recognition with the words "Hey Mona."

Figure 1. Overview of the voice information and documentation system [40].

Procedure

A total of 60 medical professionals were included in the study. To achieve a sufficient level of significance, the size of the necessary sample was calculated as follows: sample size = $[z^2 \times p(1-p)]/e^2/1 + [z^2 \times p(1-p)]/e^2 \times N]$, where N = population size, z = *z* score, e = margin of error, and p = SD. The assumptions here were as follows: the total number of health care workers in Germany is 5.8 million, of whom 10% are working in ICUs. Confidence level of 0.85, resulting in a *z* score of 1.65 and a margin of error of 0.1. As a result, the required sample size was set at n>52. The definition of "ICU-experienced" included trained physicians, medical students after their fourth study year, and ICU nurses. The participants were recruited between February 5, 2021, and May 14, 2021. Participants were recruited in different domains of ICUs in order to represent the widest possible range of potential users of an information and documentation system. Participation was voluntary and could be terminated at any time without consequences.

First, each participant was informed about all parts of the study and then asked to sign an informed consent form. This was followed by the completion of a questionnaire about demographics, professional background, and technical affinity. The latter was measured using the validated "Fragebogen zur Erfassung der Technikaffinität als Umgang mit und Einstellung zu elektronischen Geräte" (TA-EG, "Questionnaire for the assessment of technology affinity as handling and attitude toward electronic devices") questionnaire [41] (Multimedia Appendix 1).

The participants then moved over to the study location. In order to reproduce the high noise level of ICUs during the COVID-19 pandemic, the tests were performed in a noisy simulation environment where other people were simultaneously working and moving around. The participants were asked to work on 6 different tasks typical in ICU workflow. The first 3 of the tasks were documentation tasks, followed by an assessment of a patient's status (either lactate trend or creatinine levels), and the last one was the generation of the ICU-relevant score "sequential organ failure assessment." Details on the given tasks are presented in Textbox 1. This list of tasks had to be completed with each of the examined systems mentioned above. Details about the questionnaires and methodology used can be found in Multimedia Appendix 2. The order in which the participants were presented with the different study arms was randomized before the start of the study using the randomize functionality of Excel (Microsoft Corp). The crossover design was chosen to ensure the comparability of all 3 interventions with respect to confounding variables. In addition, it allowed the risk of first- and second-type errors to be kept as low as possible when needing to minimize the number of necessary participants during the COVID-19 pandemic. While the participant executed the

tasks, the time needed was measured for each system. Each participant completed the tasks with the respective systems in all study arms. The order of steps in the study can be seen in Figure 2. The detailed solution pathway for each task completion can be seen in Multimedia Appendix 3.

Textbox 1. Tasks presented to the study participants.

Documentation

- "Document 300 mg amiodarone IV now"
- "Document 1.5 g piperacillin/tazobactam (Tazobac) intravenously now/at 10:00 AM"
- "Document the administration of a red blood cell concentrate/fresh frozen plasma at 1:00 AM for procedures numbered 1101002233 and indication active bleeding"
- "Document 20 mg furosemide now"

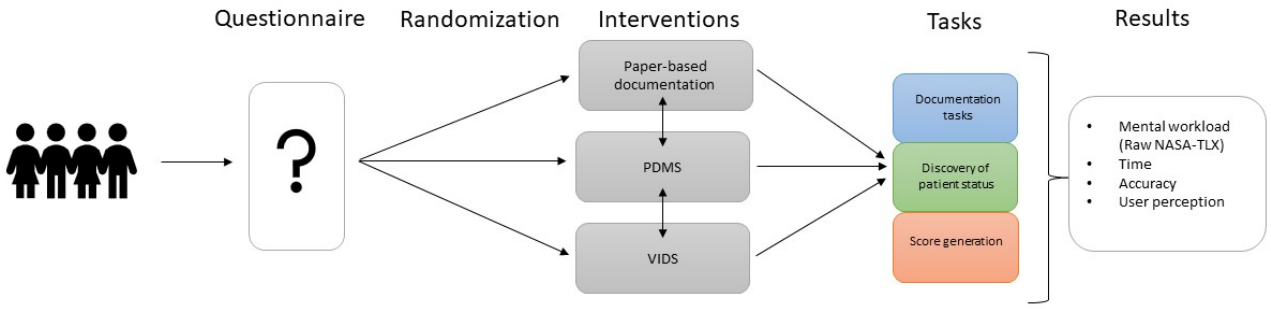
Discovery of patient status

- "What was the lactate trend in the last 12 hours?" Or "how did the creatinine levels develop within the last 4 days?"

Score generation

- "What is the patient's current SOFA score?"

Figure 2. Study procedure. NASA-TLX: National Aeronautics and Space Administration Task Load Index; PDMS: patient data management system; VIDS: voice information and documentation system.



After completing all tasks for 1 study branch, the participants filled out the German translation of the Raw National Aeronautics and Space Administration Task Load Index (NASA-TLX; Raw Task Load Index [RTLX]), a 6-item questionnaire that assesses subjective workload in 6 subscales without using a weighted ranking [42,43]. The shorter version of the NASA-TLX has great use in industry and research due to its simplicity while being equivalent to the task load index, and is thus recommended as a workload assessment tool [44]. For each participant, a mean value was calculated from the answers to the 6 subscales. A high RTLX score correlates with a high mental workload.

Lastly, the participants completed a final questionnaire to assess subjective user perception. This included the meCUE2.0, which is a questionnaire measuring user experience [45]. The meCUE2.0 was filled out for every system (Multimedia Appendix 2). The answers to the 6-point Likert scale were converted into numerical values so that the number 6 represents a maximum positive user experience. Additionally, the net promoter score (NPS) for each system was assessed. This score is a market research metric correlating with actual consumer behavior. It analyzes how likely a company or system is to be recommended by dividing the participants into detractors, neutrals, and promoters [46].

All questionnaires were filled out on a tablet using a publicly accessible, web-based survey system (LimeSurvey, version 3.23.3). Participants' responses were recorded for each task and subsequently compared against a clinically validated gold standard to assess accuracy. The gold standard was determined by 2 independent ICU specialists. A third independent ICU specialist was consulted in case of disagreement between the 2 physicians to determine the solution for the gold standard. Each error was counted as a negative point. Errors were defined as responses that deviated from the independently generated gold standard or tasks that were not completed.

There was no involvement of patients; all the data used were anonymous and fictitious.

Statistical Analysis

All statistical preprocessing and analysis were carried out using Excel and SPSS Statistics 27 (version 27.0.0.0; IBM Corp). For all statistical procedures, the α level was set at .05. The results were rounded to 2 decimal digits. According to the central limiting value theorem, an approximative normal distribution was assumed as the sample size was more than 30 [47]. The Levene test was used for the homoscedasticity requirement. A repeated, nonparametric, 1-way ANOVA was used in order to examine potential statistical differences between the different study arms.

Ethical Considerations

This study was approved by the ethics commission of the Medical Faculty of Rheinisch-Westfaelische Technische Hochschule Aachen (EK370/19).

Results

Overview

A total of 60 participants were included in the study; no dropouts occurred during the course of the study. Of the 60 participants, 26 identified as male and 34 as female. The average age was 32.87 (SD 12.46) years. The age ranged from 21 to 63 years. The groups were represented by 43% (26/60) physicians, 40% (24/60) students, and 17% (10/60) ICU nurses. Within their respective professional groups, 32% (19/60) reported 3-5 years of work experience, 27% (16/60) >10 years, and 18% (11/60) 5-10 years. Overall, 17% (10/60) had <1 year of work experience, and 7% (4/60) of participants reported experience of 1-3 years. In total, 6 participants reported having a native language other than German. Overall, 63% (38/60) of the 60 participants worked in a top-level hospital (>500 beds), 25% (15/60) in an upper-level hospital (300-500 beds), and 12% (7/60) in a primary care hospital (up to 300 beds). The technology affinity score was assessed with a mean of 3.70 (SD 0.47). The detailed characteristics of the study can be found in Table 1.

Table 1. Study population.

Variable	Value (n=60)
Age (years), mean (SD)	32.87 (12.46)
Gender, n (%)

Objective Parameters

The results of the analysis of the objective parameters—accuracy, time, and mental workload—showed that the participants performed best using the VIDS prototype. The exact results can be seen in Table 2. The differences between the systems were then analyzed using repeated measures ANOVA with a Greenhouse-Geisser correction.

Table 2. Descriptive statistics and objective parameters.

System	Accuracy, mean (SD)	Time (seconds), mean (SD)	RTLX[a], mean (SD)
VIDS[b]	0.28 (0.52)	195.45 (79.08)	3.49 (1.52)
PDMS[c]	0.75 (0.88)	491.03 (177.63)	4.17 (1.62)
Paper	2.37 (1.46)	763.93 (242.14)	6.31 (1.71)

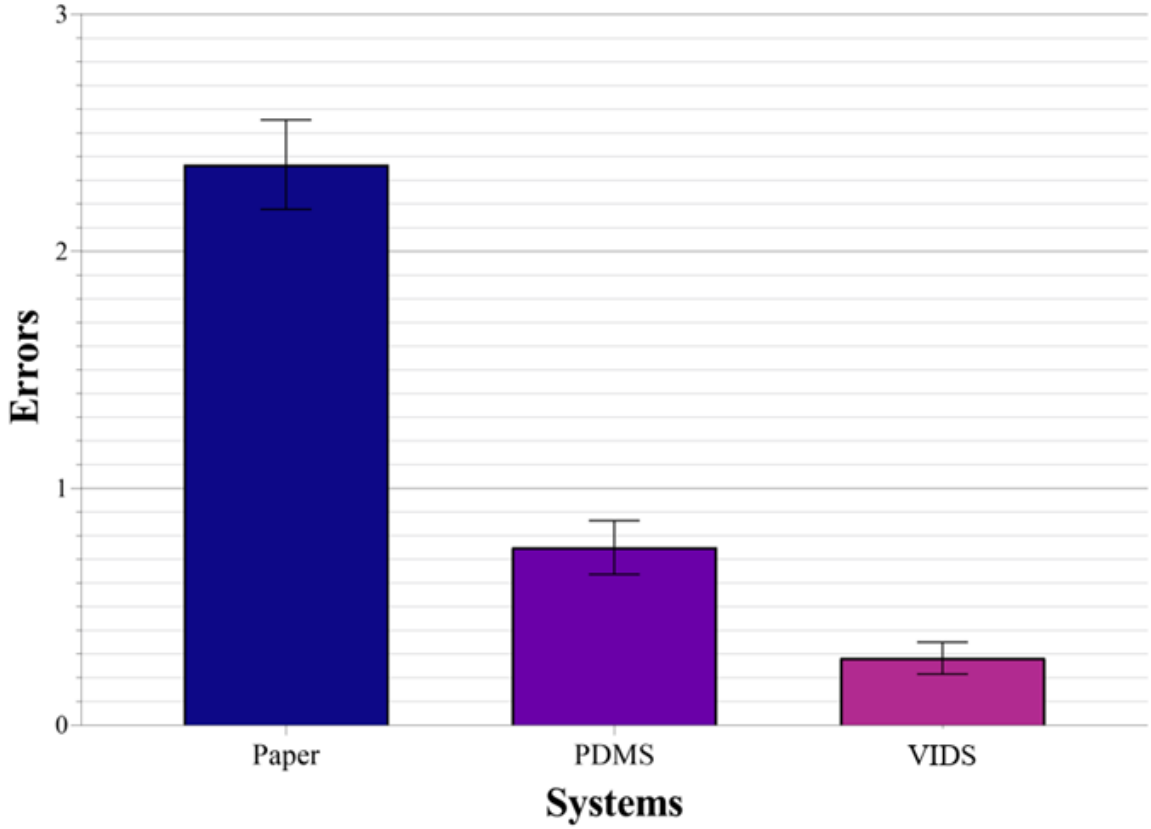
[a]RTLX: Raw Task Load Index.

[b]VIDS: voice information and documentation system.

[c]PDMS: patient data management system.

The analysis determined that there is a statistically significant difference in the errors made (n=60; $F_{1.73, 101.77}$=78.92; η_p^2=0.57; *P*<.001). The statistically significant difference is visualized in Figure 3. The effect size is Cohen *d*=1.15 and thus shows a large effect [48]. Post hoc analysis with a Bonferroni adjustment revealed that by using the VIDS, significantly fewer errors were made compared to PDMS (1-tailed t_{59}=3.45; Cohen *d*=0.45; *P*=.03) to paper-based documentation (t_{59}=11.2; Cohen *d*=1.45; *P*<.001) [49]. Using PDMS, significantly fewer errors were made compared to paper-based documentation (t_{59}=8.3; Cohen *d*=1.07; *P*<.001) [49].

Figure 3. Mean errors with standard error of the mean. PDMS: patient data management system; VIDS: voice information and documentation system.



Similar results were seen in the analysis of the time needed by the participants when completing the tasks, as can be seen in Figure 4. A statistically significant difference between the 3 systems was proven (n=60; $F_{1.65, 97.25}$=188.84; η_p^2=0.76; Cohen *d*=1.79; *P*<.001) [48]. The post hoc analysis with Bonferroni adjustments confirmed that the use of the VIDS was statistically significantly faster (VIDS to PDMS: t_{59}=12.48; Cohen *d*=1.61; *P*<.001; VIDS to paper: t_{59}=20.41; Cohen *d*=2.63; *P*<.001; PDMS to paper: t_{59}= 7.78; Cohen *d*=1; *P*<.001) [49].

The repeated measures ANOVA of the mental workload also showed a statistically significant difference between the use of the 3 systems (n=60; $F_{1.82, 107.11}$=56.91; η_p^2=0,49; Cohen *d*=0.98; *P*<.001), as shown in Figure 5 [48]. However, the post hoc analysis with Bonferroni adjustments only proved a statistically significant higher mental workload using paper-based documentation compared to PDMS (t_{59}=9.27; Cohen *d*=1.2; *P*<.001) and VIDS (t_{59}=9.16; Cohen *d*=1.18; *P*<.001) [49]. There is no statistically significant reduction in workload when using VIDS compared to PDMS (t_{59}=2.4; *P*=.06) [49].

Figure 4. Mean measured time in between the study arms with standard error of the mean. PDMS: patient data management system; VIDS: voice information and documentation system.

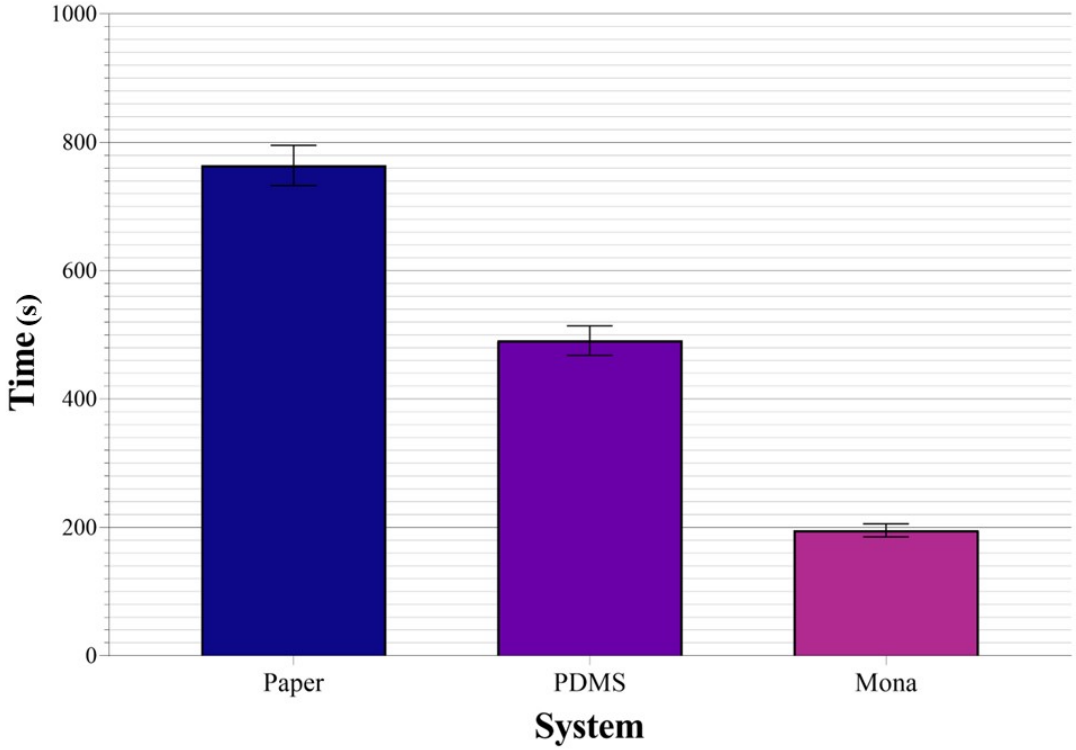


Figure 5. Raw Task Load Index (RTLX) with standard error of the mean. PDMS: patient data management system; VIDS: voice information and documentation system.

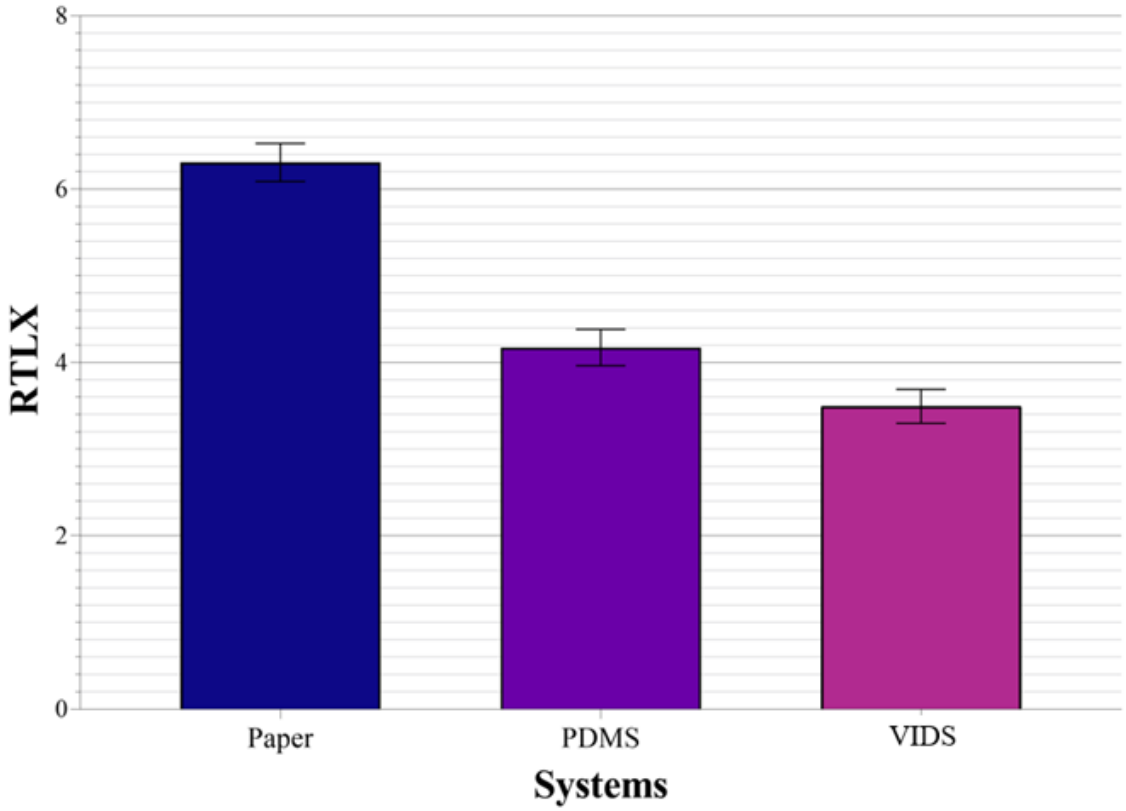
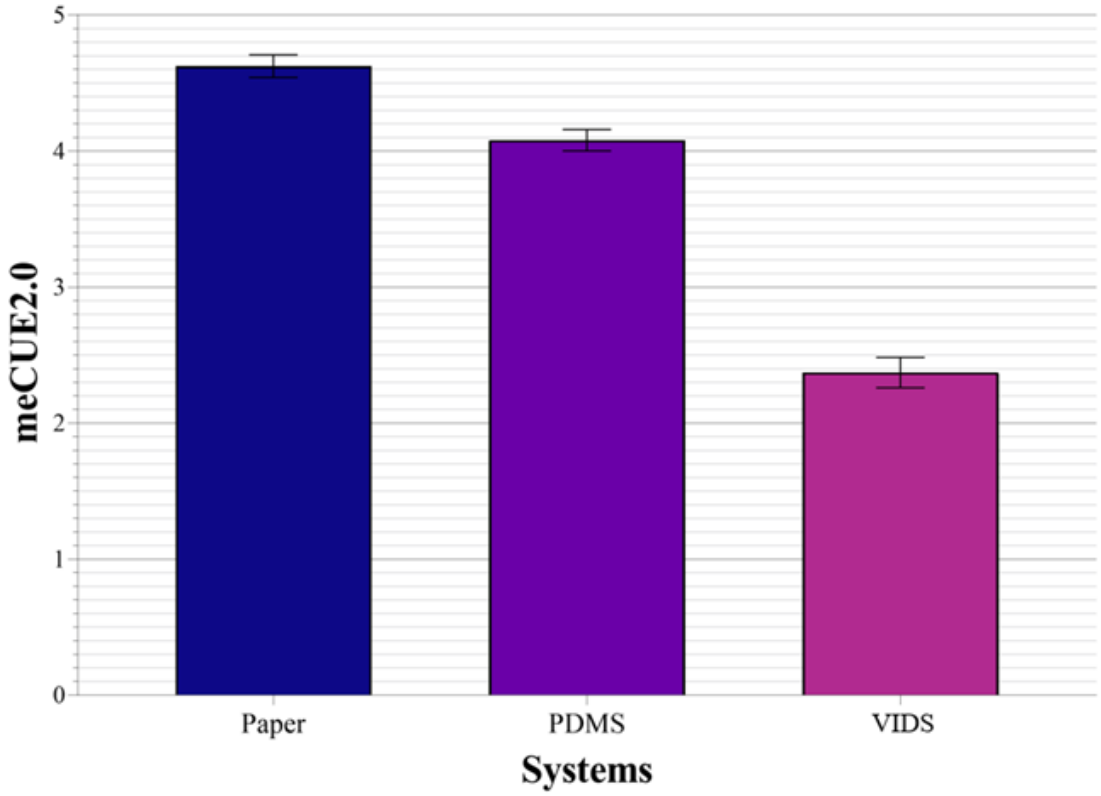


Subjective User Experience

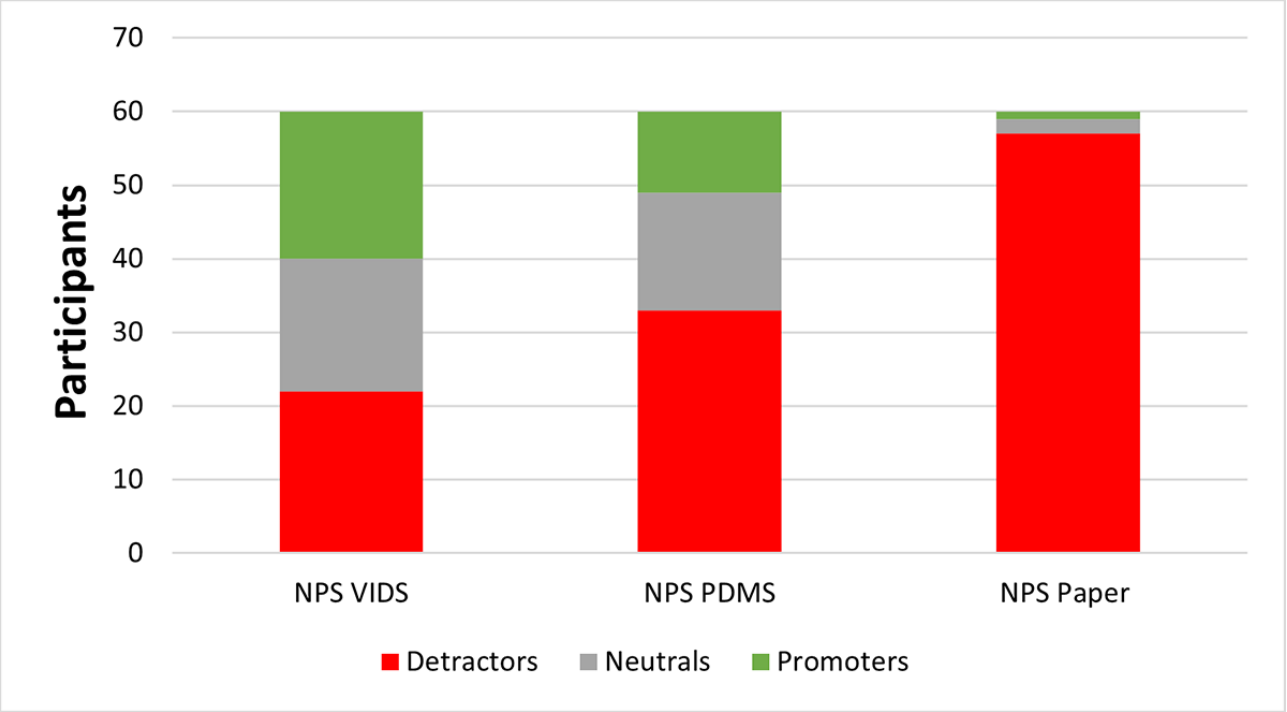
In order to evaluate the subjective user perception, the answers of the meCUE2.0 were analyzed. The average meCUE2.0 score was 2.37 (SD 0.86) for paper documentation, 4.08 (SD 0.61) for PDMS, and 4.63 (SD 0.64) for VIDS (Figure 6). Thus, VIDS showed the highest user satisfaction, while the participants felt least satisfied with using paper-based documentation. The meCUE2.0 was further analyzed using the mean scores of each participant for each of the 3 systems. This assumption was tested using a repeated measures ANOVA followed by pairwise comparisons with Bonferroni correction. The ANOVA showed after Greenhouse-Geisser correction (Mauchly W=0.9; P=.04) a significant difference between the 3 tested systems (n=60; $F_{1.81, 106.78}$=144.73; η_p^2=0.71; P<.001). The effect size is Cohen d=1.56, thus corresponding to a strong effect [48]. The pairwise comparisons with Bonferroni correction proved a statistically significant difference between all 3 systems with regard to user experience (P<.001) [49]. The effect size is Cohen d=0.61 for the comparison of VIDS with PDMS (t_{59}=–4.7), Cohen d=1.87 for VIDS with paper documentation (t_{59}=–14.5), and Cohen d=1.57 for PDMS with paper-based documentation (t_{59}=–12.17). Consequently, the effect size always corresponds to a strong effect [48].

Figure 6. Mean meCUE2.0 score and standard error of the mean. PDMS: patient data management system; VIDS: voice information and documentation system.



For each system, the NPS was calculated according to the given formula (NPS = promotors [% of all participants] minus detractors [% of all participants]) and compared as relative values. The NPS is a score correlating with actual consumer behavior and thus the ability of the company or system to be recommended [46]. The score is divided in promotors (score of 9 or higher), detractors (score of 6 or lower), and neutral users (score of 7-8). The distribution of the promotors and detractors can be seen in Figure 7. The comparison showed that the NPS for VIDS is 11.12 times higher than for PDMS and 28.27 times higher than for paper-based documentation (Figure 7).

Figure 7. Distribution net promoter score (NPS). PDMS: patient data management system; VIDS: voice information and documentation system.



The advantages of new, technologically advanced documentation systems could potentially be based on the technical affinity of the participants. In order to explore this assumption, we analyzed the effect of technical affinity on the results. The participants were grouped into high and low technical affinity groups using a median split according to the results of the TA-EG questionnaire. The analysis showed that the technical affinity has no statistically significant impact on the performance of the systems (Multimedia Appendices 4 and 5). Accordingly, it can be assumed that the prototype is beneficial regardless of the user's affinity for technology.

Discussion

Overview

In reaction to the increasing workload in intensive care medicine and the growing ability to integrate AI applications into clinical routines, new technologies emerge, aiming to improve the treatment of patients with critical illnesses. This study was conducted in order to assess the performance, documentation accuracy, mental workload, and user experience associated with tasks typical of the ICU while using 2 established systems (paper-based documentation [PDMS] and an AI-based [VIDS]).

A total of 60 participants, consisting of physicians, nursing staff, and medical students, completed a set of defined tasks with each system. This was complemented by the completion of several questionnaires. With the time taken, the errors made, and the questionnaires, we compared the 3 systems objectively and based on the users' subjective experiences. The results showed a statistically significant benefit in the objective variables of time and mistakes when using the VIDS. These advantages of the AI-based system are in line with several studies showing that speech recognition can reduce the documentation burden [32,34,35]. The results of this study should encourage the continuation of developing this and other AI-based software to reproduce these results in a real clinical setting.

Furthermore, not only the time needed to complete the tasks but also the errors made compared to the primarily established gold standard were significantly reduced when using the VIDS. This can be explained by the AI-based automated completion of the tasks and answers to the questions asked. Voice recognition in combination with AI reduces the number of necessary steps that the user has to take in order to correctly complete a task or answer a question. Therefore, fewer errors can be made. The significantly reduced error rate might also be due to the data presentation and user interface of the software. As Ahmed et al [17] showed in 2011, the presentation of data has a significant impact on the error rate.

Objective variables are important when evaluating the usefulness of a new system; however, subjective perception and workload are equally relevant. Comparing the RTLX results for each system showed that the VIDS and the PDMS were equivalent, as no statistically significant difference between these 2 systems could be observed. The graphical analysis of the data showed a discernible advantage of the AI-based system; however, this has not proven to be statistically significant. Because we had to limit the required time for study participation, the number of tasks to be completed within the study arms had to be limited as well. The VIDS used in the study was in prototypic stages and has potentially not yet shown its full strengths in terms of usability, consequently reducing mental workload. Therefore, future studies should elaborate on to what extent the further development of the VIDSs contributes to a change in this effect.

The questionnaires aiming to evaluate the subjective user experience confirmed that the participants felt an advantage when using the VIDS compared to PDMS and paper-based documentation (Multimedia Appendix 6). The meCUE 2.0 showed a statistically significantly higher score for the user

experience compared to PDMS and paper documentation. As a high score represents a positive user experience, the results underline that new approaches are not only objectively but also subjectively advantageous in the defined tasks we tested.

These 2 analyses of the subjective user experience were filled out after the participants completed all tasks with every system. The results underline that the VIDS have not only shown equivalence and advantage, respectively, in the objective variables but also in the perceptions of the participants. This goes in line with a 2019 study by Momenipur et al [7] showing that physicians also feel constant time pressure while working and underlined the major importance to improve the subjective work experience and efficiency [7]. The results of the study suggest that by using voice-based software solutions, this can potentially be achieved. This is further underlined by the outcome of the perceived speed of documentation. A total of 80% (48/60) of the participants ranked the VIDS highest. Therefore, the work time was not only statistically significantly less when using the VIDS compared to PDMS and paper-based documentation but also subjectively the lowest. This is especially relevant, as Tajirian et al [50] showed in their study in 2020 that physicians tend to overestimate the time they spend with electronic health records.

Limitations

Clearly, this study has some limitations. High efforts were undertaken in order to reduce confounders and circumstances between the study arms. However, as the 3 observed interventions are very different in technical requirements, input methods, and distribution among ICUs, the study can only be an indication for the acceptance and performance of these systems. Further studies in real-world ICUs are currently in preparation. These studies will analyze the accuracy, efficiency, and mental workload when using the new AI-based VIDS within an operating ICU. These studies will particularly analyze the roots of the observed effects (eg, which technical aspect contributes to what extent) in order to further direct development and progress in this field. Further, the analysis between different VIDSs and different user groups (eg, linguistic backgrounds and age) will be a closely analyzed. Furthermore, the study could not be performed in a real ICU setting due to infection constraints during the COVID-19 pandemic. Even though we tried to reproduce the high noise level of ICUs by performing the tests in a noisy simulation environment, studies in actual ICUs will have to be conducted in order to confirm the results. Another limitation of the study results from the tasks observed. The comparison of 3 different interaction methods, all developed in different decades, using very different technologies, and also requiring different training levels, is challenging and can only give an indication of the value of these systems in real-world health care usage. We attempted to overcome this by using standardization as much as possible and varying interventions in order to limit crossover effects. Additional studies are needed, taking in particular the technical details of VIDS and PDMS (eg, voice recognition, language understanding, data processing, and user interface) into account to make targeted development possible and address potential usability restrictions. As we only tested 3 aspects of the complex work on ICUs with predefined tasks, larger studies will have to confirm the benefits of the new software within the actual workflow of ICUs. Implementing complex IT systems, such as PDMS and VIDS, in a health care workflow certainly produces logistical and economic challenges, as new monitors and systems have to be installed during ongoing patient care in the ICU. Further, networking and IT infrastructure are required, and hospital prerequisites, such as the presence of digital patient data, have to be fulfilled. As documentation is an absolute necessity in patient care, this implementation might lead to disturbances and consequently increased workload, an effect that has to be taken closely into account.

Consequently, in order to assess the full picture of a system's performance, it is required to consider the user's personal perception as well as the objective measurements [50]. The well-being of the medical staff is closely connected to patient safety [10]. In the ranking of the highest user satisfaction, the VIDS was chosen most often on the first rank, as can be seen in Multimedia Appendix 7. This implies that using VIDS can potentially improve the quality of care and patient safety.

Conclusions

A high standardization and objectification of the systems studied was one of the main goals of the study. Nevertheless, the diversity of the investigated systems, the different user interfaces, and the usage contexts inevitably create an inhomogeneity that cannot be completely eliminated. Therefore, the approach of this study was to choose a usage-centric and user-centered object of study. By choosing a diverse set, including novel and well-established metrics, we also tried to focus on the multidimensionality of the results. In order to enable the greatest possible comparability of the developed systems, the adoption of such a measurement method is essential.

Nevertheless, the published approach is only one of the possible solutions to the problem. At this point, we would like to explicitly encourage the use of the protocols we have developed and to further improve and objectify them. In the long term, only based on an established, manufacturer-independent protocol is it possible to approximate the comparison between the different approaches. As novel systems are arising, the proposed study protocol could be the starting point for the development of an industry-wide, vendor-independent accepted standard.

Overall, the results of this study confirm the potential of the use of AI in the clinical setting to reduce workload and improve patient care. The workload in ICUs is growing due to an increasing amount of data collected and the need to document, analyze, and interpret these data points for each patient. In conclusion, AI-based systems like VIDS have the potential to reduce this workload and improve evidence-based and safe patient care.

Conflicts of Interest

AP, LM, and GM are cofounders of Clinomic GmbH. AP and LM are chief executive officers of Clinomic GmbH. Abstract

Background: Patients develop pressure injuries (PIs) in the hospital owing to low mobility, exposure to localized pressure, circulatory conditions, and other predisposing factors. Over 2.5 million Americans develop PIs annually. The Center for Medicare and Medicaid considers hospital-acquired PIs (HAPIs) as the most frequent preventable event, and they are the second most common claim in lawsuits. With the growing use of electronic health records (EHRs) in hospitals, an opportunity exists to build machine learning models to identify and predict HAPI rather than relying on occasional manual assessments by human experts. However, accurate computational models rely on high-quality HAPI data labels. Unfortunately, the different data sources within EHRs can provide conflicting information on HAPI occurrence in the same patient. Furthermore, the existing definitions of HAPI disagree with each other, even within the same patient population. The inconsistent criteria make it impossible to benchmark machine learning methods to predict HAPI.

Objective: The objective of this project was threefold. We aimed to identify discrepancies in HAPI sources within EHRs, to develop a comprehensive definition for HAPI classification using data from all EHR sources, and to illustrate the importance of an improved HAPI definition.

Methods: We assessed the congruence among HAPI occurrences documented in clinical notes, diagnosis codes, procedure codes, and chart events from the Medical Information Mart for Intensive Care III database. We analyzed the criteria used for the 3 existing HAPI definitions and their adherence to the regulatory guidelines. We proposed the Emory HAPI (*EHAPI*), which is an improved and more comprehensive HAPI definition. We then evaluated the importance of the labels in training a HAPI classification model using tree-based and sequential neural network classifiers.

Results: We illustrate the complexity of defining HAPI, with <13% of hospital stays having at least 3 PI indications documented across 4 data sources. Although chart events were the most common indicator, it was the only PI documentation for >49% of the stays. We demonstrate a lack of congruence across existing HAPI definitions and *EHAPI*, with only 219 stays having a consensus positive label. Our analysis highlights the importance of our improved HAPI definition, with classifiers trained using our labels outperforming others on a small manually labeled set from nurse annotators and a consensus set in which all definitions agreed on the label.

Conclusions: Standardized HAPI definitions are important for accurately assessing HAPI nursing quality metric and determining HAPI incidence for preventive measures. We demonstrate the complexity of defining an occurrence of HAPI, given the conflicting and incomplete EHR data. Our *EHAPI* definition has favorable properties, making it a suitable candidate for HAPI classification tasks.

Introduction

Background and Significance

Hospital-Acquired Pressure Injury, a Key Nursing Metric

Localized damage to the skin or underlying tissues characterizes pressure injury (PI). PI is typically found over a bony prominence or under a medical device and can be caused by lying down or sitting in one place for too long without much movement [1,2]. Hospital-acquired PI (HAPI) is classified according to the PI stage and the time of its development or progression. HAPI is associated with extended hospital stays, high readmission rates, reduced quality of life, and mortality [3]. HAPI is the most frequent preventable adverse event in hospitals according to the Center for Medicare and Medicaid (CMS) and the second most common claim in wrongful death lawsuits [3]. CMS and the Agency for Healthcare Research and Quality (AHRQ) consider HAPI a "never event," that is, events with profound financial penalties to providers on reimbursement [4]. More than 2000 US hospitals are part of the National Database of Nursing Quality Indicators program to measure nursing quality metrics, that is, events that are directly associated with the quality of nursing care. The National Database of Nursing Quality Indicators requires participating facilities to perform a quarterly survey of patients to estimate the incidence of HAPI [2]. Thus, accurate information on the incidence of HAPI in a health care unit is critical for assessing nursing quality and planning by hospital administrators.

Electronic Health Records and HAPI Identification, Opportunities, and Challenges

Electronic health records (EHRs) provide extensive information on existing and new PIs, including diagnosis codes; characteristics in structured charts, such as stage, depth, and location of PIs; and PI keywords in semistructured or unstructured clinical notes. Automatic detection of HAPI in EHRs using computational models facilitates clinical decision-making and patient care [5]. Predictive models for HAPI depend on the quality, dependability, and consistency of the data set. However, the complexity and subjectivity of PI screening, detection, and staging impact the reliability of PI documentation. PI documentation reliability also depends on the competency and continuity of nursing staff and their roles as well as changes in data entry or the EHR system.

Despite advances in prevention and treatment, HAPI persists and is difficult to identify from EHRs. Data sources provide contradictory information on PIs. Furthermore, the predictive model accuracy relies heavily on the definition of HAPI and accurate labels. Previous studies using EHR data have used inconsistent definitions of the HAPI. Some describe medical conditions that indicate HAPI [2,6,7]; some identify HAPI in all records associated with a hospital stay [7-9]; and others use prior laboratory data to predict HAPI [10].

Inconsistent HAPI labels adversely impact the model performance in HAPI classification and complicate comparison of multiple models. Thus, the correct identification of HAPI labels from EHR data is essential for HAPI studies. Assessing the performance of machine learning models for HAPI tasks using fixed benchmark data requires accessing appropriate clinical data from EHR databases, unifying multiple data sources, and using them consistently with regulatory guidelines. Here, we propose a HAPI definition that meets these requirements.

Toward a Unified HAPI Definition and More Accurate HAPI Classification

We illustrate the challenges in detecting HAPI in EHRs using the Medical Information Mart for Intensive Care III (MIMIC-III) [11] as a case study. MIMIC-III is one of the most widely used open benchmark data sets, built over CareVue and Metavision EHR systems that encompass approximately 59,000 hospital stays. The patient data include demographics, vital signs, laboratory results, physiological measurements, diagnoses, and clinical and nursing notes.

This study highlights the gaps between existing HAPI definitions for MIMIC-III and the guidelines set by CMS and other regulatory bodies. We propose the Emory HAPI (*EHAPI*) definition, which better adheres to the regulatory guidelines. We then demonstrate the impact of our improved definition in training a more accurate HAPI classification model. The classification performance was evaluated using a manually labeled set from nurse annotators as a proxy for the HAPI ground truth.

Our main contributions are as follows:

1. An improved HAPI definition that leverages diverse data sources and accounts for their reliability while adhering more closely to clinical guidelines
2. Illustrating the impact of the noncomprehensive HAPI definition on training a HAPI prediction model

To achieve these objectives, we pursue the following steps: (1) describe challenges in finding evidence for HAPI within different sources in the MIMIC-III data set, (2) use nursing expertise with clinical information to prioritize and combine conflicting data sources, (3) establish core parameters for a practically reasonable HAPI definition, and (4) determine the impact of the definition on the performance of tree-based and neural network–based HAPI classifiers.

Methods

Overview of Data Sources for PI in Hospital Stays

There are 4 major sources of EHR data that may contain information on PI: patient chart events, diagnosis codes, notes, and procedures performed.

Chart Events

Chart events constitute the largest portion of structured clinical data and include many medical services, including laboratory tests, vital signs, nurses' assessments, and general indicators such as patient mental status. Chart events are time-stamped and provide information on the time and order of events during the hospital stay.

Diagnosis Codes

For billing purposes, each hospital stay contains a limited set of diagnosis codes. These codes usually include the most important diagnoses during the hospital stay; however, financial concerns and imperfect mapping of clinical findings to predetermined codes can impact this.

Notes

Clinical notes include any unstructured text information such as radiography reports, electrocardiogram reports, discharge summaries, admission notes, and daily notes made by the care team.

Procedure Codes

Procedure codes indicate timed medical services and surgeries.

PI staging is a core element of the HAPI deterioration status from admission to discharge. Most modern clinical information systems, including the Metavision and CareVue clinical information systems in the MIMIC-III and Emory Healthcare's clinical data warehouse, contain PI staging events and notes. Multimedia Appendix 1 [12] summarizes the details of the PI data sources in the MIMIC-III.

Ideal HAPI Criteria Based on Guidelines

Regulatory authorities identify HAPI using many elements, including the presence of PIs at admission and discharge, changes in stages, unit transfers during admission, and patient death. CMS provides several inclusion and exclusion criteria for HAPI [13-15]. One inclusion criterion is the presence of one or more new or worsened PIs at discharge compared with admission. This includes stages 2 to 4, or PIs not staged owing to slough or eschar, nonremovable dressing or device, or deep tissue injury. Another inclusion criterion is an unstageable PI on admission that is later staged. This is coded on discharge assessment as "present on admission," with the earliest assessed numerical stage. A patient stay is excluded if data on new or worsened stages 2, 3, and 4, or unstageable pressure ulcers, including deep tissue injuries, are missing on the planned or unplanned discharge assessment. In addition, a patient stay is excluded when the patient died during the hospital stay.

The standard practice for newly admitted patients is the completion of admission assessment, as close as possible to the time of admission and within 24 hours. AHRQ also suggests "performance of comprehensive skin assessment within 24 hours of admission" to accurately assess PI rates [16]. The National Pressure Injury Advisory Panel (NPIAP) reference guide [17] defines the facility-acquired rate as the "percentage of individuals who did not have a pressure injury on admission who acquire a pressure injury during their stay in the facility."

Existing MIMIC-III HAPI Case Definitions and Their Limitations

There are 4 existing HAPI definitions for MIMIC-III, which are summarized in the subsequent section. Detailed flowcharts for the various definitions are provided in Multimedia Appendix 1.

Recurrent additive network for temporal risk prediction (CANTRIP) [10] focused on predicting HAPI 48 to 96 hours before its first appearance, or date of event (DOE). The DOE was defined as the first occurrence of either mention of PI-related keywords in time-stamped hospital notes or a PI staging chart event (≥stage 1) >48 hours after admission. Other stays without a DOE were marked as controls. Unfortunately, the CANTRIP case definition included deceased patients and healed or improved PIs.

Cramer et al [6] sought to develop a screening tool for PI by using the first 24 hours of data. They identified HAPI cases using only the PI staging chart events occurring 24 hours after admission. It excluded stage 1 PIs and "unable to stage" and deep tissue injury PIs. Similar to CANTRIP, the Cramer case definition included deceased patients and healed or improved PIs. Other stays constituted the control group.

Sotoodeh et al [9] explored the use of negation preprocessing on clinical text to detect PI. Case patients were defined using International Classification of Diseases (ICD)-9 codes or PI-specific keywords in the clinical notes. Similar to CANTRIP and Cramer definitions, deceased, healed, or improved PIs were included in the case definition. However, in contrast to the CANTRIP and Cramer definitions, they did not consider PI staging chart events. Control stays were defined as the absence of both ICD-9 codes and PI-specific keywords.

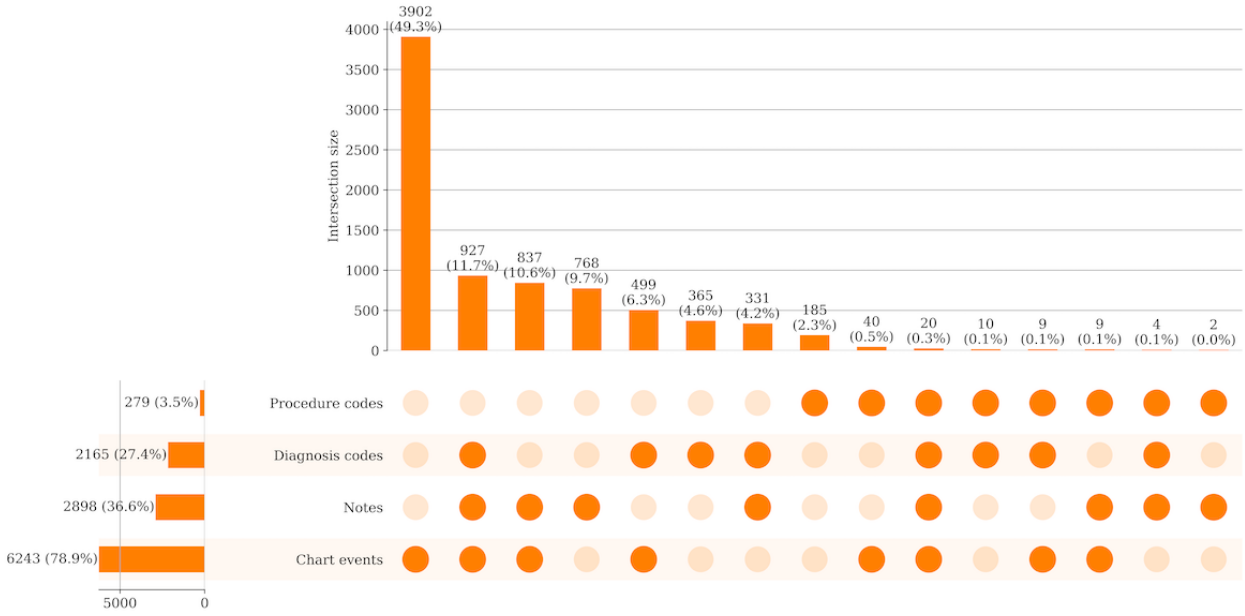
Cox et al [7] focused on identifying appropriate risk factors for PI by using selected variables from the existing literature. They identified a subset of patients who did not have preexisting PI on admission. However, the inclusion and exclusion criteria for identifying HAPI were not explicitly mentioned and are therefore not presented here.

Other studies have focused on predicting HAPI by using other EHR databases. Ranzani et al [8] focused on predicting PI within 30 days of intensive care unit admission in the first 24 hours. They excluded patients who had a preexisting PI on admission or developed PI within the first 48 hours. The case definition was similar to that of CANTRIP, except that notes were not used. Song et al [18] also proposed an early assessment tool for PI risk using 28 relevant features from existing literature. However, the case definition was not discussed in detail. Finally, Hyun et al [19] developed a machine learning model to predict the HAPI. HAPI cases were defined as those containing an ICD-9 code associated with a PI.

EHAPI Case Definition in MIMIC-III

On the basis of existing and ideal HAPI criteria, we identified several essential elements to create a HAPI case definition using EHR data and applied it to MIMIC-III. MIMIC-III has limitations, that is, incongruence of data sources regarding PIs presence and complexity of extracting stage data to verify PI deterioration criteria from admission to discharge, for stays with only comments about PIs in nursing notes and not as timed structured data (Figure 1 and section *Limitations and Future Work*). These limitations inform this exemplar MIMIC-III HAPI case definition.

Figure 1. Medical Information Mart for Intensive Care III (MIMIC-III) data sources consistency for pressure injury (PI) hospital stays.



For the HAPI criteria, we can include or exclude deceased patients, set a minimum age, and consider either 24 or 48 hours from admission to determine admission PIs status. Further decisions for HAPI criteria include the set of clinical events related to PI staging data, the minimum numerical stage for HAPI, numerical stage values assigned to deep tissue injury and unstageable PIs, and the inclusion or exclusion of healed or improved PIs at discharge. Moreover, in addition to staging events, to determine HAPI labels, we considered the presence of certain keywords or diagnosis codes in the notes. We propose a more comprehensive version of the previous definitions, *EHAPI*. The *EHAPI* definition is based on the updated version of the HAPI criteria as determined by the CMS, NPIAP, and AHRQ guidelines [2,14-16]. We extracted data from the admission, patient, and intensive care unit stay tables in the MIMIC-III to construct features and remove irrelevant stays from our analysis.

Our case definition considered only new PIs or PIs that deteriorated by discharge, which required determining the PI stages at admission and discharge for each hospital stay. If a patient had multiple hospital stays, we treated each stay separately. Moreover, in MIMIC-III, a hospital stay encompasses ≥1 intensive care unit stays. Staging occurred within 24 hours of admission. Stage 4 is deep PI, and "unable to stage" was coded as 0. In the absence of the PI stage information at admission, the stage was set to 0. Discharge stage was set as the last recorded stage above 2 occurring later than 24 hours of admission, considering deep tissue injury as stage 3 and "unable to stage" as stage 5. "Unable to stage" was set to stage 5 to capture all possible HAPI irrespective of the admission stage. On the basis of NPIAP documentation [20], deep tissue injury was either stage 3 or 4 PI. Therefore, to allow exclusion from the HAPI criteria because of stage improvement during the stay, we coded deep tissue injury as stage 4 at admission and stage 3 at discharge.

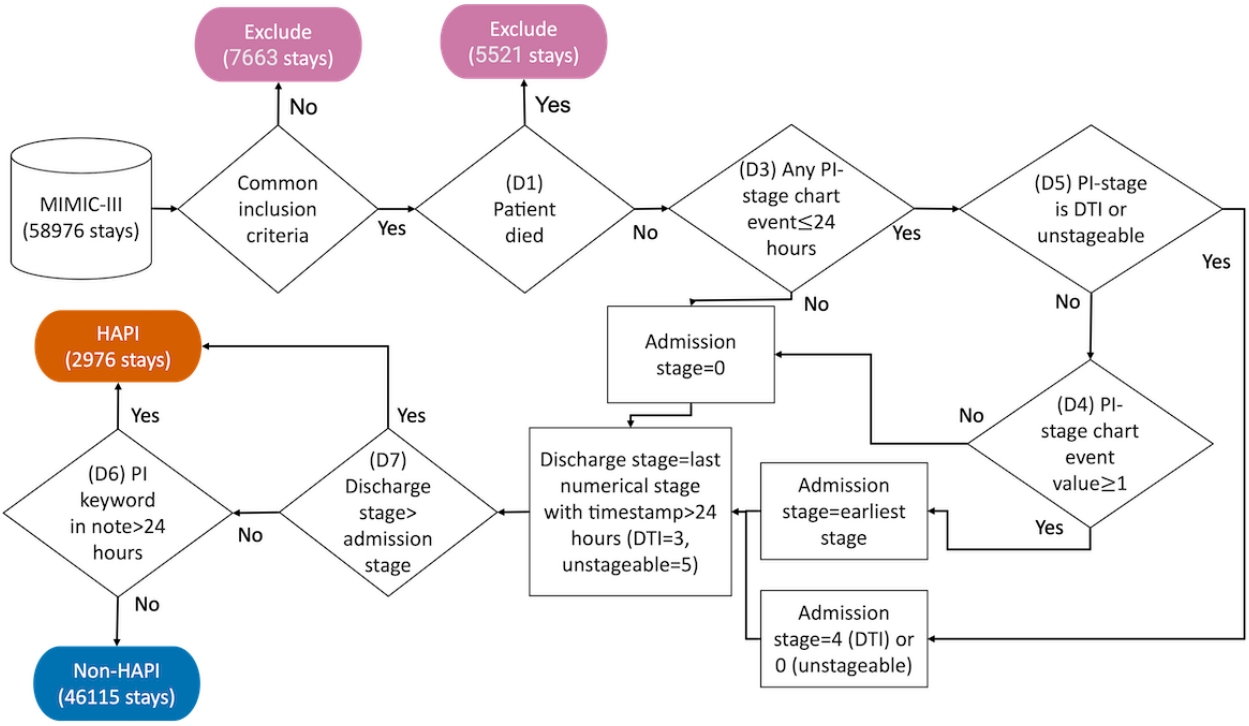
We excluded the stays that did not meet the common inclusion criteria. The common inclusion criteria across the four definitions were as follows: (1) presence of at least one clinical note, (2) documented discharge time as after admission time, (3) the patients aged <15 years, and (4) no admission documentation of a PI. *EHAPI* excluded patients who died in the hospital. We excluded deceased patients for three reasons: (1) adherence to CMS guidelines (including the need for a discharge PI stage that is not available in deceased patients), (2) potential bias of the computational model toward learning characteristics of deceased patients instead of HAPI, and (3) weakness and fragility in patients who have terminal illness result in PI occurrence and do not reflect poor nursing care quality. We conducted an experiment that included deceased patients and observed that some deceased patients were classified as HAPI when they were not HAPI cases.

We found that some HAPI cases lacked PI staging events and yet contained PI keywords in their notes. Thus, the *EHAPI* also checked the PI-related keywords that occurred in notes later than 24 hours after admission. We scanned all stays for PI-related keywords mentioned in notes later than 24 hours after admission; if present, we considered these cases to be HAPI cases. We used negation detection and analyzed the notes of these cases to ensure that the keywords were not spurious (Multimedia Appendix 1). Other stays constituted the control

group. Figure 2 provides the flowchart for the *EHAPI* case definition process.

To ensure the generalizability of the *EHAPI* definition, Multimedia Appendix 1 shows the HAPI-related SNOMED and ICD-10 codes used in many clinical information systems. However, the keywords for notes may need to be tailored to each hospital system. For details of the PI lists, keywords, and mappings in MIMIC-III used for the *EHAPI*, CANTRIP, Cramer, and Sotoodeh definitions, we refer the reader to Multimedia Appendix 1.

Figure 2. Flowchart for the Emory hospital-acquired pressure injury (*EHAPI*) definition. Common inclusion criteria across existing definitions and *EHAPI* are the presence of notes, patients aged 15 years and older, discharge time after admission time, and no pressure injury (PI) diagnosis on admission. D: dimension; DTI: deep tissue injury; HAPI: hospital-acquired pressure injury; MIMIC III: Medical Information Mart for Intensive Care III.



Assessing Impact of HAPI Labels on Classification Performance

We compared the 3 existing HAPI definitions for HAPI classification in MIMIC-III with our *EHAPI* definition. One systematic review [21] study looked at data-driven models for PI prediction and risk assessment and concluded that many of these predictive models were difficult to compare because they were not externally validated and did not use the same data set.

Event Time Stamp Definition

For each hospital stay, we identified an event time stamp for feature construction. The idea is that for HAPI cases, HAPI-related information is not directly or indirectly present in the features (ie, target or label leakage). Similarly, for non-HAPI cases, we prevented biasing the classifier from predicting longer note durations that would be associated with non-HAPI stays. The event time stamp for HAPI cases is the time of the first PI stage assessment that occurred later than 24 hours after admission. The assessment is the earliest time stamp of either the PI staging chart event or the mention of any of the defined PI keywords in the notes.

For control stays, we matched the non-HAPI duration distribution with the HAPI duration distribution. We modeled the duration of the notes in case stays (the time difference between the earliest note and event time stamp) as a random variable. We used the *scikit-learn* [22] package to learn the density distribution for this random variable (ie, the estimated distribution with the smallest chi-square score). We then sampled the duration from this estimated distribution for the allowed note length for control stays. Each sampled duration pairs with a true duration length by preserving the ranked order (ie, the fifth smallest duration of sampled length and true length paired with each other). The minimum sampled length and true duration length then serve as the event time stamp (ie, earliest note+sampled length) for the control stay. Thus, if the sampled event time stamp exceeds the stay duration, then the event time stamp is the original stay discharge time.

Notes for HAPI Classification

Hospital stay features are based on patient notes. Machine learning models then only use notes with a time stamp before the event time stamp, or notes of interest, as features. If there were no notes of interest, the stay was excluded from the experiments. The notes of interest were then concatenated into a single document. This minimized the potential for label or target leakage, where HAPI-related information was directly or indirectly present in the features. For instance, defined PI-related keywords do not appear in the concatenated document. Similarly, the feature construction excludes notes after the first staging assessment, thereby preventing implicit PI-related words.

Thus, feature construction excludes all elements discussed in the definition of the HAPI.

Classifiers

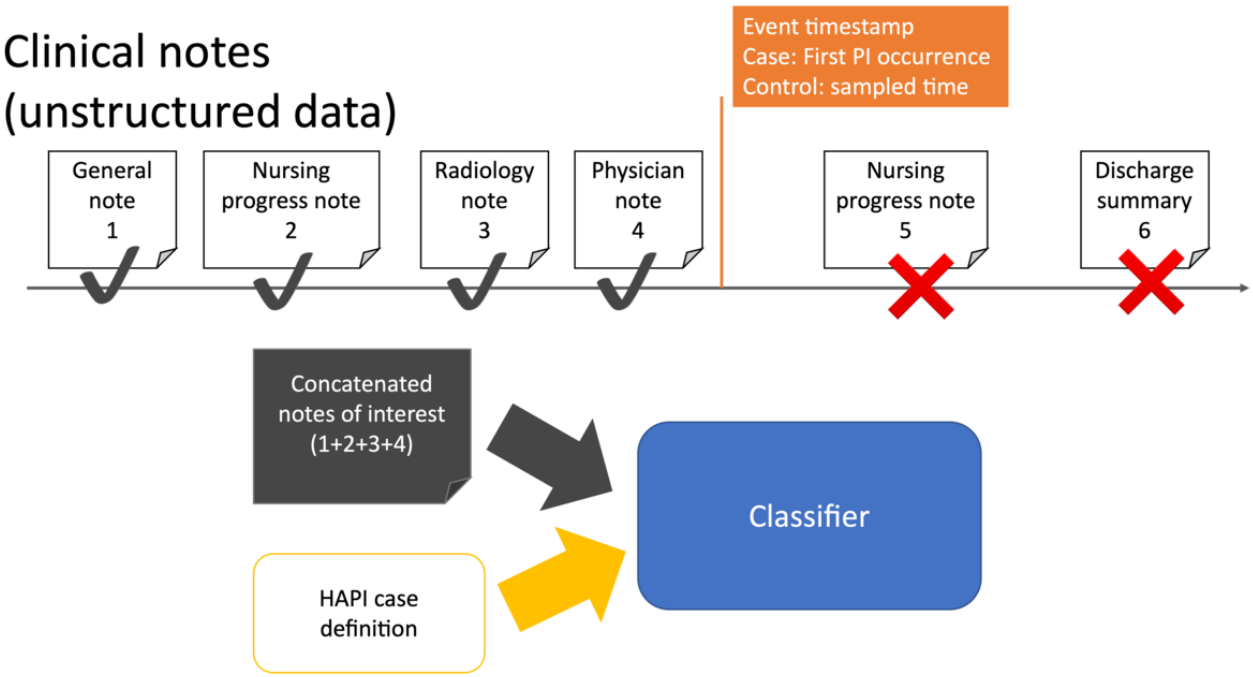
We chose 2 classifiers to demonstrate that the relative impacts of HAPI labels from the case or control definitions are independent of classifier choice. We chose gradient boosting, a tree-based classifier, and a sequential neural network–based classifier. The latter consisted of input word embedding learned from the features of each definition, a global max pooling layer, and several dense layers. The selected classifiers offer superior performance compared with other tested classifiers (ie, decision tree, logistic regression, support vector machine, multilayer perceptron, random forest, or AdaBoost).

The term frequency–inverse document frequency vector of the abridged notes (described in the aforementioned section) is the feature vector of each stay for the tree-based classifier (with a 5000-word vocabulary). The sequential neural network model uses a sequence of 800 words for each document. The 4 different HAPI definitions (ie, CANTRIP, Cramer, Sotoodeh, and *EHAPI*) used the same features to yield unbiased model performance comparisons with different definitions.

Train-Test Compositions and Evaluation Metrics

Because HAPI criteria differed across definitions, the samples for the prior papers were different (eg, *EHAPI* discards deceased patients, but others have it either as a case or control). Nevertheless, there were considerable case overlaps across the samples (Figure 3). For a valid comparison, we created 10 different test sets consisting of three parts: (1) consensus HAPI case stays where the definitions agreed, (2) randomly subsampled consensus HAPI control stays, and (3) manually annotated stays where the definitions disagreed. For the latter stays, our nursing experts, a coauthor (WZ), and her nurse colleague (Deborah Silverstein, DNP) assessed and labeled 97 patient stays for HAPI based on the EHR data. The 97 stays constructed each constituent subset proportional to the total size of the differently labeled stay subset (Table S1 in Multimedia Appendix 1). Annotation relies not only on nursing guidelines but also on nursing experience and case discussion between the 2 nurses. Furthermore, one of our nurse annotators (Deborah Silverstein, DNP) was unaware of the *EHAPI* criteria and labeled the samples from a clinical practitioner's perspective. Out of the 97 admissions, our nursing experts marked 19 as HAPI.

Figure 3. An illustrative example of the feature construction used to train the classifier including determination of the notes of interests using the event time stamp. Feature construction excludes notes 5 and 6 since they are after the event time stamp. HAPI: hospital-acquired pressure injury; PI: pressure injury.



The manually annotated subset was augmented with consensus stays. There were 219 HAPI cases identified by the 4 definitions, which were included in the 10 test samples. The remaining 3620 non-HAPI stays were randomly sampled from the 41,241 admissions where all 4 definitions agreed on the label. Each test set contained 3936 stays and 7% HAPI prevalence. The main difference between each test set was the 3620 randomly sampled non-HAPI consensus stays, as the 97 manually annotated stays and 219 consensus HAPI cases were present in all test sets.

For each definition, the training samples were the remaining eligible stays that were not in the shared test set. As an example, because CANTRIP did not exclude stays with deceased patients, we included these in the training sample. The training labels were set using definition-specific HAPI criteria. Therefore, although the test samples and labels were the same, the classifier trained for each definition had a different training set and definition-specific label. Figure 3 illustrates the overall process for training the classifier, including the feature construction and label determination.

For the experiments, 5-fold cross-validation of the training set determined the best classifier hyperparameters, as shown in Table S2 in Multimedia Appendix 1. The test performance was the average of 10 different test and training data partitions. Given the unbalanced classes, we report both area under the precision-recall curve (AUPRC) and area under the receiver operating characteristic curve (AUROC).

Ethical Considerations

The patients were not explicitly recruited to acquire the data used in this work. The MIMIC-III data set has been deidentified through elimination of attributes revealing patients' identity.

Approval for data collection, processing, and release for the MIMIC-III database was granted by the Institutional Review Boards of the Beth Israel Deaconess Medical Center (Boston, United States) and Massachusetts Institute of Technology (Cambridge, United States).

Results

Consistency of MIMIC-III Data Sources for PI Hospital Stays

Even without consideration of patient attributes or timing, evidence shows conflicts among data sources for identifying PI case hospital stays in MIMIC-III. Figure 1 presents an UpSet plot that summarizes the intersection of PI-related information across the 4 data sources (ie, procedure codes, diagnosis codes, notes, and chart events) for stays with at least one data source indication of PIs (7908 total stays). The data source bar charts (bottom left side) plot the cardinality (or size) of the number of stays with the data source indication. Chart events were the most common indicator (6243/7908, 78.95%), whereas procedure codes only appeared in 3.53% (279/7908) of the stays. The bar charts along the x-axis plot the size of the intersections among the observed set combinations. The results demonstrate limited consensus among the data sources, as only 0.25% (20/7908) of the stays had PI documentation across all data sources. Even agreement among ≥3 data sources was relatively low, with 945 stays (927+9+9). This can be contrasted with 49.34% (3902/7908) and 9.71% (768/7908) of the stays containing only an indication in the chart events and notes, respectively.

Analyzing Differences in HAPI Case Definitions

On the basis of the 4 HAPI case definitions, there are 8 dimensions in which the criteria diverge. The exclusion criteria encompass deceased patients (D1), minimum age (D2), and the amount of time to ascertain PIs on admission (D3). The determination of HAPI includes the minimum PI stage (D4), consideration of deep tissue injury or unstageable events (D5), use of PI-specific keywords in the notes (D6), calculation of deteriorating or new PIs (D7), and use of ICD-9 codes (D8). Table 1 summarizes the decisions along these 8 dimensions for the 4 different definitions. As can be observed from the table, *EHAPI* definition excludes the deceased entirely from case or control and ascertains whether the PI deteriorated or newly developed. Both the Cramer and Sotoodeh definitions yielded substantially lower estimates of HAPI prevalence, whereas CANTRIP had the highest prevalence at 8.46% (4261/50,376).

An UpSet plot capturing the overlap between HAPI stays across the 4 definitions is shown in Figure 4. Only 4.63% (219/4731) of HAPI stays shared 4 definitions. CANTRIP had the highest number of unique positive stays (n=1134), arising from considering PI stages above 1 and deep tissue injury and unstageable events as positives. We observed 315 stays unique to *EHAPI*, attributed to the cutoff period (24 vs 48 with CANTRIP). *EHAPI* had the highest overlap, 53.98% (2554/4731) with CANTRIP, followed by Cramer at 22.53% (1066/4731) and Sotoodeh at 17.84% (844/4731). The details of the number of PIs identified using notes, staging, and ICD-9 codes for each definition are provided in Multimedia Appendix 1.

Table 1. Definition properties and compositions along the 8 criteria dimensions (Ds).

Definition	D1[a]	D2[b]	D3[c]	D4[d]	D5[e]	D6[f]	D7[g]	D8[h]	Cases, n (%)
EHAPI[i] (n=44,823)	Yes	15	24 h	2	Yes	Yes	Yes	No	2976 (6.64)
CANTRIP[j] (n=50,376) [10]	No	15	48 h	1	Yes	Yes	No	No	4261 (8.46)
Cramer (n=50,276) [6]	No	18	24 h	2	No	No	No	No	1572 (3.13)
Sotoodeh (n=50,276) [9]	No	18	N/A[k]	N/A	N/A	Yes	No	Yes	1027 (2.04)

[a]D1 denotes the decision of whether to exclude deceased.

[b]D2 refers to the minimum age in years.

[c]D3 indicates the cutoff period for determining preexisting pressure injury (PI).

[d]D4 characterizes the minimum numerical PI stage.

[e]D5 signifies whether deep tissue injury or unstageable PI staging chart events are hospital-acquired pressure injury (HAPI).

[f]D6 represents whether PI keywords present in notes are considered an HAPI event.

[g]D7 designates whether the criteria captured worsening or newly developed PI.

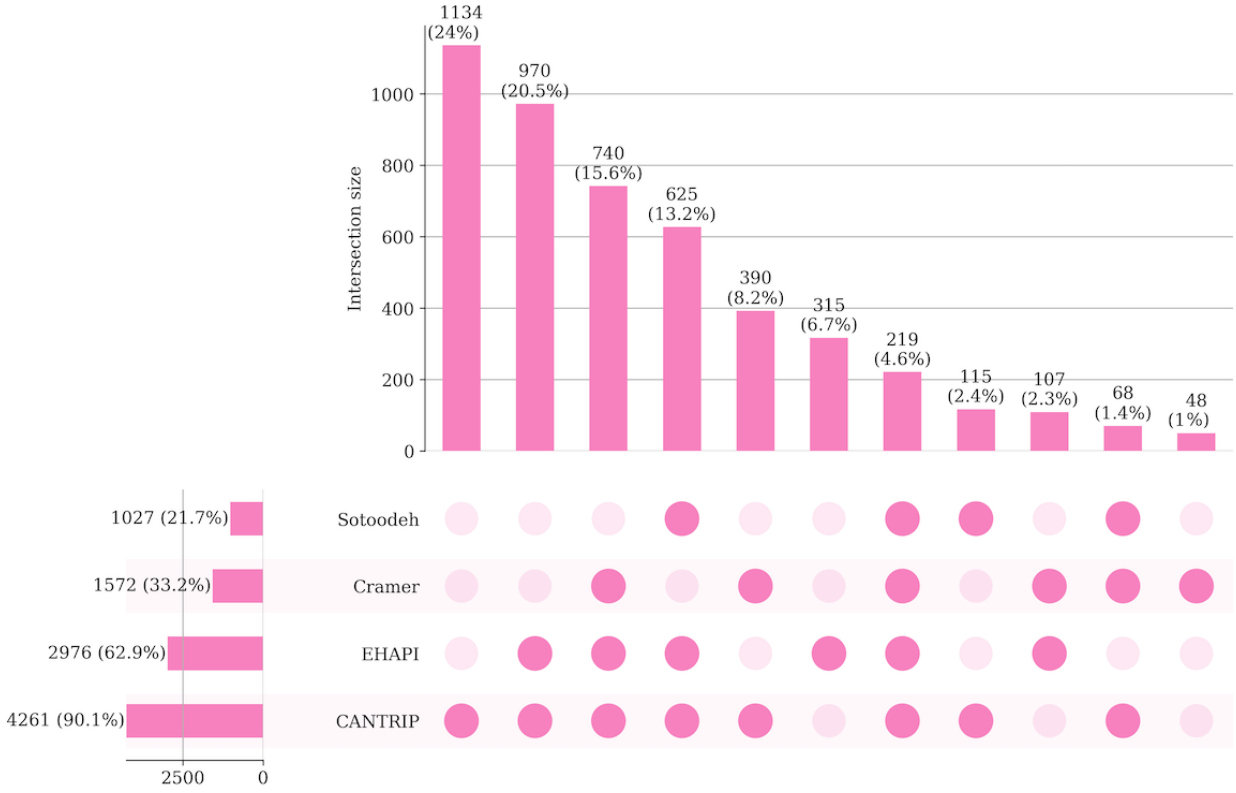
[h]D8 captures whether International Classification of Diseases 9 codes use HAPI for identification.

[i]*EHAPI*: Emory hospital-acquired pressure injury.

[j]CANTRIP: recurrent additive network for temporal risk prediction.

[k]N/A: not applicable.

Figure 4. Overlap of hospital-acquired pressure injury (HAPI) stays across the 4 definitions. CANTRIP: recurrent additive network for temporal risk prediction; *EHAPI*: Emory hospital-acquired pressure injury.



Impact of HAPI Labels on Classification Performance

We evaluated the performance of the gradient boosting and sequential neural network classifiers trained on labels determined by the 4 HAPI definitions by using AUPRC and AUROC for each case. Table 2 presents the results for the 10 described test sets. Table S3 in Multimedia Appendix 1 summarizes the performance based on the test label source (ie, nurse or consensus). Classifiers trained on the *EHAPI* criteria performed better than those trained on other 3 criteria with an improvement in AUROC up to 0.03 and in AUPRC up to 0.11. A 1-sided paired *t* test (1-tailed) between *EHAPI* and the next best performing definition (CANTRIP) resulted in a *P* value of <.001 for AUPRC and AUROC for the better-performing gradient boosting classifier and machine epsilon for other classifiers and definitions (except neural networks and CANTRIP), demonstrating the merits of the *EHAPI* definition. Further analysis of the models' performance stability and the most important words in each setting are provided in Figure S6 and Table S4 in Multimedia Appendix 1. A GitHub repository [23] contains scripts for these experiments, the generation of the stay labels, and the other presented results.

Table 2. Classifiers' performance for the 4 hospital-acquired pressure injury definitions in Medical Information Mart for Intensive Care III over 10 test sets. The results represent the average across test sets with the SD in parenthesis and the *P* value.

Definition	Gradient boosting				Neural networks			
	AUPRC[a]		AUROC[b]		AUPRC		AUROC	
	Mean (SD)	*P* value	Mean (SD)	*P* value	Mean (SD)	*P* value	Mean (SD)	*P* value
EHAPI[c]	0.46 (0.015)	N/A[d]	0.90 (0.003)	N/A	0.44 (0.015)	N/A	0.88 (0.004)	N/A
CANTRIP[e] [10]	0.44 (0.017)	≤.001	0.89 (0.003)	≤.001	0.41 (0.010)	≤.001	0.88 (0.005)	.02
Cramer [6]	0.35 (0.015)	≤.001	0.87 (0.005)	≤.001	0.38 (0.022)	≤.001	0.86 (0.006)	≤.001
Sotoodeh [9]	0.33 (0.015)	≤.001	0.87 (0.004)	≤.001	0.35 (0.015)	≤.001	0.86 (0.006)	≤.001

Discussion

Principal Findings

Given the low concurrence of PI between data sources, any HAPI classification requires careful reconciliation of conflicts between data sources. On the basis of discussions with our nursing collaborators (WZ, RN, PhD; Deborah Silverstein, RN, DNP; and RLS, RN, DNP), we prioritized data source reliability as (1) chart events, (2) notes, and (3) diagnosis codes. Charting events were least likely to have a false positive and had better coverage than the other 2 data sources. The nurses indicated that PI indications from notes have false positives, as keywords are preceded by a negative word (ie, no PI), or denote suggestions for PI prevention. Diagnosis codes include only the most prominent diagnoses and might include diagnoses of earlier admissions. In addition, their lack of time stamps prevents investigation of the deterioration condition of the HAPI. Because procedure codes are not specific and inconsistent with other PI sources, we excluded them from the *EHAPI* definition.

As shown in Table 2, the classifiers trained using the *EHAPI* definition achieved the best performance. Moreover, the AUROC of the resulting classifiers from 4 definitions were consistently high (≥0.86). The high AUROC is consistent with the CANTRIP results (AUROC of 0.87) [10] and Sotoodeh results (AUROC of 0.95) [9]. However, the AUPRC remains unacceptable, with the highest performance achieved by gradient boosting (0.46). These values are consistent with the existing literature, as CANTRIP reported precision and recall of 0.42 and 0.71, respectively [10], and Cramer reported precision and recall of 0.09 and 0.71, respectively [6]. This illustrates that to identify the HAPI cases, the computational model generates a sizeable portion of false positives.

Limitations and Future Work

CMS-defined guidelines specify that HAPI are only newly developed, unhealed, or deteriorated PIs. Unfortunately, this involves matching admission and discharge PIs, as a patient may be admitted with >1 PI and discharged with more or fewer PIs. The deterioration condition describes each PI individually. However, given the limited data in the event table of MIMIC-III, our case criteria assume that stays are associated with only one PI. Further analysis of multiple possible PI locations yielded better grouping. However, unless skin assessments at admission and discharge are documented in a structured format, matching PIs is difficult. Ideally, the “deteriorated PI” criterion applies to positive PI samples using patient notes as well. However, information on the PI stage is difficult to obtain from notes and, thus, is not implemented in the current case definition. We plan to study the HAPI in other data sets that have better PI documentation practices to fully understand the impact of multiple PIs.

Another limitation of our study is the use of a simple negation detection algorithm to identify false positives occurring with positive PI mentions in the clinical notes. The keyword list disregarded structure matches such as “bedsore: none,” and the negation detection mainly captures instances of text that mentioned “no bedsore observed.” However, instances of negation in more complex textual descriptions may be missed, thus creating false positives in the identified 2976 HAPI stays. A manual inspection of the 1175 case stays labeled through the PI keyword mentions route is left for future work.

Enhancing the manually labeled samples in the 10 test sets beyond the 97 randomly selected ones is another avenue for future research. The small curated set was not large enough for stand-alone analysis, as it yielded large performance variations across the test sets. Unfortunately, it was labor intensive for our nursing annotators to annotate the samples; thus, further annotation is beyond the scope of this work.

In addition, we note that our assessment of the impact of the HAPI definition is based only on MIMIC-III. Furthermore, MIMIC-III contains data collected only in critical care settings. To better understand the performance implications of the HAPI definition, applying implications to other settings, such as the general care units, as well as other health care systems, is needed. We plan to apply these *EHAPI* criteria to define HAPI in more data sets.

In addition to the focus on critical care stays, the MIMIC-III has unique demographic characteristics, such as predominantly Caucasian. We plan to test the generalizability and impact of the *EHAPI* case definition against more data sets with diverse demographics including higher percentages of African American, Asian, and Hispanic individuals or different insurance compositions.

A recent systematic review on the utility of decision support systems for PI management concluded that their adoption in practice has clinical significance in terms of reducing PI incidence and prevalence, but statistical significance was not observed [24]. This emphasizes the importance of studying practical challenges in the adoption of data-driven PI methods by nurses. Moreover, the practical deployment of a computational model necessitates a higher AUPRC to prevent false alarms. Thus, an open question is whether the integration of other patient information in addition to clinical notes, such as physiological measurements, patient demographics, and medications, yields better predictive performance.

Conclusions

An accurate definition of HAPI based on clinical data is critical for automating nursing quality metrics and for valid comparisons of HAPI machine learning models. However, one of the major challenges is the inconsistency of the PI indicators across various data sources. We demonstrate the lack of congruency between the 3 existing HAPI definitions for MIMIC-III and highlight the gaps between each definition and the CMS and AHRQ regulatory guidelines. We then created a refined definition, the *EHAPI*, that more closely reflects the regulatory guidelines. Our experimental results using 2 different classifiers illustrate the impact of the definition on the predictive performance when evaluated on an unseen combination of a small, manually labeled set by 2 nurse annotators and a random sample of the consensus set (ie, all 4 definitions agree on the labels). This reinforces the need for a high-quality standardized HAPI definition, as the *EHAPI* achieves a better predictive performance across multiple test sets.

Acknowledgments

The authors express their deepest gratitude to the following nurse collaborators: Cynthia A Oster, PhD, RN, APRN, MBA, ACNS-BC, ANP, FAAN, Nurse Scientist for Patient Safety—Emory Healthcare, Adjunct Assistant Professor—Nell Hodgson Woodruff School of Nursing, Emory University; and Deborah Silverstein, DNP, APRN, FNP-C, Instructor, Nell Hodgson Woodruff School of Nursing, Emory University. The authors also thank the anonymous reviewers for their suggestions and comments.

This research was supported by the National Library of Medicine of the National Institutes of Health under the award number R01LM013323-01.

Data Availability

Medical Information Mart for Intensive Care III (MIMIC-III) data can be downloaded from the PhysioNet webpage after completing the required Collaborative Institutional Training Initiative, data or human subjects research training. The scripts used to preprocess the data and obtain the presented results can be found in the GitHub repository.

Authors' Contributions

All authors conceptualized the study. MS designed and conducted the data analysis and generated the results. MS conducted the data preprocessing. MS is responsible for the integrity of the work. MS drafted the paper. WZ and RLS provided nursing expertise throughout the study and provided recommendations for study parameters. All authors participated in the writing and revising of the manuscript. All aspects of the study (design; management, analysis, and interpretation of data; writing of the report; and decision to publish) were led by the authors. All authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Multimedia Appendix 1

The supplementary material containing the Medical Information Mart for Intensive Care III details for the Emory hospital-acquired pressure injury definition, additional comparisons between the 4 case definitions, and further experimental results related to this study.

Abstract

Background: The accuracy of electronic health records (EHRs) for identifying postpartum depression (PPD) is not well studied.

Objective: This study aims to evaluate the accuracy of PPD reporting in EHRs and compare the quality of PPD data collected before and after the implementation of the *International Classification of Diseases, Tenth Revision* (*ICD-10*) coding in the health care system.

Methods: Information on PPD was extracted from a random sample of 400 eligible Kaiser Permanente Southern California patients' EHRs. Clinical diagnosis codes and pharmacy records were abstracted for two time periods: January 1, 2012, through December 31, 2014 (*International Classification of Diseases, Ninth Revision* [*ICD-9*] period), and January 1, 2017, through December 31, 2019 (*ICD-10* period). Manual chart reviews of clinical records for PPD were considered the gold standard and were compared with corresponding electronically coded diagnosis and pharmacy records using sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). Kappa statistic was calculated to measure agreement.

Results: Overall agreement between the identification of depression using combined diagnosis codes and pharmacy records with that of medical record review was strong (κ=0.85, sensitivity 98.3%, specificity 83.3%, PPV 93.7%, NPV 95.0%). Using only diagnosis codes resulted in much lower sensitivity (65.4%) and NPV (50.5%) but good specificity (88.6%) and PPV (93.5%). Separately, examining agreement between chart review and electronic coding among diagnosis codes and pharmacy records showed sensitivity, specificity, and NPV higher with prescription use records than with clinical diagnosis coding for PPD, 96.5% versus 72.0%, 96.5% versus 65.0%, and 96.5% versus 65.0%, respectively. There was no notable difference in agreement between *ICD-9* (overall κ=0.86) and *ICD-10* (overall κ=0.83) coding periods.

Conclusions: PPD is not reliably captured in the clinical diagnosis coding of EHRs. The accuracy of PPD identification can be improved by supplementing clinical diagnosis with pharmacy use records. The completeness of PPD data remained unchanged after the implementation of the *ICD-10* diagnosis coding.

Introduction

Postpartum depression (PPD), major or minor depressive episodes occurring within 12 months after childbirth, is a common obstetric complication in the United States, with a prevalence of 13.2% in 2018 [1]. The American College of Obstetricians and Gynecologists recommends all obstetrics care providers conduct comprehensive screening for PPD and anxiety disorders using a validated instrument for each patient separately during their postpartum visit [2]. Meanwhile, the American Academy of Pediatrics recommended routine PPD screening to be integrated at well-child visits (1-, 2-, 4-, and 6-month infant visits) [3]. The US Preventive Services Task Force also supports the provision of depression screening during postpartum visits, citing moderate net benefits for identifying those affected and recommending referrals to counseling interventions [4]. It is important to identify those with PPD because undetected or untreated depressive episodes can negatively impact the patient and their infant's health and well-being. For instance, about 9% of pregnancy-related deaths were due to mental health conditions [5]. Early PPD was also associated with increased behavior disturbances in the infant [6]. Moreover, other potential risk factors, including a prior history of depression, depression and anxiety episodes during pregnancy, preterm birth and lower infant birth weight, traumatic birth experience, stressful life events during early postpartum, and low social support, have been linked with PPD [7-9].

Health systems previously used the *International Classification of Diseases, Ninth Revision* (*ICD-9*), an official coding system to identify hospital-related diagnoses and procedures in the United States [10]. However, the Kaiser Permanente health systems shifted to using the *International Classification of Diseases, Tenth Revision* (*ICD-10*) codes after October 1, 2015, which has significant improvements over *ICD-9* for many clinical codes [11]. However, Stewart et al [12] concluded that there is a need to perform a validation of diagnosis codes for each mental health condition following the *ICD-10* transition. Colvin et al [13] used a data linkage of national pharmacy records and hospital admission information to identify patients with major depressive episodes in pregnancy but found the use of either source alone to be inadequate.

While there are multiple validated scales to screen for PPD, like the Patient Health Questionnaire (9-item) and the Edinburgh Postnatal Depression Scale, validation of these measures has been performed using *ICD-9* or *ICD-10* diagnostic codes as the gold standard [14,15]. Several studies have also developed machine learning algorithms using electronic health record (EHR) data to create risk-based models and examined whether they can predict PPD in large health care systems, relying on PPD ascertained using *ICD-9* or *ICD-10* codes [16,17]. However, the accuracy of *ICD-9* and *ICD-10* codes as the gold standard in ascertaining PPD has not been established previously. Prior validation of *ICD-9* and *ICD-10* found high positive predictive values (PPVs) for ascertaining general depression (89.7% and 89.5%, respectively), but these were not specific to the postpartum period [18]. This study aimed to assess the validity of ascertaining PPD diagnosis using the EHR from a large integrated health care delivery system, Kaiser Permanente Southern California (KPSC).

Methods

Cohort Selection

We identified a random sample of 400 women with live birth records in the Air Pollution and Pregnancy Complications in Complex Urban Environments (APPCUE) study [19] between January 1, 2008, and December 31, 2018, within KPSC, a large integrated health system. The APPCUE study was a retrospective cohort study conducted in collaboration between KPSC and the University of California, Irvine with access to KPSC's comprehensive EHRs. The APPCUE study included all singleton births at KPSC facilities. The EHRs contain patient-level data from out- and inpatient clinical care, including *ICD-9, Clinical Modification* or *ICD-10, Clinical Modification* diagnosis and procedure codes, as well as pharmacy and laboratory test records. From 236,759 pregnancies during the study period, we excluded pregnancies resulting in nonlive births (n=8422) and patients who were not members from the start of their pregnancy through a 1-year postpartum period (n=70,836) to have a complete medical history for this validation study. Of the remaining 157,501 pregnancies, we selected a random sample of 400. Simple random sampling was used to select 100 patients from groups based on EHR data: those without any diagnostic or pharmacy use record for PPD, those with only a diagnostic code for PPD, those with only a pharmacy record indicating treatment for PPD, and those with both diagnostic and pharmacy indications. Additionally, each sample was evenly split (50 each) between the *ICD-9* diagnosis code era (date of delivery 2012-2014) and the *ICD-10* era (2017-2019).

Outcomes

EHR outcomes were determined by the presence of PPD diagnosis codes in inpatient or outpatient encounters in the 12 months after delivery, new prescription order, or pharmacy dispense for the treatment of PPD. Diagnosis codes during the *ICD-9* coding period were 300.4, 309.0, and 311 and during the *ICD-10* period were F32.9, F33.0, F33.2, F33.3, F33.41, F33.9, F34.1, F43.21, and F53.0. Medications included were bupropion, Celexa, citalopram, Cymbalta, desvenlafaxine, duloxetine, Effexor, escitalopram, fluoxetine, Lexapro, paroxetine, Paxil, Pristiq, Prozac, sertraline, venlafaxine, Wellbutrin, and Zoloft.

Gold standard PPD outcomes were determined by review of health records by trained research personnel, who documented any diagnosis or finding of PPD in the record, including in free-text encounter notes, as well as any prescription given for the treatment of PPD. These included new prescriptions for the treatment of PPD. PPD diagnosis and medication were documented independently, both for the EHR data and the chart review. A mother was considered to have PPD if she had either a diagnosis or a prescription noted in the EHR within 1 year postpartum.

Quality Assurance

Multiple individuals were trained on reviewing charts, and a double chart review was performed at the beginning of data

collection as a training exercise and near the middle and at the end of data collection to verify data quality and consistency. At each point, eight charts were randomly selected for review by two abstractors. In case of disagreement on the findings, abstractors met with the trainer to determine the correct result.

Statistical Analysis

The patient population was described in terms of demographics, smoking status, prenatal care, and birth weight using percentages. These characteristics were also described for the study population of the APPCUE study [19] and all live births among KPSC members and the state of California during the study timeframe. The chi-square test was used to compare the distribution of characteristics in the study sample to the APPCUE population, all KPSC births, and the California birth cohort.

Manual chart review findings were treated as the true PPD status. The sensitivity, specificity, PPV, and negative predictive value (NPV) of the electronic records to identify true PPD status were calculated and presented as a percentage and 95% exact binomial CI. Agreement between electronic records and manual review was calculated using the kappa statistic, which adjusts for agreement expected due to random chance, and its 95% CI. The area under the receiver operating characteristic curve was calculated. Each measure was calculated overall and within the *ICD-9* and *ICD-10* coding eras separately. There was no missing data for PPD status; those without documented PPD diagnosis or medication were taken to not have PPD. For patient characteristics, a missing category was included when presenting the data.

The primary analysis focused on the ability of EHRs to capture PPD, while secondary analyses examined the agreement of diagnosis and prescription records separately. The sample size was selected so that the expected width of the CIs for sensitivity and PPV would be at most 10% for the full sample and 13% for the *ICD-9* and *ICD-10* periods if the true sensitivity and PPV were 80%. Higher sensitivity and PPV would yield narrower CIs. The STARD (Standards for Reporting Diagnostic Accuracy Studies) guidelines were followed. All analyses were performed in SAS version 9.4 (SAS Institute).

Ethics Approval

The study was approved by the institutional review board of KPSC and received a waiver for informed consent (IRB 12110).

Results

Cohort Selection

Table 1 shows the distribution of the APPCUE study cohort as well as the overall KPSC birth cohort during the study period. Nearly half (194/400, 48.5%) were Latina, most (379/400, 94.8%) received prenatal care starting in the first trimester, and most (354/400, 88.5%) delivered at 37 weeks of gestation or later. The study sample generally has very similar characteristics to the APPCUE study cohort overall and all KPSC births during the period, though there are some differences relative to all deliveries in the state of California, notably a higher percentage of non-Hispanic White mothers (113/400, 28.3% vs 372,037/2,874,396, 12.9%), older mothers (259/400, 64.8% age ≥30 years vs 1,465,998/2,874,396, 50.0%), and generally higher educational attainment (199/400, 49.8% with at least a college degree vs 1,047,594/2,874,396, 36.5%).

Table 1. Characteristics of the study sample and women delivered in all Kaiser Permanente Southern California (KPSC) hospitals and the state of California (2012-2014 and 2017-2019).

[c]Data from the natality information of the Center for Disease Control and Prevention [20].

[d]Data not available.

Outcomes

The overall agreement of EHR-identified PPD (based on either a diagnosis or a prescription) with medical record review was high, with a kappa of 84.7% (95% CI 78.8%-90.6%). The EHR identified 281 of 286 cases (sensitivity 98.3%, 95% CI 96.0%-99.4%) while maintaining high specificity (95.0%, 95% CI 88.7%-98.4%), PPV (93.7%, 95% CI 90.3%-96.1%), and NPV (95.0%, 95% CI 88.7%-98.4%). There was little difference in the overall agreement between the *ICD-9* coding era (κ=86.0%, 95% CI 78.0%-94.0%) and the *ICD-10* era (κ=83.4%, 95% CI 74.8%-92.1%; Table 2).

[h]*ICD-9: International Classification of Diseases, Ninth Revision.*

[i]*ICD-10: International Classification of Diseases, Tenth Revision.*

Electronic diagnosis records alone were not able to accurately identify PPD, only identifying 187 of 286 cases (sensitivity 65.4%, 95% CI 59.6%-70.9%), with low NPV (50.5%, 95% CI 43.4%-57.6%). PPV (93.5%, 95% CI 89.1%-96.5%) and specificity (88.6%, 95% CI 81.3%-93.8%) were high, however (Table 2). Results were similar when using EHR prescription records alone (sensitivity 67.8%, 95% CI 62.1%-73.2%; specificity 94.7%, 95% CI 88.9%-98.0%; PPV 97.0%, 95% CI 93.6%-98.9%; NPV 54.0%, 95% CI 46.8%-61.1%).

Considering only medication data, the reliability of EHR data for identifying prescriptions for PPD was high, with an overall kappa of 92.5% (95% CI 88.8%-96.2%). Agreement was very high in both the *ICD-9* (κ=92.0%, 95% CI 86.6%-97.4%) and *ICD-10* eras (κ=93.0%, 95% CI 87.9%-98.1%; Table 3). Sensitivity, specificity, PPV, and NPV were all at or above 96% (Table 3).

Agreement for *ICD* diagnostic codes between EHR and manual chart review was much lower overall (κ=55.0%, 95% CI 47.1%-62.9%; Table 3). The PPV was high (90.0%, 95% CI 85.0%-93.8%), with sensitivity lower (72.0%, 95% CI 66.0%-77.5%) and specificity and NPV much lower (both 65.0%, 95% CI 58.0%-71.6%; Table 3). Agreement was similar

between the *ICD-9* (κ=58.0%, 95% CI 47.1%-68.9%) and *ICD-10* (κ=52.0%, 95% CI 40.5%-63.5%) eras (Table 3).

Quality Assurance

During the training process, 8 charts were independently reviewed by two chart abstractors. Their assessments of medication use for PPD agreed for all 8 records (100%), while the assessment of a diagnostic finding agreed for 7 (88%). After training was complete, another 8 records were independently reviewed. All 8 (100%) agreed in their findings for both medications and diagnoses.

Discussion

Principal Findings

This validation study demonstrated the potential to improve the accuracy of PPD case identification from an EHR when using diagnosis codes in conjunction with pharmacy records. The combination of clinical codes and prescription pharmacy records yielded much greater sensitivity and NPV, with no notable loss in specificity or PPV, compared with using either the diagnosis codes or pharmacy records alone. Using either record alone would result in significant undercounting, each missing about one-third of those with PPD, compared to the 95% identified using both together. Furthermore, we observed no significant difference in the *ICD-9* and *ICD-10* codes in terms of ascertaining PPD cases.

We found that electronic records of PPD diagnosis were not a reliable indicator of PPD diagnostic findings identified through chart review, relative to pharmacy records. Pharmacy records have both a sensitivity and specificity much higher than that seen for diagnosis codes.

The quality of data extracted from EHRs for pharmacoepidemiologic research has been proven to be valuable. Although using clinical diagnosis codes for perinatal epidemiology studies has limitations, the use of KPSC's comprehensive pharmacy use records enhances the identification of PPD cases (sensitivity 98.3%, specificity 95.0%, PPV 93.7%, and NPV 95.0%).

While switching from *ICD-9* to *ICD-10* coding created some complexity, we did not see a significant difference in the accuracy of the electronic diagnosis records between the *ICD-9* and *ICD-10* coding eras. This is reassuring, as studies would not need to be limited to one era or the other for the sake of accuracy. Additionally, the prevalence of PPD identified in both periods is essentially the same, suggesting that both *ICD-9* and *ICD-10* coding systems identify patients with PPD at the same

rate, negating any need to adjust prevalence estimates to account for the difference.

Accurate characterization of those with PPD is crucial to performing valid research on this condition. Many researchers rely on electronic records due to a lack of access to detailed patient histories or a lack of time to review these records. Our study suggests that researchers can accurately identify PPD from EHRs using both diagnosis and pharmacy records.

Comparison to Prior Work

Prior research validating diagnosis codes for identifying general depression found the PPV to be similar to that seen in our study (89.7% for *ICD-9* and 89.5% for *ICD-10*), but these were not specific to the postpartum period [18]. These findings highlight the continuing debate regarding the use of diagnosis codes alone for epidemiological studies. Our study concurs with prior findings that the sensitivity and specificity of case ascertainment can be improved by concurrently using both diagnosis and pharmacy records [13]. Therefore, researchers should not rely exclusively on either diagnostic codes or pharmacy records for PPD case ascertainment.

Strengths and Limitations

There are some potential limitations to this study. First, while the KPSC EHR is comprehensive, it may not capture care received outside the system if it is not submitted for reimbursement. Specifically, members may receive mental health counseling from non-KPSC providers, and a PPD diagnosis made in that setting may not be entered into the KPSC medical record, resulting in a potentially missed PPD diagnosis and an underestimate of the sensitivity of diagnosis coding. However, these diagnoses may still be identified during regular clinical care within KPSC, hence limiting the number of potentially missed diagnoses.

Second, misclassification is also possible as variables were ascertained from clinical diagnosis codes and pharmacy record notes. In addition, there is the potential for misclassification of PPD within the data sources if women are unaware of the condition, do not seek medical care, or the diagnosis or treatment is not recorded in the clinical notes. Any completely undocumented cases would result in an underestimate of PPD in the population, though its potential effect on our validation is unknown. Finally, due to the small number of records reviewed in some groups, we were not able to look for differences in medical record accuracy within subsets of the population, including by age and race/ethnicity. If differences are present, this will limit the generalizability of these findings to other populations with different demographics.

Strengths of this study include the comprehensive medical record and chart review conducted to identify PPD in this patient population. The training and validation of the chart review process helped to ensure that the gold standard PPD identification was accurate.

Conclusions

This validation study of PPD that was carried out in a large integrated health care system in Southern California has demonstrated that PPD data ascertainment based on a combination of diagnosis codes and prescription medication records from the EHR is highly accurate for pharmacoepidemiologic studies. Neither diagnosis codes alone nor prescription records alone are sufficient to capture PPD cases.

Acknowledgments

Funding for this research was provided by National Institute of Health grant R01 ES030353-01 to DG (Kaiser Permanente Southern California) and JW (University of California, Irvine). The opinions expressed are solely the responsibility of the authors and do not necessarily reflect the official views of the funding agency. The Air Pollution and Pregnancy Complications in Complex Urban Environments (APPCUE) study team would like to thank Kaiser Permanente members who contributed electronic health information to this study.

Data Availability

Most of the data that support the findings of this study are available on request from the corresponding author. The complete data set is not publicly available due to privacy, institutional approval, and/or ethical restrictions. Study data come from patient electronic health records and birth certificates from the state of California. Data from patient health records cannot be shared without signed confidentiality agreements. Some of the data that support the findings of this study are available from the state of California. Restrictions apply to the availability of these data, which were used under license and approval for this study. Data can be made available by the authors provided that all required approvals are obtained from the departments in the state that oversees the use of state vital records data. To obtain California birth certificate data, researchers can email cphs@chhs.ca.gov or visit their website [21]. Requests for data may be sent to JS (Jeff.M.Slezak@kp.org) and DG (Darios.T.Getahun@kp.org).

Conflicts of Interest

The Air Pollution and Pregnancy Complications in Complex Urban Environments (APPCUE) study team led the design of the study and interpretation of the results. NK, CA, and JCC have no competing interests. JS receives research support from the National Institutes of Health (NIH), Pfizer Inc, Dynavax Technologies, and ALK. DG receives research support from NIH, National Institute of Environmental Health Sciences (NIEHS), Department of Health and Human Services, National Institute of Child Health and Human Development, Patient-Centered Outcomes Research Institute, Garfield Memorial Fund, Bayer AG, and

Hologic, Inc. JW receives research support from NIEHS, the California Air Resources Board, and the Health Effects of Air Pollution Foundation. Kaiser Permanente Southern California (KPSC) led the design of the study and interpretation of the results in collaboration with study team members from the University of California, Irvine (UCI) and the University of Southern California (USC). JS conducted the analyses, which were reviewed by study team members from KPSC, UCI, and USC.

Abstract

Background: The 2009 Health Information Technology for Economic and Clinical Health Act sets three stages of Meaningful Use requirements for the electronic health records incentive program. Health information exchange (HIE) technologies are critical in the meaningful use of electronic health records to support patient care coordination. However, HIE use trends and barriers remain unclear across hospitals in South Carolina (SC), a state with the earliest HIE implementation.

Objective: This study aims to explore changes in the proportion of HIE participation and factors associated with HIE participation, and barriers to exchange and interoperability across SC hospitals.

Methods: This study derived data from a longitudinal data set of the 2014-2020 American Hospital Association Information Technology Supplement for 69 SC hospitals. The primary outcome was whether a hospital participated in HIE in a year. A cross-sectional multivariable logistic regression model, clustered at the hospital level and weighted by bed size, was used to identify factors associated with HIE participation. The second outcome was barriers to sending, receiving, or finding patient health information to or from other organizations or hospital systems. The frequency of hospitals reporting each barrier related to exchange and interoperability were then calculated.

Results: Hospitals in SC have been increasingly participating in HIE, improving from 43% (24/56) in 2014 to 82% (54/66) in 2020. After controlling for other hospital factors, teaching hospitals (adjusted odds ratio [AOR] 3.7, 95% CI 1.0-13.3), system-affiliated hospitals (AOR 6.6, 95% CI 3.2-13.7), and rural referral hospitals (AOR 8.0, 95% CI 1.2-53.4) had higher odds to participate in HIE than their counterparts, whereas critical access hospitals (AOR 0.1, 95% CI 0.02-0.6) were less likely to participate in HIE than their counterparts reimbursed by the prospective payment system. Hospitals with greater ratios of Medicare or Medicaid inpatient days to total inpatient days also reported higher odds of HIE participation. Despite the majority of hospitals reporting HIE participation in 2020, barriers to exchange and interoperability remained, including lack of provider contacts (27/40, 68%), difficulty in finding patient health information (27/40, 68%), adapting different vendor platforms (26/40, 65%), difficulty matching or identifying same patients between systems (23/40, 58%), and providers that do not typically exchange patient data (23/40, 58%).

Conclusions: HIE participation has been widely adopted in SC hospitals. Our findings highlight the need to incentivize optimization of HIE and seamless information exchange by facilitating and implementing standardization of health information across various HIE systems and by addressing other technical issues, including providing providers' addresses and training HIE stakeholders to find relevant information. Policies and efforts should include more collaboration with vendors to reduce platform

compatibility issues and more user engagement and technical training and support to facilitate effective, accurate, and efficient exchange of provider contacts and patient health information.

Introduction

Health information exchange (HIE) has great potential to support patient transitions and achieve substantial financial and societal benefits across the fragmented United States health care system [1-3]. According to the 2009 Health Information Technology for Economic and Clinical Health (HITECH) Act, there are three stages of Meaningful Use. The goal of Stage 1 of Meaningful Use from 2009 to 2010 was to establish the US federal government's Meaningful Use incentive programs and to motivate health care professionals and institutions to capture, protect, and electronically store data, thus promoting wide adoptions of electronic health records (EHRs) [4]. Stage 2 of Meaningful Use—which began in 2014—emphasized the use and documentation of advanced clinical processes that guided the information exchange between providers and patients and between providers in the same practice to improve treatment adherence and care coordination. In 2015, the Centers for Medicare & Medicaid Services launched Stage 3 of the Meaningful Use requirements for the EHR Incentive Program. In Stage 3, eligible hospitals must demonstrate the interoperability of EHR systems in different practices with a focus on improving patient outcomes [5], such as improved coordination and efficiency of care by reducing the replication of health care services [6,7]. Previous studies have suggested that HIE implementation can also improve quality of care and holds promise to help achieve the goals of other policies, such as the Hospital Readmission Reduction Program [8,9].

Given the potential benefits, the Centers for Medicare & Medicaid finalized a rule to promote HIE and set exchanging all "necessary health information," including courses of illness, treatment, and discharge goals, with health care providers at the next level of care as a condition of participation in Medicare [10,11]. Although primary care providers strongly agree that meeting the Stage 3 care coordination criteria would improve patients' treatment [12], small, rural, and critical access hospitals (CAHs) were less likely to participate in national networks and state, regional, or local health information organizations (HIOs) than other hospitals as of 2018 [13]. Hospitals having a larger market share or those in less competitive markets had a greater probability of HIE participation [14], and nonprofit and publicly owned hospitals were more likely to participate in HIE than for-profit hospitals [15]. Moreover, larger hospitals were more likely to exchange health information internally than with outside hospitals [16]. However, despite the increasing proportion of hospital engagement, patient health information was not exchanged as needed [17]. Emergency department physicians reported that HIE sometimes disrupted their workload [18]. At the organization level, the rates of HIE upon transfer from psychiatric units lagged that from general medicine or surgery hospitals reported as of 2016 [11]. CAHs have been struggling to keep up with other advanced functions, even when these hospitals had EHRs as of 2018 [19], and physicians in solo practices and nonprimary care specialties also lagged [20]. Besides substantially poorer health care infrastructure [21,22], rural hospitals were least likely to have patient engagement capabilities or clinical information available electronically from outside providers [23]. Difficulties in sending and receiving health information and complex workflows are still the main barriers [12]. Previous research pointed out that developers need to work with health care providers to ensure HIE tools are integrated into existing workflows [24]. Costs of electronic interface development might also be a key barrier to fully integrated HIEs [25].

In South Carolina (SC), state-level efforts to encourage HIE were funded by the US Department of Health and Human Services during this time. Building upon existing statewide data infrastructure, SC became an early adopter of HIE starting in 2008 [26]. However, adverse effects of privacy regulation on the successful implementation and use of HIE also raised wide concerns [3], presenting a crucial obstacle to facilitating the exchange of health information between hospitals and across different health systems or distinct physician practices [27]. Because data on the implementation of HIE and barriers to exchange and interoperability of patient health information across hospitals in SC remains unknown, we pursued this study to provide insight for the state government to enact purposive policies and intensive efforts to promote wider participation in and use of HIE. The anticipated benefits gained from HIE come from the realized exchange and use of patient health information across health care providers; thus, whether these health information technologies are run in a supportive environment raised concerns about the barriers SC hospitals face. Previous studies found that technical and cost issues and privacy and security concerns could hinder HIE implementation during the process of HIE expansion [28,29], even with an increasing adoption of EHRs in the United States [30]. As qualification to participate in HIE does not necessarily lead to the use of HIEs [25], identifying and assessing related obstacles may inform policy efforts to address health care providers' concerns about their HIE use for improved health outcomes when most hospitals have met the criteria of Meaningful Use Stage 3 [27]. As an early adopter of HIE [26], SC, which contains some very rural areas, may have faced unique challenges that might be insightful for the adoption and use of HIE across hospitals and other health care facilities in other states or regions with similar settings. Therefore, using the most recent available survey data, we aimed to explore changes in the proportion of HIE participation and associated factors between 2014 and 2020 and barriers to interoperability as of 2020 across SC hospitals to inform policy makers and providers on how to enact additional policy

interventions to ensure HIE adoption and use for a patient-centric health care system.

Methods

Study Design

We conducted a retrospective, longitudinal analysis of 69 individual hospitals in SC using the American Hospital Association (AHA) Annual Surveys IT Supplement from 2014 to 2020. This survey was sent to the chief executive officer of every hospital in the United States for completion by themselves or by the most knowledgeable person in each hospital. The AHA Annual Survey included questions about organization structure, technology adoption, and other topics about service provision. The AHA Annual Survey IT Supplement database collects data on facility-level adoption and implementation of the US Department of Health and Human Services Promoting Interoperability initiative, including computerized system capabilities, patient engagement, HIE, barriers to HIE and interoperability, and other factors [31]. The response rates of the AHA IT survey among SC hospitals ranged from 44.9% in 2014 to 59.4% in 2020. The primary question was whether a hospital participated in local HIE activities in a year. According to the AHA Annual Survey, HIE involvement was assessed by indicating the level of participation in a state, regional, and/or local HIE or HIO. Using historical responses, we were able to carry forward and impute the missing values of 14 hospitals based on the following scenarios:

1. Hospitals that responded as having participated in HIE in the previous and subsequent years but did not respond to the survey in a given year were coded as participants.
2. Hospitals reporting no participation in the previous and subsequent years but did not respond to the survey in a given year were coded as nonparticipants.
3. Hospitals that reported no local HIE/HIO or no participation in HIE/HIO in a given year but did not respond in the previous year were coded as nonparticipants in the previous year. For example, if a hospital did not participate in HIE in 2015 and did not report whether they participated in 2014, the hospital would be coded as nonparticipants in 2014.
4. Hospitals that reported having participated in HIE/HIO in the previous year but did not respond in a given year were coded as nonparticipants.

The final analytic data set included 69 unique hospitals, but varied by year, ranging from 56 hospitals in 2014 to 66 hospitals in 2020. In 2014, of the 56 hospitals, only 27 responded on barriers to send or receive patient health information and other barriers related to exchanging patient health information. In 2020, of the 66 hospitals, 40 responded on barriers to send or receive patient health information and other barriers related to exchanging patient health information.

Variables

The primary independent variable was hospital location by rurality, categorized by Rural-Urban Commuting Area codes into urban (primary codes: 1-3) or rural (4-10). We also derived the following factors from the AHA Annual Surveys: number of beds staffed (1, <100 beds; 2, 100-299 beds; 3, >300 beds), teaching status, ownership (public nonfederal, private for-profit, or private nonprofit hospitals), system-affiliated hospitals (yes or no), primary services code (general or specialty hospitals), Medicare payment scheme (prospective payment system, CAHs, rural referral hospitals or sole community hospitals), ratio of Medicare inpatient days to total inpatient days, and ratio of Medicaid inpatient days to total inpatient days. Furthermore, we set survey year as covariate to examine annual linear trends in the proportion of HIE adoption across SC hospitals.

The second outcome variable was barriers to send, receive, or find patient health information to or from other organizations or hospital systems, which was not imputed because the barriers can change over time. To capture the main barriers to exchange and interoperability of patient health information, each hospital was asked, “Which of the following issues has your hospital experienced when trying to electronically (not eFax) send, receive or find (query) patient health information to/from other organizations or hospital systems?” Per the Healthcare Information and Management System Society, interoperability is the ability of different information systems, devices, and applications to access, exchange, integrate, and cooperatively use data, while exchange is the ability to send or to receive information but not necessary to integrate and harmonize data for further use [32].

Statistical Analysis

We first compared hospital characteristics by the status of HIE participation and presented geographic distributions of HIE participation across SC hospitals in 2014 and 2020. We then conducted chi-square tests to compare hospital characteristics by HIE participation status. Cross-sectional multivariable logistic regression models clustered at the hospital level to account for repeated observations and weighted by bed size were used to identify factors associated with HIE participation across hospitals. Additionally, we calculated the frequency of hospitals reporting each barrier related to electronically sending or receiving patient health information or other financial or technical barriers to exchanging patient health information. All analyses were conducted using Stata 15.0 (StataCorp LLC).

Ethical Considerations

The University of South Carolina Institutional Review Board exempted this study protocol.

Results

Proportion of Hospitals With HIE Technologies

In 2014, 24 of 56 (43%) hospitals reported participating in HIE. Private for-profit hospitals, nonteaching hospitals, small hospitals (<100 beds), non–system-affiliated hospitals, and specialty hospitals were less likely to participate in HIE than their peers. In 2020, 54 of 66 (82%) hospitals reported participating in HIE (Table 1). In 2020, 77% (13/17) of rural hospitals reported participating in HIE, which was comparable to the 84% (41/49) participation rate among urban hospitals. Between 2014 and 2020, there was an increasing trend in HIE participation among sample hospitals (Figure 1). The geographic distribution of these hospitals per their self-reported HIE

participation status is illustrated in Figure 2. In 2020, hospitals in the Upstate region mostly participated in HIE or HIO, whereas hospitals in many rural counties did not participate despite the HIE network availability in their local areas. The proportions of rural and urban hospitals with HIE or HIO participation increased at similar rates between 2014 to 2020 (Multimedia Appendix 1).

Figure 1. Proportion of hospitals with health information exchange technologies from 2014 to 2020. The proportion of hospitals participating in a health information exchange HIE or HIO increased over time (P<.001). Results stratified by hospital location can be found in Multimedia Appendix 1. HIE: health information exchange; HIO: health information organization.

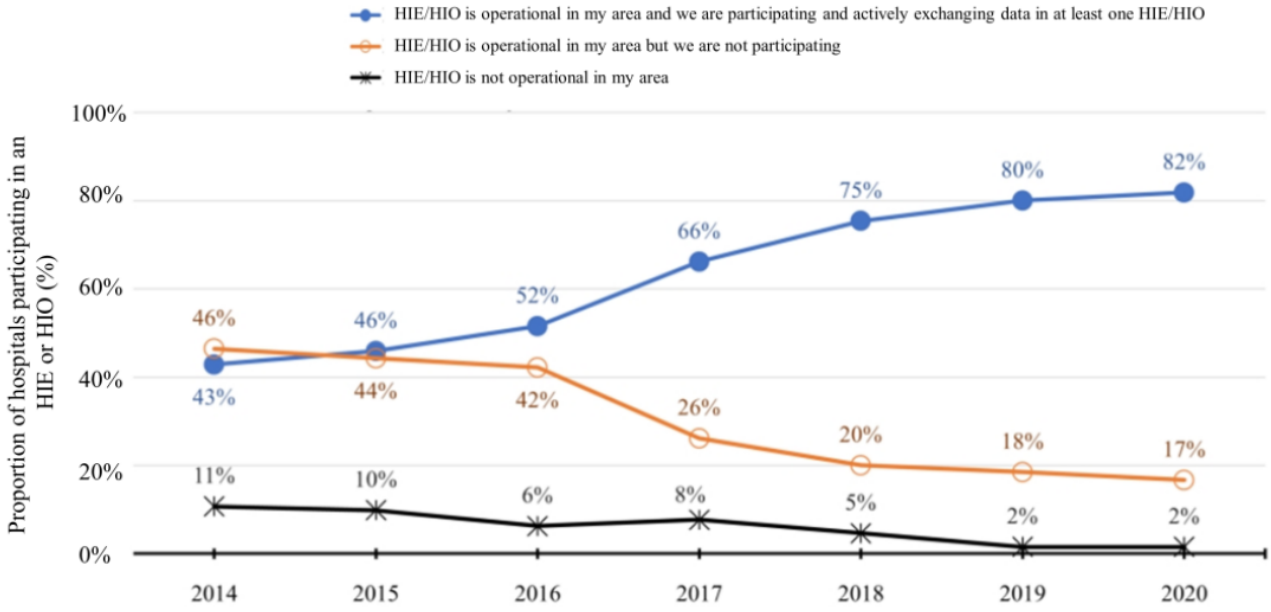

Figure 2. Geographic distribution of HIE participation across South Carolina hospitals in 2014 and 2020. HIE: health information exchange; HIO: health information organization.

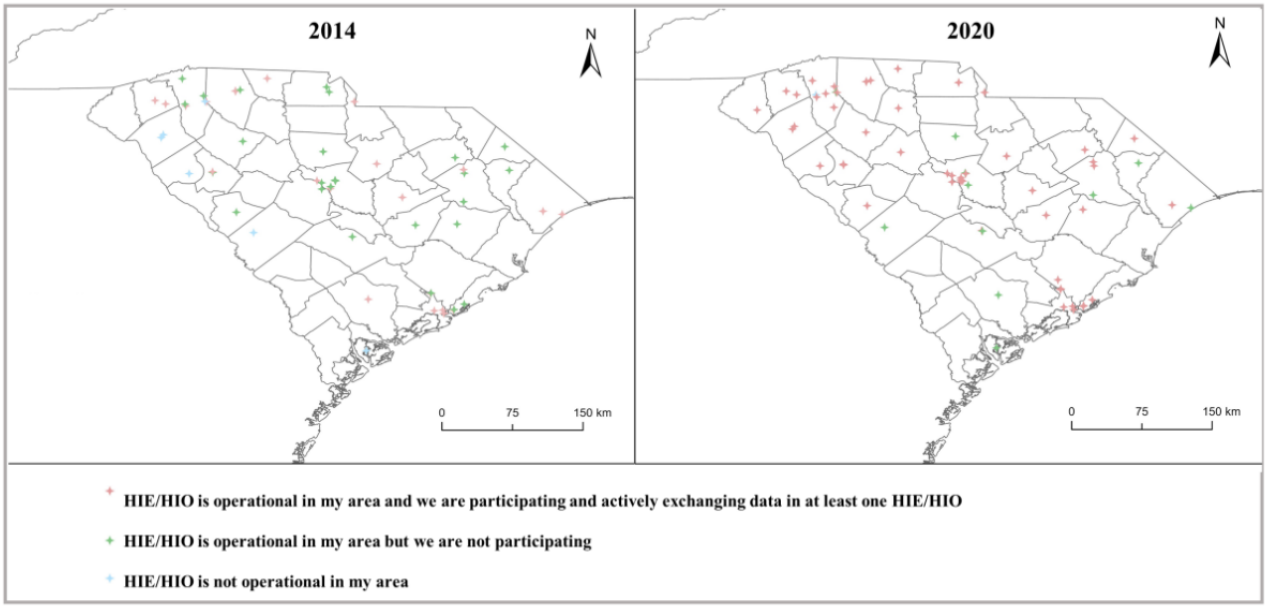
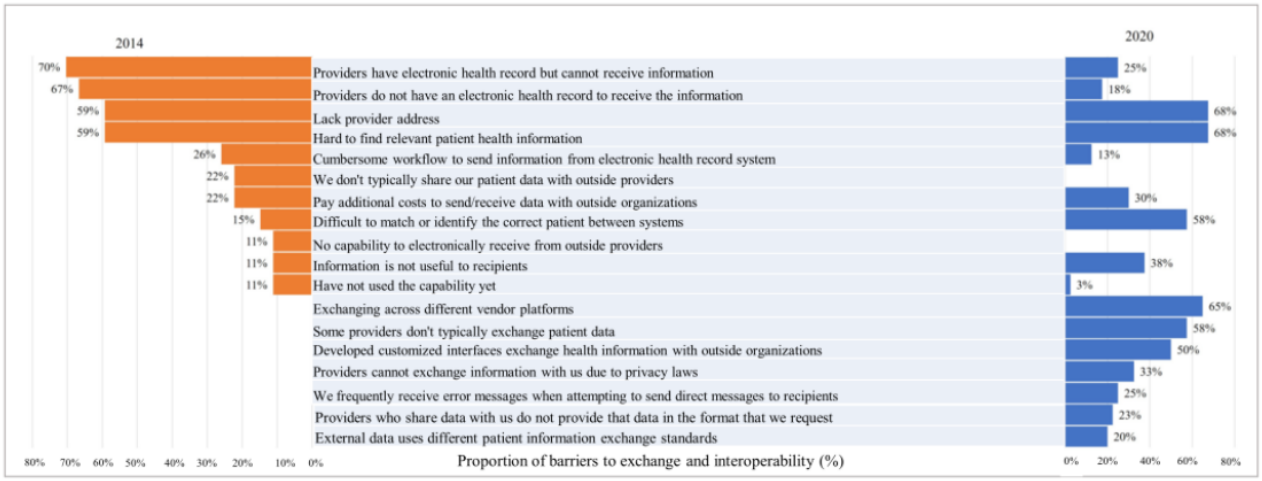


Barriers to Exchange and Interoperability Across SC Hospitals

As shown in Figure 3, among hospital respondents, the leading barriers to HIE in 2020 were difficulties in locating the contact information of the providers to send patient health information (27/40, 68%) and finding relevant patient health information (27/40, 68%), followed by several technical and systemic issues, including exchanging across different vendor platforms (26/40, 65%), difficulty matching or identifying the correct patient between systems (23/40, 58%), and providers that do not typically exchange patient data (23/40, 58%). Additionally, 33% (13/40) of sample hospitals reported that providers could not exchange information due to privacy laws as barriers to exchange and interoperability. In 2014, the most commonly reported barriers to exchange and interoperability were providers having EHRs but being unable to receive information (19/27, 70%), providers lacking an EHR to receive information (18/27, 67%), difficulty locating providers' address (16/27, 59%), difficulties in finding relevant patient health information (16/27, 59%), and cumbersome workflow to send information from the EHR system (7/27, 26%).

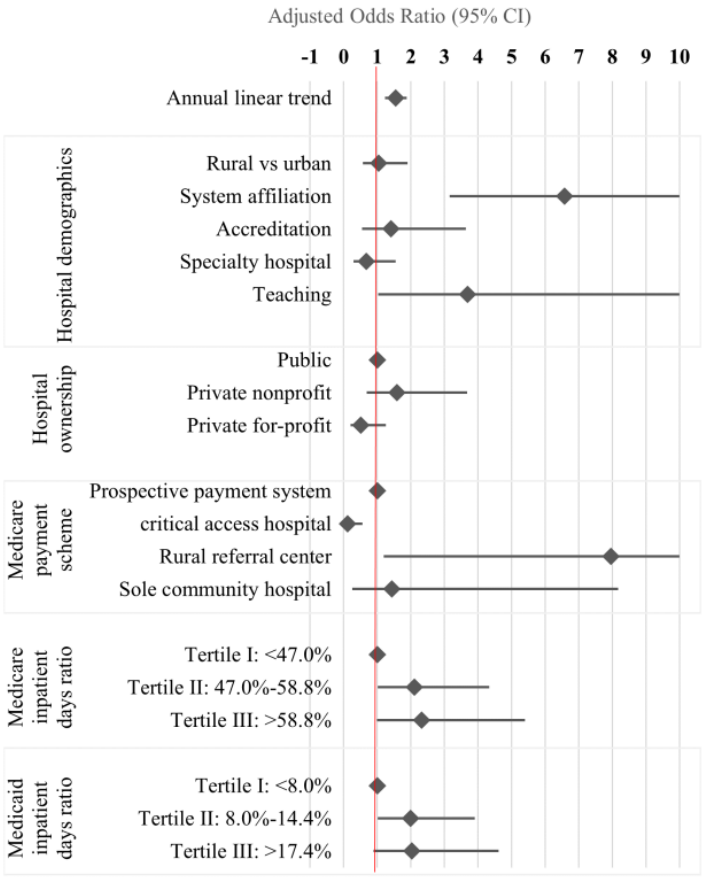
Figure 3. Barriers to exchange and interoperability across South Carolina hospitals in 2014 (n=27) and 2020 (n=40). EHR: electronic health record.



Factors Associated With Hospitals' HIE Participation

After controlling for other hospital factors, teaching hospitals (adjusted odds ratio [AOR] 3.7, 95% CI 1.0-13.3), rural referral hospitals (AOR 8.0, 95% CI 1.2-53.4), and system-affiliated hospitals (AOR 6.6, 95% CI 3.2-13.7) had higher odds of participating in HIE, whereas CAHs (AOR 0.1, 95% CI 0.02-0.6) were less likely to participate in HIE. Hospitals with greater ratios of Medicare inpatient days to total inpatient days or Medicaid inpatient days to total inpatient days also reported higher odds of HIE participation (Figure 4).

Figure 4. Multivariable analysis of factors associated with hospitals' participation in health information exchange from 2014 to 2020. Multivariable logistic regression models were used with adjusted odds ratios and 95% CIs calculated from standard errors clustered at the hospital level and weighted by hospital bed size.



Discussion

Principal Findings

In 2014, the Office of the National Coordinator for Health Information Technology launched a 10-year road map for the United States to achieve interoperability of EHRs by 2024. In this longitudinal observational study of 69 SC hospitals, we found that federal and state efforts to build an HIE system across all hospitals have been successful in SC, with over 80% of SC hospitals participating in HIE as of 2020; however, there is still a long way to go to achieve Meaningful Use Stage 3 for improved health outcomes. We also found teaching hospitals, system-affiliated hospitals, rural referral hospitals, and hospitals with greater ratios of Medicare or Medicaid inpatient days to total inpatient days were more likely to participate in HIE, while CAHs were less likely to participate in HIE. Yet, key barriers for effective use of HIE for patient care coordination and improved health outcomes remain, including technical, data management, and legal issues. These findings highlight the need to ensure the accuracy of patient information, standardization of health information across various systems, and training of privacy and security regulations to optimize HIE use for data exchange and patient care transition.

As of 2020, although over 80% of SC hospitals participated in HIE, our findings suggest that rural hospitals experienced no greater probability of HIE participation. This might be caused by multiple barriers to HIE implementation, including challenges with reporting, workflow, and technology capacity (eg, availability of adequate broadband), even with generous financial incentives [21]. Our findings also indicate that CAHs were less likely to participate in HIE than prospective payment system hospitals, leading to delayed development of EHR interfaces by private hospitals at the early stage of HIE expansion. This result is consistent with the findings of a previous study that CAHs with EHRs still struggle to keep up with other advanced functions, such as patient engagement and clinical data analytics, as of 2018 [19]; these hospitals face skyrocketing costs and a lack of technical expertise when developing HIE interfaces, making HIE adoption a prohibitive move [19,25]. Given that CAHs were less likely to adopt advanced functions for electronic records [33], challenges for CAHs to participate and use HIE may be further exacerbated. Moreover, hospitals with a greater ratio of Medicaid or Medicare inpatient days to total inpatient days reported higher probabilities of HIE participation. This result was consistent with prior research, indicating that broader changes in the payment of care may encourage health care providers to use EHRs [34].

Many barriers to HIE implementation and use exist. Despite the HIE functionality, we found that much critical information was missing or hard to find. For example, over two-thirds of HIE-active hospitals reported difficulties locating providers' addresses to send and receive information or finding relevant patient health information. Even with information availability, some had difficulties matching or identifying the correct patients between health care or EHR systems. On top of the information discontinuity, technical challenges in exchanging across different vendor platforms and the fact that some providers do not typically exchange patient data with outside providers further fuel the structural obstacles to the exchange and interoperability of patient health information across hospitals. In the era of telehealth and HIE across clinicians and hospitals for optimal quality of care [35,36], it is striking to find over half of SC hospitals reported barriers to the exchange of patient health information across different vendor platforms. Over half of providers do not typically exchange patient data, which may be because increasing data volumes and types is difficult and labor-intensive to match [37,38]. These barriers raise concerns of approaches at systematic and provider levels to improve the quality of health information, the health information system, and telehealth services.

Lacking provider addresses and difficulties in finding relevant patient health information were the main barriers to exchange in SC hospitals in 2014, suggesting that compatibility issues between EHRs and HIE systems are a significant systematic barrier [39]. Technical integration across distinct EHR platforms can be a real challenge given that Stage 1 of Meaningful Use did not require usability, data integrity, harmonization, and terminology mapping and matching among certified EHR systems. Moreover, the inability to get vendor support to address specific needs within hospitals limits the use of HIE for patient care transitions. Vendor issues are inextricably linked to EHR utility in many cases. Hospitals often need to use additional tools (eg, web-based data entry platforms) to retrieve specific data from their EHRs, limiting interoperability and optimization of HIE among hospitals.

Ensuring usability of information in clinical decision-making and the perception of accomplishing goals is critical for ensuring the sustainability of HIE use across hospitals facing barriers to exchange and interoperability [40]. However, in 2020, nearly 40% of hospitals reported that many recipients of electronic care summaries found that the information was not useful, and about 30% of providers could not exchange health information due to privacy laws or additional costs, which have posed obstacles to the use of HIE among health care providers. Given that physician-level variation in EHR documents can impede effective use of patient health information [41], the use of HIE may be lower when patients are unfamiliar with the health care provider [42]. This result might also be related to the fact that health care providers are more concerned about economic and competitive risks than perceived benefits [14,27]; therefore, they may complain about these issues [27], which might hinder the use of HIE in SC hospitals and discourage opportunities for improving patient care and outcomes [40]. Additionally, a previous study revealed that state and federal health information privacy laws, beyond economic and technical barriers, have been a significant obstacle to expanding HIE [27]. As the exchange of patient health information is a trust-related behavior, providers' perceived trust in HIE's technical capabilities, skills, and benefits warrants improvement [43]. Use of HIE by the "marquee user" should aim to attract more users to the platform and eliminate these barriers [16]. These findings suggest that the existing infrastructure may not consider the unique needs of patients who often access multiple health care service sites across multiple geographies. As many nontechnological factors may hinder the effective use of HIE

[44], more efforts beyond addressing workflow and technical issues are needed to make the HIE sustainable [45]. This result also raises concerns about the full connectivity of the statewide framework, including connecting unaffiliated ambulatory care practices [46] and skilled nursing facilities [47].

Limitations

This study has some limitations. First, the AHA Annual Surveys IT Supplement asked about hospital-wide use of HIE via a single item, and the hospitals did not report the extent of use. About 60% of hospitals responded to items on the barriers to exchange and interoperability. Assuming that SC hospitals without HIE tend not to respond to items on the barriers to exchange and interoperability, the current state-level barriers to exchange and interoperability may be underestimated. Second, we did not have data about local HIE needs. Third, the sample hospitals that reported actively participating in HIE may not have exercised HIE to its full potential. Fourth, the AHA Annual Surveys IT Supplement did not collect comprehensive vendor-specific information, and heterogeneity of vendors was not accounted for in this study. Nevertheless, our findings have revealed vendor-specific barriers to exchange and interoperability. Future research is warranted to examine how often HIE has been used across patients or patient visits/admissions and to assess key factors facilitating the optimal use of HIE.

Conclusions

Nearly all hospitals in SC participate in HIE. However, barriers to exchange and interoperability remain, including technical, data management, user training and support, and legal issues, highlighting a crucial missed opportunity to improve health outcomes. These findings imply the need to incentivize optimization of HIE and seamless patient information exchange across facilities by facilitating and implementing standardization of health information across various HIE systems and by training HIE stakeholders about privacy and security regulations to ensure smooth, safe, and secure patient care transitions. Future policies and efforts should promote collaborations with vendors to reduce platform compatibility issues and increase user engagement and technical training and support to facilitate effective, accurate, and efficient exchange of patient health information.

Acknowledgments

PH received funding to support this research from the South Carolina Health and Human Service Department.

Authors' Contributions

PH and ZL designed the study; PH performed the data analysis; all authors were involved the interpretation of the results; ZL and PH drafted the manuscript; and MAM, JME, and DW critically revised the manuscript.

Abstract

Background: Interoperability—the exchange and integration of data across the health care system—remains a challenge despite ongoing policy efforts aimed at promoting interoperability.

Objective: This study aimed to identify current challenges and opportunities to advancing interoperability across stakeholders.

Methods: Primary data were collected through qualitative, semistructured interviews with stakeholders (n=24) in Ohio from July to October 2021. Interviewees were sampled using a stratified purposive sample of key informants from 4 representative groups as follows: acute care and children's hospital leaders, primary care providers, behavioral health providers, and regional health information exchange networks. Interviews focused on key informant perspectives on electronic health record implementation, the alignment of public policy with organizational strategy, interoperability implementation challenges, and opportunities for health information technology. The interviews were transcribed verbatim followed by rigorous qualitative analysis using directed content analysis.

Results: The findings illuminate themes related to challenges and opportunities for interoperability that align with technological (ie, implementation challenges, mismatches in interoperability capabilities across stakeholders, and opportunities to leverage new technology and integrate social determinants of health data), organizational (ie, facilitators of interoperability and strategic alignment of participation in value-based payment programs with interoperability), and environmental (ie, policy) domains.

Conclusions: Interoperability, although technically feasible for most providers, remains challenging for technological, organizational, and environmental reasons. Our findings suggest that the incorporation of end user considerations into health information technology development, implementation, policy, and standard deployment may support interoperability advancement.

KEYWORDS

interoperability; health information exchange; health information technology; electronic health record; usability

Introduction

Background

Starting with the Health Information Technology for Economic and Clinical Health (HITECH) Act in 2009, the United States has invested over US$ 36 billion to promote interoperability—the ability of 2 or more systems to exchange and use information [1-3]—through health information exchange (HIE) networks and electronic health records (EHRs). HITECH promoted the adoption and implementation of certified EHRs by providing financial incentives through its "meaningful use" programs and funded grants that helped establish regional HIE networks [4]. Some of these financial incentive programs, such as the state Medicaid Provider Incentive Program (MPIP) were phased out in 2021. However, subsequent legislation such as the Patient Protection and Affordable Care Act reinforced this financing by advancing payment and care delivery models that use risk-based contracts to incentivize quality of care and patient outcomes, such as accountable care organizations, value-based care [5], and patient-centered medical homes [6], which stand to benefit from enhanced electronic data exchange. Other population health policy programs, including Comprehensive Primary Care (CPC) [7], CPC-Plus [8], and Primary Care First [9], further rely on robust data exchange among regional providers. Ongoing federal policy development has continued and enhanced support for meaningful use programs through the Medicare Access and Children's Health Insurance Program Reauthorization Act of 2015, leading to the Promoting Interoperability Program in 2018.

Recent reports show that 96% of acute care hospitals and 80% of primary care providers (PCPs) have implemented certified EHRs with interoperability capabilities [10,11]. However, actual use of data from an HIE network in clinical care encounters remains low [12]. Researchers have identified several barriers to the use of HIE networks, including poor user interfaces and lack of leadership support [13-15]. Although interoperable health information technology (HIT) is theorized to address these barriers, it continues to elude the health care system [16,17]. For instance, a recent study found that only 45% of all US hospitals engaged in the 4 core elements of interoperability, such as the capability of different EHR systems to find, send, receive, and use or integrate clinical information with one another [16]. Further, rural and smaller hospitals, ambulatory practices, as well as those ineligible for meaningful use incentives (eg, rehabilitation, long-term care, or behavioral health providers [BHPs]) lag behind large, integrated systems in adopting interoperability [18,19].

To promote interoperability, the 21st Century Cures Act (21CCA; 21CCA 2016) mandated the sharing of certain data elements, placed restrictions on information blocking, and promoted the use of application programming interfaces (APIs; eg, Fast Healthcare Interoperability Resources [FHIR]). The 21CCA also established the Trusted Exchange Framework Common Agreement (TEFCA) that provides an infrastructure model and governing approach for HIE networks [20]. However, in the sixth national survey of HIEs, 56% (84/151) of the regional HIEs planned to participate in TEFCA [21], which points to ongoing challenges that continue to limit data exchange. HIEs that intended to participate in TEFCA already had connections with HIEs in other states and participated in at least one national network. Therefore, the decision to participate in TEFCA may be determined by the alignment of HIE processes with existing data sharing rather than convincing HIEs of the benefits of participation [21].

Purpose

In alignment with policy efforts geared toward the promotion of interoperability, this study aimed to explore provider perspectives on the current state of interoperability challenges. Given the confluence of timing around the conclusion of state MPIPs and the ramp up of 21CCA and TEFCA, questions remain about the progress and remaining challenges related to achieving an interoperable health system. Moreover, previous research on interoperability typically focuses on a single perspective rather than those of multiple stakeholders. This multistakeholder lens is particularly relevant to consider when examining interoperability, as a key goal of this innovation is to connect disparate parts of the health system. Specifically, we conducted semistructured interviews with a stratified sample of key informants, including providers and individuals in leadership positions representing diverse organizations in Ohio, to identify barriers and facilitators to interoperability. The study's findings add to the body of knowledge about interoperability and may contribute to the efforts of state agencies and federal policy makers, such as the Office of the National Coordinator for Health Information Technology and the Centers for Medicare and Medicaid Services, to advance interoperability. For instance, our findings may provide evidence that supports alignment between the Health Insurance Portability and Accountability Act (HIPAA) with HITECH and 21CCA. Finally, technology vendors may benefit from increased understanding of the end user perspective of their applications to develop user-friendly software.

Methods

Study Setting and Design

We used a cross-sectional qualitative design to solicit multistakeholder perspectives on the state of interoperability in Ohio. Ohio provided financial incentives for the adoption of interoperable EHRs for eligible professionals and hospitals through the MPIP. Eligible professionals included those with an active Ohio Medicaid Provider Agreement, such as physicians, optometrists, dentists, certified nurse-midwives, nurse practitioners, and physician assistants practicing in a federally qualified health center or a rural health center led by a physician assistant. Eligible hospitals were also required to have an active Ohio Medicaid Provider Agreement and include acute care hospitals, critical access hospitals, cancer hospitals, and children's hospitals. Ineligible providers included most behavioral and mental health, long-term care, and home health providers. MPIP operated through 7 incentive cycles, with the final cycle occurring in 2021. On the basis of the 2021 Ohio Medicaid Electronic Health Records Survey for Practices and Hospitals [22], 23.87% (5593/23,435) of the eligible providers and hospitals had received at least one MPIP payment, 96.06%

(5280/5593) of the MPIP recipient providers and hospitals had adopted and used an EHR, and 90.73% (16,188/17,842) of those who did not receive an MPIP payment had adopted and used an EHR. Among the 735 ineligible providers, 72.1% (530/735) reported adopting and using an EHR. Epic Systems Corporation is the most prevalent EHR vendor in the state, with 36.80% (2058/5593) of MPIP recipient providers and hospitals and 56.56% (10,092/17,842) of non-MPIP recipient providers and hospitals using an Epic EHR. However, though Epic remained the EHR of choice for group practices (across multiple or single sites) and hospitals, individual practices were more likely to choose other EHR vendors (eg, NextGen and eClinicalWorks). Among the ineligible providers, there was substantial variation in EHR vendors, and CareLogic was the single most prevalent EHR vendor, with 7.8% (57/735) of providers adopting it. Presently, Ohio has 2 large-scale regional HIEs that facilitate electronic exchange of patient data. Almost 31.64% (7416/23,435) of MPIP eligible providers and hospitals had existing arrangements with the regional HIEs to share electronic patient-level clinical data, whereas 21.5% (158/735) of MPIP ineligible providers participated in the regional HIEs.

Data collection and analysis were guided by the technology-organization-environment (TOE) framework [23]. TOE is an organization-level theory that has been applied to explain how the 3 interacting contextual domains (ie, technology-organization-environment) influence a health care organization's technology-related decision-making [24].

Ethics Approval

This study was considered to have minimal risk and was approved by the Ohio State University institutional review board (2021B0378).

Sample Selection

We used a stratified purposive sampling approach to gather diverse perspectives on interoperability based on four representative groups: (1) acute care and children's hospital leaders, (2) PCPs, (3) BHPs (ie, providers or organizations that provide care for mental health, substance use disorders, stress-related physical symptoms, and life stressors and crises), and (4) regional HIEs (ie, organizations that facilitate information exchange within a network of facilities within a geographic boundary). In addition, both rural and urban subsamples within each of the 3 provider groups were interviewed to ensure geographic representation. We focused on key informants with first-hand perspectives on HIT adoption and its future directions. These key informants were administrative leaders with clinical and nonclinical backgrounds within organizations with decision-making capacity regarding HIT (eg, chief medical information officers, executive directors, chief executive officers, and strategy officers). The study leads received a list of potential key informants from the Ohio Department of Medicaid. Emails were sent to gauge interest in participation; key informants who agreed to participate (20 of 38 organizations invited) were then interviewed. To eliminate any potential conflict of interest, the Ohio Department of Medicaid was not notified of who agreed or refused to participate, and did not participate in any interviews.

Data Collection

We conducted semistructured interviews with key informants from July to October 2021. The interview guide was developed to ask about EHR implementation in general, the alignment of public policy with organizational strategy, interoperability implementation challenges, and opportunities to improve HIT effectiveness. The interview guide was piloted with administrative leaders (n=2; eg, chief information officer) at an urban hospital in Ohio. This process yielded two versions of the semistructured interview guide for (1) providers (ie, those from hospitals, primary care, and behavioral health) and (2) representatives of HIEs (Multimedia Appendix 1). All interviews were conducted remotely via Zoom and audio recorded.

Data Analysis

Interviews were transcribed verbatim and analyzed using directed content analysis—an approach that begins with the a priori codes from the TOE framework yet is permissive of emergent themes [25]. The coding team (DMW, WLT, and LP) met weekly to discuss the interviews and preliminary findings throughout the data collection phase. A preliminary codebook was developed by reviewing transcripts and identifying broad themes that emerged from the interview transcripts to organize the data into the 3 TOE domains. Next, to build consensus on the coding guide, the analysis team collectively reviewed common transcripts (n=3) to compare results, refine the codebook, and reconcile any coding discrepancies. The remaining transcripts were divided by organization type for coding. The team continued to compare findings throughout the analysis phase to achieve thematic saturation. The trustworthiness of our findings is ensured by our rigorous and iterative approach to analysis [26]. NVivo software (version 12) was used to support data coding and analysis.

Results

Overview

Overall, 24 key informants were interviewed representing 20 distinct organizations: 5 hospitals, 7 PCPs, 6 BHPs, and 2 HIEs. Of the 20 organizations, 15 (75%) were located in urban areas (Table 1).

Below, we report on the key themes and subthemes of the analysis organized by the domains of the TOE framework, including comparing and contrasting those that cut across organizational types as well as those specific to each individual organization.

Table 1. Key informant interview sample characteristics[a].

Organization type	Interviewees (n=24), n (%)	Organizations (n=20), n (%)	Urban area organizations (n=15), n (%)
Acute care and children's hospital	5 (21)	5 (25)	4 (27)
Primary care provider	7 (29)	7 (35)	5 (33)
Behavioral health provider	10 (42)	6 (30)	4 (27)
Regional health information exchange	2 (8)	2 (10)	2 (13)

[a]Some interviews (n=3) included multiple key informants.

Technology Domain

Overview

Three themes within the technology domain that related to the usability and technological aspects of interoperability were identified: (1) implementation challenges, (2) interoperability capabilities, and (3) opportunities (Table 2).

Table 2. Themes and primary subthemes in the technology domain.

Theme and primary subtheme	Representative quote
Implementation challenges	
Maintaining growing number of applications	"There's been an explosion of health IT [information technology] applications, vendors and products over the past decade, many of whom overlap and functionality intersect in ways that don't really allow for great interoperability, so just the challenge of sort of how do you meet all the needs, using all the various products out there, and still have a cohesive, reliable, safe experience is a challenge." [Hospital representative #15]
Integrating diverse sources of data into unified medical record	"Our community health centers are on a lot of different EHR [electronic health record] platforms, and those platforms don't talk to each other, and so the interoperability that we all desire is still not really there. So, we...are utilizing a health population, a population health tool that can sit over any EHR [electronic health record] platform, and that is allowing us to get some of the data aggregated, in spite of the lack of interoperability and communication between different EHRs." [Primary care provider #22]
Interoperability capabilities	
Connecting to state-hosted registries and databases (ie, state immunization registry)	"Every hospital has this issue, is that there's not really a good way to leverage the data being collected by the state vital statistic[s] for our use...We really get no automatic notification that a patient has died. They die elsewhere, and the state finds out because there's a death certificate somewhere, but our HIM [health information management] department is sort of stuck almost to the point of reading obituaries trying to figure out what patients to mark...It's really hard, from our perspective to reach out to a family with an appointment reminder about a patient who died, and it's just, not only is it horrible customer service and patient experience or family experience to do that...I think more connection points with actually the state for some of this basic stuff like birth records and death records and marriage certificates where names are changing and that information's sitting there, but it seems to be behind this kind of either bureaucratic or policy firewall." [Hospital representative #15]
Exchanging data across the continuum of care	"In our long-term care systems, it would be nice for us to be able to exchange information about those patients, especially with medications, make sure their medications are set up and they know everything that the patient's on. One thing, too, is provide our providers with information, a little bit more timely from the long-term care facilities to keep them from being readmitted or admitted to the hospital. So that's something we'd like to be able to do. Another thing would be the merging of medical records for both mental health and their regular healthcare." [Primary care provider #6]
Reliance on regional HIEs[a] for data exchange	"I see a lot of potential for us to be able to really be part of that health information exchange network, and use our EHR [electronic health record] system to do a lot of that in the background, as opposed to currently what we are doing is we have access to [regional HIE] portal to get the community health record, the information, but that takes staff time. You know, a lot of training, and so it's not really fully integrated into our EHR [electronic health record], and it's not fully integrated into our clinical practice processes." [Behavioral health provider #17]
Opportunities	
Using new population health software to improve interoperability	"That's the beauty of it. So, I...mentioned computer vision[b], so what that's compared to if you wanted to do that in the past, you would have had to have a pretty labor-intensive interface between the platform and each individual practice's EHR [electronic health record], right. And that's a huge level of effort that most people can't really get to, and that's why the computer vision piece of that really makes sense. You don't have to have that, well, it's still fancy, it's fancy in a different way, you don't need a fancy interface, you're using the computer vision[a] to match the patients." [Hospital representative #21]
Integrating care coordination programs to improve social needs referrals	"Back to the social determinants...the opportunity to connect to external things like Aunt Bertha or NowPow or Healthify, one of those products that helps kind of do closed loop referral, and whether we'll do that within Epic...I think those...are helping us kind of reach our goals around reducing health disparities." [Primary care provider #14]
Using FHIR[c]-based applications to advance interoperability	"We are just implementing our FHIR [Fast Healthcare Interoperability Resources] layer right now. What I will tell you is while FHIR [Fast Healthcare Interoperability Resources] is definitely a direction of the future, it is not broadly deployed in the marketplace and not broadly deployed in the workflow or business applications to great extent. But it is, definitely will be an important factor as we move into the future. But it also will not be the silver bullet that everybody's hoping it was going to be." [HIE representative #8]

[a]HIE: health information exchange.

[b]Computer vision is a field of technology that enables devices such as smart cameras to acquire, process, analyze, and interpret text, images, and videos.

[c]FHIR: Fast Healthcare Interoperability Resources.

Implementation Challenges

For hospitals, a primary concern focused on the growing number and proliferation of application types (eg, EHR, personal health records, HIE, and population health platforms) that contain health information and can be used in clinical encounters. These applications were viewed as difficult and costly to maintain. Similarly, these applications do not use a common data structure and storage format, resulting in too many places for data to be located and for clinicians to search for useful information. The lack of interoperability necessitates that providers leave the EHR to access other applications. As one hospital representative stated as follows:

> *...It's one of those things where now you've got to subscribe to it [eg, a regional HIE], and it's another place [eg, application] for you to go to look for more information [eg, patient clinical data]...There's too many places for data to land and get sent. People just stop looking.* [Hospital representative #10]

HIE leadership echoed this perspective, adding that a lack of interoperability was an impediment to creating a complete medical record. PCPs noted similar issues related to the number and type of applications needed to overcome gaps in interoperability, such as population health tools (eg, Innovaccer). In contrast, for BHPs, interoperability across applications was not discussed; instead, remarks focused on off-the-shelf EHR systems being misaligned to the specific requirements for BHPs, such as lacking additional protections for substance abuse data.

Interoperability Capabilities

Hospitals described advanced interoperability functionality and attributed their advanced capabilities to their EHR vendor rather than the regional HIEs. The regional HIEs were helpful for exchanging continuity of care documents [27] but did not facilitate the integration of information across EHRs. Typically, hospitals only expressed limitations with interoperability functionality as being a function of data recipients' capacities. For instance, a major concern for hospitals was connecting and being able to integrate EHR data with state-hosted information systems such as the state immunization registry, vital statistics, death certificates, or birth records.

Hospitals and PCPs both noted limitations of exchanging data across the continuum of care, such as with long-term care and BHPs. PCPs additionally noted interoperability challenges with hospitals in their own health systems even when they all used the same EHR vendor, as some vendors are not capable of data exchange in different instances of the same EHR.

BHPs described much more basic data exchange capabilities relative to hospitals and PCPs. For instance, they mentioned that their data exchange is primarily focused on billing. In contrast to hospitals, BHPs mentioned a greater reliance on the regional HIEs for access to health records from other providers and event notifications. The regional HIEs echoed this relationship and discussed how BHPs lag in their interoperability capabilities.

Opportunities

Hospitals described opportunities related to new population health platforms that may be able to improve interoperability without the costs associated with interfacing with different EHR systems or HIEs. Both hospitals and PCPs felt that increasing analytic rigor and predictive modeling with artificial intelligence and machine learning would support their population health efforts. API-based data exchange was generally identified as an opportunity to promote interoperability. Hospitals mentioned that the use of applications with this technology will benefit remote patient monitoring and chronic care management. API-based data sharing was also identified as an opportunity to improve interoperability in behavioral health despite the focus on more basic technological opportunities, such as increasing EHR functionality.

The regional HIEs also shared these perspectives on API-based data sharing and were particularly attentive to FHIR APIs for the development and implementation of EHR-integrated applications to advance interoperability. FHIR-based applications were also expected to improve patient access to their medical records. Although most hospitals and PCPs offered patient access to their medical records through patient portals at the time of our study, these were not unified across providers. FHIR-based applications could potentially enable broader patient access through a unified patient portal that collects information from disparate providers. However, the regional HIEs tempered this enthusiasm, recognizing that FHIR-based applications are not currently broadly deployed in existing technology builds.

Hospitals, PCPs, and HIEs also discussed using care coordination programs (eg, Aunt Bertha) that can track referrals to social service agencies that address social determinants of health (SDoH). These providers described collecting SDoH data in discrete data fields but also noted that the lack of standardization of SDoH data fields remains problematic and results in questionable data quality and limited ability to combine data across sources. Efforts to develop SDoH data standards, such as the Gravity Project [28], were raised as opportunities to improve the interoperability of SDoH data.

Organization Domain

Overview

We identified two themes within the organizational domain that affected interoperability: (1) facilitators and (2) strategic alignment (Table 3).

Table 3. Themes and primary subthemes in the organization domain.

Themes and primary subthemes	Representative quote
Facilitators	
Relationship with EHR[a] vendor	"They [EHR vendor] are as interested in making sure that interoperability happens as what we are and so when we start to look at different interfaces that we need to have built, whether it's to another vendor, like Cerner or eClinicalWorks, then Epic builds that interface, so that it makes it easier on both ends, to make that connection." [Hospital representative #3]
Data standards adoption	"I think standards, the general and the meaningful use did quite a bit of pushing this sort of embracing of standards around things like nomenclatures, terminologies that allow for transmission of information. Prior to this we're pretty much stuck with HL7 [Health Level 7] and custom specifications, but now with just CPT [current procedural technology] or ICD [International Classification of Disease] but, between SNOMED [Systematized Nomenclature of Medicine] and LOINC [Logical Observation Identifiers, Names and Codes] and RxNorm and CVX [vaccine administered] codes for immunizations and it's gotten a lot better." [Hospital representative #15]
Senior leadership support	"The biggest thing [to support data gathering and integration] is the addition of scribes. Adding on that expense of additional manpower to do that data entry for the providers to get them to where they're comfortable with...what is pertinent to that visit. It may be an ER [emergency room] visit, is it a recent CT [computerized tomography scan], so that way staff isn't trying to print the last X-amount of things and really all they wanted was one thing, so trying to streamline that to get the physicians the information they need, but having a team around them, to help them put the information back in and alleviate that work from them." [Primary care provider #16]
Strategic alignment	
Payment program participation impacts technology purchasing decisions	"We are in CPC [Comprehensive Primary Care]-Ohio and CPC+ [Comprehensive Primary Care Plus]. We're also doing Primary Care First and I have a number of value-based commercial contracts that we deal with as well. We are not an ACO [accountable care organization]. Our new software with our population health software that's been added to our regular EMR [electronic medical record] should help greatly with that and that's the reason we did it is because we're getting into more value-based contracts. I think that's something that will improve our outcomes for our patients and improve our financial return as well." [Primary care provider #6]
Using interoperability to develop cross-sector alignment and stakeholder consensus	"I'd love to see us in the state of Ohio come together at kind of a developer's conference or something...How can we come together and figure out how to make this work better for Ohio? And I know that sounds really altruistic because everyone's trying to run a business and all that, but it just seems like there's so much overlap and you think—I'll use the example with us: I'm sitting on a mountain of data. Right, and so it just drives me bonkers to hear of a small mom-and-pop startup software company, who has to go out and buy a big giant data warehouse, you know, big giant SQL server and pay licenses and then they contact all the hospitals in the doctor's office and say, give me all your data, right. And we're just duplicating these silos. Not too long ago, I was giving a presentation, I said, how many of your hospital systems have a population health strategy? And, of course, 100% of them raised their hand, right. And I said so you've invested millions into giant data warehouses to support population health, you know. Right? And they all go, yeah. Like, well so did all the HIEs[b] [health information exchanges], so did the state of Ohio, you know. ODH [Ohio Department of Health] is trying to, like we're all we're all spending—Microsoft and Oracle and all those guys are making money hand over fist. Because we can't get ourselves organized." [HIE representative #4]
Different perspectives on the value of interoperability	"They didn't see how interoperability would help them take care of their patients any better. And our team even said, 'Well, you can get lab results like instantaneously.' 'Yeah, you know, but I get them a day late. It's fine.' ...I think that's the other challenge is really, is that one example, or is that some X percent of providers in the state of Ohio who don't see value in that interoperability." [HIE representative #4]

[a]EHR: electronic health record.

[b]HIE: health information exchange.

Facilitators

A consistent subtheme related to the importance of relationships with the EHR vendor to support interoperability emerged. Hospitals placed considerable value on their relationship with Epic and perceived the high concentration of state-wide Epic institutions and the integration between HIEs and Epic as a benefit. Hospitals also mentioned the push for data standards through meaningful use as facilitating interoperability.

PCPs described the important role of senior leadership, who can designate sufficient human resources for tasks that typically increase clinical workload, such as data gathering before appointments. These staff resources can help physicians access and use information from other sources.

Strategic Alignment

A critical driver for interoperability among hospitals was their participation in value-based payment programs and population health initiatives. To facilitate the data exchange and integration

for care coordination, billing, and reporting required to support these programs, hospitals reported purchasing EHRs for network partners that lacked these advanced capabilities, thus promoting interoperability among their clinical partners. Likewise, hospitals preferred to develop their own in-house population health analytics platforms rather than outsource this function to HIEs.

PCPs also felt that interoperability is central to achieving strategic goals such as population health management, which is integral to participation in alternative payment models (ie, accountable care organizations, CPC-Ohio, CPC-plus, and Primary Care First). They noted the benefits of event notifications made possible by admission, discharge, and transfer feeds that allow PCPs to be notified when their patients have received care in other settings and follow-up accordingly with them to meet their needs.

Conversely, BHPs indicated that they were not participating in value-based purchasing programs to the same degree. However, similar to hospitals and PCPs, their technology investment decisions were guided by their participation in payment programs with sponsors (eg, Health Resources and Services Administration and Substance Abuse and Mental Health Services Administration) that require specific reports, although they may not necessarily aid in interoperability.

The regional HIEs viewed the development of their exchange networks as an opportunity to advocate for cross-sector alignment, particularly as it pertains to streamlining duplicate efforts toward population health management. They remarked that regional HIEs are in a unique position to negotiate partnerships that address the concerns of different stakeholders. Finally, the regional HIEs noted challenges related to some organizations, particularly BHPs, not viewing interoperability as valuable to their organization or aligning with their strategy.

Environment Domain

Within the environmental domain, a policy theme was identified that focused on how policy may hinder or facilitate interoperability (Table 4).

Hospitals felt that there was room for a greater policy push for managed care plans to initiate value-based payment contracts and distribute incentives to providers. Hospitals also felt the costs of interoperability, such as establishing admission, discharge, and transfer feeds or registry reporting, fall predominantly on hospitals, yet there are no corresponding changes to reimbursement. Similarly, BHPs also desired additional funding to support their adoption of advanced EHR systems.

All providers, including the regional HIEs, also noted the considerable impact of 42 Code of Federal Regulations (CFR) Part 2 (ie, Substance Abuse Confidentiality Regulation) as limiting interoperability and connectivity with BHPs. Despite the general recognition of the policy's good intentions, it was viewed as negatively impacting clinical care. Some key informants felt that this policy was incongruent with new information blocking rules as part of the 21CCA. The regional HIEs also saw consequences of this policy with respect to responding to public health emergencies such as the opioid epidemic. BHPs, PCPs, and the regional HIEs all advocated for aligning 42 CFR Part 2 with the HIPAA to clarify what is protected and not shareable versus what can be shared for continuity of care.

Table 4. Themes and primary subthemes in the environment domain.

Policy	Representative quote
Push insurance plans to participate in value-based payment programs	"The way to actually advance Triple Aim[a], right, is, is to have these accountable care organizations and really strongly incent the provider organizations to get on board with them. Well, if it's like pulling teeth to get the Medicaid [insurance plans] to work with us on that, then that's limited. And so I haven't seen a lot of folks...in Columbus really encouraging, like, what are they doing to really encourage that those accountable care incentives get down to the provider level. So there's the CPC+ [Comprehensive Primary Care Plus] program, which is good to a point, because that gives primary care providers some funds upfront to theoretically invest in all this stuff. We're experiencing now is [Medicaid insurance plans] came on board for [ACO[b] Network], but none of the other providers are, and they're coming up with excuses why they don't want to do it. It's like, how come someone in Columbus isn't telling them to get on board with a [ACO Network] program." [Hospital representative #21]
Increase funding for adoption of interoperable EHR[c]	"Most people don't realize going into an implementation is how much it will cost you...more of those incentives, I think, would be beneficial even if it's for individuals moving to a better record that will allow them to do more of the communication between systems and all that. Our current system will never have that capability." [Behavioral health provider #18]
Substance abuse confidentiality requirements (42 CFR[d] Part 2) limit interoperability with behavioral health providers	"When you go back to advocacy, the biggest thing we need to do around that in my world again is to align the Part 2 information with more the HIPAA[e] [Health Insurance Portability and Accountability Act] guidelines, so we can make sure that that information gets out to the primary care providers, gets out to those entities that are trying to support these people. I think that's one of the biggest roadblocks to taking the next step and helping with the opioid crisis, because again, I think Ohio has done some great work here, but our hands are kind of tied right now, because of the federal rules. And so advocating through the state up to the feds to better align those rules so information can be shared, is probably pretty key." [HIE[f] representative #8]
Align 42 CFR Part 2 with HIPAA to clarify what is protected data and what can be shared	"We would love to see movement on the alignment with 42 CFR [Code of Federal Regulations] and HIPAA [Health Insurance Portability and Accountability Act], which would allow sharing without having to always parse out." [Behavioral health provider #7]
Information blocking continues to exist	"I think the feds really need to step up some of their efforts a little bit, and I've been pretty vocal with folks at ONC [Office of the National Coordinator] in DC is data sharing is one part of that information blocking conversation. We've got to got to do a better job really supporting that and pushing on EMR [electronic medical record] vendors to send all the data. It makes it very, very challenging to match up data if somebody says, I can't send you addresses. Well then, that data is almost worthless when you're talking about trying to track that by zip code and say, hey public health, you're having an outbreak in zip code 12345. So, if you don't get addresses from some of the EMRs [electronic medical records], you know, there's not enough expectation I don't think even in the HL7 [Health Level 7] standards and some of the others." [HIE representative #4]
TEFCA[g] is helpful to establish standards, but could be expanded to promote adoption of FHIR[h]	"And to my point, the national effort, right now, that is looking at expanding the national scope of exchange, it came out of the Cures Act, called TEFCA, the Trusted Exchange and Common Agreement Framework, the standards that they have just pushed out do not include FHIR [Fast Healthcare Interoperability Resources] as a standard...And again, don't get me wrong, it is going to be the way of the future, and you have to be able to integrate that into your technology stack, but we've got a ways to go." [HIE representative #8]

[a]Triple Aim refers to an approach to optimizing health system performance based on improving population health, enhancing the care experience, and reducing costs [29].

[b]ACO: accountable care organization.

[c]EHR: electronic health record.

[d]CFR: Code of Federal Regulations.

[e]HIPAA: Health Insurance Portability and Accountability Act.

[f]HIE: health information exchange.

[g]TEFCA: Trusted Exchange Framework Common Agreement.

[h]FHIR: Fast Healthcare Interoperability Resources.

The regional HIEs noted some specific concerns, given their experience in the COVID-19 response. First, they described a need for greater enforcement of information-blocking rules. The implications of information blocking were particularly notable during the pandemic when withheld information about addresses prevented HIE from tracking COVID-19 at the local level. Second, the regional HIEs felt that HIPAA guidance on reporting on geographic areas with less than 20,000 patients is both vague and confusing, limiting population health efforts.

Finally, the regional HIEs also mentioned that TEFCA helps to establish standards but did not include any information about FHIR-based standards. They noted that this update would be helpful to promote adoption of FHIR-based applications [30].

Discussion

Principal Findings

The near-ubiquitous adoption of certified EHRs over the past decade has resulted in the capture of vast amounts of data across the care continuum. Recent policy efforts such as the 21CCA aim to promote vendor-agnostic integration of external data into the EHRs of all provider types and address information blocking to mitigate challenges. However, questions persist about how well these efforts assist health care organizations in achieving interoperability. Our study examined perspectives from a variety of provider types in Ohio on the state of interoperability. We identified important barriers and facilitators to interoperability among hospitals, PCPs, BHPs, and regional HIEs.

Our findings related to implementation issues within the technology domain suggest that the proliferation of applications that address various use cases promotes capture of rich data.

However, from an end user perspective, this approach can create inefficiencies because of excess information. User interfaces that do not embed multiple discrete applications within the EHR may ultimately create a fragmented medical record, which makes it harder to find relevant information. These types of information silos of patient data can potentially jeopardize patient safety, care quality, and organizational efficiency [31,32]. Fragmented or siloed information may also contribute to provider burnout [33]. Thus, our findings highlight a need for user-centric approaches in technology design and implementation to translate increased information access to use.

Providers did note that technological advances such as computer vision-based population health software (eg, Innovaccer) can help overcome these barriers by pulling data directly into the EHR without requiring back-end integration. Likewise, the growing support for API-based data sharing can further support interoperable information exchange between dissimilar EHR vendors. APIs can extend EHR capabilities [34], although this potential remains unrealized to date. Recent initiatives such as TEFCA that mandate sharing standardized sets of data and promote the use of FHIR APIs are expected to facilitate interoperability in the coming years [30]. Moreover, the API approach has the potential to facilitate population health analytics using machine learning techniques [35].

Within the technology domain, our findings reiterated a gap between hospitals and PCPs at one end of the spectrum and BHPs at the other with respect to their interoperability capabilities. This gap may be a result of most BHPs being ineligible for federal incentive programs [18]. This omission likely not only disincentivizes the adoption of advanced EHRs capable of interoperability among BHPs but also discourages investment and development by EHR vendors of tools designed to meet the needs of BHPs [36].

In addition, across the technology, organization, and environment domains and across provider types, a notable issue that emerged from the key informant interviews was the limitation on interoperability imposed by 42 CFR Part 2, a rule that restricts sharing substance use and behavioral health data. Our findings suggest that despite its intentions, 42 CFR Part 2 effectively operates to prevent, or severely limit, BHPs from participating in exchange. In addition to potential medical errors, this restriction may result in missing data from analytic data sets used by providers, insurers, or researchers [37]. Further, providers expressed concern that this rule may no longer be in alignment with 21CCA information-blocking rules. Moving forward, modifications to 42 CFR Part 2 may be necessary to support further interoperability. Consideration of end user needs and incorporating perspectives of BHPs are essential in any policy changes to carefully consider the need for privacy related to substance use and behavioral health data balanced against the benefits of interoperability [38]. To this effect, the United States Department of Health and Human Services issued a Notice of Proposed Rulemaking in November 2022 [39]. The Notice of Proposed Rulemaking proposes to permit the use and disclosure of Part 2 records based on a single prior signed consent, to expand prohibitions on the use and disclosure of Part 2 records in legal proceedings and to expand patient rights that align with the HIPAA Privacy Rule. The importance of this issue has recently become more visible because of concerns around the protections of reproductive health information following increased abortion restrictions because of the overturning of the *Roe versus Wade* supreme court case [40,41]. The revisions to Part 2, if enacted, would not only help BHPs engage in interoperability but would also provide greater protection for how sensitive health data can be used in legal proceedings.

Interestingly, hospitals attributed their interoperability capabilities more to their relationship with EHR vendors as opposed to the regional HIEs. This finding is likely a consequence of the strong foothold of Epic in Ohio. From an operational and governance standpoint, providers may face fewer barriers to participating in Epic's Care Everywhere vendor-mediated HIE network. Conversely, participation with a regional HIE may require further effort to establish data exchange policies that require buy-in from multiple stakeholders. Vendor-mediated HIE may address barriers to use, such as the need to leave the EHR to access information. Nonetheless, these vendor-mediated HIEs may create a divide in HIE participation between providers with different vendors [42]. Indeed, as the HITECH funding period drew to a close, the number of state and regional HIEs declined, partly because of the mergers of regional HIEs, funding challenges, and competition from vendor-mediated HIEs [43]. Vendor-mediated and regional HIEs are not necessarily mutually exclusive, although regional HIEs may be more inclusive of a range of provider types. Policies targeted at supporting regional HIEs may be necessary to counteract the market forces of vendor-mediated HIEs and keep interoperability obtainable for nonhospital or hospital-affiliated practices.

Our findings related to strategic alignment may offer useful policy recommendations; provider participation in value-based payment programs plays a critical role in how providers are considering (or not considering) investments in interoperability. To the extent that most of a provider's patients are beneficiaries of these programs, providers may expand the breadth of their interoperability functionality, such as participation in regional HIEs or use of population health platforms to meet the needs

of that particular patient population [44]. Key informants also described the use of social needs referral platforms; however, developing exchange with non-HIPAA–covered social service or community-based organizations can be challenging without properly aligned incentives [45]. In addition to clarifying HIPAA rules around exchange with noncovered entities, the expansion of value-based payment programs may leverage HIT investment. Further, regional HIEs may be well positioned to advocate for cross-sector strategic alignment.

The providers in our study reported capacity-related challenges in interoperability with public health agencies. Chronically underfunded public health systems impeded efficient and timely electronic information exchange during the COVID-19 pandemic [46]. In response, the Centers for Disease Control and Prevention launched the Data Modernization Initiative, resulting in changes to core data sources and facilitating access to electronic case reports and the COVID electronic laboratory reporting that makes test results available. Other initiatives such as TEFCA, through their emphasis on interoperability, are also expected to mitigate challenges, particularly from differing vocabulary standards. Other barriers to interoperability in public health arise from the complex legal and regulatory environment [47]. Even though 21CCA established a legal framework to address information blocking [48], the HIEs participating in our study reported information blocking that prevented tracking cases of COVID-19. Moving forward, it will be critical to monitor the impact of the Data Modernization Initiative and TEFCA on the interoperability of public health data.

Limitations

We purposely sampled from multiple stakeholders to gain a representative perspective on interoperability. The design focused on breadth across providers rather than depth within a specific provider type or within a single health care organization. Similarly, the study only included Ohio stakeholders, which minimizes variation in the policy environment and may limit generalizability.

The sampling approach was designed to include individuals with decision-making authority with respect to HIT. These perspectives may differ from those of other end users. Finally, owing to time and resource constraints, the interview guide may not have probed all issues relevant to interoperability but was purposefully open-ended to allow participants to discuss topics they deemed important.

Conclusions

Our findings suggest that despite the ubiquity of data and applications, seamless interoperability into a comprehensive medical record, both within and across providers, remains out of reach. Technological solutions offer promise to overcome these challenges. Likewise, the expansion of value-based payment programs can further incentivize interoperability. Although policy initiatives to expand interoperability existed, they were often misaligned to operational needs and may not be sufficient to overcome market forces. A policy focus toward embracing user-centric design to incorporate end user experience into HIT development may overcome barriers associated with achieving interoperability.

Abstract

Background: Clinical practice guidelines (CPGs) and associated order sets can help standardize patient care and lead to higher-value patient care. However, difficult access and poor usability of these order sets can result in lower use rates and reduce the CPGs' impact on clinical outcomes. At our institution, we identified multiple CPGs for general pediatrics admissions where the appropriate order set was used in <50% of eligible encounters, leading to decreased adoption of CPG recommendations.

Objective: We aimed to determine how integrating disease-specific order groups into a common general admission order set influences adoption of CPG-specific order bundles for patients meeting CPG inclusion criteria admitted to the general pediatrics service.

Methods: We integrated order bundles for asthma, heavy menstrual bleeding, musculoskeletal infection, migraine, and pneumonia into a common general pediatrics order set. We compared pre- and postimplementation order bundle use rates for eligible encounters at both an intervention and nonintervention site for integrated CPGs. We also assessed order bundle adoption for nonintegrated CPGs, including bronchiolitis, acute gastroenteritis, and croup. In a post hoc analysis of encounters without order bundle use, we compared the pre- and postintervention frequency of diagnostic uncertainty at the time of admission.

Results: CPG order bundle use rates for incorporated CPGs increased by +9.8% (from 629/856, 73.5% to 405/486, 83.3%) at the intervention site and by +5.1% (896/1351, 66.3% to 509/713, 71.4%) at the nonintervention site. Order bundle adoption for nonintegrated CPGs decreased from 84% (536/638) to 68.5% (148/216), driven primarily by decreases in bronchiolitis order bundle adoption in the setting of the COVID-19 pandemic. Diagnostic uncertainty was more common in admissions without CPG order bundle use after implementation (28/227, 12.3% vs 19/81, 23.4%).

Conclusions: The integration of CPG-specific order bundles into a general admission order set improved overall CPG adoption. However, integrating only some CPGs may reduce adoption of order bundles for excluded CPGs. Diagnostic uncertainty at the time of admission is likely an underrecognized barrier to guideline adherence that is not addressed by an integrated admission order set.

Introduction

Problem Description

Clinical practice guidelines (CPGs) are designed to help standardize and disseminate evidence-based practices for various disease processes. Implementation of CPGs has been shown to decrease variation in care delivery, reduce costs, and improve patient outcomes [1-3]. However, clinician adherence to CPGs in many contexts remains suboptimal, impeding the delivery of high-value patient care [4,5].

Clinical decision support (CDS) systems integrated into the electronic health record can address some of these barriers and improve CPG adoption [6]. For example, order bundles serve as the building blocks for comprehensive order sets, which allow physicians to place multiple evidence-based orders for a single diagnosis with a few keystrokes without having to search individually for each order. CPG-associated order sets aggregate CPG-recommended therapies into a single order set, reducing the cognitive and physical work burden on clinicians to follow guidelines [6-9]. The use of CPG-associated order sets has improved outcomes in sepsis, pneumonia, and many other diseases [6,7,10,11].

Despite this evidence, we found that many CPG-associated order sets were used in <50% of eligible encounters in our own health system. The lack of order set adoption leads to less penetration of CPGs into clinical practice and reduces CPG impact on outcomes.

Available Knowledge

Research into guideline nonadherence thus far has demonstrated that barriers to guideline adoption are often context-specific and difficult to generalize to different settings [5]. In a systematic review of clinician surveys investigating potential barriers to guideline adherence, commonly identified barriers included lack of awareness or familiarity, lack of agreement or outcome expectancy, inertia from previous practice, and existing external barriers [5].

Order bundles embedded into larger order sets can be a powerful tool in improving CPG adoption [6,12]. For example, Munasinghe et al [10] incorporated multiple CPG order bundles into admission order sets and demonstrated improved adoption. However, unintended consequences, including increased physical and cognitive workload, can also result when these order sets demonstrate poor usability or are implemented at the wrong time in the clinician workflow [4,8]. Insufficient customization of order set content, mismatches between technology and human practices, and inadequate maintenance and modification of order sets have all been shown to contribute to order set nonuse and subsequent exposure to potential medical errors [4,8,9].

Furthermore, diagnostic uncertainty and increasing patient complexity also contribute to guideline nonadherence, which may be appropriate in certain contexts [13-15]. Single-diagnosis guidelines may be too simplistic to apply to the majority of patients [16]. Diagnosis codes have proven to be a poor marker of these barriers [14,15,17], and a lack of clear definitions continues to make them difficult to measure [14].

It remains unknown what CDS designs best address these barriers and most improve CPG adherence.

Rationale/Specific Aims

Our purpose for this project was to provide higher-value care through improved adherence to evidence-based CPGs at our institution. In preliminary data described elsewhere [18], we found that common reasons among local frontline providers for not adopting CPG order sets in eligible populations included lack of awareness (32%) and forgetting to use the stand-alone CPG-specific order set (20%). We therefore implemented a new CDS system in our admission process in the form of embedded CPG order bundles integrated into the general pediatrics admission order set that were identical to CPG-specific order bundles in the existing stand-alone CPG-associated order sets. Our primary aim was to increase CPG-specific order bundle use for eligible patients admitted on the general pediatrics service by 20% from July 2019 to May 2021. The primary aim was determined by the project stakeholder team to likely be an achievable improvement based on initial data that many CPGs demonstrated an <50% adherence rate, as well as an improvement that would justify the anticipated effort to complete the project. Secondary aims included determining if there were differences in order bundle use between specific CPGs at the intervention site and comparing CPG order bundle adherence between the intervention site and another hospital within the same health system where the intervention was not implemented.

Methods

Context/Setting

This study was performed on the general pediatrics service in an academic urban children's hospital within a 3-hospital, 638-bed pediatric health system serving the greater Atlanta, Georgia, area. Over 90 pediatric and family medicine residents rotate through the general pediatrics service each year and are overseen by 16 pediatric hospital medicine faculty members at the intervention hospital. Our institution uses an official electronic health record supplied by Epic Systems. Currently, there are over 20 general pediatric-specific CPGs customized to local workflows that are available for use through the institutional intranet. Prior to the intervention, 15 of the CPGs had their own stand-alone order set to facilitate adherence.

The intervention was implemented at 1 of 3 freestanding children's hospitals; this was an academic tertiary care center staffed primarily by resident teams with pediatric hospital medicine attendings. The nonintervention site was a hybrid community-academic hospital primarily staffed directly by pediatric hospital medicine attendings within the same health system.

Intervention

Planning the Intervention

Stakeholders included representatives from the Pediatric Hospital Medicine service, the Department of Clinical Effectiveness, and the Department of Quality and Safety, as well as a clinical informaticist, a human factors engineer, a

medical student, and a quality improvement methodology expert. This team met formally multiple times in the planning stages of the project and while formal problem analysis was underway before the intervention.

Preintervention problem analysis has been previously described [18]. Briefly, we identified patients eligible for a CPG order set for whom it was not ordered; we contacted the admitting provider within 2 weeks, inquired about reasons for CPG nonuse from a predefined list (we also added categories as needed), and asked for narrative comments. Based on these results, we created a Pareto chart that identified the most common barriers to CPG order set use: (1) lack of awareness or forgetting to use the CPG (2), eligibility for multiple CPG order sets at the time of admission, and (3) use of a similarly named order set that was not the intended CPG order set.

The Intervention

CPG-specific order bundles were integrated into the general pediatrics admission order set for better visibility and more efficient usability. Order bundles for 6 CPGs were chosen for the intervention, including asthma, complicated pneumonia, heavy menstrual bleeding, migraine, musculoskeletal infection, and uncomplicated pneumonia. These incorporated CPGs were chosen because they either (1) demonstrate low guideline order set use, (2) are very common, or (3) represent important improvement areas in antimicrobial stewardship. Order bundles were added to a section titled "Common Guidelines and Pathways—General Pediatrics" (Figure 1).

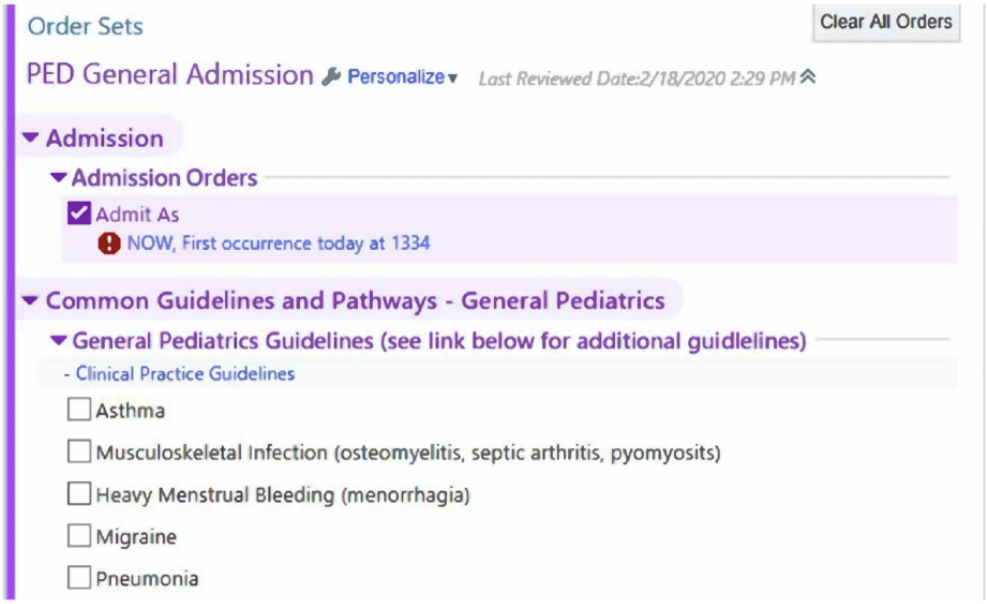
Orders in each CPG order bundle were identical to the existing stand-alone CPG-associated order sets. Within each order bundle, embedded hyperlinks referenced the published CPG and relevant literature from which recommendations were made and referenced common target disease pathogens for bundles that recommended empiric first-line antibiotics. For patients that qualified for multiple CPG order sets, the integrated order set also allowed for the selection of multiple relevant order bundles within the order set.

Prior to implementation of the integrated order set into a live production environment, formative usability testing and summative usability testing were both completed. Usability testing aimed to test the effectiveness and iteratively improve the intervention in a simulated environment. Results are reported elsewhere [18].

To address the barrier of similarly named but non-CPG order sets being used accidentally, we identified order set "mimics" by searching the system with common clinical synonyms for each CPG. Similarly named order sets were retired from the production environment after obtaining approval from both the order set owners and the corresponding CPG owners. In total, 9 mimics were identified, and all of these were subsequently retired after owner approval. Additionally, all relevant CPG-associated order sets were reviewed and updated, if necessary, for both naming consistency and related search terms.

After the integrated order set was implemented into a live production environment, an update outlining the new CDS tool and its capabilities and expected use was emailed to all current and incoming residents to review and presented at the weekly resident educational conference.

Figure 1. Integrated general pediatrics admission order set with clinical practice guideline order bundles.



Study of the Intervention and Measures

All patients aged 0 to 21 years who were admitted to the general pediatrics service and met the eligibility criteria for any one of the incorporated CPG order sets based on preexisting computable population definitions were included in this study. This study used a quasi-experimental design, analyzing pre- and postintervention CPG order set adherence at both the intervention site and a nonintervention site. Our primary exposure was intervention period, with the preintervention period defined as July 1, 2019, to June 3, 2020, and the postintervention period as June 4, 2020, to May 28, 2021, as the integrated order set went live on June 4, 2020, at the intervention site.

Our primary outcome was the proportion of appropriate CPG order set use for eligible patients at the time of admission. To evaluate the impact of our intervention, we adopted existing automated queries to assess whether the clinician used the appropriate CPG order set, a wrong but similarly named order set, or the available general pediatrics admission order set. We also reviewed whether the "CPG guideline initiation order" was signed, which is a prechecked order in all our included CPG order sets. Through the query, demonstrated use of the CPG-associated order bundle and the presence of the guideline initiation order were assumed to represent appropriate guideline order set use. Encounters where the clinician appeared to use the appropriate guideline order set or bundle but the guideline initiation order was absent were manually chart reviewed to confirm appropriate order set use. All encounters that appeared eligible but where the clinician did not appear to demonstrate appropriate guideline order set use were manually chart reviewed to ensure CPG eligibility at admission throughout the study period. Eligibility was based on defined eligibility criteria in each published CPG. All manual chart review was completed by a pediatric hospital medicine fellow using both the Epic electronic health record and the Phrase Health system.

The pre- and postintervention proportion of CPG-eligible admissions for which the CPG order set or bundle were used was compared at the intervention hospital, where the integrated order set was implemented into the production environment. Data in this context were considered our "intervention cohort." The proportion of appropriate CPG order set use for eligible patients was also compared in the same study period at the nonintervention hospital within the same health system, where the integrated order set was not implemented. This hospital uses the same CPGs and associated order sets and serves a similar patient population in the greater Atlanta area; it was thus considered our "nonintervention cohort." The purpose of having both intervention and nonintervention cohorts in this study was to better assess whether the observed outcomes were directly related to our intervention rather than secular trends.

In this intervention, there was concern that surfacing some guidelines in the integrated order set but not others could lead to the unintended consequence of reducing order set use of CPGs that were not included in the intervention. Therefore, pre- and postintervention use of CPG order sets that were not initially included in the integrated admission order set (acute gastroenteritis, croup, bronchiolitis) was assessed as a "balancing cohort."

Evaluation of Diagnostic Uncertainty

As our intervention was created to address lack of knowledge and awareness of guidelines, we hypothesized that it would not address diagnostic uncertainty, an underrecognized barrier that may influence order set adoption. In a post hoc analysis, we therefore aimed to evaluate the presence of diagnostic uncertainty at the time of admission to determine if this barrier accounted for a larger proportion of CPG order bundle nonuse after the intervention.

All eligible encounters where the associated CPG order set was not used were manually chart reviewed to assess the presence of diagnostic uncertainty throughout the entire study period. Diagnostic uncertainty was defined based on an algorithm (Multimedia Appendix 1) adapted from the approach of Bhise et al [15] to measuring diagnostic uncertainty in primary care. In the algorithm, encounters needed to include direct or indirect markers of uncertainty in documentation, initial definitive treatment had to have been withheld while awaiting further diagnostic workup or observation, and an operational definition of diagnostic uncertainty had to be met. Two members of the research team, a pediatric hospital medicine fellow and a pediatric resident, completed the manual chart review based on information available in the initial history and physical documentation and reported the presence or absence of diagnostic uncertainty. Interrater reliability was assessed to confirm reliability between the 2 researchers' assessments. After chart review, the number of eligible encounters where the CPG-associated order set was not used that demonstrated the presence of diagnostic uncertainty was compared before and after implementation to determine the change in proportion after the intervention.

Analysis

Data were summarized using counts and percentages by site (intervention and nonintervention), period (pre- and postintervention), and guideline (eg, asthma or heavy menstrual bleeding). Binary logistic regression was used to analyze overall and by-guideline associations between use of appropriate CPG-specific order bundle (yes vs no) and period (pre- and postintervention) across sites via statistical interactions. We further ran binary logistic regression models evaluating the association between use of appropriate CPG-specific order bundle and period in the balancing cohort and relevant guidelines. Results are presented as contingency tables with odds ratios (ORs), 95% CIs, and corresponding *P* values. All analyses were conducted using SAS (version 9.4; SAS Institute), and significance was assessed at the .05 level. Percent adherence for eligible encounters by month for the intervention cohort was tracked and plotted on a statistical process *P* chart with annotations for the order set clean up and integrated order set go-live interventions.

Ethical Considerations

This study was deemed by the Children's Healthcare of Atlanta Institutional Review Board to be nonhuman-subjects research as a quality improvement study (STUDY00000367).

Results

The integrated order set went live on June 4, 2020. From January 1, 2019, to May 28, 2021, a total of 1664 encounters were identified as eligible for a CPG order set based on preexisting computable population definitions. Of these encounters, 1052 were preimplementation (Figure 2) and 612 were postimplementation (Figure 3).

Figure 2. Preintervention admission encounters for the intervention cohort. CPG: clinical practice guideline.

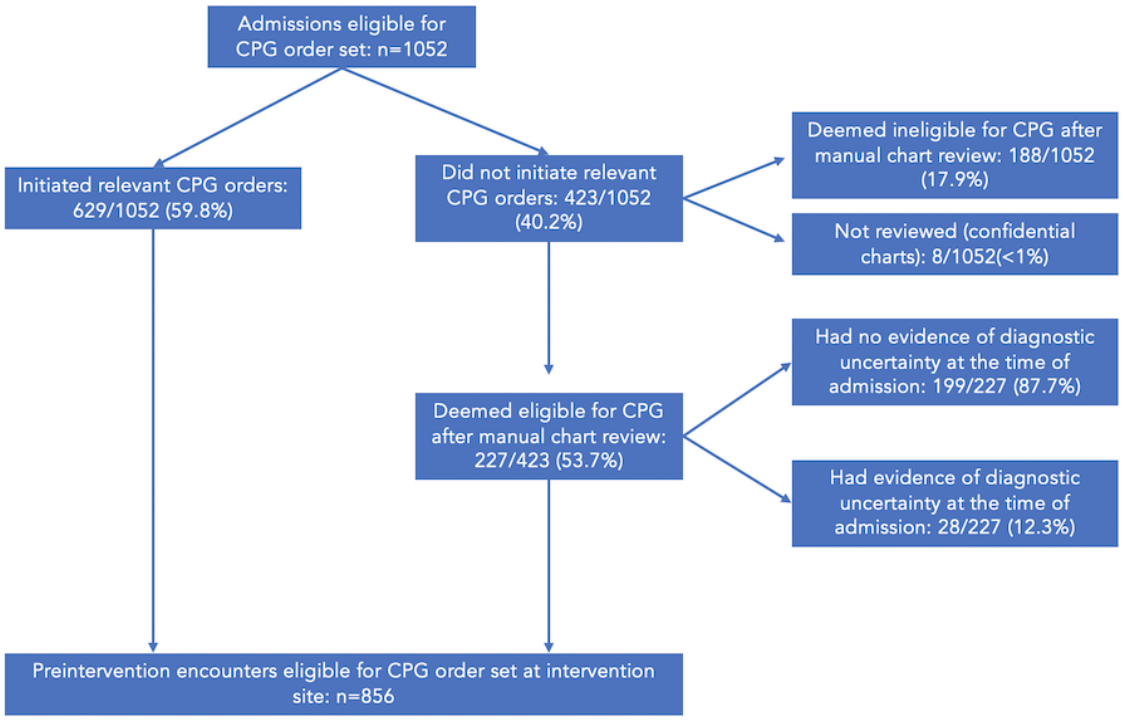


Figure 3. Postintervention admission encounters for the intervention cohort. CPG: clinical practice guideline.

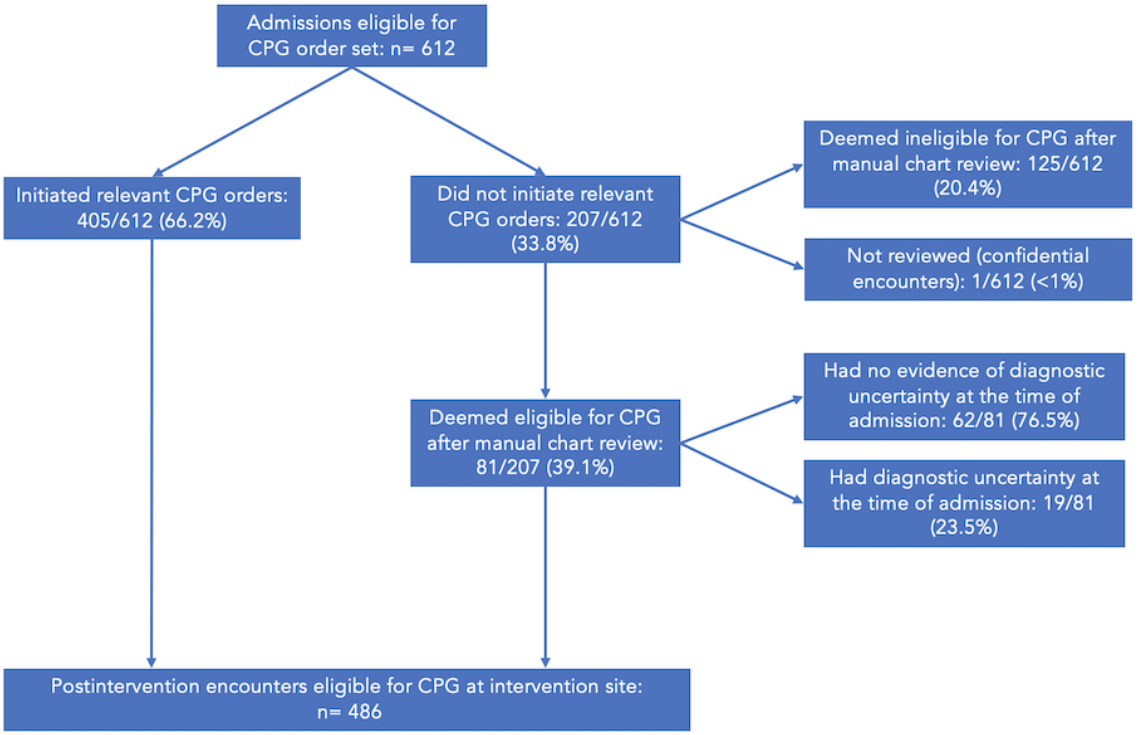

The number of encounters was unbalanced, partially due to lower-than-average admission volumes as a result of the COVID-19 pandemic. We manually reviewed all encounters that appeared eligible by computable definitions for a CPG order bundle where the CPG order bundle was not used: 423/1052 (40.2%) encounters before the intervention and 207/612 (33.8%) after the intervention. Of the encounters that were reviewed, 188/1052 (17.9%) before the intervention and 125/612 (20.4%) after the intervention were excluded by manual review for not meeting eligibility criteria. Overall rates of exclusion were similar when comparing the difference before and after the intervention (17.9% before and 20.4% after the intervention; 95% CI –6.62% to 1.51%, *P*=.22).

CPG order set use rates for included CPGs were tracked over time (Figure 4).

The trend in monthly adherence was positive following implementation and demonstrated special cause variation

beginning in August 2020, 8 weeks after the integrated order set went live. The rate of order set use at the intervention site for integrated CPGs increased from 73.5% before the intervention to 83.3% after the intervention (OR 1.80, 95% CI 1.36-2.39). Order set use rate at the nonintervention site, where the integrated order set was not implemented but mimics were also deleted, increased from 66.3% to 71.4% during the same study period (OR 1.27, 95% CI 1.04-1.54). Of note, this increase in the nonintervention cohort appeared driven by musculoskeletal infection (OR 2.84, 95% CI 1.49-5.40) and asthma (OR 2.15, 95% CI 1.22-3.79), as seen in Table 1. When comparing ORs between the intervention and nonintervention cohorts, the intervention cohort had significantly improved order set use from before to after the intervention relative to the nonintervention cohort (intervention OR 1.80 (95% CI 1.36-2.39) vs nonintervention OR 1.27 (95% CI 1.04-1.54; *P*=.045).

When broken down by disease-specific CPGs, all integrated CPGs showed positive adherence trends after implementation in the intervention cohort but with different effect sizes. Heavy menstrual bleeding and pneumonia had more improvement than musculoskeletal infection or migraine (Table 1). Adherence in asthma, for which the CPG order set has historically high use rates, remained excellent after the intervention (92.1%-95.5%; OR 1.81, 95% CI 0.95-3.45). Adoption of CPG order bundles that were not included in the integrated admission order set (including bronchiolitis, acute gastroenteritis, and croup) decreased from 84% to 68.5% following the intervention (OR 0.41, 95% CI 0.29-0.59). Of note, this was largely driven by bronchiolitis, where adoption changed from 86.9% to 75.7% after the intervention (OR 0.47, 95% CI 0.28-0.78), as seen in Table 2.

In a post hoc analysis, based on the observation that improvements were lower for musculoskeletal infection and migraine, we reviewed 308 eligible encounters where a CPG order bundle was not used to evaluate the presence of diagnostic uncertainty at admission. One reviewer (a pediatric hospital medicine fellow) completed manual chart review on all charts and a second (a pediatric resident) reviewed a random subsample of 50 encounters (16%), with interrater reliability measured by the Cohen κ (κ=0.73, *P*<.001). The proportion of eligible encounters where the CPG order set was not used that demonstrated diagnostic uncertainty increased from 12.3% (28/227) before implementation to 23.4% (19/81) after implementation (OR 2.18, 95% CI 1.12-4.16).

Discussion

Summary

The integration of CPG order bundles into a general pediatric admission order set improved CPG adoption in a stand-alone academic pediatric hospital compared to a control hospital within the same health system. In a post hoc analysis, the disease processes with lower diagnostic uncertainty at the time of admission saw the greatest improvement from this intervention.

Interpretation

CPG adoption improved both in relation to preintervention encounters at the same hospital and in relation to encounters at a similar hospital within the same institution where the integrated order set was not released. This suggests that the increase in CPG adherence was directly related to the implementation of the integrated order set at the study site. While CPG adherence also significantly improved at the nonintervention hospital, the improvement seen at the intervention site was significantly more than that at the nonintervention site. Additionally, improvement was only seen for 2 of the 6 guidelines (asthma and musculoskeletal infection) at the nonintervention site, compared to all 6 guidelines showing a trend toward improvement at the intervention site. This change may reflect the removal of known CPG order set “mimics” at both locations prior to the integrated order set implementation, as this was identified as a barrier to CPG adherence in prior work. While some CPGs demonstrated improvements of close to 20%, overall improvement did not meet our initial primary aim of 20% increased adherence after the intervention. This is likely due to finding a higher than anticipated preintervention overall adherence rate, largely driven by the CPG for asthma, which has historically high adherence rates.

Nonincorporated CPGs demonstrated a reduction in order set use following implementation of the integrated order set. This finding was largely attributable to a decrease in bronchiolitis guideline adherence. The timing of this intervention, in June 2020, correlated to multiple surges of SARS-CoV-2 infections. We are unable to distinguish whether the reduction in adherence was due to our intervention or the change in the management of respiratory infections during this time. Future studies that incorporate a more comprehensive list of CPGs may elucidate how this decision support design affects nonincorporated CPGs.

The presence of diagnostic uncertainty was not initially identified as a primary barrier to guideline adherence based on frontline clinician queries during this study [18]. In our analysis, the proportion of eligible encounters without CPG adherence that demonstrated diagnostic uncertainty increased following the implementation of the integrated order set. Our intervention addressed other drivers, but not diagnostic uncertainty, which may explain a higher fraction of diagnostic uncertainty in encounters without a CPG order bundle after implementation. Alternative designs that account for the change in diagnostic certainty across a hospitalization may demonstrate a better job of improving CPG adherence.

While previous literature has shown that CPGs and associated order sets can successfully decrease variation in care delivery and improve patient outcomes [19-22], the context in which decision support is aligned into the workflow remains of utmost importance for the success of these interventions [4]. Combining alerts with order sets has been shown to have success in specific contexts [23,24] but risks generating alert fatigue and requires considerable disease-specific logic behind the alert. Alternatively, automating order suggestions through machine learned patterns of order use was shown to influence ordering behavior [4,25] but may not reflect evidence-based recommendations and can be resource intensive.

Furthermore, increasing patient medical complexity and diagnostic uncertainty leads to a workflow mismatch when coupled with single diagnoses or simplified guidelines. This gap was largely underrecognized by clinicians when self-reporting barriers to guideline adherence [18] and likely requires decision support in a different context or format to overcome than admission order sets. Mehta et al [16] sought to integrate CDS into documentation workflows through problem-oriented templates aimed at improving documentation

for patients with multiple problems and to provide greater evidence-based prompts and organization. While demonstrating potential to provide recommendations during the documentation process, potentially a better context to address diagnostic uncertainty, clinicians are still called upon to label diagnoses for their patients at a point in time when this may still be unclear. Further research into the most effective format and context for CDS to address diagnostic uncertainty is needed.

Limitations

This study has several limitations. First, results may not be generalizable, as this was a multisite, single-system study focused on a single service. Different contexts, organizational cultures, and electronic health record vendors could affect the feasibility and impact of this intervention. Second, due to the COVID-19 pandemic, hospital admission volumes were significantly lower, and admissions consisted of fewer respiratory illnesses in the postimplementation period, potentially creating pre- and postintervention cohorts that were less similar. Additionally, due to time and resource constraints, a single chart reviewer was used for charts flagged as nonadherent to confirm eligibility. Despite this limitation, pre- and postimplementation rates of exclusion were similar, suggesting this did not have a significant influence on results. Lastly, in a post hoc analysis of diagnostic uncertainty, only one reviewer reviewed all nonadherent charts to determine the presence of uncertainty. The development of an algorithm for uncertainty and an assessment of interrater reliability for a subset of charts attempted to address this limitation and minimize subjectivity.

Conclusion

The integration of CPG-specific order bundles into a general pediatrics admission order set improved overall CPG adoption by addressing the most commonly reported barriers to CPG adherence by clinicians. Further improvement in guideline adherence could be seen with integration of a more comprehensive list of available guidelines for a particular service. Diagnostic uncertainty at the time of admission is likely an underrecognized barrier to guideline adherence that is not fully addressed with an integrated admission order set. Further work is needed to determine the impact of an integrated admission order set on clinical outcomes and what types of clinical decision support could better address the presence of diagnostic uncertainty.

Acknowledgments

We would like to acknowledge Christy Bryant for her assistance in building the redesigned order set as well as the pediatric residents and attendings who participated in all stages of this study. JM, SK, SG, and ID's participation was supported by the Emory Department of Pediatrics and Children's Healthcare of Atlanta through the Warshaw Fellow Research Award.

Authors' Contributions

JM, SK, CS, DR, and EO conceptualized and designed the project. JM performed manual chart review for nonadherence. JM and JG created the algorithm for diagnostic uncertainty and performed chart review for diagnostic uncertainty. JG structured and wrote Multimedia Appendix 1 with input from JM. ID and SG performed statistical analysis and contributed to interpretation of results. All authors discussed the results and conclusions of the study. JM wrote the manuscript with contribution and input from all authors.

Conflicts of Interest

EO is a cofounder of and has equity in Phrase Health, a clinical decision support analytics company. He receives no direct revenue from this relationship. No other authors declare any conflicts.

Abstract

Background: In the Medical Informatics in Research and Care in University Medicine (MIRACUM) consortium, an IT-based clinical trial recruitment support system was developed based on the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM). Currently, OMOP CDM is populated with German Fast Healthcare Interoperability Resources (FHIR) using an Extract-Transform-Load (ETL) process, which was designed as a bulk load. However, the computational effort that comes with an everyday full load is not efficient for daily recruitment.

Objective: The aim of this study is to extend our existing ETL process with the option of incremental loading to efficiently support daily updated data.

Methods: Based on our existing bulk ETL process, we performed an analysis to determine the requirements of incremental loading. Furthermore, a literature review was conducted to identify adaptable approaches. Based on this, we implemented three methods to integrate incremental loading into our ETL process. Lastly, a test suite was defined to evaluate the incremental loading for data correctness and performance compared to bulk loading.

Results: The resulting ETL process supports bulk and incremental loading. Performance tests show that the incremental load took 87.5% less execution time than the bulk load (2.12 min compared to 17.07 min) related to changes of 1 day, while no data differences occurred in OMOP CDM.

Conclusions: Since incremental loading is more efficient than a daily bulk load and both loading options result in the same amount of data, we recommend using bulk load for an initial load and switching to incremental load for daily updates. The resulting incremental ETL logic can be applied internationally since it is not restricted to German FHIR profiles.

Introduction

Background and Significance

Randomized controlled trials are the gold standard to “measure the effectiveness of a new intervention or treatment” [1]. However, randomized controlled trials are limited regarding the representative number of persons included and, therefore, restricted in their external generalizability. To gain more unbiased evidence, observational studies focus on real-world data from large heterogeneous populations.

To support observational research, we already provide a transferable Extract-Transform-Load (ETL) process [2] to transform German real-world data to the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) [3] provided by Observational Health Data Sciences and Informatics (OHDSI) [4], which supports the possibilities for multicentric and even international studies. Due to the heterogeneity of the structure and content of the data from the data integration centers within the Medical Informatics Initiative Germany (MI-I) [5], the Health Level 7 (HL7) [6] Fast Healthcare Interoperability Resources (FHIR) communication standard was specified among all German university hospitals. Consequently, we used FHIR as the source for our ETL process. The FHIR specification is given by the core data set of the MI-I [7]. FHIR resources can be read from an FHIR Gateway [8] (PostgreSQL database) or FHIR Server (eg, HAPI [9] or Blaze [10]). As the target of our ETL process, we used OMOP CDM v5.3.1 [11]. The implementation of the ETL process was done using the open source framework Java SpringBatch [12]. Our

ETL process has been implemented in accordance with the default assumption as described in the Book of OHDSI [13], where the OHDSI community defines the ETL process as a full load to transfer data from source to target systems. This approach is efficient for a dedicated study where data gets loaded once without any update afterward but inefficient if it comes to the need for updated data on a daily basis.

Latter is the case for the developments around the improvement and support of the recruitment process for clinical trials, which the Medical Informatics in Research and Care in University Medicine (MIRACUM) [14] consortium, as part of the MI-I funded by the German Federal Ministry of Education and Research, is working on. In this context, an IT-based clinical trial recruitment support system (CTRSS) based on OMOP CDM was implemented [15]. The CTRSS consists of a screening list for recruitment teams that provides potential candidates for clinical trials updated on a daily base. To enable the CTRSS to provide recruitment proposals, it is necessary to transform the data in FHIR format at each site from the 10 MIRACUM data integration centers into the standardized format of OMOP CDM. The procession of FHIR resources to OMOP CDM through our ETL process has already been successfully tested and integrated at all 10 German university hospitals of the MIRACUM consortium.

So far, our ETL process is restricted to a bulk load of FHIR resources to OMOP CDM. This implied that all FHIR resources are read from the source. To enable the CTRSS to provide daily recruitment proposals, our ETL process has to be executed every day as a full load. However, an everyday full load is not efficient because often only a small amount of source data has changed during loading periods, which results in unnecessary long execution times considering a full load for daily executions. Consequently, the computational effort that comes with the daily execution of the bulk load is not efficient in the context of the CTRSS.

Thus, a new approach is needed to only process FHIR resources that were created, updated, or deleted (CUD) since the last execution of the ETL process once an initial load has been executed. This loading option is known as incremental loading.

Objective

To keep the bulk load option for dedicated studies and still be performant toward daily changes in the source data, a combination of bulk load and incremental load is needed. To reduce the additional effort in implementing a second independent ETL process for incremental loading, it is our aim to extend our existing ETL process with the option of incremental loading. During our research, we focused on the following four research questions:

1. What requirements need to be considered when integrating incremental loading into our existing ETL process design?
2. What approaches already exist for incremental ETL processes?
3. How can the identified requirements from research question 1 be implemented in our existing ETL process design?
4. Does incremental loading provide an advantage over daily bulk loading?

Methods

Analysis of the Existing ETL FHIR-to-OMOP Process

To determine the requirements for integrating incremental loading into our existing ETL process design, we performed an impact analysis focusing on the whole ETL process as well as, in more detail, the three main components of it, namely, Reader, Processor, and Writer as presented by Peng et al [2]. Regarding the whole ETL process, the following 3 requirements were needed:

- Requirement A: It is necessary to provide the user with the ability to distinguish between bulk loading and incremental loading.
- Requirement B: For incremental loading, it is further essential that the Reader of the ETL process is able to detect changes in the source system and reads only CUD-FHIR resources on a daily basis.
- Requirement C: During the processing of updated and deleted FHIR resources, duplicates and obsolete data should be avoided in OMOP CDM to guarantee data correctness.

Considering the semantic mapping from FHIR MI-I Core Data Set (CDS) to OMOP CDM and the Writer of the ETL process as described by Peng et al [2], incremental loading has no impact on both. In summary, incremental loading requires an adjustment of the implementation of the Reader and Processor.

Literature Review

To identify approaches that might be adaptable to our existing ETL design and fulfill the 3 requirements in the previous section, we conducted a first literature review on July 14, 2021; a second one on November 28, 2022; and a third one on February 22, 2023 (Multimedia Appendices 1, 2, and 3). Table 1 includes the search strings and the number of results for three literature databases.

Table . Literature review: database, search string, and number of results.

Database	Search string	Results, n
PubMed	All fields: (incremental) AND ((etl) OR (extract transform load))	7
IEEE Xplore	(("All Metadata": incremental) AND ("All Metadata": etl OR "All Metadata": extract transform load))	15
Web of Science	ALL=(incremental) AND (ALL=(etl) OR ALL=(extract transform load))	46

We included only articles from 2011 to 2022 in English. After removing duplicates, 51 items were left. These were screened independently by two authors (EH and MZ). Through the title and abstract screening, we identified 12 relevant articles. After the screening of the full texts, we included 8 articles within our research. Reasons for excluding the other articles were other meanings of the abbreviation "ETL," ETL tools without regard to theoretical approaches of incremental loads, focus on application instead of ETL process and theoretical approach, and quality and error handling without focus on a theoretical approach.

Only 2 of the 8 articles addressed ETL processes for loading patient data into OMOP CDM. Lynch et al [16] introduced an approach for incremental transformation from the data warehouse to OMOP CDM to prevent incremental load errors. They suggest basing the development on a quality assurance process regarding the data quality framework by Kahn et al [17]. Furthermore, they generated ETL batch tracking ids for each record of data during the transformation to OMOP CDM. For 1:1 mappings, they created custom columns in the standardized OMOP CDM tables, and for 1:n or n:1 mappings, they used a parallel mapping table to store the ETL batch id and a link to the corresponding record in OMOP CDM. Lenert et al [18] describe an automated transformation of clinical data into two CDMs (OMOP and PCORnet database) by using FHIR. Therefore, they use the so-called subscriptions of FHIR resources. These subscriptions trigger a function to create a copy of the FHIR resource and its transmission into another system whenever an FHIR resource is created or updated.

Despite OMOP CDM being the target database, the literature search revealed different concepts for incremental ETL itself. Kathiravelu et al [19] described the caching of new or updated data in a temporary table. Of the 8 articles, 7 described various methods for incremental updates, particularly focusing on change data capture (CDC). All describe different categories of CDC, like timestamp-based, audit column–based, trigger-based, log-based, application programming interface–based, and data-based snapshots [16,18,20-24]: (1) Lynch et al [16] and (2) Lenert et al [18] focused on triggers; (3) Wen [20] focused on timestamps and triggers; (4) Thulasiram and Ramaiah [21] and (5) Sun [22] focused on timestamps; (6) Hu and Dessloch [23] focused on timestamps, audit columns, logs, triggers, and snapshots; and (7) Wei Du and Zou [24] focused on snapshots and MapReduce.

In summary, the literature review revealed adaptable approaches, which can be applied for the implementation of requirements B and C. However, no approaches could be found in the literature for requirement A. For this reason, we have to define a new method to enable both bulk and incremental loading in one ETL process. The concrete integration of the approaches into our existing ETL design is described in more detail in the following sections.

Incremental ETL Process Design

Enabling Both Bulk and Incremental Loading

For the specification, if the ETL process should be executed as bulk or incremental load, we added a new Boolean parameter in the configuration file of the ETL process called APP_BULKLOAD_ENABLED. According to the desired loading option, the parameter has to be adjusted before executing the ETL process, with "true" results in a bulk load and "false" results in an incremental load. During the execution of the ETL process, this parameter is further taken into account for the Reader and Processor of the ETL process [2] to distinguish between the needs of bulk and incremental load (eg, to ensure that the OMOP CDM database is not emptied at the beginning of the ETL process execution during an incremental load).

Focusing on CUD-FHIR Resources Since the Last ETL Execution

Our purpose of incremental loading was to focus only on CUD-FHIR resources since the last time the ETL process was executed (whether as bulk or incremental load). Consequently, the ETL process for incremental load has to filter only CUD-FHIR resources from the source. The literature research showed that there are various CDC approaches to detect changes in the source. In our case, FHIR resources in the FHIR Gateway and FHIR Server contain metadata, such as a timestamp indicating when an FHIR resource was created, updated, or deleted in the source (FHIR Gateway: column last_updated_at; FHIR Server: meta.lastUpdated). That is why we used the timestamp-based CDC approach to filter FHIR resources, which have a timestamp specification after the last ETL execution time.

To ensure the filtering for the incremental load, we added two new parameters in the configuration file of the ETL process: DATA_BEGINDATE and DATA_ENDDATE. Both parameters have to be adjusted before executing the ETL process as incremental load. During the execution, the ETL process takes these two parameters into account and only reads FHIR resources from the source that has a metadata timestamp specification that is in [DATA_BEGINDATE, DATA_ENDDATE].

Guarantee Data Correctness in OMOP CDM

To avoid duplicates in OMOP CDM when processing updated and deleted FHIR resources, their existence in OMOP CDM has to be checked during the processing. The FHIR resources themselves do not have a flag that indicates whether they are new or have been changed. Only deleted FHIR resources can be identified by a specific flag in the metadata. To assess the existence of FHIR resources in OMOP CDM, a comparison of the data of the read FHIR resources with the data already available in OMOP CDM has to be done.

The literature research showed an approach to generate a unique tracking id per source data during the transformation process and its storage in OMOP CDM [16]. We decided against the approach of generating an additional id because FHIR resources already contain two identifying FHIR elements themselves: id and identifier. The id represents the logical id of the resource per resource type while the identifier specifies an identifier that is part of the source data. Both FHIR elements allow the unique identification of an FHIR resource per resource type. However, the standardized OMOP CDM tables do not provide the possibility to store this information from FHIR. Furthermore,

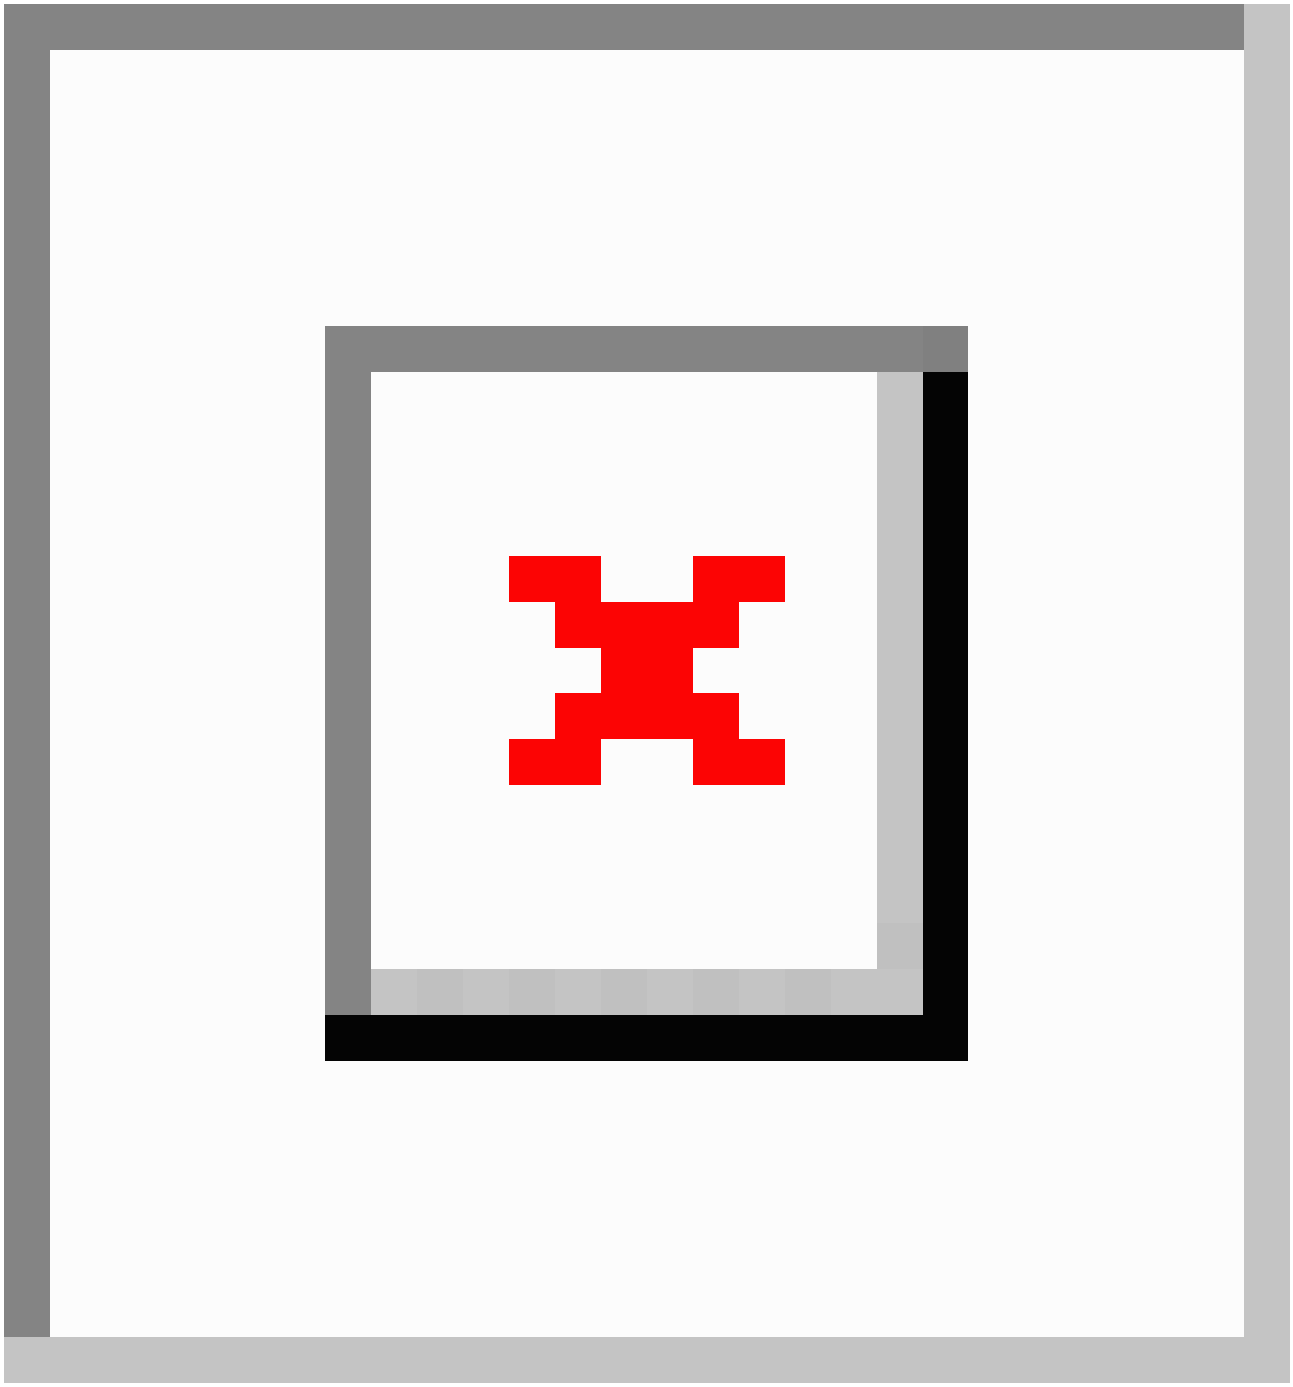
OMOP CDM has its own primary keys for each record in a table independent of the id and identifier used in FHIR. Consequently, after transforming FHIR resources to OMOP CDM, the identifying data from FHIR resources will be lost.

To solve this problem, we need to store the mapping between the id and identifier used in FHIR with the id used in OMOP CDM. Due to the fact that the id of an FHIR resource is only unique per resource type and one FHIR resource can be stored in OMOP CDM in multiple tables, we additionally have to specify the resource type. As mentioned above, Lynch et al [16] presented an approach to store the mapping between tracking ids for source records and ids used in OMOP CDM by using a mapping table and custom columns in OMOP CDM. We have slightly customized this approach and adapted it into our ETL design. Contrary to the use of both mapping tables and custom columns, we considered each approach separately.

Our first approach uses mapping tables for each FHIR resource type in a separate schema in OMOP CDM. With this approach, the Writer of the ETL process has to fill additional mapping tables beside the standardized tables in OMOP CDM. Our second approach focuses on two new columns in the standardized tables in OMOP CDM called “fhir_logical_id” and “fhir_identifier.” These columns store the id and identifier of the FHIR resource. Furthermore, we appended an abbreviation of the resource type as a prefix to the id and identifier of FHIR (eg, “med-” for Medication, “mea-” for MedicationAdministration, or “mes-” for MedicationStatement FHIR resources). In consequence, the combination of the prefix with the id and identifier and its storage in OMOP CDM enables the unique identification of FHIR resources in OMOP CDM. Since the mapping tables and two new columns are required exclusively for the ETL process, the analysis of data across multiple OMOP CDM databases is not affected.

Based on the unique identification of FHIR resources in OMOP CDM, it is now possible to guarantee data correctness in OMOP CDM during incremental loading. Figure 1 shows the exemplary data flow for Condition FHIR resources for the second approach with two new columns. First, the Processor extracts the id and identifier used in FHIR. After that, the prefix is added to both values. Regardless of whether the data was created, updated, or deleted in the source, the ETL process next verifies each processed FHIR resource’s existence in OMOP CDM using the mapping tables or two new columns. During the verification, records are deleted in OMOP CDM if they were found. This approach is also used for updated FHIR resources to avoid incomplete updates for cross-domain mappings in OMOP CDM. Consequently, we do not perform updates on the existing records in OMOP CDM except Patient and Encounter FHIR resources to ensure referential integrity in OMOP CDM. In case FHIR resources are marked as deleted in the source, the processing is completed. Otherwise, the same semantic mapping logic as for bulk loading [2] applies afterward, and the data of the FHIR resources are written to OMOP CDM as new records with new OMOP ids.

Figure 1. Excerpt of the data flow of the Condition Processor. CDM: Common Data Model; FHIR: Fast Healthcare Interoperability Resources; OMOP: Observational Medical Outcomes Partnership.



Evaluation of the Incremental Load Process

For the evaluation of the incremental load process, we defined and executed two ETL test designs. First, we tested which approach to store the mapping between id and identifier used in FHIR with the id used in OMOP CDM was the most performant. For this purpose, we implemented a separate ETL process version for each approach. Afterward, we executed the ETL process as bulk load first and as incremental load afterward, and compared the execution times between the mapping table approach and the column approach. For further evaluation of the incremental load process, we have chosen the most performant approach, resulting in a new optimized ETL process version for the second ETL test design.

To test the achievement of the 3 requirements identified during the initial analysis of our ETL process, we defined and executed a second ETL test design (Table 2) that compares the results of bulk loading with those of incremental loading regarding performance and data correctness. Our hypotheses here are that the execution time of incremental loading alone is less than bulk loading including daily updates and that the amount of data per table in OMOP CDM is identical after incremental loading and bulk loading, including daily updates.

Table . Extract-Transform-Load test design regarding performance and data correctness.

Test focus	Hypothesis
Performance	t(bulk loading (3 mon)) + t(incremental loading (1 d)) < t(bulk loading (3 mon)) + t(bulk loading (3 mon + 1 d))
Data correctness	#((bulk loading (3 mon)) + (incremental loading (1 d))) = #(bulk loading (3 mon + 1 d))

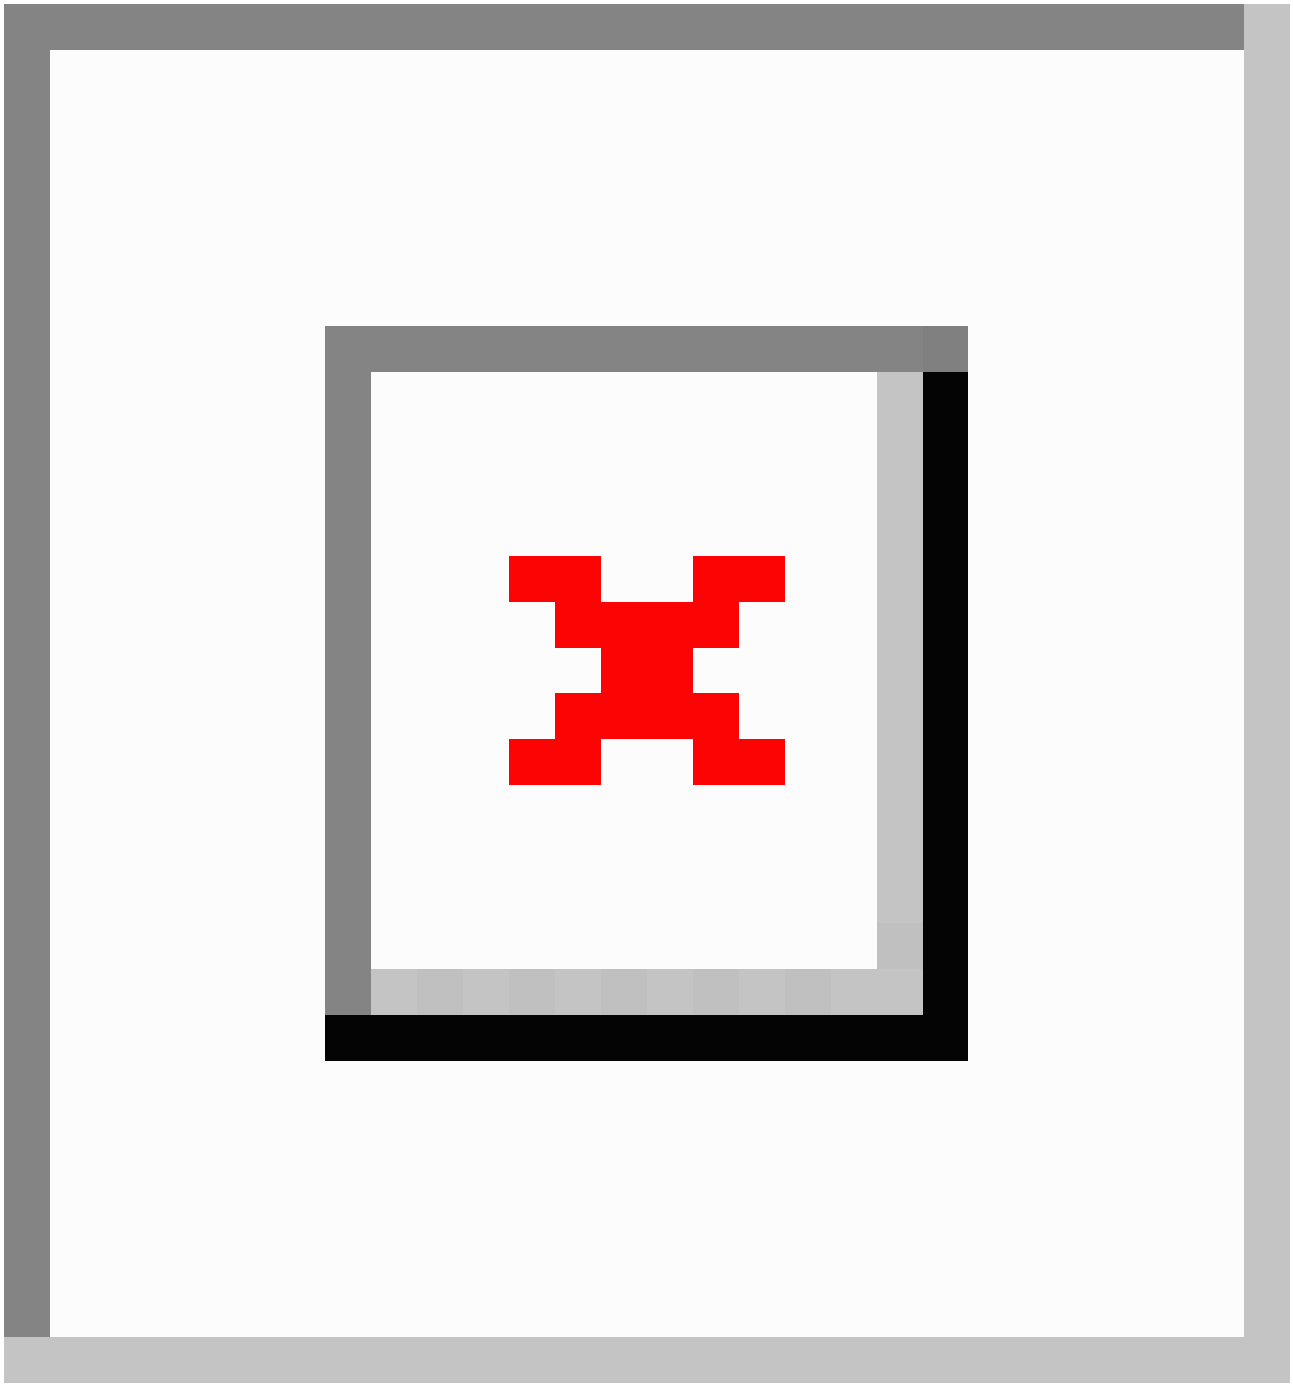
For both ETL test designs, we used a total of 3,802,121 synthetic FHIR resources version R4 based on the MI-I CDS version 1.0, which were generated using random values. Furthermore, we simulated CUD-FHIR resources for testing incremental loading for 1 day. For the simulation, we checked the frequency distribution of CUD data per domain in our source system with real-world data for 8 days and calculated the average value (see Multimedia Appendix 4). In addition, we set up one OMOP CDM v5.3.1 database as the target and executed the ETL process according to our test designs. For both ETL tests, we tracked the execution times based on the time stamps in the logging file of the ETL process until the corresponding job finished successfully. In a second step, we recorded the data quantity for each filled table in OMOP CDM and compared the results between the two ETL loading options for the second ETL test.

Results

Architecture of the ETL Process

The implemented ETL process extension for incremental loading of FHIR resources to OMOP CDM has not changed the basic architecture of the ETL process as proposed by Peng et al [2], consisting of Reader, Processor, and Writer (Figure 2). The only addition is a switch at the beginning of the ETL process, which allows the user to select between bulk load and incremental load (requirement A). Moreover, we configured the Reader for incremental loading of CUD-FHIR resources on a daily basis (requirement B). In the Processor, we added the logic of the verification of CUD-FHIR resources and their deletion from OMOP CDM if they already exist (requirement C).

Figure 2. Architecture of the FHIR-to-OMOP Extract-Transform-Load process including incremental load. CDM: Common Data Model; FHIR: Fast Healthcare Interoperability Resources; OMOP: Observational Medical Outcomes Partnership.



The ETL process covering bulk and incremental load is available in the OHDSI repository ETL-German-FHIR-Core [25].

Findings of the First ETL Test

The first ETL test focused on the performance measurement of the mapping table approach versus the column approach. First, we executed both ETL approaches as a bulk load. The column approach took about 30 minutes to transform FHIR resources to OMOP CDM. In contrast, the mapping table approach was still not finished after 4 hours. Therefore, we stopped the ETL execution and did not test the incremental loading anymore. Consequently, for the incremental ETL design, we decided to use the column approach due to its better performance and executed the subsequent performance evaluations with it.

Findings of the Second ETL Test

The second ETL test dealt with testing our two hypotheses in Table 2. First, we compared the execution times between a bulk load (3 mon + 1 d) and an initial bulk load (3 mon) followed by an incremental load (1 d). For this, each loading option was executed three times. Based on the results, we calculated the average execution times. The performance results (Multimedia Appendix 5) show that an initial bulk load (13.31 min) followed by a daily incremental load (2.12 min) is more efficient than an everyday full load (17.07 min). Looking at the percentage improvement in performance, it can be shown that incremental loading had 87.5% less execution time than a daily full load

(2.12 min compared to 17.07 min). Referring to our first hypothesis, we were able to prove our initial assumption.

After the execution of both loading options, we further checked the data quantity for each filled table in OMOP CDM and compared the results of it. As shown in Table 3, both loading options resulted in the same amount of data (Multimedia Appendix 5). Consequently, we were also able to confirm our second hypothesis regarding data correctness in OMOP CDM.

Table . Results of the data quantity comparison in the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) between bulk and incremental load.

	Bulk load (3 mon + 1 d), n	Bulk load (3 mon) + incremental load (1 d), n

Discussion

Principal Findings

Based on the partial results for research questions 1 and 2, we defined three methods to integrate incremental loading into our ETL process design. In this context, the 3 identified requirements from the initial analysis could be implemented by taking existing approaches from the literature into account (research question 3). Moreover, the incremental load process was tested at 10 university hospitals in Germany and ensures daily data transfer to OMOP CDM for the CTRSS. This proves that the ETL process is also suitable for real-world data, although it was developed with synthetic data.

Currently, our ETL process requires FHIR resources following the MI-I core data set specification. However, our initial requirements analysis showed that the implemented incremental ETL logic does not affect the semantic mapping from FHIR to OMOP CDM described by Peng et al [2]. In consequence, the incremental ETL logic is independent of the data available in the FHIR format. Therefore, it can be used to incrementally transform international FHIR profiles such as the US Core Profiles [26] to OMOP CDM.

Limitations

Nevertheless, the ETL process has limitations in its execution capabilities. As our FHIR resources comprise a logical id corresponding to the id in our source system, our ETL process is currently not able to deal with changing server end points, resulting in changing logical ids. Additionally, so far, we have not included an option to automatically start incremental loading nor do we support real-time streaming (eg, via Apache Kafka [27]). These limitations are part of future work.

To evaluate incremental loading compared to bulk loading, we performed two ETL tests (research question 4). The results of the performance tests showed that the column approach is more performant than the mapping table approach. Our suspected explanation for this is that the mapping table approach requires additional tables to be filled besides the standardized tables in OMOP CDM. Consequently, during the verification of FHIR resources in OMOP CDM, a lookup and deletion in several tables (mapping tables and standardized tables) is necessary, whereas the column approach only accesses the standardized tables.

Referring to our two hypotheses regarding performance and data correctness between incremental loading and bulk loading, we showed that our initial assumptions were proven. With the option of an incremental ETL process, we were able to reduce execution times to provide data in OMOP CDM on a daily basis, without data loss compared to the bulk load ETL process. For our future work, we want to further evaluate at what point bulk load is more worthwhile than incremental loading. The results of these evaluations will be incorporated into the automation concept.

During the productive use of the ETL process, we identified two issues that have to be considered in the context of incremental loading to OMOP CDM. First, OHDSI provides a wide range of open-source tools (eg, ATLAS [28]) for cohort definitions or statistical analyses. To make ATLAS work on the data in OMOP CDM, a summary report has to be generated in advance using ACHILLES [29] (Automated Characterization of Health Information at Large-Scale Longitudinal Evidence

Systems), an R package that provides characterization and visualization. Regarding the incremental ETL process, ACHILLES has to be run after each successful execution of the incremental ETL process.

A second issue that needs to be addressed relates to the ids in the standardized tables in OMOP CDM. The incremental loading process requires the assignment of new ids in the OMOP CDM. While this was not a problem during development, it becomes obvious when a large amount of data is processed. In this context, the maximum id in the tables of OMOP CDM was reached, which led to a failure of the ETL process. We need to pay special attention to this point and find a solution (eg, by reusing deleted ids or by changing the ETL process in a real updating ETL process). As this problem does not occur during the bulk load process, a current workaround is to start that process if the incremental load fails, which is possible as our process comprises bulk and incremental load options.

Conclusions

The presented ETL process from FHIR to OMOP CDM now enables both bulk and incremental loading. To receive daily updated recruitment proposals with the CTRSS, the ETL process no longer needs to be executed as a bulk load every day. One initial load supplemented by incremental loads per day meets the requirements of the CTRSS while being more performant. Moreover, since the incremental ETL logic is not restricted to the MI-I CDS specification, it can also be used for international studies that require daily updated data from FHIR resources in OMOP CDM. To be able to use not only the logic of incremental loading internationally, but the whole ETL process itself, the support of arbitrary FHIR profiles is needed. This requires a modularization and generalization of current ETL processes. For that, we will evaluate the extension to metadata-driven ETL in the near future.

Acknowledgments

The research reported in this work was accomplished as part of the German Federal Ministry of Education and Research within the Medical Informatics Initiative, Medical Informatics in Research and Care in University Medicine (MIRACUM) consortium (FKZ: 01lZZ180L; Dresden). Abstract

Background: The COVID-19 pandemic has spurred large-scale, interinstitutional research efforts. To enable these efforts, researchers must agree on data set definitions that not only cover all elements relevant to the respective medical specialty but also are syntactically and semantically interoperable. Therefore, the German Corona Consensus (GECCO) data set was developed as a harmonized, interoperable collection of the most relevant data elements for COVID-19–related patient research. As the GECCO data set is a compact core data set comprising data across all medical fields, the focused research within particular medical domains demands the definition of extension modules that include data elements that are the most relevant to the research performed in those individual medical specialties.

Objective: We aimed to (1) specify a workflow for the development of interoperable data set definitions that involves close collaboration between medical experts and information scientists and (2) apply the workflow to develop data set definitions that include data elements that are the most relevant to COVID-19–related patient research regarding immunization, pediatrics, and cardiology.

Methods: We developed a workflow to create data set definitions that were (1) content-wise as relevant as possible to a specific field of study and (2) universally usable across computer systems, institutions, and countries (ie, interoperable). We then gathered medical experts from 3 specialties—infectious diseases (with a focus on immunization), pediatrics, and cardiology—to select data elements that were the most relevant to COVID-19–related patient research in the respective specialty. We mapped the data elements to international standardized vocabularies and created data exchange specifications, using Health Level Seven International (HL7) Fast Healthcare Interoperability Resources (FHIR). All steps were performed in close interdisciplinary collaboration with medical domain experts and medical information specialists. Profiles and vocabulary mappings were syntactically and semantically validated in a 2-stage process.

Results: We created GECCO extension modules for the immunization, pediatrics, and cardiology domains according to pandemic-related requests. The data elements included in each module were selected, according to the developed consensus-based workflow, by medical experts from these specialties to ensure that the contents aligned with their research needs. We defined data set specifications for 48 immunization, 150 pediatrics, and 52 cardiology data elements that complement the GECCO core data set. We created and published implementation guides, example implementations, and data set annotations for each extension module.

Conclusions: The GECCO extension modules, which contain data elements that are the most relevant to COVID-19–related patient research on infectious diseases (with a focus on immunization), pediatrics, and cardiology, were defined in an interdisciplinary, iterative, consensus-based workflow that may serve as a blueprint for developing further data set definitions. The GECCO extension modules provide standardized and harmonized definitions of specialty-related data sets that can help enable interinstitutional and cross-country COVID-19 research in these specialties.

Introduction

The COVID-19 pandemic has led to unprecedented, strong efforts in connecting nationwide and international research to help manage the disease and its effects on public health. To enable research across different health care providers, institutions, or even countries, interoperability between medical data systems is essential [1]. Therefore, early in the pandemic, the German Corona Consensus (GECCO) data set was developed in a collaborative effort to provide a standardized, unified core data set for interinstitutional COVID-19–related patient research [2]. The GECCO data set specifies a set of 81 essential clinical data elements from 13 domains, such as anamnesis and risk factors, symptoms, and vital signs, that have been selected by expert committees from university hospitals, professional associations, and research initiatives. Since its development, the GECCO data set has been implemented in a large number of institutions, most notably in virtually all German university hospitals, which now provide access to the GECCO data set in the context of the German COVID-19 Research Network of University Medicine ("Netzwerk Universitätsmedizin") [3,4].

The GECCO data set was developed to contain as many relevant data elements as possible but few enough to keep the effort of implementing the data set manageable. Therefore, the data set contains mostly data elements of general research interest, excluding data elements that are only of interest for particular medical specialties or use cases. These data items are considered part of domain-specific extension modules of the GECCO data set, which are introduced in this paper.

We aimed to develop domain-specific extensions to the GECCO data set that cover the most relevant data elements for COVID-19–related patient research in the infectious disease (with a focus on immunization), pediatrics, and cardiology medical specialties. To that end, we first developed a workflow that aims at providing data set definitions that (1) contain the most relevant data elements for the research aims of the end users and (2) can be applied universally across institutions and countries. We then followed that workflow with different groups of medical experts from different medical specialties to define extension modules that are relevant for research regarding immunization, pediatrics, and cardiology.

These extension modules complement the GECCO core data set and use the same international health IT standards and terminologies as those in the GECCO data set, such as the Systematized Nomenclature of Medicine-Clinical Terms (SNOMED CT) [5], the Logical Observation Identifiers Names and Codes (LOINC) [6,7], and the Fast Healthcare Interoperability Resources (FHIR) [8,9] standard. The extension modules were developed in close alignment with the GECCO data set to ensure interoperability and compatibility with existing definitions.

We herein describe the consensus-based data element selection and data format definition workflow that we applied in close collaboration with medical experts from 3 specialties—infectious diseases (with a focus on immunization), pediatrics, and cardiology (ie, for content definition)—as well as medical information specialists and FHIR developers (ie, for technical aspects). This workflow may serve as a blueprint for the further development of consensus-based data set definitions.

Methods

Workflow Definition

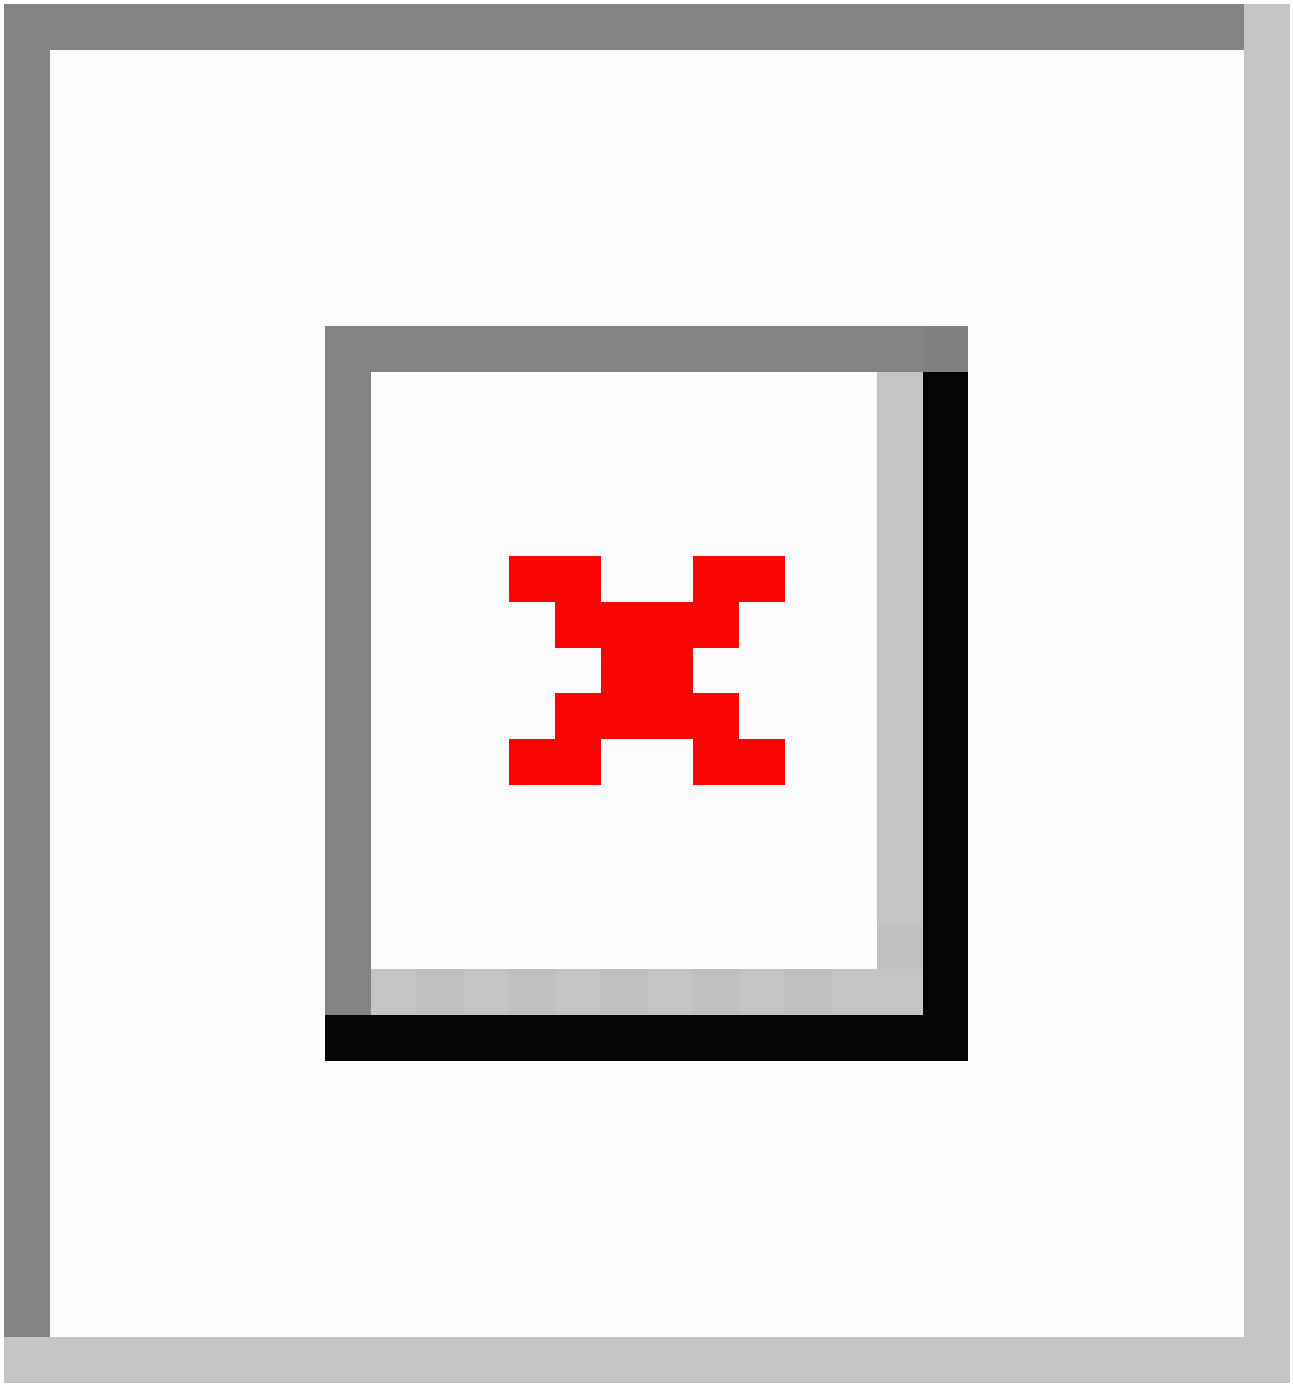
We aimed to develop a workflow to create data set definitions that are (1) content-wise as relevant as possible to a specific field of study and (2) universally usable across computer systems, institutions, and countries (ie, interoperable). We based the specification of the workflow on our experience with the definition of the GECCO data set, during which health professionals from 50 institutions (university hospitals, professional associations, and other relevant organizations) participated to define the most relevant data elements for general-scope, COVID-19–related research [2]. To fulfill the first requirement (relevancy), we decided to leave the full responsibility of data element selection to groups of medical professionals of the respective specialty, with only minimal interference by the medical information specialists. We deliberately did not specify the exact process of how the group of medical experts could select the data elements (eg, literature

review, focus groups, and consensus-based processes) to allow for the maximal flexibility of the data set definition workflow, with respect to the medical experts' values and preferences. To fulfill the second requirement (interoperability), we adopted a model that was loosely based on the data FAIRification workflow of Jacobsen et al [10]; the mapping, quality assurance, and publication steps are outlined in detail below.

Selection of Data Items

The content of the domain-specific research data sets was defined by medical domain experts in a transparent workflow (Figure 1). The involvement of the medical domain experts as the end users of the data to be provided ensured that the contents of the data sets were aligned to the actual research needs. In our project, the so-called *subject- and organ-specific working groups* of the National Pandemic Cohort Network ("Nationales Pandemie Kohorten Netz" [NAPKON]) served as the domain-specific groups of medical experts. These groups were established by a voluntary association of medical experts from the medical specialties within the nationwide NAPKON project in Germany. Each of the subject- and organ-specific working groups elected a board, and all communication between the data set developers and the working groups was organized and carried out via the working groups' boards. In preparation for the GECCO extension modules, we invited the subject- and organ-specific groups for infectious diseases (with a focus on immunization), pediatrics, and cardiology to provide up to 50 data elements (with up to 10 response items each) that were, in the view of the medical experts, the most relevant to patient-related COVID-19 research in these medical specialties and not already included in the GECCO core data set. If necessary, more data items or response options could be provided in coordination with the medical information specialists. The provided data items were then reviewed by the medical information specialists, and a first definition of the contents of the extension module was returned to the respective subject- and organ-specific working group for approval or change requests. After approval by the subject- and organ-specific working group, the definition of the extension module content was considered finalized.

Figure 1. Flowchart of the consensus-based, interdisciplinary data set definition and mapping workflow for the domain-specific COVID-19 research data sets. FHIR: Fast Healthcare Interoperability Resources.



Development of the Standardized Data Formats

To map the data items selected by the subject- and organ-specific working groups to international standard vocabularies, we performed a consensus-based mapping procedure, wherein every concept was mapped to appropriate vocabularies—the SNOMED CT for general concepts [11]; LOINC for observations [7]; *International Statistical Classification of Diseases and Related Health Problems, 10th Revision, German Modification* for diagnoses [12]; Anatomical Therapeutic Chemical Classification System for Germany for drugs and active ingredients [13]; and Unified Code for Units of Measure for measurement units [14]—by 2 medical information specialists independently. Ambiguities and nonmatching mappings were then discussed among the medical information specialists and in close collaboration with the medical experts of the subject- and organ-specific working groups until consensus was achieved. The data item–to-concept mappings were annotated on ART-DECOR, an open-source collaboration platform for creating and maintaining data set element descriptions [15].

As for the GECCO data set, the format for data exchange was specified by using Health Level Seven International (HL7) FHIR resources. The mapping of data items to FHIR resources was performed in an iterative, consensus-based workflow among the medical information specialists. Wherever possible, published FHIR profiles from the GECCO data set, the Medical

Informatics Initiative [16], or the National Association of Statutory Health Insurance Physicians ("Kassenärztliche Bundesvereinigung") [17]—in this order of priority—served as the base definition for the future extension module profiles.

The profiles and value sets were specified by using the FHIR Shorthand (FSH) language (version 1.2.0) and translated to Structure Definition JSON files by using the HL7 FSH SUSHI software package (version 2.2.3) [18,19]. We required that at least one exemplary instance be defined for every profile. The syntactic validation of the profile and value set definitions was performed through the error-free conversion of the FSH files to JSON via SUSHI, and the subsequent validation of each profile and their defined instances was performed by using the HL7 FHIR validator as implemented in the FSH Validator Python package (version 0.2.2) [20]. After the successful syntactic validation of a set of profiles, the profiles were subjected to a 2-stage review process, as follows. First, the profiles and the corresponding value sets and extensions were internally reviewed for semantic appropriateness with the GECCO core developer (JS). After all necessary changes and approval by the internal reviewer, the profiles were subjected to the second review round by an external FHIR development expert. Subsequent to necessary corrections and the approval of the external reviewer, the respective profiles, together with their value sets and, optionally, extensions and code systems, were considered finalized and published to the main branch of the Git repository. The subsequent and ongoing maintenance phase of the data set definitions involves inviting implementers and users to report any issues that they encounter with the definitions, in order to ensure their accuracy and relevance over time.

The whole development process was performed collaboratively on GitHub. The syntactic validation of the profiles was performed via continuous integration/continuous development workflows, which were implemented as GitHub actions. Semantic validation during the internal and external review rounds was performed by using pull requests to 2 different Git branches. After the final approval, profiles and value sets were merged into the main branch of the respective extension module's repository, which served as the publication branch of that module. Since then, maintenance requests and updates of the extension modules have been handled via GitHub issues. All kinds of relevant changes have become subjects of the internal review, as defined above; major changes (eg, nontechnical corrections) are additionally exposed to the external review.

Implementation guides were created for all 3 extension modules, using the FHIR IG Publisher tool and a customized template for the implementation guides' HTML pages [21]. The implementation guides were published to GitHub pages, where they remain automatically synchronized with the main branch of the respective repository via continuous integration/continuous development workflows.

Ethics Approval

This study did not involve any human or animal experiments. No permissions were required to access any data used in this study.

Results

Data Set Definition Workflow

We developed an interdisciplinary, iterative, expert consensus–based workflow for the initial definition of domain-specific COVID-19 research data sets based on 2 key requirements. The first key requirement for the content of the data sets was that the content definition (ie, selection of data elements) was to be performed under the full responsibility of a group of medical experts to ensure that the selected data elements were truly those that are required for research in the respective medical specialty. The second key requirement was to produce FAIR (Findable, Accessible, Interoperable, Reusable) digital assets [22], that is, the data set definitions should be represented in FHIR profiles and implementation guides, and these should be registered on open platforms (ie, findable); they should be retrievable through open, free, standard protocols (ie, accessible); they should use only standard, international medical terminologies, such as SNOMED CT and LOINC (ie, interoperable); and they should be released with rich usage guides and examples (FHIR implementation guide) and under a permissive license (ie, reusable).

To fulfill these requirements, the data set definition workflow consists of the following 6 phases: content definition, mapping, quality assurance, publication, an optional public review, and maintenance (Figure 1). In the content definition phase, a group of medical experts from a particular medical specialty are approached by the medical information specialists and asked to provide a list of the data elements that are the most relevant to patient-related COVID-19 research in the respective medical specialty. How the medical expert group compiles the list in detail is left to their discretion (eg, based on systematic literature review or Delphi consensus processes). The medical information specialists only review the provided lists for consistency and redundancy and compile the final content definition in agreement with the medical expert group. In the mapping phase, all data elements are then mapped to international terminologies in consultation with the group of medical experts. Based on these, a logical model and the mappings of data elements to FHIR resources are established. In the quality assurance phase, the FHIR specifications are syntactically validated by using the HL7 FHIR validator as implemented in the FSH Validator Python package (version 0.2.2) [20] and then subjected to a 2-stage review process, during which 2 individual data interoperability and harmonization experts validate the specifications semantically, that is, they validate that the data elements defined by the group of medical experts are appropriately mapped to international standards. After any required changes, the logical model and the FHIR implementation guide are published and are openly accessible to the research community in repositories that fulfill the FAIR criteria as closely as possible, such as ART-DECOR [15] for the logical model and GitHub or the FHIR Implementation Guide registry for the implementation guide [23]. If desired, the initial release of the data set definition can be subjected to public review and balloting processes, which allow stakeholders to provide feedback and suggest changes. The public review and balloting processes provide an opportunity to obtain broader

input from and facilitate consensus building among the research community and stakeholders. Any changes resulting from the review and balloting processes can then be incorporated into the data set definition according to the herein presented workflow, and the updated version is released and maintained according to the same workflow. In the maintenance phase, the medical information specialists invite implementers and users of the data set definitions to report any issues they encounter with the definitions via GitHub issues or email, in order to ensure their accuracy and relevance over time. During the maintenance phase, requests for changes or updates to the data set definition should generally be limited to minor issues or corrections, as adding new data elements or making significant modifications to the definition would require running the entire workflow from the beginning.

Data Set Contents

Groups of Medical Experts

In the context of the NAPKON project of the German COVID-19 Research Network of University Medicine [24], so-called *subject- and organ-specific working groups* were established by the voluntary association of medical experts from different medical specialties. In preparation for the domain-specific data set definitions that extend the GECCO core data set, the working groups for infectious diseases (with a focus on immunization), pediatrics, and cardiology were invited by the data set development group to provide up to 50 data elements (with up to 10 response items each) that were of particular interest to their field, concerned patient-related COVID-19 research, and were not already included in the GECCO core data set. For the immunization data set definition, physicians from the COVIM (Collaborative Immunity Platform of the Netzwerk Universitätsmedizin) study for the determination and use of SARS-CoV-2 immunity [25-27] assumed the role of the organ-specific working group, as no such working group had been established previously.

Overview

We extended the GECCO core data set by developing domain-specific data set definitions for a total of 250 new data items—48 for the immunization extension module, 150 for the pediatrics extension module, and 52 for the cardiology extension module. These data items were collected, via an iterative consensus-based approach, from the subject- and organ-specific working groups, and they fall under 10 of the 13 data categories of the GECCO data set (Table 1). Data elements and the number of items for each individual extension module are shown in Tables 2, 3, and 4. The full lists of items are shown in the Tables S1-S3 in Multimedia Appendix 1.

Table . Number of data items per GECCO[a] data set category for each extension module.

GECCO data category	GECCO extension module		
	Immunization data items (N=48), n	Pediatrics data items (N=150), n	Cardiology data items (N=52), n
Anamnesis and risk factors	13	21	6
Complications	24	47	7
Demographics	__[b]	6	—
Epidemiological factors	—	—	—
Imaging	—	2	36
Laboratory values	1	27	2

[a]GECCO: German Corona Consensus.

[b]FHIR: Fast Healthcare Interoperability Resources.

All data items were mapped to the appropriate FHIR resources (Observation, Condition, Procedure, MedicationStatement, Encounter, Questionnaire, QuestionnaireResponse, Immunization, ImagingStudy, List, and Specimen), and 26, 14, and 18 profiles (25, 17, and 12 value sets) were created for the immunization, pediatrics, and cardiology extension modules, respectively. The data items that were already part of the GECCO data set and not removed during the data selection step were taken from the GECCO data set and referenced as such in the implementation guides.

The implementation guides for the three extension modules have been published on GitHub pages [28-30]. The source FSH files have been published on GitHub [31-33]. Logical models and data set descriptions are hosted on ART-DECOR, an open collaboration platform for modeling data set definitions, their descriptions, and their terminology bindings [34-36].

Discussion

Principal Findings

We herein present an interdisciplinary, iterative, consensus-based workflow for the definition of research data sets, focusing on creating data sets with the most relevant data elements for a particular field of study and on creating universally usable data sets according to the FAIR principles [22]. We applied the workflow to develop 3 GECCO extension modules that contain data items that are relevant for COVID-19–related patient research on infectious diseases (with a focus on immunization), pediatrics, and cardiology. These extension modules complement the GECCO core data set for domain-specified research. The data items are represented in HL7 FHIR profiles and use international terminologies to ensure a harmonized, standardized, and interoperable data set definition for these medical domains. The provision of data according to the extension modules introduced in this paper will enable cross-institutional and cross-country data collection and collaborative research with a particular focus on immunization, pediatrics, and cardiology.

We have specified and implemented an interdisciplinary, iterative, consensus-based workflow for the selection of data items and the development of the data set definition. Close collaboration and constant feedback loops with domain experts from various medical specialties right from the beginning of a project, as performed in this study, are key for the successful development of a useful data set definition. Indeed, since the selection of relevant data items in this study was driven by the end users of the data set, who are the researchers that later will be using the data for their specialized areas of research, the semantic usability of the data sets is guaranteed. Likewise, having medical information specialists develop the formal data set specification ensures the technical interoperability and usability of the data set definition. In this study, we focused on the initial development of interoperable data set definitions for COVID-19–related patient research on infectious diseases (with a focus on immunization), pediatrics, and cardiology. To ensure the continued accuracy and relevance of the data set definitions, such data set definitions should be regularly subjected to public review and balloting processes following the initial development. For example, a revised version of the GECCO data set will undergo HL7 balloting, pending stakeholders' approval.

Although general interoperability in health care and clinical research is difficult to achieve, we focused on achieving syntactic and semantic interoperability of the data set definitions,

which are 2 of the 4 levels into which interoperability can be distinguished, alongside technical and organizational interoperability [8]. We pursued semantic interoperability by using international standardized vocabularies, such as those provided by the LOINC and SNOMED CT vocabularies, to ensure that the meanings of the data elements and their interpretations were unambiguous. We pursued syntactic interoperability by using an open standard for data representation, namely the HL7 FHIR standard, which provides a flexible and extensible framework for exchanging data elements and resources between different systems and applications. We did not focus on organizational interoperability in our work, as this requires coordination and alignment between different health care organizations and stakeholders, which can be challenging in practice. Although we did not specifically address organizational interoperability in our study, we believe that our approach to achieving semantic and syntactic interoperability can contribute to broader efforts toward achieving organizational interoperability over time.

In addition to the successful development of data set definitions, several factors determine a successful deployment or the use of the developed extension modules [37]. First and most importantly, clear and concise documentation of how to implement and provide data using the data set definition is required. For FHIR-based data set definitions, so-called *implementation guides* are used to provide a narrative overview as well as technical details on the data set definition [38]. Thus, we have created and published implementation guides for each of the here developed extension modules. Second, the example implementations of the extension modules serve as a blueprint for developers and data engineers who implement the extension modules for their clinical databases. From our experience with the implementation of the GECCO data set, well-defined example data items may be of equal if not higher importance than the technical description of the data set specification, as developers and engineers tend to use the examples as blueprints for their implementation. Thus, we equipped every FHIR profile defined in the extension modules with at least one example. These examples are incorporated and issued within the implementation guides of the modules. Specifically, we aimed to provide 1 example for each different category of response option per profile. Third, the actual implementation of the extension modules should be part of follow-up infrastructure projects to supply funding and resources for filling the data set definition with actual data. For the GECCO data set, this is ensured by follow-up projects of the German COVID-19 Research Network of University Medicine (“Netzwerk Universitätsmedizin”), such as CODEX+ (Collaborative Data Exchange and Usage), which includes several implementation tasks that are actively using the GECCO data set items [39] and further projects [40-43]. Fourth, once the data set definitions are implemented and leveraged in use cases, additional demands to the data set are likely raised, or issues with existing definitions are revealed. The maintenance of existing definitions (eg, performing technical corrections, evolving the definitions, or adding new items) is, therefore, necessary and must be organized and funded. Last, successful use of the extension modules is also highly dependent on the degree of interoperability of the data set definitions [1,44,45]. For example, the use of questionnaires to assess certain features is common in clinical research. However, depending on the exact wording of the question and the number and wording of response options, results from different studies might not be directly comparable even if they assessed the same features, as the questions and response options differ between studies. In the presented extension modules, several items were at first specified in a questionnaire-like fashion, and the direct implementation of these as Questionnaire resources in FHIR would have limited the applicability of such data elements, especially when aiming to map these elements from an electronic health record system. In these cases, we revised the data element specification to use interoperable concepts rather than questions. Here, repeated consultation with and final approval of the group of medical experts were key to being able to convert questions into interoperable concepts that convey the same information as that intended by the content definition of the group of medical experts. In general, we recommend not to use Questionnaire and QuestionnaireResponse FHIR profiles in cases where the information to be represented can be modeled by using more general, interoperable concepts and FHIR resources.

The challenges of creating and harmonizing COVID-19 data sets are not unique to our work, and although initiatives, such as the Clinical Data Interchange Standards Consortium (CDISC), have released guidance on how to represent COVID-19 research data in a standardized format [46], the actual selection of the relevant biomedical concepts to be represented is left to the implementers. We explicitly selected the data elements for COVID-19–related patient research that are the most relevant for further characterizing patients with respect to research in infectious diseases (with a focus on immunization), pediatrics, and cardiology. However, we recognize the need for ongoing collaboration and standardization efforts to maximize interoperability and facilitate data sharing and analysis. Such efforts include integrating the GECCO data set with other COVID-19–related data sets and standards, both within and between countries. For example, we are currently harmonizing the GECCO data set with the ORCHESTRA (Connecting European Cohorts to Increase Common and Effective Response to SARS-CoV-2 Pandemic) project, which intends to create a harmonized and standardized data set for a pan-European cohort for COVID-19 research [40]. To facilitate the mapping of the data items that were developed in our work and represented in HL7 FHIR to the CDISC Study Data Tabulation Model standard, the organizations behind the two standards have collaboratively developed a comprehensive implementation guide, thereby enabling mapping between the different standards, ensuring compatibility, and facilitating interoperability across systems [47]. Moving forward, we encourage developers of tools and resources to facilitate the mapping and harmonization of different data standards, and we look forward to continued collaboration with the wider research community to address these challenges and advance COVID-19 research.

Conclusion

We herein introduce the development workflow and the resulting data set definitions for GECCO extension modules for the immunization, pediatrics, and cardiology domains. We have defined and implemented a workflow in which interdisciplinary

teams of medical domain experts, medical information specialists, and FHIR developers closely collaborate in an iterative, consensus-based fashion for the successful development of useful and interoperable data set definitions. This workflow may serve as a blueprint for further data set definition projects, such as the further development of data set definitions for extending the GECCO core data set. The extension modules described in this work have been validated and published. Their implementation and active use are anticipated in the context of current nationwide COVID-19 research networks in Germany.

Acknowledgments

The NAPKON ("Nationales Pandemie Kohorten Netz"; German National Pandemic Cohort Network) project is funded under a scheme issued by the Network of University Medicine (Nationales Forschungsnetzwerk der Universitätsmedizin [NUM]) by the Federal Ministry of Education and Research of Germany (Bundesministerium für Bildung und Forschung [BMBF]; grant number 01KX2021). The funding body did not take a role in the design of the study, in the development of the data set, or in the writing of the manuscript. We thank Yannick Börner for his valuable contribution to the definition of the Fast Healthcare Interoperability Resources (FHIR) profiles. We thank all members of the subject- and organ-specific working groups.

Data Availability

The implementation guides for the three extension modules have been published on GitHub pages [28-30]. The source Fast Healthcare Interoperability Resources Shorthand (FSH) files have been published on GitHub [31-33]. Data set descriptions can be found on ART-DECOR [34-36].

Authors' Contributions

All authors contributed to the development of the extension modules. GL, TH, SB, LR, JS, AB, and ST performed terminology mapping, FHIR profiling, and critical review of the concept and resource mappings. TH, SB, and LR defined the data sets in ART-DECOR. DH, FK, LES, FE, NT, RB, AF, and MD developed and compiled the list of data items for the data sets. SR, LL, and MU coordinated the project and the consensus finding process within and between working groups. JJV, CvK, and ST conceived the work. GL drafted the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

ST is the vice chair of Health Level Seven International (HL7) Germany. The other authors declare that they have no competing interests.

Abstract

Background: Studies on competency in medical education often explore the acquisition, performance, and evaluation of particular skills, knowledge, or behaviors that constitute physician competency. As physician competency reflects social demands according to changes in the medical environment, analyzing the research trends of physician competency by period is necessary to derive major research topics for future studies. Therefore, a more macroscopic method is required to analyze the core competencies of physicians in this era.

Objective: This study aimed to analyze research trends related to physicians' competency in reflecting social needs according to changes in the medical environment.

Methods: We used topic modeling to identify potential research topics by analyzing data from studies related to physician competency published between 2011 and 2020. We preprocessed 1354 articles and extracted 272 keywords.

Results: The terms that appeared most frequently in the research related to physician competency since 2010 were *knowledge*, *hospital*, *family*, *job*, *guidelines*, *management*, and *communication*. The terms that appeared in most studies were *education*, *model*, *knowledge*, and *hospital*. Topic modeling revealed that the main topics about physician competency included *Evidence-based clinical practice*, *Community-based healthcare*, *Patient care*, *Career and self-management*, *Continuous professional development*, and *Communication and cooperation*. We divided the studies into 4 periods (2011-2013, 2014-2016, 2017-2019, and 2020-2021) and performed a linear regression analysis. The results showed a change in topics by period. The *hot topics* that have shown increased interest among scholars over time include *Community-based healthcare*, *Career and self-management*, and *Continuous professional development*.

Conclusions: On the basis of the analysis of research trends, it is predicted that physician professionalism and community-based medicine will continue to be studied in future studies on physician competency.

Introduction

Background

Medical publications began defining competencies in the 1970s [1-3]. Physician competency refers to the essential qualities that a physician should possess. The search for physician competency begins with the question of what it means to be a physician. Competency connotes various ideas, such as which physician traits are desired by society and what supports and promotes this transition of identity. Competency entails the concept of the physician as a professional, what the physician can do, and how the physician approaches their practice [4]. In summary, competency is considered a complex set of behaviors built on the components of knowledge, skills, attitudes, and competence as a personal ability [5]. Competency in this study is the core competency required to successfully perform a physician's job and includes knowledge, skills, and attitude, regardless of the specific major.

In the medical profession, the competency theme began by pursuing ways for the medical circle to improve the performance of health care workers. The issue arose in response to the growing demands of medical consumers and society as a neoliberalistic ideology spread in the 1970s and consumers' awareness of their rights increased. In 1972, the American Academy of Pediatrics discussed physician competency by publishing a foundation for evaluating pediatricians' competency [3]. In 1978, the World Health Organization found the cause of declines in medical service quality to be inadequate education and attempted to improve health care providers' competencies through Competency-Based Curriculum Development in Medical Education [6]. Since then, this approach has influenced medical education globally, starting with the Royal College of Physicians and Surgeons in Canada and the Accreditation Council for Graduate Medical Education in the United States. Similar programs have been established worldwide, influencing strategies for global human resources and international partnerships for medical training [7]. These include the Outcome Project of the US Accreditation Council for Graduate Medical Education, General Medical Council's Tomorrow's Doctors [8-10], Scottish Doctor [11], and Canadian CanMEDS framework [12].

For physicians, competency varies depending on the clinical, cultural, and geographical context [13]. In medical practice, the perception of a medical professional's competent role changes continuously over time. In the early 19th century, physicians applied ointments and drew blood but did not deliver babies. In the 21st century, physicians are required to use advanced technologies and artificial intelligence in medical surgeries [14,15]. The ability to use technologies required by future health care systems is a challenge for physicians. However, at the same time, communication with patients and colleagues and interprofessional teamwork are essential human skills, and personal traits, such as empathy, humility, compassion, emotional intelligence, and a passion for continuous learning are also emphasized. Varying levels of health care infrastructure over time [16]; social awareness of minority groups [17]; and occasional health care challenges, such as global pandemics [18], emphasize certain specific physician competencies. Physicians' competency, initially discussed within the scope of their social accountability, includes changes in their roles from the perspective of patients, health care, and self-management [19] of their health and wellness [20]. Thus, physicians' abilities reflect their social situation and demands. In addition, physicians' core abilities are expected to change over time. Therefore, this study, which analyzed changes in physician competency by period, will help understand the social demands expected of physicians in each period and identify research topics that should be important in medical education in the future.

To date, studies on physician competency have focused on literature review [21-23] or meta-analyses [24,25]. However, systematic literature reviews have limitations in deriving comprehensively synthesized results because their analyses focus on narrow areas such as subjects, variables, environment, and intervention. In medical education, studies on competency often explore the acquisition, performance, and evaluation of particular skills, knowledge, or behaviors that constitute physician competency. Some of these studies examined patient-physician communication [26], risk management for emergency physicians, technical skills in robotic surgery in urological practice [27], and the instruction of medical staff [28]. Nevertheless, such approaches fail to convey the trends in physician competency research because they explore the essential medical skills for a specific task in a certain context. In addition, people may have different thoughts about the core competencies that physicians should possess. For example, a patient's expectations of a physician's ability may differ from a senior physician's expectation of a junior physician's ability. Therefore, a more macroscopic method is required to analyze the core competencies of physicians in this era.

Recently, new big data analysis techniques such as social network analysis and topic modeling have been used. These approaches have the advantage of organizing the knowledge structure context by forecasting the trajectory of change in research and future issues and revealing the correlation between concepts. Social network analysis involves detecting influential core keywords in a vast amount of text and showing the relationship between keywords, allowing researchers to comprehend the context intuitively [29,30]. Topic modeling detects hidden topics in text data, analyzes the association and distribution of each topic, and provides integrated information [31]. From a microscopic perspective, it identifies core topics and their relationships. From a macroscopic perspective, it identifies the flow and context of core topics and the trend of topics by period [32]. Text network analysis and topic modeling are ideal approaches for analyzing trends in research on physicians' competencies and accomplishing research objectives.

Objectives

The research problems based on the abovementioned research necessity are as follows:

1. Extract core keywords from physician competency studies and create a network

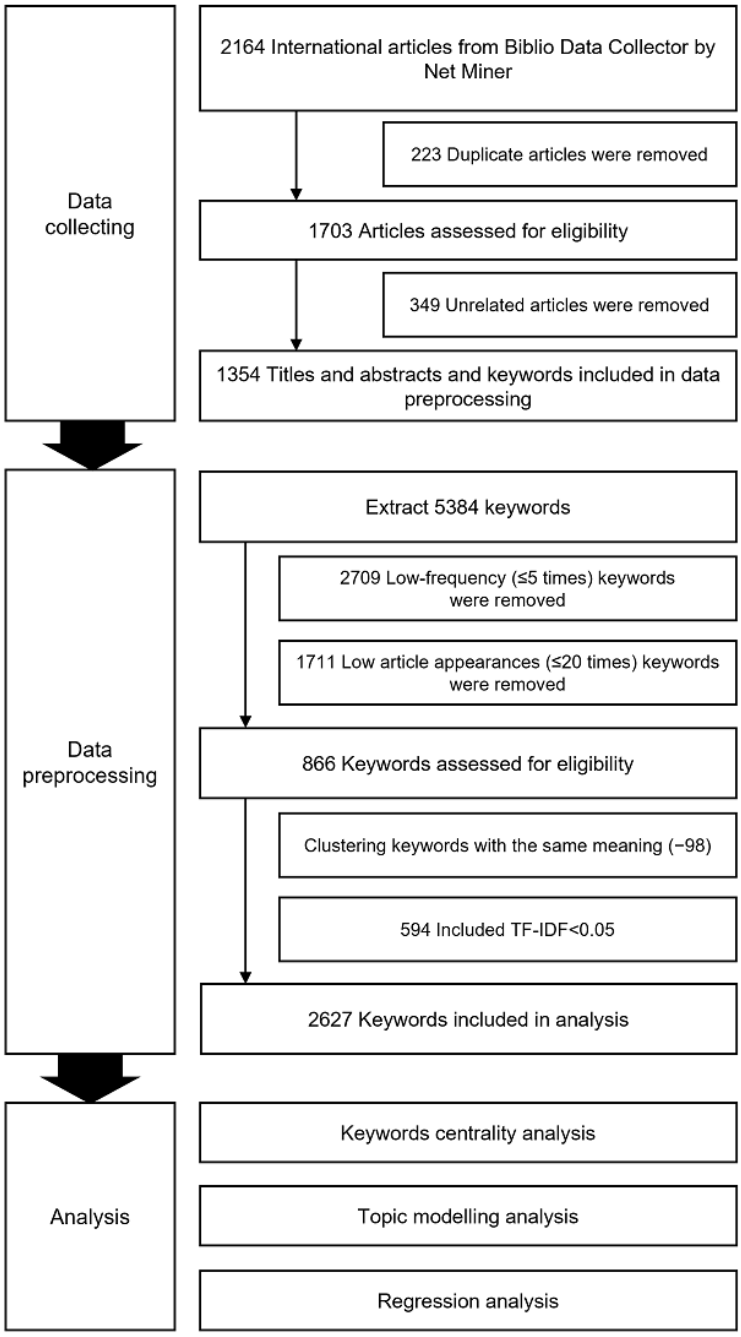
2. Examine the structure and characteristics of the network created based on physician competency studies
3. Examine the main topics through topic modeling in physician competency studies
4. Examine the trend of physician competency studies by topic based on time flow

Methods

Data Collection

To examine the flow of academic research on physician competency, we selected related research articles as raw data, which were collected using NetMiner Biblio Data Collector (Cyram Inc). We selected 10 years (2011-2020) and collected 2164 articles on physician competency published in *Springer* using the following keywords: "(doctors or physicians) AND ((competence or competency or competencies) or (expertise or expert or proficiency) or (responsibility or accountability or liability or blameworthiness) or (profession or occupation or roles or duties or jobs) or (performance and practice) or professionalism))." After eliminating 810 articles that overlapped or were unrelated, 1354 articles remained for our analysis. The research flow is illustrated in Figure 1.

Figure 1. Flow of research procedures. TF-IDF: term frequency–inverse document frequency.



Data Preprocess

Because we could not use the original text in the preselected articles in the analysis, we processed the sentences into separate words as units of analysis. The collected papers consisted of natural language sentences such as theories, knowledge, and opinions. However, the sentences cannot be used directly in the analysis. Therefore, steps must be taken to convert each sentence into an individual word that can be analyzed [33]. In this study, to extract nouns, adjectives, and verbs, we used the morpheme-refining function of the NetMiner program and extracted 5384 words from the titles, abstracts, and keywords of the research articles. Preprocessing was performed to convert these words into analyzable keyword data.

Nouns that were unsuitable for analysis were eliminated. First, we removed words that appeared 5 times or keywords that did not appear in more than 20 of the 1354 articles. In the final stage, we eliminated infrequently appearing words (<5 times) and extremely common words that appeared frequently in all papers (term frequency–inverse document frequency<0.05) [34]. After preprocessing, 272 words were extracted.

Social Network Analysis

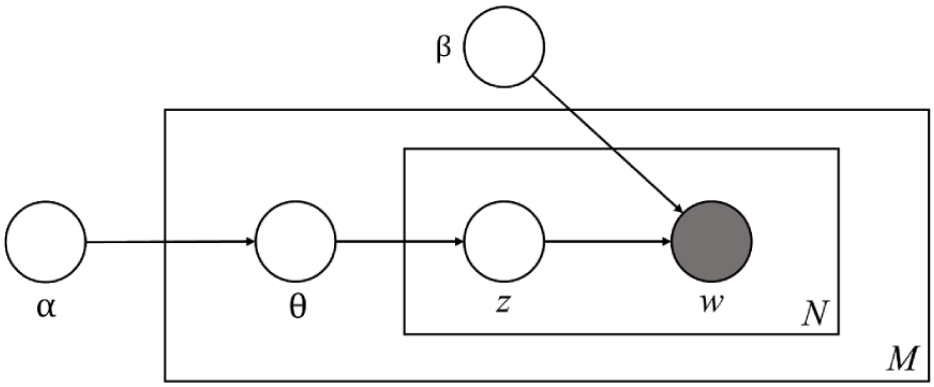
In this study, social network analysis was used to examine the knowledge structure and characteristics through keyword extraction and network generation from physician competency studies, designated as research problems 1 and 2. In addition, the roles of keywords in the network were determined by assessing their importance using social network analysis techniques such as degree centrality, closeness centrality, and betweenness centrality. Social network analysis determines core nodes based on degree centrality, closeness centrality, and betweenness centrality. The degree centrality of a node increases with the number of nodes directly connected to it. Thus, the degree centrality indicates the influence of a node (keyword) based on the number of connected nodes. The betweenness centrality indicates the centrality of a node (keyword) between 2 other nodes (keywords). Betweenness centrality increases when the number of times a node appears on the shortest path between 2 other nodes increases. Keywords with high betweenness centrality control the information flow and exert a substantial influence on the overall connectivity of the network. To visually understand the positions and relationships among keywords, we used spring mapping from NetMiner 4.0. Spring mapping maximizes the characteristics of branching out the graph by placing the connected nodes closer and the disconnected nodes farther, using a simulated annealing technique to balance the 2 forms of distance.

Topic Modeling

To address research problem 3, we conducted topic modeling to explore the topic areas of physician competency research. Topic modeling was performed using keywords extracted from social network analysis. NetMiner 4.0 was used as the analysis program. Topic modeling is used to predict latent topics based on the association of multiple words in a text. Topic modeling extracts topics from research papers through keyword exploration, which helps recognize knowledge structures and patterns [35]. Knowledge structures are defined as a visualization of keyword clustering and a network map of how concepts in domain knowledge are interrelated [36]. This pattern is defined as the process of change in the knowledge structure over a period [37]. Topic modeling, as a big data analysis technique, provides a quantitative approach for identifying previously undiscovered macrotopic areas in physician competency research. Topics were extracted by applying a latent Dirichlet allocation (LDA) algorithm. The LDA algorithm is a probability model for predicting hidden topics by analyzing the distribution of words observed in a document. It is useful for reducing the data size and producing consistent topics.

Figure 2 shows a graphical model of LDA. The boxes in the figure are “plates,” which represent duplicates. The outer plate represents the document (M) and the inner plate represents repeatedly selected topics (z) and words (w) within the document (N). “ ” indicates the distribution of topics in the document. Both “α” and “β” are hyperparameters that indicate Dirichlet distribution. LDA cannot be directly used to determine the number of topics, so the third hyperparameter is the “number of topics” the algorithm will discover. The probability calculation formula is as follows [38]:

Figure 2. Illustration for the conceptual model of latent Dirichlet allocation. α: a parameter that represents the Dirichlet prior for the document topic distribution; β: a parameter that represents the Dirichlet for the word distribution; θ: a vector for topic distribution over a document d; z: a topic for a chosen word in a document; w: specific words in N; M: document length; N: number of words in the document.



To increase the accuracy of the results, appropriate Cronbach α values, β values, number of topics, and keywords should be determined [39]. To evaluate how well each keyword described each topic, we used one of the topic consistency metrics, the silhouette coefficient. The silhouette coefficient is an indicator that evaluates how well keywords, which are components of a topic, are classified [40]. A value closer to 1 indicates that the keywords within each cluster are well formed. Moreover, good clustering means that similarity to other topics is low and keywords within the same cluster describe a topic well. For topic t characterized by a higher-order word set W_t (any word whose probability exceeds a predefined threshold or a fixed number of high-order words), the consistency formula is defined as follows [41]:

In this study, we set the term frequency–inverse document frequency threshold value at 0.5 and word length at 2. We used a silhouette coefficient to calculate the optimal values for Cronbach α, β, and the number of topics. A silhouette coefficient (or score) closer to 1 had higher explanatory power, validating Cronbach α, validating β, and the number of topics and descriptions of the object in the topic model were well matched. We also used a silhouette-clustering configuration. To determine the optimal number of topics, we conducted a comprehensive analysis by varying the number of topics from 5 to 30 and exploring Cronbach α values ranging from .01 to .99 as well as β values ranging from .01 to .99. The silhouette coefficient was used as the evaluation criterion. Our findings revealed that the highest silhouette coefficient of 0.782 was achieved using a Cronbach α value of .89, a β value of .97, and 6 topics. Subsequently, we proceeded with topic modeling using the identified parameters.

Analysis of Change in Topics by Period

To address research problem 4—the change in topics in physician competency research over time—the analysis was divided into 4 periods: 2011-2013, 2014-2016, 2017-2019, and 2020-2021. We divided the period into before and after the COVID-19 outbreak, and the researchers discussed and classified them. Subsequently, we analyzed how the percentages of each topic changed. To categorize the topics by checking the pattern of increased or decreased topics by period, we performed a linear regression analysis using SPSS (version 23.0; IBM Corp). We used the categorized periods as independent variables, and the percentage of each topic as the dependent variable. Following the linear regression analysis, we classified the keywords into 4 types based on the regression coefficient sign (+ or −) and the significance probability (P value): hot, warm, cool, and cold. If the coefficient is positive and the significance probability is ≤.05, it is classified as a "hot topic" with increasing research interest. Conversely, if the coefficient is negative and the significance probability is ≤.05, it is classified as a "cold topic" with decreasing research interest. Meanwhile, the clusters that were either positive or negative with no statistical significance and with a significance probability of ≥.05 were classified as "warm" and "cool" topics, respectively [42].

Ethics Approval

This study was conducted after obtaining approval from the Medical Research Ethics Review Committee of Chungnam National University Hospital (CNUH 2021-02-025).

Results

Core Keywords From Physician Competency Studies

Between 2011 and 2020, the words that appeared most frequently in physician competency studies were *knowledge* (604 times), *hospital* (598 times), *family* (597 times), *job* (573 times), *guideline* (491 times), *management* (482 times), and *communication* (443 times). The words that appeared in most studies were *education* (n=256), *model* (n=243), *knowledge* (n=238), and *hospital* (n=234). Table 1 presents the 25 words with the highest frequency and the number of articles in which they appeared.

Table 1. High-ranking keywords by frequency in research.

Rank	Keyword	Frequency, n	Articles in which it appears, n
1	Knowledge	604	238
2	Hospital	598	234
3	Family	597	161
4	Job	573	111
5	Guideline	491	164
6	Management	482	206
7	Communication	443	154
8	Education	437	256
9	Model	425	243
10	Assessment	407	150
11	Attitude	388	151
12	Information	381	213
13	Health care	379	196
14	Experience	368	224
15	Medication	356	64
16	Intervention	332	152
17	Cancer	330	89
18	Disease	313	150
19	Change	276	147
20	Need	268	196
21	Development	255	170
22	Behavior	253	87
23	Barrier	238	97
24	Evidence	234	158
25	Practice	227	199

Social Network Analysis

Table 2 presents keyword degree, closeness, and betweenness centrality from physician competency studies. Each keyword and its degree are as follows. The higher the degree of the keyword, the stronger the influence in the network. The keywords with the highest degree and closeness centrality were, in order, *model* (0.988 and 0.988, respectively), *education* (0.981 and 0.982), *experience* (0.973 and 0.975), *health care* (0.973 and 0.975), *hospital* (0.973 and 0.975), and *information* (0.973 and 0.975). The keywords with the highest betweenness centrality were, in order, *model* (0.007), *education* (0.006), *knowledge* (0.006), *management* (0.006), and *education* (0.006). In total, 29 words belonged to the top 30 keywords in all 3 centrality types. The keywords with a high degree centrality were also high in closeness centrality. However, the betweenness centrality of environment was higher than the degree and closeness centrality. Figure 3 shows the network map for centrality.

Table 2. High-ranking keywords by degree, closeness, and betweenness centrality.

Topic Modeling

Regarding the number of topics from physician competency studies, we decided on 6 topics (silhouette=0.782) by considering the silhouette coefficient and the validity of interpretation. The core keywords by topic are listed in Table 3. The top keywords in topic 1 were *management*, *intervention*, *disease*, *cost*, and *medication*. The top keywords in topic 2 were *family*, *health care*, *information*, *community*, and *need*. The high-ranking keywords in topic 3 were *knowledge*, *attitude*, *cancer*, *guideline*s, and *barrier*s. The high-ranking keywords in topic 4 were, in order, *hospital*, *job*, *burnout*, *model*, *gender*, and *intention*. The top keywords in topic 5 were, in order, *assessment*, *education*, *competency*, *development*, and *graduation*. Finally, the high-ranking keywords in topic 6 were, in order, *communication*, *consultation*, *experience*, *emergency*, and *feedback*.

Topic groups were labeled based on high-ranking core keywords in terms of probability distribution: topic 1, *Evidence-based clinical practice*; topic 2, *Community-based healthcare*; topic 3, *Patient care*; topic 4, *Career and self-management*; topic 5, *Continuous professional development*; and topic 6, *Communication and cooperation*. On the basis of the nature of the topics, we divided the topic groups into 2 domains: those related to job competency and those related to personal competency. The job domain includes topics 1, 2, 3, and 6, and the personal domain includes topics 4 and 5. Figure 4 presents the results of visualizing the 7 networks of core keywords using a topic-keyword map.

Table 3. Core keywords by topic.

Rank	Domain and topic					
	Job				Personal	
	Evidence-based clinical practice	Community-based healthcare	Patient care	Communication and cooperation	Career and self-management	Continuous professional development
1	Management	Family	Knowledge	Communication	Hospital	Assessment
2	Intervention	Health care	Attitude	Consultation	Job	Education
3	Disease	Information	Cancer	Experience	Burnout	Competency
4	Cost	Community	Guideline	Emergency	Model	Development
5	Medication	Need	Barrier	Feedback	Gender	Graduate
6	Diagnosis	Choice	PCP[a]	Child	Intention	Error
7	Diabetes	Clinic	Activity	Change	Career	Learning
8	Adherence	Model	Experience	Interaction	Life	Examination
9	Guideline	Mental	Confidence	Evaluation	Engagement	Model
10	Change	Education	Counseling	Model	Manager	Framework

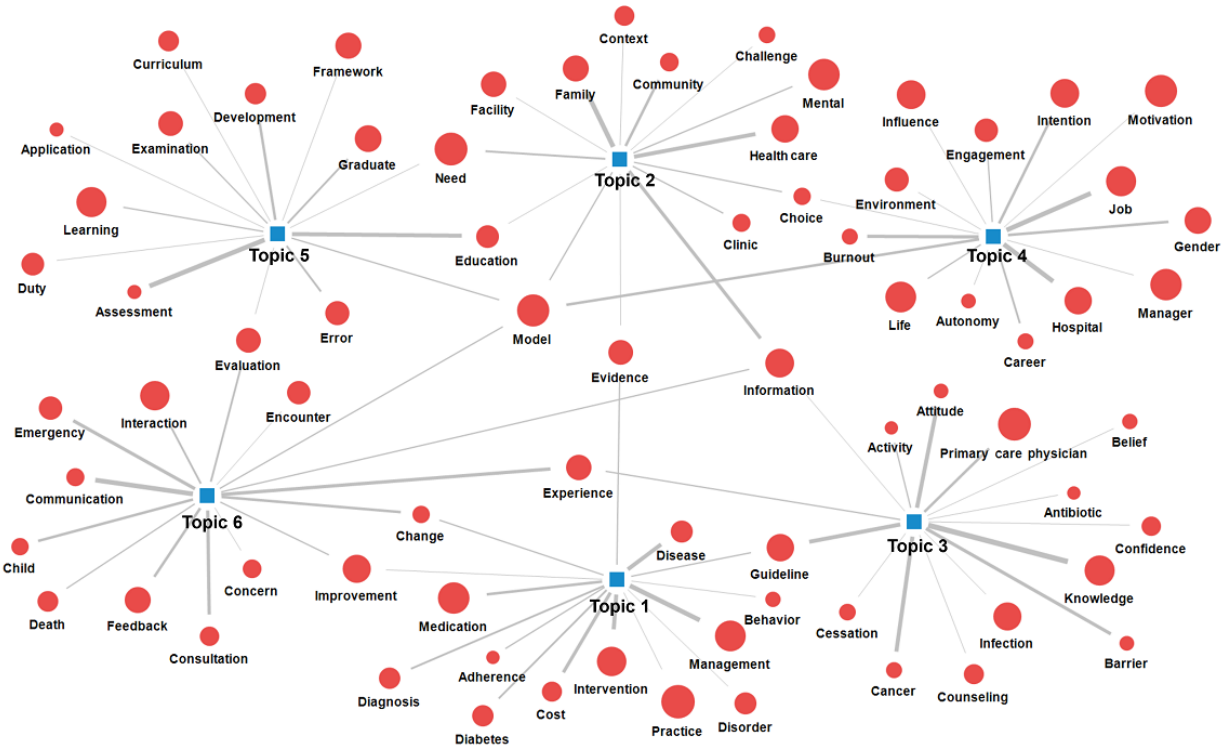
Figure 4. Topic modeling network: topic-keyword map.



Core Topics by Period

Table 4 presents the changes in topics over time and Table 5 lists the rate of each topic during this period. Over the past 10 years, each topic has been studied with similar weights. Communication and cooperation accounted for 18.61% (252/1354) of the articles, followed by Evidence-based clinical practice at 17.73% (240/1354) and Continuous professional development at 16.77% (227/1354). Regarding the domains, studies related to physicians' job competencies accounted for 61.21% (910/1354), whereas those related to physicians' personal competencies accounted for 32.79% (444/1354).

Table 4. Number of research on 6 topics by year (n=1354).

Domain and topic	2011 (n=82)	2012 (n=107)	2013 (n=98)	2014 (n=152)	2015 (n=134)	2016 (n=120)	2017 (n=125)	2018 (n=141)	2019 (n=129)	2020 (n=167)	2021 (n=99)	Total (n=1354)
Job, n (%)												
Evidence-based clinical practice	15 (6.3)	24 (10)	24 (10)	27 (11.3)	22 (9.2)	21 (8.8)	25 (10.4)	26 (10.8)	25 (10.4)	21 (8.8)	10 (4.2)	240 (100)
Community-based health-care	11 (5.2)	13 (6.1)	13 (6.1)	22 (10.3)	26 (12.2)	22 (10.3)	17 (8)	18 (8.5)	20 (9.4)	29 (13.6)	22 (10.3)	213 (100)
Patient care	13 (6.3)	22 (10.7)	6 (2.9)	29 (14.2)	12 (5.9)	15 (7.3)	18 (8.8)	23 (11.2)	14 (6.8)	36 (17.6)	17 (17.6)	205 (100)
Communication and cooperation	20 (7.9)	21 (8.3)	22 (8.7)	25 (9.9)	30 (12)	21 (8.3)	22 (8.7)	21 (8.3)	25 (9.9)	24 (9.5)	21 (8.3)	252 (100)
Personal, n (%)												
Career and self-management	11 (5.1)	13 (6)	16 (7.4)	25 (11.5)	19 (8.8)	22 (10.1)	20 (9.2)	24 (11.1)	26 (12)	30 (12)	11 (13.8)	217 (100)
Continuous pro-fessional devel-opment	12 (5.3)	14 (6.2)	17 (7.5)	24 (10.5)	25 (11)	19 (8.4)	23 (10.1)	29 (12.8)	19 (8.4)	27 (12)	18 (7.9)	227 (100)

Table 5. The topic frequency and possession during the period (n=1354).

Domain and topic	Period 1: 2011-2013 (n=287)	Period 2: 2014-2016 (n=406)	Period 3: 2017-2019 (n=395)	Period 4: 2020-2021 (n=266)	Total (n=1354)
Job, n (%)					
Evidence-based clinical practice	63 (22)	70 (17.2)	76 (19.2)	31 (11.6)	240 (17.7)
Community-based healthcare	37 (12.9)	70 (17.2)	55 (13.9)	51 (19.2)	213 (15.7)
Patient care	41 (14.2)	56 (13.8)	55 (13.9)	53 (19.9)	205 (15.1)
Communication and cooperation	63 (225)	76 (18.7)	68 (17.2)	45 (16.9)	252 (18.6)
Personal, n (%)					
Career and self-management	40 (13.9)	66 (16.3)	70 (17.7)	41 (15.4)	217 (16)
Continuous professional develop-ment	43 (15)	68 (16.8)	71 (18)	45 (16.9)	227 (16.8)

Dividing the period into 3-year groups, *Evidence-based clinical practice* (63/240, 26.3%) and *Communication and cooperation* (37/213, 12.9%) were studied most often during the first period (2011-2013), whereas research on *Community-based healthcare* (41/205, 14.3%) and *Career and self-management* (40/217, 13.9%) was conducted on a small scale. *Communication and cooperation* was studied most often during the second period (2014-2016), but the weight decreased compared with the first period (from 22% to 18.7%).

The topics that increased in weight compared with the first period were *Career and self-management* (from 13.9% to 16.3%) and *Continuous professional development* (from 15% to16.8%). During the third period (2017-2019), *Evidence-based clinical practice* (76/240, 19.2%) was studied the most, followed by *Continuous professional development* (71/227, 18%) and *Career and self-management* (70/217, 17.7%). During the fourth period, which covers the COVID-19 pandemic (2020-2021), *Patient care* (53/205, 19.9%) and *Community-based healthcare* (51/213, 19.2%) were the most studied. Compared with the third period, *Patient care* increased from 13.9% to 19.9%, and *Community-based healthcare* increased from 13.9% to 19.2%. Conversely, there were decreases in *Evidence-based clinical practice* (from 19.2% to 11.6%), *Career and self-management* (from 17.7% to 15.4%), and *Continuous professional development* (from 18% to 16.9%).

Regarding the overall possession during the first 3 periods before the COVID-19 pandemic, there was increased research interest in *Career and self-management* (from 13.9% to 16.3% to 17.7%) and *Continuous professional development* (from 15% to 16.8% to 18%) but decreased interest in *Communication and cooperation* (from 22% to 18.7% to 17.2%). In the fourth period, during the COVID-19 pandemic, there was increased research interest in *Community-based healthcare* (45/252, 16.9%) and *Patient care* (53/502, 19.9%) but decreased interest in *Evidence-based clinical practice* (31/240, 11.6%), *Career and self-management* (41/217, 15.4%), and *Continuous professional development* (45/227, 16.9%).

In terms of domains, studies on physicians' personal competencies increased from the first to the third period (from 28.9% to 33% to 35.7%, respectively). However, it decreased

to 32.3% between 2020 and 2021 after the COVID-19 outbreak. Studies on physicians' job competency gradually decreased (from 71.2% to 67.8% to 64.3%), before increasing to 67.8% during the fourth period.

Topic Characteristics by Period

Table 6 presents the topic characteristics for each period. We performed linear regression analysis to examine the characteristics of the 6 topics. Three topics were classified as *hot topics* with a positive regression coefficient and statistical significance: topic 2 (B=1.315; t_9=2.621; *P*=.03), topic 4 (B=1.758; t_9=5.414; *P*=.001), and topic 5 (B=1.339; t_9=2.963; *P*=.02). We found no *cool* (negative regression coefficients and no statistical significance) or *cold* topics (negative regression coefficients and no statistical significance). Figure 5 shows the subject possession during this period.

Table 6. Regression analysis results for each topic.

Domain and topic	B	β	*t* test (*df*)	*P* value	Durbin-Watson statistic	Topic type
Job						
Evidence-based clinical practice	0.388	.339	1.019 (9)	.34	1.535	—[a]
Community-based healthcare	1.315	.680	2.621 (9)	.03	1.181	Hot
Patient care	1.248	.426	1.331 (9)	.22	2.960	—
Communication and cooperation	0.248	.251	0.733 (9)	.48	1.775	—
Personal						
Career and self-management	1.758	.886	5.414 (9)	.001	2.013	Hot
Continuous professional development	1.339	.723	2.963 (9)	.02	2.157	Hot

Discussion

Principal Findings

In this study, we used social network analysis to examine keywords and their relationships in physician competency studies conducted over the past 10 years. Topic modeling identified the top 5 research topics, visualized the relationships among them, and described the research possession over time. Discussions on physicians' competency arose in the 1990s because of the social atmosphere of consumerism, which demands accountability in all aspects of the profession. The medical and health care field emphasizes physicians' roles and attitudes, reflecting the demands of medical consumers, such as citizens [43] and local communities [44]. Educational institutions have received demands to improve the curriculum considering educational outcomes [4,45]. Since the 1990s, some

countries have begun to define the competence of their physicians and specify their components [46]. After the "Project on the future global role of the physician in healthcare" of the World Federation for Medical Education in 2012, it has become more active in many countries [7]. As a goal of the medical community, a competency model for desirable physicians was constructed in the 2000s, centered on Canada [46], the United States [47], the United Kingdom [48], and Scotland [11]. Since then, scholars have actively studied the development of the curriculum and revision of content, reflecting this competency model [8,49,50]. The physician competency studies conducted since 2010, which we analyzed, are on the continuum of physician competency studies carried out over the past 20 years in a large framework.

The words that appeared most frequently in physician competency studies since 2010 are, in order, *knowledge*, *hospital*, *family*, *job*, *guideline*, *management*, and *communication*. The words that appeared in most studies were *education*, *model*, *knowledge*, and *hospital*.

Previously, a physician's professional competence was defined as the habitual and careful use of communication, knowledge, skills, clinical reasoning, emotions, values, and reflection in everyday care for the benefit of individuals and communities [51]. The keywords frequently used in this study had a broad coverage, including the knowledge and context necessary for physicians to perform medical practice, a standardized framework necessary to meet social needs, and traits pertaining to physician groups or individuals.

In the network of top keywords, the keywords with high degree and closeness centrality values were *model*, *education*, *experience*, *health care*, and *hospital*s. Keywords with high betweenness centrality values were *model*, *education*, and *knowledge*. The keyword that emerged in the centrality analysis was *change*. Degree centrality indicates the number of times a node appears simultaneously with other nodes in a network. Closeness centrality connotes the distance between nodes within a network, and betweenness centrality connotes the role of a *bridge* between different nodes within a network. Network centrality analysis of keywords revealed that the 2 central nodes leading physician competency studies over the past 10 years were *model* and *education*. *A model* refers to a pattern, plan, or demonstration that illustrates the structure or work of an object, system, or concept. In competency studies, *model* began with a core competency model that explained what constitutes a physician. Later, scholars focused on different models essential for medical practice, such as specific clinical contexts, resident training, patient-physician communication, leadership [52], and health care management.

Competency-based education for medical students and residents refers to an educational method that uses the content or criteria derived from the previous competency model. In other words, a professional's competency should be built gradually based on scientific knowledge, basic clinical skills, and moral development. Education and experience are essential for acquiring or maintaining expertise in a professional. Song et al [53] conducted a bibliometric analysis of medical expertise from 2010 to 2019. According to these studies, academic journals on medical education primarily include studies on expertise. Likewise, studies on physician competency over the past 10 years have examined methods for developing, implementing, and evaluating competency through education.

Through topic modeling, we identified 6 latent topics. Topic modeling is a researcher-centered content analysis method that identifies a specific pattern assumed to be latent in a document or text and derives a potentially meaningful topic. We also set topic names based on keywords derived from this study. On the basis of relevance of the topic, we divided it into 2 domains: job and personal competency. The job domain comprises *Evidence-based clinical practice*, *Community-based healthcare*, *Patient care*, and *Communicationand cooperation*, whereas the personal domain comprises *Career and self-management* and *Continuous professional development*. The topics derived from topic modeling in this study cover the criteria for physician competency suggested in many countries. In Canada, the Canadian Medical Education Directions for Specialists [46] organized physician roles into 7 competencies: medical experts, communicators, collaborators, leaders, health advocators, scholars, and professionals. In the United Kingdom, "Good Medical Practice 2020" [54] describes physician competency in terms of 4 core competencies: knowledge, skill, and performance; safety and quality; communication, partnership, and teamwork; and trust maintenance. In the United States, the Accreditation Council for Graduate Medical Education laid out 6 core competencies [46] focusing on the areas of physician activities: patient care, professionalism, interpersonal and communication skills, medical knowledge, systems-based practice, and practice-based learning and improvement.

They also comprise the complex knowledge, skills, and attitudes that physicians must possess. Previous studies have emphasized the topics of physician competency research resulting from this study [5]. First, *Evidence-based clinical practice* is a core competency required for clinicians. It provides a framework for integrating research evidence into health care delivery [55], including patient history taking and analysis, physical examination, and diagnostic accuracy. The implementation of evidence-based practice principles has resulted in notable advances in improving the quality of delivered health care [56]. In addition, over the last 20 years, evidence-based practice has been increasingly integrated as a core component of undergraduate, postgraduate, and continuing education health programs worldwide [12]. Second, *Community-based healthcare* is increasingly emphasized in terms of the need for improvement from a broad cultural and institutional perspective to improve the quality of medical care [57]. *Community-based healthcare* has recently attracted more attention, as primary care is emphasized to solve social problems such as population aging and COVID-19 [58].

Third, the topic of *Patient care* means patient-centered care (PCC). PCC enhances health outcomes, such as improved patient satisfaction, behavior change, trust, patient adherence, providers' clinical accuracy, disease management plans, and active patient self-management [59]. Therefore, PCC is a crucial attribute of high-quality health care services [60]. Fourth, physicians' interpersonal and communication skills have a significant impact on patient care. Furthermore, it is correlated with improved

health outcomes and quality [61]. Ineffective communication skills are associated with malpractice claims and suits [62] and medication errors [63]. Communication is a core clinical skill that can be taught and learned [64]. Moreover, interprofessional communication skills are essential competencies for medical students to become physicians [65].

Fifth, among the 2 topics belonging to the personal domain, *Career and self-management* is related to physicians' burnout. Job satisfaction can affect physicians' physical and mental illnesses, such as depression and burnout [66], and is related to patient safety and quality of care [67]. In addition, burnout syndrome is a major concern in occupational health [55]. Therefore, organizations should emphasize the importance of physicians' self-care (rest, a healthy lifestyle, breaks, and sufficient sleep) and regular burnout screening [68]. Finally, *Continuous professional development* refers to the attitude of lifelong learning as a professional. Through professional development such as lifelong learning, medical specialists maintain their professional competence in addition to keeping track of and gaining advancing knowledge [69]. Furthermore, continuing professional development and lifelong learning are crucial for securing high-quality health care, patient safety, and societal trust in the health care system [70]. In other words, the subdomains of physician competency emphasized in many countries have been the main research topics over the past 10 years. Specifically, the main research topics include *Evidence-based medicine* (an explicit means for generating an important answerable question, interpreting new knowledge, and judging how to apply that knowledge in a clinical setting) [71]; *Community-based healthcare* (emphasizes social responsibility); *Patient care* (considering the patient's condition and circumstances throughout the treatment process); *Communication and cooperation* with patients, families, and colleagues; *Career and self-management*; and *Continuous professional development* for maintaining competency as scholars and professionals.

An examination of the changes in research topics over the past 10 years revealed that more studies have been conducted on job competencies than on physicians' personal competencies. Personal domain studies gradually increased from the first to the third period; however, after the COVID-19 outbreak (2020-2021), the number of job domain studies increased.

The most studied topic was *Communication and cooperation*. The topics that showed an increasing frequency and possession before the COVID-19 outbreak (first to third period) were *Career and self-management* and *Continuous professional development*; studies on *Communication and cooperation* showed a decreasing frequency and possession. Studies on *Evidence-based clinical practice* have also gradually decreased (first through second through fourth periods), except during the third period.

Most studies conducted before the COVID-19 outbreak covered physicians' individual professionalism [10,72]. However, during the COVID-19 pandemic (fourth period), studies on *Community-based healthcare* and *Patient care* increased. This can be explained as follows: physicians' social responsibility and community-centered care began to be emphasized during the COVID-19 pandemic, and the importance of care centered on patients and communities has resurfaced. Particularly during the COVID-19 pandemic, many problems threatened patients' health because of the gap in health and medical care, despite individual physicians' expertise and commitment. These challenging social situations highlight the importance of *Community-based healthcare* [73,74].

In times of crisis, the role of physicians can be broadened. For example, physicians have a duty not only to take care of their patients but also to protect them from infection, and thus take care of their families [18]. In addition, social interventions, such as school closures, affect the supply and demand for medical personnel. However, it is not easy to clarify whether a physician's role in situations such as COVID-19 is regular duty. Nevertheless, COVID-19 has broadened the demand for physicians' roles and competencies. This was also manifested in "hot topics" that have gradually increased over the past 10 years, such as *Community-based healthcare*, *Career and self-management*, and *Continuous professional development*. This indicates that topics related to *Community-based healthcare* are gradually becoming more important [73,74], as are topics related to the professionalism of individual physicians [10,51,53,72].

On the basis of the results of this study, the keywords that many researchers were interested in over the past 10 years were *model* and *education*. Therefore, they developed competency-based education and training systems at the hospital, university, and national levels. Consequently, many countries and training institutions, such as hospitals and universities, have developed and educated physicians with competency-based curricula. This was effective in cultivating physicians' competency in responding to social needs.

The topics we should pay attention to are *Community-based healthcare*, *Career and self-management*, and *Continuous professional development*, which are research topics that have gradually increased with time. This indicates that the scope of physicians' competencies has been studied more extensively and comprehensively than in the past. It is meaningful in that it defines physicians' competency as the ability to develop into professional and social leaders, beyond just the ability necessary to perform a job.

The general public's and patients' expectations and consciousness of medical care are changing, and the medical system pursued by society is also changing. Consequently, perceptions of the roles of medicine and physicians are rapidly evolving. In line with these changes, research on the core competencies of physicians must be conducted using more detailed competencies and major fields.

Limitations

This study had some limitations. First, it was difficult to repeat the keyword refining process in the keyword network analysis. To eliminate researcher subjectivity, we have described the analytical procedure in this study. Second, the study period was not equally divided. The last period is short, covering only 6 months, between 2020 and 2021. Because we forecasted that the effect of the COVID-19 pandemic since December 2019

would be reflected between 2020 and the first half of 2021, we set these periods separately. Considering the gap between the time of undertaking and publishing this study, it is unreasonable to argue that the last period accurately reflected the pandemic. However, we believe that it is worth examining the effect of the pandemic because of its global nature, which surpasses its regional and cultural characteristics.

Third, similar to other studies, we explored articles published in English. Physician competency studies are influenced by cultural and social demands and changes in the context of medical services. Although we did not identify the regions in which the studies were published, similar studies on medical professionalism [52] and medical education [75] led us to believe that the English publications in this study were from North America, Europe, or parts of Asia. Future studies should analyze the differences in research trends in physician competency based on culture and region. Finally, this study investigated the core competencies for successfully performing a physician's job, regardless of the specific major. Subsequently, we can research physician's competencies for each major.

Conclusions

The top research topics on physician competency over the past 10 years are *Evidence-based clinical practice*, *Community-based healthcare*, *Patient care*, *Career and self-management*, *Continuous professional development*, and *Communication and cooperation*. The discussion of physician competency entails the establishment of a physician's fundamental roles and competencies based on a constantly changing health care environment and the implementation of education from studying to competency acquisition. Studies on competency include discussions on the model physician desired by society, as well as the issue of wellness encompassing an individual physician's job choice and quality of life.

The hot topics in physician competency studies conducted within the past 10 years are *Community-based healthcare* in the job domain and *Career and self-management* and *Continuous professional development* in the physician's personal domain. These 2 areas are hot topics that have gradually gained interest over time.

Abstract

Background: Oral health surveys largely facilitate the prevention and treatment of oral diseases as well as the awareness of population health status. As oral health is always surveyed from a variety of perspectives, it is a difficult and complicated task to gain insights from multidimensional oral health surveys.

Objective: We aimed to develop a visualization framework for the visual analytics and deep mining of multidimensional oral health surveys.

Methods: First, diseases and groups were embedded into data portraits based on their multidimensional attributes. Subsequently, group classification and correlation pattern extraction were conducted to explore the correlation features among diseases, behaviors, symptoms, and cognitions. On the basis of the feature mining of diseases, groups, behaviors, and their attributes, a knowledge graph was constructed to reveal semantic information, integrate the graph query function, and describe the features of intrigue to users.

Results: A visualization framework was implemented for the exploration of multidimensional oral health surveys. A series of user-friendly interactions were integrated to propose a visual analysis system that can help users further achieve the regulations of oral health conditions.

Conclusions: A visualization framework is provided in this paper with a set of meaningful user interactions integrated, enabling users to intuitively understand the oral health situation and conduct in-depth data exploration and analysis. Case studies based on real-world data sets demonstrate the effectiveness of our system in the exploration of oral diseases.

visual analytics; oral health data mining; knowledge graph; multidimensional data visualization

Introduction

Background

It is well known that oral health affects systemic health. Oral infections and inflammatory factors have been proven to be highly related to chronic diseases, such as cardiovascular and cerebrovascular diseases and diabetes mellitus [1]. In the field of clinical medicine, oral diseases can be prevented and treated by means of regular professional dental treatments and appropriate oral hygiene practices, which would do great favors for oral health, advance systemic well-being, and improve the quality of life.

As an effective way to investigate oral health status, oral health surveys can determine the frequency, intensity, and spread of oral diseases, such as oral behaviors, oral health cognition, and quality of life in a particular time frame [2]. On the basis of the analysis and mining of oral health surveys, we can obtain deeper

insights into the oral health status of individuals, understand oral diseases, and identify their impacting factors.

However, oral health surveys are always conducted from different perspectives and thus, are presented in the form of multiple dimensions. Traditional data mining methods always use simple statistical charts to visualize surveys, which are limited for the efficient and intuitive mining of deep-seated information. For example, it is difficult to observe the differences and similarities among different oral diseases. The oral health status across different areas and age groups lacks representative descriptions and intuitive comparisons. Thus, it is a difficult task to gain insights from multidimensional oral health surveys, especially for the exploration of relationships among diseases, behaviors, symptoms, and other attributes.

After a series of in-depth discussions with domain experts in the field of stomatology, it was concluded that a visualization system can deliver more comprehensive, interactive, and understandable information to users, which can further help them analyze oral health data rapidly and effectively. However, some challenges remain in implementing an oral health survey–oriented visualization system:

- Challenge 1: both oral diseases and related individuals have different general traits, which makes it difficult to present and compare the different characteristics of oral diseases in addition to their related populations (groups).
- Challenge 2: the occurrence and progression of oral diseases have their own rules, and unhealthy or careless behaviors will prompt the rise of oral diseases. Therefore, it is necessary to investigate the correlations between the diseases and behaviors.
- Challenge 3: oral health surveys include a rich set of data attributes, such as groups, diseases, and behaviors, which present various semantic relationships. It would be of great interest to explore the semantic relations from multidimensional attributes and provide an intelligent retrieval tool based on these relations.

To address the challenges, we developed a visualization framework for the visual analytics and deep mining of multidimensional oral health surveys. First, we designed a set of visualizations to depict the characteristics of diseases and groups combined with multidimensional attributes, such as the struct view, radar view, and cloud view, allowing the comparison of the different traits between various oral diseases and groups (challenge 1). We then designed a scatterplot matrix to analyze the correlation between diseases, behaviors, symptoms, and cognition based on group information, which can further help users discover the relationships among diseases, behaviors, and other attributes (challenge 2). Furthermore, a knowledge graph was designed to integrate diseases, groups, behaviors, and other information, allowing users to gain an overarching view of people with oral diseases. In addition, a query function was provided to conduct personalized retrieval, allowing users to obtain a more detailed understanding of human interests (challenge 3). A visualization framework was implemented to integrate a set of meaningful interactions, allowing users to obtain deeper insights into the patterns of oral diseases according to their requirements. Case studies based on real-world data sets were conducted to demonstrate the effectiveness of our system in visual analytics and deep mining of oral health surveys.

The major contributions of our work are summarized as follows:

- The characteristics of diseases and groups were depicted through portraits in light of multidimensional attributes, enabling users to intuitively and efficiently convey and disseminate information.
- A visualization framework was implemented to enable users to visually analyze and deeply mine the correlation features among oral diseases, behaviors, symptoms, and cognitions.
- A knowledge graph visualization was designed to generate structured knowledge containing semantics, supporting efficient queries on groups or attributes to grasp the semantic characteristics of multidimensional oral health surveys from macro and micro perspectives.

Related Work

This section covers 3 relevant topics: survey data visualization, multidimensional data visualization, and knowledge graph–based data mining.

Survey Data Visualization

Questionnaire survey is a key research tool to uncover and probe the existing states in many research domains [3]. Visualization provides analysts with deeper insights of information through visual recognition. Many researchers have applied data visualizations to realize hidden information capture and personalized exploration of questionnaire data. For example, Drapala et al [4] designed multidimensional data visualizations to explore surveys for the evaluation of information systems. Zhang et al [5] visualized the questionnaire data collected from patients and committed to predetermining orphan disease.

Surveys are widely used in medicine [6]. The World Health Organization provides guidelines for national oral surveys, enabling massive epidemiological studies and discussing survey principles. Powell et al [7] conducted a web-based questionnaire to determine the characteristics of health information seekers visiting a national health service website. O'Brien et al [8] conducted a web-based survey to investigate the use of disability and rehabilitation services among Canadian adults living with HIV. Aggarwal et al [9] piloted a large number of patient samples to explore the patients' views on using their health data in artificial intelligence research. Nakamura et al [10] compared clinicians' and patients' perspectives on treating the symptoms of acute cerebral hemorrhage using survey data.

Multidimensional Data Visualization

Multidimensional data visualization [11] aims to express complex data in a visually intuitive format, using interactive elements to enable users' comprehension of the correlation among various dimensions of the data. With the development of science and technology, multidimensional data have been reflected in a variety of fields. The oral surveys used in this study were multidimensional data with attributes, such as diseases, regions, ages, and behaviors. Currently, multidimensional data visualization includes spatial mapping, glyph [12], small multiples [13], and other methods. Examples

of spatial mapping include scatterplot matrices [14,15], parallel coordinates [16,17], table lenses [18], pixel charts [19], and dimensionality reduction [20,21]. Scatterplot matrices and parallel coordinates are the 2 most widely used multidimensional data visualization strategies. The scatterplot matrix presents high-dimensional data using scatterplots, arranging them based on attributes. This mapping from multidimensional to 2D space helps identify correlations, clusters, outliers, and other notable characteristics. It is a valuable tool for exploring and analyzing complex data sets. Parallel coordinates use a series of parallel axes to represent each variable dimension of high-dimensional data, with the position along each axis corresponding to the variable's value.

In addition to the conventional multidimensional visualizations mentioned above, users can use data portraits [22] to define and describe the various attributes of objects. Data portraits provide a more tangible representation of multidimensional data, allowing for a condensed and effective perception of information panoramas; for example, Xiong and Donath [23] proposed a novel graphical representation based on users' past interactions, encoding people's data with flower and garden metaphors. He et al [24] used accounting indexes to draw the data portrait of the value creation index of all 17 industries, by means of which the characteristics of various industries under COVID-19 can be captured. In this study, we applied data portraits to depict diseases and groups of different regions, genders, and ages.

Knowledge Graph–Based Data Mining

The knowledge graph, introduced by Google in 2012 to refine its search engine, is a typical multilateral relational graph comprising entities and relationships [25]. It serves as a semantic network that reveals the connections between various elements. Knowledge extraction [26], knowledge fusion [27], and knowledge reasoning [28] are the fundamental components involved in constructing a knowledge graph. Knowledge extraction is the process of extracting valuable structured information from large-scale text data, where entity extraction [29] refers to identifying specific entity objects in the text, whereas relation extraction involves extracting the associations and connections between entities. Knowledge fusion involves leveraging technologies such as information extraction, entity alignment, and relationship linking to integrate knowledge from multiple knowledge graphs. This integration results in a more comprehensive, consistent, and accurate knowledge system that enhances knowledge discovery, inference, and application. Knowledge reasoning can generate new factual conclusions by using entity and relation information, thereby expanding the knowledge graph. This process can be categorized into 3 types: logical rule–based reasoning [30], distributed feature representation–based reasoning [31], and deep learning–based reasoning [32].

The data derived from knowledge reasoning can be leveraged in a variety of downstream tasks related to knowledge graphs, such as recommendation systems [33], question answering [34], and information retrieval [35]. For instance, Li et al [36] introduced KG4Vis, a knowledge graph–based visual recommendation method that learns the embedding of knowledge graph entities and relations to capture ideal visual rules. Sousa and Couto [37] provided a new system, named K-BiOnt, by integrating knowledge graphs into biomedical relation extraction, improving the system's ability to identify true relations. Tang et al [38] proposed an intelligent question-answering search system for electric power domain knowledge. The system uses knowledge reasoning to retrieve and analyze information accurately and presents the query results in a visual format. Latif et al [39] developed a visualization system, VisKonnect, to analyze the intertwined lives of historical figures according to the events they participated in through a knowledge graph.

Methods

Oral health data are introduced in this section. A series of analytical tasks are then defined following a thorough discussion with dental experts. Further presentation of the pipeline of our visualization system is encouraged, with the goal of completing the desired analysis tasks.

Data Description

In this study, the real-world data set was obtained from the Oral Health Status Survey and Prevention of Common Diseases in Zhejiang Province [40]. The survey covered several areas, including Jianggan, Hangzhou; Yuyao, Ningbo; Luqiao, Taizhou; Wenling, Taizhou; Wuyi, Jinhua; and Liandu, Lishui. The respondents were from 5 age groups: 3 to 5 years, 12 to 15 years, 35 to 44 years, 55 to 64 years, and 65 to 74 years, representing both urban and rural communities. The data set depicts the oral health status of individuals in 5 age groups in these 6 regions as well as behaviors, symptoms, and cognition associated with oral health. In total, 17 diseases, 14 behaviors, 10 symptoms, and 11 cognitions were considered as research qualities after sorting.

Ethical Considerations

As the data used in the study were deidentified, no ethical approval was sought.

Task Analysis

After detailed discussions with domain experts in the form of structured interviews, we developed a list of analytical tasks for the visual analysis of oral health based on oral health survey reports.

Task 1: How Can the Characteristics of Various Oral Diseases Be Described and Compared?

There are many types of oral diseases, including caries, periodontal disease, and oral mucosal disease. Unfortunately, some simple traditional statistical analyses struggle to uncover the underlying characteristics of the various diseases behind the data. Is a disease, for example, more likely to occur in men or women? At what age group may a malady be more likely to happen? Intuitive and efficient induction will play a vital role in medical research as well as in the formulation of preventive measures.

Task 2: How Can We Describe and Compare the Characteristics of Oral Diseases Among Different Groups?

Different age, region, and gender groups exhibit distinct overall characteristics in terms of prevalence and related attributes. Analyzing various groups based on disease, behavior, symptoms, cognition, and other dimensions can address the limitations of traditional summary evaluations. It enables us to grasp the specific requirements of different groups, aids in the efficient allocation of medical resources to enhance medical service quality, and provides a more comprehensive and precise depiction of the overall disease situation and characteristics of individuals.

Task 3: How Can the Association Among Oral Diseases, Behaviors, Symptoms, and Cognition Be Explored and Presented?

Each disease has its own set of rules regarding its occurrence and development, and it is often the case that bad behavior or carelessness can contribute to the likelihood of developing a disease. Is smoking associated with gum bleeding? Is tooth loss associated with food restriction symptoms? Grasping the relationship between oral diseases, behaviors, cognitions, and symptoms and how these factors interact with each other is a nontrivial task that requires the analysis of intricate and abstract data.

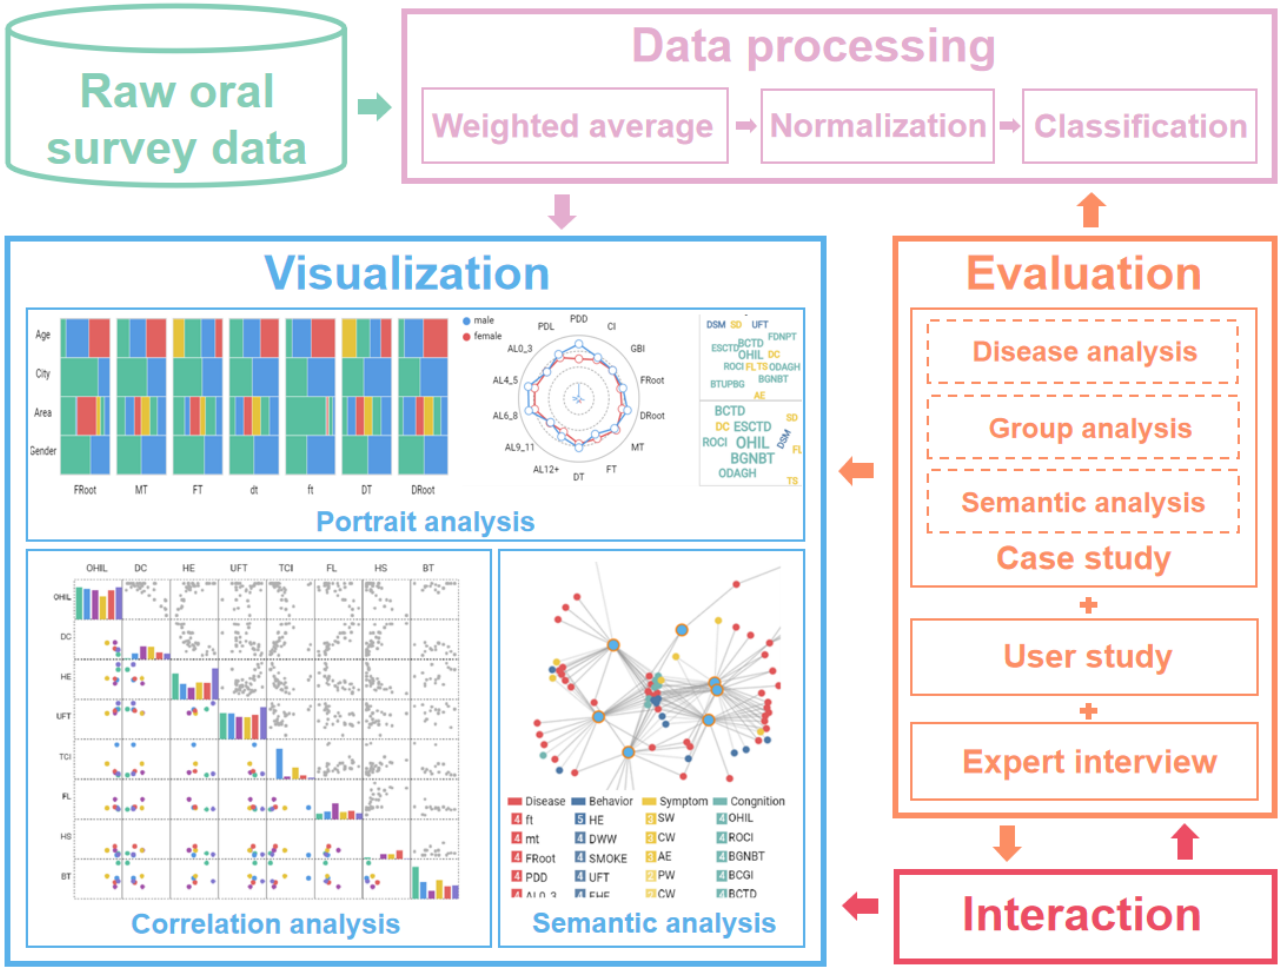
Task 4: How Can Semantic Information of Data Be Revealed in Interpretable Insight and Offer Assistance for Personalized Investigation?

How can we enhance and present the relationship between diseases, behavior, and other factors discovered after mining the correlation? How can users swiftly grasp the traits of specific diseases or groups at a detailed level? In addition, how can users gain a comprehensive understanding of the overall semantic context encompassing diseases, groups, behaviors, and other attributes from a macro perspective? Using effective visualizations can substantially aid users in comprehending and preventing oral diseases, promoting health awareness, and fostering healthy coping strategies.

System Overview

In this study, we developed a multidimensional survey visualization system for oral health that enables users to perceive the characteristics and patterns of oral diseases. Figure 1 shows the pipeline of the system to illustrate the design and implementation of the visualization framework.

Figure 1. The pipeline of our visualization system.



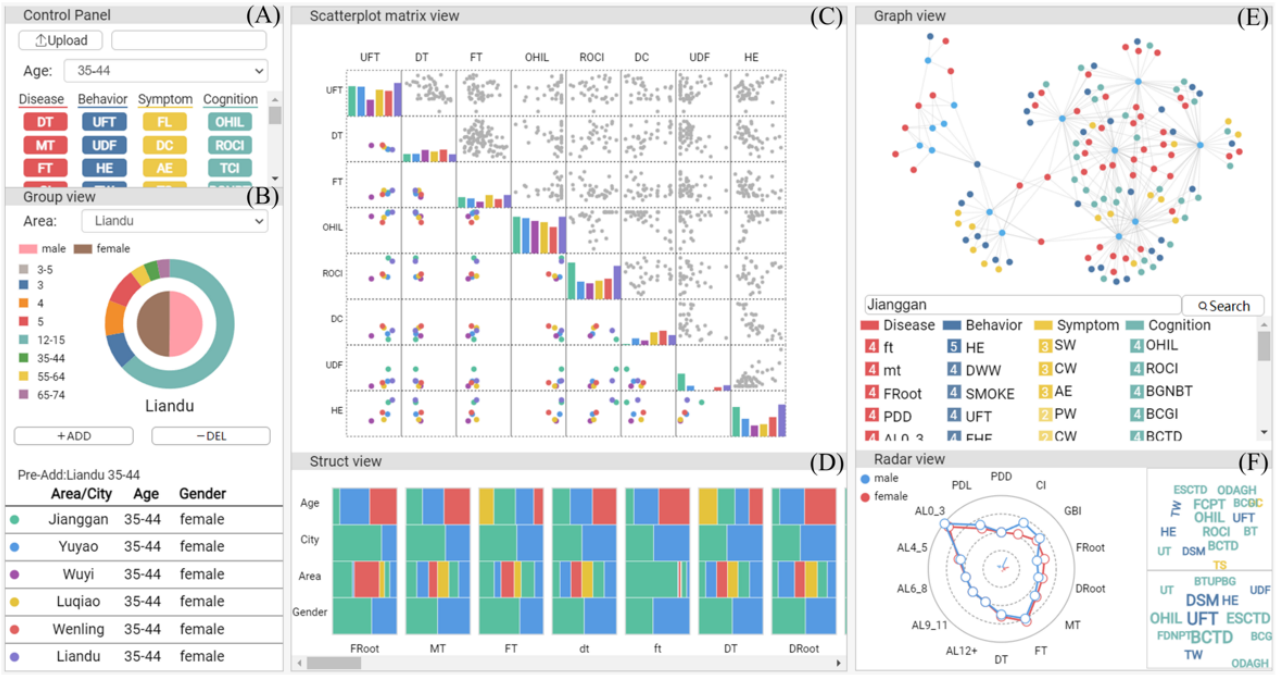
Before visualization, the original oral survey report data set is loaded and preprocessed in 3 steps: weighted evaluation, normalization, and classification. Then, rich visualizations are leveraged for the visual analysis of multidimensional oral health

data, focusing on portrait analysis, correlation analysis, and semantic analysis. Various types of views, including the struct view, radar view, and cloud view, are used to depict the data portraits of diseases and groups. A scatterplot matrix view can be used to examine the correlation of attributes between groups and analyze the differences between groups. A graph view is used to link groups, diseases, behaviors, symptoms, and cognitions, thereby uncovering the semantic associations. Thereafter, the system's effectiveness in revealing multidimensional oral health surveys is evaluated through case studies, user studies, and expert interviews. In addition, a rich visual interface and user-friendly interactions are provided for users to explore the multidimensional oral health data in depth.

Visual Exploration

We developed a user-friendly visualization system to help users observe oral disease characteristics, disease-behavior correlations, and the semantic information of diseases and multidimensional attributes. This system includes a control panel (Figure 2A), group view (Figure 2B), scatterplot matrix view (Figure 2C), struct view (Figure 2D), graph view (Figure 2E), and radar view (Figure 2F), offering user-friendly interaction.

Figure 2. The visualization interface for a multidimensional oral health survey. (A) A control panel enabling users to load data sets and select attribute labels for different groups. (B) The group view to show the composition features and allow users to select groups. (C) The scatterplot matrix view to reveal the correlation features of attributes. (D) The struct view to present the characteristics of oral diseases. (E) The graph view illustrating the semantic knowledge of attributes such as population and disease. (F) The radar view with 2 cloud views to reveal the characteristics of different groups on attributes such as diseases and behaviors. AE: ashamed to eat; AL: attachment loss; BCGI: Bacteria can cause gum inflammation; BCTD: Bacteria can cause tooth decay; BGNBT: Bleeding gums are normal when brushing teeth; BT: brush the teeth; BTUPBG: Brushing teeth is useless in preventing bleeding gums; DC: difficulty chewing; CW: communication worry; DRoot: decayed teeth root due to caries; DROOT: decayed teeth root due to caries; DT: decayed tooth; DW: dietary worry; ESCTD: Eating sugar can cause tooth decay; FCPT: Fossa closure can protect the teeth; FDNPT: Fluoride does not protect teeth; FHE: father's highest education; FL: food limitation; FRoot: fill teeth root due to caries; FROOT: fill teeth root due to caries; ft: fill deciduous tooth due to caries; FT: fill tooth due to caries; GBI: bleeding gums index; HE: highest education; HS: hinder to speak; MHE: mother's highest education; MT: missing tooth; OC: only child; OHIL: Oral health is important to life; PDD: periodontal pocket depth; PDL: periodontal pocket depth 4~6mm; PW: pronunciation worry; ROCI: Regular oral check-ups are important; SD: swallowing discomfort; ST: Time since the last dental visit; SW: sleep worry; TCI: Tooth condition is innate, not acquired; TS: tooth sensitivity; TW: toothwash within 12 months; UT: Use the toothpick.



Data Portrait Analysis

Struct View

To visually and effectively depict different diseases, we designed the struct view. Disease profiles are presented as large rectangles containing smaller rectangles, categorized by area, gender, age, and city. Each small rectangle's width represents the prevalence rate of the disease, whereas its color is randomly chosen. Clicking a small rectangle on the screen will display the region, gender, age, and urban and rural areas, along with the prevalence value. In total, 17 diseases were identified. To accommodate the limited screen space and enhance visual presentation, users can use sliding blocks.

Radar View

Radar view is a widely used metaphor in visualization. It allows for the presentation and comparison of group characteristics based on area, age, and gender. We developed a radar view specifically for this purpose. When the user selects a group, the radar view displays the disease attribute values in the specified region and age group for both men and women. Each axis maps the number of teeth with a type of oral disease to comprehend and compare the oral disease status of men and women in a fixed region and fixed age from a single radar view. By choosing different radar views, we can also compare different age groups and regional groups from the list.

Cloud View

To indicate distinct behaviors, symptoms, and cognitions of each group and explore their correlation with diseases, we offer cloud views that correspond to male and female groups in addition to the radar view. The original data provide the prevalence rate and average number of teeth for the disease attribute in each group. However, the attributes related to behaviors, cognition, and symptoms are usually represented by the proportions of individuals in different degrees. Drink sweat milk, for instance, divides individuals into 4 categories: seldom, 1 per month, 1 per week, and ≥1 per day. It is challenging to evaluate and compare the strengths of each group in these attributes. To address this, we calculated the weighted average and converted it to a value between 0 and 1, known as the strength value. Words are color-coded based on their attribute category, and their size indicates the attribute strength. In this way, users can gain a more intuitive understanding of the behaviors, cognition, and symptoms of different groups and compare them to disease features in the radar view.

Correlation Analysis

We used a scatterplot matrix (Figure 2C) to infer the correlations among complex data attributes. The scatterplot matrix, an extension of the scatterplot for multidimensional data, is crucial for visualizing binary relationships. Nevertheless, the number of matrix elements that can be displayed is constrained by screen size when there are too many dimensions. Here, we applied internet-based methods for users to select the disease, behavior, cognition, and symptom tags in the control panel. The selected tags served as dimensions in a scatterplot matrix view. As we need to use groups to model the associations between the attributes, we first selected several groups within the group view (Figure 2B). In the scatterplot matrix view located on the diagonal, the histogram is used to show and compare the performance of the selected groups in the corresponding attributes. For disease attributes, the height of the bar maps the prevalence, whereas for behaviors, cognitions, or symptoms, the height of the bar depicts the strength value. Scatterplots outside the diagonal are deployed to present 2-by-2 relationships between attributes, with each scatter representing a group. The scatterplot has 2 dimensions: the strength value of the attribute or the normalized number of teeth. Owing to their symmetrical nature, we designed a matrix above the diagonal that offers relationships for all groups, whereas the matrix below the diagonal presents the relationships of the currently selected group under the corresponding attributes. The distribution of scattered points serves as a visual representation of the correlation between the multidimensional attributes.

Semantic Analysis

How can acquired knowledge be logically and scientifically presented after obtaining relevant features and information? We constructed a large-scale knowledge graph (Figure 2E) consisting of entities such as groups, diseases, behaviors, symptoms, and cognitions and established relations among groups and diseases, behaviors, symptoms, and cognitions. These relations can be broken down into 4 categories: *group has diseases*, *group holds behaviors*, *group shows symptoms*, and *group carries cognitions*. There are 112 group entities in the graph; for example, “Jianggan District, 12-15 years old, female.”

To characterize groups based on multidimensional attributes and establish the association between groups, we categorized the average tooth value for disease and the strength values of behavior, symptoms, and cognition under the guidance of experts. By considering the numerical distribution of all groups across each attribute and their respective strengths, we divided them into 4 to 5 categories. There are 66 disease entities, including the 4 categories of decayed tooth (DT) due to caries: *almost noDT (DT1)*, *mild DT (DT2)*, *moderate DT (DT3)*, and *severe DT (DT4)*. Similarly, behaviors, symptoms, and cognitions were classified into entities according to their strength value, with a total of 38 behavior entities, 30 symptom entities, and 60 cognition entities. This enables semantic associations among groups, diseases, behaviors, symptoms, and cognitions through the knowledge graph, providing users with a precise and comprehensive semantic expression. To efficiently extract group or attribute characteristics from large-scale entities, we set up a search function in our hub. Users can input keywords related to the node they wish to query, such as groups, diseases, behaviors, cognitions, and symptoms. When searching for a single group or multiple groups, associated disease, behavior, cognition, and symptom entities will be displayed below the search box, organized by category, and ranked to provide a visual description of various attributes of the group. Users can infer the risk of oral diseases through their own similar groups from group-related behaviors, cognitions, symptoms, and other attributes and further grant decision evidence for the prevention of oral diseases. Thus, the visualization tool can easily allow users to identify and intervene in potential oral disease risks and enable medical teams to formulate personalized prevention strategies.

Visual Interface

We provided a rich set of interactions to assist users in conducting an in-depth analysis of multidimensional oral health surveys. Groups, diseases, behaviors, cognitions, and symptoms can be selected by users, thus enabling personalized and targeted exploration. We offer operations for data loading in the control panel, as shown in Figure 2A. Users can select labels from 4 categories on the control panel: disease, behavior, symptom, and cognition labels. We provided different labels for different age groups because of substantial variations in survey data across age groups. We provided a nested pie chart to display the sample size composition of the groups in 6 regions, including urban and rural areas. The inner circles indicate gender, whereas the outer circles indicate age. Users can select a region, choose age and gender within the corresponding pie chart, and click the “Add” button to include the selected group. After adding the groups, they are displayed in a list below the button, distinguished by random colors. In this way, the chosen label determines the attributes of the scatter matrix, whereas the chosen groups facilitate attribute comparison in the diagonal. All attribute features of the chosen group are also visible in the cloud view and radar view. The graph view shows the semantic relationships of all groups and attributes and offers search capabilities to aid in investigating specific groups and attributes.

Results

Overview

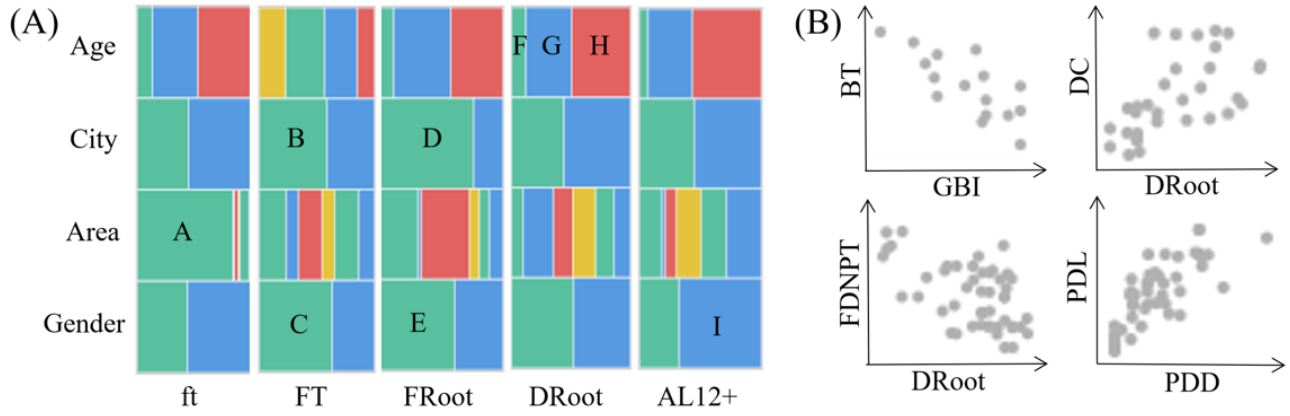
As a web-based visual analysis system, this system was developed using the classic front-end–based frame of ES6+d3.js+csv. A Windows platform with a 2.3 GHz Intel Core i7 CPU and 16 GB of memory was used as the front-end page server. The evaluation experiments were performed using a Google Chrome web browser. Our system can facilitate the efficient and intuitive information mining of experts and users regarding oral diseases. Case studies, user studies, and expert interviews were conducted to demonstrate the usability and viability of our system.

Case Study

Case 1: Disease Analysis

Each disease has its own characteristics, and we introduced a structural view to reveal the characteristics of various diseases. As shown in Figure 3A, we recorded the patient composition of 5 diseases, fill deciduous tooth due to caries (ft), fill tooth due to caries (FT), decayed teeth root due to caries (DRoot), fill teeth root due to caries (FRoot), and attachment loss (AL)12+, in the 4 dimensions of age, city (urban or rural), area, and gender. We found that the width of block A is much larger than that of the 5 blocks on its right. Block A represents the proportion of people with ft in Jianggan. We examined the economic situation of 6 regions with this question in mind. Jianggan exhibits the best overall development among the 6 areas, which explains the higher prevalence of children with filling caries in Jianggan. Blocks B, C, D, and E represent the proportion of urban and female patients with FT and FRoot, respectively. These findings suggest that urban residents possess a better understanding of filling decayed teeth and roots compared with rural residents, and women demonstrate higher awareness than men. Blocks F, G, and H illustrate the proportions of individuals, aged 35 to 44 years, 55 to 64 years, and 65 to 74 years, with DRoot, which shows that the risk of DRoot will increase with age. Similarly, AL12+ is also more likely to occur in the older adult population. Block 1 represents the proportion of men with AL12+, which indicates that men are more likely to experience significant periodontal AL.

Figure 3. Characteristics and risk factors for diseases. (A) Portraits selected from the struct view. (B) Attribute correlations selected from scatterplot matrix. AL12+: attachment loss ≥12 mm; BT: brush the teeth; DC: difficulty chewing; DRoot: decayed teeth root due to caries; FDNPT: fluoride does not protect teeth; ft: fill deciduous tooth due to caries; FT: fill tooth due to caries; FRoot: fill teeth root due to caries; GBI: bleeding gums index; PDL: periodontal pocket depth 4~6mm; PDD: periodontal pocket depth ≥6 mm.



"You get what you grow, you get what you grow." Oral diseases do not just appear out of nowhere; they are frequently tightly tied to certain actions and cognition. These diseases bring symptoms that affect our daily lives, and some can even spread and lead to other illnesses. As shown in Figure 3B, we intercepted 4 pairs of examples of correlation from the scatterplot matrix view: disease and behavior, disease and symptom, disease and cognition, and disease and disease. We can see that bleeding gums index (GBI) is negatively correlated with brush the teeth, DRoot is positively correlated with difficulty chewing, DRoot is negatively correlated with fluoride that does not protect teeth, and periodontal pocket depth (PPD) of ≥6 mm was positively correlated with the periodontal pocket length of 4-6 mm.

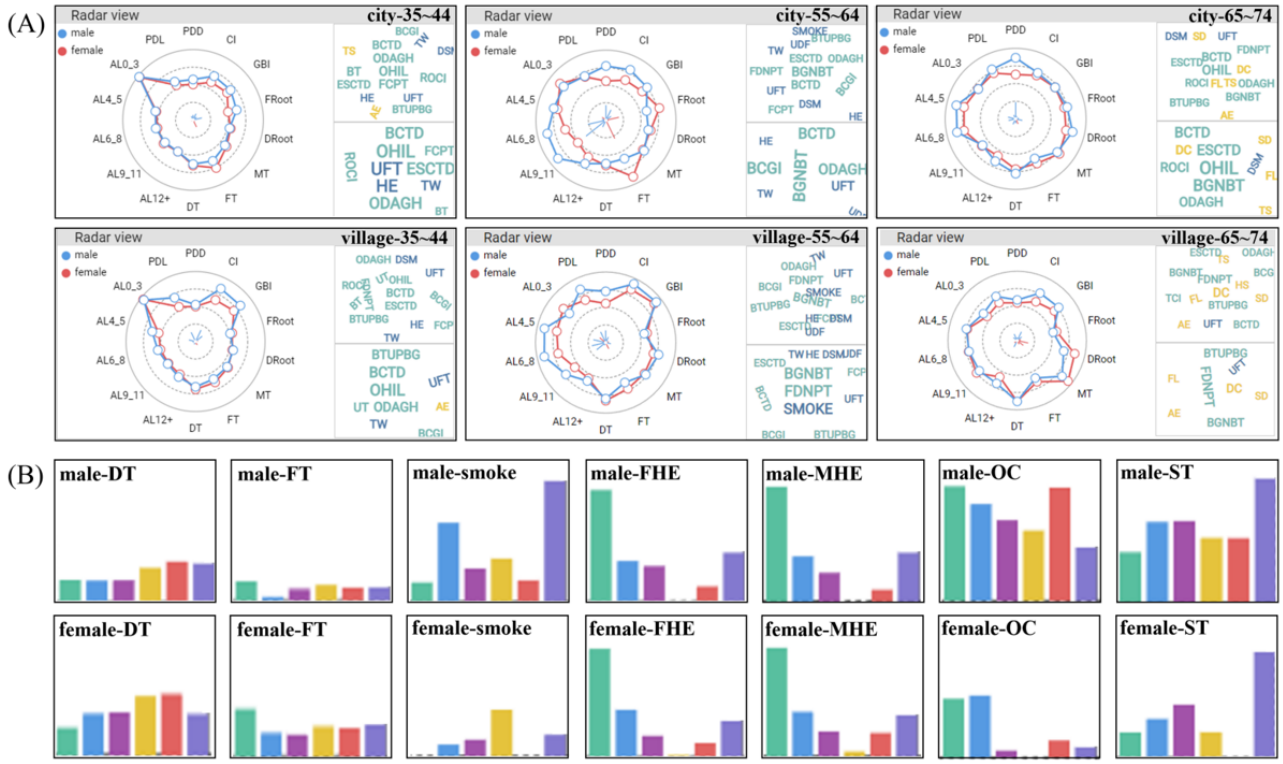
We have summarized some information after a thorough disease analysis. The periodontal health of men is significantly lower than that of women, and individuals lack caries awareness and treatment, and the rate of caries filling treatment is generally low. Middle-aged and older adult groups need to take more proactive measures to prevent and treat periodontal disease in rural areas, which is significantly lower than that in urban areas.

Case 2: Group Analysis

We proceeded with our investigation of the group after examining the characteristics of diseases. The radar view and cloud view in Figure 4A show the diseases, behaviors, symptoms, and cognitions of urban and rural groups of people aged 35 to 44 years, 55 to 64 years, and 65 to 74 years. The horizontal comparison reveals age characteristics, the vertical comparison reveals urban and rural characteristics, and the figure reveals gender characteristics. We learned that the overall disease conditions of the 35 to 44 years age group were less severe than those of the older group. With increasing age, AL, missing tooth (MT) due to caries, DRoot, and DT due to caries showed a deteriorating trend. In the cloud view, the number of yellow words representing symptoms of the group from 65 to 74 years was significantly higher than that of the age group from 35 to 34 years (data for the 55-64 years age group are unavailable and thus not included). When comparing urban and

rural regions, it is evident that the occurrence rates of calculus index, GBI, and DT due to caries were higher in rural areas, whereas FRoot and FT exhibited lower rates. Behaviors such as highest education, use fluoride toothpaste, and toothwash within 12 months, indicated in blue, and cognition, indicated in green, were generally stronger in cities than in villages. Analyzing men and women (55-64 years age group) in the city through the radar view and cloud view, it is apparent that men have greater severity of periodontal diseases, such as PPD ≥6mm, calculus index, GBI, and AL. On the other hand, women showed significantly higher occurrences of FRoot and FT than men, suggesting that women in this group were more conscious of filling teeth due to caries.

Figure 4. Characteristics and comparison of groups. (A) Radar views and cloud views of male and female groups of 3 ages in city and village. (B) The bar charts in the scatterplot matrix of boy and girls aged 12-15 years in each attribute in 6 regions. AE: ashamed to eat; AL: attachment loss; BCGI: Bacteria can cause gum inflammation; BCTD: Bacteria can cause tooth decay; BGNBT: Bleeding gums are normal when brushing teeth; BTUPBG: Brushing teeth is useless in preventing bleeding gums; DC: difficulty chewing; DRoot: decayed teeth root due to caries; DROOT: decayed teeth root due to caries; DT: decayed tooth; ESCTD: Eating sugar can cause tooth decay; FCPT: Fossa closure can protect the teeth; FDNPT: Fluoride does not protect teeth; FHE: father's highest education; FL: food limitation; FROOT: fill teeth root due to caries; ft: fill deciduous tooth due to caries; FT: fill tooth due to caries; GBI: bleeding gums index; HE: highest education; MHE :mother's highest education; MT: missing tooth; OC: only child; OHIL: Oral health is important to life; PDD: periodontal pocket depth; PDL: periodontal pocket depth 4~6mm; ROCI: Regular oral check-ups are important; ST: time since the last dental visit; TCI: Tooth condition is innate, not acquired; TS: tooth sensitivity.



The scatterplot matrix views facilitate intuitive comparison of attributes between different groups, as depicted in Figure 4B. This figure presents behavior comparisons between boys and girls aged 12-15 years in 6 regions: Jianggan, Yuyao, Luqiao, Wenling, Wuyi, and Liandu (from left to right). Each column represents a region, allowing for comparisons across different regions within each subpart. For example, the attributes of father's highest education and mother's highest education indicate that boys and girls in Jianggan outperform those in other regions. In addition, Liandu exhibits a longer time since the last dental visit (ST) compared with others. In the attributes smoke, only child, and ST, boys are significantly more numerous than girls, while in DT and FT, girls are more numerous than boys.

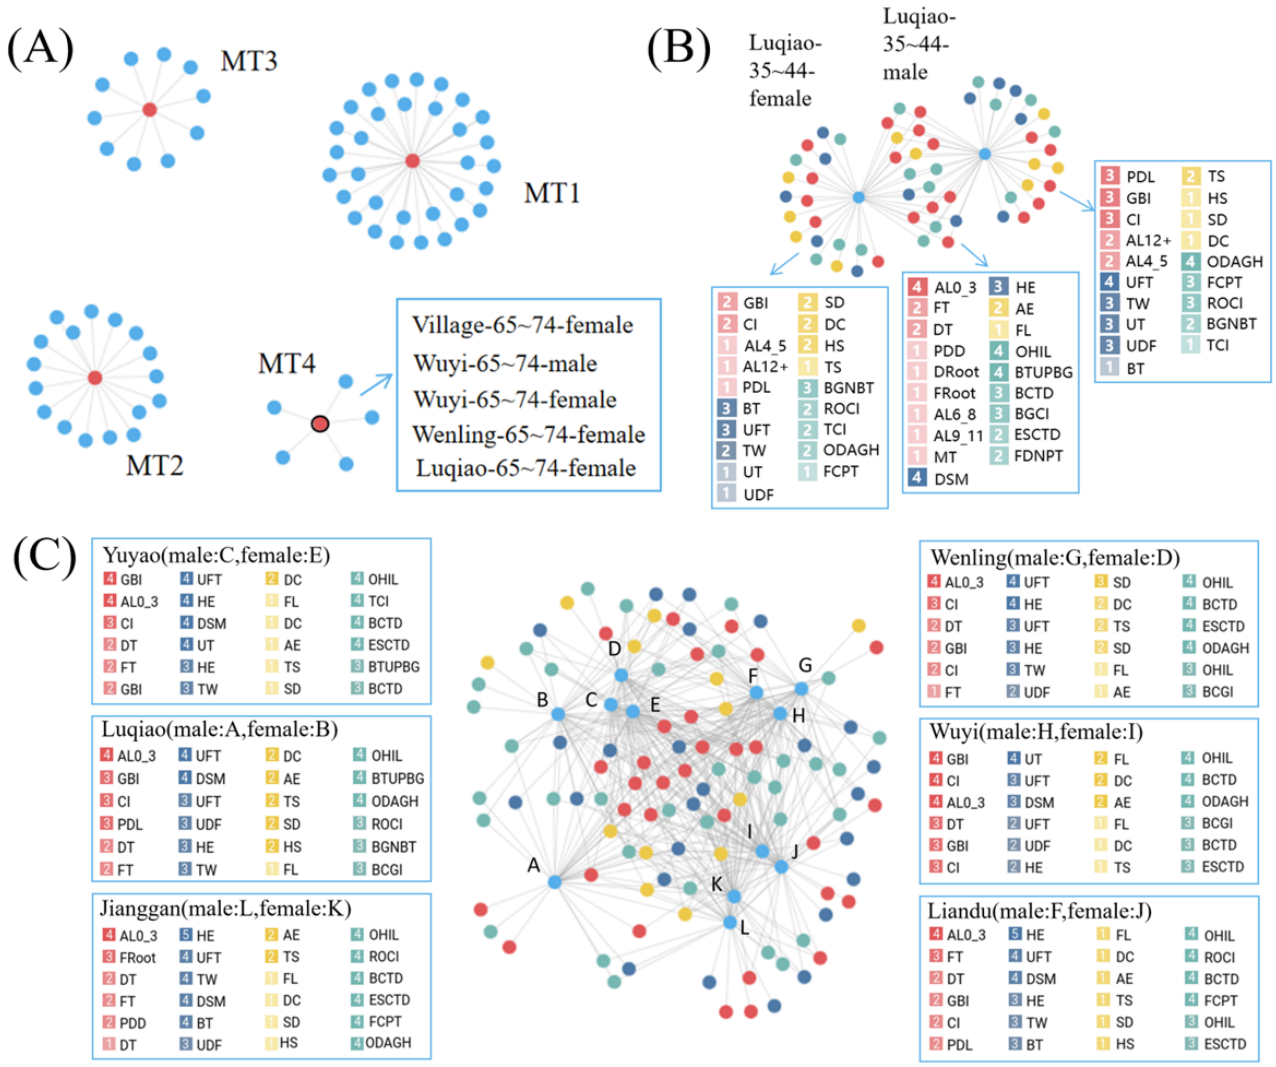
We summarized some information after a comprehensive group analysis. There are differences in oral health conditions. The higher quality of dental care and periodontal health in rural areas compared with urban areas may be because of the difference in economic prosperity and level of education and knowledge about oral health between the two. There are gender differences in oral health conditions. The mean and rate of caries in women were slightly higher than those in men, whereas the number of caries fillings and periodontal health in women were better than those in men. There are age differences in the oral health conditions. The prevalence of dental loss and periodontal diseases increased as individuals aged, especially among the older adult group with a weak awareness of the treatment of dental loss and caries. This information can aid medical teams in developing targeted and personalized prevention strategies to address these gender and age disparities in oral health.

Case 3: Semantic Analysis

We constructed a macro knowledge graph for groups, diseases, behaviors, symptoms, and cognitions, effectively converting complex and diverse objects into accessible and intuitive information. Figure 5A shows the semantic association between the different degrees of MT due to caries and the population.

MT1, MT2, MT3, and MT4 represent disease severity, with the population classified accordingly. Not only diseases but also behaviors, symptoms, and cognitive attributes can be categorized. Figure 5A displays the information of the group linked to the MT4 entity node, revealing that the severe dental disease group consisted entirely of older adults aged 65 to 74 years.

Figure 5. Discovery of query based on knowledge graph. (A) Similarity and difference attribute information of different degrees of MT due to caries and population. (B) Similarity and difference attribute information of different gender groups. (C) Similar and difference attribute information of different area groups. AE: ashamed to eat; AL: attachment loss; BCGI: Bacteria can cause gum inflammation; BCTD: Bacteria can cause tooth decay; BGNBT: Bleeding gums are normal when brushing teeth; BT: brush the teeth; BTUPBG: Brushing teeth is useless in preventing bleeding gums; CW: communication worry; DC: difficulty chewing; DRoot: decayed teeth root due to caries; DROOT: decayed teeth root due to caries; DT: decayed tooth; DW: dietary worry; ESCTD: Eating sugar can cause tooth decay; FCPT: Fossa closure can protect the teeth; FDNPT: Fluoride does not protect teeth; FHE: father's highest education; FL: food limitation; FROOT: fill teeth root due to caries; ft: fill deciduous tooth due to caries; FT: fill tooth due to caries; GBI: bleeding gums index; HE: highest education; HS: hinder to speak; MHE: mother's highest education; MT: missing tooth; OC: only child; OHIL: Oral health is important to life; PDD: periodontal pocket depth; PDL: periodontal pocket depth 4~6mm; PW: pronunciation worry; ROCI: Regular oral check-ups are important; SD: swallowing discomfort; ST: Time since the last dental visit; SW: sleep worry; TCI: Tooth condition is innate, not acquired; TS: tooth sensitivity; TW: toothwash within 12 months; UT: Use the toothpick.



After exploring the groups corresponding to the attributes, we further explored the attributes of groups. Figure 5B illustrates the corresponding attribute association between men and women aged 35 to 44 years in Luqiao, and the commonalities and differences between groups are intuitively presented. For example, AL in both groups was mild, whereas men were more likely than women to have PDL.

Figure 5C illustrates the data for those aged 35 to 44 years in 6 regions. It provides a comprehensive overview of the semantic relationships between these groups, highlighting shared characteristics as well as unique attributes. Notably, we observed a consistent association between the groups facilitated by distinct attributes. Groups from the same region or gender exhibit stronger connections. Specifically, there was a significant overlap in attributes between Jianggan men (point L) and Jianggan women (point K), indicating a close relationship. In addition, a strong association exists between Jianggan women (point K) and Wuyi women (point I).

We summarized some information after a thorough semantic analysis. All age groups exhibited low performance in actions,

including using fluoride toothpaste, dental floss, and scheduling timely visits to an oral hospital. Thus, these actions should be appreciated and strengthened. Middle-aged individuals and older adults still have poor health knowledge and awareness of health care. It is necessary to disseminate and strengthen certain cognitions, such as the knowledge that fossa closure and fluoride can protect teeth.

User Study

To further evaluate the effectiveness of our system, we invited 20 undergraduate and graduate students (12 male students and 8 female students) in digital media technology to participate in a user study. We first introduce the purpose and features of this system and then teach students how to use it. Typically, users need only 10 to 15 minutes of training time to understand the meaning of each view and the function of our system. Afterward, they were asked to perform a series of tasks over a defined period, which were closely related to the analysis tasks in *Methods* section. The specific tasks were as follows:

- Disease
  - Task 1.1. Which disease is more prevalent in Jianggan than in other areas?
  - Task 1.2. Which gender has the highest prevalence of AL12+ disease?
- Group
  - Task 2.1. What are the 3 main behavioral characteristics of the male population aged 55 to 64 years in Jianggan?
  - Task 2.2. Which area has a higher prevalence of DRoot among girls aged 12 to 15 years?
- Correlation
  - Task 3.1. Is GBI positively or negatively correlated with use of the toothpick (UT)?
  - Task 3.2. Which disease is most likely to present with symptoms of difficulty chewing?
- Semantics
  - Task 4.1. What are the groups with severe DT (DT4)?
  - Task 4.2. What are the common characteristics of the women aged 55 to 64 years in Luqiao and Wenling?

To further demonstrate the effectiveness of the system, users will perform the task twice, once without the system and once with it. When the system was not applicable, we provided the users with a condensed version of the surveys. For each experiment, we set the maximum completion time to 90 seconds. Table 1 and Figure 6 record the percentage of the users able to complete the task correctly in a given time and the average and SD of the time completed.

Figure 6. User study results. (A) Comparison of completion time. (B) Completion of accuracy rate. DT: decayed tooth system for data mining; OUR: use our system for data mining; SUR: data mining without our system.

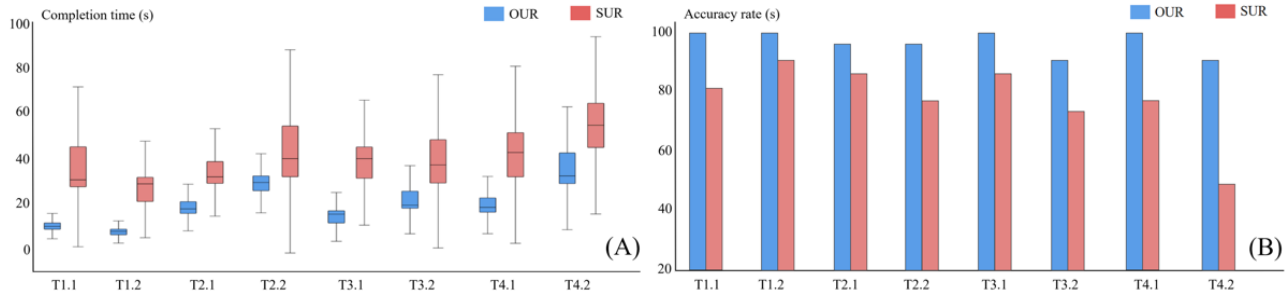


Table 1 presents completion time, average completion time, and standard completion time for both cases. Figure 6 displays specific completion time and accuracy rate through a box chart and a bar chart. It is obvious that using this system would result in more accurate and efficient exploration of oral health surveys. In addition, we collected user feedback after performing the above tasks. They all agreed that the system was quite intriguing and may give them a more intuitive understanding of oral health.

Table 1. User study results.

Category and user task	Accuracy rate (%)		Average completion times (s)		Standard completion times (s)	
	OUR[a]	SUR[b]	OUR	SUR	OUR	SUR
Disease						
T1.1	100	80	10.47	38.33	10.1	30.45
T1.2	100	90	8.2	26.99	8.1	28.68

[a]OUR: use our system for data mining.

[b]SUR: data mining without our system.

Expert Interview

After domain experts used this system to examine oral survey data, we conducted a semistructured interview to collect their opinions on system capability, visual design, and interaction.

System Capability and Effectiveness

The experts expressed their appreciation for the functions provided by this system. They concluded that the system makes it possible for both experts and regular users to quickly and intuitively perceive the initially complex and laborious large-scale oral survey data as well as to easily compare the characteristics of various diseases and groups. Moreover, they agreed that the system effectively revealed the correlation among diseases, behaviors, symptoms, and cognitions. In particular, the oral survey data were transformed into a knowledge graph, a novel approach that is not commonly used in daily survey data analysis. By leveraging the knowledge graph and its query function, this breakthrough enables researchers to go beyond traditional methods that focus on specific tasks and features. It allows them to comprehend large-scale data with complex semantic patterns, making it easier to understand. Ultimately, it greatly enhances their insights into the data.

Visual Design and Interactions

Domain experts praised the user-friendly interface and the well-designed system, aligning each view with its respective function and interaction. The layout facilitates rich interactions, correlation discovery, semantic analysis, and attribute feature exploration. Users can easily comprehend and use them without prior knowledge. One of the experts recognized the scatterplot matrix view's value in conveniently analyzing group comparison and attribute correlation simultaneously. Another expert emphasized the search capability of the knowledge graph, which allowed him to independently examine valuable information that was difficult to find in regular visual graphs. He suggested that it would be better if the system could offer label options or prompts to explore the nodes. Overall, the experts evaluated the system's integration of visualizations and interactions, offering a comprehensive range of intelligent explorations for oral health surveys.

Discussion

Principal Findings

A series of studies and experiments have demonstrated that our system can help users understand their oral health conditions and conduct in-depth data exploration and analysis. Furthermore, we conducted a thorough investigation of the visualization analysis tools to compare them with our system. We found that existing tools and libraries provide a rich set of plotting capabilities. However, the visualization analysis tools used in our study are primarily oriented toward specific tasks to visually present and obtain deep insights into oral health surveys. It is implemented using web-based technologies such as the D3.js visualization framework, which offers greater flexibility and customization options for analyzing oral health report data. Existing tools related to oral health analysis mostly include 3D digital dental model software and oral x-ray image processing software, which provide detailed visualization of dental structures. Nevertheless, these tools fail to capture the broader context of oral health such as group characteristics and disease patterns. Moreover, they often provide simple chart-based visualizations, such as pie charts and bar charts, lacking the personalized visualization design and interactive features essential for the comprehensive examination of intricate data. Therefore, it was concluded that our system allows for more customized visualizations based on specific requirements, facilitating a more detailed analysis of oral health surveys.

Overall, our system has specific advantages compared with other analysis tools; however, there are also some issues that

are not well solved, which will be addressed in future work. (1) Scalability is the major concern of this system. The current design in the scatterplot matrix view displays up to 8 attributes and 6 groups simultaneously, whereas the struct view shows up to 7 diseases simultaneously. Even if we set the interaction or scrolling function in it, it still imposes a heavy memory burden on users. Therefore, in the future, we intend to tackle the problem of how to show information more effectively in a limited screen space. (2) Despite its ability to analyze various factors, such as groups, diseases, behaviors, and other attributes in existing data, it currently lacks the capability to predict oral health for new groups or individuals. Combining the deep learning model and oral health professional knowledge, learning from existing multidimensional surveys, and predicting the prevalence of unknown groups will be the focus of future work. (3) In this study, the oral health sample was limited to Zhejiang Province, with a small-scale and narrow regional span, resulting in insufficient group differences. Future studies should consider the multidimensional feature of the disease to explore more robust results. We plan to expand our data collection by conducting oral surveys in additional regions, enabling a more comprehensive exploration of oral health from various dimensions.

Conclusions

In this study, we proposed a visualization framework for multidimensional oral health surveys. We drew data portraits for diseases and groups based on multidimensional attributes. Then, we built correlation patterns for diseases, behaviors, symptoms, and cognitions to reveal their correlation features. On the basis of the extricated knowledge of diseases, groups, behaviors, and other attributes, a knowledge graph is provided to reveal the semantic information. A series of user-friendly interactions are integrated to propose a visual analysis system that can help users further explore the regulations of oral health conditions. Case studies based on real-world data sets demonstrate the effectiveness of our system in the exploration of oral diseases, thereby offering enhanced data analysis capabilities and decision support for health care teams.

Abstract

Background: The COVID-19 pandemic has significantly altered the global health and medical landscape. In response to the outbreak, Chinese hospitals have established 24-hour fever clinics to serve patients with COVID-19. The emergence of these clinics and the impact of successive epidemics have led to a surge in visits, placing pressure on hospital resource allocation and scheduling. Therefore, accurate prediction of outpatient visits is essential for informed decision-making in hospital management.

Objective: Hourly visits to fever clinics can be characterized as a long-sequence time series in high frequency, which also exhibits distinct patterns due to the particularity of pediatric treatment behavior in an epidemic context. This study aimed to build models to forecast fever clinic visit with outstanding prediction accuracy and robust generalization in forecast horizons. In addition, this study hopes to provide a research paradigm for time-series forecasting problems, which involves an exploratory analysis revealing data patterns before model development.

Methods: An exploratory analysis, including graphical analysis, autocorrelation analysis, and seasonal-trend decomposition, was conducted to reveal the seasonality and structural patterns of the retrospective fever clinic visit data. The data were found to exhibit multiseasonality and nonlinearity. On the basis of these results, an ensemble of time-series analysis methods, including individual models and their combinations, was validated on the data set. Root mean square error and mean absolute error were used as accuracy metrics, with the cross-validation of rolling forecasting origin conducted across different forecast horizons.

Results: Hybrid models generally outperformed individual models across most forecast horizons. A novel model combination, the hybrid neural network autoregressive (NNAR)-seasonal and trend decomposition using Loess forecasting (STLF), was identified as the optimal model for our forecasting task, with the best performance in all accuracy metrics (root mean square error=20.1, mean absolute error=14.3) for the 15-days-ahead forecasts and an overall advantage for forecast horizons that were 1 to 30 days ahead.

Conclusions: Although forecast accuracy tends to decline with an increasing forecast horizon, the hybrid NNAR-STLF model is applicable for short-, medium-, and long-term forecasts owing to its ability to fit multiseasonality (captured by the STLF component) and nonlinearity (captured by the NNAR component). The model identified in this study is also applicable to hospitals in other regions with similar epidemic outpatient configurations or forecasting tasks whose data conform to long-sequence time series in high frequency exhibiting multiseasonal and nonlinear patterns. However, as external variables and disruptive events were not accounted for, the model performance declined slightly following changes in the COVID-19 containment policy in China. Future work may seek to improve accuracy by incorporating external variables that characterize moving events or other factors as well as by adding data from different organizations to enhance algorithm generalization.

Introduction

Background

COVID-19 is the most severe global pandemic of the 21st century, which has brought major changes to the global health care environment [1]. According to statistics from the World Health Organization, there have been >760 million confirmed cases of COVID-19 worldwide, including nearly 7 million deaths to date. Although the World Health Organization has declared that COVID-19 no longer constitutes a "public health emergency of international concern," it remains a serious infectious disease that will persist for the foreseeable future. Moreover, since the onset of the epidemic, numerous epidemic infections have also emerged, including influenza A, respiratory syncytial virus infection, and mycoplasma pneumonia. Successive waves of respiratory infections led to a significant increase in the number of patients presenting with fever. This prompted governments and hospitals to take measures for patient management to prevent viral transmission and control the risk of hospital-acquired infections [2,3].

In China, since the outbreak of COVID-19, most public hospitals have established fever clinics that can achieve individual closed-loop management in the clinics themselves (as shown in Figure 1). This enables the centralized treatment of patients with fever infections. As mandated by the National Health Commission, the allocation of resources and the operation in fever clinics must strictly adhere to established guidelines [4] to minimize the risk of hospital infection. Some hospitals even operate their fever clinics 24/7. Despite the relaxation of China's epidemic containment policy since the end of 2022, many hospitals continue to operate their fever clinics as usual.

The presence of epidemics and the establishment of continuously operating fever clinics are altering visitation patterns, particularly among pediatric patients. Compared with adult patients, pediatric patients require more attentive care from both their guardians and medical staff, and their conditions are more prone to relapse, resulting in a continuous and intensive trend of fever clinic visits among pediatric patients during the pandemic. This poses great challenges for hospital outpatient management and the prevention of hospital-acquired infections. In this context, there is growing interest in the study of outpatient visit forecasting.

Forecasting visits to fever clinics offers numerous benefits for hospital management. Accurate and timely visit forecasts can facilitate the rational allocation of manpower and medical consumables in outpatient departments as well as the refined management and scheduling of medical equipment and facilities. Moreover, hour-level outpatient visit forecasts can provide a valuable decision-making reference for patients' time management, enhancing efficiency for both hospitals and patients. Hourly visits to fever clinics can be characterized as a long-sequence time series in high frequency owing to their high sampling rate and large time window. The unique visitation patterns of children with fever will also certainly be reflected in the time-series data. Therefore, a peer-to-peer approach capable of uncovering the intrinsic patterns of pediatric fever clinic visit time series and establishing accurate and fine-grained visit forecast models is highly desirable.

Related Work

Time-series analysis and forecasting have been widely applied in various fields, such as disease analysis [5-9], hospital operation management [10-14], and drug management [15-18]. Numerous studies have been conducted to forecast daily and hourly arrivals or occupancies in emergency departments. Hertzum [19] and Choudhury and Urena [20] effectively predicted hourly arrivals using autoregressive integrated moving average (ARIMA) models, whereas Becerra et al [21] studied a seasonal ARIMA (SARIMA) forecast model based on daily emergency admissions for respiratory outpatients. Cheng et al [22] and Whitt and Zhang [23] applied SARIMA with an external repressor to forecast hourly occupancy. Deep learning algorithms, such as the variational autoencoder proposed by Harrou et al [24] and the long short-term memory (LSTM) used by Etu et al [25], have also been applied to such problems, demonstrating that prediction results can significantly aid decision support in hospital management. Zhang et al [26] and Sudarshan et al [27] incorporated external variables, such as calendar and meteorological information, into the LSTM model, verifying the improvement in the accuracy of the models established in their research case.

Khaldi et al [28] investigated a hybrid model combining artificial neural networks with ensemble empirical mode decomposition, which exhibited better approximation and generalization capabilities than the benchmarking models when applied to weekly arrivals in emergency departments. Deng et al [29] proposed a hybrid ARIMA-LSTM model optimized by the backpropagation neural networks that achieved more accurate and stable predictions than the respective single models and the traditional hybrid model when forecasting weekly and monthly outpatient visits to the respiratory department. Perone [30] used single-step time-series methods and their feasible ensembles to forecast the arrival of hospitalized patients with COVID-19 presenting with mild symptoms, as well as those in intensive care units. They discovered that hybrid models were significantly better at capturing linear, nonlinear, and seasonal pandemic patterns than their respective single models on both time series.

Although numerous studies have been dedicated to forecasting outpatient visits, the time-series models used in existing hospital visit forecasting studies are limited in their ability, for they handle only a single seasonality pattern. When applied to long-sequence time series in high frequency, these models are unable to capture all seasonal patterns present in the data, resulting in the loss of data features and increased difficulty in forecasting. This is the significant drawback of single-seasonal-pattern models. Additionally, although cross-validation has been conducted in previous time-series studies to evaluate model performance, it has rarely been used as a basis for comparing the forecasting performance of models across different forecast horizons, leading to an incomplete analysis and evaluation of the predictive capabilities of different models. This study aimed to address these limitations.

Objective

In this study, we aimed to develop a reliable forecasting model for the hospital management of fever clinics. Unlike previous studies, we focused on establishing models suitable for long-sequence time series in high frequency. The model needed to meet the following 3 requirements to facilitate our fever clinic visit forecast task. Firstly, we prioritized hourly forecasts over daily forecasts to predict fever clinic visits, as this allows for greater flexibility in hospital management and resource allocation. Second, an ideal model should be capable of making medium- to long-term forecasts (eg, 15 days) on high-frequency time-series data to aid hospital managers in making informed

decisions. Finally, the model should be scalable and stable and exhibit robust performance.

To this end, we first conducted an exploratory analysis of time-series data to uncover the patterns and features of fever clinic hourly visit time series and then used an ensemble of time-series models and their combinations for fever clinic visit forecasting. For model evaluation, we used cross-validation to compare the accuracy of all models across different forecast horizons and analyzed the results. Exploratory analysis can help discover the inherent laws of data, which makes it easier to find models that fit the characteristics of the data. Cross-validation across different forecast horizons helps find models with superior scalability and stability. These are the 2 points that represent the main highlights of our research compared with existing work.

Methods

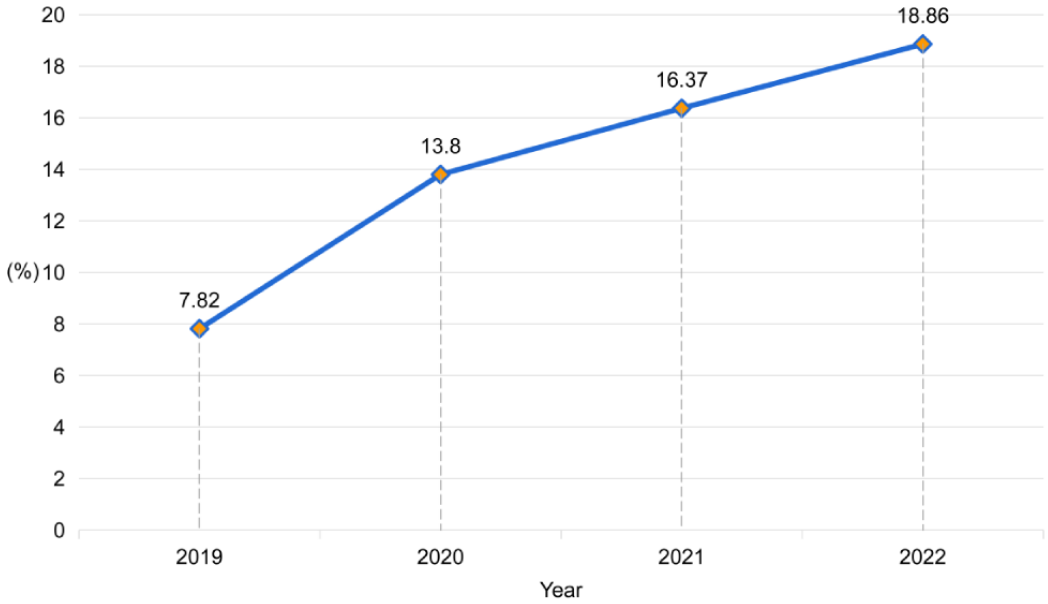
Ethical Considerations

The authors are accountable for all aspects of the work and are responsible for ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved. This study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). The study was approved by the Academic Ethics Committee of the Children's Hospital of Zhejiang University School of Medicine (2020-RIB-058). The requirement for individual consent for this retrospective analysis was waived.

Study Participants

This study focused on the Children's Hospital of Zhejiang University School of Medicine, a preeminent comprehensive class A tertiary children's hospital located in the Zhejiang province, China. In response to the COVID-19 outbreak in 2020, the hospital's fever clinic transitioned to a 24-hour emergency operation mode, providing uninterrupted care for pediatric patients. The fever clinic operates as an autonomous department fully equipped with comprehensive medical resources. Figure 2 presents data illustrating the proportion of fever clinic visits relative to the total number of outpatient visits over the past 4 years. The data revealed a consistent increase in the proportion of fever clinic visits, with a notable surge in 2020.

Figure 2. The ratio of fever clinic visits to the total number of outpatient visits over the past 4 years.



Data Collection and Preprocessing

The data set used in this study consisted of authentic data extracted from the electronic medical record (EMR) text of the aforementioned hospital's fever clinic. Data were collected from January 23, 2020, to May 23, 2023, encompassing the onset of the COVID-19 outbreak and the phases of strict containment policy (January 2021 to November 2022) and open containment policy (December 2022 to present) implemented in the region. We tallied hourly fever clinic visits based on patients' initial visit records in the EMR and divided each day's 24-hour data into 24 nonoverlapping segments. Our data set comprises a time series of 29,208 data points (1217 days × 24 hours) representing hourly visits. Our data set exhibited a paucity of missing data, which we addressed by filling sporadic gaps in the hourly count with a value of 0. Outliers were identified through the remainder sequence obtained via seasonal-trend decomposition using Loess (STL) decomposition and defined as values exceeding 3 IQRs from the central 50% of the data. These outliers were subsequently smoothed using linear interpolation.

To further scrutinize our data set, we conducted statistical analyses based on children's developmental stages as determined by their educational level [31]. The total number of patients was 1,590,909, and we divided them into the following 5 groups: infants (aged 0-2 years; n=661,425, 41.58%), preprimary children (aged 3-5 years; n=599,464, 37.68%), primary school children (aged 6-11 years; n=302,046, 18.99%), junior secondary students (aged 12-14 years; n=25,364, 1.59%), and senior secondary students (aged 15-17 years; n=2610, 0.16%). Table 1 depicts fever clinic visits for each group, revealing that the patients were predominantly infants and preprimary children.

Furthermore, we extracted International Classification of Diseases, 10th Revision disease diagnosis codes [32] from the EMR data and compiled statistics on related diseases in the fever clinic. Our results indicate that respiratory diseases constitute the largest proportion (738,635/1,590,909, 46.43%) of fever clinic cases, followed by infectious and parasitic diseases (347,199/1,590,909, 21.82%) and digestive diseases (174,814/1,590,909, 10.99%), all of which are influenced by climate change.

	0-2 years	3-5 years	6-11 years	12-14 years	15-17 years
Girls, n	297,590	283,567	141,768	10,887	1221
Boys, n	363,835	315,897	160,278	14,477	1389

Exploratory Data Analysis

Before constructing forecasting models, it is imperative to comprehend the behavior of data in the time domain. Using statistical graphics and data visualization techniques, time-series patterns can be extracted and interpreted, facilitating model selection and minimizing errors.

Graphic Analysis

Figure 3 depicts the hourly fever clinic visit time series from our data set. We plotted time-series data before and after the changes in the epidemic containment policy, with December 19, 2022, as the separation point. To identify the underlying patterns in the time series, we analyzed the data from a seasonal perspective. Given that our data are hourly, they may exhibit 3 types of seasonality: daily, weekly, and yearly. These patterns are plotted in Figures 4-6.

As illustrated in Figure 4, the diurnal pattern of fever clinic visits exhibited relatively fewer visits during the early morning hours, with 3 prominent peaks occurring at 9 AM, 2 PM, and 8 PM, indicating heightened visitation. Figure 5 reveals that visitation peaks are most pronounced on Mondays and Tuesdays, diminishing on Wednesdays and Thursdays before a resurgence from Friday through the weekend. Despite an overall decline in fever clinic visits in 2023 due to the relaxation of COVID-19 policies, the time series which consists of data spanning over 3 years still exhibits clear annual periodicity. As shown in Figure 6, values fluctuate systematically with seasonal and even monthly variations, with elevated values during winter, diminished values during spring, and peak outpatient periods coinciding with summer vacation. The location of troughs in Figure 6 appears to be influenced by movable holidays such as the Chinese New Year. From Figures 4-6, we can deduce that the time series exhibits conspicuous multiseasonal patterns, including daily, weekly, and yearly seasonalities, thereby exhibiting robust predictability.

Autocorrelation Function Analysis

The analysis of autocorrelation function (ACF) and partial ACF (PACF) for sample data is a crucial approach for identifying the characteristics of seasonal time series and proposing appropriate candidate models [33]. The lag k autocorrelation coefficient r_k, as measured by ACF, quantifies the linear correlation between 2 observations, y_t and y_{t-k} can be expressed per the following formula:

where y_t represents the value of the time series at time t,  is the mean, and T is the length of the time series. PACF, by contrast, measures the direct correlation between y_t and y_{t-k} while isolating the effects of periods other than k from the analysis.

Figures 7 and 8 depict the sample ACF and PACF for the initial 48 lags derived from the hourly fever clinic visitation data and their corresponding seasonal differential data. As illustrated in Figure 7, the ACF values are uniformly positive and exhibit symmetrical, humped shapes with spike values occurring at multiples of 24-hour intervals, whereas the PACF values exhibit decay in seasonal lags at multiples of 24 hours. These observations suggest that the hourly visit time series is nonstationary and lacks a discernible trend, yet it exhibits strong daily seasonality. Consequently, a seasonal difference by daily period (24 hours) can be applied to generate a stationary time series. As demonstrated in Figure 8, the ACF decays exponentially to approximately 0 after 5 lags, with a downward spike at the first seasonal lag, whereas the PACF exhibits tailing off within each daily periodicity. This indicates the presence of short-term autocorrelation within the differential series as well as a strong negative autocorrelation with 1 seasonal lag. Therefore, it is feasible to achieve short-term forecasts and single seasonal (daily seasonal) forecasts through autocorrelation-based modeling.

Figure 7. Autocorrelation function (ACF) and partial autocorrelation function (PACF) of the hourly fever clinic visit time series.

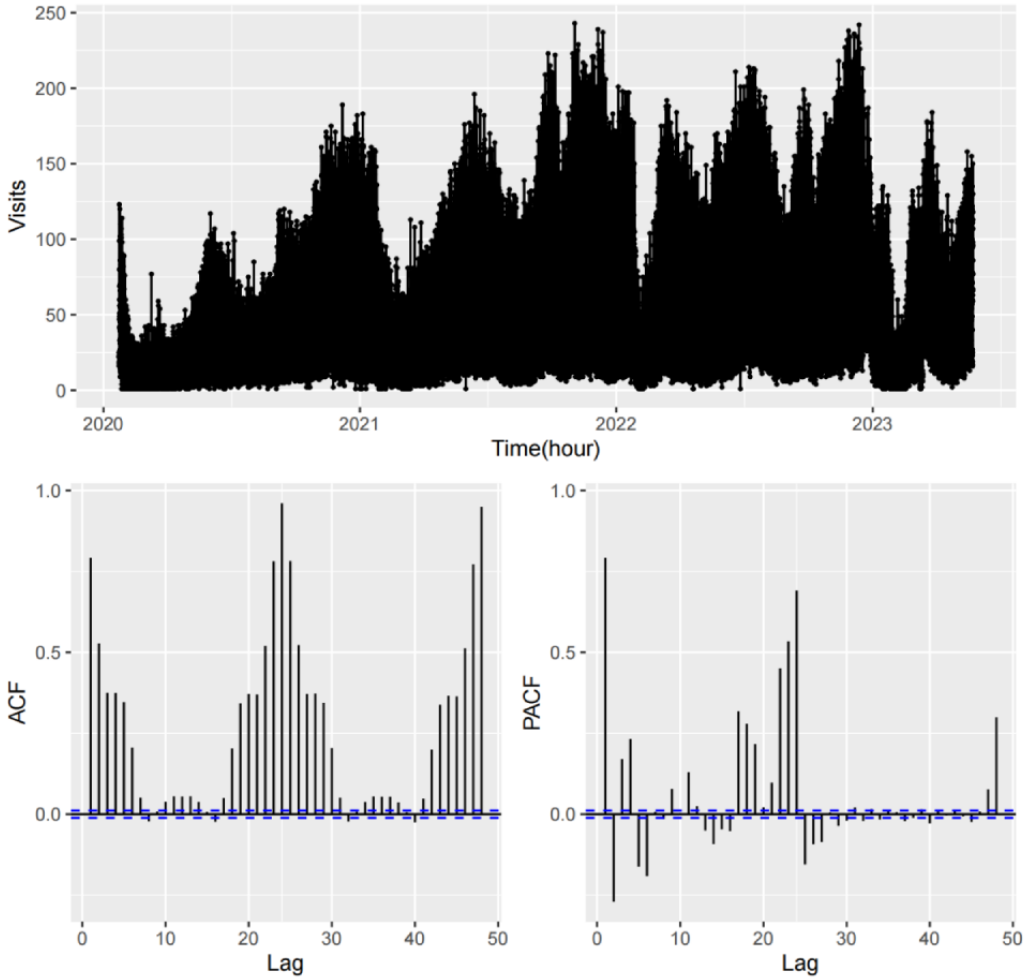

Figure 8. Autocorrelation function (ACF) and partial autocorrelation function (PACF) of the seasonal differential hourly fever clinic visit time series.

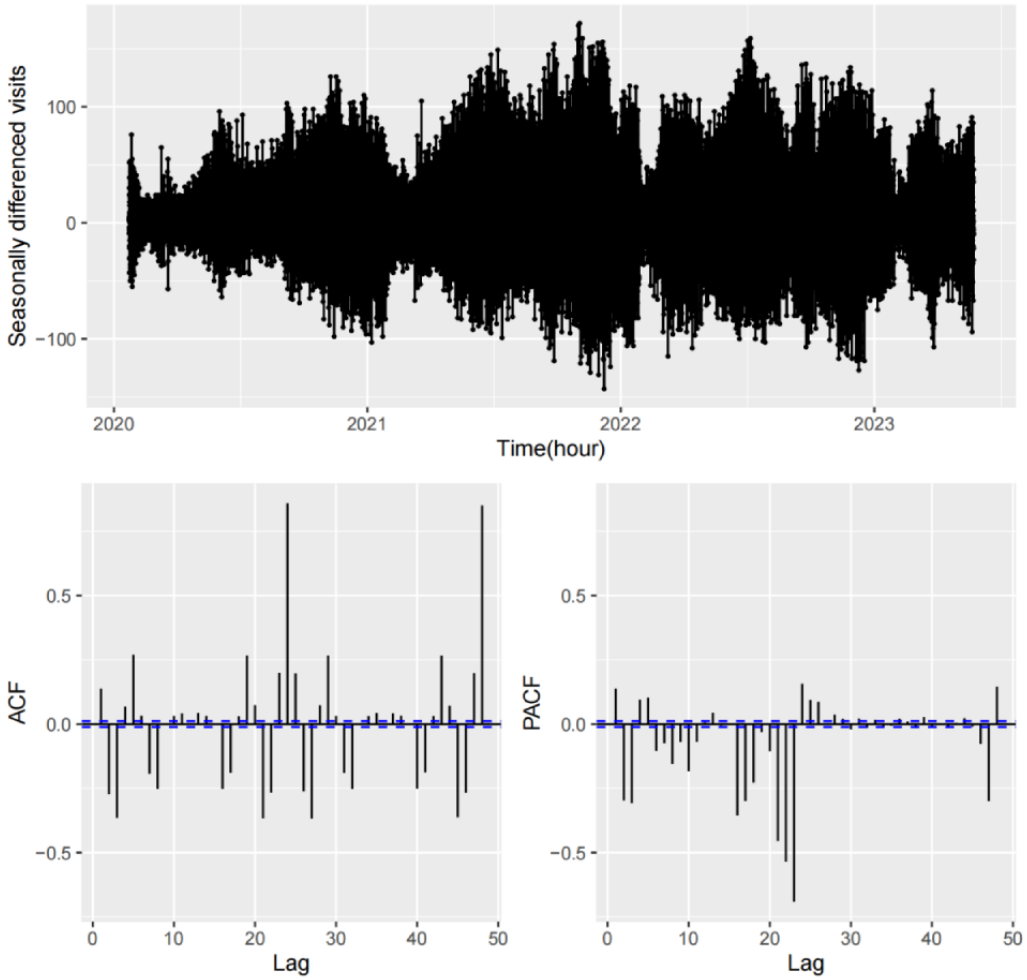


STL Analysis

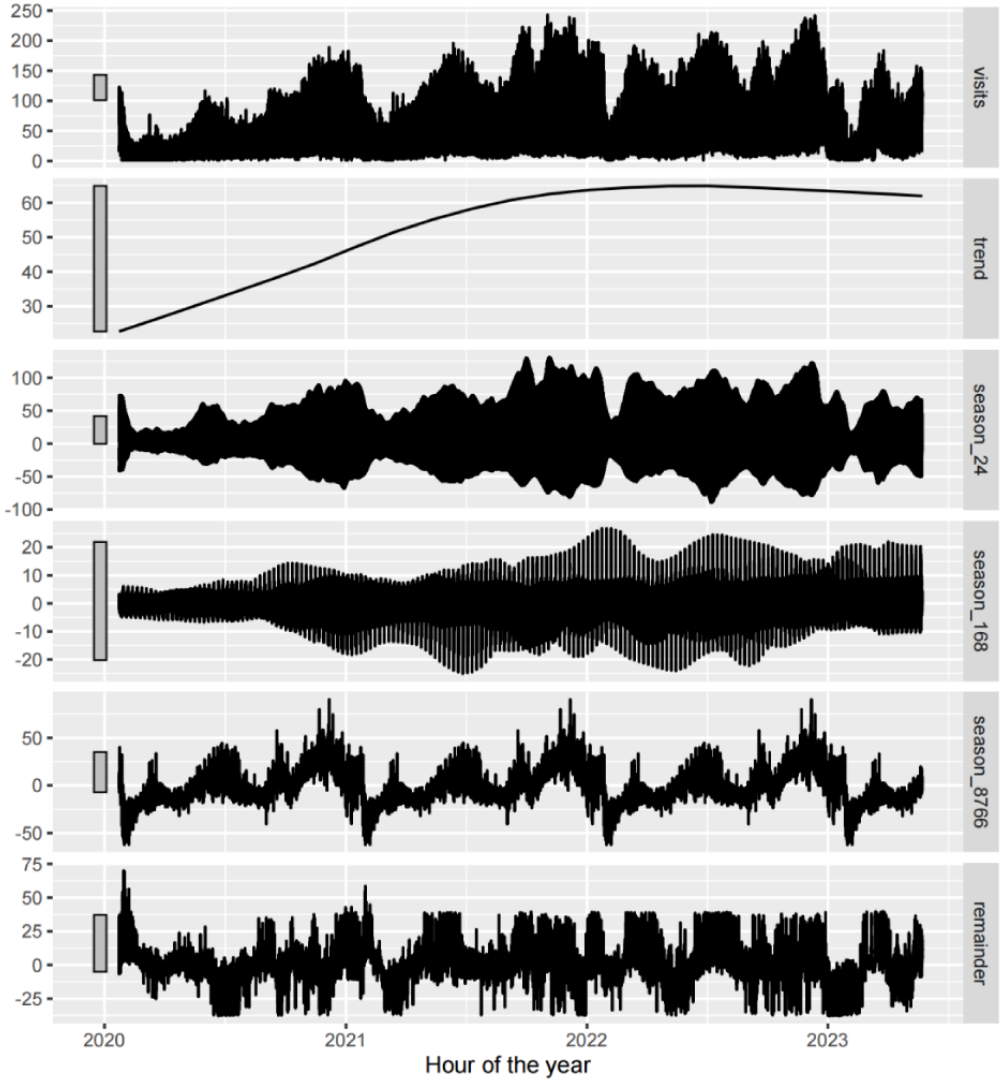
The decomposition of a time series can be used to assess its strength of trend and seasonality. The STL, developed by Cleveland et al [34], constitutes a filtering procedure for decomposing a time series into trend, seasonal, and remainder components in an additive manner. This methodology was subsequently extended to facilitate the decomposition of time series exhibiting multiple seasonal patterns [35].

Figure 9 shows the application of STL to hourly fever clinic visit data, yielding multiple seasonal components as well as trend and remainder components. As expected, 3 seasonal patterns were evident, corresponding to the time of day (third panel), time of week (fourth panel), and time of year (fifth panel).

Note the vertical scales of all panels in Figure 9; the trend panel has the widest bar compared with the other panels, which means that the trend has the narrowest range and, consequently, accounts for only a small proportion of the variation within the data series. The weekly seasonality panel exhibits similar characteristics. In addition, the bars on the daily and yearly seasonality panels are only slightly larger than that on the data panel, indicating that the daily and yearly seasonality signals are largely related to variations in the data series.

It can be inferred that the number of visits exhibited an upward trend during the first 2 years, followed by a modest decline commencing at the end of 2022. However, the impact of this change in trend on the overall time series is negligible. Consequently, the influence of changes in the epidemic containment policy on the data can be ignored. Concurrently, the weekly seasonality inherent within the series is relatively weak and exerts minimal influence on temporal variations within the time series, whereas daily and yearly seasonalities exert a more pronounced effect. Furthermore, it is evident that the daily seasonal pattern undergoes temporal variations, whereas the yearly seasonal pattern appears relatively fixed. Therefore, for long-term forecasting, it is advisable to incorporate yearly seasonal lag data. Finally, the panel at the bottom exhibits large random fluctuations owing to its slightly larger size relative to the data panel. This suggests the presence of additional nonlinear signals infiltrating the residual components, potentially attributable to outliers or unaccountable factors.

Figure 9. Seasonal-trend decomposition using Loess on the hourly fever clinic visit time series.



Theory and Calculations

This section delineates the models used in this study and explains the forecast accuracy measures used in the evaluation of model performance.

Forecasting Models

Before conducting experiments, we established a benchmark method as the standard to ensure that the performance of the other selected models surpasses that of it. As a benchmark approach, it is reasonable to consider the prevailing seasonality in the time series. We set the seasonal naive (SNaive) method as our benchmark, given its utility for highly seasonal data. This method sets each forecast such that it is equal to the last observed value from the corresponding season. Here, the predicted value for the forecast horizon h is considered to be equivalent to the observed value from the previous day. Formally, the forecast for time $T+h$ is expressed as

where m represents the specified seasonal period. This approach requires no parameterization or setup and is frequently used as a benchmark method rather than a model of choice.

Time series exhibiting trends or seasonality are not stationary, as their statistical properties vary over time. In such instances, nonstationary time series can be rendered stationary through the application of differencing techniques. The ARIMA model constitutes a combination of differencing with autoregressive and moving average (MA) components, which were first proposed by Box and Jenkins [36], and is commonly denoted as ARIMA(p,d,q). Autoregressive refers to the regression of a variable in the model on its own lagged or prior values, whereas MA incorporates the dependency between an observation and a residual error derived from an MA model applied to lagged observations. However, the ARIMA model is only applicable to nonseasonal data. The SARIMA model, denoted as ARIMA(p,d,q)(P,D,Q)$_m$, was derived by incorporating additional seasonal terms into the ARIMA model. It should be noted that the SARIMA model can only specify a single seasonal period parameter, rendering it capable of handling only single seasonality. A mathematical exposition of the ARIMA and SARIMA models can be found in Multimedia Appendix 1.

As demonstrated in the *STL analysis* section, STL has been applied to the hourly fever clinic visit time series exhibiting multiple seasonality. This can be conceptualized as decomposition into 3 seasonal components and seasonally

adjusted components. The STL method is based on the performance of weighted local regressions (Loess) on seasonal indices and the trend, with Loess constituting a methodology for estimating nonlinear relationships. This approach confers benefits upon statistical methods by providing a more versatile and robust decomposition procedure than their intrinsic mechanism [37]. The improved algorithm for multiple seasonality uses an iterative method to obtain seasonal components sequentially in ascending order of cycles and finally to compute the trend component in the last iteration [35]. The forecasting approach based on the STL method is defined as the STL forecasting (STLF) model. In this approach, each seasonal component is forecasted by the SNaive method corresponding to the seasonal lags, whereas seasonally adjusted data are forecasted using a nonseasonal ARIMA model. Evidently, this forecasting approach has an advantage in handling multiple seasonal patterns for a long time series, in contrast to the SARIMA model, which is limited to handling single seasonality.

Artificial neural network is based on a structure comprising an input layer, hidden layers, and an output layer, facilitating the modeling of complex nonlinear relationships between response variables and their predictors. The neural network autoregressive (NNAR) model uses lagged values of the time series as inputs to the neural network, with the last observed values from the corresponding season also incorporated as inputs. Generally, the notation NNAR(p,P,K)$_n$ is used to denote the presence of p lag inputs, P seasonal lag inputs, and K neuron nodes in the hidden layer, where m represents the seasonal period. A model can be defined as $y_t=f(y_{t-1},y_{t-2},\ldots,y_{t-p},y_{t-m},\ldots y_{t-Pm})+\varepsilon_t$, where f represents the nonlinear function of the feed-forward network with a single hidden layer, and ε_t is the residual series. In contrast to traditional time-series methods, the network may be applied iteratively, with predictions incorporated as inputs alongside historical data when forecasting additional steps ahead.

In addition, hybrid combinations of the aforementioned models include hybrid SARIMA-STLF, hybrid NNAR-STLF, hybrid SARIMA-NNAR, and hybrid SARIMA-NNAR-STLF. In these hybrid models, multiple forecasts are combined by averaging the forecasts of individual models. This constitutes a straightforward yet effective means of enhancing the forecast accuracy [38]. Moreover, fixed weights facilitate the identification of optimal solutions more effectively than weights that are based on the random statistical variables derived from changing data.

Accuracy Measures

We used root mean squared error (RMSE) and mean absolute error (MAE) to assess the performance of the applied models. Given that the training set is denoted as $\{y_1,y_2,\ldots y_T\}$ and the testing set as $\{y_{T+1},y_{T+2},\ldots\}$, the forecast deviation between the actual observations y_t on the testing set and the corresponding forecasts  can be denoted as  . The formulas for calculating each of these metrics are as follows:

where n represents the total number of observations for the evaluation process. Both RMSE and MAE are scale-dependent metrics. RMSE operates on the principle of averaging errors and is more sensitive to outliers, whereas MAE is calculated from the median of errors and is more robust to outliers.

Results

Overview

In this section, we present the results of the evaluations of all the candidate forecasting models. Hourly visits to the fever clinic were forecasted for the subsequent 15 days, with accuracy calculated based on the forecasted values over this period. The 8 evaluated models were SNaive (as a benchmark), SARIMA, STLF, NNAR, and combinations of these models (excluding SNaive), hybrid SARIMA-STLF, hybrid NNAR-STLF, hybrid SARIMA-NNAR, and hybrid SARIMA-NNAR-STLF. For model training, we used data from January 23, 2020, to April 23, 2023, as the training set and data from April 24, 2023, to May 8, 2023, as the testing set. The performances of the models were compared based on the accuracy of their forecasting results on the testing set.

Model Estimation

Given that the SNaive, SARIMA, and NNAR models are only capable of handling a single seasonal period, we used a daily season period as the seasonal frequency parameter for hourly data. This corresponds to a lag of 24 in SNaive and m=24 in both SARIMA and NNAR. The specifications and estimations for all the models are detailed in Tables 2 and 3. For the selection of hyperparameters and fitting of model parameters, we used the fable toolkit in the R programming language (R Core Team) for implementation.

The SARIMA modeling process was implemented using a variation of the Hyndman-Khandakar algorithm [39], in which parameter D was chosen by an extended Canova-Hansen test [40], and d was chosen through successive Kwiatkowski-Phillips-Schmidt-Shin unit-root tests [41]. Once d and D were determined, a stepwise search was conducted to traverse the ARIMA order space from the initial candidate parameters, selecting values for p, q, P, and Q by minimizing the corrected Akaike's information criterion until the residuals met the white noise conditions. The modeling process for nonseasonal ARIMA was similar, with the exception that the seasonal hyperparameters were set to 0 (P=D=Q=0). After identifying the model orders (hyperparameters p, d, q, P, D, and Q) with the lowest corrected Akaike's information criterion, the model parameters were estimated on the training set using the maximum log-likelihood estimation. In this study, the best-fitting models for SARIMA and STLF on our training data were ARIMA(0,0,5)(0,1,1)$_{24}$ for SARIMA and ARIMA(2,1,2) for STLF. The estimated coefficients for these models are listed in Table 4.

For the NNAR model, the seasonal parameter P was set to 1, and the p parameter was selected from the optimal linear autoregressive(p) model fitted to the seasonally adjusted data (obtained through STL) according to the AIC. The k parameter was rounded to the nearest integer of (p+P+1)/2. In this study,

the best-fitting model for this approach was an average of 20 networks NNAR(44,1,22)$_{24}$, each consisting of a 44×22×1 network with inputs {y_{t-1},y_{t-2},...y_{t-44}} and 22 neurons in the hidden layer. For 1-step-ahead (1 hour ahead) forecasting, available historical inputs were used, whereas for 2-step-ahead forecasting, the 1-step forecast was used as an input along with historical data. This process was executed iteratively until all the required forecasts were computed [38].

Forecasting Results

The forecasting results of all the evaluated models are shown in Figures 10 and 11. The distribution of the predicted values varies among the models. However, for short-term future data, each model appears to be capable of capturing the majority of their hourly features. It is evident that the prediction and observation lines of all the models are in reasonable agreement. However, as the forecast horizon increases, the agreement between the predicted and actual values of each model diminishes significantly. For further quantitative comparison of the model performance, we calculated the forecast errors within the subsequent 15 days for each model using the accuracy metrics RMSE and MAE. All results are presented in Table 5, which reveals that the hybrid SARIMA-NNAR-STLF model has both the lowest MAE (8.16) and the lowest RMSE (11.09), whereas STLF performs the worst.

Figure 10. Comparison of 15-day forecasts generated using single models with actual observations. NNAR: neural network autoregressive; SARIMA: seasonal autoregressive integrated moving average; SNaive: seasonal naive; STLF: seasonal and trend decomposition using Loess forecasting.

[f]SNaive: seasonal naive.

Cross-Validation

To mitigate the risk of overfitting and determine the optimal hyperparameters for our models, we employed a cross-validation technique based on a rolling forecasting origin [42]. The forecasting origin was advanced incrementally by a fixed number of observations, with forecasts generated at each origin. As the origin progressed, the testing set was incorporated into

the training set for subsequent iterations. Figure 12 illustrates the construction of our cross-validated training and testing sets. To ensure the complete coverage of each month in the testing set, we initiated our analysis with a training set comprising 19,848 observations (827 days), incrementing the size of successive training sets by 720 steps (30 days) with each iteration. This allowed us to generate 1-to-720-step-ahead forecasts and conduct 13 iterations of cross-validation to evaluate the forecasts throughout the entire year. During these iterations, the largest validation set spanned from January 23, 2020, to May 23, 2023, with the training set ranging from January 23, 2020, to April 23, 2023, and the testing set from April 24, 2023, to May 23, 2023.

Forecast accuracy was computed by averaging over the testing sets. This cross-validation method is well suited to account for the temporal dependency between observations in time series, effectively mitigating overfitting while providing a more robust evaluation of model performance [43]. Furthermore, the construction of a rolling length training set is advantageous for validation in multiseasonality cases. The forecast accuracy of all the models for the subsequent 15 days, as determined by cross-validation, is presented in Table 6. The results indicate that the hybrid NNAR-STLF model is the optimal model for this case, as it has both the lowest RMSE (20.1) and the lowest MAE (14.3).

Figure 12. Illustration of the rolling forecasting origin cross-validation methodology.

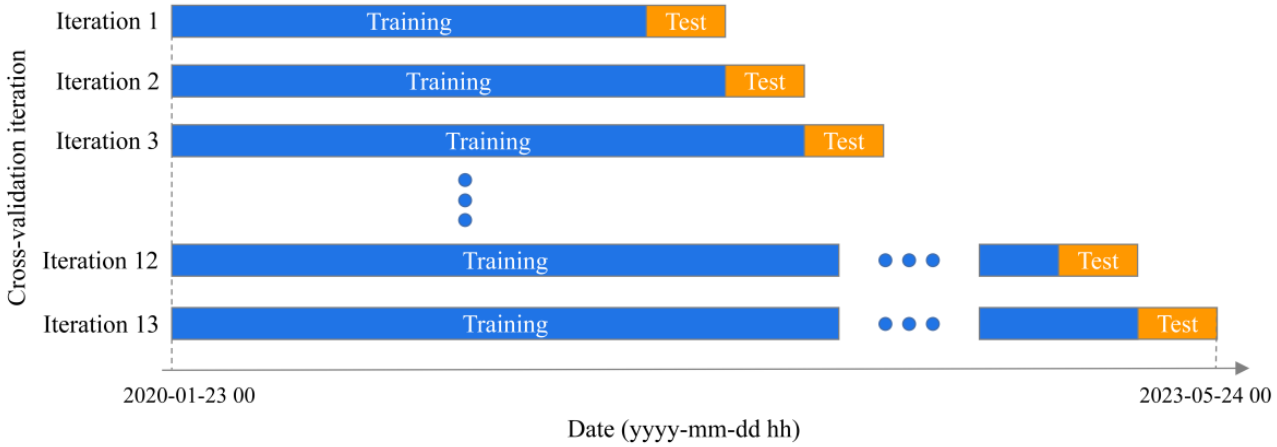

Table 6. Accuracy metrics of all the models for the 15-day forecast by cross-validation.

Model	RMSE[a]	MAE[b]
Hybrid NNAR[c]-STLF[d]	20.1	14.3

[f]SNaive: seasonal naive.

Forecast Horizon Accuracy

Although cross-validation has been used in previous studies for performance evaluation, it has rarely been conducted across different forecast horizons. In this study, we not only assessed the accuracy of hourly forecasts for fever clinic visits within a 15-day window but also examined the accuracy of various forecast horizons to provide a more robust basis for identifying the optimal model. Forecast errors across forecast horizons ranging from 1 to 30 days ahead were compared using cross-validation. Specifically, the forecast horizon accuracy was calculated by comparing all the predicted values with their corresponding observed values in the hourly series within a specific 1-day range, representing the model's predictive power

on the i-th day ahead (i=1,...,30). As such, the accuracy metrics for different forecast horizons are independent of one another. The results of our analysis are presented in Figures 13 and 14, which depict the RMSE and MAE values for all the models across different forecast horizons. The calculation of RMSE and MAE was based on the average value obtained across all rolling testing sets in cross-validation.

As shown in Figures 13 and 15, for all the models, the RMSE and MAE values exhibit an overall upward trend as the forecast horizon increases, although not strictly monotonically in some cases. In general, the further ahead we forecast, the greater the uncertainty associated with our predictions. Moreover, the disparity in forecast accuracy among the models also increases with the number of days ahead of the forecast, indicating a widening gap in performance.

Among single models, STLF exhibited superior predictive performance only when forecasting more than 5 days in advance, with the RMSE and MAE values remaining relatively low, especially when forecasting more than 10 days in advance. This highlights the model's advantages in medium- to long-term forecasting. Compared with the benchmark SNaive model, the largest difference in RMSE occurred at a forecast lead time of 17 days, with STLF achieving a value of 22.5 (7.4 lower than that of SNaive), whereas the largest difference in MAE occurred at a forecast lead time of 24 days, with STLF achieving a value of 20.5 (6.2 lower than that of SNaive). In addition, the NNAR model exhibited considerable advantages in short-term forecasting, particularly for forecasts that were 1 to 3 days in advance, with both RMSE and MAE values being the lowest among all the single models (RMSE: 14.3, 15.6, and 16.7; MAE: 10.6, 11.3, and 12.3). However, its performance in medium- to long-term forecasting is more modest.

For hybrid models, the performance was generally superior to that of their constituent single models. Comparing the results for both single and hybrid models, the hybrid NNAR-STLF model exhibited the lowest values for both RMSE and MAE across nearly all forecast horizons, with RMSE ranging from 13.6 (1st day ahead) to 28.3 (30th day ahead) and MAE ranging from 10.8 (1st day ahead) to 21.5 (23rd day ahead). It is evident that the hybrid NNAR-STLF model outperforms in all 3 cases (short-, medium-, and long-term forecasting), indicating that it may be considered the optimal model. However, not all the hybrid models performed well. For example, the hybrid SARIMA-NNAR model exhibited a relatively poor performance compared with both single and other hybrid models. Nonetheless, on the whole, the hybrid approach did have a positive impact on forecasting.

Figure 13. Root mean squared error (RMSE) values calculated for different forecast horizons ranging from 1 to 30 days ahead. NNAR: neural network autoregressive; SARIMA: seasonal autoregressive integrated moving average; SNaive: seasonal naive; STLF: seasonal and trend decomposition using Loess forecasting.

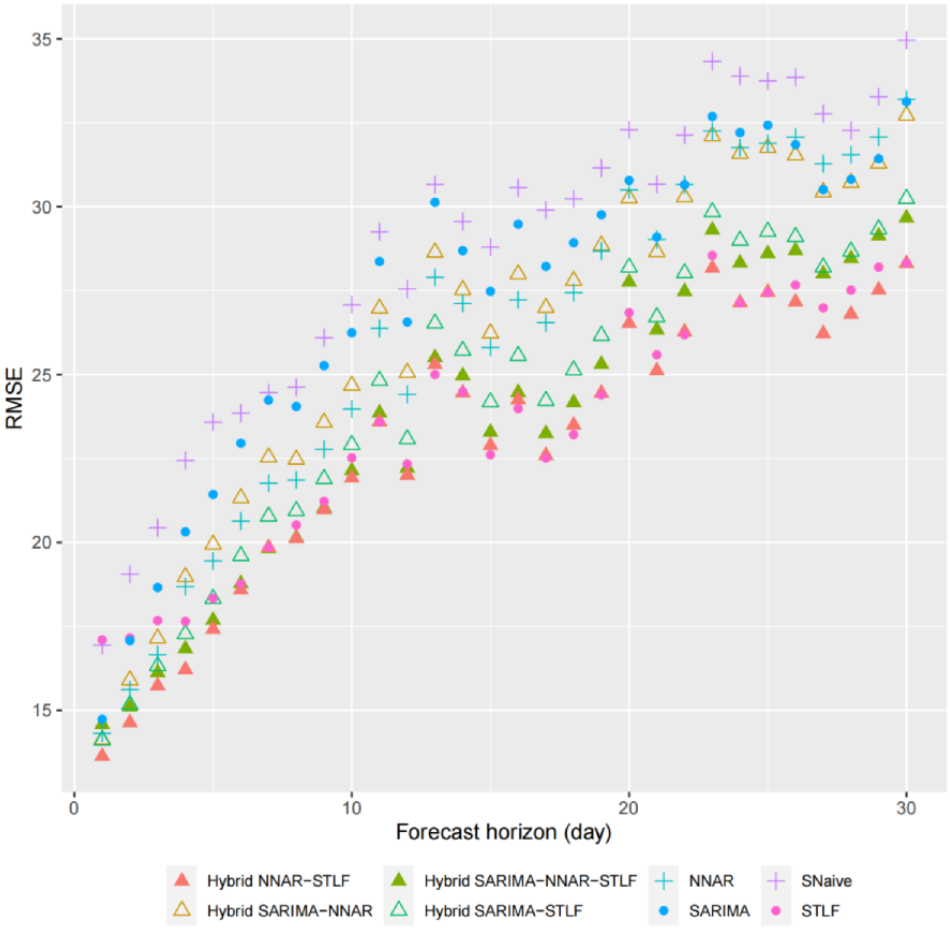

Figure 14. Mean absolute error (MAE) values calculated for different forecast horizons ranging from 1 to 30 days ahead. NNAR: neural network autoregressive; SARIMA: seasonal autoregressive integrated moving average; SNaive: seasonal naive; STLF: seasonal and trend decomposition using Loess forecasting.

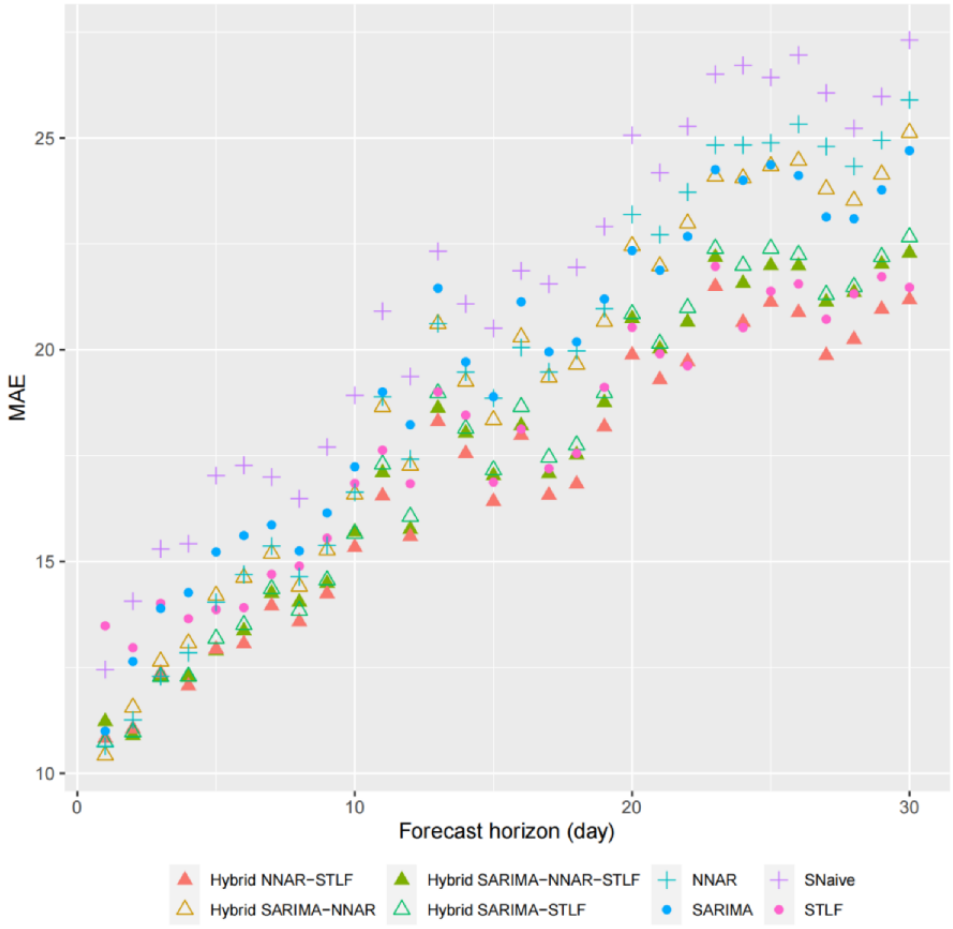

Figure 15. Monthly aggregated root mean squared error (RMSE) and mean absolute error (MAE) box plot.

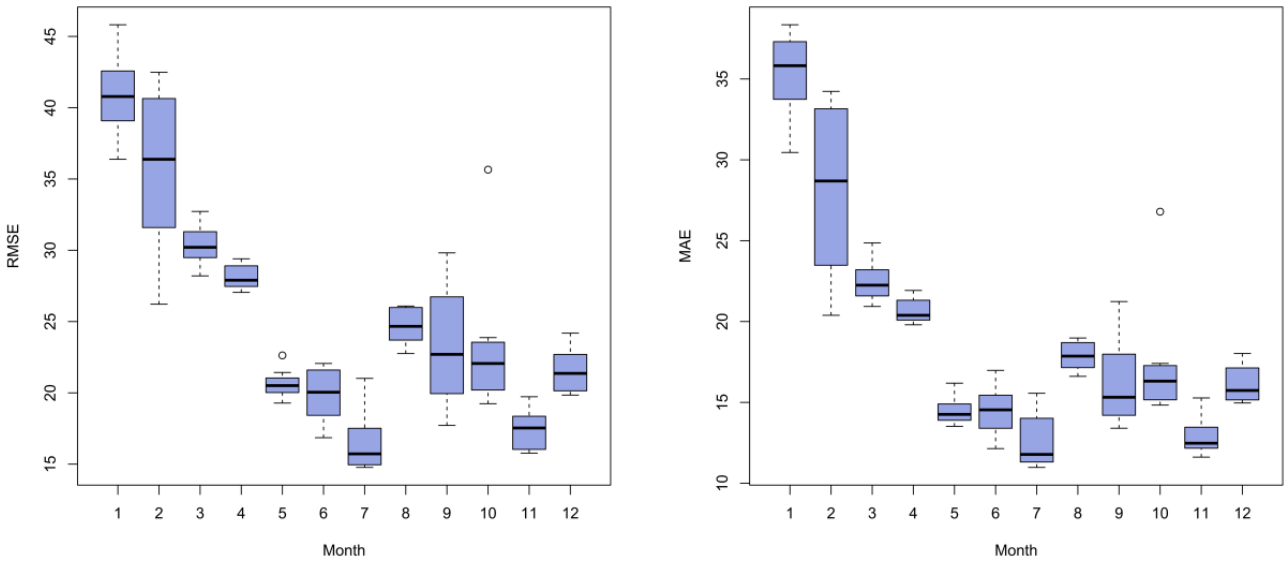

Discussion

Principal Findings

The hourly visit data from our hospital's fever clinic can be characterized as a time series of long sequences in high frequency. Through exploratory analysis using data visualization, ACF, and STL methods, we observed that the time series exhibited multiseasonality and nonlinearity in its temporal patterns. To achieve our goal of generating hourly forecasts of fever clinic visits in the medium- to long-term horizons, we evaluated an ensemble of individual and hybrid models. In selecting and combining models, we considered their ability to capture multiseasonality and handle nonlinear features.

Our analysis revealed that hybrid models generally outperformed individual models, with the hybrid NNAR-STLF model emerging as the optimal model for our purposes. It exhibited the smallest error in the 15-day forecast horizon (RMSE at 20.1 and MAE at 14.3) and demonstrated a stable advantage in prediction accuracy across forecast horizons ranging from 1 to 30 days ahead. This indicates that it possesses strong scalability and generalization capabilities for predicting multiseasonal periods in time-series data.

Hourly forecasts of fever clinic visits can be leveraged to enhance intelligent outpatient management and provide a sound basis for resource allocation at multiple levels. On the one hand, hospitals can use forecast results to implement flexible scheduling strategies, such as adjusting the number of doctors on duty and modifying registration limitations for specialist doctors and their working hours. On the other hand, during peak seasons and times, hospitals can adapt their facilities and human resources, including the number of service windows, medical technicians, nurses, and outpatient volunteers, to better meet the demands of outpatient operations in accordance with the forecast results. Furthermore, accurate visit forecasts can be used to schedule patient appointments and recommend optimal visitation times, thereby improving efficiency for both hospitals and patients. It is evident that hourly visit forecasts can more effectively support these requirements.

Interpretation of the Findings

Single Models

SNaive and SARIMA are applicable only to time series with a single seasonal pattern. However, the time series for hourly fever clinic visits exhibits 3 seasonal patterns: daily, weekly, and yearly. This results in poor forecast accuracy for both SNaive and SARIMA. By contrast, NNAR takes lagged values as input to the neural network, establishing a more complex nonlinear relationship between forecasts and historical observations than statistical models, allowing it to capture the asymmetry of cycles. However, as it uses forecast values from previous steps as variables for subsequent steps, errors can propagate through the forecast process. In addition, its use of only a single seasonal lag as a forecast variable limits its effectiveness in medium- to long-term forecasting. STLF uses a strategy that captures more comprehensive data characteristics during the forecasting process. It first uses the SNaive method to forecast 3 seasonal components separately and then applies the ARIMA model to forecast seasonally adjusted data. Because hourly data exhibit large daily seasonality variation, relatively low weekly seasonality variation, and relatively fixed yearly seasonality variation, STLF is particularly effective for time series exhibiting yearly seasonal patterns. As such, STLF has an advantage in forecasting long-sequence time series. However, the remainder of STL is somewhat large, indicating that there may be additional factors not accounted for in STLF, such as calendar effects or special events [44].

Hybrid Models

The hybrid model integrating STLF and NNAR has the enhanced ability to capture the multiseasonal and nonlinear characteristics of time series and thus improved forecast accuracy across various forecast horizons. This can explain why the hybrid NNAR-STLF model exhibits the best overall performance among all the models. By contrast, the hybrid SARIMA-NNAR-STLF model exhibits a strengthened autocorrelation between its components and the daily seasonal lag owing to the single-season cycle limitation imposed by the SARIMA component. As a result, the prediction accuracy gap between hybrid NNAR-STLF and hybrid SARIMA-NNAR-STLF widens with increasing forecast horizon, although the inclusion of NNAR does result in a slight improvement in prediction accuracy. The hybrid SARIMA-NNAR model, which lacks the ability to handle multiseasonal patterns, exhibits a distinct disadvantage in medium- to long-term forecasting, with the poorest performance in both cases.

Implication of Errors on Real-World Applications

Inaccurate forecasts can impede effective hospital management and even interfere with decision-making processes. For example, if predicted visits are significantly lower or higher than the actual number, this can result in either inadequate or redundant allocation of personnel, consumables, and facilities. The former can negatively impact the patient's treatment experience through long wait times, overcrowding, and resource shortage, whereas the latter can lead to resource waste and increased operating cost for the hospital.

Limitations and Future Prospects

In this study, we used individual time-series models and their combinations to forecast hourly visits to fever clinics in children's hospitals. Although the optimal hybrid NNAR-STLF model was able to capture the multiseasonality and nonlinear characteristics present in the time-series data, it still produced large errors in forecasting certain months owing to unaccounted external factors. Figure 15 displays the RMSE and MAE box plots for the forecast results from all the models across different months. Statistically, forecast errors were the largest in January and February, with suboptimal errors also observed in March and April. This may be attributed to the influence of the Chinese New Year, which typically falls in January or February. According to Chinese tradition, economic and social activities throughout the community are affected in the months before and after the festival.

Furthermore, the relaxation of COVID-19 containment policies in December of the previous year may have also impacted fever clinic visits. As January was the peak of the first wave of positive COVID-19 cases following the policy adjustment, data after this month lacked sufficient historical training samples, resulting in decreased prediction accuracy after January 2023. Despite this, the continued prevalence of respiratory epidemics in the postepidemic era has led to the retention of high levels of fever clinic visits, because of which fever clinic visit forecasting is still of great significance for clinical decision-making.

In future work, we will account for the effects of moving holidays and disruptive events, as the incorporation of external variables may improve the forecast accuracy [45]. The data set used in this study was obtained from a prominent provincial

public children's hospital in the Yangtze River Delta region of China. Our findings have implications for large hospitals in other regions that have established 24-hour fever clinics. However, to enhance the generalizability of our model, we will incorporate fever clinic visit data from additional medical institutions and construct high-quality, multicenter data sets for model training. Furthermore, this study used a naive averaging strategy to integrate the hybrid model results. The development of more effective fusion strategies represents another important direction for future research.

Conclusions

In this study, we investigated the problem of visit forecasting in a fever clinic in a large public children's hospital in China. Given the changes in clinics' operational mode and patient visitation patterns following the outbreak of the COVID-19 epidemic, developing new forecasting models is essential for supporting intelligent hospital management. The retrospective data on hourly visits to the fever clinic can be characterized as a long-sequence time series in high frequency, with distinct temporal patterns and statistical characteristics inherent to pediatric clinics. Therefore, to identify appropriate models that accurately fit the data and exhibit robust generalization for practical management, we conducted an exploratory data analysis to reveal the seasonality and structural properties of the time-series data. On the basis of these results, we validated an ensemble of time-series models, including individual models and their combinations. We cross-validated their accuracy performance across different forecast horizons. The hybrid NNAR-STLF model was identified as the optimal model for our problem because of its ability to fit multiseasonal patterns and nonlinearity in the time-series data. Its strong performance across different forecast horizons, as indicated by the cross-validation results, further demonstrates its robustness for multiseasonal time series. The model identified in this study is applicable to hospitals with similar outpatient configurations or time series characterized as long sequence in high frequency. We also provided a new research paradigm for other time-series studies, that is, conducting an exploratory analysis revealing data characteristics before model development. However, the existing models do not account for the effects of exogenous variables, such as moving holidays and disruptive events. Future work will explore more comprehensive methods for incorporating external variables and other factors (eg, temperature, humidity, and pollutant levels) into the models to improve their prediction accuracy.

Acknowledgments

This work was supported by the National Key Research and Development (R&D) Program of China (2019YFE0126200), the National Natural Science Foundation of China (62076218), and the Medical Health Science and Technology Project of Zhejiang Provincial Health Commission (2023KY832). The methods of visit forecasting for fever clinics proposed in this work are part of the technical framework designed for the fundings. However, the funding bodies played no role in the writing of the manuscript.

Data Availability

All the data used in this study were obtained from the electronic medical record of the fever clinic at the Children's Hospital of Zhejiang University School of Medicine. The raw electronic medical record data cannot be shared publicly because of the regulatory and legal restrictions imposed by the hospital. However, the data sets generated during this study are available from the corresponding author upon reasonable request, and the code used by this study is public in the GitHub repository [46].

Abstract

Background: Synthetic data generation (SDG) based on generative adversarial networks (GANs) is used in health care, but research on preserving data with logical relationships with synthetic tabular data (STD) remains challenging. Filtering methods for SDG can lead to the loss of important information.

Objective: This study proposed a divide-and-conquer (DC) method to generate STD based on the GAN algorithm, while preserving data with logical relationships.

Methods: The proposed method was evaluated on data from the Korea Association for Lung Cancer Registry (KALC-R) and 2 benchmark data sets (breast cancer and diabetes). The DC-based SDG strategy comprises 3 steps: (1) We used 2 different partitioning methods (the class-specific criterion distinguished between survival and death groups, while the Cramer V criterion identified the highest correlation between columns in the original data); (2) the entire data set was divided into a number of subsets, which were then used as input for the conditional tabular generative adversarial network and the copula generative adversarial network to generate synthetic data; and (3) the generated synthetic data were consolidated into a single entity. For validation, we compared DC-based SDG and conditional sampling (CS)–based SDG through the performances of machine learning models. In addition, we generated imbalanced and balanced synthetic data for each of the 3 data sets and compared their performance using 4 classifiers: decision tree (DT), random forest (RF), Extreme Gradient Boosting (XGBoost), and light gradient-boosting machine (LGBM) models.

Results: The synthetic data of the 3 diseases (non–small cell lung cancer [NSCLC], breast cancer, and diabetes) generated by our proposed model outperformed the 4 classifiers (DT, RF, XGBoost, and LGBM). The CS- versus DC-based model performances were compared using the mean area under the curve (SD) values: 74.87 (SD 0.77) versus 63.87 (SD 2.02) for NSCLC, 73.31 (SD 1.11) versus 67.96 (SD 2.15) for breast cancer, and 61.57 (SD 0.09) versus 60.08 (SD 0.17) for diabetes (DT); 85.61 (SD 0.29) versus 79.01 (SD 1.20) for NSCLC, 78.05 (SD 1.59) versus 73.48 (SD 4.73) for breast cancer, and 59.98 (SD 0.24) versus 58.55 (SD 0.17) for diabetes (RF); 85.20 (SD 0.82) versus 76.42 (SD 0.93) for NSCLC, 77.86 (SD 2.27) versus 68.32 (SD 2.37) for breast cancer, and 60.18 (SD 0.20) versus 58.98 (SD 0.29) for diabetes (XGBoost); and 85.14 (SD 0.77) versus 77.62 (SD 1.85) for NSCLC, 78.16 (SD 1.52) versus 70.02 (SD 2.17) for breast cancer, and 61.75 (SD 0.13) versus 61.12 (SD 0.23) for diabetes (LGBM). In addition, we found that balanced synthetic data performed better.

Conclusions: This study is the first attempt to generate and validate STD based on a DC approach and shows improved performance using STD. The necessity for balanced SDG was also demonstrated.

Introduction

Machine learning (ML) techniques have been applied in health care with remarkable success over the past decade. ML has the potential to improve tasks in various fields in the medical industry [1]. Analysis of clinical data to predict risk factors and degrees of association between diseases [2] is one of the major advancements achieved using ML. However, the application of ML in real-world clinical environments remains difficult owing to clinical limitations, such as data scarcity, data privacy, and data imbalance [3]. In this context, generative adversarial networks (GANs) [4] have emerged as one of the most important types of ML-based generative models in health care [5].

GAN algorithms generate large amounts of synthetic patient data, which can serve as an appropriate alternative to real data [6-8]. A GAN comprises 2 models trained using an adversarial process, in which one model—the "generator"—generates synthetic data, while the other—the "discriminator"—distinguishes between real and synthetic data. Conventional GAN algorithms have been enhanced and repurposed for clinical tabular data [9-11]. In addition, GANs alleviate clinical limitations and facilitate the application of ML in health care [3,12]. Beaulieu-Jones et al [13] used the auxiliary classifier generative adversarial network (ACGAN) to generate synthetic SPRINT (Systolic Blood Pressure Intervention Trial) data for privacy-preserving data sharing. Baowaly et al [14] generated synthetic electronic health record data using the medical generative adversarial network (MedBGAN) to resolve the data-sharing problem. Izonin et al [15] created an enlarged data set based on a GAN to improve the accuracy of diagnostics tasks. Wang et al [16] developed a framework to generate and evaluate synthetic data, while simultaneously preserving the complexities of real data and ensuring privacy.

Nevertheless, the application of existing models and algorithms, which are not tailor-made for tabular health care data, to synthetic data generation (SDG) in this field remains unsuitable. Some do not consider the characteristics of health care tabular data [17]. To generate synthetic tabular data (STD), while preserving data with logical relationships, the relationships between columns in the original data (OD) must be considered. The OD have a logical relationship between each column: For example, measurement of the drinking attribute is performed using the binary classification "yes" or "no." If the value of this attribute is "no" in some records, the corresponding value of the subattribute "How much do you drink per week?" must be 0. However, poorly designed GANs may generate synthetic data containing impossible values, for example, a record indicating "drinking: no" and "How much do you drink per week?: 10." This can potentially affect the quality of the generated synthetic data and make them unreliable for certain analyses. To prevent this, filtering methods in GANs have been developed. Both the conditional tabular generative adversarial network (CTGAN) [18] and the copula generative adversarial network (CopulaGAN) [19] use conditional sampling (CS) as a filtering method to forcibly express logical relationships. CS is a method used in the CTGAN and CopulaGAN. CS works through a process of rejection sampling, in which multiple iterations of row sampling occur until a satisfactory row that meets the established conditions is obtained. The performance is also compared on balanced and imbalanced synthetic data sets. However, filtering methods exclude record data based on predefined condition columns after STD generation, ignoring meaningful information contained in the excluded records. To mitigate this risk, it is important to carefully consider the specified conditions and to ensure that they are representative of the broader population.

In addition, although it is generally accepted that balanced data perform better in classification, there has been little research based on experiments that clearly demonstrate how much class-balanced tabular synthetic data are required to improve model performance. Therefore, our experiments suggest that when creating a reference table, we should consider how much data to create so that the classes are balanced when generating synthetic data.

In this study, we proposed an SDG framework to overcome the aforementioned challenges in clinical data generation. The remainder of the paper is organized as follows. The *Methods* section describes the basic characteristics of the study population and the divide-and-conquer (DC)–based SDG strategy, defines the division criteria, presents the problem statement for a filtering method, and presents the SDG process and verification methods. The *Results* section compares the prediction performances of the proposed approach and CS. Moreover, the quality of the generated STD is estimated. Finally, the *Discussion* section elaborates further on the experimental design, results, limitations, and conclusions.

Methods

Ethical Considerations

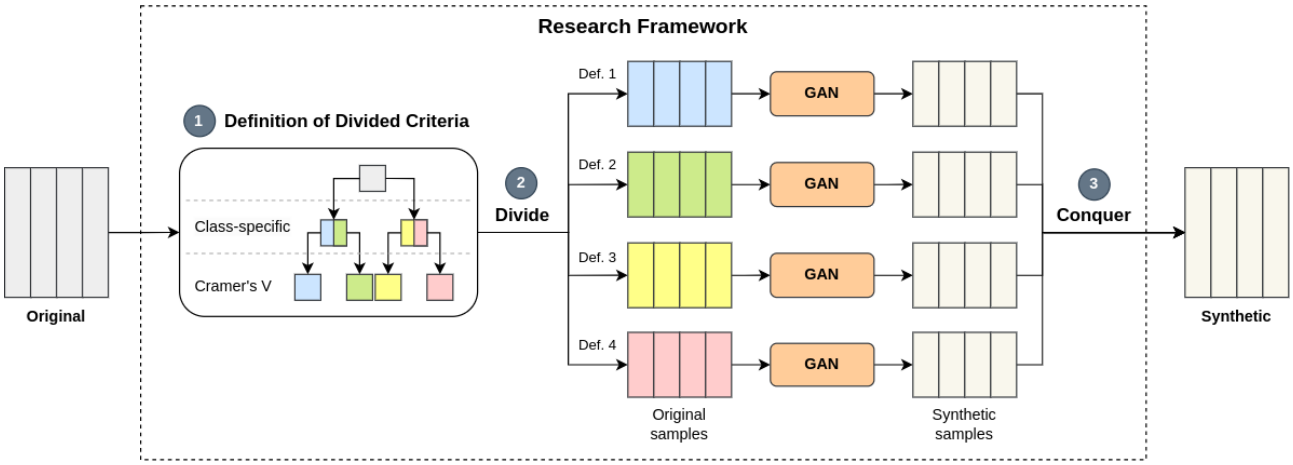
The study design was approved by the Ethics Review Board of the National Cancer Center Institutional Review Board (IRB no: NCC2022-0281).

Research Framework

The DC-based research framework, as depicted in Figure 1, generates STD, while preserving data with logical relationships to enable comparison in terms of data reliability and

investigation of the factors affecting ML model performance. In the division step, the entire data set was divided into several subsets based on the division criteria. In the conquer step, different subsets generated via the GAN were combined into 1. Following STD generation, model performances achieved using classification algorithms, such as the decision tree (DT), the random forest (RF), Extreme Gradient Boosting (XGBoost), and the light gradient-boosting machine (LGBM), in both DC- and CS-based approaches of the CTGAN and CopulaGAN were compared. Moreover, ML model performance on balanced synthetic data and imbalanced synthetic data was also compared.

Figure 1. DC-based research framework using GANs. Def.: definition; GAN: generative adversarial network.



Definition of the Cramer V and Class-Specific Division Criteria

In this study, the division criteria involved 2 main components, class-specific and the Cramer V criteria. The class-specific criterion enabled the selection of different feature subsets for all classes, allowing for subsamples that were tailored to the unique characteristics and behavior of each class. Meanwhile, the high correlation-based criterion identified variables with high correlation scores by computing the Cramer V correlation matrix. The reason for using the Cramer V criterion as the second division criterion was to preserve the logical relationships in the OD in the synthetic data. These variables were then used as the basis for defining logical relationships of data that would guide the division of the data set into subsamples. These 2 criteria provided a robust and effective approach to analyzing the data and identifying meaningful patterns and relationships within them.

Class-Specific Criterion

We used a class-specific division criterion [20], which enabled the selection of different feature subsets for all classes. This yielded a comprehensive list of data set allocation attributes and values by deconstructing the OD set into smaller, more refined subsets. These subsets were subsequently classified based on the dependent classes between different classes, which in turn represented unique sets of class-based criteria. This enabled the selection of a different feature subset for each class. This approach is particularly useful when dealing with data sets comprising classes with unique characteristics and behaviors. The class-specific criterion enables the creation of subsamples tailored to each class, in turn leading to more accurate predictions and better insights.

Cramer V Criterion

We used the Cramer V correlation to identify high correlation patterns in the data set. The Cramer V criterion is a measure of substantive importance used to measure how strongly 2 categorical fields are related to each other. Its value ranges from 0 to 1, where 0 represents no association between the categorical variables and 1 represents complete association in the contingency table. The Cramer V correlation coefficient can be calculated using the formula provided in Equation 1:

where V denotes the Cramer V correlation coefficient, χ^2 denotes the chi-square statistic of the contingency table, N denotes the total number of observations in the contingency table, r denotes the number of rows in the contingency table, and c denotes the number of columns in the contingency table.

The steps in calculating the Cramer V correlation coefficient are as follows:

- Step 1: Calculate χ^2, which is a measure of the association or independence between 2 categorical variables represented in a contingency table and quantifies how much the observed frequencies would deviate from the expected frequencies if the variables were independent. A higher χ^2 value suggests a stronger association between the variables.
- Step 2: Determine the scaling factor, which is necessary to normalize the Cramer V correlation coefficient. The scaling factor is calculated as min(r – 1, c – 1), where (r – 1) and (c – 1) represent the degrees of freedom associated with the rows and columns in the contingency table, respectively. By taking the minimum of (r – 1, c – 1), the formula scales χ^2 appropriately, avoiding overestimation of the association in situations in which one variable has more categories than the other. The purpose of this scaling factor is 2-fold: (1) It ensures that the Cramer V correlation coefficient, which is the final result, falls within the range of 0-1. This range makes the coefficient interpretable and suitable for comparison across different data sets. (2) It normalizes χ^2

by considering the dimensions of the contingency table (number of rows and columns) and the degrees of freedom. This normalization avoids overestimating the strength of the association in situations in which one variable has more categories than the other.
- Step 3: Calculate the Cramer V correlation coefficient. The final result is a value that ranges from 0 to 1, where 0 indicates no association (variables are independent) and 1 represents a perfect association in the contingency table. This coefficient helps interpret and compare the degree of association across different data sets and contingency tables.

We computed the Cramer V correlation matrix for all pairs of categorical variables in the data set. If the variables had a score of 1, it meant that these variables were representative of the characteristic of the OD. These highly related variables should certainly be represented in the synthetic data for fidelity, which is a statistical measure of similarity. In other words, a Crammer V score of 1 was the threshold and variables scoring 1 were used as the division criteria.

Logical STD in Health Care

National clinical databases differ based on the organization, but clinical data sets are valuable resources [17] that provide insights into improving patient care and organizational efficiency. However, the quality and quantity of clinical data can be limited, especially in cases where data privacy concerns restrict access to real-world data sets. SDG has emerged as a promising solution to this problem, enabling organizations to create new data sets that capture the characteristics of real-world data accurately. However, illogical STDs are frequently generated when simply designed GAN models are used, which induces learning of irregular relationships between the main attribute and its subattributes.

Divide-and-Conquer Approach for Logical STD

As mentioned in the previous section, CS can be a useful approach for generating synthetic data. However, it suffers from the risk of information loss owing to the dependence on condition columns. This is particularly pertinent in cases involving a tabular health care data set, because each of its columns contains significant information [21]. To address these issues, we proposed a DC-based alternative approach.

DC is an easily implementable computing approach [22]. It divides an original problem into several subproblems, analyzes them separately, and then combines the results to obtain the overall solution [23]. DC can be used to generate high-quality synthetic data by dividing the OD set into smaller subsets based on a set of predefined division criteria. This facilitates the specification of complex or multidimensional conditions, while simultaneously reducing the risk of information loss. We followed these steps in the DC approach to generate high-quality synthetic data:

- Step 1: To define the division criteria, we used a methodology involving a class-specific criterion and the Cramer V correlation coefficient. This approach enabled the selection of a different feature subset for each class and consideration of the relationships between different variables to determine the degrees of association.
- Step 2: Based on the defined division criteria, we divided the OD into subsets containing each criterion separately as a specific pattern or relationship. Subsequently, these subsets were used to train GANs on specific patterns and relationships. As a result, the generated STD preserved the patterns and relationships of each subset.
- Step 3 (conquer): The synthetic data corresponding to the different subsets were combined. The generated STD preserved the underlying patterns and relationships within each subset of the OD.

This DC-based approach enabled STD that reflected the underlying patterns and relationships within each subset of the OD accurately.

Generation and Verification of STD

Generative Adversarial Networks

In this study, we used 2 generative models, the CTGAN and CopulaGAN, to generate synthetic data:

- The CTGAN is specifically designed for generating synthetic data from tabular data. The CTGAN exhibits several unique features, including the ability to handle discrete and continuous features, the use of conditional generators, and sampling-specific training to avoid mode collapse and data imbalance problems.
- CopulaGAN uses copulas to model the joint distribution of input features. Copulas are statistical models that describe the dependence structures between random variables, and they have been demonstrated to be effective in modeling complex dependencies between features in real-world data sets.

Prediction Methods

In this study, we validated mortality prediction performance using 4 different classifiers: DT, RF, XGBoost, and LGBM. We used these classifiers to train the ML models and evaluated their performances in predicting mortality in our data set. A sufficiently large training data set was generated in the experiment, and the 4 ML algorithms were used to generate mortality prediction models for patients with non–small cell lung cancer (NSCLC).

- The DT [24] is a commonly used tool. Essentially, a DT is a supervised model that classifies or performs predictions on data sets based on rules in the data. To reach a decision, a DT learns by posing binary questions, which can be represented using a tree structure. The data set is divided hierarchically to contain the greatest amount of information, while branching from the root node. The data are split repeatedly until each segmented region contains a single target value.
- The RF [25] was developed by Leo Breiman and Adele Cutler. It is an extension of the bagging method, which combines the output of multiple DTs to yield a single result. In other words, DTs consider all possible feature splits, while RFs only select a subset of these features. Each tree in an RF ensemble consists of a training set with bootstrap samples. One-third of it is set aside as testing data, known as the out-of-bag (OOB) sample. For a regression task,

individual DTs are averaged, and for a classification task, a majority vote is used to obtain the predicted class. Finally, the OOB sample is used for cross-validation.

- XGBoost [26], a scalable tree-boosting system, is used to solve both classification and regression problems and is a popular algorithm because of its good performance and resource efficiency. XGBoost was developed to handle sparse data. It is an innovative tree learning algorithm that handles instance weights in inexact tree learning, which is a justified weighted quantile sketch procedure. XGBoost enables parallel and distributed computing, which accelerates both learning and model exploration. It exploits out-of-core computation, which enables the construction of an end-to-end system.
- The LGBM [27] is a tree-based learning algorithm with a gradient-boosting framework. In an LGBM, the tree expands vertically compared to other algorithms, in which it expands horizontally. In other words, an LGBM uses a leaf-wise structure, while other algorithms use level-wise structures. An LGBM chooses a leaf with the maximum delta loss to expand, enabling the leaf-wise algorithm to reduce greater loss than its level-wise counterparts.

Experimental Setting

Data Set

Study Population

The Korea Association for Lung Cancer Registry (KALC-R) was developed in cooperation with the Korean Central Cancer Registry and the Lung Cancer Registration Committee. Approximately 10% of NSCLC cases listed in this registry were surveyed in this study. The survey population comprised 13 regional cancer centers and 39 hospitals with numerous registrations [28,29]. Our study used a nonduplicate sample comprising data of 5281 subjects obtained from the KALC-R 2014 and 2015 data sets. Entries with missing and unknown values for weight, height, forced vital capacity (FVC), diffusing capacity of the lungs for carbon monoxide (DLCO), the chemotherapy tumor, extent of spread to lymph nodes, and presence of metastasis (TNM) stage (n=1773, 33.6%), and NSCLC (n=1204, 22.8%) were excluded. This study population (N=2304) was then divided into a development group (n=1616, 70.1%) and a validation group (n=688, 29.9%) via stratified random sampling. The development group used GAN learning for STD and model training for short-term prediction models. The validation group evaluated model performance in terms of ML models in accordance with the quality of prediction. The primary endpoint was defined to be 1 year after the diagnosis of NSCLC for all causes of death.

Moreover, we selected 2 well-known publicly available data sets: the breast cancer data set from the University of California, Irvine (UCI) *Machine Learning Repository* [30] and the diabetes data set [31]. The breast cancer data set comprises real patient data obtained from the Institute of Oncology, Ljubljana, in 1988, aimed at predicting the recurrence of breast cancer. The diabetes data set describes the clinical care at 130 US hospitals and integrated delivery networks from 1999 to 2008. The classification task predicts whether a patient will be readmitted within 30 days.

Comparison of Basic Characteristics

We analyzed the fundamental characteristics of the data sets of patients of NSCLC, breast cancer, and diabetes and further compared the following basic characteristics of different groups for NSCLC survival, breast cancer recurrence, and diabetes readmission in the development data:

- NSCLC: The NSCLC data set exhibited similar distributions across various variables, including age, height, weight, FVC, forced expiratory volume in 1 second (FEV1), DLCO, smoking history (pack-years), gender, Eastern Cooperative Oncology Group (ECOG) performance status, pathological type, epidermal growth factor receptor (EGFR) mutation status, anaplastic lymphoma kinase immunohistochemistry (ALK IHC), anaplastic lymphoma kinase fluorescence in situ hybridization (ALK FISH), cancer stage, curative operations, radiotherapy (RT), chemotherapy, and cause of death. The survival group exhibited lower values for age, height, smoking history (past and current), ECOG performance status, specific cancer types (squamous cell carcinoma, large-cell carcinoma), cancer stage, and palliative chemotherapy compared to the death group. Conversely, the survival group had higher values for weight, FVC, FEV1, DLCO, DLCO percentage, nonsmoking status, adenocarcinoma, positive EGFR mutation, positive ALK IHC, positive ALK FISH, curative operations, RT, and curative chemotherapy.
- Breast cancer: The breast cancer data set also showed comparable distributions for variables, such as age, menopausal status, tumor size, invasive/involved (inv) nodes, node caps, malignancy degree, breast location, breast quadrant, irradiation, and recurrence events. The recurrence group had lower values for age, early menopause (at or before age 40 years), tumor size, inv nodes, node caps, lower malignancy degrees (1 and 2), right breast, breast quadrant, and irradiation compared to the nonrecurrence group. In contrast, the recurrence group had higher values for premenopausal status, malignancy degree (3), and left breast.
- Diabetes: In the diabetes data set, basic characteristics revealed similar distributions for variables, such as hospital stay duration, laboratory procedures, medications, outpatient visits, emergency visits, inpatient stays, diagnoses, race, gender, age, medical specialty, glycated hemoglobin (A1C) results, diabetes medications, and readmission events. The readmitted group displayed lower values for the number of procedures, certain demographics (African American and other races, males), age, medical specialty (except others), A1C result (except none), insulin usage, changes in treatment, and certain diagnoses compared to the nonreadmitted group. Conversely, the readmitted group showed higher values for time spent in the hospital, number of lab procedures, number of medications, number of outpatient visits, number of emergency visits, number of inpatient stays, number of diagnoses, Caucasian race, females, other medical specialties, no A1C result, and diabetes medication (metformin, glipizide, glyburide) usage.

A detailed comparison of the characteristics of different data sets is presented in Multimedia Appendix 1.

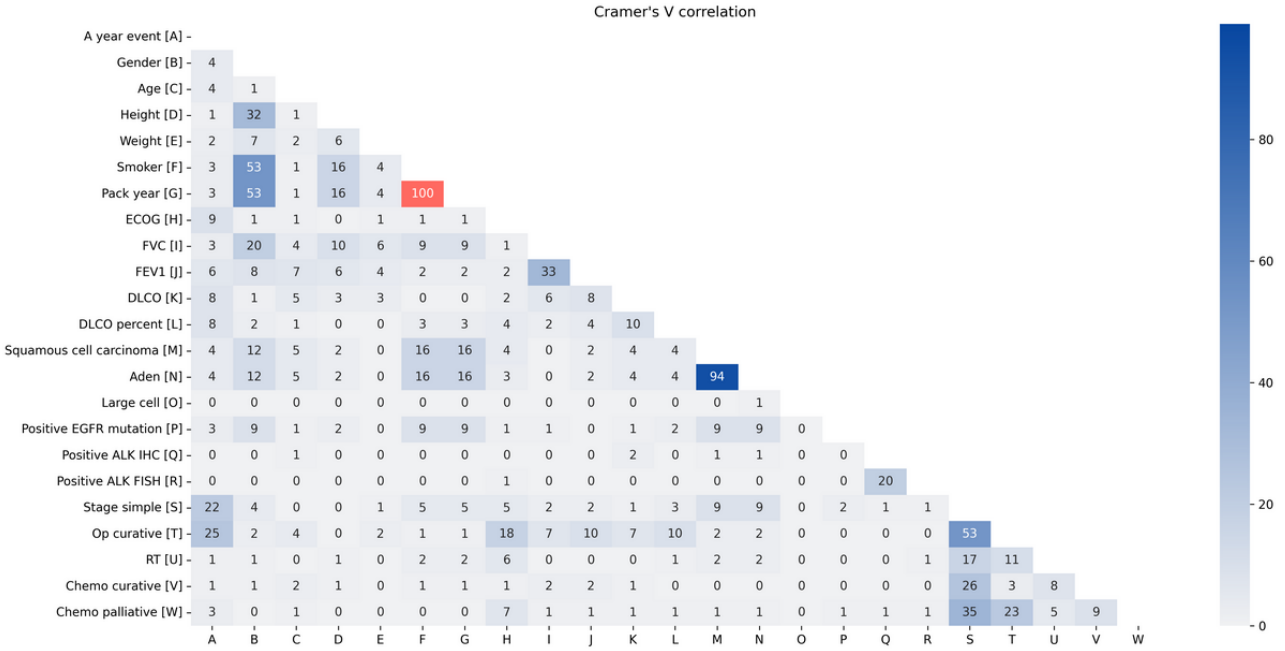
Data Split

Division Criteria Analysis

First, we used class-specific division on the "adverse event" feature, which represents dependent classes, and divided the data into death and survival groups. Next, the Cramer V correlation coefficient was applied after converting all variables into the categorical format. The highest correlation score (V=1, highlighted in red in Figure 2) in NSCLC data was observed between smoking status and pack-years of smoking. This indicates a strong association between these 2 variables, suggesting that individuals who smoke more frequently are more likely to be current or former smokers. Therefore, the "smoker" feature was identified as a key division criterion in our data set. Following the definition, we created a subsample consisting of only those patients in the data set who were smokers and had a pack-year of more than 0. In conclusion, the data were divided into distinct smoker and nonsmoker groups. In other data sets, we did not find a high correlation score, as seen in Multimedia Appendix 2.

By applying the aforementioned division criteria, we obtained 4 small samples from the data set: death-smoker, death-nonsmoker, survival-smoker, and survival-nonsmoker. These samples were used for further performance validation and fidelity tests. Finally, our data set was successfully partitioned for the purposes of our study.

Figure 2. Cramer V correlation coefficient of lung cancer data. Aden: adenocarcinoma; ALK FISH: anaplastic lymphoma kinase fluorescence in situ hybridization; ALK IHC: anaplastic lymphoma kinase immunohistochemistry; chemo curative: curative chemotherapy; chemo palliative; palliative chemotherapy; DLCO: diffusing capacity of the lungs for carbon monoxide; ECOG: Eastern Cooperative Oncology Group; EGFR: epidermal growth factor receptor; FEV1: forced expiratory volume in 1 second; FVC: forced vital capacity; OP curative: curative operations; RT: radiotherapy.



Metrics

Performance Evaluation Metrics

The ability of the synthetic data to achieve good predictive performance in downstream modeling tasks was evaluated using metrics, such as the area under the curve (AUC) and the F_1-score. This is important as the generated synthetic data must be useful for predictive modeling for it to lead to actionable insights.

The AUC is a performance metric that measures the ability of a binary classifier to distinguish between positive and negative classes. It is calculated as the area under the receiver operating characteristic (ROC) [32] curve. ROC curves are graphical representations of the relationship between the false-positive rate (FPR) and the true-positive rate (TPR), plotted along the x and y axes, respectively. The AUC ranges from 0 to 1, where 1 represents perfect classification performance and 0.5 indicates perfectly random performance. The formula for the AUC is given by Equation 2:

The F_1-score is a measure of the balance between precision and recall, where precision is defined as the fraction of true positives among all predicted positives and recall is defined as the fraction of true positives among all actual positives. The F_1-score ranges from 0 to 1, where 1 represents perfect precision and recall and 0 represents the worst-possible scores. The formula for the F1-score is given by Equation 3:

Quality Evaluation Metrics

Shape and pair trend metrics [33] are commonly used to evaluate the fidelity of STD, that is, their similarity to the distribution of real-world data. Shape refers to the overall distributional shape of a data set, including factors such as the degree of skewness or kurtosis. Pair trend, in contrast, refers to the relationship between pairs of features in the data set. Although shape analysis focuses on individual features of a data set, pair

trend analysis provides information about the overall structure and relationships between features. To evaluate the distribution shapes of numerical columns, we used the Kolmogorov-Smirnov statistic (KSS), which is defined as the maximum difference between the cumulative distribution functions (CDFs). CDFs determine the probability that a random observation taken from the population will be less than or equal to a certain value. Conversely, for categorical columns, we used the total variation distance (TVD). The formulas for KSS and TVD scores are given by Equations 4 and 5, respectively, where x represents a single column. Similarly, pair trend metrics were considered to consist of 2 measures, correlation similarity and contingency similarity, for numerical and categorical columns, respectively. Equations 6 and 7 present the formulas for correlation and contingency similarity scores, respectively, where x and y together denote a pair of columns.

By computing separate scores for each column and pair of columns, an individual score was obtained for every column. The final score (value between 0 and 1, with a higher score representing higher quality) was obtained by averaging individual scores. These statistical metrics assessed the similarity or dissimilarity between the distributions of samples in the OD and STD. They provided quantitative measures for evaluating how closely the data sets matched in terms of distribution shapes, relationships between variables, and contingency structures. The final aggregated score represented the overall quality or fidelity of the OD compared to the STD. All 4 measures used for evaluating the fidelity of the OD compared to the STD are summarized in Table 1.

Table 1. Comparison of measures for evaluating fidelity between the OD[a] and the STD[b].

Measure	Purpose	Application	Computation	Interpretation
KSS[c]	Measures the similarity and dissimilarity of distribution shapes between OD and STD	Numerical	Calculates the maximum difference between the CDFs[d] of OD and STD	A higher score indicates greater dissimilarity in distribution shapes, with 0 representing identical distributions.
TVD[e]	Quantifies the difference between probability distributions of categorical data in OD and STD	Categorical	Measures the "closeness" between probability mass functions of OD and STD distributions	A score of 0 implies identical distributions, while higher scores indicate increasing dissimilarity.
Correlation	Evaluates the similarity or dissimilarity of relationships between pairs of numerical variables between OD and STD	Numerical	Measures the absolute squared difference between correlation coefficients of OD and STD pairs	A score of 0 indicates perfect similarity in relationships, while higher scores suggest weaker similarity or even dissimilarity.
Contingency	Assesses the similarity of relationships between pairs of categorical variables in OD and STD	Categorical	Calculates the sum of absolute differences between corresponding cells in contingency tables (cross-tabulations) of OD and STD	A score of 0 signifies perfect similarity in contingency structures, while higher scores indicate less similarity.

[a]OD: original data.

[b]STD: synthetic tabular data.

[c]KSS: Kolmogorov-Smirnov statistic.

[d]CDF: cumulative distribution function.

[e]TVD: total variation distance.

Results

Generation and Validation of STD

To generate logical STD, we trained the CTGAN and CopulaGAN using existing CS filtering. Next, we used the proposed DC-based method before training the CTGAN and CopulaGAN without CS filtering. The volume of the generated data set was set to 5000. Moreover, we generated 2 types of STDs, a balanced data set with equal class distributions between samples in a 50:50 ratio and an imbalanced data set with a 1:100 class distribution ratio between samples (ie, each dependent variable occurred 100 times less frequently than its counterpart).

To verify the superiority of the proposed DC-based method in the generation of logical STD, we evaluated each STD item using 4 different ML models (DT, RF, XGBoost, and LGBM). Table 2 presents the validation results of the DT classifier. The AUC and F_1-score values of the NSCLC, breast cancer, and diabetes OD were 66.06% and 66.11%, 61.14% and 49.64%, and 65.58% and 47.82%, respectively. The highest AUC of 74.87% was achieved by generating synthetic data using the DC strategy with the CopulaGAN, while the highest F_1-score of 71.99% was achieved using the DC strategy with the CTGAN for NSCLC data. The highest AUC of 73.31% was achieved by generating synthetic data using the DC strategy with the CTGAN, while the highest F_1-score of 68.92% was achieved using the DC strategy with the CopulaGAN for breast cancer data. The highest AUC of 61.57% was achieved by generating synthetic data using the DC strategy with the CTGAN, while the highest F_1-score of 53.8% was achieved using the DC strategy with the CopulaGAN for diabetes data.

The validation results obtained using the RF classifier are presented in Table 3. The AUC and F_1-score values of the NSCLC, breast cancer, and diabetes OD were 84.81% and 72.74%, 69.37% and 60.01%, and 62.13% and 47.73%, respectively. The highest AUC and F_1-score of 85.61% and 75.09%, respectively, were achieved by generating synthetic

data using the DC strategy with the CTGAN for NSCLC data. The highest AUC and F_1-score of 78.05% and 71.03%, respectively, were achieved by generating synthetic data using the DC strategy with the CTGAN for breast cancer data. The highest AUC and F_1-score of 59.98% and 53.47%, respectively, were achieved by generating synthetic data using the DC strategy with the CTGAN for diabetes data.

Table 4 presents the validation results obtained using the XGBoost classifier. The AUC and F_1-score values of the NSCLC, breast cancer, and diabetes OD were 83.07% and 71.14%, 71.21% and 62.89%, and 67.02% and 48.91%, respectively. The highest AUC and F_1-score of 85.20% and 74.78%, respectively, were achieved by generating synthetic data using the DC strategy with the CTGAN for NSCLC data. The highest AUC and F_1-score of 77.86% and 70.58%, respectively, were achieved by generating synthetic data using the DC strategy with the CTGAN for breast cancer data. The highest AUC and F_1-score of 60.18% and 53.93%, respectively, were achieved by generating synthetic data using the DC strategy with the CTGAN for diabetes data.

Finally, Table 5 presents the validation results obtained using the LGBM classifier. The AUC and F_1-score values of the NSCLC, breast cancer, and diabetes OD were 84.09% and 71.30%, 75.84% and 62.07%, and 67.88% and 47.89%, respectively. The highest AUC and F_1-score of 85.14% and 74.40%, respectively, were achieved by generating synthetic data using the DC strategy with the CTGAN for NSCLC data. The highest AUC and F_1-score of 77.86% and 70.58%, respectively, were achieved by generating synthetic data using the DC strategy with the CTGAN for breast cancer data. The highest AUC and F_1-score of 60.18% and 53.93%, respectively, were achieved by generating synthetic data using the DC strategy with the CTGAN for diabetes data.

In general, the results demonstrate that STD generated using the DC approach had the best quality in terms of the AUC and F_1-score. Moreover, higher performance was observed when STD were generated solely using the DC approach compared to STD obtained using the original training data. Moreover, balanced data sets consistently exhibited better performance than imbalanced ones.

In addition, we assessed the quality of the generated STD by evaluating their fidelity with respect to shape and pair trend metrics. The results are presented in Tables 6-8. The DC strategy with the CTGAN achieved the highest mean shape score of 90.49 (SD 0.07), 91.71 (SD 0.12), and 98.60 (SD 0.13), the highest mean pair trend score of 83.92 (SD 0.10), 82.72 (SD 0.13), and 96.70 (SD 0.26), and the highest mean overall score of 87.20 (SD 0.08), 87.21 (SD 0.09), and 97.65 (SD 0.27) on the NSCLC, breast cancer, and diabetes data sets, respectively. These findings suggest that the DC strategy with the CTGAN could be a promising approach for generating synthetic data with high fidelity. Moreover, we carried out a number of visualization experiments comparing the OD and the STD, as shown in Multimedia Appendix 3.

Discussion

Principal Findings

Preserving data with logical relationships while generating STD using GANs has not been sufficiently researched. Some GANs, such as the CTGAN and CopulaGAN, use CS filtering to determine the exclusion of record data based on predefined condition columns after generating STD. However, this is highly dependent on condition columns, which may lead to meaningful information in the excluded records being ignored. To resolve this problem, we proposed a DC-based approach in this paper, as shown in Multimedia Appendix 4.

The proposed DC-based approach was verified to produce STD involving logical relationships between columns. As the division strategy, we used class-specific and the Cramer V criteria sequentially. First, we used a class-specific criterion to classify dependent classes between survival and death groups. Subsequently, we measured the relative degrees of association among pairs of variables based on the Cramer V correlation coefficient in order to identify strong evidence for meaningful correlations between columns. In terms of a high Cramer V correlation coefficient (=1), smoker and nonsmoker groups were selected as division criteria. Using this, the OD was divided into smaller data sets comprising hierarchical group data that considered class-specific aspects of learning. Further, the division criteria of the DC strategy avoided the problem of ignoring some records owing to overreliance on condition columns.

To compare the logical STD generation approaches, we trained the CTGAN and CopulaGAN with CS filtering and compared their performances with those of ML models trained using a DC approach without CS filtering. The results demonstrated that the epochs hyperparameter was sensitive, with a significant impact on the quality of synthetic data generated using the CTGAN and CopulaGAN. Specifically, the results depended considerably on the value of the epochs hyperparameter, ranging from 100 to 500. We used a grid search algorithm to identify an optimal value for the epochs hyperparameter, as shown in Multimedia Appendix 5. Regularization hyperparameters, such as grid search, are essential to the generalization of ML models [34]. They work well with low-dimensional hyperparameter spaces and ample computational resources [35]. A grid search involves testing a range of hyperparameter values and evaluating the performance of the model corresponding to each value. In our case, we tested epoch values of 100, 200, 300, 400, and 500 and evaluated the resulting synthetic data using a variety of metrics, including distributional similarity, feature correlation, and downstream performance in predictive models. Our findings highlight the importance of carefully selecting hyperparameters during GAN training to generate synthetic data from clinical data sets. The sensitivity of the epochs hyperparameter underscores the necessity of systematic approaches, such as grid search, to identify optimal values.

Generally, ML training on imbalanced data sets leads to failure to properly learn the distributive characteristics of the data and, consequently, unfavorable accuracies across the data classes [36]. We generated balanced and imbalanced STD by regulating the volumes of the dependence variables for comparison. These data were used to develop ML models (DT, RF, XGBoost, and LGBM), and their AUC and F_1-score were measured on the verification data set. The hyperparameter of each model was tuned via a grid search for the number of epochs. All balanced synthetic data exhibited higher performance on the prediction models (DT, RF, XGBoost, and LGBM) compared to imbalanced synthetic data. Therefore, we recommend that the volume of balanced dependence variables be considered during SDG using GANs.

Finally, the DC-based approach was observed to exhibit several potential advantages over CS. First, deconstruction of the division criteria into simpler subrules enables the specification of complex or multidimensional conditions. Second, training the GAN on each subrule independently reduces the risk of information loss by CS, as the GAN can focus on generating synthetic data that accurately reflect the distribution of the data for each subrule. Finally, combining the results of the subrules enables the generation of synthetic data that satisfy all the

original logical rules, without requiring complex and potentially overspecified conditions.

Thus, the main contribution of this paper is to demonstrate the viability of the proposed STD generation method to serve as a revolutionary new alternative to existing counterparts in the development of ML-based prediction models.

Limitations

Our study is limited in terms of the low dimensionality and count of data collected from a single country. In practical health care, low-dimensional and sparse data are often derived from strict data preprocessing, a detailed design for the target population, or exact primary endpoints. In this paper, data containing essential variables were collected from 13 regional cancer centers and 39 hospitals via sampling. However, patients with NSCLC from only a single country were considered, potentially introducing racial bias. We intend to overcome this limitation in future works by applying the proposed framework to data collected from other countries.

The DC-based STD learning strategy may be difficult to apply in the case of sparse data and multiple division criteria. Indiscriminate use of the strategy, even in the presence of a large amount of data, can be problematic because the use of multiple division strategies induces a lack of learning data, which motivates the generation of inappropriate synthetic data. Therefore, it is important to establish appropriate criteria for the division strategy (eg, the class-specific and Cramer V criteria proposed in our study). We recommend that the class-specific criterion be used as an essential strategy in the first division criteria. The Cramer V criterion should be used to calculate correlations between variables, enabling sufficient discussion about the group of candidates for division and helping decide the need for division.

One potential challenge with the DC approach is that the subrules and the combinations of results require careful consideration. If the subrules are not well defined or the combinations of results are not appropriate, the resulting synthetic data may not accurately reflect the characteristics of real-world data. Additionally, if data with logical relationships are highly interdependent, it may be challenging to break them down into independent subrules. Despite these potential challenges, the DC approach exhibited great promise in generating synthetic data from data with logical relationships on clinical data sets.

Conclusion

Our study demonstrated problems of CS-based STD generation techniques and the feasibility of DC-based STD generation to address those problems. Further, the effectiveness of the generated STD to enable the application of ML models was verified, revealing that they improve prediction performance.

Acknowledgments

This study was supported by a grant (no: 2310440-1) offered by the National Cancer Center of Korea, Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (no: NRF-2022R1F1A1075041), and the Korea Health Technology R&D Project through the Korea Health Industry Development Institute, funded by the Ministry of Health & Welfare, Republic of Korea (no: HI21C0974).

Data Availability

Anyone can use the original data after registering as a member on the Korea Central Cancer Registry (KCCR) portal [37] and passing through the data application and review. Users need to fill out an application form, including a research proposal describing how they will use the data and that the data access request will be accessed by the KCCR and the National Statistics Office. All synthetic data can be shared for research purposes by contacting the authors.

All code for data generation and validation associated with the current submission is available in a GitHub repository [38].

Abstract

Background: There is a variety of libre/free and open-source software (LIFOSS) products for medicine and health care. To support health care and IT professionals select an appropriate software product for given tasks, several comparison studies and web platforms, such as Medfloss.org, are available. However, due to the lack of a uniform terminology for health informatics, ambiguous or imprecise terms are used to describe the functionalities of LIFOSS. This makes comparisons of LIFOSS difficult and may lead to inappropriate software selection decisions. Using Linked Open Data (LOD) promises to address these challenges.

Objective: We describe LIFOSS systematically with the help of the underlying Health Information Technology Ontology (HITO). We publish HITO and HITO-based software product descriptions using LOD to obtain the following benefits: (1) linking and reusing existing terminologies and (2) using Semantic Web tools for viewing and querying the LIFOSS data on the World Wide Web.

Methods: HITO was incrementally developed and implemented. First, classes for the description of software products in health IT evaluation studies were identified. Second, requirements for describing LIFOSS were elicited by interviewing domain experts. Third, to describe domain-specific functionalities of software products, existing catalogues of features and enterprise functions were analyzed and integrated into the HITO knowledge base. As a proof of concept, HITO was used to describe 25 LIFOSS products.

Results: HITO provides a defined set of classes and their relationships to describe LIFOSS in medicine and health care. With the help of linked or integrated catalogues for languages, programming languages, licenses, features, and enterprise functions, the functionalities of LIFOSS can be precisely described and compared. We publish HITO and the LIFOSS descriptions as LOD; they can be queried and viewed using different Semantic Web tools, such as Resource Description Framework (RDF) browsers, SPARQL Protocol and RDF Query Language (SPARQL) queries, and faceted searches. The advantages of providing HITO as LOD are demonstrated by practical examples.

Conclusions: HITO is a building block to achieving unambiguous communication among health IT professionals and researchers. Providing LIFOSS product information as LOD enables barrier-free and easy access to data that are often hidden in user manuals of software products or are not available at all. Efforts to establish a unique terminology of medical and health informatics should be further supported and continued.

health informatics; ontology; free/libre open-source software; software applications; health IT; terminology

Introduction

Background

Libre/free and open-source software (LIFOSS) products are increasingly used to support various tasks in health care. LIFOSS generally refers to software products with openly available source code that users and developers can view, analyze, modify, and redistribute.

For example, there are free and open-source software products to implement radiology information systems, picture archiving and communication systems (PACS), patient administration systems, and electronic health record (EHR) systems. Especially in low-resource settings, using LIFOSS can help establish computer-based health information systems [1-3]. Along with their use in hospital and medical practice settings, LIFOSS products are available for mobile health, telemedicine, and public health (eg, [4,5]). Moreover, the COVID-19 pandemic has led to the development of numerous mobile applications for contact tracing, risk assessment, or appointment scheduling, which are often based on LIFOSS and used both in low-resource settings and industrial countries [6,7]. Since 2010, the Medfloss.org database has provided descriptions of LIFOSS used in health care and medicine [8]. As of October 2022, it lists 385 software products and describes them by characteristics like "license," "application type," "enterprise function," "language," "platform," and "home page." Due to the iterative and sometimes uncontrolled growth of the self-developed nomenclature over the last few years, there are several inconsistencies in the software descriptions on Medfloss.org. First, there are misleading assignments of descriptors to characteristics. For example, "laboratory," "cellular networks," and "virtual reality" are listed as enterprise functions supported by a software product. However, they describe the setting where the software might be used or special features of the software. Second, the lack of uniform terminology in health informatics has led to the use of synonyms or overlapping terms. For example, the borders between "electronic health systems," "electronic medical record systems," and "hospital management systems" are not clearly defined, sometimes leading to ambiguous descriptions of software products. The lack of uniform terminology for describing medical and health care software products and LIFOSS is also apparent when analyzing comparisons of LIFOSS for EHR systems. In several studies published during the last 15 years [1-3,9-11], each research group selected different criteria and descriptors for comparing the technical and functional characteristics of EHR systems.

Indeed, the lack of uniform terminology is not restricted to LIFOSS. There are already several terminologies in health care and health informatics that could potentially be used to describe software. For example, in addition to allowing for precise descriptions of disease patterns, SNOMED (Systematized Nomenclature of Medicine) lists health occupations and environments that may describe the health facilities or settings in which LIFOSS is used. The World Health Organization (WHO) classifies digital health interventions by hierarchies or lists of clients, health care providers, health system managers, data service features, and application system categories [12]. The Health Level 7 (HL7) EHR System Functional Model is a comprehensive catalogue of EHR systems' features [13]. Finally, some health informatics textbooks provide systematic collections of application systems in health care and their typical features (eg, [14]). However, at first sight, these different terminologies are not easily comparable with each other due to the use of synonyms or homonyms. Linking these different terminologies requires semantic analyses based on a uniform set of concepts, along with easy-to-use methods and tools to link these data.

Linked Open Data (LOD) are regarded as the state-of-the-art principle for linking and structuring concepts from different terminologies. LOD are identifiable by a URI and provided using the Resource Description Framework (RDF) standard [15].

Benefits of Unified LIFOSS Terminology Using LOD

A unified LIFOSS terminology using LOD has several advantages. First, the use of predefined and open terminologies supports the search for and comparison of software products. Second, further knowledge, such as results of assessment and evaluation studies, can be linked easily to the software descriptions and thus support evidence-based health informatics. For example, linking systematic descriptions of software products with descriptors from other projects can support ontology-based approaches to software requirements engineering [16].

The Austrian-German research project "Health Information Technology Ontology (HITO)" aims to systematically describe software products and their installations in health care. It uses an underlying ontology named HITO, LOD methods and tools, and freely available catalogues to describe software characteristics. HITO is developed based on different use cases in which precise software descriptions are needed, such as when selecting LIFOSS or commercial software products, searching for evidence about the installation of software products, and communicating about software products among stakeholders in health care. In this paper, we focus on LIFOSS products and describe them with the help of openly available catalogues. Especially for LIFOSS products, information about software characteristics is freely available, and LIFOSS developers are likely to recognize the potential advantage of spreading knowledge about their products with the help of LOD.

Objectives

This study aims to (1) describe LIFOSS systematically with the help of precise descriptors that are captured in HITO and (2) publish HITO and HITO-based software product descriptions as LOD using Semantic Web tools for viewing and querying LIFOSS data on the World Wide Web.

Methods

Requirements Elicitation

Initial Steps

As the first step toward precise descriptions of software products, the classes and relationships that are useful to describe software products had to be identified. HITO was developed and refined iteratively by collecting requirements of several use

cases. Each use case focused on a situation in which a clear terminology for software products was considered essential. These use cases dealt with the description of LIFOSS or commercial software products for potential and current users in health care settings or the description of software product installations in evaluation studies on health IT interventions. We selected diverse use cases to identify the most relevant characteristics for these diverse situations. Based on these use cases, we incrementally built the ontology that contains a general pattern for describing software products in health care.

Use Case 1: Evaluation of Digital Health Interventions

The first HITO use case dealt with evaluation studies in health informatics. In evaluation studies, it is crucial to carefully describe the intervention in a reproducible and clear manner to allow generalizability of the findings and their aggregation, for example, in the form of systematic reviews. We used an inductive approach and extracted software descriptions from 24 randomly selected published health IT evaluation studies [17]. We found that software product installations were mainly described by their features, application system type, organizational units where they are used, and user groups. These characteristics were specified as classes and added to HITO (Table 1). Altogether, the software descriptions found in evaluation studies are sparse and concentrate on selected evaluated features. Evaluation studies also often use inconsistent terms, which motivated us to develop a clear terminology for software products.

Table 1. HITO[a] classes to describe software products in health IT evaluation studies (HITO use case 1).

HITO class (characteristic of software products)	Description and examples
Software product	Piece of software that is sold as a commercial product or distributed under an open-source license
Feature	Functionalities offered by a software product that directly contribute to the fulfillment of 1 or more enterprise functions (eg, email notification of new results, user directory to control any access)
Application system type	Commonly used names for categories of software product installations in health care (eg, radiology information system, CPOE[b] system)
Organizational unit	Health care setting in which the software product is used and an evaluation study was conducted (eg, laboratory, department of pediatrics)
User group	Health care staff who uses the software product installation (eg, nurse, radiologist)

[a]HITO: Health Information Technology Ontology.

[b]CPOE: computerized physician order entry.

Use Case 2: Description of LIFOSS With Medfloss.org Project Database

In the LIFOSS use case, we extended the list of HITO classes by carefully analyzing the Medfloss.org project database. Medfloss.org aims to offer an overview of LIFOSS projects related to medical informatics and health care [8]. Although Medfloss.org is not maintained anymore, it is still provided in cooperation with 3 LIFOSS-related working groups of the International Medical Informatics Association, the European Federation for Medical Informatics Association, and the International Society for Telemedicine and eHealth. Within Medfloss.org, the LIFOSS products are described by using a predefined set of categories.

We started this use case by surveying 2 operators of the Medfloss.org database. They were asked independently to answer a survey with 11 open questions and 1 closed question. The survey asked about the users of Medfloss.org, the relevance of the categories used to describe software products, and the positive and negative experiences with the categories used to describe LIFOSS.

The results of this survey show that Medfloss.org is intended to be used by physicians or other health care staff, IT administrators, information managers, and software developers to select appropriate LIFOSS for certain health care tasks. Each LIFOSS product is described by 11 categories, such as “enterprise function,” “application type,” and “license,” on the platform. For each category, the list of descriptors has grown over the years as new LIFOSS descriptions were added.

The answers of the platform operators dealing with the assessment of the current terminology and its representation on the platform were arranged according to a SWOT (Strengths, Weaknesses, Opportunities, and Threats) analysis (Textbox 1).

Both operators rated the “enterprise function,” “application type,” “status,” “license,” “standard,” “language,” “client type,” and “platform” categories of Medfloss.org terminology as “important” or “very important” for the description of LIFOSS. The categories “popularity,” “database,” and “programming language/toolkit” were rated less important by 1 of the website operators.

The strengths of the Medfloss.org terminology used include the rough categorization of software products by application system types and the faceted search on the website that is based on categories for describing the software. However, the survey showed that the categories currently lack the possibility to describe the functionalities and application types with enough precision. Therefore, an opportunity to support Medfloss.org terminology may be to integrate existing terminologies such as WHO’s classification of digital health interventions [12] or the HL7 EHR System Functional Model [13]. Furthermore, the folksonomy (ie, the collection of users’ tags for certain objects) of the platform users is not handled by the search functions on Medfloss.org [18].

Based on the SWOT analysis, we selected 9 (out of 10) of the Medfloss.org categories and added these to HITO (Table 2). Some classes used on Medfloss.org were renamed, such as "standard," which was changed to "interoperability standard" to sum up interoperability standards, as well as frameworks describing how to use interoperability standards, such as Integrating the Healthcare Enterprise (IHE). A more fine-grained classification according to interoperability levels was examined for common interoperability standards but proved to be impractical. Many interoperability standards such as HL7 Fast Healthcare Interoperability Services (FHIR) can be assigned to multiple interoperability levels. The Medfloss.org category "programming language/toolkit" was split into 2 classes to distinguish between these different concepts.

Textbox 1. SWOT (Strengths, Weaknesses, Opportunities, and Threats) analysis for Medfloss.org.

Strengths

- Current set of categories to describe libre/free and open-source software
- Rough categorization by application system types
- Usefulness of the categories to provide a faceted search on the platform

Weaknesses

- Conceptual overlaps in categories (eg, electronic health record and electronic medical record)
- Missing hierarchies for enterprise functions
- Missing detailed functional descriptions

Opportunities

- Enhancements of categories by existing terminologies seems possible
- Modeling of user group–dependent categories may increase usefulness

Threats

- No handling of synonyms within users' search terms

Table 2. HITO[a] to describe LIFOSS[b] products (HITO use case 2).

Medfloss.org class name	HITO class	Description and examples
Client type	Client	The client type on which a software product can be run (mobile, native, or web).
Database	Database management system	Some examples are PostgreSQL[c] or MySQL.
Enterprise function	Enterprise function	Describes what action humans or machines must carry out in a certain enterprise to contribute to its mission or goals (eg, patient admission, order entry).
Home page	Home page	Home page of the software product or its development project.
Standard	Interoperability standard	Ability of 2 or more components to exchange information and to use the information that has been exchanged. Under this class name, interoperability standards (eg, HL7[d] FHIR[e] or DICOM[f]) or frameworks describing how to use standards (eg, IHE[g]) are summed up.
Language	Language	Languages in which the software product is available (eg, English, French, and German).
License	License	The license under which a software product is distributed.
Platform	Operating system	The operating system a software uses (eg, Windows). A software product might be able to run on a variety of operating systems.
Programming language/toolkit	Programming language	The programming language used to develop a software product (eg, Java or Python).
Programming language/toolkit	Programming library or toolkit	Programming toolkits are utility programs that are used to develop and maintain software. Programming libraries are a collection of prewritten functions that are ready to be used in coding. Both help programmers develop software in a fast and safe manner.

[c]SQL: Structured Query Language.

[d]HL7: Health Level 7.

[e]FHIR: Fast Healthcare Interoperability Resources.

[f]DICOM: Digital Imaging and Communications in Medicine.

[g]IHE: Integrating the Healthcare Enterprise.

Further HITO Use Cases

We summarized 3 further use cases that have not elicited new HITO classes related to software product characteristics.

The third use case deals with the description of commercial software products used in health care. This use case confirmed the set of HITO classes that we already identified by describing LIFOSS products. However, for commercial software products, it is quite challenging to describe them based on these classes because meaningful descriptions of commercial software products are rarely publicly available.

In the fourth use case, the existing HITO classes were linked with competency levels for IT staff in health care organizations, which might be useful for creating job advertisements.

In the fifth use case, findings from the HITO project were discussed with practitioners like hospital chief information officers and industry representatives to discuss the applicability and broader use of the HITO project's findings in practice.

Software Product Descriptions as LOD

After building HITO from the described use cases, we published HITO and HITO-based software product descriptions using LOD.

LOD are web data with an open license. They allow the use of Semantic Web tools for viewing and querying LIFOSS data on the World Wide Web. LOD also allow for linking and reusing existing terminologies. To be considered "5-star LOD," the data need to be machine-readable, presented in a nonproprietary format, use open standards of the World Wide Web Consortium (W3C), and be linked to other data [15]. We strived to achieve 5-star linked open HITO data.

Accordingly, we used RDF Schema (RDFS) and the Web Ontology Language (OWL). RDFS and OWL are W3C standards used to define the types of elements of discourse as classes. The *class* "software product," for example, represents the set of all individual software products. *Properties* represent possible binary-typed relationships between individuals of certain classes, for example, between software products and features. Using RDF, facts (relationships between individuals) are expressed as subject-predicate-object triples, whose elements may be defined and stored in different places. This allows for reusing existing vocabularies and interlinking with existing knowledge bases, forming the LOD cloud. Each RDF resource (a class, an individual, or a relationship) has a URL where it is published both in human-readable (ie, HTML) format and in machine-processable RDF serialization format. To browse RDF data comfortably, tools like RickView [19] can be used and modified. SPARQL Protocol and RDF Query Language

(SPARQL) end points allow free access to structured read-only queries for humans and as application programming interfaces (APIs) for several tools.

Integration of Software Product and Health-Related Terminologies

One advantage of LOD is their easy integration of existing data sources that are already available in RDF format. Therefore, for the HITO classes (Tables 1 and 2) that characterize software products, we searched for "catalogues" (ie, lists of terms that can be used as instances for the respective class). For the selection of suitable catalogues, we defined the following criteria:

[The catalogue should be authored by an established scientific or standardization organization.] OR [The catalogue must be scientifically plausible with regard to reproducibility, having undergone peer-review or having been developed by more than 5 persons.] OR [The catalogue must be openly available and developed by a large community.]

We used a broad literature and web search and our knowledge of the field to identify related taxonomies and catalogues that can be useful for describing instances of HITO classes (Table 2). In the following paragraphs, we provide a brief overview of the catalogues we investigated.

We started with DBpedia, a popular and large knowledge base comprising billions of triples extracted from Wikipedia, texts, and other sources [20,21]. We analyzed DBpedia to identify possible instances or subclasses for the HITO classes. For the classes "language," "operating system," and "programming language," we found DBpedia classes with suitable instances that we replaced the associated HITO classes with to increase interoperability. Other instances of DBpedia classes, such as the "license" class, were not suitable for integration because DBpedia does not semantically differentiate between licenses for software products and licenses for other purposes, like drivers' licenses. For software product licenses, we integrated subclasses of the class "open-source software license" derived from the Software Ontology for biomedical software [22].

The most challenging task was the integration of catalogues for the classes "application system type," "enterprise function," "feature," "organizational unit," and "user group," for which we needed instances or subclasses related to health care. We checked the following sources for the integration of catalogues into HITO:

- HL7 EHR System Functional Model [13]: Using the examples of 2 installations of commercial software products for EHR systems, we assessed whether the features of the software product could be described by this model. We found that the whole list of conformance criteria defined in this model would be too detailed for a HITO catalogue. However, the section labels that are provided by this model, such as "manage allergy, intolerance, and adverse reaction list," provide an appropriate level of detail for feature descriptions in HITO.
- The textbook by Winter et al [14] describes a set of application system types and a set of enterprise functions in hospitals. An analysis of Medfloss.org revealed that the sets of enterprise functions or application system types could be used to tag 71% and 42%, respectively, of 356 Medfloss.org software products analyzed in use case 2 [23]. Due to the textbook's focus on hospitals, appropriate terms for software products used in other health institutions or for public health were missing.
- Taxonomy for health IT by Varshney et al [24]: The application system types identified by Varshney and colleagues proved to be too coarse-grained for classification. Only 105 (29%) of 356 Medfloss.org software product entries could be classified by the taxonomy [23].
- WHO classification of digital health interventions [12]: This multiaxial classification lists system categories and interventions for clients, health care providers, health system managers, and data services. The 25 system categories correspond to application system types in HITO, and their strength lies in their focus on application systems for health care networks rather than for single institutions. For the hierarchically grouped interventions such as "2.10 laboratory and diagnostics imaging management" and "2.10.1 transmit diagnostic result to healthcare provider," a more differentiated assignment to functions and features in the context of HITO is needed. Therefore, "2.10 laboratory and diagnostics imaging management" is listed as an enterprise function in HITO, whereas "2.10.1 transmit diagnostic result to healthcare provider" is listed as a feature in HITO.
- SNOMED Clinical Terms (CT) [25]: For the 24 evaluation studies analyzed in use case 1, we found that the software products' user groups or the organizational units where the software products are used can sufficiently be described by subclasses of SNOMED CT's "occupation" or "environment" classes, respectively.
- Features for PACS selection [26]: The PACS features described on 3 hierarchy levels were transformed into a flat list of 38 features useful for describing examples of PACS software products.
- The LIS (laboratory information system) Functionality Assessment Toolkit of the Association for Pathology Informatics [27]: This toolkit lists 850 functionality statements and describes a methodology for selecting a LIS. In comparison to the other feature catalogues we described, the functionality statements are very detailed. For integration into HITO, a clustering of the functionality statements would be necessary to obtain a manageable LIS feature list.

Describing Software Products Using HITO

With the help of HITO and the selected catalogues we described, 25 LIFOSS products were described. These were selected to represent different application system types and due to their comprehensive, openly available documentation. For the description of supported enterprise functions and features, we extracted terms from the software product documentation and linked as many as possible to catalogue entries of HITO. Information about the LIFOSS products was extracted by 1 team member (author MB) and checked by another team member (author FJ).

Results

HITO was modeled and published using Semantic Web technologies. The Unified Modeling Language class diagram in Figure 1 describes the structure of HITO. The classes shown to the left of "software product" describe the general characteristics of software products. For classes with domain-specific instances (ie, application system type, feature, enterprise function, organizational unit, and user group), we applied a scheme of 3 interrelated classes named <*classname*>Catalogue, <*classname*>Classified, and <*classname*>Citation. A <*classname*>Catalogue is a health IT–related collection, such as the HL7 EHR Functional Model or the WHO classifications for digital interventions. A <*classname*>Classified is a category that belongs to exactly 1 catalogue. A <*classname*>Citation is a textual label extracted from available software manuals, descriptions, and studies and thus represents a part of the folksonomy contained in HITO [28].

To illustrate how this scheme applies, we describe the domain-specific characteristics of the Orthanc software [29,30] in Table 3. The developers of Orthanc refer to it as "mini-PACS," "DICOM (Digital Imaging and Communications in Medicine) server," "VNA (vendor-neutral archive)," and "viewer of medical images." These terms are assigned to the software product Orthanc as "application system type citations." In turn, "DICOM server" and "mini-PACS" have links to the classified application system type "PACS" from the application system type catalogue in Winter et al [14]. The supported enterprise function citations extracted from the Orthanc website, such as "image archiving," "image management," and "research about the automated analysis of medical images," were linked to the more general terms "laboratory and diagnostics imaging management" and "research and education" from enterprise function catalogues. For the 16 feature citations extracted from the Orthanc online documentation, we identified linkable classified features of the WHO classification of digital health interventions and the PACS feature list. Some classified features or enterprise function terms have direct links to the software product. These assignments had no match with citations and were done by domain experts.

Overall, with the help of HITO, we described 25 LIFOSS products in similar detail as Orthanc. All software product descriptions are available as LOD. We described HITO classes and relationships of the ontology and individual software products using RDF. The HITO SPARQL end point [31] allows queries using SPARQL (Figure 2).

The RickView application allows for browsing through the ontology and knowledge base [32]. Another suitable way to query is with a faceted search [33], whereby integrated terminologies can be used to find software products of a certain application system type or supporting combinations of features and functions (Figure 3).

The ontology is also publicly available under version control in a GitHub repository [34]. It can be downloaded in RDF Turtle format to be viewed in ontology editors like Protégé. HITO is dedicated to the public domain and uses a Creative Commons Zero v1.0 Universal license. There are a few exceptions for integrated terms from SNOMED [25] and the WHO classification of digital health interventions [12].

Figure 1. The Health Information Technology Ontology (HITO), version 22.05, specifies the classes and relationships that are used to describe software products. The complete class diagram is available on the HITO website [28].

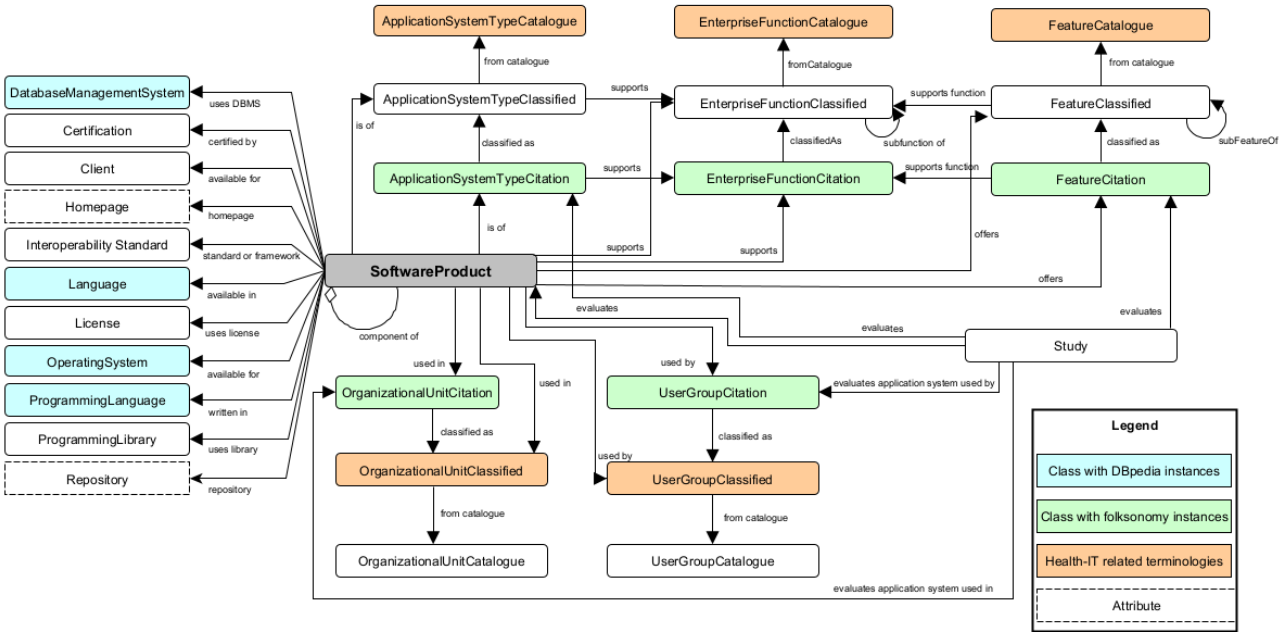

Table 3. Application system types, supported functions, features, user groups and organizational units of the Orthanc software.

<className> and <classname>Citation from the software documentation	<classname>Classified in HITO[a] (<classname>Catalogue)
Application system type	
DICOM[b] server	PACS[c] (application systems in [14])
mini-PACS	PACS (application systems in [14])
VNA[d]	N/A[e]
Viewer of medical images	N/A
Web viewer	N/A
Enterprise function	
N/A	Execution of radiological examinations (enterprise functions from [14])
Image archiving	Laboratory and diagnostics imaging management (enterprise functions from [12])
Image communication	Laboratory and diagnostics imaging management (enterprise functions from [12])
Image distribution	Laboratory and diagnostics imaging management (enterprise functions from [12])
Image management	Laboratory and diagnostics imaging management (enterprise functions from [12])
Research about the automated analysis of medical images	Research and education (enterprise functions from [14])
Feature	
N/A	Capture diagnostic results from digital devices (features from [12])
Data management for clinical routine and medical research	N/A
DICOM identifiers	N/A
DICOM network protocol	N/A
Evaluations Report	N/A
Injury surveillance system registration report	N/A
Listing available servers	N/A
Plugin mechanism to add new modules	N/A
Retrieve images	N/A
Retrieving DICOM resources from WADO-RS[f] server	Compatibility and integration with other systems and products (PACS feature list [26])
Search the content	N/A
Send images	N/A
Sending DICOM resources to a STOW-RS[g] server	Compatibility and integration with other systems and products (PACS feature list [26])
Test the connection	N/A
Top diseases report	N/A
User group	
Radiologist	Radiologist occupation [25]
Researcher	Researcher occupation [25]
Software/hardware integrators in the medical field	N/A
Network engineer	N/A
Physicist	Physicist occupation [25]
System engineer	N/A

Discussion

Principal Results

In this project, we identified characteristics useful for describing software products and systematically captured them as classes in HITO. Accordingly, we exploited the properties of ontologies that enable semantic description and linking of data.

For a thorough functional description of software products in health care, we described the enterprise functions supported and features offered by the software products. For health-specific characteristics of software products, we analyzed and integrated existing terminologies for enterprise functions, features, application system types, organizational units, and user groups as catalogues. Because we expected the relevant sources for such catalogues to come not only from science but also from practice, a systematic review of the scientific literature for health IT–related terminologies would not have led to sufficient results. Accordingly, we based the selection of catalogues on statements by domain experts among the project team and project partners, supplemented by targeted PubMed and Google searches on specific application system types.

Thus, we used a case-based and agile approach to identify classes, relationships, and catalogues best suited for describing software products in health care. In the use cases considered so far, ontological reasoning had no relevance. Therefore, to date, only few axioms are used in HITO. As the next step toward more interoperability with other formal ontologies, HITO could use an upper-level ontology such as Basic Formal Ontology [35], General Formal Ontology [36], or gist [37]. A first feasibility check of these ontologies showed that the gist ontology, which defines typical upper-level business concepts, may be the most appropriate for the scope of HITO.

With the help of HITO, we described 25 LIFOSS products in detail that, together with less detailed descriptions of single commercial software products and software products extracted from evaluation studies, form our knowledge base. The descriptions of these software products could be regarded as a proof of concept. However, we noticed the interpretative degrees of freedom in assigning correct enterprise functions and features to software products. To ensure the validity of further software descriptions, it would be helpful to calculate interrater reliability among 2 independent experts. For this, further software product entries of the Medfloss.org database that have not yet been considered in HITO's knowledge base could be used.

As postulated by Berners-Lee [15], HITO's availability as LOD facilitates its barrier-free access and use. In particular, the integrated catalogues for enterprise functions, features, and application system types provide HITO users with rich terminology for functionalities of software products. However, since there is more than 1 catalogue for each of these characteristics, new terminological problems arise. The

catalogue entries of different catalogues must be mapped to each other to achieve comparability of software products described with the help of different catalogues. Linking these catalogues is part of ongoing research. Together with the folksonomy terms that are already connected to catalogue entries, HITO users will be able to retrieve the most suitable software using a broad range of search terms. The catalogues currently integrated into HITO focus more on health care rather than on medical research tasks (ie, software products like research databases may not be sufficiently described by HITO). However, integrating further catalogues describing research-related enterprise functions or features could be possible.

Nevertheless, publishing HITO and its knowledge base as LOD implies that the contents of HITO are available under an open license. Thus, for the broadly accepted nomenclature SNOMED CT, we could only check the principal suitability of the SNOMED "environment" and "occupation" concepts based on a small set of examples that we included in HITO with permission from SNOMED International. Due to license requirements, SNOMED CT terms cannot be made available as LOD.

In summary, HITO provides an openly available framework for the description of health care–related software that can be used by researchers who publish studies on digital health interventions or by developers and users who need to describe software.

Conclusions

We recognize that health informatics continues to face a terminology problem. Establishing a uniform terminology for software products used in health care is currently unachievable due to several coexisting terminologies from both research and practice. Linking the terms from different terminologies by similarity relationships is the first step toward more transparency. This will also help identify misunderstandings that may be caused by synonyms, homonyms, or conceptual overlaps. Simply knowing that the term "EHR system" can stand for an institutional or cross-institutional application system or a collection of digital documents related to a person's health prevents problems related to misunderstanding. A researcher authoring a study on a digital health intervention by an EHR system knows that the term "EHR system" must be further specified, for example, by enterprise functions and features as listed in HITO.

Nevertheless, we should further strive for a consented, uniform terminology of health informatics. Taking different coexisting terminologies as a basis, methods of qualitative content analyses such as inductive category formation [38], supported by (semi)automatic text extraction, may lead the way toward an established language for health informatics.

Acknowledgments

The work presented here is part of the project "HITO: a Health IT Ontology," funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) - WI 1605/11-1 and the Austrian Science Fund (I 3726-N31). The publication of this article was partly funded by the Open Access Publishing Fund of Leipzig University, supported by the German Research Foundation for the Open Access Publication Funding program.

Abstract

Background: The Systematized Medical Nomenclature for Medicine–Clinical Terminology (SNOMED CT) is a clinical terminology system that provides a standardized and scientifically validated way of representing clinical information captured by clinicians. It can be integrated into electronic health records (EHRs) to increase the possibilities for effective data use and ensure a better quality of documentation that supports continuity of care, thus enabling better quality in the care process. Even though SNOMED CT consists of extensively studied clinical terminology, previous research has repeatedly documented a lack of scientific evidence for SNOMED CT in the form of reported clinical use cases in electronic health record systems.

Objective: The aim of this study was to explore evidence in previous literature reviews of clinical use cases of SNOMED CT integrated into EHR systems or other clinical applications during the last 5 years of continued development. The study sought to identify the main clinical use purposes, use phases, and key clinical benefits documented in SNOMED CT use cases.

Methods: The Cochrane review protocol was applied for the study design. The application of the protocol was modified step-by-step to fit the research problem by first defining the search strategy, identifying the articles for the review by isolating the exclusion and inclusion criteria for assessing the search results, and lastly, evaluating and summarizing the review results.

Results: In total, 17 research articles illustrating SNOMED CT clinical use cases were reviewed. The use purpose of SNOMED CT was documented in all the articles, with the terminology as a standard in EHR being the most common (8/17). The clinical use phase was documented in all the articles. The most common category of use phases was SNOMED CT in development (6/17). Core benefits achieved by applying SNOMED CT in a clinical context were identified by the researchers. These were related to terminology use outcomes, that is, to data quality in general or to enabling a consistent way of indexing, storing, retrieving, and aggregating clinical data (8/17). Additional benefits were linked to the productivity of coding or to advances in the quality and continuity of care.

Conclusions: While the SNOMED CT use categories were well supported by previous research, this review demonstrates that further systematic research on clinical use cases is needed to promote the scalability of the review results. To achieve the best out-of-use case reports, more emphasis is suggested on describing the contextual factors, such as the electronic health care system and the use of previous frameworks to enable comparability of results. A lesson to be drawn from our study is that SNOMED CT is essential for structuring clinical data; however, research is needed to gather more evidence of how SNOMED CT benefits clinical care and patient safety.

Introduction

Background

The Systematized Medical Nomenclature for Medicine–Clinical Terminology (SNOMED CT) is an extensive, multi-hierarchical clinical terminology system. It provides a standardized and scientifically validated way of representing clinical information [1]. The application possibilities of SNOMED CT are well documented [1-5], and various guides describe the following types of implementation: clinical records, knowledge representation, data aggregation, and analysis. Specifically, the previous literature describes the various development goals of SNOMED CT. For example, SNOMED CT can be used as a standard for electronic health records (EHRs) for classifying or coding clinical information. Additionally, standardized terminology advances data indexing, storing, and retrieving. This supports sharing of patient information across medical domains and organizations in ways that promote continuity of care. As a large-scale terminology system, SNOMED CT also enables knowledge representations in clinical guidelines and care pathways, which can be used, for example, with decision support [2-5].

Data recorded in EHRs are primarily used to provide care to patients. The potential of SNOMED CT to improve data quality and facilitate interoperability, and thus improve patient safety, has long been noted in existing research. Studies have shown that structured and standardized EHRs also increase data reuse possibilities [6]. The European Union and the US Healthcare Information Technology Standards Panel have noted possibilities provided by SNOMED CT and taken steps toward increasing semantic interoperability, reuse, and the exchange of health data. Data recorded in local systems can also be used to support the achievement of broad health policy goals. The importance of SNOMED CT is expected to gradually grow, but at the same time, there is a need to tackle the complex implementation challenges that may arise [1,7,8].

When implemented in EHRs, SNOMED CT is used to represent clinical information consistently and comprehensively [1,2]. Despite the widespread adoption of EHRs that are certified to follow terminology standards, and although SNOMED CT is used in more than 50 countries, there are only a few published reviews about its clinical use. Most studies have focused on theory and predevelopment or design [1,2,8,9]. Moreover, studies in the past have analyzed general factors related to EHR adoption but have not explored the factors associated with less advanced EHR product implementations as compared to more advanced and mature EHR systems. In the context of SNOMED CT implementation, the maturity of an EHR system is a relevant factor to appropriately maximize the benefit from previous experiences [10-12].

In summary, even though SNOMED CT has been extensively studied as a clinical terminology system, previous research has repeatedly documented a lack of detailed evidence for SNOMED CT in clinical use cases [2,3]. Considering that implementing SNOMED CT is a challenging proposition [2], the identification of specific barriers and facilitators to implementing SNOMED CT in clinical use is of paramount importance to further promote its adoption. Evidence from use cases might support implementation and provide guidance on avoiding deployment pitfalls. Therefore, we aimed to explore the available evidence in previous literature reviews of clinical use cases of SNOMED CT integrated into EHR systems or clinical applications during the last 5 years of continued development [2,3,5,13].

Objectives

The aim of this review is to provide an overview of published studies on SNOMED CT clinical use cases in the context of EHRs. In this study, we apply categories from previous research for analyzing use purpose and use phase for the terminology. Moreover, we present core benefits by summarizing the observations from the EHR use cases [3,5,13].

Our research questions are as follows: (1) What are the main clinical use purposes of SNOMED CT during the last 5 years of development? (2) What kinds of use phases of SNOMED CT are identified in these studies? and (3) What are the summarized clinical benefits documented in each SNOMED CT use case?

Methods

To explore EHR-related SNOMED CT use cases in recent research, our research team set out to conduct a systematic literature review. Our team consisted of a medical expert with decades of experience in clinical care and two health and medical informatics experts. To analyze EHR use cases where SNOMED CT terminology was applied, we extended the concept of EHR systems to cover EHR-related applications and software in clinical use. The word “clinical” refers to “medical work or teaching that relates to the examination and treatment of ill people” [14]. In our review, a use case consisted of SNOMED CT integrated into an EHR system in various stages of use, either in preuse development or in design, piloting, testing, implementation, use, or postimplementation evaluation [15].

The team followed the Cochrane review protocol [16] to plan the necessary steps for this study design (Multimedia Appendix 1). Within the team, the application of the protocol was modified step-by-step to fit the research problem by first defining the search strategy, identifying the articles for the review by isolating the exclusion and inclusion criteria for assessing the search results, and lastly evaluating and summarizing the review results.

We defined our search strategy by adding variations of search terms and testing the suitability against the search results. A search with key words “EHR,” “EMR,” “electronic health record,” or “electronic health record system” produced a large number of search results. Combining these terms with

"SNOMED CT" produced relevant search results for our review purposes. Furthermore, adding filters (Textbox 1) did not cause a significant change in the search results. A search of PubMed using the systematic-review methods filter was undertaken in March 2022 and resulted in 162 original articles after removing duplicates (Figure 1). Our results cover the last 5 years of research; thus, our review forms a continuation of previous reviews [2-5].

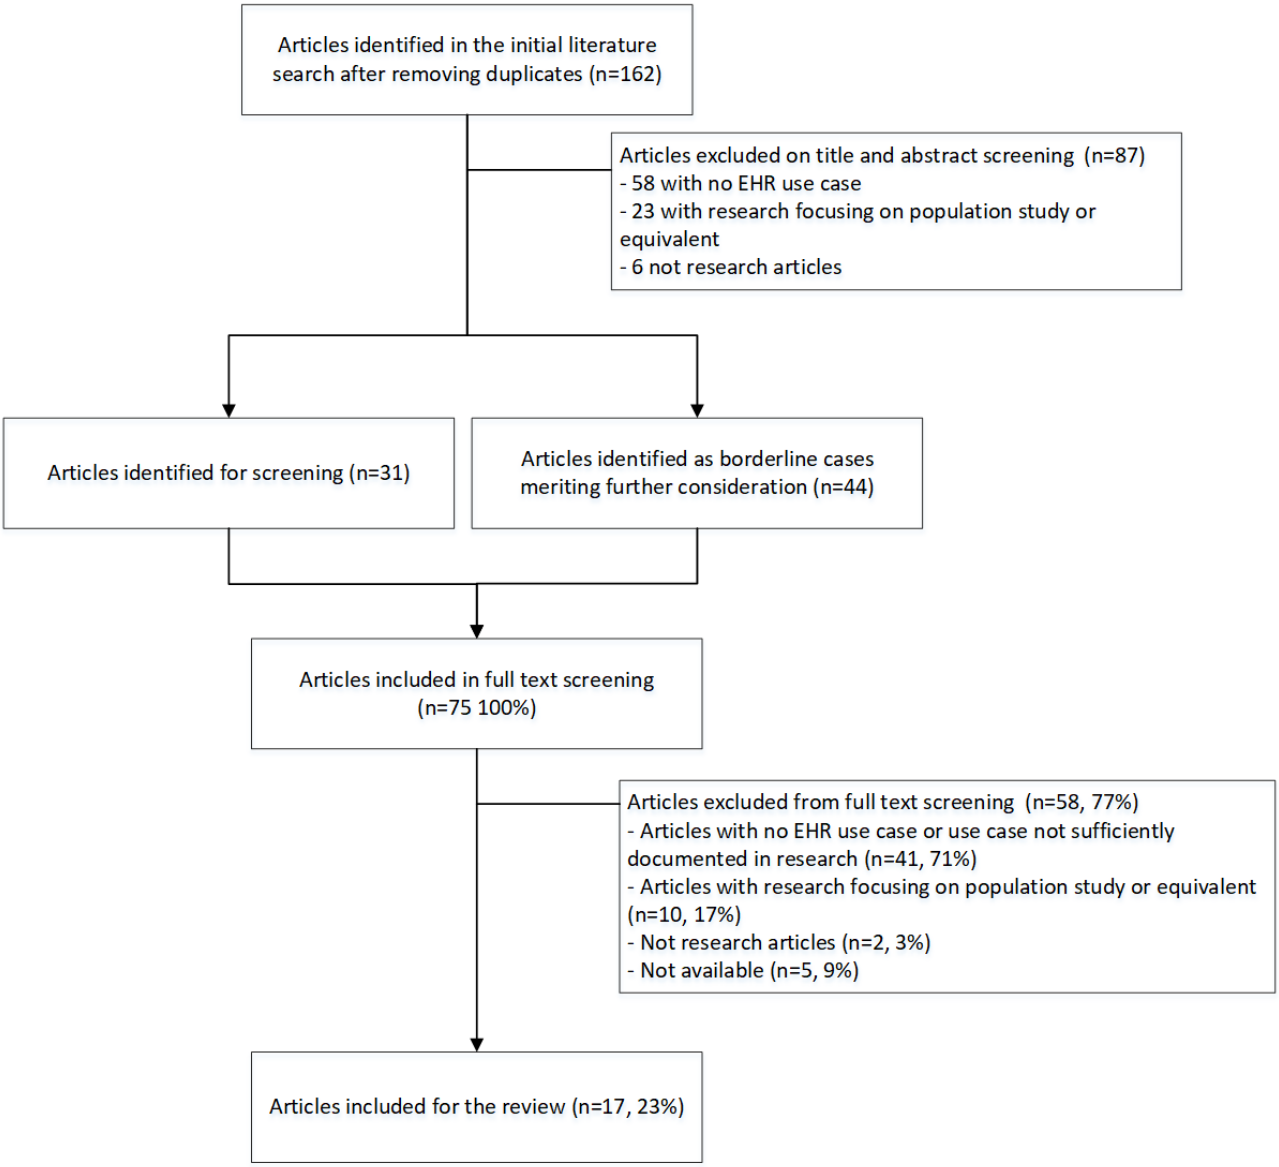
Figure 1. Application of the review protocol as a flowchart. EHR: electronic health record.



The exclusion and inclusion criteria were defined before conducting the search. We based our criteria on our research questions and previous research. We defined the exclusion criteria as follows: First, the original article had to document an EHR use case where SNOMED CT was being tested, piloted, implemented, or used in a clinical context. This excluded, for example, research concentrating on theoretical building, evaluation, or validation of SNOMED CT. Second, we excluded population studies and, for example, cohort studies where SNOMED CT was used to define, extract, and harmonize study data and where no EHR-related design or use goals were documented. Third, we excluded editorials, posters, and other

such sources to limit the review to original research articles. While reading the articles, we discussed how well the exclusion criteria corresponded to the delimitation made based on our research questions and the conclusions we arrived at while reading the research content as presented in the original articles.

After the first exclusion based on article headings and abstracts, we had excluded 87 articles. We included 31 articles that seemed to relate to our research question. Moreover, 44 borderline cases merited special consideration to determine if they should be excluded or included (Figure 1). The two researchers set out to read a total of 75 full-text articles. The information extraction and documentation template for final inclusion had been defined based on previous research [3,5,13] and research team agreement (Table 1). During the final reading, the documentation template for information extraction was concurrently refined.

Figure 1 illustrates how the search results were analyzed during exclusion and inclusion screening. In the end, we included 17 original articles in the review analysis. Our final inclusion was confirmed by the research documentation that illustrated the SNOMED CT use case in an EHR or EHR-related application and software in clinical use.

Table 1. Criteria to categorize Systematized Nomenclature of Medicine–Clinical Terminology use in the review.

Criteria	Definition
Clinical use context	Refers to clinical domain or specialty as documented in the study.
EHR[a] system	Refers to EHR systems or other EHR-related applications or software as documented in the study.
Users	Refers to intended users of the SNOMED CT[b] integrated into the EHR as documented in the study.
SNOMED CT use category	Refers to primary purpose for using SNOMED CT as documented in the study [3,5,13]. Based on research team agreement, the following categories were used: standard for EHR or for a clinical application, retrieval or analysis of patient data, data extraction (used to classify or code in a study), proving merit of SNOMED CT, and development of automated coding.
SNOMED CT use phase	Refers to the stage of the SNOMED CT use as documented in the study [3,5]. The stages used by the research team were "in development," "in pilot," "in implementation," "in use," and "after implementation [or in use] evaluation" (ie, proof of merit). Thus, for example, theoretical research was excluded.
SNOMED CT core benefits	Refers to research team's summary of which areas of identified benefits the research added value to, if available [3,5]. The categories were "improving quality of care and patient safety"; "improving continuity of care"; "enabling a consistent way of indexing, storing, retrieving, and aggregating clinical data"; "improving data quality"; and "improving coding productivity."

[b]SNOMED CT: Systematized Nomenclature of Medicine–Clinical Terminology.

Results

Characteristics of the Publications

In total, we analyzed 17 articles [17-33]. The earliest research selected for the final review was published in June 2017 and the last in February 2022. On an annual basis, the largest number of articles was published as late as 2021 (6/17). The country of publication was identified for all publications. The country that published the highest number of articles was the United Kingdom (5/17), followed by the United States (3/17), Australia (2/17), and Spain (2/17). Canada, Denmark, Switzerland, the Republic of Korea, and Germany each accounted for one use case. The selected articles were published in 13 different peer-reviewed journals. The characteristics of the publications are summarized in Multimedia Appendix 2.

Contextual Factors of the Clinical Use Cases

To verify the appropriateness of the use cases in regard to our research questions, the clinical context was described for 14 articles. In the remaining 3 articles (3/17), the clinical context was not named, but the research account otherwise described the clinical use case in relation to EHR use. With respect to specialties, 2 cases were from neurology, and 1 case each from pulmonology (asthma), cardiology, oncology, general medicine, pediatrics, and rare diseases. One of the cases did not describe an exact specialty but concerned the prehospital unit in emergency care, and one concerned an outpatient clinic. Four cases mentioned either primary care or tertiary care.

The EHRs were poorly described in most of the articles, and specific descriptions of the EHRs did not follow any uniform structure. Thus, the nature of the results is descriptive. Only one of the publications named the exact product. That study concerned a comprehensive hospital information system, a high-maturity EHR with tools for functions such as supporting care coordination and continuity of care. One of the systems was described as a prehospital patient record that was not integrated into the hospital EHR. One system used by general practitioners consisted of integrated software for clinical use, and one was described as a primary care EHR. Six systems (6/17) were hospital EHRs. Among the system types were also the following: an "outpatient and inpatient EHR," a "centralized EHR with web-interface," and a "local EHR." One of the use cases described the system generally as an "ehr."

To further verify the clinical orientation of the use cases, we analyzed the professional groups involved in each of them. Although users were described, it was not clearly stated which professional groups were the intended users of SNOMED CT (eg, nursing informatics, medical informatics, or multi-professional users). Seven of the use cases (7/17) described the users in an exact way. Four cases (4/17) were

applied by physicians, 2 (2/17) by nurses, and 1 by physicians and nurses. Two of the cases (2/17) were applied by a multi-professional team of clinicians, clinical and medical informatics professionals, clinical domain experts, terminologists, and clinical coders. Two of the articles specifically concerned clinical coders. Two of the remaining cases were generally described as having been applied by "clinicians." Four of the cases (4/17) concerned researchers themselves, for whom specific clinical backgrounds were not reported. Contextual factors are presented in Multimedia Appendix 3.

SNOMED CT Use Purpose

All 17 articles described one or several use purposes for the terminology. Implementing SNOMED CT as a standard terminology in the EHR was typically grounded on clinical needs for standardizing patient information. Here, the SNOMED CT use purpose refers specifically to the primary use goal of the terminology as integrated or being implemented into an EHR. The most common category of use purpose (8/17) was SNOMED CT adopted as a common standard for EHRs. An additional 2 studies (2/17) described the goal of implementing SNOMED CT as a standard in a separate clinical application integrated in the EHR system. The use cases described communication and coordination needs, such as between hospital units or between inpatient and outpatient care, with the goal of promoting more reliable continuity of care and ultimately a higher quality of care. Accurate and timely diagnosis information with SNOMED CT deployment was reported as a crucial clinical need since it is major information in patient care. In 2 of the studies, SNOMED CT was implemented into the documentation of the problem list to increase the usefulness of the patient information and to organize the problem list content. Additionally, SNOMED CT was used to ensure effective data migration between systems.

The primary use purpose described in 2 articles was to retrieve or analyze patient data for clinical research. This enhanced data retrieval, analysis, and sharing for clinical research across multiple hospitals. Multisite data sharing and distributed analysis was supported by common terminology and by common data models. These 2 use cases utilized a medical annotation toolkit that included a web interface for extracting needed concepts. An additional 2 studies focused on data extraction, where SNOMED CT was used to classify and code patient data for research purposes. The use purpose in these 2 studies was building clinical pathways and patient selection criteria based on terminology coding. Natural language processing of clinical, pathology, and genomics data was used for further clinical research. Moreover, the use cases illustrated the challenges of data sharing between inpatient care and a virtual hospital visit.

Two of the original articles described, to a degree, the already established use of SNOMED CT with a focus on proving the merit of the terminology use in a clinical setting. The reasons for poor clinical coding of patient data after 2 decades of EHR use are manifold; two main reasons are lack of motivation and training. Support tools for the interoperable recording of diagnostic, treatment, and interventional patient information can be advanced, for example, with domain-specific development. One of the articles documented automated clinical coding as the driving purpose for SNOMED CT development. The development of computer-assisted coding may, through careful review and validation, improve the productivity of clinical coders. Different classification systems, such as the International Classification of Diseases–10, are typically linked and mapped to SNOMED CT for suitability in clinical use. An overview of the SNOMED CT use purposes is provided in Multimedia Appendix 3.

SNOMED CT Use Phase

The phase of use was identified in the literature with varying accuracy, which is why the research team discussed these categories during the analysis. Clinical use phase was documented in all 17 articles (100%), but in ambiguous ways. The most common category of use phases was SNOMED CT in development, which was documented in 6 articles (6/17). Development was described as an iterative process of analysis, validation, and standardization or building and mapping EHR-structured content that requires coordination and communication between stakeholders to improve the quality of care; as such, this was expected to be a process that could span several years.

SNOMED CT in use was identified as the use phase in 5 EHR-related use cases (5/17) and in implementation in 4 use cases (4/17). In the EHR-related use cases, SNOMED CT had been chosen as the base terminology system in the EHR or in a specific domain documented in the research to improve clinical information recording and coding, develop clinical pathways, and extract clinical data. The implementation cases addressed specifically improved the clinical recording of patient data by supporting clinicians' language and semantic selection with SNOMED CT or with a combination of SNOMED CT and other classification or terminology systems. In addition, 1 article documented a pilot use of SNOMED CT in EHR use cases, and 2 articles described the merits of SNOMED CT use with a more proven merit approach or through after-implementation evaluation. The pilot case evaluated cases of missing or mislabeled clinical data with, for example, nonstandard concepts or use of abbreviations. The evaluation of SNOMED CT use aimed to determine what had been achieved with fully integrated EHR services in patient care and to evaluate the impact of using SNOMED CT to record clinical meanings. As additional benefits, the secondary use purpose for using patient information was mentioned. An overview of the SNOMED CT use phase is provided in Multimedia Appendix 3.

Core Benefits of SNOMED CT

The research team identified and summarized core benefits of SNOMED CT as documented in the 17 use cases. The team categorized the benefits based on the previous literature (Multimedia Appendix 3). The core benefits were related to terminology use outcomes. The most common category was increased data quality, with 8 articles (8/17). Semantic-level core benefits were built on the scope and comprehensiveness of the terminology. In the use cases, SNOMED CT supported not only clinical meaning standardization but also the language of choice. For clinical use purposes, custom concept dictionaries or language-specific subsets were built for a chosen language.

Further benefits of implementing SNOMED CT were 2-fold: the parallel development of EHR technology and standardization. One UK use case documented evidence of increased interface usability and user satisfaction by clinicians. However, clinicians reported that adopting a new approach for data recording was a gradual process requiring time.

Four articles (4/17) documented the benefits category of enabling a consistent way of indexing, storing, retrieving, and aggregating clinical data. One use case concentrated on the benefits for data retrieval. Documented benefits pointed to the documentation of clinical events with richer detail. The productivity of coding was the main benefit categorized in 1 use case, increased quality of care in 2 use cases, and increased continuity of care in 1 use case. These benefits depended on the possibility of accessing more complete and coherent patient information, regardless of where it was recorded, to support safe patient care. Additionally, in 1 use case, the core benefit was successful implementation of a new EHR through harmonizing data structures. An overview of the SNOMED CT core benefits is provided in Multimedia Appendix 3.

Discussion

Summary of Findings

This systematic review identified 17 articles in which SNOMED CT was implemented and used in a clinical context in EHRs or related clinical applications. We aimed to confirm whether research has developed to allow for a shift of focus from previously published reviews that described potential use toward studies documenting plausible benefits of SNOMED CT. We present findings related to clinical use purposes, use phases, and core benefits of SNOMED CT over the last 5 years of ongoing efforts. These review categories are based on previous research [3,5,13] that provided a strong starting point for this analysis.

The use purpose for SNOMED terminology based on previous research (Table 1) was identified in all the articles reviewed. As we evaluated the use cases, these categories served our research material well. The most applied use purpose category was SNOMED CT as the planned standard for EHRs or other related applications. Other frequently applied use categories were the goals of using SNOMED for retrieving and analyzing patient data or implementing the terminology to advance the coding of patient data. Only 2 of the articles in the review entailed proof of merit of EHR implementation as the use purpose category. Based on these results, the initial observation was that there might be a level of interconnectedness between the use purpose and use phase. To prove this, data on the maturity of EHR solutions are needed to research the possible interconnectedness of EHR use and SNOMED CT. Moreover, it might be relevant to analyze relationships between use purpose and use phase. This requires testing the categories and their possible relationships with different data sets.

Regarding the use phase results, all the reviewed articles included descriptions of the SNOMED CT use phase, although details of related contextual factors, such as clinical environment, varied. This hampered the assessment of the overall picture of the use phase. Considering the results, this may be a feature of this specific material, being typical of EHR-related use cases of SNOMED CT. Thus, in the future, it may prove fruitful to pay particular attention to the descriptions of these types of SNOMED CT use cases. We propose to describe the phase of use in a more structured and contextual manner. This kind of accuracy would increase the scalability of the use-case results. Lee et al [3] have already highlighted that only a few SNOMED CT implementation cases are being published in the scientific literature. Through the systematic investigation of previous theoretical work [3], and with time, more comparable scientific publications on SNOMED CT use cases in a clinical context could be published.

Based on our review, there is still little research evidence on the benefits for clinical use of SNOMED CT in EHR-related use cases. We identified the following frequently reported categories of core benefits: improvement of data quality and enabling a consistent way of indexing, storing, retrieving, and aggregating clinical data. Closely related to these benefits were improvement in quality of care—with the goal of achieving better patient safety—and, based on better data quality, enabling better continuity of care. Additionally, the review found individual remarks on improving the productivity of coding though automation or through terminological support for clinical users. Such tools had potential to increase user satisfaction, although there was evidence for a need to involve clinicians from different domains in development. Evidence of practical advancement may motivate various clinical specialties to become more involved in SNOMED CT development work from early on.

Although previous research has categorized the possible benefits of SNOMED CT [3,5], the core benefits in our review were summarized by the research team. By doing this, we aimed to describe the specific benefits of the EHR-related use of SNOMED CT. The objective is to highlight that the categorization applied in this study (Table 1) requires further testing with different data to assess its validity. The set of categories applied by our research team was not proven to be comprehensive or exhaustive. Therefore, in future research, it could prove relevant to carefully evaluate SNOMED CT use cases from the perspective of typical benefits. Additionally, it could be important to research what kinds of disadvantages, risks, and bottlenecks can be detected. By evaluating different use cases, it might be possible to extract the general success factors of clinical SNOMED CT implementation. Overall, the evaluation of SNOMED CT implementation requires more attention. As an example, the European large-scale implementation of SNOMED CT, which is being funded by the European Commission, could at the same time advance evaluation studies or require systematic evaluation as a part of the funding process.

Our review revealed that the EHR system or related software were poorly described in most of the articles, and specific descriptions of the EHRs were scattered due to a lack of uniform structure for such descriptions. This is clearly an issue that would require more attention in future use-case descriptions, given the fact that SNOMED CT is designed to support the use of EHRs. To describe the capabilities and overall maturity of

the EHR system is core information in use case descriptions if the research result aims to benefit the clinical implementation process by avoiding previous obstacles and possible mistakes. We recognize that addressing potential mistakes does not mean that specific implementation experiences are universally generalizable, but that such implementation is required to be adapted to other clinical contexts. To promote the scalability of previous experiences, we suggest, for example, the application of the electronic medical record maturity model (EMRAM) in future use cases. EMRAM is a widely used tool developed by the Healthcare Information and Management Systems Society to measure the rate of adoption of EHR functions in health care settings. Its stages match the technological progress of the overall digitalization of the health care setting. Moreover, one possible starting point for future studies is to recognize specific use cases for software applications in clinical specialties, in which SNOMED CT would be valuable to accelerate and facilitate specific types of clinical implementations.

Limitations

This systematic review has limitations that could affect the plausibility of the results. The methods and results of our systematic review are transparently reported in detail to allow readers to assess the trustworthiness and applicability of our findings [16]. However, even though the review's methodological basis [16] is scientifically recommended, the varying levels of description in the research articles proved to be challenging; for example, the descriptions of background variables led to partial imprecision in the results. This especially affected the categories regarding the clinical context and type of EHR. The study's risk of bias was carefully considered during the research process, and no assumptions were made about missing or unclear information from the studies.

We aimed to avoid missing key studies and to minimize bias by conducting a thorough and comprehensive literature search. However, our search entailed only one database, PubMed. Nevertheless, according to recent literature, PubMed can be used as a principal search system [34]. PubMed is well suited for evidence synthesis in the form of systematic reviews since it meets all necessary performance requirements, such as the formulation of queries, the correct interpretation of queries by the system, and the reproducibility of searches. At the same time, it is impossible to be certain that a system that has proven to be successful in specific tests will not fail under different circumstances [34,35]. Moreover, not all SNOMED CT implementation projects are published in the scientific literature [3]. Thus, it is important to recognize that relevant information on clinical use cases may be found in different types of literature.

Conclusions

This literature review demonstrates that systematic reviews are relevant to the development of an understanding of SNOMED CT use and its possible benefits in further facilitating multi-professional, clinically driven implementations by summarizing essential findings based on evidence-based results. Clinical use cases are needed to promote the scalability of review results. To achieve the best out-of-use case reports, more emphasis should be placed on describing the contextual factors, such as the electronic health care system currently in use and the use of previous frameworks, to allow the comparability of results. Regarding future research, although other systematic reviews have addressed similar questions to ours, this review is necessary to shift the focus onto more clinically grounded implementation outcomes and benefits of the use of SNOMED CT. Generally, further research evidence is still needed to determine how exactly SNOMED CT benefits clinical care and patient information quality.

Abstract

Background: There is a flora of health care information models but no consensus on which to use. This leads to poor information sharing and duplicate modelling work. The amount and type of differences between models has, to our knowledge, not been evaluated.

Objective: This work aims to explore how information structured with various information models differ in practice. Our hypothesis is that differences between information models are overestimated. This work will also assess the usability of competency questions as a method for evaluation of information models within health care.

Methods: In this study, 4 information standards, 2 standards for secondary use, and 2 electronic health record systems were included as material. Competency questions were developed for a random selection of recommendations from a clinical guideline. The information needed to answer the competency questions was modelled according to each included information model, and the results were analyzed. Differences in structure and terminology were quantified for each combination of standards.

Results: In this study, 36 competency questions were developed and answered. In general, similarities between the included information models were larger than the differences. The demarcation between information model and terminology was overall similar; on average, 45% of the included structures were identical between models. Choices of terminology differed within and between models; on average, 11% was usable in interaction with each other. The information models included in this study were able to represent most information required for answering the competency questions.

Conclusions: Different but same same; in practice, different information models structure much information in a similar fashion. To increase interoperability within and between systems, it is more important to move toward structuring information with any information model rather than finding or developing a perfect information model. Competency questions are a feasible way of evaluating how information models perform in practice.

Introduction

Background

Increased use of standards is often suggested as part of the solution to the problem of siloed and unusable information in electronic health records (EHRs) [1], but there is no consensus yet on what standards to use [2]. Instead, there is a flora of standards and the same information is structured with different standards in different settings [3-5]. There are different types of information standards. Some standards primarily aim to

structure information within systems (intraoperability), whereas some are geared toward sharing information (interoperability) [6], but often, both types of standards may be used in both settings. The standards differ between and within themselves regarding the "boundary problem" [7,8], that is, the demarcation between what information is structured with the information model and what is structured with terminology or values. The standards also differ regarding if terminology is stated or not and if so which terminology. Additionally, the terminologies are sometimes standards in themselves (eg, Logical Observation Identifiers Names and Codes [LOINC] or Systematized Nomenclature of Medicine Clinical Terms [SNOMED CT]) but sometimes system-specific or information model–specific value sets.

This combination of possibilities leads to a flora of informatics components, seemingly nonreusable between settings, as noted in previous works [2,9]. However, if the information models structure information in similar ways and there is some agreement on terminologies, perhaps a way forward would be to continue using different standards. Information exchange would be facilitated but not plug and play, as the content would be similar, and the workload of structuring health care information could be shared between users of different information models. Previous work has compared system configurations in relation to a single standard and showed that different system configurations could be unified [10,11]. Works comparing different standards have shown discrepancies in coverage and lack of alignment, primarily regarding terminologies [12,13]. Our hypothesis is that the differences between information models are overestimated. This work contributes by evaluating both the amount and type of differences between models and by providing and testing a method for comparing structure and terminology choices of different standards.

Aim

This work aims to explore if a possible solution to the challenge of sharing information and burden of modelling work within health care would be to continue using different information models. This work also aims to assess the usability of competency questions (CQs) for the evaluation of information models within health care.

Research Questions

The objective of this study was to answer the following 2 research questions:

1. How does the content of health care information differ between information models?
2. Is the method of CQs a feasible way of comparing content in information models?

Methods

Choice of CQs

There are quantitative methods to evaluate information structures in use today. For example, the CAMMS (Common Assessment Method for Standards and Specifications) [14] is an established guide in Europe for assessing a wide range of aspects with primarily a quantitative outcome. The aim of this work was, however, to examine *how* a sample of clinically relevant information is structured with different information models and not *how much* of the information the models could structure. To expose how information was structured, a method with qualitative results, that is, including structure and terminology of content, was needed. CQs have been used to evaluate ontologies for a long time [15]. In brief, the ontology is tested by selecting a relevant scenario and then posing questions to the ontology to see if and how the information needed to describe the scenario is structured within the ontology. CQs yield both quantitative and qualitative data. To our knowledge, CQs have not yet been used to evaluate the combination of information model and terminology within health care.

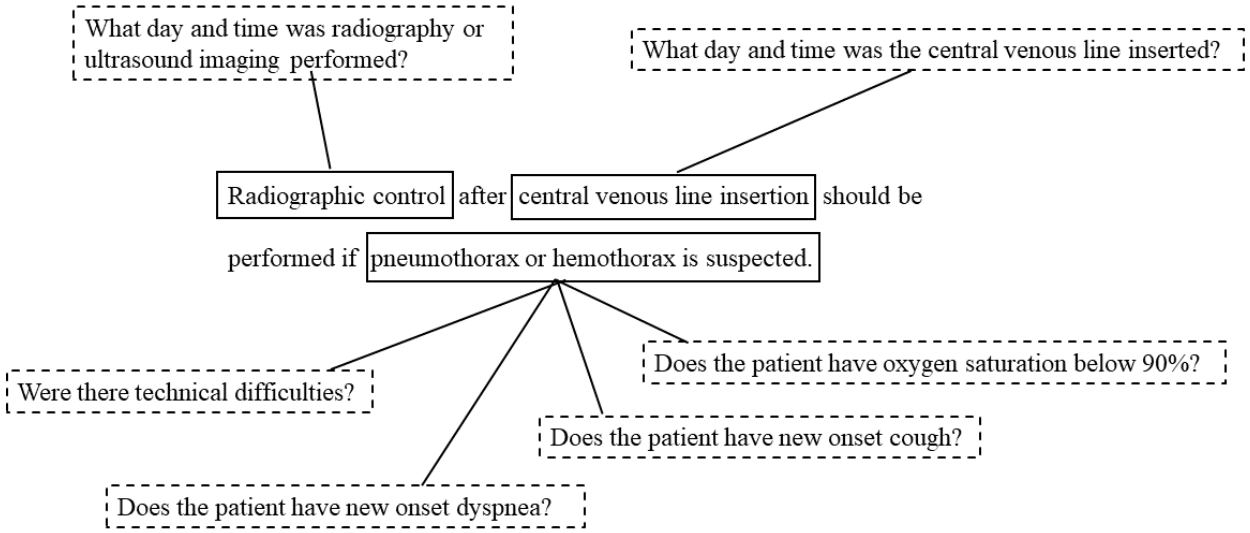
Development of CQs

Domain knowledge has been used as the basis for CQs previously by, for example, Cui [16]. Guidelines are an established textual source for domain knowledge within health care, and we thus chose to use recommendations in a guideline as scenario for developing the CQs. The use of information needed to follow best practice as a starting point ensured that the study examined the tested information models regarding clinically relevant information as opposed to theoretical possibilities or boundaries. Any topic within health care could have been used as a starting point for this work. Central venous lines (also called central catheters) are one of the many domains where structured documentation could support adherence to best practice and facilitate research to develop best practice. To prevent misinterpretations due to translation during the work, we chose to work with Swedish guidelines [17]. In the chosen guideline, there were 104 recommendations that covered preparation, insertion, care, and removal of central venous catheters. Examples from the guidelines are as follows:

1. The tip of the central venous line should be placed distally in the superior caval vein or the right atrium, and the location should be controlled at the time of insertion.
2. Bandages with polyurethane film should be replaced every 3-5 days during inpatient care.
3. At emergency insertion of a central venous line, the advantages of a central venous line should be weighed against the risk of hemorrhage.

The recommendations in the guideline were graded as beneficial, equivocal, or harmful. All recommendations graded as beneficial were placed in a random order and CQs were developed iteratively from the top. Formulating the CQs is a semantic task. The recommendation was read, and if needed, divided into sections, and then questions were developed to cover all the information mentioned in the recommendation. An example is shown in Figure 1.

Figure 1. An example of a recommendation (center) with developed competency questions (in dashed boxes).



Recommendations that contained information not documented in the patient record, for example, "All departments using central venous lines should have access to blood- and catheter tip–culture techniques" were considered out of scope in this study and omitted. When the recommendations were not specific enough to develop CQs, the associated text in the guideline was used to interpret and operationalize the recommendation. For example, for the recommendation "Radiographic control after central venous line insertion should be performed if pneumothorax or hemothorax is suspected," the text "Patients with pneumothorax who need treatment show new respiratory symptoms (dyspnea or cough) or oxygen saturation in blood lower than 90%" and "the risk increases with technical difficulties" was used to interpret the patients who had conditions indicative of pneumothorax or hemothorax.

The purpose of the study determines the number of CQs developed and used [18]. The focus of this work was on comparing how the different models structured clinically relevant information rather than the entire scope of each information model. During data collection, new CQs were iteratively developed and posed until further questions did not add additional types of clinical information. This is defined as the saturation point [19,20]. Despite this, a gap was discovered during data analysis regarding anatomical locations, which had not been covered by any of the initial CQs. Therefore, the next 2 recommendations in the randomized list containing information about the anatomical location were included as well. In total, 36 CQs based on 10 recommendations were developed. See Multimedia Appendix 1 for the list of included recommendations and developed CQs.

Materials

The information models tested and compared in this study were a purposive sample. In this study, the information models are the "participants" that were selected "based on the researchers' judgment about what potential participants will be most informative" [18]. The intention was to compare some typical models that were in use already and some models that were often recommended. The included information models differ in nature in several aspects, but they are all aimed at structuring data and thus impact interoperability. See Table 1 [21-32] for the included information models.

Table 1. Information models included in this study.

Information model	Description by information model provider
Information standards	
FHIR[a] [21]	FHIR is a standard for health care data exchange, published by HL7[b] [21]
openEHR [22]	openEHR is a nonprofit organization that publishes technical standards for an EHR platform along with domain-developed clinical models to define content [23]
HCIM[d] [24]	HCIMs are used to capture functional semantic (nontechnical) agreements for the standardization of information used in the care process [25]
IPS CDA[e] [26]	The goal of this project is to identify the required clinical data with associated vocabulary bindings and value sets for patient summary…and to build an international document and associated templates based on HL7 CDA R2…with value sets to support data elements within those templates [27]
Standards for secondary use	
OMOP[f] [28,29]	The OMOP Common Data Model allows for the systematic analysis of disparate observational databases. The concept behind this approach is to transform data contained within those databases into a common format (data model) as well as a common representation (terminologies, vocabularies, coding schemes) and then perform systematic analyses by using a library of standard analytic routines that have been written based on the common format [30]
SPOR[g] [31]	The purpose of SPOR is to, by means of integration with existing local operation planning systems, retrieve data from the perioperative process and thus offer a tool for local and national quality development (translation by authors) [32]
System-specific formats	
Electronic health record A	A health care information system used by approximately 70,000 health care staff
Electronic health record B	A health care information system developed and supplied by a global vendor

[a]FHIR: Fast Healthcare Interoperability Resources.

[b]HL7: Health Level 7.

[c]HCIM: Health and Care Information Model.

[d]IPS CDA: International Patient Summary Clinical Document Architecture.

[e]OMOP: Observational Medical Outcomes Partnership.

[f]SPOR: Svenskt Perioperativt Register.

Information about the information standards and standards for secondary use were sought on publicly available sources online. Fast Healthcare Interoperability Resources (FHIR) and openEHR have national and local profiles in addition to the internationally published standards available, for example, on Simplifier [33] and in national or local clinical knowledge manager repositories [22]. An initial survey of these resources did not show profiles directly focused on the application domain, and hence, these resources were not included. The information standards are in continuous development; the latest available version was used and cited (see individual references). Draft versions were included when there was no published version of a relevant component. The Health and Care Information Models (HCIMs) are a precursor for International Organization for Standardization (ISO) 13972 [34], which were not yet published as a standard when work began, and they were therefore used as an example of that standard. The International Patient Summary (IPS) is published as both Clinical Document Architecture (CDA) and FHIR. Since FHIR was included separately, the IPS CDA format was chosen.

Templates from 2 EHR systems were included. The material consisted of locally configured user interfaces of the systems and not an information model or database model; thus, the types of results differ between the 2 EHR systems and the other included models. Further, the 2 EHR systems offer a wide possibility for users to configure templates paired with limited reference information models, and thus, the results in this work provide examples of use in the selected EHR systems. The results might have been different if an application domain other than central venous lines had been used.

SPOR (Svenskt Perioperativt Register) and the 2 EHR systems often structure the information according to the specific situation where the templates are used, as opposed to the information standards and OMOP (Observational Medical Outcomes Partnership), which are intended to be general purpose. Thus, for SPOR and the EHR systems, we have included examples of data elements where generic elements do not exist. For example, SPOR had a data element for “kind of venous access,” with access devices in the value set, where the information standards often had a generic device type data element, which could hold any device type.

Answering the CQs

A table with the recommendations and corresponding CQs was developed. For each model, the authors together modelled the information needed to answer the CQs based on information available on the internet about the models. Both the structure of the information model, that is, what archetype/profile/entry

and element was used, and terminological content, that is, what code/codesystem/unit, was documented. As an illustration, the answers for the CQ "Does the patient have new onset dyspnea?" are displayed in Table 2. For details, please see Multimedia Appendix 2. Note that the CQ does not specify what "new" means, that is, in terms of hours or days, but to determine if a symptom is new by any definition, the time of onset is needed.

Table 2. Example results for "Does the patient have new onset dyspnea?" for selected information models.

Element and value	Value set
FHIR[a] condition resource	
condition.code = 267036007 |Dyspnea (finding)|	SNOMED CT[b] descendants of 404684003 |Clinical finding (finding)| (Example)
condition.onsetTime	ISO[c] 8601

For some standards, the same information could be structured in several ways. For example, with FHIR, the information needed to answer, "What day and time was the central venous line inserted?" could be structured with both a Procedure Resource and a DeviceUseStatement. With openEHR, both Evaluation Medical Device and Action Procedure could be used. In these cases, all options were documented as results. The answers to the questions were influenced by the knowledge of the modelers answering them. The background knowledge that the authors have together was estimated to be comparable to that of a system implementer. One of the authors (DK) is, by training, a computer scientist and health informatician with experience in, for example, European Committee for Standardization and ISO standards and EHR system configuration as well as SNOMED CT. The other author (AR) is a medical doctor and health informatician with experience in structuring quality registers, SNOMED CT, and EHR system configuration. Since the authors performed the modelling, they were both researchers and participants at the same time. This gave extra insights and understanding of the work performed but also introduced a risk of bias. However, none of the authors have either any background or held any position with any of the above organizations that biased the results in any way.

Assessment of Coverage

The models were graded for content coverage by type of clinical information. Coverage was graded into "structured" if the information needed to answer the CQs for that type of information was structured. It was graded "partially structured" when only parts of the information were structured. "Not structured" was used when there was no structure and "missing" when the information was not present in the information model.

Assessment of Content Differences

Tables were developed for structure and coding. For each combination of models, the way or different ways the information was structured was evaluated. The number of possible ways for each model was used as the denominator and the number of ways that were similar enough to be used in interaction with the other model was used as the numerator, and the ratios of the 2 compared models were multiplied. For example, procedure type could be structured in only 1 way in FHIR but in 2 separate ways in SPOR (see Table S1 in Multimedia Appendix 2)—all 3 had a similar distribution of information between element and value, and this thus gave the following result: $1/1 \times 1/2 = 50\%$.

Another example is procedure status where HCIM had no status field but instead used a time stamp (see Table S2 in Multimedia Appendix 2). The other models, if anything, had a coded value for status, and the result for HCIM was thus 0 for all combinations for this type of information: $0/1 \times x/y = 0\%$.

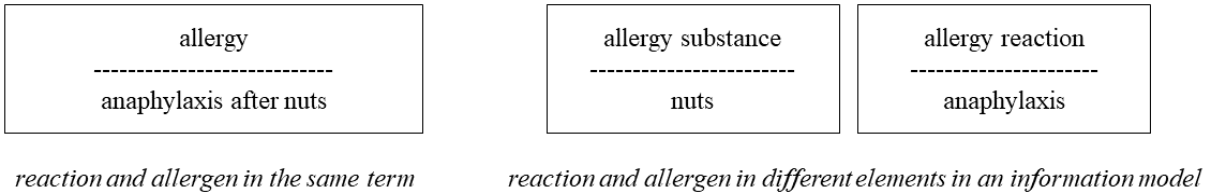
The value sets were assessed separately in the same fashion. Where a model had several possible terminologies, those that would have been used for the information needed to answer the CQs were used. The SNOMED CT Global Patient Set [35] and full SNOMED CT were considered usable in interaction, and LOINC terms that were in the same LOINC group were also considered sufficiently similar. For model-specific value sets, common in, for example, status elements, the included values were compared and if they were equivalent, this counted as

usable in interaction. All binding strengths have been assigned equal weight. When no value set was recommended, this was given the value 0.

Definitions

Information models, terminologies, and ontologies are all developed to structure information about things. In some subject areas, ontologies are in themselves sufficient to structure most information, whereas in health care, information models and terminologies or ontologies are usually used in conjunction. A division between information model and terminology is useful, as it makes the requirements on the terminology less complex. However, it leads to what is sometimes called the boundary problem, that is, the difficulty of deciding what information should be structured with the information model and what information should be structured with the terminology [7,8] (see example in Figure 2).

Figure 2. Examples of different ways of using information model and terminology in conjunction.



When not otherwise stated, we use the term information model for an information model, including its terminology bindings, that is, the terminologies or ontologies stated in it, when present. The term element is used for parts of the information model, sometimes also called attributes or headings. A value set is the stated terms or codes that are allowed for a certain element. Sometimes, a value set included entire terminology, for example, LOINC, International Classification of Diseases Tenth Revision (ICD-10), or SNOMED CT. Value set specifications may provide a binding strength to describe the flexibility with which members can be used while being compatible with the value set definition. For example, the FHIR framework provides 4 levels of binding strength: required (value set cannot be changed, eg, by extension), extensible (value set can be extended), preferred (the value set is recommended but not mandatory), and example (value set is an example only) [36]. For easier comparison of results, we have interpreted the binding strengths in the information models and described them using the FHIR definitions above.

Results

Research Question 1: How Does the Content of Health Care Information Differ Between Information Models?

The answers to the CQs included repeating types of information. The types of information are listed in Table 3, and the results below are presented per type. Note that the results depict the information needed to answer the CQs and not an overall evaluation of that information type.

Table 3. Types of information.

	Explanation	Example of competency question
Time and period	Point or period of time	What day and time was the central venous line inserted?
Procedures	Type, location, and status	Has the patient undergone radiography or ultrasound imaging?
Conditions	Type and status	Does the patient have renal impairment?
Causalities	Linking between elements or a specific causality element	Is the catheter occlusion considered due to thrombotisation?
Medications	Medicinal product	Has the patient received anticoagulant therapy?
Device types	Type or model of device used	What type of dressing was used?
Results of examinations	Type of examination and result	Does the patient have oxygen saturation below 90%?
Complex professional judgments	Assessments based on several discrete inputs and medical experience, often accompanied by motivation and degree of certainty	Is the patient's life at risk? What is the patient's need for central venous access?

Coverage

Results regarding coverage, that is, what information the included models had capacity to structure in a way that allowed answering of CQs, is provided per information model and type of information in Figure 3. With some exceptions, the differences in coverage were small between the included information models. The information standards and OMOP had the broadest coverage, providing structure for most types of information. SPOR could only structure information that was

requested when the registry was constructed. The EHRs could hold more information than the table implies, but some of the information was locked into structures, making it difficult to find or use it in other situations. For example, in EHR B, information about radiographic control after insertion of a central venous catheter could be found under the heading "use," where the options were "accepted for use," "may be used before radiographic control," "may not be used before radiographic control," and "other." Structures like this in EHR B were designed per instantiation and thus likely vary between settings.

Content Differences

Overall, the differences regarding the structure of information between the included information models were small. On average, 45% of the included structures were identical between models, that is, had the same demarcation between information model and terminology (Figure 4). The choice of terminology, however, showed a greater variation with, on average, only 11% overlap between models (Figure 5). Differences regarding structure were smaller than those regarding terminology (see Figure 6 for results per information type). Qualitative data on the content, that is, how information was structured and terminology was used, are presented as per the type of information below. The full result tables are provided in Multimedia Appendix 2. In the value set columns in the tables of Multimedia Appendix 2, all value sets listed within the information model are provided, although not all of them were relevant to the CQs. However, in our analysis, only the relevant value sets were considered.

Time and Period

Time is repeated in many different types of structures and thus not comparable in the same way as the other information types; hence, no table for time and period is provided in Multimedia Appendix 2. The information standards and OMOP used ISO 21090 [37] and ISO 8601 [38]. Since ISO 21090 is based on ISO 8601, they are equivalent in this setting. It was not possible to determine the exact format for the Swedish SPOR or the EHRs. Some modules in EHR B only handled time of documentation, as opposed to time of the actual event, procedure, or discovered condition. There were differences between the information models on how periods were represented. FHIR and IPS CDA used interval data types, while HCIM relied on having distinct data elements for start and end points of the period. openEHR had 3 different approaches. For action archetypes, periods could be deduced from the time difference between time-stamped events. For observation archetypes, time-related information was represented through the reference model, and for evaluation archetypes, distinct data elements were used for temporal information, similar to HCIMs.

Procedures

Information about procedures contain type of procedure (eg, insertion of central venous line), status of the procedure (eg, completed), and sometimes a location where the procedure was performed (eg, left subclavian vein). In FHIR, openEHR and OMOP procedures using a device could also be structured with the device as central information (for results regarding this, see "Device Types" below).

Procedure Type

All information standards and OMOP had a coded element within a dedicated procedure structure. SPOR and the 2 EHRs additionally had procedure-specific elements with a Boolean value. Of the information standards, none but HCIM strictly bound the procedure type to a terminology. HCIM had a binding strength of required and mandated the use of a code element in their ISO 21090–inspired CD datatype. The most commonly recommended terminologies in the included information models were SNOMED CT and the Swedish procedure classification KVÅ (Klassifikation av vårdåtgärder [39]; Swedish version and extension of Nordic Medico-Statistical Committee Classification of Surgical Procedures [40]) due to the Swedish context of some of the included information models. FHIR and IPS CDA used SNOMED CT, whereas HCIM and OMOP allowed several different value sets. The information models that used SNOMED CT pointed to different subsets. The Swedish registry SPOR and the 2 EHRs used KVÅ. They also, at times, used the term or code for the procedure as a question answered with a Boolean, for example, "C250 fluoroscopy during the procedure: yes/no."

Procedure Status

All models that had a stated status used a separate element for this. HCIM had no explicit representation of procedure status; instead, time could be both in the past and future, indicating performed or planned procedures. It was unclear how planned but not performed procedures could be discerned from performed procedures as time passes. The standards for secondary use only represented performed procedures, and this was sufficient for answering the CQs in this work. The EHRs had multiple structures. FHIR, openEHR, and IPS CDA used coded text with native value sets, which were not always one-to-one mappable between each other.

Procedure Body Location

The body location of a procedure can be represented either within the value for the procedure type (see above) or in a separate element. All models except OMOP had one or many ways to separately structure body location. FHIR, openEHR, HCIM, and SPOR also had additional elements for laterality or location qualifiers. In FHIR and openEHR, these were placed

in an extension and cluster, respectively. Many procedures have multiple possible locations, for example, regarding placing a central venous line–relevant location includes place of insertion (eg, left arm), the vessel in which the catheter is placed (eg, upper caval vein), and catheter tip location (eg, left atrium). None of the information models had a means to express the role of the body location in the procedure. All information standards, except openEHR, used SNOMED CT body structures. SPOR and the 2 EHRs used system-specific value sets.

Conditions

Condition Type

The demarcation between information model and terminology was identical for conditions in all the investigated models, except SPOR, which had an additional structure with separate Boolean elements for key conditions. Most of the compared information models used SNOMED CT as terminology, followed by ICD-10.

Condition Status

All information standards, OMOP, and EHR B, structured the status of the condition in a separate element. The information standards had at least 2 elements to capture both status (eg, present, resolved, absent) and certainty of the status (eg, unconfirmed, established, suspected). The difference between status of a condition and the certainty of the condition can lead to ambiguities; for example, in the FHIR Condition Resource, it was possible to have an active (clinicalStatus) and at the same time refuted (verificationStatus) condition. Two of the openEHR code sets and the code sets in HCIM contained codes from SNOMED CT but used different concepts, and the value sets were fully disjoint. All other codes were information model–specific. Most code sets had different granularity, that is, number of codes, making one-to-one mapping between them difficult.

Causality

Causality is a relation between entities where one is the cause of another, for example, that a deep vein thrombosis is a consequence of a central venous catheter. Of the included models, only openEHR had a separate element to document causality. openEHR also contained a LINK class, which would support this purpose, but there was no generic code set for the type of linking. In FHIR, there was a “dueTo” extension, which allowed linking conditions to their causes. The CDA standard had provisions for linking any CDA instance to any other instance, but this feature was not used for causality within the IPS CDA implementation guide. Both EHRs had structured lists for specific settings, for example, “reason for extraction” with local codes in the value set.

Medications

Only information regarding the type of medicinal product has been evaluated in this work. Information structures of timing, dosage, dose form, and substances were not included. The structure of information on medications varied depending on stage in the process of medication, that is, for example, prescribing, dispensing, administration, or consumption. There were 2 general patterns: one where there was a single coded element for the medicinal product and one where there was a complex structure of multiple elements, such as active ingredient, dose, and dose form. The information models that had terminology bindings pointed to multiple terminologies, except FHIR that stated SNOMED CT. EHR A used the Anatomic Therapeutic Chemical classification system and the Swedish national medicinal products terminology [41]; the configuration for EHR B was not finished at the time of data collection.

Device Types

Devices vary from short-time use artefacts as dressings to permanent implants as pacemakers. The results show how information about the type of devices was structured when the device was the central information. Several of the models had further elements for additional details, for example, batch number, size, or manufacturer. This was not included in this work. The information standards and OMOP had dedicated elements for devices with the name of the device in the value set, whereas SPOR and the EHRs used a terminology-bound element with a Boolean or a value set to further specify the device. FHIR, HCIM, IPS CDA, and OMOP all pointed to SNOMED CT as terminology. In general, it was also possible to document information about a device within the procedure where it was used as a distinct procedure type. This can be done with a term or concept where the device is included, for example, 1172566008 |Insertion of central venous catheter (procedure)|, but FHIR also permitted a separate element within the procedure class holding the device (in this example, 52124006 |Central venous catheter, device (physical object)|).

Results of Observations

Common observations are bedside measurements, assessment scales, and laboratory results. Information regarding observations is often a combination of a question, a result value, and a unit. Sometimes these entities were structured in separate elements, and sometimes, a part of the information was structured by terminology binding the element. For example, a measurement of the oxygen saturation could be structured into “Measurement = oxygen saturation, value = 98, and unit = %” as well as “oxygen saturation in percent = 98.” There were 2 distinct approaches to representing the results of the observations. FHIR, IPS CDA, OMOP, and EHR A rely on external terminologies to express the type of observation, whereas openEHR and HCIM develop specific information models to express the type of observation where the name of the element was bound to a terminology. SPOR and EHR B had specific elements in the information model for observations but without any terminology binding.

Complex Professional Judgments

None of the included models had a structured way to document complex judgments such as “How big problems can be expected if the central venous line is replaced?” or “Is the patient’s life at risk?”

Research Question 2: Are CQs a Feasible Way of Comparing Content in Information Models?

Development of CQs

In total, 36 CQs covering 10 recommendations were developed (Table 4). For 7 of the recommendations, the information in the recommendation was enough to develop the CQs—a task performed in a few minutes. For 2 recommendations, additional information from the guidelines was needed. One recommendation required information on what substances were included in "ADP (adenosine diphosphate) receptor antagonists" and "novel oral anticoagulants," which was not present in the guidelines.

Table 4. Information needed to develop the competency questions.

	Recommendations (n=10), n	Competency questions (n=36), n
Recommendation only	7	19
Recommendation and textual guideline	2	10
Additional information needed	1	7

As described in the Methods section, the initially assumed saturation point was revised during analysis of results, and additional CQs were developed for 2 recommendations.

Answering the CQs

The most effort in data gathering was spent on searching information about the information models and modelling. CQs covering information frequently documented in a structured way, for example, "Does the patient have renal impairment?" were relatively straightforward to answer with all the included models. For information that is rarely structured, for example, "Was a micro punction needle used?" or "What problems can be expected if the central venous line is replaced?" much time was spent on searching information about the different models to minimize risk that a possible solution was missed. The amount of work performed in modelling the information needed for the CQs is comparable to that performed in a real-life setting modelling clinical information. Time consumption thus varied widely both depending on complexity of the area and how well the chosen information model handled the area.

Assessment of Coverage and Content Differences

The results from the modelling work were complex, especially when information could be structured in several ways with the same information model or when terminology binding included multiple value sets. This was demanding to capture in a spreadsheet, but evaluation of tools was beyond the scope of this work.

Discussion

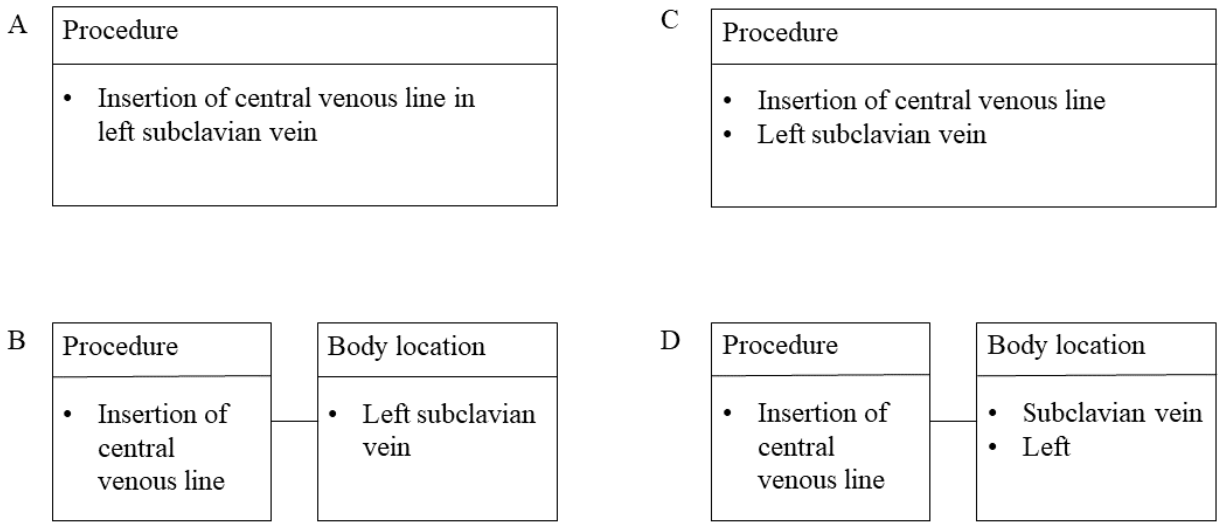
Research Question 1: How Does the Content of Health Care Information Differ Between Information Models?

When compared pairwise, the 8 included models had, on average, 45% identical structures and 11% terminologies that were sharable. Most overlaps regarding structure were present between information standards. Content that is not identical can still be similar, and our assessment is that the similarities were larger than the differences between the compared information models in general. The information models included in this study could represent most information required for answering the CQs.

Structure

Conditions and procedures have the highest overlap in structure. This information is thus readily sharable despite using different models if the used terminologies are the same or translatable. Representations of observations could be expected to be well-standardized due to its maturity but had only 40% overlap, mainly due to 2 different patterns of demarcation between information model and terminology. The same problem was present for medications and device types. Another common demarcation issue, present also for procedures and conditions, was that the EHRs and SPOR commonly used complex elements with a yes/no tick box, that is, with Boolean data type, whereas the information standards split the same information into several elements. Complex elements with tick boxes are tempting when developing structures for a specific use case but makes information sharing with structures developed for other use cases difficult. Conversion between these types of demarcation may be possible but includes risk of information loss and builds maintenance burden. In this material, the body locations for procedures and conditions could be represented either in a complex value for the procedure/condition itself (eg, insertion of central venous line in left subclavian vein or kidney failure) or separated in different ways (see examples in Figure 7). Similar issues can occur with other related information such as method.

Figure 7. Examples of using terminology or separate elements and classes. A. Using 1 element in 1 class instance. B. Using 2 elements in 2 class instances. C. Using 2 elements in 1 class instance. D. Using 3 elements in 2 class instances.



When sharing information structured with different demarcations, a compositional terminology for describing both the elements of the information model and the values in the model can be beneficial [42]. A compositional terminology allows for composition and decomposition of meaning, for example, splitting “kidney failure” into “organ failure” and “kidney” or vice versa. The information standards and OMOP all refer to SNOMED CT as a possible terminology for this type of information, and SNOMED CT logic representation may, in select cases, be used to transfer between different demarcations. For this to be possible, both the element name and the value must be terminology bound to concepts or postcoordinated expressions that are logically defined in relation to each other. Some use cases such as laterality are in that sense likely to be easier to coordinate, while others may introduce significant complexities regarding postcoordination or development of new concepts. Sometimes, different elements were mandatory in different models. In such cases, it might not be possible to share data even when the information is decomposable because obligatory information might be missing.

Terminologies

When the demarcation between information model and terminology is the same and the only difference between models is regarding terminology, information sharing possibilities depend on how easily those terminology-encoded values are converted into each other. All models used internal model-specific value sets for some elements. For example, in this material, the values for status for both procedures and conditions were different in all the included models, not only regarding terms but also by the number of values, making one-to-one mapping very difficult, not to say impossible, without information loss or distortion. Some values were, however, present in the code sets of all information models; for example, all models had a value to represent the status “the patient has this condition now” and that could thus be mapped between models. This confirms previous work, which showed that Apgar score representation had similar structures in HL7v3 DMIM (Health Level 7 version 3 Domain Message Information Model) and openEHR but were poorly bound to terminology [2] and that few value sets were aligned between the models when comparing openEHR and 3 HL7 formats for adverse sensitivity [12], although in the latter case, a joint openEHR-FHIR review has improved alignment [43].

The openEHR archetypes studied in this work were outliers compared to the other included information models in that few specific external terminologies were referred to. According to openEHR methodology, terminology binding is postponed to the templating phase, but while reviewing international templates, no additional terminology bindings were found. In this material, FHIR, HCIM, IPS CDA, and OMOP on the other hand often referred to external international terminologies, especially for larger value sets.

Where the models point to an existing terminology, there will be times when a suitable concept does not exist and therefore needs to be developed. In this material, there was, for example, no suitable concept within SNOMED CT to document the type of bandage used, despite SNOMED CT being the recommended terminology for several of the models. SNOMED CT provides the possibility to post coordinate concepts. However, postcoordination has drawbacks; for example, many health care information systems lack the capability to handle postcoordinated expressions, and postcoordinated expressions lack a human-readable term. Further, the concept model must permit the needed modelling, and the concepts needed for modelling must exist or be created [3]. Postcoordination has thus not been included as a possibility for value sets based on SNOMED CT.

Using the same terminology does not necessarily mean that the exact same code is used. For example, SNOMED CT contains 233527006 |Central venous cannula insertion (procedure)|, which has 16 more granular child concepts, and any of these could be used to document the insertion of a central venous

catheter where SNOMED CT is the recommended terminology. Lack of concepts, and to an extent, the lack of capabilities to postcoordinate have led to the development of national or implementation-specific extensions to many international terminologies, including SNOMED CT and ICD-10.

Internal Variability

The information standards aim to cover a wide range of information and offer complex structures to achieve this. They also sometimes have several different ways to structure the same information on varying levels of detail, leading to internal variability. This has been shown in evaluations of implementations of information models [13,44]. The standards for secondary use had a more rigid structure, only permitting 1 way to structure per type of information. The EHRs aim to capture all information and rely on free text to a higher degree than the other included types of models. Free text is, however, very hard to share unambiguously. Some information relevant in this work was structured very specifically in the EHRs, for example, "radiographic control before use of central venous catheter." Other types of radiography procedures were not examined but it is unlikely that all radiography examinations are structured like this, and this is thus an example of the same procedure being structured in multiple ways also in the EHRs.

In FHIR and openEHR, structured information could be added in extensions or slots. In our material, this was found for causality (FHIR), procedure body location (FHIR and openEHR), and medication detail (openEHR). These might be tempting if the other option is free text; however, additions like this risk add to complexity and internal variability. Where information can be structured in several ways, there is a risk that instantiated information is erroneous, for example, an "upper arm fracture in the leg." Having multiple elements to construct the meaning of a clinical statement increases the need for the sophisticated validation of information either during or after data entry to avoid mishaps.

Areas of Poor Coverage

Complex professional judgments were not possible to structure with any of the included models. Perhaps complex professional judgments are most easily documented as free text. Placing them in a terminology-bound element in an information model would facilitate identifying and sharing the information despite it being unstructured. openEHR and FHIR were the only included models that could structure causality, both by using extension and slots, thereby opening the potential for a higher degree of variability.

Research Question 2: Are CQs a Feasible Way of Comparing Content in Information Models?

The CQ method was a good way to probe deeper into information models from a clinically relevant perspective. The CQs revealed the types of information that were poorly structured or completely omitted—areas that are easily overseen when assessing the same information model from a theoretical perspective. One could argue that CQs leave the door ajar to bias from the evaluator, as opposed to a more formal method where the information models are described in the same format and then compared [45,46]. However, the information models relevant to compare are only available in different formalisms, often specific to the respective model, thereby restricting the use of such formal methods. Further, formal comparisons between models that differ in their demarcation between information model and terminology is not possible unless all elements are terminology bound to a machine-readable terminology, which they rarely are. Care should be taken when deciding how much effort to put into answering the CQs. Those covering information rarely structured are laborious to answer and perhaps more useful as a marker for where information is so complex that free text is the most suitable way to document it.

To cover all possible types of information, it might be necessary to push beyond the initially deemed saturation point. Perhaps, future work could use a 2-step saturation point by first developing CQs until no new types of information are uncovered and then modelling answers for the developed CQs, omitting those that duplicate already performed modelling work. This would avoid massive duplicative modelling.

Limitations

The CQs do not push the boundaries of what the information models can handle. For example, multiple body locations or status other than "performed" or "present" for procedures or conditions are not included nor are many of the intricacies about pharmaceutical information. There might be greater differences between models than this work has revealed. The information modelling done in this work is best effort but not best possible. The modelling was not discussed with additional parties external to this study; however, this might be in correspondence with results in a real-life setting, where the amount of effort is limited by existing resources, including access to domain and informatics experts.

Conclusions

Formal comparisons between information models show incompatibilities that are often merely theoretical [4,47], whereas practical work has shown that conversion between models for secondary use is doable [5,10,11]. This work shows that in practice, different information models structure much information in a similar fashion. To increase interoperability within and between systems, it is thus more important to move toward structuring information with any information model than finding or developing a single, perfect information model. When choosing an information model, one should consider that international standards have the best coverage and overlap between information models. They are also likely to be more widely adopted, decreasing the need for conversion before information exchange and have more users putting effort into developing them. As a final delimiter, assess the demarcation between information model and terminology and choose an information model that is similar to those of whom information is to be shared with. Put effort into decreasing internal variability and increasing terminology binding to external terminologies. The CQ method was successfully applied to the challenge of comparing health care information models. This method is a feasible way of evaluating how information models perform in practice, thereby adding valuable qualitative data on similarities and differences.

Acknowledgments

AR developed the competency questions. AR and DK performed modelling, analysis of results, and writing together. Thanks to Eva Blomqvist for contribution to initial ideas and anonymous reviewers for valuable comments.

Abstract

Background: Electronic patient portals are online applications that allow patients access to their own health information, a form of asynchronous virtual care. The long-term impact of portals on the use of traditional primary care services is unclear, but it is an important question at this juncture, when portals are being incorporated into many primary care practices.

Objective: We sought to investigate how an electronic patient portal affected the use of traditional, synchronous primary care services over a much longer time period than any existing studies and to assess the impact of portal messaging on clinicians' workload.

Methods: We conducted a propensity-score–matched, open-cohort, interrupted time-series evaluation of a primary care portal from its implementation in 2010. We extracted information from the electronic medical record regarding age, sex, education, income, family health team enrollment, diagnoses at index date, and number of medications prescribed in the previous year. We also extracted the annual number of encounters for up to 8 years before and after the index date and provider time spent on secure messaging through the portal.

Results: A total of 7247 eligible portal patients and 7647 eligible potential controls were identified, with 3696 patients matched one to one. We found that portal registration was associated with an increase in the number of certain traditional encounters over the time period surrounding portal registration. Following the index year, there was a significant jump in annual number of visits to physicians in the portal arm (0.42 more visits/year vs control, $P<.001$) but not for visits to nurse practitioners and physician assistants. The annual number of calls to the practice triage nurses also showed a greater increase in the portal arm compared to the control arm after the index year (an additional 0.10 calls, $P=.006$). The average provider time spent on portal-related work was 5.7 minutes per patient per year.

Conclusions: We found that portal registration was associated with a subsequent increase in the number of some traditional encounters and an increase in clerical workload for providers. Portals have enormous potential to truly engage patients as partners in their own health care, but their impact on use of traditional health care services and clerical burden must also be considered when they are incorporated into primary care.

Introduction

Electronic patient portals are online applications that allow patients access to their own health information, a form of asynchronous virtual care. There has been a great deal of recent interest in patient portals, accompanied by increasing technology adoption by both clinicians and patients [1-3]. The COVID-19 pandemic has also highlighted the importance of virtual care, an area already identified as a national health care priority [4]. Although portal features vary, the safe communication channels in portals may provide alternative ways for patients to obtain services traditionally provided in person, such as renewing prescriptions, sending and receiving secure messages, obtaining test results, and booking appointments [5]. A recent survey indicated that approximately 20% of Canadians had accessed some of their own medical information electronically, and that almost 80% were interested in doing so [6]. However, that survey did not specifically address portals or patient access to their medical information in primary care practice settings, and we are not aware of any studies examining Canadian portal adoption in primary care. Our understanding of the potential value of patient portals is nascent, with portals expected to contribute to more authentic collaboration between clinicians and patients.

The long-term impact of portals on traditional primary care services is unclear, but it is an important question at this juncture, when portals are being incorporated into primary care practices. Many studies reporting on the impact of portals on the use of traditional services evaluated systems that only provided options for web messaging or booking appointments [7-13]. All existing studies that investigated portals with more diverse features were conducted in medical networks, such as health maintenance organizations, where the portals provided access across sectors, including primary care, specialty care, and hospital care; these studies may not be relevant to portals incorporated into exclusively primary care practices. Past studies also reported inconsistent findings regarding the impact of portals on traditional health care use. Some studies demonstrated an increase in visits [14-16] or telephone calls [17]. Others demonstrated no change in visits [18], a reduction in visits [19], or a reduction in hospital readmissions [20]. All these studies also had limited time frames, examining only the period 12 to 30 months after portal registration.

To our knowledge, no long-term evaluation of the impact of a primary care patient portal on traditional health care use has been conducted to date. Providers have expressed interest in patient portals but also concerns regarding medicolegal risk and clerical workload [21]. Some have described an increased clerical burden associated with portals as part of the electronic health environment [12,22]. For instance, a qualitative study examining online patient access to their own health records found that providers felt that their workload had increased as a result [23], while another found that some providers anticipated fewer administrative requests for information when patients had access to their own health records [24]. One study found that online patient access to encounter notes did not significantly affect physician workload [25], although others have described high volumes of portal messages sent by patients [26]. However, no studies have actually tracked the provider time spent specifically on portal-related work. There have also not been any large studies of the impact of electronic patient portals in a Canadian setting. We sought to investigate how an electronic patient portal affects traditional, synchronous, primary care health care use over a much longer time period than any existing studies, and to assess the impact of portal messaging on clinicians' workload.

Methods

We conducted a propensity-score–matched, open-cohort, interrupted time-series (ITS) evaluation of a primary care portal from its implementation in 2010.

Setting and Study Participants

The practice was a semirural interprofessional clinic in southeastern Ontario, Canada, where 12 family physicians and other allied health providers provide comprehensive primary care under a single-payer model. Under this publicly funded model, physician compensation is primarily through capitation payments for rostered patients. The primary care patient portal initially offered access to laboratory results, the ability to enter vital signs such as blood pressure measurements, and the ability to view when certain screening maneuvers were due. Additional features were introduced over time, including the ability to receive secure messages (in 2012), send secure messages (in 2015), book appointments (in 2016), and renew prescriptions (in 2018.) All practice patients were invited to join the portal via email, posters, and telephone reminders and at in-person encounters.

We collected data for all practice patients except those seen exclusively for focused care (eg, obstetrical care). We retained data from all patients only for the period they were aged 18 years or older. Among patients who adopted the portal, we excluded those for whom we did not have at least one year of data prior to and following their portal registration (ie, index) date. For non–portal patients, we excluded those who did not have at least two consecutive years of data between 2009 and 2019.

Matching

We calculated propensity scores to estimate the probability of individuals registering for the portal using logistic regression [27,28]. Propensity scores were derived based on sex, age, whether the patient was rostered to the family health team, the presence of specific diagnoses on the index date, and the number of in-person and telephone encounters, as well as the number of unique medications prescribed in the 12 months prior to the index date. During the study time period, all appointments with medical doctors (MDs), nurse practitioners (NPs), and physician

assistants (PAs) were in person. Since education and income level were recorded for approximately a third of patients, these measures were not included in the propensity score matching. Control patients were entered into the equation for each year they were eligible (ie, for each year they had at least one year of data prior to and after the index date), with their corresponding profile for that year. July 1 of that year was considered the index date.

Variables, Data Sources, and Measurement

The study period was January 2002 through December 2019. We extracted electronic medical record information on patient age, sex, education, income, enrollment with the practice, and presence or absence of specific diagnoses on the index date. We also extracted the dates of in-person encounters with MDs, NPs, and PAs; dates of triage calls (TCs) to the practice triage nurses; and prescription dates and prescribed medications. Prescribed medications included only those that were identified as distinct medications using Anatomical Therapeutic Chemical codes. Diagnoses were defined based on diagnostic codes, using the earliest date when the diagnostic code was applied.

In order to study the clinician workload associated with the portal, two providers (KF and MF) time stamped their portal messages between February 20, 2020, and February 25, 2021. This allowed us to estimate the average provider time spent per message. We also collected the total number of portal messages sent by all providers to all portal patients between January 1, 2019, and December 31, 2019, in order to determine the average amount of time spent per patient on portal-related work.

Analyses

We described the profile of eligible patients prior to matching on their index date for portal patients on July 1 of the median year for which they were eligible to be matched for non–portal patients and again for the matched patients on their index date in both arms. The main study outcome was the frequency of in-person encounters with MDs, NPs, or PAs, as well as frequency of TCs. We used an ITS design to evaluate the impact of portal registration on use of these traditional health care services over time and compared use by portal users to their matched controls. We present the results in the usual ITS format, defining time relative to the index date with year 0 representing the 12 months preceding and including the index date and each time unit representing a 12-month interval. The ITS model includes time as a linear variable to model for an underlying linear time trend and the portal enrollment (ie, the intervention) as a dummy variable. Intervention and time interaction is also included in the model to identify the effect of the intervention on both arms (ie, portal and non–portal) over time.

We plotted the annual number of in-person encounters with MDs, in-person encounters with NPs or PAs, and TCs across time and overlaid the estimates derived from the ITS equations. During the study time period, all appointments with MDs, NPs, and PAs were in person. Because the year-0 results showed a spike in service use in both study groups, likely related to the attribution of the index date, we excluded that year from the ITS model. Also, although the spike in service use at year 1 in the portal arm may represent a transient change in behavior associated with the initial adoption, we also excluded this from the ITS to obtain a more reliable estimate of the impact of portal adoption over time, recognizing that this approach omits significant use; this should be considered in result interpretation.

We also depicted the number of visits per calendar year for patients who adopted the portal grouped by year of portal registration to demonstrate the pattern of changes in these visits over time for the intervention arm.

Ethics Approval

Ethics approval was received from the Bruyère Research Ethics Board (M16-20-012).

Results

Matching

Of the 14,894 patients who met the study criteria, 7247 (48.7%) were portal participants. Of these, 3696 were matched one to one with a control patient (Figure 1). The profile of all eligible patients before and after propensity matching is shown in Table 1. Before matching, portal users differed from non–portal users, but after matching, the mean propensity scores of the 2 groups and their index years, the prevalence of chronic conditions, sex, rostering status, and total visits and medications in the previous years showed good agreement. Income and education levels, which could not be included in the propensity score derivation because of poor data completeness, remained higher in the portal group.

We used a caliper of 0.2 for matching and limited the potential matching pool for each portal patient to non–portal patients with an index date that was within 1 year of the portal patient's index date. We identified all potential controls for each portal patient and assigned matches prioritizing first portal patients who had a unique match, then non–portal patients who had a unique portal match. We repeated this after each match to minimize loss of controls. When more than one match was possible, we attributed the control patient whose propensity score was closest to the portal patient's score. The balance of baseline covariates between the matched portal users and non–portal users was assessed using standardized differences, with values <0.1 representing negligible differences.

Figure 1. Study patient selection.

[a]Index date for unmatched control patients: July 1 of the median year of their eligible time period.

[b]The value of n for 2010 was smaller than 6. The cells for 2010, 2014, and 2018 therefore do not have precise values due to ethics agreements.

[c]Income and education level were not available for all patients.

[d]CAD $1.00=US $0.75 on January 12, 2023.

[e]Number of medications prescribed and number of encounters refer to the 12-month period prior to the index date. The medication records were mapped to the Drug Product Database to assign Anatomical Therapeutic Chemical codes and schedules based on drug identification numbers. We excluded 12.5% of medication records, including records for medications classified as “over-the-counter” or “ethical” in the schedules from the Drug Product Database (4.9%) and medications reclassified manually as “over-the-counter,” “other,” or “N/A” (4.7%). Medications with no drug identification number were classified manually. Those which could not be attributed a drug identification number were also excluded (2.9%). Variable categorization for number of visits, telephone calls and medications was based on clinical judgement and the number of participants in each category.

Analyses

We plotted the number of visits in relation to the index year for portal and control patients, the estimated slopes for the years before and after the transition, and the shift in visits at the index date derived from the ITS equation (Figures 2-4). The information for the years prior to the index date for portal patients demonstrates their annual visits for the years prior to their registration on the portal. The index date for the control patients was assigned to be within 1 year of the portal’s patient index date in order to control for temporal factors such as health care use trends. The outputs of the ITS analyses are provided in Table 2. The intercepts and slopes prior to the index year were similar in the control and portal arms for MDs, NPs/PAs, and TCs (*P*>.05). After the index year, there was a significant jump in MD visits in the portal arm (0.42 more visits/year vs control, *P*<.001) but not for NP or PA visits. The TCs also showed a greater increase in visits in the portal arm compared to the control arm after the index year (0.102 more visits/year vs control, *P*=.006).

Figure 2. Interrupted time series for MD face-to-face visits for portal patients versus controls. The intercepts (*P*=.86) and slopes (*P*=.15) prior to the index year were similar in the control and portal arms. After the index year, there was no significant change in the number of MD visits in the control arm. However, in the portal arm, there was a significant jump in number of visits and a new intercept (0.42 more visits/year vs control, *P*<.001). The slope for MD visits increased after the index date in the control arm but became negative in the portal arm, representing an annual reduction of 0.054 visits per year for the portal arm compared to the control arm (*P*=.001). The two slopes would be expected to cross after 10 years. CLI: confidence limit interval; MD: medical doctor.

	Portal Patients	Control Patients	*P* value
Preintervention slope	0.023	0.0089	
Postintervention slope	-0.010	0.045	
Intervention absolute increase in annual # of visits	0.42	0.0022	<.001

Figure 3. Interrupted time series for nurse practitioner or physician assistant face-to-face visits for portal patients versus controls. The intercepts (*P*=.59) and slopes (*P*=.12) prior to the index year were similar in the control and portal arms. After the index year, there was not a significant change in the number of nurse practitioner or physician assistant visits in the portal arm compared to the control arm (*P*=.21). The slope flattened after the index date in the control arm, but it was relatively unchanged in the portal arm, demonstrating an annual increase of 0.028 visits per year in the portal arm compared to the control arm (*P*=.01). CLI: confidence limit interval; PA: physician assistant; NP; nurse practitioner.

	Portal Patients	Control Patients	*P* value
Preintervention slope	0.039	0.049	
Postintervention slope	0.036	0.0071	
Intervention absolute increase in annual # of visits	0.058	-0.011	.21

Figure 4. Interrupted time series for triage calls for portal patients versus controls. The intercepts (*P*=.10) and slopes (*P*=.26) prior to the index year were similar in the control and portal arms. The number of triage calls following the index year showed a higher value than anticipated based on the preindex slope in the control arm (0.062 more calls annually, *P*=.02), but a significantly greater jump after the index year in the portal arm (0.10 more calls annually, *P*=.006). The slopes for annual triage calls were similar in the pre- and postindex periods for both the control arm and portal arm. CLI: confidence limit interval.

	Portal Patients	Control Patients	*P* value
Preintervention slope	0.040	0.045	
Postintervention slope	0.050	0.055	
Intervention absolute increase in annual # of visits	0.16	0.062	.006

Table 2. Outputs of the interrupted time series. “Annual visits” indicates slope; “period” indicates the pre- or postindex period.

[a]Control arm intercept.

[b]Pre–index date slope of annual visits for the control arm.

[c]Change in number of visits in year 2 post–index date relative to that anticipated from preindex slope for the control arm.

[d]Change in the slope of annual visits in the postindex period relative to the preindex period for the control arm.

[e]Difference between the portal arm and control arm in the intercept.

[f]Difference between the portal arm and control arm in the pre–index date slope of annual visits.

[g]Difference between the portal arm and control arm in the change in number of visits in year 2 post–index date relative to that anticipated from preindex slope.

[h]Difference between the portal arm and control arm in the change of the slope of annual visits in the postindex period relative to the preindex period.

We also plotted the visit rates for each year for patients having enrolled in the portal, grouped by year of portal registration (Figures 5-7).

The 2 physicians who time stamped 2061 portal messages spent an average of 3.83 minutes on each message. We also extracted the total number of portal messages sent by all providers between January 1 and December 31, 2019, and found that an average of 1.49 messages were sent to each portal patient in the practice. Thus, the average amount of provider time devoted to portal messages was estimated to be 5.7 minutes per portal patient per year.

Figure 5. Number of visits to medical doctors per calendar year for each patient group (registered on the portal in 2011-2012, 2013-2014, 2015-2016, and 2017-2018). To reduce noise, the number of visits represents the running average of that year, the previous year, and the following year. The MD visits showed a slight increase in the number of visits in the years immediately following portal registration, followed by an apparent drop in annual rate of visits.

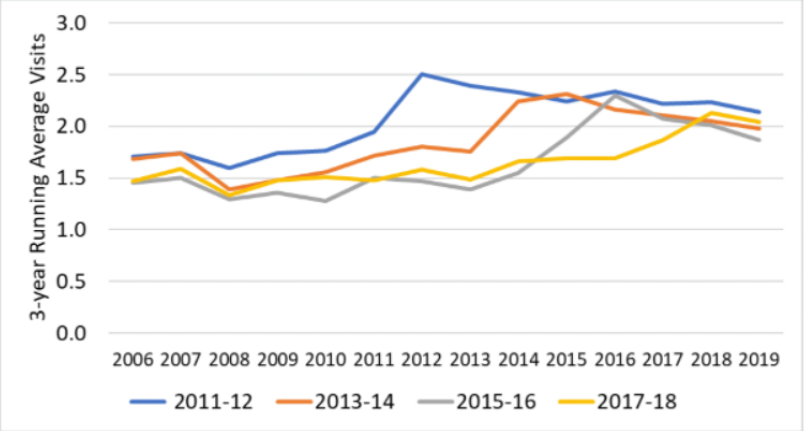

Figure 6. Number of visits to nurse practitioners or physician assistants for each patient group (registered on the portal in 2011-2012, 2013-2014, 2015-2016, and 2017-2018). To reduce noise, the number of visits represents the running average of that year, the previous year, and the following year. The NP and PA visits began in 2006 and show a rapid rise in the number of visits until 2010, then a considerable flattening of that slope afterwards with a potential small spike following the year of registration.

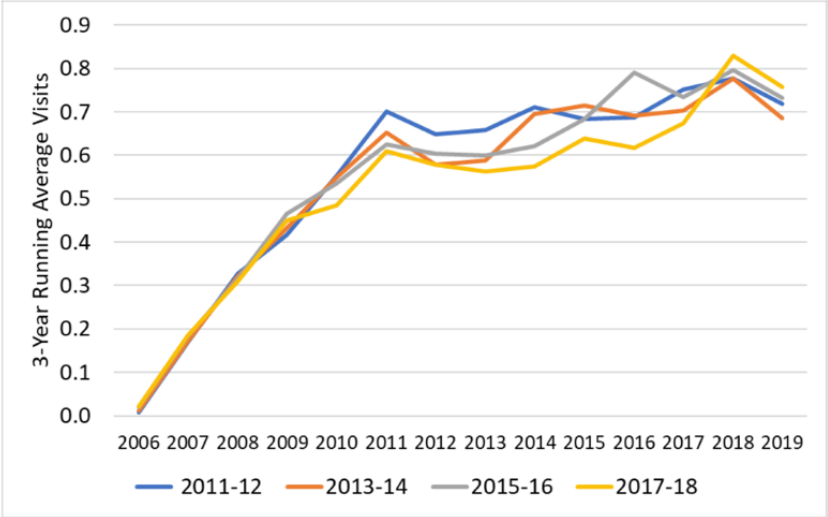

Figure 7. Number of triage calls per calendar year for each patient group (registered on the portal in 2011-2012, 2013-2014, 2015-2016, and 2017-2018). To reduce noise, the number of visits represents the running average of that year, the previous year, and the following year. The nurse triage calls were introduced in 2010 and show a consistent rise in frequency over time with a small increase in calls associated with the year of portal registration.

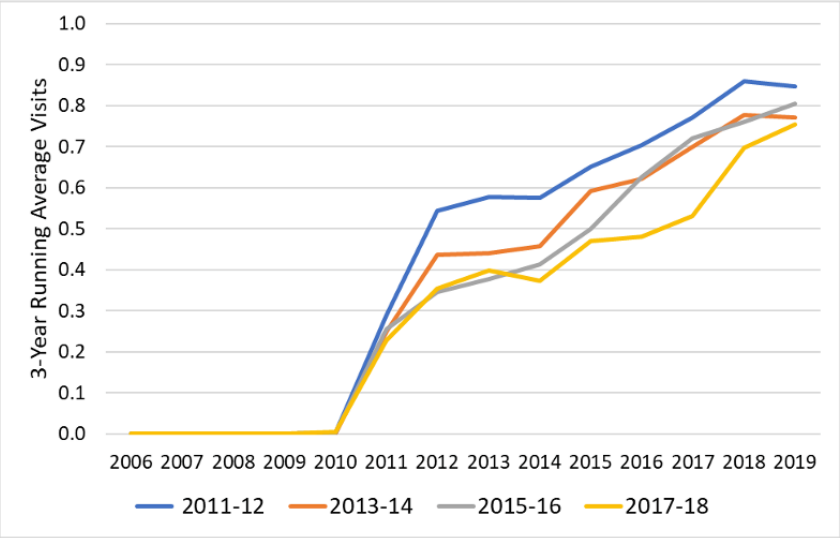

Discussion

Main Findings

Our findings suggest that portal registration is associated with an increase in service use, but that some reductions may be expected over subsequent years. Compared to matched controls, portal registration was associated with a significant initial increase in the number of in-person MD encounters and telephone calls, but a subsequent drop in the rate of MD visits and increase in NP visits over time. MDs spent an estimated 5.7 minutes per patient annually to respond to portal messages.

Limitations and Comparison With Prior Work

We believe that ours is the first study to examine the trend in encounters after portal registration over an extended time span and the first study to examine the impact of an exclusively primary care portal on traditional health care usage. It is possible that the observed increase in encounters was due to differences between the two groups that were not captured in the propensity matching. For instance, patients might have registered on the portal when they developed a new health concern, anticipating an increased requirement for health services. The reason for the gradual decrease in MD visits but increase in NP visits that took place after the initial jump in MD visits associated with portal registration is difficult to determine without further study. It is possible that patients initially presented to their own physician after sending them a portal message or viewing results, but the physician shared follow-up care with the nurse practitioner or physician assistant.

There may have been differences in areas such as electronic literacy or internet access that were not identified. It is also possible that the higher frequency of in-person encounters after portal registration was due to increased engagement by patients in their health. For instance, access to laboratory results may have generated questions from patients [29]. Increased awareness of being due for cancer screening or diabetes or blood pressure monitoring may have resulted in a higher number of encounters but improved quality of care or patient satisfaction. We did not examine these areas as they were beyond the scope of this study, but they would benefit from future research. While some past studies demonstrated improvements in certain health outcomes associated with electronic patient portals [30-33], only a few were based in primary care [31,34]. Several systematic reviews that evaluated a variety of portals in different practice settings suggested that portals or similar digital health services may result in improved patient satisfaction, but they did not demonstrate a meaningful impact on health outcomes, cost, or use [35-40].

We found that providers spent less than 6 minutes per year on clerical work for each patient registered on the portal. This is a small amount of time per patient but is significant when considering the context of an entire primary care practice. We note that the time-stamping of messages was performed during the COVID-19 pandemic, while the number of messages sent by all providers was collected prior to 2020. We consider that even if the COVID-19 pandemic resulted in an increased number of messages, the provider time per message would not have changed significantly. Therefore, our estimate of portal-related clerical work reflects prepandemic time requirements, and these may have increased since 2020 due to increased patient interest in asynchronous virtual care. This would also be an area for further study. Portals that do not allow incoming messages or any secure messaging would reduce or eliminate this time requirement but might also limit patient engagement and other potential benefits of the portal. Since the clerical burden associated with electronic environments in health care has been associated with professional burnout, [22,26] it is important to consider the provider time requirement associated with patient portals. The time and cost associated with incorporating a patient portal are currently not specifically addressed in either fee-for-service or capitated Canadian primary care funding models.

There are other limitations to this study. We examined the long-term impact of an electronic patient portal in a single

primary care practice, which may not be reflective of the impact in other primary care practices. However, portal adoption has not been widespread for long enough to allow study of the long-term impact of portals across multiple sites. Additionally, the impact of patient portals in other settings, such as hospitals, laboratories, or specialist practices, may be quite different. Further research is needed into electronic patient portals in different settings to determine their impact on various health outcomes.

Conclusions

Electronic patient portals are increasingly being adopted by providers and sought after by patients. We found that portal registration was associated with a subsequent increase in the number of some traditional encounters and a small increase in clerical workload for providers. Portals have enormous potential to truly engage patients as partners in their own health care, but their impact on use of traditional health care services and clerical burden must also be considered when they are incorporated into primary care.

Abstract

Background: Hydroxychloroquine (HCQ) is commonly used for patients with autoimmune conditions. Long-term use of HCQ can cause retinal toxicity, but this risk can be reduced if high doses are avoided.

Objective: We developed and piloted an electronic health record–based dashboard to improve the safe prescribing of HCQ within the Veterans Health Administration (VHA). We observed pilot facilities over a 1-year period to determine whether they were able to improve the proportion of patients receiving inappropriate doses of HCQ.

Methods: Patients receiving HCQ were identified from the VHA corporate data warehouse. Using PowerBI (Microsoft Corp), we constructed a dashboard to display patient identifiers and the most recent HCQ dose and weight (flagged if ≥5.2 mg/kg/day). Six VHA pilot facilities were enlisted to test the dashboard and invited to participate in monthly webinars. We performed an interrupted time series analysis using synthetic controls to assess changes in the proportion of patients receiving HCQ ≥5.2 mg/kg/day between October 2020 and November 2021.

Results: At the start of the study period, we identified 18,525 total users of HCQ nationwide at 128 facilities in the VHA, including 1365 patients at the 6 pilot facilities. Nationwide, at baseline, 19.8% (3671/18,525) of patients were receiving high doses of HCQ. We observed significant improvements in the proportion of HCQ prescribed at doses ≥5.2 mg/kg/day among pilot facilities after the dashboard was deployed (–0.06; 95% CI –0.08 to –0.04). The difference in the postintervention linear trend for pilot versus synthetic controls was also significant (–0.06; 95% CI –0.08 to –0.05).

Conclusions: The use of an electronic health record–based dashboard reduced the proportion of patients receiving higher than recommended doses of HCQ and significantly improved performance at 6 VHA facilities. National roll-out of the dashboard will enable further improvements in the safe prescribing of HCQ.

Introduction

Hydroxychloroquine (HCQ) is among the most commonly used medications for patients with autoimmune conditions and received special attention in 2020 as a potential treatment for COVID-19, resulting in drug shortages for chronic users [1]. These drug shortages, combined with recent guidelines emphasizing toxicities associated with long-term use, highlighted the issue of prescribing HCQ in appropriate doses. Long-term use of HCQ, especially at higher doses, can cause severe retinal toxicity in some patients. The risk of this toxicity is reduced if the average daily dose of HCQ is ≤5 mg/kg/day [2,3]. However, recent studies have revealed that 30%-40% of patients prescribed HCQ receive doses >5 mg/kg/day [4,5].

Previous studies have shown that enterprise-wide national dashboards are capable of improving care, but they have not been developed quickly enough, or disseminated widely enough, to make meaningful, population-level impacts on process or outcome measures [6-10]. Local, electronic health record (EHR)–based medication safety dashboards have been used to support medication safety but have not been scaled to date [11-14].

In this study, we sought to develop and deploy a national EHR-based medication safety dashboard within the Veterans Health Administration (VHA) to reduce inappropriate HCQ dosing. The VHA is the largest integrated health care delivery system in the United States, serving over 9 million veterans nationwide. Six VHA pilot facilities were enlisted to test the dashboard and invited to participate in monthly webinars. We followed pilot facilities over a 1-year period to determine whether they were able to improve the proportion of patients receiving inappropriate doses of HCQ.

Methods

Dashboard Development

The dashboard was developed as part of an ongoing project to improve the safe prescribing of high-risk disease-modifying antirheumatic drugs among VHA patients by the San Francisco VA's Measurement Science Quality Enhancement Research Initiative. It was created using PowerBI (Microsoft Corp), a data management software package available within the VHA for approved users with secure access to EHR data. The VHA's corporate data warehouse (CDW), which contains national VHA EHR data, served as the data source for the dashboard (Multimedia Appendix 1). PowerBI allows developers to extract, analyze, and display data from a variety of sources and features interactive tables and graphs that can be filtered or expanded using a graphical user interface [15]. Notably, PowerBI dashboards are "read-only," that is, users can see and filter data elements, but in order to change data (eg, update the dose of HCQ), they must do so within the EHR.

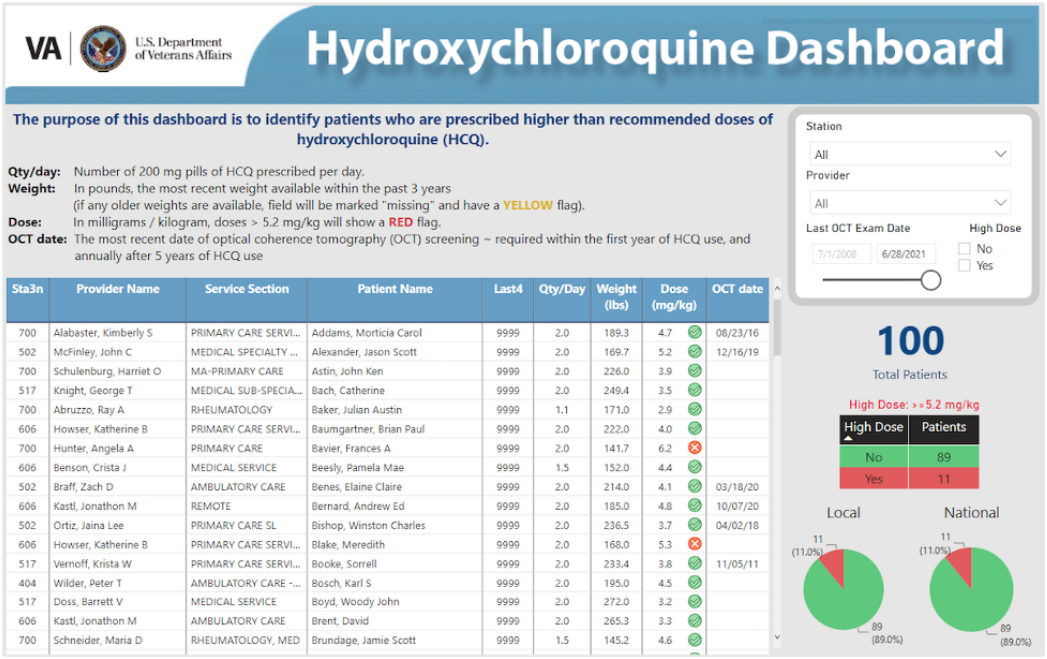
Facilities, Patients, and Data Elements

All 130 VHA facilities were eligible to be included in the study. We excluded 1 facility that had transitioned to the Cerner EHR and did not have patient data available in VistA, and 1 facility with fewer than 10 patients on HCQ, leaving 128 facilities for the analysis. Patients from included facilities in the VHA with a current, active prescription for HCQ were included in the data captured by the dashboard. Patients were excluded if the patient was deceased, or if the HCQ prescription indicated that it was a placebo or study drug. We extracted values for each patient's most recently prescribed HCQ dose (in mg per day), derived from the "quantity dispensed" and "days-supply" fields in the medication order. We also extracted the most recently captured body weight (in kg) to calculate the HCQ dose in mg/kg/day. These data were then linked to Microsoft PowerBI Gateway servers, which are automatically updated every 24 hours to reflect new information from CDW (Multimedia Appendix 1).

Dashboard Features

Figure 1 illustrates the dashboard using fictitious patient data. The dashboard displayed patient identifiers (first and last name, last 4 digits of their social security number, and VHA facility), the number of HCQ pills prescribed per day, most recently documented weight, date of most recent documented optical coherence tomography (OCT) exam, and prescriber name and service. Calculated fields included HCQ dose in mg/kg/day based on weight and the number of pills prescribed per day. Rows were marked with a red x-mark if the HCQ daily dose was calculated to be ≥5.2 mg/kg/day (vs a green check mark if <5.2 mg/kg/day) in the column immediately to the right of the dose. Patients without a recorded weight within the past 3 years were flagged with a yellow circle, indicating missing data. Rows could be filtered by facility location, provider, OCT exam date, or by HCQ dose. The dashboard also displayed national-, facility-, and prescriber-level performance (proportion of patients with HCQ doses ≥5.2 mg/kg/day out of the total number of patients receiving HCQ) shown as pie charts for benchmarking. A user guide and video tutorial for the dashboard were available via a web-based link on the dashboard landing page. User interactions (number of times the dashboard is accessed per authorized user) were tracked using the PowerBI Activity Log feature [16].

Figure 1. The hydroxychloroquine patient safety dashboard (using fictitious data). The dashboard was created using the Microsoft PowerBI software. Sta3n: unique medical facility codes for each VA station; Last 4: last 4 digits of a patient's social security number needed to identify a patient in the computerized patient record system (CPRS).



Study Period

Initial queries using CDW and PowerBI began in June 2020. The beginning of the study period—when baseline data collection on HCQ dosing across all VHA facilities started—began on August 11, 2020, prior to sharing the dashboard with any pilot testing facilities (see Multimedia Appendix 2). Of note, the final dashboard was developed over a period of under 5 months (June 2020 to October 2020).

Pilot Testing Facilities

We enlisted rheumatology providers, pharmacists, and dermatologists from 6 VHA pilot facilities to test the dashboard between October 26, 2020, and December 6, 2021. Pilot facilities were selected based on their willingness to participate in a related study involving screening for infections prior to immunosuppression. The 6 VHA pilot facilities included Ralph H Johnson VA Medical Center, Charleston, SC; Palo Alto VA Health Care System, Palo Alto, CA; VA Portland Health Care System, Portland, OR; Raymond G Murphy VA Medical Center, Albuquerque, NM; San Francisco VA Medical Center, San Francisco, CA; and Puget Sound/Seattle VA Healthcare System, Puget Sound, WA.

Pilot facilities were invited to use the dashboard via email. Once they agreed, they were granted secure access along with any additional staff at that facility. All facilities were trained in the use of the dashboard via a web-based webinar. Site personnel were invited to participate in web-based meetings of a Rheumatology Quality and Safety Workgroup to share feedback, address any barriers, and update information on the use of the dashboard, every other month. Each facility leader was also sent a quarterly facility-specific report via email with run charts depicting the proportion of patients on HCQ at doses ≥5.2 mg/kg/day and the number of times their facility accessed the dashboard during that quarter.

Each pilot facility was encouraged to develop an individualized workflow for use of the dashboard. For example, some facilities would check the dashboard weekly or monthly, while others used the downloadable report feature to distribute flagged patients to individual providers or trainees. All facility workflows included review of the dashboard, review of EHR charts of flagged patients, and HCQ dose adjustment if appropriate.

Control Facilities

Facilities in the control group did not have access to the dashboard and were not contacted as part of this study. Data on patients receiving HCQ were collected from CDW using the same process as was used for pilot facilities.

Complex Medication Instructions and Policy Change

On the dashboard, HCQ dose in mg/kg/day was calculated based on the number of pills prescribed and the patient's most recent weight. However, occasionally, HCQ orders had complex instructions (eg, "Take 2 pills Monday through Friday, and 1 pill on Saturdays and Sundays"), which resulted in miscalculations of the daily dose based on these fields. Two authors (AM and GS) reviewed 939 randomly selected charts and found 3% (28/939) of HCQ orders contained complex instructions. In order to reduce the chances of misclassifying patients as having an inappropriate HCQ dose due to complex instructions or fluctuating patient weights, on November 30, 2020, we made a policy change to designate doses of ≥5.2 mg/kg/day as "high dose" (as opposed to doses ≥5.0 mg/kg/day).

Covariates and Descriptive Variables

We assessed facility characteristic variables that might be important in relation to medication safety practices in general and HCQ dosing specifically: facility region (Midwest, North Atlantic, Continental, Southeast, and Pacific); facility

complexity (high, medium, and low); and the total number of patients prescribed HCQ at the facility [17].

In addition, we reported facility-level HCQ patient characteristics including the proportion of patients who were ≥55 years; self-identified non-Hispanic White, self-identified Hispanic or Latinx; with at least 1 VHA rheumatology clinic visit within 12 months of the beginning of the study period; and with a rural residence. Facility-level HCQ patient clinical factors included the proportion of patients with rheumatic diseases (rheumatoid arthritis, systemic lupus erythematosus [SLE], or other); with OCT exam documented; and the proportion with inappropriate HCQ dosing at baseline (August 11, 2020). A patient was considered to have a diagnosis if they had at least 2 codes (at least 30 days apart) for a specific condition listed here: rheumatoid arthritis, SLE, polymyalgia rheumatica, discoid lupus, nongout crystal arthropathy, undifferentiated connective tissue disease, sarcoidosis, antiphospholipid antibody syndrome, mixed connective tissue disease, systemic sclerosis, osteoarthritis, inflammatory myopathies (including polymyositis and dermatomyositis), psoriatic arthritis, ankylosing spondylitis, antineutrophil cytoplasmic antibody-associated vasculitis, other vasculitis (including Kawasaki disease), dermatitis, or giant cell arteritis.

Statistical Analysis

Descriptive statistics were used to summarize facility characteristics and facility-level patient characteristics. We used interrupted time series (ITS) analysis to assess the effects of the dashboard on observed changes in the proportion of patients with HCQ doses ≥5.2 mg/kg/day. ITS is a strong quasiexperimental study design that can be used for single- and multiple group comparisons. In an ITS analysis, the outcome variable of interest (eg, the average proportion of patients with HCQ doses ≥5.2 mg/kg/day) is observed over multiple time periods before and after an intervention that is expected to "interrupt" the trend over time. ITS has been previously found useful when evaluating health care interventions for its ability to evaluate the causal impact of policy changes and health care interventions without random assignment [18,19]. We used the *itsa* command, which is available in the official Stata packages *newey* and *prais* [19].

Due to large variability in key facility characteristics observed at baseline between pilot and control facilities (proportion of patients on HCQ at doses ≥5.2 mg/kg/day, facility complexity, and mean number of patients prescribed HCQ at the facility; ITS regression output are displayed in Multimedia Appendix 3), we opted to implement a robust matching method using synthetic controls to measure the impact of the dashboard on HCQ dosing at the pilot facilities. Using this approach, pilot facility performance was compared to matched synthetic controls using the *synth* package in Stata [20]. Synthetic controls were constructed from a weighted combination of control units not exposed to the dashboard but with preintervention outcome dynamics and covariate levels similar to the pilot facilities prior to any interventions [21]. Matching was based on observed changes in the proportion of patients with HCQ doses ≥5.2 mg/kg/day, facility complexity, and the mean number of patients prescribed HCQ at the facility. To assess the balance of the pilot facilities and their synthetic controls, we used the absolute standardized mean difference (ASMD). As a rule of thumb, ASMD < 0.10 is an indicator of a good balance between synthetic control unit and a treated unit [22].

As part of the multiple group ITS analysis, pilot facilities were compared to synthetic controls in weekly increments of the proportion of patients with HCQ doses ≥5.2 mg/kg/day. We estimated the coefficients using segmented ordinary least square (OLS) linear regression models in which the errors were assumed to follow a first-order autoregressive process [19]. The model was specified to base the pooled autocorrelation estimate on the autocorrelation of the residuals. We expressed the effect of the dashboard on the proportion of patients with HCQ doses ≥5.2 mg/kg/day as intercept and slope changes. The intervention date was set as October 26, 2020 (the date the pilot facilities were granted access to the dashboard). We incorporated the policy shift (shift from recording the proportion of patients receiving ≥5.0 mg/kg/day to those receiving ≥5.2 mg/kg/day on November 30, 2020) using established methods [18].

Statistical analyses were performed using Stata 15 (StataCorp LLC). A P value <.05 was used as the criterion for statistical significance.

Secondary Analyses

As secondary analyses, we compared the 6 pilot facilities to other facilities using modified Xbar-R charts. We used Microsoft QI Macros, a statistical process control software package plugin for Microsoft Excel, to generate modified Xbar-R charts to analyze the overall trends and stability in the proportion of patients with HCQ doses ≥5.2 mg/kg/day over time. Upper and lower control limits varied based on the average proportion of patients with HCQ doses ≥5.2 mg/kg/day. A continuous change of 6 or more points in a row or 8 or more points on the same side of the centerline is considered a significant trend [23].

We performed 2 separate comparisons: (1) pilot facilities versus all other facilities nationally and (2) pilot facilities versus matched control facilities. Matched control facilities were selected based on (1) the slope of proportion of patients prescribed HCQ at doses ≥5.2 mg/kg/day during the baseline period (August 11, 2020, to October 25, 2020); (2) the total number of patients prescribed HCQ; and (3) high facility complexity. Since pilot facilities had a mean) of 228 (SD 69) patients prescribed HCQ, we required matched control facilities to have at least 75 patients prescribed HCQ. Application of these criteria resulted in 8 matched control facilities, which were all included in the matched control sensitivity analysis.

Feedback From Pilot Facilities

At the end of the study period, clinicians at pilot facilities were sent a confidential survey to solicit quantitative and qualitative feedback about the dashboard. The 14-item survey included questions about the capacity in which sites used the dashboard, usability of the dashboard, suggestions for improvement, and the likelihood of recommending the dashboard to a colleague or trainee.

Ethics Approval

All VHA authors of this manuscript attest that the activities that resulted in producing this manuscript were conducted as part of a nonresearch evaluation under the authority of the National Rheumatology Field Advisory Committee and Center for Medication Safety. This work was approved by the VA Quality Enhancement Research Initiative (QUERI; IRB 15-18358).

Results

Pilot Facilities and Workflows

We identified 18,525 total users of HCQ nationwide in the VHA, including 1365 patients at the 6 pilot facilities. Across the 6 pilot facilities, 36 providers were granted access to the dashboard including 14 rheumatologists, 12 physician residents, 3 rheumatology fellows, 2 nurse practitioners specializing in rheumatology, 2 clinical pharmacists, 1 dermatologist, 1 registered nurse coordinator, and 1 primary care physician. Different pilot facilities developed different workflows around dashboard use to suit their needs. Some facilities requested access for all their clinicians (attendings and trainees) and had each one review their own patients. Others had a designated reviewer who checked the dashboard once a month or once a quarter. Another was able to download a spreadsheet containing the dashboard data and distribute it securely for clinician review (an example of typical dashboard clinic workflow for users is available in Multimedia Appendix 4). All pilot facilities had at least 20 interactions with the dashboard starting in October 2020; the median weekly number of dashboard interactions over the course of the study period was 8 (IQR 4-15).

Baseline Facility Characteristics

Table 1 shows the characteristics of pilot facilities at all facilities nationally. Nationwide, at the start of the study period, 19.8% (3671/18,525; range 4.26% to 44%) of patients prescribed HCQ were receiving HCQ ≥5 mg/kg/day versus 16.1% (220/1365) among pilot facilities.

Table 1. Facility characteristics and practice-level patient characteristics for the pilot versus all facilities at baseline (November 8, 2020).

Facility characteristics	Pilot facilities (n=6)	All facilities (N=128)
Complexity[a], n (%)		
High complexity	6 (100)	84 (66)
Medium complexity	0 (0)	18 (14)
Low complexity	0 (0)	26 (20)
Geographic location, n (%)		
Continental	0 (0)	24 (19)
Midwest	0 (0)	26 (20)
North Atlantic	0 (0)	36 (28)
Pacific	5 (83)	22 (17)
Southeast	1 (17)	20 (16)
Total patients prescribed HCQ[b], mean (SD)	228 (69)	146 (107)
Facility-level HCQ patient characteristics, mean (SD)		
Proportion of male patients	0.72 (0.05)	0.71 (0.10)
Proportion of patients aged >55 years	0.79 (0.10)	0.76 (0.09)
Proportion of non-White patients	0.33 (0.10)	0.32 (0.18)
Proportion of Hispanic/Latinx patients	0.05 (0.03)	0.05 (0.04)
Proportion of patients who visited a VA rheumatology clinic within 1 year of baseline	0.44 (0.08)	0.59 (0.19)
Proportion of patients with a rural residence	0.33 (0.02)	0.32 (0.21)
Facility-level HCQ patient clinical factors, mean (SD)		
Proportion of patients with rheumatoid arthritis[c]	0.43 (0.15)	0.45 (0.10)
Proportion of patients with systemic lupus erythematosus[c]	0.14 (0.02)	0.16 (0.04)
Proportion of patients with other rheumatic disease[c]	0.20 (0.12)	0.20 (0.12)
Proportion of patients with HCQ dose ≥5 mg/kg/day at baseline (August 11, 2020)	0.16 (0.03)	0.20 (0.07)

[a]Station complexity: high complexity facilities have large levels of patient volume, patient risk, teaching and research, and contain level 4 to 5 intensive care units; medium complexity facilities have medium levels of patient volume, medium patient risk, some teaching and/or research, and contain level 3 and 4 intensive care units; low complexity facilities have the smallest level of patient volume, little or no teaching/research, the lowest number of physician specialists per patient, and contain level 1 and 2 intensive care units.

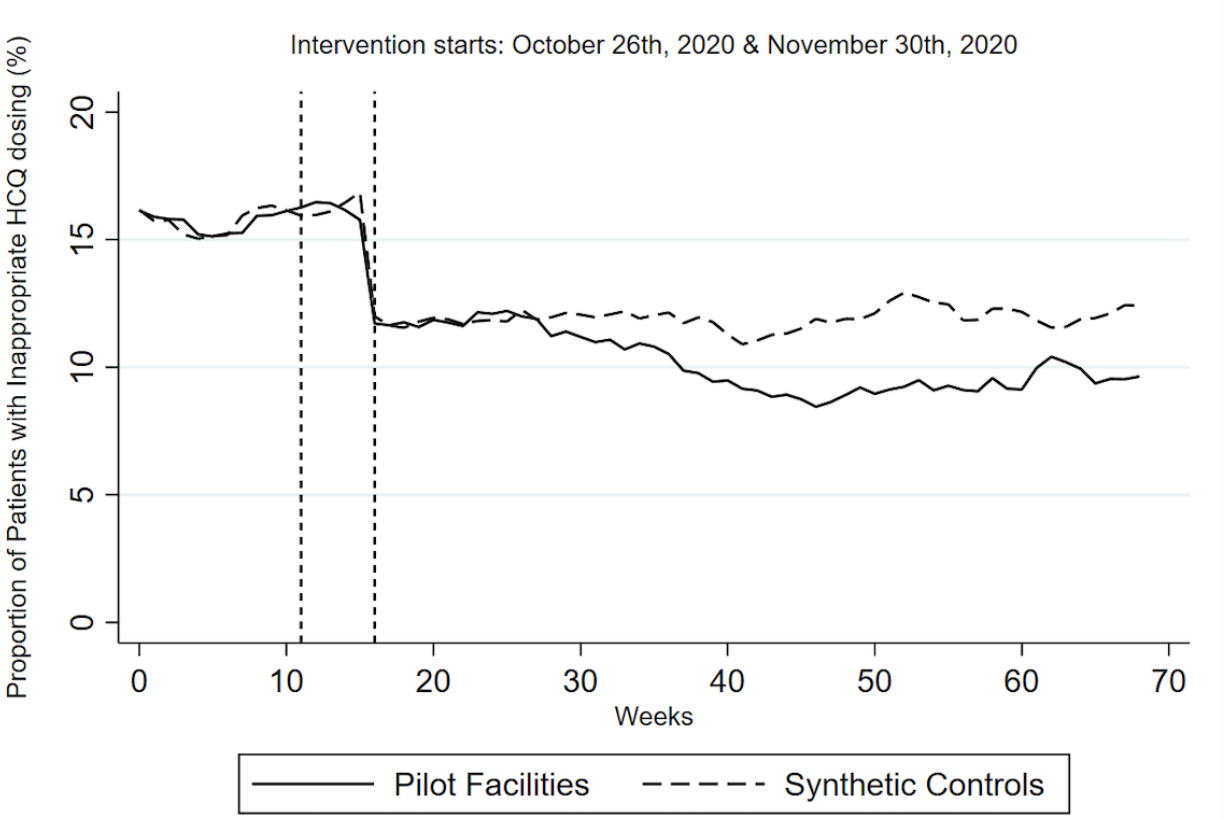
[b]HCQ: hydroxychloroquine.

[c]Rheumatic diseases were identified as veterans with 2 or more ICD-10 codes within the same disease category, separated by 30 or more days. Other autoimmune rheumatic diseases included: polymyalgia rheumatica, discoid lupus erythematosus, nongout crystal arthropathy, undifferentiated connective tissue disease, sarcoidosis, antiphospholipid syndrome, mixed connective tissue disease, systemic sclerosis, osteoarthritis, inflammatory myopathies (including polymyositis and dermatomyositis), psoriatic arthritis, ankylosing spondylitis, antineutrophil cytoplasmic antibody-associated vasculitis, and other vasculitis (including Kawasaki disease), lymphocytic infiltrates of the skin, or giant cell arteritis.

ITS Analysis With Synthetic Controls

Pilot facilities and synthetic controls were well matched in their predictor balance (ASMD=0.05). The postintervention linear trend showed pilot facilities' proportion of patients with HCQ doses ≥5.2 mg/kg/day changed by –0.06 (95% CI –0.08 to –0.04) after the policy change, while the synthetic controls remained stable (0.006; 95% CI –0.00 to 0.01), with a statistically significant difference between the 2 groups by the end of the study period (–0.06; 95% CI –0.08 to –0.05; Multimedia Appendix 5 and Figure 2).

Figure 2. Synthetic control analysis with mean proportion of patients with high HCQ doses among the 6 pilot facilities and synthetic controls. The first intervention (October 26, 2020) was the date on which the dashboard was shared with the 6 pilot facilities. The second intervention (November 30, 2020) captured the policy change of adjusting the "high dose" definition ≥5.0 mg/kg/day to ≥5.2mg/kg/day to account for complex prescription instructions. HCQ: hydroxychloroquine.



Secondary Analyses

As seen in Multimedia Appendix 6, the modified Xbar-R control chart showed meaningful improvements in the proportion of patients receiving HCQ doses ≥5.2 mg/kg among pilot facilities over the course of the study period. There was a downward trend of 21 points outside of the upper and lower control limits, indicating a significant overall average process change. In contrast, the 8 matched control facilities' proportion remained stable (ie, within the control limits). A comparison of pilot facilities to all other facilities nationally revealed similar results (Multimedia Appendix 7).

Feedback From Pilot Sites

Six clinicians, 1 from each pilot facility, responded to the web-based survey. Of these 6 clinicians, 5 reported that the dashboard was extremely easy to use, 5 answered they were extremely likely to use the dashboard in the future, and 5 responded they were extremely likely to recommend the dashboard to a colleague or trainee.

Discussion

In an era where the complexity of care and the number of evidence-based practices are ever expanding, the cognitive load required to address these practices during a short office visit can be overwhelming for clinicians. EHR-based dashboards are 1 method to support clinicians in evidence-based care of their patients. In this study, we developed an EHR-based medication safety dashboard to improve the safe prescribing of HCQ within the VHA. As part of a multipronged intervention, we found that audit and feedback via the dashboard resulted in a clinically meaningful and statistically significant reduction in the proportion of patients receiving high doses of HCQ among pilot facilities. Based on our linear postintervention trends, on the assumption that all facilities will behave similarly to the pilot sites, it would take approximately 4 years to reduce the proportion of patients receiving high HCQ doses from 16% to less than 5%.

Several features of the infrastructure available through the VHA made this a successful pilot. First, enterprise-wide PowerBI software was easily accessible as a pre-existing software suite available within the VHA for internal users. A new workspace was requested and granted within 48 hours; no new software installation was required. Second, it was straightforward to query VHA CDW data and then link these data to PowerBI servers. Construction of a first prototype of the dashboard took only a few months, and the final version (after several iterations) was available in 5 months. Beyond the VHA infrastructure, this pilot was feasible because of its limited scope to a single medication—HCQ comes in a single pill size, and most prescriptions have the number of pills dispensed corresponding to the daily dose, which facilitated calculating dose in mg/kg/day. Finally, because of its intuitive user interface, training required to use the dashboard by pilot sites was minimal.

There are few descriptions of EHR-integrated medication safety dashboards in the literature, and those that have been reported

have also been successful [24]. For example, with the use of the UK SMASH dashboard, the prevalence of potentially unsafe prescribing of nonsteroidal anti-inflammatory drugs and other medications was reduced by 41% at intervention facilities [10,11]. Another, US-based, local, pharmacist-led medication safety program, which included a dashboard and educational outreach, reduced errors by 27%-49% after 6 and 12 months of use [25]. Several US patient registries have also developed clinician-facing dashboards to improve quality and medication safety and demonstrated significant improvements over time [26].

Although our pilot project was successful, we do note some limitations for the dashboard. First, although the development and validation of data in the dashboard were smooth, there were a small fraction of patients whose calculated doses remained inaccurate due to complex instructions that did not match the number of pills supplied. We attempted to mitigate these inaccuracies by only flagging doses ≥5.2 mg/kg/day instead of 5 mg/kg/day. We made this choice to avoid falsely labeling HCQ orders as high at the expense of missing some patients receiving doses above those recommended in the latest guidelines. Further work is needed to explore whether this tradeoff is worthwhile, especially since many clinicians use complex dosing in order to avoid average daily doses of ≥5 mg/kg/day, so the use of complex instructions may be correlated with appropriate dosing. In the future, 1 potential solution could be to develop an algorithm that captures information from the complex instructions using natural language processing techniques. Second, many pilot users requested additional features that are not available through PowerBI. Most importantly, users wished to be able to annotate dashboard tables directly or unflag patients who might be receiving higher than recommended doses of HCQ deliberately due to severe disease. Unfortunately, these features were not available in the VHA implementation of PowerBI at the time of this study.

One critical question for the future is whether the improvements observed in this pilot study will be sustainable. Clinician buy-in and ongoing utilization are crucial to the effectiveness of this dashboard as a sustainable audit-and-feedback tool [25]. Several of our pilot facilities started using this dashboard as a component of their routine quality improvement activities and reported dashboard use as part of a pay-for-performance program. Other facilities incorporated its use into trainee quality improvement activities. These additional use cases make sustainability more likely.

Another important question for future studies is about the clinical effects of reducing HCQ doses for some patients. Some recent observational studies have suggested that patients with SLE who decrease their HCQ dose may be at increased risk for disease flares [27,28]. It seems unlikely that small changes in dosing would have a large effect, but nevertheless, this is an important question to investigate. Unfortunately, since this is a national study limited by using structured EHR data, it is impossible to ascertain the condition of any specific patient before or after introducing the dashboard.

Moving forward, we will test the effects of the dashboard in a national roll-out across all VHA facilities. Additional mixed methods research will aid our understanding of provider adoption and sustained use of the dashboard and whether other interventions are needed to support safe prescribing of HCQ (eg, clinical decision support for weight-based dosing, or other pharmacy-based alerts or workflows) [29]. We also plan to roll-out additional dashboards focused on other important rheumatology safety issues, including pretreatment screening for latent infections in patients receiving biologic and targeted small molecule medications and HLA B:5801 testing for eligible patients receiving allopurinol. Our hope is that with a suite of dashboards and associated toolkits, quality improvement activities will be more feasible for all clinicians.

In summary, we successfully developed and deployed an EHR-based medication safety dashboard to improve the safe prescribing of HCQ within the VHA. The use of the dashboard significantly reduced the proportion of patients receiving higher than recommended doses of HCQ at 6 VHA facilities. National roll-out of the dashboard will enable further improvements in the safe prescribing of HCQ.

Acknowledgments

This work was funded by the VA Quality Enhancement Research Initiative (QUERI) grant QIS 19-459.

Data Availability

The data that support the findings of this study are available from the Department of Veterans Affairs, but restrictions apply to the availability of these data. Data are, however, available from the authors upon reasonable request and with permission of the Department of Veterans Affairs.

Authors' Contributions

AM made substantial contributions to the conception, design, data analysis and interpretation, and the creation of the dashboards that were used in this work. GT contributed to the study design, the creation of the dashboard, and assisted with the interpretation of the data used in this work. SS and ZI made substantial contributions to the data analysis and interpretation of the data along with assistance with the drafting of the manuscript. MAW, JD, IE, JB, LB, LC, KR, EW, and MS made substantial contributions to the data acquisition and the revisions to the manuscript. GS made substantial contributions to the conception, study design, data interpretation, and drafting of the manuscript for submission. All authors read and approved the final manuscript.

Conflicts of Interest

ZI is an employee at BMS.

Abstract

Background: Personal health records (PHRs) are consumer-centric tools designed to facilitate the tracking, management, and sharing of personal health information. PHR research has mainly been conducted in high-income countries rather than in low- and middle-income countries. Moreover, previous studies that proposed PHR design in low- and middle-income countries did not describe integration with other systems, or there was no stakeholder involvement in exploring PHR requirements.

Objective: This study developed an integrated PHR architecture and prototype in Indonesia using design science research. We conducted the research in Indonesia, a low- to middle-income country with the largest population in Southeast Asia and a tiered health system.

Methods: This study followed the design science research guidelines. The requirements were identified through interviews with 37 respondents from health organizations and a questionnaire with 1012 patients. Afterward, the proposed architecture and prototype were evaluated via interviews with 6 IT or eHealth experts.

Results: The architecture design refers to The Open Group Architecture Framework version 9.2 and comprises 5 components: architecture vision, business architecture, application architecture, data architecture, and technology architecture. We developed a high-fidelity prototype for patients and physicians. In the evaluation, improvements were made to add the stakeholders and the required functionality to the PHR and add the necessary information to the functions that were developed in the prototype.

Conclusions: We used design science to illustrate PHR integration in Indonesia, which involves related stakeholders in requirement gathering and evaluation. We developed architecture and application prototypes based on health systems in Indonesia, which comprise routine health services, including disease treatment and health examinations, as well as promotive and preventive health efforts.

Introduction

Background

Current trends in health informatics encourage the transition from institution-centric to patient-centric health care [1]. The use of IT is not only for patients in health care settings but also for all individuals who want to maintain health and are involved in disease prevention and health promotion [1]. Personal health records (PHRs) are consumer-centric tools designed to facilitate the tracking, management, and sharing of personal health information [1]. PHRs contain medical data and information about a patient that are managed by the patients themselves [2]. PHRs form a trend from information controlled by the health system to information controlled by individuals [3].

In its simplest form, a PHR is a stand-alone application (stand-alone PHR) and is not connected to other systems [4]. In a more complex form, the health information provided by the PHR is linked to the electronic health record or electronic

medical record (tethered PHR) [4]. Furthermore, PHRs can be connected to various health data sources to obtain and transmit data (integrated PHR) [4]. An integrated PHR is the most ideal form of PHR as implementing PHRs in this way has the potential to improve the quality, accessibility, and delivery of health services [3].

A previous review on the implementation of PHRs shows that PHR research has mainly been conducted in high-income countries rather than in low- and middle-income countries [5]. Few studies that have been conducted in low- and middle-income countries aim to propose PHR applications for certain purposes, such as pediatric vaccination [6], or specific diseases, such as metabolic syndrome management [7], chronic heart failure [8], and kidney transplant [9]. These studies focused on the usability of PHRs and did not describe integration with other systems or applications. A study by Abdulnabi et al [10] described PHR interoperability by designing a distributed PHR model. However, there was no stakeholder involvement in exploring PHR requirements.

Using design science, we complement gaps from previous studies by developing a PHR model that is integrated with various systems, and we involve relevant stakeholders to explore the requirements and evaluate the proposed PHR model. We conducted the research in Indonesia, a low- to middle-income country with the largest population in Southeast Asia [11,12]. In Indonesia, health services are delivered by the public and private sectors. In the public sector, health facilities comprise hospitals (general and specialty) and *pusat kesehatan masyarakat* or primary health centers (Puskesmas). In the private sector, health facilities comprise hospitals and primary care clinics. In addition, there is the Social Security Agency for Health or *Badan Pelaksana Jaminan Sosial Kesehatan* (BPJS Kesehatan) that administers the national health insurance program (*Jaminan Kesehatan Nasional* [JKN] or national health insurance). Patients with JKN must follow a tiered referral flow starting from primary care facilities as gatekeepers for JKN patients before being referred to hospitals. Without a referral letter, JKN patients are not allowed to go directly to a hospital or specialist clinic except in an emergency [13].

In addition to health efforts that focus on treating and curing diseases, there are also Healthy Family (Keluarga Sehat) and Community Healthy Life Movement (Germas) programs that are managed by the Puskesmas and focus on promotive and preventive health efforts [14,15]. Currently, health development policies in Indonesia are directed at improving access to and quality of health services, with an emphasis on increasing promotive and preventive health efforts supported by innovation and the use of technology [16]. Integrated PHRs can be an opportunity to improve access to and quality of health services in Indonesia by using IT [17].

Objectives

As a technological solution for integrated PHRs in Indonesia, this study developed an integrated PHR architecture and prototype in Indonesia using the design science research (DSR) approach by Hevner et al [18]. The DSR approach was chosen in this study as the goal of DSR is to focus on designing systems that not only are practical but can also contribute to knowledge. The question that will be answered in this research is as follows: How are the architectural designs and prototypes of integrated PHR applications in Indonesia? The design of the PHR model, which was developed using a DSR approach, can provide an overview for developing PHRs using scientific theory and methods. The results of this study are expected to be a guide for health facilities or health policy makers in integrating PHRs and health applications in Indonesia.

Methods

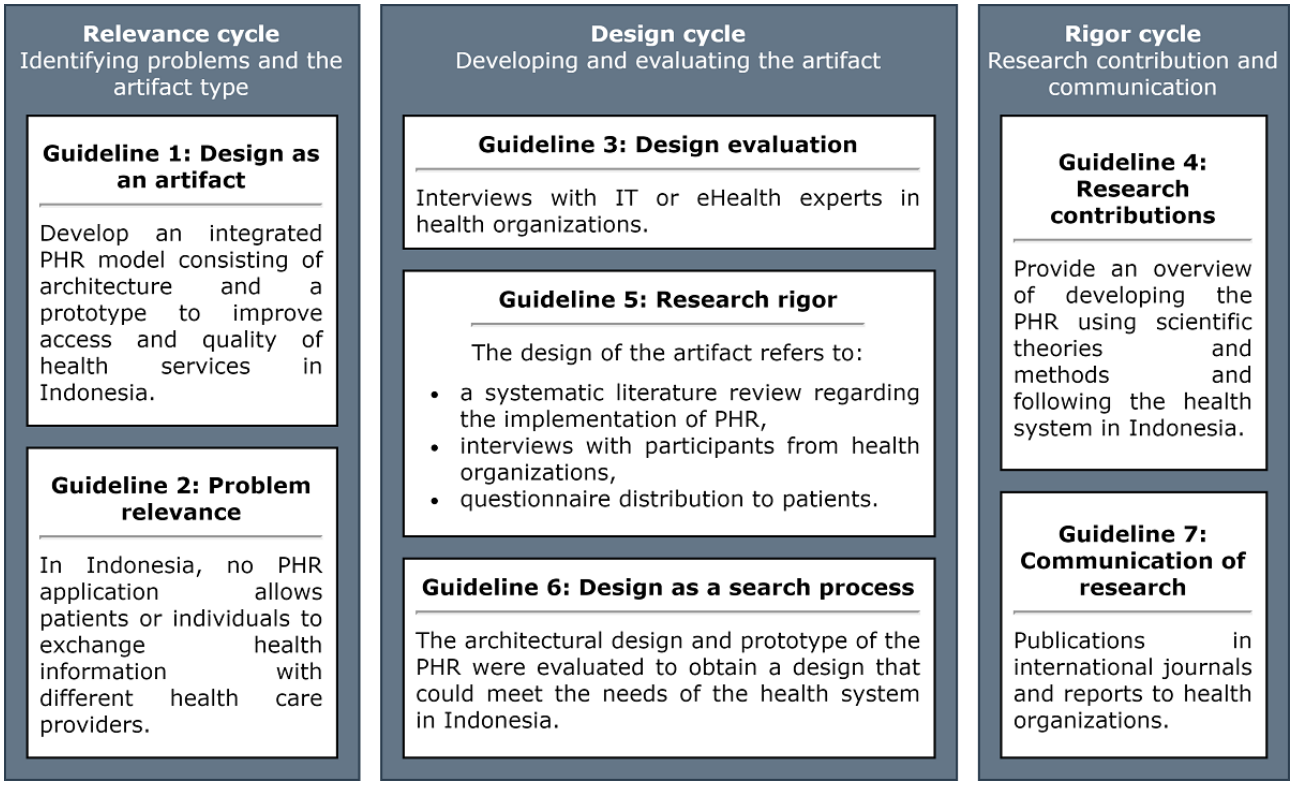
Design Science

This study was conducted using a DSR approach [18]. In DSR, the details or stages of design and development may vary even though the focus of the research is on artifact design [19]. Peffers et al [20] describe 6 activity-based methodologies for DSR, whereas Hevner et al [18] define 7 guidelines for DSR. This study follows the DSR guidelines defined by Hevner et al [18], which are grouped into 3 cycles or phases comprising the relevance cycle (identifying problems and the artifact type), design cycle (developing and evaluating the artifact), and rigor cycle (research contribution and communication; Figure 1 [5]). These guidelines have been followed by DSR studies in low- and middle-income countries to develop health information systems such as mobile health (mHealth) [19,21-27]. The guidelines by Hevner et al [18], as a necessary element in DSR, are also consistent with the DSR methodology by Peffers et al [20].

The artifacts developed in this study are architecture and application prototypes. Integrated PHR requirements were carried out based on a systematic literature review regarding functionalities and issues in the implementation of PHRs [5], literature studies on health regulations in Indonesia, interviews with health organizations, and questionnaire distribution to patients. The requirements mentioned by health organizations in the interviews were categorized and grouped into themes that were defined by Harahap et al [5] and combined with requirements from patients. The architectural design then became a reference for designing the application prototype.

This study used a purposive sampling method to select participants who had the required knowledge regarding PHR implementation. The health organizations from which participants were interviewed were health facilities (private and government hospitals, Puskesmas, and clinics), health regulators (Ministry of Health and BPJS Kesehatan), and health application vendors. Data were collected through semistructured interviews between August 19, 2020, and January 15, 2021, and between October 1, 2021, and October 11, 2021. Interviews were conducted on the web using Zoom Cloud Meetings (Zoom Video Communications) and audio recorded with the participants' consent. Each interview lasted between 30 and 60 minutes. The interview questions are attached in Multimedia Appendix 1.

Figure 1. Design science research guideline [5,18]. PHR: personal health record.



The questionnaire was distributed to patients who met the criteria of respondents being Indonesian citizens aged ≥17 years. Before the questionnaire was distributed, we conducted a readability test to ensure that all the items on the questionnaire could be understood by the respondents in terms of writing and sentence meaning. The readability test was conducted on 6 respondents from September 25, 2021, to September 28, 2021. After the readability test, we made a revision based on the input given by the respondents. Questionnaires were distributed on the web through messaging applications such as WhatsApp (Meta Platforms), Telegram (Telegram FZ LLC), and Line (Line Corporation), as well as social media such as Facebook and Twitter, from October 28, 2021, to November 20, 2021. Questionnaire data were analyzed using descriptive statistics in Microsoft Excel (Microsoft Corp) and SPSS Statistics (version 28; IBM Corp).

To evaluate the artifacts, this study used the evaluation guidelines defined by Venable et al [28] and the evaluation criteria defined by Hevner et al [18]. The goal of the evaluation was to determine the suitability of the design for the needs of health services in Indonesia. The architectural design and application prototype were evaluated qualitatively through interviews with IT or eHealth experts. The evaluation of the architecture design aimed to assess the completeness and conformity with the health system in Indonesia. The evaluation of the application aimed to assess functionality and usability.

This study used the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines as a comprehensive checklist that covers the necessary components of qualitative research (Multimedia Appendix 2 [29]). Interview data were analyzed using content analysis techniques in NVivo (version 12; QSR International). The content analysis steps comprised decontextualization, recontextualization, categorization, and compilation [30]. In decontextualization, the authors read the transcribed text and broke down the text into smaller meaning units. Each identified meaning unit was labeled with a code. In recontextualization, the original text was reread alongside the final list of meaning units. In the categorization process, themes and categories were identified. The categorization for the requirement analysis was based on the functionalities and issues in the implementation of PHRs defined by Harahap et al [5]. The categorization for the architectural evaluation interview was carried out based on the architectural components, whereas the categorization for the prototype evaluation interview was carried out based on the implemented functions in the PHR application. At the compilation stage, the authors wrote the results of the analysis.

Ethics Approval

The authors obtained a letter of ethics approval from the Faculty of Computer Science, University of Indonesia, to conduct data collection with letter S-1122A/UN2.F11.D1/PDP.01/2020. The author submitted the letter to the respondents and provided a brief explanation of the study objective. Each respondent verbally provided consent to participate during the interview.

Results

Artifact Development

Respondent Demographics

We interviewed a total of 37 respondents. The respondents were from 10 first-level health facilities (n=6, 60% Puskesmas and n=4, 40% clinics) and 15 referral-level health facilities (n=9, 60% government hospitals and n=6, 40% private hospitals); 5%

(2/37) of respondents were from the Ministry of Health, 3% (1/37) of respondents were from BPJS Kesehatan, and 8% (3/37) of respondents were health application vendors. A total of 73% (27/37) of respondents were male, and 27% (10/37) were female. Most respondents (24/37, 65%) were from the Special Capital Region of Jakarta, whereas others were from Jawa Barat (6/37, 16%), Bali (3/37, 8%), Banten (1/37, 3%), the Special Region of Yogyakarta (1/37, 3%), Riau (1/37, 3%), and Sulawesi Selatan (1/37, 3%). Detailed respondent information is provided in Multimedia Appendix 3.

A total of 1343 respondents filled out the questionnaire. However, there were 24.65% (331/1343) of invalid or duplicate data, so the total valid data from filling out the questionnaire were from 75.35% (1012/1343) of respondents. A total of 37.55% (380/1012) of respondents were male, 62.45% (632/1012) were female, and most (606/1012, 59.88%) lived in Greater Jakarta. Most respondents were aged 20 to 30 years (376/1012, 37.15%; Table 1).

Table 1. Demographics of questionnaire respondents (n=1012).

Demographics	Respondents, n (%)
Sex	
Male	380 (37.5)
Female	632 (62.5)
Age (years)	
17-20	207 (20.5)
20-30	376 (37.2)
31-40	148 (14.6)
41-50	134 (13.2)
51-60	125 (12.4)
>60	22 (2.2)
Domicile	
Greater Jakarta	606 (59.9)
Java island other than Greater Jakarta	279 (27.6)
Outside Java island	78 (7.7)
Education level	
Primary school	0 (0)
Junior high school	1 (0.1)
Senior high school	315 (31.1)
Diploma	62 (6.1)
Bachelor’s degree	415 (41)
Master’s degree	173 (17.1)
Doctorate	46 (4.5)
Familiarity with the use of IT	
Excellent	298 (29.4)
Good	519 (51.3)
Okay	191 (18.9)
Bad	2 (0.2)
Very bad	2 (0.2)

Requirements

Health Organization Requirements

The functions recommended by respondents from health organizations included functions related to access to health records for patients, such as viewing diagnostic data, laboratory and examination results, and medical history:

> *They can view data from medical visits, such as lab results, and x-ray results. Then, you can also see the medical history, including the diagnosis.* [Head of IT, General hospital (GH) 3]

Respondents also mentioned the need for a function to view health facility profiles, such as the list of services and the

availability of beds. Other recommended functions were paying for medical expenses, billing, and claiming health insurance:

> *List of services that can be provided because each hospital is different.* [Physician, GH8]
>
> *If there is a bill for the patient, it will be created to be given to the patient.* [Health application vendor, vendor (VDR) 1]

Respondents also suggested the need for a function for patients to manage information related to medication consumption, such as viewing the history of medication that has been consumed, ordering medication, and scheduling medication consumption:

> *Ordering medicine according to a prescription, then delivery of the medicine.* [Health application vendor, VDR3]
>
> *There is a function for medication consumption.* [Head of IT, primary health care (PHC) 8]

Another recommended function was a feature that patients can use to interact or communicate on the web with medical personnel in health facilities. Communication can occur through chat, messages related to health consultations, or video calls:

> *Communication to hospital and telemedicine with video.* [Head of IT, private hospital (PH) 3]

In addition, respondents mentioned the need for features for patients to manage appointments with medical personnel at health facilities. With this feature, patients can register themselves for treatment at health facilities, including choosing a physician:

> *There is an online registration for patients...there must be information on what time they should be treated.* [Head of IT, GH6]

Respondents also recommended a function for patients to access disease-related information and health tips, such as how to maintain a healthy lifestyle. Others suggested a function for patients to manage their health data to support preventive health efforts or disease prevention. In addition, this function could assist in the recovery from certain diseases that require ongoing health management activities. For example, patients could input data on vital signs and physical activities:

> *There are health articles that can be used when other features are not used. The available information depends on patients' health conditions. This could include articles on healthy lifestyles such as safe cosmetics, or nail care.* [Head of IT planning strategy, health regulator (HR) 2]
>
> *Monitoring tracking is also a very good opportunity because health is not only about curing, we also need preventive measures so that we don't get sick.* [Head of IT, PH2]

In addition to functional requirements, respondents mentioned the need for PHR integration. PHR functionality can be integrated with health applications or other existing data sources, such as electronic medical records in health facilities, to obtain medical summaries, such as diagnoses, laboratory and examination results, and medical history. PHRs also need to be integrated with the referral information system (*sistem informasi rujukan terintegrasi*) to obtain patient referral history and integration with vaccine data, especially for needs during the COVID-19 pandemic:

> *It needs to be integrated with electronic medical record data from health facilities.* [Member of data and information center, HR1]
>
> *We need to integrate data from SISRUTE because it records data from several health facilities. If the patient is referred, the data should be recorded.* [Head of IT, GH5]

PHRs also need to be integrated with BPJS Kesehatan for JKN patients and integrated with web-based payments for patients who seek treatment at health facilities and do not use health insurance:

> *Need to be integrated with BPJS health.* [Head of IT, GH3]
>
> *For payments, it is integrated with online payments.* [Health application vendor, VDR3]

PHRs can be integrated with teleconsultation applications for communication between patients and medical personnel, as well as with pharmacies for ease of ordering medicines. In addition, for the convenience of monitoring personal health data such as physical activities, PHRs need to be integrated with wearable devices. Moreover, PHRs need to be integrated with the healthy family or *Program* Indonesia *Sehat dengan Pendekatan Keluarga* application to support healthy family programs at the Puskesmas and with the national health data repository owned by the Ministry of Health:

> *For prescription, the application needs to be connected to the pharmacy.* [Physician, PH5]
>
> *Regarding fitness, it is difficult to implement, unless you can access data from wearable devices such as smartwatches.* [Member of data and information center, HR1]
>
> *We have a healthy family application (PIS-PK) to record family information related to individual family members, and it is not from the results of the medical examination.* [Head of IT, HR1]

Respondents also mentioned security aspects that need to be applied to PHRs, such as access control, audit trails, data encryption, and data backup. Authentication and authorization are needed in the implementation of PHRs. An audit trail is required to review who is accessing and what data have been accessed in the PHR. A data backup option is required to avoid the risk of data loss. In addition, PHRs need to implement important data encryption, such as passwords:

> *There must be a data backup.* [Head of IT, GH2]
>
> *There is a log in the application to see what time the user logged in and what features were accessed.* [Head of IT, PHC1]

PHRs need to implement user manuals or guidance options to help users understand the information contained in them. In addition, PHRs need to have customization options based on the availability of the internet network as several regions in Indonesia have poor internet connections:

Provide user manuals, video manuals, or readable manuals. [Health application vendor, VDR1]

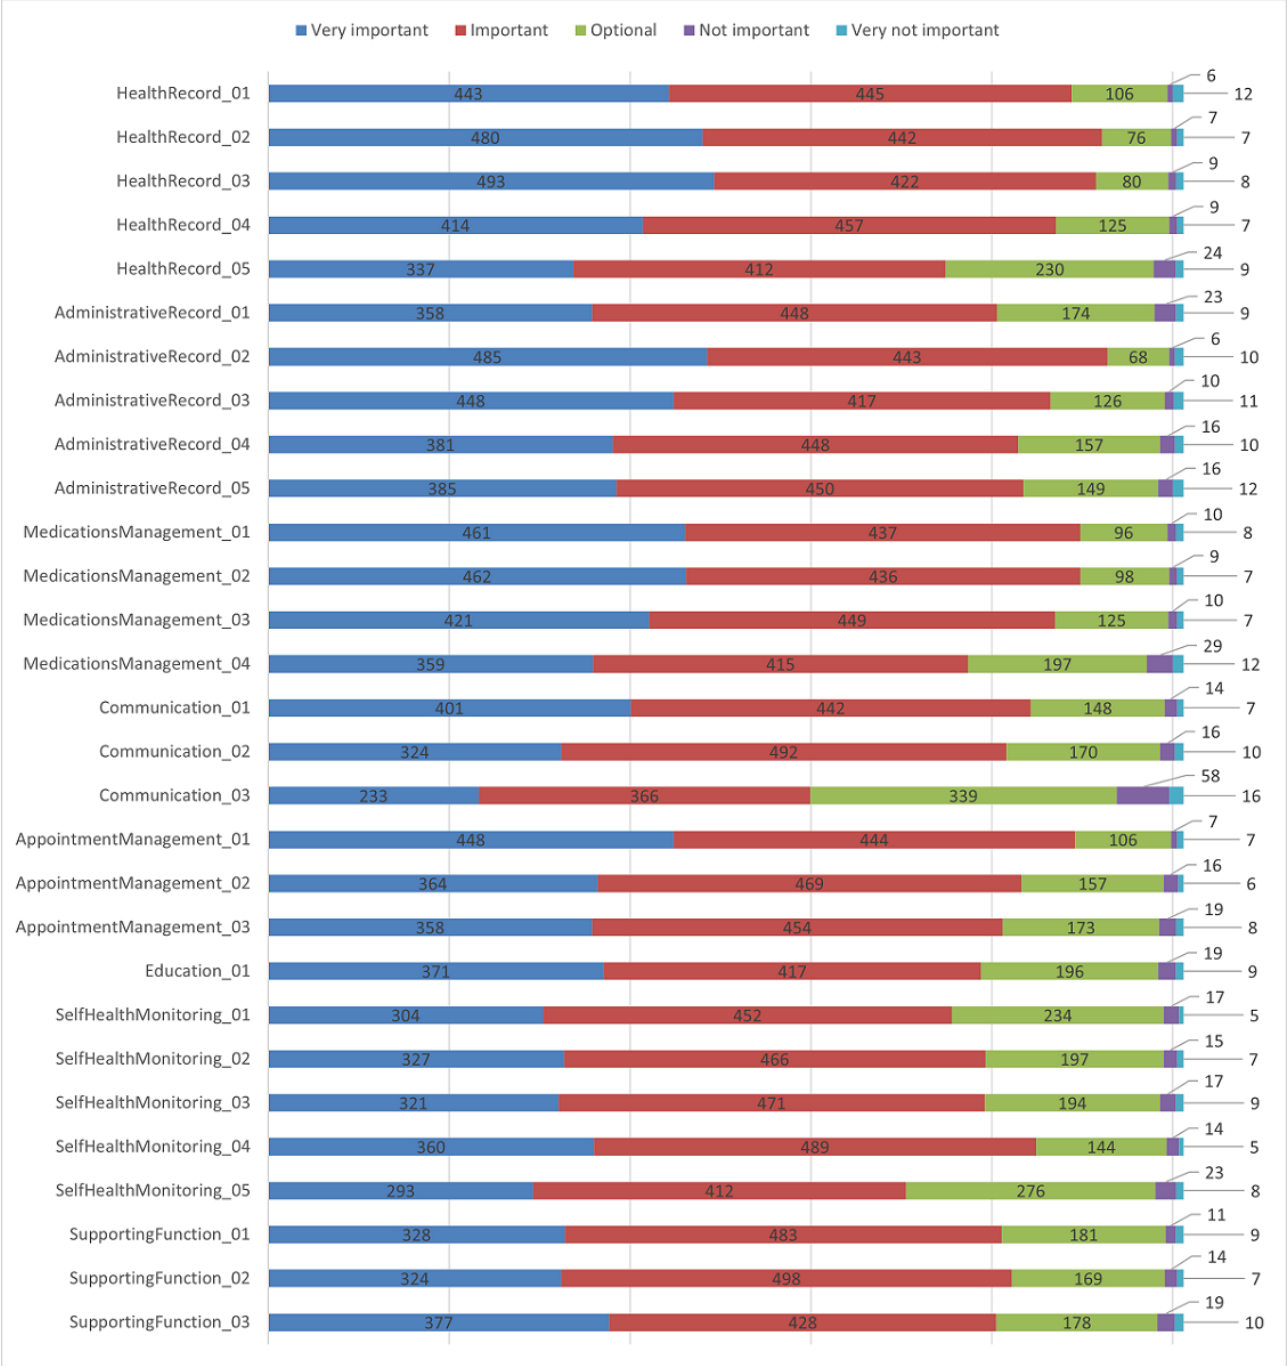
For areas with poor internet network, the application should still be accessible. [Physician, GH8]

Patient Requirements

A total of 70.06% (709/1012) of respondents had used health applications, whereas 29.94% (303/1012) had never used health applications. For each respondent who had used a health application, the questions asked were the health application used, the platform used to access the health application, the length of use of the health application, the frequency of use of the health application in the last 6 months, the features used in the health application, reasons for using health applications, challenges when using health applications, organizations that must be integrated or connected with health applications, and the most important components of a health application (Multimedia Appendix 4).

Respondents were also asked to rate how important the PHR functionalities were based on the previous review (Harahap et al [5]), which comprised health records, administrative records, medication management, communication, appointment management, education, self–health monitoring, and supporting function. The functionality codes for each PHR module are summarized in Multimedia Appendix 5. Respondents were asked to provide an assessment with the following scores: 1=*Very Not Important*, 2=*Not Important*, 3=*Optional*, 4=*Important*, and 5=*Very Important*. The mean was then calculated for each functionality. If the mean of the functionality was <4, then the functionality did not need to be implemented in the integrated PHR model. On the basis of the results of the questionnaire, 27 functionalities had a mean of >4. However, the functionality of sending messages or chatting with support groups and family members in the PHR application (Communication_03) and the functionality to connect wearable devices with the PHR application were considered important by fewer respondents (SelfHealthMonitoring_05), with a mean of <4. Figure 2 shows the respondents' scores for each PHR functionality.

Figure 2. Respondents' scores for each personal health record functionality.



Summary of User Requirements

The requirements of health organizations and patients were grouped into PHR modules and functionalities based on the study by Harahap et al [5], which comprised health records, administrative records, medication management, communication, appointment management, education, and self–health monitoring. In addition, there were emergency modules obtained from patients' requirements as well as security modules and supporting functions to meet the nonfunctional requirements of PHRs. In the health record module, there were functions to view the results of medical examinations, medical history, referrals, and vaccinations. In the administrative records module, there were functions for patient profiles, health facility profiles, physician profiles, health insurance, and payments and billing. In the medication management module, there were functions for medication history, medication reminders, and medication orders. In the communication module, there was a messaging function (SMS text message or video call). In the appointment management module, there were functions for registration, appointment history, reminders or notifications, and ambulance. In the education module, there was a health article function. In the self–health monitoring module, there were health data tracking functions, health dashboards, health calculators, and early warning notifications. In the emergency module, there was an emergency contact function. In the security module, there were authentication, authorization, audit log, and backup functions. In the supporting function module, there were user manual and offline functionalities. A summary of the PHR

module and functionality based on the requirements of the respondent group is provided in Multimedia Appendix 6.

Architecture Development

Overview

This study used The Open Group Architecture Framework (TOGAF) to design the architecture of an integrated PHR system in Indonesia. On the basis of previous studies, TOGAF provides a complete process and methodology to develop architecture [31]. Moreover, TOGAF is the most suitable architectural framework for application in the health sector as it provides a complete architectural development process and can be adapted to the health sector [32,33]. The TOGAF referred to in this study is the TOGAF version 9.2. The Architecture Development Method in the TOGAF can be modified to suit specific needs [34]. In this study, the scope of architectural development was to design information system architecture. Therefore, the TOGAF components needed comprised architecture vision, business architecture, application architecture, data architecture, and technology architecture as required components in designing information system architecture [35].

Architecture Vision

According to the TOGAF 9.2, an architectural vision is a brief description of the target architecture that describes the business value and changes that will result from successful implementation. Architectural vision serves as a vision and boundary in the development of a more detailed architecture [34]. The value that is expected to be provided by the integrated PHR is a complete medical history by allowing patients to obtain medical information from different health facilities. Integrated PHRs can also minimize unnecessary health examinations as patients can share their medical history with their physicians so that physicians have information about previous examinations that have been carried out by patients. In addition, the integrated PHR facilitates communication between patients and physicians and helps patients with administrative activities such as registration, appointments, and payment of medical expenses. Integrated PHRs can also help patients manage health outside the health care environment, such as tracking food consumption and physical activity according to the patient's needs and health conditions.

On the basis of the user requirements and literature review, we formulated architecture principles for integrated PHRs in Indonesia following the TOGAF 9.2 (Table 2). These comprise business, data, application, and technology principles [34]. The business principles comprise information management as everybody's business, business continuity, service orientation, compliance with the law, and patient-centeredness. Data principles comprise data being an asset, shared, and accessible; common vocabulary and data definitions; and data security. Application principles comprise technological independence and ease of use as well as functionality completeness. The technology principles comprise interoperability and ease of access.

Table 2. Architecture principles.

Domain and principle	Description	References
Business		
Information management is everybody's business	To support health services, health organizations and patients need to be involved in managing information on the PHR[a].	• The Open Group [34] • Harahap et al [36]
Business continuity	The PHR has an optional function that allows users to use it with a poor internet connection.	• The Open Group [34] • Harahap et al [36]
Service orientation	The services provided by the PHR are integrated with health care activities in Indonesia.	• The Open Group [34] • Harahap et al [36]
Compliance with the law	The PHR needs to comply with all applicable laws, policies, and regulations in Indonesia.	• The Open Group [34] • Harahap et al [36]
Patient-centeredness	The PHR is designed for patients to have health information from various sources.	• The Open Group [34] • Harahap et al [36]
Data		
Data are an asset	The data on the PHR could assist the decision-making of health care providers or patients in managing their health.	• The Open Group [34] • Harahap et al [36]
Data are shared	Data can be shared between patients and health care providers.	• The Open Group [34] • Harahap et al [36]
Data are accessible	Access to accurate data is needed to improve quality and efficiency in the management of patient health.	• The Open Group [34] • Harahap et al [36]
Common vocabulary and data definition	The data on the PHR must have the same definition across health organizations to allow for data sharing.	• The Open Group [34] • Harahap et al [36]
Data security	A security mechanism is needed to protect the data stored or exchanged on the PHR.	• Harahap et al [5] • The Open Group [34] • Harahap et al [36]
Application		
Technology independence	The PHR can be integrated with various applications on different platforms.	• The Open Group [34] • Harahap et al [36]
Functional completeness	The PHR provides functionalities to support promotive, preventive, curative, and rehabilitative health services in Indonesia.	• Harahap et al [5,36]
Ease of use	The PHR should be easy to use so that users can complete their tasks.	• Harahap et al [5] • The Open Group [34] • Harahap et al [36]
Technology		
Interoperability	The PHR needs to have interoperability standards for sharing data among stakeholders and health information systems.	• Harahap et al [5] • The Open Group [34] • Harahap et al [36]
Ease of access	The PHR needs to be implemented using common technology used by the community to facilitate easy access to information.	• Harahap et al [36] • Kharrazi et al [37]

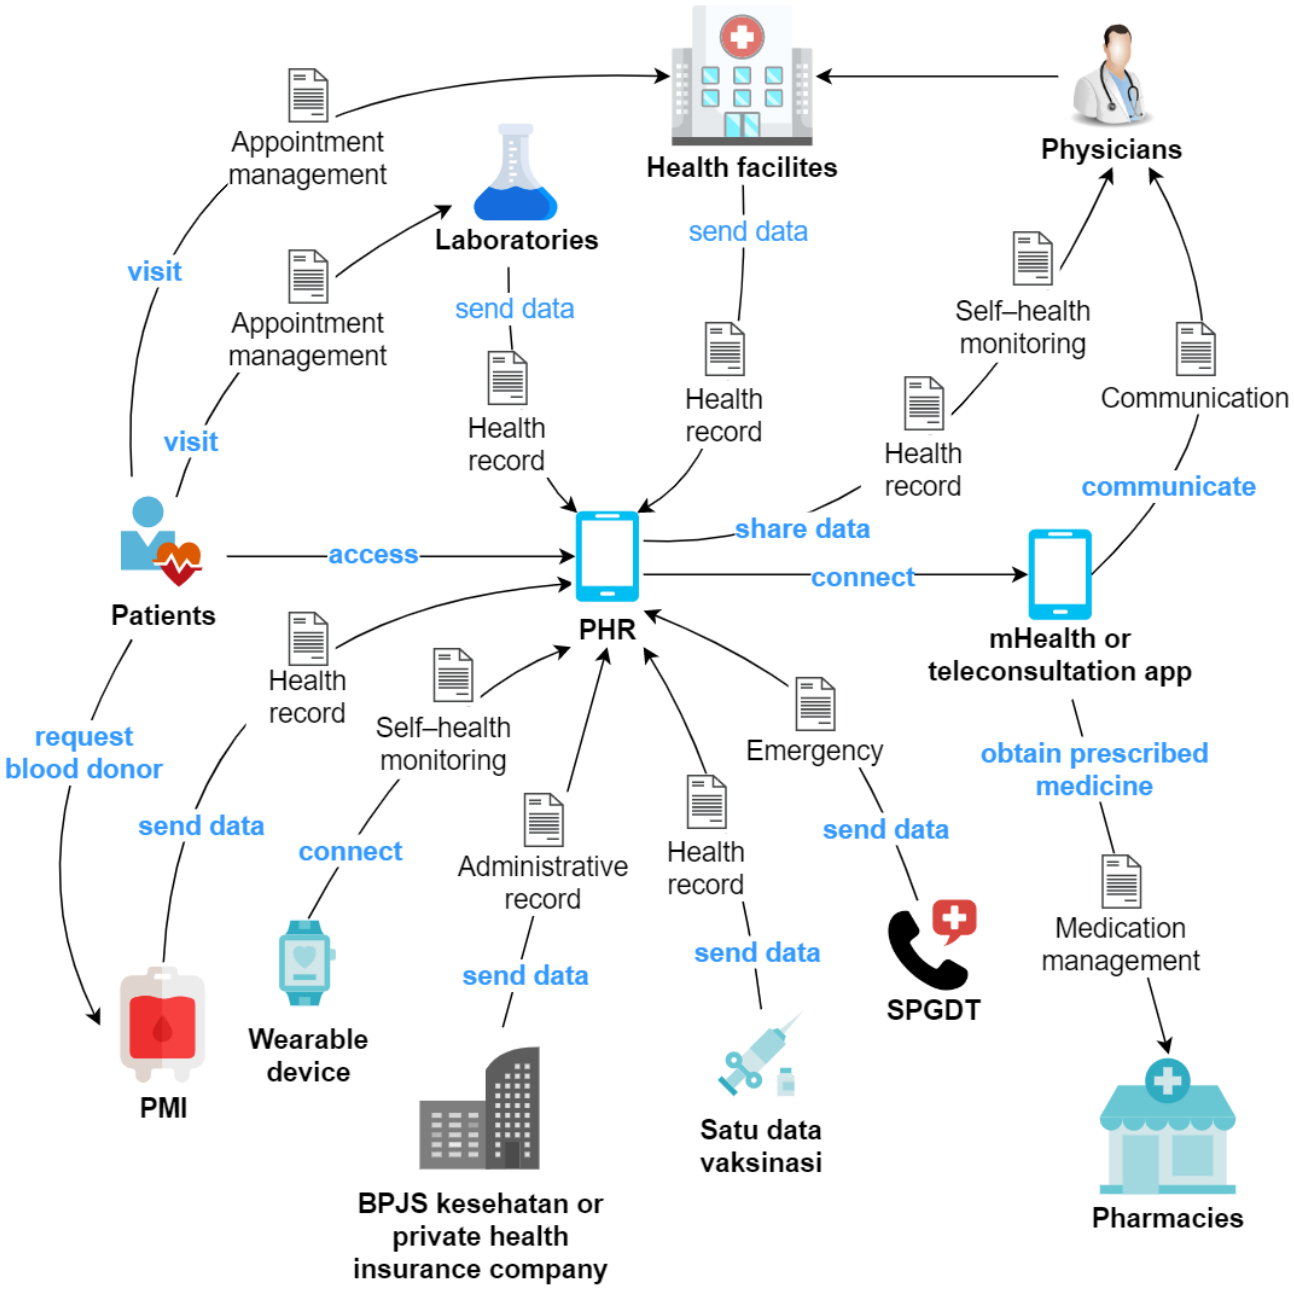
[a]PHR: personal health record.

Business Architecture

Business architecture defines the business strategy, governance, organization, and key business processes [34]. On the basis of the interviews with participants from health facilities and a review of health regulations in Indonesia, the business process for PHRs can be divided into health care business processes, self–health monitoring business processes, vaccination business processes, and home care business processes. Each of these process flows can be seen in Multimedia Appendix 7. The main parties involved in the PHR are patients, physicians, health facilities, laboratories, the *Palang Merah Indonesia* or Indonesian Red Cross (PMI), BPJS Kesehatan or other private health insurance companies, and pharmacies.

On the basis of the flow of the process, we added a rich picture to describe the data exchange on PHRs in the health care process (Figure 3). Patients register to make visits to health facilities or laboratories. Patients who need blood donors can also submit a blood donation request to the PMI. Patients can share their health records or personal health monitoring data with their physicians. Patients who have received health services will receive their data in the PHR. Patients can connect the PHR with wearable devices to record personal health monitoring data. Patients can connect the PHR to BPJS Kesehatan or other health insurance companies to obtain their status. Patients can communicate with their physicians or receive their prescribed medicine at pharmacies through the mHealth apps or teleconsultation applications that are connected with the PHR. Moreover, patients can receive vaccination data through the PHR, which is linked to the Ministry of Health vaccine data (*satu data vaksinasi*). The PHR can also connect with an integrated emergency management system (*sistem penanggulangan gawat darurat terpadu*) to obtain the nearest emergency service contacts.

Figure 3. Rich picture of personal health record (PHR) data exchange in the health care process. BPJS: Badan Pelaksana Jaminan Sosial Kesehatan or Social Security Agency for Health; mHealth: mobile health; PMI: Palang Merah Indonesia or Indonesian Red Cross; SPGDT: sistem penanggulangan gawat darurat terpadu or integrated emergency management system.

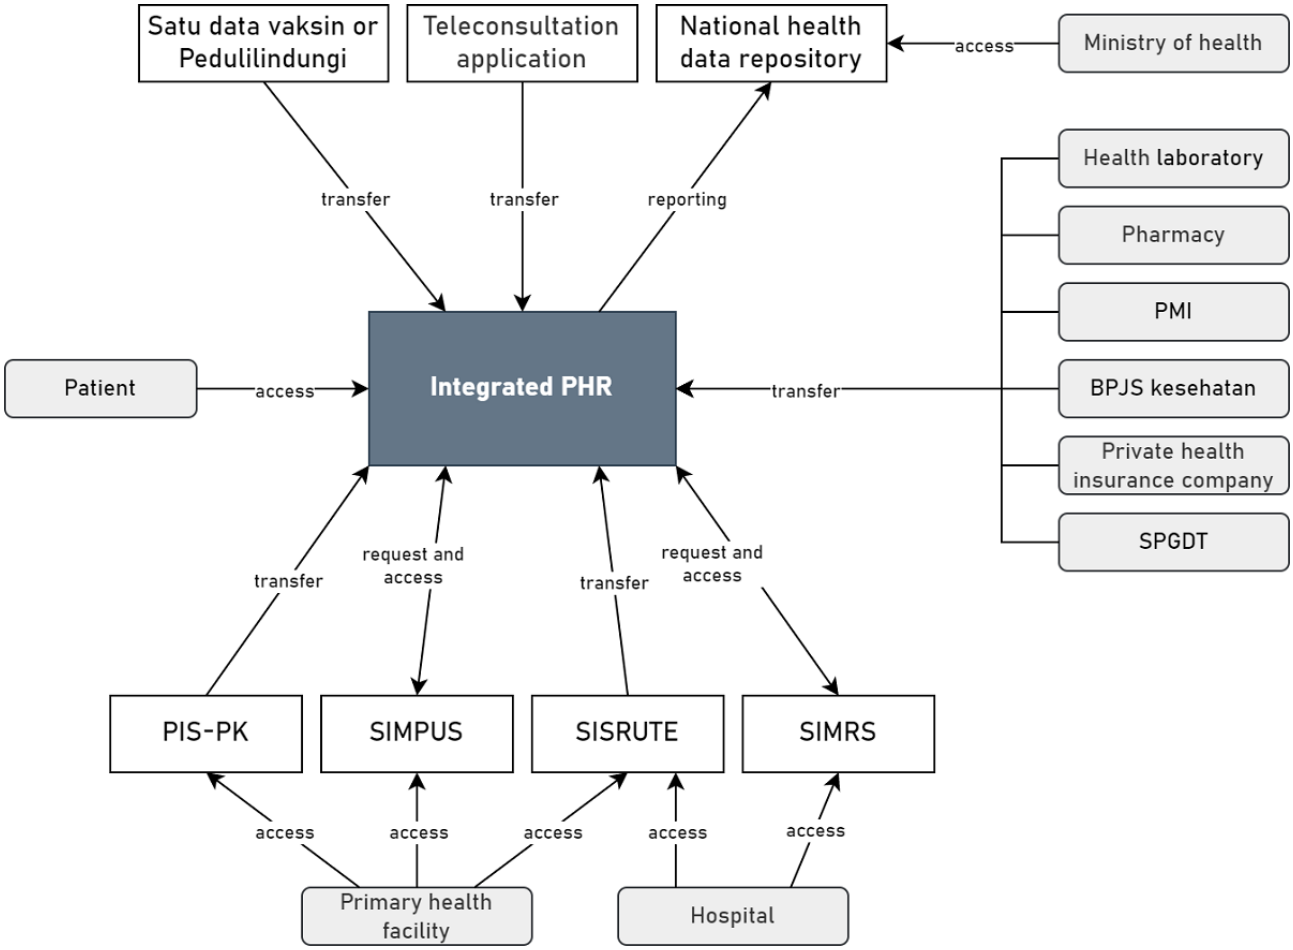


Application Architecture

The TOGAF 9.2 defines application architecture as a blueprint for the applications to be developed, their interactions, and their relationship to the organization's core business processes [34]. On the basis of the results of interviews and questionnaires, parties that need to be integrated into PHRs are primary health facilities (Puskesmas and clinics), referral health facilities (government and private hospitals), health laboratories,

pharmacies, *satu data vaksinasi*, mHealth app or teleconsultation application providers, BPJS Kesehatan, private health insurance companies, and the Ministry of Health. In addition, PHRs need to have the option to connect with wearable devices for tracking health data and family members. On the basis of the results of the business architecture design, other parties that need to be integrated with PHRs are PMI and the integrated emergency management system (*sistem penanggulangan gawat darurat terpadu*). Health facilities are the parties that are most integrated with the information in the PHR. The PHR is integrated with hospital information systems (*sistem informasi manajemen rumah sakit*) in referral health facilities and primary health care information systems (*sistem informasi puskesmas*) in primary health facilities to access health records. In addition to hospital information systems (*sistem informasi manajemen rumah sakit*) and primary health care information systems (*sistem informasi puskesmas*), the PHR is integrated with an integrated referral information system (*sistem informasi rujukan terintegrasi*), which is used by health facilities in Indonesia to access patient referrals. Especially for Puskesmas, the PHR can be integrated with the *Program* Indonesia *Sehat dengan Pendekatan Keluarga* information system. Figure 4 summarizes the integration of the PHR with health information systems or health care providers in Indonesia.

Figure 4. Data exchange of the personal health record (PHR) in Indonesia. BPJS: Badan Pelaksana Jaminan Sosial Kesehatan or Social Security Agency for Health; PIS-PK: Program Indonesia Sehat dengan Pendekatan Keluarga; PMI: Palang Merah Indonesia or Indonesian Red Cross; SIMPUS: sistem informasi puskesmas or primary health care information system; SIMRS: sistem informasi manajemen rumah sakit or hospital information system; SISRUTE: sistem informasi rujukan terintegrasi or referral information system; SPGDT: sistem penanggulangan gawat darurat terpadu or integrated emergency management system.

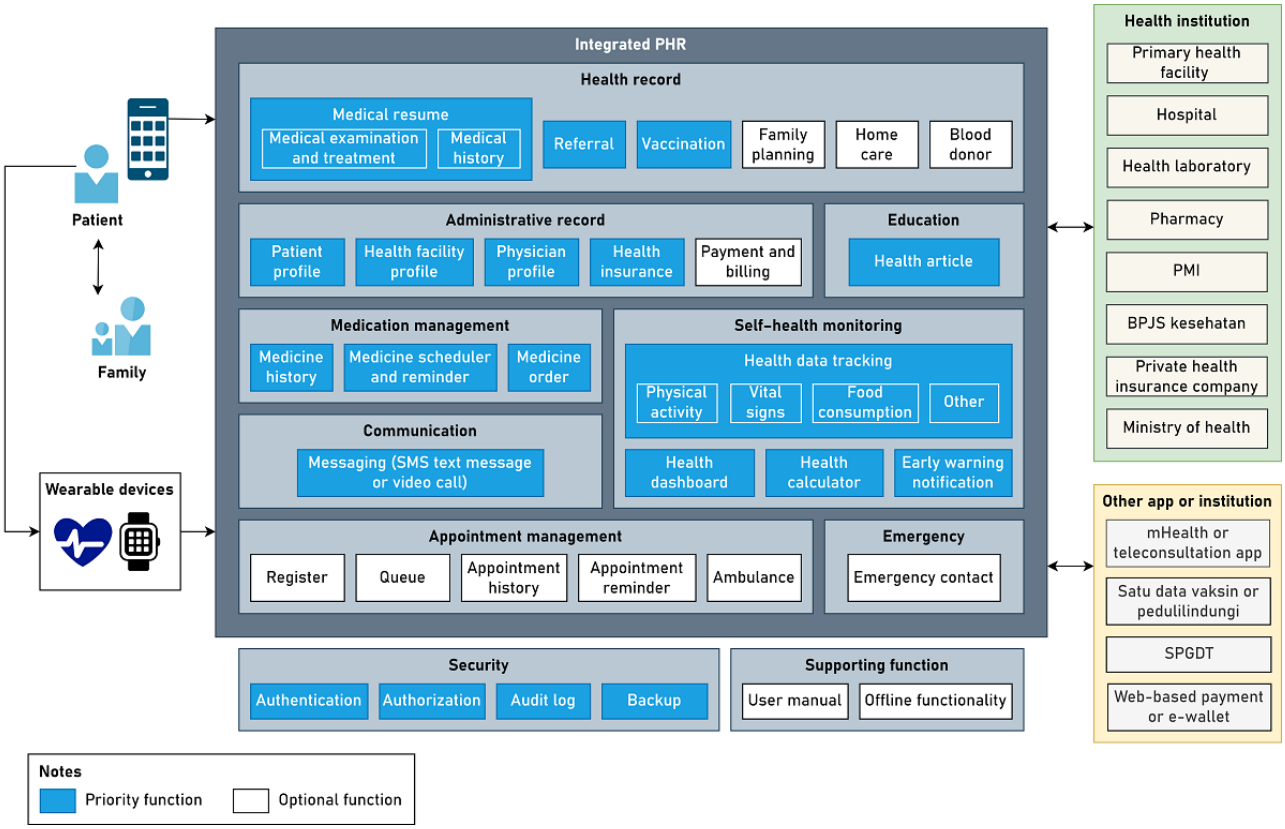


The modules in the PHR comprise health records, administrative records, medication management, communication, appointment management, education, self–health monitoring, security, supporting functions, and emergency. In the health record module, the functionalities comprise a medical summary (results of physical examinations and medical support as well as disease and medication history), referrals, and vaccinations. This module also adds the functions of family planning, home care, and blood donors based on the identification of activities in the business architecture. In the administrative record module, the functionalities comprise patient profiles, health facility profiles, health personnel profiles, health insurance, and payments and billing. In the medication management module, the functionalities comprise medication history, medication reminders, and medication orders. In the communication module, the functionalities comprise messaging. In the appointment management module, the functionalities comprise registration, appointment history, reminders, notifications for appointments, and ambulance services. In the education module, the functionalities comprise health articles containing information on disease problems and health tips. In the self–health monitoring module, the functionalities comprise health data tracking, health dashboards, health calculators, and

alert notifications. In the emergency module, the functionalities comprise emergency contacts.

We also designed the modules and functionalities to meet the nonfunctional requirements of PHRs. The modules comprise security and supporting functions. In the security module, the functionalities comprise authentication, authorization, audit logs, and data backup. In the supporting function module, the functionalities comprise user manual and offline functionality. The functionalities that need to be prioritized for implementation in PHRs are functions related to health management (health care, health prevention, and health promotion) and functions to support information security, whereas other functionalities such as functions related to administration and supporting functions are optional. To access the PHR, the platform used is a smartphone as, based on the results of the questionnaire, it is the most widely used platform by the public to access health applications. Figure 5 summarizes the integrated PHR system model in Indonesia.

Figure 5. Modules and functionalities of the integrated personal health record (PHR) system in Indonesia. BPJS: Badan Pelaksana Jaminan Sosial Kesehatan or Social Security Agency for Health; mHealth: mobile health; PMI: Palang Merah Indonesia or Indonesian Red Cross; SPGDT: sistem penanggulangan gawat darurat terpadu or integrated emergency management system.



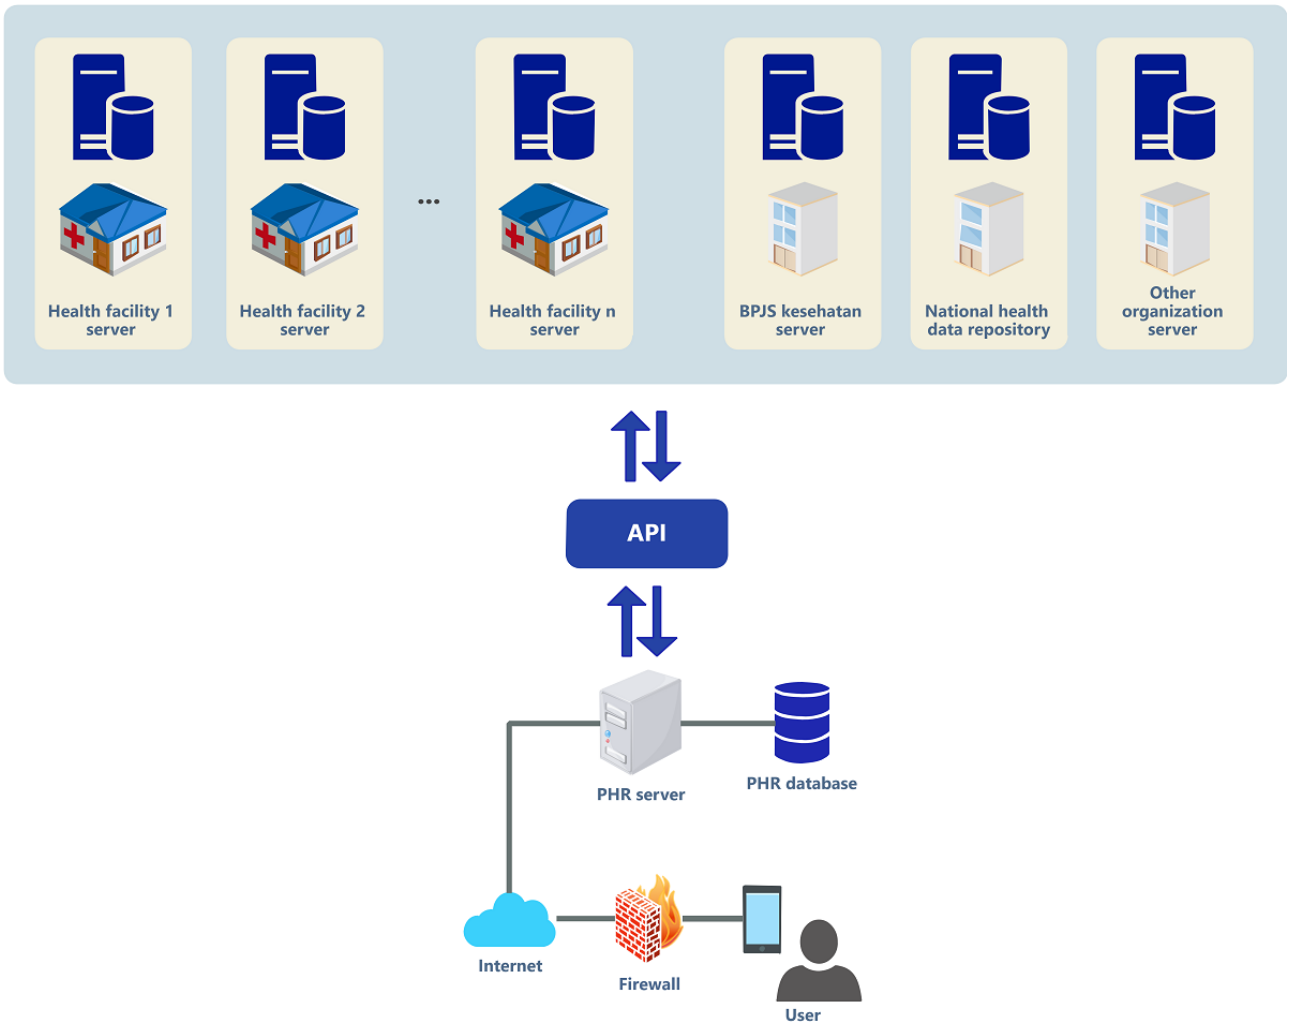
Data Architecture

The TOGAF 9.2 defines data architecture as the logical and physical structure of the organization's data assets and data management resources [34]. We grouped data in PHRs into 3 data categories comprising master, transaction, and reference data [38,39]. Transaction data relate to data that are recorded every time a transaction occurs, such as medical records, vaccinations, and health referrals. Master data are data that do not change and do not need to be recorded in every transaction, such as patient and health facility data. Reference data are a collection of values or classifications that can be referenced by master and transaction data.

Technology Architecture

The technology architecture for PHRs is described in the form of a high-level architecture to illustrate the technology required for PHR implementation and integration with other systems (Figure 6). Patients or individuals access the PHR through a mobile app. PHR development uses the React Native cross-platform app development that can be implemented on the Android or iOS platforms. The PHR application is accessed by users via the internet, and a firewall is used for security. The PHR server comprises an application server and a database server. The application server provides access to data for the user, whereas the database server provides the data requested by the application server [40].

Figure 6. Technology architecture. API: application programming interface; BPJS: Badan Pelaksana Jaminan Sosial Kesehatan or Social Security Agency for Health; PHR: personal health record.



An application programming interface (API) is used as an intermediary for interaction between the PHR and other information systems. The type of API used is Fast Healthcare Interoperability Resources (FHIR). FHIR is an international standard recommended by the Ministry of Health to solve the problem of data exchange in health information systems in Indonesia [17]. FHIR is flexible and can be adapted to stakeholder needs, clinical specifications, and health policies. FHIR can be used to manage a single data entity (eg, heart rate), groups of data entities (eg, vital signs, medications, and allergies), or electronic recording systems such as PHRs. Therefore, FHIR is suitable for exchanging data on PHRs as PHRs aim to collect and exchange individual health data [41].

Prototype Development

The main actors involved in health care and management activities are patients and physicians. Patients are actors who receive health services and play a role in managing their health through applications. Physicians are actors who provide health services to patients. Physicians comprise general practitioners and specialists. The functionalities developed in the prototype design are priority functions defined in the application architecture, which comprise medical summaries, referrals, vaccinations, health facility profiles, physician profiles, patient profiles, messaging, medication history, medication reminders, medication orders, health data tracking, health calculators, health articles, and notifications. An explanation of the design requirements for each function and the actors involved is presented in Table 3. We developed a high-fidelity prototype for a mobile app. Some examples of patient and physician prototype designs are shown in Figures 7 and 8, respectively.

Table 3. Design requirements for application prototype.

Function	Description	Actor
Medical summary	View the history of patient visits to health facilities, including detailed examination results	Patient and physician
Referral	View patient referral history and detailed examination results from each patient referral	Patient and physician
Vaccination	View a patient's vaccination history	Patient and physician
Health facility profile	Search for health facilities and see the nearest health facility	Patient
Health facility profile	View detailed health facility information	Patient and physician
Physician profile	View the profile of physicians who have treated patients	Patient
Physician profile	Manage physician profile	Physician
Patient profile	Manage patient profiles, including adding family members, connecting with BPJS[a] Kesehatan or other health insurance companies, and connecting with wearable devices	Patient
Patient profile	View a list of patients who have been treated	Physician
Messaging	View lists and details of messages between patient and physician	Patient and physician
Medication history	View a list of past or current medications	Patient
Medication reminder	Manage reminders to take medication	Patient
Medication order	Obtain the prescribed medicine at the pharmacy	Patient
Health data tracking	Record health monitoring data such as physical activity, food consumption, and others	Patient
Health data tracking	View the health monitoring dashboard that has been created by the patient	Patient and physician
Health calculator	Perform patient health calculations such as BMI	Patient
Health article	Read health articles, such as information about disease problems or health tips	Patient
Notification	Receive notifications such as incoming messages, documents sent, or reminders to perform certain activities	Patient and physician

[a]BPJS: Social Security Agency for Health or Badan Pelaksana Jaminan Sosial Kesehatan.

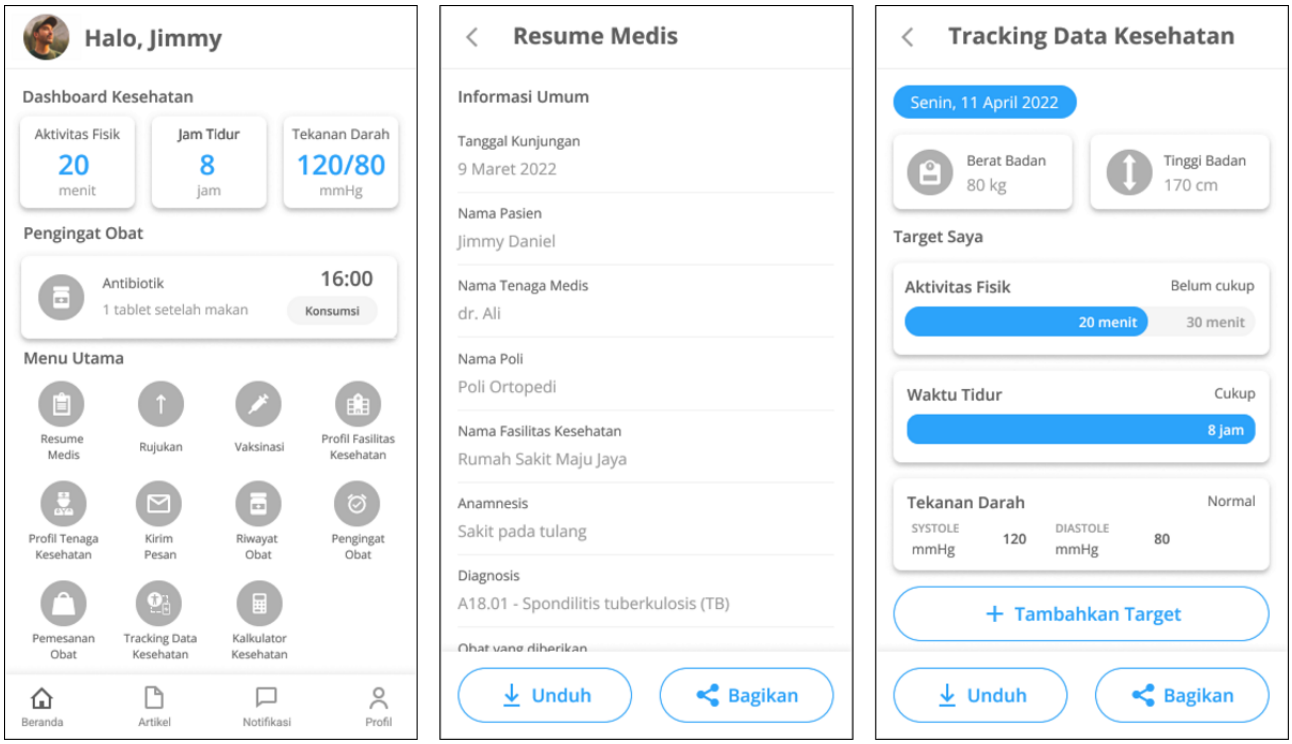

Figure 8. Example of the home page, patient profile, and physician profile from the physician prototype.

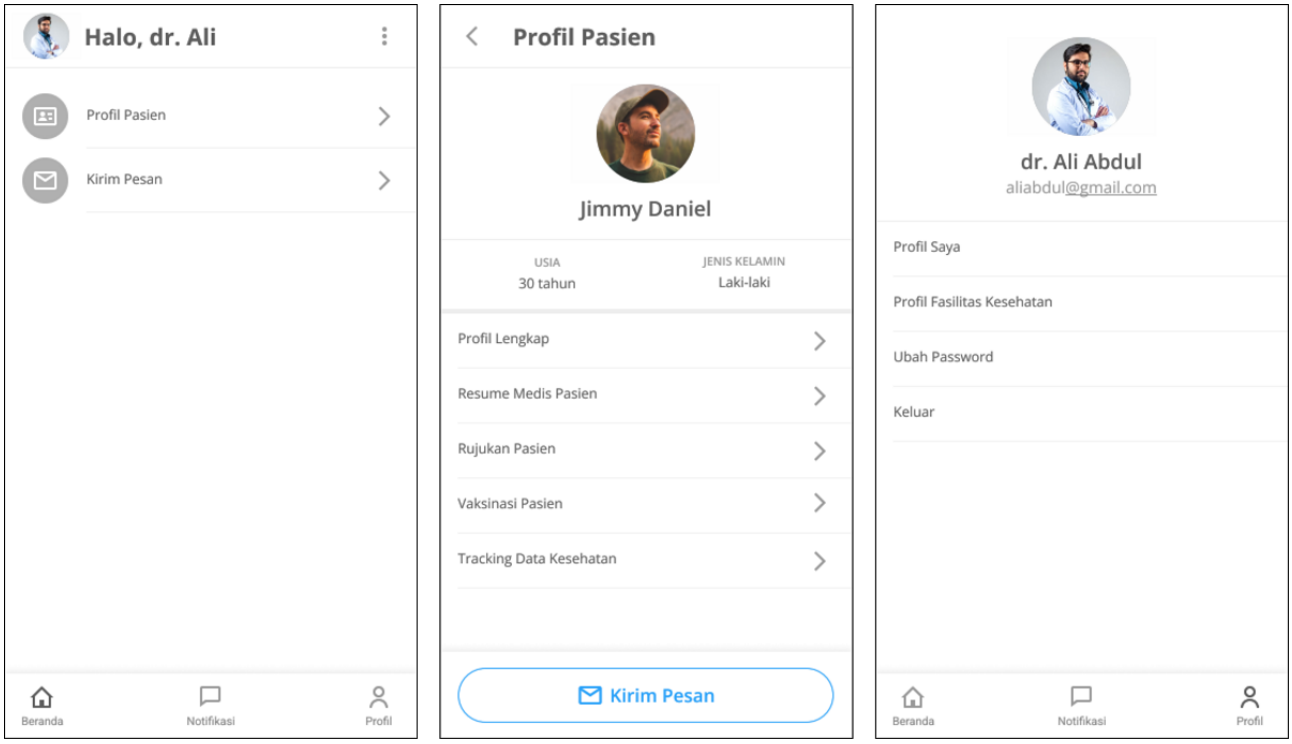

Artifact Evaluation

Respondent Demographics

To evaluate the architectural design and application prototype, we conducted interviews with IT or eHealth experts. Interviews were conducted with 6 respondents: 1 (17%) respondent from the Ministry of Health, 1 (17%) academician, 1 (17%) respondent from a government hospital, 1 (17%) respondent from a private hospital, and 2 (33%) health application vendors. Interviews were conducted from April 5, 2022, to April 8, 2022, with an interview duration of 40 to 60 minutes. The information of the respondents is presented in Table 4.

Table 4. Respondent demographics.

Respondent code	Sex	Role	Work experience (years)
E1	Male	Health application vendor	1-5
E2	Female	Academician	1-5
E3	Male	IT management in the Ministry of Health	>10
E4	Male	IT management in a government hospital	>10
E5	Male	IT management in a private hospital	>10
E6	Male	Health application vendor	>10

Architecture Evaluation

The evaluation was carried out to assess the suitability of the integrated PHR design for the needs of health services in Indonesia (Table 5). All respondents (6/6, 100%) stated that the architectural vision and business architecture in the PHR architectural design described the needs of health services in Indonesia. Regarding the integration in the application architecture, there were several recommendations from respondents regarding parties that needed to be integrated with the PHR but were not described in the application architecture design. Other parties that need to be integrated with the PHR include billing gateways for the payment function (respondent E1) and the Directorate General of Population and Civil Registration for patient identity (respondents E2 and E3). A respondent (E4) suggested adding a health screening function to the PHR. Another respondent (E3) suggested making the messaging and medication order functions optional as they can be connected with other applications. Regarding data architecture, respondent E6 commented that the data architecture was sufficient as long as there was an explanation of the data source in the PHR. For security, respondents suggested more options for authentication methods, such as biometrics (respondent E1) and face recognition (respondent E5). Regarding technology architecture, 100% (6/6) of the respondents stated that the use of an API was a suitable solution for integration between PHRs and other applications in Indonesia. Respondent E3 commented that FHIR was the right type of API to use for PHR implementation. For security and privacy needs, respondents also agreed with the use of firewalls in the technology architecture.

On the basis of the evaluation with IT and eHealth experts, improvements were made by adding billing gateways and Directorate General of Population and Civil Registration to the application architecture (Figure 9). Improvements were also made to the modules and functionality of the integrated PHR system in Indonesia in application architecture (Figure 10). In the medication management module, the medication order function was changed from a priority function to an optional function that can be connected with mHealth apps or teleconsultation applications in Indonesia. In the communication module, the messaging function was also changed from a priority function to an optional function that can be connected with mHealth apps or teleconsultation applications in Indonesia. Improvements were also made by adding a health screening function to the self–health monitoring module. In the security module, authentication methods were added, including passwords, biometrics, and face recognition. Descriptions of each module and functionality in the PHR are summarized in Multimedia Appendix 8. Improvements to the data architecture were made to add health screening data to the transaction data category. Data categories with data groups and descriptions in the PHR are described in Multimedia Appendix 9.

Table 5. Summary of personal health record (PHR) architecture evaluation results.

Architecture component	Evaluation criteria	Evaluation results	Respondent
Architecture vision	Suitability for the health services in Indonesia	It is sufficient to describe the needs of health services in Indonesia	E1, E2, E3, E4, E5, and E6
Business architecture	Conformity with the process of health services in Indonesia	It is sufficient to describe the needs of health services in Indonesia	E1, E2, E3, E4, E5, and E6
Application architecture	Integration with health information systems or other parties	Integration with billing gateway	E1
Application architecture	Integration with health information systems or other parties	Integration with Dukcapil[a]	E2 and E3
Application architecture	Completeness of functionality	Messaging and medication orders as optional functions	E3
Application architecture	Completeness of functionality	Addition of health screening function	E4
Application architecture	Completeness of functionality	Addition of authentication method options such as biometrics and face recognition	E1 and E5
Data architecture	Data requirements and completeness	Data architecture is sufficient as long as there is an explanation of the data source in the PHR	E6
Technology architecture	Technology requirements for PHR implementation	The architecture already describes the technology requirements for PHR implementation	E1, E2, E3, E4, E5, and E6

[a]Dukcapil: Directorate General of Population and Civil Registration.

Figure 9. Design improvements to the data exchange in the personal health record (PHR) in Indonesia. BPJS: Badan Pelaksana Jaminan Sosial Kesehatan or Social Security Agency for Health; Dukcapil: Directorate General of Population and Civil Registration; mHealth: mobile health; PMI: Palang Merah Indonesia or Indonesian Red Cross; SPGDT: sistem penanggulangan gawat darurat terpadu or integrated emergency management system.

Prototype Evaluation

The evaluation of the prototype design resulted in suggestions for improvements related to the main functions developed in the prototype design (Table 6). Suggestions for improvements that need to be made were the functions of medical summary, referral, vaccination, physician profile, messaging, medication history, medication reminder, medication order, health data tracking, notification, and patient profile. In the medical summary, referral, and vaccination functions, a respondent (E3) suggested adding a patient identification number. Some examples of the prototype improvements are shown in Figure 11.

In the medical summary function, suggestions for improvement were the addition of the patient's overall medical history (respondent E3) and the addition of the patient's medical record number (respondent E5) to the medical summary details. The addition of the patient's overall medical history aimed to make it easier for patients to view their complete medical history without having to look at the details of each medical summary one by one. The patient's medical record number was intended to be the patient's identity number at the health facility.

In the referral function, suggestions for improvement were the addition of information on the actions given before the patient was referred (respondent E1) and the reason for the patient being referred (respondent E2) in the referral details. Other suggestions for improvement were the addition of information on the type of referral, such as back referral (respondent E2). This information is needed for the continuous treatment of patients as health workers who treat patients need to know the complete condition of the patient.

In the vaccination function, suggestions for improvement included adding other types of vaccinations apart from COVID-19 (respondents E1, E2, E3, and E4). Additional types of vaccinations are needed so that this function can be used not only during the COVID-19 pandemic but also after it ends. In addition, in the vaccination function, it was recommended that the patient be able to view the vaccination history of family members (respondent E1).

In the physician profile function, the suggestion for improvement was changing the physician's ID to the *Surat Izin Praktik* number (respondents E1, E2, and E4) in the detail of the physician profile as the *Surat Izin Praktik* number is the standard numbering used for every health facility in Indonesia. Another suggestion for improving this function was the deletion of information to view the recommendations of the nearest physician (respondents E3 and E5). This is because, in implementation, it will be difficult to obtain updated information on physicians' availability around the patient's location.

In the messaging function, the suggestions for improvement were to link this function to health applications or teleconsultation applications that already exist in Indonesia. The goal is to facilitate the implementation of the PHR application as other applications can handle the messaging function. This respondent (E3) also suggested doing the same for the medication order function.

In the medication history function, a suggestion for improvement was given by a respondent (E1) to add medication categories, such as generic or patent. The respondent also gave suggestions on the medication reminder function to add information on how to take the medication. Another suggestion for improvement in medication reminders was the need to add information on whether the medication should be fully consumed (respondent E5).

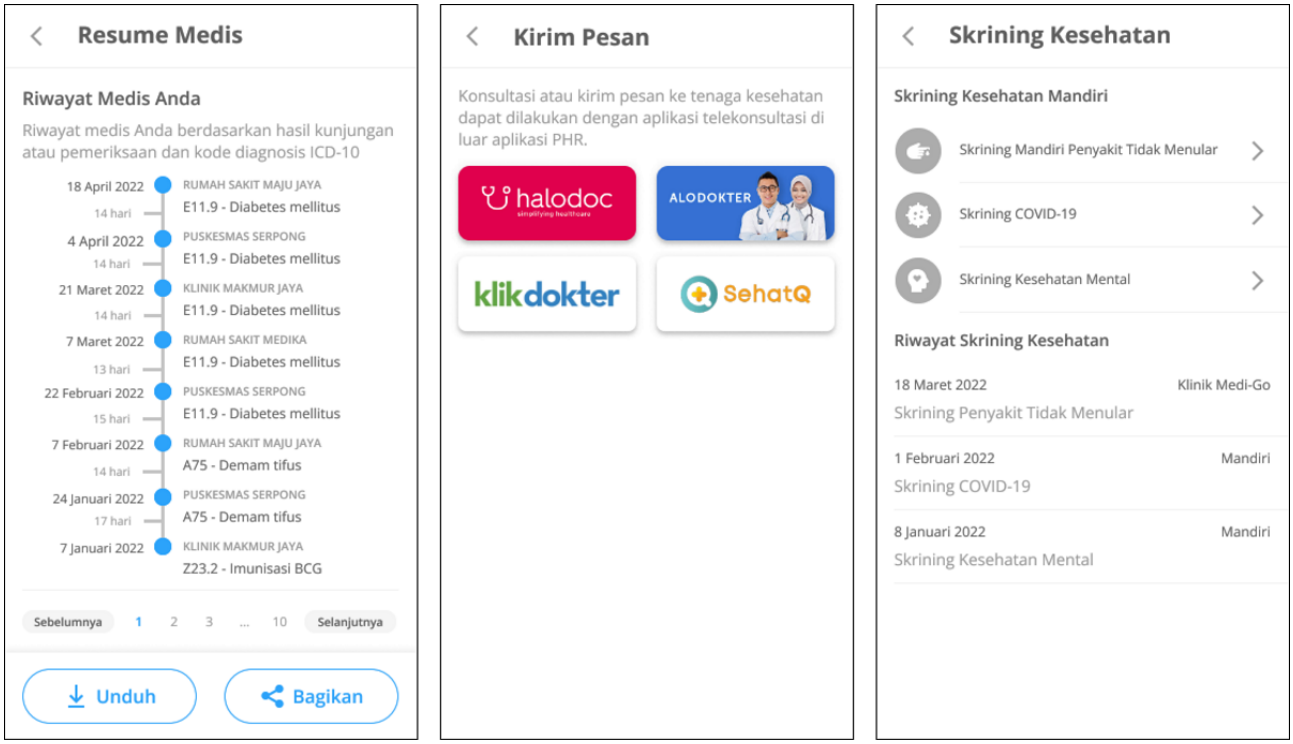
Table 6. Summary of prototype evaluation results.

Actor and function	Evaluation result
Patient	
Medical summary	• Add a medical summary dashboard to view the patient's overall medical history (respondent E3) • Add the patient's NIK[a] number (respondent E3) • Add the patient's medical record number to the medical summary details (respondent E5)
Referral	• Add reason for referral (respondent E2) • Add medication treatment information to referral details (respondent E2) • Add referral type (respondent E2) • Add the patient's NIK number (respondent E3)
Vaccination	• Add vaccine category other than COVID-19 vaccine (respondents E1, E2, E3, and E4) • Add the patient's NIK number (respondent E3)
Physician profile	• Change physician ID to SIP[b] number (respondents E1, E2, and E4) • Delete nearest physician recommendations (respondents E3 and E5)
Messaging	• Link to other health applications (respondent E3)
Medication history	• Add patent or generic medication category (respondent E1)
Medication reminder	• Add the way of taking the medication (respondent E1) • Add information on whether the medication must be fully consumed or not (respondent E5)
Medication order	• Link to other health applications (respondent E3)
Health data tracking	• Add weekly health data tracking dashboard (respondent E1) • Add sample health data tracking input page (respondent E5)
Notification	• Display changes to distinguish read from unread notifications (respondent E1)
Patient profile	• Add other security options such as biometrics (respondent E1) • Add blood type to patient profile details (respondent E2) • Add marital status to patient profile details (respondent E5)
Other	• Add log-in or registration options with Gmail (respondent E1) • Add health screening function (respondent E4)
Physician	
Patient profile	• Add a dashboard to view patients who need to be responded to (respondent E1) • Add menu of patient health screening results (respondent E4)
Notification	• Add sample notification for referral (respondent E2)
Physician profile	• Delete the function to view the health facility profile on the physician profile (respondents E4 and E5)

[a]NIK: Nomor Induk Kependudukan (patient identification number).

[b]SIP: Surat Izin Praktik number (standard numbering used for every health professional or health care provider [physician, nurse, and midwife] in Indonesia).

Figure 11. Examples of prototype improvements.



In the health data tracking function, suggestions for improvement were the need for a weekly health dashboard to observe trends in patient health tracking (respondent E1). Another suggestion was to add a sample data input page for this function (respondent E6). In the notification function, the suggestion for improvement was the need for display adjustments to indicate the difference between read and unread notifications (respondent E1).

In the patient profile function, suggestions for improvement included the need for security options other than passwords, such as biometrics (respondent E1). In the detailed patient profile, additional information was needed, such as blood type (respondent E2) and marital status (respondent E5). In addition to the functions that have been discussed, respondent E4 gave suggestions to add a health screening function to the PHR, including independent health screening or health screening in primary health facilities.

In the evaluation of the prototype design for the physician, suggestions for improvement were the addition of a dashboard to see patients who need to be responded to (respondent E1) and the addition of patient health screening results following the suggestions for the prototype design for patients (respondent E4). Another improvement suggestion was the addition of a notification example for referral data that are sent from patients to the physician (respondent E2). Furthermore, for the user profile function, suggestions for improvement were to remove unnecessary information, such as the profile function of health facilities (respondents E4 and E5).

Discussion

Principal Findings

This study designed an integrated PHR system architecture in Indonesia and an application prototype. In Indonesia, there are various mHealth apps or teleconsultation applications, such as AloDokter, Halodoc, and Mobile JKN. AloDokter and Halodoc are connected to health care providers, mostly private clinics and hospitals, whereas Mobile JKN is for JKN patients in primary health facilities such as Puskesmas and clinics. However, the exchange of health information in these applications is one-way, from the health facility or physician to the patient. Previous research on the adoption of PHRs has also found that health facilities in Indonesia generally do not provide web-based access to patients' health records [36]. This study provides a PHR model that is connected with various health care providers and is integrated into routine health care practice in Indonesia.

A review conducted by Hoque et al [42] stated that most health applications or mHealth research in low- and middle-income countries do not follow the design science approach. The DSR approach informs how artifact validation is carried out so that it can provide evidence that the designed artifact is useful and meets the users' requirements [21]. This study uses a DSR approach with evaluations carried out by IT or eHealth experts so that the PHR design follows the practice of health services in Indonesia.

The architecture development based on the TOGAF can describe the need for integration into the PHR by describing who are the stakeholders involved in the PHR. Architecture development using the TOGAF can help align business processes, data, applications, and IT infrastructure [43]. The architectural design developed in this study covers the provision of essential or basic

routine health services that always exist in the community, such as health examinations, disease treatment, and immunization [44]. The development of this PHR can also support national health priorities and the Germas program, which prioritizes promotive and preventive health efforts, especially for the prevention and control of noncommunicable diseases [45].

The application prototype in this study was developed as a mobile app. The increasingly widespread use of smartphone apps in the community and the ease of access to smartphones encourage the adoption of PHRs on mobile devices, or mobile PHRs [37]. In Indonesia, the number of smartphone users has reached 167 million, or 89% of the total population [46]. The results of the questionnaire in this study on the use of health applications section also showed that smartphones were the most popular devices for patients or individuals to access health applications in Indonesia. Smartphones also offer unique features such as a camera, GPS, and touch screen that can be used to extend the usefulness of mobile PHR, such as scanning and importing paper documents, recording certain symptoms, creating videos, or scanning bar codes for medical purposes [37].

Implications

As explained in the Introduction section, previous research on PHR design in low- and middle-income countries [6-9] has involved users in exploring the needs and usability of the PHR design. However, they did not explain the integration of the PHR with other health applications. Although there is a study describing PHR integration using the distributed PHR model, this study did not involve users or stakeholders in designing the model [10]. Our study complements the gaps in previous studies in low- and middle-income countries by designing an integrated PHR in Indonesia, which involves related stakeholders in requirement gathering and evaluation.

The theoretical implications of this research are the contribution to the field of PHR research by presenting design science as an approach for designing an integrated PHR system for a low- or middle-income country context that takes into account the specific characteristics of the Indonesian health care system. By using DSR, it can be ensured that the PHR model developed is based on scientific theory and methods. In addition, the DSR approach helps researchers understand existing health care systems and the needs of various stakeholders, such as patients, health care providers, and health regulators, in developing PHRs. DSR then includes evaluating the proposed PHR model, which can help identify any issues and make necessary improvements so that the designed PHR can follow the health system in Indonesia.

We developed architecture and application prototypes based on health systems in Indonesia, which comprise routine health services, including disease treatment and health examinations, as well as promotive and preventive health efforts. In addition, in this study, there are health referral functions that have not been discussed in the previous review of PHR functionality [5] and other studies in low- and middle-income countries [6-10]. This referral function is needed as the health system in Indonesia has a tiered referral program that should be followed by JKN patients [13].

The practical implication of this study is that this research is expected to be a guide for health regulators, health facilities, or health application vendors in designing an integrated PHR system in Indonesia. The architectural design in this study can provide an overview to integrate the PHR into the health services process in Indonesia, information about parties that need to be integrated into the PHR, and technology that can be used for PHR implementation. The prototype design in this study provides a guideline to implement PHR functions that focus not only on health care but also on disease prevention and health promotion.

Conclusions

The architecture design of the integrated PHR system in Indonesia refers to the TOGAF version 9.2, which is divided into 5 components: architecture vision, business architecture, application architecture, data architecture, and technology architecture. We developed a high-fidelity prototype for patients and physicians. The functionalities that were implemented were the priority functions defined in the architecture. The architecture evaluation stated that the architecture design had already described the needs and processes of health services in Indonesia as well as the technology needed for implementation. Improvements were made to the application architecture and data architecture to add the stakeholders that need to be integrated and the required functionality to the PHR. Prototype evaluation resulted in adding the necessary information to the functions that were developed, such as linking the medication order and messaging functions to the teleconsultation application and adding a health screening function. The limitation of this research is that the evaluation only focused on assessing the suitability of the integrated PHR model for the needs of health programs in Indonesia from the perspective of IT or eHealth experts. Future studies should be conducted to evaluate the prototype PHR from the perspective of patients and physicians as the primary users of the PHR.

Acknowledgments

This work was supported by a Pendidikan Magister Menuju Doktor untuk Sarjana Unggul grant from the Ministry of Research, Technology, and Higher Education, Republic of Indonesia, with research grant contract NKB-341/UN2.RST/HKP.05.00/2021.

Authors' Contributions

NCH designed the study, performed data collection, analyzed the data, and wrote the paper. PWH designed the study, provided writing assistance, and approved the final version to be submitted. ANH provided writing assistance and approved the final version to be submitted.

Abstract

Background: Due to the importance of radiologic examinations, such as X-rays or computed tomography scans, for many clinical diagnoses, the optimal use of the radiology department is 1 of the primary goals of many hospitals.

Objective: This study aims to calculate the key metrics of this use by creating a radiology data warehouse solution, where data from radiology information systems (RISs) can be imported and then queried using a query language as well as a graphical user interface (GUI).

Methods: Using a simple configuration file, the developed system allowed for the processing of radiology data exported from any kind of RIS into a Microsoft Excel, comma-separated value (CSV), or JavaScript Object Notation (JSON) file. These data were then imported into a clinical data warehouse. Additional values based on the radiology data were calculated during this import process by implementing 1 of several provided interfaces. Afterward, the query language and GUI of the data warehouse were used to configure and calculate reports on these data. For the most common types of requested reports, a web interface was created to view their numbers as graphics.

Results: The tool was successfully tested with the data of 4 different German hospitals from 2018 to 2021, with a total of 1,436,111 examinations. The user feedback was good, since all their queries could be answered if the available data were sufficient. The initial processing of the radiology data for using them with the clinical data warehouse took (depending on the amount of data provided by each hospital) between 7 minutes and 1 hour 11 minutes. Calculating 3 reports of different complexities on the data of each hospital was possible in 1-3 seconds for reports with up to 200 individual calculations and in up to 1.5 minutes for reports with up to 8200 individual calculations.

Conclusions: A system was developed with the main advantage of being generic concerning the export of different RISs as well as concerning the configuration of queries for various reports. The queries could be configured easily using the GUI of the data warehouse, and their results could be exported into the standard formats Excel and CSV for further processing.

Introduction

Background

Examinations performed by the radiology departments of hospitals, such as creating X-ray, computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound images, are fundamental for many kinds of clinical diagnoses. Therefore, optimizing the use of radiology is important for any clinician working with it as well as for any patient being examined there. Such optimization has several advantages for the hospital, such as shorter times patients need to stay there as well as the ability to perform more radiologic examinations. It also has advantages for the patient, such as shorter times to wait for the radiology appointment as well as reduced radiation exposure, if unnecessary repeated examinations of the same body region are avoided.

Objectives

This optimization requires a good overview of the various key metrics of radiologic services and their changes over time. A systematic approach for computing such metrics is building and using a radiology data warehouse. The main requirements for a radiology data warehouse solution are:

- Generic data import from the underlying radiology information system (RIS), for example, via an intermediate data format
- Tools for enriching the basic data with inferred data via a preprocessing step, which allows for more simple and compact queries on the data
- An expressive query language
- A comfortable graphical user interface (GUI) for the query language, including the ability to specify the resulting reports as tables, graphs, or a standard export format for further processing
- An efficient engine for answering queries and generating reports

These requirements are further explained in the following sections.

State of the Art

The relevance of calculating the key metrics of radiology data [1], as well as the types of metrics, that are most interesting for radiology exports [2,3] has already been described. In addition, the benefits of presenting such metrics in an easily understandable dashboard [4,5] have been explained. Although such solutions have been implemented for many different uses cases [6-9], all of them use a fixed interface to 1 or multiple specific hospital information systems and provide the user with only a fixed selection of predefined calculations. In other systems, the primary goal is to show data from individual patients [10-12], which only allows for a limited amount of filtering and no user-defined queries on the data. Other approaches use a data warehouse [13,14] to unite data from several (still fixed) hospital information systems into a unified representation and therefore allow for various user-defined queries to be executed but are missing a GUI for users to specify their queries and instead have their users either use Microsoft Excel or Structured Query Language (SQL; ISO/IEC Joint Technical Committee 1/Subcommittee 32/Working Group 3) for report creation. For importing data into a clinical data warehouse, more generic solutions exist [15,16] but without an option to calculate additional features during the import. This could make certain types of reports difficult or, depending on the query language of the clinical data warehouse, even impossible to create. These solutions are further discussed in comparison to the developed solution in the final section.

For hospitals whose data have been used during the development of this system, the state of the art for calculating key metrics of their radiology data was to do so manually in Excel. Although this allows for many different reports to be created, it has several drawbacks, which are also discussed in the final section. An intermediate result of this work has already been described [17]. This is described in more detail, together with the improvements in the final result, in the following sections.

Requirements

Generic Data Import Into a Data Warehouse

A radiology data warehouse primarily needs data of the examinations (type of modality, date and time of the request, execution, and documentation of each examination), relevant basic and radiologic patient data, the medical question for the examination as well as the radiologic diagnosis, and information about the radiologic equipment used. Since hospitals use many kinds of RIS, the use of an intermediate data format facilitates the data import and makes it independent of the internal data structure of the RIS. In this project, an Excel (or comma-separated value [CSV]) table was used as an intermediate format, in which the RIS data could be exported and from which it could then be imported into the data warehouse. If a hospital could only export its RIS data into JavaScript Object Notation (JSON) format (a proprietary one or a standard one such as Health Level Seven [HL7] Fast Healthcare Interoperability Resources [FHIR]), the relevant information from this format could also be converted into a table (using an Excel or a CSV file) that uses the structure described in the next section. All the hospitals whose data were used during the development of this system were only able to provide Excel exports of their RIS data.

Semantic Preprocessing of the Basic Data

To make queries on the radiology data easier, preprocessing of basic data is useful. Therefore, additional values were inferred from the basic data during the import into the data warehouse. Two types of preprocessing were necessary for this project: The first type was calculations performed by combining information from the basic data. Examples of such precomputed values are the difference between the time when an examination was requested and the time when it was performed as well as the time when the radiologic images were interpreted. This is usually not available in the RIS directly but can be easily computed from the individual time stamps. The second type was standardizations of the basic data. For example, the medical question for the examination could be either available as unstructured text using different wordings or as a hospital-specific code, which must be associated with a readable, standardized description, for example, by using a regular

expression during the import. As new kinds of queries are requested, additional data may be required. Because of this, another requirement is the ability to perform an incremental update of the data warehouse with just the new data instead of deleting and reimporting everything that has already been loaded into it.

Types of Queries and Query Language

The developed system should be able to support a wide range of different calculations. The calculations requested by the hospitals with whose data the system has been used so far could be separated into 5 different categories, which are described here:

- Patients, appointments, and examinations per modality: The most common metric was the number of patients, radiology appointments, and examinations in the radiology department for each modality. Additionally, these numbers were separated between inpatients and outpatients, the department of the hospital requesting an examination, the region of the body that was examined, or the shift during the day in which the examination took place. All these numbers were used to provide a general overview of the use of the radiology department.
- Use of radiologic devices: A radiology department usually has many different devices for different modalities as well as often multiple devices for a single modality. To better distribute examinations and clinicians on these devices, their use is 1 of the requested calculations. The metrics for this use included the number of examinations and patients per device. Furthermore, the time for each examination as well as the vacancy between examinations were evaluated.
- Length of a patient's stay in the hospital: Depending on the disease, different lengths of stay in the hospital are necessary. To evaluate whether patients were staying longer in the hospital than expected, which results in a reduced capacity for new patients, the actual stay times were compared with the ones suggested by clinical guidelines.
- Waiting times: Short waiting times are in the interest of both the patient and the clinician requesting a radiologic examination. Therefore, for each modality, the time between the request of an examination, the actual appointment in the radiology department, and the availability of the clinical findings after the examination were calculated and compared.
- Multiple examinations for the same question: To find the answer to a specific medical question, in many cases, 1 kind of radiologic examination works best. If such radiologic examination is performed directly by an experienced radiologist (who also verifies whether the requested examination makes sense for the medical question), the chances are high that only 1 examination is necessary to answer the medical question. However, if for 1 medical question, multiple examinations with the same or with different modalities are performed, the patient has increased radiation exposure and fewer radiology appointments are available for other patients. To measure this, first, all the different sequences of modalities for different kinds of medical questions were calculated. Afterward, the number of patients with such sequences were counted and compared. In addition, the total time for which a patient with such repeated examinations stays in the hospital was evaluated.

The query language used by the developed system must be able to support these kinds of queries as well as additional ones requested by the hospitals. This is also important for evaluating possible ways in which any of these metrics can be improved. For example, unnecessary multiple examinations can perhaps be explained by too few available devices for the modality recommended for a question or by missing staff to operate a device. To verify whether the measures taken are successful, the query language must also be able to analyze the change in the metrics over time.

A common set of queries for data saved in the same way furthermore allows for an easy comparison of the calculated number between different hospitals. In addition, as none of the mentioned categories depends on a specific hospital, all these calculations can be performed for any hospital (even in different countries) if it is able to provide the necessary data from its RIS.

A Comfortable GUI for the Query Language and the Result Specification

Although the query language should be usable in textual form, a GUI is also required to create queries in a graphical way and automatically create the corresponding textual queries. As with the query language, the GUI should also allow for the layout of the requested report to be specified. The results of queries should be shown to the user as a table or as a graph. Furthermore, the results should be exportable into the standard formats Excel and CSV so that they can be further processed.

Furthermore, the GUI should make the system (with a limited amount of training) usable by the clinicians themselves and therefore should not require any knowledge of computer science.

Efficiency Requirements

Importing data into the data warehouse as well as creating reports using the query language on these data both should happen in a reasonable amount of time. For the initial import, the tool should not need longer than a few hours, and for querying the data, most of the queries should return their results in about 1 second, while more complex queries should not run for more than a few minutes. These requirements are necessary so that a user can quickly start to use the system and, while using it, easily try different variations of a query without a long waiting time for each result.

Methods

Ethical Considerations

In this paper only retrospective, pseudonymized patient data for patients with age groups below and above 18 years with a few attributes only about their radiologic examinations were used (dates, modality, device, localization, radiologic query, boolean values for insurance [statutory or private], boolean values for the type of stay in the hospital [inpatient or outpatient]). De-pseudonymization of the data was not possible for the authors of the study. Therefore, no ethics approval was necessary.

Concept

Processing Radiology Data for Importing It Into a Data Warehouse

The data from the RIS of the hospitals were provided to the tool as an Excel, CSV, or JSON file, in which each row represents a single examination. Each column in this file is 1 attribute, and the names of these attributes are written in the first row of the file.

To map these columns to attributes in the structure of the data warehouse, a configuration file (using Excel or CSV as well) was used. This file contained 1 row for each attribute and specified the name, identifier, and data type to use (eg, numbers or texts) when importing them together with the concrete values into the data warehouse. The columns containing the required metadata (eg, identifiers) must be specified in this configuration file as well.

As mentioned in the previous section, some values for the requested reports must be calculated based on the exported RIS data. To do this, several options were offered. Additional columns were added to the RIS export performing the calculations. These were then imported into the data warehouse like any other column in the RIS data by specifying them in the configuration file. The configuration file also provided an option to replace textual values with other values, which could, for example, be used to replace an abbreviation in the RIS export with a longer form. For more advanced calculations, several programming interfaces were offered and could be implemented for any value requiring such a calculation.

All the values from the RIS, together with the calculated values, were then saved to the data warehouse, and an index was created on them for increased query performance.

Creating Reports

As soon as all the needed values were saved in the data warehouse, queries on these data were run to calculate and create the requested reports. For this purpose, a query language was used to define the structure of the report. This was done by first specifying attributes to be queried as well as constraints on the values of these attributes. In the next step, these attributes were combined with the logical operators “and”, “or,” and “not.” These single attributes or groups of attributes were then used to specify the rows and columns of the requested report. For every combination of attributes in each row and each column, a query was created, resulting in the cells of the report. If additional constraints on all cells were required, other attributes were used to specify filters. Finally, the query language specified what type of count (examinations, appointments, or patients) should be returned. All this was either specified in textual form or graphically using the GUI of the data warehouse. To create a report, the query for each cell was run on the data and, depending on the configuration, the number of examinations, appointments, or patients was returned.

By using a query language like this, it is easily possible to run modifications of a query, which is further simplified by the ability of the data warehouse to save a query and load it again later.

After a query was configured and executed, the interface of the data warehouse showed the results as a table and provided the option to export this table into the standard formats Excel and CSV. The results of some predefined queries were also shown as graphics.

Implementation

The Clinical Data Warehouse PaDaWaN

PaDaWaN (short for Patient Data Warehouse Navigator) [18] was used as the clinical data warehouse. Its core is a database containing all the used medical information and a separate index to increase the speed of queries on the data. To specify the queries, PaDaWaN uses its own query language as well as its own web interface. Furthermore, it provides the ability to export and save query results. All these parts are described in more detail in the following sections.

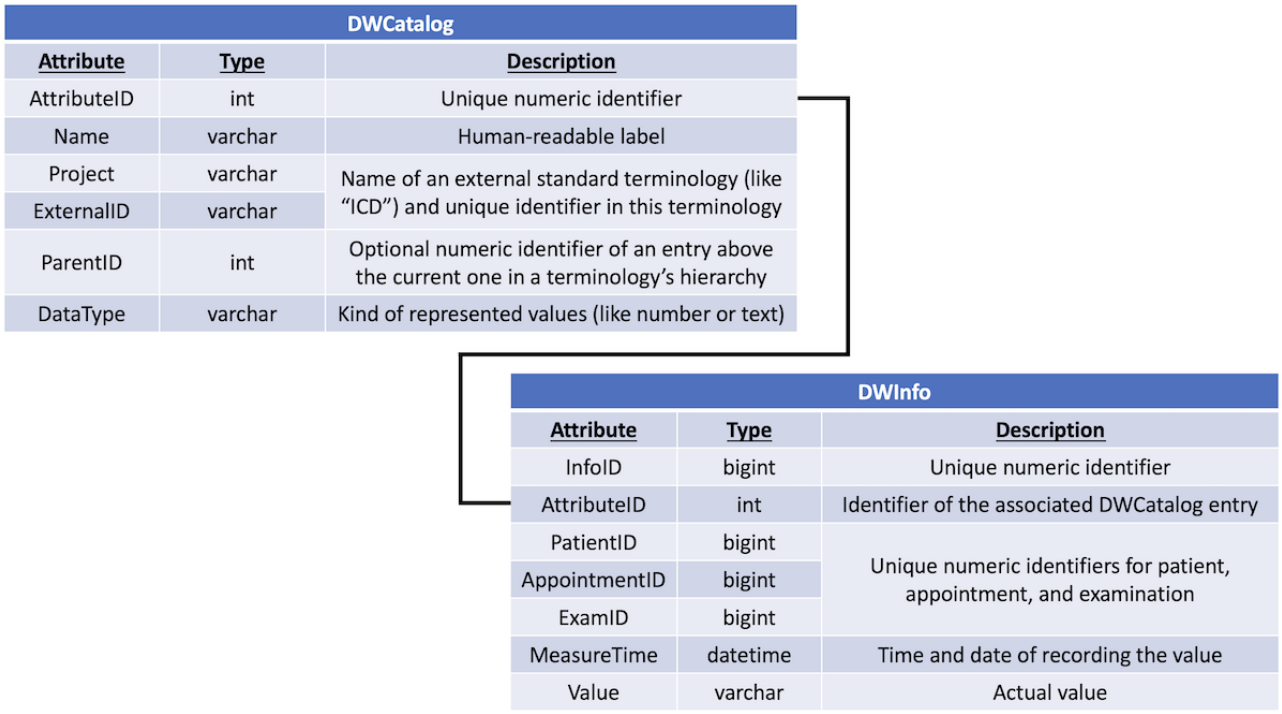
Database Structure

PaDaWaN stores its data in a database, which could be either a Microsoft SQL [19] or a MySQL [20] database. The table structure is based on the entity attribute value model [21]. It consists of 2 main tables, as shown in Figure 1.

The first table (DWCatalog) contains a catalog of all the possible types of information in PaDaWaN. This could represent, for example, different types of diagnoses or laboratory measurements. Each entry in this table is uniquely identified by a numeric AttributeID as well as by the combination of ExternalID (the ID in the terminology defining the entry, such as, the International Classification of Diseases [ICD] code [22] I50) and Project (the name of the whole terminology, such as “ICD”). AttributeID is automatically generated by the database and is only valid for a single installation of the system. As further explained later, only the combination of ExternalID and Project is used to identify entries from this table in a query, and therefore, only this combination must be unique among different systems if the same query should be used for all of them. For easier usage in the PaDaWaN interface, every entry has a readable name (eg, “heart failure”). The ICD terminology, for example, uses a hierarchal structure. To save this or any other hierarchy among the attributes, the ParentID field is used and contains the AttributeID of the entry, that is, the parent of the current entry. The kind of data (eg, Boolean, number, or text) that could be saved for an entry is specified with the DataType field.

In the DWInfo table, all the concrete patient data are saved. Each entry in this table is uniquely identified with an automatically generated numeric InfoID and is associated with a type of information from the DWCatalog table by its AttributeID. With the other ID fields, each entry in this table is also associated with a patient, appointment, and examination. The time and date on which a value has been recorded is saved in the MeasureTime field. The actual value (eg, the content of a patient’s discharge letter) is stored as text in the Value field.

Figure 1. Structure of the 2 main tables in PaDaWaN's database containing all the possible types of information (DWCatalog) and the information itself (DWInfo). ICD: International Classification of Diseases; PaDaWaN: Patient Data Warehouse Navigator.



DWCatalog

Attribute	Type	Description
AttributeID	int	Unique numeric identifier
Name	varchar	Human-readable label
Project	varchar	Name of an external standard terminology (like "ICD") and unique identifier in this terminology
ExternalID	varchar	
ParentID	int	Optional numeric identifier of an entry above the current one in a terminology's hierarchy
DataType	varchar	Kind of represented values (like number or text)

DWInfo

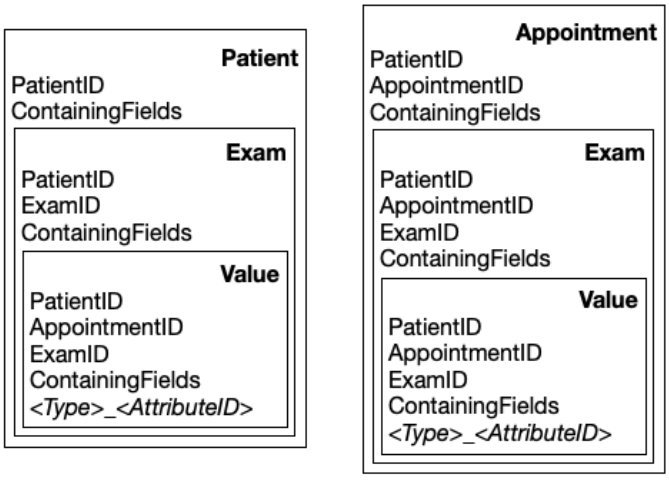
Attribute	Type	Description
InfoID	bigint	Unique numeric identifier
AttributeID	int	Identifier of the associated DWCatalog entry
PatientID	bigint	Unique numeric identifiers for patient, appointment, and examination
AppointmentID	bigint	
ExamID	bigint	
MeasureTime	datetime	Time and date of recording the value
Value	varchar	Actual value

Index Structure

To increase the speed of queries on the data in PaDaWaN's database, it was indexed with Apache Solr [23]. Solr saves data in documents, and the schema used for PaDaWaN is shown in Figure 2.

PaDaWaN offers the ability to search for data on 3 different levels: patients, appointments, and examinations. If a search is conducted on any of these levels, all patients/appointments/examinations should be found, containing all the requested combinations of attributes and values. To accomplish this in Solr, PaDaWaN uses Solr's feature to store documents nested in other documents. As shown in Figure 2, a document is created for each patient and each appointment. Another document is created for each examination and is stored inside the patient and appointment documents. Finally, for every value, another document is created and stored inside both examination documents. Although this approach requires more disk space as each value is saved twice, this greatly increases the speed of queries being run on the patient level compared to a document structure, where the appointments are nested inside the patient documents. Each document contains all the available IDs, as described in the previous section. Additionally, all of them contain a field named ContainingFields, which stores the AttributeIDs of all values contained in the current document. This allows a query to restrict the number of top-level documents it must search on for concrete values of the attributes. These values are stored in a field in the value document, whose name is generated by combining the attribute's type with its ID.

Figure 2. Document structure of PaDaWaN's Solr index using nested documents for examinations and values in separate parent documents for patients and appointments. In addition to the numeric identifiers for patients, appointments, and examinations under ContainingFields, all AttributeIDs of all values inside a document and its children are saved. The values themselves are stored in dynamic fields named with a combination of their type and AttributeID. PaDaWaN: Patient Data Warehouse Navigator.



Query Language

To specify the structure of the requested tabular result, PaDaWaN uses its own query language called Medical XML Query Language (MXQL). In the following example, the result table contains 2 rows and 2 columns. The rows contain 2 different types of modalities (X-ray and CT scan), and the columns contain 2 regions of the human body (abdomen and thoracic spine). For each combination of a row and a column, the number of matching patients from hospital A is returned. In the first cell, for example, the number of patients who undergo an X-ray examination of the abdomen is counted. This query is shown in MXQL in Figure 3 and in PaDaWaN's GUI in Figure 4. The result in Excel can be seen in Figure 5. This is a simple example used to explain the query language, PaDaWaN's GUI, and its export capabilities, and the results shown in Figure 5 may also be retrieved directly from an RIS (depending on its capabilities).

Each query in MXQL must contain at least the following 2 elements: Query and Attribute. Query is the root XML element and contains the whole rest of the query. Attribute contains information about the catalog entry whose values should be queried. To identify this catalog entry, Attribute uses the "domain" and "extID" properties, which map to the Project and ExternalID columns of the DWCatalog database table described before. The remaining elements of the query are optional and used for more complex queries. In the example query shown in Figure 3, the Attribute elements are further constrained to only match specific values for the catalog entries. This is done with the contentOperator and desiredContent properties, where desiredContent contains a value to be matched and contentOperator the way it should be matched. The IDFilter element is used to specify on which level all the attributes in the query should be combined. In the example in Figure 3, this is set to "PID," which means that all the attributes must have the same PatientID and that the number of matching patients should be returned by such a query. The last remaining elements of the query are DistributionRow, DistributionColumn, and DistributionFilter. They are used to return counts of multiple combinations of Attributes in a single query. Each DistributionRow becomes a row in the created result, and similarly, each DistributionColumn becomes a column. The DistributionFilter can be used to apply further constraints on all the combinations of rows and columns. Finally, the displayName property of the Attribute element can be used to provide a name for the created rows and columns. Not shown in the example is the ability of MXQL to combine multiple attributes with the logical combinations "and" and "or," which could even be nested inside another combination. MXQL also allows for the logical operator "not" to be added to any attribute.

Here, only the MXQL features used for this project are described. A complete documentation of this query language (in German) can be downloaded from PaDaWaN's website [24].

Figure 3. Sample query in PaDaWaN's query language MXQL. This query returns counts of patients (specified with the filterIDType "PID") for each combination of attributes specified as DistributionRows and DistributionColumns. In this example, the first combination would be all X-ray examinations of the abdomen. DistributionFilter restricts all the combinations to patients from hospital A. MXQL: Medical XML Query Language; PaDaWaN: Patient Data Warehouse Navigator.

```
<Query>
  <IDFilter filterIDType="PID">
    <DistributionRow>
      <Attribute domain="generated_attributes" extID="modality_group"
      displayName="X-Ray" contentOperator="EQUALS" desiredContent="X-Ray"/>
      <Attribute domain="generated_attributes" extID="modality_group" displayName="CT"
      contentOperator="EQUALS" desiredContent="CT"/>
    </DistributionRow>
    <DistributionColumn>
      <Attribute domain="generated_attributes" extID="body_region_group"

Figure 4. Web interface of PaDaWaN with the query from Figure 3. On the left side, the catalog of available attributes is shown and can be hierarchically expanded as well as searched. On the top of the right side, the query itself can be configured by dragging items from the catalog to create rows (Zeilen in German), columns (Spalten in German), and filters. With the 3 radio buttons in the top middle, the kind of IDs to be counted can be specified. Although meaning something else in German in this project, the buttons from left to right are used for patients, appointments, and examinations. The row of buttons in the middle are used to execute a query (Suchen in German) as well as to save and load queries (Speichern and Laden in German, respectively) and to export their results. After executing a query, the bottom right of the GUI shows its result (Ergebnis in German). The remaining buttons were not used for this project. The query shown here creates rows for X-ray (Rö: short form in German) and CT scan (CT: short form in German) examinations and columns for examinations of the abdomen and the thoracic spine (BWS: short form in German). The filter then restricts everything to just examinations from the hospital (Klinik in German) A. The remaining elements of the GUI were not used for this project. CT: computed tomography; GUI: graphical user interface; PaDaWaN: Patient Data Warehouse Navigator.

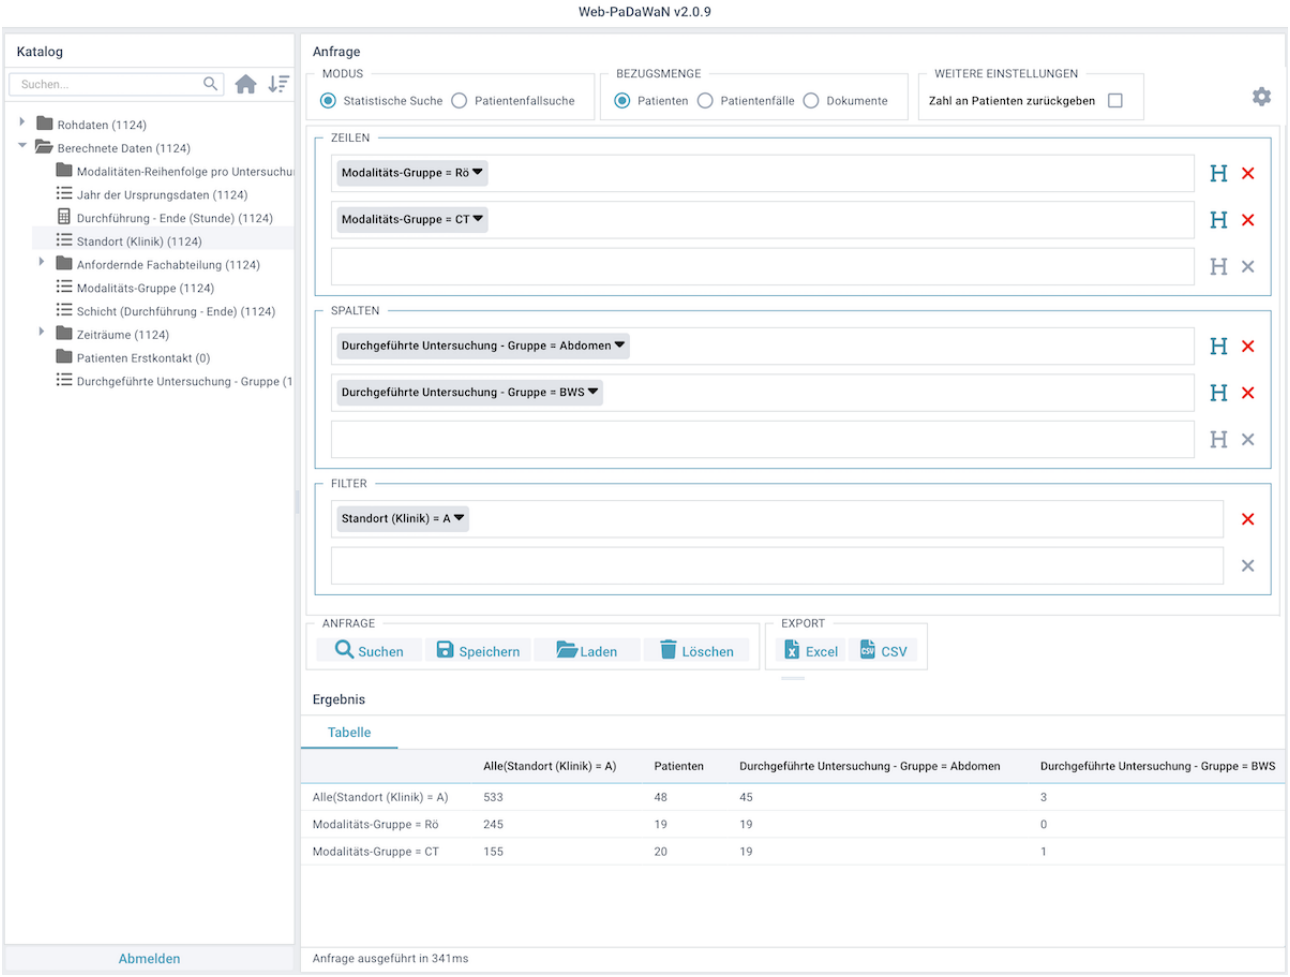

Figure 5. PaDaWaN Excel export for the query from Figures 3 and 4, where the number of patients with different kinds of radiology examinations (as rows) is counted for multiple regions of the human body (as columns). CT: computed tomography; PaDaWaN: Patient Data Warehouse Navigator.

	A	B	C
1		Abdomen	Thoracic Spine
2	X-ray	19	0
3	CT	19	1

Web Interface

PaDaWaN has its own graphical web interface allowing a user to search the available attributes, graphically configure a MXQL query, and preview the result table. The interface with the MXQL query from Figure 3 looks like Figure 4.

On the left side of the interface, the content of PaDaWaN's DWCatalog table (explained before) is shown and can be hierarchically expanded and searched. With the 3 radio buttons in the top middle of the GUI, the level on which all the attributes in the query should be found (for this project, patients, appointments, or examinations) can be configured. Via drag and drop, any attribute from the catalog can be placed in any section of the query to configure either rows (*Zeilen* in German), columns (*Spalten* in German), or filters (like that explained in the previous section). Finally, a configured query can be run by

pressing the Search button (*Suchen* in German). With the Save and Load buttons (*Speichern* and *Laden* in German, respectively), a configured query can be saved and any saved query can be loaded. The next 2 buttons provide the option to export a queried result in either Excel or CSV format. The bottom of the right half of the GUI shows the tabular result (*Ergebnis* in German) created after running a query. By clicking any of the attributes in the query on the right side of the GUI, a dialog box appears, where, for example, the value of an attribute that should be counted can be configured. In this example these values are *Rö* (short in German for X-ray), *CT*, *Abdomen*, *BWS* (short in German for thoracic spine), and *A* (for the name of the hospital; *Klinik* in German). All the remaining buttons were not used for the queries in this project.

Export of Query Results

PaDaWaN also offers an option to export query results in either Excel or CSV format using the Excel or CSV button, respectively, in Figure 4. When the query has finished, an Excel or a CSV file is created and offered as a download. When running the query shown in MXQL in Figure 3 and in the GUI in Figure 4, the Excel export looks like that in Figure 5.

As configured in the query, each row is a different kind of radiologic examination, and each column contains a different region of the human body. As the query was configured to return the number of matching patients, the first number means that in this (small and artificially generated) data set, 19 patients underwent an X-ray examination of the abdomen.

Export of the Radiology Data

For the developed system, data from a hospital's radiology department are needed. The system should be usable by many different hospitals with many kinds of RISs. Therefore, Excel, CSV, and JSON are used as the formats in which the RIS data can be exported and then imported from this file into PaDaWaN. As mentioned in the Introduction section, if a hospital is only able to provide its RIS data as a JSON file, this can also be transformed into a table and then saved as either an Excel or a CSV file. A part of an RIS Excel export is shown in Figure 6.

Figure 6. Sample of an RIS Excel export containing information about 1 examination in the radiology department per row and 1 attribute per column. CID: Case identifier; CT: computed tomography; RIS: radiology information system.

	A	B	C	D	E	F	G	H	I
1	Location	Device	Start of examination	CID	Examination-short	Examination-long	Insurance	Type of stay	Modality

14	Location 1	1-Xray	19-01-01 04:49	10	XT1R	Right big toe radio	private	outpat	Xray

Exporting uses a simple structure, where each row represents a single examination of a patient and each column contains 1 attribute with information about the examination. The title of the attribute must be given in the first row. The only required pieces of information are the ID of the patient's stay in the hospital, the start date and time of the examination, and the modality performed. All the remaining attributes could be different for each hospital, and the way they are imported into PaDaWaN is explained in the next section.

All the IDs that were used for this project had already been pseudonymized during the RIS export.

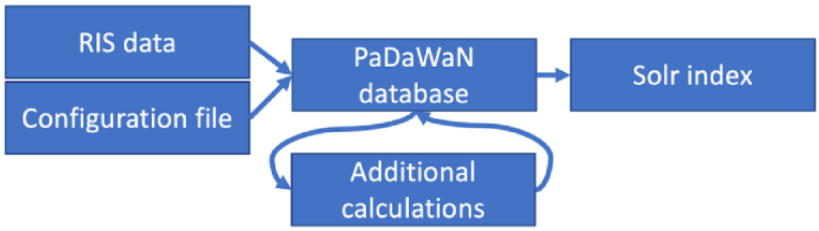
Import of the Radiology Data Into the Data Warehouse

The RIS export, as described in the previous section, was imported into PaDaWaN using the following steps:

- Step 1: A configuration file is created to specify the mapping of the RIS export columns to PaDaWaN catalog entries.
- Step 2: Using this configuration file, the data in the RIS export are converted to PaDaWaN database entries.
- Step 3: Additional precalculations are performed on the RIS data using an interface provided, and the results are saved in PaDaWaN's database as well.
- Step 4: A Solr index is created on these data.

An overview of this process is shown in Figure 7. Each step is described in more detail later.

Figure 7. Overview of the process for importing radiology data into the data warehouse. First, a configuration file is created and used to import the exported RIS data into PaDaWaN's database. On these data, additional precalculations are then performed. Finally, a Solr index is created for all the data in PaDaWaN's database. PaDaWaN: Patient Data Warehouse Navigator; RIS: radiology information system.



Configuration File to Map the Radiology Data to the Data Warehouse's Structure

An Excel (or CSV) configuration file was used to specify the mapping of the columns in the RIS export to the data structure of PaDaWaN. A configuration file for the data in Figure 6 would look like that in Figure 8.

The first row of this file must always look like that shown in Figure 8. Each of the following rows represents 1 column from the RIS export. If any of these columns should be ignored, they can be left out. The columns of the configuration file are used for specifying the PaDaWaN catalog entry that should be created (with the name from the DisplayTitle column and ExtID and DataType being directly used for database columns with the same names). The DataType "SingleChoice" is used for textual values with only a limited number of possible options (eg, modality). The ColumnName and ColumnNumber columns are used to identify a column in the RIS export. The ValueMappings column can be used to map abbreviations or codes in the RIS data to more readable names. Finally, the MetaDataType column is used to specify which columns contain which type of identifiers, the time an examination was performed, and the modality.

Figure 8. Sample of an Excel configuration file to specify the mapping between an RIS export and PaDaWaN's data structure. The ColumnName and ColumnNumber columns must match a column in the RIS export. The DisplayTitle, ExtID, and DataType columns are mapped to the corresponding columns in PaDaWaN's DWCatalog table. With ValueMappings, column abbreviations in the RIS export can be mapped to their longer form. The final column is used to specify which RIS column contains which type of metadata. CID: Case identifier; PaDaWaN: Patient Data Warehouse Navigator; RIS: radiology information system.

	A	B	C	D	E	F	G
1	**ColumnName**	**DisplayTitle**	**ExtID**	**DataType**	**ColumnNumber**	**ValueMappings**	**MetaDataType**
2	Location	Location	locatic	SingleCho	1		
3	Device	Device	statior	Text	2		
4	Start of exami	Start of exan	execSt	DateTime	3		MeasureTime
5	CID	Case identifi	cid	Text	4		CaseID
6	Examination-s	Code of exar	taskCc	Text	5		
7	Examination-l	Name of exa	taskTe	Text	6		
8	Insurance	Type of insu	payUn	SingleCho	7		
9	Type of stay	Type of stay	caseTy	SingleCho	8	inpat:inpatient;c	
10	Modality	Modality	modal	SingleCho	9		Modality

Import Process of the Radiology Data Using the Configuration File

When starting the import of the RIS export, first, the configuration file, as explained before, is read and then all the columns specified in the rows of the configuration file are imported into PaDaWaN.

For this, first, an entry in PaDaWaN's DWCatalog table is created with the values from the configuration file. To import concrete values from any column in the RIS export into PaDaWaN's DWInfo table, some metadata are required: PatientID, AppointmentID, and ExamID, as well as MeasureTime. These are specified with the MetaDataType column in the configuration file.

With the catalog entry and the metadata, each value in each column of the RIS export was saved into PaDaWaN's database.

Calculating and Importing Additional Values Based on the Radiology Data

As some calculations are not possible with PaDaWaN's query capabilities or would require complex queries, several interfaces (written in Kotlin [25]) are provided to specify additional calculations that should be executed during the RIS data import. Initially, for all these interfaces, the properties of the PaDaWaN catalog entry that should be created must be provided. Additionally, the RIS column names required for the calculation must be specified. The provided interfaces can then be used to either specify calculations that should occur for each examination (eg, calculating the shift during a day in which an examination was performed) or once for all examinations (eg,

to calculate sequences of examinations that have been performed for a single patient and for the same medical question with 1 or multiple modalities).

During the execution of all the implementations, the catalog entry specified by each implementation is created and the implemented methods to calculate the values and save them to the database are called.

Creating an Index on All Imported and Calculated Values

The last step during the import process of the RIS data is the creation of a Solr index on the data from PaDaWaN's database. For this purpose, all the values are fetched from the database and documents in the structure described before are created. These documents are then sent to Solr, which creates its index on them.

Incremental Updates of the Data Warehouse for New or Updated Radiology Data

The process of importing all the RIS data into PaDaWaN as well as creating a Solr index on it takes some time (shown in the next section). During the work on this project, additional calculations on the RIS data, updates on existing calculations, and additional information from the RIS were needed in many cases. The whole process described in the previous section could be run again, which resulted in most values being imported or calculated again, although they did not change.

Therefore, a separate configuration file could be given to the importer, containing just the names of the attributes from the RIS export or from the implemented interfaces, that had to be processed. When using this option, just the columns and calculations of these attributes are processed and saved to the database. Afterward, Solr's ability to perform atomic updates [26] is used. In this way, the whole documents do not have to be created and indexed again, but instead, only small parts for the updated or added attributes are deleted and then added with the new values to the existing documents.

Another possibility for new radiology data would be data from new patients. In this case, the additional data can be exported from the RIS into a separate file and then the whole import process described before can be run for just this file so that only the new data are added to the database and the index and no processing of the existing data must be done again. If a near-real-time evaluation of the data is requested by a hospital, this process can also be run immediately any time new data are added to the RIS.

Performing Calculations on the Data Using the Data Warehouse and Exporting Their Results

After the RIS data and any additional calculations on them are saved to and indexed by PaDaWaN, PaDaWaN's web interface is used to create and run queries on these data. The usage of the interface as well as the query capabilities have already been described in the section on PaDaWaN before.

The process of creating a new query involves first specifying all the attributes for rows and columns whose combinations should be counted in the result. Optionally, additional filters can be configured for all these combinations. Next, the user chooses whether the number of matching patients, appointments, or examinations should be returned. Finally, the query is run (the matching MXQL query is automatically created by the web interface), and its result is either shown directly in the GUI or is exported to an Excel or a CSV file.

For reusing queries, PaDaWaN also provides an option to save and load queries.

PaDaWaN's web interface uses a REST-based interface, which can also be used directly without the GUI. To do so, the query must be created as an MXQL string and can then be sent to the interface. When PaDaWaN has finished the execution of the query, the result can be received in JSON format or as an Excel or a CSV file.

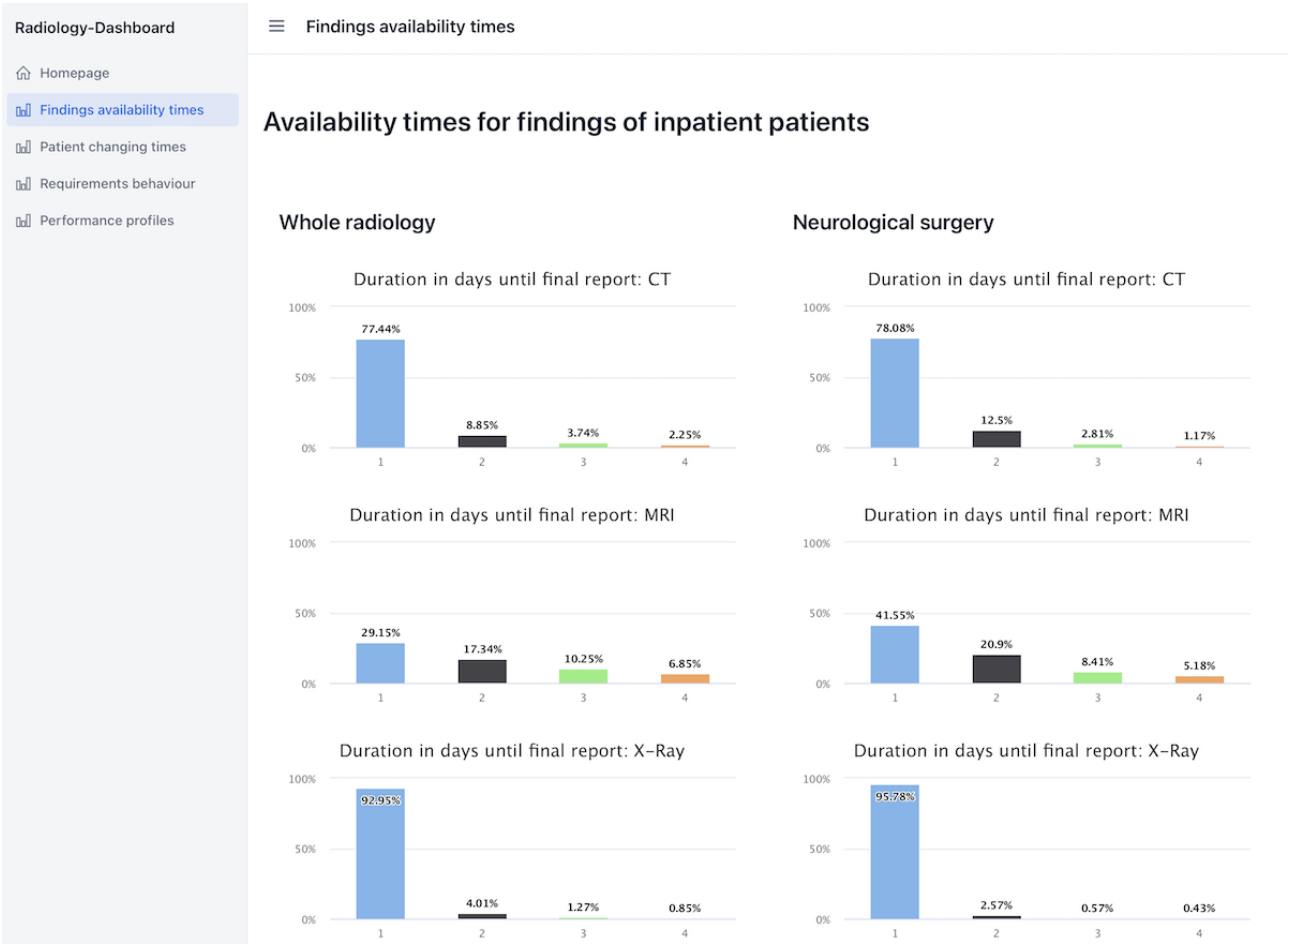
Presentation of Results Calculated by the Data Warehouse

As PaDaWaN allows for exporting of results into the standard formats Excel and CSV, these results can be easily imported by many different tools to perform further calculations or to create graphics. To present the 4 most common types of calculations for the hospitals involved in this project as graphics, a simple web dashboard was created and is shown in Figure 9.

The example calculates for all inpatients the percentage of findings for 3 modalities that has been available for 1, 2, 3, or 4 days after the examination in the radiology department. These numbers are further compared between the whole radiology department and just examinations that have been requested by the neurological surgery department.

To calculate these numbers, matching PaDaWaN queries were created and saved. When opening this dashboard, the queries were loaded and executed, and the numbers were extracted from PaDaWaN's result table.

Figure 9. Simple web dashboard with graphics for the 4 most common types of calculations on the radiology data of the hospitals involved in this project. The graphics in this figure show what percentage of findings for a radiological examination is available in up to 1, 2, 3, or 4 days. This is given for the 3 most common modalities and is compared between examinations in the whole radiology department and only the ones requested by neurological surgery. CT: computed tomography; MRI: magnetic resonance imaging.



Results

Technical Evaluation

In the following sections, details about the used data themselves as well as about the import and report creation process are presented.

Used Data

The developed system was tested with RIS exports from 4 different hospitals from different regions of Germany. Some of these data are shown in Table 1.

Table 1. Information about the used radiology exports of 4 different hospitals from Germany.

Details	Hospital A	Hospital B	Hospital C	Hospital D
Hospital sites, n	1	2	2	3
Time of data	2018	2019 to September 2020	2018 to June 2021	2019 to 2021
Patients, n	13,603	125,732	N/A[a]	N/A[a]
Appointments, n	28,886	384,186	307,174	241,148
Examinations, n	52,542	487,474	599,481	296,614
Values imported, n	2,50,001	11,650,688	15,014,221	5,339,024
Values generated, n	555,859	18,848,459	8,151,85	2,974,740
RIS[b] export size (MB)	14.9	75.7	56.1	21.7

[a]N/A: not applicable. The data from hospitals C and D contained no patient identifier, so the number of patients could not be specified.

[b]RIS: radiology information system.

The data were provided as an Excel export from the RISs of the hospitals. The last 3 hospitals had multiple radiologic sites in different cities. In addition, the time for which the data were exported was different, ranging from 1 year for the first hospital to 3.5 years for the third one. Only in the exports of the first 2 hospitals was a (pseudonymized) patient identifier included, so the number of patients could only be calculated for these 2 hospitals. Each value in a single cell of the RIS exports was imported into the data warehouse, and their number is specified in Table 1. For comparison, the number of values that were generated during the import is also specified. Numbers related to the import process are presented in the next section. Finally, in the last row, the size of the Excel files exported from the RIS is shown.

Process of Importing the Radiology Data Into the Data Warehouse

For the data of all 4 hospitals, a separate virtual machine (running in the internal network of the university of Würzburg) was created, and each of them was configured with 4 CPUs and 32 GB of RAM and stored on a solid-state drive (SSD). Inside of these machines was installed Ubuntu 20.04.4, together with MySQL 8.0.28, Java 11.0.14, and Solr 8.11.1. PaDaWaN's web interface was run on an Apache Tomcat [27] 10.0.18 server. On these virtual machines, the RIS exports were imported into PaDaWaN, resulting in the numbers shown in Table 2, which are discussed in the next section.

For 3 of the hospitals (the ones with data from multiple sites and years), the RIS export was provided as several Excel files, which were imported 1 by 1. Their number is specified in the first row of the first section of Table 2. After processing all files, the Solr index creation began.

The next row of Table 2 shows the total time needed for loading the RIS exports and saving their values to PaDaWaN's database. The number of attributes in the RIS export is specified in the last row of the first section.

Table 2. Numbers measured while importing radiology exports into the data warehouse.

Details	Hospital A	Hospital B	Hospital C	Hospital D
RIS data import				
Imported files, n	1	4	8	3
Import time (hours:minutes:seconds)	0:02:22	0:18:11	0:21:06	0:07:07
Imported attributes, n	45	26	11	18
Additional calculations				
Calculations, n	10	14	9	8
Time for each calculated attribute (seconds), mean (SD)	4.7 (2.9)	23.0 (30.2)	9.3 (2.3)	11.7 (8.0)
Total time (hours:minutes:seconds)	0:00:47	0:21:31	0:11:11	0:04:40
Index and database				
Solr index creation time (hours:minutes:seconds)	0:04:02	0:31:28	0:16:49	0:12:06
Time of the total process[a] (hours:minutes:seconds)	0:07:12	1:11:15	0:49:13	0:23:57
Database size (GB)	1.3	15.8	11.4	3.7
Solr index size (GB)	1.4	15.1	2.2	3.8
Incremental updates				
Examinations per day, mean (SD)	144 (61.8)	763 (288.5)	469 (200.3)	271 (222.3)
Time for adding these examinations[b] (hours:minutes:seconds)	0:00:18	0:01:29	0:01:00	0:00:28

[a]Total time for importing all attributes, calculating additional ones, and creating the Solr index.

[b]Time for incrementally adding just this average number of examinations per day.

In the second section of Table 2, numbers related to the additionally performed calculations are shown. These are the number of calculated attributes, the average time needed to calculate and save them to the database, and the total time for calculating and saving all these values.

The second-to-last section of Table 2 starts with the time needed to create a Solr index of all the imported values as well as the time needed for the whole import process of each hospital. In the last 2 rows, the size of the created database and Solr index is specified.

In the final section of Table 2, additional numbers related to the ability of the developed system to perform incremental updates are shown. Therefore, the average number of examinations per day for each hospital was calculated and then the time was measured to incrementally add just this number of examinations (along with additional calculations on them) to PaDaWaN's database and index.

Creating Reports on the Radiology Data With the Data Warehouse

Many reports were created using the data of all 4 hospitals, depending on the requirements of each hospital. Three reports

of different complexities, which were requested by most of the hospitals and were possible with the data provided by all of them, were created to show the time PaDaWaN needed to calculate those reports and export them as an Excel file. For each report, the number of matching examinations was restricted with MXQL to only include the data of 1 year. In all 3 reports, the 4 most common types of modalities for the hospitals (X-ray, CT, MRI, and ultrasound) were used. The following reports were created:

- Report 1: Number of examinations performed for the 4 modalities (as rows of the query) and for the types of stay in the hospital (inpatient or outpatient, as columns of the query)
- Report 2: Number of examinations performed for the 4 modalities (as rows of the query) and for the different hours of the day (from 8:00 a.m. to 7:00 p.m., as columns of the query)
- Report 3: Number of examinations requested by all the different organizational units of each hospital (as rows of the query) for the 4 modalities (as columns of the query)

The numbers related to the creation of these reports are shown in Table 3 and are discussed in the next chapter.

One Solr query was created for each possible row-column combination, which is why the number of executed Solr queries for each report equaled the number of rows multiplied by the number of columns. These numbers were identical for all 4 hospitals in the first 2 reports, as they used the same rows and columns. In the last report, 1 row was created for each organizational unit of the hospital, resulting in different numbers of rows for each hospital.

Table 3 also shows the average time in milliseconds Solr needed for each single query, as well as the total time to run all the Solr queries and export their results as an Excel file.

Table 3. Numbers related to the process of creating 3 reports of different complexities with the data warehouse.

Report and details	Hospital A	Hospital B	Hospital C	Hospital D
Report 1				
Rows, n	4	4	4	4
Columns, n	2	2	2	2
Solr queries, n	8	8	8	8
Time[a] (ms), mean (SD)	79.5 (111.6)	185.3 (264.0)	90.3 (117.3)	95.3 (180.7)
Total time	645 ms	1 s 489 ms	728 ms	767 ms
Report 2				
Rows, n	4	4	4	4
Columns, n	12	12	12	12
Solr queries, n	48	48	48	48
Time[a] (ms), mean (SD)	18.3 (7.7)	67.8 (23.3)	22.6 (12.4)	21.8 (13.7)
Total time	904 ms	3 s 275 ms	1 s 110 ms	1 s 69 ms

Total time	2 s 315 ms	82 s 233 ms	15 s 201 ms	84 s 758 ms

[a]Average time for the execution of each Solr query.

Comparison With the Creation of Reports Directly in Excel

Before using the developed tool, all 4 hospitals created such reports directly in Excel. To evaluate possible improvements compared to the report creation in Excel, this manual process was performed for new reports of different complexities with the largest data set (of hospital B) with the data of 1 year.

When the reports are created directly in Excel, nothing needs to be imported. Nevertheless, to simplify the calculations on the data, all the RIS exports of the considered year were combined into a single Excel file. The calculations otherwise executed during the import process were performed directly in Excel by using Excel formulas in new columns. As all these calculations were executed on each opening of the Excel file, all the RIS data, together with the calculated values, were then copied to another Excel file so that working with the data was faster.

The reports themselves could be created directly in Excel in many ways. If just single numbers are required, Excel's built-in filter capabilities can be used. To create the reports for this evaluation, Excel formulas were used to define the value of

each cell. These formulas were then copied to all the other cells, and their restrictions were adapted according to each row and column of the report that had to be created.

The results of this comparison are discussed in the next section.

User Feedback

Because the usage of the developed system consisted of various reports requested by the participating hospitals, their feedback was evaluated by describing the requests that could and that could not be created on the data provided by them.

In general, the requests could be divided into those of interest to all hospitals and special requests by an individual hospital. Of general interest was, for example, the number of patients, appointments, and examinations; the use of devices; repeated examinations of the same body region; and the waiting time for an examination. Specialized reports were mainly created for hospital B, which has the largest radiology department among the participating hospitals. The concrete reports that were created for each hospital are listed next.

Reports for Hospital A

- Specifically for patients with multiple myeloma or a hepatocellular carcinoma the number of patients for each modality and quarter of the year as well as for each type of stay in the hospital and each clinical department requesting a radiologic examination for such patients has been counted.
- For the same two types of diseases the number of patients with repeated examinations using the same or different modalities was counted.
- For two clinical departments requesting radiologic examinations the time between the request and the availability of the radiologic report has been evaluated.

Reports for Hospital B

Each of the following reports was requested for each site of the hospital as well as for regular radiology and neuroradiology:

- The number of patients, appointments, and examinations for each modality was counted. In separate reports, these numbers were further split by each shift and hour during the day or the body regions listed for the next report.
- For repeated examinations using the same or different modalities for the same body region, the number of patients was counted. The body regions of interest for this hospital were the abdomen, the cervical spine, the thoracic spine, the lumbar spine, the ankle joint, the knee joint, the hip joint, the shoulder joint, and the liver. In another report, the total time for these sequences of modalities was evaluated.
- For each modality, the time between the request for an examination and the actual start of it, as well as the availability of the radiologic report, was evaluated. In a similar way, the duration for just the examination itself was evaluated.
- The use of each radiologic device was evaluated by the duration for just the examination itself as well as the duration from the start of an examination until the start of the next examination using the same device.
- For another report, the number of patients at the radiology department for the first time or using each modality for the first time during a year was counted.
- The number of examinations was also counted for patients not older than 18 years and for the following special treatments: osteodensitometry, teleradiology, mammography, and nuclear medicine.
- Specifically for radiologic examinations of the spine, the difference between the actual time a patient stayed in the hospital in comparison to the time recommended by a clinical guideline was evaluated.

Reports for Hospital C

- The number of appointments and examinations for each modality was counted for each site of the hospital and each year. These numbers were calculated separately for each hospital department requesting a radiologic examination, for each shift during the day, for each type of stay in the hospital, and for each type of insurance a patient has.
- Only the number of MRI examinations was calculated for each hospital site and year separated by the following body regions: spine, abdomen, upper abdomen, pelvis, small intestine, joints, soft tissues of the neck, hand, foot, chest, skull, shoulder, and heart.

Reports for Hospital D

- For each site of the hospital, each year, type of stay in the hospital, and shift, the number of appointments and examinations was counted for each modality.
- Because for this hospital, the names of external private medical practices requesting radiologic examinations were also provided, the number of appointments and examinations requested by each of them was also counted for each hospital site, year, and modality.

With these reports, all the requests of hospitals A and B and some of the requests of hospitals C and D could be fulfilled. As mentioned before, hospitals C and D were not able to provide patient identifiers along with the rest of their exported data, and therefore, no number of patients and no sequences of multiple examinations (as they usually do not occur during the same appointment) could be calculated. The data provided by hospitals C and D also contained no time stamps except the time an examination started, and therefore, no time differences between, for example, the request for an examination and the actual appointment or the availability of the radiologic report, could be evaluated.

However, as long as the hospitals were able to provide the necessary data, all their requests could be fulfilled, and therefore, all of them were satisfied with the developed system.

Discussion

Principal Findings: Used Data

As shown by the numbers in the previous section, the imported data was diverse, with different numbers of years and attributes. The number of generated values was different as well (depending on the requested reports). However, some hospitals were not able to provide all the data for their requested reports,

such as hospitals titled C and D, which could not (or only with a lot of effort) provide a patient identifier, which resulted in the inability to create any reports with counts of patients. Nevertheless, due to its configurable and modular approach, the developed system can be used for these RIS exports as well, only requiring the creation of a new configuration file as well as some implementations of the interfaces for additional calculations. For hospital B, by far, the maximum number of reports was created, which resulted in the number of generated values exceeding the number of imported ones. One of these calculations, for example, was to count how many patients encountered multiple examinations for the same medical question with the same or different modalities. This directly pointed out multiple cases in which, for example, X-ray examinations had been conducted, followed by a CT or MRI examination, where only a CT or MRI examination would have been necessary, resulting in unnecessary radiation exposure for the patients as well as unnecessary radiology appointments.

Process of Importing the Radiology Data Into the Data Warehouse

When comparing the different numbers related to the import process, we found a correlation between the number of generated and calculated values and the time the developed tool needed to process them. However, even the RIS export with the maximum imported and calculated values (of hospital B) needed only about 1 hour 10 minutes for the whole process, making it fast to use even when installed in a new environment. For most reports, this time is only needed once, and multiple different reports can be created with the system afterward. If adaptions are needed (like for additional calculations during the import process), the mechanism for incremental updates can be used so that the time until the adaptions can be used for reports is even shorter. The storage required for the database and the Solr index together (31 GB for the largest data set of hospital B) can be easily found on many existing systems, and therefore, in most cases, no additional drives need be bought when using this tool. As shown in Table 2, the sizes of the database and Solr index were nearly identical for 3 of the hospitals. The difference between these sizes for hospital C was the reason that the data provided by it as well as the calculated values were mostly Boolean values. Although they are saved in similar form as other types of values in the database, the Solr index does not need to save and process any concrete textual or numeric value for them, resulting in the Solr index being a lot smaller than the database.

Creating Reports on the Radiology Data With the Data Warehouse

For many kinds of reports, the developed system can calculate and export them in a few seconds, as shown in Table 3. This allows a user to quickly iterate and try multiple configurations of a query. By using the preview option of PaDaWaN's interface, intermediate results do not always have to be exported to Excel or CSV. Even the third report in Table 3 could be created in less than 1.5 minutes for all 4 hospitals, although many single Solr queries were necessary for them. In all these reports, the queries were similar, resulting in the average time for each query becoming shorter with the total number of queries. Another observation from the created reports is that with a larger Solr index (hospital B has the largest one), the average time for each Solr query more than doubles compared to the reports created for the other hospitals but still goes down to 25 ms during the creation of the third (and largest) report.

Comparison With the Creation of Reports Directly in Excel

When comparing the developed tool with report creation directly in Excel, except for the combination of data from multiple Excel files into 1 (which is not necessary for the developed tool, because the RIS data are combined into 1 database and Solr index), no import of data are required, making this step faster and easier in Excel. However, for the calculation of additional values depending on the type of calculation, the required Excel formulas can get quite complex and are therefore more difficult to develop and maintain compared to a calculation written using the Kotlin method. To circumvent this disadvantage, Excel's ability to add scripts [28] can be used. During the creation of reports, the main disadvantage of using only Excel is the requirement for complex formulas, making the whole report more difficult to create and maintain compared to configuring a query in PaDaWaN's web interface. Especially the addition/deletion of an attribute to/from any row, column, or filter is easy in PaDaWaN's GUI, while this requires a user to adapt the Excel formulas in every cell. Therefore, PaDaWaN allows for easy ad hoc adaptation of reports even while discussing them with clinicians. Such ad hoc adaptation also benefits from the fast execution times of most PaDaWaN queries, as explained before. The drawbacks resulting from the use of Excel formulas for creating reports can be partially overcome by using Excel's feature to create pivot tables. This allows a user, in a similar way to PaDaWaN, to configure rows, columns, and filters of the requested table as well as the kind of numbers (eg, counts of patients or examinations) that should be returned. The disadvantages of this feature are that no logical combinations of attributes for a single column, row, or filter can be specified and would require additional precalculated columns. It also lacks PaDaWaN's ability for advanced searches on textual data directly as part of the query [18]. Altogether this evaluation showed that although most kinds of reports can be somehow created with Excel, especially more complex queries are difficult to configure and maintain there, while this can be done easily in PaDaWaN's GUI. A limitation of the developed tool is the requirement for an initial setup and for additional training of the clinicians on how to use it, while Excel is a tool that is already installed in many hospitals and many clinicians are already familiar with its usage.

Comparison With Alternative Solutions

In addition to the creation of reports directly in Excel, other solutions already exist that provide a user with key metrics on medical data. A comparison of the solutions introduced in the State of the Art section is presented in Table 4.

Table 4. Comparison of different existing solutions to calculate key metrics of radiology data (or of medical data in general in the last column).

Solution	Studies					
	[6-9]	[10]	[11]	[12]	[13,14]	[15,16]
Graphical results	Yes	No	Yes	Yes	No	Yes
Graphical query definition	No	Limited	Limited	Limited	No	Yes
User-defined queries	No	Limited	Limited	Limited	Yes	Yes
Additional calculations during import	N/A[a]	No	No	No	No	No
Import independent of a specific RIS[b]	No	No	Yes	No	No	Yes

[a]N/A: not applicable. Because these solutions operate directly on a radiology information system (RIS), no intermediate storage is used and therefore no additional attributes can be saved to it.

[b]RIS: radiology information system.

The first 4 solutions provide dashboards for the following uses cases: general imaging use [6], ordered and performed imaging studies for the emergency department [7], scheduled and in-progress examinations in pediatric radiology [8], and various metrics on orders, acquisition, interpretation, and reporting of radiologic images [9]. Although all of them could present their results as graphics, no additional queries (in addition to the ones predefined for the graphics) could be performed. Furthermore, the solutions only work with 1 or multiple specific RISs.

The next 3 solutions work in a different way, as their primary purpose is to display information about individual patients who are currently treated (or about to be treated) in the radiology department [10-12]. The values shown by them can be filtered, for example, by a specific type of examination, but no real queries on these data can be defined by the user. The graphics provided by Henkel et al [11] are limited to single patients and show, for example, the history of 1 of their laboratory values. Munbodh et al [12] also provide predefined graphics for the total number of examinations of different kinds during the past month. Although they all use intermediate storage for all the patients' data from the hospitals and RISs, no additional calculations on these data can be performed during the import, and of the 3, only the solution provided by Henkel et al [11] is not tied to a specific hospital or RIS.

The next 2 solutions use a data warehouse as a business intelligence tool for the radiology department [13] and combine radiology with pathology data [14]. Although both solutions allow for user-defined queries to be executed, these queries must be specified using Excel or SQL and not via a GUI. They also cannot create graphics from the query results and are tied to a specific RIS. Additionally, no precalculations on the RIS data can be performed and saved in the data warehouse.

The last 2 solutions are importers for i2b2 [15] and for i2b2 as well as PaDaWaN [16] and are not dependent on a specific RIS. They can use all the capabilities of these data warehouse solutions, including the ability for user-defined queries via a GUI and to show some predefined graphics based on these queries. However, because no additional calculations can be performed and saved to the data warehouse during the import, some kinds of reports are difficult or even impossible to create (eg, the evaluation of repeated examinations of the same body region). The developed system has the capability of additional calculations and therefore supports the most diverse kinds of reports.

Verification of the Calculated Metrics

As mentioned in the Introduction section, there are 2 main purposes of calculating all these metrics: From a patient's perspective, the waiting time for an appointment in the radiology department should be as short as possible and the exposure to radiation should be as low as possible. The hospital, however, wants to maximize its profits. By reducing the time until a diagnosis has been made, the patients can stay in the hospital for fewer days, which therefore allows the hospital to treat more patients. In addition, by eliminating or at least reducing unnecessary repeated examinations of the same region of the body, the radiology department also has the capacity to treat more patients. Treating more patients results in more profit for the hospital and shorter waiting times for patients. The reduction in unnecessary examinations also lowers the patients' exposure to radiation. Thus, both main purposes of the developed system can be achieved if metrics concerning the waiting times for appointments and diagnosis as well as repeated examinations can be calculated. The way this can be done has already been described before. For a hospital to be able to improve these metrics, it is also important that potential reasons for longer waiting times and repeated examinations be evaluated. Just from the RIS data themselves, this is, for example, possible by comparing the use of different radiologic devices to check whether the purchase of additional devices is necessary. Another possibility is the comparison of different hospital departments that request radiologic examinations. If a metric is significantly worse for one department compared to others, maybe the communication between this department and radiology needs to be improved. However, the developed system is not limited to RIS data alone. By combining these data with other data from the hospital information system in the data warehouse, additional possibilities for improvements can be found. For example, by comparing the diagnosis made by the radiology department with the final clinical diagnosis, the quality of the radiologic diagnosis can be evaluated. In addition, because the data warehouse can store data from multiple years, along with their time stamps, the developed system also supports the verification if any measure taken results in the desired improvement of specific metrics.

Limitations of and Bias in the Calculated Metrics

As all the metrics calculated by the developed system are based on data from the RIS and the hospital information system, their quality directly depends on the quality of the hospital's documentation. As this is not verifiable by the developed tool, it could only be assumed that this is done correctly. As mentioned in the previous paragraph, it is also important for the developed system that potential reasons for, say, longer waiting times for an appointment be evaluated. If, for example, a difference between the radiologic diagnosis and the final clinical diagnosis is not documented, it cannot be checked as a potential reason for longer waiting times or unnecessary examinations. In general, inferring conclusions from the calculated metrics can be difficult if potential causes are not documented. For example, if for a medical question, the ideal radiologic examination would be MRI, it may not be conducted, because it is too expensive or enough devices are not available. This could, for example, be further validated by comparing the performed examination with the one recommended by clinical guidelines (like the ones provided by the German Radiation Protection Commission [29]). Another potential bias in the calculated metrics may result from radiologic examinations that are performed externally (eg, at a private medical practice). If not properly documented, this is a missed indicator for the need for additional devices or employees. By combining RIS data with additional data from the hospital in the data warehouse, the text search capabilities of the data warehouse can potentially be used to find information about such external examinations in the patient's discharge letter. Additionally, the interpretation of the metrics could be different among different hospitals, resulting in limitations of the comparability of the metrics between them. Although, for example, a waiting time of a few days for an appointment in the radiology department could be acceptable for one hospital, it could be inacceptable for another one.

Conclusion

To summarize, the developed system has its main advantages in being generic concerning the export of different RISs as well as concerning the configuration of queries for various reports. To use it, the only requirement is the ability of an RIS to create an Excel, CSV, or JSON export. This can then be imported by creating a simple configuration file in Excel or as a CSV file as well. During the import process, additional values can be calculated by implementing several provided interfaces. If further values should be added later, this is easily possible with the ability to use incremental updates. Various reports with any combination of and restriction on the imported attributes can then be graphically configured using PaDaWaN's web interface. Finally, the results of these reports can be exported into the standard formats Excel and CSV so that they can be easily processed with many different tools.

The whole tool as a Docker [30] image, a sample RIS export, and a configuration file are publicly available on PaDaWaN's website [31].

The developed tool can in the future be further enhanced by, for example, adding the ability to calculate other numbers than the count of patients, appointments, or examinations, such as the average of numeric values found by a query. To improve the presentation of the results, the current ability to create graphics for some predefined reports can also be extended to be configurable by a user and therefore allow for the creation of many kinds of graphical reports.

Abstract

Background: In recent years, many researchers have focused on the use of legacy data, such as pooled analyses that collect and reanalyze data from multiple studies. However, the methodology for the integration of preexisting databases whose data were collected for different purposes has not been established. Previously, we developed a tool to efficiently generate Study Data Tabulation Model (SDTM) data from hypothetical clinical trial data using the Clinical Data Interchange Standards Consortium (CDISC) SDTM.

Objective: This study aimed to design a practical model for integrating preexisting databases using the CDISC SDTM.

Methods: Data integration was performed in three phases: (1) the confirmation of the variables, (2) SDTM mapping, and (3) the generation of the SDTM data. In phase 1, the definitions of the variables in detail were confirmed, and the data sets were converted to a vertical structure. In phase 2, the items derived from the SDTM format were set as mapping items. Three types of metadata (domain name, variable name, and test code), based on the CDISC SDTM, were embedded in the Research Electronic Data Capture (REDCap) field annotation. In phase 3, the data dictionary, including the SDTM metadata, was outputted in the Operational Data Model (ODM) format. Finally, the mapped SDTM data were generated using REDCap2SDTM version 2.

Results: SDTM data were generated as a comma-separated values file for each of the 7 domains defined in the metadata. A total of 17 items were commonly mapped to 3 databases. Because the SDTM data were set in each database correctly, we were able to integrate 3 independently preexisting databases into 1 database in the CDISC SDTM format.

Conclusions: Our project suggests that the CDISC SDTM is useful for integrating multiple preexisting databases.

Introduction

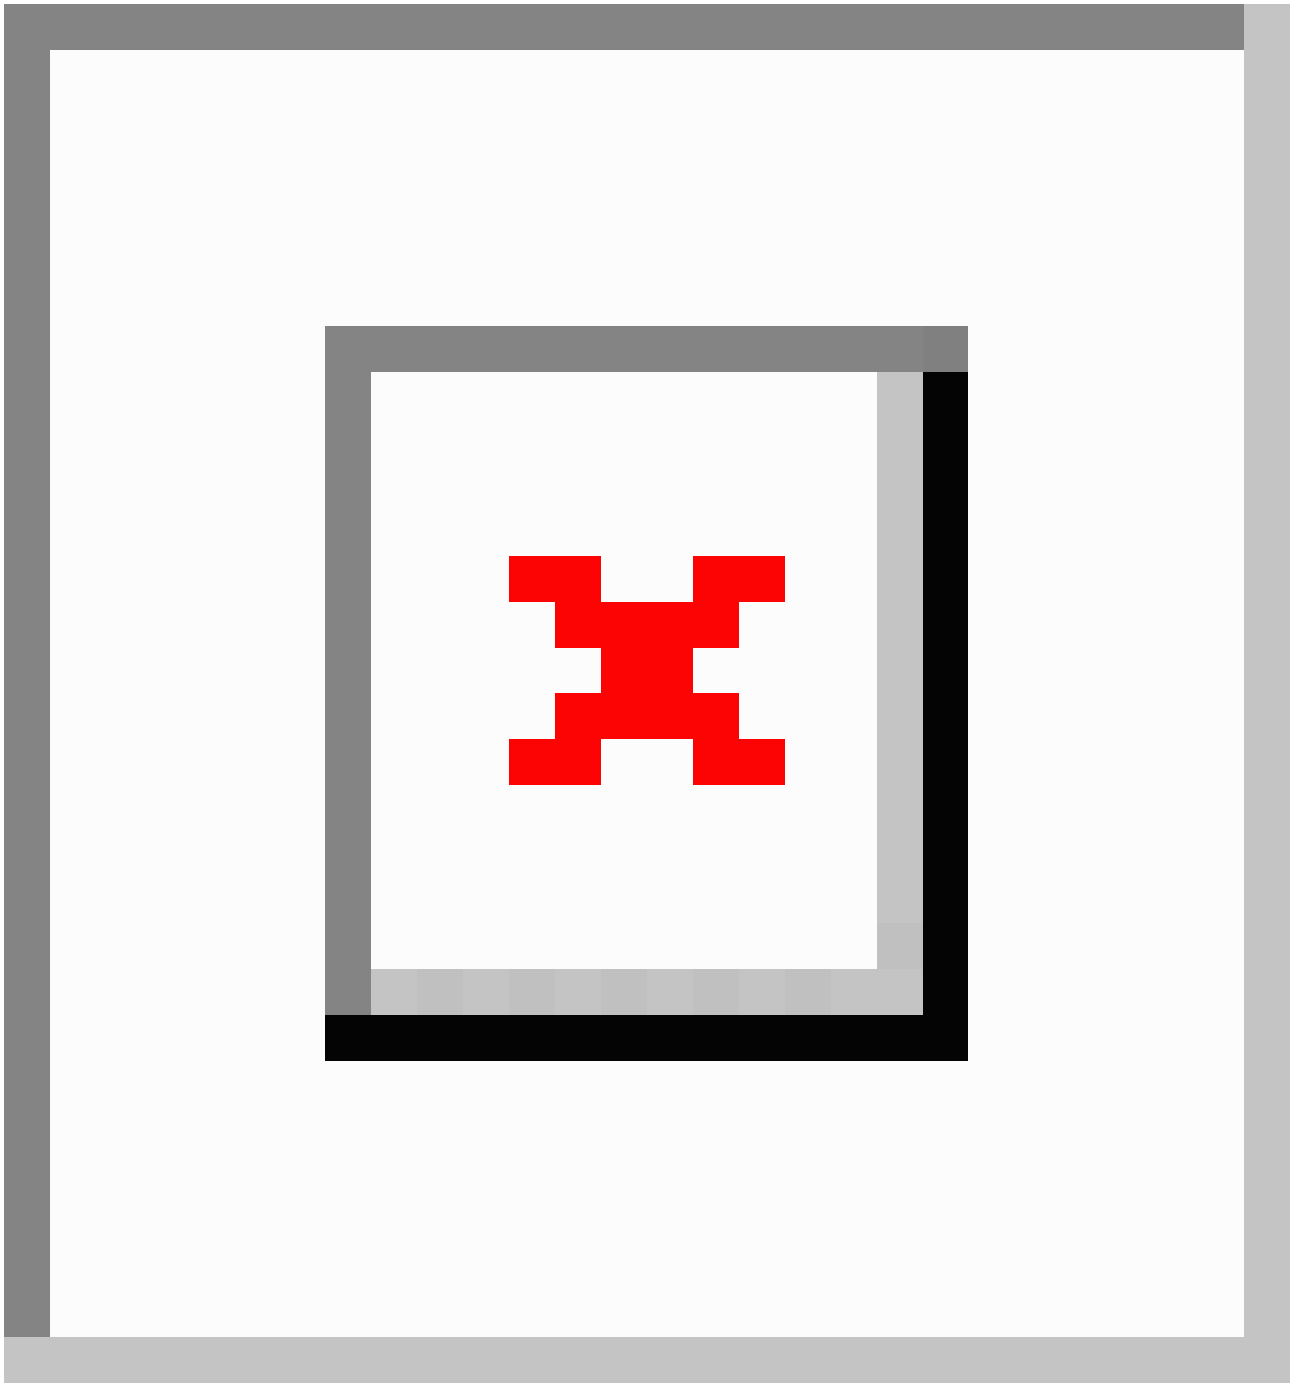
To use medical databases efficiently in clinical research, methods that efficiently integrate multiple databases must be established. The International Committee of Medical Journal Editors (ICMJE) requires researchers to include a data sharing statement when submitting a manuscript [1]. Moreover, there is a growing focus on the sharing of clinical research data and its uses. However, the current ICMJE statement makes no

mention of specific data standards for data sharing. Therefore, a discussion regarding specific ways to share data collected in clinical research is needed.

Recently, several medical societies and research groups have formed registries and conducted large cohort studies. The integration of databases with the same disease focus enables the analysis of data for many end points and patients. The reanalysis of data comprising large cohorts such as pooled analysis has statistical power and derives more reliable results [2]. For example, the Premenopausal Breast Cancer Collaboration, supported by the National Cancer Institute in the United States, published the results of several studies that used pooled analysis methods to integrate data from 20 independent cohort studies [3].

The Clinical Data Interchange Standards Consortium (CDISC) is a nonprofit, global organization that has developed several data standards to streamline clinical research [4]. The Study Data Tabulation Model (SDTM) is a data standard model for the sharing and integration of research data, which was initially developed to standardize the tabulation of clinical trial data submitted to the Food and Drug Administration (FDA) [5]. The concept of the CDISC SDTM is shown in Figure 1. The CDISC SDTM consists of several domains derived from clinical aspects, and each domain is identified by a unique 2-letter code [6]. Metadata are described in the data definition document named "Define" that is submitted with the data to regulatory authorities [7]. Each data item collected in different databases, using the SDTM and Define.xml, enables one to unify variable names and codes easily. Clinical research data warehouses using the CDISC SDTM are considered useful for data sharing in academic research.

Figure 1. Clinical Data Interchange Standards Consortium (CDISC) Study Data Tabulation Model (SDTM) concepts. eCRF: electronic case report form.



The integration of multiple data sets is difficult even among studies focused on the same disease. Major hurdles of data integration include the lack of standardization for the data format, variable names, and variable codes. Due to these problems, the manual conversion of data involves a large workload, which is likely to incur human error. Because the standardization of variable names and codes makes it easy to build a statistical data set, the CDISC SDTM provides a unique solution for database integration. However, many cohort studies have been conducted using a paper case report form (CRF) and formatted into data sets as a comma-separated values file or a spreadsheet file. It is difficult to convert these legacy data sets into the CDISC SDTM format because the variables need to refer to the CDISC variables and controlled terminology (CT).

Research Electronic Data Capture (REDCap) is an electronic data capture system developed by Vanderbilt University [8-10]. The “field annotation” function, introduced in REDCap version 6.5, can store meta-information for various standards related to clinical research, such as the CDISC, Systematized Nomenclature of Medicine (SNOMED), and Logical Observation Identifiers Names and Codes (LOINC). We previously developed “REDCap2SDTM,” a tool for parsing SDTM meta-information in the “field annotation” function and generating an XML file (Define-XML v2.0) with SDTM data [11,12]. This tool enables the efficient generation of SDTM

data from multiple preexisting research data sets, and it has been validated for SDTM data generation based on hypothetical clinical trial data. However, only a few data integration projects using an actual research data set were carried out [13-15].

The purpose of this project was to design a practical working model for integrating preexisting databases using the CDISC SDTM. Here, we report the pragmatic conversion of multiple preexisting databases based on the CDISC SDTM format.

Methods

Ethical Considerations

Since this study was conducted on the structure of the database and not on patients, this study is outside the scope of ethical guidelines.

Project Structure

This project required multiple skill sets. A board-certified nephrologist (Japanese Society of Nephrology) with expertise in immunoglobulin A (IgA) nephropathy (including patient characteristics, laboratory data, and disease-specific items) confirmed the data structure in detail and constructed the independent database in REDCap. In parallel, a clinical data manager with CDISC SDTM expertise set the SDTM metadata in each variable. We outsourced the modification of REDCap2SDTM to a contract research organization to improve the efficiency of the SDTM data generation. The diagram of the study structure is shown in Figure 2.

Data Source

IgA nephropathy is the most common type of chronic glomerulonephritis in Japan. IgA nephropathy is a refractory disease in which 30% to 40% of patients reach end-stage renal failure after approximately 20 years [16]. Various clinical features and a chronic course are the hallmark of this disease; therefore, a database that collects multiple items and a prognosis is needed. To date, the IgA Nephropathy Working Group in Progressive Renal Diseases Research, affiliated with Research on Intractable Diseases from the Ministry of Health, Labor and Welfare of Japan, has conducted 3 cohort studies with over 1000 participants in each cohort. However, the collected items and data structures in each cohort study were not standardized, making the construction of an integrated database difficult. The number of collected items and the data structure of each cohort are shown in Table 1.

Table . Characteristics of each cohort studies.

Cohort	Items in the data set, n	Sites, n	Data structure
A	57	6	Vertical format: with repeated measurement data
B	65	6	Horizontal format: no repeated measurement data
C	582	42	Horizontal format: no repeated measurement data

Outline of Multiple Database Integration Work

The integration of multiple preexisting databases comprised the following three phases: (1) the confirmation of the variables in detail, (2) SDTM mapping, and (3) SDTM data generation and integration. The details of each phase are given below.

Phase 1: Confirmation of the Variables in Detail

In most cases, variable names differ by study, and the types of data also vary (date, digits, categorical variable, etc). Therefore, we set common values between each database in this phase.

Preexisting research data are stored in various formats between studies, including spreadsheets with a horizontal data (denormalized) structure. Since many SDTM domains are defined by a vertical data (normalized) structure, the data structure was transformed.

The main tasks of this phase were as follows:

- Standardize the variables in detail: code categorical data and nominal variables, unify date types (eg, YYYY/MM/DD), and improve the data format and the number of digits in clinical laboratory data in each data set
- Manage the data structure: transform repeated data from a horizontal structure to a vertical structure
- Validate the definition of variables: clarify data definitions and create a definition document in cooperation with specialists

Phase 2: SDTM Mapping

The CDISC has CT [17], and the terms used for each variable are specified in the *SDTM Implementation Guide* [6]. Through the use of CT, variables that were arbitrarily coded in different data sets can be derived as the same code. For example, if 1 data set coded male individuals as 1 and female individuals as 2 and another data set coded male individuals as 0 and female individuals as 1, the CT would code male individuals as “M” and female individuals as “F.” Therefore, the SDTM format data sets derived “M” for male individuals and “F” for female individuals. However, not all codes have specified CT, and coding lists for variables that are not specified must be created.

The domain model of the SDTM has a fixed domain of evaluation items to be stored. Therefore, each item in the data set must be mapped to the appropriate domain. For example, the “DM” domain contains the background of the patients (demographics), which includes age, sex, and race. The variable names were specified in each domain of the SDTM, for example, “SEX” for sex and “LBORRES” for laboratory results. Items with a unique code, such as sex, do not require a test code; the metadata are defined by the domain name “DM,” and the variable is named “SEX.” For items with various kinds of values, such as serum creatinine, a test code needs to be specified. For example, the meta-information of the creatinine test value must be defined by the domain name “LB,” the variable name “LBORRES,” and the test code “CREAT.” In addition, disease-specific end points are not defined in the standard domain of the SDTM. The SDTM does not allow new variables to be added arbitrarily; therefore, new variables must be defined in conjunction with the parent record using “supplemental qualifiers.” We determined the SDTM test code based on the appropriate code list from the SDTM CT.

Generally, in clinical studies, nominal scales (eg, male and female) are replaced by codes in the analysis. The method of assigning the code differs depending on the research and the data set, and recoding is necessary during database integration. We set both the domain and the meta-information of each data set based on the definitions confirmed in phase 1.

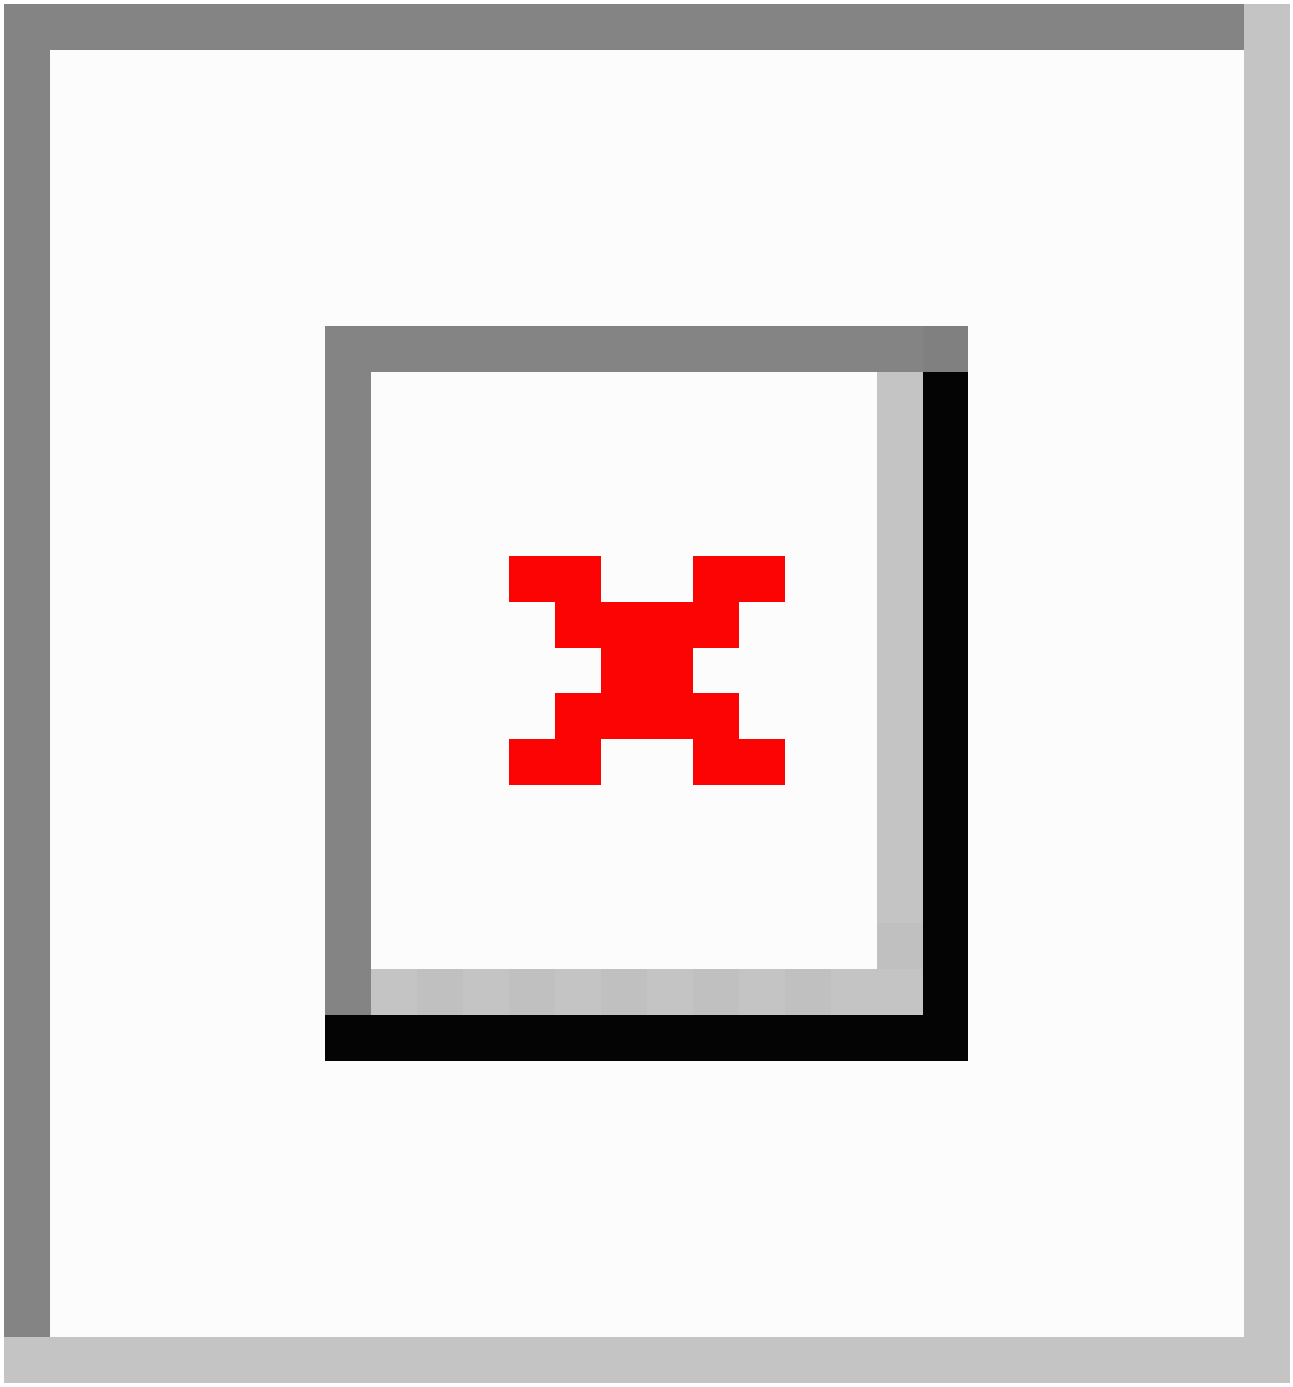
The main tasks of this phase were as follows:

- Recoding: map nominal variables and codes according to the CT or custom coding lists
- SDTM metadata mapping: map existing data variables to the SDTM domains

Phase 3: Generate SDTM Data in the Operational Data Model Format

In this phase, the SDTM metadata were manually set in the “field annotation” function (Figure 3). Subsequently, the data, including the data dictionary with the SDTM metadata, were downloaded in the Operational Data Model (ODM) format with SDTM metadata. Finally, REDCap2SDTM automatically generated each data set in the ODM format with the SDTM metadata.

Figure 3. Screenshot of “field annotation.” SDTM: Study Data Tabulation Model.



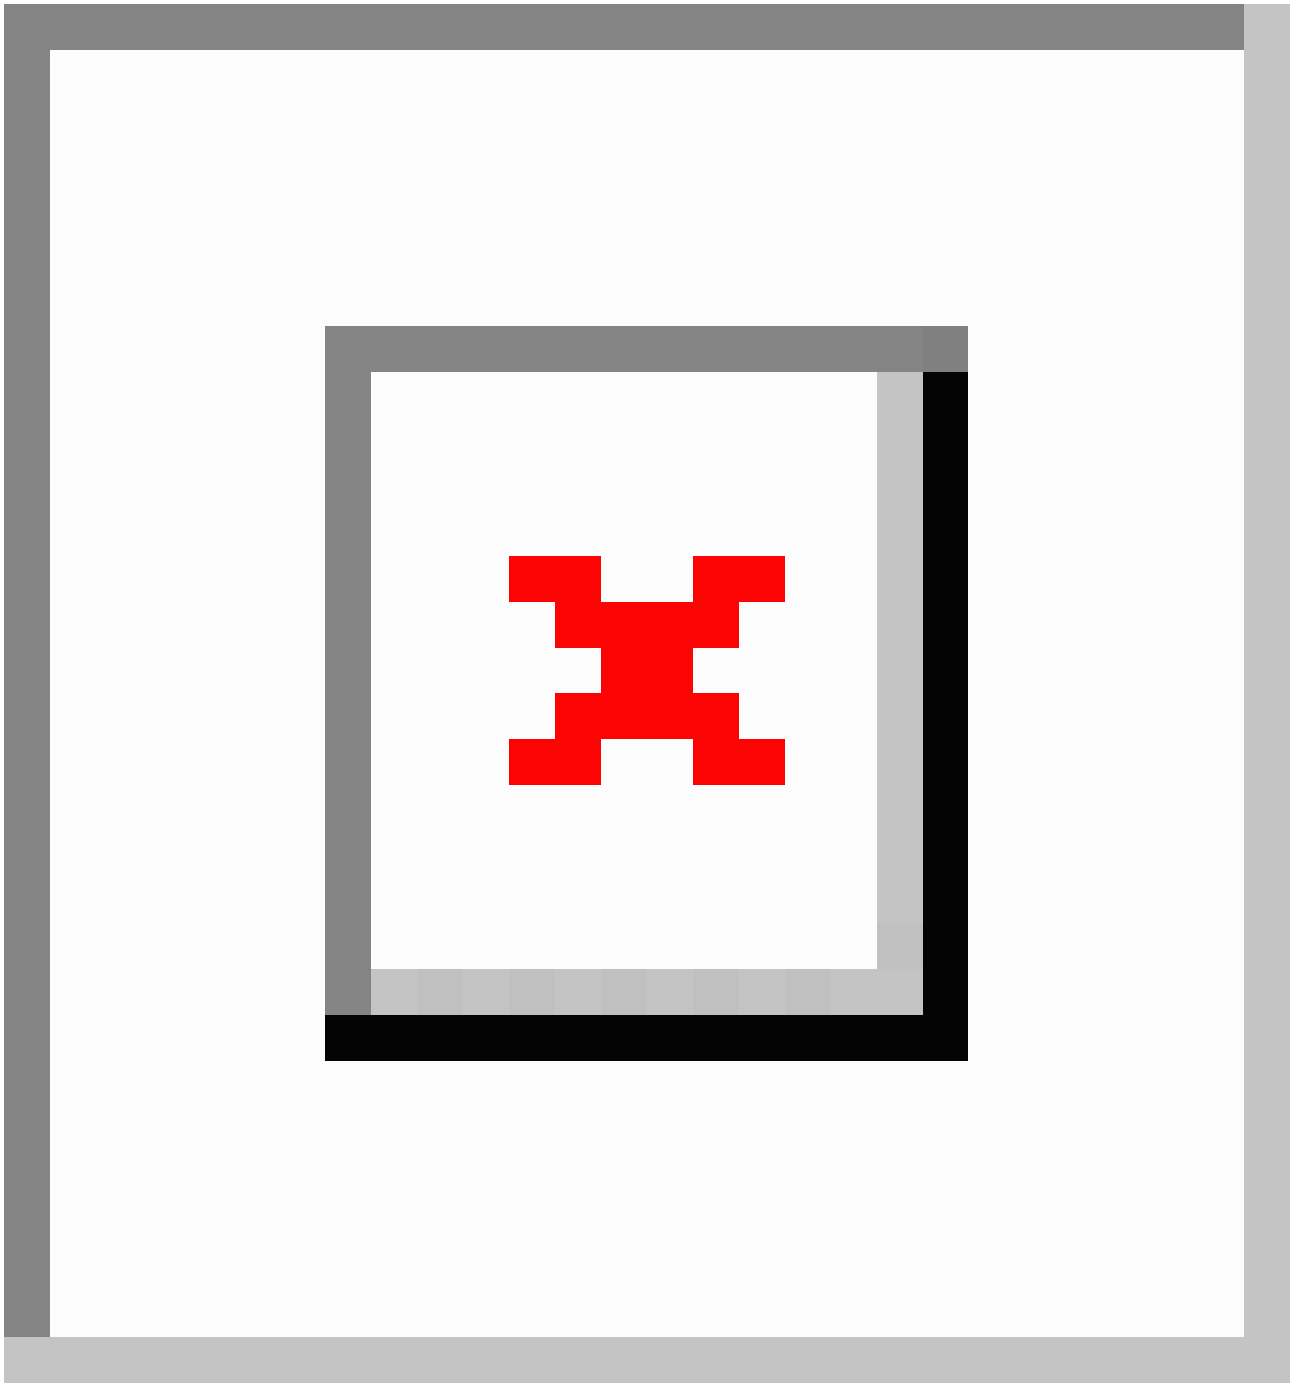
Common items in all data sets must be assigned the same metadata. Therefore, it is necessary to identify common items in all data sets to confirm the consistency of the metadata.

The main tasks of this phase were listed as follows:

- Check the consistency of the metadata: unify common items between each data set
- Generate SDTM metadata from each database: download and record data and data dictionaries and generate SDTM metadata with REDCap2SDTM
- Output SDTM metadata in the ODM format: retrieve the SDTM metadata output from REDCap2SDTM

A summary of the data integration process is shown in Figure 4.

Figure 4. Diagram of the study structure. CDISC: Clinical Data Interchange Standards Consortium; ODM: Operational Data Model; REDCap: Research Electronic Data Capture; SDTM: Study Data Tabulation Model.



REDCap2SDTM Version 2

REDCap2SDTM combined formatted ODM data that were embedded with 3 pieces of metadata (ie, SDTM domain name, variable name, and test code) into the field annotation of REDCap as the metadata corresponding to the variable name of the data set, to convert the database into the SDTM format. This tool dynamically generates SDTM data and a Define.xml file by parsing. The syntax of the meta-information is the CDISC Define-XML version 2.0 “ItemDef element.” REDCap2SDTM version 2 parses the object identifier attribute value and uses that information for mapping (eg, “IT.VS.VSORRES. SYSBP” and “IT.AE. AETERM”) [11,12].

The CDISC ODM is a vendor-neutral, platform-independent data format for exchanging and storing clinical research data and metadata that can be shared between different software systems [18]. In this case, we modified REDCap2SDTM to adopt the CDISC ODM format (REDCap2SDTM version 2; Multimedia Appendix 1). Due to this modification, REDCap2SDTM version 2 could convert the SDTM data to the ODM format and could expand to handle variables across multiple domains.

Results

This project was conducted from July 2018 to January 2019. Items were selected for integration in the SDTM metadata based on the opinions of the board-certified nephrologist.

Regarding disease-specific items, the histological classification of the disease was defined in the "SUPPMH" domain; items related to family history were defined in the "SUPPDM" domain, and the number of steroid pulse therapies was defined in the "SUPPCM" domain. The following domains were generated in this study: "DM" (demographics), "CM" (concomitant medications), "LB" (laboratory test results), "VS" (vital signs), "SUPPCM," "SUPPDM," and "SUPPMH."

The preexisting database included 57 total items for cohort A, 65 total items for cohort B, and 582 total items for cohort C. The metadata were set for 40 items for cohort A, 18 items for cohort B, and 102 items for cohort C. We found 17 common items. Finally, a total of 119 items were set for the SDTM metadata. Of these, 56 items used the nominal scale, 48 items could be recoded using CT, and 8 items required independently created code lists. Disease-specific items, such as the pathological classification based on the clinical guidelines for IgA nephropathy in Japan [19] and the Oxford classification [20], required their own code list. Table 2 lists the SDTM metadata of key items.

The data dictionary and ODM data were outputted from REDCap, and REDCap2SDTM version 2 was used to output the data in the SDTM format. The items defined by individual names in each database were collated based on the metadata by the CDISC SDTM.

Table . SDTM[a] metadata of the key items.

Items		Cohort A	Cohort B	Cohort C	SDTM metadata
Sex		Sex	Sex	Sex	DM.SEX
Birthday		Birth_date(Y/M/D)	Birth_date(Y/M/D)	birth date	DM.BRTHDTC
Age		__[b]	—	Age	DM.AGE
Vital sign					
	Systolic blood pressure	sbp_bx	sbp_bx	Sbp	VS.VSORRES.SYSBP

Discussion

Strength of This Study

Integrating multiple preexisting databases through collaboration between the disease specialist and clinical data manager enabled the use of legacy data. Our project suggested that properly defining CDISC SDTM metadata allowed for the integration of multiple preexisting databases. In this paper, we focused on the technical aspect. Although the utility of this concept has been verified with hypothetical data, there are few reports that generate SDTM data from actual clinical databases focused on technical aspects in detail.

The CDISC SDTM

The definition of metadata using the CDISC SDTM is important. The CDISC is a nonprofit, global organization that consists of pharmaceutical companies, contract research organizations, academic research organizations, and IT vendors. Pharmaceutical companies and contract research organizations account for 34% of the entities within the CDISC, whereas academic research organizations account for only 7% [21]. This imbalance may have arisen because those submitting a regulatory application to the FDA or the Pharmaceuticals and Medical Device Agency are required to comply with CDISC standards [22]. Therefore, there is a strong awareness of the CDISC as a tool for regulatory submissions, but few researchers are aware that the CDISC SDTM concept can be used to standardize data.

The mission of the CDISC is to develop and support global, platform-independent data standards that enable information system interoperability to improve medical research and related areas of health care. Following this statement, we have succeeded in integrating 3 databases by incorporating the CDISC SDTM concept into the standardization of multiple databases. Since this database complies with the standardization of the CDISC SDTM, this integrated database can be compared to other clinical trials or it can be used as a historical control. Our study shows that the CDISC SDTM is not only a necessary tool for applying for the approval of regulatory submissions but also for data standardization and integration. In recent years, the CDISC has partnered with REDCap to make Clinical Data Acquisition Standards Harmonization eCRF metadata available in the REDCap Shared Instrument Library [22,23]. It is expected that the researchers will be able to import CDISC SDTM metadata directly into their REDCap projects for immediate use in clinical trial data collection. In the future, CDISC SDTM data will be generated more easily.

We were able to develop the methodology for integrating multiple preexisting databases in just 6 months. This timely integration was due to the collaboration of specialists in the disease area and a data manager familiar with the CDISC SDTM, allowing each phase to proceed simultaneously and resulting in a fast integration time. Inconsistencies in the coding method of the nominal scale hindered the integration of multiple databases. However, in this study, codes defined individually for each database were automatically recoded to substantially reduce the required work hours, which also contributed to the fast integration time. When coding terms not defined by CT, such as terms that are specific to the disease area, a code list should be created following thorough discussions with specialists, referring to therapeutic area standards [24]. It is important to improve work efficiency by making the best use of existing materials. Although the preexisting databases were integrated in this study, even in cases where the data were updated longitudinally, it is possible to integrate data with the SDTM, provided that the meta-information for the evaluated item is defined.

Currently, there are several medical standards. Observational Medical Outcomes Partnership (OMOP), which is managed by Observational Health Data Science and Informatics [25], aimed to standardize interoperability observational databases such as electric medical records and claim data. HL7 Fast Healthcare Interoperability Resources (FHIR) [26] is the standard for medical information exchange. In this study, we used the CDISC SDTM because, at the time, it was the most widely used standard with many accumulated findings. We plan to expand this project to support the OMOP Common Data Model and FHIR in the future.

Issues for Integration

We observed the following points when integrating the preexisting clinical databases: (1) the variability of the collected items and (2) the complexity of the test code. The items in the preexisting cohort studies used in this project were not standardized and were not defined in detail; therefore, we clarified the meaning of the variables based on expert opinions. Clarifying data definitions is difficult for data managers who lack the requisite background knowledge.

In addition, we were faced with large differences in the number of items collected from each preexisting cohort study. As previously mentioned, 57 and 65 items were collected in cohorts A and B, respectively, far fewer than the 582 items collected in cohort C, which included data related to concomitant medications. However, because information on concomitant medications is often missing, it is considered a difficult item to use for analysis. Generally, information on concomitant medications is not used for analysis and is not collected in precise clinical trials. To avoid complications in the integration process, information collected on concomitant medications should focus on those related to the disease area or should be divided into categories prior to collection. These findings were obtained by scrutinizing the differences in the items collected in each database prior to generating the metadata.

The complexity of the test code was clarified during the generation of the metadata. As described above, the amount of the urinary protein was defined as both “PROT” and “PROT24.” Because the details of proteinuria are not defined in CT, there is a risk for inappropriate metadata. These findings suggest that the generation of metadata requires a deep understanding of the disease in addition to the concepts of the CDISC SDTM. In this study, the clinical data manager who had knowledge of the CDISC SDTM was responsible for generating the metadata in collaboration with a specialist in the disease area. Currently, clinical data managers primarily play an active role in prospective clinical trials. Thus, the main responsibilities of the clinical data manager are planning the clinical trial, assisting

with the creation of the protocol and CRF, cleaning the data, confirming data consistency, and managing data quality in clinical trials. We believe that the clinical data manager will play an important role for data integration projects in the near future. Collaborations between the clinical data manager and the disease specialist will likely become even more important.

Limitations

This project had several limitations. First, the data of the cohort studies did not cover all domains of this disease. In the future, we would like to increase the number of integration examples and generalize the program to cover all domains. Second, a great deal of time was spent manually setting the metadata. In the future, it may be beneficial to automatically refer to the shared metadata from the CDISC Library or to develop a tool that allows artificial intelligence to suggest the metadata using therapeutic area standards. Third, REDCap2SDTM version 2 required input for the ODM format. Several programs that generate ODM or Define-XML data from a spreadsheet are available from the CDISC Open Source Alliance [27]. We will consider embedding these programs into REDCap2SDTM version 2 in the future.

Conclusion

Our results suggest that the CDISC SDTM is useful for integrating multiple preexisting databases with variable names and codes. We hope that this research will contribute to the use of legacy data sets.

Abstract

Background: Digitization offers a multitude of opportunities to gain insights into current diagnostics and therapies from retrospective data. In this context, real-world data and their accessibility are of increasing importance to support unbiased and reliable research on big data. However, routinely collected data are not readily usable for research owing to the unstructured nature of health care systems and a lack of interoperability between these systems. This challenge is evident in drug data.

Objective: This study aimed to present an approach that identifies and increases the structuredness of drug data while ensuring standardization according to Anatomical Therapeutic Chemical (ATC) classification.

Methods: Our approach was based on available drug prescriptions and a drug catalog and consisted of 4 steps. First, we performed an initial analysis of the structuredness of local drug data to define a point of comparison for the effectiveness of the overall approach. Second, we applied 3 algorithms to unstructured data that translated text into ATC codes based on string comparisons in terms of ingredients and product names and performed similarity comparisons based on Levenshtein distance. Third, we validated the results of the 3 algorithms with expert knowledge based on the 1000 most frequently used prescription texts. Fourth, we performed a final validation to determine the increased degree of structuredness.

Results: Initially, 47.73% (n=843,980) of 1,768,153 drug prescriptions were classified as structured. With the application of the 3 algorithms, we were able to increase the degree of structuredness to 85.18% (n=1,506,059) based on the 1000 most frequent medication prescriptions. In this regard, the combination of algorithms 1, 2, and 3 resulted in a correctness level of 100% (with 57,264 ATC codes identified), algorithms 1 and 3 resulted in 99.6% (with 152,404 codes identified), and algorithms 1 and 2 resulted in 95.9% (with 39,472 codes identified).

Conclusions: As shown in the first analysis steps of our approach, the availability of a product catalog to select during the documentation process is not sufficient to generate structured data. Our 4-step approach reduces the problems and reliably increases the structuredness automatically. Similarity matching shows promising results, particularly for entries with no connection to a product catalog. However, further enhancement of the correctness of such a similarity matching algorithm needs to be investigated in future work.

Introduction

Background

Over the last decade, the amount of electronically available data in the health care domain has increased enormously worldwide. Much of the data is generated during the processing of administrative claims, through documentation processes in electronic health records (EHRs) performed during patient treatments, or via data feeds from mobile devices providing patient-reported outcomes. Therefore, it is not surprising that real-world data (RWD) are becoming more important for health care research. RWD studies can be considered complementary to randomized controlled trials (RCTs), as they allow the results of RCTs to be confirmed in much larger cohorts and over a longer period. Compared with RCTs, RWD studies allow for better external validity and better generalizability, and they not only offer opportunities for long-term surveillance of drug products but also are cost-effective and time-saving [1].

Drug surveillance systems, such as the US Food and Drug Administration's Sentinel initiative, are critical for promoting postmarket drug safety [2-8]. The European Medicines Agency has also started to establish research infrastructure based on RWD to support pharmacovigilance [9]. In addition, the European Health Data and Evidence Network [10] emerged to establish transnational research networks based on a common data model that enables standardized RWD and methods for observational studies to generate real-world evidence. Recently, the European Health Data and Evidence Network has begun to collaborate with the European Medicines Agency to address COVID-19 [11].

However, the original purpose of RWD generation during patient treatment is not primarily aimed at its use in research. Therefore, notable problems have been identified regarding the replication and validity of observational research results based on RWD. To ensure the reliability and robustness of the results from RWD research, these issues have to be addressed, as they become even more important when observational studies are conducted across countries at large scale.

Data harmonization, the use of international standards and terminologies, a common data model, methods, and tools for data analyses that increase the reproducibility of results are needed [12]. These gaps are being addressed by the International Observational Health Data Sciences and Informatics community, which provides the common data model called the Observational Medical Outcomes Partnership (OMOP) and standardized analysis tools based on OMOP. It also includes standardized vocabularies that contain translations between national terminologies and internationally acknowledged terminologies, for example, Systematized Nomenclature of Medicine-Clinical Terms, Logical Observation Identifiers Names and Codes, Anatomical Therapeutic Chemical (ATC) classification, and RxNorm [13]. OMOP allows RWD to be stored in the same way, regardless of data origin, thus ensuring the use of RWD in international, large-scale observational studies. Compared with similar projects such as Informatics for Integration Biology and the Bedside or the National Patient-Centered Clinical Research Network, Observational Health Data Sciences and Informatics-OMOP meets the needs of observational RWD studies well [14]. Many RWD studies on OMOP have shown that drug data at the ingredient level are sufficient to answer their research questions [15]. Although drug data with details on dosage and units for drug exposure can be important for observational research on drug effectiveness and drug safety with the same drug at different doses, the availability of the drug ingredient is the least common denominator and the basic requirement for drug-related RWD studies on OMOP. Therefore, drug prescription data must be available in a structured format that does not necessarily include the name of the drug product but at least the ingredient information. For drug utilization research, the World Health Organization recommends the use of ATC classification, which divides drugs into different groups based on the organ or system on which they act [16]. ATC classification includes a hierarchy based on 5 different levels, with ATC level 5 being the chemical substance that represents the active ingredient of a drug product [17]. Each approved drug product on the market is assigned a specific ATC level 5 code. The National Institutes of Health Collaboratory recommends assessing and reporting the quality of EHR data for clinical reuse in terms of data completeness, accuracy, and consistency [18]. Weiskopf et al [19] also determined that the completeness and correctness of data are of special importance for data quality improvement.

Objective

To the best of our knowledge, there is no existing approach to systematically analyze and improve the structuredness of drug prescription data for observational research. Thus, in this study, we systematically analyzed the structuredness of EHR drug prescriptions to determine the ratio between structured drug prescription data containing ATC code level 5 and free-text drug prescriptions without an available standard concept based on the 14 ATC groups of level 1. In addition, we presented an approach to improve the structuredness of drug prescription data by introducing an automatic detection method for ATC code determination. To ensure the robustness and accuracy of the results of automatic detection, we introduced a validation step based on existing text-mining algorithms.

Methods

Study Details

This retrospective, noninterventional study systematically reviewed drug prescriptions based on real-world observational data at the University Hospital Carl Gustav Carus Dresden (UKD), Germany. This study was based on fully anonymized data and did not include any correlations with individual patients. All inpatient drug prescriptions, including acute medications, from 2016 to 2020 were included in the study, without restriction to specific conditions or treatments. The original data were recorded in the ORBIS hospital information system from Dedalus, using the ORBIS module, "KURV," that represents the patient curve including medication data. A total of 1,768,153 drug prescriptions were reviewed from the hospital information system records. Drug prescription data from other systems (eg, intensive care units and chemotherapy) were excluded because data in those systems were completely

structured and stored in separate backend systems. The data used for this study were provided by the Data Integration Centre at the UKD, which was established with funding from the German Federal Ministry of Education and Research as part of the Medical Informatics Initiative in Germany.

Ethics Approval

The study was approved by the Ethics Committee of the Technical University of Dresden as a retrospective, observational, noninterventional, nonhuman subject study (SR-EK-521112021).

Data Set Details

The following 2 data sets were used: drug prescription data (data set 1) and drug product catalog data (data set 2). The drug product catalog was exported from the UKD Enterprise-Resource-Planning system on November 16, 2021, and contained the drug product name, drug ingredient name, ATC level 5 code, drug dose and unit information, and legacy products. In addition, 2 other data sets were derived from data set 1. First, an aggregated data set (data set 3) was generated based on the grouped data set 1 for all the unstructured drug prescription entries. The grouping activity to create data set 3 was performed on the MEDICATION column of data set 1 by grouping all entries in the data element MEDICATION using the Python library Pandas and its *groupby* function. Frequency information for each unique MEDICATION record was added to data set 3. The data set (data set 4) contained a subset of the first 1000 most frequent entries from data set 3 and additional results from the manual evaluation step.

All the metadata elements of the data sets presented above that are relevant to this study are illustrated and described in detail in Table 1. Drug prescriptions selected from the drug catalog data are labeled as *structured data* (eg, “IBUPROFEN STADA 600 mg Zäpfchen | [Ibuprofen natrium, Ibuprofen]”) based on the contents of the STRUCTURE column of data set 1. Drug prescriptions that were not selected from the drug product catalog are designated as *unstructured data* (eg, “Ibuprofen 600” and “Ibuprofen”).

Table 1. Description of relevant data set with its metadata elements.

Data set and data element	Data type	Description
DS[a]1 initial data set with all drug prescriptions		
MEDICATION	String	Free text or predefined value, chosen from an available fixed drop-down menu that contains product names, derived from the drug product catalog, when creating a new drug prescription
YEAR	Number	Extracted from the prescription start date information for further statistical analyses
STRUCTURE	Boolean	TRUE if MEDICATION was chosen from the drug catalog or FALSE if the free text was entered
ATC[b]_L5	String	ATC code level 5 available in case STRUCTURE is true otherwise empty
DS2 drug catalog data		
Product_name	String	Product name as listed in the ERP[c] system
Ingredient_name	String	Ingredient name as listed for the product
Atc_code	String	ATC code level 5
DS3 grouped DS1 by MEDICATION data element		
MEDICATION	String	Grouped unstructured free-text entries
FREQUENCY	Number	Summed up the occurrence of the MEDICATION text field to determine the most relevant free-text drug prescriptions
Step1	String	Algorithm 1 result as an ATC code or empty if no match
Step2	String	Algorithm 2 result as an ATC code or empty if no match
Step3	String	Algorithm 3 result as an ATC code or empty if no match
DS4 most frequent 1000 entries of DS3 (sorted by frequency)		
MEDICATION	String	Grouped unstructured free-text entries
FREQUENCY	Number	Summed up the occurrence of the medication text field
Step1	String	Algorithm 1 result as an ATC code or empty if no match
Step2	String	Algorithm 2 result as an ATC code or empty if no match
Step3	String	Algorithm 3 result as an ATC code
Eval1	Boolean	Algorithm 1 evaluation result
Eval2	Boolean	Algorithm 2 evaluation result
Eval3	Boolean	Algorithm 3 evaluation result
True12	Boolean	TRUE if the same result for algorithm 1+2
True13	Boolean	TRUE if the same result for algorithm 1+3
True23	Boolean	TRUE if the same result for algorithm 2+3
True123	Boolean	TRUE if the same result for algorithm 1+2+3
CORRECT	String	Corrected ATC code. in case no algorithm determined the correct result, entered manually in the evaluation step
COMMENTS	String	Any comments or additional information if needed
FINAL	String	Finally determined ATC code for all entries or labels in case no ATC code could be determined (labels are introduced in the methods validation section in detail)

[a]DS: data set.

[c]ERP: Enterprise-Resource-Planning.

Data Analysis

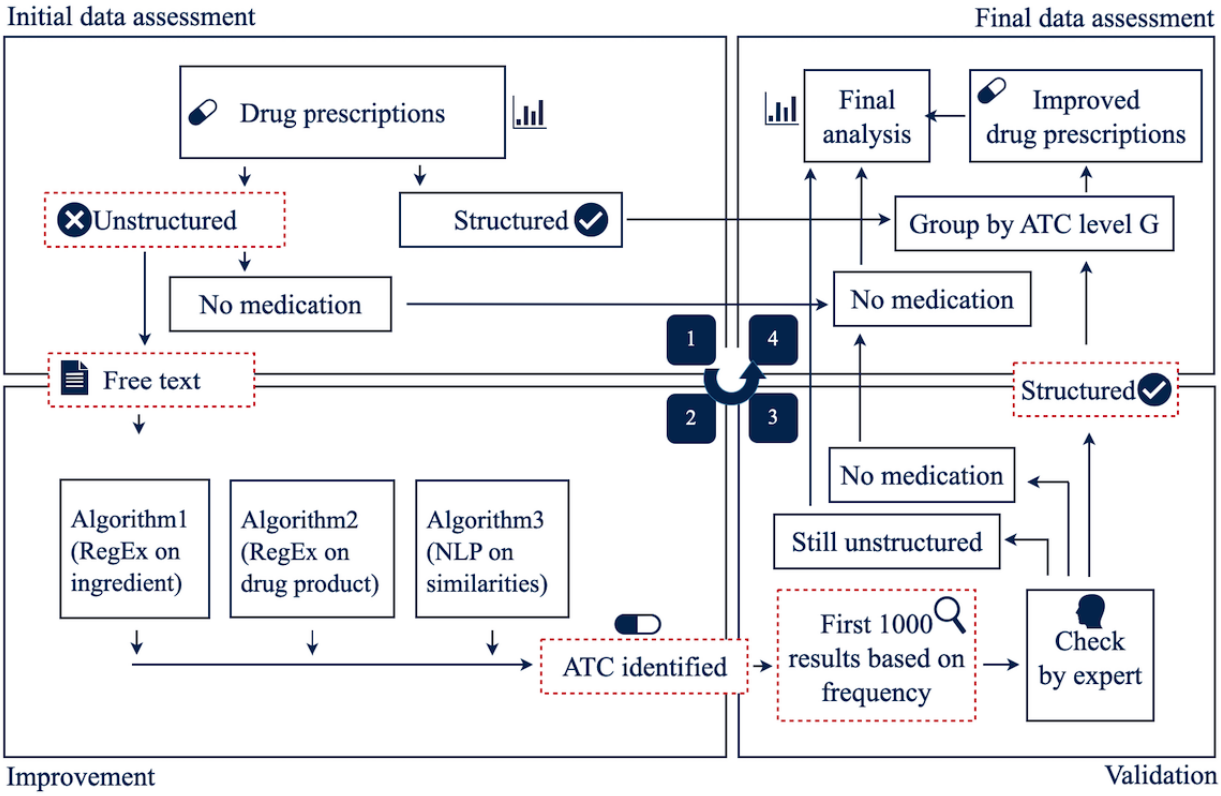
Overview

Data analysis consisted of a 4-step process, as shown in Figure 1. The first step of the process was an initial data quality analysis to determine the overall ratio of structured to unstructured drug prescriptions.

To improve the structure of the drug prescriptions, 3 existing algorithms were applied to automatically identify correct ATC codes for the unstructured drug prescriptions. The identified ATC codes were then manually reviewed by experts

(pharmacists and medical information scientists) and checked for correctness. This step also included the identification of existing patterns that can help conclude the reliability of the automatically identified ATC codes for unstructured data. Finally, the results of the previous 3 steps were consolidated to assess the degree of improvement achieved in unstructured drug prescriptions. To ensure expert coverage of the entire process, an interdisciplinary team of pharmacists, computer scientists, and medical informatics researchers was formed.

Figure 1. Data analysis 4-step approach. ATC: Anatomical Therapeutic Chemical; NLP: natural language processing.



Initial Data Assessment

Initially, the ratio of structured to unstructured drug prescriptions was determined for data set 1. For this purpose, the STRUCTURE data element of data set 1 was used to subdivide the data into 2 groups. If the value of STRUCTURE was TRUE, the record was considered to be structured; otherwise, it was unstructured. Subsequently, the unstructured subset of drug prescriptions was grouped by the data element MEDICATION as data set 3, and the frequency was calculated and added as the data element FREQUENCY.

The first manual review of the grouped drug prescriptions (data set 3) was done by the interdisciplinary team of experts to identify records that are not drug prescriptions but other instructions, such as orders for blood counts or other laboratory and measurement orders (eg, “BGA”—laboratory request for blood gas analysis, “BE”—request to nurses for taking a blood sample, and “BB”—laboratory request for blood count). This task resulted in a set of rules (Multimedia Appendix 1) to allow the automated search and identification of medication entries that needed to be excluded for further steps.

Improvement

Unstructured drug prescriptions (usually provided as free text) were used as inputs for the improvement step. Preprocessing of the drug prescription was not performed previously. In this step, 3 different algorithms were implemented to automatically identify ATC level 5 codes based on the MEDICATION text.

The algorithms were based on a different mechanism for matching the MEDICATION text of data set 1 with the product catalog data elements INGREDIENT_NAME and PRODUCT_NAME of data set 2, as described in detail in Table 2.

Table 2. An overview of algorithms for Anatomical Therapeutic Chemical (ATC) code identification for unstructured drug prescriptions.

Algorithm	Mechanism	Data input for comparison		Result data
		Data set 1	Data set 2	
1	String comparison	MEDICATION	Ingredient_name	ATC code
2	String comparison	MEDICATION	Product_name	ATC code
3	Similarity matching	MEDICATION	INGREDIENT_NAME and PRODUCT_NAME	ATC code+similarity score

Algorithms 1 and 2 rely on simple string comparisons to recognize either the ingredient name or product name within the drug prescription. Algorithm 3 performs natural language processing (NLP) based on similarity matching between the data element MEDICATION in data set 1 and the 2 data elements PRODUCT_NAME and INGREDIENT in data set 2 with the Python library *FuzzyWuzzy* [20] using Levenshtein distance because it has shown promising results in other health care research areas [21,22]. The best similarity score result was 100, which meant that the components of the string MEDICATION were entirely contained in INGREDIENT_NAME or PRODUCT_NAME. The lower the similarity score, the less similar the MEDICATION string is compared with the drug catalog entries. This algorithm provided up to 3 possible ATC codes, sorted in descending order based on their similarity scores. To determine the most promising method of the *FuzzyWuzzy* library for our implementation, we defined that the word order in the data element MEDICATION is irrelevant and can be different from the compared strings in INGREDIENT_NAME and PRODUCT_NAME. All words from the entry of the data element MEDICATION must be included in the entry of INGREDIENT_NAM*E* or PRODUCT_NAME, but not vice versa. This led to the implementation of the method *token_set_ratio*. This method tokenizes both strings to be compared, changes the upper case to the lower case, and removes punctuation. It then sorts the tokens alphabetically and split them into 2 groups: the intersection group (tokens that are the same in both strings) and the remainder group (tokens that differ in compared strings). The *token_set_ratio* method compares the intersection group with the intersection and remainder of the first string and then the same with the remainder of the other string and finally takes the highest results of this comparison as the final result. As shown in the following example (Textbox 1), the *token_set_ratio* method provides the best results concerning the given requirements.

Textbox 1. An example of the token_set_ratio method.

```
d1 = “Stada paracetamol”
d2 = “paracetamol Stada 400 mg”
Print(“Ratio: ”, fuzz.ratio(d1.lower(),d2.lower()))
Print(“Partial Ratio: ”, fuzz.partial_ratio(d1.lower(),d2.lower()))
Print(“Token Sort Ratio: ”, fuzz.token_sort_ratio(d1.lower(),d2.lower()))
Print(“Token Set Ratio: ”, fuzz.token_set_ratio(d1.lower(),d2.lower()))
Ratio: 54
Partial Ratio: 65
Token Sort Ratio: 83
Token Set Ratio: 100
```

The algorithms were applied to data sets 1 and 3. The results of the algorithms in data set 3 were also used in data set 4. The concordance between the results for each permutation (algorithms 1+2, 1+3, 2+3, and 1+2+3) was also calculated. The complete source can be accessed on Zenodo [23].

Validation

The validation step consisted of manual checks of the automatically generated ATC codes by the same interdisciplinary team as in the previous steps. It was performed on a subset of the most common free-text prescriptions. To maintain the validation effort proportionate to the benefit, a minimum target was defined for the manual validation process of unstructured drug prescriptions to cover at least 80% of structured and manually validated unstructured entries combined. During the validation step, information was added to each algorithm to determine whether the correct ATC code, wrong ATC code, or no ATC code was identified. If no algorithm identified the correct ATC code, it was determined by manual validation when possible. If an entry was found to generally have no drug prescription, it was marked as an additional entry without drug prescription with the keyword “nomed.” For drug prescriptions that require further specification to determine the exact ATC level 5 code, the manual review checks whether the ATC level 4 or 3 code can be determined based on the free text of the drug prescription, otherwise the entry was flagged as unspecific with the keyword “unspec.” All unstructured drug prescription entries for which no validation of the automatically generated ATC codes was performed were marked with the keyword “no_eval.”

The results of the manual validation were summarized to identify any patterns that can help improve the robustness of the results of automatically detected ATC codes based on the total findings and correctness of each algorithm, the concordance level between the results of algorithms 1, 2, and 3, and the Levenshtein similarity score for algorithm 3. For algorithm 3, we used a 2-tailed *t* test implemented in Python to determine whether there was a significant difference between the means of the Levenshtein similarity score for the correct and incorrect results.

In addition, the incorrect results were examined in more detail by the interdisciplinary team to identify patterns that would reveal important reasons and similarities related to the ingredients of concern (ATC) to the greatest extent possible.

Final Data Assessment

For the final data assessment, the results of the step improvement and validation documented in data set 4, including correctly identified ATC level 5 codes or “nomed,” “unspec,” or

"no_eval" labels, were merged with the original drug prescription data from data set 1. Thus, the final data assessment was executed based on the algorithm results and manual validation. The total number of drug prescription records was determined for each of the 14 ATC groups, including the proportion of structured versus unstructured data per ATC group. In addition, the total number of unique ATC level 5 codes, including their structuredness, as well as the most frequent ATC level 5 codes used in drug prescription of the data set 1 are presented. This allows a ranking of the structuredness based on the ATC groups and ATC codes.

Results

Initial Data Assessment

The initial assessment revealed 843,980 (n=1,768,153, 47.73% drug prescriptions in the data set 1) structured drug prescriptions. The proportion of unstructured drug prescriptions that required further investigation was 52.27% (924,173 drug prescription entries). A small set of rules, for example, all drug prescription entries starting with laboratory or measurement orders (Multimedia Appendix 1), identified a total of 160,896 (9.1% of all drug prescriptions) entries as no drug prescription data and reduced the unstructured drug prescriptions requiring review for the next steps to 763,277 (43.17% of all drug prescriptions).

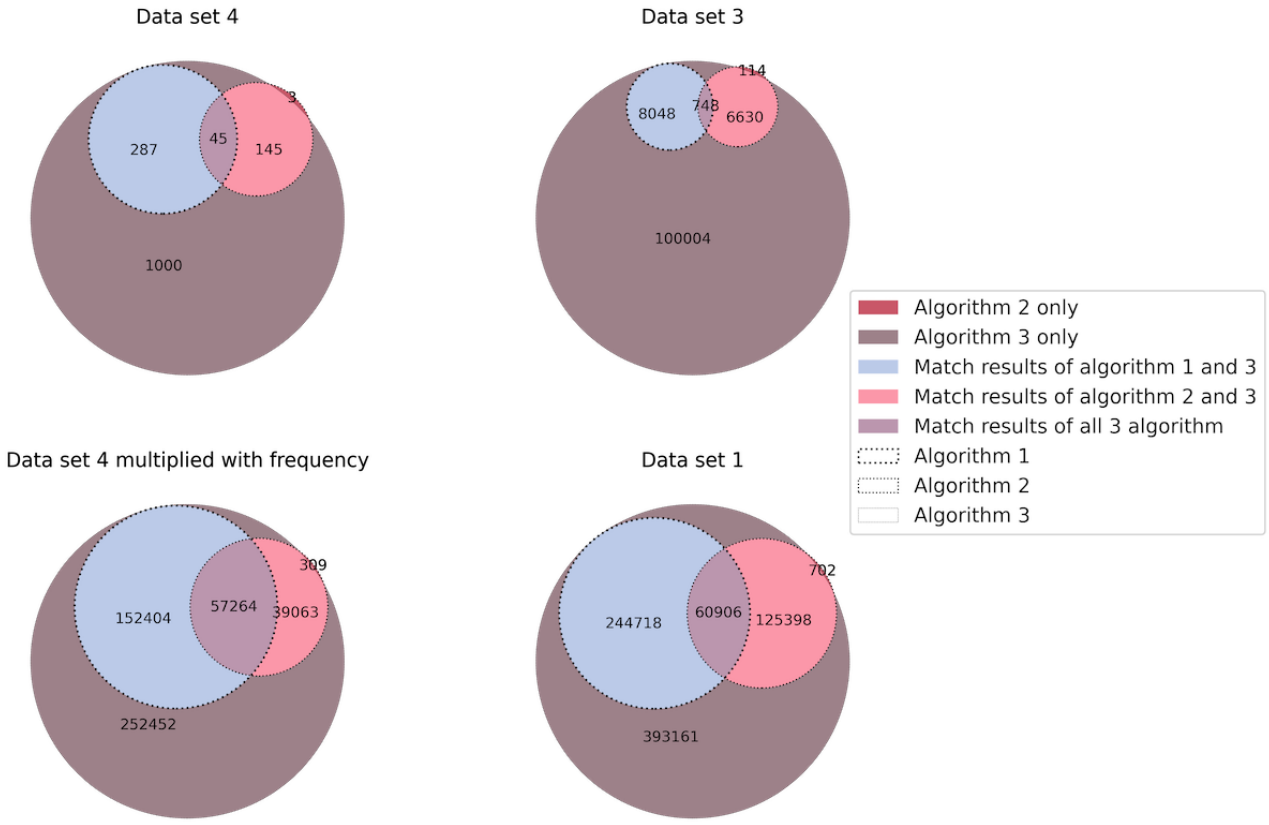
Grouping the unstructured drug prescriptions based on the MEDICATION data element of data set 1 resulted in a total of 100,004 (n=924,173, 10.82%) unique free-text entries that were entered as medication prescription information and stored as data set 3 after adding the frequency for each free text.

Improvement

The quantitative performance of the algorithms was very different, as each algorithm returned a different number of results. Algorithm 3 provides an ATC code for all unstructured drug prescriptions, owing to its implementation and nature.

Algorithm 1 (based on ingredient matching) identified ATC codes for 8048 unique free texts. Multiplied by the frequency of each text entry, this yielded a total of 244,718 (32.06%) drug prescriptions of the total 763,277 unstructured drug prescriptions. The quantitative outcome performance of algorithm 2 (based on the drug product) is lower than that of algorithm 1, as it identified ATC codes for 6744 unique free texts. This represents a total of 126,100 (16.52%) drug prescriptions of the total 763,277 unstructured drug prescriptions. At this point, no statement can be made about the correctness of the algorithm results, but the analysis of the match rate between all algorithms shows matching rates for the total number of unstructured drug prescriptions and the most frequent 1000 free-text entries as illustrated in Figure 2.

Figure 2. Match rates of algorithm results calculated for all data sets under inspection.



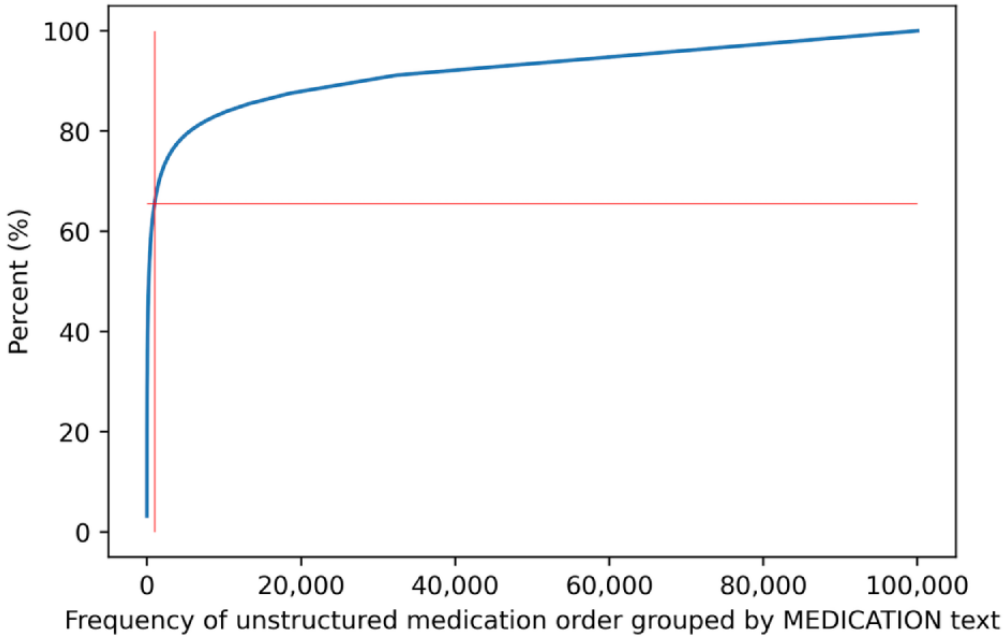
Validation

The manual validation step was performed on the most frequent 1000 free-text entries, which already covered 66.56% (615,129/924,173) of all unstructured drug prescriptions, as shown in Figure 3. Together with the proportion of structured drug prescriptions (843,980/1,768,153, 47.73%) and entries without medication (166,307/1,768,153, 9.4%) that were

identified during the initial data analysis, the structuredness could potentially be increased to 85.18% (1,506,059/1,768,153) of all medication prescriptions.

For the most frequent 1000 free-text entries (data set 4), algorithm 1 returned 286 (28.6%) correct results, 1 (0.1%) incorrect result, and no results for 713 (71.3%) entries. Algorithm 2 returned 142 (14.2%) correct results, 6 (0.6%) incorrect results, and no results for 852 (85.2%) unique entries. Algorithm 3 returned 765 (76.5%) correct results and 235 (23.5%) incorrect results. We also determined the correctness in terms of the result match rates between the algorithms, as shown in Figure 2, for data set 4. After the manual validation of data set 4, the returned ATC codes were always correct if all algorithms or algorithms 1 and 2 returned the same results.

Figure 3. Percentage of the most frequent 1000 of all unstructured drug prescriptions.



For the matching results of algorithms 1 and 3, we noted a minor discrepancy and identified 5 incorrect results out of 286, which were related to sodium chloride drug prescriptions in 4 out of 5 cases, and another incorrect result was returned for the ingredient aciclovir. The manual review revealed that an ATC code could not be provided because of missing details that was due to the ATC code at ATC level 1 varying by route of administration (eg, oral, parenteral, and conjunctival). For the matching results of algorithms 2 and 3, we identified only 1 incorrect result related to the ingredient telmisartan because the drug prescription was for a combination drug (telmisartan and diuretics), whereas the algorithms identified only the ATC code of the single ingredient telmisartan.

For the data set 4, a significant difference in the means of the Levenshtein similarity score was found between the correct and incorrect results (see Table 3 for descriptive statistics) with a P value of 2.4×10^{-47}, which is well below the significance level α (.05). This means that the higher the Levenshtein similarity score, the higher the probability of result correctness. Speaking in terms of absolute numbers, for entries with a Levenshtein similarity score >84.28, the results can be assumed to be correct with a low error rate.

Table 3. Descriptive statistics for Levenshtein similarity score for correct and wrong results.

Descriptive statistics	Algorithm 3	
	Correct	Wrong
Count	766	234
Frequency, n (%)	416,585	84,598
Values, mean (SD)	84.28 (14.86)	67.18 (15.52)
Range (%)	21-100	29-100
Percentile		
25th percentile	76	55
50th percentile	87	63
75th percentile	96	75

The 234 incorrect results returned only by algorithm 3, with 4.78% (84,598/1,768,153) of drug prescriptions, can be categorized into four groups: (1) manually identified additional entries without drug prescriptions for which the applied rules did not work; (2) specification generally not possible owing to missing information; (3) restriction to ATC level 3 or 4 because of nonspecific drug prescription information; and (4) other reasons. We found 16 entries (multiplied by frequency=5411) with no additional drug prescription entries. For an additional 11 (multiplied by frequency=2187) entries, no ATC code could be provided because the dosage form or dose was missing. For 2 drug prescriptions (multiplied by frequency=2610) of insulin therapies, there was a restriction to ATC level 3. Another 2 (multiplied by frequency=887) entries were restricted to ATC level 4 sodium chloride prescriptions.

For the other 203 misidentified entries, we examined the subset of 26 entries where algorithm 3 returned results with a Levenshtein similarity value of ≥80 because it is an indication of correctness but unfortunately did not apply to all results. A small group of 26 results with a Levenshtein similarity value of ≥80 was still incorrect. The main reason for the errors in these results was that the ATC codes for the ingredients differed by dosage form and when combined in a drug product, as shown in Table 4. Most incorrect results (15 out of 26) were caused by the absence of the ingredient dosage form in the free text, especially for sodium chloride, prednisolone, dimetindene, aciclovir, and hydrocortisone. The full data set 4 with all the algorithm outcome quality data elements listed in Table 1 is available in Multimedia Appendix 2.

Table 4. Wrong results of algorithm 3 with Levenshtein similarity score ≥80.

Medication free text	Wrong result	Levenshtein similarity score	Correct result	Reason

Final Data Assessment

Compared with the initial data assessment in which we could only distinguish between structured and unstructured drug prescriptions, we were able to perform a percentage distribution between structured and unstructured drug prescriptions for each of the 14 ATC level 1 groups after applying the algorithm. The final results are presented in Table 5, which shows the number of structured drug prescriptions versus the number of unstructured drug prescriptions per ATC level 1 group. The total number of drug prescriptions per ATC level 1 group, including percentages, provides an overview of the most and least frequently prescribed drugs sorted by the 14 ATC level 1 groups. For completeness, we added 3 additional rows to Table 5 containing the number of unstructured entries identified as other orders (no_med), the number of unstructured entries identified as unspecified entries (unspec), and the remaining unstructured data for which no validation was performed; thus, no statement on the correct ATC code was possible. ATC level 1 group "N – Nervous system" was the most common group with 24.1% (322,286/1,337,565) of the initial data set 1, followed by "B – Blood and blood forming organs," "A – Alimentary tract and metabolism," and "C – Cardiovascular system" with approximately 19% each.

Figure 4 illustrates the structuredness of the data for each of the 14 ATC level 1 groups. The ATC level 1 group with the most structured data was "S – Sensory organs" with 98.03% (5077/5179) structured data, followed by the group "H – Systemic hormonal drugs, excluding sex hormones and insulins" with 79.9% (51,296/64,199) structured data. ATC level 1 groups "R – Respiratory system," "C – Cardiovascular system," "J – Anti-infective for systemic use," "V – Various," "B – Blood and blood forming organs," and "N – Nervous system," ranged from 61% to 70% structured data. ATC group "P – Antiparasitic products, insecticides, and repellents" had the lowest percentage of structured drug prescriptions at only 23.4% (342/1461).

In total, 742 ATC level 5 codes (ingredients) were identified in the drug prescription data.

The structuredness of the ingredients varied widely, showing a wide range of structuredness among ingredients, as shown in Figure 5, where each of the 742 ATC level 5 codes (ingredients) is represented by a single dot. The y-axis represents the degree of the structuredness between 0% and 100%. The x-axis represents the frequency of each ATC level 5 code in data set 1, with a limitation of 85.18% (1,506,059/1,768,153) structured and evaluated unstructured data. There were only 4 ATC level 5 codes that were each used more than 45,000 times in drug prescriptions, namely N02BB02 (metamizole), B05BB01 (sodium chloride), A02BC02 (pantoprazole), and N02AA05 (oxycodone).

Table 5. Number of Anatomical Therapeutic Chemical (ATC) codes by ATC level 1 for structured, unstructured, and combined data.

ATC 1st level	Structured drug prescriptions (n=843,980), n/N (%)	Unstructured drug prescriptions for evaluated subset (n=924,173), n/N (%)	Total number (n=1,768,153), n/N (%)
N – Nervous system	197,831/322,286 (61.38)	124,455/322,286 (38.62)	322,286/1,337,565 (24.1)
B – Blood and blood forming organs	164,032/251,120 (65.32)	87,088/251,120 (34.68)	251,120/1,337,565 (18.77)
A – Alimentary tract and metabolism	137,988/250,543 (55.08)	112,555/250,543 (44.92)	250,543/1,337,565 (18.73)
C – Cardiovascular system	170,703/247,629 (68.93)	76,926/247,629 (31.07)	247,629/1,337,565 (18.51)
J – Anti-infective for systemic use	60,844/88,659 (68.63)	27,815/88,659 (31.37)	88,659/1,337,565 (6.63)

Figure 4. Structuredness of drug prescriptions by ATC groups for 85.18% of initial data set DS1. ATC: Anatomical Therapeutic Chemical.

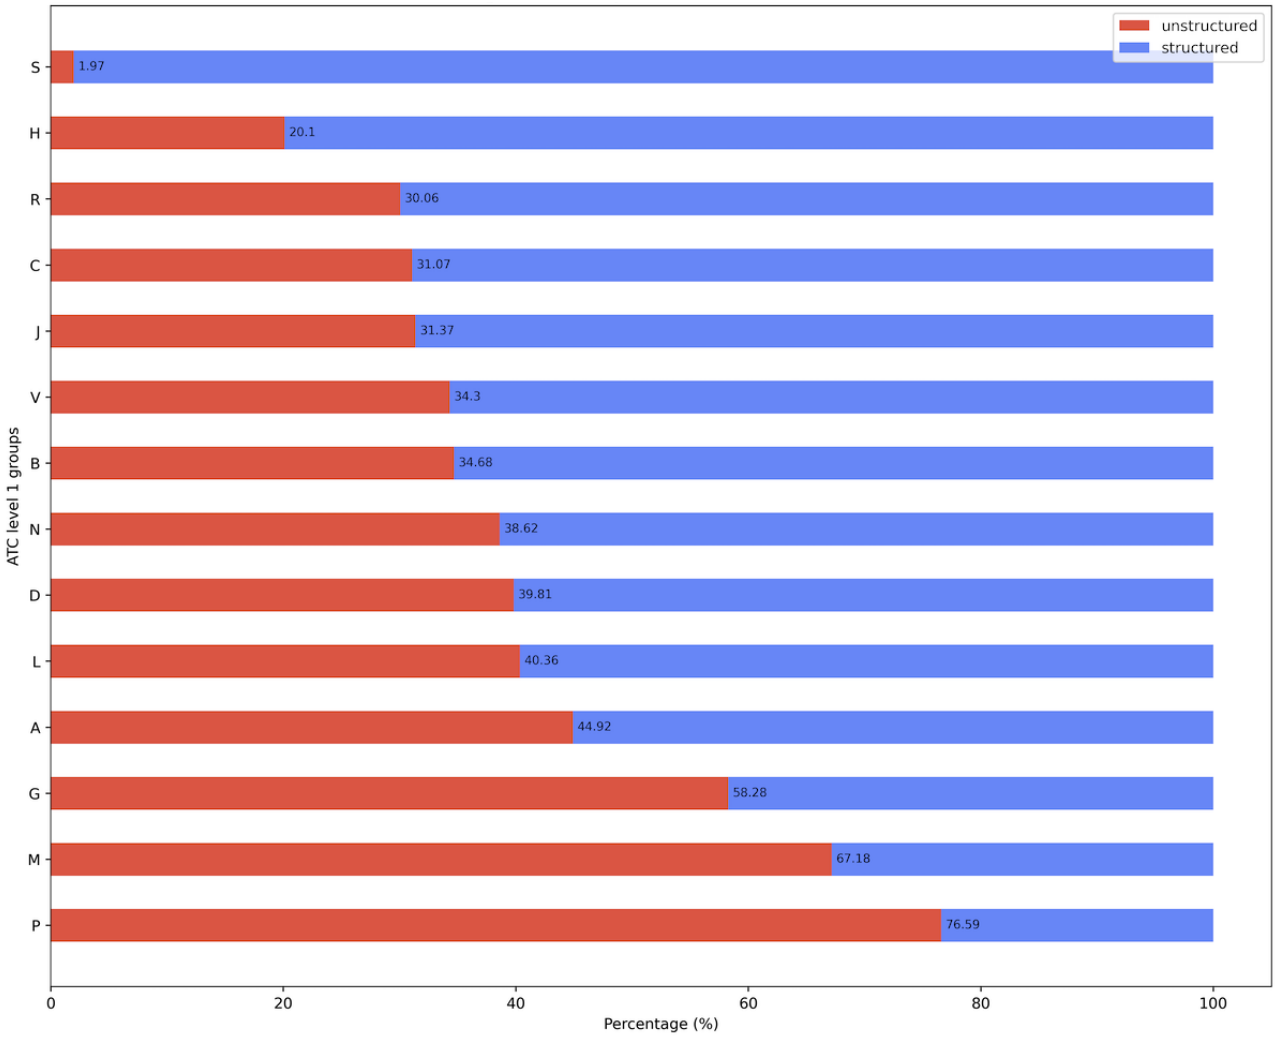

Figure 5. Structuredness of drug prescription by ATC L5 (a) total unstructured data and (b) by each ATC L1 group. A: Alimentary tract and metabolism; ATC: Anatomical Therapeutic Chemical; B: Blood and blood forming organs; C: Cardiovascular system; D: Dermatologicals; G: Genito urinary system and sex hormones; H: Systemic hormonal drugs, excluding sex hormones and insulins; J: Anti-infective for systemic use; L: Antineoplastic and immunomodulating agents; L1: level 1; L5: level 5; M: Musculo-skeletal system; N: Nervous system; P: Antiparasitic products, insecticides, and repellents; R: Respiratory system; S: Sensory organs; V: Various.

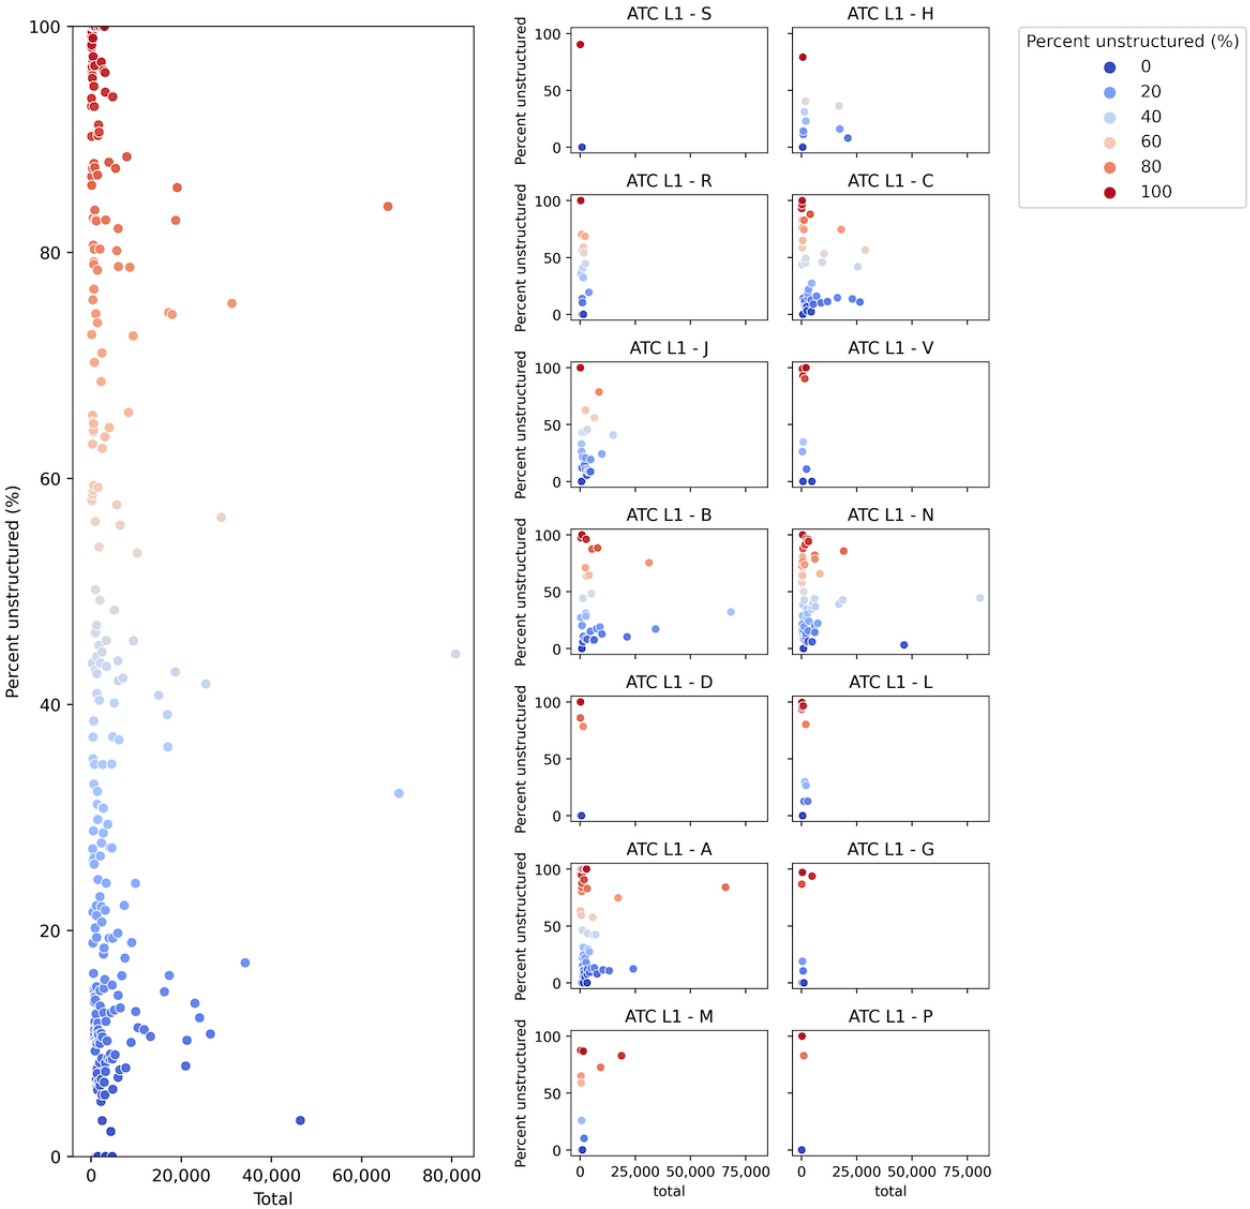

Together, these 4 ATC level 5 codes accounted for 14.79% (261,460/1,768,153) of the total data in the data set 1. Pantoprazole had the lowest level of structured data for these 4 ingredients (10,490/65,861, 15.93%), whereas oxycodone had the highest level of structured data (44,952/46,434, 96.81 %). Multimedia Appendix 3 contains the complete list of all ingredients with their ATC level 5 codes, number of structured, unstructured, and total drug prescriptions. In addition, it includes the percentage strength of each ingredient, ordered by the total number of drug prescriptions, starting with the largest number.

Discussion

Principal Findings

Our 4-step approach ensures data quality assessment as recommended by Zozus et al [18]. We provide transparency by reporting the structuredness of drug prescriptions. In addition, our approach improved the structuredness and thus the completeness of drug prescription data. This leads to better usability for secondary use on research infrastructure, such as the OMOP based ATC codes accompanied by manual review.

The initial analysis of the drug data showed a ratio of 52.3% unstructured to 47.7% structured drug prescriptions. With the algorithms presented, the structuredness could be increased to 85.1% with 1 level of evaluation. For the evaluation of the initial data set 1, manual examination of the most frequent 1000 free-text entries was sufficient, and we were able to achieve the targeted minimum coverage of 80%. Algorithm 3, which was based on similarity matching, was found to quantitatively outperform the other 2 algorithms, providing results for all unstructured drug prescriptions. In terms of the reliability of the results, algorithm 3 had a correctness rate of only 76.5%.

Therefore, the evaluation phase was critical to manually correct all incorrectly derived ATC codes. In addition, the manual evaluation process was critical in identifying patterns that can be used to determine the reliability of the algorithms based on additional factors, such as algorithm-to-algorithm matches and the Levenshtein similarity score of algorithm 3. When all 3 methods or algorithms 1 and 2 yielded the same ATC code, the algorithm results were considered correct in each case. The scoring process yielded a minuscule percentage of incorrect results (approximately 1.5%) when algorithms 2 and 3 or 1 and 3 yielded the same results.

The patterns identified are a good indication that can help increase the reliability of the results without further manual evaluation, compared with the overall correctness of 76.5% (765/1000) found for algorithm 3 results. The Levenshtein similarity score revealed another trend for algorithm 3: incorrect results had a significantly lower mean similarity score than correct results. The exceptions have been isolated to a small number of ingredients, reasons such as missing dosage form and dosage information, and cases where the same ingredients were used for single and combination drug products, resulting in separate ATC codes. The quality of the RWD has a major impact on the results of observational studies that rely on it. It is important to ensure that RWD data are suitable for use in observational studies [24] and that any limitations or quality concerns are explicitly stated [25].

Limitations

Currently, the analyzed data set is limited to inpatient drug prescriptions from the University Hospital Carl Gustav Carus Dresden. No drug prescription data from intensive care medicine were included, and no other institution has used our technique yet. Outliers or rare patterns may have gone undetected because the study was limited to the first 1000 free-text prescriptions. Although this covers most of the data, the results of the algorithm for the remaining free-text entries are yet to be evaluated. This study does not include an outcome evaluation of additional drug prescription entries based on identified patterns. Currently, the method is limited to determining ATC codes for unstructured drug prescriptions and does not consider other terminologies such as RxNorm.

Comparison With Prior Work

Most studies evaluating the quality of RWD data refer to the dimensions of completeness and accuracy compared with predefined gold standard data that vary by publication, as identified by Weiskopf et al [19]. We did not define our gold standard based on RWD sources but used the internationally recognized and widely used terminology ATC as standardized terminology and provided a method to automatically determine the appropriate ATC for drug prescription data that are unstructured and available only as free text. Wang et al [26] developed a rule-based data quality system with >6000 criteria for plausibility testing (eg, pregnancy is not plausible in male patients) but did not address data harmonization by mapping unstructured free-text data to defined terminologies for research. Unlike Schmidt et al [27] and Kahn et al [25], our study not only focus on data quality assessment but also defines the absence of structure in the data as free text without a corresponding ATC code and builds on previous research by proposing a method to improve unstructured data by automatically annotating the appropriate ATC code.

The high proportion of free-text or unstructured drug prescriptions was due to the hospital's prescription system and local conditions. According to previous studies on the data structure in RWD [28], this is a widespread challenge in Germany. However, the issues of dealing with unstructured data in EHR records that prevent interoperability are widespread as stated by Kruse et al [29,30] in their systematic reviews of existing literature on the use of EHR data that need to be addressed to ensure "fitness for use" in general. Compared with the well-established Unified Medical Language System MetaMap [31,32], which has been used by industry and academia for many years, our NLP approach focuses on a lightweight implementation. On the one hand, this limits the configuration possibilities, but on the other hand, it reduces the computational efforts and promotes the performance of the ATC code recognition. Because MetaMap focuses only on English and does not support German drug catalogs, our approach closes this gap and can be adapted to other languages as well.

Future Work

The presented 4-step approach can be applied to any RWD with unstructured data such as conditions, procedures, or test results. This approach will be tested in the future on other sites that provide drug data and product lists with ATC codes. In the next phases, further research will be conducted on pattern recognition to enable reliable prediction of the accuracy of results for specific ATC codes rather than manually checking them. In addition, new NLP-based algorithms will be implemented to improve the overall reliability of the results. Furthermore, our approach can be applied to other hospital sites that participate in the German Medical Informatics Initiative [33,34] in the following steps. Our approach is not limited to the German language. Because the only requirement is to provide a common list of ingredients or drug products for comparison with unstructured free text, this can work for any other language if compared texts are available in the same language.

Conclusions

RWD observational research requires a high level of data structuredness. Even more critical is the awareness of limitations as well as transparency of the level of structure of the data on which the research is based. Using drug prescriptions as a first use case, we were able to investigate and improve the structure of RWD, which can be applied to other RWDs in the future. Although the presented methods require manual verification to ensure that the results are correct, the methodology is promising and can be used to improve structuredness of data.

Acknowledgments

Abstract

Background: To discover new knowledge from data, they must be correct and in a consistent format. OntoCR, a clinical repository developed at Hospital Clínic de Barcelona, uses ontologies to represent clinical knowledge and map locally defined variables to health information standards and common data models.

Objective: The aim of the study is to design and implement a scalable methodology based on the dual-model paradigm and the use of ontologies to consolidate clinical data from different organizations in a standardized repository for research purposes without loss of meaning.

Methods: First, the relevant clinical variables are defined, and the corresponding European Norm/International Organization for Standardization (EN/ISO) 13606 archetypes are created. Data sources are then identified, and an extract, transform, and load process is carried out. Once the final data set is obtained, the data are transformed to create EN/ISO 13606–normalized electronic health record (EHR) extracts. Afterward, ontologies that represent archetyped concepts and map them to EN/ISO 13606 and Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) standards are created and uploaded to OntoCR. Data stored in the extracts are inserted into its corresponding place in the ontology, thus obtaining instantiated patient data in the ontology-based repository. Finally, data can be extracted via SPARQL queries as OMOP CDM–compliant tables.

Results: Using this methodology, EN/ISO 13606–standardized archetypes that allow for the reuse of clinical information were created, and the knowledge representation of our clinical repository by modeling and mapping ontologies was extended. Furthermore, EN/ISO 13606–compliant EHR extracts of patients (6803), episodes (13,938), diagnosis (190,878), administered medication (222,225), cumulative drug dose (222,225), prescribed medication (351,247), movements between units (47,817), clinical observations (6,736,745), laboratory observations (3,392,873), limitation of life-sustaining treatment (1,298), and procedures (19,861) were created. Since the creation of the application that inserts data from extracts into the ontologies is not yet finished, the queries were tested and the methodology was validated by importing data from a random subset of patients into the ontologies using a locally developed Protégé plugin (“OntoLoad”). In total, 10 OMOP CDM–compliant tables (“Condition_occurrence,”

864 records; “Death,” 110; “Device_exposure,” 56; “Drug_exposure,” 5609; “Measurement,” 2091; “Observation,” 195; “Observation_period,” 897; “Person,” 922; “Visit_detail,” 772; and “Visit_occurrence,” 971) were successfully created and populated.

Conclusions: This study proposes a methodology for standardizing clinical data, thus allowing its reuse without any changes in the meaning of the modeled concepts. Although this paper focuses on health research, our methodology suggests that the data be initially standardized per EN/ISO 13606 to obtain EHR extracts with a high level of granularity that can be used for any purpose. Ontologies constitute a valuable approach for knowledge representation and standardization of health information in a standard-agnostic manner. With the proposed methodology, institutions can go from local raw data to standardized, semantically interoperable EN/ISO 13606 and OMOP repositories.

KEYWORDS

health information interoperability; health research; health information standards; dual model; secondary use of health data; Observational Medical Outcomes Partnership Common Data Model; European Norm/International Organization for Standardization 13606; health records; ontologies; clinical data

Introduction

The term primary use of health data encompasses the generation and use of data within the context of individual health care in hospitals and physicians’ offices to serve direct care needs [1]. The term secondary use of health data is defined by the American Medical Informatics Association as “non-direct care use of PHI [personal health information] including but not limited to analysis, research, quality/safety measurement, public health, payment, provider certification or accreditation, and marketing and other business including strictly commercial activities” [2]. Although they can be further categorized [3], one of the main types of secondary uses is research.

Clinical data sharing for research is highly relevant from a scientific, economic, and ethical perspective [4]. The overwhelming increment in the volume of available data is directly related with the emergence of a new paradigm of scientific methodology in which massive amounts of data are processed and analyzed for obtaining knowledge through machine learning and data mining algorithms [5].

Despite the growth of big data technologies and the use of artificial intelligence, in order to discover new knowledge from data, they must be correct and in a consistent format, which requires a great amount of resources for cleaning, binding, and organizing them. The semantics of data is a key component regarding the aforementioned challenges. To use the electronic health record (EHR) data for different projects, it must maintain its semantics and context, independently of any particular use case. This is especially important in research, where EHR reuse processes are often based on black boxes on which the final data customer is unaware of how the data uploaded to their research database were recorded, extracted, and transformed [6].

A common health information standard should be used in both primary and secondary use to share clinical information in a way that it can be unequivocally interpreted, both syntactically and semantically, by 2 or more systems. European Norm/International Organization for Standardization (EN/ISO) 13606 is a health information standard that seeks to define a rigorous and stable architecture for communicating the health records of a single patient, preserving the original clinical meaning. It is based on a dual model that includes a reference model (RM; with the necessary components and their constraints to represent EHR extracts) and an archetype model (AM; for the formalization of clinical-domain concepts according to the RM) [7,8]. Archetypes allow the formal representation of the structure of clinical information and its meaning (through terminology binding) so that it is automatically processable by information systems.

Furthermore, the EN/ISO 13940 norm [9] provides a conceptual framework centered in the clinical process. This norm, based on a clinical perspective, defines the system of concepts that are necessary for achieving continuity in the caregiving process, including both the content and the context of the health activities. This ample norm defines the concepts relative to health care actors, health problems, sanitary activities, health care processes, sanitary planification, time-related concepts, responsibilities, and information management.

Moreover, the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) defines a common format (data model), as well as a common representation (terminologies, vocabularies, and coding schemes), to allow systematic analyses of disparate observational databases using a library of standard analytic routines that have been written based on the common format [10]. The OMOP CDM is considered by several authors as the most adequate data model for sharing data in EHR-based longitudinal studies [11-13].

This paper describes the work carried out between Hospital Clínic de Barcelona (HCB), Hospital 12 de Octubre (H12O), and Instituto de Salud Carlos III (ISCIII), which seeks to consolidate clinical data of hospitalized patients with COVID-19 from different hospitals in joint repositories, structured with EN/ISO 13606 and then normalized according to the OMOP CDM.

The aim of this study is to design and implement a scalable methodology based on the dual-model paradigm and the use of ontologies to consolidate clinical data from different organizations in a standardized repository for research purposes without loss of meaning. This implies a series of particular objectives such as (1) to define a set of relevant clinical and

biochemical variables of patients hospitalized with COVID-19, (2) to model a set of standardized archetypes based on EN/ISO 13606 to communicate such information, (3) to conceptually represent those clinical variables by means of ontologies, (4) to generate EN/ISO 13606–standardized EHR extracts of COVID-19 patients, and (5) to map and transform the source data to create OMOP CDM–compliant tables.

Methods

Ethical Considerations

This study was approved by the Hospital Clínic de Barcelona Ethics Committee for Investigation with Drugs (HCB/2018/0573).

Cohort Inclusion Criteria

We included in this project patients with COVID-19 admitted to the emergency room (ER) or hospitalized between February 17, 2020 (beginning of the first wave in Spain), and February 15, 2022 (end of the sixth wave in Spain).

Methodology

The following methodology comprises a series of steps in order to achieve the study's objectives.

Step 1: Definition of Clinical Variables, Data Structures, and EN/ISO 13606 Archetypes

The first step consists in deciding the clinically relevant variables that should be included. Afterward, the data structures must be defined, including the fields, their descriptions, and the standardized terminologies and classifications to be used.

Since OMOP CDM is intended for secondary use of data (specifically, for biomedical research), its granularity is somewhat reduced when compared to raw data captured in hospitals. For this reason, the Medical Informatics Unit (MIU) at HCB decided to first standardize the data according to EN/ISO 13606, in order to have semantically interoperable EHR extracts with the maximum level of detail.

Therefore, the MIU at HCB and the Data Science Unit at H12O defined the EN/ISO 13606 archetypes to be used, modeled with the software LinkEHR [14] created by VeraTech for Health. The data types used are those established by the standard's RM.

This RM has multiple components, including the entry (a result of 1 clinical action, 1 observation, 1 clinical interpretation, or 1 intention) and its elements (the leaf node of the EHR hierarchy, containing a single data value). In our project, the archetypes modeled at the entry level of the RM were the following: diagnosis, episodes, limitation of life-sustaining treatment, administered medication, cumulative drug dose, prescribed medication, movements between units, clinical observations, laboratory observations, patients, health problems, and procedures. These archetypes were registered under a Creative Commons license (ID 2204210968527), so that any user who follows the license terms can share and adapt them [15]. Figure 1 shows a mind map of the diagnosis entry archetype as an example.

Figure 1. Mind map of the EN/ISO 13606 "diagnosis" archetype in Spanish, modeled with LinkEHR. The "diagnosis" entry has 6 elements: episode_id, diagnosis, diagnosis_datetime, patient_id, diagnosis_id, and source. Each of them has its corresponding data type. EN/ISO: European Norm/International Organization for Standardization.

Step 2: Identification of Data Sources and Extract, Transform, and Load

Afterward, the corresponding data sources must be identified, in order to carry out the extract, transform, and load (ETL) process. In our case, these sources were (1) structured data from HCB's health information system (HIS), SAP; (2) unstructured data from HCB's HIS. A collaborative work with Barcelona Supercomputing Center (BSC) allows for the recognition of clinical entities through natural language processing and its extraction as normalized structured data; (3) outpatient setting structured data from Agència de Qualitat i Avaluació Sanitàries de Catalunya.

Since the last 2 sources come from separate projects whose description is besides the objective of this paper, we will focus on the first one. Archetypes created in the previous step were used as templates for identifying data in the aforementioned sources. Periodic meetings were held with the Information Technology Department at HCB to identify the location of the data and the transformations needed to obtain the structured data defined in the previous step. Once this was achieved, the tables were loaded into a MySQL database hosted on a dedicated server of the MIU.

Step 3: Creation of EN/ISO 13606 EHR Extracts From Source Data

Once the final data set is obtained, data must be transformed to create EHR extracts normalized according to EN/ISO 13606. This transformation includes mapping of local variables to standardized nomenclatures and classifications (Systematized Nomenclature of Medicine—Clinical Terms (SNOMED CT), International Classification of Diseases 10—Clinical Modification (ICD-10-CM), Logical Observation Identifiers Names and Codes (LOINC)), assigning readable descriptions to local codes, and categorizing certain concepts (eg, grouping hospital units according to the level of care).

This process is performed by mapping archetypes to the implicated information systems, without the need to modify them. This approach allows the automation of data extraction and the reuse of this methodology for other use cases with very little effort, which constitutes one of the great advantages of dual-model strategies.

In our case, we carried out this process with the help of VeraTech for Health, our technical partners, using LinkEHR, thus creating extracts on our dedicated server and constituting an EN/ISO 13606 standardized clinical repository. Figure 2 shows a test example of an EN/ISO 13606 EHR extract (without real-patient data). In this extract, the ICD-10-CM code H40.9 (unspecified glaucoma) is being communicated, alongside its date and time of record and the ID of the clinical episode it pertains to.

```

Step 4: Creation of Ontologies

Traditionally, clinical concepts and the relationships between them have been poorly developed in HISs. The MIU at HCB developed OntoCR, an ontology-based clinical repository, conforming to EN/ISO 13606 standard [16,17]. The use of ontologies allows for the definition of a conceptual architecture centered on the representation of the clinical process, while the use of EN/ISO 13606 allows syntactic and semantic interoperability between systems. EN/ISO 13940 was also used to define the generic concepts needed to achieve continuity of care, representing both the content and the context of the health care services.

One of the main advantages of ontologies is their flexibility to perform changes with minimum use of resources, adapting to an ever-changing environment. Likewise, ontologies allow the addition of conceptual layers, thus mapping locally defined concepts to health information standards, facilitating the communication of information without loss of meaning.

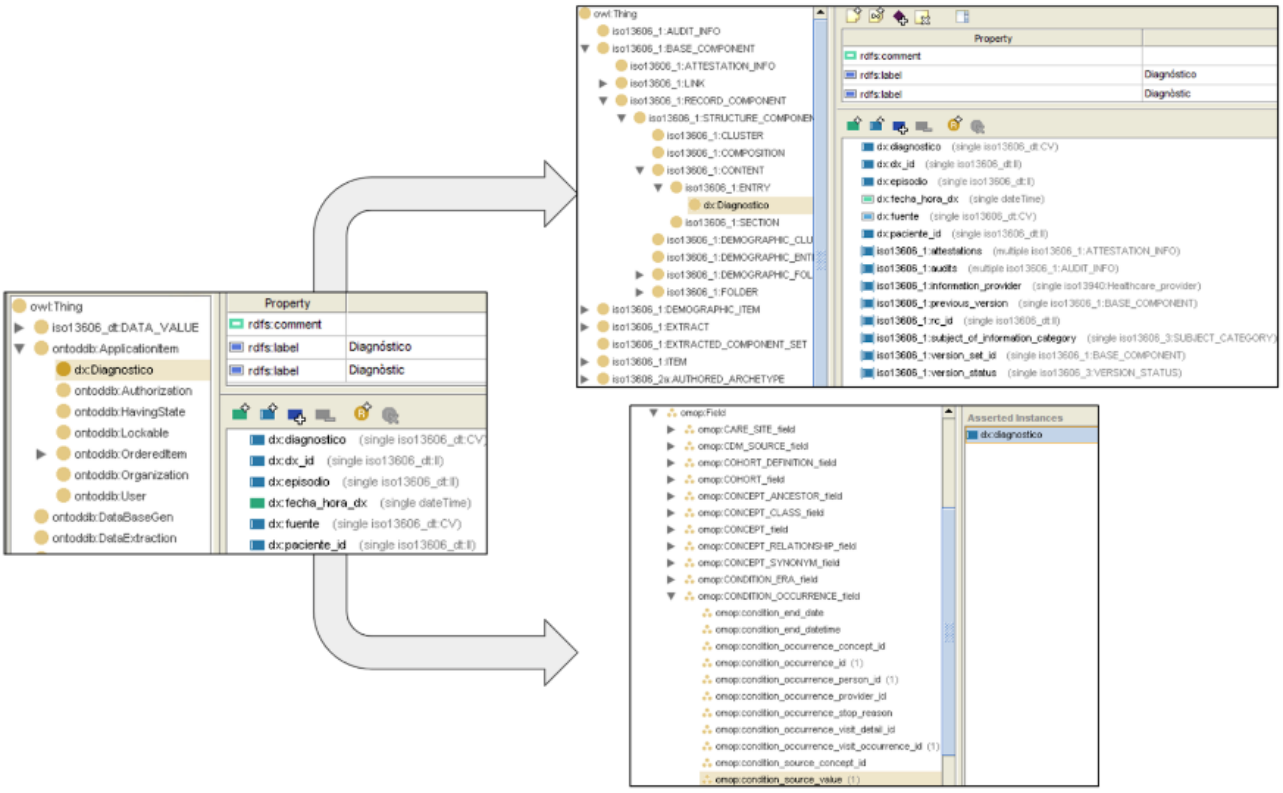
A relational database (OWL-DB) is used for storing ontologies and instantiated data, designed according to the Web Ontology Language (OWL) specification [18]. The ontologies in this project were created using Protégé, a free, open-source ontology editor created by Stanford University that fully supports OWL and Resource Description Framework (RDF) specifications from the World Wide Web Consortium [19]. A plug-in developed by our team, the OWL-DB plugin, connects Protégé with the OWL-DB module at the storage level.

These ontologies were conceptualized in 3 different layers. The first one describes the concepts modeled in the archetypes, with the classes and properties that describe the data structure defined in the first phase. Data types according to the EN/ISO 13606 RM were used.

In the next layer, we used a locally created ontology that reproduces the EN/ISO 13606 RM and AM. By creating an additional ontology that maps the archetypal concepts to the EN/ISO 13606 model, we structured our data according to the standard. In this layer, each entry-level archetype is represented in a separate ontology.

As with EN/ISO 13606, we created an ontology that models the OMOP CDM and afterward mapped archetypal concepts to the corresponding meta-class of the standard. So, the third layer consists of ontologies for each archetype that reproduce concepts according to the OMOP CDM structure. Figure 3 shows these 3 ontologies. The left image (ontology of the AM of diagnosis) depicts the class "Diagnosis" with its properties diagnosis, diagnosis_id, episode, diagnosis_datetime, source, and patient_id. In the upper-right image, a new ontology was created where the class "Diagnosis" was modeled as a subclass of "iso13606: Entry," thus inheriting its properties defined in the RM. Finally, in the lower right image, a third ontology maps the property diagnosis with OMOP CDM's metaclass "condition_source_value."

Figure 3. Ontologies of the archetype model of diagnosis (left) and its mapping to the EN/ISO 13606 structure (upper right) and the OMOP CDM (lower right) in Spanish, edited with Protégé software. EN/ISO: European Norm/International Organization for Standardization; OMOP CDM: Observational Medical Outcomes Partnership Common Data Model.



Afterward, these ontologies must be loaded into a production environment of OntoCR so as to generate the structure that can receive instantiated data of patients and store it.

Step 5: Integration of EN/ISO 13606 Extracts Into the Ontology-Based Clinical Repository and Extraction of Data as OMOP CDM–Compliant Tables

Once the ontological structure is ready to receive the data, the EHR extracts must be inserted into the repository, thus incorporating the normalized, instantiated data. We initially explored the possibility of adapting a preexisting application programming interface (API) that was used for the same purpose in a previous project. However, the resources needed for its adaptation were significantly elevated, and its scalability reduced. Therefore, we decided to work on an application that identifies each archetype node within the extract and inserts it into its counterpart in the OWL file. This is facilitated by the representation in the ontologies of each archetype, their nodes, and the data types used (compliant with EN/ISO 13606).

Finally, data stored in the ontology-based clinical repository needs to be extracted through SPARQL queries, a language used for graph databases. Since archetypal concepts have been previously mapped to the OMOP CDM, by performing these queries, the extraction process is simplified. If there are cases in which data needs to be transformed to fit the CDM, such transformations can be included in the queries or carried out via SQL queries once relational tables are obtained.

In Figure 4, a SPARQL query for extracting data for the OMOP CDM PERSON table is shown. Attributes that are not present in the ontological repository must still be included in the SELECT clause so as to create the corresponding table column without any instantiated data. Since EN/ISO 13606 data types were used in the extracts and modeled in the ontologies, they were also represented in the queries (see the lower lines of SPARQL code).

Figure 4. SPARQL query for the "Person" table of the OMOP CDM. OMOP CDM: Observational Medical Outcomes Partnership Common Data Model.

```

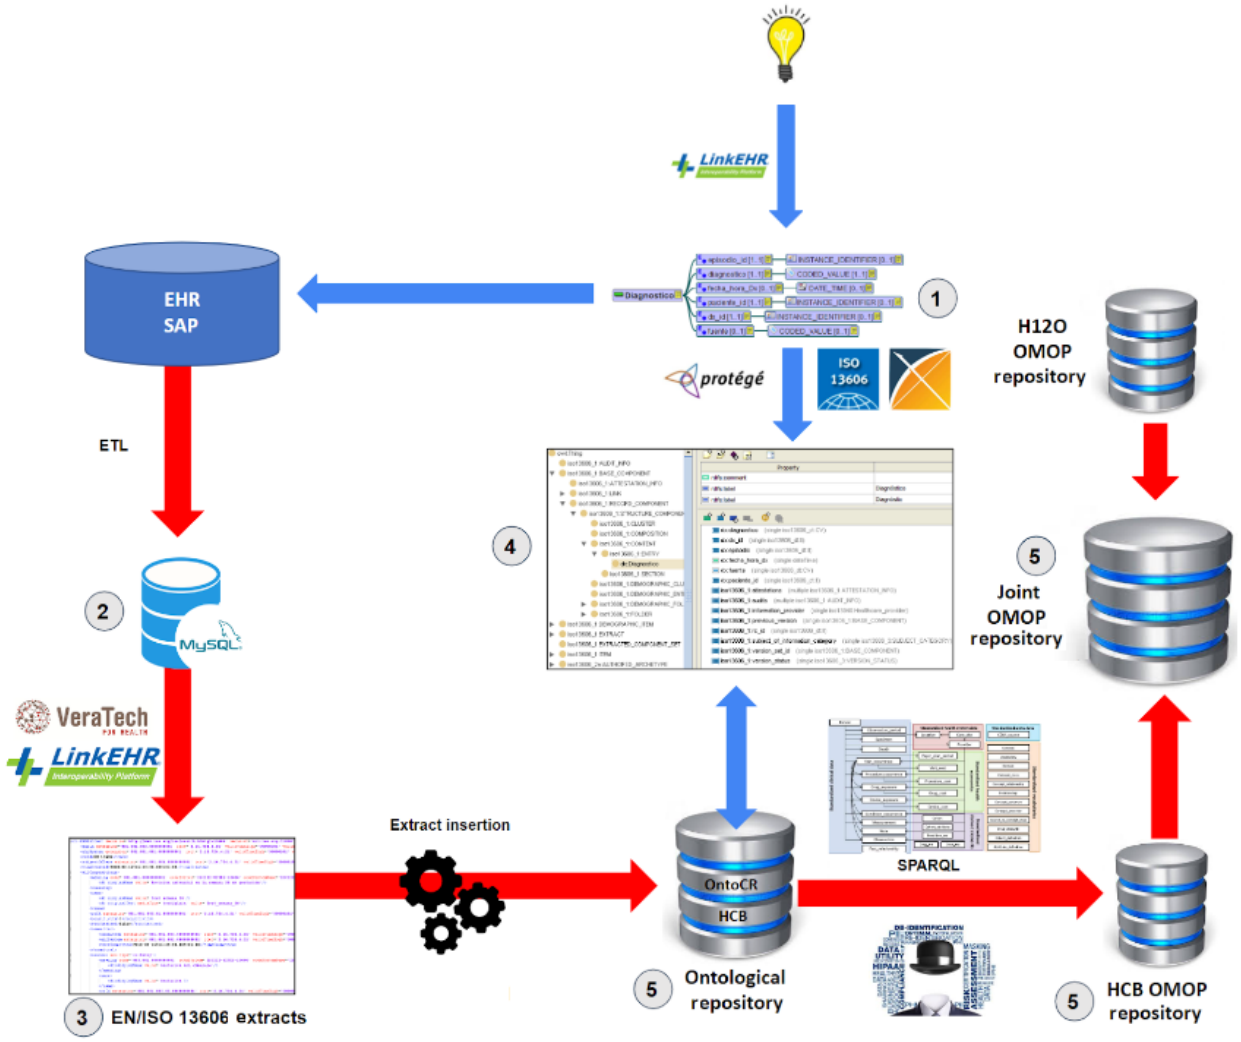
Data anonymization is performed by the IT department at this level using an institutional software solution. This way, EN/ISO 13606 extracts contain identified data that can be used for primary uses, while OMOP CDM tables are anonymized for secondary uses.

Once obtained, the anonymized data can be consolidated in a joint OMOP CDM repository with other institutions that use the same standard (in our case, H12O). OMOP CDM has a large number of tables, divided into 6 groups: standardized clinical data, standardized health system data, standardized derived elements, standardized health economics, standardized metadata, and standardized vocabularies. Our OMOP CDM repository contains the following tables, which are part of the standardized clinical data: "Condition_occurrence," "Death," "Device_exposure," "Drug_exposure," "Measurement," "Observation," "Observation_period," "Person," "Visit_detail," and "Visit_occurrence."

Figure 5 shows an overview of the whole process. The knowledge modeling starts with the creation of EN/ISO 13606 archetypes based on clinical concepts, which are then represented in ontologies that map them to EN/ISO 13606 RM and OMOP CDM. These ontologies are uploaded to OntoCR without instantiated patient data yet.

Figure 5. General overview of the process. Red arrows indicate data flow, while blue arrows indicate knowledge-related processes. Numbers indicate the deliverables within each step. EHR: electronic health record; EN/ISO: European Norm/International Organization for Standardization; ETL: extract, transform, and load; H12O: Hospital 12 de Octubre; HCB: Hospital Clínic de Barcelona; OMOP: Observational Medical Outcomes Partnership.



The data-related processes begin with the archetype-based extraction of raw data from our local system into a MySQL database and its transformation to create EN/ISO EHR extracts, which are then inserted into OntoCR via an application specifically developed for this project. SPARQL queries are performed against this ontological repository to obtain an OMOP CDM repository that is consolidated with H12O in a joint one.

Results

Methodology

The main deliverable of this project is the methodology described in the previous section. By following the aforementioned steps, any health care institution can go from local raw data to standardized, semantically interoperable EN/ISO 13606 and OMOP repositories. This methodology also led to the creation of 12 EN/ISO 13606-standardized archetypes that model important clinical variables in the ER and hospitalization settings, allowing the reuse of clinical information by using it in accordance with the Creative Commons terms.

Ontologies

Another interesting result of this study is the development of the ontologies that represent OMOP CDM, as well as their mappings to EN/ISO 13606 AM and RM. This process was carried out by members of the MIU at HCB after carefully reading the pertinent documentation of these standards and designing the optimal way of using them to represent clinical concepts.

Furthermore, representing clinical variables by means of ontologies is another way of reusing clinical information. With the creation of new ontologies for each project at HCB, where we have developed the ontology-based clinical repository OntoCR, we continue to extend our clinical knowledge representation.

EN/ISO 13606 Extracts

Table 1 shows the correspondence between EHR archetypes, OMOP CDM tables, number of extracts created throughout the study, and the number of COVID-19 patients they pertain to. We have included the diagnoses recorded in the episodes of the study period as well as the historical ones. Health problem

entries are part of the aforementioned project with BSC to extract clinical entities from unstructured texts through natural language processing, so they will not be included in this table.

Table 1. Correspondence between EHR[a] archetypes, OMOP CDM[b] tables, number of extracts created throughout the study, and the number of patients they pertain to.

EHR archetype	OMOP CDM table	EN/ISO[c] 13606 extracts, n	Patients, n
Patient	"Person"	6803	6803
Episode	"Visit_occurence"	13,938	6791
Diagnosis	"Condition_occurrence"	190,878	6799
Cumulative drug dose	"Drug_exposure"	262,770	5630
Administered medication	"Drug_exposure"	262,770	5630
Prescribed medication	"Drug_exposure"	341,986	5639
Movements between units	"Visit_detail"	47,817	6791
Clinical observation	"Measurement"	6,736,745	5973
Laboratory observation	"Measurement"	3,392,873	6001
Limitation of life-sustaining treatment	"Observation"	1298	1142
Procedure	"Procedure_occurrence"	19,861	4994

[c]EN/ISO: European Norm/International Organization for Standardization.

OMOP CDM–Compliant Clinical Tables

We still do not have the final number of records in our OMOP tables, since the initial approach of adapting the preexisting API had to be replaced by the creation of the application that inserts data from the extracts into the ontologies. However, an OMOP database for a random small subset of patients was successfully created to test the queries and validate the methodology. This was performed using a locally developed Protégé plugin ("OntoLoad") that imports a set of data from a relational database into the ontologies [17]. Table 2 describes the OMOP tables that were created.

Table 2. OMOP CDM[a]-compliant clinical tables created for a random small subset of patients.

OMOP CDM table	Patients, n	Records, n
"Condition occurrence"	121	864
"Death"	110	110
"Device_exposure"	3	56
"Drug_exposure"	106	5609
"Measurement"	3	2091
"Observation"	3	195
"Observation_period"	897	897
"Person"	922	922
"Visit_detail"	250	772
"Visit_occurrence"	897	971

Discussion

Principal Results

This study proposes a methodology for standardizing clinical data, thus allowing its reuse without any change in the meaning of the modeled concepts. Although the focus of this paper is health research, our methodology suggests that the data be initially standardized according to EN/ISO 13606 to obtain EHR extracts with a high level of granularity that can be used for any purpose, as previous studies have suggested [20]. Afterward, its transformation to OMOP CDM–compliant tables allows its consolidation in joint repositories for research purposes.

Although EN/ISO 13606 was chosen because of the operational mechanisms it offers for data exchange, due to the flexibility and standard-agnostic nature of our methodology, there is complete independence regarding any specific standard. Thus,

by modeling ontologies of other standards and mapping them to local variables, we may, for example, carry out transformations between EN/ISO 13606, OpenEHR [21], Fast Healthcare Interoperability Resources (FHIR) [22], OMOP CDM, and Informatics for Integrating Biology and the Bedside (i2b2) [23] with the minimum use of resources and without the need for changes in the database structure. Health information standards such as EN/ISO 13606 and OpenEHR allow the modeling and formalization of clinical knowledge through their RMs and archetypes [24], and ontologies are precisely a tool for carrying out such tasks. This is what makes them ideal in the context of an implementation of a dual-model strategy, allowing the representation of concepts in the health domain, its standardization, and the storage of instantiated patient data.

Furthermore, ontologies provide several advantages for the conceptualization of entities in a domain. It explicitly represents domain knowledge, allows the application of inference processes, enables the reuse of domain knowledge, allows data aggregation, and detects new associations between concepts [17].

It is clear for us that loading normalized data onto clinical repositories (instead of ad hoc data loading) provides many benefits. It is possible to reuse the same interoperability standards used in health care, adapting them to this new paradigm [25]. This approach allows the availability of clinical data for further single- or multicenter research.

We would like to highlight the vital importance of continuous collaborative research. This study is framed within a continued line of research since 2009 between HCB, ISCIII, and H12O. In this line of collaborative research, a standardized and transparent process has been designed and implemented for obtaining standardized data models for research from EHR raw data. Hence, in the first stage, the basis for a semantically interoperable clinical information management system based on EN/ISO 13606 was defined, proving that clinical information residing in heterogeneous systems could be normalized, combined, and communicated without loss of meaning. In the second stage, a common information model that reflects the clinical process and the relationships between the clinical records components was developed. In the third stage, a normalized information model based on EN/ISO 13606 archetypes was implemented and applied to local information systems for specific clinical use cases. With this model, it is possible to construct and order information recovered from these complex systems for the exchange of integral health and social information of patients and to use it for secondary purposes.

Comparison With Prior Work

Many of the requisites of clinical data repositories for primary use are common to those for secondary use, such as normalized clinical information models, controlled terminologies, identification of actors, and contextual information. Developments carried out for primary use repositories are also profitable for secondary uses, and the progresses derived from secondary uses accelerate the advances in shared clinical records. A lot of work has been reported in this field throughout the globe in the last years, which has led to developing policies, repository models and its application in the form of competitive projects [2,26,27].

It is very usual for researchers to resort to the generation of their own data for research and its manual introduction into data management systems. It is also quite common for them to use general purpose tools, particularly spreadsheets, as data management systems [28], while there is perception of a high need of additional support for the analysis of high volumes of data. This represents a significant problem, since these applications cannot guarantee the consistency of data, and they present difficulties for sharing and consolidating data and a limited capability of data exploitation.

Different methodologies have been proposed to create OMOP repositories from raw data. Some approaches are based on a simple mapping of local variables to their OMOP CDM counterparts, an alignment of vocabularies using the Athena tool provided by OHDSI and an ETL process through SQL scripts [29]. Other authors have proposed transforming source data to RDF, carrying out a semantic mapping (in some cases, using an ontological representation of OMOP CDM), and loading it to a data store [30,31].

Likewise, other standard-agnostic approaches have been reported in the literature. The ongoing INFOBANCO project of the Madrid Region [32] seeks to create a platform for the management, persistence, exchange, and reuse of health data focused on applying each health information standard for the purpose it was intended to, offering multiple interoperability and exploitation services suited for specific use cases [24]. Furthermore, the 3-pillar strategy of the Swiss Personalized Health Network [33] pursues a semantically interoperable clinical data landscape based on a multidimensional encoding of concepts, an RDF-based storage and transport of the instances of these concepts and a conversion of RDF to any target data model.

Strengths and Limitations

This study has many strengths that are worth mentioning. On the one hand, it describes a real-world collaborative effort between 3 health care institutions in Spain to model, share, and consolidate standardized patient data. Furthermore, the standard-agnostic nature of the proposed methodology leads to a significant scalability, allowing transformation between different health information standards and common data models. The software used in our methodology (LinkEHR, Protégé, and Liferay) either have a free version or are open source, which make them accessible to low-income areas and institutions with limited funding for interoperability projects.

We must also mention the limitations of this study. First of all, the ontology-based clinical repository used in our institution was developed throughout many years, and it might not be a suitable approach for institutions that seek a rapid implementation of a methodology. This can limit the external validity of the study. Moreover, since the tool to insert data from standardized extracts into the ontologies is not ready yet, we still have not completed the creation of OMOP CDM tables. However, an OMOP CDM database for a small subset of

patients was successfully created to test the queries and validate the methodology.

Next Steps

The MIU team at HCB is working on creating the ontological representation of different health information standards (FHIR and OpenEHR) and CDMs (i2b2, International Cancer Genome Consortium Accelerating Research in Genomic Oncology (ICGC Argo) [34], and Clinical Data Interchange Standards Consortium (CDISC) [35]). This will extend the current metamodel and allow us to carry out multistandard transformations, which will also help us compare the performance of such standards for different scenarios.

Conclusions

Semantic interoperability plays a very important role within HISs, providing meaning and clinical context to the clinical information and allowing for better clinical decision-making and research. This study has demonstrated that ontologies constitute a valuable approach for knowledge representation and standardization of health information in a standard-agnostic manner. With the proposed methodology, institutions can go from local raw data to standardized, semantically interoperable EN/ISO 13606 and OMOP repositories.

Acknowledgments

This study is also framed within the Spanish Secretary of State for Telecommunications and Digital Infrastructure's "Plan de Impulso de las Tecnologías del Lenguaje" (Plan TL). We would like to thank the Instituto de Salud Carlos III (ISCIII), VeraTech For Health, and Barcelona Supercomputing Center for their collaboration on this project. This work was supported by the ISCIII and cofunded by the European Union (grant PI18/00890, PI18/00981, and PI18CIII/00019).

Abstract

Background: Approaches to addressing unwarranted variation in health care service delivery have traditionally relied on the prospective identification of activities and outcomes, based on a hypothesis, with subsequent reporting against defined measures. Practice-level prescribing data in England are made publicly available by the National Health Service (NHS) Business Services Authority for all general practices. There is an opportunity to adopt a more data-driven approach to capture variability and identify outliers by applying hypothesis-free, data-driven algorithms to national data sets.

Objective: This study aimed to develop and apply a hypothesis-free algorithm to identify unusual prescribing behavior in primary care data at multiple administrative levels in the NHS in England and to visualize these results using organization-specific interactive dashboards, thereby demonstrating proof of concept for prioritization approaches.

Methods: Here we report a new data-driven approach to quantify how "unusual" the prescribing rates of a particular chemical within an organization are as compared to peer organizations, over a period of 6 months (June-December 2021). This is followed by a ranking to identify which chemicals are the most notable outliers in each organization. These outlying chemicals are calculated for all practices, primary care networks, clinical commissioning groups, and sustainability and transformation partnerships in England. Our results are presented via organization-specific interactive dashboards, the iterative development of which has been informed by user feedback.

Results: We developed interactive dashboards for every practice (n=6476) in England, highlighting the unusual prescribing of 2369 chemicals (dashboards are also provided for 42 sustainability and transformation partnerships, 106 clinical commissioning groups, and 1257 primary care networks). User feedback and internal review of case studies demonstrate that our methodology identifies prescribing behavior that sometimes warrants further investigation or is a known issue.

Conclusions: Data-driven approaches have the potential to overcome existing biases with regard to the planning and execution of audits, interventions, and policy making within NHS organizations, potentially revealing new targets for improved health care service delivery. We present our dashboards as a proof of concept for generating candidate lists to aid expert users in their interpretation of prescribing data and prioritize further investigations and qualitative research in terms of potential targets for improved performance.

KEYWORDS

dashboard; data science; EHR; electronic health records; general practice; outliers; prescribing; primary care

Introduction

There is recognition that evidence-based decision-making in the National Health Service (NHS) in England is critical to maintaining standards of care while reducing NHS spending [1] and the UK government has recently consulted on wide-ranging plans to "digitize, connect, and transform the health and care sector," with a key priority being data-driven innovation. Flagship initiatives such as Getting It Right First Time [2] and RightCare [3] focus on identifying and addressing unwarranted variation in the NHS. Such initiatives can be limited in their scope in that the "data-driven" element of the work often focuses on assessing performance relative to recommendations that are defined prospectively rather than employing hypothesis-free data-driven methodologies to make objective assessments as to where opportunities for improvement might exist.

Monthly prescription data for every general practice in England has been made available to the public since 2010, via the NHS Business Services Authority [4]. This data set includes product and month of prescribing, the number of items prescribed and the total quantity, making it very amenable to detailed analysis for the purposes of original research [5-9] and systematic audits and reviews [10,11]. These data, made navigable via interactive dashboards [12,13], are commonly used by NHS staff—in particular, medicines optimization (MO) teams—to monitor performance on key prescribing indicators, compare performance to peer organizations, inform prioritization of work streams, estimate the impact and feasibility of interventions, or create customized outputs according to local priorities. Mining these data systematically for unusual prescribing behavior could help identify where service delivery improvements are possible in the absence of human bias or expectation. Such "unbiased" or "hypothesis-free" approaches might aid local decision makers when designing appropriate interventions and policies.

The value of deploying systematic analyses to large prescribing data sets has been demonstrated elsewhere. Using regional prescribing claims data from Germany, researchers were able to identify practices prescribing more "third-level" medications (ie, not first- or second-line treatments) than expected using funnel plots and mixed effects models [14]. Our own group has successfully deployed similar outlier detection methodology on a national scale to show that the prescribing of 2 antipsychotic drugs, in very limited use nationally, is concentrated in 2 small geographic regions of England [15]. More complex outlier analysis of wholesale codeine time series data has identified significant shifts in supply occurring around the time of regulatory changes (specifically, the up-scheduling of low-dose codeine products from over-the-counter to prescription-only) [16].

We run OpenPrescribing [13], a website that allows public interrogation and visualization of primary care prescription data at multiple administrative levels in the NHS in England. We have previously deployed novel methodologies to identify changes over time in any one of the 80 measures implemented in OpenPrescribing, providing monthly alerts to notify practitioners when their prescribing rates deviate from the norm and may require clinician attention [17]. These measures have been selected on the basis of clear guidance being available from health authorities and are subject to initial and continuing review by clinicians, pharmacists, and epidemiologists. OpenPrescribing has 20,000 unique users every month and thousands of subscribers to our innovative organization email alerts service [17].

We set out to develop new hypothesis-blind data science techniques to identify unusual prescribing behavior, thereby providing proof of concept for such an analysis and illustrating potential opportunities for service improvement. Using this approach, we have no hypothesis with regard to where interesting patterns might be found (ie, which clinical area or which organization), we only have an expectation of what would constitute an interesting pattern in the data. We applied this methodology to 6 months of national prescribing data to identify outliers at multiple administrative levels of the NHS in England during that time period, presenting the most extreme outliers in each organization for the consideration of expert users to prioritize for further review, qualitative research, and interpretation within the local context.

Methods

Study Design

Prescribing practice was analyzed by conducting a retrospective cohort study using prescribing data from all English NHS general practices, primary care networks (PCNs), clinical commissioning groups (CCGs), and sustainability and transformation partnership (STPs; Textbox 1).

Textbox 1. National Health Service (NHS) England administrative organizations.

- Primary care in England is delivered by individual general practices, with one or more general practitioners. Almost all (>99%) practices are grouped together with other local primary care provision to form primary care networks, typically representing 30,000-50,000 people [18]. In the study period, practices were also grouped together into Clinical Commissioning Groups (CCGs) which were clinically-led organizations responsible for the commission of primary (and secondary) care in a geographical region [19]. As of April 2021, there were 106 CCGs in England. In the study period, CCGs were clustered into Sustainability and Transformation Partnerships (STPs) [20]. As of May 2020, there were 42 STPs in England. In July 2022, CCGs and STPs were replaced with 42 integrated care boards (ICBs), though the data used in this study predates this change.
- Also important in this architecture are the medicines optimization teams—NHS staff who provide expert advice with regard to medicines commissioning, finance, and safety [21]. Medicines optimization teams have historically operated at the level of CCGs (or their sub-ICB replacements) but are increasingly operating at the broader level of ICBs.

Data Source

Data for the period June 1, 2021, to December 1, 2021, were extracted from the OpenPrescribing database; this 6-month study period was used so as to smooth out short-term fluctuations (by aggregating multiple months of data) while keeping to a relatively recent time frame (so that the data remain relevant). OpenPrescribing imports openly accessible prescribing data from the large, monthly files published by the NHS Business Services Authority, which contain data on cost and items prescribed for each month for every typical general practice and CCG in England, dating back to mid-2010 [4,22]. These data are published only at the level of organization; patient-level data are not made available. Detailed methods for the creation of OpenPrescribing, including data management, aggregation, and cleaning, are available elsewhere [23]. The monthly prescribing data sets contain 1 row for each different medication and dose in each prescribing organization in NHS primary care in England, describing the number of items (ie, prescriptions issued) and the total cost. These data are sourced from community pharmacy claims data and, therefore, contain all items that were dispensed. All available prescribing data were extracted for institutions identified as "typical" general practices; all other organizations, such as prisons or specialist community clinics, were excluded using NHS Digital organization data [24]. We limited our analysis to the 2369 chemicals from chapters 1-15 of the British National Formulary (BNF) to exclude chapters not following a chemical and subparagraph structure, those which largely cover nonmedicinal products such as dressings (see Textbox 2 for further information regarding prescribing terminology).

Textbox 2. Prescribing terminology.

- The public prescribing data made available by the National Health Service Business Services Authority uses a pseudo-British National Formulary (BNF) classification. The most granular level of data is at "presentation" level, which includes information on the prescription medicine, brand, strength, and formulation. This data can then be grouped using the pseudo-BNF hierarchy, using products, chemical substances, subparagraphs, paragraphs, sections, and chapters, with decreasing specificity. Chapters are defined according to body system, for example, gastrointestinal system, cardiovascular system, and respiratory system.
- "Chemical" in this context refers to the standard International Nonproprietary Name (INN) for the active constituent of the medicine and does not include any further specification by preparation, dose, or brand. BNF subparagraphs can be used to identify groups of chemicals belonging to the same class.
- The majority of chemicals have all available preparations included in a single chemical definition; for example, all atorvastatin preparations (including liquid and tablets) are included in 2.12: Cardiovascular system—lipid-regulating drugs (chemical code: 0212000B0).
- However, there are some instances where the same chemical is used in different body systems with system-specific presentations, and therefore the same INN will appear multiple times in a chapter that most reflects its use. For example, the INN dexamethasone appears in 3 separate chapters within the pseudo-BNF hierarchy and therefore will have separate chemical groupings:

6.3: Endocrine system—corticosteroids (endocrine), which include oral and parenteral preparations (chemical code: 0603020G0)

11.4: Eye—corticosteroids and other anti-inflammatory preparations, which include ocular preparations (chemical code: 1104010I0)

12.1 Ear, Nose, and Oropharynx—drugs acting on the ear, which ear preparations (chemical code: 12101050)

Outlier Detection

We were interested in detecting outliers with regard to *chemicals* (see Textbox 2 for further information). We first calculate a prescription rate for each chemical in each practice; specifically, we calculate the number of prescriptions containing our chemical of interest and divide this by the number of prescriptions containing chemicals of the same BNF subparagraph, for example, all statin prescriptions as a proportion of all lipid-regulating drugs. This captures the prescribing rate for the chemical of interest as compared to all drugs in the same class in a single practice. This ratio is calculated across all practices, and the mean and SD are calculated. The ratios in each practice are then reexpressed as *z* scores using this mean and SD. A *z* score is the number of SDs that a given data point is away from the mean. The *z* scores are used to rank all chemicals within a practice in terms of their outlier status (the most extreme outliers occupying the top and bottom of this ranked list).

This process is repeated at 3 higher administrative levels—STP, CCG, and PCN—to generate the equivalent ranked list of

prescribing outliers for these larger organizations. Results for all 4 administrative levels are presented, as each organization retains some decision-making power with regard to prescribing. At the practice or PCN level this will be individual or group general practitioner decisions based on their practice population, but MO teams at the STP and CCG level will also monitor prescribing behavior to inform prescribing policy (and formulary) for these wider geographic regions.

Visualization of Organization-Level Results

An interactive dashboard has been created at OpenPrescribing [25] for each organization, where data describing 20 of the most extreme outliers are summarized as follows: 10 where prescribing in the organization is *higher* than other peer organizations, and 10 where prescribing in the organization is *lower* than other peer organizations. Tables are provided for both sets, which summarize the following values for each chemical: *Chemical Items* and *Subparagraph Items* are the number of prescriptions for the chemical and BNF subparagraph, respectively; *Ratio* is the *Chemical Items* as a proportion of *Subparagraph Items* for the chemical in the organization of interest; *Mean* and *SD* summarize this ratio over all organizations; and *z score* is the *Ratio* reexpressed as a *z* score. This same information is described visually by a density plot (provided in the Multimedia Appendices), where the distribution of ratios across all organizations is captured by a blue line, with the ratio for the organization of interest indicated by a vertical red line. Densities are generated using the Seaborn kdeplot() function, setting the bandwidth for smoothing as suggested by Scott [26].

User Feedback

Links to early prototypes were shared directly with a group of interested clinicians and pharmacists by email. Any feedback gained was used to inform the iterative development of the tool and proposed visualizations of the results. Further to this, the tool was shared more widely (via Twitter), and formal feedback was collected via a Google form (Textbox 3). Additional unstructured feedback was compiled from direct emails and mentions on social media.

Textbox 3. Outlier detection feedback form.

Respondent details:

- Email. Free text
- Which organization's report are you giving feedback on? Free text
- Please describe your relationship to the organization (eg, doctor, practice nurse, or commissioner). Free text

Understandability:

- Does this report make sense to you? Yes or No
- Any further comments on the understandability of the report(s). Free text

Interest:

- Is it interesting? Yes or No
- Any further comments on the interestingness of the report(s). Free text

Utility:

- Is it useful? Yes or No
- Any further comments on the usefulness of the report(s). Free text

Individual items:

- Thinking about where your prescribing is higher than most, please describe any observations you have on any individual items. Free text
- Thinking about where your prescribing is lower than most, please describe any observations you have on any individual items. Free text

Improvements:

- What, if anything, would you change about the report(s)? Free text

NHS Devon CCG Case Study Details

RC (who, in addition to his role at the Bennett Institute, is also Deputy Director for MO at NHS Devon) emailed a link to the dashboard containing sparkline graphs for NHS Devon to pharmacist colleagues in his MO team. These graphs provided new insights to the team, which would have been impractical to achieve using existing data analysis workflows (eg, custom queries in OpenPrescribing or ePACT2). The MO team met to discuss what the causes behind the deviation might be in each case. Where it could not be determined that there was a clinically justifiable reason for being an outlier, the MO team gathered further relevant prescribing data from routine sources such as OpenPrescribing, ePACT2, and PrescQIPP. This allowed deeper exploration of prescribing patterns related to the outlier chemical (eg, trends over time and the rate at which alternative medications were prescribed). The MO team continues to

investigate these data to decide whether an intervention is appropriate.

Software and Reproducibility

Data management was performed using Python 3.8.1 and Google BigQuery, with analysis carried out using Python. Code for data management and analysis is archived on the internet [27] and dashboards are available on the OpenPrescribing website [25].

Patient and Public Involvement

We publicized this tool via social media and actively sought feedback from interested health care professionals and members of the public to inform its iterative development via a survey (see User Feedback section above). We will continue to seek and consider feedback via these same channels as the tool is developed. We have developed a publicly available website [13] through which we invite any patient or member of the public to contact us regarding this study or the broader OpenPrescribing project.

Results

Outlier Detection

We developed interactive dashboards for every practice in England to highlight unusual prescribing. The outlying chemicals (ie, the 10 chemicals ranked highest and 10 chemicals ranked lowest by *z* score) identified using our methodology are described in Table 1. Both counts of unique chemicals and summary statistics of *z* scores are provided at each of the 4 administrative levels. Those outlying chemicals that are "higher than most" will all have positive *z* and as such are summarized using the maximum, median, Q1 and Q3; similarly, outlying chemicals that are "lower than most" will have negative *z* scores, and are summarized using the minimum, median, Q1 and Q3. A measure of the variation in the *z* score amongst all organizations at the same administrative level can be obtained by calculating the Inter Quartile Range (IQR), defined as Q3-Q1.

Table 1. Summary statistics for z scores calculated for outlying chemicals across the 4 administrative levels. Outlying chemicals are those occurring in the top 10 (ie, "Higher than most") or bottom 10 (ie, "Lower than most") by z score in at least one organization at the corresponding administrative level.

Organization type	Unique chemicals, n	Higher than most			Lower than most		
		Maximum	Median	Q1-Q3	Minimum	Median	Q1-Q3
STP[a] (n=42)	680	6.33	5.42	4.6-6.24	−6.33	−2.35	−2.87–−2.08
CCG[b] (n=106)	1138	10.20	5.79	4.59-7.77	−10.20	−2.30	−2.81–−1.99
PCN[c] (n=1257)	1416	2528.09	5.28	4.17-7.56	−159.77	−2.18	−2.67–−1.9
Practice (n=6476)	1346	6825.50	5.23	3.93-7.77	−307.23	−2.08	−2.57–−1.76

[a]STP: sustainability and transformation partnership.

[b]CCG: clinical commissioning group.

[c]PCN: primary care network.

While the median values for the "higher than most" outlying chemicals are similar, the IQR (Q3-Q1) values demonstrate that variation between peer organizations decreases with the size of the organization; the least amount of variation is observed between STPs, and the most amount of variation is observed between practices. More outlying chemicals are identified in smaller organizations (PCNs and practices). With regard to outlying chemicals identified as being prescribed at lower rates compared to peer organizations, both the median and IQR of the *z* scores are very similar across all organization types. For both sets of outlying chemicals, the most extreme outliers occur further away from the mean as the organization size decreases; the maximum value for the "higher than most" outlying chemicals *increases* with the size of the organization and the minimum value for the "lower than most" outlying chemicals *decreases* with the size of the organization. The *z* scores for "higher than most" outlying chemicals are more extreme than the "lower than most" outlying chemicals in all organization types.

Organization-Level Results Visualization: Case Study of NHS Devon CCG

NHS Devon CCG is the fifth largest CCG in England, commissioning health care for 1.2 million people in the southwest of England. The top 10 chemicals that are prescribed at *higher* rates here compared to other CCGs are shown in the top portion of Table 2, while the top 10 chemicals that are prescribed at *lower* rates are shown in the bottom portion of Table 2 (a listing of the specific products and a sparkline plot, showing graphically where the ratio value for this CCG occurs in the context of the same ratio in all CCGs, are provided in Multimedia Appendix 1). These prescribing outliers for this CCG have been reviewed by the local MO team, to provide likely explanations for the outlier prescribing.

Table 2. The outlier detection dashboard for NHS[a] Devon clinical commissioning group (CCG)[b].

BNF[c] chemical (number of products)	Chemical items, n	BNF subparagraph	Subparagraph items, n	Ratio	Mean	SD	*z* score
Prescribing where NHS Devon CCG is *higher* than most							
Levobupivacaine hydrochloride (1)	130	Local anesthetics	20,482	0.01	0	0	10.2
Gripe mixtures (1)	1	Sodium bicarbonate	56	0.02	0	0	8.34
Gluten free pastas (3)	4	Foods for special diets	9199	0	0	0	7.97
Epoetin zeta (1)	2	Hypoplastic, hemolytic, and renal anemias	18	0.11	0	0.01	7.52
Flumetasone pivalate (1)	333	Otitis externa	19,724	0.02	0	0	6.98
Gluten free or wheat free cereals (1)	2	Foods for special diets	9199	0	0	0	6.81
Levofloxacin (2)	1372	Quinolones	4754	0.29	0.05	0.04	6.61
Liquefied phenol (1)	1	Phenolics	3	0.33	0.01	0.06	5.83
Ruxolitinib (1)	2	Other antineoplastic drugs	1494	0	0	0	5.10
Ferrous gluconate (1)	10,437	Oral iron	90,095	0.12	0.03	0.02	3.66
Prescribing where NHS Devon CCG is *lower* than most							
Sodium bicarbonate (3)	55	Sodium bicarbonate	56	0.98	1	0	–8.34
Ciprofloxacin (6)	2989	Quinolones	4754	0.63	0.86	0.05	–4.22
Dexamethasone (2)	13,061	Otitis externa	19,724	0.66	0.79	0.05	–2.71
Fexofenadine hydrochloride (6)	33,711	Antihistamines	169,747	0.20	0.36	0.07	–2.33
Oral rehydration salts (8)	1942	Oral sodium and water	5010	0.39	0.65	0.11	–2.27
Betamethasone esters (12)	1672	Topical corticosteroids	141,063	0.01	0.03	0.01	–2.20
Fusidic acid (1)	359	Antibacterials	13,283	0.03	0.08	0.03	–2.12
Senna (9)	39,769	Stimulant laxatives	110,838	0.36	0.55	0.1	–2.03
Ticagrelor (3)	2285	Antiplatelet drugs	467,104	0	0.02	0.01	–2.02
Lactulose (2)	19,621	Osmotic laxatives	127,773	0.15	0.28	0.06	–1.89

[a]NHS: National Health Service.

[b]"The results of our outlier detection methodology are provided as interactive dashboards; here, the 10 chemicals where prescribing in National Health Service (NHS) Devon CCG is higher than most and the 10 chemicals where prescribing in NHS Devon CCG is lower than most, are presented. British National Formulary (BNF) chemical is the chemical of interest (number of products indicates how many products are represented by the BNF chemical). Chemical items provide the number of prescribing items containing this chemical. BNF subparagraph is the BNF subparagraph to which the chemical belongs, and subparagraph items is the number of prescribing items containing an item belonging to this BNF subparagraph. Ratio, Mean, SD, and *z* score place the chemical items count in the context of the subparagraph items count as described in the Methods section.

[c]BNF: British National Formulary.

Focusing on the results for flumetasone pivalate, we can see that 1.7% (n=333) of the 19,724 "Otitis externa" items contain flumetasone pivalate and that this is 6.98 SDs above the mean for all CCGs (the sparkline plot provided in Multimedia Appendix 1 demonstrates visually where this 1.7% falls [red line] in the distribution across all CCGs [blue line]).

Several of the chemicals prescribed more often in NHS Devon CCGs than other CCGs are defined as first-line treatments in local formularies, for example, flumetasone pivalate [28] and levofloxacin [29]. Corresponding patterns of underprescribing can be seen in the "lower than most" results table for similar chemicals, specifically, ciprofloxacin (an alternative to levofloxacin) and dexamethasone (an alternative to flumetasone pivalate).

The lower prescribing rates for fusidic acid reflect a change in this CCG to prescribe this chemical by specialist recommendation only [30], due to rising costs [31] and a narrow spectrum of action. The lower rates of prescribing for senna and lactulose are also likely due to a formulary shift in this CCG toward macrogols [32]. Finally, the low prescribing rate of betamethasone esters is also expected as these chemicals are nonformulary in this CCG [33].

This dashboard also demonstrates a valid use for low-number results. Gluten-free pastas and cereals—something that we have previously identified as having high variability in prescribing

rates [34]—were not recommended to be prescribed by the NHS in the study period (NHS England issued advice to CCGs in November 2018 with the recommendation to restrict gluten free prescribing to bread and flour mixes [35]), so should not appear at all. The identification of this low-number outlier via our methodology has prompted further work within NHS Devon CCG to clarify how this prescription was generated and processed.

User Feedback

Through the formal Google form and direct correspondence with interested parties, we received feedback for a prototype version of the dashboard from 6 individuals. An example of this prototype is shown in Multimedia Appendix 2, showing 5 top and bottom outlying chemicals. Several respondents indicated that the results were expected (ie, results echoed internal reporting or were aligned with local prescribing policies); while this indicates that our tool is working, 1 user did question what the added value was above existing reporting. Other users stated that the tool had revealed unexpected results worthy of follow-up.

There were multiple requests to present more than the top and bottom 5 results (eg, the top and bottom 10 or 20 results) to explore the data in more detail. Users recognized that extreme outliers could be derived from very small numbers of patients or items; some requested that results with small counts be removed, though others recognized that these may be important, particularly in practices or PCNs. There was a suggestion that users could choose to have low numbers suppressed or displayed, depending on whether their focus was systemic anomalies or rogue prescriptions. There were also requests to include other data in the results, including cost and highlighting drugs on the "*Not Suitable to Prescribe*" list.

There were other requests that were more relevant to the design of the tool than the analysis itself. The feedback demonstrated that users required more information to interpret and understand the data (ie, *z* scores, ratios, means, and SDs) and that with this additional explanation, more could be made of the graphical summary. There was also a request for an improved user experience regarding navigating to practices via the drop-down sections (which could be implemented as an organizational search).

We used the most common feedback to inform further development, and the released version of the dashboards now includes the top and bottom 10 outlying chemicals and optional filtering of low numbers. To provide a clear illustration of how the dashboards changed in response to user feedback, the corresponding update for Multimedia Appendix 2 is shown in Figures S1 and S2 in Multimedia Appendix 3.

Discussion

Summary

We have developed and implemented a new hypothesis-free methodology to detect unusual or "outlier" prescribing rates of chemicals in a single organization in relation to all "peer" organizations. We have applied this methodology to 6 months of national prescribing data to quantify how typical the prescribing is for individual chemicals at multiple administrative levels (practice, PCN, CCG, and STP) over the time period. We have displayed these results via interactive dashboards. We have sought and will continue to seek user feedback to inform development and incrementally improve usability and functionality.

Summary statistics demonstrate that the number of outlying chemicals increases as the size of the organization decreases and that more extreme outliers are identified among smaller organizations, demonstrating that there is more variability in prescribing behavior among practices than there is among larger administrative organizations. The data also demonstrate, however, that outliers *do* occur when comparing larger organizations to each other. While there is less variation between STPs, the median *z* score for "higher than most" and "lower than most" outliers among STPs is 5.42 and 2.35, respectively; these *z* scores are both more than 2 SDs from the mean. The ranking of these quantifications allows us to identify the most extreme outliers in terms of prescribing behavior at each organizational level. A case study of an individual CCG (NHS Devon) demonstrated that our methodology identified prescribing patterns that aligned with local prescribing guidance, but also detected patterns that warranted further investigation. It is not appropriate to formally assess the utility of our methodology as there are many legitimate reasons that a chemical may be an outlier in a particular organization. Some of the reasons are as follows: prescribing guidance as defined by local formulary may differ from elsewhere; local prescribing policy may place responsibility for prescribing particular drugs in secondary care rather than primary care; clinicians may be reluctant to change medication for patients who are stable on a long-established medication regime (in particular the elderly or vulnerable); or there is a justified preference for other drugs in the same class. Given the complexities of interpreting these data, we present this tool as a proof of concept and starting point for NHS organizations to perform and plan internal audits rather than a definitive reporting tool.

Strengths and Weaknesses

Our approach combines a comprehensive national prescribing data set with a well-understood system for drug classification, thereby capturing the national context at high resolution and allowing the interpretation of prescribing behavior for *all* chemicals at multiple administrative levels of the NHS in England, all of which retain some decision-making power with regard to prescribing. The methods used are well established and easy to understand, readily amenable to visual presentation as graphs, and allow prioritization of results by ranking. Our approach has utility in other contexts, and repurposing it to gain a greater understanding of other NHS data (eg, hospital prescriptions) would be straightforward.

We also note some limitations. First, the calculation of *z* scores using mean and SD assumes a normal distribution. This is more likely to be the case where numbers of items prescribed are high (aggregated to STP or CCG), but may not be the case where number of items are low (aggregated to PCN or practices, or where the items are more rarely prescribed). Second, this approach can generate very large *z* scores where SDs are tight

or item numbers generally are very low. An example of this can be seen in Figure S1 in Multimedia Appendix 3; while the ratio generated by the number of prescribed items containing Sodium aurothiomalate is very low ($1/114{,}367=8.74\times10^{6}$), the tight SDs observed across the whole population of STPs translate this small value into a large *z* score. Expert users may be seeking out such results to identify very rare prescribing items (low number results did prove important in the NHS Devon case study), but they may also wish to suppress such results to focus on more commonly prescribed chemicals. To accommodate this and in line with our user feedback, we have implemented the option to show or hide counts of 5 or less. We also recognize that the process by which we have sought user feedback thus far could be prone to bias, in that specific users were targeted due to their expertise and familiarity with such tools so as to enable rapid development.

Findings in Context

This is one of a suite of tools that we are seeking to develop at OpenPrescribing, each of which captures variability with a view to leveraging further insight from the data sets to which we have access. We make extensive use of decile plots to place individual organizations into a wider context [5,6,36] and have applied algorithms to identify when those individual organizations start to deviate from the rest of their peers [17]. We have also used deciles to summarize financial data and estimate potential savings if "price-per-unit" costs were aligned with the lowest decile [7]. These methodologies all have the potential to support NHS organizations in England to guide audits, prioritize and shape new policies, and crucially assess the impact of those interventions with regard to patient care and cost savings.

Policy Implications and Interpretation

The Department of Health and Social Care consultation explicitly recognizes the value of near real-time data release and the potential of data-driven insights to guide targeted policy making [37]. The methodology described here contributes toward that key priority by exposing specific patterns in data that warrant attention that may have otherwise been obscured. We do not advocate that our approach be used in isolation, but rather as a starting point for expert users to interpret within the local context and make evidence-based decisions about priorities and planning. By updating these dashboards on a regular basis, we hope to provide decision makers with near real-time feedback so as to monitor performance and respond quickly when necessary. Comprehensive coverage of the opportunities and challenges that exist in encouraging widespread adoption of these approaches across the NHS in England is provided in the Goldacre Review [38].

Future Research

Areas for further research include the implementation of a systematic and unbiased approach to collecting and inviting user feedback, enhancing results output as determined by ongoing user feedback (eg, new functionality, information, or visualizations), updating the dashboards in line with recent structural changes to the NHS in England (specifically, Integrated Care Boards replacing STPs), and consulting with patient and public involvement and engagement groups to maximize value for the patient community. The long-term aim is to incorporate regular updates as part of an organization's page on the OpenPrescribing website; the frequency of these updates (annual vs monthly) and the extent to which historical dashboards would be available for each organization have yet to be determined but would be a focus of the enhanced user consultation described above. Ultimately, our aim would be to provide organization specific alerts to notify staff where prescribing behavior appears to be different to their peers.

Conclusions

Capturing the variability in prescribing rates among peer organizations permits the hypothesis-free identification of prescribing outliers. We have applied such an analysis to 6 months of national prescribing data and made the most extreme prescribing outliers in each organization publicly available as interactive dashboards. We intend that these dashboards prompt further qualitative analysis within the individual organizations to identify where service delivery improvements could be made.

Acknowledgments

We are grateful to wider NHS colleagues for discussions that have informed our work on this topic. Conceptualization was done by HC, BM, BG, and AJW. JM, DE, PI, and SB were involved in data curation. LEMH, JM, BM, and AJW performed formal analysis. HC, BG, and AJW were responsible for funding acquisition. LEMH, JM, HC, BM, RC, OM, and AJW conducted investigation. LEMH, JM, HC, BM, RC, and AJW carried methodology. DE, PI, SB, and TOD were involved with the resources. JM, DE, PI, SB, and TOD were responsible for software. Supervision was done by BG. LEMH, JM, HC, BM, and AJW were responsible for visualization. LEMH, JM, HC, BM, and AJW were responsible for writing original draft. LEMH, JM, HC, BM, RC, OM, BG, and AJW were responsible for writing review and editing. BG is the guarantor. This project is funded by the National Institute for Health Research (NIHR) under its Research for Patient Benefit (RfPB) Programme (grant PB-PG-0418-20036). The views expressed are those of the author(s) and not necessarily those of the NIHR or the Department of Health and Social Care. Funders had no role in the study design, collection, analysis, and interpretation of data; in the writing of the report; and in the decision to submit the paper for publication.

Conflicts of Interest

All authors have completed the International Committee of Medical Journal Editors' uniform disclosure form at www.icmje.org/coi_disclosure.pdf and declare the following: BG has received research funding from the Laura and John Arnold Foundation, the NHS National Institute for Health Research (NIHR), the NIHR School of Primary Care Research, the NIHR

Oxford Biomedical Research Centre, the Mohn-Westlake Foundation, NIHR Applied Research Collaboration Oxford and Thames Valley, the Wellcome Trust, the Good Thinking Foundation, Health Data Research UK, the Health Foundation, the World Health Organization, UKRI, Asthma UK, the British Lung Foundation, and the Longitudinal Health and Wellbeing strand of the National Core Studies program; he also receives personal income from speaking and writing for lay audiences on the misuse of science. NJD and JM have been employed on grants received by BG. JM is the recipient of a doctoral studentship from the Wellcome Trust.

Multimedia Appendix 1
The outlier detection dashboard for Devon CCG (including product listings and sparkline plots). The results of our outlier detection methodology are provided as interactive dashboards; here the ten chemicals where prescribing in NHS Devon CCG is higher than most and the ten chemicals where prescribing in NHS Devon CCG is lower than most are presented. Data for each result is highlighted in grey with additional information provided below with no highlighting. BNF Chemical is the chemical of interest (all products represented by this BNF chemical are provided as additional information). Chemical Items provides the number of prescribing items containing this chemical. BNF Subparagraph is the BNF Subparagraph to which the Chemical belongs and Subparagraph Items is the number of prescribing items containing an item belonging to this BNF Subparagraph. Ratio, Mean, std and Z-score place the chemical items count in the context of the subparagraph items count as described in the methods. The sparkline plot provided as additional information for each result shows where the Ratio value for this CCG occurs (vertical red line) in the context of the same Ratio in all CCGs (summarised by the blue line). The y axis is density (see Methods).

Multimedia Appendix 2
Prototype dashboard showing the top and bottom five outlying chemicals for Cumbria and northeast STP. BNF Chemical is the chemical of interest, Chemical Items provides the number of prescribing items containing this chemical. BNF Subparagraph is the BNF Subparagraph to which the Chemical belongs and Subparagraph Items is the number of prescribing items containing an item belonging to this BNF Subparagraph. Ratio, Mean, std, and Z_Score place the chemical items count in the context of the subparagraph items count as described in the methods. The sparkline plot shows where the ratio value for this STP occurs (vertical red line) in the context of the same ratio in all STPs (summarised by the blue line).
[DOCX File , 419 KB - medinform_v11i1e44237_app2.docx]

Multimedia Appendix 3
Example dashboard showing the top ten outlying chemicals for Cumbria and northeast STP. BNF Chemical is the chemical of interest, Chemical Items provides the number of prescribing items containing this chemical. BNF Subparagraph is the BNF subparagraph to which the chemical belongs and Subparagraph Items is the number of prescribing items containing an item belonging to this BNF Subparagraph. Ratio, Mean, std, and Z score place the chemical items count in the context of the subparagraph items count as described in the methods. The sparkline plot shows where the ratio value for this STP occurs (vertical red line) in the context of the same Ratio in all STPs (summarised by the blue line). Example dashboard showing the bottom ten outlying chemicals for Cumbria and northeast STP. See Figure S1 for definitions of each column.

Abstract

Background: Nursing narratives are an intriguing feature in the prediction of short-term clinical outcomes. However, it is unclear which nursing narratives significantly impact the prediction of postoperative length of stay (LOS) in deep learning models.

Objective: Therefore, we applied the Reverse Time Attention (RETAIN) model to predict LOS, entering nursing narratives as the main input.

Methods: A total of 354 patients who underwent ovarian cancer surgery at the Seoul National University Bundang Hospital from 2014 to 2020 were retrospectively enrolled. Nursing narratives collected within 3 postoperative days were used to predict prolonged LOS (≥10 days). The physician's assessment was conducted based on a retrospective review of the physician's note within the same period of the data model used.

Results: The model performed better than the physician's assessment (area under the receiver operating curve of 0.81 vs 0.58; *P*=.02). Nursing narratives entered on the first day were the most influential predictors in prolonged LOS. The likelihood of prolonged LOS increased if the physician had to check the patient often and if the patient received intravenous fluids or intravenous patient-controlled analgesia late.

Conclusions: The use of the RETAIN model on nursing narratives predicted postoperative LOS effectively for patients who underwent ovarian cancer surgery. These findings suggest that accurate and interpretable deep learning information obtained shortly after surgery may accurately predict prolonged LOS.

Introduction

Postoperative length of stay (LOS) is an important indicator of hospital management efficiency. A precise estimate of LOS optimizes hospital bed availability and resource allocation, thereby improving health outcomes and lowering costs [1,2]. There is an increasing need to predict LOS using electronic health records (EHRs) with machine learning methods [3-6]. EHRs contain data on patients' demographics, diagnoses, medications, vital signs, and laboratory results, which are fed into deep learning algorithms. For example, Safavi et al [7] have suggested a feedforward neural network model comprising clinical and administrative data extracted from EHRs to predict discharge from inpatient surgical care. Zhang et al [8] have investigated a prediction model for next-day discharge using EHR access logs combined with gradient-boosted ensembles of decision trees. For this study, we refer to Stone et al [9] for a comprehensive review of the prediction of hospital LOS.

We focused on nursing narratives in EHRs as a promising predictor of postoperative LOS. Nursing narratives are representations of the nursing process and contain data regarding when and how nursing actions are performed on patients [10,11]. Analyses of nursing notes using machine learning models have shown promising results in predicting short-term patient outcomes [12,13]. We have previously reported that a deep learning model based on nursing narratives can effectively predict postoperative LOS [14]. However, a fundamental problem of deep learning models is their lack of interpretability, which restrains their clinical applicability [15,16]. Moreover, our previous study implemented long short-term memory using frequencies of individual nursing narrative entries for 5

postoperative days as features, which limited the power of dependencies between time steps of sequence data.

To overcome this issue, various interpretable artificial intelligence models have been examined [17]. The Reverse Time Attention (RETAIN) model is an interpretable predictive model developed for application with EHR data. RETAIN's major advantage is its high accuracy while remaining clinically interpretable by adapting a 2-level neural attention mechanism in a recurrent neural network architecture. Consequently, RETAIN can detect both influential nurse visits and clinical features [16]. Several studies have demonstrated the clinical utility of the RETAIN model in diverse clinical contexts [18-23]. AlSaad et al [21] have shown a simplified version of the RETAIN architecture that significantly predicted preterm birth and enabled individual-level prediction explanations at the visitation level and medical code level (*International Classification of Diseases, Ninth Revision* [*ICD-9*] or *ICD-10* codes). Rasmy et al [23] have adapted a language model that combined the RETAIN model with two independent EHR databases; this model achieved a high degree of accuracy in predicting both heart failure and the onset of pancreatic cancer.

In this study, we examined the performance of an interpretable deep learning model using longitudinal nursing narratives to predict prolonged LOS and extracted the significant nursing narrative features to better understand the prediction model.

Methods

Ethical Considerations

This study was approved by the Seoul National University Bundang Hospital (SNUBH) Institutional Review Board (B-2011/646-104 for model development; B-2103-675-101 for physician comparison).

Setting

ICD-10 diagnosis code C56 was used to identify the study population. Data were retrospectively collected from patients admitted to the SNUBH for first-time ovarian cancer surgery between 2014 and 2021.

We divided the data into two parts by period: the internal data set (collected between January 2014 and September 2020) and the external validation data set (collected between October 2020 and February 2021) [24]. We chose the most recent 5 months of data as the external validation data set. The internal data set was used for training, validating, and testing the model, while the external data set was used for evaluating the final performance of the model and comparing the results with the physician's assessment.

The exclusion criteria included readmission, admission with postoperative LOS <3 days, and patients who underwent surgery <20 times in the internal data set (Figure S1 in Multimedia Appendix 1). Postoperative LOS was chosen as the outcome variable because in-hospital LOS can be affected by several nonoperational factors such as patient characteristics or social circumstances, type of admission, patient place of residence, emergencies, or weekend admissions [9,25,26]. The postoperative LOS was defined as the number of days from the date of the index operation to the date of discharge, where the date of the index operation, denoted as day 0, was defined as the date in any of the operation-related nursing narratives. For example, if a patient was discharged on day 0, the postoperative LOS was 1.

Nursing Narratives

We extracted nursing narratives chronologically. At SNUBH, nursing narratives are easily integrated into a structured database because individual features are mapped to unique codes [11,27]. For instance, the nursing narrative "checked the vital signs" is mapped to code N1, whereas "no dizziness" is mapped to code N2. A nurse enters patient statuses in the EHR system by searching nursing narratives using keywords such as "vital" or "dizzy" and selecting the appropriate nursing narratives from the list of related narratives. Some nursing narratives allow for the inclusion of additional information such as body temperature or free text [14]. Consequently, patient information was entered as a combination of unique codes (eg, N1, checked the vital signs, or N2, checked whether the patient felt dizzy), code entry time, and a specific value such as body temperature. These structured nursing narrative sets allowed us to retrieve patient information without the need for natural language preprocessing.

RETAIN Architecture

Prolonged LOS was defined as events ≥10 postoperative days, which was the third quantile of postoperative LOS in both the internal and external validation data sets. Our results showed that the volume of nursing narratives entered within 3 postoperative days was high and tended to decrease afterward; therefore, we decided to use patient information within 3 postoperative days, that is, from day 0 to day 2 (Figure S2 in Multimedia Appendix 1). The extracted time series of nursing narratives and corresponding unique codes were inverted to 3D arrays (patients, postoperative days, and nursing narratives' unique codes).

The internal data set was randomly split, allocating 60% (n=192) of participants to the training set and 20% (n=64) of participants each to the validation and testing sets. The training set was used to train the models, the validation set was used to determine the values of the hyperparameters that increase the area under the receiver operating curve (AUC), and the test set was used to evaluate the performance of the best model. The best model was also applied to the external validation data set. Therefore, the performance of the best model was measured twice (the test set of the internal data set and the external validation data set). Furthermore, we compared the performance of the external validation data set with the physician's assessment. The RETAIN model was constructed with two neural attentions that can identify influential nurse visits and meaningful features. The RETAIN model uses linear embedding to enhance interpretability. The contribution score was calculated using visit-level attention weights, variable-level attention weights, and embedding weights.

The default settings for RETAIN were used. L2 regularization for the final classifier weight, input embedding weight, and alpha-generating weight was set to 0.0001 for all models. Following a learning process using batch sizes of 8, 16, and 32,

the model with the highest AUC performance on the test set was selected as the best model. If models had the same AUC value, the one with the highest sensitivity was selected as the best model.

Model Interpretation and Influential Features Extraction

The RETAIN model reported the contribution scores that represented the extent to which each feature contributed to the prediction. In this study, features with a high contribution score were associated with a high likelihood of prolonged LOS. We identified the input features with high contribution scores as influential features, which showed a significant difference between prolonged and short LOS via a *t* test with a *P* value cutoff of .05.

Comparison Between the Deep Learning Model and a Physician's Expert Clinical Assessment

We compared the deep learning model and a physician's assessment vis-à-vis their predictive capability for prolonged LOS. A gynecologic oncologist with 15 years of experience reviewed patients' demographics, progress notes, surgical reports, and clinical notes available within 3 postoperative days. Blinded to the final discharge date, the physician predicted whether patients would experience prolonged LOS. The DeLong test was used to compare the AUCs of the deep learning model and a physician assessment [28].

Visualization and Statistical Analysis

Statistical analyses were performed using Python (version 3.9.13; Python Software Foundation), RETAIN (version 1.0; Edward Choi) [16], and R (version 4.0.5; R Foundation for Statistical Computer) software. The influential features were visualized using the ComplexHeatmap package in R software.

Results

Patient Characteristics

This study retrospectively enrolled 354 patients (n=320 in the internal data set and n=34 in the external validation data set; mean age 54, SD 13 years; Table S1 and Figure S1 in Multimedia Appendix 1). A total of 51,603 nursing narratives in the internal data set composed the model inputs. Patients in the prolonged LOS group were older (for instance, in the internal data set, the mean age was 57, SD 12 years and 52, SD 14 years in the prolonged LOS and short LOS groups, respectively; *P*=.002) and had higher total nursing narrative volumes (mean 188, SD 62 vs mean 150, SD 33 narratives within 3 postoperative days; *P*<.001). The. nursing narrative entries per nurse visit were similar (mean 5.6, SD 8.4 vs mean 5.9, SD 7.9 for the prolonged LOS and short LOS groups, respectively; *P*=.64), but more frequent nurse visits were observed in the prolonged LOS group (mean 33, SD 9 vs mean 25, SD 9 visits within 3 postoperative days; *P*=.03).

Prediction of Prolonged LOS via RETAIN

The experimental scheme is shown in Figures S2 and S3 in Multimedia Appendix 1. The RETAIN model was developed using the internal data set, while the model's performance was calculated and compared to a physician's expert clinical assessment using the external validation data set. The predictive contribution score derived from the RETAIN model indicates the probability of prolonged LOS. Patients with a final predictive score >0.5 were classified as expected prolonged LOS events. The RETAIN model reported the scores for each patient and nursing narrative; these scores were used to determine highly influential nursing narratives. We determined potent nursing narratives for each patient based on patient-wise normalization scores, after applying normalization using a patient-centric mean and SD. Thereafter, influential nursing narratives were defined as those consistently showing a statistically significant difference in the raw contribution score between the prolonged and short LOS groups.

Table 1 shows a comparison between the model's performance and a physician's expert clinical assessment, considering various nursing narrative sets. The model trained with nursing narratives showed an AUC of 0.81. The deep learning model performed better than the physician's assessment (AUC 0.58; *P*=.02; Figure S4 in Multimedia Appendix 1).

Table . Model performance on the internal and external validation set.

Data set and model	AUC[a]	Accuracy	Sensitivity	Specificity	F_1-score	P value[b]
Internal data set						
RETAIN[c] with nursing narratives	0.76	0.80	0.55	0.91	0.63	N/A[d]
External validation data set [e]						.02
RETAIN with nursing narratives	0.81	0.85	0.44	1.00	0.62	
Physician assessment	0.58	0.65	0.44	0.72	0.40	

[a]AUC: area under the receiver operating curve.

[b]The DeLong test was conducted to compare the AUCs of the RETAIN model and physician assessment.

[c]RETAIN: Reverse Time Attention.

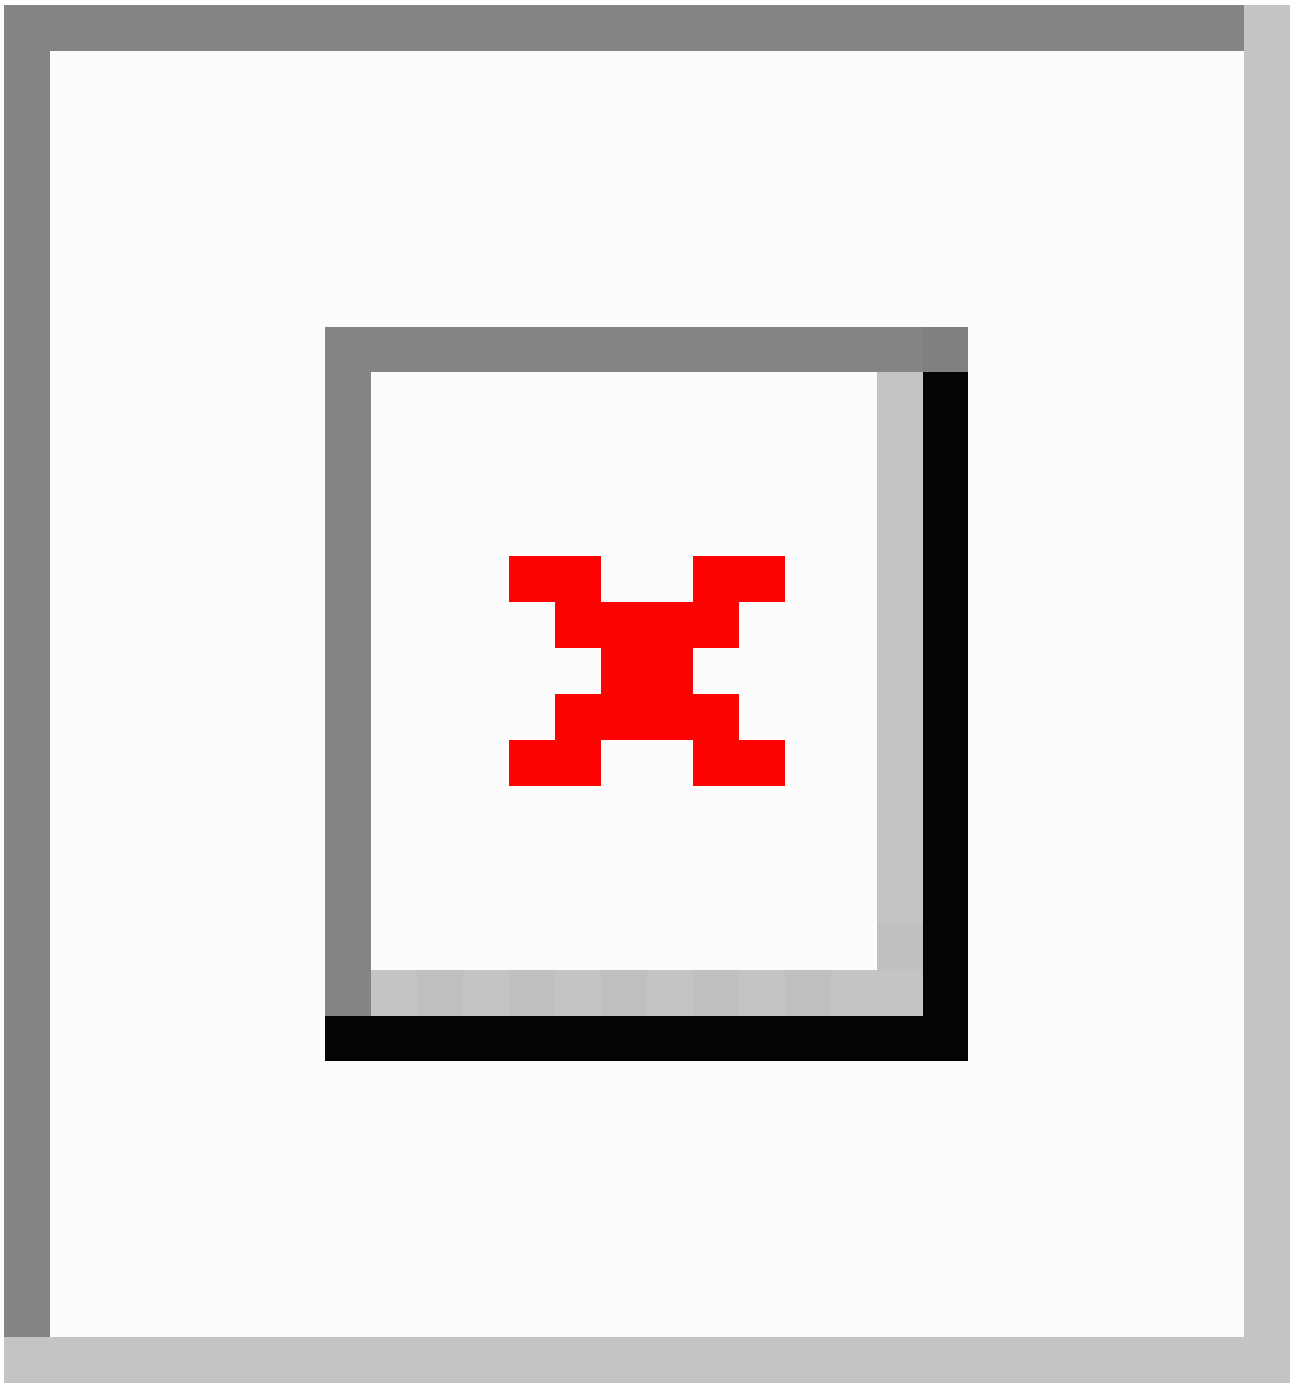
[d]N/A: not applicable.

[e]The RETAIN model performance and physician assessment were compared using the external validation data set. A total of 34 patients were available for 3 postoperative days.

Influence of Nurse Visits on the Prediction of Prolonged LOS

Examples of contribution score graphs were visualized for patients in the prolonged and short LOS groups (Figure 1). As expected, the patients in the prolonged LOS group exhibited high contribution scores. Nurse visits on the first postoperative day (ie, day 1) were identified as highly influential because nursing narratives entered on that day exhibited higher contribution scores.

Figure 1. Highly influential nursing narrative (NN) examples presenting the differences between the prolonged and short LOS groups' contribution score graphs. NNs are arranged in chronological order, while the corresponding scores are represented as dots. The predictive score indicates the probability of prolonged LOS, which was estimated by the Reverse Time Attention model, with (A) a postoperative LOS of 11 days (predictive score: 0.90) and (B) a postoperative LOS of 4 days (predictive score: 0.01). LOS: length of stay.



Highly influential narratives showing statistically significant differences in contribution scores between the prolonged and short LOS groups included the following: "confirmed by a doctor," "injected intravenous patient-controlled analgesia [PCA]," "injected intravenous fluids," "no PCA side effects," "observed the pattern of Jackson-Pratt [J-P] tube drainage," "patient's pain in surgical area was tolerable," "provided mental support," "maintained J-P tube," "maintained Foley catheter," "no oozing in the drainage tube insertion area," "measured body temperature," "provided safety care," and "notified a doctor" (Figures 2 and 3). The three most influential narratives (according to their lower *P* values) were "confirmed by a doctor," "injected intravenous PCA," and "injected intravenous fluids" (Table 2), whose contribution scores were visualized by *t*-distributed stochastic neighbor embedding (Figure 4).

Figure 2. Heat map visualizing the contribution scores of highly influential nursing narratives (NNs). NN-level normalized contribution scores were calculated for patients of the external data set. The *P* value represents the results of the *t* test for raw contribution score comparison between the prolonged LOS and short LOS groups. J-P: Jackson-Pratt; LOS: length of stay; PCA: patient-controlled analgesia.

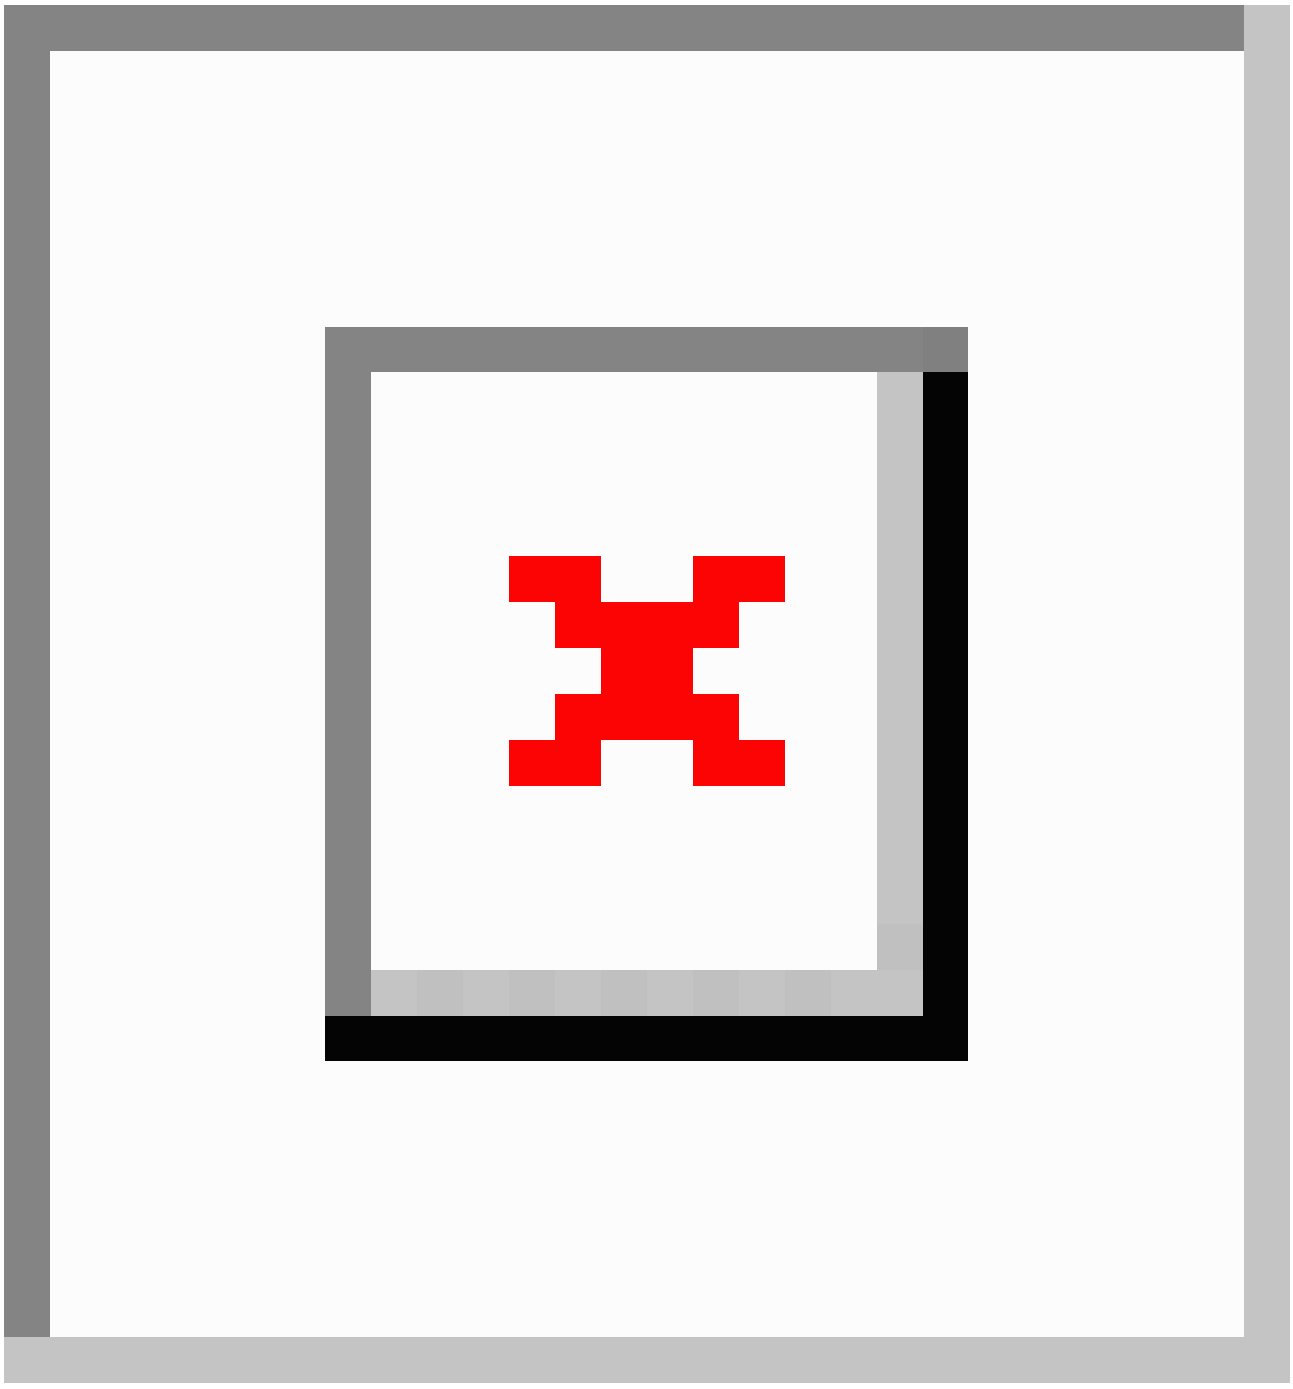


Figure 3. The contribution score graph highlights highly influential nursing narratives (NNs) of the prolonged LOS group, with the NNs arranged in chronological order. The areas of the corresponding contribution scores are filled. The predictive score indicates the probability of a prolonged LOS. The patients with predictive scores >0.5 were classified as expected prolonged LOS. The most influential NNs are represented as orange dots. (A) Postoperative LOS: 11 days; predictive score: 0.9; (B) postoperative LOS: 10 days, predictive score: 0.67; (C) postoperative LOS: 14 days, predictive score: 0.63. J-P: Jackson-Pratt; LOS: length of stay; PCA: patient-controlled analgesia.

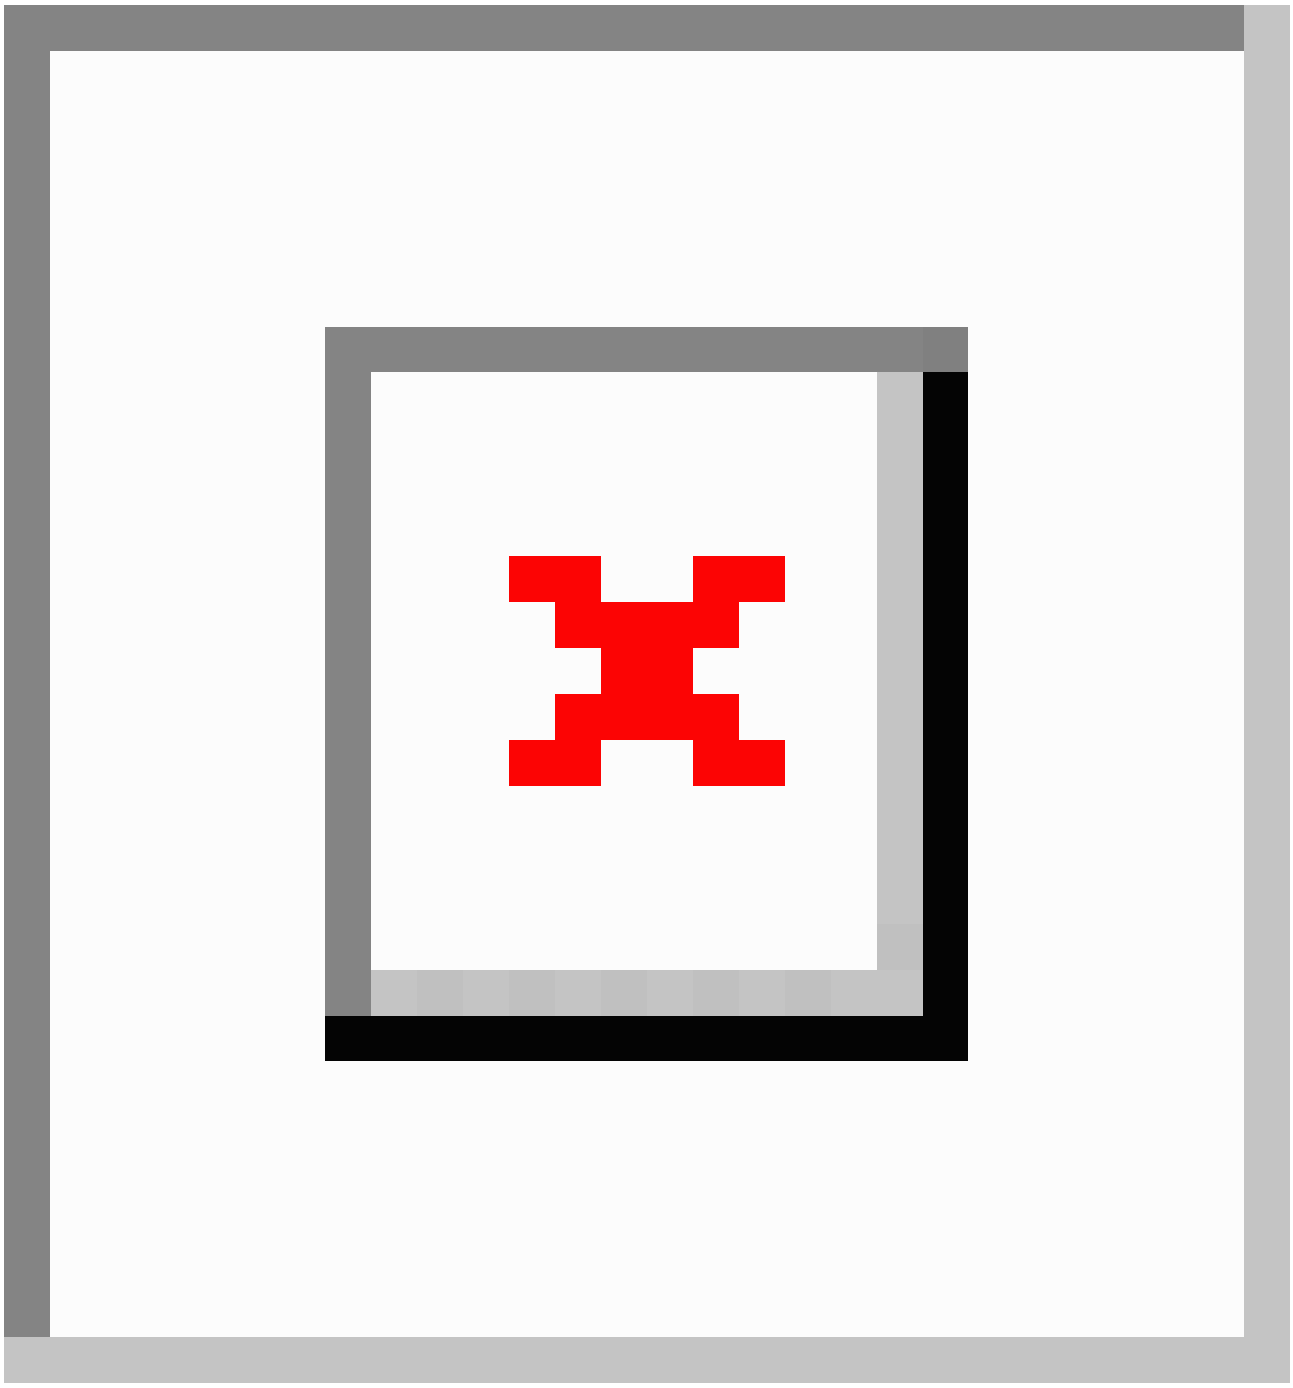

Table . Contribution scores of influential nursing narratives.

Nursing narratives	Internal data set (n=320)			External validation data set (n=34)		
	Prolonged LOS[a], mean (SD)	Short LOS, mean (SD)	*P* value[b]	Prolonged LOS, mean (SD)	Short LOS, mean (SD)	*P* value[b]
Confirmed by a doctor	0.044 (0.038)	–0.001 (0.021)	<.001	0.030 (0.033)	0.000 (0.020)	.002
Injected intravenous PCA[c]	0.012 (0.046)	–0.074 (0.041)	<.001	–0.030 (0.047)	–0.076 (0.035)	.003
Injected intravenous fluids	0.012 (0.044)	–0.066 (0.036)	<.001	–0.009 (0.043)	–0.057 (0.036)	.003
No PCA side effects	–0.002 (0.058)	–0.092 (0.052)	<.001	–0.037 (0.055)	–0.094 (0.044)	.004
Observed the pattern of J-P[d] tube drainage	0.016 (0.039)	–0.039 (0.033)	<.001	–0.001 (0.038)	–0.039 (0.034)	.007
Patient's pain in the surgical area was tolerable	0.019 (0.036)	–0.031 (0.027)	<.001	–0.011 (0.025)	–0.034 (0.024)	.02
Provided mental support	–0.004 (0.043)	–0.065 (0.060)	<.001	–0.009 (0.026)	–0.053 (0.056)	.03
Maintained J-P tube	0.019 (0.036)	–0.035 (0.031)	<.001	–0.005 (0.040)	–0.034 (0.031)	.03
Maintained Foley catheter	0.019 (0.019)	0.002 (0.007)	<.001	0.011 (0.017)	0.003 (0.006)	.045
No oozing in the drainage tube insertion area	0.011 (0.022)	–0.008 (0.017)	<.001	0.001 (0.004)	–0.009 (0.016)	.06
Measured body temperature	0.008 (0.025)	–0.018 (0.027)	<.001	0.003 (0.009)	–0.007 (0.017)	.11
Provided safety care	0.026 (0.027)	0.006 (0.012)	<.001	0.020 (0.019)	0.011 (0.016)	.18
Notified a doctor	0.021 (0.019)	0.004 (0.010)	<.001	0.012 (0.017)	0.006 (0.010)	.24

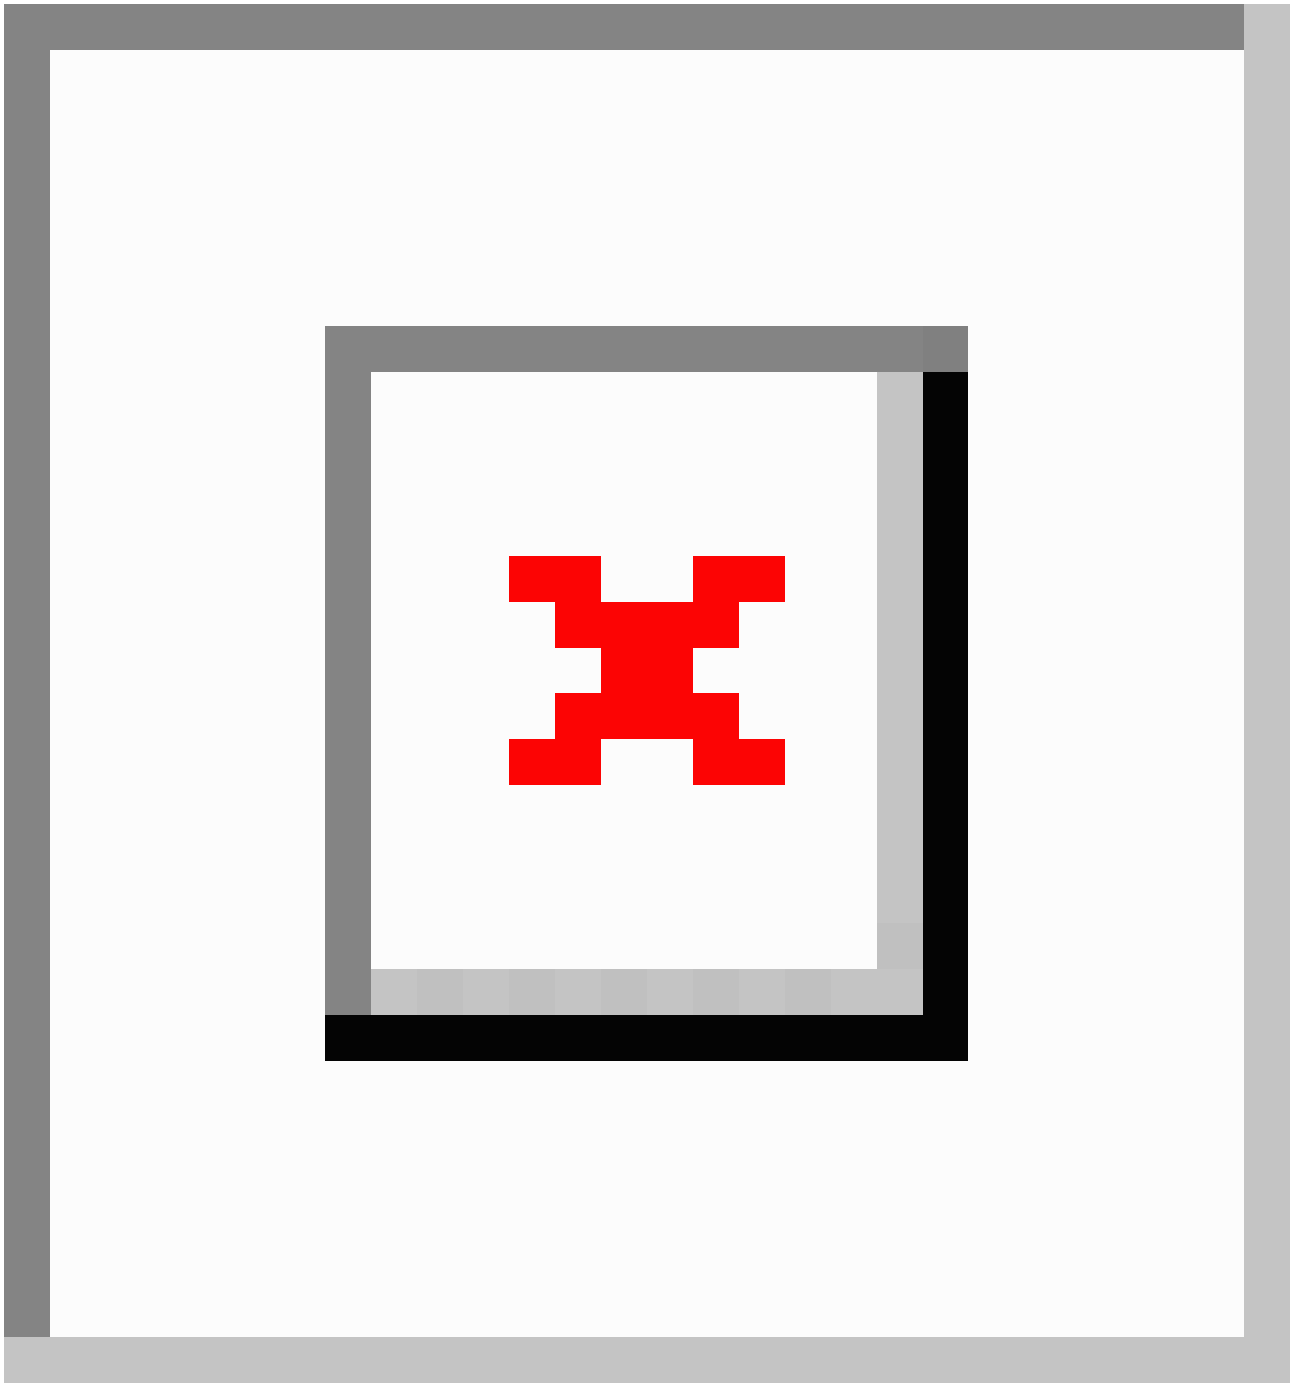
[a]LOS: length of stay.

[b]*P* values represent the results of the *t* test for raw contribution scores compared between the prolonged and short LOS groups.

[c]PCA: patient-controlled analgesia.

[d]J-P: Jackson-Pratt.

Figure 4. T-distributed stochastic neighbor embedding plot using the top three highly influential nursing narratives; the contribution score was estimated from the external data set. LOS: length of stay; PCA: patient-controlled analgesia.



Once the three most influential nursing narratives were identified, we further investigated the total number of entries and the first entry time since the handoff. The "confirmed by a doctor" narrative reoccurred in the prolonged LOS group (mean 5.8, SD 4.4 vs mean 3.1, SD 2.3 nursing narratives in the prolonged and short LOS groups, respectively) and was entered earlier (Table S2 in Multimedia Appendix 1). Conversely, the narratives "injected intravenous PCA" and "injected intravenous fluids" exhibited similar entry values but were entered a few hours later in the prolonged LOS group.

Discussion

Principal Results

In this study, a RETAIN model was used to predict postoperative LOS using nursing narratives. The model achieved a higher AUC value of 0.81 compared to the physician assessment's AUC of 0.58 (P=.02). Highly influential nursing narratives were identified that differed in their contribution scores between the prolonged and short LOS groups, including confirming by a doctor, administering intravenous PCA, and providing intravenous fluids.

To our knowledge, this is the first study to extract nursing narratives' influential features by normalizing contribution scores estimated via RETAIN. By investigating these influential features, we discovered that the volume and timing of individual narratives are key factors. The likelihood of prolonged LOS increases if a physician must check the patient more often or if intravenous fluids or intravenous PCA are administered late. This degree of interpretability was not achievable in previous studies that relied on volume-centric statistical methods and conventional deep learning models.

Strengths

This study demonstrated that nursing narratives can accurately predict the postoperative LOS of patients who underwent surgery for ovarian cancer. We implemented an interpretable deep learning model to identify highly influential nursing narratives. Notably, nursing narratives entered one day after surgery were the primary predictors for prolonged LOS.

Nursing narratives, serving as proxies for the care given to patients, demonstrated predictive value for LOS. Nursing narratives thus reflect the actions and interventions carried out by health care professionals. By identifying highly influential nursing narratives and presenting the different action timing and volume of each narrative, we enhanced the model's interpretability and showed that the relevant nursing activities could serve as indicators for LOS.

These findings support other studies that have shown that nursing notes may predict short-term patient outcomes more accurately than physician notes [29,30]. Nurses frequently summarize patients' situations by describing their symptoms, as well as their nursing actions and responses, without the restriction of structured forms [31-33]. Thus, nursing notes serve as a snapshot of patients' current statuses and exhibit a higher degree of freedom compared to physicians' notes, which provide a problem-focused summary. In a prospective cohort of patients who are critically ill, nurses predicted in-hospital mortality slightly more accurately than physicians, whereas the latter predicted long-term outcomes more accurately [29]. Huang et al [30] applied natural language processing to free-text nursing notes to predict multiple outcomes, including prolonged hospital stay or mortality, using the Multiparameter Intelligent Monitoring of Intensive Care III. This study also acknowledged the superior predictability value of nursing notes over physicians' notes when using refined features within the first 48 hours of admission. However, none of these studies presented the additional interpretation of specific nursing notes.

Furthermore, this study showed that the total volume of nursing narratives is a significant factor for prolonged LOS, which was consistent with previous studies conducted in different settings. Schnock et al [34] have conducted a multicenter qualitative study in intensive and acute care units to discover nursing documentation patterns indicating recovery patterns. Woo et al [35] have used the natural language processing of nursing notes from patients admitted to home care and found that the frequency of wound infection–related text in nursing notes increased before hospitalization or emergency department visits. However, these studies faced a common barrier to using nursing notes: the extraction of standardized information. Accordingly, there is a significant need for health care providers to standardize nursing assessments and free-text notes [30].

We showed that the nursing narratives "confirmed by a doctor," "injected intravenous PCA," and "injected intravenous fluids" were relevant to a prolonged stay for patients with surgical procedures. These narratives suggested that a patient's condition is complicated, and additional support for pain management or fluid management was required. Timely communication and collaboration between nursing and medical staff, effective pain management, and appropriate fluid management are important considerations in surgical patient care, which can impact the LOS and overall patient outcomes.

Limitations

This study had several limitations. First, this study was based on data from a single-hospital EHR system. The EHR system at SNUBH allows for the standardization of nursing narratives, which enables the creation of a structured database. However, in most hospitals, free-text nursing notes are common; therefore, the preprocessing of natural language is required to generalize this study's findings. As a starting point, it is worthwhile to examine the highly influential nursing narratives identified in our study. Second, we chose nursing narratives entered within a 3-day postoperative interval, which can be shortened in future studies. For example, 2-day postoperative data have been used in several studies [9,30]. Furthermore, a strategic patient care plan that combines a short-interval model and a long-interval model could be developed. Third, this study's sample size was small, while the model was developed in a single-disease setting. To consider the dependency of nursing narratives according to different surgery and patient settings, transfer learning (in which a model trained in a larger population is fine-tuned with an independent surgery setting) can be considered. Future studies with multiple hospital settings and multimodal features are required [36]. Fourth, like other machine learning models, training and testing a model requires a large amount of data, and multiple validation sets are needed to avoid overfitting [37]. In addition, as the RETAIN model receives input values for each variable and visit level, it may be difficult to apply the model to unstructured data such as free text or data that cannot be classified by date. Finally, it is important to acknowledge that physician assessments were done retrospectively, potentially not capturing dynamic clinical situations.

Future Perspectives

Collecting a larger data set that includes a wider range of patients and additional predictors such as laboratory data or comorbidity information is essential. We firmly believe that integrating nursing narratives with broader information, including physician assessments, can lead to a better prediction model.

Conclusions

In this study, an interpretable prediction model for a longer postoperative LOS was developed using nursing narratives. The day after surgery was the most critical time for prediction, and influential nursing narratives were revealed. Although nursing narratives serve as proxies for the care given to patients, our study suggests that they have the potential to be predictors for

LOS. The developed model can help identify patients with a prolonged hospital stay at the right time, thereby improving patient care and reducing hospital management burden. To strengthen the evidence supporting the predictive value of nursing narratives, either alone or in combination with broader information such as physician assessment, a larger data set would be beneficial.

Our study highlights that nursing narratives are predictors for prolonged LOS in patients undergoing ovarian cancer surgery. We emphasize the comprehensive nature of nursing actions and their timing in predicting patient outcomes and suggest methods to incorporate into a prediction model.

Abstract

Background: Radiology reports are usually written in a free-text format, which makes it challenging to reuse the reports.

Objective: For secondary use, we developed a 2-stage deep learning system for extracting clinical information and converting it into a structured format.

Methods: Our system mainly consists of 2 deep learning modules: entity extraction and relation extraction. For each module, state-of-the-art deep learning models were applied. We trained and evaluated the models using 1040 in-house Japanese computed tomography (CT) reports annotated by medical experts. We also evaluated the performance of the entire pipeline of our system. In addition, the ratio of annotated entities in the reports was measured to validate the coverage of the clinical information with our information model.

Results: The microaveragedF_1-scores of our best-performing model for entity extraction and relation extraction were 96.1% and 97.4%, respectively. The microaveragedF_1-score of the 2-stage system, which is a measure of the performance of the entire pipeline of our system, was 91.9%. Our system showed encouraging results for the conversion of free-text radiology reports into a structured format. The coverage of clinical information in the reports was 96.2% (6595/6853).

Conclusions: Our 2-stage deep system can extract clinical information from chest and abdomen CT reports accurately and comprehensively.

Introduction

Radiology reports are important for radiologists to communicate with referring physicians. The reports include clinical information about observed structures, diagnostic possibilities, and recommendations for treatment plans. Such information is also valuable for various applications such as case retrieval, cohort building, diagnostic surveillance, and clinical decision support. However, since most radiology reports are written in a free-text format, important clinical information is locked in the reports. This format presents major obstacles in secondary use [1,2]. To address this problem, a system for extracting structured information from the reports would be required.

Natural language processing (NLP) has demonstrated potential for improving the clinical workflow and reusing clinical text for various clinical applications [3-5]. Among the various NLP tasks, information extraction (IE) plays a central role in extracting structured information from unstructured texts. IE mainly consists of two steps: (1) the extraction of specified entities such as person, location, and organization from the text and (2) the extraction of semantic relation between 2 entities (eg,*location_of*and*employee_of*) [6,7].

Earlier IE systems mainly used heuristic methods such as dictionary-based approaches and regular expressions [8-10]. To extract clinical information from radiology reports, the Medical Language Extraction and Encoding system [11] and Radiology Analysis tool [12] have been developed. To detect clinical terms, these systems mainly use predefined dictionaries such as the Unified Medical Language System [13] and their customized dictionaries and apply some grammatical rules to present them in a structured format.

The major issues of these systems include the lack of coverage and scalability [14]. A dictionary-based system often fails to detect clinical terms such as misspelled words, abbreviations, and nonstandard terminologies. Building exhaustive dictionaries to enhance the coverage and maintaining them are highly labor-intensive. It is also challenging to apply complicated grammar rules according to the context of the reports. In addition, IE systems based on dictionaries and grammar rules are highly language dependent and do not scale to other languages. The Medical Language Extraction and Encoding system and Radiology Analysis tool only cover English clinical texts and cannot handle non-English clinical texts. Languages other than English, including Japanese, do not have sufficient clinical resources such as the Unified Medical Language System. This has been a major obstacle in developing clinical NLP systems in countries where English is not the official language [15].

Recently, machine learning approaches have been widely accepted in clinical NLP systems [16,17]. Hassanpour and Langlotz [18] used a conditional random field (CRF) [19] for extracting clinical information from computed tomography (CT) reports. They showed that their machine learning model had a superior ability compared to the dictionary-based systems.

Deep learning approaches have drawn a great deal of attention in more recent studies. Cornegruta et al [20] built a bidirectional long short-term memory (BiLSTM) model [21] to extract clinical terms from chest x-ray reports. Miao et al [22] built a BiLSTM model to handle Chinese radiology reports. Both studies reported that deep learning approaches yielded better results than dictionary-based approaches.

Various state-of-the-art deep learning models have been applied to extract named entities [18,20,22]. Clinical systems such as concept extraction can be achieved though extracting named entities alone, whereas the relation extraction step is needed to obtain structured information about concepts and their attributes [23,24]. Extracting comprehensive information in a structured format is desirable when developing a complex system.

Xie et al [25] developed a 2-stage IE system for processing chest CT reports. They exploited a hybrid approach involving deep learning to extract named entities and a rule-based method to organize the detected entities in a structured format. They reported that their deep learning model achieved better performance, whereas the rule-based structuring approach degraded the overall performance, since the rule-based approach could not capture the contextual relations in the reports. Jain et al [26] developed RadGraph, an end-to-end deep learning system for structuring chest x-ray reports. They reported that their schema had a higher report coverage in their corpus.

In this study, we developed a 2-stage deep learning system for extracting clinical information from CT reports. For secondary use of the radiology reports, we believe that our system has some advantages compared with recent related works [18,20,22,25,26]. First, our 2-stage NLP system can represent clinical information in a structured format, which can be challenging when only using an entity extraction approach. Second, although the rule-based approach struggled to extract relations between entities in the reports [25], leveraging state-of-the-art deep learning models leads to superior performance. Third, previous studies [18,20,26] have combined clinical information about factual observations and radiologist interpretations into single entity, even though they have different semantic roles in the context. According to the context, distinct entity types are defined in our information model, which allows it to capture detailed clinical information in the reports. To structure the report more appropriately, we defined distinct entities for 2 different clinical pieces of information.

The rest of this paper is organized as follows. First, an information model was built, mainly comprising observation entities, clinical finding entities, and their modifier entities. Second, a data set was created using in-house CT reports annotated by medical experts. Third, state-of-the-art deep learning models were trained and evaluated to extract the clinical entities and relations. The entire performance of our 2-stage system was also evaluated. Finally, we evaluated the coverage of the clinical information in the CT reports using our information model.

The development of the information model was already reported in our previous study [27]. However, the previous study only focused on extracting entities and did not cover extracting relations between the entities. This study developed a 2-stage system containing entity extraction and relation extraction modules. Furthermore, although the previous study only used chest CT reports, a data set using abdomen CT reports was created in this study to validate the generalizability of our information model and 2-stage system.

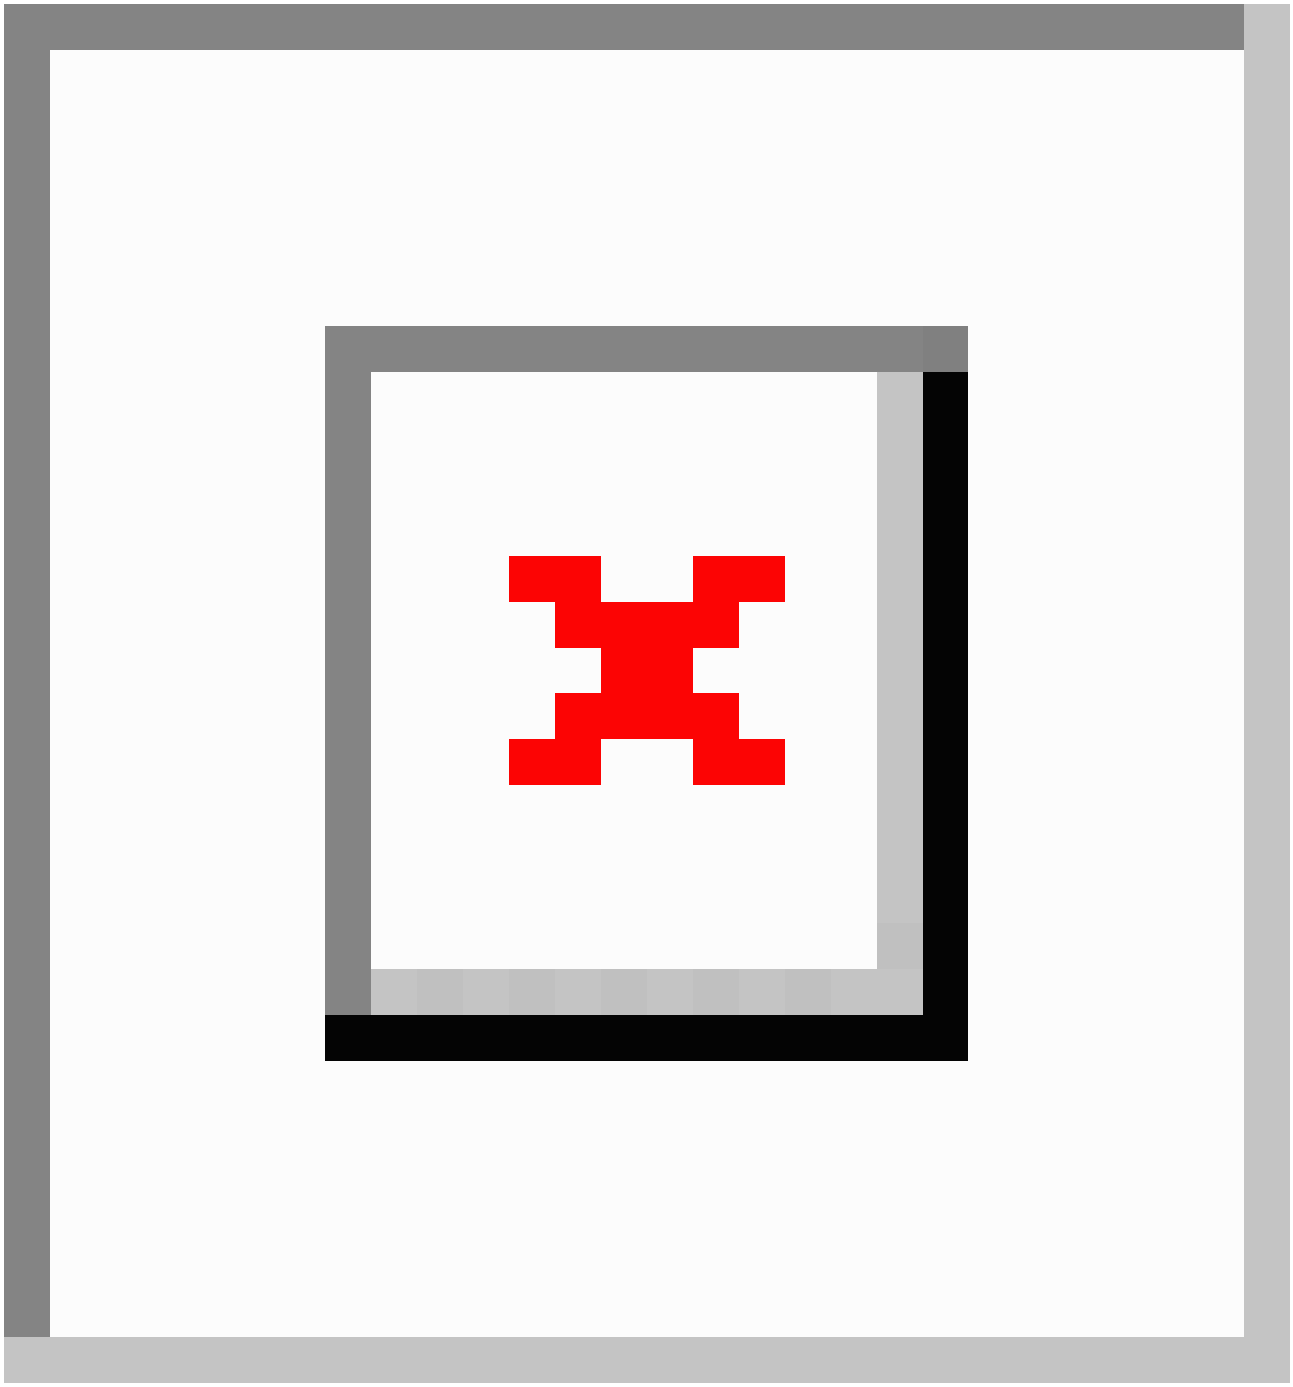
Methods

Our Information Model

An information model was built for extracting comprehensive clinical information from free-text radiology reports. Our information model contained observation entities, clinical finding entities, and modifier entities. Observation entities are specific terms representing observed abnormal features such as “nodule” or “pleural effusion.” Clinical finding entities encompass terms such as “cancer,” including diagnoses given by the radiologists based on the observation entities. Modifier entities are subdivided into the following entities: anatomical location, certainty, change, characteristics, and size. Thus, 7 entity types were defined in our information model. A detailed description of our information model is provided in our previous study [25].

Furthermore, modifier and evidence relations between entities were defined. A modifier relation is derived from an observation or a clinical finding entity and a modifier entity. This relation type gives clinical information, such as the anatomical location of the observations and the characteristics of the clinical findings. An evidence relation is derived from an observation entity and a clinical finding entity. This relation is also clinically meaningful in capturing the diagnostic process of the radiologist. Report examples of entities and relations are shown inFigure 1.

Figure 1. Report examples of entities and relations. IPMN: intraductal papillary mucinous neoplasm.



Data Set

Radiology reports from 2010 to 2021 that were stored in the radiology information system at Osaka University Hospital, Japan, were used. They consisted of 912,505 reports written in Japanese. To create a gold standard data set, 540 chest CT reports and 500 abdomen CT reports were randomly extracted. The remaining unannotated reports (911,465 reports) were used to pretrain the model.

Ethical Considerations

This study was performed in accordance with the World Medical Association Declaration of Helsinki, and the study protocol was approved by the institutional review board of the Osaka University Hospital (permission 19276). Only anonymized data were used in this study, and we did not have access to information that could identify individual participants during the study.

Annotation Scheme

Overall, 3 medical experts (2 clinicians and 1 radiological technologist) performed the annotation process. The gold standard data sets of chest and abdomen CT reports were developed by different annotation methods.

For the chest CT reports, the data set that was developed in our previous study was leveraged [25]. After making minor adjustments for entities, the relation types between entities were newly annotated by 2 clinicians. Following a guideline describing the rules and annotation examples, they

independently annotated each report. Disagreements between the annotators were resolved by discussion. The interannotator agreement (IAA) score for the entities was 91%, as reported in our previous study [27]. To calculate the IAA score for the relations, we used Cohen κ [28], resulting in an IAA score of 81%. Both IAA scores indicated very high agreement [29].

For the abdomen CT reports, to reduce the burden of the annotation work, a deep learning model trained on the chest CT reports was implemented to preannotate the entities and relations in the reports. Annotators were provided with the preannotated reports, and they modified the result according to the guidelines. We did not compute IAA scores for the abdomen data set because it was preannotated by the deep learning model.

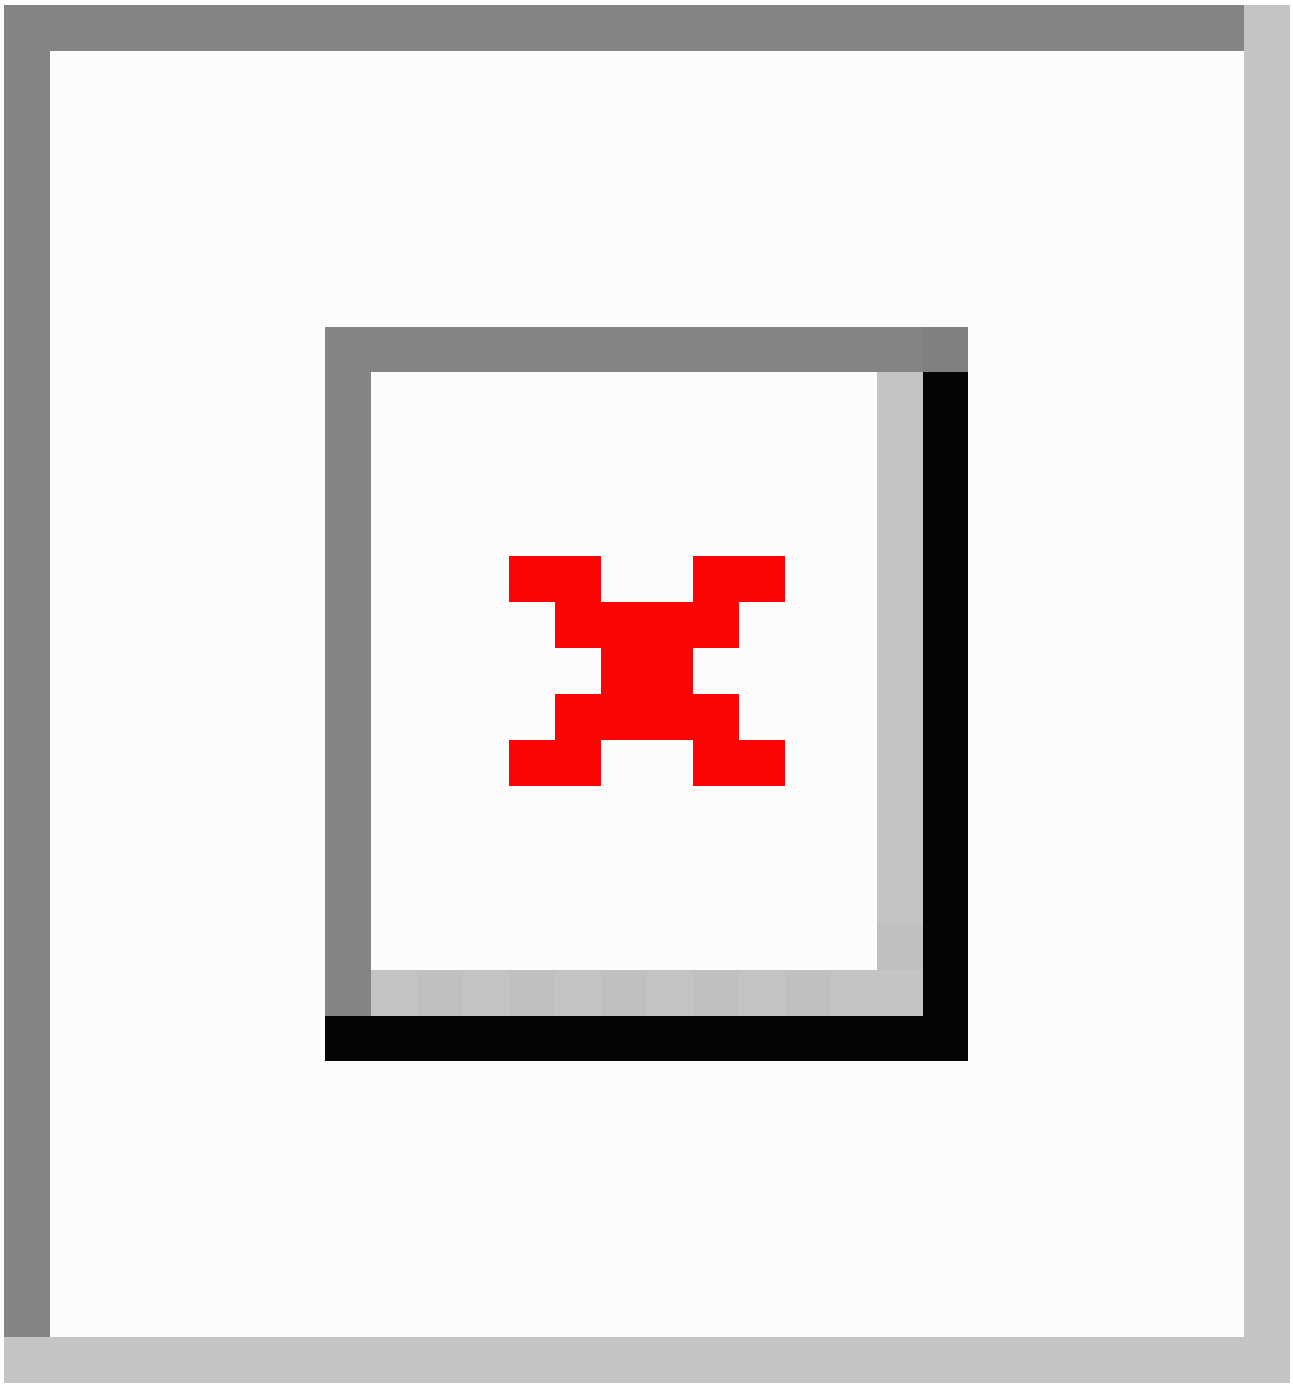
All entities and relations were annotated using BRAT (Stenetorp et al [30]). The number of annotated entities and relations are shown inMultimedia Appendix 1.

Our 2-Stage System

Overview

An overview of our 2-stage system is shown inFigure 2. The system pipeline mainly consists of 2 deep learning modules. In the first step, our module extracts the clinical entities in the radiology reports according to the predefined information model. The extracted entities are fed into subsequent modules. In the second step, the relation between clinical entities is extracted. The details of each module are described in the subsequent sections.

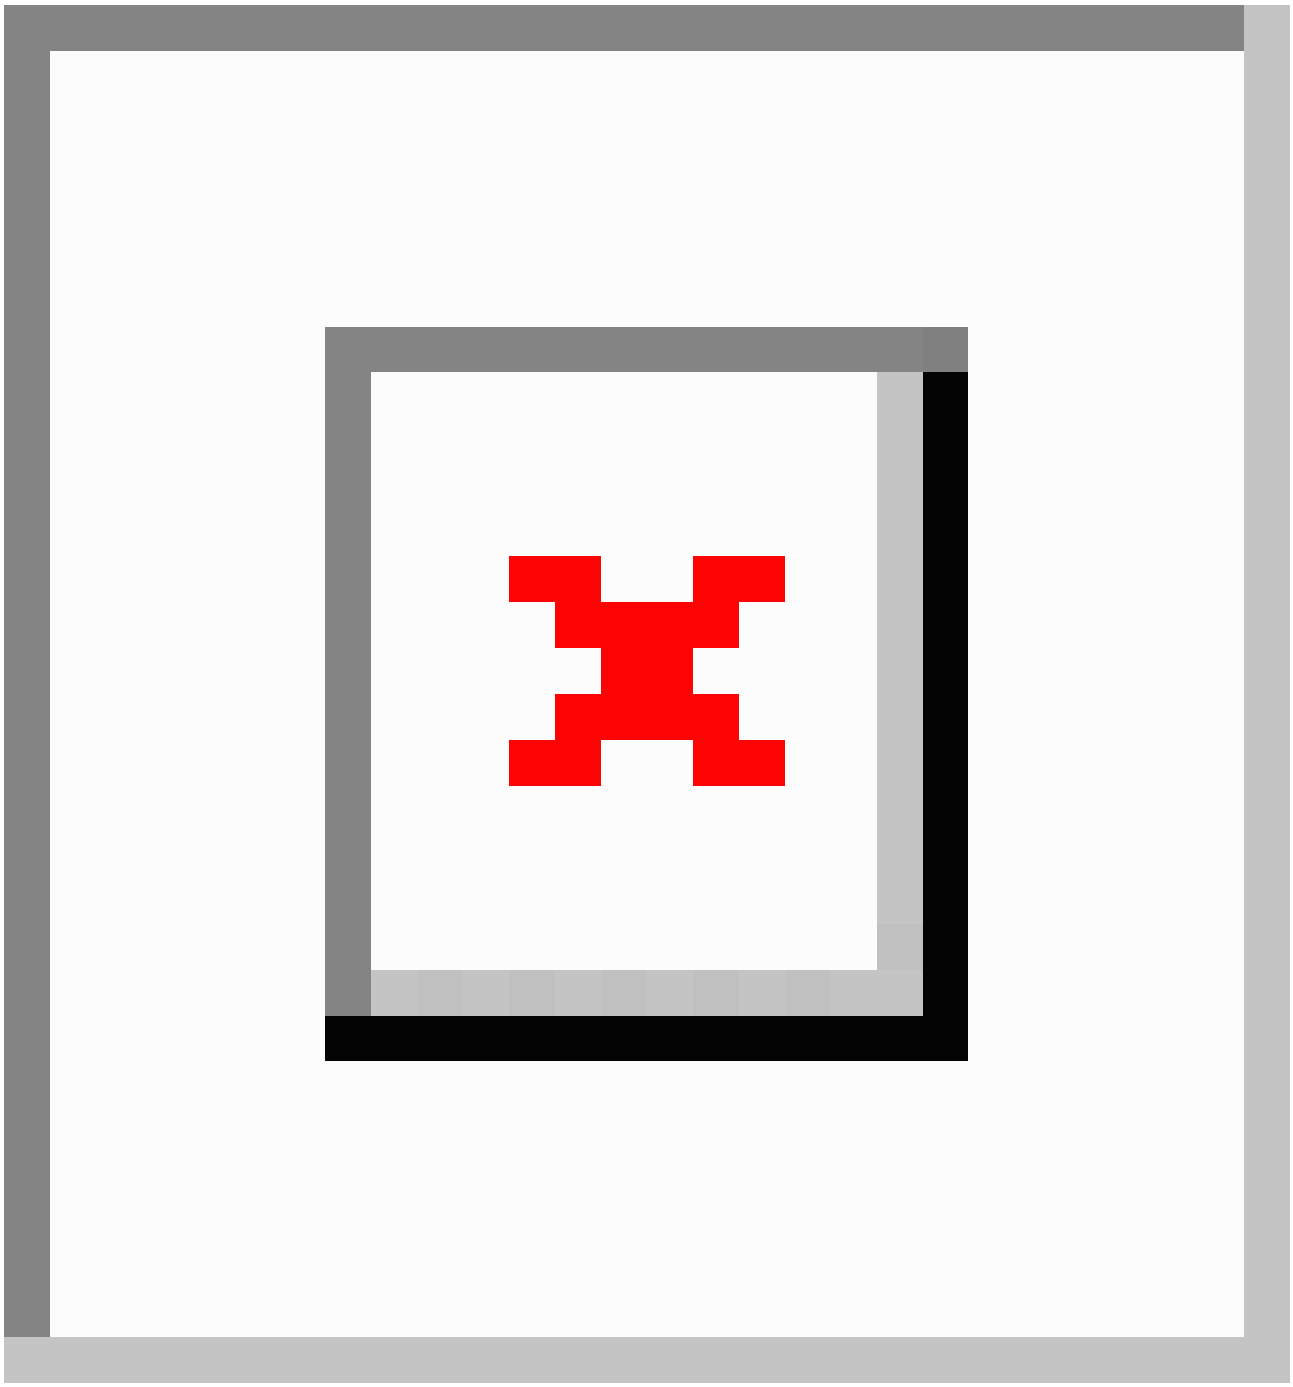
Figure 2. Overview of our 2-stage deep learning system.



Entity Extraction

According to the predefined information model, this module extracts clinical entities from a report. Named entity recognition (NER) [31] is well suited for this task. As a preprocessing pipeline, the report was segmented into sentences using regular expressions, and each sentence was tokenized with MeCab (Kyoto University Graduate School of Informatics and Nippon Telegraph and Telephone Corportation's Communication Science Research Institute) [32]. Then, a sequence of tokens was fed into the model. To represent the spans of specified entities, the IOB2 format [33], which is a widely used tagging format in NER tasks, was used. In this format, the B and I tags represent the beginning and inside of an entity, respectively, and the O tag represents the outside of an entity. A tagging example is illustrated inFigure 3.

Figure 3. An illustration of the entity extraction module. BERT: Bidirectional Encoder Representations from Transformers; BiLSTM: bidirectional long short-term memory; CRF: conditional random field.



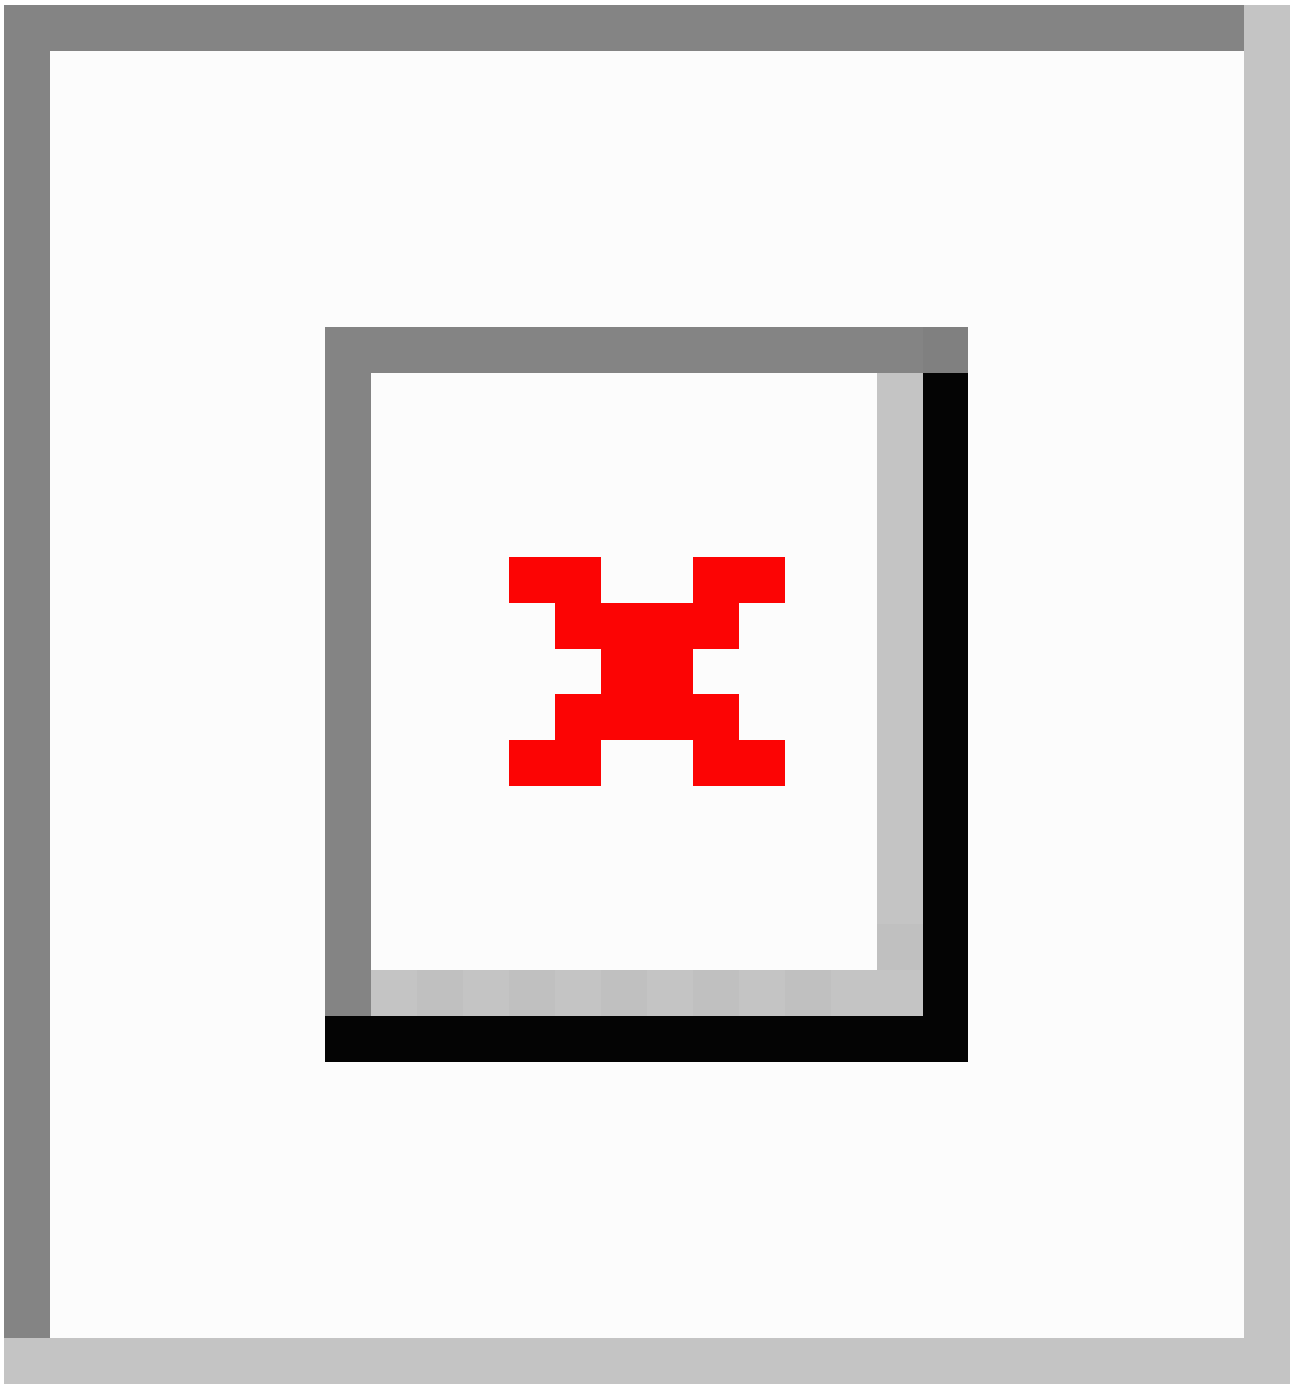
State-of-the-art deep learning models for NER—BiLSTM-CRF [34], BERT [35], and BERT-CRF—were compared.

Relation Extraction

Following the implementation of the entity extraction module, reports with clinical entities were obtained. As a preprocessing pipeline of relation extraction, the original sentences of the report were reconstructed by concatenating sentences from the

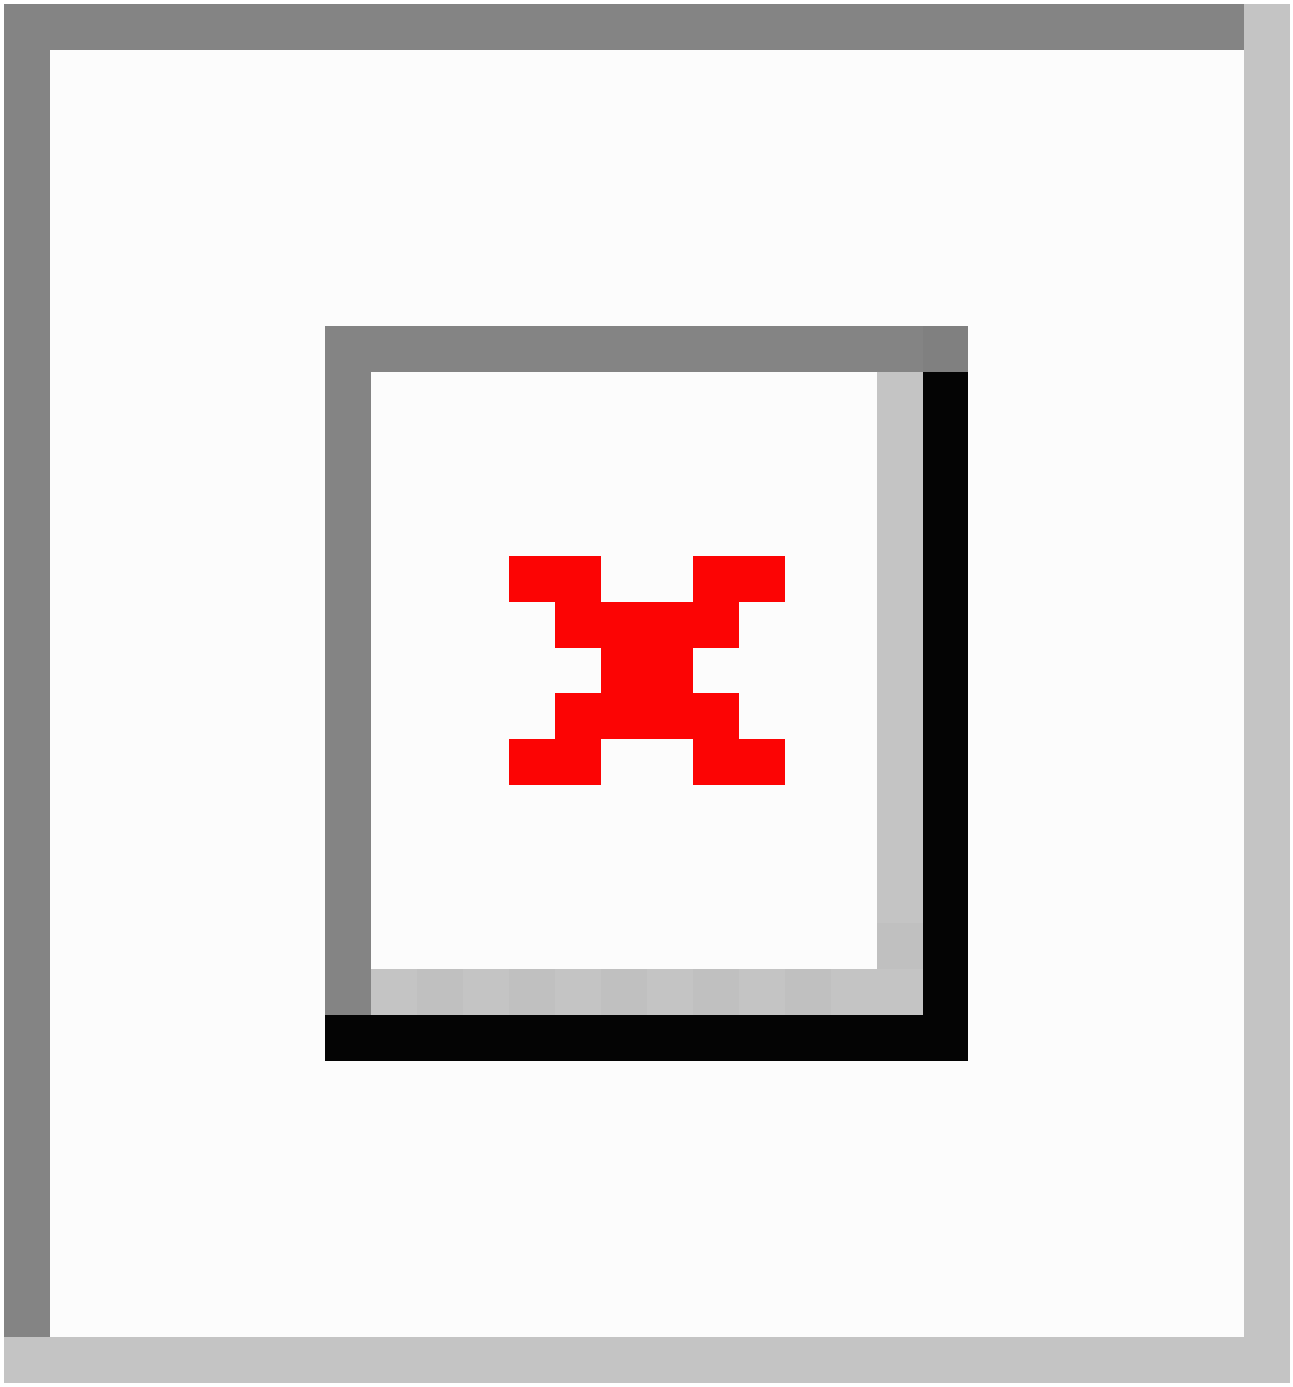
beginning to the end. This was implemented for extracting relations across multiple sentences in a report. Next, the pipeline generated possible candidate relations by each relation type in a report (seeFigure 4). Then, this module solved a binary classification problem to determine the existence of relations given the candidate relations.

Figure 4. Example of instances generated for relation extraction. In this case, 6 candidate relations were generated from 2 observations and 3 modifiers. CT: computed tomography.



Next, we explain how we represented each relation candidate in a fixed-length sequence. Previous studies have introduced a method to add position indicator tokens to the input sequence to indicate the entity span of the pair in the sequence [36,37]. We expanded this method to allow the representation of the entity types. These position indicator tokens are referred to as "entity span tokens." For example, the input sequence of the model representing the relation between an observation entity and an anatomical location modifier entity was represented as follows: "A 3 cm <OBS> nodule </OBS> is in the <AE> right upper lobe </AE>." Here, "<OBS>," "</OBS>," "<AE>," and "</AE>" are entity span tokens. Possible entity span tokens were appended to the vocabulary, and thus, an entity span token was treated as a single token. The input sequence containing 4 entity span tokens was fed into the model. A classification example is illustrated inFigure 5. All generated relation candidates were transformed into fixed-length sequences and fed into the model.

Figure 5. An illustration of the relation extraction module. BERT: Bidirectional Encoder Representations from Transformers; BiLSTM: bidirectional long short-term memory.



The BiLSTM attention model [38] and BERT model were compared. For the BiLSTM attention model, the output vector representation for classification was obtained from the weighted sum of the sequence vector representations. For the BERT model, the representation of the first "[CLS]" token for classification was used, which is a straightforward sequence classification tasks introduced by the original BERT.

Experimental Settings

Data Set Splitting

A total of 540 annotated chest CT reports were divided into 3 groups: 378 reports for training, 54 reports for development, and 108 reports for testing. Similarly, a total of 500 annotated abdomen CT reports were divided into 3 groups: 350 reports for training, 50 reports for development, and 100 reports for testing. In total, 728 reports for training, 94 reports for development, and 208 reports for testing were prepared.

Parameter Optimization

For the BiLSTM-CRF model, a minibatch stochastic gradient descent with momentum was used, and the initial learning rate and momentum were set to 0.1 and 0.9, respectively. The learning rate was reduced when theF_1-score of the development data set stopped improving. Learning rate decay and a gradient clipping of 5.0 were used. Dropout [39] was applied on both the input and output vectors of the BiLSTM model. A batch

size of 16, a dropout rate of 0.1, a word embedding dimension of 100, and a hidden layer dimension of 512 were chosen. For the BERT model, $BERT_{BASE}$was used, which has 12 layers of transformer blocks, 768 hidden units, and 12 self-attention heads. The model was fine-tuned with the initial learning rate of 5×10^{-5}, a batch size of 16, and training epochs of 10. The best hyperparameter setting was chosen using a development data set.

Domain Adaptation

Previous studies have reported that pretraining the domain corpora improved the model performance for various downstream tasks [27,40,41]. However, some studies have pointed out that domain adaptation (DA) leads to a degradation in model performance due to forgetting general domain knowledge [42,43]. To validate the effect of DA in our experiments, we evaluated the model performance with and without DA for both the entity extraction and relation extraction models.

For pretraining the word embeddings of the BiLSTM model with the general domain, Japanese Wikipedia articles [44] (12 million sentences) were used. For pretraining the word embeddings of the BiLSTM model with DA, 911,465 in-house radiology reports were used. We used word2vec (Mikolov et al [45]) for both tasks of pretraining the word embeddings.

For the BERT model, the publicly available pretrained Japanese BERT (Tohoku NLP Group and Tohoku University) [46] was first initialized. The model was pretrained using Japanese Wikipedia articles. The $BERT_{BASE}$subword tokenization model pretrained with whole word masking was chosen. For DA, continued pretraining using 911,465 in-house radiology reports for approximately 100,000 steps using a batch size of 256 was implemented.

Evaluation Metrics

To validate the capability of our system, we conducted 2 experiments. First, the performances of the deep learning modules were calculated. In this experiment, the mean scores were obtained over 5 runs with different parameter initializations to mitigate the effects of a random seed. For both the entity extraction and relation extraction, theF_1-score was used for evaluation. For the entity extraction, entity-levelF_1-score was used as an evaluation metric, and the results were aggregated by microaveraging. Second, to validate that our information model encompassed clinical information in the reports, we measured the coverage with the following formula:

where B-tagged tokens and I-tagged tokens were annotated as entities represented in the IOB2 format [33], and O-tagged tokens as outside entities were not annotated. Following to the scope definition of our information model, the sentences that only contained information about the technique of the imaging test, the surgical procedures of the patients, and recommendations were excluded. Punctuations and stop words were also excluded from the calculation. The list of stop words is presented inMultimedia Appendix 2.

Results

Entity Extraction

Table 1shows the performance metrics for the entity extraction model. The BiLSTM-CRF model with DA achieved a microaveragedF_1-score of 96.1%. In our experiments, the BiLSTM-CRF model with DA achieved the best performance of all the microaveraged scores. For the BERT model, concatenating the CRF layer to the output of the BERT improved the meanF_1-scores with and without DA. Given that the BiLSTM-CRF model with DA yielded the highest meanF_1-score, it was used as the entity extraction module for our system and was used for the remaining experiments.

Table . Comparison of entity extraction models using meanF_1-scores.

Model	Without DA[a], meanF_1-score (%)	With DA, meanF_1-score (%)
BiLSTM[b]	95.2	*96.1*[c]
BERT[d]	94.8	95.2
BERT-CRF[e]	95.1	95.4

[a]DA: domain adaptation.

[b]BiLSTM: bidirectional long short-term memory.

[c]The best performance is italicized.

[d]BERT: Bidirectional Encoder Representations from Transformers.

[e]CRF: conditional random field.

The detailed performance of BiLSTM-CRF model with DA is shown inTable 2. In the test set using chest and abdomen reports, theF_1-scores of observation, clinical finding, anatomical location modifier, certainty modifier, and size modifier entities were over 95%, whereas the change modifier and characteristics modifier entities had lowerF_1-scores than the other entities.Table 2also shows that the test set of abdomen reports had a 0.5% higherF_1-score than the chest reports. On the test set of abdomen reports, the clinical finding and change modifier entities achieved betterF_1-scores than the chest reports, with an increase of 2.9% and 2.5%, respectively. Conversely, the observation and characteristics modifier entities using the test set of chest

reports obtained betterF_1-scores than the abdominal reports, with an increase of 1.0% and 2.6%, respectively.

Table . Comparison of the results of the entity extraction model for the test set of chest and abdomen reports.

Entity type	Chest reports,F_1-score (%)	Abdomen reports,F_1-score (%)	Chest and abdomen reports,F_1-score (%)
Observation	96.1	95.1	95.6
Clinical finding	94.2	97.1	96.1
Anatomical location modifier	96.3	96.3	96.3
Certainty modifier	98.6	99.1	98.9
Change modifier	90.5	93.0	91.5
Characteristics modifier	89.5	86.9	88.5
Size modifier	98.7	98.7	98.7
Microaverage	95.8	96.3	96.1

Relation Extraction

The performances of the relation extraction models were compared. In this experiment, to focus on evaluating the relation extraction module, human-annotated entities were used for the input of each model.Table 3shows the comparisons of the performance of the relation extraction models. A microaveragedF_1-score of 95.6% was achieved for the BiLSTM attention model with DA and 97.6% for the BERT model with DA, which indicated that both classification models could achieve a satisfactory performance for relation extraction. Pretraining with domain corpora improved the performance of both relation models. In contrast to the experimental results of the entity extraction models, the BERT model outperformed the BiLSTM attention model by 2.0% in theF_1-score.

Table . F_1-score of the relation extraction models.

Model	Without DA[a], microaveragedF_1-score (%)	With DA, microaveragingF_1-score (%)
BiLSTM[b]	95.5	*95.6*[c]
BERT[d]	97.2	*97.6*

[a]DA: domain adaptation.

[b]BiLSTM: bidirectional long short-term memory.

[c]The best performance is italicized.

[d]BERT: Bidirectional Encoder Representations from Transformers.

The performance difference between the chest and abdomen reports was also compared (Table 4). TheF_1-scores of the modifier relation were almost the same for the chest reports and abdomen reports, whereas the evidence relation was 6.3% lower in the abdomen reports than the chest reports.

Table . Comparison of the results of the relation extraction model for the test set of chest and abdomen reports.

Relation type and entity type		Chest reports,F_1-score (%)	Abdomen reports,F_1-score (%)	Chest and abdomen reports,F_1-score (%)
Modifier relation				
	Anatomical location	97.9	97.6	97.6
	Certainty	99.4	99.5	99.4
	Change	95.4	95.0	95.1
	Characteristics	95.1	96.5	95.7
	Size	99.1	98.0	98.8
Evidence relation				
	Clinical finding	96.7	90.4	94.9
Microaverage		97.7	97.4	97.6

Our 2-Stage System

To evaluate the performance of the entire pipeline of our system, the performance of the relation extraction module using the output of the entity extraction module was examined. According to the experimental results, the BiLSTM-CRF and BERT models were used for the entity extraction model and relation extraction model, respectively.Table 5shows that the performance of the 2-stage system obtained an overallF_1-score of 91.9%. The overallF_1-score was 5.7% lower than the results using the human-annotated entities, as shown inTable 3. This decrease is reasonable since the misclassification of entity extraction is fed into the relation extraction model in this experiment.

Table . TheF_1-score of our 2-stage system.

Relation type and entity type		2-Stage system,F_1-score (%)
Modifier relation		
	Anatomical location	92.8
	Certainty	96.3
	Change	81.4
	Characteristics	84.7
	Size	94.6
Evidence relation		
	Clinical findings	87.1
Microaverage		91.9

Coverage of Clinical Entities

The test set of reports contained an average of 11.9 sentences. An average of 1.0 (8.4%) out of 11.9 sentences about the technique of the imaging test, the surgical procedures of the patients, and recommendations were excluded from the calculation.Table 6shows the coverage of clinical entities with our information model. The coverage of the clinical entities across entire sequence was 70.2% (7050/10,036). We observed that 96.2% (6595/6853) of tokens were annotated when punctuations and stop words were excluded from the sequences.

Table . Coverage of the clinical entities with our information model.

Token scope	Annotated tokens , n/N (%)
Entire sequence	7050/10,036 (70.2)
Without punctuations and stop words	6595/6853 (96.2)

Error Analysis

A quantitative error analysis was further performed to understand our 2-stage system. For the entity extraction module, we found that the entity mentions that rarely occurred in our corpus were likely missed. To evaluate this empirically, 2 additional test sets were used.

1. Major test set: entity mentions that occurred multiple times in the training set
2. Minor test set: entity mentions that only occured once or did not occur in the training set

Table 7shows the comparison of the result of the major and minor test sets with the original test set (Table 3). In the major test set, theF_1-score of the overall entities was improved by 2.1% (from 96.1% to 98.2%). This increase was also observed in the individual entities except for the size modifier entity. However, theF_1-score of the overall entities was markedly decreased by 9% in the minor test set. This was expected as the deep learning model struggled to predict the samples that were rare or unseen in the training set. Another reason for this difference may be the difficulty in determining the appropriate entities for the minor mentions. We observed that annotation disagreements during the adjudication process occurred more frequently for the minor mentions than the major mentions. Interestingly, we found that the size modifier was robust to the minor entity mentions. The simplicity of these entity mentions, such as “5 cm” and “30×14 mm,” may have contributed to the result. Our analysis shows that the entity extraction module could extract frequent entity mentions in the training set accurately; however, there remains much room for improvement regarding rare or unseen terms in the training set.

Table . Error analysis.

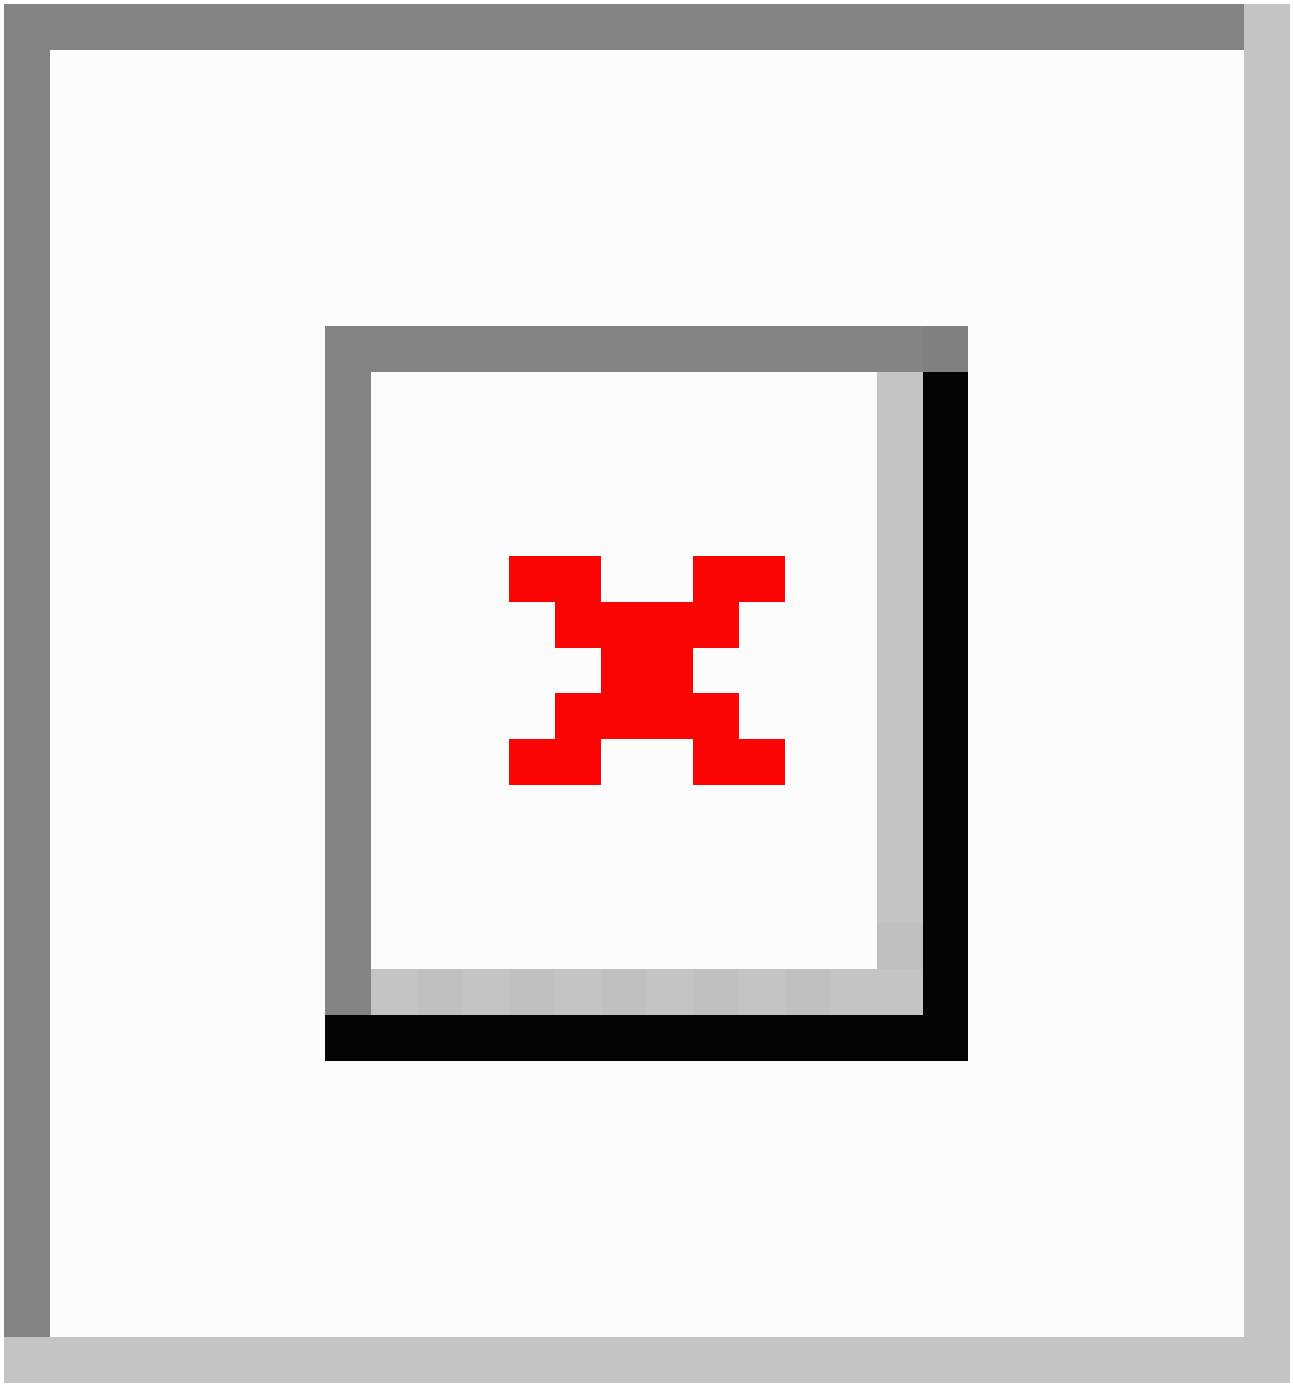
Entity type	Original test set,F_1-score (%)	Major test set		Minor test set	
		F_1-score (%)	Difference from the original test set	F_1-score (%)	Difference from the original test set
Observation	95.6	97.9	+2.3	82.0	–13.6
Clinical finding	96.1	97.9	+1.9	87.8	–8.2
Anatomical location modifier	96.3	98.7	+2.4	89.6	–6.7
Certainty modifier	98.9	99.3	+0.4	80.5	–18.4
Change modifier	91.5	93.5	+2.0	89.0	–2.5
Characteristics modifier	88.5	95.5	+7.1	61.5	–26.9
Size modifier	98.7	98.	–0.3	98.2	–0.6
Microaverage	96.1	98.2	+2.1	87.1	–9.0

To decrease the ratio of rare or unseen terms in the test set, more samples would be required in the training set. However, it is inefficient to sample reports randomly to improve the overall performance. For an efficient sampling strategy, active learning [47,48] may be a promising approach that allows for the selective sampling of reports in the current module.

The performance of the entity extraction and relation extraction modules were compared using the test set of chest and abdomen reports, respectively. For the entity extraction, theF_1-score of the clinical finding entities in the test set for the abdomen reports was 2.9% better than that of the chest reports. In the abdomen reports, it was often written using terms such as “肝臓：n.p. (Liver: n.p.)” when there were no particular findings for a specific organ. This simple expression, “n.p.,” constituted 66.2% of the clinical finding entities in the test set of the abdomen reports, which substantially impacted the performance.

The overall performance of the relation extraction module demonstrated excellent performance on the test set for both the chest and abdomen reports. However, theF_1-score for the evidence relation between the observation and clinical finding entities was 6.3% lower on the test set of the abdomen reports than that of the chest reports. We found a few examples where the observations and clinical findings were clinically related; however, we could not determine if the observation was the diagnostic basis for the finding. The first example shown inFigure 6indicates that the “whirlpool sign” was the observation for the diagnostic basis of an “intestinal obstruction (イレウス),” whereas no observation was found for the diagnostic basis of an “intestinal obstruction (イレウス).” Even though a “whirlpool sign” was clinically related to an “intestinal obstruction (イレウス),” the evidence relation cannot be derived from this example. However, our model misclassified this as a positive example of the evidence relation. In the second example, annotators did not assign the evidence relation between “air” and “biloma,” since they considered that the “air” has already disappeared. However, we discussed that the clinical finding of “biloma” was actually derived from the evidence of an unchanged “low density area (低吸収域)” and disappeared “air.” Thus, the model prediction was more preferable than the gold standard. To derive the diagnostic basis, it is preferable to consider information about the observation and its modifying entities.

Figure 6. Misclassification examples of the relation extraction model (blue highlighted relations are examples of false positives).



Discussion

Principal Findings

Table 3shows the performance of the entity extraction model, which yielded a microaveragedF_1-score of 96.1%. TheF_1-scores of the observation entity and the clinical finding entity were 95.6% and 96.1%, respectively. These superior performances are desirable for our system since the observation and clinical finding entities are principal components of our information model. Moreover,Table 5shows that the modifier relation with the certainty entity also had superior performance. These results suggest that our system will be applicable for practical secondary uses, such as a query-based case retrieval system [49]. However, to reuse radiology reports for various clinical applications, improvements in extracting the change modifier and characteristics modifier would also be required.

BiLSTM Versus BERT

Table 3shows that the BiLSTM-based model achieved better performance than the BERT-based model in the entity extraction task, whereasTable 5shows that the BERT-based model outperformed the BiLSTM-based model in the relation extraction task. We considered that the differences between entity and relation extractions might be due to their task characteristics. Local neighborhood information and the representation of the token itself are considered important in the entity extraction task, whereas more global context

information is required in the relation extraction task, especially for long-distance relations. Due to their attention mechanism, BERT and other transformer-based models are capable of learning long-range dependencies [50], which probably contributed to the superiority of the BERT model in the relation extraction task.

DA Performance

Tables 1and3show the comparison results of the model performances with and without DA for each task. These results indicate that DA is beneficial for performance improvement, regardless of the architecture of the model. Since our system focuses on extracting information from radiology reports, we consider that the problem of forgetting general domain knowledge to be outside the scope of this study.

Coverage of Clinical Entities

The coverage of the clinical entities with our information model was calculated. Sentences about the technique of the imaging test, the surgical procedures of the patients, and recommendations were excluded from the calculation, as such information was outside of the scope of our information model. Punctations and stop words were also excluded from the calculation. A total of 96.2% (6595/6853) of tokens were annotated, which indicates that our information model covered most of the clinical information in the reports.

Limitations

This study has a limitation in terms of generalizability, since we only used 1 institutional data set for evaluation. More data sets outside our institution would be needed to ensure generalizability. Although we validated the capability of our system using only chest and abdomen CT reports, fine-tuning of the deep learning models with reports for other body parts and modalities would be required for various secondary uses.

Furthermore, we are aware that there is still a gap to bridge to reuse radiology reports for various applications. As reports usually contain misspellings, abbreviations, and nonstandard terminologies, we believe that term normalization techniques [51,52] would be needed for clinical applications.

Conclusions

This study developed a 2-stage system to extract structured clinical information from radiology reports. First, we developed an information model and annotated in-house chest and abdomen CT reports. Second, we trained and evaluated the performance of 2 deep learning modules. The microaveragedF_1-scores of our best model for entity extraction and relation extraction were 96.1% and 97.4%, respectively. The entire pipeline of our system achieved a microaveragedF_1-score of 91.9%. Finally, we measured the ratio of annotated entities in the reports. The coverage of the clinical information in the reports was 96.2% (6595/6853). To reuse radiology reports, future studies should focus on term normalization. We also plan to develop a platform that allows us to evaluate the generalizability of our system using reports from outside of our institution.

Acknowledgments

Abstract

Background: Large language models have had a huge impact on natural language processing (NLP) in recent years. However, their application in epidemiological research is still limited to the analysis of electronic health records and social media data.

Objectives: To demonstrate the potential of NLP beyond these domains, we aimed to develop prediction models based on texts collected from an epidemiological cohort and compare their performance to classical regression methods.

Methods: We used data from the British National Child Development Study, where 10,567 children aged 11 years wrote essays about how they imagined themselves as 25-year-olds. Overall, 15% of the data set was set aside as a test set for performance evaluation. Pretrained language models were fine-tuned using AutoTrain (Hugging Face) to predict current reading comprehension score (range: 0-35) and future BMI and physical activity (active vs inactive) at the age of 33 years. We then compared their predictive performance (accuracy or discrimination) with linear and logistic regression models, including demographic and lifestyle factors of the parents and children from birth to the age of 11 years as predictors.

Results: NLP clearly outperformed linear regression when predicting reading comprehension scores (root mean square error: 3.89, 95% CI 3.74-4.05 for NLP vs 4.14, 95% CI 3.98-4.30 and 5.41, 95% CI 5.23-5.58 for regression models with and without general ability score as a predictor, respectively). Predictive performance for physical activity was similarly poor for the 2 methods (area under the receiver operating characteristic curve: 0.55, 95% CI 0.52-0.60 for both) but was slightly better than random assignment, whereas linear regression clearly outperformed the NLP approach when predicting BMI (root mean square error: 4.38, 95% CI 4.02-4.74 for NLP vs 3.85, 95% CI 3.54-4.16 for regression). The NLP approach did not perform better than simply assigning the mean BMI from the training set as a predictor.

Conclusions: Our study demonstrated the potential of using large language models on text collected from epidemiological studies. The performance of the approach appeared to depend on how directly the topic of the text was related to the outcome. Open-ended questions specifically designed to capture certain health concepts and lived experiences in combination with NLP methods should receive more attention in future epidemiological studies.

Introduction

Understanding human language is not a trivial task for machines. Natural language processing (NLP), that is, the analysis of free text with computational methods, has existed as a scientific field for more than half a century [1]. The introduction of large language models was a major leap for the field around the millennium [2]. The essentials of NLP have been reviewed recently with a clinical target audience in mind [3]. Text can be considered as a sequence of characters or words. These linguistic building blocks are referred to as tokens. Once a text is parsed into tokens, a mathematical representation is generated. The most common approach is to use word embeddings—mapping tokens to numerical vectors. These embeddings are trained (assessed in a data-driven manner) on large data sets, and their key feature is that they preserve the relationships between related words. Transformers, introduced in 2017 [4], are currently the most popular underlying model architecture as they excel at

contextualizing words in sentences. The vast amount of easily accessible textual data on the internet represents a massive resource for training language models. As compared to supervised machine learning (ML) approaches where the outcome (target) is available in the training data set, the situation is more complicated with language modeling, where the assignment of labels is not always straightforward. One popular approach, also applied in one of the most influential language models—Bidirectional Encoder Representations from Transformers (BERT) [5], is masked language modeling, that is, masking a certain proportion of words and considering them as outcomes to be predicted based on the preceding sequences of words. Another approach used in the development of BERT is the prediction of the next sentence in a text out of several options. This is a semisupervised training strategy that makes it possible to turn vast amounts of texts, for example, the English-language Wikipedia corpus, into a training set for a language model [5]. Technological advancements in computational tools (eg, graphical processing units and parallelization) have allowed language models to increase massively in size to hundreds of billions of parameters in recent years and have pushed performance closer and closer to human level in various NLP tasks [5-7]. These language models, developed by tech giants or their subsidiaries, are used in search engines, language translators, and auto-correct functions, among others, affecting our everyday lives.

Large language models have a broad scientific potential as well, and with the advent of transfer learning, they are more and more available for those who do not necessarily have the computational resources of tech giants. Transfer learning is the reuse of a pretrained model for a new data set or even a new prediction task that is different from the one it was originally trained for [8]. This approach unlocks the potential of ML for smaller studies by using knowledge representations (in a form of pretrained parameters) learned in large data sets. The significance of the method for NLP was first demonstrated by Howard and Ruder [9], who improved the predictive performance on several NLP benchmarks by ~30% by training a universal language model and reused it for specialized tasks via transfer learning. Even though transfer learning broadens the group of potential users of large language models and deep learning in general, it still requires specialized skills to apply these models. Web services to automate the training and deployment of ML models (automated ML [AutoML]) have been developed to overcome this barrier and unlock the potential in deep learning for researchers without specialized ML skills; however, their use is not common in the clinical research community [10,11].

In addition to knowledge identification (named-entity recognition), synthetization, or discovery in the scientific literature [12], NLP has had an impact on clinical research with applications mostly focusing on the analysis of electronic health records or social media data [13,14], most likely due to the large size of these data sources. However, the potential in free-text data and NLP are to date not fully exploited in classical epidemiological studies. It is likely that NLP performs better than classical regression prediction models in certain settings, but not all, depending on the content of the input text and the outcome to be predicted.

We designed a case study to evaluate the performance of large language models, trained via AutoML, in predicting current reading comprehension and future BMI and physical activity based on essays written by 11-year-old children about how they imagine themselves as 25-year-olds. We then compared this with a classical regression approach, including demographic and lifestyle factors that were selected based on prior domain knowledge as predictors. We explicitly aimed to study and compare the predictive ability of the models (accuracy or discrimination), without the consideration of etiology as it is only on this benchmark that ML and traditional models can currently be compared.

Methods

Data Source

The National Child Development Study (NCDS) originally included 17,415 individuals born in the same week of 1958 in England, Wales, or Scotland [15]. In a total of 12 sweeps, cohort members have been followed since then via interviews, surveys, and biomedical measurements, mostly focusing on health and sociodemographic information not only of the participants but also to some extent their parents. In this study, we used information from baseline (at birth in 1958), sweep 1 (age 7 years in 1965), sweep 2 (age 11 years in 1969), and sweep 5 (age 33 years in 1991) [16-18].

The three outcomes are (1) reading comprehension score (continuous) at age 11 years; (2) BMI (continuous) at age 33 years; and (3) physical activity (binary) at age 33 years. Reading comprehension (score range: 0-35) was assessed using a test filled out at school. The original test is available on the web on the UK Data Service portal [17]. BMI was calculated as weight (kg) divided by height (m) squared based on anthropometric measurements taken at the time of the interview. Physical activity was assessed with 2 questions, asking whether participants do any sport or exercise, and if so, how often. Participants were considered as physically active if they reported exercising at least once a week.

At the age of 11 years, the children were asked to write an essay about how they imagined themselves as 25-year-olds [16]. The instructions were the following: “Imagine that you are 25 years old now. Write about the life you are leading, your interests, your home life and your work at the age of 25. (You have 30 min to do this.).” Out of the 13,669 essays, 10,567 (77.31%) were transcribed [19], which served as the input for the deep learning analyses.

We had access to the following variables that were available at the birth of the participants: sex, ethnicity, birth weight, gestational age at birth, parity, age and BMI of the mother and father, whether the mother spoke English at home, mother’s smoking habit prior to pregnancy, and social class of the head of the household. Moreover, there was information available on the children’s eating habits at age 7 years (appetite and overeating) and BMI, lifestyle (how often they read books, used parks, and did sports activities), and general ability score (similar

to an IQ test) at age 11 years. These variables, selected based on prior knowledge in relation to the outcomes, are only a minor subset of those available in the cohort. Extensive descriptions of the different sweeps of the study are available on the web on the UK Data Service portal [16-18].

Predictive Modeling and Performance Evaluation Strategy

An analytical sample was defined for each of the 3 outcomes. A random sample of approximately 15% of the participants was reserved as a test set in each of the 3 analytical samples before developing the models, and the remaining 85% constituted the development set. In the AutoML approach, the development set was further split into a training set (80%) and a validation set (20%). All reported performance metrics were evaluated on the test sets.

The root mean square error (RMSE) was used as a performance metric for the continuous outcomes, that is, reading comprehension and BMI. Additionally, 95% CIs for RMSE were calculated using the basic bootstrap method with the *boot* package (version 1.3-28) in R (The R Foundation for Statistical Computing). To provide a benchmark RMSE score for comparison, we applied and evaluated a naive approach, that is, assigned the mean value of the outcome from the development data set as predictions in the test set.

Discrimination, measured by the area under the receiver operating characteristics curve (AUC ROC), was used as a performance metric for the binary outcome: physical activity. The naive benchmark was random assignment, and thus, an AUC ROC of 0.5 was defined.

Classical Approach: Regression Models

Regression models included predefined sets of variables that could vary for the 3 outcomes based on prior epidemiological knowledge. Models were fitted using the entire development set after applying multiple imputation (within the development set for each particular outcome) by chained equations to impute missing predictors (*mice* R package; version 3.14.0). We generated 10 imputed samples with the maximum number of iterations set to 30. Estimates were then pooled from the 10 resulting models. The *mice* models derived in the development sets were subsequently applied to the test sets to avoid information leakage.

Reading comprehension score and BMI were modeled using linear regression. For the reading comprehension outcome, we fitted 2 models, with and without including the general ability score among the predictors. The binary outcome physical activity at age 33 years was modeled with logistic regression. The complete list of variables included in each model are shown in Tables 1 and 2.

Table . Linear regression coefficients from prediction models for reading comprehension score and BMI.

Predictor	Reading comprehension score at age 11 years (n=8890)			BMI at age 33 years (n=6010)	
	Imputed, n (%)	Model 1 coefficients (95% CI)	Model 2 coefficients (95% CI)	Imputed, n (%)	Model coefficients (95% CI)

Deep Learning Approach: NLP Using Large Language Models

We used an AutoML tool, AutoTrain by Hugging Face [20], to develop our NLP prediction model. AutoTrain is a web-based service to train and deploy state-of-the-art ML models (text or tabular as of June 2022). The data sets were uploaded as comma-separated values files including 2 columns: the essays (as text) and the outcome. AutoTrain then split this data set into a training set (80%) and a validation set (20%) and started training (fine-tuning) a variety of pretrained large language models. The number of models can be defined by the user. We chose n=15 for this study. After the training process for all 15 models was complete, we accessed the best-performing model through Hugging Face's application programming interface from Python (Python Software Foundation) and evaluated predictive performance on the reserved 15% in the test set. We did this for all 3 outcomes.

Ethical Considerations

We analyzed a publicly available, anonymized data set; therefore, our study did not require ethical approval.

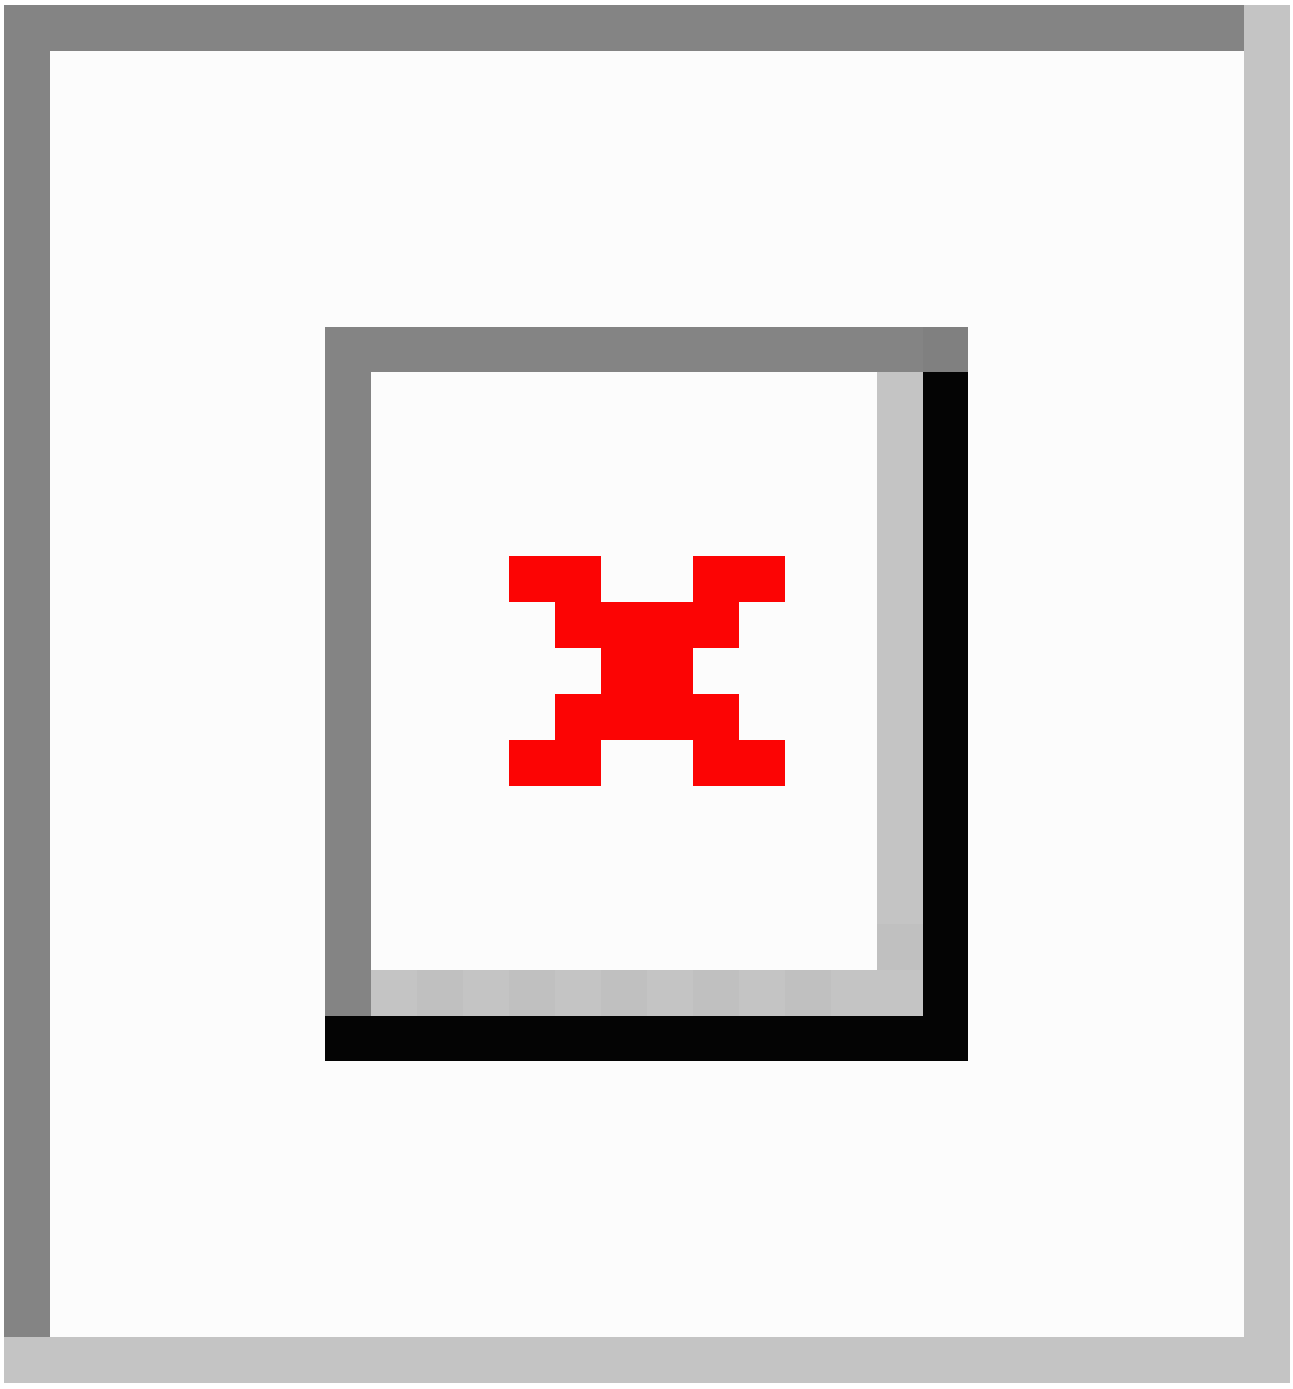
Results

Reading Comprehension Score (Age 11 Years)

Out of 10,567 participants with transcribed essays, 10,490 (99.27%) completed the reading comprehension test, forming the analytical sample for this outcome. From the 10,490 participants, a random sample of 1600 (15.25%) participants were set aside for testing (test set), leaving data from 8890 (84.75%) participants for model development (development set). Reading comprehension scores ranged from 0 to 34, with a median value of 16 (IQR 12-20). The distribution was similar in the test set and only differed slightly in the maximum (35) and the upper-quartile (21) values.

The main results are shown in Figure 1. The naive benchmark had an RMSE of 6.07 (95% CI 5.89-6.26), which was outperformed by both the classical regression and the deep learning approach. The linear regression model without the general ability score had an 11% better performance than the naive benchmark with an RMSE of 5.41 (95% CI 5.23-5.58). This was further improved when including the general ability score in the model (4.14, 95% CI 3.98-4.30). The best performance and thus lowest RMSE was achieved by the deep learning approach (3.89, 95% CI 3.74-4.05), corresponding to a 36% lower RMSE than the naive benchmark.

Figure 1. Performance of the prediction models versus the benchmark approach (naive prediction: assignment of the mean value from the training set) for (A) reading comprehension score and (B) BMI. Root mean square errors (RMSEs) are presented with 95% CIs. Percentages represent differences compared to the benchmark approach. NLP: natural language processing.



The linear regression models revealed that several predictors were associated with the reading comprehension score. Male sex, European ethnicity, having older parents, being the first child in the family, higher birth weight, higher socioeconomic status, reading books often, and having a higher general ability score were all positively associated with reading comprehension. Regression coefficients are presented in Table 1.

BMI (Age 33 Years)

The analytical sample for the BMI analysis consisted of 7060 participants who later had their weight and height measured at age 33 years. From the 7060 participants, a random sample of 1050 (14.87%) participants were set aside for testing model performance, leaving 6010 (85.13%) participants in the development set. BMI values ranged from 12.3 to 50.6 kg/m^2 in the development set and from 15.0 to 50.8 kg/m^2 in the test set. Median values were similar: 24.3 (IQR 22.3-27.1) and 24.4 (IQR 22.2-26.8) kg/m^2, respectively.

Performance metrics are shown in Figure 1. The naive benchmark had an RMSE of 4.45 (95% CI 4.09-4.78), which was similar to the performance of the deep learning approach (4.38, 95% CI 4.02-4.74). The regression model performed ~13% better, achieving an RMSE of 3.85 (95% CI 3.54-4.16).

Several variables were associated with BMI at age 33 years according to the regression model, including sex, ethnicity, parental BMI, parity, maternal smoking before pregnancy, use and access to parks, and BMI at age 11 years. Regression coefficients are presented in Table 1.

Physical Activity (Age 33 Years)

We had information on physical activity at age 33 years from 7304 participants. We selected 1100 (15.06%) of them randomly for the test set, leaving 6204 (84.94%) participants for model development. Overall, 68.75% (4265/6204) and 69.55% (765/1100) were physically active in the development and test sets, respectively. The logistic regression and NLP approaches had the same performance (AUC ROC=0.55, 95% CI 0.52-0.60), representing poor discriminatory power. There were a few variables associated with the outcome in the logistic regression model: sex, socioeconomic status, mother's BMI, sport activities, and use or access to parks at age 11 years. Odds ratios are presented in Table 2.

Discussion

Our study demonstrated the potential of using deep learning–based large language models for text prediction in epidemiological studies and compared it to classical statistical methods. We observed different rankings of predictive performance between the deep learning and classical approaches across the 3 outcomes. The performance of the deep learning approach appeared to depend on how closely the actual task, that is, writing an essay about the future, was related to the outcome. Writing and reading skills among children are expected to be associated with each other, so the language model could have picked up on linguistic features such as grammatical correctness, vocabulary, complexity of sentences, etc, which led to the NLP method clearly outperforming linear regression when predicting the reading comprehension score. This was still true when the general ability score was added to the regression model as a predictor, despite its high correlation with reading comprehension. However, this performance came with a computational price. Large language models include hundreds of millions or even billions of parameters, whereas our regression model included 26. In addition to simplicity, interpretability is another positive feature of linear regression. The model revealed several strong predictors and quantified associations via interpretable regression coefficients, for example, a social gradient with about a 5-point estimated difference between the highest and lowest socioeconomic classes. Although the coefficients are expressed in easily understandable units, they should not be interpreted in the etiological sense, unless a causal framework is applied. With the increasing interest in ML and causal inference, the development of ML methods integrating causal structures is warranted [21].

Epidemiologists and clinicians are comfortable with interpreting the usual measures of association: linear regression coefficients, odds ratios, or hazard ratios. Although we are far from understanding the overall nature of large language models, there are emerging methods in explainable artificial intelligence (AI) that can help to understand the driving factors of at least individual predictions (eg, which features or specific expression in a text led to a prediction). However, they are yet to be integrated into AutoML tools. Access to explainable AI tools (eg, LIME [22]) as part of AutoML solutions is likely to contribute to a more widespread use of deep learning in epidemiological research, where we often ask etiological questions and predictive performance is not necessarily the main focus.

Children were directly asked about their interests as 25-year-olds as part of the essay task, which could potentially include information on physical activity. We therefore expected a similar performance for the NLP and regression approaches. Both approaches picked up some signals in the data, demonstrated by discrimination nominally exceeding random assignment (AUC ROC=0.5), but their performance was still poor and statistically not different from each other. A previous study from the NCDS reported that 42% of boys and 34% of girls mentioned physical activity in their essays [19]. The authors then used this information to predict their physical activity patterns during adulthood, and they found a positive association among boys, but not girls. Pongiglione et al [19] used a 2-step approach: first, they applied a supervised ML method (support vector machines) to extract information on physical activity identity from the essays and, second, used that variable to predict the physical activity in adulthood with a separate logistic regression model. The drawback of this approach is that it needs a subset of the data set to have labels for the intermediate outcome (whether physical activity was mentioned in the text or not), which can be time-consuming and labor-intensive for large data sets. Once some labels are available and the prediction model has reasonable performance, the approach can handle large amounts of data to classify the rest of the essays. We have demonstrated that large language models can be directly applied on the data without first generating new intermediate labels.

The major difference between the study by Pongiglione et al [19] and ours, and in general between many epidemiological and data science approaches, is whether the focus is on the causal understanding of associations (etiology) or on prediction. Although the 2 approaches require different study designs and interpretation, the conflation of etiology and prediction is still common in clinical research (eg, causal interpretation of strong predictors) [23]. Our study showed that despite identifying variables strongly associated with the outcome, overall predictive performance might be poor. Therefore, we should be careful when interpreting and drawing causal conclusions from the results of models developed with a predictive aim and avoid mistakenly stating that altering the level of a component of a predictive model would change the risk of the outcome.

Similar evidence also exists regarding the prevention of obesity. In a meta-analysis of 15 prospective studies, Simmonds et al [24] reported that children or adolescents with obesity were about 5 times more likely to be obese in adulthood than those without obesity. In our study, we also found a strong association between BMI in childhood and adulthood; however, the linear regression model performed only slightly better than the naive benchmark, whereas the NLP approach did not outperform the benchmark at all. We were not surprised that NLP performed worse than regression, considering that these approaches had

matching performance in predicting physical activity, and obesity was not expected to be directly mentioned in the essays, in contrast to physical activity. In general, the results for this outcome strengthen our previous argument that prediction can be difficult even if well-established associations are present at the population level.

The development of prediction models, regardless of the use of ML or classical methods, is not a trivial task (handling of missing data, variable selection, reporting, etc) [25-28]. This is often reflected in the quality of prediction studies and the fact that only a small proportion of published prediction models are actually used in clinical practice [29]. AutoML does not offer a solution for this, as careful study design is still crucial. However, it makes the use of deep learning techniques (including pretrained models) more feasible for epidemiologists, who can use their resources on study design instead of programming tasks. Faes et al [10] recently reported a study where physicians (non-AI experts) achieved similar performance to expert-tuned algorithms in several medical image classification tasks [10]. We only needed to use programming in the NLP analysis to preprocess the essays and for the evaluation of the results, whereas the rest of the process was completed in a browser environment (model evaluation became available in AutoTrain by Hugging Face soon after we finished our analyses). AutoML solutions are often claimed to democratize ML; however, the financial costs are still not negligible. It is indeed a positive development that technical skills and computational resources no longer pose as strong a barrier as before. We should be vigilant that this increased accessibility is accompanied by an increased focus on good study design and research quality. An aspect that AutoML might have a positive influence on is knowledge translation. With the AutoML approach we used, the deep learning model became available right after training and could be used to make predictions for new samples either in the browser or via an application programming interface. The developer can choose to keep the model private or make it public so that the research community can reuse it as a pretrained model, either directly or after fine-tuning, thus potentially leading to multistep, incremental transfer learning.

A major strength of our work is the use of deep learning methods that are currently state of the art in NLP to exploit an innovative data source—in this case, text written by participants in a cohort study. We compared these models with standard methods in epidemiology and discussed similarities and differences between the classical and data science approaches. A strength of deep learning methods in general is the potential reuse of extant trained models. Although the interest in transfer learning is rapidly increasing in clinical research, it is still an almost unknown concept in the epidemiology community, despite some studies demonstrating major benefits, even for tabular data [30,31]. To increase the impact of prediction studies, especially those using ML and deep learning methods, authors should be encouraged to deposit their models on the web and make them openly available. This is a common practice in the data science community, as most developers depend heavily on pretrained deep learning models due to computational requirements. The Hugging Face Model Hub has >50,000 pretrained models, which fits well with the FAIR (findability, accessibility, interoperability, and reusability) principles on reusing digital assets in an open and inclusive manner [32]. In a clinical research setting, even if data accompany publications, which is still rarely the case, sharing resources is almost exclusively restricted to data sets and analysis code.

The children's essays used in our NLP models were not designed to be used for specific prediction tasks. Our main aim was to demonstrate the use of deep learning–based large language models and to compare them to the classical statistical methods used in epidemiological research. In showing that NLP methods can extract features from these texts that are associated with certain traits, our study points toward the potential for extracting meaningful additional data from other extant free-text data sources. Each text data source will have its own historical peculiarities and specific characteristics. In our case, the essays were written half a century ago by children. The practical utility of the presented models outside the context of the UK 1958 birth cohort is consequently likely limited without transfer learning via fine-tuning for adaptation to a new context. It should be noted that language models are usually trained on texts from the internet (eg, Wikipedia) and, as such, mostly represent texts written in the past few decades. Where older texts are included—for example, from older, digitized books—sources will represent texts selected for publication at the time. In all cases, texts written by children are likely to be severely underrepresented in training sets.

A previous review of the clinical literature found no evidence for ML having better predictive performance than traditional statistical methods [33]. Considering the trade-off in the loss of easy interpretability, in most studies, the use of ML does not offer any benefits as long as clinical researchers mostly work with tabular data. However, the integration of new data sources in epidemiological studies (text, medical images, and time series) is only possible by applying deep learning and often transfer learning, which also gives us the opportunity to reuse knowledge between studies. With regard to NLP, large language models have almost achieved human-level performance for various specific tasks; therefore, it may become possible for open-ended questions or essays to replace or at least complement long questionnaires (eg, on diet) in large epidemiological studies. Moreover, NLP offers computational methods, for example, for the analysis of interview transcripts in qualitative studies, which might contribute to closing the gap between qualitative and quantitative research. Byrsell et al [34] analyzed transcribed emergency calls to detect out-of-hospital cardiac arrests using deep learning, and Fagherazzi et al [35] recently gave an overview of the potential of vocal biomarkers (containing both linguistic and acoustic features) in clinical research and practice. With the large-scale collection of such and other novel data types, potentially in combination with tabular data, the role of deep learning in epidemiological research is likely to increase as well. However, we can only exploit its potential and develop high-quality prediction models for clinical or public health use in close collaboration between the data science and clinical research communities.

Acknowledgments

AH is supported by a Data Science Emerging Investigator grant (NNF22OC0076725) by the Novo Nordisk Foundation. DRW and AH are employed at Steno Diabetes Center Aarhus, which is partly funded by a donation from the Novo Nordisk Foundation. The funders had no role in the design of the study. The authors are grateful to all participants of the National Child Development Study and the investigators for making the data openly available.

Data Availability

The data set can be accessed through the UK Data Service after a simple registration process [16-18].

Abstract

Background: Predicting which treatment will work for which patient in mental health care remains a challenge.

Objective: The aim of this multisite study was 2-fold: (1) to predict patients' response to treatment in Dutch basic mental health care using commonly available data from routine care and (2) to compare the performance of these machine learning models across three different mental health care organizations in the Netherlands by using clinically interpretable models.

Methods: Using anonymized data sets from three different mental health care organizations in the Netherlands (n=6452), we applied a least absolute shrinkage and selection operator regression 3 times to predict the treatment outcome. The algorithms were internally validated with cross-validation within each site and externally validated on the data from the other sites.

Results: The performance of the algorithms, measured by the area under the curve of the internal validations as well as the corresponding external validations, ranged from 0.77 to 0.80.

Conclusions: Machine learning models provide a robust and generalizable approach in automated risk signaling technology to identify cases at risk of poor treatment outcomes. The results of this study hold substantial implications for clinical practice by demonstrating that the performance of a model derived from one site is similar when applied to another site (ie, good external validation).

Introduction

Optimizing Health Care Systems

One of the main challenges in designing an efficient health care system is to prevent offering too many resources to some patients and too little to others. In other words, the challenge is to maximize the opportunity for appropriate care at an individual level [1]. The recent strive for precision or personalized medicine aims to improve health care systems by tailoring treatments to patients more effectively. Patients are grouped in terms of their expected treatment response using diagnostic tests or techniques [2]. However, precision medicine remains a challenge in mental health care because treatments are effective *on average*, but it is difficult to predict exactly whom they will work for [3,4]. Stepped care principles provide a framework to allocate limited health care resources and have been proven to be cost-effective for depression and anxiety [5,6]. In stepped care, treatments start with low intensity unless there is a reason to intensify. Such reasons are identified during treatment when there is a lack of confidence in a positive outcome given the current treatment trajectory. To this extent, routine outcome monitoring (ROM) could be used to observe patterns of early treatment response and identify which patients will probably not benefit from their current treatment [7,8].

Identification of Nonresponders

The system can be improved by earlier and more accurate identification of those nonresponders so that patients do not have to endure periods of care in which they do not improve and could potentially lose interest and drop out. On top of that, scarce health care resources are not wasted by engaging in treatment without the desired effect. However, misclassification comes with a cost. Incorrectly classifying patients as needing more intensified treatment results in the unnecessary use of health care resources on patients who would have benefited from a shorter low-intensity treatment. In many Dutch clinics providing basic mental health care, ROM measurements are part of routine care. This raises the question of whether these ROM data could be used to provide accurate prognostic feedback and support a clinician in maximizing the opportunity for appropriate care on the individual level.

Predicting Outcomes With Machine Learning During Treatment

Techniques from the field of machine learning are aimed at making accurate predictions based on patterns in data. Machine learning can help to identify robust, reproducible, and generalizable predictors of treatment response [3,9-11], and has already been used in health care research, for example, in predicting health care costs and outcomes [12-15]. By discovering associations and understanding patterns and trends within the data, machine learning has the potential to improve care. Machine learning permits a finer detection of which patients are at an elevated risk of experiencing persistent poor and costly health outcomes, and may thus give impetus to a more efficient, personalized, and proactive type of mental health care. Inspired by this knowledge, the study aims to use machine learning on ROM data as a feedback device to signal which patients have an elevated risk of a poor response to treatment [16]. However, the use of complex data, and the associated increasingly complex models, challenges researchers to ensure that these models are clinically interpretable rather than a “black box” [17,18].

Independent Validation

After developing a prediction model, it is recommended to evaluate model performance in other clinical data that was not used to develop the model, as mentioned in the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) statement. For example, such a validation would require researchers to have access to a similar data set (ie, in terms of predictor variables and outcomes) stemming from a similar population/clinic and compare model performance on this external independent data set (ie, cross-site design). The lack of independent validation is a major limitation of the extant machine learning literature in health care [19]. In a recent review on machine learning for suicide prediction, the majority of studies reviewed split the data into training and testing sets, whereas none of the studies used a cross-site design in which a model was trained using data from one site and evaluated using data from another [20]. Another recent review looking at applications of machine learning algorithms to predict therapeutic outcomes in depression concluded that most studies did not assess out-of-sample estimates of model fit, which limited their generalizability and likely overestimated predictive accuracy [15]. Therefore, the aim of this study was 2-fold: (1) to predict patients’ response to treatment in Dutch basic mental health care using limited commonly available data from routine care and (2) to compare the performance of these machine learning models across three different mental health care organizations in the Netherlands by using clinically interpretable models. By using commonly available data from routine care, the technical implementation of the model in clinical practice would be straightforward.

Methods

Study Design and Data Collection

Data on mental health treatment and outcomes were collected by a data collection protocol. Mental health care sites from 6 regions in the Netherlands were involved. Patients were treated for mild to severe mental health problems, low risk of suicide, or dangerous behavior. The data set consisted of patient records with a completed treatment from 2014 to 2018. A completed treatment in this setting consists of around 5-12 sessions [21]. The protocol consisted of a predefined set of variables with clear definitions and coding for each variable.

For treatment records to be included in this study, the availability of at least the ROM data as well as certain other variables that could be used for predictions was required. As ROM questionnaires are not mandatory in routine care, ROM data were not available for all patients at all measurements. Records were included when ROM data were available at the start of, during, and at the end of treatment. Of the 6 participating regions, 3 had sufficient treatment records (>1000) with nonmissing values and were included in the study (region 1: n=3020; region 2: n=1484; region 3: n=1948). In each region, patients were treated in multiple settings in both urban and rural areas. A set of 26,912 records had to be excluded from the three sites because there was a missing ROM measurement at either the start or end, such that the outcome could not be determined, or there was no measurement during treatment, such that early treatment response patterns could not be determined. To assess the comparability of the included and excluded treatment records in our analysis, a comparison was made regarding age, sex, diagnosis, and baseline severity between both groups (Table 1).

Table . Comparison of patient characteristics between the included and excluded treatment records.

		Included (n=6452)	Excluded (n=26,912)
Sex, n (%)			
	Female	4077 (63.2)	16,872 (62.7)
	Male	2375 (36.8)	10,040 (37.3)
Age category (years), n (%)			
	<30	1978 (30.7)	8671 (32.2)
	30-40	1541 (23.9)	6701 (24.9)
	40-50	1238 (19.2)	5298 (19.7)
	50-60	1154 (17.9)	4119 (15.3)
	≥60	541 (8.4)	2123 (7.9)
Diagnosis group, n (%)

[a]OQ-45.2: Outcome Questionnaire.

Data Description

This study used treatment records, as opposed to patient records. A treatment record was started whenever a patient began treatment within one of the participating centers. As a result, some patients could have multiple treatment records (355/6452, 5.5% of the records were not unique). ROM assessed the development in symptom severity and functioning using the standardized Dutch version of the Outcome Questionnaire (OQ-45.2) [22]. The OQ-45.2 contains three subscales: Symptom Distress, Interpersonal Relations, and Social Role. The psychometric properties of the Dutch OQ-45.2 are adequate [23].

The idea of this study was to support a stepped care framework by predicting, during treatment, undesired outcomes at the end of treatment. These predictions can trigger a reconsideration of the chosen treatment plan to improve the probability of a desired outcome after finishing the treatment. Desired treatment outcomes are highly personal and dependent on the type of treatment and setting. For this study, we choose to define undesired outcomes as nonimprovement. Based on the principles of reliable change [24], we defined nonimprovement as improving less than a medium effect size on the Symptom Distress subscale of the OQ-45.2 [25]. Our study used data from the so-called *basic mental health care* in the Netherlands. Basic mental health care is cost-effective short-term mental health care with an average Cohen *d* effect size of 0.9 [21]. Despite this high effect size, the aim of this short-term treatment of 5-12 sessions is primarily to increase self-direction and get patients back on track without care as soon as possible. In this study, individual treatment goals were unknown, and therefore, it was decided to define nonimprovement as less than a medium effect size. This is a little more than half of the average improvement in this mental health care setting. Our clinical outcome was derived from the observed change in the Symptom Distress scale on the OQ-45.2. Patients with less than half of an SD improvement in symptom severity at the end of treatment were classified as having an “undesired clinical outcome” (called *nonimprovement* henceforth). With the SD of the Symptom Distress subscale in a Dutch clinical population being 16 [23], nonimprovement was defined as a patient not improving at least 8 points on the Symptom Distress subscale of the OQ-45.2.

An early change was defined as the difference in ROM at baseline and the first ROM during treatment. For both the summed scale scores on the OQ-45.2 as well as the individual items, early change variables were created. Besides the ROM data, a set of clinical and demographic variables were included for prediction such as main diagnosis, age, and living condition. The total set consisted of 163 variables, of which 144 were related to the scores on the OQ-45.2 and 19 to the context of the patient.

Modeling and Validation Strategy

The data set was split across all included locations so that models could be trained on a single location and externally validated on each of the other locations. Nonimprovement was predicted for each location separately based on all available predictors using least absolute shrinkage and selection operator (LASSO) models. LASSO was used both to guarantee interpretability for intended model users and to facilitate explicit comparison between prediction models built in different locations. Moreover, as several measures were derived from the same questionnaire, this could have led to multicollinearity between predictors in the data set. LASSO is a technique that has been argued to be able to deal with multicollinearity and still provide stable and interpretable estimators [26]. All numeric variables were centered and scaled.

Using 10-fold cross-validation with 10 repeats, the optimal hyperparameter was determined by considering 100 possible penalty values (ie, λ) between 0.001 and 1000. For the LASSO

with the optimized penalty, the probability threshold was tuned by optimizing F_1-scores over 36 possible probability values between 0.3 and 0.65. The final LASSO model selected for each site was then applied to each of the other sites for model assessment, reporting sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and area under the curve (AUC) using the optimized probability threshold.

Bootstrapping was used to estimate model performance in the site in which the model was built to have an internally validated measure of model performance to compare with the two externally validated measures of model performance by estimating CIs for all performance scores (ie, sensitivity, specificity, PPV, and NPV). The bootstraps were performed by sampling each data set 1000 times with replacement, resulting in 1000 simulated data sets for each site. The final LASSO model of each of the 3 site-specific models was then applied to the bootstrapped data set, resulting in 1000 confusion matrixes per site. Next, the 2.5 percentile and 97.5 percentile for each performance indicator (ie, sensitivity, specificity, PPV, and NPV) were used to determine the 95% CI for each estimate.

All analyses were performed in R (version 4.0.0; R Foundation for Statistical Computing) [27]. The package *caret* was used to build the models [28]. The package *glmnet* was used to perform the LASSO regression [29]. The package *pROC* was used to analyze the AUCs [30].

Ethical Considerations

Since the database was anonymized with statistical disclosure control techniques [31], there was no need for informed consent or approval by a medical ethics committee (Dutch Civil Law, Article 7:458).

Results

The total data set used in the analyses contained information on 6452 treatment records and included anonymized demographic variables, care-related variables, and information about the severity and types of complaints. The characteristics of the patient populations within each site are shown in Table 2. There are notable differences between baseline symptom severity, the distribution of the main diagnosis, and the percentage of patients with a paid job between sites.

[a]OQ-45.2: Outcome Questionnaire.

The nonzero LASSO coefficients are shown in Table 3. The most important coefficients, in terms of relative coefficient size, were related to early changes in the Symptom Distress subscale of the OQ-45.2, and the change in the total score of the OQ-45.2. The self-blame measurement at the start of treatment was the only other nonzero coefficient at each of the 3 regions. The coefficient for paid employment stands out in the region 1 model, and age had a notable coefficient in regions 1 and 3. Furthermore, the models contained smaller nonzero coefficients that varied between each site (eg, some OQ-45.2 variables were nonzero in some of the models but not in all of the models). The results of the hyperparameter tuning are shown in Table 4. As shown, the threshold to define a positive class was set between 0.30 (region 4) and 0.34 (region 3), with λ varying from 0.02 (region 5) to 0.16 (region 3).

Table . Nonzero least absolute shrinkage and selection operator coefficients of the three models.

Table . The parameter settings of the three models.

	Lambda	Probability
Model region 1	0.16	0.34
Model region 2	0.03	0.3
Model region 3	0.02	0.32

The performance of the three models is shown in Table 5. Each model (row) has been evaluated internally and two times externally. Each site (columns) has been used three times: one time for internal validation and two times for the external validation of the other models. The diagonal contains the three internal validations. The CIs of the AUCs overlap, which

indicate that there were no significant differences in the overall performances of the models. The AUCs of the three models in the three internal validations were 0.77 (region 2) and 0.80 (regions 1 and 2). The AUCs of the six external validations ranged from 0.77 to 0.80. An overview of the associated confusion matrixes is attached in Multimedia Appendix 1.

Table . Comparison of internally (diagonal) and externally validated results within each site with 1000 bootstrapped CIs for regions 1, 2, and 3.

Metrics		Region 1 validation	Region 2 validation	Region 3 validation
Region 1 model				
	Sensitivity (95% CI)	0.784 (0.760-0.809)	0.762 (0.725-0.800)	0.780 (0.747-0.813)

Discussion

Evaluation of Three Models at 3 Sites

The aim of this study was to use machine learning to predict which patients would not substantially benefit from treatment across 3 different mental health care organizations in the Netherlands by using clinically interpretable models. This study used a cross-site design in which the performance of a model developed in one site was compared to the model performance on an external independent data set (ie, 3 × 3 cross-site design, as per the TRIPOD statement). Data from ROM, among other clinical and demographic data, were used for the predictions.

Both the AUC of the internal validations of the three models and the corresponding external validations were in the range of 0.77 to 0.80, indicating fair to good model performance [32]. In addition, the CIs of the AUCs overlapped in each of the 9 evaluations, indicating that the performance estimates were robust and likely to be generalizable to different settings. This could be explained by the fact that LASSO regression is known to be less prone to overfitting compared to other machine learning algorithms, and when evaluated with 1000 times bootstrapping, the internal validations give a good indication of overall performance.

All three models generalized well to the other sites. This is an interesting finding and a promising result for the scalability of the implementation of machine learning models. Decentralized data can be gathered, within the boundaries of the General Data Protection Regulation. A model can be developed within the context of one site and then be exported to other sites, even if those other sites differ in certain characteristics. For example, in this research, the 3 sites differed in geographical location from more rural to urban. The patient populations differed, with some significant differences in the distribution of important variables such as main diagnosis, baseline symptom severity, and percentage of patients with paid employment. The data sources differed in the type of electronic health record system used in clinical practice. Despite these substantial differences, we were able to develop three robust machine learning models with acceptable AUCs that could be applied in all 3 settings.

The sensitivity and specificity of the three models were consistent in each of their external validations. There were differences in these metrics between models, mainly caused by a trade-off between sensitivity and specificity when evaluating model performance with metrics from the confusion matrix. The models of regions 1 and 2 were more shifted toward a higher sensitivity and the model of region 3 toward a higher specificity. However, these differences were a shift in the balance rather than an *absolute difference* between the models, as was indicated by the comparable AUCs.

To give some insight into the practical utility of the model, the results can be translated to a hypothetical clinical scenario. Imagine a health care professional with a caseload of 30 patients working in region 2, with a model created in region 1. About 10 of the 30 patients will not improve according to our data (34%). The model is used by the clinician to support the identification of potential nonimproving patients during treatment. With a sensitivity of 0.76 and a specificity of 0.65 (the results of model 1 applied to region 2), 15 patients will be classified as nonimprovers and 15 will be classified as improvers. Among the improvers, 13 of them will actually improve (ie, NPV=0.84), and among the nonimprovers, 8 of them would actually not improve (ie, PPV=0.52). For half of the patients who are classified as nonimprovers, therefore, the discussion would not be necessary at that time. So the question is whether these models are already good enough to actually use in practice. The idea is that when the model indicates that a patient is on track, there is little reason to change treatment. When the model indicates an elevated risk of nonimprovement, the clinician and patient should discuss the situation and adapt treatment plans if necessary. It is therefore important to see such machine learning models not as black-and-white decision tools but as complementary tools in the identification and stratification of patients in need of more or less care.

Predictive Variables

Although this research was aimed at making predictions, rather than explaining relations, we used LASSO regression to inform clinicians about how the algorithm works. In the health care setting, this is important as health care professionals often want to understand which parameters affect and how they contribute to a prediction [33]. By looking at the coefficients of each LASSO model, it can be concluded that the algorithms rely on the variables' early change in the Symptom Distress subscale and the total scores of the OQ-45.2, as well as having a paid job at the start of the treatment and age. In a paper by McMahon [34], several other studies are mentioned in which early symptom improvement, or lack of it, has been associated with psychiatric treatment outcomes. In a study by Lorenzo-Lucas et al [35], being unemployed, among other factors, predicted a lower likelihood of recovery. There were certain individual OQ-45.2 questionnaire items that were associated with nonzero LASSO coefficients. However, these items differed between the sites, and the size of the coefficients were relatively low. We are, therefore, reluctant to generalize findings on these individual OQ-45.2 items, with small nonzero coefficients, to future prediction research.

The high relative importance of the early change variable (ie, in terms of the absolute values of the coefficients) is likely to contribute to good external model validation, as it is a straightforwardly defined predictor that is less likely to be subject to sampling variation. Furthermore, given the high importance of early change in the model, one could even advocate for an alternative simpler predictive model (ie, a "rule of thumb") using early change only (or combined with weaker predictors, eg, age and employment status).

Strengths and Limitations

The main strength of this study is that we used a 3 × 3 cross-site design to develop and evaluate the algorithms, resulting in three models with an independent validation of their performance. In addition, LASSO regression was used, which is a parametric approach, resulting in a prediction model that is still relatively easy to interpret. Moreover, LASSO is less prone to overfitting, which increased the generalizability of the results. Furthermore, with the use of a data protocol with clear data definition descriptions, we could use readily available data from routine care in the Netherlands, meaning that our approach could easily be adopted in other Dutch basic mental health care organizations using ROM (the R scripts to build and validate the models are available on request). This study has a number of limitations that need to be acknowledged. First, we limited our analysis to treatment records with complete data only. In addition, we could not use every variable described in the data protocol because of missing values on these variables in one of the sites. Moreover, we had to exclude a large set of records because of missing data on the OQ-45.2. However, the excluded group of patients did not substantially differ in sex, age, diagnosis, or baseline symptom severity. Nonetheless, we would like to emphasize that our models cannot be directly applied to other patient populations. Second, our data did not contain information on whether the outcome of the ROM had already been used to alter the treatment strategy. This would underestimate the impact of early change, as patients with only minor or no clinical improvements would have been given a possibly more intensive treatment for them to respond to the treatment. Third, although it is difficult to estimate the required sample size for developing a prognostic model, our data had a relatively small sample size [36]. Fourth, this study chose to define an undesired outcome as improving with less than a medium effect size. However, the definition of an undesired outcome is subjective and will differ between different types of treatment settings. Therefore, our definition cannot directly be generalized to other settings, and each research should make an effort to define a relevant undesired outcome for that domain with experts from clinical practice.

This study was performed within the context of a stepped care framework, in which treatment optimization is required during treatment. Our models heavily rely on predictors derived from early change patterns and can, therefore, not be applied at the start of treatment. Other research could analyze which type of predictors are more suited for a matched care framework and to what extent accurate predictions can be made in treatment response.

Conclusion

Machine learning models provide a robust and generalizable approach in automated risk signaling technology to identify cases at risk of poor treatment outcomes. The results of this study hold substantial implications for clinical practice by demonstrating that the performance of a model derived from one site is similar when applied to another site (ie, good external validation). This is a promising result for the scalability of machine learning models developed in single-center studies. Our findings confirm that routine monitoring provides valuable information that can be used in prognostic models to predict treatment outcomes. Such prognostic models can be used as complementary tools for practitioners in a stepped care framework.

Abstract

Background: Electronic health records (EHRs) have yet to fully capture social determinants of health (SDOH) due to challenges such as nonexistent or inconsistent data capture tools across clinics, lack of time, and the burden of extra steps for the clinician. However, patient clinical notes (unstructured data) may be a better source of patient-related SDOH information.

Objective: It is unclear how accurately EHR data reflect patients' lived experience of SDOH. The manual process of retrieving SDOH information from clinical notes is time-consuming and not feasible. We leveraged two high-throughput tools to identify SDOH mappings to structured and unstructured patient data: PatientExploreR and Electronic Medical Record Search Engine (EMERSE).

Methods: We included adult patients (≥18 years of age) receiving primary care for their diabetes at the University of California, San Francisco (UCSF), from January 1, 2018, to December 31, 2019. We used expert raters to develop a corpus using SDOH in the compendium as a knowledge base as targets for the natural language processing (NLP) text string mapping to find string stems, roots, and syntactic similarities in the clinical notes of patients with diabetes. We applied advanced built-in EMERSE NLP query parsers implemented with JavaCC.

Results: We included 4283 adult patients receiving primary care for diabetes at UCSF. Our study revealed that SDOH may be more significant in the lives of patients with diabetes than is evident from structured data recorded on EHRs. With the application of EMERSE NLP rules, we uncovered additional information from patient clinical notes on problems related to social connectionsisolation, employment, financial insecurity, housing insecurity, food insecurity, education, and stress.

Conclusions: We discovered more patient information related to SDOH in unstructured data than in structured data. The application of this technique and further investment in similar user-friendly tools and infrastructure to extract SDOH information from unstructured data may help to identify the range of social conditions that influence patients' disease experiences and inform clinical decision-making.

Introduction

There is growing recognition that addressing social determinants of health (SDOH)—the conditions in which people are born, grow, work, live, and age—in patient care is necessary for achieving optimal and equitable diabetes outcomes [1,2]. Prior evidence has shown that SDOH, particularly related to low socioeconomic status, affect disparities in the health care

experience of patients with diabetes [3-5]. It is therefore imperative to better understand and intervene on SDOH to prevent negative clinical outcomes for patients and other downstream diabetes health care burdens and disparities [6]. SDOH can impact health equity in both a positive and negative way, thus leading to a gradient of health outcomes [7]. In this study, we focused on SDOH as a social risk factor on health outcomes.

Electronic health records (EHRs) are now becoming a resource to understand patients' SDOH context in ways that could inform clinical practice. However, it remains unclear how accurately EHR data reflect patients' lived experience of SDOH. Historically, EHRs have yet to fully capture SDOH due to challenges such as nonexistent or inconsistent data capture tools across clinics, lack of time and training, the burden of extra steps for the clinician, and the need for manual input, which can be a slow process [8]. Although structured data fields in EHRs for screening SDOH using *International Classification of Diseases (ICD)* codes have become more widespread, these are often not used by clinicians [9]. A better source of SDOH data from the EHR may be unstructured clinical notes, which provide qualitative detail beyond what is captured in structured data fields.

SDOH embedded in clinical notes could be captured quickly using natural language processing (NLP), but a corpus is hard to generate, and data access can be challenging, often requiring advanced programming skills. Novel and innovative high-throughput tools that automate and streamline the process of extracting SDOH data from clinical notes would prove useful to researchers and clinicians without advanced programming skills. Additionally, creating a high-throughput method of identifying SDOH mappings to structured and unstructured patient data has the potential to reduce physician charting burden and improve SDOH data in the EHR.

In 2018, researchers from the University of California, San Francisco (UCSF) created the Compendium of Medical Terminology Codes for Social Risk Factors that maps SDOH to existing ICD codes [10] (referred to hereafter as SDOH ICD Compendium or Compendium). The Compendium contains codes related to 20 SDOH-related risk and resilience factors from four medical vocabularies (LOINC, SNOMED CT, *International Classification of Diseases, Tenth Revision, Clinical Modification [ICD-10-CM]*, and Current Procedural Terminology) [10]. The Compendium allows us to identify existing codes related to social risk factors and their ontology.

In this study, we additionally leveraged two high-throughput tools for identifying SDOH mappings to structured (ICD codes) and unstructured (clinical notes) patient data: PatientExploreR and Electronic Medical Record Search Engine (EMERSE) [11]. We used these existing tools to first identify a cohort of patients within the EHR and explore the structured SDOH ICD Compendium codes (within PatientExploreR) and then to explore textual/unstructured data within the notes of the same patient population using the EMERSE NLP platform (grounded in the terminology from the SDOH ICD Compendium). This allowed us to identify and compare SDOH documentation in both structured and unstructured EHR data in records from patients with diabetes. Our working hypothesis was that these tools would reveal greater information about SDOH among these patients—through the mining of unstructured data—than is captured solely by structured data.

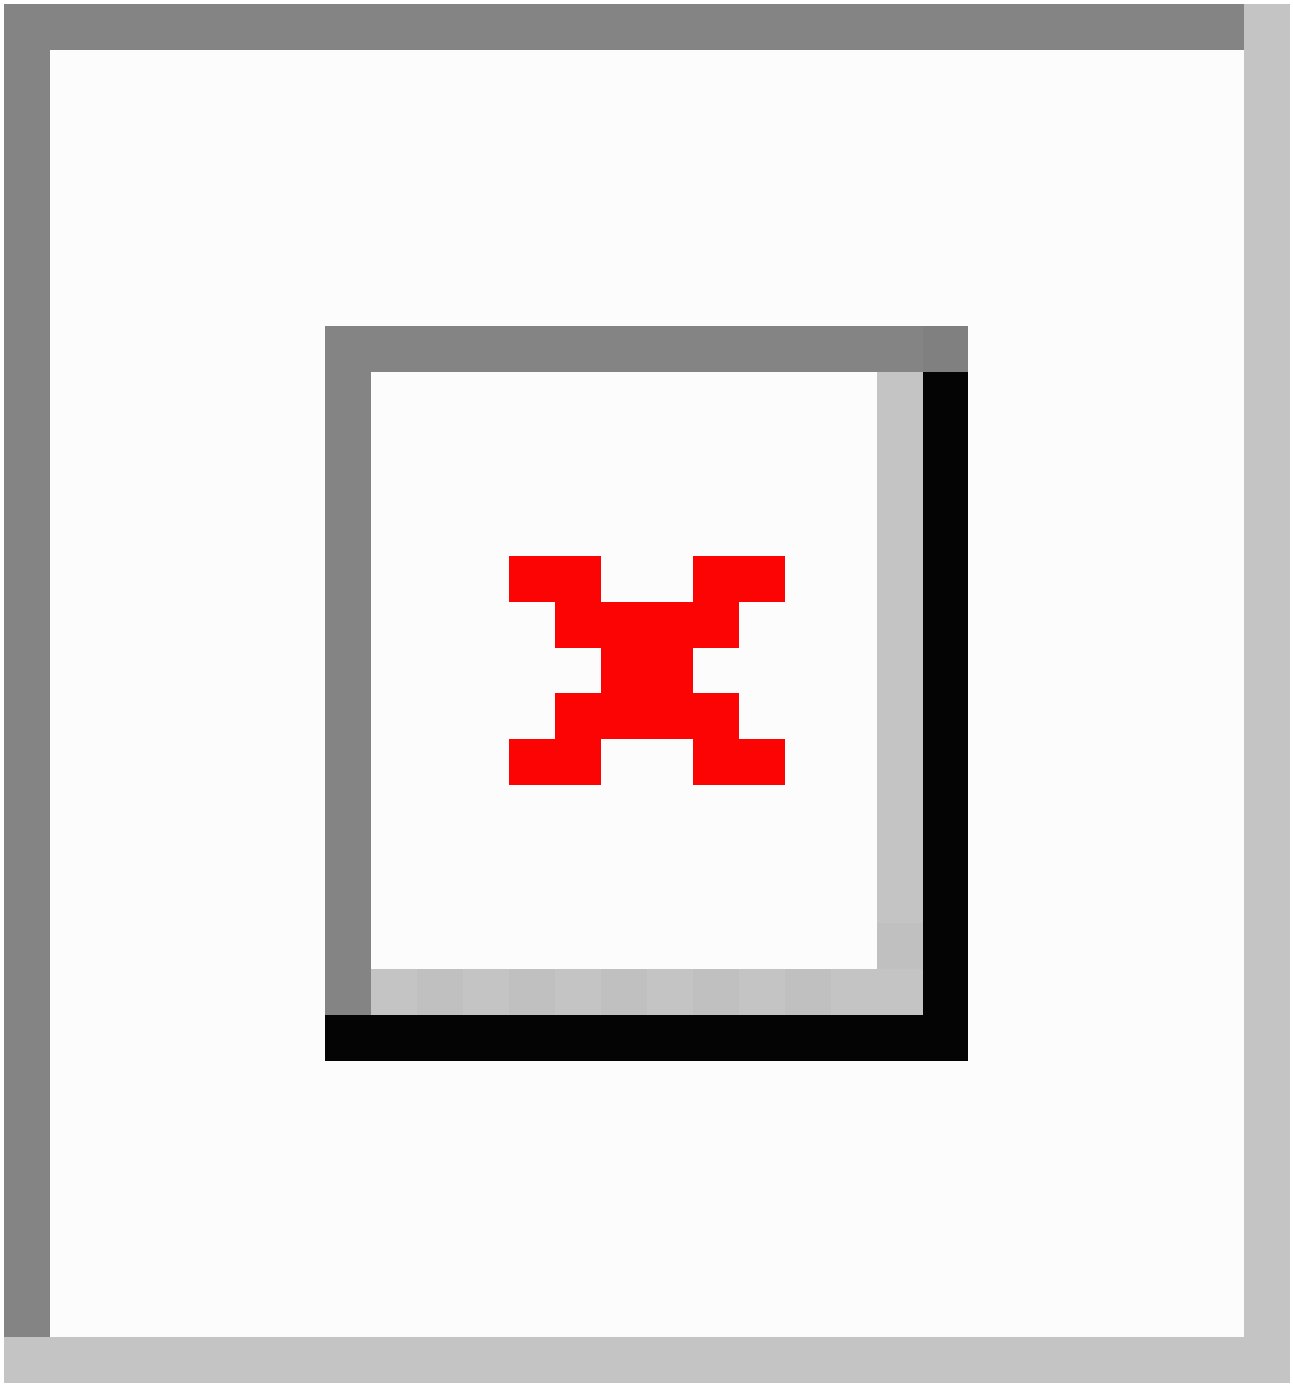
Methods

Deidentified Clinical Data Warehouse and PatientExploreR

UCSF EHR data were extracted using the SQL-based deidentified Clinical Data Warehouse (De-ID CDW) and PatientExploreR. The De-ID CDW is a deidentified database copy of high-value UCSF EHR data (Figure 1). De-ID CDW files are updated monthly, are not subject to Health Insurance Portability and Accountability Act (HIPAA) restrictions on research use, do not require institutional review board approval or an honest broker intermediary, and are available to the UCSF research community at no charge.

The De-ID CDW includes data from UCSF's Epic-based EHR tool and historical EHR data prior to Epic adoption. The De-ID CDW includes the following data elements from the Epic EHR at UCSF Health: patient demographic and geographic information, allergies, billing, coverage, diagnoses, encounters, immunizations, lab, medication orders, procedure orders, providers, clinical notes, and vitals.

Figure 1. Clinical data landscape. CDW: Clinical Data Warehouse; DB: database; De-ID: deidentified; OMOP: Observational Medical Outcomes Partnership; PACS: picture archiving and communication system; Pat Exp: PatientExploreR.



PatientExploreR is a user-friendly R Shiny application that enables rule-based mining of structured, clinical, patient-level interactive dynamic reports using Boolean operators and provides auto-generated visualization of clinical data. PatientExploreR's data pipeline comes from the De-ID CDW, and exploration of the EHR data requires no advanced programming skills, as PatientExploreR data can be queried and extracted in a web-based format.

Data Inclusion Criteria

For this study, we queried PatientExploreR to identify all adult patients (≥18 years of age) receiving primary care services for diabetes between January 1, 2018, to December 31, 2019. Primary care patients were defined as those who had completed two office visits with a primary care department on different dates of service and who had a documented encounter diagnosis of diabetes (type I or type II; *ICD-10-CM*: E10, E11) [12]. We excluded patients who were receiving only specialist care for diabetes as there may be systematic differences in patients receiving specialist care compared to primary care. Additionally, a specialist's documentation related to SDOH may differ from that of primary care physicians and be less generalizable [13].

EMERSE NLP Methods

EMERSE clinical notes are deidentified through automated machine redaction using a protected health information filter [14] (Figure 2). A visualization of the machine-redacted clinical notes data flow is provided in Figure 3. We used EMERSE to

extract clinical notes through a user-friendly interface [11]. We applied advanced built-in NLP query parsers implemented with JavaCC. The Lucene package enabled us to create our own rule-based approach queries through an application programming interface and provided parsing, tokenization features, and proximity searches [15]. We included clinical notes categorized as progress notes, telephone encounters, history and physical examinations, and assessment and plan notes.

Figure 2. Process of Philter deidentification software for University of California, San Francisco, clinical notes. DB: database; HIPAA: Health Insurance Portability and Accountability Act.

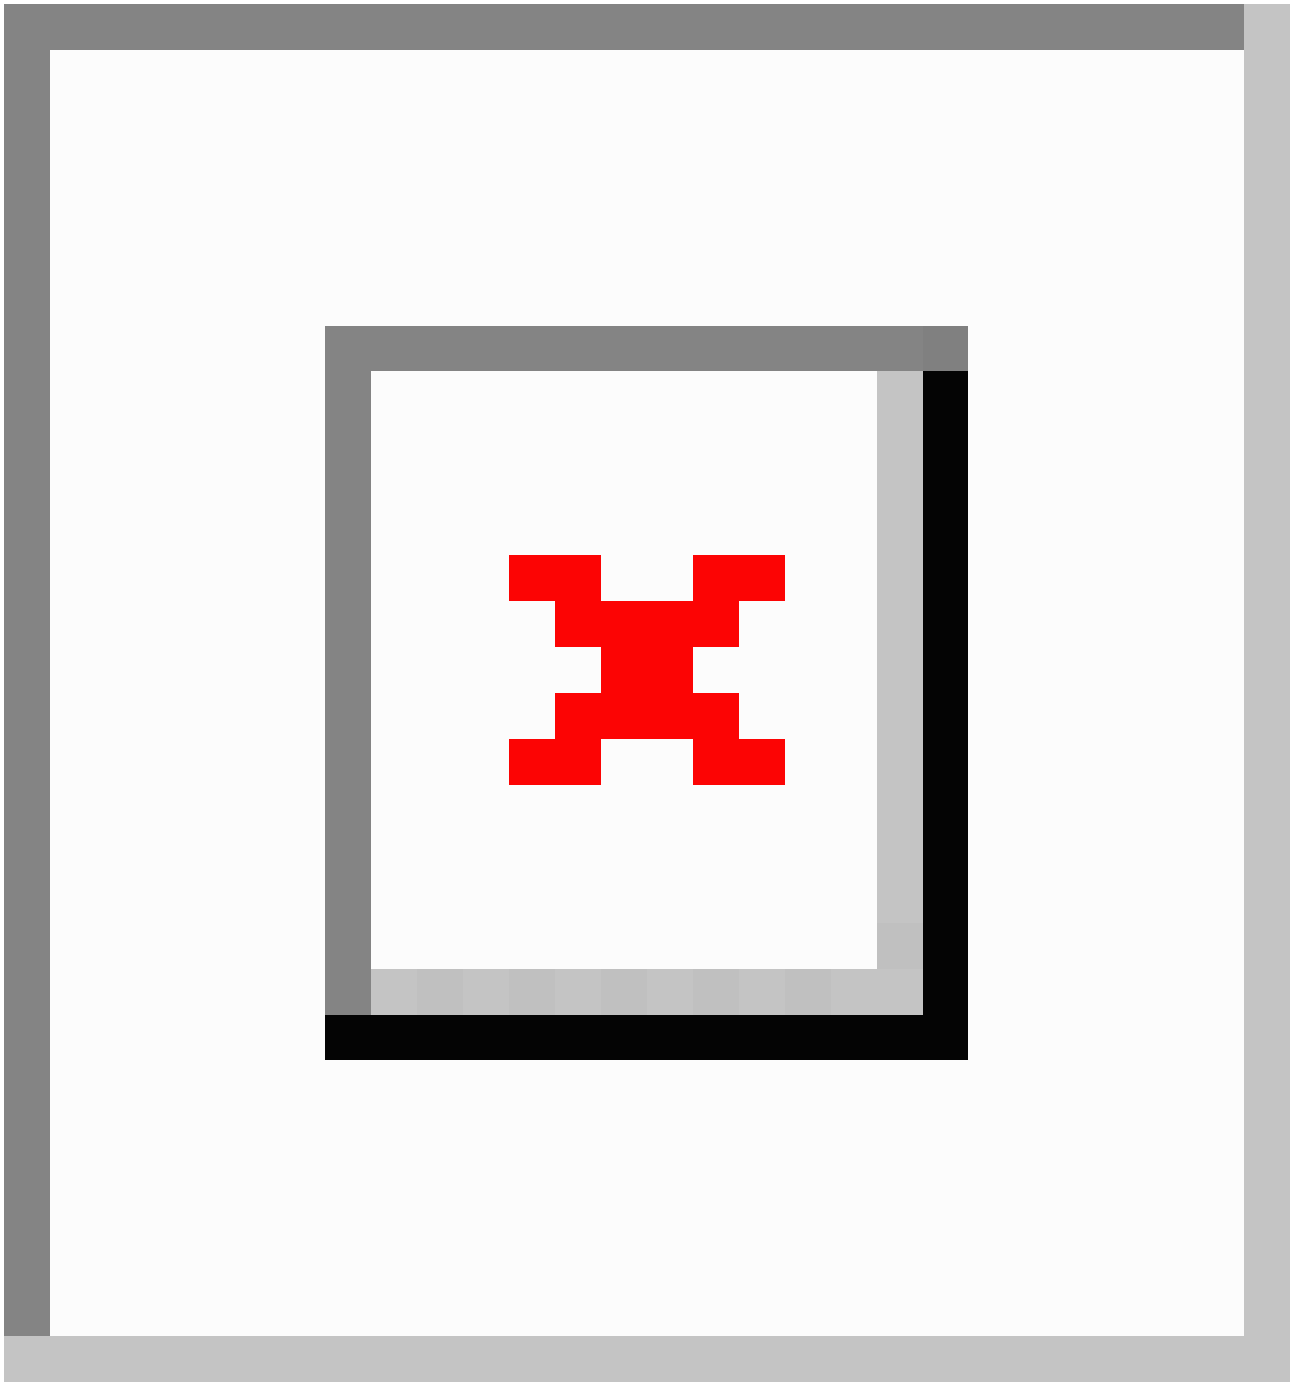


Figure 3. Schematic illustrating machine-redacted clinical notes data flow. SCP: secure copy protocol.

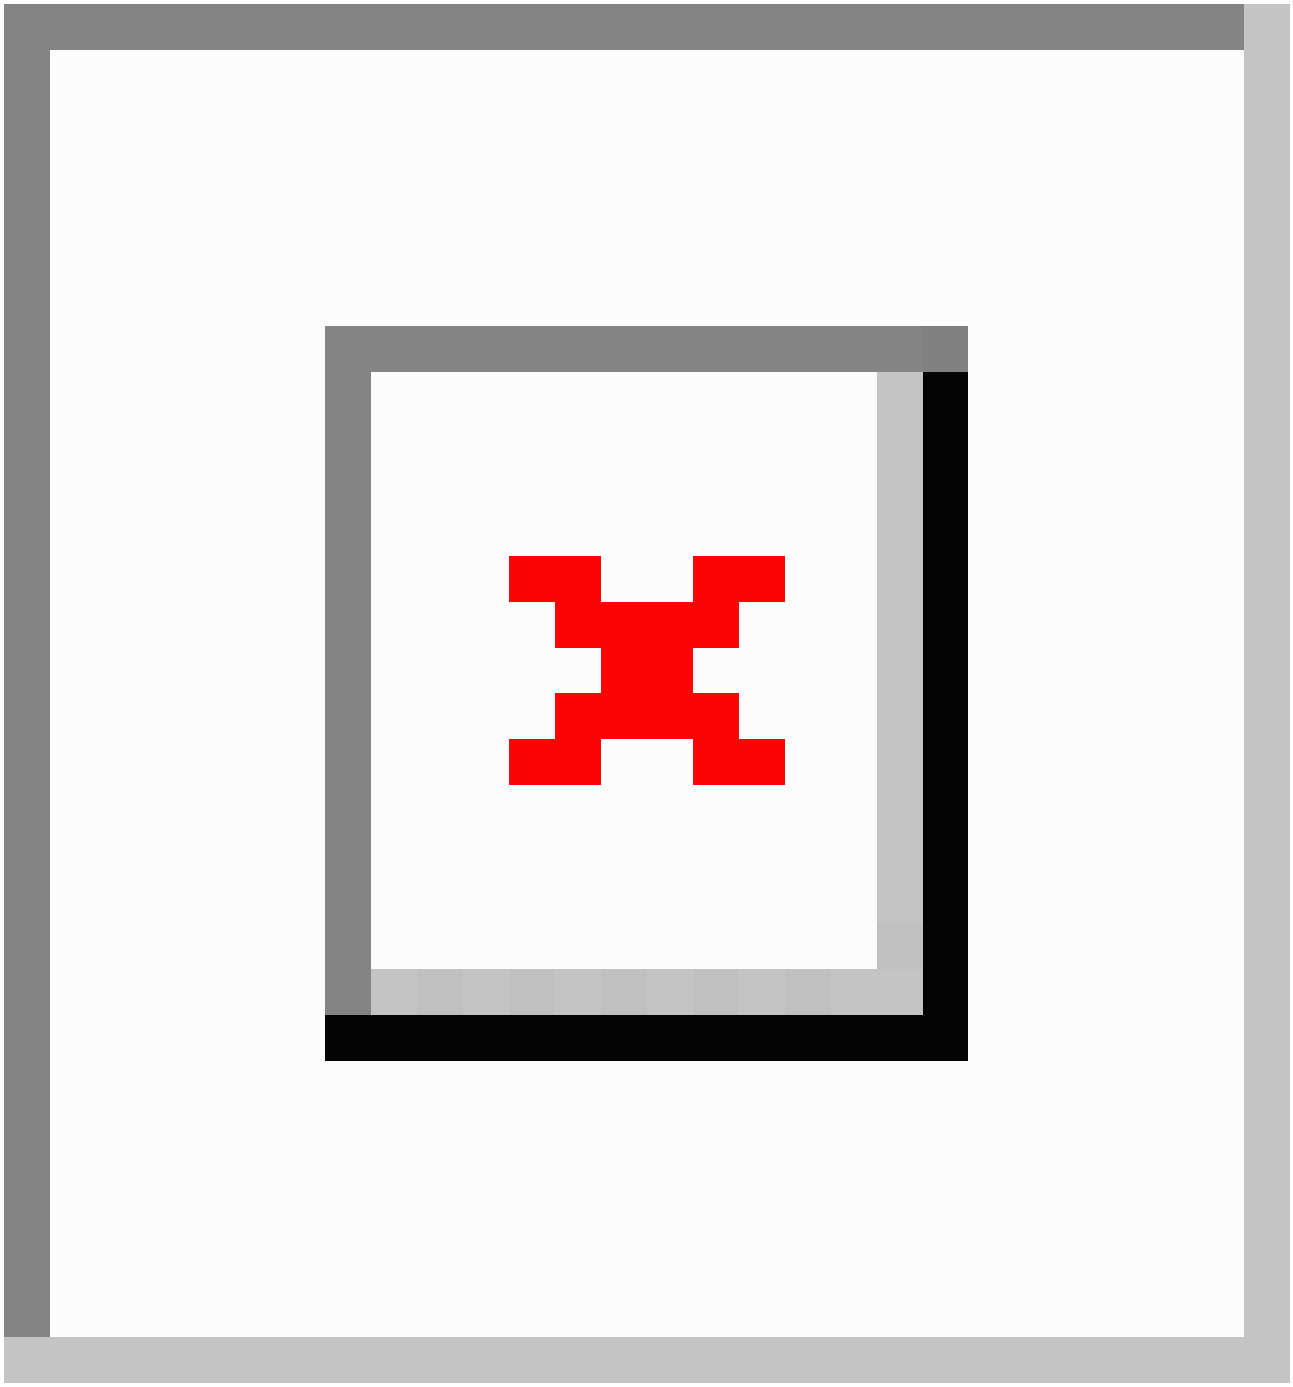
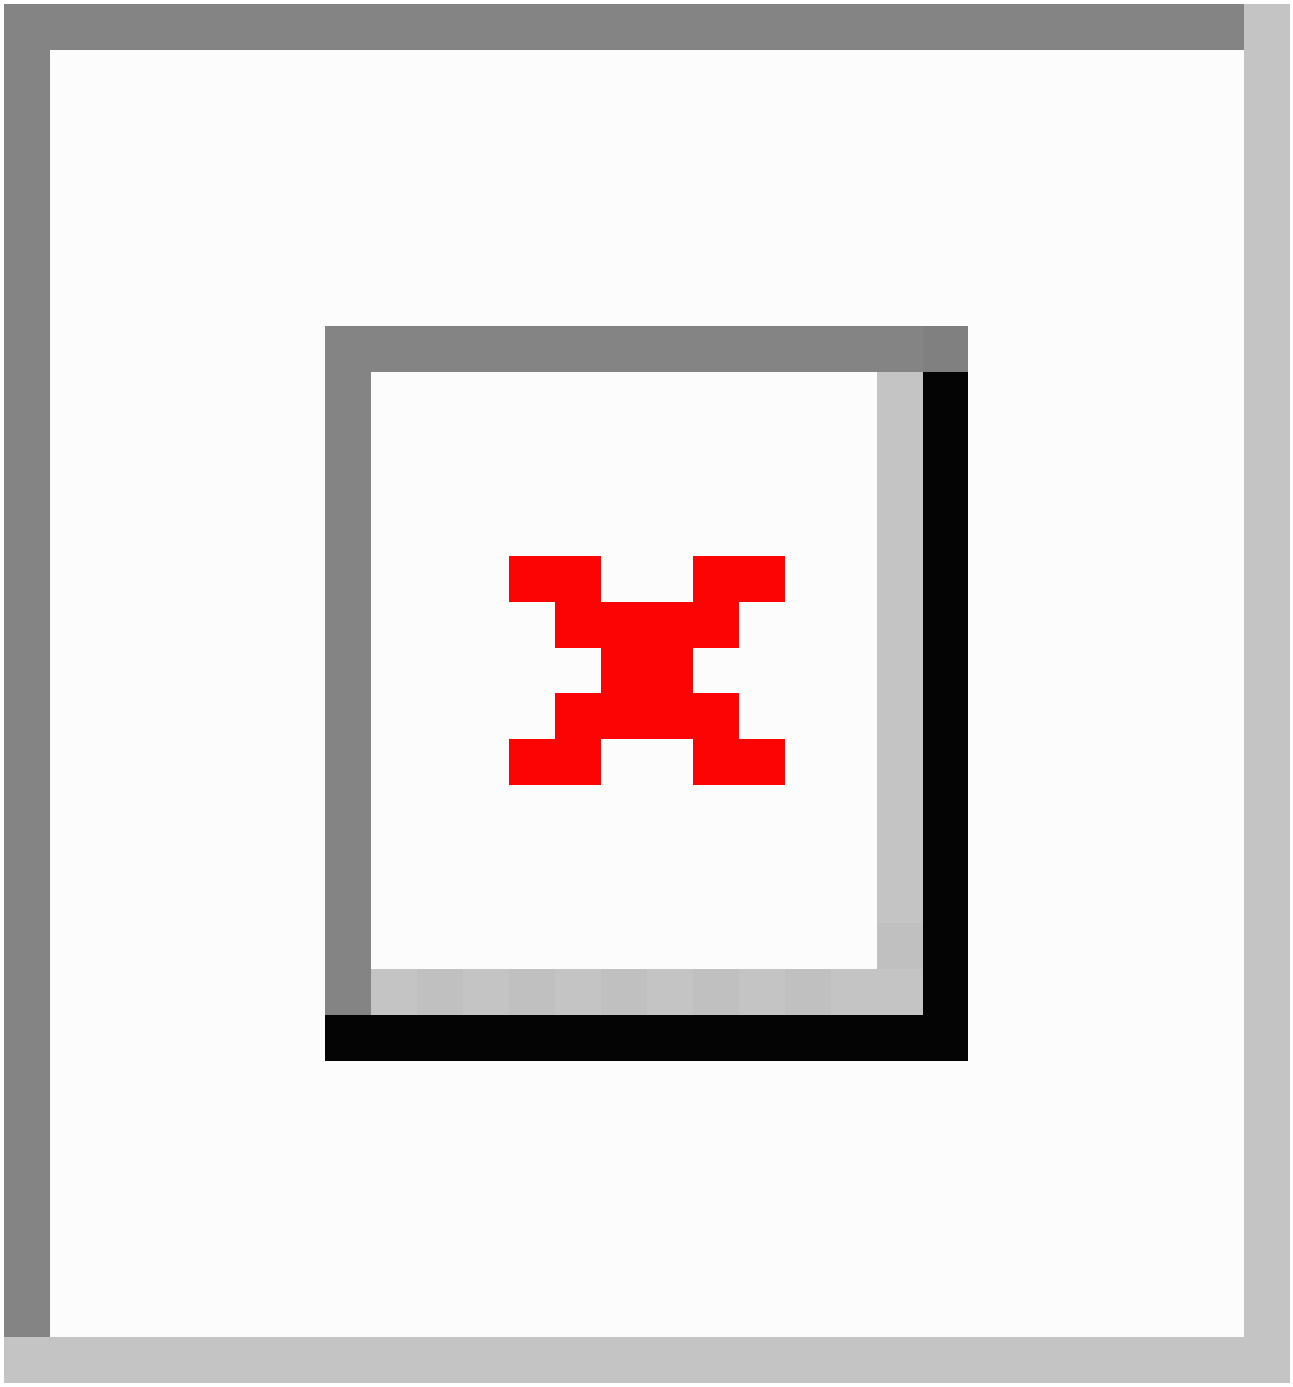


Text Corpus for NLP

For the same cohort of patients with diabetes identified within PatientExploreR, we then conducted a second exploration of SDOH documentation within the unstructured clinical notes (Figure 4). We linked the deidentified patient identifiers from PatientExploreR to the EMERSE platform, in which we were able to explore retracted clinical notes for the same patients during their primary care encounters within the same time period.

Figure 4. Study flow. CDW: Clinical Data Warehouse; DeID: deidentified; EMERSE: Electronic Medical Record Search Engine; MRN: medical record number; NLP: natural language processing.



To compare the SDOH ICD Compendium codes from the structured EHR data to the unstructured clinical notes, we first transformed the Compendium into a set of textual search terms and concepts that would emerge within the free-text sections of the physician's note. We used expert raters to develop a corpus using SDOH in the Compendium as a knowledge base as targets for the NLP text string mapping to find string stems, roots, and syntactic similarities in the clinical notes of patients with diabetes. To reduce false positives, we applied Boolean logic and proximity searches to create an exclusion term list within the NLP rule (Table 1). We determined a priori that the threshold to stop making changes to a rule was when it impacted less than 1% of the cohort.

Table . Natural language processing (NLP) rules.

SDOH[a]	NLP rule
Social connections/isolation	(“social isolation”~10th OR “socially isolated”~10th OR “feeling lonely”~10th OR “Loneliness” OR “isolation sad”~5) NOT (“no loneliness”~5 OR “not lonely”~5 OR “no social isolation” OR “denies loneliness”~4 OR “doesn't feel lonely” OR “isolation 14”~6 OR “can lead to loneliness and isolation” OR “isolation quarantine”~10th OR “isolation none”~5)

[a]SDOH: social determinants of health.

Validation

Two independent reviewers (SM and JA) manually assessed the clinical notes for each SDOH domain to validate the classification performance of the NLP rule. One reviewer (SM) manually reviewed 100% of the clinical notes from each SDOH domain to validate the NLP rule’s classification performance. Reviewers tagged the clinical note as a true positive if the narrative had at least one mention of the social risk factor associated with the respective SDOH domain (Table 2).

Table . Examples of true-positive and false-positive terminologies.

SDOH[a] domain	True-positive terminology	False-positive terminology
Social connections/ isolation	"Pt has difficulties with her mother and social isolation"	"She is deeply concerned about her son's social isolation"
Employment	"Currently unemployed"	"Unemployed son"
Housing	"Pt with unstable housing situation, homeless"	"Volunteers at the animal shelter"
Food insecurity	"Diet remains problem with severe food insecurity"	"Food insecurity: none"
Education	"Never went to school and cannot read"	"Cannot read fine print as well, notes older glasses work better at near"
Finance	"Pt has low income subsidy, financial difficulties"	"Withdrawn cognition: poverty of thought"
Stress	"Feeling very stressed"	"Wife is stressed or complaining"

[a]SDOH: social determinants of health.

A second reviewer (JA) conducted a 2-step validation process. First, all the patients with clinical notes tagged "positive" for SDOH social risk factors by SM were reviewed by JA to ascertain the observed proportional agreement. Second, we randomly sampled 10% of clinical notes from each SDOH domain to ascertain the interrater agreement between SM and JA.

Statistical Analysis

We use the Center for Medicaid Services *ICD-10* Z code groupings to calculate the prevalence of patients with SDOH documented within their structured data [16]. Our first goal was to understand SDOH documentation discrepancies between structured and unstructured clinical notes. Our second goal was to use a user-friendly informatics tool, EMERSE, to develop an NLP rule for each SDOH domain that was able to identify patients with clinical notes containing documentation of the SDOH domains. As part of the validation process, we calculated the proportion of observed agreement and Cohen kappa between the two independent reviewers for each SDOH domain (Multimedia Appendix 1).

Ethical Considerations

The institutional review board at the University of California San Francisco approved this study (IRB number: 18-25696).

Results

We identified 4283 adult (≥18 years of age) patients with 30,288 clinical notes receiving primary care for their diabetes (type I or type II; *ICD-10-CM*: E10, E11) at UCSF from January 1, 2018, to December 31, 2019. In the structured data, 16 (0.38%) patients had *ICD-10* Z60 codes for social connectionsisolation, 14 (0.33%) patients for stress, 4 (0.09%) patients for employment insecurity, 26 (0.61%) patients for housing insecurity, 39 (0.91%) patients for food insecurity, 4 (0.09%) patients for problems related to education, and 4 (0.09%) patients for financial insecurity (Table 3).

Table . Prevalence of patients with SDOH documentation in structured and unstructured data.

SDOH[a] (*ICD-10*[b] code)	Patients in structured data (n=4283), n (%)	Patients in unstructured data (n=4283), n (%)
Social connections/isolation (60.2, 60.4, 60.8)	16 (0.38)	197 (4.60)
Employment (56.0, 56.1, 56.2, 56.89, 56.9)	4 (0.09)	197 (4.60)
Housing (59.0, 59.1, 59.8)	26 (0.61)	111 (2.59)
Food (59.4, 59.41)	39 (0.91)	102 (2.38)
Education (55.0, 55.1, 55.2, 55.3, 55.4, 55.8, 55.9)	4 (0.09)	35 (0.82)
Finance (59.5, 59.6, 59.7)	4 (0.09)	113 (2.64)

[a]SDOH: social determinants of health.

[b] *ICD-10: International Classification of Diseases, Tenth Revision*

Social Connections/Isolation

Social connections/isolation (*ICD-10-CM* Z60) was defined as a lack of social connections or feelings of isolation or loneliness [10,16]. The NLP rule identified a total of 313 patients with documentation of social connections/isolation in their clinical notes. Of the 313 patients, 15 had a confirmed *ICD-10-CM* Z60 groupings diagnosis within their structured data, and 298 patients did not. A manual review of the clinical notes confirmed social connections/isolation problems for 197 (62.9%) of the 313 patients (Table 4).

Table . Manual review of clinical notes identified by the EMERSE NLP rules.

EMERSE[a] NLP[b] rule (+)	Manual review (+), n	Manual review (–), n	Total, n
Social connections/isolation	197	116	313
Employment	197	161	358
Housing	111	316	427
Food	102	55	157
Education	35	36	71
Finance	113	98	211
Stress	222	288	510

[a]EMERSE: Electronic Medical Record Search Engine.

[b]NLP: natural language processing.

Employment Security

Employment insecurity (*ICD-10-CM* Z56) was defined as problems related to employment, unemployment, job loss, and work-related stressors [10,16]. The NLP rule identified a total of 358 patients with documentation of employment insecurity in their clinical notes. Of the 358 patients, 3 had a confirmed *ICD-10-CM* Z56 diagnosis and 355 patients did not. One patient did not have any clinical notes registered in the EMERSE system. Among 358 patients identified by the NLP rule, a manual review of the clinical notes confirmed problems related to employment for 197 (55%) patients (Table 4).

Housing Security and Quality

This category included homelessness, problems with eviction, unsafe housing conditions (eg, mold), and unstable housing using the *ICD-10-CM* Z59 groupings [16]. The EMERSE NLP rule identified a total of 448 patients with documentation of housing insecurity/poor quality in their clinical notes. Of the 448 patients, 23 had confirmed Z59 diagnosis in their structured data and 425 patients did not. Among the 448 patients identified by the NLP rule, a manual review of the clinical notes confirmed problems with housing security and quality for 111 (24.8%) patients (Table 4).

Food Security

Food insecurity (*ICD-10-CM* Z59.4) was defined as a lack of adequate food or intermittent access to food [10,16]. The NLP rule identified a total of 157 patients with documentation of food insecurity in their clinical notes. Of the 157 patients, 39 had a confirmed *ICD-10-CM* Z59.4 or *ICD-10-CM* Z59.41 diagnosis code in their structured data and 118 patients did not. Among 118 patients identified by the NLP rule, a manual review of the clinical notes confirmed food insecurity for 102 (65%) patients (Table 4).

Education

The education category included patients with problems related to education, unable to read/write, or no formal education using the *ICD-10-CM* Z55 grouping [16]. The NLP rule identified a total of 71 patients with documentation of problems related to education in their clinical notes. Of the 71 patients, 4 had a confirmed *ICD-10* Z55 diagnosis code in their structured data and 67 did not. Among the 71 patients identified by the NLP rule, a manual review of the clinical notes confirmed problems related to education for 35 (49.3%) patients (Table 4).

Finance

Financial insecurity (*ICD-10* Z59.5) was defined as patients reporting financial burdens, low income, poverty, or no income [10,16]. The NLP identified a total of 211 patients with documentation of financial insecurity in their clinical notes. Of the 211 patients, 4 had a confirmed *ICD-10* Z59.5, *ICD-10* Z59.6, or *ICD-10* Z59.7 diagnosis code in their structured data and 207 did not. Among the 211 patients identified by the NLP rule, a manual review of the clinical notes confirmed financial insecurity for 113 (53.6%) patients (Table 4).

Stress

Stress was defined as the lack of relaxation and leisure, and difficulties with life management [10,16]. The NLP rule identified a total of 510 patients with documentation of stress in their clinical notes. Of the 510 patients, 11 had a confirmed *ICD-10* Z63.7, *ICD-10* Z63.79, *ICD-10* Z73.2, or *ICD-10* Z73.3 diagnosis code in their structured data and 499 did not. Among the 510 patients identified by the NLP rule, a manual review of the clinical notes confirmed stress for 222 (43.5%) patients (Table 4).

Interrater Reliability

Observed proportional agreement between both reviewers ranged between 0.98 to 1 for the SDOH domains. The observed proportional agreement refers to the clinical notes in which both reviewers one and two have flagged as a positive for a social risk factor. Cohen kappa ranged from 0.21 to 1 (Multimedia Appendix 1). The validation process allowed us to understand the performance of the NLP rule's classification. Overall, we discovered how much more the unstructured data yields about a patient's SDOH in comparison to structured data.

Discussion

Findings

We included seven SDOH domains—social connections/isolation, problems related to employment, financial insecurity, housing insecurity, food insecurity, education, and stress—and conducted a manual review of clinical notes to validate the SDOH identification. Our study identified a greater

proportion of individuals with diabetes who have an SDOH documented in their EHR when including clinical note data instead of structured data fields alone. In our sample, clinicians frequently captured information in their clinical notes about SDOH in the daily lives of their patients with diabetes, but they did not transfer it to the structured data field on the record, which is a core implementation consideration as the federal government and other agencies are looking to incentivize SDOH screening in the near future [17]. These documentation gaps may contribute to an underestimation of the overall impact of social (including material) and psychological factors on the health outcomes of people with diabetes that contribute to ongoing health disparities.

To the extent that information about SDOH is already being captured by clinicians in unstructured fields, informatics tools like NLP might be used to decrease new clinician structured field documentation burdens. The identification and classification of patients with SDOH using NLP methods is a complex process that involves the understanding of clinical note semantics, lexicon development, categorization, and manual validation.

There was a wide variation in the prevalence of SDOH elements in the unstructured data versus the structured data. The range of variation in the unstructured data depended on the SDOH domain—from 111 (24.8%) patients for housing insecurity compared to 197 (62.9%) patients for social connections/isolation. The findings highlight that future descriptive research should combine the usage of structured and unstructured data.

Comparability

Our study findings are consistent with prior studies that found that EHR structured data underestimates SDOH. These studies found that less than 1% of cohorts had respective *ICD-10-CM* diagnosis codes for SDOH [18-21] documentation. Previous studies have shown that documentation about SDOH such as housing insecurity or lack of social connections or isolation, is 2-fold higher in unstructured data than in structured data [21-24]. However, none of these studies focused on patients with chronic health conditions like diabetes.

Strengths and Limitations

To our knowledge, this is the first study to use PatientExploreR and EMERSE, two high-throughput tools, to identify SDOH mapping in structured and unstructured data for a population of patients with a specific chronic health condition. Neither tool requires users to have prior expertise in programming skills, which makes it accessible to a wider audience of clinicians and researchers. We used the compendium of medical terminology codes for social risk factors as a new data source to generate a corpus. The wider application of this adaptable technique may help to more robustly identify social factors that influence disease management and outcomes for a range of diseases and conditions and inform clinical decision-making.

There are several limitations of this study. This study was conducted using patient-level data from the UCSF medical system, which may limit external validity to the general population of patients with diabetes [25]. However, future work includes validating our NLP rules for a different patient population within the UCSF medical system. It is important to note that our inclusion criteria required patients to have a diagnosis code for diabetes, and this may have missed patients who had diabetes detected via medications or laboratory testing. Although we validated the NLP rule classification performance by manually reviewing the clinical notes that EMERSE deemed as containing SDOH documentation, we were unable to manually validate the clinical notes that our NLP rule did not pick up. This is a limitation as we were unable to calculate sensitivity, specificity, and common metrics to understand our NLP rule's performance. Our NLP rules did not perform well for the following SDOH domains as we identified more false positives than true positives: housing security and quality, financial insecurity, and stress. This warrants further optimization to understand how these SDOHs are characterized within the clinical notes. Some SDOH domains may be more nuanced in terms of the language providers use to note them. This study discovered many false positives from the cases identified by the EMERSE NLP rule. High rates of false positives warrant further optimization of our NLP rule and understanding semantic differences of how SDOH are characterized within patient clinical notes. Future work will focus on enhancing the NLP rule and significant curation. Given the descriptive nature of this study, we did not assess the effects of the temporality of a patient's SDOH, but we conducted a chart review to validate and assess the patient history of SDOH to the extent possible in unstructured notes.

Despite these limitations, this method has proven useful for clinicians and researchers interested in high-throughput ways to capture additional SDOH information related to patients to inform clinical decision-making. The ability to identify patients who are at risk via a streamlined high-throughput method can prevent downstream health burdens of social risk factors. Future work could focus on developing a rule-based machine learning algorithm to create and refine NLP rules associated with the other SDOH domains (eg, inadequate access to health care, incarceration, safety, and transportation barriers). Additionally, it is important for future work to understand the semantic variations that are used to characterize SDOH in clinical notes. Future research in this area to understand whether the performance of the NLP rule differed by certain patient characteristics (eg, age, race, and sex) would be valuable.

Conclusion

Using unstructured data of patients with diabetes via EMERSE, we discovered more patient information related to a set of SDOH than we identified using structured data alone. Application of this technique, and future investments in similar user-friendly tools and infrastructure for capturing information from unstructured EHR data, may help to identify the range of social conditions that influence patients' disease experience and inform clinical decision-making. If these data lead to improvements in clinical care and connections to social services, they are likely to result in improved patient health outcomes and, ideally, contribute to reducing health disparities.

Abstract

Background: Clinical electronic medical records (EMRs) contain important information on patients' anatomy, symptoms, examinations, diagnoses, and medications. Large-scale mining of rich medical information from EMRs will provide notable reference value for medical research. With the complexity of Chinese grammar and blurred boundaries of Chinese words, Chinese clinical named entity recognition (CNER) remains a notable challenge. Follow-up tasks such as medical entity structuring, medical entity standardization, medical entity relationship extraction, and medical knowledge graph construction largely depend on medical named entity recognition effects. A promising CNER result would provide reliable support for building domain knowledge graphs, knowledge bases, and knowledge retrieval systems. Furthermore, it would provide research ideas for scientists and medical decision-making references for doctors and even guide patients on disease and health management. Therefore, obtaining excellent CNER results is essential.

Objective: We aimed to propose a Chinese CNER method to learn semantics-enriched representations for comprehensively enhancing machines to understand deep semantic information of EMRs by using multisemantic features, which makes medical information more readable and understandable.

Methods: First, we used Robustly Optimized Bidirectional Encoder Representation from Transformers Pretraining Approach Whole Word Masking (RoBERTa-wwm) with dynamic fusion and Chinese character features, including 5-stroke code, Zheng code, phonological code, and stroke code, extracted by 1-dimensional convolutional neural networks (CNNs) to obtain fine-grained semantic features of Chinese characters. Subsequently, we converted Chinese characters into square images to obtain Chinese character image features from another modality by using a 2-dimensional CNN. Finally, we input multisemantic features into Bidirectional Long Short-Term Memory with Conditional Random Fields to achieve Chinese CNER. The effectiveness of our model was compared with that of the baseline and existing research models, and the features involved in the model were ablated and analyzed to verify the model's effectiveness.

Results: We collected 1379 Yidu-S4K EMRs containing 23,655 entities in 6 categories and 2007 self-annotated EMRs containing 118,643 entities in 7 categories. The experiments showed that our model outperformed the comparison experiments, with F_1-scores of 89.28% and 84.61% on the Yidu-S4K and self-annotated data sets, respectively. The results of the ablation analysis demonstrated that each feature and method we used could improve the entity recognition ability.

Conclusions: Our proposed CNER method would mine the richer deep semantic information in EMRs by multisemantic embedding using RoBERTa-wwm and CNNs, enhancing the semantic recognition of characters at different granularity levels

and improving the generalization capability of the method by achieving information complementarity among different semantic features, thus making the machine semantically understand EMRs and improving the CNER task accuracy.

Introduction

Background

Abundant medical data have been accumulated since the development of the hospital information system, among which the electronic medical records (EMRs) contain information closely related to patients' diagnosis and treatment processes [1]. As important records of patients' medical activities, effective extraction and use of the medical information contained in EMRs could provide clinical decision-making support for doctors and realize personalized medical guidance and health management for patients. It could also help biomedical researchers discover the tacit medical knowledge, thus providing ideas for studies of the association between diseases, the relationship between symptoms, the prediction of diseases and therapies, complication prediction, comorbidity analysis, etc. The medical information would be rapidly extracted from the unstructured EMRs through named entity recognition (NER). NER is a basic task of natural language processing, which will lay the foundation for the construction of medical knowledge graphs, medical knowledge bases, and so on by steps such as medical entity structuring, medical entity standardization, and medical entity relationship extraction. It will also provide fundamental support for practical application scenarios such as medical knowledge retrieval systems, clinical decision support systems, clinical event extraction, and so on [2,3].

Clinical NER (CNER) refers to the recognition of entities such as anatomy, disease, symptoms, clinical examination, medication, surgical procedure, and so on from EMRs [4,5]. Chinese CNER is more difficult than English NER for several reasons. First, Chinese words lack space segmentation and have blurred boundaries. Second, the composition of a Chinese entity is complex and may contain various figures, letters, and abbreviations. Third, Chinese grammar is complicated, and the same word may represent different entity types in different contexts. Therefore, Chinese CNER remains a research focus.

Recently, the features of radicals for Chinese characters have been widely used to improve the efficiency of different Chinese natural language processing tasks [6-8]. Chinese characters, known for thousands of years, are highly developed morpheme scripts that are still used worldwide with unique ideology [9]. Chinese characters include single-component and multiple-component characters. A single-component character cannot be divided, for example, "心 (heart)," "手 (hand)," and "口 (mouth)," and so on; whereas a multiple-component character is composed of basic components, accounting for >90% of Chinese characters [10], for example, the radical for "呕 (vomit)" and "吐 (vomit)" is "口 (mouth)," and the radical for "肿 (swelling)" and "胀 (swelling)" is "月 (month)," which refers to meat or organs in ancient times. Chinese characters are divided into associative compound characters, indicative characters, pictographic characters, and picto-phonetic characters based on their characteristics. In addition, Chinese characters are also called square characters, as they are square, and there are 8 structures of Chinese characters that are subdivided based on their intrinsic shape and construction. Therefore, Chinese characters contain rich deep semantic information. Applying radicals, phonological codes, shape structures, and other features would help to improve Chinese CNER accuracy.

The contributions of this study are as follows: (1) using pretrained language model (PLM) Robustly Optimized Bidirectional Encoder Representation from Transformers Pretraining Approach Whole Word Masking (RoBERTa-wwm) with a dynamic fusion transformer layer to obtain the semantic features of Chinese characters; (2) using CNNs for extracting the radicals and picto-phonetic features of Chinese characters through the 5-stroke code, Zheng code, phonological code, and stroke code; (3) converting Chinese characters into square images, extracting Chinese character image features from another modality by CNNs, and deeply capturing the pictographic characteristics of Chinese characters; and (4) improving the semantic recognition ability of the model at different levels of granularity, achieving information complementarity between different semantic features, and improving the effect and generalization ability of the model based on multisemantic features.

Related Works

Medical NER

In recent decades, the medical NER is still a research focus. Medical NER research has 3 main development stages as follows: based on dictionaries and rules, based on statistical machine learning, and based on deep learning.

The dictionary-based [11-13] methods need to construct a domain dictionary in advance to achieve medical NER by matching algorithms. The accuracy of this method is relatively higher. However, it may be affected by the large number, strong specialization, and high complexity of Chinese medical entities. In addition, medical terminologies are updated quickly with the rapid development of the medical field, and the lack of new terminologies will also affect medical NER accuracy. The rule-based [14,15] methods need experts in a particular field to formulate the rule templates based on information such as context grammar and structure. However, the rules are poorly universal in different fields. The methods based on dictionaries and rules [16-18] are poorly generalized, time-consuming, and

objective, as much time and labor are required. Therefore, many scholars have gradually applied methods based on statistical machine learning on medical NER. The commonly used methods include maximum entropy [19], support vector machine [20,21], hidden Markov model [22,23], and conditional random fields (CRF) [24,25]. However, these methods rely on large-scale annotation data sets [26] and manual feature selection [13,27]. Moreover, the quality of the selected features will directly affect the medical NER results.

With the continuous development of deep learning, Cocos et al [28] found that deep learning has advantages over traditional machine learning. It can automatically extract the characteristics of various levels and reduce the subjectivity of artificial feature selection. This thereby improves the result accuracy. The commonly used deep learning models include convolutional neural networks (CNNs) [29], recurrent neural networks [30], long short-term memory (LSTM) [31], Word to Vector (Word2Vec) [32], Bidirectional Encoder Representation from Transformers (BERT) [33], and so on. However, fully extracting the data features by using a neural network alone is challenging. Most scholars took Long LSTM-CRF as the main framework to make up for the medical NER deficiency using a single neural network [34]. The Bidirectional LSTM-CRF (BiLSTM-CRF) [35] model was then developed. This model could better capture contextual information as an important milestone in medical NER and has been widely used in the medical field [36,37]. To improve the ability to capture details and extract features of medical NER models, many studies added Word2Vec with static representation [38], Global Vectors for Word Representation [39] with static representation, Embeddings from Language Models (ELMo) [40,41] with dynamic representation, CNN [42], and attention mechanism [43] to the BiLSTM-CRF model. Some studies [44,45] have shown that the application of the BiLSTM-CRF model combined with the word vector generated by BERT could significantly improve medical NER accuracy. BERT provided a more accurate word representation and achieved better task results than traditional word vector methods. As per the specialty of medicine and the characteristics of Chinese characters involved, the clinical dictionaries, root-level features, parts of speech, radicals, and phonological codes have been added in the BiLSTM-CRF model in some studies [46-51] for improving Chinese CNER performance.

PLMs Technique

PLMs are pretrained on a large-scale corpus to obtain prior semantic knowledge from unlabeled text and improve the effectiveness of different downstream tasks. The word vector generated by a bidirectional language model BERT with stacked transformer substructures contains not only the preliminary information from the corpus training but also the encoded contextual information. Some robust versions of BERT have been constructed since BERT was proposed in 2018. For example, the RoBERTa model [52], which replaces the static (MASK) strategy with a dynamic (MASK) strategy, and the words (MASK) in each sequence dynamically change in different epoch trainings. In addition, the RoBERTa model is retrained with bigger batches and longer sequences, and the next-sentence prediction task, which is not related to the downstream task, is canceled during the pretraining. Compared with the BERT model, the RoBERTa model performs better on multiple natural language processing tasks. However, the character-level RoBERTa model does not fit the Chinese natural language processing, as the different segmentation modes between Chinese and English words suffer a limitation of lacking word information. Then, the word-level RoBERTa-wwm model [53] was proposed based on Chinese characteristics, which greatly improved the text representation ability in Chinese [54].

Methods

Data Collection

The Yidu-S4K data set, shared publicly by YiduCloud, is derived from the Chinese EMRs entity recognition task of the China Conference on Knowledge Graph and Semantic Computing 2019 [55]. It contains 1379 EMRs with 6 entity types, including Disease (medically defined disease and diagnoses made by physicians based on etiology, pathophysiology, pathological classification, and clinical staging); Anatomy (anatomical parts of the body where disease, signs, and symptoms occurred); Laboratory (physical or chemical tests performed by the laboratory department in clinical work); Image (imaging [x-ray, computed tomography, magnetic resonance imaging, positron emission tomography-computed tomography, etc], ultrasound, and electrocardiogram); Medicine (specific chemical substances used for disease treatment); and Operation (treatments focused on surgery such as excision and suturing performed by the physician locally on the patient's body).

Self-annotated EMR data, collected from publicly desensitized Chinese EMR websites [56], contain 2007 EMRs. As per the Terminology of Clinical Medicine issued by the National Health Commission of the People's Republic of China, we used the BIO (B signifies the beginning of an entity, I signifies that the word is inside an entity, and O signifies that the word is just a regular word outside of an entity) tagging method to pretag 7 entity types in the EMRs, including Disease (same definition as the Yidu-S4K data set); Symptoms (abnormal manifestations as perceived by the sensory organs of patients and physicians); Anatomy (same definition as the Yidu-S4K data set); Examination (includes imaging examinations and laboratory tests mentioned in the Yidu-S4K data set); Instrument (apparatus and mechanical equipment for disease prevention, diagnosis, treatment, health care, and rehabilitation); Medicine (the same definition as the Yidu-S4K data set); and Operation (same definition as the Yidu-S4K data set). Subsequently, 4 medical experts manually checked and corrected the tags. The interclass correlation efficient consistency test revealed that we had good annotation quality.

The ratio of the training set to the test set of the EMRs was 7:3. The Yidu-S4K data set was preprovided with 1000 EMRs as the training data sets (1000/1379, 72.52%) and 379 EMRs as the test data sets (379/1379, 27.48%). The self-annotated data set was divided by randomization into 1401 EMRs as the training data sets (1401/2007, 69.81%) and 379 EMRs as the

test data sets (606/2007, 30.19%). Table 1 lists the details of the different types of entities in the 2 EMR data sets.

Table 1. The statistics of different types of entities in 2 electronic medical record data sets

Data sets and entity type	Training set, n	Test set, n
Yidu-S4K		
Disease	4212	1323

Ethical Considerations

Ethics approval was not required because the patient's private information was masked by the website.

Experiments Settings

In this study, all the experiments were conducted by Python [57] and PyTorch [58]. Table 2 shows the experimental parameters. The experiments used *RoBERTa-wwm-ext-large* model pretraining data, optimized parameters using Adam W, dropout to prevent overfitting, the batch size of 32, BiLSTM hidden layer dimension of 768, maximum sequence length of 510, RoBERTa-wwm dimension of 768, semantic feature dimension of 124, and image feature dimension of 128. On 2 Chinese CNER data sets, we used the same parameters.

Table 2. Parameter settings.

Parameter	Value
Dropout	0.5
Epoch	Optimization
Optimization	Adam W
Learning rate	0.0001
Batch size	32
BiLSTM[a] hidden layer	768
Max_len	510
RoBERTa-wwm[b] feature dimension	768
Semantic feature dimension	124
Image feature dimension	128

[a]BiLSTM: Bidirectional Long Short-Term Memory.

[b]RoBERTa-wwm: Robustly Optimized Bidirectional Encoder Representation from Transformers Pretraining Approach Whole Word Masking.

Evaluation Metrics

The experiments used precision, recall, and F_1-score to evaluate the model performance. The formulas for each index are as follows:

$$Precision = TP / (TP + FP) \quad (1)$$

$$Recall = TP / (TP + FN) \quad (2)$$

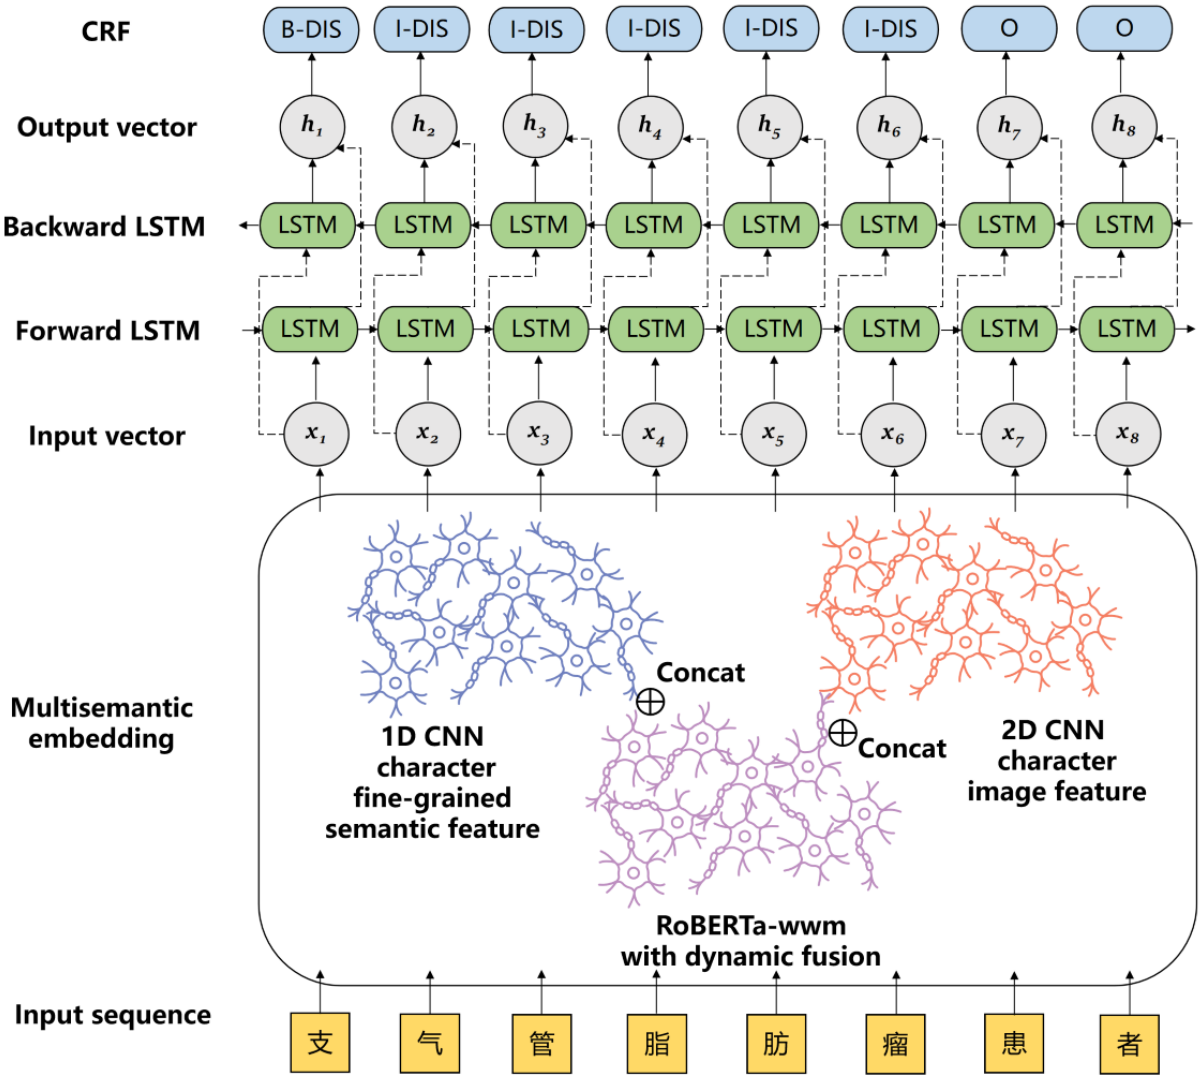
$$F_1\text{-}score = (2 \times precision \times recall) / (precision + recall) \quad (3)$$

where precision is the proportion of positive samples in all samples predicted to be positive; recall is the proportion of positive samples in all positive samples; F_1-score is the harmonic mean of precision and recall; true positive (TP) is the number of positive samples predicted to be positive, that is, the number of correctly recognized entities; false positive (FP) is the number of negative samples predicted to be negative, that is, the number of incorrectly recognized other texts as entities; and false negative (FN) is the number of positive samples predicted to be negative, that is, the number of unrecognized entities.

Model Overview

In this study, we proposed a CNER model based on multisemantic features, as shown in Figure 1. First, we used RoBERTa-wwm, the PLM, to obtain the embedded representation at the word level. Dynamic fusion is performed on the semantic representation generated by each transformer layer to make full use of RoBERTa-wwm representation information. Then, the embedded Chinese character fine-grained feature representation, including the 5-stroke code, Zheng code, phonological code, and stroke code, is extracted by 1D CNN, whereas the embedded Chinese character image representation is extracted from another modality by 2D CNN, with the Chinese characters as square images. Finally, the above multisemantic vectors were input into the BiLSTM layer for encoding and were decoded in the CRF layer to predict the tag probability.

Figure 1. The main architecture of our model. 1D CNN: 1D convolutional neural network; 2D CNN: 2D convolutional neural network; B-DIS: beginning of disease entity; CRF: conditional random fields; h: embedding of output character; I-DIS: inside of disease entity; LSTM: long short-term memory; O: other type; RoBERTa-wwm: Robustly Optimized Bidirectional Encoder Representation from Transformers Pretraining Approach Whole Word Masking; x: embedding of input character.



Multisemantic Embedding Layer

Overview

Many Chinese characters have retained their original connotations, as they originated from pictographic characters in ancient times. Moreover, the inherent fine-grained character information contained in Chinese characters often implies more additional semantic information. Accordingly, we obtained the 5-stroke code, Zheng code, phonological code, and stroke code information, as shown in Table 3, of the Chinese characters from ZDIC [59] and embedded them in the model. In addition, Chinese characters are squares, and different shapes and structures express different types of information. Characters with similar intrinsic characteristics may have similar meanings. Therefore, we took Chinese characters as graphics and obtained semantic information on Chinese character connotations from another modality. Multisemantics could obtain information comprehensively and learn a better feature representation by making use of information complementarity and eliminating the redundancy among different semantic features compared with a single-semantic feature, resulting in a more generalized model.

As shown in Figure 2, we converted the Chinese character 5-stroke code, Zheng code, phonological code, and stroke code into one-hot vector encoding and interpreted the Chinese characters as 14×14 images. Subsequently, we used a 2-layer CNN deeply extracting the Chinese character multisemantic features. Through the Convolution layer with the *ReLU* activation function, max pooling layer, and dense layer, we obtained the multisemantic vectors that could be embedded in the BiLSTM layer.

Table 3. Example of Chinese characters' coded information from ZDIC.

Character	5-stroke code	Zheng code	Phonological code	Stroke code
呕 (vomit)	kaqy	jhos	ǒu	2,511,345
吐 (vomit)	kfg	jbvv	tù	251,121
肿 (swelling)	ekhh	qji	zhǒng	35,112,512
胀 (swelling)	etay	qch	zhàng	35,113,154
心 (heart)	nyny	wz	xīn	4544
手 (hand)	rtgh	md	shǒu	3112

Figure 2. The process of obtaining Chinese character multisemantic features by convolutional neural network. RoBERTa-wwm With Dynamic Fusion

When RoBERTa-wwm pretrains the corpus, it is segmented on the language technology platform established by the Harbin Institute of Technology based on Wikipedia content in Chinese, which can provide a basis for achieving wwm. As shown in Figure 3, the word "支气管 (bronchi)" in the RoBERTa-wwm model is completely masked by random wwm, whereas only single characters can be randomly masked in the BERT model, for example, only 1 character "气 (gases)" was masked in the word "支气管 (bronchi)." Thus, the RoBERTa-wwm model can learn the word-level semantic representations in Chinese.

The encoder structure of each transformer layer of the BERT model outputs had different abstract representations of grammar, semantics, and real knowledge in sentences. Studies have confirmed that each layer of the BERT model represents text information differently through 12 natural language processing tasks [60]. As shown in Figure 4, the low transformer mainly learns and encodes surface features; the middle transformer

learns and encodes syntactic features; and the high transformer learns and encodes semantic features.

The transformer structure of the RoBERTa-wwm model is consistent with that of the BERT model. To make full use of the representation information of each transformer layer, we used the RoBERTa-wwm model with dynamic fusion [61]. This helped in assigning the initial weight to the representation vector of 12 transformer layers, determining the weight during training, and weighing the representation vector generated by each layer.

Figure 3. Mask process of Bidirectional Encoder Representation from Transformers (BERT) and Robustly Optimized Bidirectional Encoder Representation from Transformers Pretraining Approach Whole Word Masking (RoBERTa-wwm).

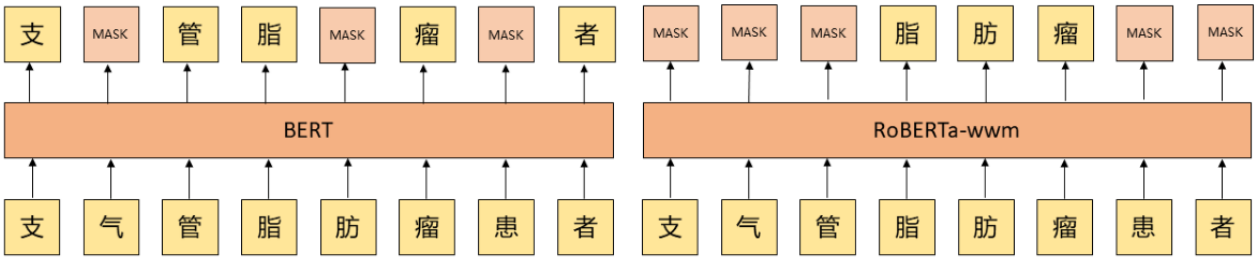

Figure 4. Coding representation of Transformer with 12 layers of Bidirectional Encoder Representation from Transformers model.

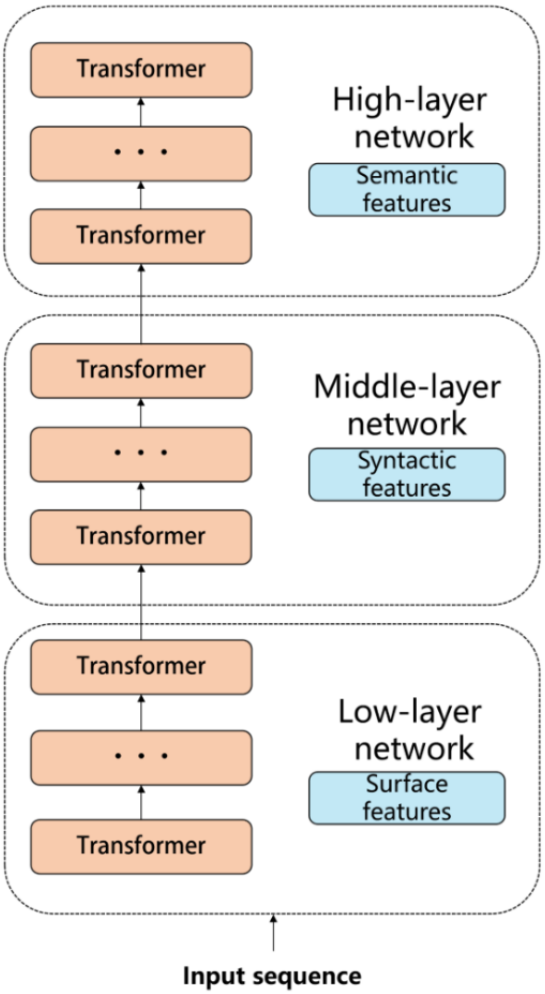

Assume that the text input sequence $seq = (x_1,x_2,x_3, \ldots, x_n)$, where n is the total length of the character contained in the sequence; x_i is the i^{th} character of the input sequence; and the fusion formula is as follows:

$$v_i^{RoBERTa\text{-}wwm} = Dense_{unit=512}(x_i)\{\sum_{i=1}^{n}\alpha_c \times h_c\}, (c \in [1,12]) \quad \textbf{(4)}$$

$v_i^{(RoBERTa\text{-}wwm)}$ is the output representation by the RoBERTa-wwm model with dynamic fusion for the current character x_i; h_c is the output representation by each transformer layer of the RoBERTa-wwm model, and α_c is the output weight value assigned to each layer by RoBERTa-wwm.

Fine-Grained Semantic Feature

5-Stroke Code

The 5-stroke code is a typical semantic code, which encodes Chinese characters according to strokes and structures. Currently, it is widely used to code Chinese characters. The expression of the 5-stroke code may inevitably repeat with the phonological code, for example, the 5-stroke code for "亦 (also)" is "you," while the phonological code for "亦 (also)" is also "you" [62]. Hence, we combined the 5-stroke code and Zheng code to compensate for the encoding deficiency. We used the 5-stroke code in Zdic.net to vectorize the Chinese characters using the following formulas:

$$p = f_{fc}\ (seq)\ \textbf{(5)}$$

$$vifc=efc\ (pi),\ (i \in Z \cap i \in\ [1,n])\ \textbf{(6)}$$

where f_{fc} represents the function that maps the input character sequence into the 5-stroke code and v_i^{fc} represents the 5-stroke code vector corresponding to x_i.

Zheng Code

The Zheng code was created by famous Chinese literature professors as per the strokes and roots of Chinese characters through in-depth research on the patterns and structures of Chinese characters. The early Microsoft operating system in Chinese adopted the Zheng code as the built-in code. This indicates that Zheng code is a scientific coding of Chinese characters. Chinese characters with similar codes may contain related semantic information. Hence, the potential semantic relationship of text may be found by mining the structural information of Chinese characters using Zheng code. The Zheng code was vectorized as the 5-stroke code and has the following formulas:

$$p = f_{zc}\ (seq)\ \textbf{(7)}$$

$$vizc=ezc\ (pi),\ (i \in Z \cap i \in\ [1,n])\ \textbf{(8)}$$

where f_{zc} represents the function that maps the input character sequence into the Zheng code and v_i^{zc} represents the Zheng code vector corresponding to x_i.

Phonological Code

Over 90% of Chinese characters are picto-phonetic characters [63]. Hence, pronunciation plays an important role in the semantic expressions of Chinese characters. We used the Pypinyin toolkit to vectorize the phonological code of Chinese characters using the following formulas:

$$p = f_{pc}\ (seq)\ \textbf{(9)}$$

$$vipc=epc\ (pi),\ (i \in Z \cap i \in\ [1,n])\ \textbf{(10)}$$

where f_{pc} represents the function that maps the input character sequence into the phonological code and v_i^{pc} represents the phonological vector corresponding to x_i.

Stroke Code

Chinese characters with similar strokes may have similar meanings. The strokes of each Chinese character were encoded in ZDIC [59], where 1, 2, 3, 4, and 5 represent the horizontal stroke, vertical stroke, left-falling stroke, right-falling stroke, and turning stroke, respectively. We transformed the stroke code into a 5-dimension vector, where each dimension was the corresponding number of strokes. The stroke code was vectorized in the same manner as the 5-stroke code and has the following formulas:

$$p = f_{sc}\ (seq)\ \textbf{(11)}$$

$$visc=esc\ (pi),\ (i \in Z \cap i \in\ [1,n])\ \textbf{(12)}$$

where f_{sc} represents the function that maps the input character sequence into the stroke code and v_i^{sc} represents the stroke code vector corresponding to x_i.

To extract the fine-grained semantic features of Chinese characters deeply, we trained the character features using CNNs. The character features were trained by 2 convolutions with a kernel of 3 and *ReLU* function as well as max pooling of 2×2, where the number of output channels was the dimension of each feature vector. Finally, the 32-dimension Chinese character vector was obtained through a full connection in the dense layer, as shown in Figure 2.

Image Feature

Chinese characters have been derived from pictographic symbols since ancient times, and characters with similar symbolic appearances have similar image features. However, the fonts of Chinese characters have changed a lot over time. Simplified characters have lost much pictographic information compared with complex characters. Therefore, Cui et al [64] used Chinese character images to extract Chinese character features and achieved better performance. Wu et al [65] tried different character fonts and found that the best result was obtained by using the *NotoSansCJKsc-Regular* font. On the basis of these findings, we used the Python Imaging Library to convert *NotoSansCJKsc-Regular* Chinese characters into black-and-white images and extracted image features by 2D CNN in depth as per the following formulas:

$$e^{if\_1}=(Max\ pooling\ 1\ (Conv\ 1\ (K \otimes H))\ \textbf{(13)}$$

$$e^{if\_2}=(Max\ pooling\ 2\ (Conv\ 2\ (K \otimes H)\ \textbf{(14)}$$

$$v_i^{if}=\text{Dense}\ (e^{if\_2})\ \textbf{(15)}$$

where K is a kernel; H is the original embedded image matrix; *Conv 1*, *Max pooling 1*, *Conv 2*, and *Max pooling 2* are the first convolutions with a kernel of 3 and channel of 8, the first max pooling with the kernel of 2×2, the second convolution with the kernel of 3 and channel of 32, and the second max pooling with the kernel of 2×2, respectively; e^{if_1} is the result after the first convolution; e^{if_2} is the result after the second convolution; Dense is the process of realizing the full connection; and v_i^{if} is the final 128-dimension Chinese character image vector trained by convolution, as shown in Figure 2.

Finally, the multisemantic features $v_i^{RoBERTa\text{-}wwm}$, v_i^{fc}, v_i^{zc}, v_i^{pc}, v_i^{sc}, and v_i^{if} were embedded by the array Concat function. The formula used is as follows:

$$v_i^{input}=\text{Concat}\ (v_i^{RoBERTa\text{-}wwm}, v_i^{fc}, v_i^{zc}, v_i^{pc}, v_i^{sc}, v_i^{if})\ \textbf{(16)}$$

BiLSTM Layer

The role of BiLSTM [66] is essential in NER. As shown in Figure 1, the forward LSTM and backward LSTM are responsible for memorizing the previous and subsequent text information, respectively. By combining the 2, contextual information can be obtained simultaneously, which helps to capture the bidirectional semantic dependency information in the text. The formulas used are as follows:

$$h_i^{forward}=LSTM^{forward}(\alpha^{<i-1>}, x_i) \textbf{ (17)}$$

$$h_i^{backward}=LSTM^{backward}(\alpha^{<i-1>}, x_i) \textbf{ (18)}$$

$$h_i=[h_i^{forward}; h_i^{backward}] \textbf{ (19)}$$

where $\alpha^{<i>}$ represents the hidden layer state of the current memory cell; $LSTM^{forward}$ is the feature representation from front to back; $LSTM^{backward}$ is the feature representation from back to front; $h_i^{forward}$ is the forward semantic information obtained through the forward LSTM at the *i*-th character position; $h_i^{backward}$ is the backward semantic information obtained through the backward LSTM at the *i*-th character position; and h_i represents a combination of hidden states in both.

CRF Layer

The BiLSTM can be used to handle contextual relationships. However, it cannot consider the dependencies between tags. Therefore, it is necessary to add a constraint relation for the final predicted label by using the CRF [67] layer to ensure the predicted label rationality. Given an input sequence where $X=\{x_1,x_2,...,x_n\}$, we assume that the training output label sequence is $Y=\{y_1,y_2,...,y_n\}$, where n is the number of model labels. The sequence score of the label and the probability of the label sequence y are calculated as follows:

$$P(y|X)=e^{\sum i=1}(Z_{yi,yi+1}+P_{i+1,yi+1}) / (\sum_{(y\tilde{}\in Yx)} e^{\sum i=1}(Z_{yi,yi+1}+P_{i+1,yi+1}) \textbf{ (20)}$$

where Z is the transfer matrix; $Z_{yi,yi+1}$ is the score of the label transfer from y_i to y_{i+1}; $P_{i+1,yi+1}$ is the score of label y_{i+1} corresponding to the $i+1$th character of the input sequence; Y_x is the set of all possible label sequences. The final label of the output sequence is the set of labels with the highest probability.

Finally, we predicted the best label sequences by using the Viterbi algorithm [68] with the following formula:

$$y^*=argmax(s(X, y)) \textbf{ (21)}$$

Results

To get convincing experimental results, we ran each model 5 times and calculated the average precision, average recall, and average F_1-score.

Performance Comparison With Ensemble Models

To verify the validity of the model, we compared our model with the existing ensemble models BiLSTM-CRF, ELMo-Lattice-LSTM-CRF, ELMo-BiLSTM-CRF, all CNNs, ELMo-encoder from transformer-CRF, and multigranularity semantic dictionary and multimodal tree-NER on Yidu-S4K and self-annotated data sets, and the results are shown in Table 4. The F_1-scores of the experimental model on the Yidu-S4K data set were 18.31%, 4.15%, 4.26%, 4.12%, 3.69%, and 2.59% higher than those of the BiLSTM-CRF, all CNNs, ELMo-Lattice-LSTM-CRF, ELMo-BiLSTM-CRF, ELMo-encoder from transformer-CRF, and multigranularity semantic dictionary and multimodal tree-NER models, respectively. On the self-annotated data set, it was 5.14% higher than that of the BiLSTM-CRF. The results showed that the performance of the experimental model is superior to that of the existing model.

Performance Comparison With PLMs Related to BERT

The performance of the PLM, BERT, is a milestone in natural language processing. To verify the BERT robust version's validity of the RoBERTa-wwm model, we compared our model with the existing ensemble models with the BiLSTM-CRF, BERT-BiLSTM-CRF, and RoBERTa-wwm-BiLSTM-CRF on Yidu-S4K and self-annotated data sets, and the results are shown in Table 5. The F_1-scores of the experimental model on the Yidu-S4K data set were 18.31%, 2.99%, and 0.82% higher than those of the BiLSTM-CRF, BERT-BiLSTM-CRF, and RoBERTa-wwm-BiLSTM-CRF models, respectively, and 5.14%, 2.95%, and 1.07% higher on the self-annotated data set, respectively.

Table 5. Performance comparison of PLMs[a] on the Yidu-S4K and self-annotated data sets.

Data set and model	Precision (%)	Recall (%)	F_1-score (%)
Yidu-S4K

Performance Comparison of Each Entity

To comprehensively evaluate our model, we calculated the F_1-score for each entity type on the Yidu-S4K and self-annotated data sets, as shown in Tables 6 and 7. The F_1-score of our model on the Yidu-S4K data set for each of the 6 entity categories, except for the Image entity, increased by 0.2% to 7.6% compared with the data listed in the tables. The F_1-score for the Image entity was 0.35% lower than that of the ELMo-BiLSTM-CRF model. However, the F_1-scores for the Laboratory entity and Operation entity were 7.6% and 7.54% higher than those of the ELMo-BiLSTM-CRF model, respectively. The overall F_1-score was 4.12% higher than that of the ELMo-BiLSTM-CRF model. For the self-annotated data set, our model improved each entity in 7 categories ranging from 0.09% to 14.49% over the listed data, with a greater improvement for Instrument entities.

Table 6. Performance comparison of each entity category on the Yidu-S4K data set.

Model	F_1-score for each category (%)						
	All	Disease	Anatomy	Image	Laboratory	Medicine	Operation

Ablation Analysis

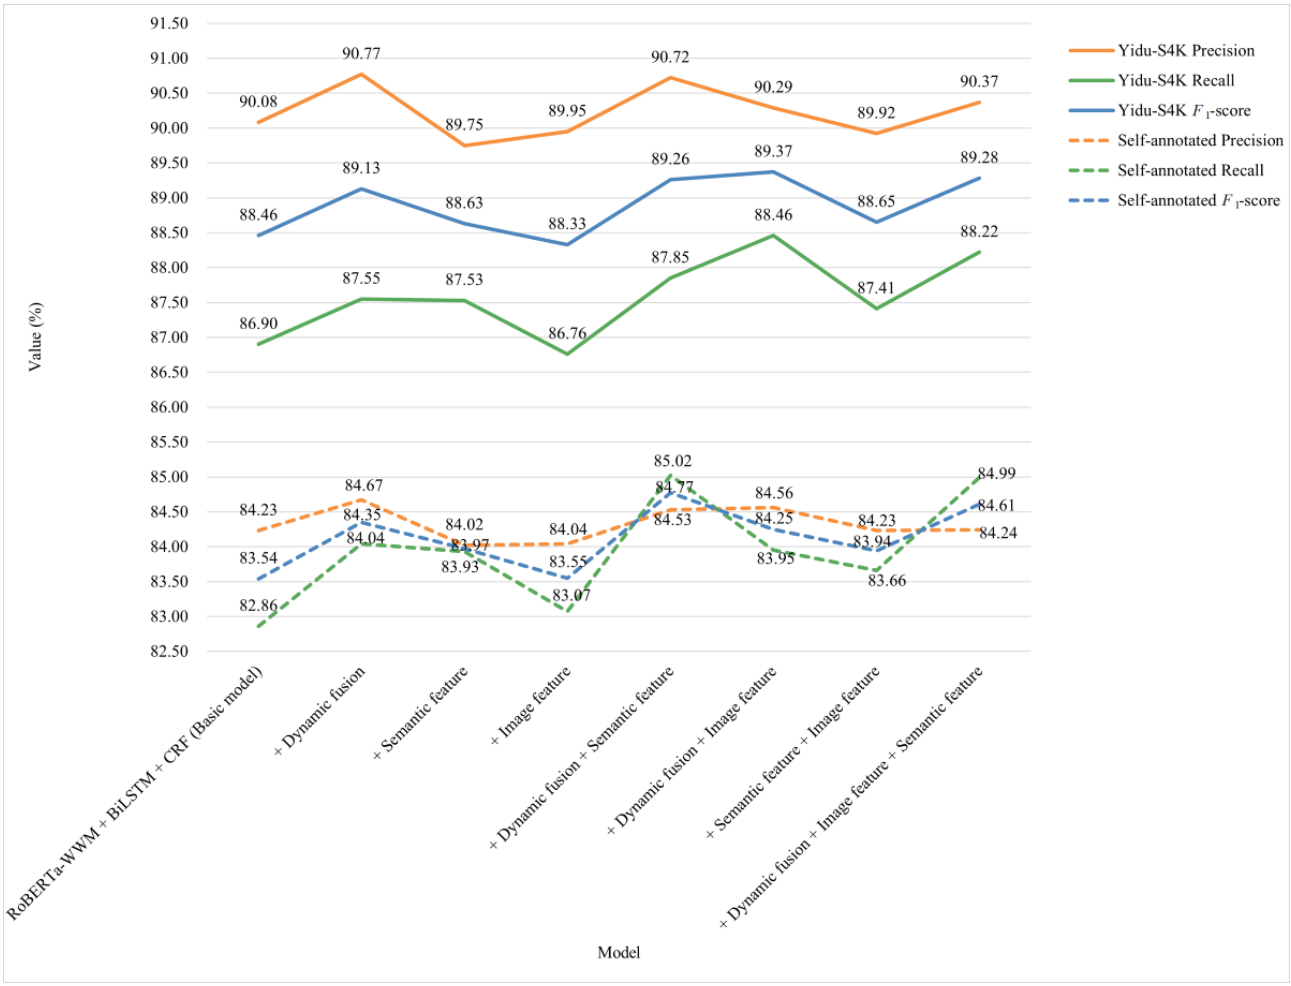
Ablation Experiments for Multisemantic Features

To verify the fine-grained semantic features and image features of Chinese characters, dynamic fusion was effective. We used the RoBERTa-wwm-BiLSTM-CRF model as the baseline to perform ablation experiments for the above contents on 2 EMR data sets, and the results are shown in Figure 5.

The performance of the model was significantly improved with the dynamic fusion of RoBERTa-wwm. After incorporating the semantic features of Chinese characters into the model alone, the overall performance of the model was not as high as that after dynamic fusion. However, the performance on both data sets was superior to that of the baseline. The performance of the model was unstable when image features of Chinese characters were added to the model alone. On the Yidu-S4K data set, the model's performance was inferior to that of the baseline, whereas on the self-annotated data set, the model's performance only improved slightly. After adding the semantic and image features of Chinese characters to the model, the performance of the model on the Yidu-S4K data set was superior to that of the baseline. Furthermore, it was better than that of the model with semantic or image features of Chinese characters alone. The performance of the model on the self-annotated data set was superior to that of the baseline and better than that of the model with the image features of Chinese characters alone. When the model combined dynamic fusion with the semantic

features and image features of Chinese characters, it was found that the performance of the model was significantly improved on the 2 data sets. Dynamic fusion with image features of Chinese characters showed the best comprehensive performance on the Yidu-S4K data set, whereas dynamic fusion with semantic features of Chinese characters achieved the best comprehensive performance on the self-annotated data set. After combining the semantic and image features of the Chinese characters and dynamic fusion, it was noted that the performance of the model was superior to that of the baseline. Because the quality of the self-annotated EMRs is inferior to that of the public Chinese EMRs corpus and the self-annotated data set contains a wider coverage of departments, the comprehensive effect of the self-annotated data set is lower than that of the YiduS4K data set in Figure 5.

Figure 5. The results of ablation experiments for mutisemantic features on the Yidu-S4K and self-annotated data sets. BiLSTM: Bidirectional Long Short-Term Memory; CRF: Conditional Random Fields; RoBERTa-wwm: Robustly Optimized Bidirectional Encoder Representation from Transformers Pretraining Approach Whole Word Masking.



Ablation Experiments for Fine-Grained Semantic Features

The fine-grained semantic features of Chinese characters used in this study included the 5-stroke code, Zheng code, phonological code, and stroke code. To verify the effectiveness of these features, we used the RoBERTa-wwm-BiLSTM-CRF model as the baseline to perform ablation experiments for the 4 features on the 2 EMR data sets, and the results are shown in Figure 6 and Figure 7.

Figure 6. The results of ablation experiments for fine-grained semantic features on the Yidu-S4K data set. BiLSTM: Bidirectional Long Short-Term Memory; CRF: conditional random fields; RoBERTa-wwm: Robustly Optimized Bidirectional Encoder Representation from Transformers Pretraining Approach Whole Word Masking.

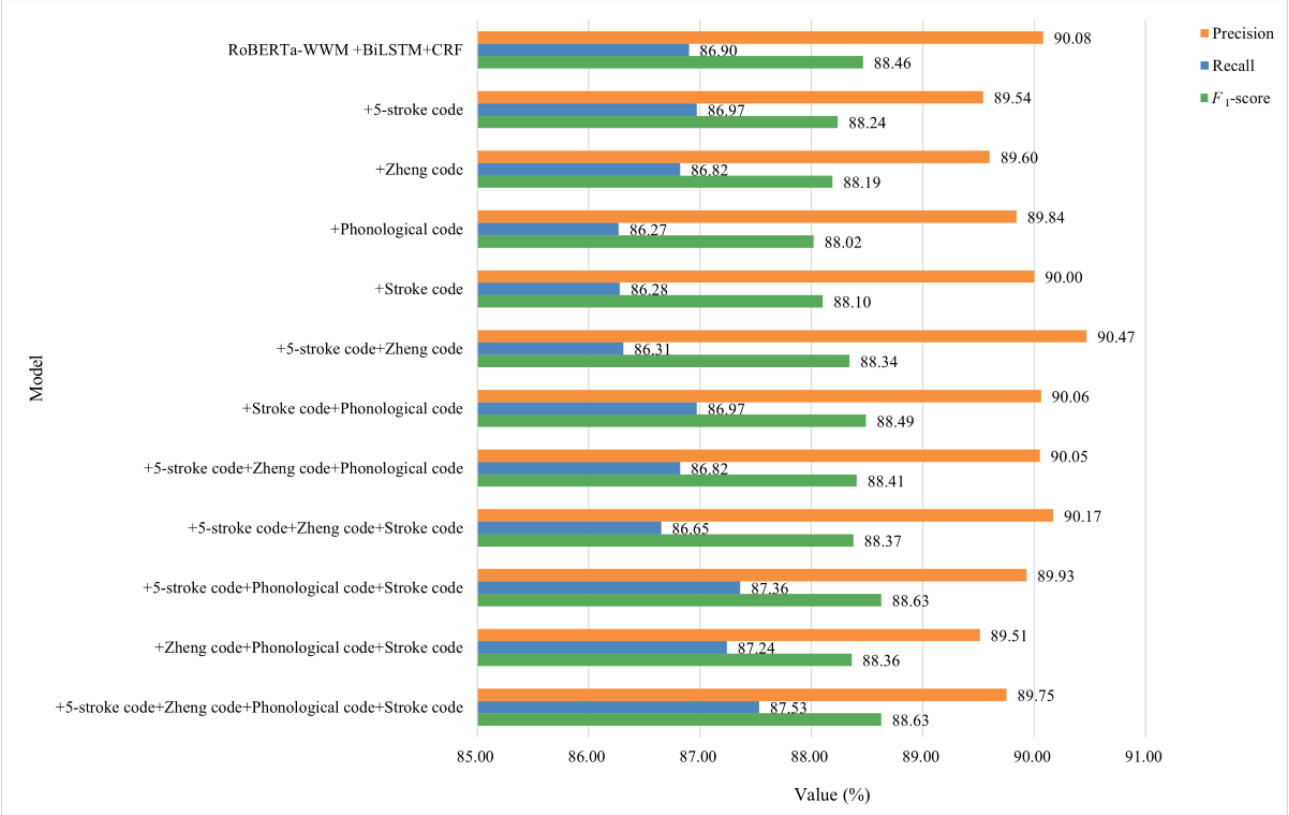


Figure 7. The results of ablation experiments for fine-grained semantic features on the self-annotated data set. BiLSTM: Bidirectional Long Short-Term Memory; CRF: conditional random fields; RoBERTa-wwm: Robustly Optimized Bidirectional Encoder Representation from Transformers Pretraining Approach Whole Word Masking.

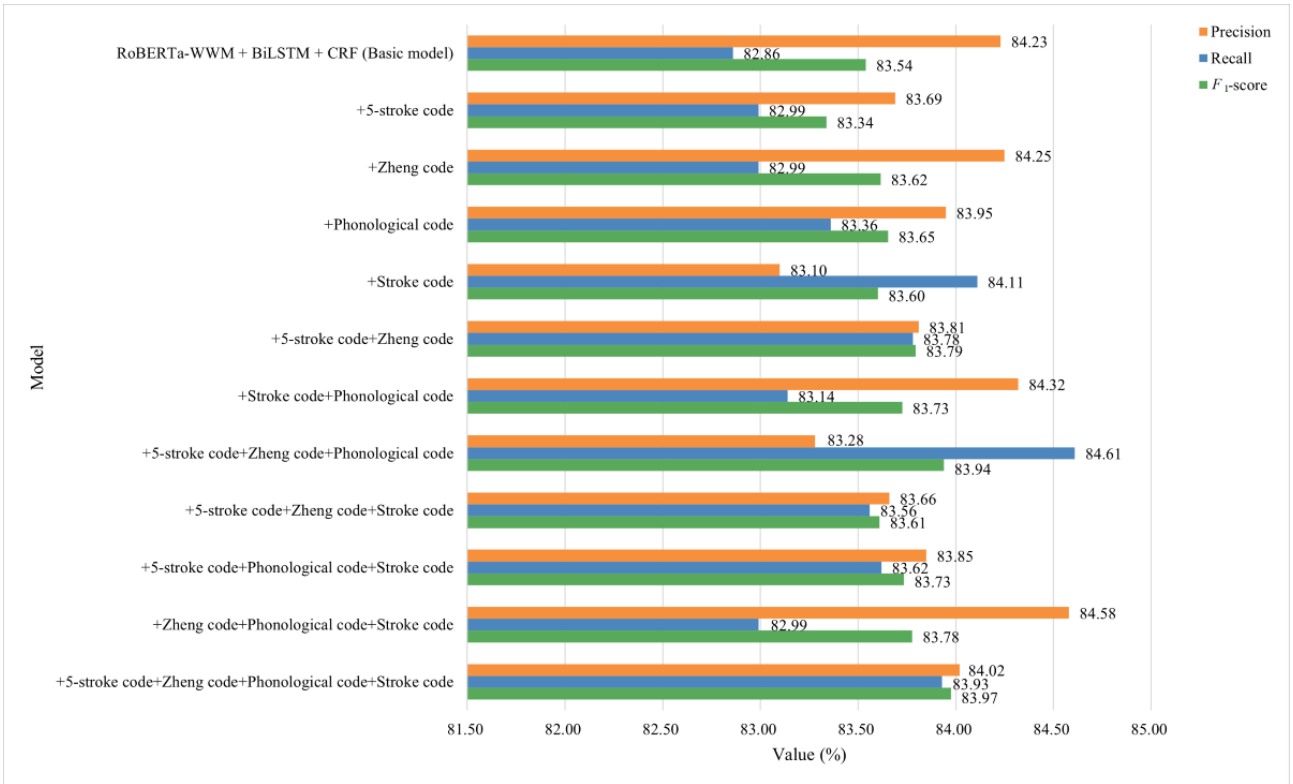

The F_1-score of the model on the Yidu-S4K data set ranked in the top 2 for the 5-stroke code and Zheng code, whereas the F_1-score on the self-annotated data set ranked in the top 2 for the phonological code or Zheng code. The performance of the

model combining 2 features (the combination of 5-stroke code and Zheng code or the combination of phonological code and stroke code) was better than that of the model with only 1 feature, regardless of the data set. On the Yidu-S4K data set, the model combining 5-stroke code+phonological code+stroke code showed the best comprehensive performance, followed by the combinations of 5-stroke code+Zheng code+phonological code, 5-stroke code+Zheng code+stroke code, and Zheng code+phonological code+stroke code. On the self-annotated data set, the model combining the 5-stroke code+Zheng code+phonological code showed the best comprehensive performance, followed by Zheng code+phonological code+stroke code, 5-stroke code+phonological code+stroke code, and 5-stroke code+Zheng code+stroke code. On the Yidu-S4K data set, only the model combining the 5-stroke code+phonological code+stroke code showed a comprehensive performance superior to that of the baseline. However, on the self-annotated data set, the comprehensive performance of all combinations was superior to that of the baseline. The performance of the model combining 3 features was less stable. The model combined 4 features on the Yidu-S4K and self-annotated data sets and achieved the best comprehensive performance among all the combinations.

Error Analysis

From Tables 6 to Table 7, our model improved the entity recognition performance of each entity category to different degrees. However, the entity recognition effect differs for each category. The F_1-scores of Disease, Anatomy, Image, Laboratory, Medicine, and Operation entity recognition on the Yidu-S4K data set were 87.91%, 87.47%, 87.66%, 83.25%, 94.98%, and 94.33%, respectively. The F_1-scores of Disease, Symptoms, Anatomy, Examination, Instrument, Medicine, and Operation entity recognition on the self-annotated data set were 82.34%, 86.93%, 85.62%, 91.31%, 69.25%, 91.28%, and 82.49%, respectively. On the Yidu-S4K data set, the precision of Laboratory entity recognition was the lowest, followed by the Anatomy entity, Image entity, and Disease entity. On the self-annotated data set, the precision of Instrument entity recognition was the lowest, followed by the Disease entity, Anatomy entity, and Operation entity. We concluded the following 7 main causes of the errors that occurred based on a review of the data set and model prediction results, as shown in Table 8.

We strictly controlled the annotation quality of both data sets. Hence, the probability of causes (1-3) was relatively low. Causes (4-6) were more likely to occur, and cause (7) mainly occurred on some entities that were less common or had fewer training samples.

Table 8. Different types of errors on 2 data sets.

Types of errors Illustrations	Example
(1) Annotation error	
1. Some manually annotated entities contained punctuation marks unrelated to the entities.	For instance, some Laboratory entities, like "PLT[a]," "NEUT[b]," and "CAE[c]," on the Yidu-S4K data set contained commas, which were correctly recognized as "PLT," "NEUT," and "CAE" in our model.
2. A few entity categories were confused.	For example, "PET-CT[d]" was manually annotated as a Laboratory entity on the Yidu-S4K data set, but our model correctly predicted as an Image entity.
(2) Inconsistent annotation	
The inconsistent annotation will affect the accuracy of machine learning.	On the Yidu-S4K data set, the character "下 (below)" expressing orientation of "剑突下 (below xiphoid)" was not annotated, and the character "部 (part)" expressing the part of "咽喉部 (hypopharynx)" was also not annotated. Most of the characters expressing specific locations were annotated.
(3) Missing annotation	
The missing annotated entity will also affect the overall effect of the model.	The Disease entity "窦性心律 (sinus rhythm)" was missed annotated on the Yidu-S4K data set, and the Medicine entity "生理盐水 (normal saline)" was missed annotated on the self-annotated data set.
(4) Entity with a non-Chinese character symbol	
Figures, letters, and other symbols cannot be extracted with more semantic features than Chinese characters. Hence, it may be difficult to recognize entities with symbols other than Chinese characters in the Chinese corpus.	The failure to recognize the non-Chinese character entities, like the Laboratory entity "AFP[e]" on the Yidu-S4K data set and the Examination entity "HCG[f]," on the self-annotated data set, so did such situations as the Medicine entity "VP[g]-16" was recognized as "VP-," and "50%葡萄糖 (50% glucose)" as "葡萄糖 (glucose)" on the Yidu-S4K data set.
(5) Presence of nested entities	
On the Yidu-S4K data set, the Disease entity and Image entity might contain the Anatomy entity.	For example, the Disease entity "二尖瓣后叶钙化 (posterior mitral valve leaflet calcification)" was recognized as the Anatomy entity "二尖瓣 (bicuspid)," and the Image entity "腹部彩超 (abdominal color doppler ultrasound)" was recognized as the Anatomy entity "腹部 (abdominal)."
On the self-annotated data set, entity nesting is more severe, the Disease entity, Examination entity, and Instrument entity might contain the Anatomy entity, and the Instrument entity might contain the Operation entity.	For example, the Disease entity "内踝骨折 (ankle fracture)" was recognized as the Anatomy entity "内踝 (medial malleolus)," the Examination entity "骨髓组织病理 (bone marrow histopathology)" was recognized as the Anatomy entity "骨髓 (bone marrow)," the Instrument entity "胸部支具 (chest brace)" was recognized as the Anatomy entity "胸(chest)," and the Instrument entity "左胸引流管 (left thoracic drainage tube)" was recognized as the Operation entity "左胸引流 (left thoracic drainage)."
(6) More entities with mixed representation	
Entity composition is more complex, mixed representations occur more often.	The Medicine entity "奥沙利铂 (乐沙定) (Oxaliplatin [Eloxatin])" on the Yidu-S4K data set was recognized as "奥沙利铂 (Oxaliplatin)" and "乐沙定 (Eloxatin)," respectively, the Disease entity "CD5[h]+弥漫大B细胞淋巴瘤 (白血病期)" on the self-annotated data set was recognized as "CD" and "弥漫大B细胞淋巴瘤 (白血病期) (diffuse large B-cell lymphoma [Leukemia stage])," and the Examination entity "肥达、外斐反应 (Widal, well-felix reaction)" on the self-annotated data set was recognized as "肥达 (Widal)" and "外斐反应 (well-felix reaction)," respectively.
(7) Insufficient entity training data	
In the case of insufficient training samples, the machine may provide inadequate training for entities, so that the machine cannot fully learn the features of such entities, failing to recognize many entities.	On the self-annotated data set, the number of Instrument entities was less than that of other categories (Table 2), accounting for only 1.52% of the total, those entities might never appear in the training data set, such as "针筒 (syringe)," "微导管 (microtubule)," "550px碳钢钻头 (550px carbon steel drill bit)," etc.

[a]PLT: platelet count.

[b]NEUT: neutrophil count.

[c]CAE: carcinoembryonic antigen.

[d]PET-CT: positron emission tomography-computed tomography.

[e]AFP: alpha fetoprotein.

[f]HCG: human chorionic gonadotropin.

[g]VP: etoposide.

[h]CD5: a differentiation antigen, cluster of differentiation 5.

Discussion

Principal Findings

In this study, we developed a Chinese CNER method based on multisemantic features. The method extracted the semantic features of text using the RoBERTa-wwm model after dynamic fusion, extracted the fine-grained semantic features of Chinese characters by 1D CNN, and converted Chinese characters into square images to extract the image features of the simplified Chinese characters from another modality by 2D CNN. We conducted a series of experiments to evaluate the model's performance on the Yidu-S4K data set and self-annotated data set; the results showed that the F_1-scores of the proposed model in this study were 89.28% and 84.61% on the 2 data sets, respectively. The model showed a higher and more stable performance in all experiments and could help recognize entities in most categories. Furthermore, its migrative property and adaptability to different data were acceptable. We also demonstrated that multisemantic features were effective through 2 ablation experiences and analyzed the error cases of NER, which might provide a basis for subsequent studies and standardization of the corpus.

Compared with ensemble models, for the BiLSTM-CRF model, the representation information of characters was obtained with the help of a vector look-up table. However, the information obtained by this method was too simple to excavate the text's semantic meaning or solve problems such as the polysemy of words. Hence, the model did not perform well. Kong et al [69] constructed a multilayer CNN to obtain short-term and long-term contextual information, and the attention mechanism was used to calculate the weight distribution in each hidden layer so that the features of each coding layer could be fully extracted and used to improve the entity recognition performance. However, this model required numerous radical and dictionary features to complete the semantic supplement of the context. Li et al [70] proposed an ELMo-Lattice-LSTM-CRF model. The ELMo word dynamic representation model could learn complicated word features and the context-based changes of these features, while the lattice structure provided extra entity boundaries and other semantic information for CNER of EMRs through the Word2Vec model and dictionaries. Li et al [41] proposed an ELMo-BiLSTM-CRF model that improved the semantic recognition ability of the machine for text. It reduced problems, such as word polysemy, when compared with the BiLSTM-CRF model and reduced the computational complexity of the lattice structure compared with the ELMo-Lattice-LSTM-CRF model. Moreover, this model could fully use contextual information by replacing LSTM with BiLSTM. Wan et al [71] fine-tuned the ELMo model based on EMRs to achieve embedding for domain-specific text and then used a transformer as an encoder to alleviate the long context–dependent problems and finally achieved CNER through CRF decoding. Wang et al [72] proposed a model for NER based on the LSTM-CRF model by storing and merging characters, words, and other features. However, as the text embedding process of this method is more complicated, it is necessary to create dictionaries of characters and words to obtain multigranularity text features at first and then store and merge the obtained features using a tree structure to achieve text embedding. These methods have achieved a few good results, but our proposed method is still competitive and has the best performance among all the models, as shown in Table 4.

Compared with PLMs related to BERT, both the BERT-BiLSTM-CRF and BiLSTM-CRF models could obtain word-level vector representations. However, the word-level vector obtained by BERT contained rich contextual characteristics, including morphology, syntax, semantics, location, and other important semantic information, which can directly improve the task performance by replacing the lattice structure and complicated text representation methods in Table 4, such as dictionaries of characters and words. Compared with BERT, RoBERTa-wwm used more data for pretraining, and the dynamic wwm allows itself to flexibly learn word-level representation information, which compensates for the shortcomings that BERT can only obtain character-level representation. Thus, richer word-based text representation information could be obtained. Combined with the experimental results in Table 4, the RoBERTa-wwm-BiLSTM-CRF model, without introducing features, outperformed the other ensemble models. Therefore, using the PLM RoBERTa-wwm with a whole word mask can effectively improve the Chinese CNER performance, thus avoiding the use of complex text embedding and feature embedding methods.

In addition, 2 ablation experiments showed that different features and means lead to different degrees of improvement in the semantic comprehension ability of the model. Multisemantic features could help the machine to obtain richer semantic information, whereas dynamic fusion could fully recognize and used the representation information so that the model performance could be comprehensively improved. Considering the heterogeneity among data, using 1 method alone or both methods may affect the generalization ability of the model. In this study, the model combining the fine-grained semantic features and image features of Chinese characters and dynamic fusion might not show the best performance. However, it was more universal and could maintain the performance at a relatively high level compared with other experimental models. Furthermore, introducing more feature engineering was conducive to fully mining the semantic information of text connotation with the help of fine-grained semantic information contained in Chinese characters and improving the performance of the model on different data sets through the cross-complementarity of different features in a relatively stable manner.

To reduce the error rate of entity recognition, specifically for human-caused errors, we could try to avoid these problems by further improving the annotation quality. For the data special characteristics or data defects, the errors might be reduced by medical knowledge, medical dictionaries, and some rules, regardless of the lack of training data.

Limitations and Future Work

The limitation of this study was that the ratio of the 6 entity types on the Yidu-S4K data set did not exactly follow 7:3, such that the ratio of the training set to test set for disease entities is approximately 0.7610:0.2390; the ratio of the training set to test

set for medicine entities is approximately 0.7898:0.2102; and the ratio of the training set to test set for all entities is approximately 0.7463:0.2537. The unbalanced data of different entity types in the training and test sets caused a performance bias. Although the ratio of the training set to the test set of the EMRs was 7:3, we could not ensure that the number of entities of each type in each EMR in the training set and test set remained at a similar ratio.

In the future, we may focus on the recognition of a specific entity type in EMRs to improve the CNER performance. In addition, we will incorporate other prior medical knowledge or assign different weights to the Chinese character semantic features and image features, such as using the attention mechanism to capture important features, to improve the performance of the model.

Conclusions

This study proposes a Chinese CNER method to learn a semantics-enriched representation of Chinese character features in EMRs to enhance the specificity and diversity of feature representations. The results showed that the model had state-of-the-art performance on 2 Chinese CNER data sets compared with existing models. We demonstrated that multisemantic features could provide richer and more fine-grained semantic information for Chinese CNER through the cross-complementarity of different semantic features. This enabled the model to learn a better feature representation and improve its generalization ability.

Acknowledgments

The authors would like to thank the YiduCloud for providing the Yidu-S4K corpora. Abstract

Background: Observational biomedical studies facilitate a new strategy for large-scale electronic health record (EHR) utilization to support precision medicine. However, data label inaccessibility is an increasingly important issue in clinical prediction, despite the use of synthetic and semisupervised learning from data. Little research has aimed to uncover the underlying graphical structure of EHRs.

Objective: A network-based generative adversarial semisupervised method is proposed. The objective is to train clinical prediction models on label-deficient EHRs to achieve comparable learning performance to supervised methods.

Methods: Three public data sets and one colorectal cancer data set gathered from the Second Affiliated Hospital of Zhejiang University were selected as benchmarks. The proposed models were trained on 5% to 25% labeled data and evaluated on classification metrics against conventional semisupervised and supervised methods. The data quality, model security, and memory scalability were also evaluated.

Results: The proposed method for semisupervised classification outperforms related semisupervised methods under the same setup, with the average area under the receiver operating characteristics curve (AUC) reaching 0.945, 0.673, 0.611, and 0.588 for the four data sets, respectively, followed by graph-based semisupervised learning (0.450, 0.454, 0.425, and 0.5676, respectively) and label propagation (0.475,0.344, 0.440, and 0.477, respectively). The average classification AUCs with 10% labeled data were 0.929, 0.719, 0.652, and 0.650, respectively, comparable to that of the supervised learning methods logistic regression (0.601, 0.670, 0.731, and 0.710, respectively), support vector machines (0.733, 0.720, 0.720, and 0.721, respectively), and random forests (0.982, 0.750, 0.758, and 0.740, respectively). The concerns regarding the secondary use of data and data security are alleviated by realistic data synthesis and robust privacy preservation.

Conclusions: Training clinical prediction models on label-deficient EHRs is indispensable in data-driven research. The proposed method has great potential to exploit the intrinsic structure of EHRs and achieve comparable learning performance to supervised methods.

Introduction

The recent rise of observational biomedical research, driven by greatly expanding electronic health records (EHRs) and the prevalence of machine learning methods, has drawn great attention [1-4]. Conventional strategies tend to screen out subgroups of interest based on expert supervision or established risk factors. An alternative data-driven paradigm extracts underlying subtypes by comprehensively profiling the longitudinal irregularity, interdimensional heterogeneity, and intrinsic homogeneity of the database, thus progressively facilitating the practice of precision medicine. For instance, the Electronic Medical Records and Genomics (eMERGE) network [5] leverages expertise from multiple institutions and communities to integrate biorepositories and EHRs to support genomic research. Observational research approaches exhibit both potential and challenges for more sophisticated data analysis.

However, the acquisition of realistic data, especially data labels, is still restricted when confronting concerns about system security, patient privacy, and intellectual property protection [6,7]. Excluding data and labels may be ubiquitous during the data collection phase. Long-term studies often lack sufficient time to gather data and have no control over the switching behaviors of patients [8,9], resulting in the loss of accurate outcome measurements.

Restrictions on transferring intellectual property among different institutions hinder the sharing of data, which is expected to be complete. Additionally, some expertise-requiring annotations are tedious and have no guarantee of correctness [10]. Generally, label deficiencies occur frequently when analyzing observational EHR data.

There have been some attempts to address insufficient labeling by realistic synthesized EHR (RS-EHR) generation. One approach to RS-EHRs is knowledge-based [11,12]. Such approaches combine publicly available statistics, clinical practice guidelines, and medical coding dictionaries to improve the fidelity of generated EHRs. However, the models are still restricted to development, testing, and public demonstrations.

Another strategy is data-driven. Generative adversarial networks (GANs) are a new class of methods for obtaining realistic synthesized data [13,14]. The philosophy of GANs is to train two networks, one generating fake samples and the other discriminating fake and real samples, in a min-max game until equilibrium is achieved, indicating that the generated fake samples cannot be distinguished from the real samples. There has been some work on applying state-of-the-art GANs to generate synthesized EHR data sets [15,16]. However, these studies have not fully applied the generated data to augment EHR computational phenotyping and classification. GANs for few-labeled data are still unlikely to recover the whole distribution of labels from the raw data set due to imbalanced labeling. Additionally, there are some arguments that GAN-generated samples are likely to copy real samples exactly, which is a potential violation of privacy [17,18].

Semisupervised learning (SSL) is a set of techniques that are usually adopted to leverage unlabeled data and an underlying data set structure. With a relatively small set of labeled data compared to that needed in supervised learning (SL), SSL can still display decent learning performance. Some previous studies used SSL to phenotype EHR databases [19,20]. These studies achieved excellent performance in EHR-based risk prediction, but the feature dimensions were restricted to discrete medical codes. GANs were adopted to boost the SSL [21], but as mentioned above, the generator was trained to eventually remember exact copies of the samples for the limited span of an EHR data set in a discrete and high-dimensional space, which therefore raised privacy concerns. SSL is a powerful tool for label-deficient circumstances but needs specifications for observational research.

Network analysis is a solution to both obstacles. Encoding the similarities among patients into their connections protects their identities. The input of the analysis is only the network structure and embedded vectors. Network analysis is the basis for manifold learning, which has an advantage in approximating the data structure in a high-dimensional space. Many manifold-based methods have prevailed in intuitively visualizing and phenotyping coordinated data sets [22-24]. Additionally, there have been quite a few attempts to extend deep learning to irregular data structures, such as graphs. Several studies have shown great performance in representative learning with SSL [25-28], and endeavors have been made to apply GANs to graphs [29-31].

However, few studies have considered exploiting the inherent network structure of an EHR database in SSL tasks. GANs on networks have not been fully investigated in terms of privacy preservation. Additionally, under various label-deficient situations, the performance remains to be evaluated. It is very promising to scale SSL and GANs to the graph structure extracted from an EHR database and to thereby acquire a new perspective on EHR data sets.

For this paper, the main contributions are as follows: (1) This study tries to address limitations due to existing label deficiency in observational EHR analytical research by extending the network analysis pipeline to EHRs. A boosting learning model is proposed by applying GAN-boosted SSL to network data extracted from label-deficient coordinated EHRs. (2) Experiments are conducted on 3 public data sets as well as one from the First Affiliated Hospital of Zhejiang University, and they are evaluated by prediction metrics that are compared to conventional learning methods. The proposed method shows superior performance over conventional semisupervised methods and indicates comparable performance with supervised learning methods when data are fully labeled. (3) To ensure the utility of the proposed model, further evaluations of data quality, nondisclosure, and memory space consumption are performed.

The proposed method shows higher data fidelity, lower precision metrics against compromised attack, and less graphics processing unit (GPU) memory consumption over conventional semisupervised methods.

Methods

Data Set Structure Conversion to a Graph

Graph structure definition and semisupervised learning on graph formularization are shown in Multimedia Appendix 1A [31-37]. According to the well-accepted assumption that a manifold is locally Euclidean in topological space, it is plausible to represent a data set X with a graph G. However, this conversion rule should be scrutinized. First, it depends on the number of edges |E| that comprise the edge set. |E| should be restricted to a range that avoids disconnected components and short circuits that obscure structural information. Second, the neighborhood searching strategy should be scalable to feature value scales and effective in practice. Third, the local density variance should be preserved during conversion, which means that the weights of edges should not be binary.

To circumvent this problem, the k-nearest neighbors (k-NN) method was selected to convert the original data set into a graph measure space. As its name indicates, the k nearest points in the Euclidean space of point x are identified as its neighbors, N_k (x). Each edge weight w_{ij} is refined with the Jaccard coefficient:

The Jaccard coefficient addresses the unified weight problem brought by k-NN searching and restricts the weights to [0,1], which scales the local densities as node degrees: $\deg(v_i) = \sum_{j \in N\_k(v\_i)} w_{ij}$. Additionally, when the lower bound is reached, the edge is removed from the graph, and eventually, nodes with degree zero will be considered noise and therefore removed. The final graph serves as one of the inputs of the GAN.

GANs for Graphs and Their Modified Losses

In this study, we focus on generating vectorized fake samples by the use of both the graph structure and coordinated features. The coordinated features of the graph structure are acquired by feeding the Jaccard graph into large-scale information network embedding [38], explicitly setting the output dimension as half of d.

The fundamentals of GAN [32,33] are presented in Multimedia Appendix 1C [31-37]. Nevertheless, it is important to take into account the unconventional loss of semisupervised adversarial learning, as insufficient labels do not effectively minimize the current adversarial learning loss. The generator is trained to produce samples that bridge the density gap between samples from distinct classes. In the case of binary classification tasks, the 2 classes are “true” and “false.” By expanding the density gap between labeled true samples, labeled false samples, and generated density gap samples, the adjusted discriminator loss can enhance semisupervised learning performance. The refined discriminator loss L_D for SSL purposes comprises semisupervised loss, entropy loss, and class distance. (1) Semisupervised loss: there are two terms; the first is the supervised loss calculated by cross-entropy between the labels and prediction. The second emphasizes the loss due to incorrect classification by SSL. λ_0 is a hyperparameter that balances these 2 terms.

$$\begin{aligned} loss_{semi} &= loss_{sup} + \lambda_0 loss_{un} \\ &= -E\_(_{xi \in XL}) \log P(y_i \mid x_i, y_i < M) \\ &- \lambda_0 \left(E_{xi \in XU} \log(1 - P(M \mid x_i)) + E_{xi \sim G(z)} \log P(M \mid x_i)\right) \end{aligned} \quad \textbf{(2)}$$

(2) Entropy regularization [39,40]: this term calculates the entropy of a distribution over all labels M to enhance the certainty of the prediction.

(3) Cluster distance loss [31]: this term tends to enlarge the density gap so that samples from different classes are separate. $h^n(x)$ is the last-layer output of the discriminator.

The final loss term for the discriminator generator is

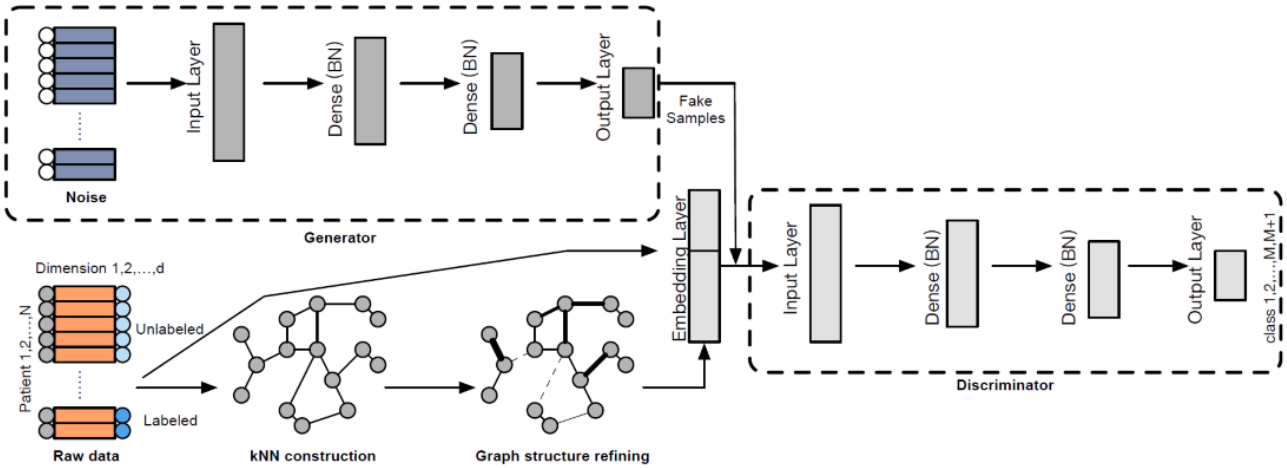
$$loss_D = loss_{Dwgp} + loss_{semi} + loss_{ent} + loss_{pt} \quad \textbf{(5)}$$

The loss of generator $_{LG}$ is also modified by adding the term (4). The final loss term for the training generator is

$$loss_G = loss_{Gwgp} + loss_{pt} \quad \textbf{(6)}$$

The network structure is illustrated in Figure 1. During the training phase, real embeddings and fake inputs of the same size are fed into the network separately in batches, with the goal of optimizing the aforementioned losses of the discriminator and generator. During 1 training epoch, batches of real labeled data, real unlabeled data, and fake data are fed into the network to calculate different loss terms for optimization. Batch normalization is conducted. After training, the discriminator loss is expected to be stable and could be exploited as a classifier for testing samples and predictions. The generator is suitable for measuring data quality and preserving privacy.

Figure 1. An overview of the proposed model. Real samples are extracted from the k-NN graph by the embedding layer, and the fake samples generated by the generator have the same dimension. Both real and fake samples are fed into and backpropagated from the discriminator in minibatches. The output layer of the discriminator is softmax. The embedding layer is a pretrained large-scale information network embedding [32]. BN: batch normalization; k-NN: k-nearest neighbors.



Data Sets and Experimental Setup

EHR data sets were obtained from public resources, including University of California Irvine Machine Learning Repository Type 2 Diabetes 30-Day Readmission (UCI-T2D) [41]; Surveillance, Epidemiology, and End Results Ovarian Cancer (SEER-OVC) [42]; and Surveillance, Epidemiology, and End Results Colorectal Cancer (SEER-CRC) [42]. The dimensional information is summarized in Table 1. Another colorectal cancer data set from the Second Affiliated Hospital Zhejiang University School of Medicine (SAHZU-CRC) was selected to investigate feasibility in practical situations. These data sets were selected because they are long-term follow-ups, the labels of which take much time and effort to obtain and are likely to be missing due to regulations on data collection. The selected features included basic demographics, medication, clinical codes, stage codes, laboratory variables, and dispositions. A basic description of the data sets and preprocessing is provided in Multimedia Appendix 1B.

We trained the proposed models for a maximum of 200 epochs using Adam optimization with a learning rate of 0.003 and a momentum of 0.5. The batch size was 128. For each class, the rate of labeled points (the label rate is the percentage of labeled points among all points) increased progressively from 5% to 25% with a step of 5%. The number of test sets was set as 20% of the data set.

Table 1. Dimensional description of the selected data sets.

Data sets	Records	Categorical variables	Numerical variables	Preprocessed dimensions	Labeling standard
University of California Irvine Machine Learning Repository Type 2 Diabetes 30-Day Readmission	61,675	44	8	57	Readmission in 30 days
Surveillance, Epidemiology, and End Results Ovarian Cancer	10,038	18	3	34	Survival over 5 years
Surveillance, Epidemiology, and End Results Colorectal Cancer	40,014	7	2	14	Survival over 5 years
Second Affiliated Hospital of Zhejiang University	1244	8	2	14	Survival over 5 years

We compared the model with the following baselines: (1) supervised learning methods, including logistic regression (LR), a support vector machine (SVM), and a random forest (RF) and (2) SSL methods, including graph-based semisupervised learning (GSSL) and label propagation (LP). All these methods are run using the *scikit-learn* Python package. The graph convolutional network (GCN) [25,27], a state-of-the-art graph-based semisupervised deep learning method, is also considered a competing method. To measure the classification performance, the accuracy and recall—for the important purpose of excluding false negative cases to conserve medical resources—and the area under the receiver operating characteristics curve (AUC) were selected as metrics. Each metric represented the average of 30 repetitions of 10-fold cross-validation training.

Ethical Considerations

This study did not involve any human or animal experiments. The UCI-T2D, SEER-OVC, and SEER-CRC data sets are public, and we complied with their ethical requirements. We also used a colorectal cancer–specific disease cohort of the Second Affiliated Hospital Zhejiang University School of Medicine; this was approved by the Human Research Ethics Committee of Zhejiang University in August 2017 (2017-067).

Results

SSL-based Classification of EHR Data

In the aforementioned experiments, the proposed method for semisupervised classification outperformed related semisupervised methods by a decent margin. Basic graph

semisupervised methods (ie, GSSL) are limited in classification performance, mostly due to their assumption that edges encode only the similarity of nodes. The spectral methods (LP and GCNs) do not perform well, perhaps because their low-order approximation may smooth the frontiers in the graph. Neither of these 2 methods consider the local properties of the input graph, and under some circumstances, they classify the majority of nodes into 1 class. Additionally, at a 10% to 15% label rate, the proposed method achieves the best performance on SEER-OVC, SEER-CRC, and SAHZU-CRC (Table 2). The AUCs declined as label rates continued to rise. GCNs, as the state-of-the-art semisupervised deep learning method, had somewhat better results for a data set with a size that can be handled by a GPU, but still exhibited worse performance than the proposed method, presumably due to oversmoothing the graphs and having less refined loss.

In regard to supervised learning, as shown by the bars in Figure 2A, even with a label rate of 10%, SSL on a graph with a GAN performed comparably to the supervised learning methods. As the portion of labeled data increased, the learning performance progressively increased, which is a consequence of the abundant information of the label distribution over the constructed graph. However, as the label rate continued to rise, the performance decreased because of mode collapse and overfitting. As the error bars show, with 10% labeled data, the standard deviations of the proposed model are slightly larger, as shown in Figures 2A and 2C, indicating a limitation of our proposed method; it only applies to certain low label-rate circumstances. When the labels are sufficient, more robust SL methods are better. However, some poorly trained and undertuned SL methods show far worse metrics in testing. Additionally, as the vector dimensions, shown in Table 1, decreased somewhat, the learning performance showed a significant decrease. This is perhaps a consequence of the lack of dimension diversity for similarity encoding and the local graph structure.

Table 2. Summary of the results of the classification AUCs for semisupervised learning methods under progressively increasing label rates. The learning performance of the graph convolutional network on the large data sets—that is, data sets other than Second Affiliated Hospital of Zhejiang University Colorectal Cancer—is unavailable due to memory limits.

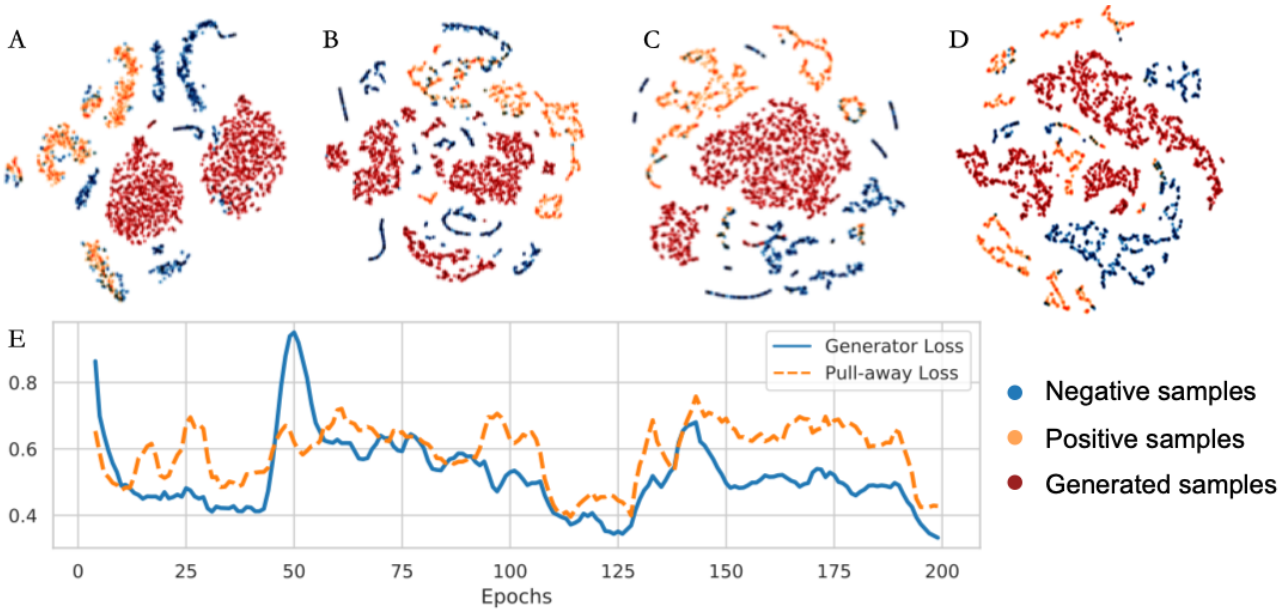
Boosting Semisupervised Learning by Generating a Density Gap

In this section, we visualize the final layer of discriminator D in the proposed method by feeding it real samples from UCI-T2D and their generated counterparts. By embedding the output layer at different iteration steps with t-distributed stochastic neighbor embedding [22], the progression of the density gap from the generated samples, described in equation 4, is verified.

In Figure 3, we can see that at the starting epochs, the generated samples are mixed with the real samples, and the different classes are not divided. During training, D gradually learns a nonlinear map to project the fake samples and real samples into distinct clusters, while G learns to generate samples to take over the central area and isolate the clusters of different classes. This process has 2 advantages. First, the fake samples from the generator are unlikely to be copies of the original data, avoiding the direct disclosure of private information. Second, the samples on the borders of different classes are more correctly divided, which not only improves the accuracy of classification but also reveals the underlying training strategy of splitting one large class into several smaller classes to obtain a better classification.

Figure 3. The progressive generation of density gaps in high-dimensional space and its visualization. (A) 0 epochs; (B) 40 epochs; (C) 80 epochs; (D) 120 epochs. The generated samples ultimately span the gap between a real and a false sample. The line chart (E) indicates the function of the pull-away term and how its optimization affects the generator and discriminator.



Fidelity Evaluation of the Generated Data

Frontier nodes are nodes at the borders of different clusters in a graph. The definition is given in Multimedia Appendix 1D. It is possible that a trained model is exploited directly for secondary purposes, such as fundamental profiling or developmental usage during the primary phase of data sharing [12]. We calculated the dimensionwise probability (DWPro) and dimensionwise prediction (DWPre) proposed by Choi et al [15] to evaluate the fidelity of the generator in our proposed model. DWPro is a basic statistical confirmation of the distributions of real data that are appropriately learned by the generator in the model. A training set R and synthetic sample set S of the same sample size are compared using the Bernoulli success probability pk of each dimension k. DWPre measures the extent to which the internal relations of every feature are captured. One dimension k is selected, and the rest of the features are used as training data. R and S are used to train the LR classifiers. Then, the dimension k is regarded as the label column for testing. It is a rational assumption that a smaller margin between the predictions of 2 models implies a better synthetic quality. The F_1-score is selected as the metric for comparison.

Figure 4 shows that all 4 data sets were depicted well from a featurewise perspective, and over half of the dots are near the diagonal line. In Figure 4C, the consistency of each feature indicates high synthetic quality. Figure 5 shows a mildly diminished learning quality considering interdimensional fidelity. However, half of the features are still likely to be inferred from the remaining columns and the same proportion of features. Considering that the generated frontier is still different from the directly generated datapoints [15,16], the fidelity is acceptable for some secondary uses.

Figure 4. Dimensionwise probability of 4 selected data sets: (A) University of California Irvine Machine Learning Repository Type 2 Diabetes 30-Day Readmission; (B) Surveillance, Epidemiology, and End Results Ovarian Cancer; (C) Surveillance, Epidemiology, and End Results Colorectal Cancer; (D) Second Affiliated Hospital of Zhejiang University Colorectal Cancer. The x-axis is the Bernoulli success probability for the features of the real data sets, while the y-axis is the corresponding value from the synthetic data. Each blue dot represents a feature of the data set. The red diagonal line indicates an identical Bernoulli success probability of both the real and generated data sets, and ideal fidelity is learned featurewise by the generator.

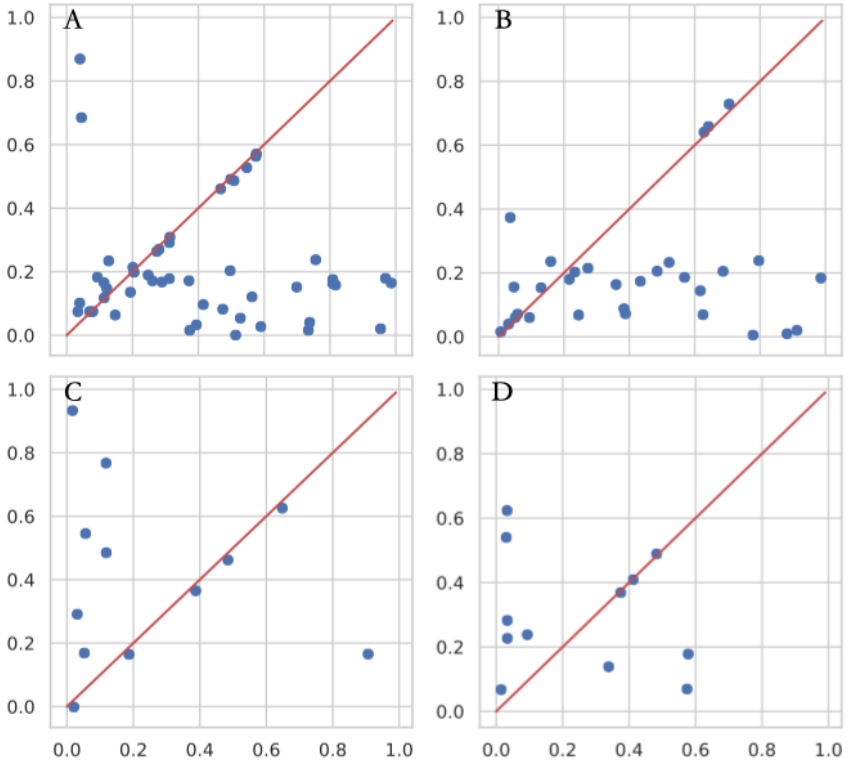


Figure 5. Dimensionwise prediction of 4 selected data sets: (A) University of California Irvine Machine Learning Repository Type 2 Diabetes 30-Day Readmission; (B) Surveillance, Epidemiology, and End Results Ovarian Cancer; (C) Surveillance, Epidemiology, and End Results Colorectal Cancer; (D) Second Affiliated Hospital of Zhejiang University Colorectal Cancer. The x-axis is the F_1-score of models trained on the real data sets, while the y-axis is the corresponding values from the synthetic data. Each blue dot represents a feature of the data set. The red diagonal line indicates that the F_1-score was identical for the models trained and tested on the real and generated data sets, and ideal interdimensional fidelity was learned by the generator.

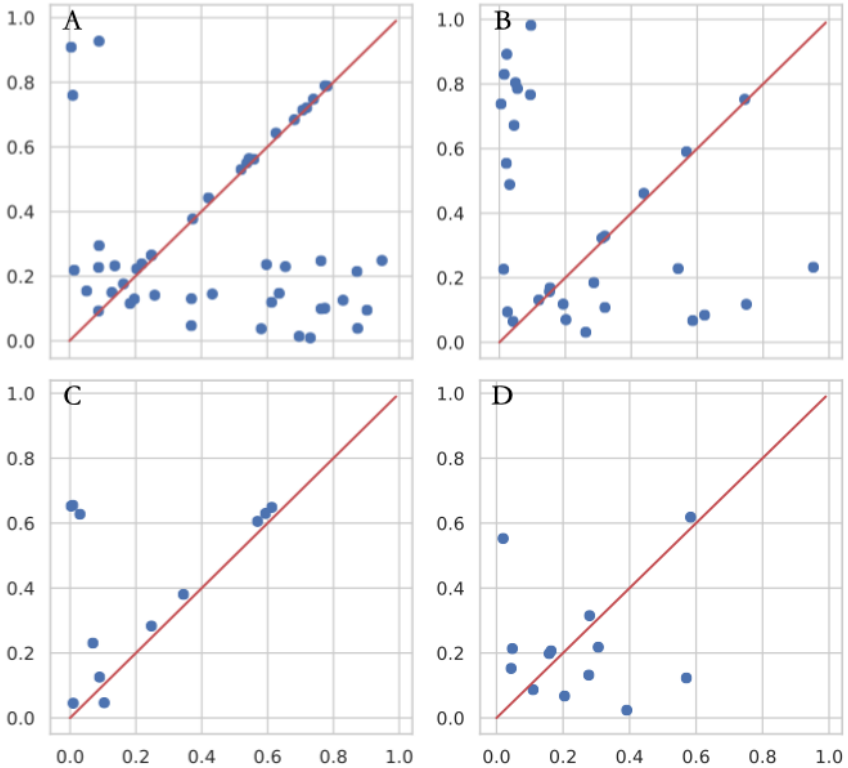
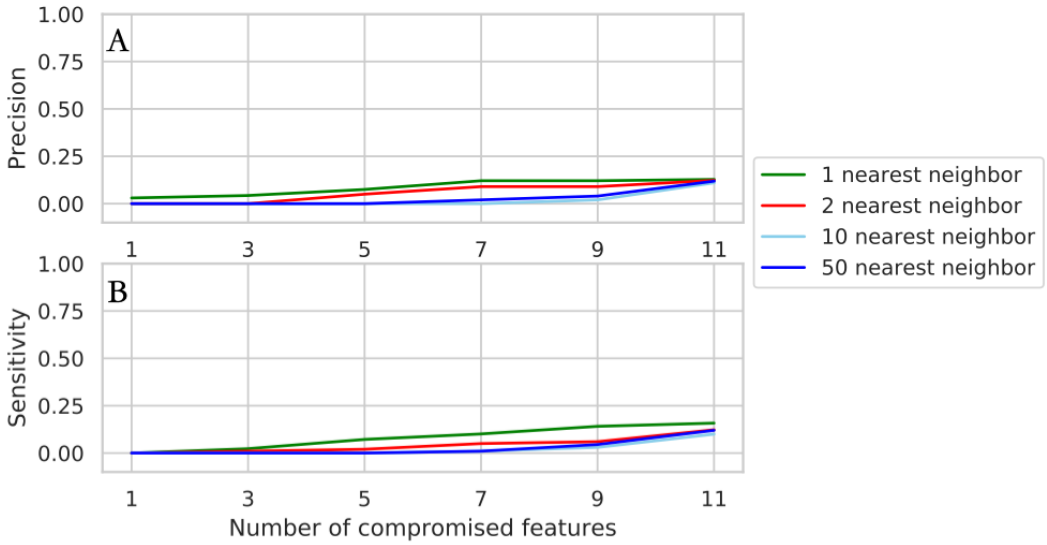


Evaluation of the Disclosure Risk of the Generated Data

The generator in our proposed model may be exploited to generate data points similar to the original data sets, posing threats to patient privacy. We need to ensure that the frontier nodes generated by the proposed model can be protected from attackers with compromised data. Therefore, a quantitative evaluation of presence and attribute disclosure was conducted on the SAHZU-CRC data set. Of the real samples N, 1% were randomly sampled, and among the 11 dimensions (the numerical dimensions are left out and the nominal columns are collapsed into 2 for simplification), a progressively increasing number of features, denoted as r, were assumed to be known by the attacker. Then, the attacker could exploit the knowledge of the data (1% × N × r) to conduct k-NN searches of the synthetic data, and the other unknown feature values were estimated according to those of the k-NN. Finally, the unknown features were compared to the real features to gain precision and accuracy. The calculation was repeated 100 times with 1% of the real records chosen at random.

Under these circumstances, the sensitivity indicates when the attacker has 1% × N × r of the disclosed data and all the synthetic data and how many records of all the positive features the attacker can correctly estimate with a 1-NN attack. The precision indicates how many features among all the features estimated positive by the attack were on average accurate. For instance, in Figure 6A, if an attacker with 1% of the records (12 of 1244 records for SAHZU-CRC) and 5 features from the real data conducts 1-NN on the synthetic SAHZU-CRC data generated by the proposed method, the positive estimation of the remaining unknown features of the real data will be 12.5% correct on average (0.125 precision), and of all the positive predictions, 15.8% will be correct (0.158 sensitivity).

Figure 6. Privacy preservation evaluation. When increasing the number of known features, the attack achieves (A) precision and (B) sensitivity with 1% compromised records from the Second Affiliated Hospital of Zhejiang University data set.



In summary, the precision and sensitivity of attacks on synthetic data is relatively low, 0.158 at best when r is 11. The most effective attack setting is 1-NN. It is difficult to estimate more information from our frontier nodes due to the modification of the network losses. Substitution of both the generator and discriminator learning strategies boosts the model performance on classification with label deficiency and provides synthetic samples capable of preventing disclosure.

Scalability of the Memory Consumption of Batch-Based Training

Because GPUs have been used in deep learning–based computation, we further examined whether the proposed method could achieve practical memory consumption. The aforementioned semisupervised methods are compared with our proposed method on memory consumption for 4 data sets. For the algorithms that do not need GPUs, their central processing unit consumption is measured.

For small data sets (eg, SAHZU-CRC), our proposed method takes up more space because of its complex network structure (Table 3). However, as the size expands, our proposed method shows the least and most stable space consumption, because minibatch training is independent of the number of samples (for SEER-CRC and SEER-OVC). Conventional network-based SSL methods tend to train on full batches. When the data set is large enough, there is a huge obstacle to storing the data in memory. Stable memory consumption implies a scalable model for training and prediction on diverse data sizes. The GCN, as a transductive SSL method, is unable to be directly scaled to larger data sets despite its excellent representative ability.

Table 3. Graphics processing unit memory consumption of the proposed method against that of typical semisupervised learning algorithms on 4 data sets. The graph convolutional network is not suitable for data sets other than Second Affiliated Hospital of Zhejiang University; therefore, only one result is shown.

Discussion

Principal Results

The proposed model fully utilizes the inner graphical structure of EHRs and provides cost-effective prediction metrics. The density gap derived from the modified network loss enables different class labels to be better distinguished. Under label-deficient circumstances, the proposed model achieves a comparable performance to that of conventional supervised learning methods where all of the training data are labeled. Specifically, with only 10% labeled data, the performance of popular supervised machine learning methods is approached, which implies there is a broad set of situations in which this model could be considered for prediction tasks. Following the same setting of label rates for the purpose of comparison, the conventional SSL methods show poor data representation ability. The learning performance, compared to that of our proposed method, shows worse stability and scalability. With the increasing label rate, the conventional SSL models display either poor performance on classification due to label deficiency or extreme cases where the classifier puts every sample into 1 class as a consequence of overfitting. Additionally, the memory cost is worth noting. Most semisupervised methods have a tendency to copy the whole graph structure into memory [19,27,43], which brings a very large burden of computational resources considering that the EHRs absorb increasingly more data.

Extracting the frontier of generated samples that shows high performance in DWPro and DWPre has potential in applying some special frontier nodes as sample data for secondary usage, in the same way as related work applies GANs to RS-EHR generation. According to related studies [15,16], generating data with adequate quality is crucial in cross-organization data sharing. The quality of the data determines the model performance on realistic data sets. Additionally, for diverse developmental needs, the more realistic the generated data are compared to the real samples, the more persuasiveness and fidelity the researching systems will acquire. The generator in our model fulfills this demand by generating similar samples to the original data after the training phase.

To reveal the hidden clinical and physiological characteristics of certain groups, EHRs are among the most reliable information sources. Nonetheless, administrative regulations and the protection of patient privacy have decreased the accessibility of EHRs for a variety of reasons and made downstream analysis inconvenient. Our method first addresses privacy considerations by transforming the data set into a k-NN graph where the similarities between different patients are re-encoded while the identifying information is hidden. Second, the vector from the embedded graph is fed into our model for further analysis. Under practical scenarios, authorization to share and use the original data will not be a necessity. Additionally, even when conventional attacks attempt to reidentify personal information from the publicly generated samples, the k-precision and k-sensitivity metrics indicate that it is quite safe if the attacker holds only a small fraction of the knowledge of the real data and conducts the most powerful 1-NN attack. Furthermore, the density gaps avoid the usual case where GANs would otherwise be trained to copy the real input, thereby shielding the patient information from another possible method of disclosure.

Limitations

The limitations of this study are still worth noting. The evaluation of how the proposed model can improve data quality and predict performance on the actual label collection phase has yet to be considered. Additionally, we excluded all patient duplicates to conduct a prediction method without considering any temporal information. Further investigation of the temporal trajectories of the same patients may reveal more of the inner mechanisms of disease progression, and localization methods of temporal and spatial structure in many other fields may address the same problem [44,45]. Additionally, the proposed model only applies to some label-rate setups, and performance diminishes as more labels become available. The thresholds for switching between the different algorithms (SSL and SL) remain to be studied. Finally, to be more protective of patient privacy and intellectual property, our future explorations include graph generation and attention mechanisms [28,29,34,46]. A whole generated graph can be taken into consideration. With the power of GANs, the underlying structure of large-scale EHRs could be preserved while achieving full anonymity.

Conclusions

EHR-based systems and observational studies with conventional learning strategies are facing diverse challenges as data and

label inaccessibility increase. Training on few labeled data is a pivotal task and needs substantial resources. Uncovering the underlying graphical structure of EHRs brings a motivating perspective and informative prerequisites to analyzing patient data. As a downstream analysis method, GAN-boosted SSL uses a graphical structure and greatly improves learning quality in label-deficient situations. GANs with refined loss also meet the demands of deidentification and decent data fidelity under multiple-source data-sharing circumstances. This combination achieves impressive performance on prediction metrics, data quality, and protection from compromising attackers over various data sets, while popular machine learning methods encounter obstacles to sufficient training. This study indicates the potential of discovering the structural features that underlie the data instead of merely feeding models coordinated data sets and using unlabeled data when label deficiency occurs.

Abstract

Background: Best Practice Alerts (BPAs) are alert messages to physicians in the electronic health record that are used to encourage appropriate use of health care resources. While these alerts are helpful in both improving care and reducing costs, BPAs are often broadly applied nonselectively across entire patient populations. The development of large language models (LLMs) provides an opportunity to selectively identify patients for BPAs.

Objective: In this paper, we present an example case where an LLM screening tool is used to select patients appropriate for a BPA encouraging the prescription of deep vein thrombosis (DVT) anticoagulation prophylaxis. The artificial intelligence (AI) screening tool was developed to identify patients experiencing acute bleeding and exclude them from receiving a DVT prophylaxis BPA.

Methods: Our AI screening tool used a BioMed-RoBERTa (Robustly Optimized Bidirectional Encoder Representations from Transformers Pretraining Approach; AllenAI) model to perform classification of physician notes, identifying patients without active bleeding and thus appropriate for a thromboembolism prophylaxis BPA. The BioMed-RoBERTa model was fine-tuned using 500 history and physical notes of patients from the MIMIC-III (Medical Information Mart for Intensive Care) database who were not prescribed anticoagulation. A development set of 300 MIMIC patient notes was used to determine the model's hyperparameters, and a separate test set of 300 patient notes was used to evaluate the screening tool.

Results: Our MIMIC-III test set population of 300 patients included 72 patients with bleeding (ie, were not appropriate for a DVT prophylaxis BPA) and 228 without bleeding who were appropriate for a DVT prophylaxis BPA. The AI screening tool achieved impressive accuracy with a precision-recall area under the curve of 0.82 (95% CI 0.75-0.89) and a receiver operator curve area under the curve of 0.89 (95% CI 0.84-0.94). The screening tool reduced the number of patients who would trigger an alert by 20% (240 instead of 300 alerts) and increased alert applicability by 14.8% (218 [90.8%] positive alerts from 240 total alerts instead of 228 [76%] positive alerts from 300 total alerts), compared to nonselectively sending alerts for all patients.

Conclusions: These results show a proof of concept on how language models can be used as a screening tool for BPAs. We provide an example AI screening tool that uses a HIPAA (Health Insurance Portability and Accountability Act)–compliant BioMed-RoBERTa model deployed with minimal computing power. Larger models (eg, Generative Pre-trained Transformers–3, Generative Pre-trained Transformers–4, and Pathways Language Model) will exhibit superior performance but require data use agreements to be HIPAA compliant. We anticipate LLMs to revolutionize quality improvement in hospital medicine.

large language models; language models; language model; EHR; health record; health records; quality improvement; Artificial Intelligence; Natural Language Processing

Introduction

Large language models (LLMs) are an exciting development in the field of natural language processing and present tremendous potential for application to clinical medicine. Language models such as Bidirectional Encoder Representations from Transformers (BERT), Robustly Optimized BERT Pretraining Approach (RoBERTa), and Generative Pre-trained Transformers (GPT) can perform complex tasks such as text classification, question answering, and text generation, which have the potential to augment physicians in providing care for patients. A clinical application of significant potential is LLM optimization of quality improvement electronic health record (EHR) Best Practice Alerts (BPAs).

EHR BPAs are powerful tools to improve patient care outcomes. Their widespread use has demonstrated better adherence to clinical guidelines, fewer medication errors, improved diabetes management, more appropriate antimicrobial prescribing, and higher rates of ambulatory preventive care, among others [1]. Nevertheless, despite these benefits, the overuse of BPAs can cause alarm fatigue and desensitization that can even lead to patient harm, as described by the Joint Commission Alert System Safety Report of 2014 [2,3]. Current BPAs are often overconservative, broadly applied to all possible patients, resulting in up to 49% to 96% of alerts being overridden or ignored [4]. A BPA will frequently be obviously inappropriate or not applicable to the patient, resulting in the physician becoming desensitized to the alert and more likely to ignore a valid alert in the future [5,6]. LLMs offer an opportunity to screen appropriate patients for BPAs.

In this paper, we propose how language models can be leveraged to read a physician's note and screen whether a patient is appropriate for a BPA. We examine an example case using a BioMed-RoBERTa artificial intelligence (AI) screening tool that selectively identifies patients who are appropriate for a deep vein thrombosis prophylaxis. Our screening tool reads each history and physical note to identify whether a patient has active bleeding (a contraindication to anticoagulation) and excludes those patients with bleeding from receiving a deep vein thrombosis prophylaxis BPA. We hope our methods will encourage the use of language models to screen patients for BPAs and improve EHR workflow.

Methods

Patient Note Data Set

The MIMIC-III (Medical Information Mart for Intensive Care) data set is publicly available and consists of more than 60,000 intensive care unit admissions from the Brigham and Women's Hospital system [7-9]. The data set includes EHR-equivalent patient data, including physician notes and medication administration data.

For this study, we selected history and physical notes from MIMIC-III for patients who did not receive an anticoagulant (therapeutic or prophylactic) at the time of admission. We selected the first 1100 history and physical notes in chronological time stamp order for inclusion in this study. Each note described a unique patient, meaning no 2 notes had the same patient identifier (subject_id). The subject_id and time stamp for each note included in our study were recorded and can be shared upon request with proper registry for the MIMIC database on the PhysioNet platform. Due to LLM token limits, patient notes were truncated to 2000 characters (RoBERTa models can receive a maximum of 512 tokens, which translates to roughly 2000 characters).

The MIMIC-III notes were then split into a training set (first 500 notes), development set (middle 300 notes), and test set (final 300 notes). The training set was used to fine-tune the AI model, the development set was used to determine model hyperparameters (learning rate, batch number, training epochs, and seed number), and the test set was used for screening tool evaluation. Cohort information can be shared upon request with registry for the MIMIC database on the PhysioNet platform.

In total, 2 physicians (TS and JW) reviewed all notes and labeled each note as either describing a patient with active bleeding or without active bleeding. Active bleeding was defined as the loss of blood from the vessels of the body either by documented visual or imaging evidence of bleeding as well as suspected bleeding documented by the physician author. These labels were used as the gold standard labels for model evaluation. If there was disagreement between labels assigned by the 2 reviewers, the case was discussed to reach a final label designation.

Language Model

The language model used in this screening tool was BioMed-RoBERTa [10] by AllenAI. BioMed-RoBERTa is a bidirectional transformer encoder based on the RoBERTa-base model published by Liu et al [11]. BioMed-RoBERTa continued pretraining beyond RoBERTa-base using 2.68 million scientific papers in the domains of biology and medicine from the Semantic Scholar corpus [10]. Therefore BioMed-RoBERTa has increased proficiency in the subjects of biology and medicine compared to RoBERTa-base.

The optimal hyperparameter settings were identified as 9 training epochs, a training batch size of 2, a learning rate of 4×10^{-5}, and a starting seed of 9. The full code can be referenced in Multimedia Appendix 1

The model performed classification for each history and physical note, classifying the note as either describing active bleeding or no active bleeding.

Code and Computing Environment

Model training and evaluation were completed in a PyCharm notebook using an Apple M2 GPU. Full code can be referenced in Multimedia Appendix 1.

Statistical Methods

Model classification performance was evaluated on a test set of 300 MIMIC patient notes. Classification performance was evaluated by a precision-recall area under the curve (AUC), a receiver operating characteristic (ROC) AUC, sensitivity, and specificity. Error was calculated using a replacement bootstraps method with 4000 bootstrapped populations from the test set. The full code can be referenced in Multimedia Appendix 1.

The statistic "increase in alert applicability" was calculated from equation 1 below.

Ethical Considerations

The MIMIC patient records database is available as an open repository for credential users registered within the PhysioNet platform. The patient records within the MIMIC database have been deidentified, and patient identifiers have been removed according to the HIPAA (Health Insurance Portability and Accountability Act) Safe Harbor provision. This study was approved and authorized by the PhysioNet Team.

The collection of patient information and creation of the MIMIC research resource was reviewed by the institutional review board at the Beth Israel Deaconess Medical Center (protocol ID 73104), who granted a waiver of informed consent and approved the data sharing initiative. Due to the waiver of informed consent and anonymous nature of the MIMIC data set, patients were not compensated for inclusion in the database or this research.

Results

The test set of 300 MIMIC patient notes included 72 patients experiencing acute bleeding and 228 patients not experiencing acute bleeding. The AI screening tool was able to achieve a precision-recall curve AUC of 0.82 (95% CI 0.75-0.89; Figure 1) and a ROC AUC of 0.89 (95% CI 0.84-0.94; Figure 2). Sensitivity was found to be 67% (95% CI 55%-77%) and specificity was found to be 95% (95% CI 92%-97%). Sensitivity, specificity, and confusion matrix data can be found in Table 1.

If this model were used to identify patients for a thromboembolism prophylaxis BPA in place of a nonselective strategy deploying an alert for all patients, this model would reduce the number of BPA alerts by 20% (240 alerts sent instead of 300) and increase applicability of the BPA by 14.8% (equation 1). This model misclassified 12 patients who did not have bleeding and would be appropriate to receive a thromboembolism prophylaxis BPA. This model captured 94.7% (216/228) of the population who would be appropriate for an alert. The model achieved a positive predictive value of 80% and a negative predictive value of 90%. Full results can be found in Table 1.

A review of notes of patients who were incorrectly classified found trends where the tool underperformed. Of the 24 patients misclassified as without bleeding, the model had difficulty identifying bleeding if it was a secondary complaint (6 patients), meaning if the patient primarily presented for another chief complaint and bleeding was incidentally noted. The model also had difficulty interpreting atypical or rare abbreviations that denoted bleeding (6 patients). This included recognizing "subdural" as an abbreviation for subdural hemorrhage (2 patients), "EBL" as an abbreviation for estimated blood loss (2 patients), and "SAH" as an abbreviation for subarachnoid hemorrhage (2 patients). For the 12 patients misclassified as with bleeding, the model had difficulty with negated bleeding phrases (7 patients), for example "denies melena," as well as notes describing chronic anemia (2 patients) or previous bleeding events in the distant past that were not currently active (2 patients).

[b]LLM: large language model.

Discussion

Principal Findings

This prototype AI screening tool shows how language models can be leveraged to optimize EHR BPAs. Our example screening tool reduced the number of patients who would trigger an alert by 20% while also increasing applicability of alerts by 14.8% compared to nonselectively sending alerts for all patients. The tool achieved impressive accuracy with a precision-recall AUC of 0.82 and ROC AUC of 0.89. We demonstrate how the ability for language models to interpret physician notes to classify patients offers a new method of targeting the most appropriate patients for a BPA with high accuracy.

Language model screening tools to target patients for BPAs are most appropriate when the alert's goal is to catch most target patients but the consequence of missing a few patients is not significant. As demonstrated by our example, language models are accurate but do occasionally misclassify patients. Example use cases appropriate for an AI screening tool would be identifying patients for discontinuation of telemetry monitoring, ascribing correct level of nursing care (inpatient vs observation), and encouraging best prescribing practices for blood products. Inappropriate examples would be situations such as medication interactions or isolation precautions. In those cases, a nonselective blanket rule-based BPA would be more appropriate.

The limitations of the screening tool evaluated in this study were its relatively small training set of 500 patient notes as well as the use of the BioMed-RoBERTa model rather than a larger model such as GPT-3 or GPT-4. Increasing the size of our training set would likely decrease many of the misclassification errors seen by our screening tool. Specifically, the misclassification errors due to misinterpretation of atypical or rare abbreviations for bleeding would be reduced with an increased training set size. A larger base model would also reduce many of the errors observed by our screening tool. RoBERTa models contain 110 million parameters trained on

160 GB of text data [11]. Larger models, such as GPT-3, consist of 175 billion parameters trained on over 40 TB of text data, nearly 10 times the size of RoBERTa, and demonstrate superior performance in negation detection and semantic understanding [12,13]. Therefore, a larger model would reduce the misclassification errors caused by misinterpretation of negated bleeding or previous bleeding events in the distant past. Our study chose BioMed-RoBERTa because its smaller size allows it to be trained on a local computing environment compliant with the HIPAA 1996 data privacy standards. Future investigations will need to secure the necessary data use agreements to use larger models (eg, GPT-3, GPT-4, or Pathways Language Model) with medical grade data, where we anticipate screening tool performance will be significantly improved.

Conclusions

In this paper, we proposed a new application for LLMs in medicine. Quality improvement BPAs can leverage LLMs to read physician notes and better identify patients for BPA alerts. We provide an example case which demonstrates the ability of a BioMed-RoBERTa to achieve impressive classification accuracy. We anticipate that as the field of clinical natural language processing continues to grow, with increasing access to larger language models, LLMs will revolutionize the field of clinical quality improvement.

Data Availability

The Python code used for this investigation is available in Multimedia Appendix 1. MIMIC (Medical Information Mart for Intensive Care) patient data is an open repository requiring registration with the PhysioNet platform. Cohort information of the history and physical notes used to train, develop, and test our screening tool in can be shared upon request with proper registry for the MIMIC database on the PhysioNet platform.

Abstract

Background: This research integrates a comparative analysis of the performance of human researchers and OpenAI's ChatGPT in systematic review tasks and describes an assessment of the application of natural language processing (NLP) models in clinical practice through a review of 5 studies.

Objective: This study aimed to evaluate the reliability between ChatGPT and human researchers in extracting key information from clinical articles, and to investigate the practical use of NLP in clinical settings as evidenced by selected studies.

Methods: The study design comprised a systematic review of clinical articles executed independently by human researchers and ChatGPT. The level of agreement between and within raters for parameter extraction was assessed using the Fleiss and Cohen κ statistics.

Results: The comparative analysis revealed a high degree of concordance between ChatGPT and human researchers for most parameters, with less agreement for study design, clinical task, and clinical implementation. The review identified 5 significant studies that demonstrated the diverse applications of NLP in clinical settings. These studies' findings highlight the potential of NLP to improve clinical efficiency and patient outcomes in various contexts, from enhancing allergy detection and classification to improving quality metrics in psychotherapy treatments for veterans with posttraumatic stress disorder.

Conclusions: Our findings underscore the potential of NLP models, including ChatGPT, in performing systematic reviews and other clinical tasks. Despite certain limitations, NLP models present a promising avenue for enhancing health care efficiency and accuracy. Future studies must focus on broadening the range of clinical applications and exploring the ethical considerations of implementing NLP applications in health care settings.

Introduction

The following manuscript was augmented by ChatGPT (versions 3.5 and 4.0; OpenAI [1]). ChatGPT-generated text is shown in Roman (unitalicized) font and has not been altered. Any modifications to the generated text, including corrections to sources or information, are explicitly indicated. Any text added or revised by human authors is shown in italics. All in-text reference citations have been reformatted to adhere to the journal's style preferences.

Natural Language Processing (NLP) has emerged as a powerful tool in recent years, enabling the processing and analysis of vast amounts of unstructured textual data in various domains,

including healthcare and clinical practice [2] *(added [3])*. The application of NLP techniques in clinical settings has the potential to revolutionize the way medical professionals manage and analyze patient information, leading to improved patient outcomes, reduced costs, and increased efficiency in medical decision-making [4] *(added [5])*.

In clinical practice, NLP can facilitate various tasks, such as disease diagnosis, treatment decision support, automation of clinical tasks, and data mining [6]. For instance, NLP algorithms have been used to screen and identify patients at risk for specific conditions [7], aid in the diagnosis of diseases by analyzing electronic health records (EHRs) [original: Demner-Fushman, D., & Chapman, W. W. (2017)] *(new [8])*, provide decision support in treatment planning [original: Wang, Y et al. (2017)] *(new [9])*, and automate routine clinical tasks [original: Devlin, J. et al. (2019)] *(new [10])*. Furthermore, NLP has been employed in the analysis of large-scale medical literature to identify trends, generate hypotheses, and inform clinical decision-making [original: Brown, T. B. et al. (2020)] *(new [11])*.

Recent advancements in NLP, particularly the introduction of transformer-based models like Bidirectional Encoder Representations from Transformers (BERT) [original: Vaswani, A et al. (2017)] *(new [12])*, Generative Pre-trained Transformers (GPT) [original: Lee et al, 2020] *(new [13])*, and their variants *(moved [14])*, have significantly improved the performance of NLP tasks, including information extraction, question-answering, and text summarization. Transformer networks leverage attention mechanisms, allowing them to learn contextual relationships between words in a given text, thus enabling a more nuanced understanding of the input data [15].

Transformer-based models like BERT and GPT work using a self-attention mechanism, allowing them to focus on relevant words in a sentence, thus capturing contextual information efficiently [16]. This approach enables precise understanding of semantic relationships, making these models adept at tasks such as named entity recognition and text summarization [12].

However, these models have limitations. The attention mechanism is resource-intensive, potentially limiting their use in constrained environments [17]. Furthermore, while able to generate plausible-sounding outputs, they may occasionally produce nonsensical or incorrect results (called “artificial hallucination”), which emphasizes the need for careful interpretation [original: McCoy et al. 2019] *(new [18])*.

These models have been successfully applied to various healthcare-related tasks, including biomedical literature mining [19], clinical concept extraction [20] *(added [21])*, and predicting patient outcomes [original: Nye et al. 2018] *(new [22])*.

Large language models (LLM) represent the cutting-edge of NLP, demonstrating exceptional performance in various tasks by leveraging their extensive pre-training on vast textual data [original: Smith et al., 2022] *(new [23])*.

Yet, despite the notable advancements in NLP and LLMs, traditional systematic reviews continue to pose significant limitations [24] *(added [25])*. Traditional approaches to systematic reviews are often labor-intensive and time-consuming, involving manual screening of literature and information extraction [26]. Such processes are not only susceptible to human error [27] but also struggle to cope with the exponential increase in available medical literature [28]. The extensive and complex nature of medical data, combined with the ever-evolving landscape of clinical research, presents a substantial challenge to traditional systematic review methods [29] *(added [30])*. Thus, there is a pressing need for more sophisticated and automated solutions, such as those provided by NLP, to handle the growing volume and complexity of medical literature [31].

In light of these developments, we aim to conduct a systematic review aided by NLP, specifically leveraging the capabilities of transformer-based models like GPT, to synthesize the existing literature on the application of NLP in clinical practice. Our review will focus on studies published between January 2020 and the present, evaluating the performance, implementation, and impact of NLP techniques in clinical settings. By integrating NLP into the systematic review process, we aim to increase the efficiency and accuracy of the review, enabling the identification of relevant studies, extraction of key information, and synthesis of findings in a more streamlined manner [32].

LLMs have been gaining traction in both social media and the scientific community. We compared the results of human researchers *(with a research experience of >7 years)* versus ChatGPT (Versions 3.5 and 4.0) in an artificial intelligence augmented systematic review. The goal was to explore the usefulness and limitations of LLMs in clinical practice, medical research and writing publications.

The main aim was to evaluate how effectively and reliably ChatGPT could support the process of conducting a medical systematic review, while also identifying potential issues and offering insights into the rapidly evolving field of artificial intelligence.

Methods

Overview

The task of conducting a systematic review was augmented using ChatGPT. ChatGPT was used for general considerations in conducting a systematic review; determining MeSH (Medical Subject Headings) terms; title, abstract, and full-text screening; limited data extraction; and text generation.

This manuscript was generated in several sections; therefore, modifications for better readability—for example, the order of text sections, numbering of references, and the use of abbreviations—are not shown. Relevant conversations with ChatGPT are provided in Figure 1 and Multimedia Appendices 1-16.

Our systematic review followed the guidelines provided by the Cochrane Handbook for Systematic Reviews of Interventions [33] *(added [34])* and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [25]. *The PRISMA flowchart is shown in Figure 2 and the PRISMA checklist in Multimedia Appendix 17.*

Figure 1. An exemplary prompt and response from ChatGPT as a multistep answer for prompt generation for the abstract text module.

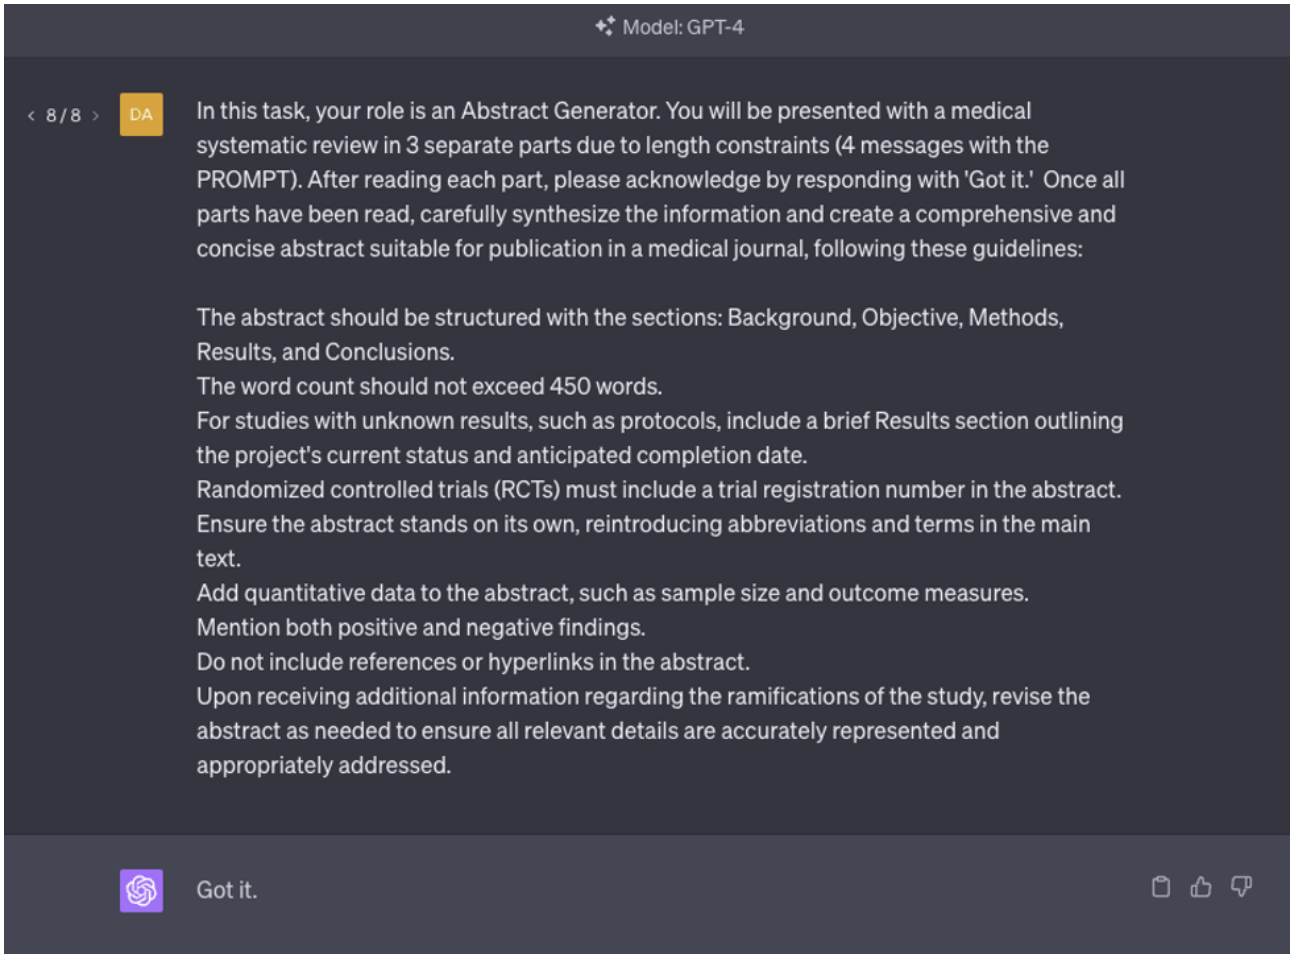

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart. *In consensus, multiple reasons possible. MeSH: Medial Subject Headings; NLP: natural language processing.

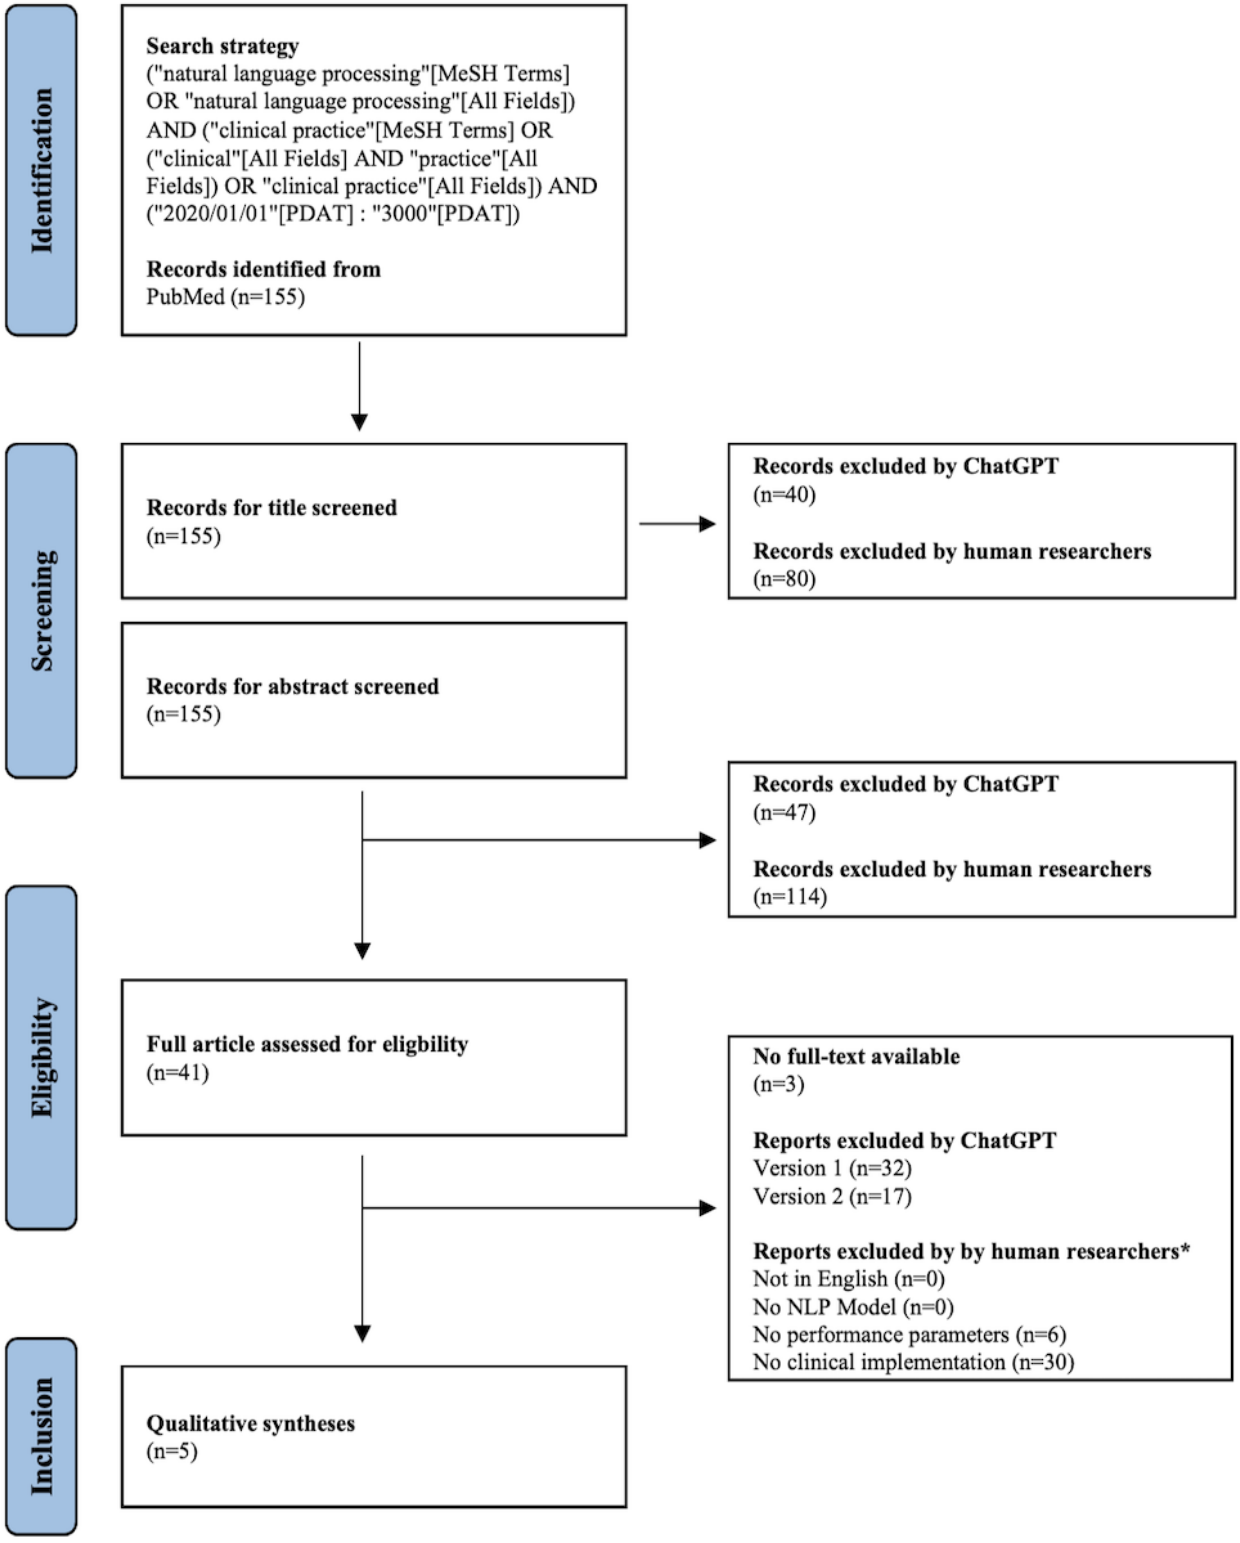

Search Strategy

We utilized ChatGPT 3.5 legacy (Version Jan 30, *OpenAI[1]*) to generate a MESH search strategy and define the inclusion and exclusion criteria for our review. *We repeated the prompts for MeSH term generation multiple times and refined the MeSH terms by narrowing overly broad terms, incorporating essential terms that were initially omitted by ChatGPT and excluding terms that were not relevant to our review.* Two human researchers, NS and DB, used the MESH terms generated for the PubMed search and retrieved a total of 155 articles. They prepared the articles for presentation to ChatGPT, presenting only the title for title screening, only the abstract for abstract screening, and only the text of the Introduction, Methods, Results, and Discussion for full-text screening, *without any reference to authors or publishing journal, etc*. NS and DB also

created all the prompts for ChatGPT and saved all interactions with the Transformer network. These interactions will be made available as supplementary materials.

Screening Process

Title and abstract screening were conducted independently by ChatGPT 3.5 legacy and the two human researchers, NS and DB. Abstracts were only included for full-text analysis when a consensus was reached between ChatGPT and the human researchers (n=41). NS and DB then generated a table for structured data extraction at the full-text screening level, which will be included in the paper.

Two separate instances of ChatGPT 3.5 legacy were used to independently screen all full texts prepared by NS and DB. NS and DB also evaluated all full-text articles (n=41) for inclusion or exclusion.

Data Extraction and Synthesis

The review of the five included articles was conducted by ChatGPT 4.0 (Version March 15). First, ChatGPT summarized each paper. Next, it was asked to generate a results section and discussion section. All authors extracted data from the included papers and reviewed the text generated by ChatGPT 4.0, making any necessary adjustments and adaptations. *Additionally, tables and charts were generated by human researchers, owing to the constraints of ChatGPT at the time of conducting this study. We extracted the following items in the extraction table (Table S1 in Multimedia Appendix 18): English language (yes/no), targeted disease, study design (randomized controlled trial; cohort study; cross-sectional study; case report or series; meta-analysis, systematic review, or review; opinion; others, experimental, or not applicable), NLP model (yes/no), sample size, performance parameters available (yes/no), clinical task (screening or risk, disease diagnosis, treatment decision, decision support, automation of clinical tasks, data mining or automated document evaluation, others, or not applicable), and clinical implementation (yes/no). The reference directory was compiled by human researchers.*

Statistical Analysis of GPT and Human Performance

In this study, we used several standard performance metrics to evaluate the effectiveness of the search strategy generated by ChatGPT. Below, we describe the calculation of each of these metrics.

Sensitivity (also known as True Positive Rate): Sensitivity is calculated as the number of true positives (TP) divided by the sum of the true positives and the false negatives (FN).

Sensitivity=TP(TP+FN)

Specificity: Specificity is calculated as the number of true negatives (TN) divided by the sum of the true negatives and the false positives (FP).

Specificity=TN(TN+FP)

Precision (also known as Positive Predictive Value): Precision is calculated as the number of true positives (TP) divided by the sum of the true positives and the false positives (FP).

Precision=TP(TP+FP)

Accuracy: Accuracy is calculated as the sum of the true positives (TP) and true negatives (TN) divided by the sum of the true positives, true negatives, false positives, and false negatives.

Accuracy=(TP+TN)(TP+TN+FP+FN)

Chance Hit Rate: The Chance Hit Rate is calculated as the sum of the product of sensitivity and prevalence, and the product of specificity and (1-prevalence).

Chance Hit Rate=(Sensitivity·Prevalence)+(Specificity·(1−Prevalence))

Statistical analysis was carried out by the human researchers due to limitations of ChatGPT at that time. The inter- and intrarater reliability, sensitivity, specificity, and other statistics were calculated using the inclusion/exclusion table created by all authors. The extracted data were compared using Fleiss and Cohen κ, correlating results from both human researchers and 2 iterations of ChatGPT 3.5 [35,36]. Consensus among human researchers was considered the gold standard to compare the performance of the human researchers with that of ChatGPT 3.5 iterations. When a specific measure was not considered as an item, we used a binary categorization of "correct" or "incorrect" as the items (ie, sample size) for assessing inter- and intrarater reliability, decided by consensus with consultation of a third human researcher.

Results

MESH Search and Screening Process

Our MESH search on PubMed yielded 155 papers. Upon screening the titles, the two human researchers included 75 papers, while ChatGPT 3.5 included 115, achieving a sensitivity of [original: 97.33%] *100%* and specificity of [original: 37.5%] *50%(precision=65.2%, accuracy=74.2%, and chance hit rate=49.2%)*. Following the abstract screening of all 155 abstracts, the two human researchers included 41 articles, while ChatGPT 3.5 included 108, resulting in a sensitivity of [original: 95.12] *100%* and specificity of [original: 34.38] 41.2% *(precision=39.6%, accuracy=56.8%, and chance hit rate=40.7%)*. A total of [original: 38] *41* articles were selected for full-text analysis, with 3 articles being excluded due to unavailability. Ultimately, 5 articles were incorporated into our systematic review [37–41].

Natural Language Processing Applications in Various Clinical Settings

Clinical Decision Support System (CDSS) for Concept-Based Searching

Berge et al. developed a machine learning-driven CDSS employing NLP for concept-based searching in a Norwegian hospital [37]. The study introduced an Information System for Clinical Concept-based Search (ICCS) CDSS, devised to detect patient allergies in EHRs using unsupervised machine learning algorithms for clinical narrative analysis. The system combines unsupervised and supervised algorithms with deterministic rules to enhance precision. In a previous study, the ICCS achieved a recall of 92.6%, precision of 88.8%, and F-measure of 90.7%. The ICCS aims to improve allergy detection and classification, thereby enhancing patient safety in anesthesia and ICU settings.

Digital Pathology Applications

Marchesin et al. investigated the use of NLP to strengthen digital pathology applications [38]. The authors introduced explainable knowledge extraction tools capable of extracting pertinent information from pathology reports. They presented the Semantic Knowledge Extractor Tool (SKET), a hybrid knowledge extraction system for digital pathology applications. SKET combines expert knowledge, pre-trained machine learning models, and rule-based techniques such as ScispaCy. The tool exhibits high performance in entity linking and text classification tasks across various cancer use-cases, surpassing unsupervised approaches. The web-based system, SKET X, enables domain experts to understand SKET's outcomes, rules, and parameters for explainable AI. Applications include automatic report annotation, pathological knowledge visualization, and Whole Slide Image classification.

Identification of Nonvalvular Atrial Fibrillation (NVAF)

Elkin et al. employed artificial intelligence with NLP to integrate electronic health record (EHR) structured and free-text data to identify NVAF, aiming to reduce strokes and death [39]. The study utilized high-definition NLP (HD-NLP) to process free text in EHRs, identifying patients with Nonvalvular Atrial Fibrillation (NVAF) and estimating their stroke and bleeding risks. NLP-assisted analysis of structured and unstructured EHR data improved detection rates and accuracy compared to structured data alone. This approach could potentially prevent 176,537 strokes, 10,575 deaths, and save over $18 billion in the first year if implemented nationally, with a net financial benefit of approximately $14.4 billion.

Cardiovascular Disease Comorbidity Assessment

Berman et al. applied NLP to assess cardiovascular disease comorbidities in the Cardio-Canary Comorbidity Project [40]. The authors demonstrated the potential of NLP in facilitating the identification of comorbidities, leading to improved patient care and outcomes in cardiovascular disease management. The modules exhibited robust performance, particularly for hypertension, dyslipidemia, and stroke, with over 95% positive predictive value (PPV) for note-level performance. The NLP modules provide an accurate, open-source system for various applications, such as population management, clinical research, and clinical trial recruitment.

Post-traumatic stress disorder (PTSD) Quality Metrics Improvement

Shiner et al. explored the use of NLP to enhance PTSD quality metrics in psychotherapy treatments for veterans [41]. The study combined structured EMR data with NLP-derived data to evaluate PTSD care quality in the Veteran Affairs system. The validated NLP algorithm displayed a high degree of agreement with template data (weighted kappa: 0.81), capturing nearly 90% of evidence based psychotherapy for PTSD visit days. The study revealed that 20% of PTSD checklist values were documented exclusively in free-text clinical notes. The findings suggest that NLP can bridge documentation gaps, provide a more comprehensive view of care quality, and improve measurement practices for PTSD patients within the Veterans Affairs healthcare system.

Comparison Between ChatGPT and Human Researchers

Except for clinical tasks (κ=0.56), both human researchers showed very good agreement (κ>0.90) for the parameters extracted from the included articles (Table 1). ChatGPT and the human researchers showed very good agreement for the article's language (κ=1), targeted disease (κ=1), NLP model (κ=0.95), sample size (κ=0.83), and performance parameters (κ=0.85); good agreement for study design (κ=0.79); moderate agreement for clinical task (κ=0.58); and only fair agreement for clinical implementation (κ=0.34). All numbers were extracted correctly from the articles by ChatGPT.

In the process of composition, ChatGPT was prompted to provide source citations (refer to Table S2 in Multimedia Appendix 19). Among the 28 references supplied, 3 were found to be fictitious: Smith, Brown & Lee (2022), Demner-Fushman & Chapman (2017), and McCoy, Hughes, Jao & Perlis (2019); this rendered the attribution of Smith, Lee and Joa uncertain. Although the other authors have multiple publications within the NLP domain, a reliable attribution remains elusive. Five of the references were thematically pertinent, yet they did not accurately substantiate the statements made. Additionally, 2 sources required corrections to their publication years. Consequently, a total of 15 references were amended, appended, or substituted.

Table 1. Inter- and intrarater reliability for extraction items using Fleiss and Cohen κ.

	All (Fleiss κ)	GPT[a] 3.5 1 vs 2 (Cohen κ)	Human researcher 1 vs 2 (Cohen κ)
Language	1	1	1
Targeted disease	1	1	1
Study design	0.7333676	0.78939034	0.94736842
NLP[b] model	0.1441441	0.947331947	1
Sample size	–0.041096	0.829723674	0.91486184
Performance	0.6847407	0.853733641	0.9425548
Clinical Task	0.5615047	0.58372457	0.56422018
Implementation	0.3531915	0.34127844	0.92132505

[b]NLP: natural language processing.

Discussion

This systematic review aimed to investigate the current natural language processing (NLP) models being used in daily clinical practice. We identified five studies that showcased various applications of NLP in clinical settings, including clinical decision support systems, digital pathology applications, identification of nonvalvular atrial fibrillation, cardiovascular disease comorbidity assessment, and PTSD quality metrics improvement. These studies highlight the potential of NLP to revolutionize healthcare by improving efficiency, accuracy, and patient care.

Berge et al. [37] presented a clinical decision support system (CDSS) that uses NLP for concept-based searching in a Norwegian hospital. Their study demonstrated the potential of machine learning-driven CDSS to improve allergy detection and classification, leading to enhanced patient safety in anesthesia and ICU settings. Marchesin et al. [38] focused on the application of NLP in digital pathology applications, showcasing how NLP can support pathologists and improve the overall quality of pathology diagnosis and patient care. Elkin et al. [39] showed the effectiveness of NLP in identifying NVAF patients, which has the potential to lead to better management of NVAF and prevent strokes and death. Berman et al. [40] utilized NLP for cardiovascular disease comorbidity assessment, illustrating the potential of NLP to facilitate the identification of comorbidities, leading to improved patient care and outcomes. Lastly, Shiner et al. [41] examined the use of NLP to improve PTSD quality metrics in psychotherapy treatments for veterans, demonstrating NLP's value in capturing important data in large healthcare systems and improving measurement practices.

The studies included in this review showcased various NLP techniques, such as machine learning algorithms, rule-based techniques, and the use of pre-trained models like ScispaCy. These approaches demonstrate the versatility of NLP in handling different clinical tasks and highlight the potential for continued development in this field. Moreover, the use of transformer-based models like GPT-3 in conducting this systematic review serves as an example of how NLP can improve the efficiency and accuracy of literature synthesis in a streamlined manner [32].

Despite the promising results, the studies included in this review also have some limitations. First, the studies are limited in terms of the variety of clinical applications and settings, as only five studies were included in the review. This could potentially limit the generalizability of the findings. Furthermore, the studies may have inherent biases and limitations that could impact the interpretation of the results. It is essential to be cautious when extrapolating these findings to other contexts and clinical settings.

Future research should focus on expanding the range of clinical applications and settings where NLP can be utilized, as well as investigating the scalability and generalizability of the identified approaches. Additionally, more studies should be conducted to explore the potential of transformer-based models like GPT-3 and BERT in clinical practice. These models have shown great promise in various NLP tasks and may offer further advancements in the field of healthcare.

In conclusion, our systematic review highlights the potential of NLP in revolutionizing clinical practice by improving efficiency, accuracy, and patient care. The studies included in this review showcase various NLP applications in clinical settings, demonstrating the versatility and potential for growth in this field. Further research is needed to expand the range of clinical applications and settings, as well as to explore the potential of transformer-based models in healthcare. As NLP continues to advance, it is expected that its impact on clinical practice will only increase, leading to improved patient outcomes and more efficient healthcare systems.

Concluding Remarks by the Human Authors

Concerning the systematic review, we only searched PubMed and no other database or registry. Furthermore, the MeSH search generated only 155 hits, and we must admit that this study does not allow us to determine whether NLPs are of practical use in clinical practice today. Since the MeSH term itself was produced by ChatGPT and the main goal of this study was to explore the usefulness of ChatGPT in performing or assisting in systematic reviews, we adhered to the generated methods; however, this compromises the quality of the

systematic review. Therefore, we do not believe that an adequate commentary on the state and usefulness of NLP in clinical practice is within the scope of this study. During the research, ChatGPT underwent several updates. We attempted to split workflows for both GPT 3.5 and GPT 4.0. Since developments on LLMs change at a fast pace, their applicability might change fast as well, which means that results from interactions and the idea of augmented or automated systematic reviews can change drastically, for example, with developments in LLMs' ability to access of databases such as PubMed or Cochrane.

We hypothesize that automated systematic reviews could become a reality in the near future. However, the current state of ChatGPT versions 3.5 and 4.0, with their multiple limitations, renders augmented systematic reviews inefficient for experienced researchers. Yet, for language correction, particularly for nonnative English speakers, and rectification of grammatical errors, or for text condensation and modification in form and wording, it proves to be of significant value. As we confined our study to ChatGPT, without the use of any plugins or application programming interface implementations, we anticipate that the forthcoming months or years will witness an increased application of LLMs in scientific research, showcasing intriguing architectures such as "Lang Chain" and "Agent GPT" as pioneering examples of more complex programs powered by LLMs.

Ethical and legal concerns about the implementation of LLMs in a scientific field as sensible as medicine have led to an ongoing discussion and should be considered before broadening the spectrum of clinical applications for NLP-driven automations. The black box issue associated with LLMs such as ChatGPT, even when using the most deterministic options, is an undeniable fact. Automatic analyses of all available literature within minutes or seconds, however, would change the way we conduct research or are able to access information in clinical practice. Further research is imperative, accompanied by a debate on the ethical implications of such potent tools and strategies to oversee and regulate the use of these models in scientific writing.

Acknowledgments

We would like to thank the researchers and authors who contributed to the studies included in this systematic review. Several parts of the text, including the original draft of the abstract, were generated using ChatGPT (versions 3.5 and 4.0, OpenAI [1]) and have been indicated as such within the manuscript.

Abstract

Background: Patients with lung cancer are among the most frequent visitors to emergency departments due to cancer-related problems, and the prognosis for those who seek emergency care is dismal. Given that patients with lung cancer frequently visit health care facilities for treatment or follow-up, the ability to predict emergency department visits based on clinical information gleaned from their routine visits would enhance hospital resource utilization and patient outcomes.

Objective: This study proposed a machine learning–based prediction model to identify risk factors for emergency department visits by patients with lung cancer.

Methods: This was a retrospective observational study of patients with lung cancer diagnosed at Seoul National University Bundang Hospital, a tertiary general hospital in South Korea, between January 2010 and December 2017. The primary outcome was an emergency department visit within 30 days of an outpatient visit. This study developed a machine learning–based prediction model using a common data model. In addition, the importance of features that influenced the decision-making of the model output was analyzed to identify significant clinical factors.

Results: The model with the best performance demonstrated an area under the receiver operating characteristic curve of 0.73 in its ability to predict the attendance of patients with lung cancer in emergency departments. The frequency of recent visits to the emergency department and several laboratory test results that are typically collected during cancer treatment follow-up visits were revealed as influencing factors for the model output.

Conclusions: This study developed a machine learning–based risk prediction model using a common data model and identified influencing factors for emergency department visits by patients with lung cancer. The predictive model contributes to the efficiency of resource utilization and health care service quality by facilitating the identification and early intervention of high-risk patients. This study demonstrated the possibility of collaborative research among different institutions using the common data model for precision medicine in lung cancer.

Introduction

Lung cancer is a well-known malignancy that causes severe respiratory symptoms. There were 1.8 million lung cancer–related fatalities and 2.2 million newly diagnosed patients worldwide in 2020 [1]. Patients with lung cancer frequently encounter complex health care challenges, such as unanticipated visits to the emergency department (ED) due to disease progression, treatment-related problems, and comorbidities [2]. Despite advances in medical technology, which have increased the survival rates of patients with lung cancer, ongoing management is still needed after initial oncology treatment due to the diverse characteristics and causes of the disease and the fact that each patient's disease stage and conditions vary [3].

Patients with lung cancer often experience acute complications or disease progression that may require urgent medical attention [4]. The frequency of ED visits among patients with lung cancer increases with the length of their survival [5]. Prior research has shown that approximately 10% of all cancer-related ED visits are attributable to lung cancer [6]. In addition, compared to patients with other types of cancer, those with lung cancer who visit the ED tend to have a worse prognosis [7]. Shin et al [8] examined the 28-day mortality rate among intubated patients with cancer in the ED. Their findings revealed that patients with lung cancer faced a higher mortality risk compared to those with other types of cancer. Another previous study found that patients with lung cancer had the highest mortality rate (48.1%) within 28 days in contrast to those with other cancers who presented to the ED with septic shock [9]. Further, a comprehensive study conducted on hospitalizations related to sepsis incidence and mortality rates among patients with cancer in the United States revealed that patients with lung cancer had the highest mortality rate [10]. These findings from previous studies demonstrate the poor prognosis for patients with severe lung cancer–related conditions in the ED.

To lower the risk of a poor prognosis, it is of the utmost importance to predict visits to the ED among patients with lung cancer in advance [11]. Nevertheless, the existing literature on this subject is limited, with only a handful of studies identifying the risk factors associated with these visits. Consequently, the lack of comprehensive research in this field hinders clinicians' ability to intervene in a timely manner. Hong et al [12] developed a machine learning–based model for predicting ED visits in patients who were undergoing radiotherapy or chemoradiotherapy. Sutradhar et al [13] proposed a risk prediction approach for ED visits among patients with cancer using the Edmonton symptom assessment system and conventional statistical analysis and logistic regression methods [13]. Sutradhar and Barbera [14] also developed a machine learning model to predict 7-day ED visits in patients with cancer using the Edmonton symptom assessment system and other clinical information. Previous studies were predominantly conducted among patients with all types of cancer, so they did not identify risk factors specific to those with lung cancer for ED visits.

Therefore, the primary objective of this study was to identify the influential factors for patients with lung cancer that may impact ED visits. This study developed a machine learning–based prediction model to forecast ED visits among patients with lung cancer using data from the Observational Medical Outcomes Partnership (OMOP) common data model (CDM) [15]. Additionally, the significance of various types of clinical information in influencing the decision-making process of the machine learning model was evaluated. The ability to predict ED visits enables health care service providers to identify high-risk patients in advance, allowing for prompt intervention and appropriate management. By intervening expeditiously, clinicians may be able to prevent or mitigate emergency situations, leading to improved patient outcomes. This study contributes to minimizing preventable health deterioration by facilitating early intervention during lung cancer treatment by clinicians.

Methods

Study Design and Source of Data

This was a retrospective observational study using electronic health records at Seoul National University Bundang Hospital (SNUBH), a tertiary general hospital in South Korea. The electronic health record data were converted to the OMOP CDM, which is a standardized data format in the observational health data sciences and informatics community. The data set comprised information from visit histories encompassing a broad range of categories, such as diagnoses, medication prescriptions, laboratory test results, performed procedures, and clinical observations.

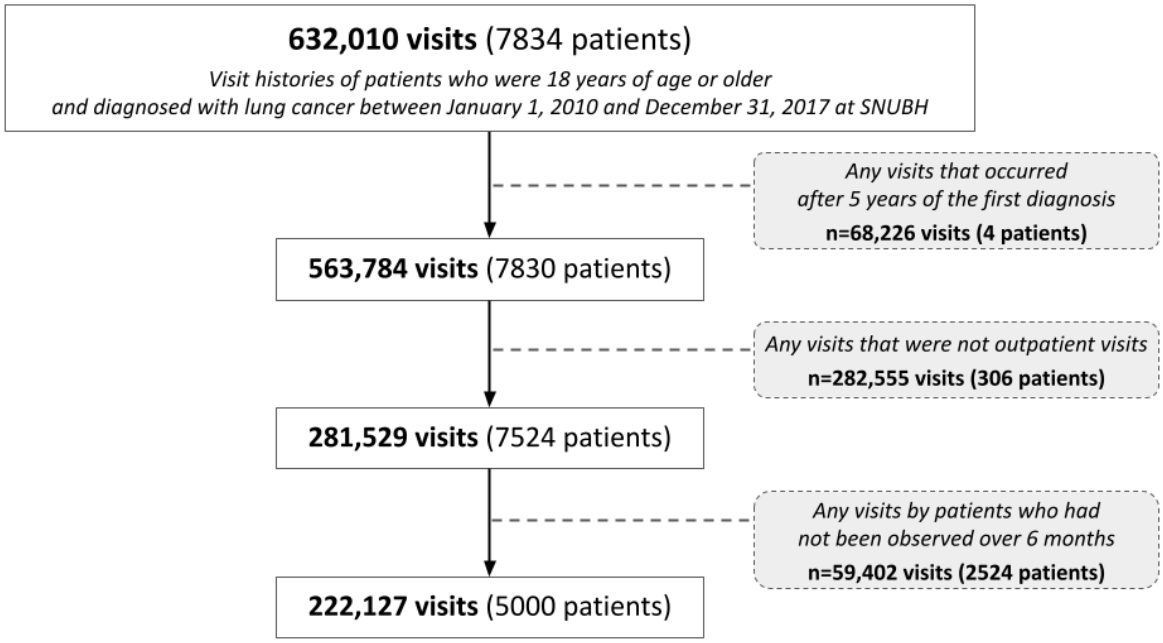
Ethical Considerations

This study was conducted with approval and waivers of informed consent or exemptions from the SNUBH institutional review board (no. X-2308-844-903). The CDM data used in this study were deidentified and are securely maintained within an internal network.

Target Population

Patients who were 18 years of age or older and diagnosed with lung cancer (International Classification of Diseases, Tenth Revision code C34: malignant neoplasm of bronchus and lung [16]) at least once between 2010 and 2017 were eligible. Figure 1 presents the inclusion and exclusion criteria for the study participants. This study included all outpatient visits within 5 years of the patient's initial diagnosis of lung cancer. Moreover, since the focus of this study was on health information routinely collected in hospitals based on the CDM, target populations should visit the hospital regularly for disease management. Considering the follow-up period in the treatment guidelines for patients with lung cancer, patients who were unable to follow up for more than 6 months during the study period were excluded.

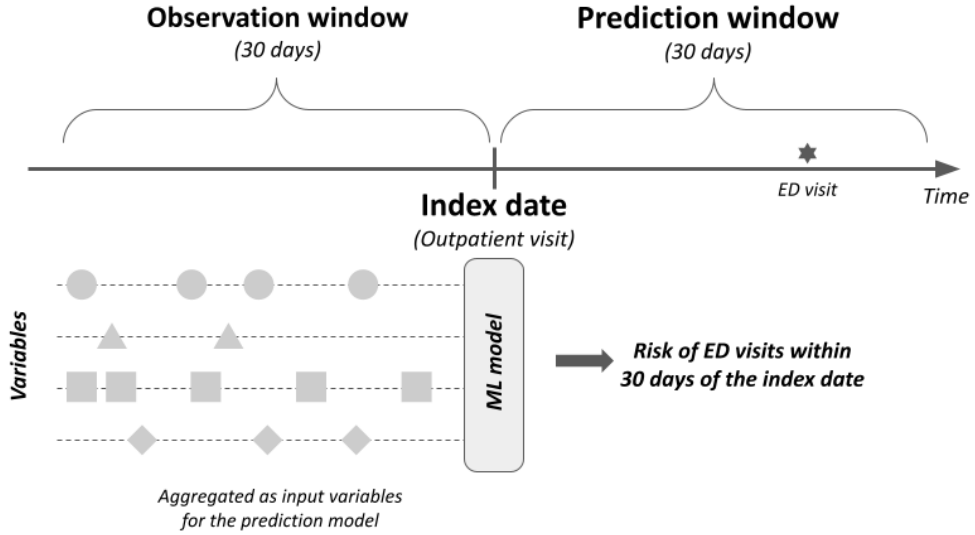
Figure 1. Flowchart of the study participant selection process. SNUBH: Seoul National University Bundang Hospital.



Primary Outcome

Figure 2 presents an overview of the observation and prediction windows for the risk prediction task. The outpatient visits were defined as the index date. Multiple outpatient visits for the same patient were considered independent index dates. During the 30 days prior to the index date, predictors were extracted and aggregated to be used as input variables for the machine learning models. The primary outcome was the occurrence of ED visits within the 30-day period following the index dates. Since the objective of this study was to predict preventable ED visits that occurred during disease progression or treatment among patients with lung cancer, the primary outcome was defined as ED visits that satisfied specific criteria. Valid outcomes were restricted to ED visits that did not result in a transfer to another hospital.

Figure 2. An overview of the observation and prediction windows for the risk prediction task. ED: emergency department; ML: machine learning.



Predictors

Data extracted from the CDM over successive time windows, referred to as the observation window, for 30 days prior to the index dates were used for candidate predictors. This included patient demographics, visit histories, clinical information, laboratory results, and vital signs. If patients had multiple records for the same data item during the observation window, the median value was calculated. Detailed information on the selected features and their data sources is presented in Multimedia Appendix 1.

The selected features used to predict the primary outcome were analyzed using statistical methods. This study provided descriptive statistics for continuous variables in the form of median and IQR values, whereas categorical variables were presented as frequencies and respective percentages. The *P* value of each variable was also calculated to explore the probability of a relationship between the selected features for

prediction tasks. In the significance test, the Mann-Whitney U test was used when analyzing continuous variables, while the chi-square test was used for categorical data.

Model Training and Evaluation

This study defined the prediction task for each event date as a binary classification problem. We used 4 different machine learning models—logistic regression, random forest, extreme gradient boosting, and light gradient boosting machine (LGBM)—to discover the model with the highest performance. These models were selected to provide a comparison of models by evaluating the performances of various alternatives, ranging from conventional linear-based approaches to more complex methods, such as ensemble-based models.

The selected features were preprocessed for use as input variables in the machine learning models. Missing values were replaced with their median value, and aberrant observations that were not acceptable from a theoretical perspective were removed based on prior research and the expertise of clinical domain experts to prevent extreme outliers from leading to failure in the prediction task. The entire data set was split into training and testing sets using repeated 7-fold cross-validation, with stratified sampling accounting for the incidence of the primary outcome. Demographic information of the patients, including age, gender, and comorbidities, was also taken into account given that some patients had made multiple outpatient visits, which corresponded to the index dates in this study. By using repeated k-fold cross-validation, the estimated performance of a machine learning model can be enhanced. The cross-validation procedure was iterated 1000 times. Finally, categorical variables were encoded, and continuous variables were normalized.

The following 4 performance metrics were used for model evaluation: area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve (PRAUC), sensitivity, and specificity. The evaluation results were reported as the average value encompassing all folds from all iterations, and the 95% CI was estimated. This approach ensures a more accurate estimate of the true unknown underlying mean performance of the model on the data set than using the standard error. Using the Shapley additive explanations (SHAP) value from the best performing model, the significance of the features was also analyzed to identify risk factors for ED visits by patients with lung cancer [17]. All the experiments were performed using the Python 3.7.6 environment (Python Software Foundation).

Results

Baseline Characteristics

A total of 222,127 outpatient visits occurred for 5,000 patients. Table 1 presents the baseline characteristics of the target population. The median age was 67.23 (IQR 60.54-75.57), and 3812 (76.24%) patients were older than 60 years. Men accounted for 64.14% (n=3322) of the participants, which was slightly greater than the number of women (n=1678). According to the Charlson comorbidity index (CCI) [18], more than 66.4% (n=3320) of participants did not have any comorbidities before being diagnosed with lung cancer. There were 1212 (24.24%) patients who had a history of smoking, while the others had no smoking history or their history was unknown. About half (n=2827, 56.54%) of the patients lived in the metropolitan area near the hospital.

Table 1. Baseline characteristics of the selected participants (n=5000).

Characteristic	Value
Age (years), median (IQR)	67.23 (60.54-75.57)
Age group (years), n (%)	
18-49	376 (7.52)
50-59	812 (16.24)
60-69	1511 (30.22)
≥70	2301 (46.02)
Gender, n (%)	
Men	3322 (64.14)
Women	1678 (35.86)
Body mass index, median (IQR)	22.90 (20.59-24.97)
Charlson comorbidity index, median (IQR)	2.95 (2.00-3.00)
Charlson comorbidity index group, n (%)	
0	3320 (66.4)
1-2	982 (19.64)
3-4	299 (5.98)
≥5	399 (7.98)
Smoking history, n (%)	
Yes	1212 (24.24)
No	957 (19.14)
Unknown	4600 (56.62)
Residence, n (%)	
Greater Seoul	2827 (56.54)
Other[a]	1071 (21.42)
Unknown	1102 (22.04)

[a]Other areas of residence included Gangwon-do, Chungcheongbuk-do, Chungcheongnam-do, Gyeongsangbuk-do, Gyeongsangnam-do, Jeollabuk-do, Jeollanam-do, Jeju-do, Daejeon, Sejong-si, Daegu, Ulsan, Busan, and Gwangju.

There were 8192 visits to the ED, and 2790 patients (55.80% of total patients) had ED visits during the course of their disease. The results of an explanatory data analysis of ED visits by the target population are displayed in Table 2. Of all the visits, 81.33% (n=6663) were from home, while the rest were from outpatient visits or other institutions, including transfers from hospitals, independent clinics, and inpatient care units. Most ED visits occurred between 7 AM and 10 PM. The median length of time spent in the ED was approximately 13.64 (IQR 2.98-15.84) hours. More than half (n=4956) of the patients were discharged home, while the remaining patients were hospitalized or died in hospital. Of all ED visits, 38.32% (n=3139) resulted in hospitalization, and 1.18% (n=97) resulted in death. The most frequent causes of visits to the ED were neoplasms, including malignant neoplasms of the bronchus and lung and secondary malignant neoplasms of other sites. The other primary causes were diseases of the respiratory system. Patients with symptoms, signs, and abnormal clinical and laboratory findings not elsewhere classified primarily visited the ED for the following reasons: fever of other and unknown origin, hemorrhage from respiratory passages, abnormalities of breathing, pain in the throat and chest, and abdominal and pelvic pain.

Table 2. Explanatory data analysis results of emergency department (ED) visits (n=8192) by selected patients.

Feature	Value
Age (years), median (IQR)	67.10 (60.26-75.50)
Gender, n (%)	
Men	5502 (67.16)
Women	2690 (32.84)
Sourced from, n (%)	
Home	6663 (81.33)

Diseases of the digestive system (K00-K93)	361 (4.41)
Diseases of the circulatory system (I00-I99)	307 (3.75)
Other	1429 (17.44)

[a]ICD-10: International Classification of Diseases, Tenth Revision.

The complete list of descriptive statistics (N=222,127) of the selected features used as input variables for the predictive model are displayed in Multimedia Appendix 2. The median value of elapsed days since the first diagnosis of lung cancer was about 333 (IQR 103.60-810.42) days. Chemotherapy was administered at 39.27% (n=87,221) of visits, compared to 16.47% (n=36,575) for radiation therapy and 2.32% (n=5159) for lung cancer–related surgery. Analgesics were administered at 27.35% (n=60,744) of visits, and the use of antibacterials for systemic use accounted for 18.83% (n=41,825) of visits. The results of blood tests revealed a median value of 6.27 (IQR 4.87-8.06) for leukocytes, 237.00 (IQR 188.00-296.00) for platelets, 61.90 (IQR 53.50-70.05) for neutrophils, and 12.10 (IQR 10.80-13.30) for hemoglobin. The shock index, which refers to the ratio of the heart rate to systolic blood pressure, was calculated from the collected vital signs and showed a median value of 0.67 (IQR 0.59-0.78).

Performance Evaluation Results of the Machine Learning Models

The performance evaluation results from the machine learning models are presented in Table 3. The overall AUROC score was ≥0.70 in all models, ranging from 0.70 to 0.73. The optimal prediction threshold was defined using the precision-recall curve since the data set had an imbalanced class distribution. The highest PRAUC score was 0.24 in the LGBM model.

Table 3. Performance comparison of the machine learning models.

Model	Sensitivity (95% CI)	Specificity (95% CI)	AUROC[a] (95% CI)	PRAUC[b] (95% CI)
LR[c]	0.76 (0.7554-0.7581)	0.54 (0.5369-0.5398)	0.71 (0.7054-0.7065)	0.22 (0.2191-0.2205)

[a]AUROC: area under the receiver operating characteristic curve.

[b]PRAUC: area under the precision-recall curve.

[c]LR: logistic regression.

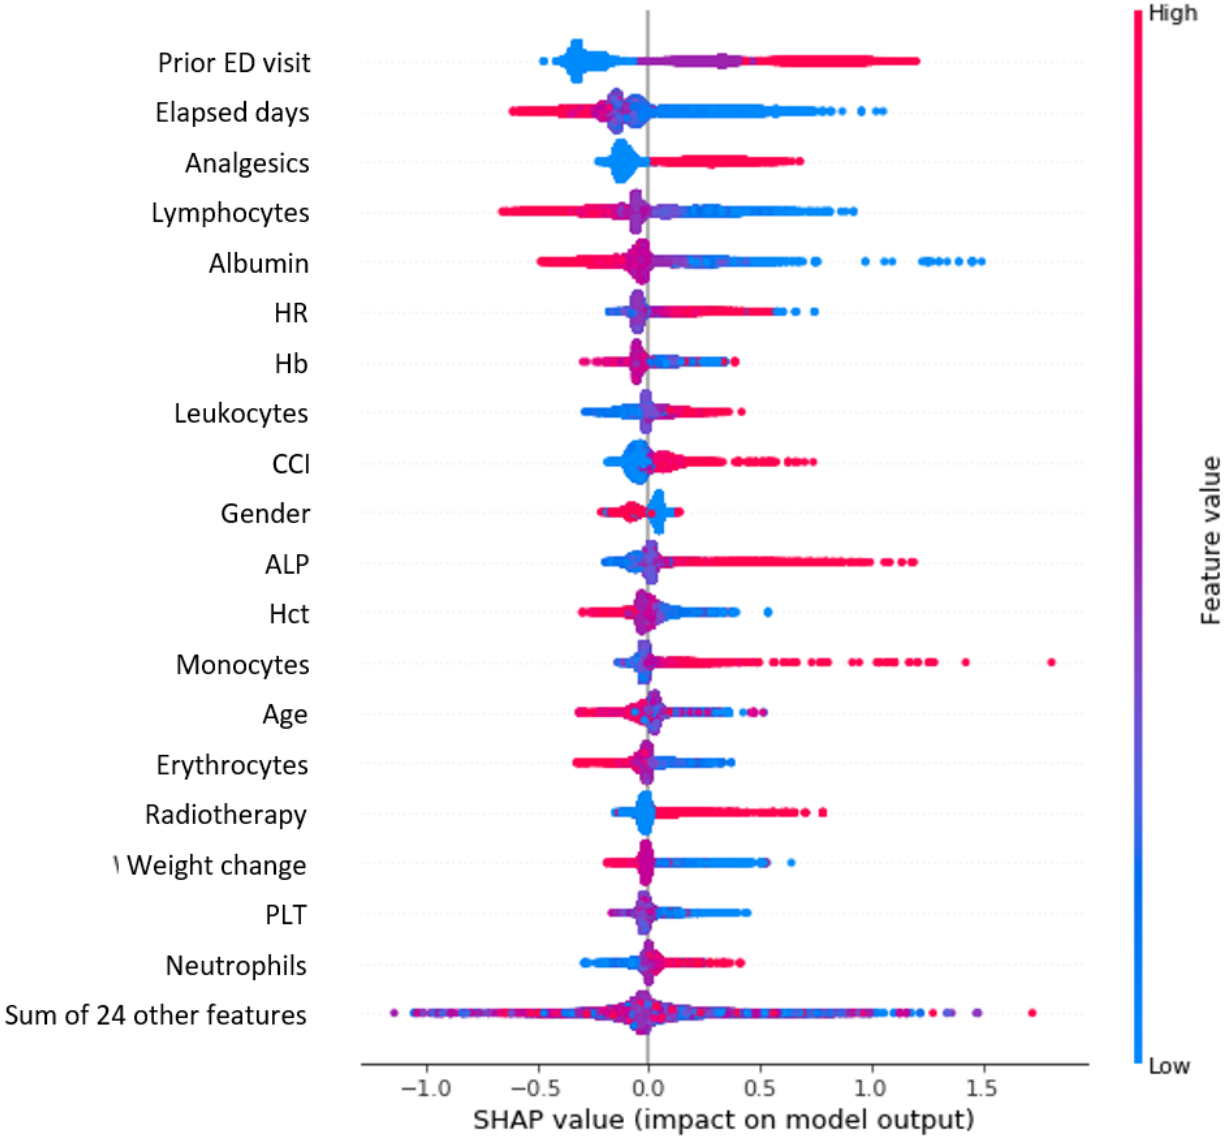
[d]RF: random forest.

[e]XGB: extreme gradient boosting.

[f]LGBM: light gradient boosting machine.

The SHAP values for the highest-performing model, the LGBM, are depicted in Figure 3. The key influencing features for predicting the risk of ED visits in the LGBM model were identified as recent ED visits, elapsed days since the initial diagnosis for lung cancer, the use of analgesics, and lymphocyte and albumin levels. The SHAP value quantifies the influence of a specific feature on the predictions; consequently, a comprehensive interpretation can be obtained by calculating the SHAP values for the model's output. As shown in Figure 3, the number of ED visits, CCI, administration of analgesics, and radiotherapy, as well as high values of leukocytes, alkaline phosphatase, monocytes, and neutrophils, increased the possibility of visits to the ED. In contrast, the combined presence of low values of lymphocytes, albumin, hemoglobin, and hematocrit indicated an increased likelihood of visiting the ED.

Figure 3. Summary plots for SHAP values in the light gradient boosting machine model. ALP: alkaline phosphatase; CCI: Charlson comorbidity index; ED: emergency department; Hb: hemoglobin; Hct: hematocrit; HR: heart rate; PLT: platelets; SHAP: Shapley additive explanations.



Discussion

This study developed a predictive model for ED visits among patients with lung cancer using machine learning and CDM data. Predicting ED visits among patients with lung cancer has numerous important implications. First, the ED visit prediction model is able to facilitate care coordination and patient management. As shown in Table 2, over 38% of all visits resulted in hospitalization. These results were marginally lower than the findings in prior literature, which indicated that 54.5% of ED visits resulted in hospitalization or death [19]. This may be due to the SNUBH-specific aspect that patients with cancer are treated via outpatient visits, and patients who were normally discharged might return to other inpatient care units or independent clinics after emergency treatments. If patients at risk could be identified during a previous scheduled session, many of these visits might be avoided. Moreover, it would be possible to perform elective procedures to manage patients at imminent risk of requiring ED visits. There have been several prior studies on predicting ED visits [20-22]; however, to our knowledge, there have been no studies predicting ED visits applicable to outpatient visits by patients with lung cancer. In addition, previous studies mainly focused on patient-reported outcomes, whereas this study mainly used clinical information, such as laboratory test results, as input variables for the prediction model. The clinical information–based machine learning model enhances the clinical use of the predictive model since patients with lung cancer continuously visit the hospital during their disease or after treatment for follow-up [23].

The identification of risk factors associated with ED visits among patients with lung cancer is another significant finding of this study. The risk factors were identified by analyzing the importance of features that influenced the decision-making of machine learning models, as shown in Figure 3, and the identified variables had a tendency to match theoretical knowledge found in the medical domain. Prior ED use was known to be a significant predictor of future ED visits for all types of patients with cancer [12]. Patients with cancer who had recently visited the ED more frequently may experience more severe symptoms, complications, or comorbidities requiring

immediate medical care, thereby increasing their likelihood of future ED visits. The number of elapsed days since the initial lung cancer diagnosis was inversely proportional to the likelihood of visiting the ED. Given that cancer-related treatments, such as surgery, chemotherapy, and radiotherapy, are typically administered within a year of diagnosis, acute diseases and transient side effects of the cancer-related treatment can result in emergency situations [24]. Similarly, the use of analgesics indicates that patients were suffering from severe pain and distress, which may have prompted visits to the ED for pain management. Several clinical pieces of information, such as laboratory test results routinely collected during cancer treatment and follow-up monitoring, were demonstrated to be useful predictors of ED visits in patients with lung cancer. Lower lymphocyte counts may indicate decreased immune function or increased vulnerability to infections, and higher leukocyte, monocyte, and neutrophil counts may be associated with inflammation; both of these abnormal values may lead to visits to the ED. Lower levels of hemoglobin, hematocrit, and erythrocyte counts may be signs of anemia, which may cause fatigue and result in visits to the ED. Significant weight loss and lower albumin levels may be associated with disease progression or malnutrition, increasing the risk of complications that may require ED visits. Similarly, a high CCI indicated the presence of multiple comorbid conditions. Elevated alkaline phosphatase levels may indicate liver or bone involvement, and decreased platelet counts may indicate thrombocytopenia, necessitating evaluation and treatment in the ED. While radiotherapy is a treatment for lung cancer, it can cause side effects and complications, such as radiation pneumonitis, that may necessitate visits to the ED. Thus, close monitoring of laboratory test results in patients with lung cancer receiving treatments or routine follow-up is necessary to prevent ED visits.

This study has several limitations. First, this study was conducted at a single institution in South Korea, a tertiary-level general hospital. Thus, regional bias may have resulted in reduced generalizability. Nonetheless, this study demonstrated the possibility of conducting observational cancer research with CDM data. Developing a predictive model using data from a single institution may lead to biased results based on regional or institution-specific characteristics, making it difficult to generalize; therefore, external validation is essential for clinical applications. Due to the heterogeneity of the format for managing medical records across institutions as well as privacy concerns, it is difficult for researchers to share data; even a collaborative study with other institutions requires immense effort, time, and resources. Ahmadi et al [25] reported that the OMOP CDM has the potential to facilitate international collaborative analyses, which is a crucial element of cancer precision medicine. Since our prediction model was developed using OMOP CDM data, it is expected that external validation will be possible for other institutions that have oncology CDM data through the observational health data sciences and informatics data network in the future. The data set used in this study is administered in accordance with the OMOP CDM, allowing different institutions to conduct collaborative research using a distributed research network.

Second, there were the inherent performance limitations imposed on the machine learning models. The primary outcome defined in this study was derived from all ED visits, only excluding the visits that resulted in patients being transferred to other institutions; therefore, there may have been non–cancer-related reasons for ED visits, such as fractures, injuries from traffic accidents, or wounds from animal attacks. In addition, a paucity of information may be one of the reasons for the results of unfavorable effects on the prediction model outcome. Staging or subtypes of lung cancer represent primary information for predicting the prognosis of patients; however, this information was not collected in our data source thus far. The acquisition of additional information could contribute to the enhancement of the predictive model's performance; therefore, the establishment of extended lung cancer–specific data sets in the CDM is needed for more precise prediction. Nevertheless, the identified risk factors for ED visits could be used in the future as an avenue for the proactive management of patients with lung cancer during treatment.

Lastly, research bias should be taken into account when interpreting the results. This study imputed missing values with the median value during the data processing phase, which could potentially have introduced bias into the analysis. However, the characteristics of clinical data are such that the lack of even a solitary test result frequently results in a substantial amount of missing data among other relevant data, indicating the presence of a clear-cut pattern. In such situations, it was noted that median imputation demonstrated performance levels that were comparable to those of more complex algorithms. Furthermore, it offered the advantage of being readily executable, thereby enhancing its efficiency in terms of time and resources. Additionally, it is critical to acknowledge that while removing outliers is a standard procedure for enhancing data quality, extreme values may have clinical ramifications due to the unique attributes of ED visits among patients diagnosed with lung cancer.

In summary, this study developed a machine learning model to predict ED visits, with a specific focus on patients with lung cancer, and identified influential factors that exerted a significant impact on the model output. Continuous monitoring of the identified influencing clinical features will allow health care providers to efficiently allocate resources, ensuring that patients with a high likelihood of requiring preventive care receive prompt attention. By identifying patients at risk, health care service providers can initiate targeted interventions, such as closer monitoring, treatment plan adjustments, and timely referrals to the most appropriate specialists. The predictive model for ED visits by patients with lung cancer developed in this study not only enhances patient outcomes but also optimizes resource utilization, reducing strain on the ED and minimizing the burden on the medical staff. Ultimately, this proactive approach contributes to preventing or mitigating emergency situations, resulting in an improved quality of life for patients with lung cancer and possibly reducing the need for hospitalization or more invasive interventions.

Acknowledgments

This research was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute funded by the Ministry of Health & Welfare, Republic of Korea (grant HI22C0471).

Authors' Contributions

AL and HP conceptualized the design of the study. SK and LS contributed to the data extraction. AL wrote the original draft. AL and HP performed the experiments and visualizations. AY and LS contributed to the data analysis and interpretation. SY revised the manuscript and supervised the research. All authors reviewed and approved the final version of the manuscript.

Abstract

JMIR Medical Informatics is pleased to offer *implementation reports* as a new article type. Implementation reports present real-world accounts of the implementation of health technologies and clinical interventions. This new article type is intended to promote the rapid documentation and dissemination of the perspectives and experiences of those involved in implementing digital health interventions and assessing the effectiveness of digital health projects.

(JMIR Med Inform 2023;11:e47695) doi:10.2196/47695

KEYWORDS

implementation science; knowledge management; knowledge sharing; digital health; implementation report

Introduction

The accelerating adoption of digital health, combined with evolving terminology and differing definitions, has created a paradox: there is an exponential increase in knowledge and information, but finding relevant data on implementation processes, and in particular errors or failures, remains a major challenge. This lack of effective documentation of implementation knowledge makes it difficult to reliably study and understand global trends in digital health project failures, exacerbated by a bias toward publishing mostly positive studies [1]. As a result, similar and avoidable mistakes are often repeated.

Digitalization offers numerous opportunities to improve the efficiency and equity of health systems. Yet, many digital health implementations stagnate in the pilot phase or fail to sustain or demonstrate impact. This not only wastes valuable resources but also further fragments already complex health systems, potentially leading to adverse health outcomes [2].

Recurrent errors contribute to inefficient implementation and scale-up, and it is crucial to consider that while new technologies offer immense potential benefits, they can also introduce risks or unintended consequences that have a direct impact on patient outcomes. For example, child mortality increased significantly at one site following the implementation of a commercial computerized physician order entry (CPOE) system [3]. This increase in mortality was primarily due to delayed administration of critical medications [4], amplified by a policy change shortly before implementation, suggesting that policy changes should be avoided during or in close proximity to a CPOE implementation process [5].

However, unintended consequences can also be positive, as demonstrated by the implementation of a telemedicine service in rural Nepal [6]. The service attracted a higher proportion of female patients, possibly due to cultural factors or minimal disruption to their daily lives, which suggests that telemedicine may improve access to health care for female patients [6].

Learning from past implementations is critical. Particularly from an ethical and human rights perspective, as in the absence of established implementation norms and best practices, implementers need to define their own standards for responsible and effective digital health implementations.

The Potential Transformative Impact of Implementation Reports

Sharing and connecting fragmented knowledge across institutional boundaries can revolutionize an industry. This is

evidenced by the aviation sector, a safety-critical industry like health care, where such collaboration has led to transformative results [7]:

> *Back in the 1930s, flying was really dangerous and passengers were scared away by the many accidents. Flight authorities across the world had understood the potential of commercial passenger air traffic, but they also realized flying had to become safer before most people would dare to try it. In 1944 they all met in Chicago to agree on common rules and signed a contract with a very important Annex 13: a common form for incidents reports, which they agreed to share, so they could all learn from each other's mistakes. Since then, every crash or incident involving a commercial passenger airplane has been investigated and reported; risk factors have been systematically identified; and improved safety procedures have been adopted worldwide.*

The aviation industry has set an exemplary precedent for how sharing mistakes can improve safety and build trust. However, much like the aviation industry in the 1930s, the digital health sector is still in the early stages: the potential to strengthen health care systems is clear, but the bigger picture and potential implications and safety risks are not yet fully understood.

JMIR Medical Informatics has created a new article type—the implementation report—to address the challenges associated with managing and effectively sharing implementation knowledge. We need implementation reports to promote greater transparency and accountability; to improve identification of best practices; to optimize resource allocation; and to help gain the trust of patients, practitioners, and other stakeholders. Implementation reports provide a framework for systematically documenting and sharing implementation knowledge, including errors and failures, and present real-world accounts of the implementation of health technologies and clinical interventions. This new article type aims to promote the rapid documentation and dissemination of the perspectives and experiences of those involved in implementing digital health interventions and assessing the effectiveness of digital health projects.

If trial and error is the key engine of evolution, achieving progress requires mechanisms to store and transmit information. DNA is the main information substrate of the evolving living world. We need similar tools, such as the implementation report, to learn and accumulate knowledge from successes and failures in digital health. By embracing the concept that "to err is evolution," we can collectively harness the power of our experiences to drive innovation and improve health outcomes.

Conflicts of Interest

None declared.

Abstract

The realm of health care is on the cusp of a significant technological leap, courtesy of the advancements in artificial intelligence (AI) language models, but ensuring the ethical design, deployment, and use of these technologies is imperative to truly realize their potential in improving health care delivery and promoting human well-being and safety. Indeed, these models have demonstrated remarkable prowess in generating humanlike text, evidenced by a growing body of research and real-world applications. This capability paves the way for enhanced patient engagement, clinical decision support, and a plethora of other applications that were once considered beyond reach. However, the journey from potential to real-world application is laden with challenges ranging from ensuring reliability and transparency to navigating a complex regulatory landscape. There is still a need for comprehensive evaluation and rigorous validation to ensure that these models are reliable, transparent, and ethically sound. This editorial introduces the new section, titled "AI Language Models in Health Care." This section seeks to create a platform for academics, practitioners, and innovators to share their insights, research findings, and real-world applications of AI language models in health care. The aim is to foster a community that is not only excited about the possibilities but also critically engaged with the ethical, practical, and regulatory challenges that lie ahead.

generative AI; health care digitalization; AI in health care; digital health standards; AI implementation; artificial intelligence

The Promise and Potential of AI in Health Care

In this editorial, we introduce a new section in *JMIR Medical Informatics*, "AI Language Models in Health Care," dedicated to exploring the transformative potential of generative artificial intelligence (AI) and the developments of cognitive AI in the health care industry. At its current stage of development, AI has already shown the potential to guide human interactions, facilitate understanding, and foster respectful communication. Most of all, with the phenomenon surrounding the global release of ChatGPT [1], it is the first time that information technology has demonstrated the ability to leverage the informational content of texts and human narratives in such a substantial way. In a world where over 65% of the population is connected to the internet [2], this potential is substantial and wide-reaching. Within the health care sector specifically, AI and large language models in particular have progressed toward fulfilling their ambitious promises. They have delivered concrete outcomes such as improving decision-making processes at all levels of influence including for patients, clinicians, health systems, and society as a whole [3]. Yet, the journey of generative AI is still nascent. While the rapid adoption of generative AI indicates its potential, concerns regarding its accuracy and preparedness in managing its associated risks remain [4]. Additionally, being in its early stages of deployment, the long-term positive impacts are anticipated but not yet fully realized or evidenced.

The Aim of This New Section

In this new journal section, we focus on generative models and how they can redefine the boundaries of health care, all while acknowledging the challenges and limitations. By spotlighting

generative models, we hope to illuminate their potential while realistically addressing the challenges associated with their implementation in diverse care settings.

The objective of this section is to highlight groundbreaking innovations empowered by AI language models with a keen focus on ensuring their safe, effective, and enduring implementation. We seek to delve into solid actionable strategies for implementation at various scales of deployment and sustainability, striving to facilitate the swift yet secure integration of these technologies into health care environments. Our ambitions extend beyond theoretical contributions; we seek mature, ready-to-implement initiatives that not only break new ground but also offer clear actionable strategies for wide-scale deployment. The goal is to leapfrog over efforts that should have been made 20 years ago and to streamline the integration process of innovations that will propel the health care sector 20 years into the future.

This section is dedicated to the implementation of AI language models in health care and focuses on prioritizing efforts that highlight the best and most accessible opportunities. Its goal is to leverage emerging technologies while aiming to deliver substantial benefits to as many people as possible.

By featuring papers with clear detailed methodologies, we aim to inspire and facilitate the adaptation and replication of these innovations across diverse health care environments. In doing so, we hope that this new section serves not only as a road map but also as an inspiration, catalyzing the ambition to redefine the limits of health care through the responsible strategic use of AI. More information on suggested topics for submission can be found in the corresponding section of this editorial.

The Nuanced Role of Generative AI in Health Care

While digitalization remains the foundation upon which our current health care advancements are built [5], it is essential to differentiate between the overarching digital transformation and the nuanced capabilities of generative AI. Generative AI models, a subset of the broader AI landscape, hold unique promise and challenges for the health care sector. Unlike traditional AI systems that operate within the confines of given data sets, generative AI can create new, unseen content [6], enhancing clinical decision-making, patient interactions, and even medical research [3]. This ability to generate information places a heightened responsibility on ensuring the reliability, accuracy, and ethics of its outputs. As we navigate the vast world of health care AI, it is imperative to hone our focus on these generative models and their distinct potential to reshape patient care, medical education, and health system operations. By emphasizing their role, we aim to highlight not only their innovative capabilities but also the accompanying challenges that need to be addressed for a meaningful and safe integration into health care environments.

Current State of Affairs: The Great Paradox

Despite significant advancements in AI often leaving populations worldwide in awe, many areas within the health care sector still notoriously fail to impress, particularly in terms of digital health standards, equitable access, and system interoperability [7]. Some medical sectors in specific places are at the forefront of scientific and technological advances, but most countries or fields like long-term care lag, trapped in the digital health standards of the 1970s. The major challenges are not the use of faxes or digital tools but rather the equity of access for society and interoperability for the most advanced systems.

As a sector receiving substantial investment, being the second-largest spending category among Organisation for Economic Co-operation and Development countries, the health care industry is more than a line item in a budget [8]. Fundamentally, it is charged with the critical task of promoting and safeguarding health—one of the indispensable pillars supporting societal stability on which all stands. Without it, everything else teeters on the edge of collapse.

The guiding principle of health care has long been “Primum non noccere,” which translates to “First, do no harm.” Yet in today’s rapidly evolving digital landscape, the traditional interpretation of this maxim can no longer serve as an excuse for inaction. In our current state, maintaining the status quo or doing nothing is, paradoxically, causing harm.

The Call to Action: Leading the Digital Charge

Digitalization, with its foundational role in ensuring data interoperability, has enabled the rise of AI in health. In turn, AI has provided a platform for the advent of advanced generative models. Today, amid this AI revolution, it is striking and unacceptable that, despite its crucial role and significant investment, health care often finds itself trailing [9,10]. As the technological landscape evolves at an unprecedented pace, we should not merely object to this essential industry remaining technologically outdated; we should insist that it leads the charge, setting the pace rather than lagging. However, this is not just about technological advancements; it is about the essence of care.

The potential of generative models in health care is vast, and our discussion should reflect an informed enthusiasm. Recognizing the capabilities and promise they bring does not mean we are overlooking the complexities. It means we are optimistic about what can be achieved without being naive about the challenges. While we push for innovation in health care, our insistence is on not only digital advancements but also meaningful, responsible, and nuanced progression. Now more than ever, advancing with clarity and purpose is the only way health care can genuinely uphold “Primum non noccere” in this digital age.

The Present Challenges: Strategies for Effective Implementation

A wealth of digital health solutions already exists [11], each seemingly more promising than the last. However, as technology advances, understanding these solutions requires increasingly specialized skills.

For instance, when users turn to chatbots such as ChatGPT for specific health care queries—be it programming a medical device or interpreting a health symptom—the ideal response from such systems should be precise, accurate, and aware of its limitations. However, instead of straightforward confessions like, "I'm unfamiliar with that programming language" or "That symptom is beyond my knowledge," these models might sometimes fabricate answers to feign understanding [12]. This tendency to generate unverified responses, without a built-in "truth threshold," not only risks misinformation but also erodes trust in these technologies in a field where clarity is paramount.

This situation underscores the imperative for the industry to enhance the reliability and transparency of such tools and, equally, for users to be aptly equipped to use and interpret these advanced technologies. They must act as a "truth threshold" for themselves, discerning the reliability of the information provided.

This represents an indispensable uphill battle to evaluate and prioritize solutions for large-scale implementation since the need has never been greater for efficient, safe, and intelligent solutions that improve performance and quality of life for patients and health care professionals while benefiting institutions and the health care system as a whole.

The Journey Forward: Meticulous Implementation and Sustainability

In light of AI's transformative potential—and recognizing it both as a beacon of groundbreaking advancements and, if unchecked, as one of the most significant potential threats to humanity—our call to action underscores the great importance of not only progressing AI's technical development and governance. It is, for example, equally crucial to address the domains of regulatory constraints, interoperability, accountability, and liability with utmost diligence [13]. Drawing a parallel from the aeronautics industry, where manufacturers, air traffic control, and stringent flight regulations collectively ensure some of the safest travel experiences [14], we believe that the journey of AI integration in health care must adopt a similar, if not greater, level of care and rigor.

However, it is pivotal to highlight that sheer development and regulations will not suffice. The essence of successful innovation lies in its effective implementation. This includes rigorous preparation, meticulous execution, and sustained support to ensure both immediate success and long-term sustainability. Given the health care industry's paramount role in life preservation and its significant costs, it is imperative that it not only aligns with technological advancements but also leads them. Leading does not mean merely developing new solutions but also ensuring they are seamlessly integrated and enduringly effective. The health care sector should be at the helm of innovation, shaping the future and guaranteeing that the innovations are not only introduced but also enduringly implemented for the benefit of all.

Suggested Topics for Submission

This section provides a list of example topics tailored to align with our broad focus on the successful implementation of AI language models in diverse health care settings. We encourage contributors to delve into the process, use, outcomes, and influential factors of AI integration, aiming for a holistic and practical discourse. The topics listed are not exhaustive, and we welcome diverse perspectives and innovative approaches.

- Comparative analyses of policies and regulations: Explore the varying landscapes of AI regulation in health care across different countries. Delve into how specific policies either facilitate or hinder the implementation of AI language models, providing insights into creating conducive environments for global adoption.
- Strategies for reliability, transparency, and ethical use: Discuss and develop strategies to ensure the ethical, transparent, and reliable application of AI language models in health care. Share best practices, guidelines, and frameworks that help in establishing trust among stakeholders and ensuring patient safety.
- Comprehensive methodologies for implementation: Provide detailed blueprints and methodologies for the successful integration of AI language models in health care settings. Focus on the entire life cycle, from initial planning and integration to long-term management, ensuring applicability for researchers, industry professionals, policy makers, and decision makers.
- Case studies on real-world impact and effectiveness: Share real-world examples illustrating the impact of AI language models on health care delivery. Highlight both successes and challenges, discussing the tangible outcomes, lessons learned, and strategies for overcoming obstacles.
- Evaluations of outcomes and impact on health care delivery: Conduct thorough evaluations of AI language model implementations, examining a wide range of outcomes including acceptability, adoption, cost-effectiveness, and impact on health care efficiency and patient satisfaction. Explore how these technologies contribute to or challenge the equity, timeliness, and patient-centeredness of health care services.

By addressing these topics, authors contribute to a collaborative, rigorous, and transformative discourse, propelling the health care sector toward seamless integration of AI language models and ensuring a lasting positive impact on global health care delivery.

Authors' Contributions

Both authors participated equally in conceptualization. While AC contributed more significantly to writing the original draft, CL contributed more to reviewing and editing.

Conflicts of Interest

CL is the editor-in-chief of *JMIR Medical Informatics*. AC is an editorial board member of *JMIR Medical Informatics*.

Abstract

Background: Throughout the COVID-19 pandemic, many hospitals conducted routine testing of hospitalized patients for SARS-CoV-2 infection upon admission. Some of these patients are admitted for reasons unrelated to COVID-19 and incidentally test positive for the virus. Because COVID-19–related hospitalizations have become a critical public health indicator, it is important to identify patients who are hospitalized because of COVID-19 as opposed to those who are admitted for other indications.

Objective: We compared the performance of different computable phenotype definitions for COVID-19 hospitalizations that use different types of data from electronic health records (EHRs), including structured EHR data elements, clinical notes, or a combination of both data types.

Methods: We conducted a retrospective data analysis, using clinician chart review–based validation at a large academic medical center. We reviewed and analyzed the charts of 586 hospitalized individuals who tested positive for SARS-CoV-2 in January 2022. We used LASSO (least absolute shrinkage and selection operator) regression and random forests to fit classification algorithms that incorporated structured EHR data elements, clinical notes, or a combination of structured data and clinical notes. We used natural language processing to incorporate data from clinical notes. The performance of each model was evaluated based on the area under the receiver operator characteristic curve (AUROC) and an associated decision rule based on sensitivity and positive predictive value. We also identified top words and clinical indicators of COVID-19–specific hospitalization and assessed the impact of different phenotyping strategies on estimated hospital outcome metrics.

Results: Based on a chart review, 38.2% (224/586) of patients were determined to have been hospitalized for reasons other than COVID-19, despite having tested positive for SARS-CoV-2. A computable phenotype that used clinical notes had significantly better discrimination than one that used structured EHR data elements (AUROC: 0.894 vs 0.841; $P<.001$) and performed similarly to a model that combined clinical notes with structured data elements (AUROC: 0.894 vs 0.893; $P=.91$). Assessments of hospital outcome metrics significantly differed based on whether the population included all hospitalized patients who tested positive for SARS-CoV-2 or those who were determined to have been hospitalized due to COVID-19.

Conclusions: These findings highlight the importance of cause-specific phenotyping for COVID-19 hospitalizations. More generally, this work demonstrates the utility of natural language processing approaches for deriving information related to patient hospitalizations in cases where there may be multiple conditions that could serve as the primary indication for hospitalization.

Introduction

Hospitalization due to COVID-19 has become a key public health indicator. One of the primary goals of vaccination against SARS-CoV-2, the etiological agent of COVID-19, is to reduce the incidence of severe disease and death, with hospitalization serving as a primary end point in vaccine efficacy trials [1]. Further, hospitalization has become a primary indicator of community transmission levels of SARS-CoV-2 infection [2], including disease severity and health system capacity [3-6]. Similarly, hospitalization due to COVID-19 is a typical outcome of interest in public health studies of COVID-19 using real-world data sources, such as electronic health record (EHR) data [7-10]. Finally, because of the rise of rapid, at-home testing for SARS-CoV-2 infection, COVID-19 cases that do not rise to the level of requiring medical attention are likely to be missed or underreported, affecting assessments of COVID-19 prevalence [11]. Thus, there is a critical need to rapidly and accurately identify hospitalizations due to COVID-19.

Due to concerns related to the hospital-based spread of SARS-CoV-2, many institutions routinely perform SARS-CoV-2 testing in patients who are admitted to the hospital, regardless of the primary reason for admission [12,13]. Although SARS-CoV-2 testing is important for guiding care and ensuring that health care professionals take precautions to prevent infection, such routine testing potentially complicates retrospective studies using real-world data sources. Specifically, it becomes challenging to distinguish a patient who was admitted because of COVID-19 from a patient who incidentally tested positive for SARS-CoV-2 infection. In both cases, patients would have a positive laboratory test result and would (presumably) have an *International Classification of Diseases, 10th Revision* (*ICD-10*) code for COVID-19. Previous reports have noted that incidental positives may account for around 26% of all COVID-19–positive patients [14].

Given the public health importance of identifying hospitalizations due to COVID-19 rather than hospitalizations in which SARS-CoV-2 infection was identified incidentally, methods (ie, computable phenotypes) are needed to distinguish the two conditions in retrospective data sources. Such phenotypes would be instrumental in retrospective studies of patients with COVID-19 and in public health surveillance. In this study, we seek to (1) motivate the need to identify patients who were admitted because of COVID-19 versus patients who incidentally tested positive for SARS-CoV-2 during admission, (2) explore the potential of using both structured data (ie, diagnosis codes, medications, and procedure codes) and unstructured data (ie, clinical notes) to construct computable phenotypes, and (3) illustrate the inferential biases that may arise if phenotyping methods cannot distinguish the reason for hospitalization.

Methods

Study Setting

We performed a retrospective study of patients aged >18 years who were hospitalized with a documented positive SARS-CoV-2 test result during January 2022. We conducted our study at Duke University Health System (DUHS), which consists of 1 quaternary academic medical center and 2 associated community-based hospitals.

Ethical Considerations

This study was designated as exempt human subjects research by the DUHS Institutional Review Board (IRB number: Pro00109397).

Study Data

Source Data

Using DUHS EHR data, we identified all patients who were admitted during the week of January 16 to 22, 2022, with documentation of a positive SARS-CoV-2 test result in the prior 20 days. Charts from this week were specifically reviewed in part due to a data request from the North Carolina Division of Public Health to understand the epidemiology of COVID-19–related hospitalizations. We excluded individuals with a resolved COVID-19 isolation status, as well as those who were admitted prior to January 1, 2022, to create a cohort of patients who were likely infected with the Omicron variant of SARS-CoV-2. During this period, the Omicron variant was the predominant SARS-CoV-2 variant in circulation within the United States and was associated with the largest wave [8] of SARS-CoV-2 infections to date. For each patient, we extracted the following data: medical record number, date of admission, hospital unit, and level of care.

To generate a criterion standard for classification, 6 trained health care professionals manually reviewed patient records for the index admission to adjudicate whether SARS-CoV-2 infection was the primary reason for admission or an incidental finding. Health care professionals attributed hospitalizations as those due to COVID-19 if admissions were due to primary manifestations of SARS-CoV-2 infection, such as hypoxia or the need for supplemental oxygen, or due to COVID-19–associated complications, such as dehydration or weakness.

Analytic Data

For each admission reviewed, we extracted structured EHR data elements recorded during hospitalization and captured within the Duke Clinical Research Datamart—an EHR database that is based on an extension of the PCORnet Common Data Model (National Patient-Centered Clinical Research Network) [15]. Clinical notes were extracted from the Duke University Electronic Data Warehouse. We extracted admission data, daily progress data, and discharge summary notes. Extracted structured data elements included demographics, service encounter characteristics, diagnoses, laboratory tests, COVID-19 vaccination status, and medications (Table S1 in Multimedia Appendix 1). Clinical notes included emergency department admission notes, progress notes, operative notes, history and physical examination notes, and discharge summaries.

Clinical Note Analysis

To analyze the clinical notes, we used the term frequency–inverse document frequency (TF-IDF) approach. The TF-IDF approach [16] generates, across the set of notes for each patient, a numeric value for each word. The word value is

based on how common the word is in a patient's set of notes (term frequency), divided by how common the word is across all of the patient's notes (inverse document frequency), resulting in a numeric representation for each word on a per-patient basis. Although this is a simple word-based representation, this approach has the following two advantages over deep learning embedding–based approaches: (1) it is possible to directly assess the importance of individual words, and (2) the TF-IDF tends to be more robust with small data sets. Notes were extracted as CSV files and concatenated for the entire encounter. We used the *nltk* package in Python (Python Software Foundation) [17] to tokenize words into a dictionary. For each document, we calculated word counts and removed any words that appeared fewer than 50 times. We then generated the corresponding weight matrix, which served as a numeric input for downstream analyses.

Analytic Approach

We first described the clinical characteristics of patients hospitalized due to COVID-19 versus those with incidental COVID-19 by using standardized mean differences (SMDs), with an SMD of 0.10 indicating a clinically meaningful difference. Next, we developed 3 classification models for COVID-19–specific hospitalization; one was based entirely on structured EHR data elements, a second was based on clinical notes alone, and a third used both structured data elements and clinical notes. We used LASSO (least absolute shrinkage and selection operator) [18] logistic regression and random forests [19] to estimate the models. Due to the relatively small sample size, we presented our results based on 10-fold cross-validation. We performed the TF-IDF approach separately within each cross-validation fold.

We evaluated the six classification models by calculating the area under the receiver operator characteristic curve (AUROC), along with associated 95% CIs. We identified the top clinical features and words that appeared in clinical notes based on the LASSO and random forest models. We plotted the precision-recall curve to better understand the performance of a classification model and assessed the impact of different rule-based phenotypes.

As a way to understand the importance and potential impact of accurate phenotyping, we performed an illustrative association analysis, evaluating the relationship between vaccination status and the following hospital outcome metrics: length of stay, intensive care unit (ICU) utilization, and in-hospital mortality. These were chosen, since they are standard quality metrics for operational purposes. We regressed each outcome onto vaccination status. We used a log-linear model for length of stay and used logistic regression for ICU utilization and in-hospital mortality. Each regression was performed by using the full cohort and compared to a model that only included patients who were determined to have been hospitalized due to COVID-19. We also tested for an interaction between vaccination status and the cause of hospitalization. We emphasize that these were illustrative analyses, and they were not meant to infer any causal effects of vaccination but rather to illustrate the importance of using cause-specific phenotyping for relevant COVID-19 outcomes.

All work was performed in R version 4.1.2 (R Foundation for Statistical Computing) [20] and Python version 3.9.1 (Python Software Foundation) [21]. The processing code is available in our GitLab (GitLab Inc) [22].

Results

Patient Characteristics

In total, we reviewed the charts of 630 patients who were admitted and tested positive for SARS-CoV-2. After excluding patients younger than 18 years and patients with privacy restrictions, our data set included 586 unique patients who were hospitalized and had tested positive for SARS-CoV-2. Of these, 224 (38.2%) were determined, through clinician review, to have been hospitalized for reasons other than COVID-19. During their assessments, our chart reviewers noted that it was often readily apparent which hospitalizations were attributable to COVID-19 and which were not.

Characteristics, by admission cause, are shown in Table 1. Compared with patients hospitalized for indications other than COVID-19, patients hospitalized due to COVID-19 were, on average, older (age: mean 62.7 years vs mean 51.9 years; SMD 0.587), and their admissions were more commonly labeled as emergency admissions (346/362, 95.6% vs 165/224, 73.7%; SMD 0.641). Furthermore, patients hospitalized due to COVID-19 were substantially more likely to receive COVID-19 therapies, including steroids (233/362, 64.4% vs 54/224, 24.1%; SMD 0.887) and the antiviral agent remdesivir (247/362, 68.2% vs 55/224, 24.6%; SMD 0.974), during their hospitalization. Patients hospitalized due to COVID-19 had lower lymphocyte counts on average compared with those of patients hospitalized for reasons other than COVID-19. Normal levels of C-reactive protein and the lack of dimerized plasmin fragment D (D-dimer) testing were associated with hospitalizations for reasons other than COVID-19.

Table . Cohort description.

Characteristics	Hospitalized due to COVID-19			Standardized mean difference

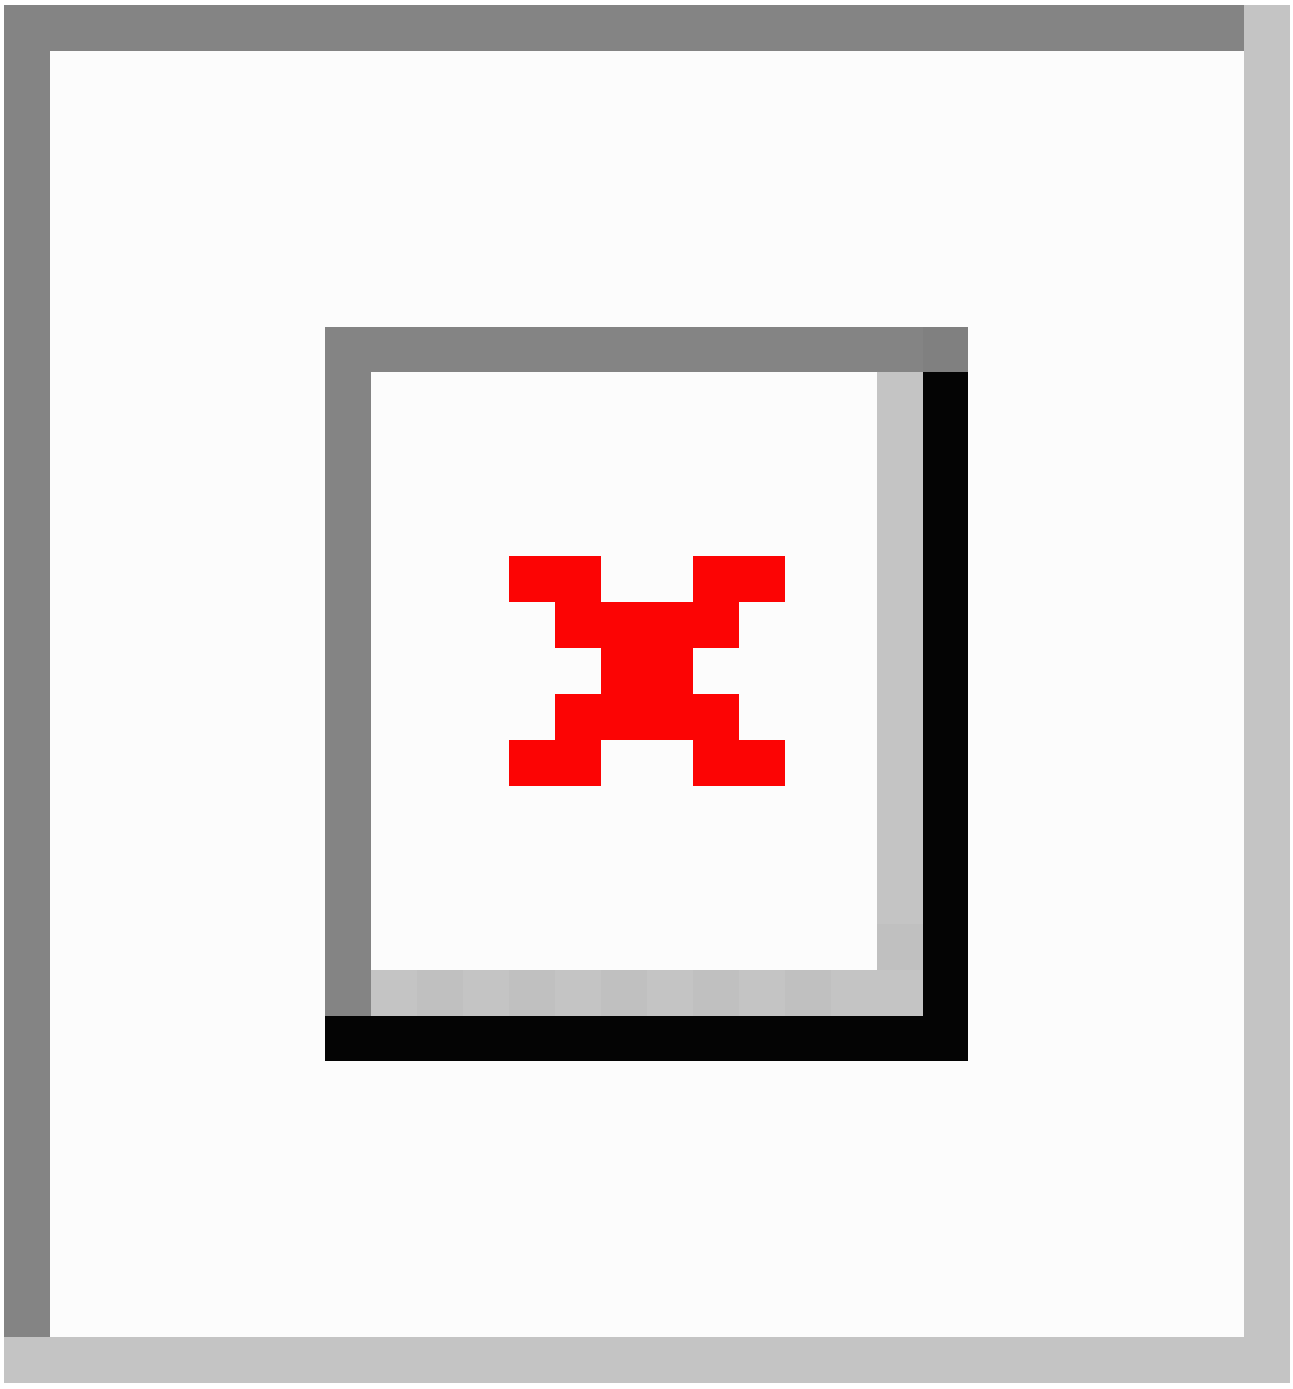
Performance of Classification Models

After tokenizing words and removing terms with fewer than 50 occurrences, our models included 7953 unique terms. There was minimal difference between the LASSO and random forest models. The random forest model based solely on clinical notes, the one based solely on structured data elements, and the one that used both clinical notes and structured data elements had AUROCs of 0.882 (95% CI 0.85-0.909), 0.829 (95% CI 0.794-0.864), and 0.890 (95% CI 0.864-0.916), respectively. The LASSO model based solely on clinical notes (AUROC=0.894, 95% CI 0.868-0.920) had better discrimination than the LASSO model based solely on structured data elements (AUROC=0.841, 95% CI 0.809-0.874; *P*<.001). The LASSO model using both clinical notes and structured data elements (AUROC=0.893, 95% CI 0.868-0.919) had similar discrimination to that of the LASSO model based solely on clinical notes (*P*=.91).

Next, we examined the top structured data elements and terms in each model (Figure 1). Highly predictive data elements and words corresponded to patient characteristics with large SMDs (Table 1). Words that are reflective of hospitalization due to COVID-19 have positive coefficients, while words reflective of hospitalization for other reasons have negative coefficients. Terms reflective of COVID-19–specific hospitalization were related to the care of patients with COVID-19, such as “remdesivir” and “dexamethason.” Other structured elements related to the likelihood of being hospitalized for COVID-19 included receipt of steroids, low lymphocyte counts, and underweight BMIs. Terms reflective of hospitalizations due to indications other than COVID-19 included strings that may be related to surgical procedures (eg, “surgic” for “surgical” or “dress” for “dressing”). For structured data elements, a lack of D-dimer collection and low ferritin levels were most commonly associated with admissions for reasons other than COVID-19. Similar features were identified from the random forest model (Figure S1 in Multimedia Appendix 1).

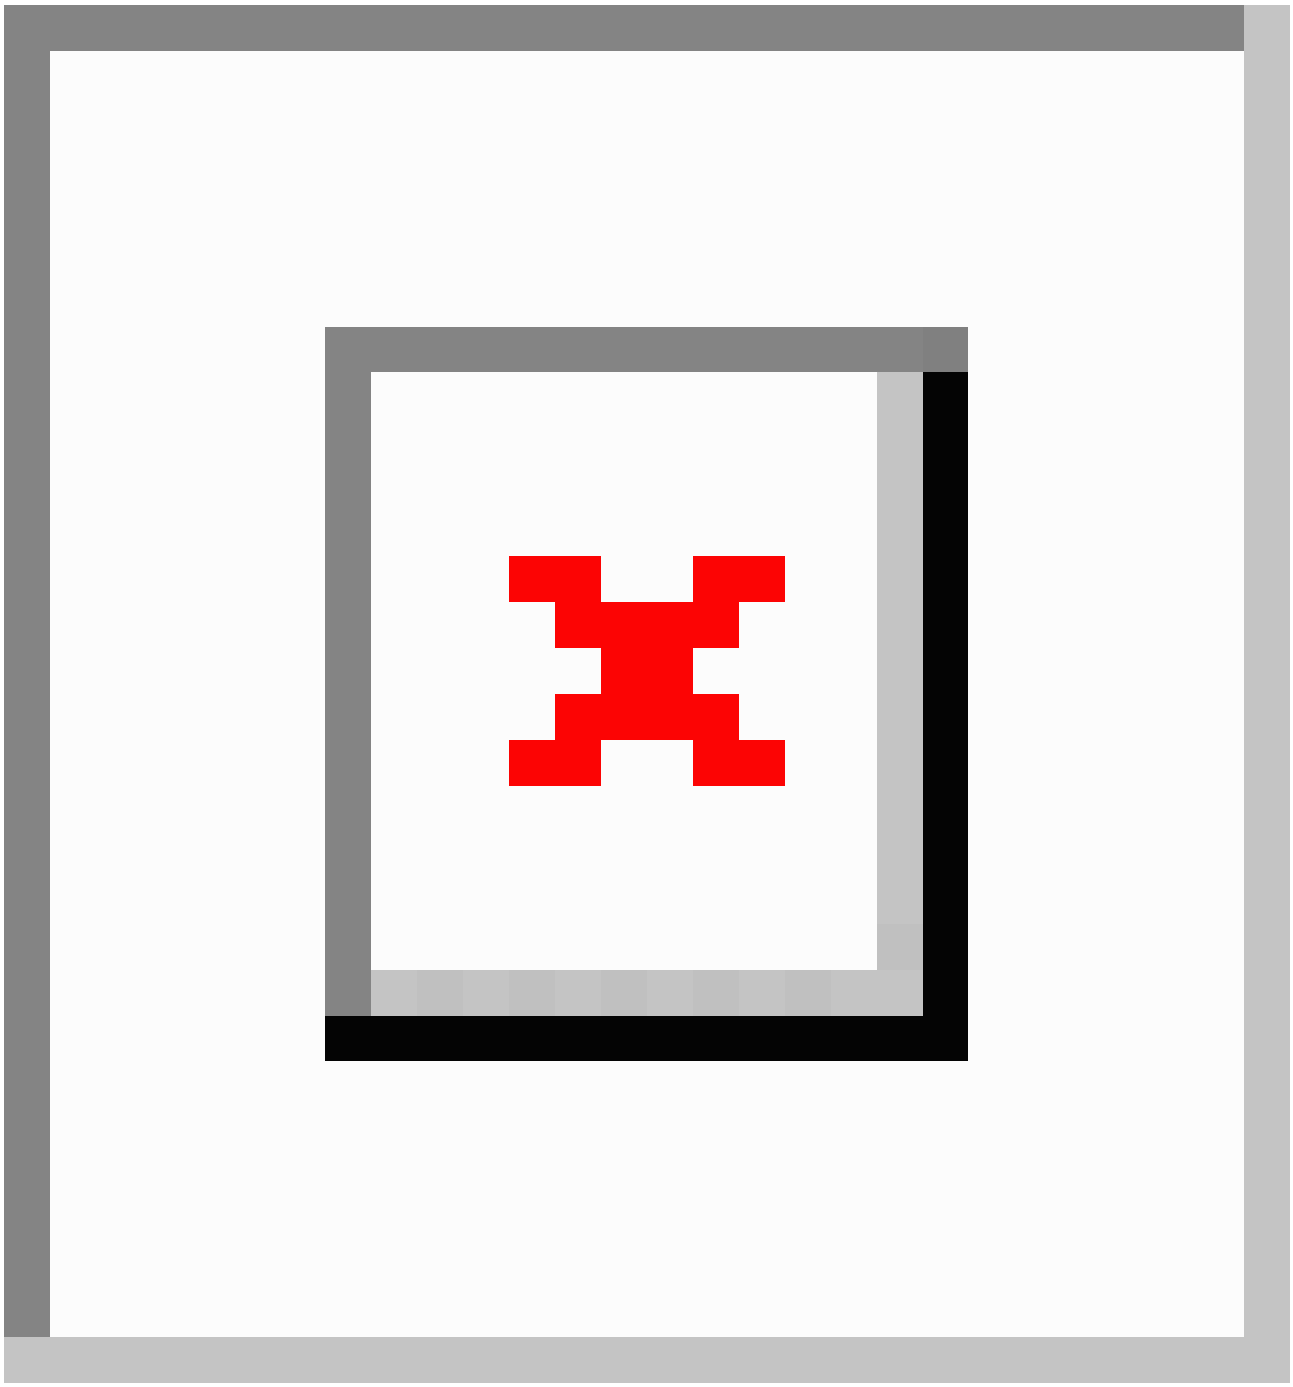
Figure 1. The top regression coefficients from the LASSO models, as reflective of variable importance for (A) the model using just structured data elements and (B) the model using just clinical notes. Values greater than 0 indicate that the feature has a positive association with hospitalization due to COVID-19, while values less than 0 indicate that a feature has a negative association.



Impact of Correct Classification

In order to assess the performance of a computable phenotype–based decision rule, we examined the precision-recall curve of the different models (Figure 2). For example, a rule that maintains a sensitivity of 90% (ie, one that would capture 90% of all patients hospitalized due to COVID-19) resulted in positive predictive values of 76%, 82%, and 84% and corresponding F_1-scores of 0.824, 0.858, and 0.869 based on structured data elements, clinical notes, and their combination, respectively. To illustrate the impact of these differences, we considered the impact of implementing each of these phenotypes at a 90% sensitivity to classify patients during the January Omicron wave. Within our health system, 1378 people were hospitalized and tested positive for SARS-CoV-2. Based on our analyses, using the LASSO-based phenotype that incorporates structured data, clinical notes, or their combination would result in approximately 244, 165, and 142 false positives, respectively.

Figure 2. Precision-recall (positive predictive value and sensitivity) curve for the different classification algorithms. This illustrates the trade-off between the identification of patients hospitalized due to COVID-19 (x-axis: sensitivity) and the accuracy of that capture (y-axis: positive predictive value). There is minimal difference between using just notes or notes with structured data elements. The model with only structured data elements performs notably worse in terms of positive predictive value at the same sensitivity thresholds. AUPRC: area under the precision-recall curve.



We next sought to evaluate the potential impact of different phenotyping methods on hospital outcome metrics, comparing a method that incorporates the reason for hospitalization versus one that does not. We used a regression analysis to assess the marginal relationship. As a use case, we evaluated associations between vaccine status and the following three hospital outcome metrics: length of stay, risk of ICU utilization, and in-hospital mortality. These evaluations were performed with the following three cohorts: all hospitalized patients, those who were determined to have been hospitalized due to COVID-19, and those who tested positive for SARS-CoV-2 but were hospitalized for unrelated reasons (Table 2). For length of stay, the magnitude of the effect of vaccine status changed based on the cohort used. In the cohort of all hospitalized patients, vaccinated patients had a shorter length of stay (relative rate 0.81, 95% CI 0.71-0.93). However, when limiting the analytic cohort to patients hospitalized due to COVID-19, there was no significant difference in length of stay for vaccinated patients versus unvaccinated patients (relative rate 0.98, 95% CI 0.83-1.16; *P* value for interaction<.001). We found similar patterns in analyses of other in-hospital outcomes; vaccination was associated with reduced risks of ICU utilization and in-hospital mortality among patients hospitalized for reasons other than COVID-19 when compared to those among patients hospitalized

due to COVID-19. Effects were robust to adjustment for age (Table S2 in Multimedia Appendix 1). These results illustrate the impact of selecting the correct cohort for analysis and the potential ramifications of using a cohort in which the reason for hospitalization has not been determined.

Table . Marginal association between vaccine status[a] and outcome metrics, unadjusted for age.

Outcome	Full cohort	Hospitalized due to COVID-19	Hospitalization unrelated to COVID-19	*P* value[b]
Length of stay, relative rate (95% CI)	0.81 (0.71-0.93)	0.98 (0.83-1.16)	0.59 (0.47-0.74)	<.001
ICU[c] utilization, odds ratio (95% CI)	1.04 (0.70-1.56)	1.25 (0.75-2.07)	0.77 (0.40-1.49)	.26
Mortality, odds ratio (95% CI)	1.02 (0.59-1.78)	1.45 (0.74-2.88)	0.48 (0.16-1.29)	.08

[a]Unvaccinated patients are the reference group.

[b]*P* value is for hospitalization due to COVID-19 versus hospitalization unrelated to COVID-19.

[c]ICU: intensive care unit.

Discussion

Principal Findings

Due to the public health importance of the accurate identification of COVID-19–related hospitalizations, there is a need for methods and computable phenotypes to identify hospital admissions in which the primary cause is COVID-19 [23]. We used machine learning methods and a physician chart review to develop a classification algorithm for hospitalization due to COVID-19. We found that 38.2% (224/586) of patients who were hospitalized at our institution during the Omicron wave and tested positive for SARS-CoV-2 infection were hospitalized for reasons other than COVID-19. These findings are in line with other recent studies, which found that an average of 26% of hospitalized patients with a positive SARS-CoV-2 test result had a primary indication for hospitalization that was unrelated to COVID-19 [14]. We found that a model based on clinical notes performed better than one based solely on structured EHR data elements. This work has important implications for retrospective analyses using EHR data to assess outcomes related to COVID-19, including vaccine effectiveness and health system capacity [24].

Prior work by Lynch and colleagues [25] evaluated the utility of *ICD-10* codes for COVID-19 diagnosis in inpatient, outpatient, emergency care, and urgent care settings during time periods across the pandemic; using a weighted, random sample of 1500 records from the Department of Veterans Affairs, they found that the COVID-19 *ICD-10* code (U07.1) had a relatively low positive predictive value across settings and time periods. These findings highlight the need for additional contextual data to identify acute cases of COVID-19. The Consortium for Clinical Characterization of COVID-19 by EHR (4CE) conducted a similar study of EHR data from 12 clinical sites to identify combinations of structured data elements to generate a reliable computable phenotype for hospitalization due to COVID-19, with a reported AUROC of 0.903 [26]. Similarly, we derived an AUROC of 0.841 based solely on structured data elements; however, we also found that that inclusion of clinical notes significantly improved the performance of the classification model (AUROC=0.893; *P*<.001). This result is not surprising, as the clinical narrative often includes important nuance, and as our chart reviewers noted, it was often readily apparent which hospitalizations were attributable to COVID-19 and which were not. Of note, chart reviewers in our study classified hospitalizations that were indirectly due to SARS-CoV-2 infection, such as those due to COVID-19–related weakness or delirium, as hospitalizations due to COVID-19, which could partly explain the observed difference in discriminatory ability between our study and the study conducted by the 4CE.

By using the TF-IDF approach in conjunction with LASSO regression, we identified both individual terms and the direction of the association between each term and the hospitalization indication. Although the TF-IDF approach is a simple natural language processing (NLP) approach, it is also very scalable, interpretable, and implementable. Our results highlight the power of even simple natural language models. The terms that best predicted hospitalizations due to COVID-19 included common descriptors that were used in the clinical care of patients with COVID-19, such as “hypox” (likely shortened from “hypoxia” or “hypoxic”), or COVID-19 therapies like remdesivir. Conversely, the terms that were not associated with hospitalizations due to COVID-19 included words related to surgery—a common indication for hospital admission that is generally unrelated to SARS-CoV-2 infection.

To help contextualize our results, we also assessed the real-world impact of using an accurate phenotype for COVID-19–specific hospitalization. In studying hospitalized patients with COVID-19, the simplest analysis would be to include all patients with a COVID-19–positive test result. As our illustrative analysis showed, when using this full but heterogeneous cohort, the results suggested that vaccination status is associated with a shorter length of stay. However, when we limited the analysis to only include patients who were identified as having been hospitalized due to COVID-19 (ie, people with symptoms of COVID-19), the analysis indicated that vaccines are not associated with a shorter length of stay. We interpreted these data as indicating that, conditional on someone being sick enough to be hospitalized due to COVID-19, vaccines provide no additional benefit in terms of the length of

hospitalization. Similar patterns were found for other hospital outcome metrics. Although this analysis was not intended to be a causal analysis, it did illustrate how the use of accurately classified cohorts is important for the calculation of standard outcome metrics and likely impacts other related association analyses.

More broadly, this work highlights the importance and challenge of phenotyping cause-specific events. Although there is rich literature on computable phenotypes, most of this literature is geared toward the identification of chronic diseases (eg, presence of asthma). However, few computable phenotypes have focused on cause-specific events (eg, asthma exacerbation). Such cause-specific phenotypes often exhibit poor specificity and can require algorithms that are more complex than those required for chronic conditions. As this work shows, and as suggested by others, NLP-based phenotyping approaches are becoming more common, and further comparisons between NLP approaches and other methods will be needed to determine whether using text data can improve cause-specific phenotypes.

Although our study used rigorous methods, there are some key limitations. First and most notably, our findings are primarily illustrative and may not represent a generalizable algorithm for phenotyping COVID-19–specific hospitalizations. This study was conducted across a single hospital system, and it may not be reflective of practices at other institutions. Importantly, we would not expect our specific phenotype algorithm to be generalizable to other institutions. Second, we only looked at 1 period of time, namely the January 2022 Omicron wave; however, there are documented differences in the rate of hospitalization and positive test results over the course of the pandemic, and our models may not accurately reflect distinguishing factors in other waves. Third, another limitation is that, given the time constraints of chart reviews, we were only able to analyze a relatively small sample. In particular, the small sample size limited our ability to apply more sophisticated NLP-based approaches, such as the use of n-grams.

Conclusions

Overall, our results show that a sizable number of people who were hospitalized and tested positive for SARS-CoV-2 were hospitalized for reasons other than COVID-19. The conflation of these individuals can impact our understanding of hospital outcome metrics. We constructed a strong classification model that can be used as a computable phenotype to distinguish patients who were hospitalized due to COVID-19 from those who incidentally tested positive for SARS-CoV-2 but were hospitalized for other reasons. Moreover, we found that while structured data elements are useful in constructing such a phenotype, clinical notes had a higher positive predictive value than that of structured data elements alone. Future work should seek to explore the generalizability of such phenotypes across institutions and different waves of the COVID-19 pandemic.

Abstract

Background: The electronic health record (EHR) targets systematized collection of patient-specific, electronically stored health data. The EHR is an evolving concept driven by ongoing developments and open or unclear legal issues concerning medical technologies, cross-domain data integration, and unclear access roles. Consequently, an interdisciplinary discourse based on representative pilot scenarios is required to connect previously unconnected domains.

Objective: We address cross-domain data integration including access control using the specific example of a unique device identification (UDI)–expanded hip implant. In fact, the integration of technical focus data into the hospital information system (HIS) is considered based on surgically relevant information. Moreover, the acquisition of social focus data based on mobile health (mHealth) is addressed, covering data integration and networking with therapeutic intervention and acute diagnostics data.

Methods: In addition to the additive manufacturing of a hip implant with the integration of a UDI, we built a database that combines database technology and a wrapper layer known from extract, transform, load systems and brings it into a SQL database, WEB application programming interface (API) layer (back end), interface layer (rest API), and front end. It also provides semantic integration through connection mechanisms between data elements.

Results: A hip implant is approached by design, production, and verification while linking operation-relevant specifics like implant-bone fit by merging patient-specific image material (computed tomography, magnetic resonance imaging, or a biomodel) and the digital implant twin for well-founded selection pairing. This decision-facilitating linkage, which improves surgical planning, relates to patient-specific postoperative influencing factors during the healing phase. A unique product identification approach is presented, allowing a postoperative read-out with state-of-the-art hospital technology while enabling future access scenarios for patient and implant data. The latter was considered from the manufacturing perspective using the process manufacturing chain for a (patient-specific) implant to identify quality-relevant data for later access. In addition, sensor concepts were identified to use to monitor the patient-implant interaction during the healing phase using wearables, for example. A data aggregation and integration concept for heterogeneous data sources from the considered focus domains is also presented. Finally, a hierarchical data access concept is shown, protecting sensitive patient data from misuse using existing scenarios.

Conclusions: Personalized medicine requires cross-domain linkage of data, which, in turn, require an appropriate data infrastructure and adequate hierarchical data access solutions in a shared and federated data space. The hip implant is used as an example for the usefulness of cross-domain data linkage since it bundles social, medical, and technical aspects of the implantation.

It is necessary to open existing databases using interfaces for secure integration of data from end devices and to assure availability through suitable access models while guaranteeing long-term, independent data persistence. A suitable strategy requires the combination of technical solutions from the areas of identity and trust, federated data storage, cryptographic procedures, and software engineering as well as organizational changes.

Introduction

Unique device identification (UDI) is a system used to identify devices within the health care supply chain based on a consistent, standardized, and unambiguous machine-readable identifier to keep track of the postmarketing performance of medical devices [1]. The performance of a hip implant, for example, cannot be evaluated without considering individual factors of the recipient [2] and the conditions of the therapeutic intervention [3]. Consequently, patient, medicine, and product have to be linked and monitored to enable a well-founded evaluation. Regardless of the still-missing legal framework conditions [4] and the existing ethical and political questions [5], digitalization of the health system is advancing [6], which is beneficial for a more holistic assessment. Either way, part of this development is the cross-domain linkage of data [7] that at least can be resolved on a patient-by-patient basis to prepare for intelligent data analysis. This requires going beyond analysis objectives to an appropriate data infrastructure, which enables different data domains to be linked while providing adequate hierarchical data access concepts. Consequently, this paper approached a framework for cross-domain cooperation and intelligent data analysis in a specific application scenario embedded in prospective digital hospital ecosystems. Linking unconnected domains inside of safe frameworks with clarified data sovereignty to enable a holistic approach to personalized treatment benefits health care, lowers risks of mistreatments, and functions as a catalyst for the optimization of medical products. This concept, based on a pilot scenario, can function as a basis to clarify unclear legal issues.

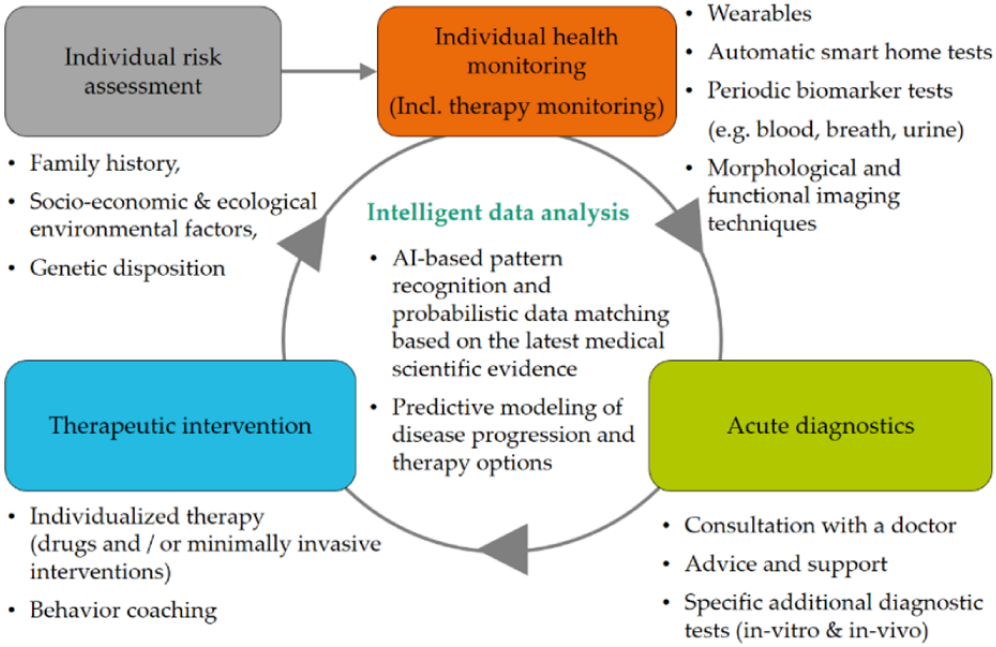
Methods

Framework Conditions for Digitization in Individualized Medicine

Intelligent Data Analysis Framework

An EHR is the systematized collection of electronically stored patient and population health data in a digital format. These records can be shared across different health care settings [8]. Records are provided through network-connected, enterprise-wide information systems or other information networks and exchanges. EHRs can include a range of data such as individual risk assessments, health monitoring, acute diagnostics, and therapeutic interventions while enabling comprehensive, intelligent data analysis, which, according to Hahn et al [9], is considered the information cycle of personalized medicine (Figure 1).

Figure 1. Information cycle of individualized medicine [9]. AI: artificial intelligence.



These data are stored as a patient digital twin in a centralized hospital information system (HIS) in the form of text, images (DICOM and other types), and scans. EHRs enable patients and hospitals to manage their health information in public (eg, hospital) and private environments as a personal health record (PHR). The information contained in EHRs is highly sensitive. Unintended exposure of these data threatens an intimate part of a patient's private sphere and may lead to undesirable consequences. The EHR is a communication tool that supports clinical decision-making, coordination of services (illness type, care type), evaluation of the quality and efficacy of care, research, legal protection, education, and accreditation, and regulatory processes. It is the business record of the health care system, documented in the normal course of its activities. Patients routinely review EHRs and keep PHR in their own digital archive or in patient portals (eg, at health insurance companies such as "TK-Safe," "Vivy," or "AOK-Gesundheitsnetzwerk" in Germany), given the patient is the owner of the EHR and PHR. The physician, practice, or organization is the owner of the physical medical record because it is its business record and property, and the patient owns the information in the medical record. Although the record belongs to the care facility or doctor, it is truly also the patient's information. EHRs should be released to other stakeholders only with the patient's permission or as allowed by law or via studies: public registry and ministries. PHRs are already on the market. The purpose of a PHR is to maintain good health and target outcomes; this could include daily vital signs (eg, blood pressure, heart rate), number of walking steps, amount of exercise, and calorie intake. In addition to these, information for medical use might be considered, such as blood type, allergies, pre-existing diseases, medicines the user is taking, emergency contact information, and information about the user's medical institution.

Synergy Potential in Information Linkage Using the Example of a Hip Implant

Neugebauer [10] stated that the digital transformation is promoted by the interaction of technologies that were previously perceived as independent of each other. Hahn et al [9] noted, in this context, that networking of the individual sectors and the structured use of integrated information are still pending. Moreover, Hahn et al [9] concluded that sustainable success can only be expected if the interlinking of technological and biomedical research on the one hand and clinical implementation and product development on the other hand are permanently guaranteed. Either way, this paper approached data-driven interdisciplinary research from an application-oriented perspective in an incident-based scenario (Figure 2). This example illustrates selected dependencies between social parameters, medical factors and technical aspects important for surgery, and healing, which are currently not linked sufficiently. In fact, it is a common practice to laboriously obtain this information on a case-by-case basis, which requires appropriate lead time before the operation; this is a major disadvantage in the case of emergency medical treatment. Consequently, this paper addressed this shortcoming and developed a possible solution scenario showing how this information can be linked at the EHR level. Moreover, we've shown how this information can be made accessible based on implant-inherent features while introducing a role model for access regulation and data protection.

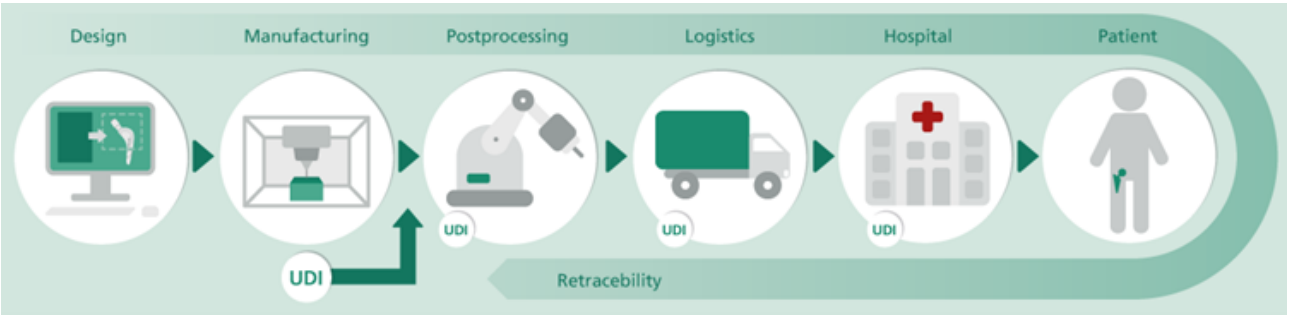
Data-Driven Networking of Information

Regulatory Demands

In the medical technology industry, quality assurance is a particular focus due to the stringent regulations. With a changeover period, the European Medical Device Regulation (MDR) EU 2017/745 came into effect in May 2021 and replaced the European directives on medical devices. The regulation obligates manufacturers to mark medical devices that are marketed in the European Union with unique codes. The main objective for the introduction of these codes is to increase patient safety. Unique product identification prevents confusion of medical devices and makes counterfeiting more difficult. The markings are implemented by the UDI system. The UDI enables tracking of medical devices, for example, from the last step of postprocessing in manufacturing where the marking is applied to the component (eg, by laser engraving). Nevertheless, the medical products can only be tracked from this point through the logistics process to the hospital. Figure 3 illustrates selected phases of a medical device life cycle covering design, manufacturing, postprocessing, logistics, and the union with the patient. Unfortunately, doubtless identification of an implant after implantation is impossible with the UDI system, which largely excludes proof of quality and originality after implantation. Across industries, product piracy is a major problem, and the estimated economic damage has been increasing over the years [11]. In addition to the generally valid comments on product piracy and its consequences, other aspects have to be considered in the field of medical technology. After the publication of the "Implant Files" in 2018 by a group of investigative journalists, the problem of defective medical devices became a sociopolitical issue [12].

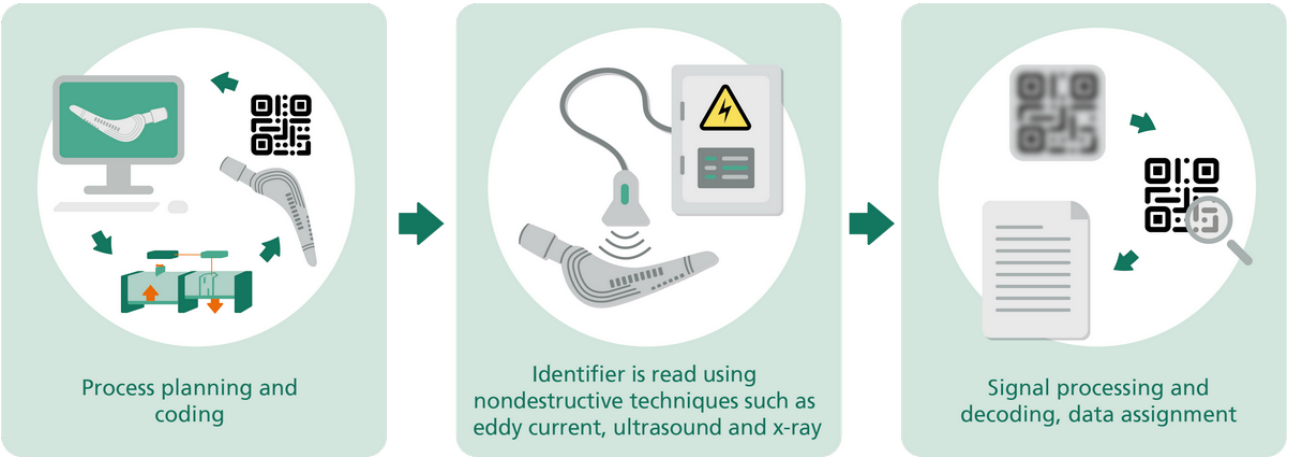
Figure 3. Retraceability of a medical device with a unique device identification (UDI).



Component-Inherent Identifier–Based Data Access

Inherent markings of implants could be a solution to prevent counterfeiting while satisfying the regulatory requirements for a machine-readable marking in the form of a barcode or data matrix. In addition, traceability can be expanded back to the design process when the inherent markings are integrated. Moreover, this simultaneously enables inclusion of the manufacturing process into the traceability chain as well (see Figure 3). Either way, the greatest potential for innovation is seen in the ability to clearly identify the implant after surgery, preferably via noninvasive technologies already available in the hospital or technologies that can be provided without great technological effort and financial investment. Either way, the inherent feature could act as a key to access distributed information (see Figure 2) after signal processing and appropriate decoding (Figure 4).

Figure 4. Principle of inherent markings in an additively manufactured implant with part identification and tracking.



Matvieieva et al [13] performed an identifier read-out applying eddy current (EC), ultrasound (US), and micro-computed tomography (CT; also in x-ray mode) as nondestructive methods. The EC, US, and x-ray techniques allow the receipt of part of the inherent data encoded in 1D and 2D codes. The feasibility of the methods was shown for 1D Pharmacode, UDI 1D Barcode (ISO 128), and UDI 2D DataMatrix for titanium, titanium alloy, and stainless steel. Due to the physical restrictions of the chosen nondestructive methods (eg, penetration depth, magnetic and acoustic wave transmission, propagation, and density), the obtained identifiers' signals have to be processed. In fact, after the identifier´s read-out, the obtained signals are processed by

morphological and mathematical operations; once decoded, they enable further linkage with data or information stored in a database (Figure 4).

Technical Focus Data

The starting point is the construction of a 3D model of a hip implant (Figure 5) based on anthropometric data or even patient-specific information in which the coding is also integrated. Considering typical hip implant sizes, geometric complexities, and quantities, 3D printing (additive manufacturing [AM]) is increasingly developing as a competitive manufacturing method [14]. Suitable AM procedures are primarily selective laser melting (SLM) [15,16] or electron beam melting [17,18]. In addition, layer-wise build-up and achievable resolution are very beneficial for the integration of inherent features during manufacturing (see Figure 3). Using these manufacturing processes, the 3D data model needs to be converted into a facet model first (mesh) [19]. Then, the parts are positioned in the build chamber, supported, and sliced using standard AM software [20]. Based on material selection criteria such as biocompatibility, the Young modulus, strength, and fatigue strength, a (certified) raw material is selected [21-23] that is particularly tailored to the AM process requirements [24]. Material selection criteria like particle size, particle size distribution, and morphology or chemical properties are continuously checked and monitored [25,26]. The SLM process data, for example, have to be qualified for applications like implants and are subdivided into predefined parameters (considered static) and parameters to be controlled by in-process sensing (considered dynamic) [27]. Either way, essential parameters are monitored and archived [28-30]. The same applies to processing data from postheat or pressure treatment [31] as well as from destructive and nondestructive material testing [32]. Moreover, mechanical postmachining, performed to adapt the implant to the recipient needs, generates data [33]. An example of this is the description of the geometric interface to the patient (bone-implant interface) including parameters such as surface roughness. The result, however, is an extensive description of the implant and the implant creation process as well as additional information such as corresponding implant tools (Figure 6). Obviously, some of this information is of interest to surgeons (medical focus), whereas information about the implant recipient and the use of the implant (social focus) are of interest to the manufacturer (Figure 2). This means, regardless of the individual legal framework, the possibility of controlled linkage of information is seen as desirable.

Figure 5. Example of the component (part) identification using a Pharmacode integrated into the hip prosthesis and data extraction from the identifier in the implanted state by computed tomography. CAD: computer-aided design; LMS: laboratory management system.

Social Focus Data

The social background of an implant-receiving patient (Figure 2) includes individual characteristics and conditions such as age, gender, lifestyle, and constitution type, which is of crucial importance for the formation of diseases, their duration, and treatment. The continuous monitoring or even documentation of this background can be ensured by a variety of technologies from the field of mobile health (mHealth), which allow broad mapping of dynamic data sets such as lifestyle and physical activities [34]. mHealth is an aspect of eHealth, although there is no universal definition of mHealth [1]. However, there is consensus that mHealth can be understood as medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices [35]. This means that mHealth can be understood as "the use of mobile communications for health information and services" as patient-individual behavior without direct involvement of the health service provider [36]. Here, mHealth is seen as the technical prerequisites to monitor and document the social focus data during healing (Figure 7) or even beyond (see Figure 2).

Figure 7. Illustration of close monitoring of healing using mobile health (mHealth) applications.

In addition to the fact that mobile communication and audiovisual interaction are the decisive enablers for mHealth, there is also the aspect of powerful sensor-based hardware and high flexibility in software development for smartphones and, to a limited extent, wearables [37]. In contrast to smartphones, wearables can be designed very specifically and can therefore be used for special applications (eg, sleep monitoring) [38]. Widespread sensor systems for smartphones include [39-41] light sensor technology (ambient light, camera system in combination with lighting), proximity sensors, acceleration sensor technology, rotation sensor technology (gyroscope), electromagnetic sensor technology, digital compass (magnetometer), acoustic sensor technology via microphone, and sensor technology for location tracking (GPS).

In contrast to smartphones, wearables are more specific for a particular application and therefore have higher specificity for the integrated sensors, so that headbands can, for example, derive targeted electroencephalography [42]. This means that targeted data collection is possible with the help of sensor technology, internal processing by specific software (eg, apps), visualization based on these data, and mostly wireless communication to third parties in the form of a uniform data image. For example, the following parameters can be acquired by means of wearables and mobile devices: heart rate and pulse oxymetry readings with photoplethysmography [43] and systems to monitor activity and sleep [11].

Hence, mHealth is seen as an enabler that contributes to rehabilitation by providing valuable data about the rehabilitation measures and patient-specific activities (Figure 6) that can be stored in the EHR. In addition, realistic load scenarios can be determined that could contribute to the further optimization of hip implants (Figure 2)—to promote healing [44] while targeting shorter hospital stays and lower treatment costs, for example [45]. In addition, mHealth can help achieve a consistent database (Figure 2) to evaluate the optimal intensity, frequency, and effects of rehabilitation from a wide variety of patients over a longer period of time as these data are currently not available or insufficient [46]. Either way, linking social focus data and production data could enable significant improvements with regard to determining the actual wearing of the implant, for example, based on characteristics such as posture, weight, and movement profiles, which are summarized here as social focus data (Figure 2).

Medical Focus Data

Both routine diagnostics and revision surgery require information about implants that were placed decades ago. Specific identification using only medical imaging is currently not possible and requires access to the documentation by the initial treating physician or hospital (Figure 2). For elective as well as acute medical interventions, this documentation is not available or only available with enormous effort. With inherent markings in the implant, it is feasible to obtain information relevant for revision surgery or routine diagnostics even after

the insertion of an implant into the human body [47] (Figure 4). To assure valid and reliable surgical planning, medical data from past treatments, especially the surgical processes, follow-up examinations, and rehabilitation measures, are needed. Insufficient information about the implant and medical focus data (Figure 2) could lead to complications during revision surgery; therefore, considerable efforts are being made to obtain this information, which significantly extends the preoperative time in the hospital and results in additional costs. In fact, an example of the necessary information about the particular implant concerns the appropriate revision instruments and the existing implant components [48-50]. Moreover, the research effort prior to the operation is continuously increasing, linked to the increasing number of operations and growing variety of implant types, sizes, variants, and material combinations. In addition to knowledge on the implant system used, information on the initial implantation process, which cannot be seen in medical images (CT, x-ray), is highly relevant for a gentle and successful revision of a hip implant. In fact, insufficient information clearly increases the risk of complications for the patient. Here, it shall be emphasized that the use of unsuitable revision instruments causes the risk of an enlargement of the wound surface resulting from an invasive procedure. This, in turn, increases the risk of infection and bleeding or even periprosthetic fracture. In addition, the inevitable prolongation of the surgery time can lead to a higher anesthetic risk, increased risk of thrombosis, and unstable cardiovascular function. Consequently, there is the obligation to report “incidents” in connection with medical devices to the German Federal Institute for Drugs and Medical Devices (BfArM), which includes an indication of the cause. Hence, unique inherent identification (Figure 4) and (partial) networking of information (Figure 2) in a transparent and retraceable database seem promising to assure a higher quality of health care [11], if unauthorized access is avoided.

Results

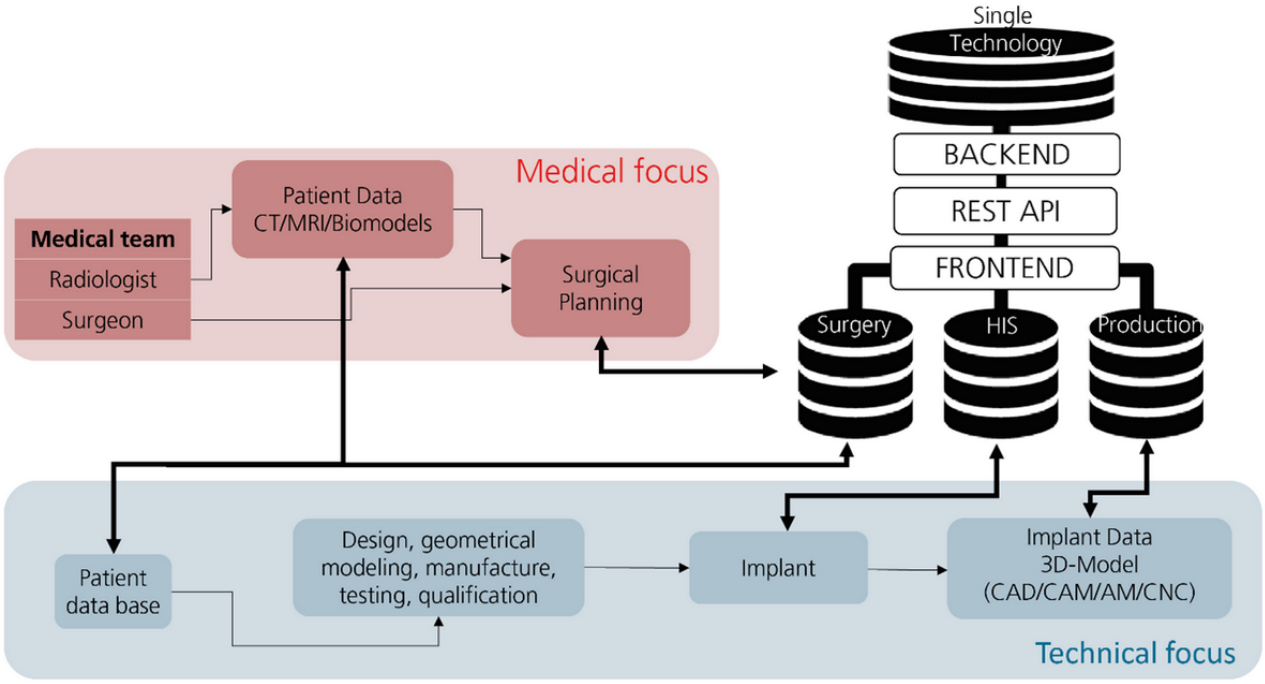
Database and Data Access

Data Integration From Heterogeneous Domains

Data integration is a crucial issue in the environment of heterogeneous patient-production data sources (Figure 2). First, there are heterogeneous data types and formats located in different databases, which implies that solving data integration challenges is a prerequisite for gaining useful information and knowledge based on appropriate analytical methods. Although concepts for databases to process heterogeneous data sets exist [51], the Laboratory Management System 4.0 (LMS 4.0) was developed specifically for the purpose of taking into account nonmedical stakeholders.

Exemplary implementation and application of this database structure were successfully demonstrated for the case of operations on the lip-jaw-palate region [52]. LMS 4.0 enables requesting data from different locations (eg, surgery, the HIS, or an implant producer) as a routine using web user interfaces. Using LMS 4.0, the surgeon collects magnetic resonance imaging results, for example, from HIS, checks patient data stored there, and has access to the integrated technical focus data (Figure 8) while planning the operational approach.

Figure 8. Partial networking of distributed data and information from different domains. AM: additive manufacturing; API: application programming interface; CAD: computer-aided design; CAM: computer-aided manufacturing; CNC; computer numerical control; CT: computed tomography; HIS: hospital information system; MRI: magnetic resonance imaging.



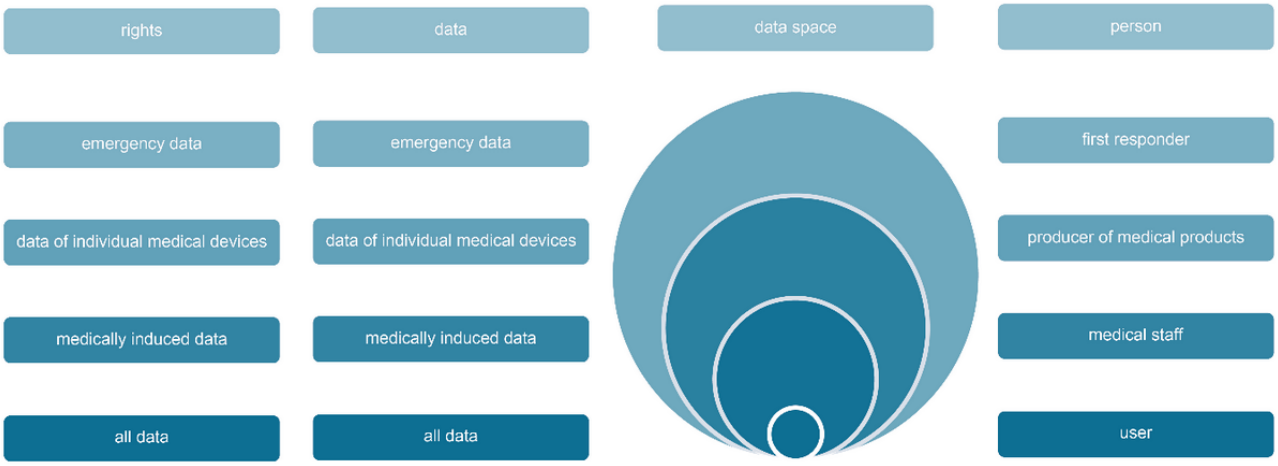
Based on integrated patient and production data, which can be expanded to an implant database that covers several manufacturers, surgical planning is simplified in order to determine which bone implant is the most suitable in the particular case, for example. Moreover, LMS 4.0 generates a dashboard and report that help the operating staff prepare for

the surgery with the selected implants through the automatic output of the associated tools and instruments. Moreover, the surgeon can use this report to prove his or her preparations for the procedure and comprehensively explain the operation to the patient. LMS 4.0 presents an architecture that implements data integration in the hospital from the production, surgery preparation, and patient data. LMS 4.0 integrates databases without any changes to the individual databases (SQL database, software back end, application programming interfaces [APIs], front end) nor any need to maintain another database. The solution combines database technology and a wrapper layer known from extract, transform, load (ETL) systems and brings it to the SQL database, WEB API (back end) layer, interface layer (REST API), and front end. It also provides semantic integration through a connection mechanism between data elements. The solution allows for integration of patient, surgery, and production data in one technological framework: data management platform and implementation of analytical methods in one end user environment. The patient data (see Figure 2) are transferred, securely, to a HIS. Medical data storage in LMS 4.0 offers a highly scalable clinic web storage service that uses cumulative digital objects (eg. patient, surgery, implant) rather than blocks or files. Object storage typically stores data, along with metadata that identify and describe the content. For metadata management and automated quality control and data fusion (ETL processes), a data consistency model (LMS I4.0 metamodel) is used to enable eventual consistency for updates or deletes to existing objects.

Role Concept for Secure Data Access

On the basis of the information domains and the links and interfaces shown in Figure 2, it becomes obvious that the database structure and the information technology (IT) system design in the back end (see Figure 8) have to accommodate different user roles to protect secure data access to sensitive patient data. Consequently, a role model was developed that takes into account both different users or user groups (eg, patients, medical staff, manufacturers of medical products, and first aid providers) as well as special situations (eg, emergency access). Deviating from static access models (role-based access control) as well as traditional shell models in this case, pure login information was linked with additional contextual information (attributed-based access control) in order to allow hierarchical access control. Either way, the principle is shown in Figure 9, indicating the 4 basic roles embedded in the defined shell model.

Figure 9. Principle of hierarchical data access based on a shell embedded role model.



Nevertheless, the person category is subdivided into 4 roles: “first responder,” “producer of medical products,” “medical staff,” and “user.” Users can view all data via a terminal device after registration, for example, with a digital health card equipped with a radio-frequency identification transponder (radio-frequency identification), and allowed to only make entries in a dedicated area of the social focus data section (Figure 2). The write permissions include data integration from fitness watches, training performance in rehab or sports facilities, and self-collected nutritional data, while interfaces to cell phone apps, for example, are available to substitute manual input. On the other hand, the medical staff can read medically relevant data and has the right to make entries in the medical focus data (Figure 2), which shows who made the entry. This corresponds to an entry in the EHR stored in the HIS (Figure 7). Producers of medical products only have access to the medical device data area, summarized as production (Figure 7). Technical focus data (Figure 2; eg, appropriate revision instruments as described in the Medical Focus Data section) are stored here, while the patient and implant are linked in the medical focus database (Figures 2 and 7). This information is requested from the manufacturer via a modified procurement process, which ensures that the agreed data are available before the invoice for the implant is paid. Consequently, all relevant product information is stored, enabling the simplification of follow-up treatments, support for minimally invasive interventions, and excluding of medical interaction. The information transfer to the manufacturer (see the Technical Focus Data section), on the other hand, can be enabled using a data integration center with a data use and access committee for research inquiries, as is currently being developed by Prokosch et al [53]. The last role in the person category is the first responder (Figure 8), which is introduced to explain the dynamic access approach. The first responder occurs in case of an accident or emergency when lifesaving measures, for example, are necessary. For example, access is granted for a certain period if several predefined factors that were detected using a fitness watch or other smart device take effect at the same time (eg, oxygen saturation in the blood, blood

pressure, or other health-endangering characteristics). However, these attributes are securely transferred to the LAB 4.0 database management system (see the Data Integration From Heterogeneous Domains section) to obtain the necessary information depending on the authorization or to allow the addition of data. For this purpose, a standardized, well-defined interface is used to realize the data exchange and integrate smart devices for pure information retrieval as well as to develop software extensions that can be used to store the data in the database while complying with access restrictions. This enables the creation of a digital ecosystem for different participants to provide patients with optimal and, above all, digital, end-to-end health care while providing adaptive access regulations meeting authenticity requirements and assuring authenticity and appropriate access tracking. A method of secure patient-centered management of EHR data, though it can also be further processed in a deidentified format for statistical purposes, has been demonstrated with blockchain technology using cancer care as an example [54].

Data Integration Scenario

Using the hospital database LMS 4.0 (Figure 8), all individual elements of the data ecosystem are presented and explained in reference to Figure 10. In fact, the data ecosystem is divided into the following 4 levels, which are distinguished for functional structuring: “data storage,” “data harmonization,” ”interfaces,“ and ”data input/data output.“ The ”data storage“ level contains different relational databases, which, again, contain medically relevant data (medical device [see the Technical Focus Data section], patient record [see the Medical Focus Data section], and health [see the Social Focus Data section]). Data preprocessing is performed at the ”data harmonization“ level (see Figures 8 and 10), which means that incoming data are adapted to the requirements of the LMS 4.0 database structure (Figure 8) and sorted, while outgoing (anonymized) data (eg, via the data integration center) are transferred via defined data exchange procedures with strictly recorded accesses. In the underlying, but closely related, ”interfaces“ level (Figure 10), interfaces are established by extensible middleware to communicate with the ”hospital database“ (see Figure 8). This enables the integration of data users from different domains and querying data from the database. The 3 levels ”interfaces,“ ”data harmonization,“ and ”data storage“ are subjected to the CIA (confidentiality, integrity, availability) triad and ensure the functionality of the system. The ”data input/data output“ level connects the ”hospital database“ with the environment. For example, manufacturers of medical devices can transfer product-specific data into the database to make the data available to hospital staff (see Figures 3 and 10). Likewise, patients can store their vital signs from wearables, for example, in this database to support long-term examinations or enable access in medical emergencies through attribute-based access control (see the Role Concept for Secure Data Access section). At the same time, patients can see their EHR, read digital doctor's notes, or view exam results. Physicians have interfaces to both connect medical exam machines to the database and write data; medical staff can also store information, and the data can be viewed hospital-wide and processed with appropriate IT systems.

Discussion

Principal Findings

The connection of different data lakes, beginning with implant design including the entire manufacturing to the medical treatment process as well as the tracking of lifetime characteristics inside of a data integration ecosystem, shown in this paper can disrupt today's health care system, leading to a cost-efficient, personalized system. The strict hierarchical data access concept based on a shell-embedded role model can be used to handle highly sensitive data and as a template to help clarify legal issues.

The overriding goal is to use digitization to improve the networking of interdisciplinary domains and to create secure interfaces for exchange as a prerequisite for intelligent data analysis. For this purpose, a representative hip implant application scenario was chosen due to an existing network of social, medical, and technical domains. Moreover, the interaction resulted from a skill- and experience-based union of implant and recipient results in an individual constellation that is subject to change over time. A key element in the resulting constellation is the UDI based on an inherent feature, which can be read out noninvasively after implantation. The permanently readable feature acts as a key to technical focus data, which represent testable or documented properties that are made available by the provider and are of direct or downstream interest. Consequently, we showed how the technical focus data can be integrated into existing data ecosystems. This, however, was only approached at the hospital level, which is explained by the unclear legal framework and the missing data infrastructure for a broader context. Nevertheless, the consolidation of distributed databases in a single technology solution is a scalable concept that can be transferred from a single hospital to a global solution. Another important aspect is that the introduced hierarchical data access is based on a shell-embedded role model and staggered user rights. Here, the attribute-based access control shall be emphasized because this represents nonrigid boundary

conditions in preparation for future regulations. The selected user profiles and the granted rights, on the other hand, are only examples that are up for discussion and need to be specified and challenged in further research. However, the data integration scenario distinguishes 4 levels of action layering data storage, data harmonization, interfaces, and the data input/data output layer, which harmonizes the application scenario and digital ecosystem. Nevertheless, future research must show how real benefit can be created through data linkage and how this can be monetized. Balancing the personal rights of the individual while achieving sustainable technological innovation is seen as the central challenge, which must be faced in a global context.

Conclusions

Personalized medicine requires cross-domain linkage of data, which, in turn, requires an appropriate data infrastructure and adequate hierarchical data access solutions.

Hip implant is a prime example of the usefulness of cross-domain linkage of data because it bundles social factors of the individual patient, medical aspects in the context of the implantation, and technical aspects of the implant.

UDI in terms of inherent identifiers can be the key to (selective) long-term data access especially if the postoperative readout is guaranteed.

SLM and electron beam melting make it possible to integrate features already inherent in the design process to close the traceability gap.

It is necessary to open existing databases using suitable interfaces for secure integration of data from end devices (eg, wearables or end users) and to assure availability through suitable access models (role-based, attribute-based, hybrid) while guaranteeing long-term independent data persistence.

A suitable strategy requires the combination of technical solutions from the areas of data storage, cryptographic procedures, and software engineering as well as organizational changes among the actors involved (eg, hospital staff, implant manufacturers, patients).

Holistic approaches require interdisciplinary cooperation and cross-domain data spaces, while innovative approaches and services must be developed prior or parallel to the ongoing clarification of the legal framework conditions.

To provide viable and transferable solutions at the time of legal clarification, cross-domain lighthouse projects are needed to assure the timely availability of digital business models, suitable data alliances, and an adequate digital infrastructure.

Acknowledgments

“Unique Device Identification Based Linkage of Hierarchically Accessible Data Domains in Prospective Surgical Hospital Data Ecosystems” is part of the Fraunhofer Light-house Project “futureAM - Next Generation Additive Manufacturing” funded internally by the Fraunhofer-Gesellschaft e.V. Partial sponsorship was received from the Else Kröner Fresenius Center for Digital Health of the TU Dresden. The article processing charge was funded by Fraunhofer.

Authors' Contributions

KK, AS, and UT conceptualized the study. AS designed the methodology and wrote the initial manuscript draft. KK and GL developed the software. KK, NM, CN, and GL performed the investigation. SI and WGD provided the resources. KK, AS, NM, CN, UT, GL, ABA, SI, and WGD reviewed and edited the manuscript. AS, UT, KK, NM, CN, ABA, and GL created the visualizations. AS and SI supervised the study. KK and AS provided project administration. SI and WGD acquired the funding. All authors read and agreed to the published version of the manuscript.

Abstract

Background: The diagnostic accuracy of differential diagnoses generated by artificial intelligence chatbots, including ChatGPT models, for complex clinical vignettes derived from general internal medicine (GIM) department case reports is unknown.

Objective: This study aims to evaluate the accuracy of the differential diagnosis lists generated by both third-generation ChatGPT (ChatGPT-3.5) and fourth-generation ChatGPT (ChatGPT-4) by using case vignettes from case reports published by the Department of GIM of Dokkyo Medical University Hospital, Japan.

Methods: We searched PubMed for case reports. Upon identification, physicians selected diagnostic cases, determined the final diagnosis, and displayed them into clinical vignettes. Physicians typed the determined text with the clinical vignettes in the ChatGPT-3.5 and ChatGPT-4 prompts to generate the top 10 differential diagnoses. The ChatGPT models were not specially trained or further reinforced for this task. Three GIM physicians from other medical institutions created differential diagnosis lists by reading the same clinical vignettes. We measured the rate of correct diagnosis within the top 10 differential diagnosis lists, top 5 differential diagnosis lists, and the top diagnosis.

Results: In total, 52 case reports were analyzed. The rates of correct diagnosis by ChatGPT-4 within the top 10 differential diagnosis lists, top 5 differential diagnosis lists, and top diagnosis were 83% (43/52), 81% (42/52), and 60% (31/52), respectively. The rates of correct diagnosis by ChatGPT-3.5 within the top 10 differential diagnosis lists, top 5 differential diagnosis lists, and top diagnosis were 73% (38/52), 65% (34/52), and 42% (22/52), respectively. The rates of correct diagnosis by ChatGPT-4 were comparable to those by physicians within the top 10 (43/52, 83% vs 39/52, 75%, respectively; *P*=.47) and within the top 5 (42/52, 81% vs 35/52, 67%, respectively; *P*=.18) differential diagnosis lists and top diagnosis (31/52, 60% vs 26/52, 50%, respectively; *P*=.43) although the difference was not significant. The ChatGPT models' diagnostic accuracy did not significantly vary based on open access status or the publication date (before 2011 vs 2022).

Conclusions: This study demonstrates the potential diagnostic accuracy of differential diagnosis lists generated using ChatGPT-3.5 and ChatGPT-4 for complex clinical vignettes from case reports published by the GIM department. The rate of correct diagnoses within the top 10 and top 5 differential diagnosis lists generated by ChatGPT-4 exceeds 80%. Although derived from a limited data set of case reports from a single department, our findings highlight the potential utility of ChatGPT-4 as a supplementary tool for physicians, particularly for those affiliated with the GIM department. Further investigations should explore the diagnostic

accuracy of ChatGPT by using distinct case materials beyond its training data. Such efforts will provide a comprehensive insight into the role of artificial intelligence in enhancing clinical decision-making.

Introduction

Decision-Making in Health Care

In health care, accurate diagnosis plays a critical role in the effective management of patients' conditions [1]. Clinicians often rely on their expertise and various case presentations to make clinical decisions. However, the increasing complexity of cases, particularly those requiring referrals to specialized departments such as general internal medicine (GIM), and the rapid expansion of medical knowledge necessitate enhanced diagnostic support. A single-center study reported diagnostic error rates of 2% in an outpatient GIM department [2], while a systematic review found that the error rates exceeded by 10% in older adult patients [3]. Such inaccuracies underline the pressing need for tools to aid physicians in making more accurate diagnoses [4]. One promising avenue being explored is the application of clinical decision support (CDS) systems.

CDS Tools

Various CDS systems, including symptom checkers [5] and differential diagnosis generators [6], have been developed over the years. The former are generally designed for the general public, while the latter are intended for health care providers. The journey of computer-aided health care traces back to the early 1970s, marked by a strong interest in harnessing computing power to enhance care quality. Historically, CDS tools often employ multistep processes that combine logical or computational processes, probability assessments, and heuristic methods. Notably, a combination of algorithms and heuristic rules has been integral to many medical applications [7]. There is evidence of CDS tools being utilized in the outpatient department of GIM [8]. However, despite the potential of CDS systems to boost diagnostic accuracy and efficiency, they often increase clinicians' workload [9], particularly due to the need for structured input data. This remains a great barrier to their widespread adoption. In this context, artificial intelligence (AI), especially large language models, provides an alternative approach for health care support [10], particularly through the AI chatbot [11].

ChatGPT in Health Care

AI chatbots such as ChatGPT have demonstrated potential in facilitating effective communication between patients and health care providers [12] and transforming medical writing [13]. ChatGPT, developed by OpenAI, is an application of large language model based on natural language processing, known as a generative pretrained transformer (GPT) [14]. It can generate human-like responses to user prompts. With the progression from the third-generation GPT (GPT-3.5) to the fourth-generation GPT (GPT-4), the model's accuracy has improved in professional examinations [15] and multiple-choice problems across various languages [16]. Yet, AI chatbots are not exempt from limitations and risks [17,18]. These limitations encompass transparency issues [19], nonspecialized medical knowledge, outdated medical information, inherent biases, and a potential to disseminate misinformation [11]. Despite these challenges, AI systems such as ChatGPT are continually improving and hold promise as essential tools for achieving diagnostic excellence [20].

To prepare for potential clinical applications of AI chatbots, it is essential to evaluate their diagnostic accuracy, particularly for complex cases that frequently necessitate referral to specialized departments such as the GIM department. If harnessed correctly, generative AI like ChatGPT could reduce the diagnostic errors attributed to the inherent complexity of the GIM domain. This would streamline the department's workflow, enhancing patient care and outcomes. The study will reveal the potential of generative AIs, including ChatGPT as the CDS, especially in the GIM department.

Previous studies have reported that the diagnostic accuracy of the differential diagnosis lists generated by ChatGPT for clinical vignettes falls between 64% and 83% [21,22]. A clinical vignette is a concise narrative used in research to present a clinical scenario. However, these earlier studies did not focus on the materials derived from the GIM department, which is known for its diagnostically challenging cases. This gap in the literature accentuates the novelty and distinctiveness of our study. We aimed to evaluate the diagnostic accuracy of the differential diagnosis lists generated by ChatGPT, specifically using clinical vignettes derived from case reports published by the GIM department. By focusing on these GIM case reports, our research potentially offers a more rigorous appraisal of the diagnostic prowess of ChatGPT compared to preceding studies. In line with this, we expect ChatGPT-4 to provide the correct diagnosis in its differential diagnosis lists with an accuracy consistent with or within the previously reported range of 64%-83%.

Methods

Study Design

We evaluated the diagnostic accuracy of the differential diagnosis lists generated by ChatGPT-3.5 and ChatGPT-4 for clinical vignettes from case reports published by the Department of GIM. The term "differential diagnosis" refers to a list of possible conditions or diseases that could be causing a patient's symptoms and signs. It is created by considering the patient's clinical history, physical examination, and the results of any investigations, thus aiding in the diagnostic process. This study was conducted at the GIM Department (Department of

Diagnostic and Generalist Medicine) of Dokkyo Medical University Hospital, Shimotsuga, Tochigi, Japan.

Ethical Considerations

Because this study used case vignettes from published case reports, approval by the ethics committee and requirement for individual consent were not required.

Clinical Vignettes

We used clinical vignettes from case reports published by the GIM Department of Dokkyo Medical University Hospital. Clinical cases that were challenging to diagnose and typically involved a high level of complexity were often referred to the GIM department. Some of these cases were published as case reports in medical journals. To find case reports published in English from our department, we searched PubMed using the following keywords on March 20, 2023: "(Dokkyo Medical University [affil]) AND (Generalist Medicine [affil]) AND (2016/4/1:2022/12/31 [dp]) AND (Case Reports [PT])." After finding 54 case reports in PubMed, 2 experienced GIM physicians (TH and RK) checked these case reports for diagnostic or nondiagnostic cases, assessed the final diagnosis, and displayed them as clinical vignettes. Two cases were excluded because they were nondiagnostic. In total, 52 cases were included in this study. For example, consider the case reports titled "Hepatic portal venous gas after diving" [23], which is mentioned as case number 3 in Table S1 of Multimedia Appendix 1 and Table S2 of Multimedia Appendix 2. From this report, we extracted the clinical vignette from the case description section: "A 68-year-old man with diabetes and...There was no evidence of pneumatosis intestinalis." Decompression sickness was determined as the final diagnosis for this case. These case reports meet the standards required for publication in peer-reviewed journals and have been written and selected by experienced GIM physicians. Each clinical vignette included the clinical history, physical examination, and results of the investigation. The title, abstract, introduction, clinical assessment, differential diagnosis, final diagnosis, figures, legends, tables, and case reports were removed from the vignettes. The final diagnosis for each case, which had been established through the usual diagnostic processes and subsequently published in these case reports, was assessed and displayed in the form of clinical vignettes. The final diagnosis was confirmed by 2 experienced GIM physicians. Discrepancies between the 2 physicians were resolved through discussions. We also assessed the publication date and status of the included case reports as open access.

Differential Diagnosis Lists Created by Physicians

The differential diagnosis lists for each clinical vignette were independently created by 3 other GIM physicians (KT, YK, and T Suzuki) not affiliated with Dokkyo Medical University. Each clinical vignette was allocated to 1 physician, resulting in an average of 17 case descriptions being handled by each physician. They were instructed to create the top 10 differential diagnosis lists in English by reading the same clinical vignettes, without consulting other physicians or using CDS tools. It is essential to highlight that the physicians did not adhere to any specific guidelines, criteria, or protocols during this process. They operated based solely on their expertise and experience. Before creating the differential diagnosis lists, they were confirmed to be unaware of the case reports, clinical vignettes, final diagnosis, and differential diagnosis lists generated by ChatGPT-3.5 and ChatGPT-4. The physicians also remained blinded to each other's assessments. A computer-generated order table determined the sequence in which the clinical vignettes were presented.

Differential Diagnosis Lists Generated by ChatGPT

We used ChatGPT, an application of the GPT-3.5 model (March 14 version; ChatGPT-3.5, OpenAI, LLC), on March 20, 2023. We also used ChatGPT, an application of the GPT-4 model (March 23 version; ChatGPT-4, OpenAI, LLC), on April 10, 2023. Neither of the ChatGPT models were specially trained or reinforced for medical diagnoses. The physician (TH) typed the following text in the prompt: "Tell me the top 10 suspected illnesses for the following symptoms: (copy and paste each clinical vignette)." The prompt was designed to encourage the ChatGPT models to generate a list of differential diagnoses. The rationale behind selecting this particular prompt was grounded in preliminary testing. In these tests, various prompts were evaluated for their effectiveness in soliciting a comprehensive list of potential illnesses. This prompt consistently yielded reliable and inclusive differential diagnoses in our initial evaluations.

To minimize potential bias, the order in which the vignettes were presented to ChatGPT-3.5 and ChatGPT-4 was determined using a computer-generated order table. To ensure no interference from previous responses, physicians cleared the previous conversation before introducing new clinical vignettes. We used the initial answers as the top 10 differential diagnosis lists generated by ChatGPT-3.5 and ChatGPT-4.

Evaluation of Differential Diagnosis Lists

Two other GIM physicians (YH and KM) evaluated whether the final diagnosis was included in the differential diagnosis lists created by the physicians and those generated by ChatGPT models. A diagnosis was labeled "1" if it accurately and specifically identified the condition or was sufficiently close to the exact diagnosis that it would enable prompt and appropriate treatment. Conversely, a diagnosis was marked as "0" if it diverged significantly from the actual diagnosis [24]. When the final diagnosis was present, the researcher further assessed its ranking within the list. Discrepancies between the 2 evaluators were resolved through discussions. The study design is illustrated in Figure 1. Examples of a differential diagnosis list generated by ChatGPT-3.5 and ChatGPT-4 are shown in Figures 2-3 and Figures 4-5, respectively.

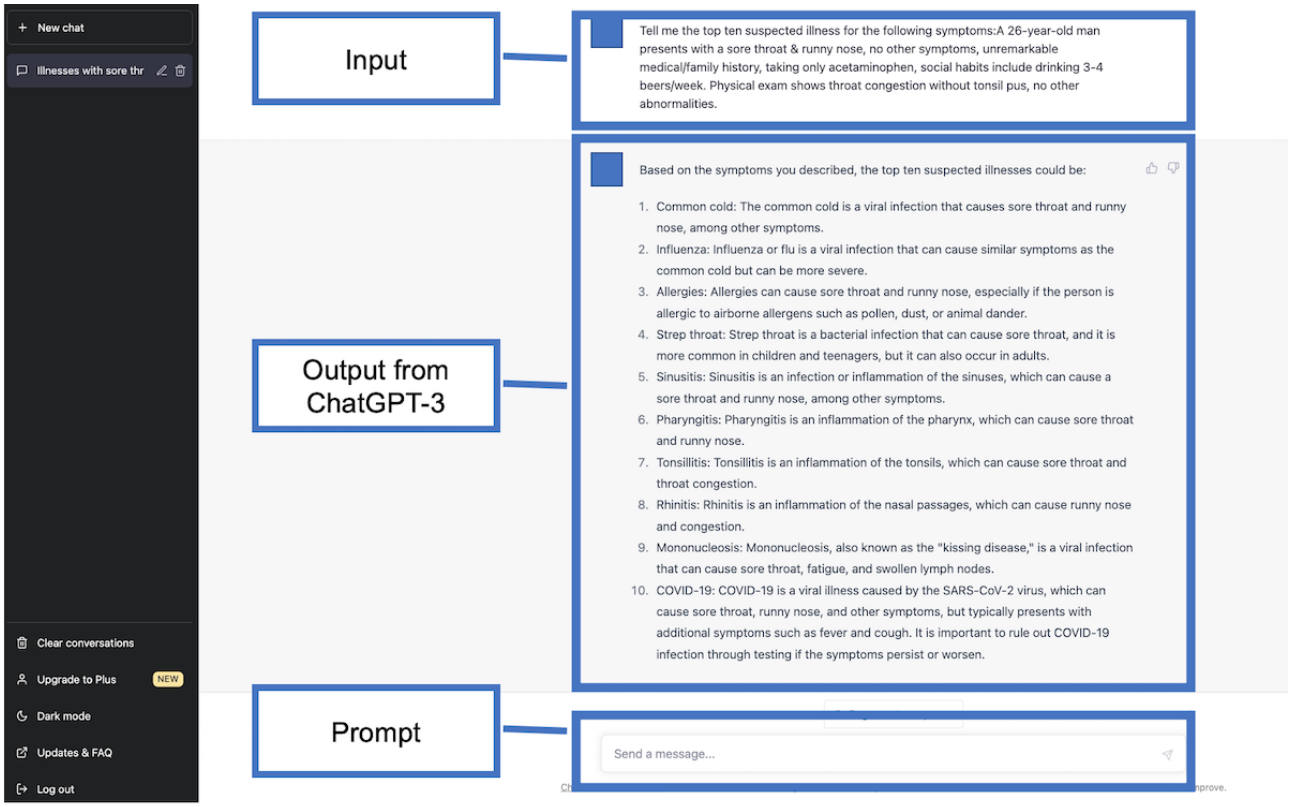

Figure 4. A differential diagnosis list generated by the fourth-generation ChatGPT for a sample case.

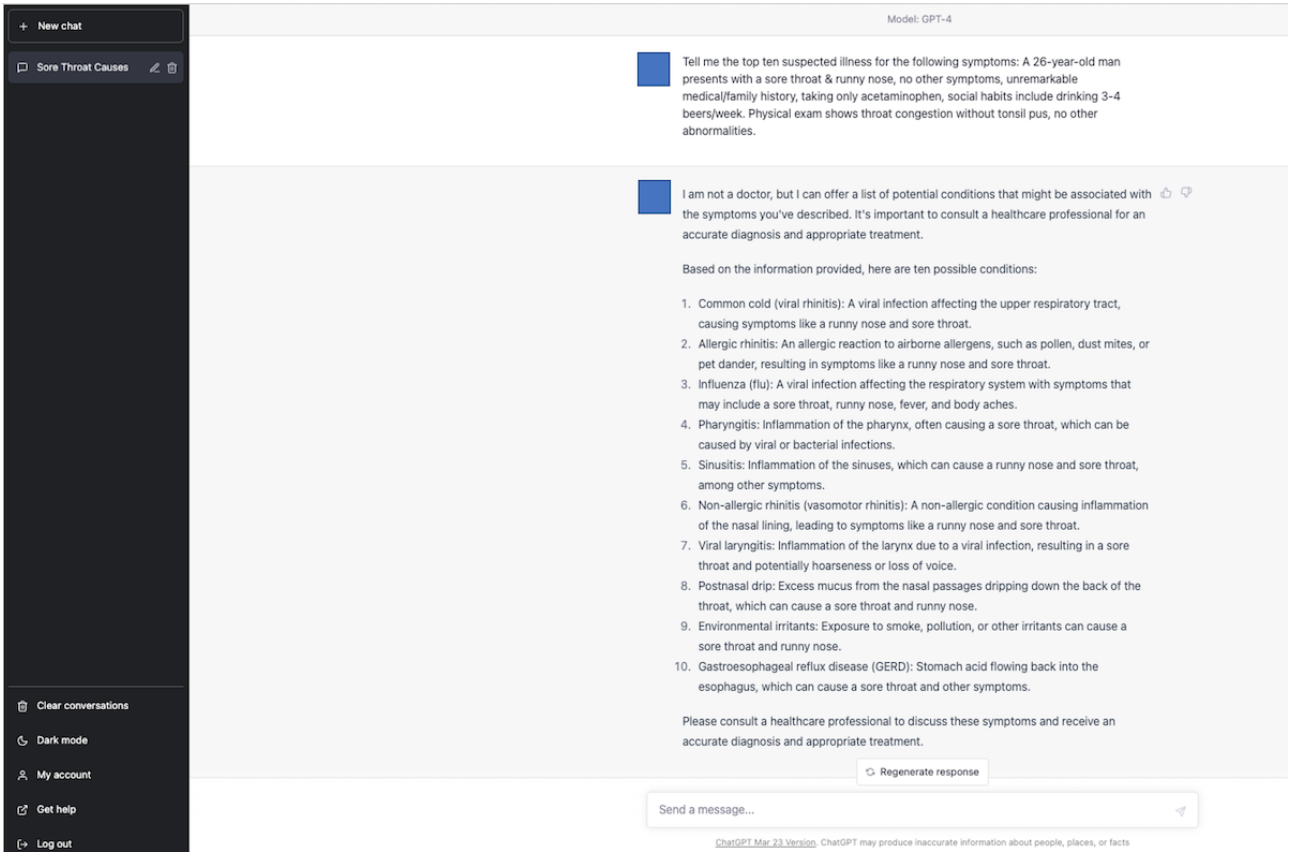

Figure 5. Explanation for the differential diagnosis list generated by the fourth-generation ChatGPT for a sample case. ChatGPT4: fourth-generation ChatGPT.

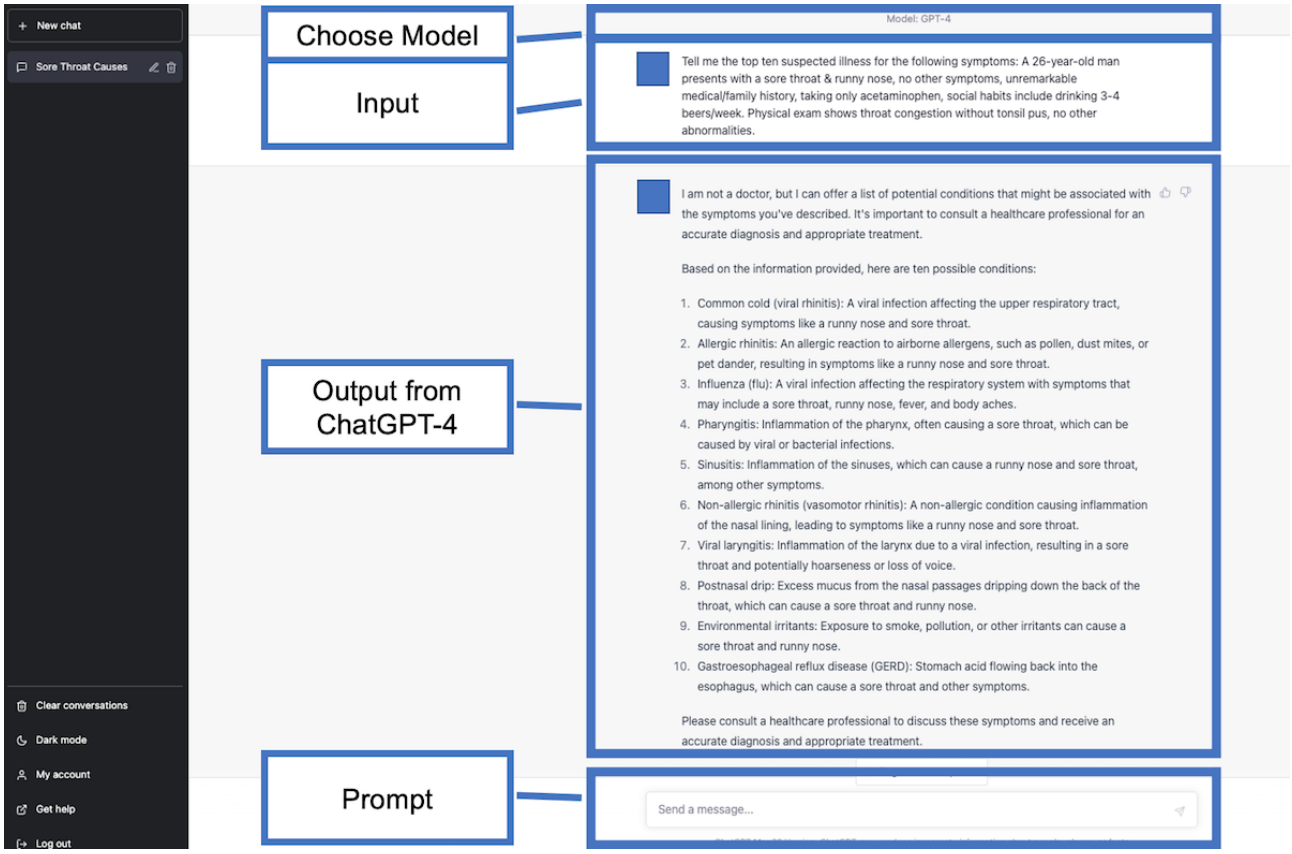

Measurements

We measured the rate of correct diagnoses within the top 10 differential diagnosis lists, top 5 differential diagnosis lists, and top diagnosis provided by ChatGPT-3.5, ChatGPT-4, and the physicians. As a binary approach, we scored the presence of the final diagnosis on the list as one and its absence as zero. For an exploratory analysis, we compared the rates of correct diagnoses in the lists generated by ChatGPT-3.5 and ChatGPT-4 between case reports that were open access and those that were not. This comparison was motivated by understanding that GPT-3.5 and GPT-4 were primarily learned from open sources available on the internet [16]. Given that these models are predominantly trained on openly accessible data, we postulated that open access case reports might yield better diagnostic results than non–open access ones. Additionally, we compared the rates of correct diagnoses within the lists generated by ChatGPT-3.5 and ChatGPT-4 based on the publishing year prior to 2021 or in 2022. This distinction arises from the knowledge cutoffs for ChatGPT-3.5 and ChatGPT-4, which were set in early 2021. Since the models would be more familiar with data before this time and less informed about subsequent publications, we hypothesized that the case reports published in the years prior to 2021 could produce better diagnostic results than those published in 2022. However, the details of the learning data source and cutoff timing were not available to the public.

Analysis

Categorical or binary variables were presented as numbers (percentages) and compared using the chi-square test. To mitigate the increased risk of type I error arising from multiple comparisons, we employed the Bonferroni correction [25]. Although alternative methods exist, we chose the Bonferroni correction for its strict control over false positives. When conducting multiple comparisons, we set the Bonferroni-corrected significance level at a P value <.02. This was derived by dividing .05 (the standard level of significance) by 3 (the number of comparisons undertaken). Both the chi-square test and the computation of the Bonferroni-corrected significance level were conducted in R (version 4.2.2; R Foundation for Statistical Computing) using the stats library (version 4.2.2).

Results

Case Report Profiles

In total, 52 case reports were included in this study, among which 39 (75%) were open access case reports. A total of 24 (46%) case reports were published prior to 2021. Of the total case reports, 12 (23%) were published in 2021 and 16 (31%) were published in 2022. The included case reports are presented in Multimedia Appendix 1.

Diagnostic Performance

Representative examples of differential diagnosis lists with the final diagnosis are shown in Table 1.

The rates of correct diagnosis by ChatGPT-4 within the top 10 differential diagnoses, top 5 differential diagnoses, and top diagnosis were 83% (43/52), 81% (42/52), and 60% (31/52), respectively (Table 2). The rates of correct diagnosis by

ChatGPT-3.5 within the top 10 differential diagnoses, top 5 differential diagnoses, and top diagnosis were 73% (38/52), 65% (34/52), and 42% (22/52), respectively. The rates of correct diagnosis by ChatGPT-4 were comparable to those by ChatGPT-3.5 within the top 10 (43/52, 83% vs 38/52, 73%, respectively; *P*=.34) and top 5 (42/52, 81% vs 34/52, 65%, respectively; *P*=.12) differential diagnosis lists and top diagnosis (31/52, 60% vs 22/52, 42%, respectively; *P*=.12), although the difference was not statistically significant. The rates of correct diagnosis by ChatGPT-4 were also comparable to those by physicians within the top 10 (43/52, 83% vs 39/52, 75%, respectively; *P*=.47) and top 5 (42/52, 81% vs 35/52, 67%, respectively; *P*=.18) differential diagnoses and top diagnosis (31/52, 60% vs 26/52, 50%, respectively; *P*=.43), although the difference was not statistically significant. Multimedia Appendix 2 shows the final diagnosis and the 10 differential diagnosis lists generated by ChatGPT-3.5 and ChatGPT-4 and those created by physicians.

Regarding open access case reports (Table 3), there were no statistically significant differences in the rates of correct diagnoses within the top 10 and top 5 differential diagnosis lists and top diagnoses generated by ChatGPT-3.5 and ChatGPT-4. Regarding the timing of publication, there were no statistically significant differences in ChatGPT-3.5 and ChatGPT-4 diagnoses between those published prior to 2021 and those published in 2022 (Table 3).

Table 1. Representative examples of differential diagnosis lists with the final diagnosis.

Final diagnosis	Differential diagnosis lists		
	ChatGPT-3.5[a]	ChatGPT-4[b]	Physicians
Tarsal tunnel syndrome	• Peripheral neuropathy • Tarsal tunnel syndrome • Lumbar spinal stenosis • Diabetes • Alcohol abuse • Vitamin B12 deficiency • Hypothyroidism • Chronic kidney disease • Multiple sclerosis • Charcot-Marie-Tooth disease	• Peripheral neuropathy • Tarsal tunnel syndrome • Lumbar radiculopathy • Small fiber neuropathy • Chronic inflammatory demyelinating polyneuropathy • Complex regional pain syndrome • Peripheral artery disease • Charcot-Marie-Tooth disease • Polyneuropathy • Leprosy	• Sarcoidosis • Chronic inflammatory demyelinating polyradiculoneuropathy • Diabetic neuropathy • Vitamin B12 deficiency • Alcoholic neuropathy • Paraneoplastic syndrome • Antimyelin oligodendrocyte glycoprotein antibody-associated disease antineutrophil cytoplasmic antibody-related vasculitis • POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, skin changes) syndrome • Restless legs syndrome
Nonepisodic angioedema associated with eosinophilia	• Eosinophilic fasciitis • Acute interstitial nephritis • Hypereosinophilic syndrome • Churg-Strauss syndrome • Idiopathic hypereosinophilia syndrome • Lymphoma • Systemic lupus erythematosus • Sarcoidosis • Infectious mononucleosis • Allergic reactions	• Eosinophilic cellulitis (Wells syndrome) • Idiopathic eosinophilic oedema • Hypereosinophilic syndrome • Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) • Drug-induced eosinophilia • Eosinophilic fasciitis (Shulman syndrome) • Kimura disease • Eosinophilic gastroenteritis • Parasitic infections • Systemic lupus erythematosus	• Hypereosinophilic syndrome • Idiopathic peripheral edema • Idiopathic angioedema • Cholinergic urticaria • Eosinophilic granulomatosis with polyangiitis • Parasitic infection • Chronic eosinophilic leukemia • Drug-induced (including supplements, herbal medicine) hypereosinphilic edema • Tuberculosis • Viral infection

Discussion

Principal Results

This study has several main findings. First, our study demonstrates the accuracy of the differential diagnosis lists generated by ChatGPT-3.5 and ChatGPT-4 for complex clinical vignettes from case reports. The rate of correct diagnoses within the top 10 and top 5 differential diagnosis lists generated by ChatGPT-4 was >80%. With a diagnostic accuracy of >80%, ChatGPT-4 can serve as a supplementary tool for physicians, especially when dealing with complex cases. Our results have demonstrated that GPT possesses diagnostic capabilities that can be comparable to those of physicians. This suggests that GPT might serve as a form of collective intelligence, capable of double-checking clinical diagnoses conducted by medical practitioners, at the very least. Second, there were no statistically significant differences in the rates of correct diagnoses by ChatGPT-3.5 and ChatGPT-4 based on the open-access status or the publication date. Both GPT-3.5 and GPT-4 models were constructed using publicly available databases and the knowledge cutoffs set in early 2021 [16,26]. Therefore, we hypothesized that open access case reports could produce better diagnostic results than non–open access ones. Additionally, we postulated that the case reports published in the years prior to 2021 could produce better diagnostic results than the ones published in 2022. The actual results were partly attributed to the limited sample size resulting from the subdivision into exploratory analysis.

Potential Implications for Clinical Practice and Medical Education

The integration of generative AI like ChatGPT into clinical settings could enhance patient care and streamline physician workflows. Given its pretraining accuracy of over 80%, physicians could receive immediate support in challenging cases, thereby minimizing diagnostic errors and enhancing patient outcomes. Furthermore, these AI systems could grant health care professionals more time for the demanding facets of patient care, allowing them to focus on more demanding aspects of patient care and potentially thereby improving health care efficiency. In an educational context, ChatGPT could be

pivotal in shaping future physicians, especially in clinical reasoning and medical knowledge acquisition [27]. Engaging with generative AIs can expose medical learners to an array of diagnoses, preparing them for complex clinical situations.

Limitations

This study has several limitations. First, the study materials were obtained solely from complex case reports published by a single GIM department at a single center. Although these case reports provided insight into challenging diagnostic scenarios, they may not capture the full spectrum of patient presentations, even within the GIM department, as they were not randomly sampled but rather selected for their complexity, unusualness, or the challenges they posed for diagnosis. Therefore, our findings have limited external validity, as they may not be generalizable to other settings. Their performance might differ in simpler or more typical clinical presentations. Second, we acknowledge the possible bias in the differential diagnosis lists. They were created by experienced GIM physicians, implying that the results might not be applicable to lists created by physicians of different specialties or with various levels of training. It would be beneficial if future studies incorporated a wider array of participants. Third, there is a limitation associated with the accessibility and recency of our study. Specifically, 75% (39/52) of the case studies were published as open access, and approximately half of the case studies were published prior to 2021. Although we did not observe statistically significant differences regarding open access and publication timing, there were some possibilities for ChatGPT-3.5, ChatGPT-4, and physicians who created differential diagnosis lists to learn these case materials directly or indirectly. The final limitation pertains to possible time lag when generating differential diagnosis lists between ChatGPT-3.5 and ChatGPT-4. In light of these limitations, future research should assess the diagnostic accuracy of ChatGPT models by using properly tuned case materials that the model has not been trained on.

Comparison With Prior Work

Our previous study [22] showed that the diagnostic accuracy of ChatGPT-3.5 was lower than that of physicians (25/30, 83% vs 59/60, 98%, respectively). In contrast, the findings of this study revealed that the rates of correct diagnoses within the top 10 (43/52, 83% vs 39/52, 75%, respectively) and top 5 (42/52, 81% vs 35/52, 67%, respectively) differential diagnosis lists, as well as the top diagnosis (31/52, 60% vs 26/52, 50%, respectively) generated by ChatGPT-4 were comparable to those by physicians. These results suggest the evolving performance of AI chatbots across different ChatGPT versions. Compared with those in the prior study [22], the rates of correct diagnoses within the top 10 (38/52, 73% vs 28/30, 93%, respectively) and top 5 (34/52, 65% vs 25/30, 83%, respectively) differential diagnosis lists and top diagnosis (22/52, 42% vs 16/30, 53%, respectively) generated by ChatGPT-3 (or 3.5) were lower in this study. This discrepancy was largely attributed to this study's emphasis on complex clinical case vignettes sourced from case reports within the GIM department, while the prior research focused on more common clinical presentations. Moreover, ChatGPT-4 provided better results in its differential diagnosis lists (43/52, 83% vs 45/70, 64%, respectively) and as its top diagnosis (31/52, 60% vs 27/70, 39%, respectively) compared with those reported in another study for New England Journal of Medicine clinicopathologic conferences [21]. These variations can be partly ascribed to differences in the study designs, including case vignettes and systems.

Compared with a previous review on symptom checkers [5], the rate of correct diagnoses within the top 10 differential diagnoses generated by ChatGPT-4 was higher (43/52, 83% vs 60.9%-76.9%, respectively) in this study. Compared with a previous review on the differential diagnosis generator [6], the rate of correct diagnoses within the top 10 differential diagnoses generated by ChatGPT-4 was higher (43/52, 83% vs 63%-77%, respectively) in this study. This discrepancy is partly due to differences in study designs, case materials, and algorithms. In the future, direct comparisons between ChatGPT and other CDS systems are required.

Conclusions

This study demonstrates the potential diagnostic accuracy of the differential diagnosis lists generated by ChatGPT-3.5 and ChatGPT-4 by using complex clinical vignettes from case reports published by the GIM department. Notably, the rate of correct diagnoses within the top 10 and top 5 differential diagnosis lists generated by ChatGPT-4 exceeds 80%. Although these results stem from a limited data set of case reports from a single department, they indicate the potential utility of ChatGPT-4 as a supplementary tool for physicians, particularly for those affiliated with the GIM department. Future research should assess the diagnostic accuracy of ChatGPT models by using properly tuned case materials that the model has not been trained on. Additionally, future investigations should evaluate the literacy level of AIs and their alignment with relevant medical text. Such efforts will ensure a comprehensive insight into the AI's possible roles in enhancing clinical decision-making processes. Moreover, as AI systems become more prevalent, their influence is expected to ripple across various facets of health care. Generative AIs have the potential to reshape patient-physician dynamics, fostering more informed interactions. They can also play a pivotal role in democratizing medical knowledge. This could lead to heightened health care accessibility, allowing even those in remote or underserved regions to glean expert medical advice. Given these profound implications, it becomes imperative to investigate the ramifications of AI integration into health care.

Authors' Contributions

TH, RK, YH, KM, KT, YK, T Suzuki, and T Shimizu contributed to the study concept and design. TH performed the statistical analyses. TH contributed to the drafting of the manuscript. RK, YH, KM, KT, YK, T Suzuki, and T Shimizu contributed to the critical revision of the manuscript for relevant intellectual content. All the authors have read and approved the final version of the manuscript. We would like to specially thank Dr Kenjiro Kakimoto, Department of Psychiatry, Nihon University School of

Medicine, for helping us with the analysis. This study was conducted using resources from the Department of Diagnostics and Generalist Medicine at Dokkyo Medical University.

Abstract

Background: The immediate use of data exported from electronic health records (EHRs) for research is often limited by the necessity to transform data elements into an actual data set.

Objective: This paper describes the methodology for establishing a data set that originated from an EHR registry that included clinical, health service, and sociodemographic information.

Methods: The Extract, Transform, Load process was applied to raw data collected at the Integrated Department of Mental Health and Pathological Addictions in Ferrara, Italy, from 1925 to February 18, 2021, to build the new, anonymized Ferrara-Psychiatry (FEPSY) database. Information collected before the first EHR was implemented (ie, in 1991) was excluded. An unsupervised cluster analysis was performed to identify patient subgroups to support the proof of concept.

Results: The FEPSY database included 3,861,432 records on 46,222 patients. Since 1991, each year, a median of 1404 (IQR 1117.5-1757.7) patients had newly accessed care, and a median of 7300 (IQR 6109.5-9397.5) patients were actively receiving care. Among 38,022 patients with a mental disorder, 2 clusters were identified; the first predominantly included male patients who were aged 25 to 34 years at first presentation and were living with their parents, and the second predominantly included female patients who were aged 35 to 44 years and were living with their own families.

Conclusions: The process for building the FEPSY database proved to be robust and replicable with similar health care data, even when they were not originally conceived for research purposes. The FEPSY database will enable future in-depth analyses regarding the epidemiology and social determinants of mental disorders, access to mental health care, and resource utilization.

Introduction

Electronic health records (EHRs) assemble and enable access to large volumes of clinical and sociodemographic data that are routinely collected by local health authorities. EHRs offer a unique opportunity to conduct research on various topics, including, among others, the patterns of health care resource use and factors that influence the course and outcomes of mental disorders in large, representative samples [1,2]. EHRs can be linked to data related to census and geolocalization information [3]; such investigations span the epidemiology of mental disorders, hospitalization rates, morbidity, and mortality.

The breadth and nature of information represented in the sample of EHRs in the mental health sector make such information

particularly suitable for using artificial intelligence (AI) and machine learning techniques, in addition to traditional methods (eg, linear regression models), in order to increase the potential for research on social and clinical factors [4].

Applications that use AI take advantage of AI's ability to process large amounts of data in order to extract information or identify underlying patterns of relationships that conventional methods may overlook [5]. AI may be particularly suitable for the investigation of large amounts of clinical data, thanks to (1) the flexibility and scalability of AI techniques, which are higher than those of traditional methods, and (2) the ability of AI to consider all of the available predictors (ie, not only a subset), which makes AI and, in particular, machine learning suitable for performing tasks such as classification, prediction, and resource optimization [5,6].

Indeed, in recent years, the use of AI techniques in mental health care research have rapidly increased, including its use to identify a disease at its earliest stages, predict illness onset in vulnerable individuals, study illness progression, optimize treatment, and discover novel therapeutic agents [7,8].

As of yet, there are few examples (mainly from the United States) of how data collected from EHRs can be successfully adapted for analysis with AI. For example, Hughes et al [9] analyzed clinical variables in the EHRs of 81,630 adults from 2 academic medical centers in Boston, Massachusetts (spanning 10 years) and identified predictors of treatment response for major depressive disorders.

Xu et al [10] compiled a data set of 11,275 patients from 5 large medical centers across New York City by using EHR data collected between 2008 and 2017; they used machine learning methods to identify markers of depression phenotypes to inform clinical decisions about patients' care. Pradier et al [11] analyzed a data set of 67,807 individuals to predict the risk of receiving a misdiagnosis of bipolar disorder among individuals with depression, using only information retrieved from EHRs. Perlis et al [12] applied natural language processing to classify the mood states of 127,504 patients, using data from an EHR.

In order to fully exploit the potential of EHRs for mental health research however, important issues need to be considered. One preliminary, controversial issue is whether the use of EHR data should be restricted to the purpose for which they were collected [13]. Indeed, privacy constraints, data security, and overall ethics regulation must be taken into account when considering whether to use EHRs for research purposes [6]. Nonetheless, nowadays, medical data that were originally collected for purposes other than research are being used to study health phenomena in many different fields, including mental health, substance use, noncommunicable diseases (eg, cancer), and health behaviors (eg, cancer screening) [14]. A further challenge is that data may not be homogeneous or may not be collected systematically, and most data are not derived from structured scales or questionnaires. The adaptation of the EHR represents the first necessary step to planning research projects that include models for predicting health resource utilization, identifying predictors of diagnostic accuracy, and differentiating between remission and chronicity, as done in other fields such as oncology [15].

Given this premise, the aim of this paper is to describe (1) the challenges and pitfalls that were encountered in the process of adapting EHR data derived from the public mental health agency in Ferrara, Italy, for research purposes and (2) the development of a data set that is suitable for analysis via AI and traditional techniques. In order to test the feasibility of using these data in analyses and the robustness of analyses based on such data, a clustering analysis was also performed, and preliminary results are presented herein.

Methods

Ethics Approval

Ethical approval was obtained by the Area Vasta Emilia Centro Ethical Committee on December 12, 2019 (protocol number: 197/2018/Oss/AUSLF). This study conforms to the principles expressed in the Declaration of Helsinki.

Setting

In Italy, mental health care is provided by departments of mental health [16-19]. The levels of care within each department of mental health include community-based mental health centers, hospital psychiatric inpatient units, and rehabilitation or residential facilities. Each community-based mental health center serves as a hub of psychiatric care for geographically defined catchment areas with 50,000 to 150,000 inhabitants [20] In Ferrara, Northern Italy, the Integrated Department of Mental Health and Pathological Addiction covers an area of 2630 km^2, with a catchment of 342,061 inhabitants as of 2020 [21].

Data Collection and EHRs

Data were collected in 2 periods that were distinct in terms of the methodology used, the psychiatric services delivered, and the level of digitalization. Data related to the first period, which began in 1925 and ended in 1990, were gathered mostly in a psychiatric asylum, during a time when digital health was not fully developed or adopted.

In 1991, the first structured EHR (ie, SIPER [Sistema Informativo Psichiatrico dell'Emilia-Romagna]) was introduced and implemented locally by the Local Health Trust of Ferrara for Mental Health in Adults. Different software programs were adopted during the years following the implementation of SIPER, and each new software program replaced the previous one by importing already existing data and adding new features (and thus information), as detailed in Textbox 1.

Textbox 1. Electronic health records implemented by the Local Health Trust of Ferrara for Mental Health in Adults in chronological order.

1. SIPER (Sistema Informativo Psichiatrico dell'Emilia-Romagna; 1991-1994) included individual demographic data, medical records, diagnoses, and health services.
2. CINECA (1994-1998) added the feature labeled as "project," which was defined as the comprehensive set of treatments and activities offered to the patient.
3. GESAP (Gestione attività Psichiatrica; 1998-2004) added information about outpatient treatment; hospitalizations in inpatient units, long-term residences, and semiresidences; and outpatient services.
4. IPPOCRATE (GPI SRL; 2004-2008).
5. EFESO (Newteam SRL; 2008-2021) added the text field labeled "evaluation and treatment area" in the medical record, structured diagnostic evaluation, pharmacological treatment prescription and administration, clinical notes, attached documents, and a feature to identify structured clinical protocols (Percorso Diagnostico Terapeutico Assistenziale; diagnostic and therapeutic care pathway).
6. CURE (Cartella Unificata Regionale Elettronica; Engineering SpA; 2021 to present) added the registration of vital signs and laboratory tests, as well as legal and administrative documentation.

Data Preparation

The first goal was the creation of a new, fully deidentified database with data available in EFESO (Newteam SRL)—a necessary step for complying with privacy constraints.

In order to remove all protected health information (PHI), source data needed to be modified. This could not be done by directly editing data in EFESO, since the source could not be altered directly. Thus, the new research database—the Ferrara-Psychiatry (FEPSY) database—was built via the Extract, Transform, Load process, which is a 3-phase process [22] in which data are first extracted from 1 source or multiple and possibly different sources (eg, databases, flat or formatted files, and web pages). Afterward, the extracted data are stored in a staging area, where they undergo transformation, such as filtering, cleaning, summarization, and normalization. Finally, the transformed data are loaded into the destination storage. For example, one type of transformation was record exclusion. We excluded records of patients that could not be unequivocally identified by the tax code—a unique 16-digit alphanumeric code that identifies a person in Italian public administration forms.

While assessing the suitability of the FEPSY database for research purposes, we noted that historical information dating back up to 1925 had also been maintained in EFESO. We understood that such data were manually imported into the electronic databases that preceded SIPER (year 1991); however, because we could not confirm the procedures, scope, and quality of this historical data import, we decided to document the existence of these data but exclude them from analysis.

More details about the FEPSY database can be found in Multimedia Appendix 1. In Table S1 in Multimedia Appendix 1, for each table in the FEPSY database, the total number of rows (number and percentage of records retained in the FEPSY database) is reported, alongside the number of records in the corresponding original EFESO table from which data were extracted (number of records in the corresponding EFESO table). As detailed in Table S1 in Multimedia Appendix 1, of the 4,264,954 records, 3,861,432 (90.54%) were kept. These records included detailed information about the patient, their illness, and the treatments provided.

In Table S2 in Multimedia Appendix 1, 2 types of anomalies for each table in the FEPSY database are described; one is date inconsistency (eg, when the closing date precedes the opening date of the medical chart), and the other is a date anomaly that was generated by the automatized mechanism that was introduced by EFESO when migrating data from IPPOCRATE (GPI SRL; August 26, 2008).

Clustering

Once the anonymized database was built, a clustering analysis was performed to investigate the data set quality. A clustering algorithm is an unsupervised machine learning technique that is used to group objects, so that objects of the same group (or cluster) are very similar to one another and objects of different groups are very dissimilar. To decide the degree of similarity (or dissimilarity) between 2 objects, various distance measures can be used, such as the Euclidean distance between (normalized) numerical representations of the objects. We tested the hypothesis that the patients modeled in the data set could be divided into homogeneous clusters. The k-means algorithm computes a numerical distance between objects to determine to which cluster they belong. However, in our case, data were categorical. In 1995, Ralambondrainy [23] introduced an approach that enables the use of the k-means algorithm with categorical data. In this approach, nominal attributes are converted into binary attributes—one for each value that the attribute can take—so that they can be considered as numerical attributes by the algorithm.

We performed the clustering analysis with the WEKA (Waikato Environment for Knowledge Analysis; University of Waikato) data mining tool, which provides an implementation of the k-means algorithm (ie, SimpleKMeans) and can handle categorical data [24]. SimpleKMeans can also handle missing values by replacing them with the mean or mode.

For this preliminary clustering analysis, we included only the patients who had at least one recorded diagnosis of a mental disorder (ie, *International Classification of Diseases, Ninth Revision* [*ICD-9*] codes 290-319) [25].

Patients were excluded if they had nonpsychiatric diagnoses (*ICD-9* codes V01-V91; 2707/46,222, 5.86%) or had never received an *ICD-9* diagnosis (5493/46,222, 11.88%). The

resulting subset for the clustering analysis included 38,022 patients.

We considered sociodemographic variables, such as biological sex, age at first visit, nationality, marital status, living situation, education, occupational status, birthplace (district), and the catchment area (district) providing care (determined by domicile postal code or by residence postal code when the domicile was missing).

Results

Sociodemographic Characteristics

The sample included 46,222 individuals, whose sociodemographic characteristics are detailed in Table 1.

Table . Sociodemographic characteristics of all of the individuals who accessed mental health services in the Ferrara province (1991-2021) and were included in the FEPSY[a] database.

Characteristic		Female patients (n=28,109)	Male patients (n=18,113)	All patients (N=46,222)
Age at first visit (years), mean (SD)		50.46 (18.82)	48.72 (19.02)	49.78 (18.91)

[a]FEPSY: Ferrara-Psychiatry.

Extract, Transform, Load Process

Built-In Tables

Built-in tables from the EFESO relational database, which are detailed in Textbox 2, were included in the FEPSY database.

Textbox 2. Built-in tables included in the FEPSY (Ferrara-Psychiatry) database.

1. Table *Patients* included individual personal data, such as name, place and date of birth, biological sex (male or female), home address, living condition, education, marital status, occupation, and other sociodemographic characteristics.
2. Table *Medical Records* contained 1 or more medical records for each patient, with information such as the date of admission, date and type of discharge, primary diagnosis of a mental disorder, and facility providing care.
3. Table *Diagnoses* included 1 or more diagnoses that were assigned to each individual. Diagnoses were classified according to the *International Classification of Diseases, Ninth Revision* (*ICD-9*) categorical system; therefore, every diagnosis included the associated *ICD-9* code, description, group, and chapter [24]. Diagnoses recorded before the introduction of the *ICD-9* were recorded in SIPER (Sistema Informativo Psichiatrico dell'Emilia-Romagna), using standardized conversion criteria [24].
4. Table *Products* referred to the different types of medical services, such as consultations or hospitalizations. A product had a start date and end date, and it may have contained 1 or more medical services.
5. Table *Medical Services* stored every service that each individual had received or undergone, such as consultations, first visits, the administration of pharmacological treatment, social skill–oriented activities, structured diagnostic assessments, and mandatory medical treatments, as well as the facility providing care.
6. Tables *Medication Prescription* and *Medication Administration* referred to the prescription and administration of pharmacological treatment, type of medication and dosage, start and stop dates, and responsible facility.
7. Table *Psychometric Tests* included every test administered to each patient and the test types, dates, questions, and scores.
8. Table *Projects* listed the treatment plans for each patient. There were individual and group projects, and within a project, there could have been 1 or more products and medical services.
9. Table *Facilities* contained all of the facilities of the Health Trust of Ferrara for Mental Health in Adults, such as hospitals, day care centers, and clinics, along with their types and locations.

Extract

Data were extracted from EFESO by using an automated procedure that executed an SQL select query. This query selected all relevant fields of a table and other useful information from linked support tables, such as the descriptions of the codes. The result of the query was stored in a Pandas DataFrame (The Pandas Development Team) [26,27], which can be easily manipulated in the next phase.

Transform

Record Exclusion

Data imported before 1991 were excluded (as detailed in the *Data Preparation* section). Some fields and records were removed [22] to ensure data consistency, because there were duplicate or erroneous records (Table S1 in Multimedia Appendix 1). These were (1) fields containing unreliable information, (2) fields that were present but not in use (their values were always null), and (3) all records marked as "deleted" (ie, wrong records that were not to be used) and all records in other tables referencing the "deleted" ones. We decided to remove 36 individuals that had unique fiscal codes but duplicate patient IDs—corresponding to 0.15% (72/48,001) of the records in the total data set—since it was not possible to determine which of the two entries was the correct one. When a patient was first included in the database, a unique identifier—the patient ID—was assigned. The combination of the tax code and the patient ID allowed for the unique identification of a patient in the database. We also excluded patients for whom a record was opened earlier than the birth date (16/48,001, 0.03%), patients with no medical records (603/48,001, 1.26%), and patients marked as "deleted" (77/48,001, 0.16%). Overall, 1.6% (768/48,001) of the total records, which related to 732 patients, were removed from the source table.

Anonymization

Anonymization was necessary in order to use the extracted data for research projects and was performed on tables *Patients* and *Medical Records*. First, the extracted records were shuffled. Afterward, the original patient and medical record IDs were replaced with a universally unique identifier (UUID), which is a 128-bit string that is usually represented as a sequence of 32 hexadecimal digits [28]. These new random, unique identifiers were generated with the *uuid4* function of the Python *uuid* package (Python Software Foundation) [29] and used as the new primary key. In order to maintain the referential integrity (ie, the primary key of one table is a foreign key in another table, meaning that they are related), the old IDs were replaced with the new ones within every table in which they appeared. Furthermore, all PHI were excluded from table *Patients*; these data included first names, last names, days and months of birth, tax codes, home addresses, phone numbers, and note fields that could potentially include personal data (eg, relatives' names). For the same reason, text note fields were also excluded from other tables, when present.

Field Transformation

Transformation was necessary for date fields. EFESO stored dates in "datetime" format, that is, "dd/mm/yyyy hh:mm." However, previous EHRs stored only the date, without the hour information. Furthermore, even when specified, the hour information is not always reliable. For this reason, the date fields were split into 2 fields—one for the date and one for the time.

Missing Values

Missing values were assessed to avoid the introduction of bias. In specific analyses, the level and pattern of missingness will be assessed for each variable included and dealt with accordingly.

Load

Data extracted from EFESO were loaded in the FEPSY database—the newly created MySQL (Oracle Corporation) relational database—by using the same automated procedure that was used to extract them. For each built-in table, an insert query, which took the values from the same DataFrame of the select query, was executed.

Analysis of the Extracted Data

The data included in the final composite FEPSY data set were those collected from 1991 to February 2021. Since 1991, each year, a median of 1404 (IQR 1117.5-1757.7) individuals had newly accessed care, and a median of 7300 (IQR 6109.5-9397.5) individuals were actively receiving care, as represented in Figure 1. Figure 2 shows the number of patients treated per year in total and by sex. The sudden decrease observed in 2009 was due to an automated closing procedure that was introduced in 2008 and retained from then on. When migrating from IPPOCRATE to EFESO, all medical records, products, and diagnoses that had not been updated in 365 days were assumed to be closed or terminated, and the missing closing date was replaced with the date of the migration to EFESO, that is, August 26, 2008.

Figure 1. New admissions per year in total and by sex (upper panel). Timeline of the electronic health records adopted by the health care agency in the Ferrara province (lower panel). CURE: Cartella Unificata Regionale Elettronica; GESAP: Gestione attività Psichiatrica; SIPER: Sistema Informativo Psichiatrico dell'Emilia-Romagna.

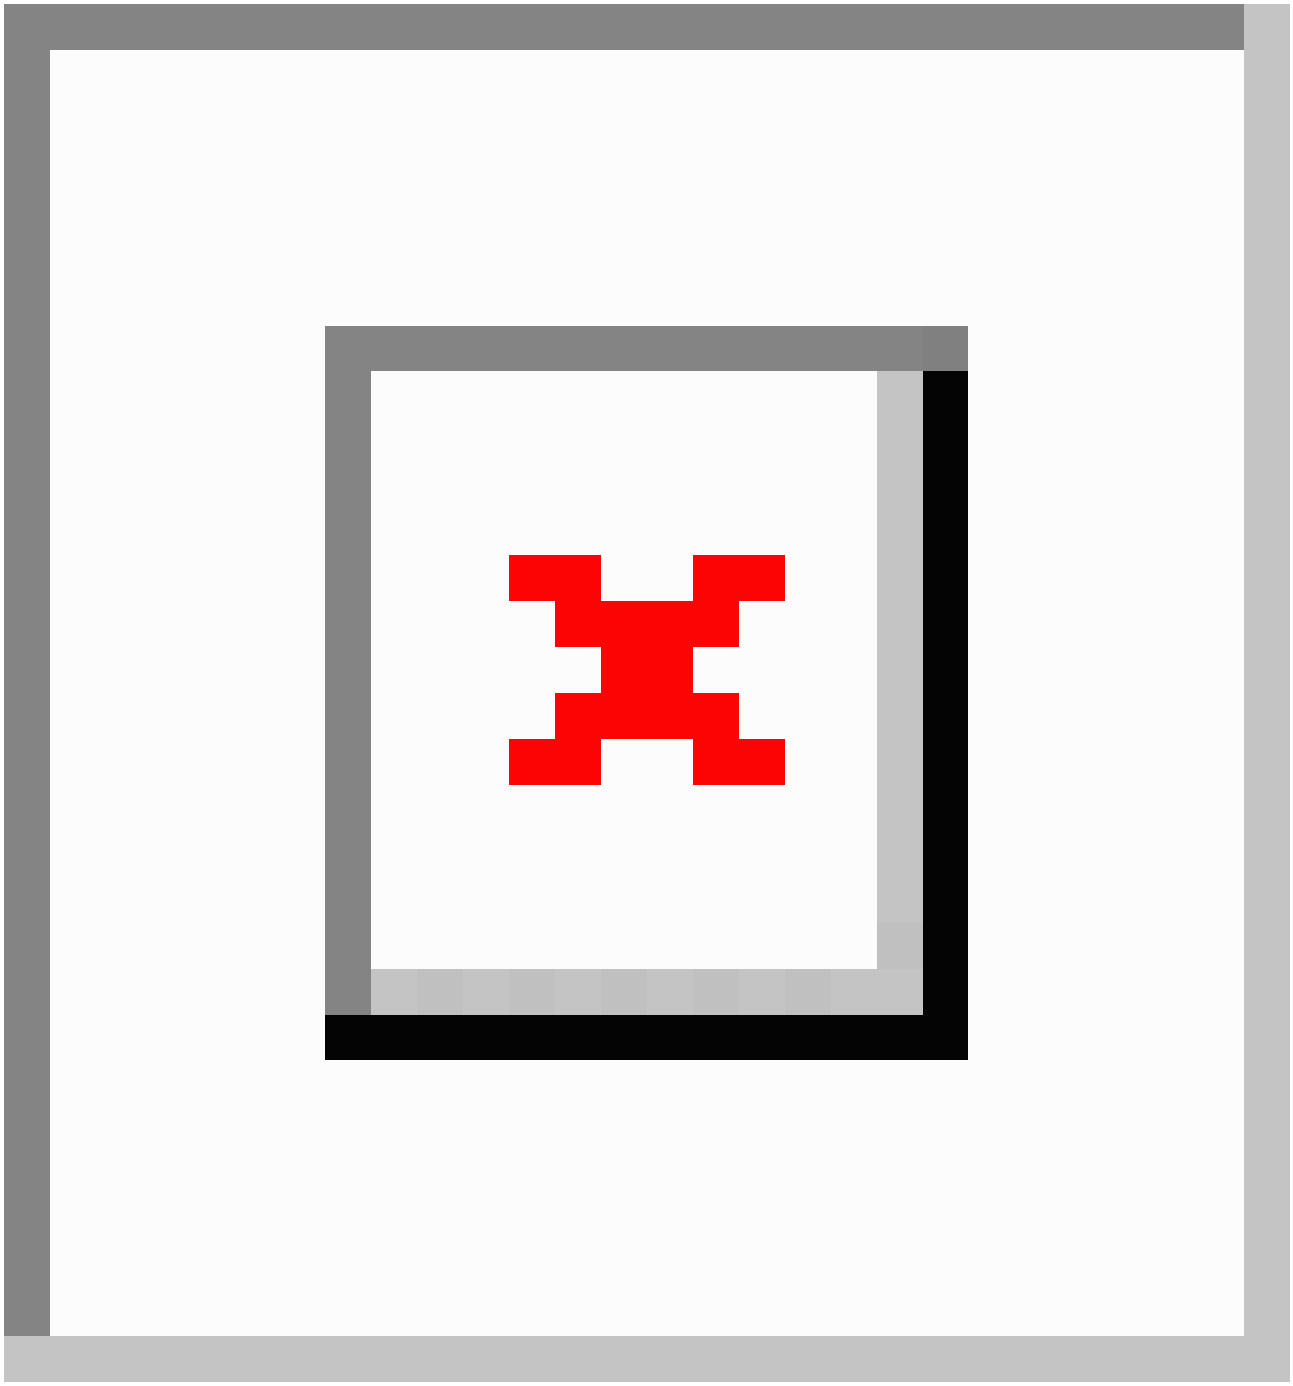

Figure 2. Patients receiving care from the mental health services in Ferrara over time (years 1991-2021), in total (continuous line) and by sex (dotted and dashed lines). CURE: Cartella Unificata Regionale Elettronica; GESAP: Gestione attività Psichiatrica. SIPER: Sistema Informativo Psichiatrico dell'Emilia-Romagna.

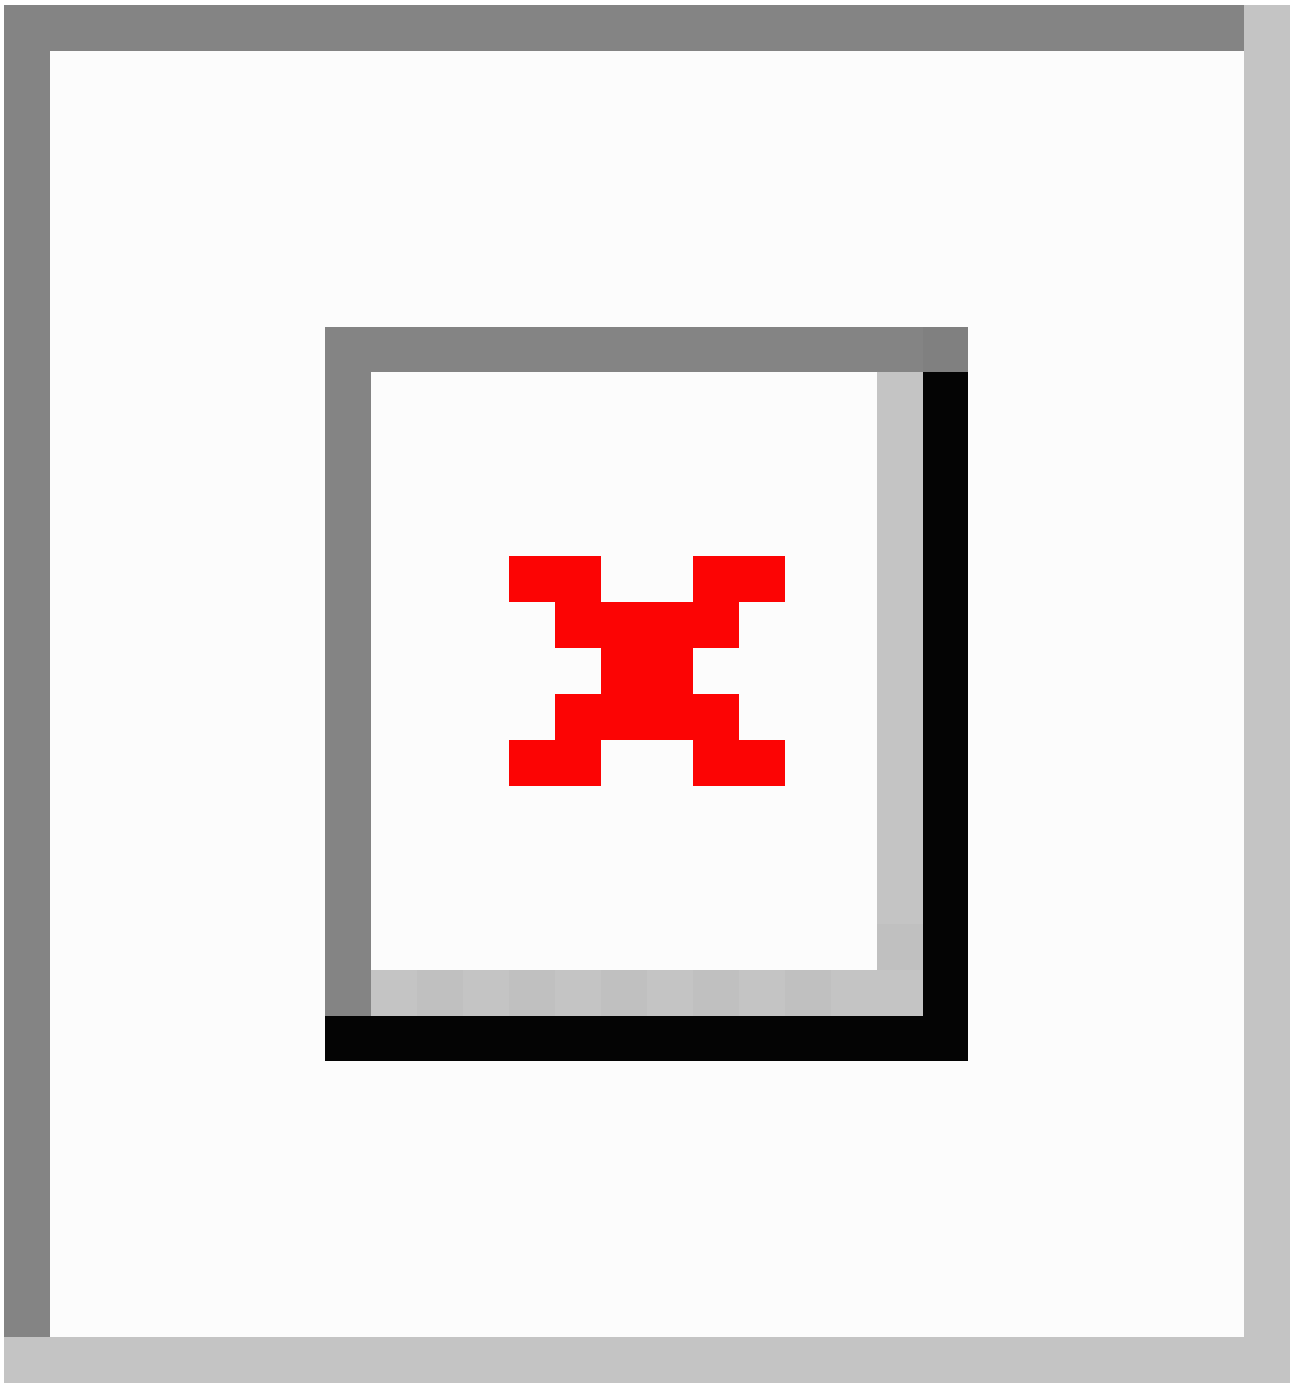


As described in Table 2, the most frequent diagnoses at first admission were depression and anxiety disorder. During the 30-year time span, more than half (32,230/46,222, 69.73%) of the patients had only 1 chart open, and only 5184 patients had at least one psychiatric hospitalization.

Table . Main clinical characteristics of the sample (N=46,222; years 1991-2021).

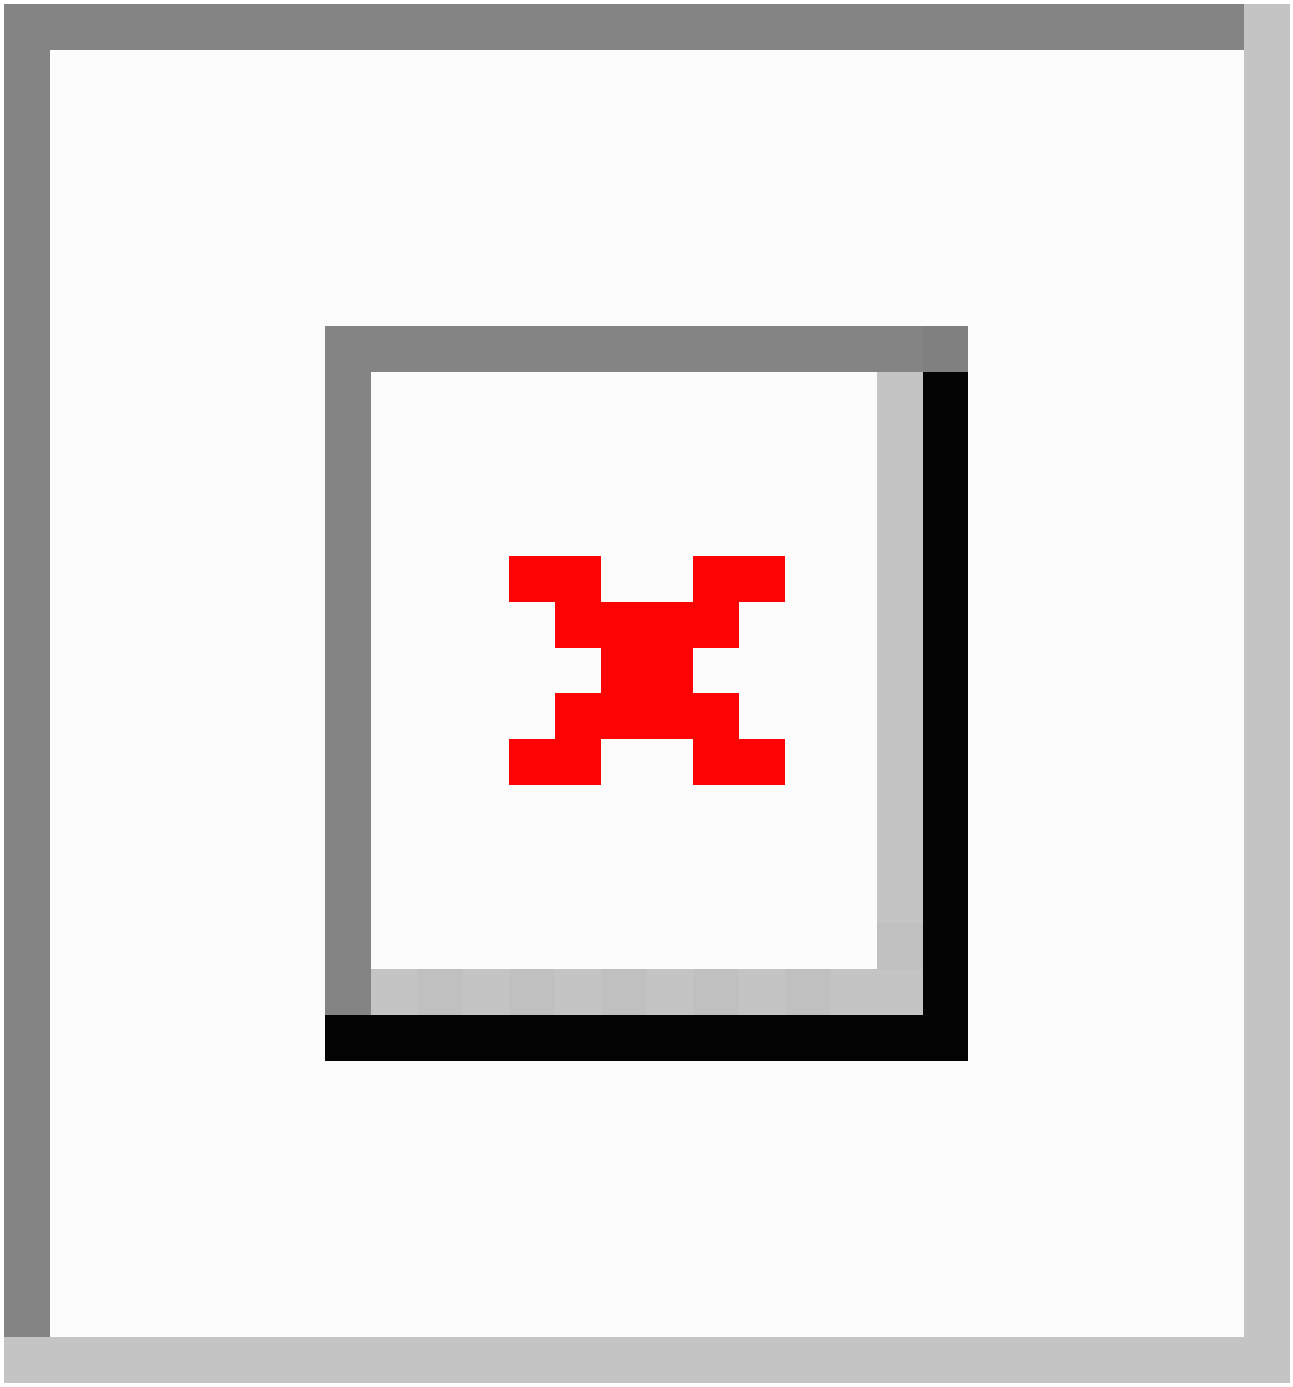
Characteristics		Female patients (n=28,109, 68.81%)	Male patients (n=18,113, 39.19%)
Age at first visit			
	Years, mean (SD)	50.46 (18.82)	48.72 (19.02)
	Years, median (range)	49.0 (0-109)	47.0 (2-98)
Number of charts/patient			
	Value, mean (SD)	1.62 (1.55)	1.64 (2.38)
	Value, median (range)	1.0 (1-63)	1.0 (1-132)
Patients with at least one hospitalization, n		2680	2504
Number of hospitalizations/patient			
	Value, mean (SD)	0.33 (2.36)	0.46 (2.35)
	Value, median (range)	0 (0-143)	0 (0-102)
Patients with at least one compulsory admission, n (%)		415 (1.48)	485 (2.68)
Duration of hospitalization			
	Days, mean (SD)	5.08 (40.89)	7.53 (62.39)
	Days, median (range)	0 (0-2661)	0 (0-4090)
First recorded mental disorder diagnosis[a], n (%)			
	Anxiety disorders	6884 (24.49)	3725 (20.57)
	Dementia and other organic disorders	2092 (7.44)	1601 (8.84)
	Depression	7648 (27.21)	3335 (18.41)
	Drug and substance use or abuse	415 (1.48)	861 (4.75)
	Eating disorders	241 (0.86)	18 (0.10)
	Intellectual disability	468 (1.66)	636 (3.51)
	Mania and bipolar disorders	713 (2.54)	460 (2.54)
	Personality disorders	1287 (4.58)	1186 (6.55)
	Schizophrenia and other nonorganic psychoses	1468 (5.22)	1515 (8.36)
	Other mental disorders	2339 (8.32)	1130 (6.24)
	No formal mental disorder diagnosis	4554 (16.20)	3646 (20.13)

[a]Mental disorder diagnoses: *International Classification of Diseases, Ninth Revision* codes 290.xx-319.xx.

Clustering Results

This analysis, which was carried out on the subset of 38,022 individuals who had at least one mental disorder diagnosis, identified 2 distinct clusters (Figure 3). One is represented by single male patients who were born in Ferrara, those who were living with parents, and those whose age at first visit was between 25 and 34 years; the other is represented by married female patients who were living with their own acquired families, those who were born outside the province of Ferrara, and those whose age at first visit was 35 to 44 years. The following sociodemographic features were similar in the two clusters: Italian nationality, individuals with a high school degree, employed individuals, and individuals who were receiving treatment in the Ferrara catchment area.

Figure 3. Results from the clustering analysis.



Discussion

Principal Findings

This study describes the process of adapting one of the longest running EHRs of public mental health care for research purposes. The FEPSY data set covers a catchment area with 342,061 inhabitants (as of 2020) and includes a total of 46,222 unique individuals who had access to mental health services over a span of 30 years (1991-2021). The FEPSY database is suitable for descriptive, predictive, and inferential analyses via conventional analysis and AI techniques, as demonstrated by the preliminary findings of the clustering analysis. To our knowledge, our database is the first of its kind in Italy. In Europe, longitudinal and prospective registries have long been in use. For example, large data sets were extracted from the Danish National Patient Registry [30] and the Danish Psychiatric Central Research Register [31]. The first data set contained data on 8,085,603 patients, which were collected from 1977 to 2012. The second data set included data on a total of 747,176 patients, which were collected from 1970 to 2010. In both cases, the register contained dates of the onset and end of any treatment, diagnoses, types of referrals, and places of treatment, thereby allowing for the possibility to perform health registry–based research [32], considering a total population of approximately 27 million.

The main finding of this study is that data that were not originally conceived for research were successfully extracted from EHR software and loaded into a new anonymized database.

This step is of foremost importance, as the data originated from an information system that was changed and updated multiple times and was not designed to allow for exploratory investigations in a structured manner. Thus, this new data set may represent the ideal setting to build, test, and refine an analytical methodology for extracting data and preparing these data for research purposes. This methodology could also be applied to other clinical data sets, such as data sets from other medical disciplines (eg, oncology), with characteristics that are similar to those of the FEPSY data set [33]. Additionally, it will be of foremost importance to validate the methodological approach and findings of upcoming research originating from the FEPSY data set by proactively seeking collaboration with other research groups, in order to enable the replication of findings from the territory of Ferrara and the use of the FEPSY data set to replicate findings from research involving other registries.

This work also allows for collaborations in terms of learning health networks, which use comparable data that originate from EHRs to support clinical decisions, improve the delivery of efficient and effective medical care, and help with the integration of research in health care [34-36].

Our results will also pave the way for an in-depth study on the use of health care resources; the results will be used to develop a system that is capable of planning the use of such resources. Such a system would optimize the use of health care resources while maintaining or possibly improving the quality of treatment. For example, in Italy, Donisi et al [37] predicted the cost of community mental health care by using clinical and sociodemographic information originating from the Psychiatric Case Register in the Verona Health District. This allowed for the linking of social deprivation to psychiatric service utilization [38] and shed a light on possible contributors to social isolation in an already vulnerable population. Our clustering analysis, which was conducted on the FEPSY data set to test its feasibility and robustness, identified 2 clusters; women appeared to access mental health services later in life and were typically married, in comparison to men. These findings were consistent with the literature [39-41] and supported the ability of the extracted data to detect known patterns, even though the results should be interpreted with caution, given the large amount of missing sociodemographic data. Clustering analyses can be useful for building prediction models and planning a department's resource allocation, as they provide relevant information on patients at presentation and on illness trajectory [42].

The process described in this paper faced 5 major challenges that we mitigated, as follows. First, the source data included several built-in structural informatic elements (so-called *tables*) that had to be screened and deleted in order to get to the core data. Second, the anonymization step was of absolute importance, and in order to both comply with privacy constraints and be able to preserve the integrity of the data, the study team decided to keep only subelements of certain data items (eg, for the birth date, only the year was kept, and for residence, only the postal code was kept). Third, in order to establish which records were correct, an iterative comparison of the FEPSY database and the local and regional database was performed by a third party who had access to PHI. Fourth, records that were deemed unreliable were excluded (eg, clinical procedures referring to nonexistent medical records). Furthermore, the data extracted from EFESO originated from different software and thus possibly generated some errors. In the FEPSY data set, these errors seem to be limited to records, and the proportion of records with errors was very low (49,854/3,861,432, 1.29%). In the end, we decided to exclude data that were collected before 1991 and duplicate patient records. Fifth, missing data challenges were also addressed, especially in the clustering process. For this purpose, the WEKA data mining tool was used.

Strengths of This Study

The quality and completeness of the collected and cleaned data, as well as the large number of records stored in the FEPSY database, resulted in the definition of a data set that is particularly suitable for automatic analysis and has appealing characteristics for research, such as a long period of data availability, great diversity in the sociodemographic factors of the patients represented, and a history of treatments and drugs administered. This could possibly represent a strong foundation for many different studies of mental illness and resource use, favoring comparisons between Italy and other countries regarding the delivery and quality of community and hospital psychiatric care [43-45]. Furthermore, the newly created database does not include sensitive information, even though this information can be retrieved by using an external supporting table created ad hoc, which could link the FEPSY data set with other data sets (eg, hospital data and tumor registries) for future research.

The novelty of this project is represented by its interdisciplinary nature (psychiatry, public health, epidemiology, sociology, mathematics, computer science, and AI), the potential versatility of the methods that can be used with the FEPSY database, and the versatility of the systems that could be created via analyses involving the FEPSY database. To our knowledge, this study is the first attempt to retrospectively build a single data set that includes more than 30 years' worth of data on mental health services in a specific area.

Such a data set would also allow for longitudinal analyses, such as those that have already been performed with the Nordic registry (a prospective registry) and, more recently, the South London and Maudsley National Health Service [46] and the Camden & Islington Research Database [47].

We believe that historical data can add value to subsequent analyses, because they allow researchers to understand how mental health services have evolved over the past decades and the extent to which phenotypical presentations of different diseases have changed over time. In light of these considerations, factors that should be taken into account are (1) potential cohort and time effects, such as historical events (eg, the Great Recession in 2008); (2) changes in legal and medical approaches to mental health; and (3) changes in the classification of mental disorders [48].

Limitations

Our findings must be interpreted in the light of some limitations. First, the sample size is limited by the geographical catchment. A larger catchment or a more densely populated region would

probably have a larger volume of treated individuals and thus have more data, which would facilitate machine learning analyses. However, we believe that even if the sample is limited by the geographical catchment, the diverse socioeconomic distribution in Ferrara is a strength that mitigates this limitation, providing insight into the possible moderator or mediator roles of socioeconomic variables that are considered social determinants of mental health. Second, another potential limitation is the missing data for some sociodemographic attributes, which may reduce the statistical power of a study [49] or affect the accuracy of machine learning algorithms [50]. In order to overcome this issue, missing values can be handled with multiple imputation methods or replaced with the mean or the mode (ie, for quantitative or qualitative data, respectively). Moreover, sociodemographic information can be drawn from external and publicly available sources, such as the Italian National Institute of Statistics [51], which includes the census of the population as well as social, economic, and environmental surveys and analyses. Lastly, there is the risk of introducing bias while building prediction models, especially when using supervised machine learning techniques, due to small sample sizes and the poor handling of missing data and overfitting [52]. With regard to the sample size, our sample appears to be sufficiently large for risk prediction analyses. Overfitting can be addressed with penalized models [53].

Future Directions

This work sets a starting point for future investigations, which can be described as follows: (1) identifying patients who have a higher severity index or chronicity level and those who require a greater use of health resources; (2) identifying and validating, by means of machine learning models, demographic, clinical, and social predictors of clinically relevant outcomes that are useful for an ad hoc programming of resources (eg, sex, gender, or social deprivation [38,39,54]); (3) further optimizing and tailoring the analysis methods, so that they can also be applied to other data sets (eg, the local mental health registries for child and adolescent neuropsychiatry and for drug addiction services); (4) interacting with international learning health networks [55-57]; and (5) linking the FEPSY data set with external data sources, such as census data, tumor registries [58], death registries, and criminal justice data [59]. As a result of the increasing digitalization of medical records, it was possible to gather years of mental health history for every patient. This will enable for the conduct of symbolic and subsymbolic analyses on time series via automatic methodologies. Classical supervised and unsupervised machine learning and deep learning techniques will be evaluated. In order to explore the relationship between sociodemographic characteristics and specific diagnostic questions (eg, the incidence and prevalence of psychosis), a supervised framework will be deployed, in which binary labels (eg, “psychosis” or “no-psychosis”) or multiple classification labels (eg, “ICD-9 diagnosis”) will be associated with the patient. The main problem to overcome will be the imbalance of the data set, that is, when there is an unequal distribution of classes in the data set. In such instances, a standard machine learning technique, such as a support vector machine or random forest [60,61], will be applied. Moreover, each patient could potentially be considered as a distinct time series by including the temporal dimension of the treatment and by applying recurrent neural networks [62,63]. By doing so, the prediction of the new onset of a disease and the subsequent use of health resources will be the focus, in order to plan and optimize health care resources.

Conclusions

The process described in this study resulted in the building of a data set that included the information of 46,222 individuals who had access to psychiatric services in the Ferrara province over the course of almost 30 years. The preliminary findings from the clustering analysis confirmed the quality of the newly established database. The process we implemented proved to be a solid method that can be replicated with similar data sets, even if they were not originally compiled for research purposes.

Acknowledgments

This work was supported by the “Fondo per l’Incentivazione alla Ricerca (FIR),” granted by the University of Ferrara in 2021 to MF, with the project titled “Intelligenza Artificiale per Predizione Diagnostica, di Carico Assistenziale, e di Esito: 40 Anni di accessi Presso i Centri di Salute Mentale della Provincia di Ferrara (AI4MentalHealth).”

Authors' Contributions

MF designed the study, wrote the first draft of the manuscript, and supervised the project. EG processed the experimental data, performed the analysis, and designed the figures. MBM, RZ, MA, GF, ID, FF, and LG were involved in planning and interpreting the results. CS, LB, and JL aided in interpreting the results. All authors discussed the results, commented on the manuscript, and approved the final version.

Conflicts of Interest

None declared.

Abstract

Background: Investigating low-prevalence diseases such as multiple sclerosis is challenging because of the rather small number of individuals affected by this disease and the scattering of real-world data across numerous data sources. These obstacles impair data integration, standardization, and analysis, which negatively impact the generation of significant meaningful clinical evidence.

Objective: This study aims to present a comprehensive, research question–agnostic, multistakeholder-driven end-to-end data analysis pipeline that accommodates 3 prevalent data-sharing streams: individual data sharing, core data set sharing, and federated model sharing.

Methods: A demand-driven methodology is employed for standardization, followed by 3 streams of data acquisition, a data quality enhancement process, a data integration procedure, and a concluding analysis stage to fulfill real-world data-sharing requirements. This pipeline's effectiveness was demonstrated through its successful implementation in the COVID-19 and multiple sclerosis global data sharing initiative.

Results: The global data sharing initiative yielded multiple scientific publications and provided extensive worldwide guidance for the community with multiple sclerosis. The pipeline facilitated gathering pertinent data from various sources, accommodating distinct sharing streams and assimilating them into a unified data set for subsequent statistical analysis or secure data examination. This pipeline contributed to the assembly of the largest data set of people with multiple sclerosis infected with COVID-19.

Conclusions: The proposed data analysis pipeline exemplifies the potential of global stakeholder collaboration and underlines the significance of evidence-based decision-making. It serves as a paradigm for how data sharing initiatives can propel advancements in health care, emphasizing its adaptability and capacity to address diverse research inquiries.

Introduction

Chronic diseases such as multiple sclerosis (MS) [1] present significant obstacles for research, primarily because of their limited prevalence, resulting in smaller study populations [2]. The scarcity of the affected individuals is reinforced when considering the dispersion of real-world data (RWD) across diverse repositories. This scarce RWD, sourced during routine clinical care [3,4], further coupled with heterogeneity in formats, quality standards, and regulatory guidelines, make the comprehensive collection and extraction of meaningful clinical insights even more challenging [5,6].

Despite these challenges, well-managed RWD have the potential to reveal significant patterns concerning diseases, patient experiences, and treatment outcomes [7,8]. For instance, during the early stages of the COVID-19 pandemic, innovative data acquisition strategies overcame data scarcity, unlocking the potential of RWD for meaningful analysis [9-11]. These specific instances underline the broader concern: the RWD landscape is rife with challenges that are often understated.

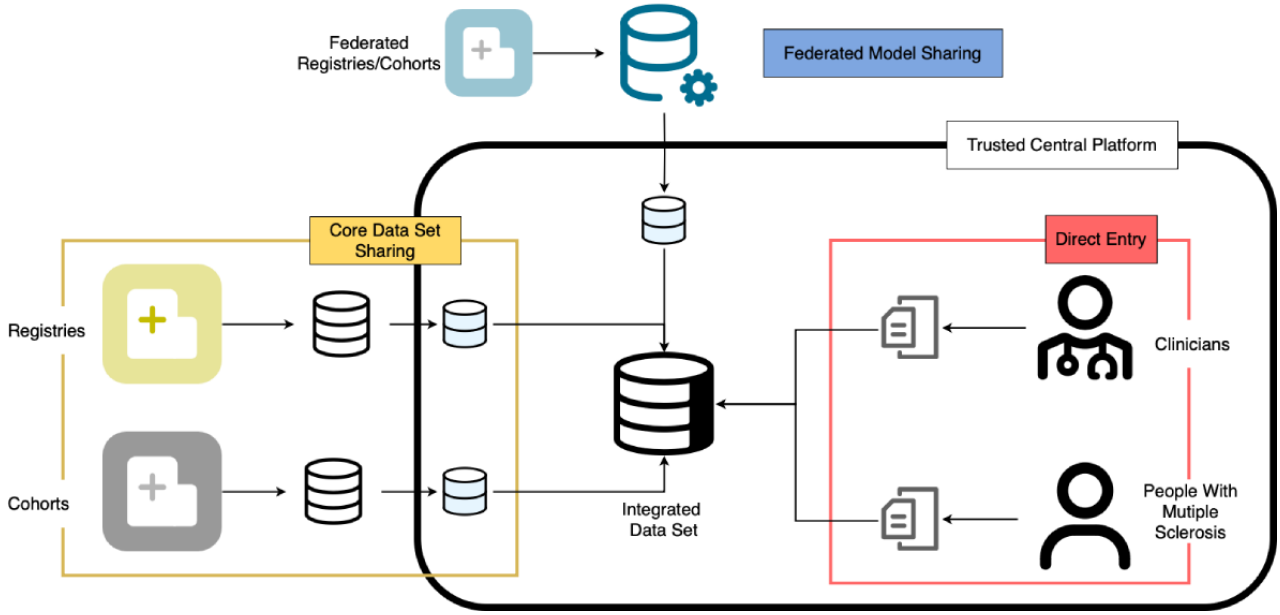
Current literature tends to oversimplify the intricate processes involved in managing RWD. These include standardization, acquisition, quality enhancement, integration, storage, governance, visualization, and eventual analysis and interpretation. Although these facets are crucial, they are often treated as isolated components rather than integral parts of an interconnected system, with certain areas occasionally overlooked [5].

Recent studies on COVID-19 bring this gap into sharper focus. Khalid and colleagues [12] focused on building analytical models by using observational health data through machine learning but did not fully emphasize the vital aspect of data acquisition in the pipeline management. By contrast, Nishimwe and colleagues [13] concentrated on data integration, gathering data from various hospitals, but did not delve into thorough in-depth data analysis. A study by Junior and colleagues [14] aimed to cover the whole data analytics pipeline but primarily focused on standardizing data from 2 different countries, giving less attention to crucial parts of RWD management, such as data acquisition, preprocessing, quality enhancement, and analysis. This fragmented focus points to the need for a more comprehensive strategy that neither compromises nor overlooks any part of the RWD management process. The absence of a holistic framework, coupled with the growing diversity and volume of RWD sources, intensifies the challenges in health care data sharing and the conversion of RWD into actionable evidence, underscoring the need for standardized management [6].

In light of these challenges, the global data sharing initiative (GDSI) emerges as an exemplary solution that addresses multiple facets of RWD management, specifically in the context of COVID-19 and MS. Prompted by the urgent need to understand COVID-19's effects on people with MS, GDSI was launched [15]. By integrating data from over 80 countries, GDSI generated globally relevant insights [7,16-19]. This large-scale effort resulted in the formation of the most extensive international cohort of COVID-19 cases among people with MS. In addition to enriching our understanding of the COVID-19 and MS interaction, GDSI showcased the enormous potential of large-scale international collaboration. Furthermore, the initiative set a methodological standard in global health research by introducing a data analysis pipeline with applications beyond MS.

This paper delves deep into GDSI's comprehensive RWD analysis pipeline, offering an end-to-end approach that spans from introducing a data dictionary to meticulous data acquisition, and ultimately, to deriving insightful clinical interpretations. One distinguishing aspect of our study lies in the pragmatic execution of this intricate end-to-end analysis pipeline. As depicted in Figure 1, we have implemented a hybrid 3-layer data acquisition architecture—all in strict compliance with the legal and ethical standards that govern data collection and dissemination. Designed for versatility and inclusivity, this architecture aimed to capture every data point possible. Concurrently, an astute approach to data integration was used, whereby these diverse data streams were seamlessly unified. This robust unified data set was then readied for further analysis and exploration.

Figure 1. The global data sharing initiative data streams detailing the initiative's inclusive approach through a hybrid 3-layer data acquisition architecture: (1) direct entry, where individuals upload their data via a web-based form; (2) core data set sharing, where registries upload patient-level data to the central platform under signed data transfer agreements and ethics approvals; and (3) federated model sharing, allowing registries with restrictive policies to participate without directly submitting patient-level data to the central platform.

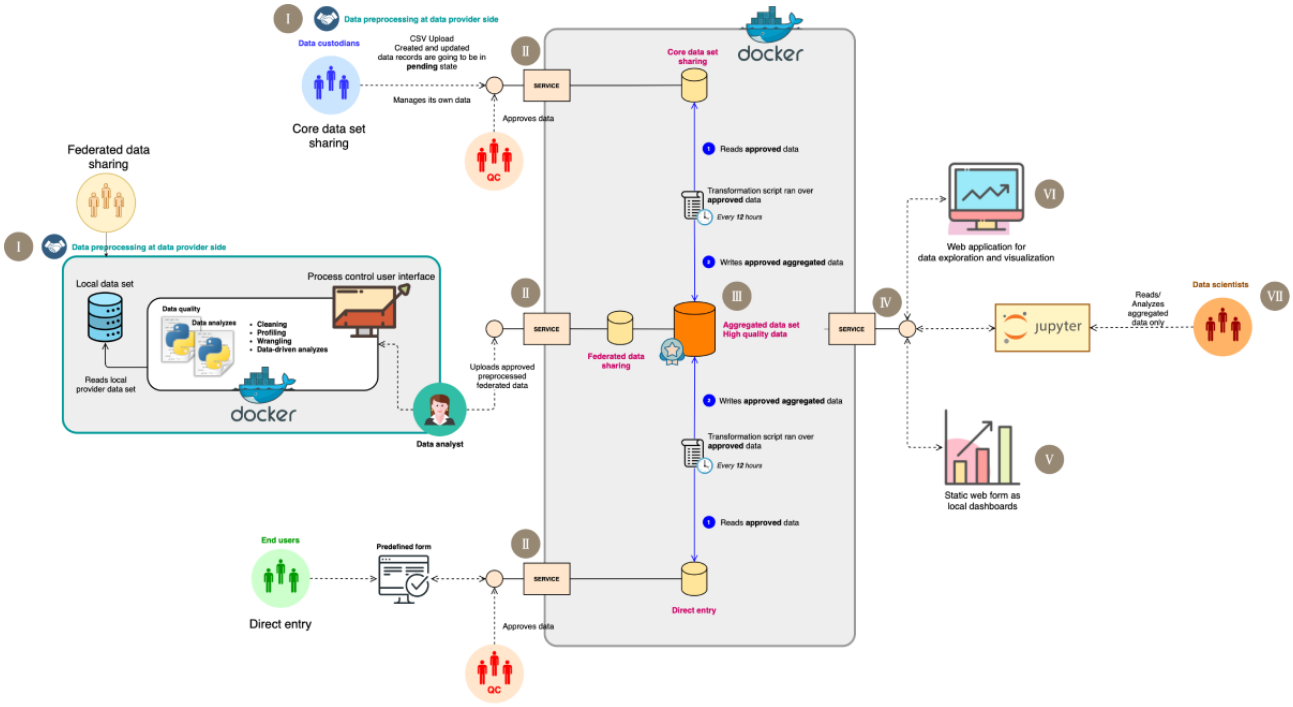


Methods

Overview of GDSI's Data Analysis Pipeline

The robustness and scale of GDSI's endeavor were mirrored by its foundational approach. As depicted in Figure 2, GDSI's RWD analysis pipeline provided the essential framework for comprehensive data management and analysis. Centralized around a core platform, this pipeline progressed through 5 key stages (1) introducing a specialized data dictionary to standardize the data; (2) data acquisition, which details the methods used to gather the data; (3) an integral step for enhancing data quality; (4) data integration, responsible for aggregating various sources; and (5) the final stage, where the consolidated data are analyzed.

Figure 2. The global data sharing initiative's end-to-end real-world data analysis pipeline. Step I illustrates the standardization process, which serves as the foundation of this architecture. In this phase, data custodians are requested to map their data to the "COVID-19 in multiple sclerosis core data set" (here referred to as the data dictionary). This process applies only to the core data set and federated model sharing registries, as direct entry is already embedded with a data dictionary via the web form. Step II involves the data acquisition pipeline, featuring distinct levels of data acquisition that depend on the data holder's willingness and internal policies, all conducted in line with ethical and legal standards. Direct entry, core data set sharing, and federated model sharing constitute the 3 data stream levels. The first 2 levels interact directly with a central platform where the core dataset is shared as static files, in this instance, Comma Separated Values (CSV), whereas federated registries necessitate additional steps before submitting outcomes to the central platform. To incorporate federated registries into the pipeline, predefined queries are dispatched alongside Docker containers to the local side of the registries. The results of these containers are then shipped back to the central platform. In step III, data from different data holders are stored in separate layers to facilitate the next data integration process. Data integration, the subsequent step in the pipeline, entails consolidating data from distinct layers into a comprehensive data set. Step IV emphasizes the utilization of the integrated data set for further data exploration and analysis. Step V highlights the local dashboard, which serves as a quality check, enabling data providers to give feedback on their uploaded data as an additional sanity check. Step VI underscores the online dashboard that has been fed by the integrated data set, utilized by the taskforce during the development of the research questions to ascertain the feasibility of the study and to monitor the data being collected. In step VII, a Jupyter Notebook is provided to the data analysis team, securely connected to the integrated data set, facilitating statistical analysis.



Ethics Approval

This study received ethics approval from the ethics committee of Hasselt University (approval CME2020/025). For an in-depth discussion concerning ethical authorization, kindly refer to Simpson-Yap et al [17].

Data Dictionary

A data dictionary serves as a guide that details the attributes of components within an information database, ensuring consistent terminology [20-22]. In the context of GDSI, this tool has proven invaluable for mitigating challenges posed by diverse languages and structures. A task force of domain experts, including epidemiologists, neurologists, and data scientists, reached a consensus on establishing the "COVID-19 in MS Core Data set" data dictionary. This guide served as a keystone for harmonizing data from various sources. To tackle interoperability, data custodians used it as a reference, enabling them to standardize their data sets and streamline the extract-transform-load process. A detailed overview of the variables employed in GDSI is provided by Simpson-Yap and colleagues [7], and a full list is accessible via the GitHub repository [23] and presented in Table S1 of Multimedia Appendix 1.

Data Acquisition

Recognizing the value of diverse data sources for research outcomes [8,24], GDSI developed a hybrid data acquisition architecture. This framework consists of 3 distinct data sharing streams: direct entry, core data set sharing, and federated model sharing. Each stream is designed to accommodate specific data environments, ensuring a comprehensive and multifaceted collection approach. The primary distinguishing factor among these data sharing streams was the extent of willingness to share clinical records with the central server. In practice, confining data collection to a singular stream would drastically reduce the data volume, making the transition of all contributors to 1 mode unattainable. GDSI's strength was rooted in its adaptability, effortlessly accommodating these 3 sharing streams and fusing them into a unified data set.

Data Sharing Streams

Direct Entry

This stream prioritized direct engagement with both clinicians and patients. Patients provided their clinical records through structured questionnaires, while clinicians offered their observations after acquiring the necessary permissions. A unique characteristic of this stream was its rapid data entry mechanism.

The predefined structure, designed to align with a condensed version of the data dictionary, ensured smooth data integration. Data were submitted via a web-based form on the centralized platform. Importantly, this form upheld patient privacy, excluding specific identifiers and enforcing stringent measures against website cookies and trackers.

Core Data Set Sharing

Adhering to the conventional approach for clinical data sharing, data providers contributed a subset of their data set to the central platform. Although this mechanism excelled in handling extensive data, it grappled with challenges related to data collaboration agreements and complex regulatory stipulations. The heterogeneity in the data format further compounded these challenges. However, the architecture of core data set sharing was designed to necessitate the schema of the data dictionary. As a result, data custodians needed to standardize their data format according to the data dictionary to upload their data using this stream. Upon achieving this congruence, custodians used the central platform's interface—a secure bridge that connected the local infrastructure of the data partners to the main platform—for data upload. For enhanced data security, once uploaded, data extraction is restricted. Additional security measures such as user activity monitoring and stringent access policies were further implemented, ensuring that registry members can only view their specific records, thus preserving data confidentiality. As the pandemic progressed, the registries were periodically invited to contribute their core data sets to the central platform.

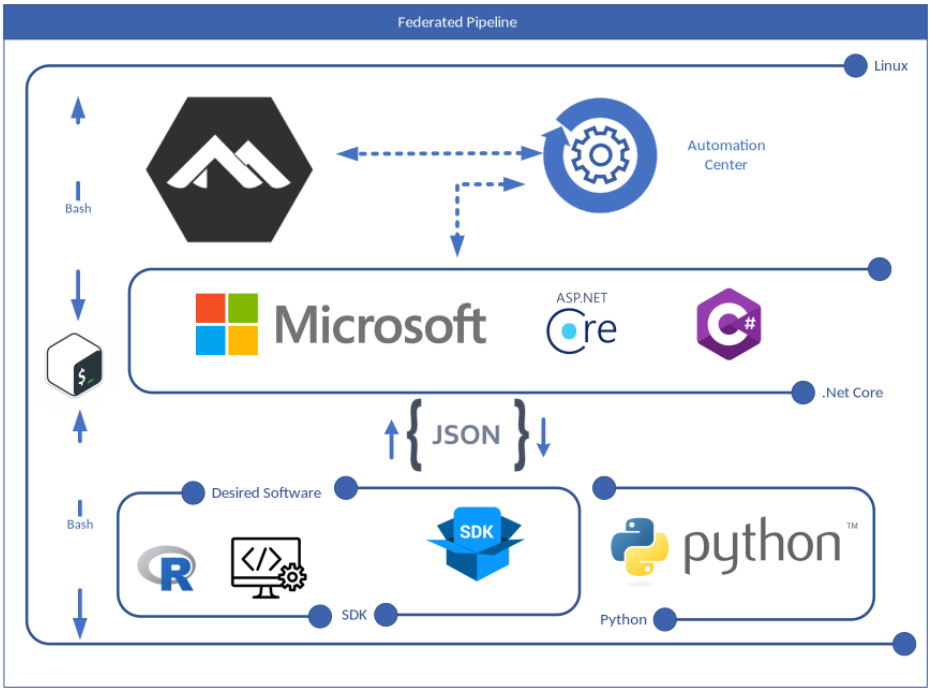
Federated Model Sharing

Addressing challenges such as strict internal policies that deterred or hindered some registries from sharing clinical records with the central platform, the federated model sharing was introduced. This decentralized solution brings a pivotal shift to regular data sharing streams. Central to this model is the principle of querying data directly at its source, thus eliminating the need to transfer patient-level data. Instead of navigating the nuances of individual patient data, this strategy consolidates multivariable categories into aggregated "buckets." These buckets are grouped categories where similar data are combined together rather than stored separately. By adopting this approach, potential risks linked to transferring patient-level data are mitigated, and the complexities tied to strict data-sharing agreements are streamlined. A detailed examination of the buckets computation methodology can be viewed in Table S2 of Multimedia Appendix 1 and within the associated GitHub repository [25].

Despite its advantages, the federated model sharing stream introduces its own challenges, especially when remote query executions result in inconsistencies across diverse systems. To compute the buckets, scripts were run locally using Docker [26] containers. Docker containers are self-contained software environments that promote standardization, which helps alleviate the typical technical challenges in such processes. These containers, referred to here as the federated pipelines, were deployed on each registry's infrastructure and were mounted with data that had already been standardized and aligned with the data dictionary, facilitating seamless execution. After computing these buckets, they were transferred to the central platform. Multiple versions of these Docker containers were used to distribute scripts across the federated model sharing registries.

The architecture of the most recent federated pipeline is presented in Figure 3 [27]. Associated resources, including a demonstrative video walk-through, operational scripts, and the Docker image, can be found in [28-31]. Furthermore, the entire source code has been made publicly accessible on GitHub [32]. This provides a thorough toolkit for those interested in understanding, replicating, or refining the framework of the federated pipeline. A comprehensive analysis of the various iterations of the federated pipeline is presented in Multimedia Appendix 2 [33].

Figure 3. The latest federated pipeline. This is a container composed of 3 primary components. The first component is the base image, which forms the bedrock of the infrastructure. This base image uses Alpine Linux as its underlying operating system, which allows the container to be fine-tuned with other software development kits for further refinements and functionalities [27]. The remaining 2 components, the backend and frontend, are constructed on top of this base image. The backend consists of a suite of Python scripts, which are tasked with data quality assessment, enhancement, cleaning, and analysis. These scripts collaboratively process the incoming mapped data, preparing it for subsequent analysis. By contrast, the frontend was crafted using Microsoft's ASP.NET Core framework and the C# programming language. Within this pipeline, there is a customizable automation center module. This module can be adapted to meet the specific needs and requests of data partners. It also integrates Crontab, a tool that automates predefined tasks and outlines complex pipelines for execution at various intervals. The automation center module also links the container to the GitHub and Docker Hub version control systems. This connection ensures the use of the most recent scripts and codes published by data analysts. SDK: software development kit.



Data Quality Assessment and Enhancement

The integrity of the acquired data set was upheld through a rigorous data enhancement and quality evaluation process, which was integrated seamlessly into the central platform. In this process, each data variable was scrutinized against a binary criterion: PASS or FAIL. If a specific data point met the pre-established benchmarks of quality and precision, it was accorded a "PASS;" otherwise, it was categorized under "FAIL." The input format for direct entry eliminated the need for additional quality checks, as validation was directly integrated into the web-based form. For the core data set sharing approach, uploaded data were immediately assessed for quality, and a real-time feedback mechanism alerted contributors to any issues, allowing for immediate corrective action. Conversely, within the federated model sharing approach, quality checks were conducted at the data source prior to aggregation.

The criteria are summarized in Table 1. In the PASS/FAIL column of this table, variables are flagged differently according to the data quality check. PASS is the flag for an accepted variable, FAIL is the flag for a dismissed variable, and EMPTY is the flag for each variable that is missing/null. Note that FAIL does not necessarily mean that the data get excluded; it is just that it is flagged as erroneous—it can also be adapted in some cases for analysis. FAIL means the following action: "Set the FAIL variable to missing, flag the variable, and keep the patient entry (row)." Additionally, specific rules were applied to dates in the data; more specifically, dates cannot be in the future (ie, if any date > date reporting, then the variable is flagged as FAIL) or before a person's birth date (ie, if any date YEAR < year_reporting - age, then the variable is flagged as FAIL). The COVID-19–related dates also must be later than the MS baseline dates (onset and diagnosis). A comprehensive version of this table is available on GitHub [34].

Table 1. Data quality assessment and enhancement: pass and fail criteria (some highlighted examples).[a]

Variable	Format	Interdependency	Pass and fail criteria
covid19_date_reporting	yyyy-mm-dd	None	if covid19_date_reporting < 2019, then fail, else pass
covid19_has_symptoms	single choice (yes/no)	covid19_sympt_fever covid19_sympt_dry_cough covid19_sympt_fatigue covid19_sympt_pain covid19_sympt_sore_throat covid19_sympt_shortness_breath covid19_sympt_nasal_congestion covid19_sympt_loss_smell_taste covid19_sympt_pneumonia	if covid19_ has_symptoms = null, then check the covid19_sympt_xx for yes if any covid19_symptxx = yes, then covid19 has symptoms = yes (for the analysis data) strict: if covid19_has_symptoms = no AND any covid19_symp_xx = yes, then fail derivation: covid19_has_symptoms is secondary to covid19_ sympt _xx if any of the single symptoms are yes, then empty(!) covid19_has_symptoms will be set to yes and vice versa (all symptoms = no, covid19_has_symptoms is set to no)
covid19_sympt_fever	single choice (yes/no)	covid19_has_symptoms	see covid19_has_symptoms
covid19_sympt_fatigue	single choice (yes/no)	covid19_has_symptoms	see covid19_has_symptoms
covid19_admission_hospital	single choice (yes/no)	None	if covid19_admission_hospital = yes AND covid19_confirmed_case = no, then fail
age_years	Integer	None	if age_years < 0 OR age_years > 110, then fail, else pass
ms_onset_date[b]	yyyy-mm-dd	ms_diagnosis_date covid19_suspected_onset	if (ms_onset_date > ms_diagnosis_date) OR (ms_onset_date > covid19_suspected_onset), then fail, else pass
edss_value[c]	Number (0.0, 10.0)	None	if edss_value < 0 OR edss_value > 10, then fail
type_dmt[d]	Single choice	None	if type_dmt = null AND type_dmt_other = null AND current_dmt = yes, then fail, else pass
has_comorbidities	single choice (yes/no)	None	if has_comorbidities = null AND any_com_xx = yes, then set has_comorbidities = yes (for analysis)

[a]67 more checks have been performed, but these checks are not presented in this table.

[b]MS: multiple sclerosis.

[c]EDSS: Expanded Disability Status Scale.

[d]DMT: disease-modifying therapy.

Data Integration

The quality-checked data acquired within each stream are stored distinctly, emphasizing the discrete nature of their origins. Consequently, the challenge emerges not just from the acquisition but notably from the critical task of integrating these separate data sets. To derive comprehensive insights, there was a paramount need to coalesce these distinct data sets into a singular unified structure. In the ensuing sections, we outline the process employed to achieve this integration and present a harmonized analytical framework.

Consider $x_i = (x_{i,1}, \ldots, x_{i,k})$ to be the list of control and response variables of patient i used in the downstream statistical analysis. N indicates the total number of patient records and K represents the number of variables of interest. For each variable type, we define a list of nonoverlapping ranges $\sum_k = \sigma_k^1, \sigma_k^2, \ldots, \sigma_k^{jk}$ that partitions the domain of each variable into distinct categories, that is, each variable $x_{i,k}$ can be categorized into a variable $y_{i,k}$ by defining $y_{i,k} = j \equiv x_{i,k} \in \sigma_k^j$ with $j \in \{1,\ldots,j_k\}$. The data extracted from the federated model sharing registries were then converted into a multivariate contingency table (S) of the patient counts for all combinations of all variables—that is, $S = \{(\sigma_0, \sigma_1,\ldots, \sigma_{K,c}): \sigma_K \in \sum_{k,c} = \sum_{i=1}^{N} I[x_{i,0} \in \sigma_0, x_{i,1} \in \sigma_1,\ldots,x_{i,k} \in \sigma_k]\}$, where $I[.]$ is the indicator function.

This set is conveniently represented as a table by considering each element of the set as a row and the columns consisting of different variable names and patient counts. This table was subsequently stored on the central platform. The same computation was performed on the direct entry and core data

set, as the raw data were available on the central platform, resulting in their specific binned count tables. Finally, all data sources were aggregated by combining their respective binned counts representation *S*. The aggregation was performed by adding the patient counts of each data source for each subgroup of variables. Then, the aggregate set was expanded into a more extended table by repeating each row several times equal to the patient count of that specific row, which resulted in a table $X \in R^{N \times K}$, with *K* as the number of variables used in the analysis and *N* as the number of patients.

Data Analysis

Following the careful integration of a diverse data set, the pivotal challenge lay in deriving actionable insights. The GDSI analysis pipeline was uniquely engineered to remain agnostic to specific clinical research inquiries. Its versatile design permitted any statistical analysis to be executed based on the variables outlined in the data integration table. The efficacy of this approach is exemplified by its application to various research questions, as highlighted in [7,16,17,19]. The analytical approach implemented by Simpson-Yap and colleagues [7] was adopted for the purpose of this paper. A multilevel mixed-effects logistic regression was employed to analyze the aggregated data table. This was performed to assess the association between disease-modifying therapies (DMTs) and several outcomes, including hospitalization, intensive care unit admission, ventilation, and death, while adjusting for variables such as age, sex, MS phenotype, and disability score. The goal of this evaluation was to determine the impact of MS-specific therapies on the severity of COVID-19. This statistical model provided a fine understanding of the complex relationship between these therapies and disease outcomes.

Results

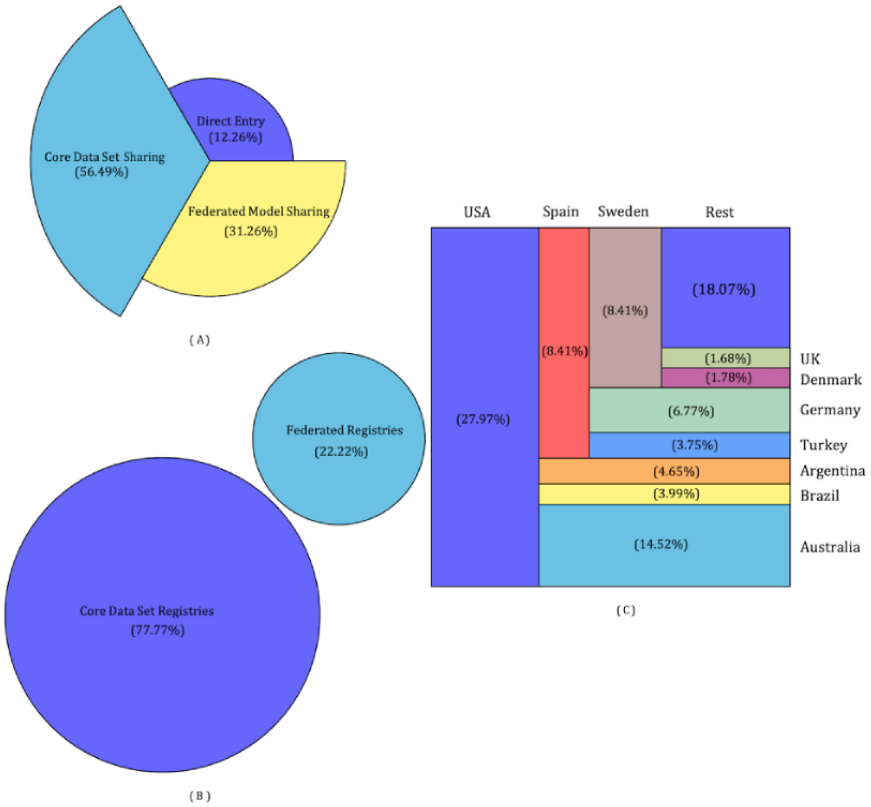
Data Acquisition

Using the pragmatic 3-layer approach of GDSI, we obtained the largest cohort of people with MS infected with COVID-19. The data were collected from 80 countries, with the top 10 contributing countries being the United States (3157/11,284, 27.97%), Australia (1639/11,284, 14.52%), Spain (949/11,284, 8.41%), Sweden (949/11,284, 8.41%), Germany (765/11,284, 6.77%), Argentina (525/11,284, 4.65%), Brazil (451/11,284, 3.99%), Turkey (424/11,284, 3.75%), Denmark (201/11,284, 1.78%), and the United Kingdom (190/11,284, 1.68%), which accounted for over 80% of the total number of records. Via direct entry, data were collected from 67 countries, with Spain contributing the largest number of records (758/1383, 54.80%), followed by the Netherlands (95/1383, 6.86%), United Kingdom (80/1383, 5.78%), United States (53/1383, 3.83%), Australia (40/1383, 2.89%), and 62 other countries (357/1383, 25.81%), resulting in a total of 1383 records. Data were collected from 18 different registries worldwide. Fourteen of these participated in core data set sharing, contributing to 6374 records. Meanwhile, 4 used the federated model sharing approach, contributing to an additional 3527 records. Table 2 enumerates these data sources. Figure 4 summarizes the number of records acquired at each stream of the data acquisition pipeline. Data acquired through direct entry have been released and are accessible through the associated PhysioNet repository [35].

Table 2. Data acquisition summary in the global data sharing initiative (N=11,284).

Method of data sharing	Values, n (%)
Direct entry	1383 (12.26)
Core data set sharing	6374 (56.49)
Federated model sharing	3527 (31.26)

Figure 4. Summary of the data acquired by implementing the 3-layer data acquisition. (A) Federated registries contribute to 31.26% (3527/11,284) of the data, while core data set sharing accounts for 56.49% (6374/11,284). (B) Only 22% (4/18) of the registries participated as federated registries. (C) A summary of the top 10 countries contributing data.



Data Analysis

Within the data analysis conducted to assess the impact of different DMTs on COVID-19 severity [7], random effects were grouped by data sources. The following variables were used: age, sex, MS phenotype, disability score, DMTs, and COVID-19 severity. Age was categorized in the following ranges: Σ_{age} = (18-50 years, 50-70 years, >70 years). Sex was binarized into male and female. MS phenotype was binarized into relapsing-remitting MS and progressive MS. The disability score was dichotomized into $\Sigma_{\text{Expanded Disability Status Scale}}$ = (0,6),(6,10). DMTs were categorized into Σ_{DMT} = (untreated, alemtuzumab, cladribine, dimethyl fumarate, fingolimod, glatiramer acetate, interferon, natalizumab, ocrelizumab, rituximab, teriflunomide, and other). COVID-19 severity was categorized into $\Sigma_{severity}$ = (hospitalization, intensive care unit admission, ventilation, death). Compared to patients using all other DMTs, those using rituximab had a higher risk of hospitalization (adjusted odds ratio [aOR] 2.76, 95% CI 1.87-4.07), intensive care unit admission (aOR 4.32, 95% CI 2.27-8.23), and artificial ventilation (aOR 6.15, 95% CI 3.09-12.27). Ocrelizumab showed similar trends for hospitalization (aOR 1.75, 95% CI 1.29-2.38) and intensive care unit admission (aOR 2.55, 95% CI 1.49-4.36) but not ventilation (aOR 1.60, 95% CI 0.82-3.14). Neither rituximab (aOR 1.72, 95% CI 0.58-5.10) nor ocrelizumab (aOR 0.73, 95% CI 0.32-1.70) were significantly associated with the risk of death. A comprehensive report of these findings can be found in Simpson-Yap et al [7].

Discussion

Insights From the GDSI Study on MS and COVID-19

The COVID-19 pandemic underscored a pressing need to understand its effect on people with MS. Recognizing the criticality of solid evidence for disease management, a global strategy involving neurologists, patients, and registries was adopted. This collaborative approach paved the way for GDSI's formation and the development of an end-to-end RWD analysis pipeline. Through this effort, GDSI emerged as the most comprehensive federated international cohort of people with MS impacted by COVID-19, becoming an invaluable resource for informed decision-making. Nevertheless, deriving conclusions from such data initiatives requires careful consideration of the inherent limitations of observational study designs. These studies provide unparalleled real-world insights, but it remains essential to situate the data within the confines of each study's specific limitations, especially when drawing from post hoc analyses based on existing information [36]. Although GDSI showcased significant advancements, challenges inherent to its structure and execution were encountered. In this section, these challenges are delineated, encompassing aspects from data collection and analysis to concerns of interoperability, data quality, governance, data sharing, and privacy. By exploring these areas, insights are provided to optimize future initiatives and fully harness the potential of RWD in the context of global collaborative learning.

Challenges and Solutions in Data Interoperability, Quality, and Governance

Interoperability and handling heterogenous data formats presented significant hurdles for GDSI. To counteract these challenges, a study-specific data dictionary was created. However, more advanced standardization methods such as a common data model [37], including Fast Healthcare Interoperability Resources [38] and Observational Medical Outcomes Partnership [39], could further enhance standardization, making it more generalized and disease-agnostic [40,41]. Building on the necessity for standardization, the significance of data quality has been universally recognized in health care, as also highlighted by various studies [42-45]. In tandem with standardization efforts, GDSI integrated an automated data quality assessment framework into its data acquisition process. However, the adoption of a generalized framework such as [46] can serve as a blueprint for enhancing data quality across various health care contexts, providing a more structured format to ensure reliability and precision. As GDSI confronted challenges related to interoperability and data quality, the initiative also had to navigate the complex landscape of regulatory compliance. Implementing a federated governance model, GDSI effectively addressed the existing needs but simultaneously revealed a gap for a data governance model in health care, namely, the absence of implementations specifically tailored for a federated framework [47]. A more universal data governance model such as the one proposed by Peregrina et al [48] could potentially fill this gap, enhancing both organizational efficiency and the quality of analytical models.

Embracing Federated Model Sharing and Privacy Concerns

Although federated model sharing offers a unique approach to draw insights from patient-level data, it is worth acknowledging that even the impersonal shared statistics inherently encode some information [49]. However, these potential risks are managed under the strict supervision of GDSI, which operates within a rigorously regulated and controlled environment with trusted partners. To further mitigate risks, the data custodians in the federated model sharing underwent a formal assessment of privacy risks after running the script and before sharing the aggregated data with the central platform. This additional layer of scrutiny ensured that any potential privacy concerns were addressed prior to data dissemination. Potential risks and their mitigation strategies were transparently communicated to all data providers via a clear analysis plan, thereby striking a robust balance between efficient data use and strict privacy and security standards. Although GDSI's federated model sharing has proven successful, it falls short in one crucial area: iterative asynchronous communication. This oversight leads to the introduction of federated learning [50], a methodology wherein a machine learning algorithm extracts knowledge from a variety of locally stored data without the need to transfer raw data enabling deploying sophisticated analysis [51]. Nonetheless, it is vital to recognize the associated risks and challenges. Federated learning or, in general, federated model sharing is not invulnerable to attacks [52,53] or privacy breaches [49].

Considering these risks, it might be necessary to re-evaluate GDSI's current assumptions of trustworthiness, inquisitiveness, and nonantagonistic behavior among all participants for a wider scope of application. Incorporating privacy-preserving algorithms such as differential privacy [54] and homomorphic encryption [55] can bolster security measures, though potentially affecting analytical performance or necessitating extensive computational resources [56]. Despite these challenges, federated learning has shown promise in a range of studies [57-61]. However, most of these analyses were tailored to specific use cases. There remains a need for a more generalized federated learning pipeline that can be applied broadly, rather than being limited to project-specific applications [62].

Recognizing the inherent risks in the federated approach, GDSI took proactive steps to ensure privacy and build trust within the entire pipeline. In response to concerns regarding privacy and tool reliability, GDSI adopted privacy-by-design principles and utilized certified toolboxes that underwent third-party verification. This approach emphasizes the continual need for assessment and evaluation of privacy safeguards.

Enhancing Collaboration: User Engagement in the GDSI Pipeline

As GDSI delved deeper into privacy and security measures, it became evident that an improved user experience was pivotal for the pipeline's success. The intricate nature of the RWD analysis pipeline, coupled with its limited visualization capabilities and an initial oversight in stakeholder inclusion, gave rise to a black box perception. Recognizing the urgent need for better communication and more user-friendly tools, GDSI instituted a dedicated task force. This team took charge from the study's inception to the formulation of evidence-based guidelines, guaranteeing that every stage aligned with the multifaceted needs of all stakeholders. By doing so, GDSI not only fostered trust and collaboration but also strongly resonated with the project's overarching principles of engagement and transparency.

The deployment of GDSI's user-centric interactive web application, complemented by detailed documentation and illustrative visuals, helped demystify the pipeline's complexity. By offering accessible and user-friendly tools, this approach fostered a more nuanced stakeholder engagement, bridging the divide between intricate operations and approachability. The effectiveness of visualization in health care is supported by various studies [63-66]. Tools such as Jaspersoft [67], Tableau [68], Looker [69], Domo [70], Tibco Spotfire [71], and Power BI [71] offer a business-level data analytics platform, underscoring the significance of converting intricate data sets into comprehensible visuals.

Pragmatism in GDSI: Balancing Innovation and Adaptation

In the conceptualization and development of GDSI, striking a balance between advanced innovation and practical inclusivity was paramount. This principle was clearly manifested in the design of the data acquisition architecture. Typically, health care frameworks gravitate toward a federated or centralized model. Yet, GDSI embraced a hybrid strategy, seeking to cater

to a broad spectrum of users and registries. This novel approach marked a significant departure from the norm, merging technological advancement with operational flexibility.

However, with innovation comes challenges. Although GDSI's analysis pipeline presents a viable technical solution for collaborative health care learning, it also grappled with broader societal challenges. One salient example was the containerization strategy. Initially promising, it met resistance from certain federated model–sharing registries because of their internal policies. Such challenges underscore the ever-present demand for adaptability amid rapid technological shifts. However, GDSI responded proactively, making the source code available and bolstering it with a comprehensive manual and robust support. Such measures exemplify GDSI's commitment to reconciling groundbreaking advancements with real-world constraints.

This commitment extended beyond technical challenges. The global reach of GDSI emphasized the importance of resource efficiency, especially in regions with limited internet connectivity. In striving for a global impact, GDSI reiterated its pledge to balance technological progress with practical considerations across diverse geographies. In light of these experiences, one thing becomes clear for the success of initiatives like GDSI: continuous education, proactive stakeholder engagement, and evidence-based demonstrations in controlled environments are not just beneficial, but they are essential.

GDSI as a Blueprint for Data-Sharing Initiatives in Biomedical Research

GDSI emerged as a pragmatic blueprint for interdisciplinary biomedical research. The meticulous planning and systematic execution of the initiative showcased how strategic processes can serve as foundational guides for upcoming biomedical consortia. The open-source resources GDSI provides [23,25,29,30,32,34,35,72-74] can be directly leveraged and adjusted after thorough assessment and evaluation. These resources bifurcate into 2 main categories: disease-agnostic and disease-specific components.

Within the context of disease-agnostic components, the architecture of GDSI's end-to-end data analysis pipeline stands out, highlighting its modularity and adaptability. This pipeline's design facilitates significant customization, catering to various data acquisition streams. The hybrid nature of the data acquisition module allows initiatives to choose one or a combination of data collection methods based on their distinct needs and policies. Additionally, GDSI's data integration framework plays a crucial role in amalgamating these diverse data sources into a unified and comprehensive data set. Together, these components offer a versatile foundation that other biomedical initiatives can adapt and leverage according to their specific requirements.

Turning to disease-specific components, aspects like the data dictionary and data quality assessments were designed primarily for the research question centered around MS and COVID-19. Even though these components are specialized, they act as guiding principles for other research ventures. The data dictionary, augmented by its metadata, provides a robust foundation for the next phases of the pipeline. It offers a detailed account of acquisition variables and sets clear data quality criteria. A significant point to note is that the data dictionary aids in determining the rules for data quality assessments, presenting a methodical approach to data validation. This thorough approach emphasizes the importance of precise planning and specificity when delving into disease-focused research questions, setting an example for other initiatives to follow.

To conclude, the flexibility and adaptability inherent in GDSI's comprehensive data analysis pipeline coupled with its disease-specific components meld to present a versatile tool for crafting sturdy data architectures across a spectrum of biomedical research landscapes. Those seeking a deeper understanding and guidance on harnessing and replicating GDSI's capabilities can refer to Multimedia Appendix 3, which offers a detailed roadmap based on GDSI's experiences and insights, a flowchart tracing the initiative from its inception to its research question resolutions, and guidance on replicating GDSI's federated model sharing infrastructure. A graphical abstract delineating the high-level architecture of this study is presented in Multimedia Appendix 4, which provides additional insights regarding the architectural framework.

Conclusion

GDSI had substantial impact that extended beyond its initial focus on COVID-19 and MS. It contributed to numerous scientific publications and played a pivotal role in shaping global guidelines for the community with MS [7,9,16-19]. This underscores the vast potential of data-driven collaborative efforts to yield improved health care outcomes. A cornerstone of GDSI's success was its RWD analysis pipeline. Crafted to navigate technical, epidemiological, and sociological challenges, this pipeline facilitated the seamless integration of varied data streams into a single data set. This cohesive strategy enabled large-scale collaborative research and offered the flexibility to accommodate the diverse policies, regulations, and needs of various data providers. Serving as a practical blueprint, GDSI addressed not only current health care challenges but also laid the groundwork for future initiatives. Its hybrid approach to data acquisition and analysis provided a scalable framework applicable to other health care sectors. In doing so, GDSI stands as a compelling example of how data sharing and collaborative learning can meaningfully advance health care research, going beyond the specific challenges of MS and COVID-19.

Acknowledgments

The author(s) have disclosed that they received financial support for the research, authorship, or publication of this paper from the following sources: the operational costs associated with this study were funded by the Multiple Sclerosis International Federation and the Multiple Sclerosis Data Alliance (MSDA) operating under the European Charcot Foundation. The MSDA is a global not-for-profit multistakeholder collaboration acting under the umbrella of the European Charcot Foundation, financially supported by a combination of industry partners, including Novartis, Merck, Biogen, Janssen, Bristol-Myers Squibb, and Roche. Additionally, this work was supported by the Flemish government through the Onderzoeksprogramma Artificiële Intelligentie Vlaanderen program and the Research Foundation Flanders for ELIXIR Belgium. QMENTA provided the central platform, while Amazon supplied the computational resources utilized in this work. The statistical analysis was conducted at the Clinical Outcomes Research Unit, The University of Melbourne, with support from National Health and Medical Research Council (1129189 and 1140766). The authors wish to extend their sincere appreciation to Nikola Lazovski for his invaluable guidance and collaboration throughout the global data sharing initiative project, especially concerning the central platform. They are also profoundly grateful to Dr Ilse Vermeulen for her unwavering support and encouragement throughout the various stages of drafting and conceptualizing the manuscript.

Authors' Contributions

AP played a major role in acquiring the data, designing the federated infrastructures, and drafting and revising the manuscript for content. LG and TP contributed to manuscript drafting and revision for content. EDB contributed to manuscript drafting and revision, played a major role in acquiring data, and contributed to the study concept or design as well as the analysis or interpretation of data. YM and LMP provided overall supervision and coordination of the study and contributed to manuscript drafting and revision for content, including writing for content.

Conflicts of Interest

AP and YM are funded by VLAIO (Flanders Innovation and Entrepreneurship) PM: Augmenting Therapeutic Effectiveness through Novel Analytics (HBC.2019.2528) and Research Council Katholieke Universiteit Leuven: Symbiosis 4 (C14/22/125) and Symbiosis 3 (C14/18/092; CELSA - Active Learning; CELSA/21/019). AP and YM are affiliated to Leuven.AI and received funding from the Flemish government (Artificial Intelligence Research Program, Research Foundation Flanders [FWO] Strategic Basic [SB] Research; S003422N). EDB was funded by an FWO-SB grant. LMP is the chair of MSDA, which received income from a range of corporate sponsors, including Biogen, Bristol Myers Squibb, Janssen Pharmaceuticals, Merck, Novartis, and Roche. LG is funded by the Flemish government under the Onderzoeksprogramma Artificiele Intelligentie Vlaanderen. TP is funded by the Flemish government under the Bijzonder Onderzoeksfonds special research fund BOF22OWB01.

Abstract

Background: The creation of computer-supported collaborative clinical cases is an area of educational research that has been widely studied. However, the reuse of cases and their sharing with other platforms is a problem, as it encapsulates knowledge in isolated platforms without interoperability. This paper proposed a workflow ecosystem for the collaborative design and distribution of clinical cases through web-based computing platforms that (1) allow medical students to create clinical cases collaboratively in a dedicated environment; (2) make it possible to export these clinical cases in terms of the Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) interoperability standard; (3) provide support to transform imported cases into learning object repositories; and (4) use e-learning standards (eg, Instructional Management Systems Content Packaging [IMS-CP] or Sharable Content Object Reference Model [SCORM]) to incorporate this content into widely-used learning management systems (LMSs), letting medical students democratize a valuable knowledge that would otherwise be confined within proprietary platforms.

Objective: This study aimed to demonstrate the feasibility of developing a workflow ecosystem based on IT platforms to enable the collaborative creation, export, and deployment of clinical cases.

Methods: The ecosystem infrastructure for computer-supported collaborative design of standardized clinical cases consists of three platforms: (1) Mosaico, a platform used in the design of clinical cases; (2) Clavy, a tool for the flexible management of learning object repositories, which is used to orchestrate the transformation and processing of these clinical cases; and (3) Moodle, an LMS that is geared toward publishing the processed clinical cases and delivering their course deployment stages in IMS-CP or SCORM format. The generation of cases in Mosaico is exported in the HL7 FHIR interoperability standard to Clavy, which is then responsible for creating and deploying a learning object in Moodle.

Results: The main result was an interoperable ecosystem that demonstrates the feasibility of automating the stages of collaborative clinical case creation, export through HL7 FHIR standards, and deployment in an LMS. This ecosystem enables the generation of IMS-CPs associated with the original Mosaico clinical cases that can be deployed in conventional third-party LMSs, thus allowing the democratization and sharing of clinical cases to different platforms in standard and interoperable formats.

Conclusions: In this paper, we proposed, implemented, and demonstrated the feasibility of developing a standards-based workflow that interoperates multiple platforms with heterogeneous technologies to create, transform, and deploy clinical cases on the web. This achieves the objective of transforming the created cases into a platform for web-based deployment in an LMS.

collaborative learning; interoperability; case-based learning; standards; clinical cases; collaborative clinical cases

Introduction

In March 2020, the World Health Organization (WHO) declared COVID-19 a pandemic [1], directly affecting traditional teaching in medical schools worldwide [2,3]. As a result, at the beginning of April 2020, classroom training activities were suspended at all universities, and students' clinical training was disrupted by the collapse of public and private hospitals [4]. This situation has prompted new teaching strategies for medical students, who could not attend traditional clinical rotations, representing one of the main challenges in this educational context [5]. In this sense, COVID-19 triggered alternative IT-based medical education methodologies, with synchronous and asynchronous mechanisms to be deployed in web-based learning environments

[6]. Afterward, web-based medical education's need for content production has quickly become apparent.

Computer-supported, didactic medical content production in web-based environments demands innovative platforms that enable collaboration among medical students and instructors. Mosaico is an example of a web platform [7] that allows users to design, perform, and assess collaborative clinical scenarios for medical students. Similar platforms have been developed to foster collaborative learning for medical education. For example, Osmosis [8] is a web and mobile learning platform that provides access to multiple clinical questions and explanations for medical student self-assessments. Wikis have also been used as collaborative platforms to build and curate didactic content in graduate medical education [9]. Vicente et al [10] created a platform to enable collaborative learning in the context of the One Health initiative, which aimed to elaborate a corpus of graduate courses or modules in multiple health care disciplines. In addition, Alicanto [11] is a web-based collaboration platform for health care professionals that helps them to share educational resources or discuss clinical cases.

The main advantage of these platforms is to support the learning of groups of students who participate in collaborative activities oriented to generating clinical cases, supporting a didactic approach based on the collaborative design of clinical cases, whose educational value has been widely demonstrated. However, its main shortcoming is that the contents produced are usually oriented to self-consumption within the tools. This restriction limits the reuse of content by not having the ability to export to other platforms, such as conventional learning management systems (LMSs) [12].

Therefore, considering the multiple challenges imposed by the COVID-19 pandemic and the adequacy of practical teaching, it becomes evident that support technology for the teaching-learning processes must allow the export and sharing of the material generated. Thus, we must expand the frontiers of knowledge and open up the consumption of clinical cases created by tools at all levels, starting with LMS platforms. Otherwise, content reuse in contexts other than production tools will be seriously hampered. This paper aimed to address this problem.

We proposed using Mosaico as a platform for the computer-supported collaborative design of educational clinical cases through collaborative clinical simulation [13,14]. To extend and democratize the content generated, Mosaico was extended with an interoperability add-on implemented with an internationally accepted standard, Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) [15], which allows the designed clinical cases to be exported to a wide variety of third-party platforms. In addition, it allowed us to connect Mosaico with Clavy [16], a tool for managing learning object repositories that enables the transformation into a wide variety of formats and has demonstrated its applicability to the generation of medical learning content from preexisting medical collections. Using Clavy's transformation capabilities, clinical cases retrieved from Mosaico and rendered in HL7 FHIR can be transformed into standardized learning content formats that can be deployed in web-based LMSs such as Moodle or Blackboard, which ultimately enabled us to meet the goal of exporting collaboratively designed Mosaico clinical cases to widely used conventional web-based learning platforms. In this sense, we linked the generation of content with its deployment, sharing it with e-learning environments and extending its application and use by medical students, who can access and share clinical content in a standardized way.

To demonstrate the feasibility of the developed ecosystem, a clinical case of chest pain that considers the whole workflow (collaborative design, transformation, deployment, and consumption) is presented.

Methods

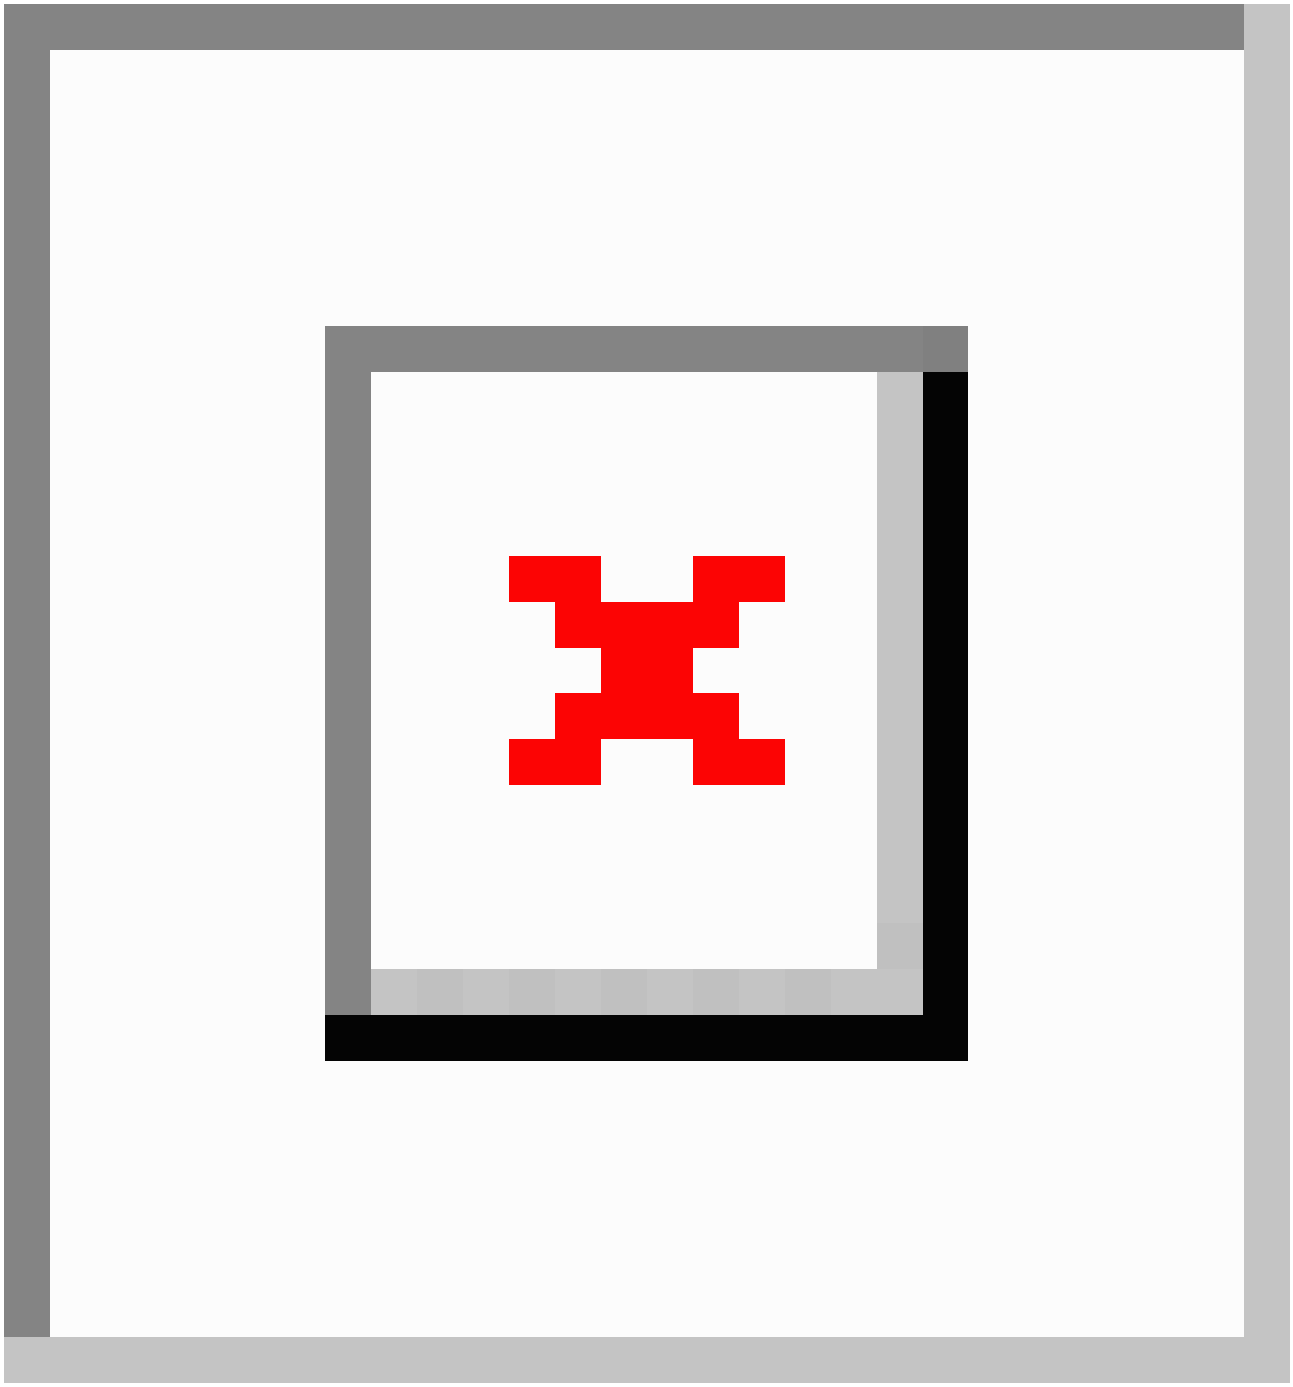
Overview

The collaborative design of clinical cases, created by medical students through a computer-based platform, supports integrating what has been learned and generating knowledge consumed by other students.

The activity diagram of Figure 1 depicts our approach to case-based learning in clinical undergraduate programs. According to this diagram, the approach comprises the following activities:

- *Collaborative design*: In this activity, while facilitated by a reputed instructor, a community of advanced students is involved in the collaborative production of clinical cases. This activity is carried out until the community reaches a clinical case that the instructor judges to be satisfactory.
- *Transformation*: In this activity, the collaboratively produced clinical cases are transformed by instructors into standardized learning packages. To do this, instructors can carry out different types of transformations, which take a given representation of clinical cases as input and generate refined representations as output. These transformations can be carried out automatically, semiautomatically (with instructors configuring some of the automatic processes involved), or manually (with instructors editing content with appropriate editing tools). The process evolves, in general, through several transformation steps until a suitable representation is reached, which is then directly exported into standardized e-learning packages.
- *Deployment*: In this activity, instructors can publish the e-learning packages resulting from the successive transformations into LMSs that support the e-learning standards used to code these content packages.
- *Consumption*: In this activity, less advanced students can take advantage of the conventional e-learning courses generated based on the clinical cases produced in the initial collaborative environment.

Figure 1. Activity diagram for the collaborative production and exploitation of clinical cases.



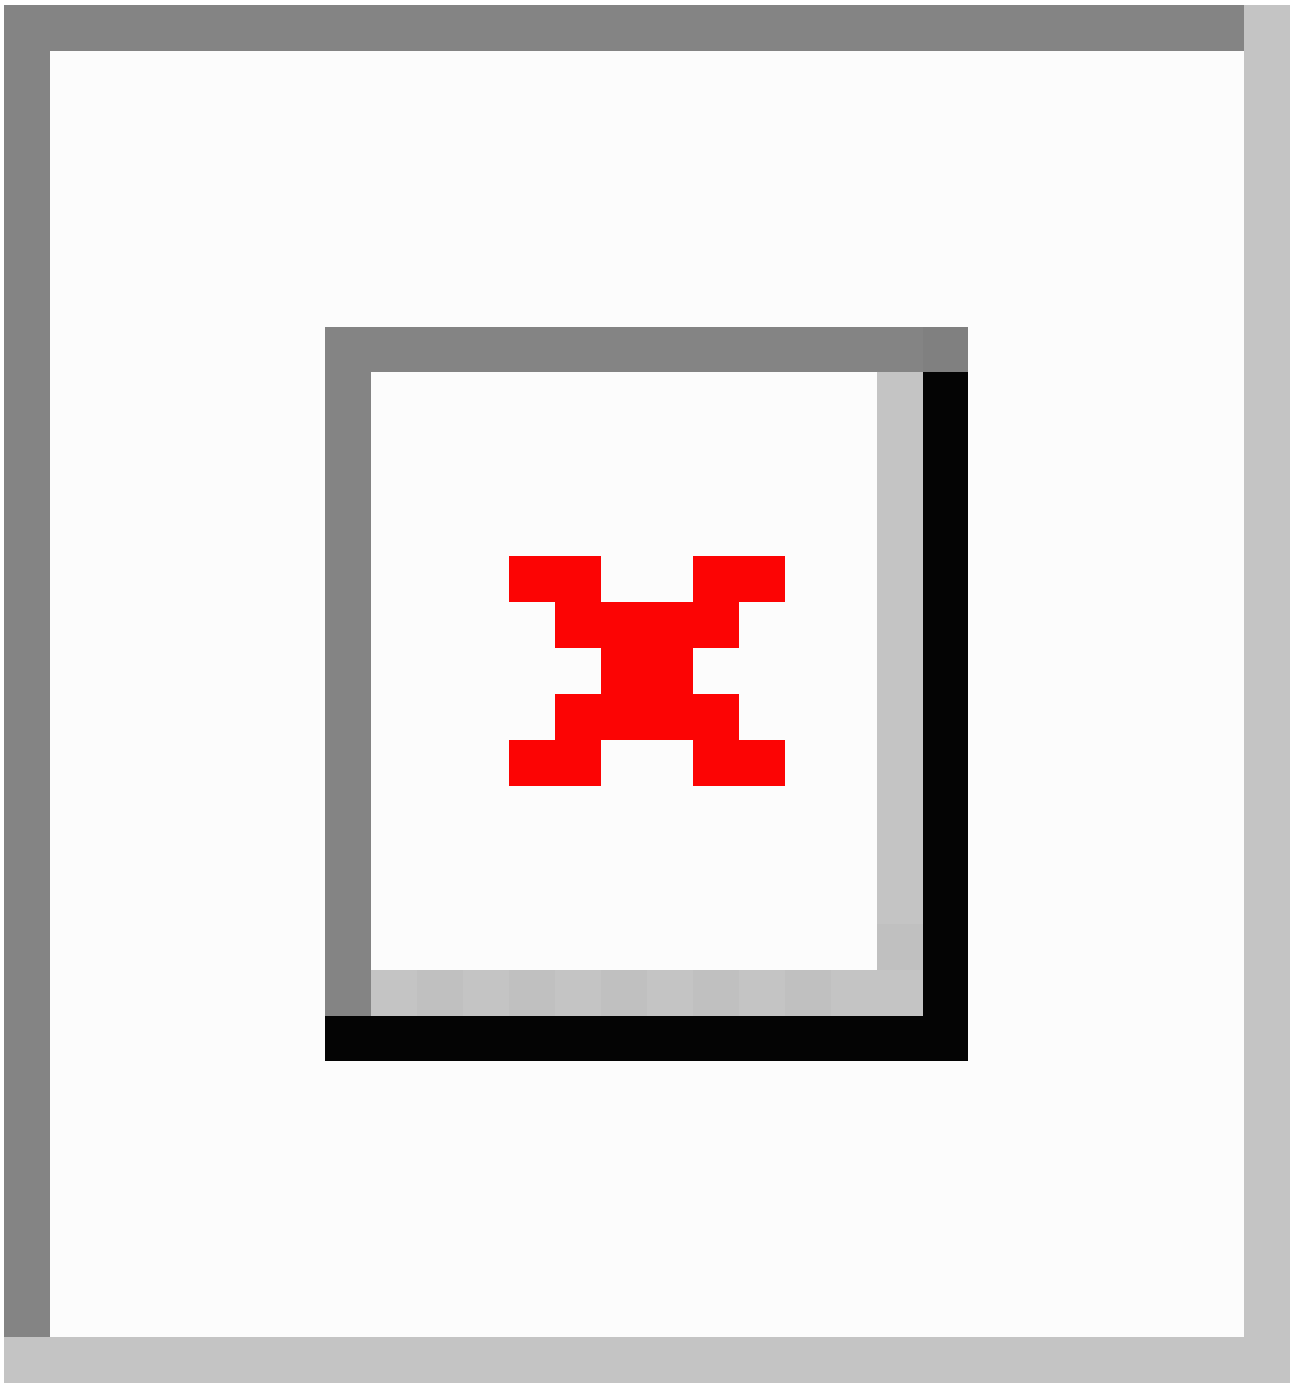
Consequently, learning occurs in two different scenarios:

1. Learning takes place during the collaborative design of clinical cases, which is oriented to the community of advanced learners mediated by the instructor (*Collaborative design* activity).
2. Once clinical cases are transformed by instructors into standardized learning packages, more conventional learning takes place based on content published in a standard LMS (*Consumption* activity).

In this context, we designed and developed a workflow ecosystem based on the collaborative cocreation of clinical cases, supported by technological platforms and global standards that allow for the standardization, export, and distribution of clinical cases for open and democratic consumption. This ecosystem, which is illustrated in Figure 2, integrates the following platforms:

- Mosaico: The platform is used in computer-supported collaborative design of clinical cases [7].
- Clavy: A tool for the flexible management of learning object repositories that is used to orchestrate the transformation stage [16].
- Moodle: The LMS orchestrates the publishing and course consumption stages in the Instructional Management Systems Content Packaging (IMS-CP) or Sharable Content Object Reference Model (SCORM) format [17].

Figure 2. Workflow of the collaborative creation of a clinical case, interoperable with Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) and packaged as Instructional Management Systems Content Packaging (IMS-CP) or Sharable Content Object Reference Model (SCORM) standard learning objects to be distributed in any learning management system (LMS) that reads these standards.

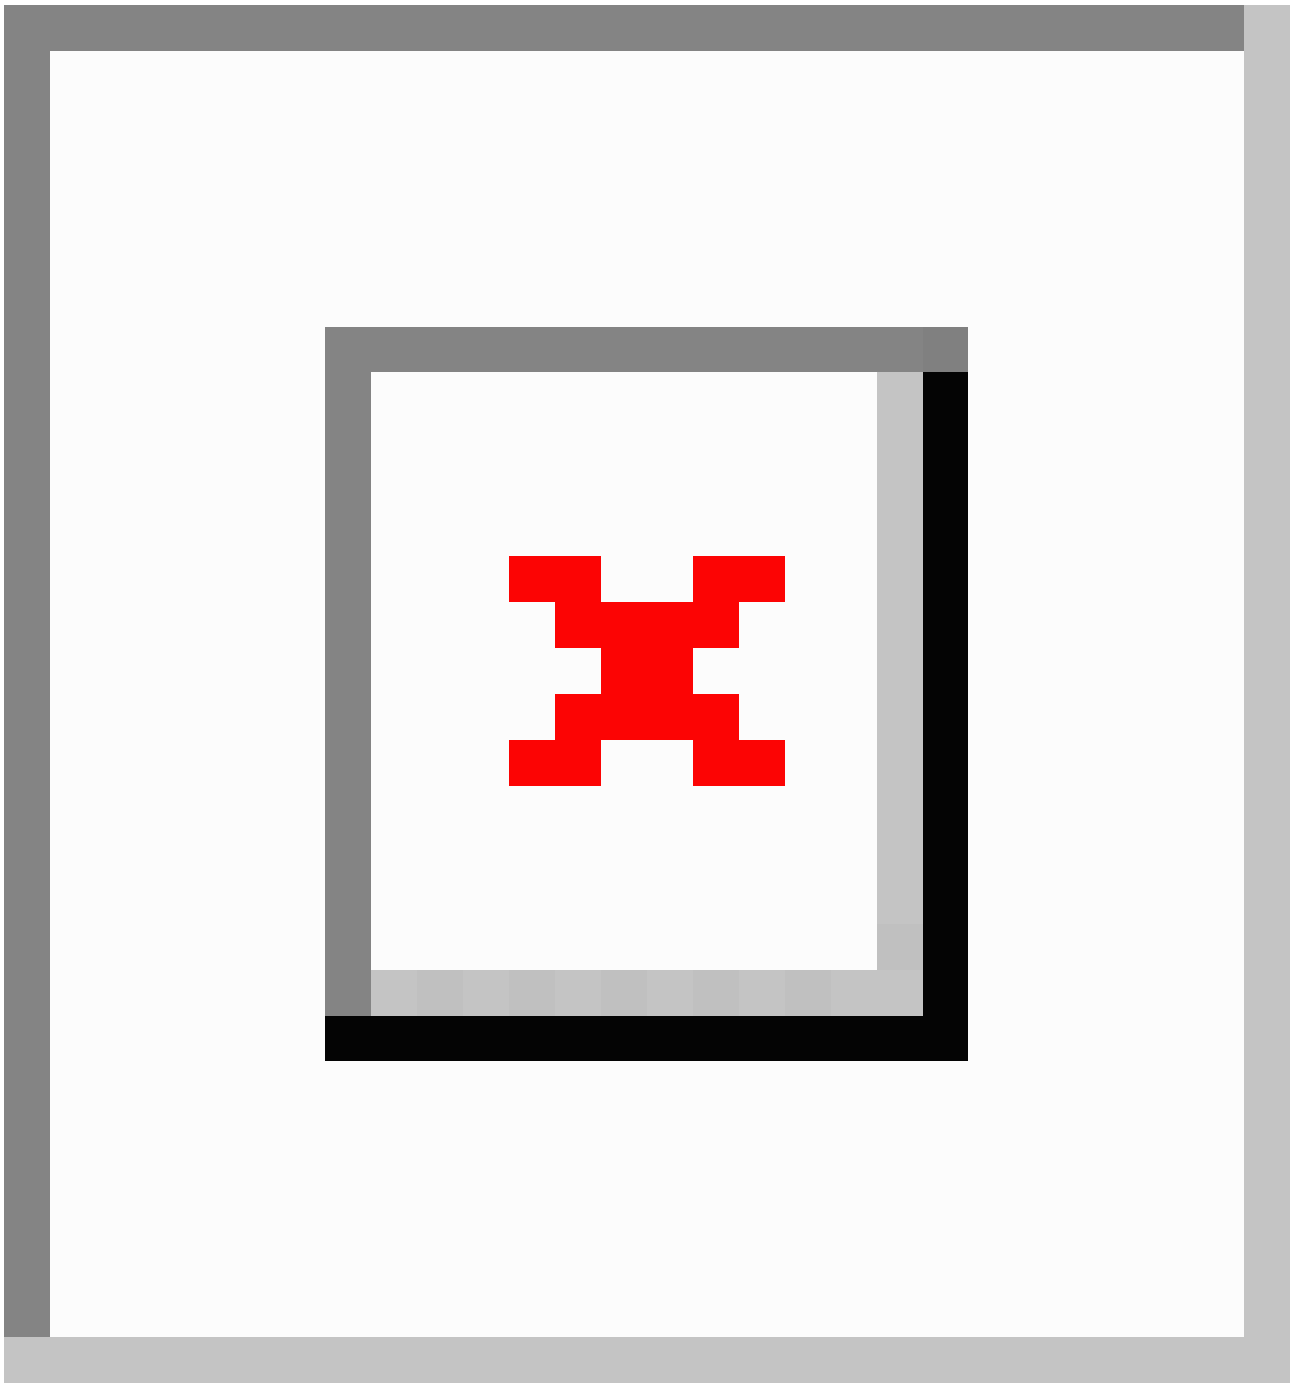


Mosaico for Designing, Performing, and Assessing Collaborative Clinical Cases

For the collaborative design of a clinical case, Mosaico provides standardized templates with all the information required. Students would write down relevant information about the clinical case, including age, sex, weight, height, physical exam, vital signs, laboratory tests, images, or videos (see Figure 3).

The web platform allows clinical cases to be generated, guided, and monitored; however, it stores them in a relational database. This does not allow records to be extracted and shared across heterogeneous technologies. In addition, Mosaico's lack of interoperability features limits the platform's use by forcing all institutions to use the same technology or make ad hoc integrations if they wish to benefit from the portfolio of clinical cases created.

Figure 3. Screenshot of the case design form provided by Mosaico, separated into the following sections: (A) patient information and vital signs, (**B**) patient's laboratory exams, and (C) images and videos (in this case, an x-ray of the thorax). HDL: high-density lipoprotein; LDL: low-density lipoprotein; VLDL: very low–density lipoprotein.



Extraction and Standardization of Clinical Cases

To provide Mosaico with interoperability capabilities, we proposed including a module that allows the transformation and export of clinical cases into a universal format—one that any other platform can easily read.

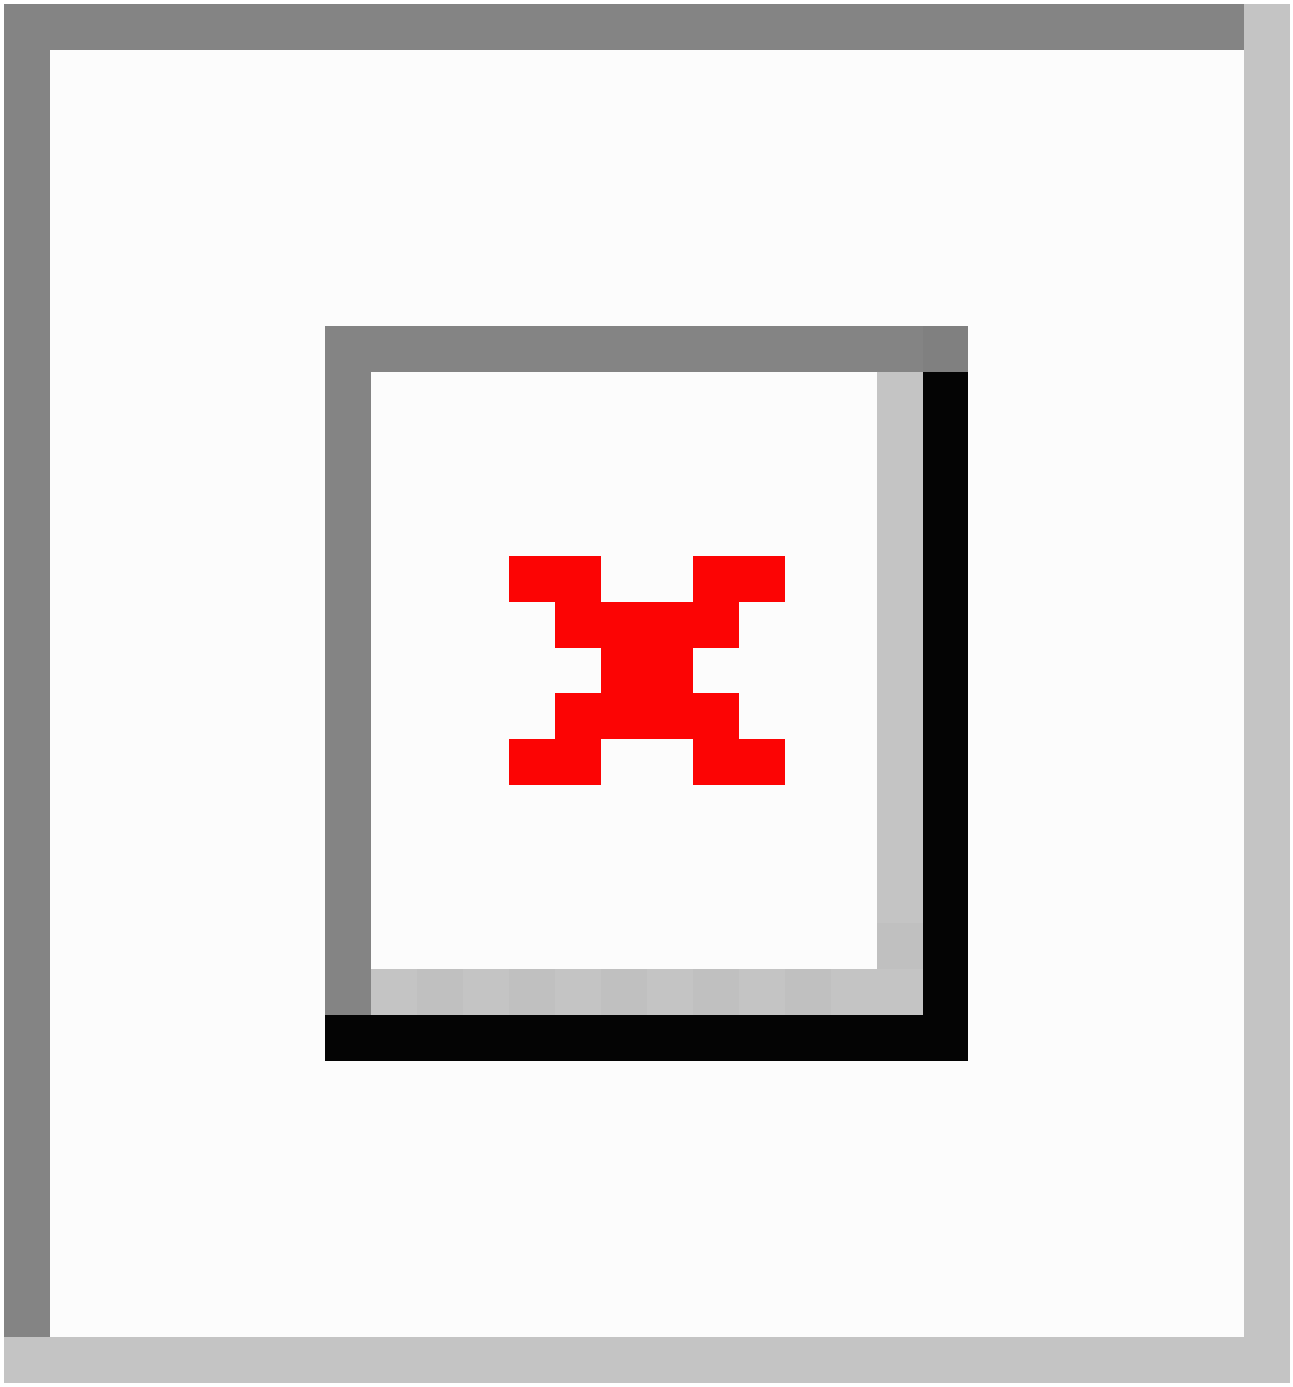
This module incorporates an interoperability layer designed and implemented through REST application programming interfaces [18] with HL7 FHIR [19] that offers clinical knowledge representation based on international standards. For this purpose, and according to the case design form provided by Mosaico (Figure 3), a set of HL7 FHIR resources would contain all the standardized clinical case information, making it easily exportable.

Transformation of Interoperable Clinical Cases With Clavy

Clavy is a learning object repository management platform based on formal grammars. Each Clavy repository comprises (1) a set of object schemata, which describes the structures of the different objects using formal grammars, and (2) the learning objects themselves. In addition, the platform fully supports Extract-Transform-Load (ETL) workflows with user-defined plug-ins and advanced editing facilities.

The tools integrated by Clavy can be accessed on the web and provide user-friendly interfaces to manage the repositories. Using these tools, domain experts without programming knowledge can use different transformations to reorganize the repository's structure, remove irrelevant information, and add new objects to this repository. For example, Figure 4 shows a screenshot that displays part of a specialized repository in the clinical domain, making it appear as a part of a schema-guided navigation tree, a part of the learning object collection, and a fragment of a particular learning object.

Figure 4. Clavy snapshot of a medical repository (navigation tree, learning object collection, and a particular learning object).



Results

Clinical Case

We applied our workflow ecosystem to generate standardized e-learning content for a relevant clinical case. The clinical case to show the proposed approach was related to a patient who consults for chest pain. The case was designed while considering all the clinical backgrounds necessary for its representation through a simulated patient. Furthermore, it was important to consider all the antecedents since the case will later be packaged and distributed to an LMS environment so that other students can consult it as study material.

Collaborative Chest Pain Case Development

Fourth-year medical students, along with an academic instructor from the University of Talca in Chile, developed the case in Mosaico by considering the following scenario:

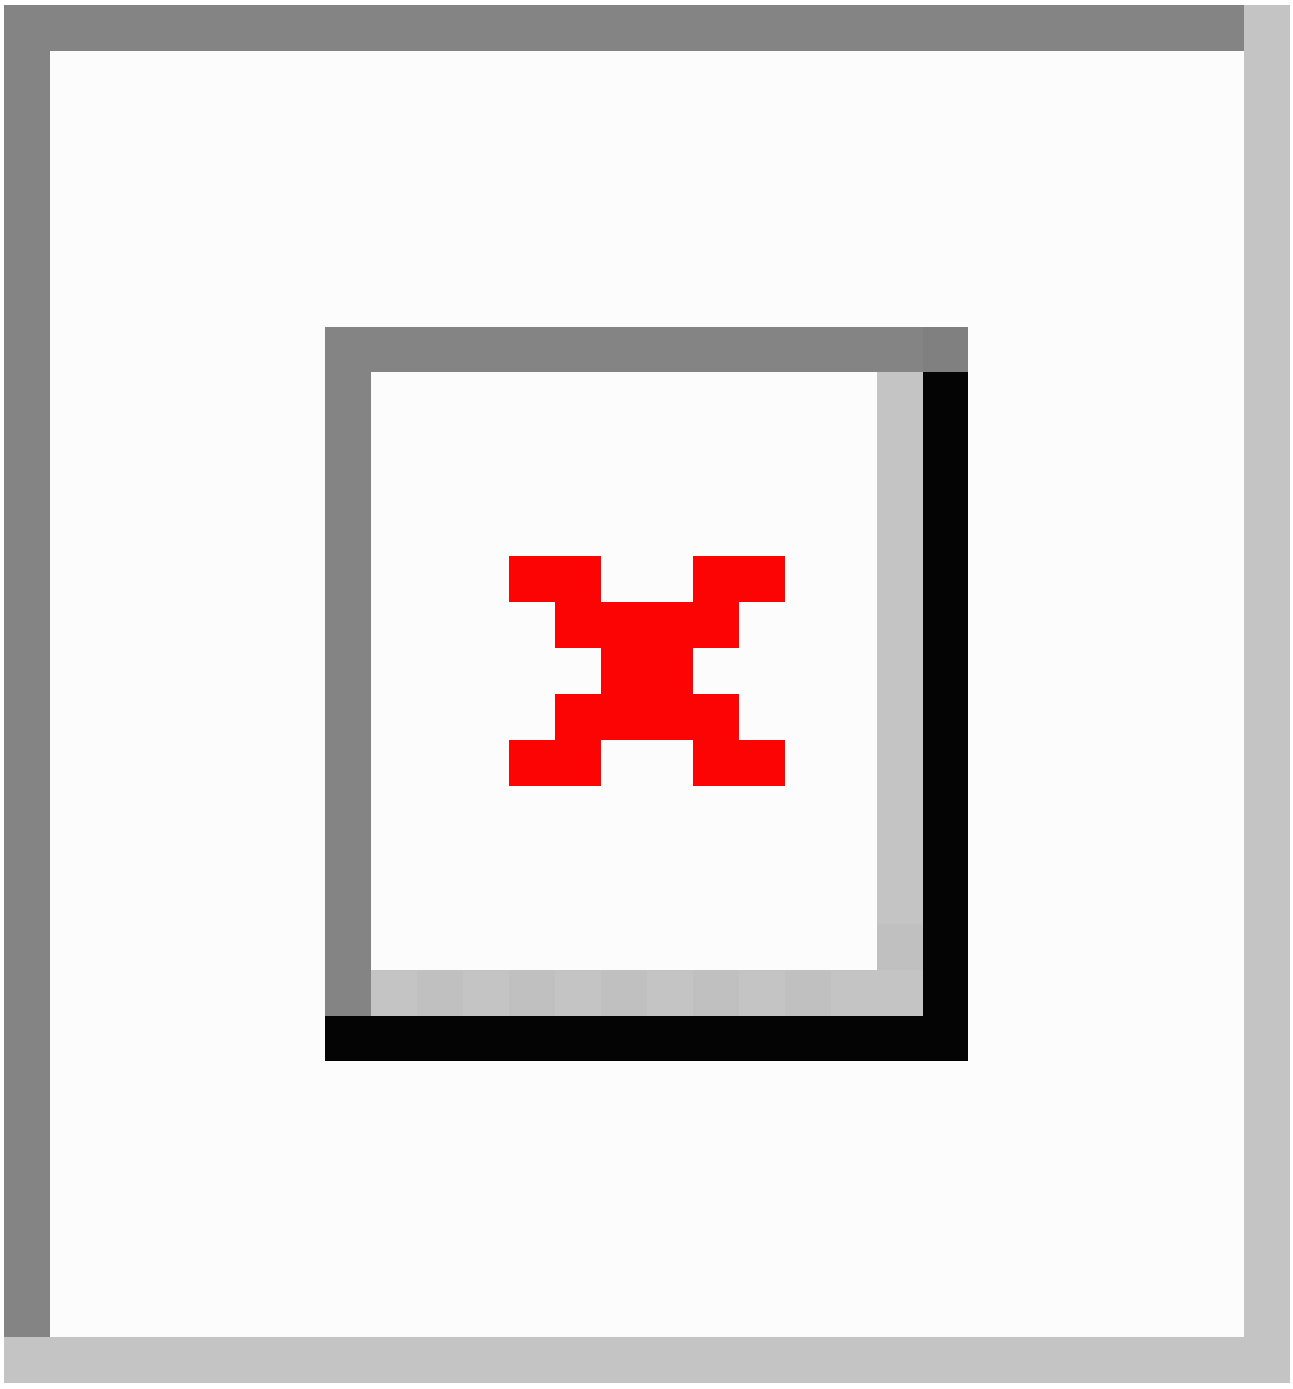
A 58-year-old male patient with a history of arterial hypertension (treated with 20 mg of enalapril every 12 h, which he takes irregularly), who works as an engineer 8 hours per day in an office, consults for oppressive chest pain in the precordial region, which is radiating to the neck and jaw, appearing at rest, and accompanied by coldness and cutaneous pallor that accentuated approximately 8 hours ago. He went to the hospital, was evaluated, and presented the following vital signs:

- Blood pressure: 170/115 mm Hg
- Heart rate: 95 beats per minute
- Respiratory rate: 22 respirations per minute
- Oxygen saturation: 98%
- Temperature: 36.7 °C

Moreover, the following complementary tests were incorporated: laboratory exams, chest x-rays, and an electrocardiogram taken in the hospital.

The case was created in Mosaico (see Figure 3) and stored in a MYSQL relational database; all data were then exported as HL7 FHIR resources. Figure 5 shows the resources involved, using a DiagnosticReport resource as the backbone of the case.

Figure 5. Chest pain case standardized with Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) resources and respective JSON structure. EKG: electrocardiogram; Rx: prescription.

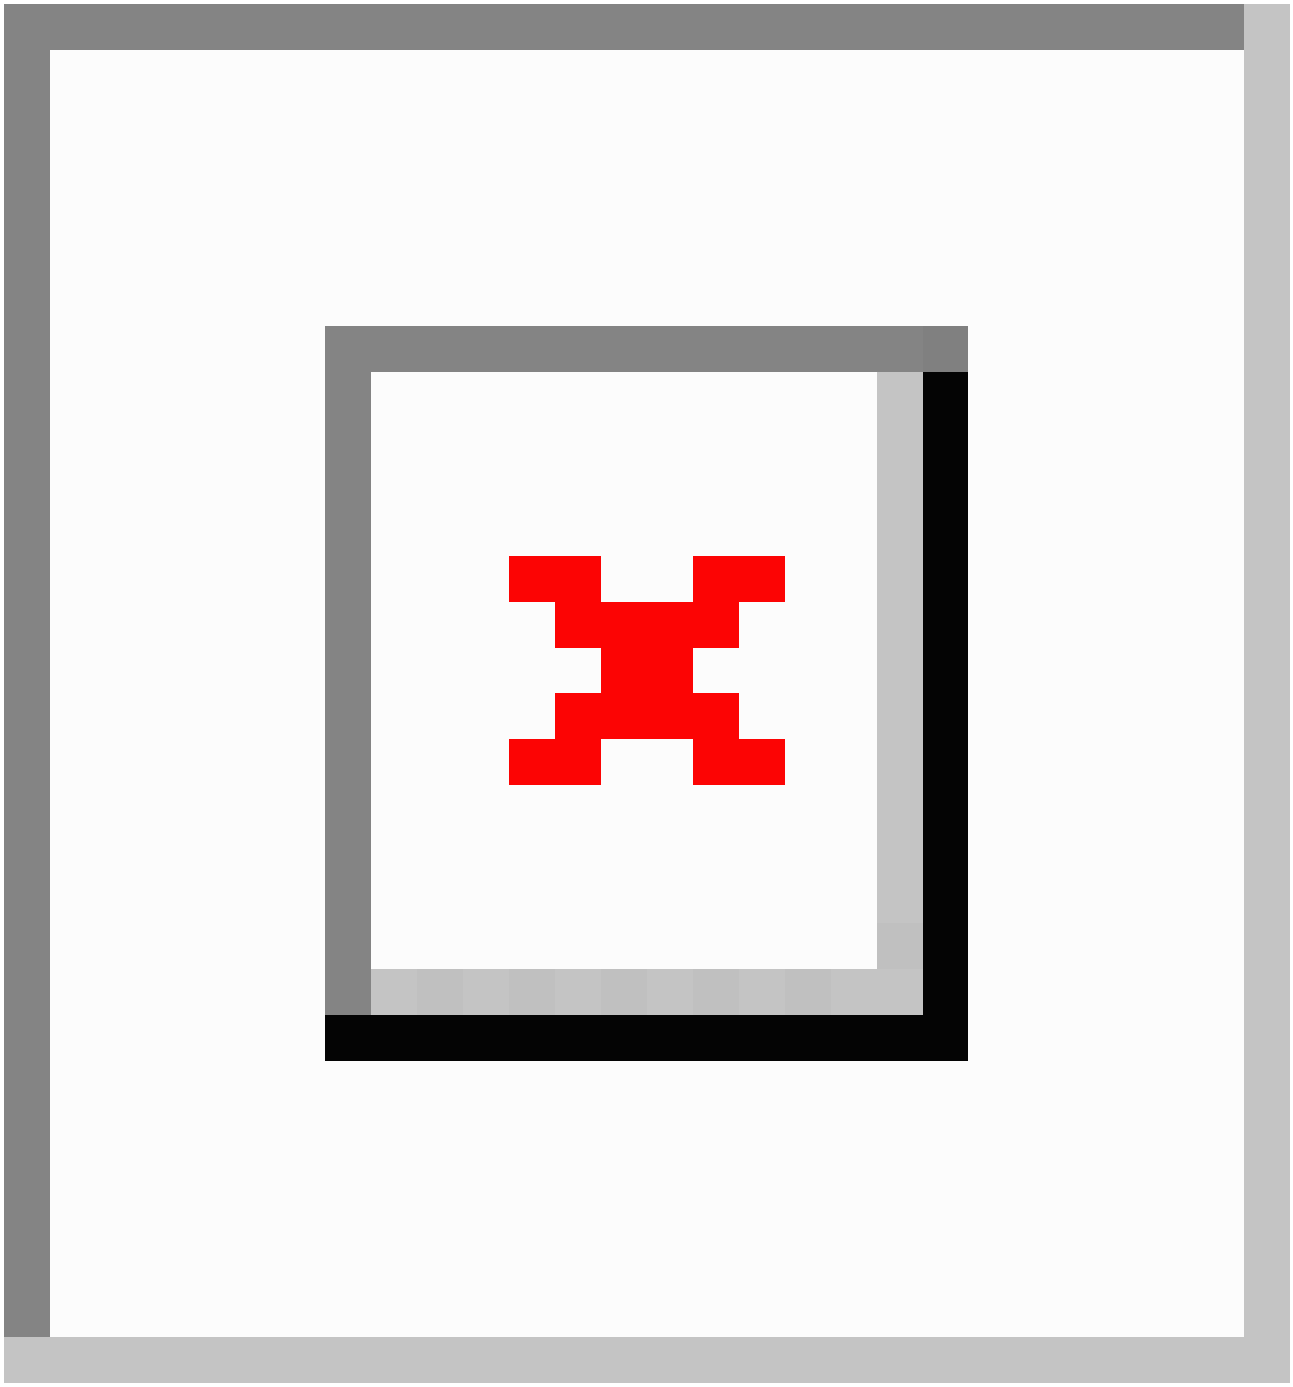


Use of Clavy to Generate Standardized e-Learning Content

Clavy was used to create an ETL pipeline to extract and transform the information created in Mosaico; this information could then be readily exported into IMS-CPs that could be deployed in an LMS, such as Moodle or Blackboard. In this way:

- The proposed pipeline begins with a generic JSON import plug-in, which lets Clavy ingest the Mosaico-generated JSON files encoding the HL7 FHIR entities associated with the clinical cases. As a result, a first repository is generated with (1) an object schema for each of the FHIR entity types ingested and (2) an object for each FHIR resource collected. Figure 6A shows a part of the Clavy schemata for the repository generated.
- Next, several automatic transformations are applied. The first transformation acts on the repository extracted by the JSON import plug-in to incorporate the FHIR semantics by making the relationships in FHIR instances explicit. The second transformation, in turn, enriches the repository with Systematized Nomenclature of Medicine (SNOMED) data. For this purpose, it detects SNOMED terms in learning objects, adds the SNOMED terms discovered to the repository as new objects, and links the FHIR entities with these new SNOMED objects as needed. Finally, the third transformation makes it possible to aggregate a set of interrelated FHIR entities into a single learning object. For this purpose, an entity that will act as the main one is selected, and a closure process is carried out to convert the nonhierarchical relationships into hierarchical ones. In this experience, the central entity chosen was the *Patient*.
- Finally, once a learning object repository focused on a particular kind of FHIR entity (*Patient*, in this case) is generated, its schema can be edited by using the Clavy repository editing facilities to accommodate all this information to the instructors' needs (in our case, the generation of standardized e-learning content). This experience allowed us to remove useless and irrelevant categories from the repository schema and, therefore, from the learning objects. Figure 6B illustrates the schema resulting from this editing step. Notice that, on the one hand, as produced by the previous transformation step, this schema characterizes only one type of learning object (*Patient*), aggregating all the relevant information in all the interrelated FHIR entities. However, on the other hand, many irrelevant FHIR information items from an educational point of view have been safely removed in this editing step.

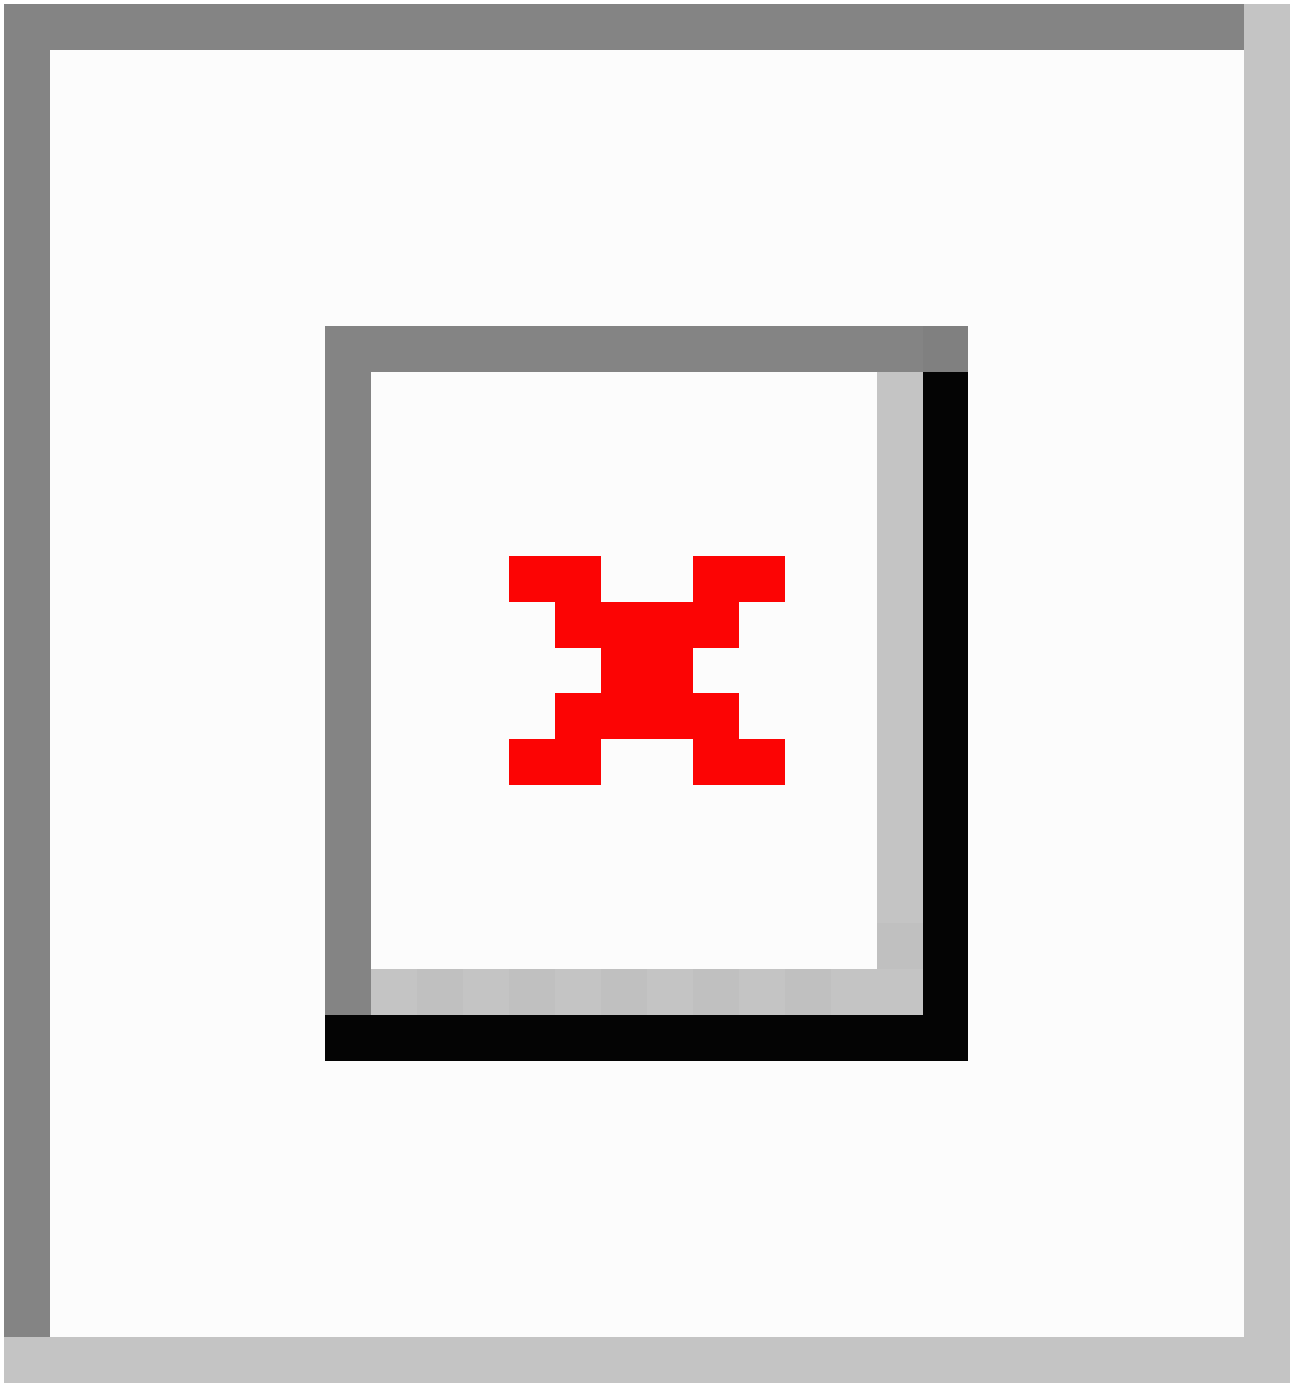
Figure 6. (A) Clavy schema for the Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) entities generated by Mosaico and (**B**) the schema for the repository that results after the transformation and editing steps.



Deployment of IMS-CP in LMS Environments

Once the information has been transformed into a structure that suits the instructors' needs, a suitable Clavy export plug-in can be applied to the resulting repository to package the clinical cases into standardized learning packages that can be loaded into conventional LMSs. In this experience, the clinical case was exported as IMS-CPs and incorporated into Moodle (see Figure 7A). Figure 7B shows an IMS-CP manifest file segment associated with the original Mosaico clinical case.

Figure 7. (**A)** A learning object associated with the Mosaico clinical case imported into Moodle's platform as an Instructional Management Systems Content Package (IMS-CP) and (**B**) an excerpt of the IMS-CP manifest file.



Discussion

Principal Findings

In this paper, we identified four key elements to enable the effective use of clinical cases in e-learning environments: (1) the effective authoring of cases, (2) the interoperability of authoring tools, (3) the transformation of cases into standard e-learning content packages, and (4) the publication of content packages on widely used e-learning platforms. For this purpose, we proposed a workflow that consistently addresses each of these critical aspects by forming a technology ecosystem supported by (1) the Mosaico collaborative clinical case authoring tool, which supports students and teachers in health care careers with the collaborative design of clinical cases; (2) the HL7 FHIR clinical interoperability standard, which makes it possible to expose relevant information from the clinical cases to third-party tools; (3) the Clavy learning object repository management tool, which allows the transformation of these clinical cases into standardized educational formats; and (4) the Moodle LMS, which makes it possible to deploy the resulting contents for their consumption.

The collaborative design supported by Mosaico [7] allows medical students to create clinical cases through standardized templates with all the information required and the possibility to integrate relevant knowledge from multiple sources. The case study regarding chest pain described in the previous section, in

which Mosaico was successfully used to produce a complex clinical case by a group of advanced students under the supervision of a medical instructor, highlights the suitability of Mosaico in orchestrating this type of collaborative clinical case authoring. At this stage, it is essential to highlight Mosaico's ability to allow the creation of clinical cases by groups of students, which can be shared and exchanged democratically within the academic community. An interesting question to discuss is the wide variety of medical scenarios that can be considered during the design of clinical cases. Since the clinical cases are created by students in the company of an academic instructor, they are never repeated. Each design session has a new case history being shared, regardless of the diagnosis.

Concerning interoperability issues, HL7 FHIR specifications or notations [20] standardize medical records by incorporating an interoperable format that increases the exchange potential of any type of health data source. As exemplified by the case study in the previous section, the interoperability layer added to Mosaico highlights the feasibility of representing complex educational and clinical cases in terms of the HL7 FHIR information models. In this regard, clinical cases created using tools such as Mosaico, represented internally in proprietary and tool-dependent formats, can be offered to third-party tools in standardized and open formats. As shown in the case study, this aspect is essential to facilitating the reuse of clinical cases in many contexts that are not necessarily anticipated. In the work described in this paper, FHIR has allowed the generation of information packages used to build digital medical repositories, which can be deployed in subsequent stages of the design process. A similar environment to the one proposed and aimed at collecting clinical case information based on FHIR notations can be found in the Public Health Automated Case Event Reporting platform [21], which uses laboratory results to extend the description of clinical cases.

Although the availability of clinical cases represented in an interoperable format, such as HL7 FHIR, facilitates their consumption by external tools, a substantial gap prevents their publication in e-learning environments. Indeed, as evidenced in the case study presented, at the syntactic level, the HL7 FHIR information packages produced by Mosaico consist of JSON files and additional associated resources (eg, clinical images). Meanwhile, they represent instances of the FHIR information models at the semantic level. In contrast, information publishable on e-learning platforms follows well-established e-learning standards (eg, IMS-CP or SCORM). Therefore, this is a domain transformation problem at the syntactic level (eg, the transformation of JSON documents into IMS-CP XML manifests) and at the semantic level (eg, the change of FHIR entity graphs into IMS-CP or SCORM organizations). As the case study shows, the Clavy platform demonstrated its ability to undertake the required transformation tasks. Indeed, in this paper, Clavy was able to convert the HL7 FHIR resources produced by Mosaico through automatic procedures, taking the resources as input and generating digital repositories to be edited and processed. In addition, during this transformation stage, the remarkable functionality of Clavy allowed text elements to be converted from Mosaico-based clinical cases into standard terms such as SNOMED Clinical Terms or Logical Observation Identifiers Names and Codes (LOINC), which adds value to the original case descriptions. The advantages of using semantic standardization terminologies have been reviewed in matters such as structured reporting [22] or health care process mining [23].

The final stage consists of generating standard educational specifications, which can be useful when spreading instructional content across diverse health care e-learning environments [24]. In this case, Clavy allowed the export of the clinical cases collected from Mosaico using standard formats such as IMS-CP or SCORM. Standard specifications have played a crucial role in applying e-learning technologies for medical education. Most of these specifications focus on the content sharing of health care learning resources that can be designed and developed collaboratively, as seen in the mEducator initiative [25]. The work presented in this paper is similar to this initiative, relying on learning objects and IMS-CP educational packages to deliver instructional clinical cases to medical students and health care practitioners. In addition, the role of technical standards in medical instructional settings has been reviewed as a part of recent digital innovations introduced in health care education and training [26]. These innovations boost the use of SCORM packages that allow e-learning developers to add enhanced interactive features and assessment procedures to the massive amount of medical knowledge available, which are traditionally stored as plain content items [27]. Moreover, they introduce the possibility of tracking user interactions with these content items to supervise their learning in clinical scenarios [28].

Conclusions

In this paper, we proposed and implemented a workflow to deploy standard e-learning content, combining Mosaico, a tool for collaborative content authoring; HL7 FHIR, a clinical information interoperability standard; and Clavy, a platform for the flexible management of learning object repositories. Through a substantial case study, we demonstrated (1) how clinical cases collaboratively developed in Mosaico can be coded and exported in HL7 FHIR, (2) how this facilitates the reuse of these clinical cases with other tools, and (3) how cases exported in HL7 FHIR can be transformed into IMS-CP e-learning packages using a tool such as Clavy. As a result, we demonstrated the feasibility of deploying collaboratively created content using proprietary authoring tools in conventional open e-learning environments.

Having demonstrated the approach's feasibility, we intend to apply it to other scenarios of collaborative production of medical e-learning content. Likewise, we want to better integrate the components that constitute the proposed workflow ecosystem to the end users transparently, thus increasing usability and the overall user experience.

Abstract

Background: National classifications and terminologies already routinely used for documentation within patient care settings enable the unambiguous representation of clinical information. However, the diversity of different vocabularies across health care institutions and countries is a barrier to achieving semantic interoperability and exchanging data across sites. The Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) enables the standardization of structure and medical terminology. It allows the mapping of national vocabularies into so-called standard concepts, representing normative expressions for international analyses and research. Within our project "Hybrid Quality Indicators Using Machine Learning Methods" (Hybrid-QI), we aim to harmonize source codes used in German claims data vocabularies that are currently unavailable in the OMOP CDM.

Objective: This study aims to increase the coverage of German vocabularies in the OMOP CDM. We aim to completely transform the source codes used in German claims data into the OMOP CDM without data loss and make German claims data usable for OMOP CDM–based research.

Methods: To prepare the missing German vocabularies for the OMOP CDM, we defined a vocabulary preparation approach consisting of the identification of all codes of the corresponding vocabularies, their assembly into machine-readable tables, and the translation of German designations into English. Furthermore, we used 2 proposed approaches for OMOP-compliant vocabulary preparation: the mapping to standard concepts using the Observational Health Data Sciences and Informatics (OHDSI) tool Usagi and the preparation of new 2-billion concepts (ie, *concept_id* >2 billion). Finally, we evaluated the prepared vocabularies regarding completeness and correctness using synthetic German claims data and calculated the coverage of German claims data vocabularies in the OMOP CDM.

Results: Our vocabulary preparation approach was able to map 3 missing German vocabularies to standard concepts and prepare 8 vocabularies as new 2-billion concepts. The completeness evaluation showed that the prepared vocabularies cover 44.3% (3288/7417) of the source codes contained in German claims data. The correctness evaluation revealed that the specified validity periods in the OMOP CDM are compliant for the majority (705,531/706,032, 99.9%) of source codes and associated dates in German claims data. The calculation of the vocabulary coverage showed a noticeable decrease of missing vocabularies from 55% (11/20) to 10% (2/20) due to our preparation approach.

Conclusions: By preparing 10 vocabularies, we showed that our approach is applicable to any type of vocabulary used in a source data set. The prepared vocabularies are currently limited to German vocabularies, which can only be used in national OMOP CDM research projects, because the mapping of new 2-billion concepts to standard concepts is missing. To participate in international OHDSI network studies with German claims data, future work is required to map the prepared 2-billion concepts to standard concepts.

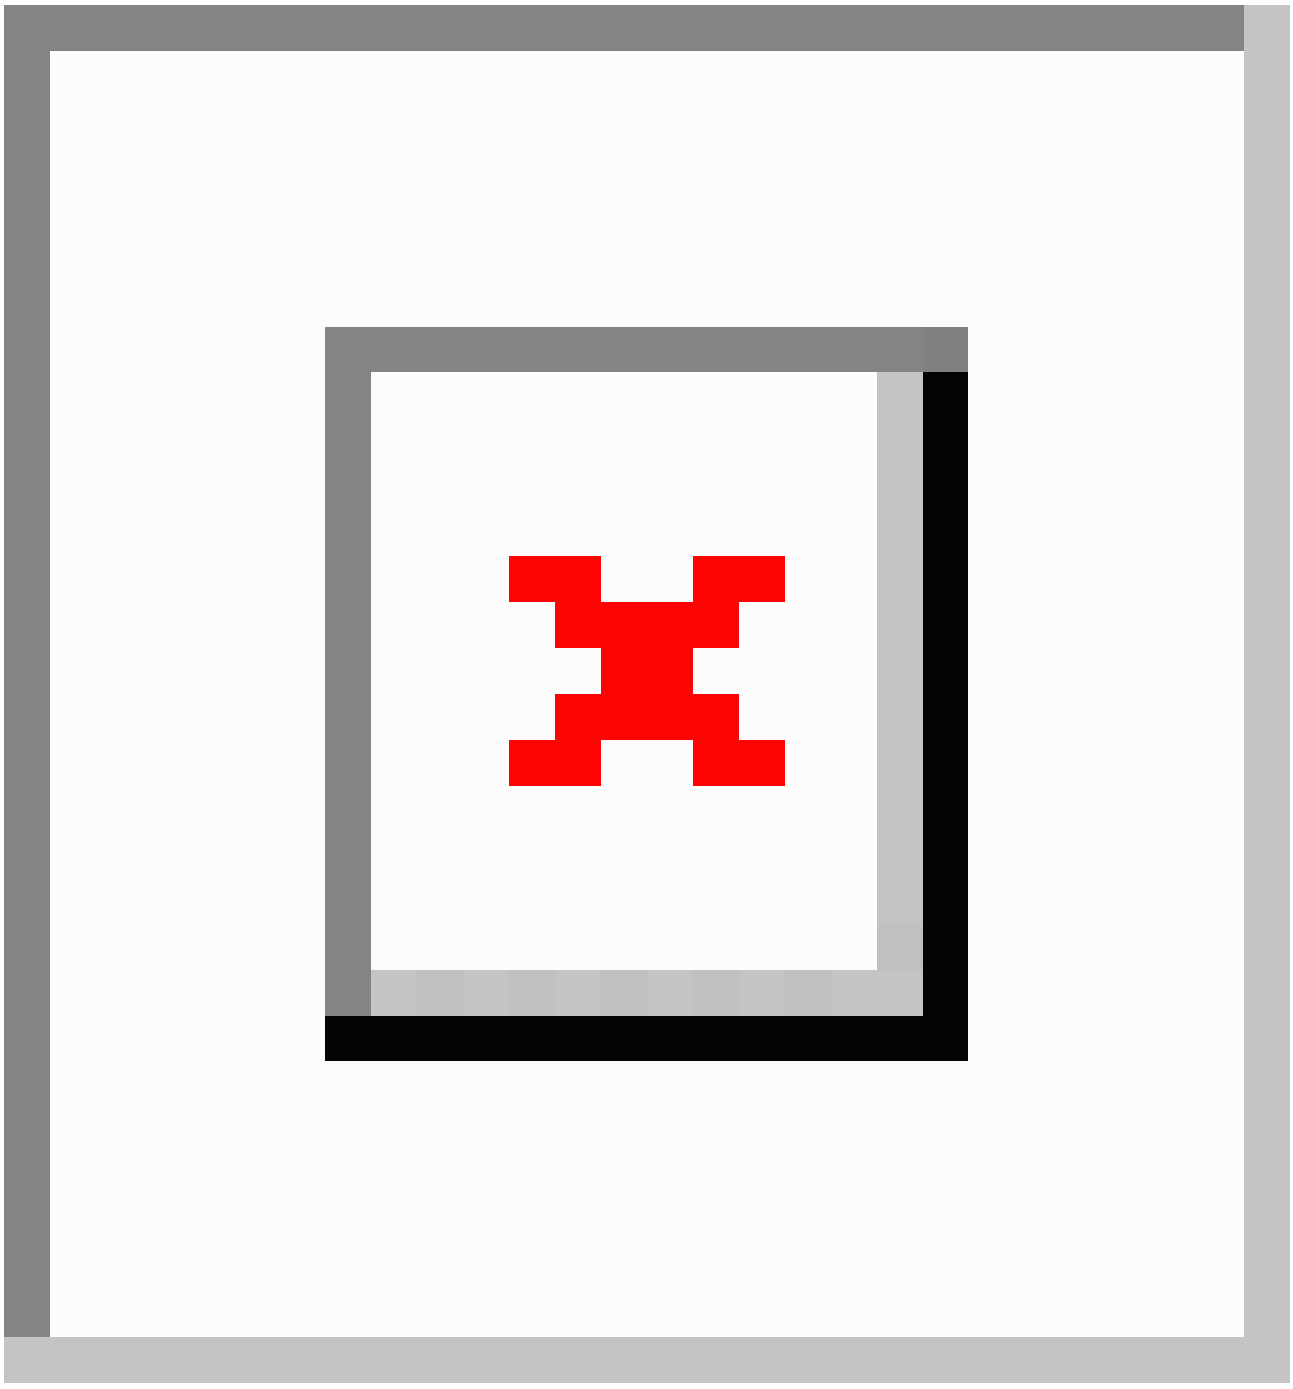
Introduction

Background and Significance

To generate reliable evidence in the health care sector, real-world data (RWD) can be used. RWD comprise observational data that are routinely collected in the context of patient care from various sources [1]. National classifications and terminologies enable the unambiguous representation of, for example, diagnoses (*International Classification of Diseases, Tenth Revision, German Edition* [*ICD-10-GM*]), procedures (*Operationen- und Prozedurenschlüssel* [Operations and Procedures Classification]), or laboratory data (Logical Observation Identifiers Names and Codes). Because these vocabularies are already routinely used for documentation within patient care settings, RWD already have a structured set of clinical information. However, each health care institution and country can have their own classifications, terminologies, or internally used set of codes. The diversity of different vocabularies is a barrier to achieving semantic interoperability and exchanging data across health care institutions and countries, as exemplarily shown in Figure 1. The code "C03" has 5 different semantic meanings covering the domains of drug, anatomic site, procedure, and condition [2]. Conducting research based on local vocabularies, terminologies, or classifications would result in custom analysis scripts for each site involved in a study. This not only entails high maintenance and time costs but is also unsustainable.

Figure 1. Overview of different meanings of the code C03 across various vocabularies. CAMS: Chinese Academy of Medical Sciences; CMS: Centers for Medicare & Medicaid Services; NCHS: National Center for Health Statistics; NHS: National Health Service; OPCS: Office of Population Censuses and Surveys; WHO: World Health Organization.



As a prerequisite for using data from heterogeneous data sources for international research and thus preventing the development of individual analysis scripts, harmonization and transformation to a common data model (CDM) are required. In recent years, the Observational Medical Outcomes Partnership (OMOP) CDM fostered by the Observational Health Data Sciences and Informatics (OHDSI) has become an essential open community data standard for research with RWD [3,4]. The OMOP CDM combines standardized data tables with centrally provided standardized vocabularies to ensure syntactic and semantic interoperability. The standardized vocabularies are represented in the OMOP CDM through concepts that enable the unique identification of all clinical events in the OMOP CDM. The concepts in the OMOP CDM are divided into standard and nonstandard concepts. Standard concepts provide normative expressions for international analyses and research based on the OMOP CDM. As an example, the Standard Nomenclature of Medicine concepts are mostly standard concepts in the OMOP CDM, for example, for the *Condition* domain. In contrast, nonstandard concepts are used to store codes of national vocabularies often used in source data, such as *ICD-10-GM*. The conversion ("mapping") of nonstandard to standard concepts is part of OMOP CDM vocabulary tables and represented as concept relationships. Similar to the concepts themselves, the mapping is provided through the central OHDSI vocabularies repository Athena [5]. The advantage of standardized OMOP

tables is that the source values and associated concepts, as well as the standardized concepts, are retained. Thus, it is always clear (1) what was part of the source data and (2) which concepts can be used for international research.

The main challenge faced by many researchers is the mapping of local source codes to OMOP CDM standard concepts [6-9]. Within our project "Hybrid Quality Indicators Using Machine Learning Methods" (Hybrid-QI) [10], we face this challenge during the transformation of German clinical data and claims data into the OMOP CDM. The aim of the project is the linkage of German clinical data and claims data into the OMOP CDM, to increase the effectiveness of quality measurement based on risk-adjusted quality indicators. To enable research based on 2 different heterogeneous data sets, the OMOP CDM is used for data harmonization. Although we have already successfully completed the semantic mapping of our clinical data [11], the mapping of German claims data comprising inpatient and outpatient data is still an open issue. To address this challenge, we focus first on the vocabularies used in German claims data as they build the basis for further semantic mapping to the OMOP CDM.

State of the Art

In an initial analysis of the current coverage of German claims data vocabularies in the OMOP CDM by Henke et al [12], it was shown that 55% (11/20) of the vocabularies are not available. Only 15% (3/20) of the vocabularies are currently present in Athena. The remaining 30% (6/20) of the vocabularies can be mapped to standard concepts in the OMOP CDM by using the *source_to_concept_map* table in the OMOP CDM. As a consequence, not all source codes used in German claims data can be represented in the OMOP CDM using standard concepts. Instead of losing the data during the transformation into the OMOP CDM, Sathappan et al [13] suggest storing the source codes in the **_source_value* columns of the OMOP CDM and mapping them to the *concept_id* of 0. However, this would again lead to the problem of using source codes for research as described earlier. In particular, the lack of associated nonstandard concepts in the OMOP CDM results in a loss of information about the vocabulary originally used in the source.

To our knowledge, no one so far has tried to prepare the missing 55% (11/20) of the German vocabularies for the OMOP CDM.

Objectives

The purpose of this paper is to increase the coverage of German vocabularies in the OMOP CDM. With our study, we want to make a major contribution to research with RWD based on the OMOP CDM by:

1. Completely transforming source codes used in German claims data to the OMOP CDM without data loss and
2. Making German claims data usable for research based on the OMOP CDM.

Methods

Ethical Considerations

Only synthesized claims data were used for our purposes, and therefore, no ethics approval was required.

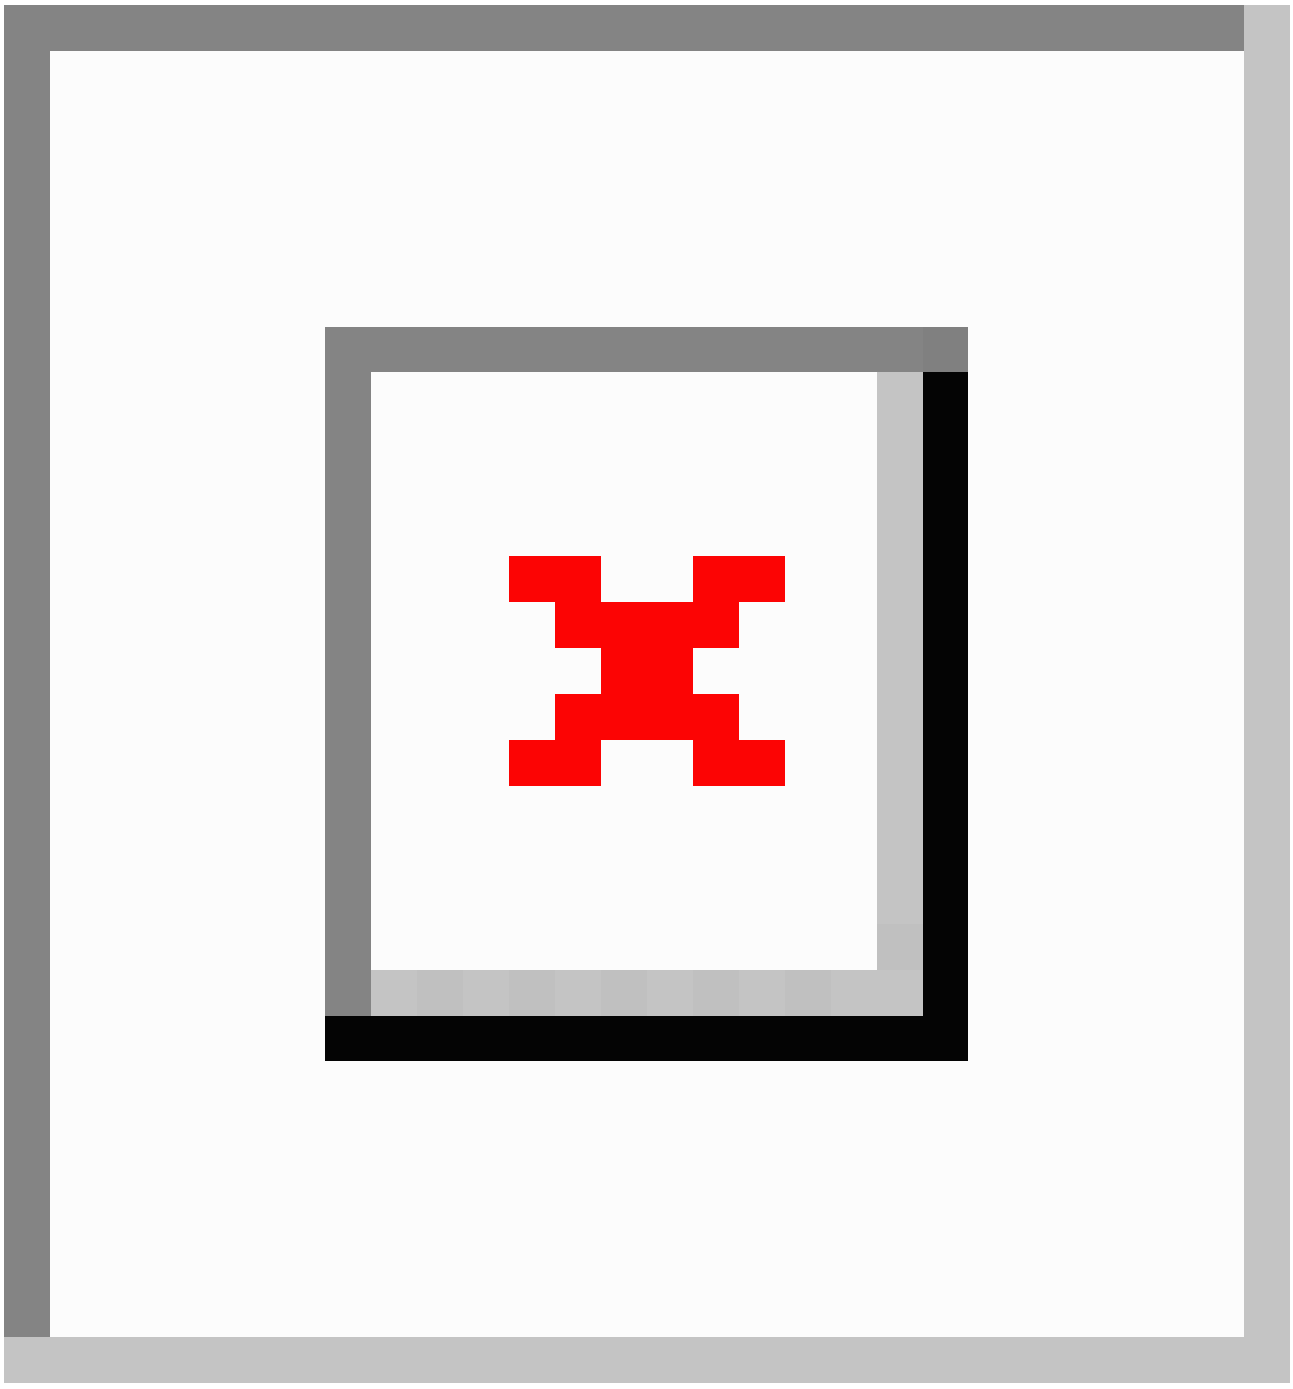
Study Data

The preparation of missing German vocabularies and its evaluation was done in the context of the Hybrid-QI project. The following four different medical indications were chosen as examples for the development of hybrid quality indicators:

1. Acute myocardial infarction
2. Cerebral infarction or intracerebral hemorrhage
3. Colorectal resection for carcioma
4. Shoulder endoprosthesis or osteosynthesis for proximal humerus fracture

To provide source data for data harmonization in the OMOP CDM, we used synthesized claims data from the German local health care funds (Allgemeine Ortskrankenkassen), which are based on real data. This data set includes billing data from 10,000 patients for a 6-year period comprising 558 MB of tabular data. For our purpose, we only focused on the source codes of the missing German vocabularies and their associated documentation or billing date. The German vocabularies considered in the following steps for the preparation in the OMOP CDM are summarized in Figure 2. We categorized the vocabularies according to their definitions and codes as remedy, billing, drug, condition, and provider vocabularies.

Figure 2. German vocabularies currently not available in the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM). ASV: Ambulante spezialfachärztliche Versorgung; EBM: Einheitlicher Bewertungsmaßstab; HMK: Heilmittelkatalog; HPNR: Heilmittelpositionsnummern; PIA: Bundeseinheitlicher Katalog für die Dokumentation der Leistungen der psychiatrischen Institutsambulanzen; PZN: Pharmazentralnummer.



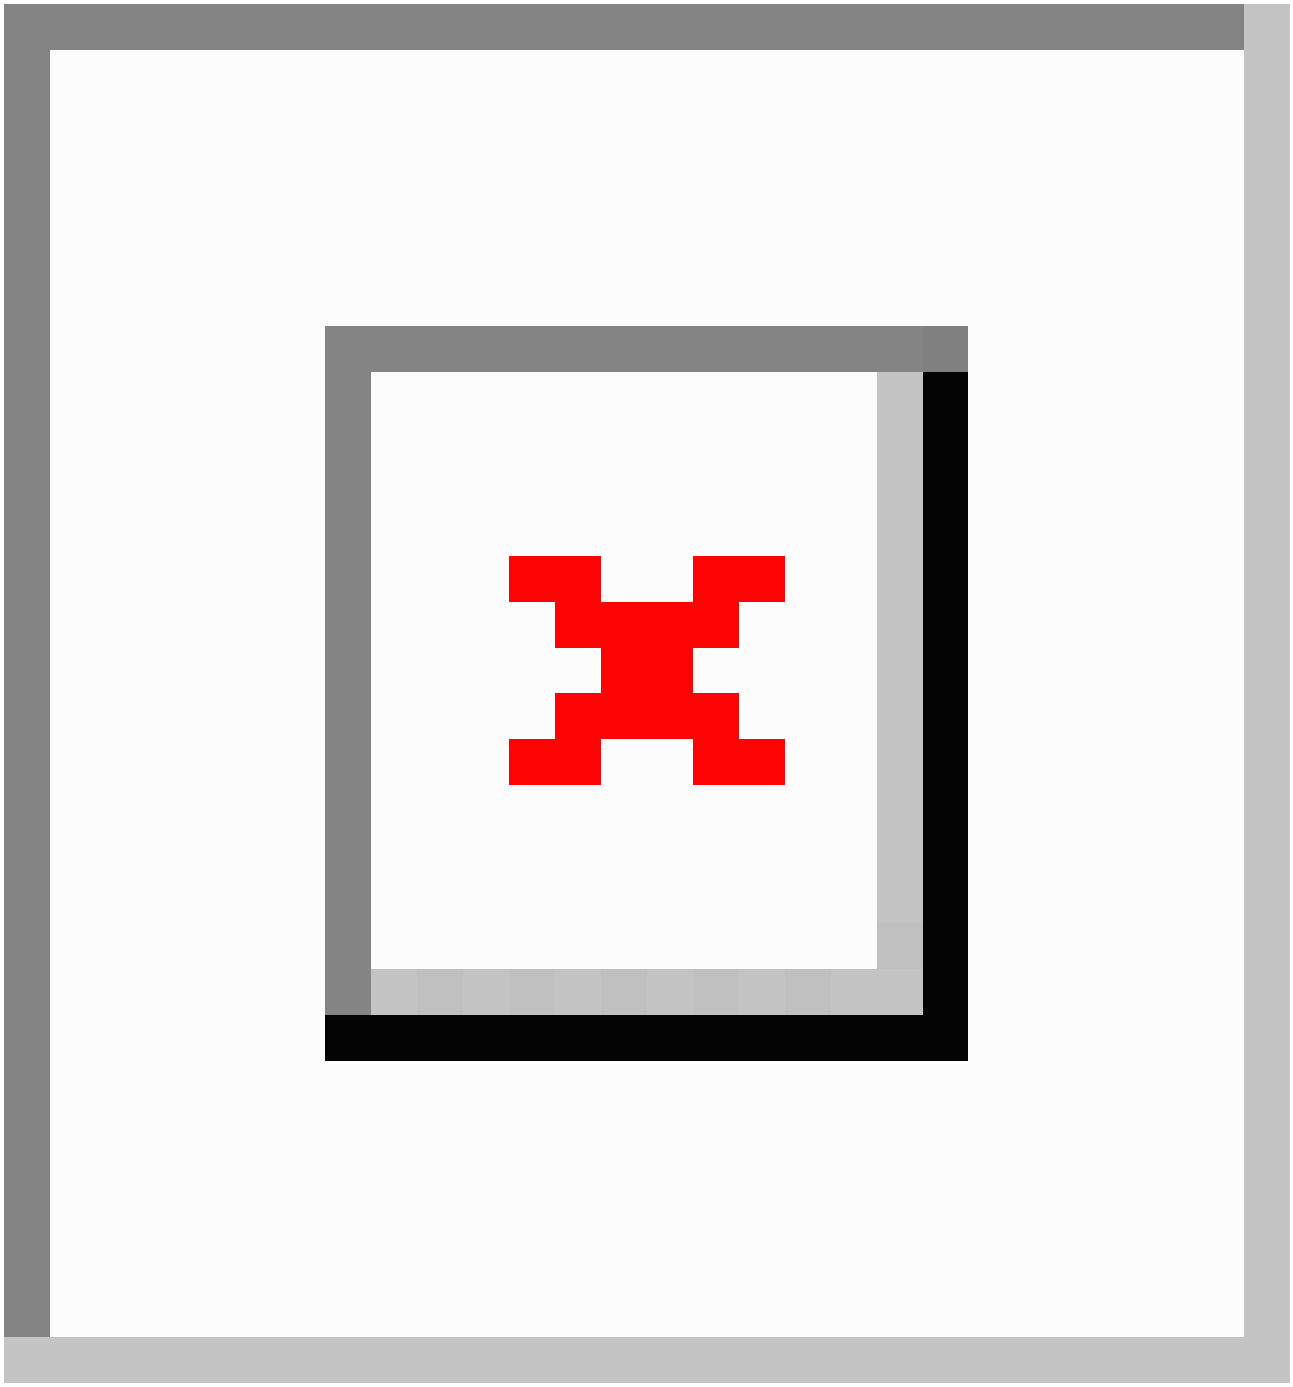
Vocabulary Preparation Approach

Overview

To prepare missing German vocabularies for the OMOP CDM, we defined an approach divided into 5 main steps (see Figure 3). First, we performed a selective search to identify all codes of the corresponding vocabulary. We especially checked the license restrictions of the vocabularies that do not permit their preparation for the OMOP CDM. Based on the search results from the first step, we summarized all codes, the hierarchy of the vocabulary, the corresponding German terms, and validity periods per vocabulary in tabular form for those vocabularies that do not have license restrictions. If no validity period was found, we used the default OMOP CDM values for *valid_start_date* (“1970-01-01”) and *valid_end_date* (“2099-12-31”) [14]. Next, we translated the German designations into English to make the semantic meaning of the codes understandable in an international context. Two researchers with domain knowledge were involved in the translations and their validation. For the fourth step of OMOP-compliant vocabulary preparation, there were 2 different methods available [15]: mapping to standard concepts using Usagi [16,17] and OMOP-compliant preparation of new 2-billion concepts (ie, *concept_id* >2 billion). Both methods are

described in more detail in the following sections. Finally, we evaluated the results from the fourth step.

Figure 3. Vocabulary preparation approach. OMOP: Observational Medical Outcomes Partnership.



Mapping to Standard Concepts

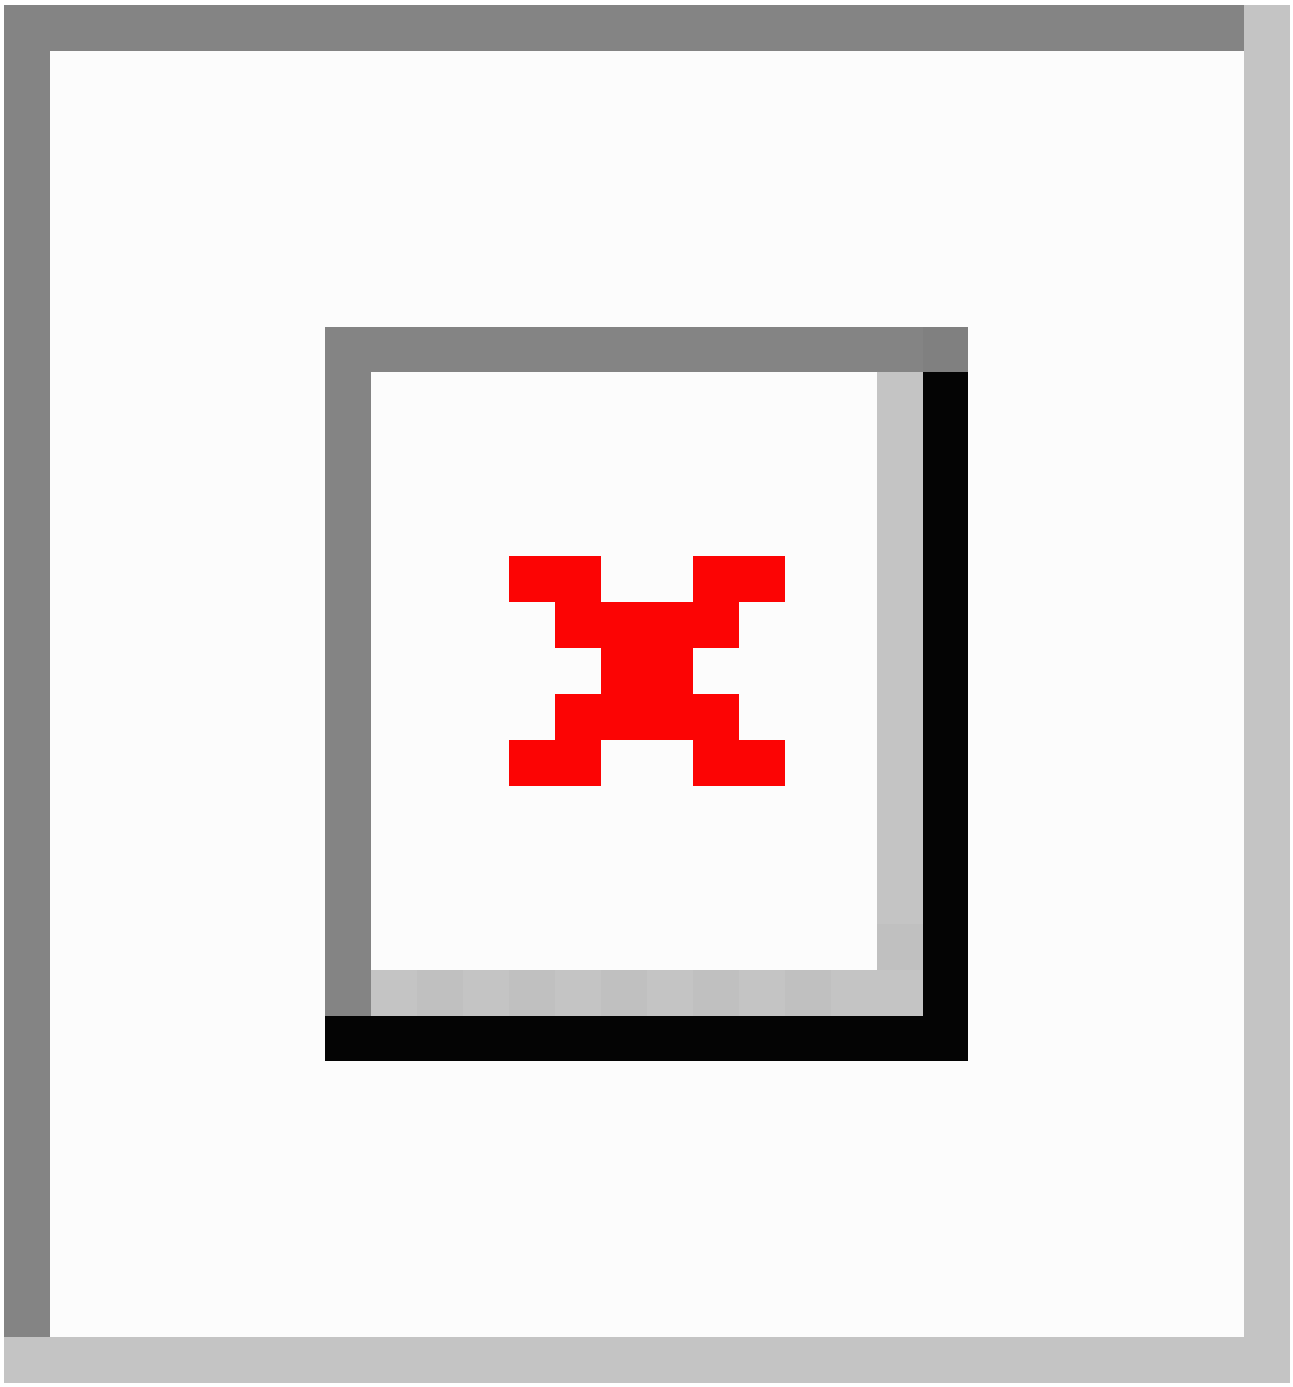
To map local codes from a source system to standard concepts used in the OMOP CDM, the OHDSI community provides the open-source tool Usagi [16,17]. Usagi uses a term-similarity approach to propose appropriate standard concepts in the OMOP standardized vocabulary based on the English designation of the source codes. In the first step, we loaded a prepared list of source codes and their German and English designations into Usagi. Next, we specified the target domain of the OMOP standardized vocabulary that should be used during the mapping, based on the categories assigned to the German vocabularies shown in Figure 2. In a team of 2 researchers with domain knowledge, we reviewed the proposals made by Usagi and jointly discussed and resolved conflicts that had arisen during the mapping process. After the 2 researchers approved all proposals, the mapping of the source codes to standard concepts was exported as a CSV file following the format structure of the OMOP CDM *source_to_concept_map* table.

New 2-Billion Concepts

If source codes cannot be mapped using the standardized OMOP vocabularies, it is possible to create new 2-billion concepts for the OMOP CDM [15], which is a number range reserved for local *concept* creation. With this approach, we prepared the missing vocabularies to be OMOP compliant for the OMOP

CDM tables *vocabulary*, *concept*, *concept_class*, and *concept_relationship*. Figure 4 shows the preparation of a new 2-billion concept for the OMOP CDM *concept* table for the *Heilmittelpositionsnummern* (HPNR; uniform list of item numbers for therapeutic services) source code "1514."

Figure 4. A new 2-billion concept in the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) *concept* table for HPNR source code "1514." HPNR: Heilmittelpositionsnummern (uniform list of item numbers for therapeutic services).



During the preparation process, it must be taken into account that the new concepts are assigned a *concept_id* >2 billion to avoid conflicts with existing OMOP vocabularies [15]. For missing source codes, for example, for hierarchy levels, we used the prefix "OMOP" followed by number sequence as the *concept_code*, similar to the *concept_codes* of the OMOP CDM vocabulary OMOP Extension; this procedure follows the convention that a combination of *vocabulary_id* and *concept_code* is supposed to be unique and serves as a secondary key. Furthermore, we had to assign *domains* and *concept_classes* to the new concepts. This was done by searching the English designation of the parent categories of the source codes in Athena and comparing it with the proposed concepts. After a review process consisting of 2 researchers, we decided on a suitable *domain* and *concept_class* and added them to the parent categories as well as to the specific source codes. After the preparation of the *concept* table was completed, we stored the hierarchical structure of the vocabulary, as well as the information about replaced invalid concepts (eg, due to a change

in the designation of a source code), in the *concept_relationship* table.

Evaluation

After the vocabulary preparation, we evaluated the mapping results from Usagi as well as the new 2-billion concepts regarding the completeness of the source codes and the correctness of the validity periods using the synthetic claims data. For both criteria, we implemented an evaluation process with Pentaho Data Integration (Hitachi Vantara) [18]. The input of this process was a list of source codes and the corresponding dates extracted from the synthetic claims data set, as well as the prepared *source_to_concept_map* or *concept* table as CSV files for each vocabulary. Consequently, no connection to an OMOP CDM database was required. Both evaluations were done by an interdisciplinary team in an iterative process until all identified errors had been resolved.

The aim of the completeness assessment was to check if all source codes are available in the prepared vocabularies. This was done by searching the source codes in the *source_code* (*source_to_concept_map*) or *concept_code* (*concept*) columns. If the result of the search had found a *concept_id*, then the codes were already present in the vocabulary; otherwise, they were missing. For both findings, the occurrence of the unique codes in the source record was then calculated and exported as CSV files as a result. In the next step, we further analyzed the missing codes—whether they were forgotten during preparation or if they displayed data quality issues—by using the vocabulary preparation approach for the missing codes, as illustrated in Figure 3.

The second evaluation focused on the correct assignment of the validity periods of the source codes in the prepared vocabularies. For this purpose, we used the source codes for which a matching *concept_id* was found during the first evaluation step. During the correctness assessment, we further checked whether the source codes with their associated dates were valid in the prepared vocabularies. The verification was based on a lookup to identify if the date used in the source was within the validity period of the vocabulary. A positive result indicated that codes were valid, and a negative result indicated that codes were invalid. For both results, we again calculated the occurrence of the unique combination of source code and date in the source and exported the results as CSV files. Afterward, we examined the invalid codes and rechecked whether the validity periods in the vocabularies contained errors.

Final Determination of the Vocabulary Coverage

According to the approach used in Henke et al [12] to calculate the initial vocabulary coverage in the OMOP CDM, we recalculated the vocabulary coverage after the vocabulary preparation. For this purpose, we took our initial list of all German vocabularies used in the claims data set and assigned them again to 3 categories: “available in Athena,” “available through interim mapping,” and “not available.” With regard to the new 2-billion concepts, we added a new fourth category called “Athena-ready.” This category was intended to show that for the new 2-billion concepts, only the external step of loading them into Athena remains. During the final determination, a score of 1 was assigned to a vocabulary if it belongs to the category, and 0 was assigned otherwise. Based on the scores, we calculated the percentage distribution among the 4 categories.

Results

Vocabulary Preparation

Within the selective search, we were able to collect information for all of the missing vocabularies shown in Figure 2 (see Multimedia Appendix 1). However, due to license restrictions, 2 vocabularies (German Diagnosis Related Groups and *Pharmazentralnummer* [Central Pharmaceutical Number]) are legally not allowed to be prepared for the OMOP CDM. For the preparation of the other missing vocabularies, we applied both approaches by using Usagi to map the OMOP CDM standard concepts and by creating new 2-billion concepts. From Table 1, it can be seen that we applied a mapping to standard concepts for 3 vocabularies: *Ambulante spezialfachärztliche Versorgung* (ASV; outpatient specialist care), diagnosis type (inpatient), and provider specialty. These vocabularies were prepared with Usagi when a comprehensive mapping to OMOP CDM standard concepts was possible. The resulting Usagi export of the *source_to_concept_map* table for each vocabulary can be found in our GitHub repository [19].

Table . Overview of vocabularies prepared with Usagi, including number of records in the *source_to_concept_map* table.

Vocabulary name	*Source_to_concept_map*, records, n
ASV[a]	68
Diagnosis type (inpatient)	6
Provider specialty	104

[a]ASV: Ambulante spezialfachärztliche Versorgung (outpatient specialist care).

For the remaining 8 vocabularies, we created new 2-billion concepts to map the source codes to unique *concept_ids* that are analogous to other nonstandard concepts in the OMOP CDM and to prevent different semantic meanings of source codes according to the example shown in Figure 1. Table 2 provides an overview of the number of newly added records for the *vocabulary*, *concept_class*, *concept*, and *concept_relationship* tables for each new 2-billion concept (see the GitHub repository [20] for details). We have prepared almost all vocabularies entirely, that is, all source codes contained in the vocabularies. The exceptions are the *Einheitlicher Bewertungsmaßstab* (EBM; German Uniform Assessment Standard) and inpatient charge types vocabularies. In the case of EBM, we prepared the EBM vocabulary widely used in Germany for the OMOP CDM. For inpatient charge types, we restricted the preparation to the

hierarchy levels “daily charges” and “case-related charges” that were relevant in the Hybrid-QI project.

Table . Overview of vocabularies prepared as new nonstandard concepts, including number of records in the *vocabulary*, *concept_class*, *concept*, and *concept_relationship* tables.

Vocabulary name	*Vocabulary*, records, n	*Concept_class*, records, n	*Concept*, records, n	*Concept_relationship*, records, n
HMK[a]	1	2	263	396
HPNR[b]	1	0	732	1344
PIA[c]	1	0	74	0
EBM[d]	1	2	3614	7348
Inpatient charge types	1	2	992	1997
Outpatient charge types (including EBM)	1	2	5647	11,280
Diagnosis type (outpatient)	0	0	4	0
Diagnosis type (inpatient)	0	0	2	0

[a]HMK: Heilmittelkatalog (catalog of physiotherapy, podological therapy, speech therapy, occupational therapy, and nutritional therapy).

[b]HPNR: Heilmittelpositionsnummern (uniform list of item numbers for therapeutic services).

[c]PIA: Bundeseinheitlicher Katalog für die Dokumentation der Leistungen der psychiatrischen Institutsambulanzen (standardized federal catalog for the documentation of services provided by psychiatric institutional outpatient clinics).

[d]EBM: Einheitlicher Bewertungsmaßstab (German Uniform Assessment Standard).

Evaluation Outcomes

For both variants of the vocabulary preparation through the *source_to_concept_map* or *concept* table, we evaluated completeness and correctness. The evaluation process implemented for this purpose has been released as a GitHub repository [20]. The process includes the extraction of source code and date information from synthetic German claims data, as well as the completeness and correctness assessment for each vocabulary. The following sections demonstrate the final results of the evaluation after multiple iterations.

Completeness

The results of the vocabulary completeness evaluation are summarized in Table 3. From the results, it can be seen that 44.3% (3288/7417) of the source codes can be found in the prepared concepts for the OMOP CDM. What stands out in the table are the EBM and ASV vocabularies. For the EBM vocabulary, 68.21% (4074/5973) of the unique codes were not found in the prepared concepts, that is, they had no *concept_id*, which resulted in 21.68% (1,422,808/6,563,865) of source records not having a *concept_id*. For the ASV vocabulary, no *concept_id* was found for 21.74% (5/23) of the unique codes. Consequently, 8.07% (44/545) of the source records did not have a *concept_id*. Furthermore, we summed up the number of unique codes and total records of the provider specialty vocabulary in Table 3. This is because the vocabulary occurred in 5 different source tables that include data about remedies, outpatient drug prescriptions, and contract medical care.

Table . Results of the vocabulary completeness evaluation.

Vocabulary name	Unique source codes without *concept_id*, n/N[a] (%)	Records without *concept_id*, n/N[b] (%)
HMK[c]	12/116 (10.34)	120/70,514 (0.17)
HPNR[d]	1/105 (0.95)	5/137,106 (0.0036)
PIA[e]	0/37 (0)	0/8721 (0)
EBM[f]	4074/5973 (68.21)	1,422,808/6,563,865 (21.68)
ASV[g]	5/23 (21.74)	44/545 (8.07)
Inpatient charge types	0/101 (0)	0/1222 (0)
Outpatient charge types	37/1062 (3.48)	1760/48,422 (3.63)
Diagnosis type (outpatient)	0/3 (0)	0/17,437 (0)
Diagnosis type (inpatient)	0/6 (0)	0/864,764 (0)
Provider specialty	0/104 (0)	0/9,057,555 (0)

[a]n=number of unique source codes with *concept_id*; N=number of unique source codes.

[b]n=number of records without *concept_id*; N=number of records.

[c]HMK: Heilmittelkatalog (catalog of physiotherapy, podological therapy, speech therapy, occupational therapy, and nutritional therapy).

[d]HPNR: Heilmittelpositionsnummern (uniform list of item numbers for therapeutic services).

[e]PIA: Bundeseinheitlicher Katalog für die Dokumentation der Leistungen der psychiatrischen Institutsambulanzen (standardized federal catalog for the documentation of services provided by psychiatric institutional outpatient clinics).

[f]EBM: Einheitlicher Bewertungsmaßstab (German Uniform Assessment Standard).

[g]ASV: Ambulante spezialfachärztliche Versorgung (outpatient specialist care).

Correctness

The correctness evaluation was performed for the source codes for which a *concept_id* was found during the completeness evaluation. Furthermore, we excluded records if they had a missing source code or date information in the source. For the diagnosis type and provider specialty vocabularies, we were unable to evaluate the correctness due to having no equivalent dates in the source. In addition, these vocabularies have default values for *valid_start_date* and *valid_end_date* in the OMOP CDM. Table 4 shows the results obtained from the correctness evaluation. Looking at the percentage of invalid unique source code–date combinations, for all 7 vocabularies, less than 1% (501/706,032) of the combinations were invalid. In comparison, considering the total number of records, less than 1% (3036/5,358,996) of the records were identified as invalid. The vocabulary with the lowest correctness was HPNR with 0.13% (442/33,439) of invalid unique source code–date combinations and 2.14% (2938/137,101) of invalid records.

Table . Results of the vocabulary correctness evaluation.

Vocabulary Name	Invalid unique source code–date combination, n/N[a] (%)	Invalid records, n/N[b] (%)
HMK[c]	2/27,197 (0.0074)	2/70,394 (0.0028)
HPNR[d]	442/33,439 (0.13)	2938/137,101 (2.14)
PIA[e]	0/2449 (0)	0/8721 (0)
EBM[f]	56/641,285 (0.0087)	95/5,141,057 (0.0018)
ASV[g]	0/490 (0)	0/501(0)
Inpatient charge types	1/1172 (0.09)	1/1222 (0.08)
Outpatient charge types	0/39,123 (0)	0/46,662 (0)

[a]n=number of invalid unique source–date combinations; N=number of unique source–date combinations.

[b]n=number of invalid records; N=number of records.

[c]HMK: Heilmittelkatalog (catalog of physiotherapy, podological therapy, speech therapy, occupational therapy, and nutritional therapy).

[d]HPNR: Heilmittelpositionsnummern (uniform list of item numbers for therapeutic services).

[e]PIA: Bundeseinheitlicher Katalog für die Dokumentation der Leistungen der psychiatrischen Institutsambulanzen (standardized federal catalog for the documentation of services provided by psychiatric institutional outpatient clinics).

[f]EBM: Einheitlicher Bewertungsmaßstab (German Uniform Assessment Standard).

[g]ASV: Ambulante spezialfachärztliche Versorgung (outpatient specialist care).

Vocabulary Coverage

After the evaluation of the prepared vocabularies, we checked the impact of the standard concept mappings and the new 2-billion concepts on the vocabulary coverage in the OMOP CDM. Table 5 shows the results of the final determination of the vocabulary coverage (see Multimedia Appendix 2). As can be seen, the percentage of unavailable vocabularies decreased noticeably from 55% (11/20) to 10% (2/20). One reason for this is the increase of interim mappings from 30% (6/20) to 45% (9/20) using the *source_to_concept_map* table. Another impact has been the creation of new 2-billion concepts for the OMOP CDM. With this approach, 30% (6/20) of the vocabularies were prepared for the OMOP CDM as Athena-ready concepts. The remaining 10% (2/20), which refers to the unavailable vocabularies, is because of the 2 missing vocabularies due to license restrictions.

Table . Vocabulary coverage of German claims data in the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) after vocabulary preparation.

Vocabulary coverage status	Vocabularies (N=20), n (%)
Available in Athena	3 (15)
Athena ready	6 (30)
Available through interim mapping	9 (45)
Not available	2 (10)

Discussion

Vocabulary Preparation Approach

With our presented approach of vocabulary preparation consisting of mapping to standard concepts and the manual creation of new 2-billion concepts, we could improve the vocabulary coverage of missing German vocabularies for use within the OMOP CDM. By preparing 10 vocabularies, we were able to show that our approach is applicable to any type of vocabulary used in a source data set. Referring to our objectives, we succeeded in mapping the majority of source codes used in German claims data to matching *concept_ids* in the OMOP CDM (objective 1). Furthermore, by mapping source codes to standard concepts and creating new 2-billion concepts in the OMOP CDM, we are now able to use German claims data for research based on the OMOP CDM (objective 2).

Nevertheless, there are limitations to our work. The first limitation relates to the reusability of the prepared vocabularies for other researchers. Our newly created 2-billion concepts are not currently available in Athena. Until the integration into Athena is done, the prepared vocabularies are available for other researchers via download from our GitHub repository [19]. When using our vocabularies in the OMOP CDM at other sites, it should be considered that conflicts with 2-billion concepts from other researchers must be avoided by agreeing on certain number ranges within the 2-billion range. A solution for this would be to set up a blank OMOP CDM database, where only the vocabularies provided by Athena are present and our prepared vocabularies are loaded afterward.

Furthermore, our results are currently limited to German vocabularies, which can only be used in national research projects using the OMOP CDM, because the mapping of new

2-billion concepts to standard concepts has not yet taken place. Consequently, the data cannot be used for international studies that are based on OMOP CDM standard concepts. To be able to participate in OHDSI network studies with German claims data, future work is required to map the prepared 2-billion concepts to standard concepts.

Vocabulary Completeness

Our vocabulary completeness evaluation showed that we are currently covering 44.3% (3288/7417) of the codes used in the synthetic German claims data set. Nevertheless, even after multiple iterative adjustments of the vocabularies for missing source codes, some source codes could still not be found in the prepared vocabularies, especially for the Heilmittelkatalog (HMK; catalog of physiotherapy, podological therapy, speech therapy, occupational therapy, and nutritional therapy), HPNR, EBM, ASV, and outpatient charge types vocabularies. The reasons for missing codes can be divided into 2 categories: data quality issues and vocabulary scope limitation. The category of data quality issues summarizes causes such as transposed digits, missing characters, or coding errors (the number zero instead of the letter "O"). Thus, these errors do not refer to incomplete prepared vocabularies but to documentation mistakes in the source. For this reason, the errors are reflected back to the data-providing site, to serve as a basis for future work regarding the development of methods to increase the documentation quality, for example, through a preprocessing of data before they are loaded into the OMOP CDM.

The category of vocabulary scope limitation mainly refers to the EBM vocabulary. For our purpose, we prepared the EBM vocabulary widely used in Germany for the OMOP CDM. However, there also exist local codes administered by the regional associations of statutory health insurance physicians, which can serve as extensions or substitutions to the Germany-wide EBM. The preparation of local EBM codes will be a part of future work.

During the implementation of the evaluation process and the analysis of the results, we encountered challenges for the outpatient charge types vocabulary. The outpatient charge types vocabulary refers to a selection of EBM codes. For this reason, 2 prepared vocabularies had to be considered in the evaluation of completeness. However, for codes that could not be found in either of the 2 vocabularies, it was not possible to assess from which vocabulary they originated. In our next steps of semantic mapping of German claims data to the OMOP CDM, we plan to write such unassignable codes with a *concept_id* of 0 to the OMOP CDM to highlight this issue.

Vocabulary Correctness

The results of the vocabulary correctness evaluation revealed invalid source codes for the HMK, HPNR, EBM, and inpatient charge types vocabularies. Looking at it in more detail, we found that both reasons for invalid codes, that is, invalid codes because of dates before the *valid_start_date* in the OMOP CDM and invalid codes because of dates after the *valid_end_date* in the OMOP CDM, occurred during our evaluation. Although the first problem occurred for all 4 vocabularies, the last 1 only occurred for the EBM vocabulary. A possible explanation for this might be the difference between the date of service provision and the date of payment in the source. Ditscheid et al [21] have already highlighted the temporal discrepancies of these 2 dates and their influence on the interpretation of results. They found that discrepancies in time could lead to an underestimation or overestimation of health service utilization regarding the death date of a patient or the change between years. They proposed to take these discrepancies "into account when requesting the data, but also in preparing and analyzing them" [21]. Consequently, when conducting research with (German) claims data based on the OMOP CDM, we must decide individually for each vocabulary which dates are appropriate for checking their validity in the OMOP CDM concept. However, since only a single piece of date information per vocabulary was available in the synthetic German claims data set, the evaluation conducted in this paper was limited to this information and should be repeated in the future in a second evaluation with more suitable date information per vocabulary.

Comparison With Prior Work

Our proposed vocabulary preparation approach is consistent with methods used by other researchers. There are many papers describing the mapping of source codes or even free texts to OMOP CDM standard concepts using Usagi [8,13,22-25]. However, many papers also describe the approach of creating new 2-billion concepts, since mapping to standard concepts is not always possible [7,9,13,26-31]. For example, Fischer et al [28] created custom concepts for the Pulmonary Hypertension Nice classification. Rinner et al [29] focused on the missing vocabulary of the Austrian pharmaceutical registration number and consequently created new records for the *vocabulary*, *concept_class*, and *concept* tables in the OMOP CDM. Sathappan et al [13] created new unique 2-billion *concept_ids* to store local questionnaire terms in the OMOP CDM. However, none of these approaches describe in detail the process of preparing missing vocabularies for the OMOP CDM. The paper by Sathappan et al [13] laid out a promising approach. However, newly created concepts were directly added as standard concepts to the OMOP CDM, which limits their use to local analysis.

Compared to other research, our approach offers 2 advantages. In terms of a guideline, the presented approach enables the preparation of missing vocabularies for the OMOP CDM for a specific site's data as well as their evaluation. Furthermore, making the vocabularies available via GitHub enables distribution and direct use of the newly created vocabularies for German data and, thus, ensures semantic interoperability across institutions in Germany.

Conclusions

With our presented vocabulary preparation approach, we took a first promising step toward using German claims data for research based on the OMOP CDM. German health care providers, institutes, and health insurance companies can use the prepared German vocabularies, as these vocabularies are part of the legal data transmission for billing processes with health insurance companies. However, the proportion of newly created 2-billion concepts cannot yet be used for international studies due to a missing mapping to standard concepts. During our next steps, we will address this problem by using Usagi to

propose a mapping from the new 2-billion concepts to standard concepts. By doing so, we also want to investigate how well the new German 2-billion concepts can be mapped to OMOP CDM standard concepts and identify the reasons why specific German codes could not be mapped (eg, missing semantic concepts or specifics of the German health care system [billing focus]). In addition, we also aim to collaborate with OHDSI to have our prepared vocabularies externally validated and subsequently integrated into Athena.

Acknowledgments

The research reported in this work was accomplished as part of the German Innovations Fund of the Federal Joint Committee in Germany (G-BA; grant 01VSF20013). The article processing charge was funded by the joint publication funds of the Technische Universität Dresden, including the Carl Gustav Carus Faculty of Medicine, and the Sächsische Landesbibliothek – Staats- und Universitätsbibliothek, Dresden, as well as the Open Access Publication Funding of the Deutsche Forschungsgemeinschaft.

Authors' Contributions

All authors contributed substantially to this work. EH contributed to writing—original draft preparation. EH and LAL contributed to table preparation and translation. EH and MZ reviewed the mapping assumptions. EH contributed to the implementation of the evaluation process. EH, TR, and M Spoden reviewed the evaluation results. EH, MZ, MK, TR, LAL, M Spoden, CG, M Sedlmayr, and FB contributed to writing—review and editing. M Sedlmayr contributed resources. All authors have read and agreed to the current version of the manuscript and take responsibility for the scientific integrity of the work.

Abstract

Background: Increasing digitalization in the medical domain gives rise to large amounts of health care data, which has the potential to expand clinical knowledge and transform patient care if leveraged through artificial intelligence (AI). Yet, big data and AI oftentimes cannot unlock their full potential at scale, owing to nonstandardized data formats, lack of technical and semantic data interoperability, and limited cooperation between stakeholders in the health care system. Despite the existence of standardized data formats for the medical domain, such as Fast Healthcare Interoperability Resources (FHIR), their prevalence and usability for AI remain limited.

Objective: In this paper, we developed a data harmonization pipeline (DHP) for clinical data sets relying on the common FHIR data standard.

Methods: We validated the performance and usability of our FHIR-DHP with data from the Medical Information Mart for Intensive Care IV database.

Results: We present the FHIR-DHP workflow in respect of the transformation of “raw” hospital records into a harmonized, AI-friendly data representation. The pipeline consists of the following 5 key preprocessing steps: querying of data from hospital database, FHIR mapping, syntactic validation, transfer of harmonized data into the patient-model database, and export of data in an AI-friendly format for further medical applications. A detailed example of FHIR-DHP execution was presented for clinical diagnoses records.

Conclusions: Our approach enables the scalable and needs-driven data modeling of large and heterogenous clinical data sets. The FHIR-DHP is a pivotal step toward increasing cooperation, interoperability, and quality of patient care in the clinical routine and for medical research.

Introduction

The increasing digitalization of health care creates vast amounts of clinical data that are collected and stored in an Electronic Health Record (EHR). Patient information from all medical domains is captured in diverse sets of data recorded in stand-alone systems. With the prevalent use of EHRs in health care organizations, there is abundant opportunity for the additional application of EHR data in clinical and translational research. For instance, such data can be used to develop artificial intelligence (AI) algorithms, which have the potential to transform patient care and medical research. Resource-intensive and inefficient clinical workflows could be optimized by the analysis of historical data with AI applications [1,2]. In particular, the time-consuming and financially costly process of identifying and enrolling the right patients into a clinical trial manually can be reduced significantly by automation [3,4]. However, the exchange of medical data remains limited due to the lack of data interoperability between health care providers, owing to outdated IT infrastructure, inconsistencies in data formats, poor data quality, inadequate data exchange solutions, and data silos [5,6]. To achieve data interoperability, the following steps must be incorporated: (1) integration of isolated data silos, (2) safe exchange of data, and (3) effective use of the available data [7]. Each of these operations includes database schema matching [8] and schema mapping [9], which allow translation of the relationships between the source database and the target data standard.

Employing a harmonized data format will facilitate the exchange of medical data, enabling wide-ranging data-driven collaborations within the private and public health care sectors. Data interoperability requires EHR data to be structured in a common format and in standardized terminologies. Standardization is often performed by adopting the Health Level 7 Fast Healthcare Interoperability Resources (FHIR) model [10], which is supported by numerous health care institutions and vendors of clinical information systems [11]. FHIR is an international industry standard that integrates diverse sets of data in well-defined exchangeable segments of information, which are known as FHIR resources. Therefore, FHIR facilitates interoperability between health care organizations and allows third-party developers to provide medical applications that can be easily integrated into the existing systems. FHIR enables the harmonization of data and thus allows standardized data processing as well as the rollout of AI applications across different clinics and hospitals regardless of which information system they use. Consequently, FHIR forms an important component for the scalable development and deployment of AI in clinics and hospitals.

However, to apply AI, the input data need to be adapted to the AI algorithms. The conventional AI frameworks such as Tensorflow [12] and Pytorch [13] require data to take a tensor form, which is a vector or matrix of n-dimensions that represents various types of data (eg, tabular, time series, image, and text). Since the FHIR format has a multilayered nested structure, a use case–specific data preprocessing is needed. For instance, depending on the AI application and the chosen data source, a custom data preprocessing pipeline should be designed leading to diminished AI scalability. Prior research addressed this problem in different forms but focused on individual applications, thereby constraining the purpose of FHIR to be applicable regardless of the use case [11]. There have been a few attempts to flatten the hierarchical FHIR structure and transform it into NDJSON-based data format [14] or tabular format saved in CSV files [15]. Such formats are more AI-friendly as they represent the data in a more accessible and standardized form for an application of common AI frameworks. Nonetheless, the NDJSON-based FHIR data transformation approach [14] does not provide data selection criteria and filtering capabilities [16]. The approach presented in [15] requires expert knowledge of FHIRPath query language. Moreover, FHIR-based data preprocessing pipelines have been implemented in different contexts, for instance, as electronic data capture [17], as a natural language processing tool [12], and as a standardization protocol based on the Resource Description Framework [6]. Despite the immense benefit they offer regarding processing EHR data, existing approaches are limited to specific use cases or require considerable data preparation to perform standardization. Furthermore, their final output is not easily accessible by common data preprocessing tools and thus hinders the application of AI.

In this paper, we address the challenge of data interoperability in the health care sector by proposing an FHIR data harmonization pipeline (DHP) that provides EHR data in an AI-friendly format. The newly developed FHIR-DHP represents a data workflow solution that includes the aforementioned operations, such as data exchange, mapping, and export. Data privacy is a delicate topic in health care and is of great ethical concern [18]. Given the degree of automation, FHIR-DHP should allow the preprocessing of unseen data in an isolated hospital environment, which makes harmonization privacy preserving.

Methods

Ethical Considerations

The authors did not seek an ethics review board assessment due to the methodology of the study, which included open datasets and data preprocessing pipelines only.

FHIR-DHP Architecture Development

In our work, we propose a generic solution to harmonize hospital EHR data. The FHIR-DHP was designed based on the extract-transform-load framework [19], in which the data are pulled out (ie, queried) from diverse sources, processed into the desired format, and loaded into a data warehouse, namely the

”patient-model” database (DB). As the hospital database contains highly sensitive patient data, it is located behind the hospital’s security infrastructure and is completely isolated from outside access. Therefore, an edge-computation solution was designed, bringing the FHIR-DHP into the hospital’s own infrastructure. The edge-computation solution represents a set of frameworks that perform data querying, preprocessing, storage, and export. In this setting, direct access to the sensitive data is not required to run the standardization pipeline. The queries to the data are defined beforehand based on the database documentation.

To bring the data into a harmonized form, we used an FHIR data model, which is applied by mapping the relationships between the source database and the desired data standard. The FHIR standard is straightforward to implement because it provides a choice of JSON, XML, or resource description format for data representation. The mapping pipeline was developed in the Python programming language to translate queried hospital data into matching FHIR concepts and save the resulting resources in JSON format. The semantics of features from the source database and FHIR concepts are examined using available database and FHIR documentation. The conversion to FHIR was designed to only support a core release 4 standard of the FHIR format to allow generic data preprocessing.

To prevent errors in the remote data standardization scenario, the syntactic validation of FHIR resources is necessary. For instance, the conversion of data types can sometimes lead to erroneous values, especially with date features. Automatic syntactic validation allows the logging of occurred errors and the improvement of harmonization pipeline when working with unseen data. When syntactic validation is completed, FHIR resources should be transferred to the data warehouse to allow the fast and easy retrieval of standardized data for AI applications.

In the final stage of data export, we designed the output that provides the benefits of the original FHIR format with a high level of clinical detail that is also easily accessible for computational tools. We wanted to restructure the data representation in a way that supports effortless data selection and filtering capabilities and would not require a knowledge of FHIRPath query language. Consequently, this output format would enable the smooth conversion of data into a “tensor” format required by conventional AI frameworks.

FHIR-DHP Validation

To demonstrate and evaluate how the FHIR-DHP works, we used the openly available Medical Information Mart for Intensive Care IV (MIMIC IV) database [20]. MIMIC IV includes patient data from the intensive care units at a tertiary academic medical center in Boston, MA, United States. We selected a wide range of tables from MIMIC IV, which cover most of the events occurring during the hospital stay as well as core patient details, information about admissions, and hospital transfers (further referred to as core tables). The event tables include laboratory results, diagnoses, prescriptions, and other details, as shown in Table 1. In addition, MIMIC IV includes the so-called reference tables containing matching dictionaries with medical terms that are used in the hospital records.

Table 1. Selected core and event Medical Information Mart for Intensive Care IV (MIMIC IV) tables as well as the reference dictionary tables that were merged together with core and event tables for Fast Healthcare Interoperability Resources mapping.

Selected core and event MIMIC IV tables	Selected MIMIC IV reference tables
Patient	—[a]
Admissions	—
Transfers	—
Chartevents	d_items
Labevents	d_labitems
Procedureevents	d_items
Prescriptions	—
Inputevents	d_items
Microbiologyevents	—
Outputevents	d_items
Procedures_icd	d_icd_procedures
Diagnoses_icd	d_icd_diagnoses

[a]Not available.

The selected tables were mapped to FHIR standard. Automatic semantic validation is unfeasible, so 2 of the authors manually validated the mapping semantics independently of each other. There are many tools that perform automatic syntactic validation, such as the Python-based package “fhir.resources” used herein [21]. To evaluate the exporting of data from the patient-model DB, we retrieved the diagnosis records.

Results

FHIR-DHP Architecture

The approach presented here represents a scalable protocol for harmonizing hospital EHR data sets based on 5 stages from data query to data export in a standardized format.

Querying Data From the Hospital Database

To connect the FHIR-DHP pipeline to the hospital DB, a communication server is employed. This server runs all necessary queries to retrieve the patient data. The query execution can be run at regular intervals as well as in batches of patients, so as not to overload the data pipeline. Furthermore, the queries prestructure the data according to their semantic relations before proceeding to data mapping.

Mapping Data to FHIR

FHIR allows describing data formats and elements that are recorded as "resources" and an application programming interface for exchanging EHRs. To perform the mappings, semantics of features from the source database and FHIR concepts are explored as well as the relationships between the data tables. Consequently, the mappings between the database tables and FHIR resources are defined. Features where a matching FHIR concept is not found are excluded. The resulting FHIR resources are then saved in JSON format.

Syntactic Validation of FHIR Mappings

During validation, mapped data are ensured to have the correct data types as well as the syntactic format where the hierarchy is maintained, and entries follow FHIR standard specifications. All mappings are validated first during the development stage to identify structural errors and data type inconsistencies. A validation algorithm is incorporated into the pipeline to confirm the correctness of the transformed data in the remote data standardization scenario.

Transferring FHIR Resources to Patient-Model DB

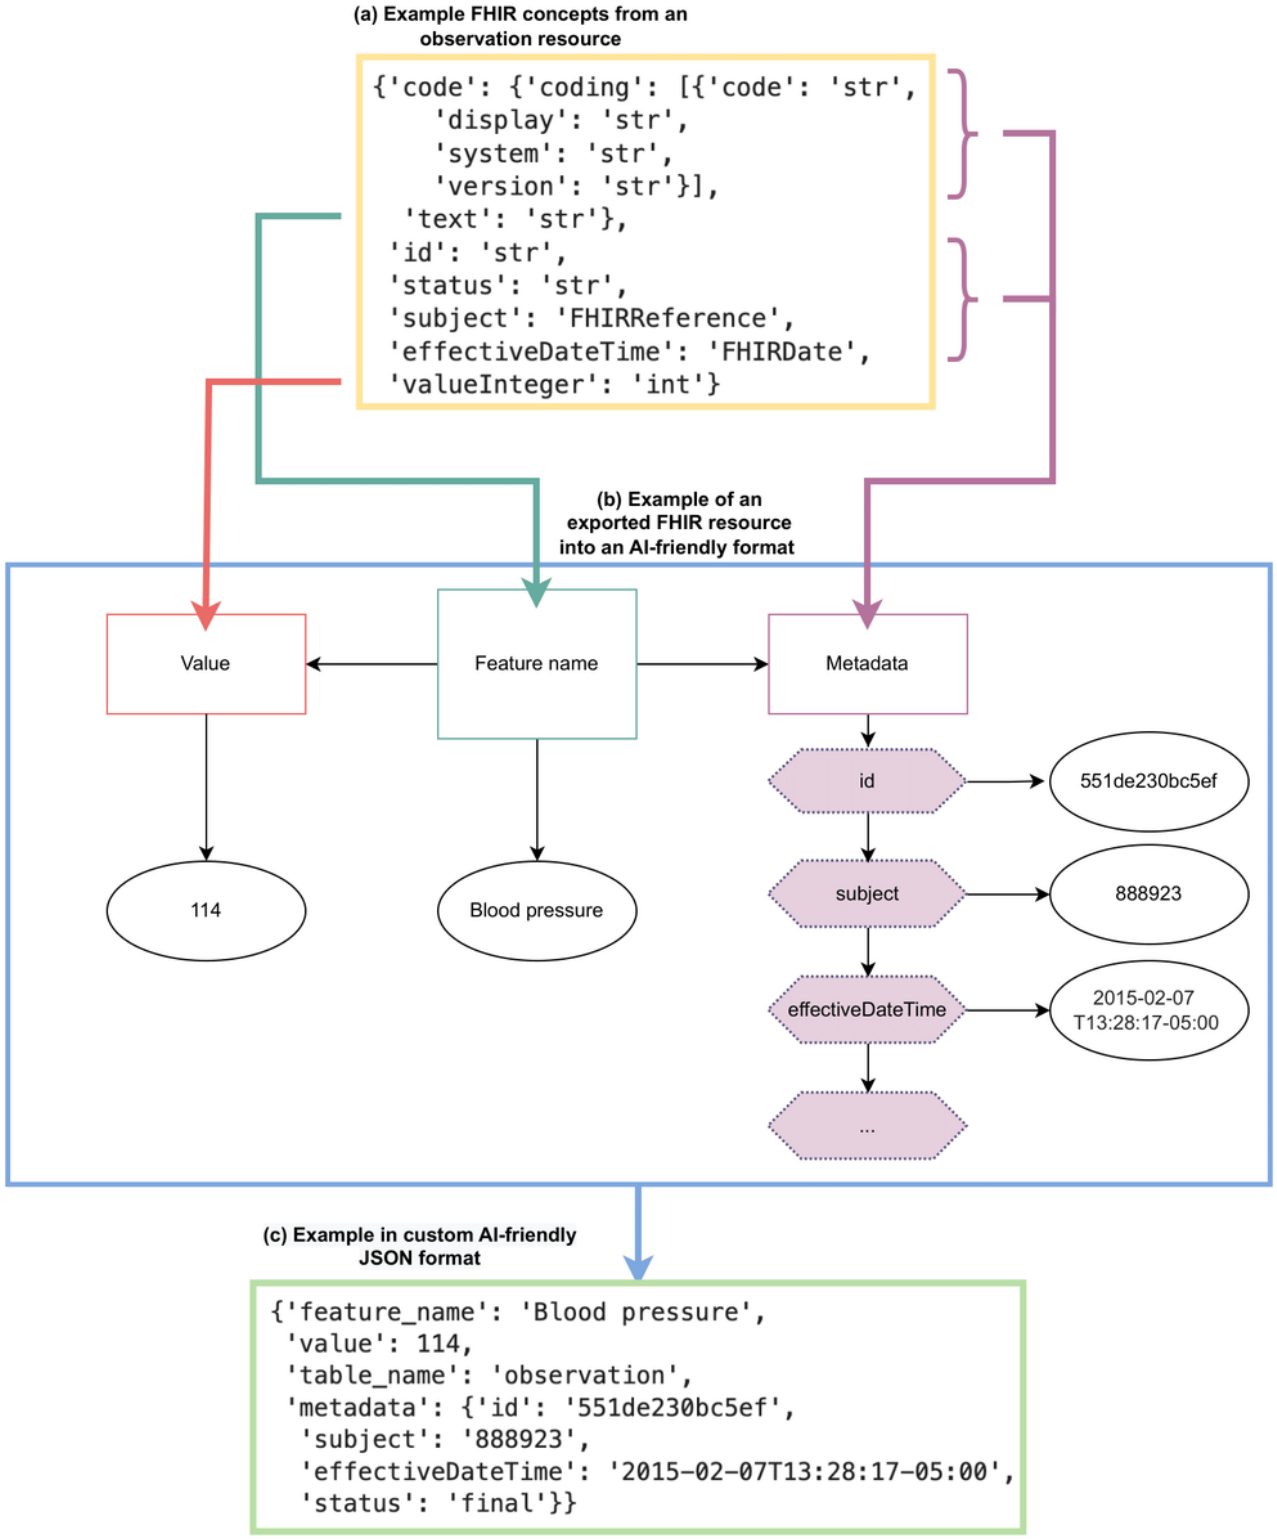
The DB of choice for the patient model is Postgres [22], which is an open-source relational DB management system featuring SQL compliance and storage of JSON documents. The database for the FHIR resources is used to harmonize the locally available data only once to allow the further application of various medical AI-based solutions. The data are stored according to FHIR resource type where each resource is saved in a separate JSON structure.

Exporting Data Into Custom JSON format

To export the data from the patient-model DB, the selection is performed by outlining the tables and features of interest in a configuration file, which is then used to determine which harmonized data should be queried. FHIRPath queries were written to retrieve all elements from FHIR resources adhering to specific formatting rules in respect of the predefined key-value structure and to place the extracted elements into the custom JSON file. Such transformation flattens the hierarchical structure of FHIR resources and makes the data more accessible for common data preprocessing tools. The final flattened output does not require expert knowledge of FHIRPath query language and supports effortless data selection and filtering. The resulting file also allows the uncomplicated conversion of data into a "tensor" format required by conventional AI frameworks and fast data selection based on the following 4 keys: feature_name, table_name, value, and metadata.

In Figure 1, we demonstrate how the FHIR-DHP recodes nested FHIR syntax to more accessible features in an AI-friendly format. Example FHIR concepts from an observation resource are given in Figure 1a, where the code's entity "text" defines the record or measurement label. The entity "text" is often duplicated in the item "display." However, depending on the coding system, this "display" item can change, whereas "text" always stays the same and is therefore used as a feature name. The information from the FHIR resource is grouped into the 4 concept keys of feature name (eg, "Blood pressure"), value (eg, "114"), table name (eg, "observation"), and metadata (Figure 1b). For a given FHIR resource type, the metadata may include concepts such as dates, references, coding system details, and resource ID, among other things. As an output, feature names together with a corresponding value and available metadata are provided in a custom JSON structure (Figure 1c). The defined format allows uncomplicated data selection and aggregation based on resource type (eg, "table_name"), feature name, and value. Additional information in a standardized format can be easily accessed from the metadata key and allows further data manipulation.

Figure 1. Conceptual overview for an exemplary Fast Healthcare Interoperability Resources (FHIR) structure and hospital record, which are transformed from FHIR standard to an artificial intelligence (AI)–friendly format.



FHIR-DHP Validation

The MIMIC IV data were queried accordingly to the defined FHIR mappings. The core and event MIMIC IV tables were merged with reference tables to contain a complete description of the hospital records. As a result, the data were grouped and restructured into the information blocks required in FHIR standard. Manual independent validation of the mapping semantics resulted in slight discrepancies, which were subsequently resolved to adhere closely to the FHIR standard. The automatic syntactic validation allowed the prompt verification of standardization operations.

Table 2 shows to which FHIR resources the MIMIC IV tables were mapped. The largest proportion of tables (4 out of 12 tables) were mapped to the *Observation* FHIR resource type, which included lab, microbiology, output, and charted events

collected throughout the patient's stay. The information on admissions and transfers was translated into the *Encounter* FHIR resource (2 out of 12 tables). Procedure events and International Classification of Diseases codes (2 out of 12 tables) were stored in the *Procedure* FHIR resource. Given that the prescriptions table contains medication requests (1 out of 12 tables) and the input events table holds records of medication administration (1 out of 12 tables), these tables were mapped to the corresponding FHIR resource types. Finally, the *Condition* FHIR resource was used to map the table with the patients' diagnosis details (1 out of 12 tables).

In Table 3, we demonstrate how the mapping of the MIMIC IV "diagnoses_icd" table to *Condition* FHIR resource was conducted. Multiple columns of the "diagnoses_icd" table such as "icd_code", "icd_version," and "long_title" were mapped to the FHIR "condition.code" concept, which has a nested structure and provides keys to store the exact International Classification of Diseases code, the version of the coding system, and the code title. The full diagnosis title was mapped both to the "display" and "text" entities.

Figure 2 shows an example of how queried diagnoses records are harmonized to an AI-friendly format. The standardization follows the FHIR-DHP stages described above. At first, the raw data from tables "diagnoses_icd" and "d_icd_diagnoses" are queried (Figure 2a) and merged accordingly to the defined FHIR mappings. Then, the features are renamed as defined in Table 3 for the FHIR condition resource, and the required entities such as "resourceType" and "id" are created (Figure 2b). Finally, the values are placed into a nested FHIR structure (Figure 2c), and subsequently, the data are transformed into a JSON format (Figure 2d), which can be automatically validated (Figure 2e) and saved in the patient-model DB. When the resource is not approved in terms of its syntactic quality (eg, data type, nested structure, or cardinality), an error is raised, which prevents the further saving of this resource in the patient-model DB (Figure 2e). Otherwise, the resource is transferred into a storage (Figure 2f), and the requested data are exported in a custom AI-friendly JSON format (Figure 2g).

We provide an example of a further 2-step transformation of harmonized diagnosis data to a "tensor" format in Multimedia Appendix 1 [12,23].

Table 2. Overview of the mappings performed on the selected Medical Information Mart for Intensive Care (MIMIC) database (DB) tables to Fast Healthcare Interoperability Resources (FHIR) types.

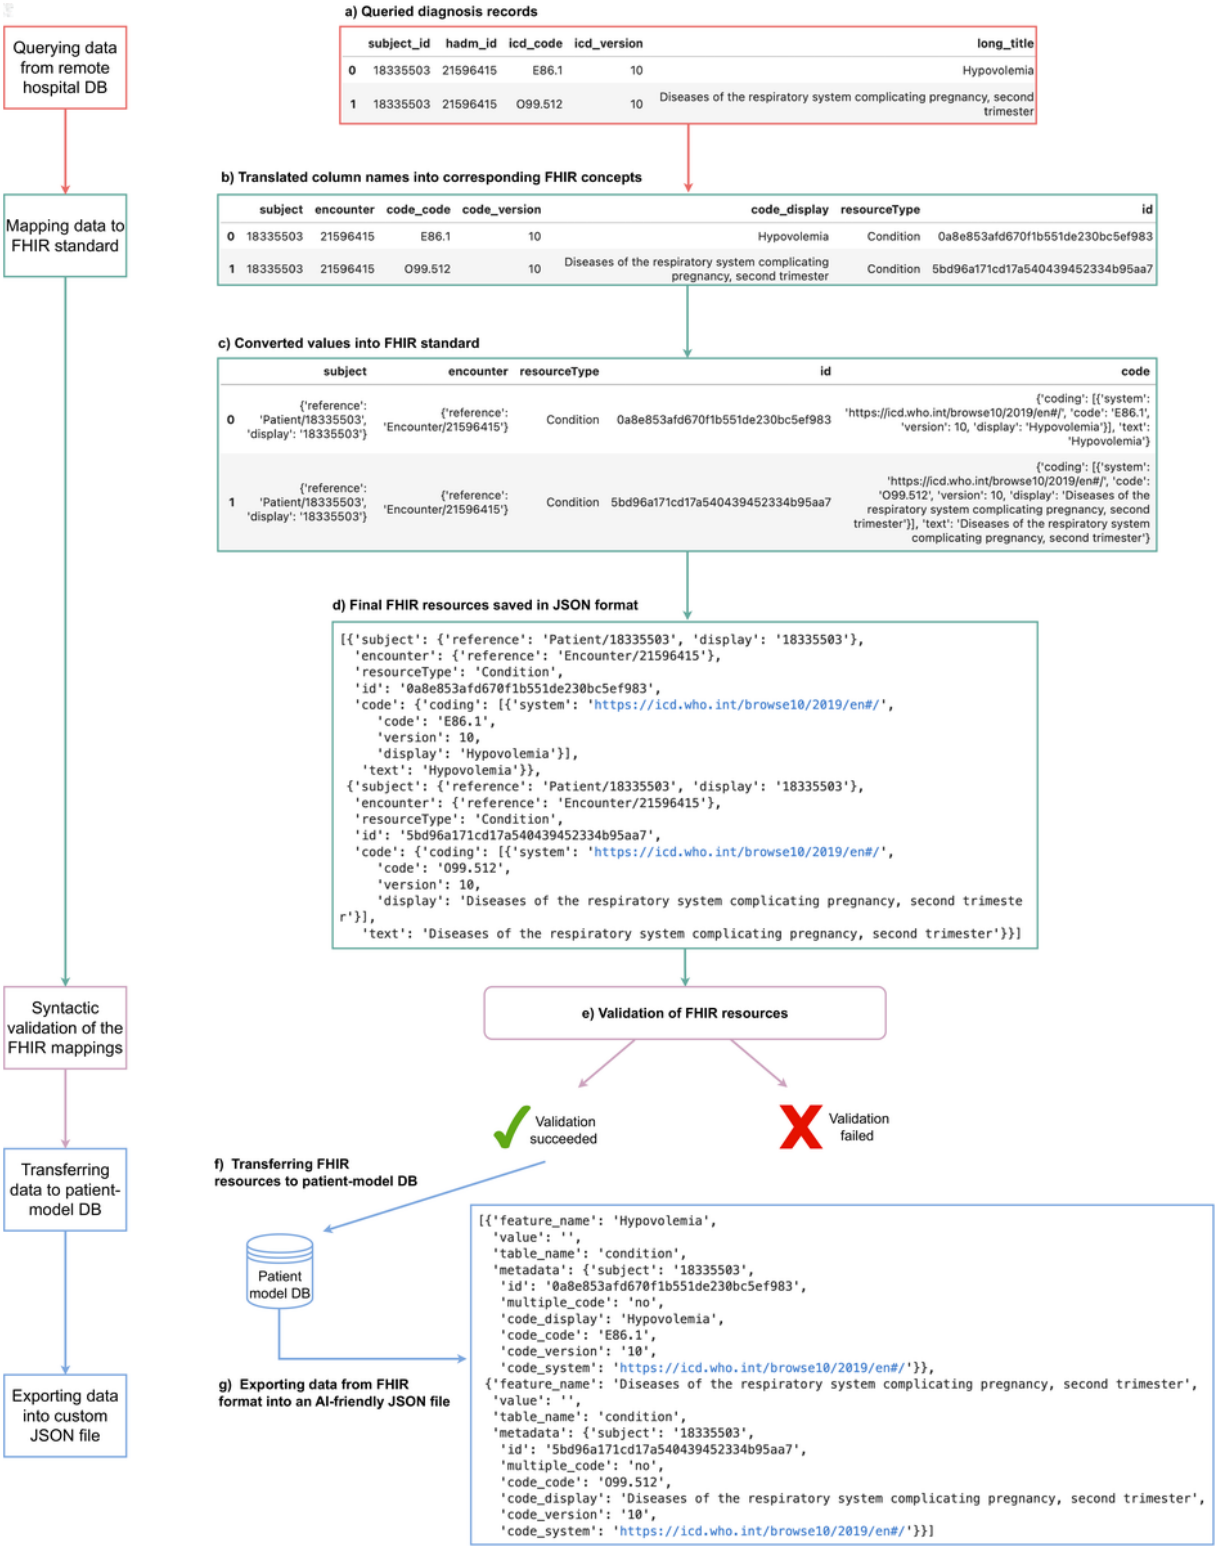
MIMIC IV DB	FHIR resource type
Patients	Patient
Admissions	Encounter
Transfers	Encounter
Chartevents	Observation
Labevents	Observation
Procedureevents	Procedure
Prescriptions	MedicationRequest
Inputevents	MedicationAdministration
Microbiologyevents	Observation
Outputevents	Observation
Procedure_icd	Procedure
Diagnoses_icd	Condition

Table 3. Mapping of "diagnoses_icd" table to Condition Fast Healthcare Interoperability Resources (FHIR) resource.

MIMIC[a] format	FHIR resource format
mimic.diagnoses_icd.subject_id	fhir.condition.subject
mimic.diagnoses_icd.hadm_id	fhir.condition.encounter
mimic.diagnoses_icd.icd_code	fhir.condition.code_code
mimic.diagnoses_icd.icd_version	fhir.condition.code_version
mimic.diagnoses_icd.long_title	fhir.condition.code_display
mimic.diagnoses_icd.long_title	fhir.condition.code_text

[a]MIMIC: Medical Information Mart for Intensive Care.

Figure 2. Flowchart showing an example diagnosis data being processed through the 5 stages in Fast Healthcare Interoperability Resources (FHIR) data harmonization pipeline (DHP). The first stage (a) includes querying of the diagnoses records, at the second stage (b-c) the data are mapped to FHIR standard, and the third stage carries out the syntactic resource validation. (f) If the FHIR resource is successfully validated, it is being transferred into the patient-model database (DB), and then (g) exported in a custom artificial intelligence (AI)–friendly JSON format.



Discussion

Principal Findings

The Harmonization of EHR data is a crucial step toward increasing cooperation, interoperability, and quality of patient care in the clinical routine and medical research. To drive the harmonization of medical data forward, we developed the FHIR-DHP and evaluated it on key MIMIC IV tables. A detailed example of data standardization was presented for clinical diagnosis records from the MIMIC IV database. The FHIR-DHP allows the querying of health data in an isolated environment by employing an edge-computation solution and a communication server, which retrieve patient data and

prestructure it for further mapping to the FHIR standard. A validation step ensures syntactic compliance and initiates the transfer of formatted data to the patient-model DB. The data export provides FHIR resources in a custom JSON file format.

Owing to the FHIR format's multilayered nested structure, its accessibility for AI algorithms is low as it requires transformation into a format compatible with common data preprocessing tools. Thus far, a number of studies have attempted to solve this problem. However, the final output of these studies has not supported data selection criteria and filtering capabilities [14] and requires expert knowledge of FHIRPath query language [15]. In this study, we introduce a custom JSON format that represents a higher level of abstraction to support easier data selection based on the following 4 keys: feature_name, table_name, value, and metadata. Moreover, the newly developed JSON structure fits the expected data format of common data preprocessing frameworks, which are designed to work efficiently with tabular data. As a result, the output presented facilitates the generic and fast deployment of AI and patient cohort identification algorithms.

In comparison to [17,24], the details of FHIR-DHP execution inside the hospital environment in respect of protecting data privacy are discussed. This step, though crucial, is often omitted and left out of the published standardization protocols. The edge-computation solution sets up the FHIR-DHP in a privacy-preserving way where the preprocessing of the patient-related data is performed inside the hospital and is completely isolated from outside access. The so-called federated learning (FL) framework [25] can be integrated into the FHIR-DHP workflow to run algorithms locally, using data from the on-premises database in the respective hospitals and to merge model parameters centrally in the cloud without any patient data leaving the hospital. The FL framework requires data to be in a consistent format across various hospital systems. The developed pipeline achieves such a format and enables the scaling of AI applications.

Thus far, there are only 2 studies attempting to perform the mapping of an MIMIC IV database [26,27]. In [26], the mapping was performed on fewer tables than our approach (8 versus 12 tables). The FHIR mappings from [27] have been recently released and were not yet widely validated. Similar to the approach taken in [17,24,26], FHIR-DHP includes the verification of the performed FHIR mapping, which is essential to ensure the validity of data transformation and to adhere to FHIR version updates. Moreover, in comparison to [17,24,26], FHIR-DHP represents a generic approach to standardize EHR data and can be applied to various hospital database systems.

With the introduction of the FHIR-DHP into the hospital environment, a number of patient-stay parameters can be potentially optimized using AI-based algorithms. For example, the length of stay as well as mortality could be reduced [28], and patients suitable for trial treatment could be automatically and efficiently identified [29]. In consequence, the financial impact on medical providers in respect of personnel time and resources would decrease considerably. The FHIR-DHP aims to bring health care closer to digital transformation and thus toward "Healthcare 4.0" [30] by making EHR data usable "from bedside-to-bench." By inverting the idea of translational research, in contrast to "from bench-to-bedside," accessing the full potential of medical big data with AI will further inform and advance basic research.

Limitations

There are several limitations that we would like to emphasize. FHIR-DHP only works with a core standard of the FHIR format. Those core FHIR resource types have a bounded set of concepts that present a constraint to mapping accuracy. Although the standard resources can be expanded using a profiling technique or FHIR extensions, the use of those would make the FHIR-DHP less generic. Hence, we implemented the mapping using only the standard FHIR resources and omitted some of the MIMIC IV data features that did not have a matching concept in FHIR. Additionally, the FHIR mapping step is subject to the extent of the detail of the database documentation used to infer the semantic and syntactic properties of the data. A solution for an automatic concept recognition can potentially solve this problem. The existing approach in [6] is limited to a small number of FHIR resources and requires an extensive data preparation. Further experiments in this direction could alleviate the concept-matching problem and the requirement for a detailed database description. Moreover, the validation and robustness of FHIR-DHP needs to be tested on other EHR data sets to evaluate its generic setup. In addition, to validate the FHIR-DHP compatibility with machine learning pipelines, further experiments are needed.

Future Prospects

The proposed FHIR-DHP pipeline highlights the therein featured essential data standardization stages and holds the potential to becoming an interoperable harmonization system with an AI-friendly data format. FHIR-DHP enables interoperability and cooperation between clinical institutions and a rapid patient cohort identification for clinical trials; it also unlocks the potential of big medical data.

Conclusions

We provide a comprehensive approach to transforming unstandardized EHR data into a harmonized multilayered nested FHIR format and then to a more readable and more efficient AI-friendly JSON structure. We developed a 5-stage data harmonization pipeline, which includes validation checks. The AI-friendly format of hospital data allows the generic and fast integration of both AI and patient cohort identification algorithms. Harmonized and standardized health care data are of great value to advancing efficiency in big data processing, cooperation, and multicenter data exchange in the clinical sector, boosting medical research, patient care, and clinical trial cohort identification. The next steps would include validating our approach in a hospital environment and applying a privacy-preserving FL framework to make use of advanced AI deployment.

Acknowledgments

This work was partially funded by the German Federal Ministry of Education and Research under Grant 16SV8559.

Availability of Data and Materials

The MIMIC IV database used in this study is openly available to credentialed users who sign the “Data Use Agreement” at PhysioNet website [20]. The code is not publicly available due to privacy, but a demo is available from the corresponding author on request.

Authors' Contributions

EW, SN, MK, JR, and AM were responsible for the study conception; EW and MK took part in data analysis; EW, SN, and EM created the figures; EW, MK, AM, and SN were responsible for methods. EW, EM, JR, and SAIK wrote the draft; BA, JB, PVB, JC, ARF, ASP, and NS reviewed and revised the work.

Abstract

Background: South Korea joined SNOMED International as the 39th member country. To ensure semantic interoperability, South Korea introduced SNOMED CT (Systemized Nomenclature of Medicine–Clinical Terms) in 2020. However, there is no methodology to map local Korean terms to SNOMED CT. Instead, this is performed sporadically and independently at each local medical institution. The quality of the mapping, therefore, cannot be guaranteed.

Objective: This study aimed to develop and introduce a guideline to map local Korean terms to the SNOMED CT used to document clinical findings and procedures in electronic health records at health care institutions in South Korea.

Methods: The guidelines were developed from December 2020 to December 2022. An extensive literature review was conducted. The overall structures and contents of the guidelines with diverse use cases were developed by referencing the existing SNOMED CT mapping guidelines, previous studies related to SNOMED CT mapping, and the experiences of the committee members. The developed guidelines were validated by a guideline review panel.

Results: The SNOMED CT mapping guidelines developed in this study recommended the following 9 steps: define the purpose and scope of the map, extract terms, preprocess source terms, preprocess source terms using clinical context, select a search term, use search strategies to find SNOMED CT concepts using a browser, classify mapping correlations, validate the map, and build the final map format.

Conclusions: The guidelines developed in this study can support the standardized mapping of local Korean terms into SNOMED CT. Mapping specialists can use this guideline to improve the mapping quality performed at individual local medical institutions.

Introduction

South Korea is a leader in global information and communication technology. According to a 2021 Organization for Economic Co-operation and Development (OECD) survey of national health data infrastructure and governance, South Korea ranked second among OECD countries on data availability, maturity, and use [1]. However, data are not used fully, owing to a lack of interoperability and data security problems [2]. Interoperability is the ability of different information systems, devices, and applications to access, exchange, integrate, and cooperatively use data in a coordinated manner [3]. This occurs within and across organizational, regional, and national boundaries. Interoperability provides timely and seamless use of information and helps to globally improve the health of individuals and populations [3]. There are 4 levels of interoperability: foundational, structural, semantic, and organizational. Among them, the key strategy for ensuring semantic interoperability is the use of standard terminology that allows concepts to be represented unambiguously between the senders and receivers of information [4].

To achieve semantic interoperability, interface or local terms extracted from natural language written by a health care provider can be stored as reference terminology, such as in the SNOMED CT (Systemized Nomenclature of Medicine–Clinical Terms; SNOMED International). The stored terms with reference terminology can then be used in classification systems such as the International Classification of Diseases (ICD) for statistical purposes [2]. Health care providers in South Korea write medical records in natural language rather than using standard interface terms. Korean Standard Classification of Disease (KCD) codes are used for mortality and morbidity reports, and electronic data interchange (EDI) codes are used for national health insurance claims. Therefore, to fully use health care data, mapping terms extracted from phrases written in natural languages or using interface terms in medical records, disease classification codes, and national health insurance claim codes to reference terminologies are required.

Various efforts have mapped the terms used to document clinical findings and procedures in electronic medical records (EMRs), classification systems such as ICD 10th revision, and existing health care terminologies such as Logical Observation Identifiers Names and Codes (LOINC) and International Classification of Nursing Practice (ICNP) to the SNOMED CT in other countries [5-11]. The South Korean government, aiming to encourage the use of standard terminology in health care institutions, joined SNOMED International as the 39th member country and introduced SNOMED CT in 2020 to ensure interoperability. Subsequently, various efforts have mapped terms used to document clinical findings and procedures in EMRs or national health checkup questionnaires, classification systems including KCD-7, and EDI codes to the SNOMED CT [12-17]. Furthermore, these results are used for research purposes in the Common Data Model [17,18].

Individual medical institutions have attempted to map their terms to SNOMED CT. However, the mapping quality cannot be guaranteed due to its sporadic and independent map development. SNOMED International introduced Snap2, a tool to support mapping. However, since the tool is based on English source terms, it is difficult to apply to the Korean terms used in South Korea. This study, therefore, aimed to develop a guideline to ensure high-quality mapping of terms used to document clinical findings and procedures in the EMRs of local institutions in South Korea to SNOMED CT. The guideline focuses on a process of defining a relationship between concepts used in EMRs and the concepts of SNOMED CT [18]. The guideline does not include organizing a mapping team or reviewing existing maps. In addition, this guideline's scope is limited to mapping to the SNOMED CT concept and excludes mapping to SNOMED CT post-coordinated expression.

Methods

The process of developing the mapping guideline was led by a mapping guideline development committee. The committee consisted of 3 mapping experts. All committee members had SNOMED CT mapping experiences spanning more than 5 years and have conducted various national projects, such as SNOMED CT mapping of KCD-7 and EDI codes supported by the Korea Health Information Service under the Ministry of Health and Welfare in South Korea. The development of the guidelines was conducted from December 2020 to December 2022.

To develop the mapping guidelines, the committee members first developed an overall structure based on a review of the existing guidelines and their own mapping and teaching experiences. An extensive literature review was performed in PubMed, MEDLINE, and Google Scholar. The existing mapping guidelines and previous studies [19-24] were reviewed according to these criteria: (1) scope and purpose, (2) involvement of the stakeholders, (3) rigor of development, (4) clarity of presentation, and (5) applicability [25]. After the review, the existing mapping guidelines and previous studies could not be used due to the following reasons: (1) not matched in scope or purpose because of mapping SNOMED CT concepts to other classification systems such as ICD-10 or ICD-9-CM [20,21], (2) limited to automatic mapping only without any information about mapping rules [21,22], (3) lack of currency in SNOMED CT, published more than 10 years ago [20,21], and (4) no detailed information on the mapping process [23,24]. As a result, version 2.0 of the SNOMED CT-AU mapping guideline, developed by the National Electronic Health Transition Authority of Australia, also known as the Australia Digital Health Agency [19], was chosen as the framework of the guideline. The SNOMED CT-AU mapping guideline clearly describes the preprocessing process, classification and validation of mapping results, and final map structures. It matches the scope and purpose of our SNOMED CT mapping guideline and uses the most recent version of SNOMED CT as a target code among the existing guidelines. In addition, it includes rigorous mapping examples. The following sections were adopted from SNOMED CT-AU: define the purpose and scope of the map, preprocessing source terms, mapping patterns, validation, and structure of the map.

Based on the committee members' experiences, the most difficult aspects of mapping between local terms and SNOMED CT were extracting and understanding the source terms, developing search terms, and searching the target SNOMED CT. However, the SNOMED CT-AU mapping guideline does not describe how to extract and understand source terms from EMRs, how to develop search terms, or how to search for target concepts using the SNOMED International browser. It is difficult for beginners to apply the existing SNOMED CT mapping guidelines, such as those of the SNOMED CT-AU. Therefore, the committee added 4 steps to the guideline: extract terms, preprocess source terms using clinical context, select a search term, and use search strategies to find SNOMED CT concepts using a browser.

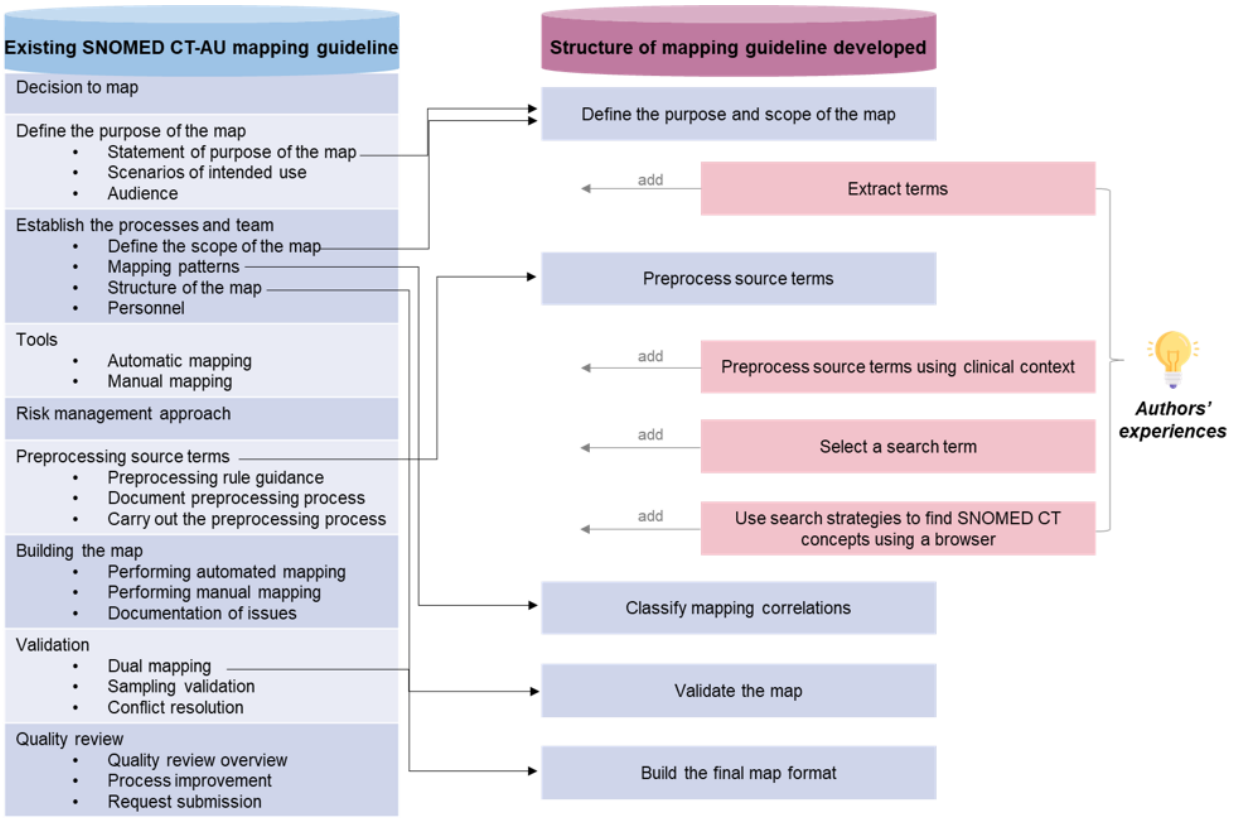
A guideline review panel was invited to validate the guideline from May 2021 to September 2022. The review panel consisted of 3 mapping experts: a professor with more than 5 years of SNOMED CT mapping experience working at a South Korean university and 2 mapping specialists with more than 3 years of mapping experience. The first author emailed, explaining the purpose of the study, and asked to review the understandability and usability of the developed guidelines and to add more mapping examples, if possible, to the panel. In addition, 2 graduate students with no mapping experience were asked to assess whether the guideline was understandable and helpful throughout the email. These 2 processes were repeated until no more issues were identified.

Results

Overview

The SNOMED CT mapping guidelines developed in this study consisted of 9 steps, as presented in Figure 1. Step 1 defines the purpose and scope of the map. Step 2 describes how to extract source terms from EMRs. Step 3 explains how to translate the source terms into Korean, how to define abbreviations or acronyms, and how to correct spelling or punctuation errors [19]. Step 4 explains how to understand the meanings of the extracted source terms to reflect clinical contexts. Step 5 describes how to select appropriate search terms to improve mapping [26]. Step 6 describes efficient strategies to search for SNOMED CT concepts using a browser [27]. Step 7 describes how to classify the correlation between source terms and target SNOMED CT [5,7,28-31]. Step 8 explains how to validate the adequacy and accuracy of the map [19]. The final step explains how to document the final map [32]. The SNOMED CT examples used in this guideline are taken from the international edition, released on January 31, 2023.

Figure 1. Overview of the developed guideline structure. SNOMED CT: Systemized Nomenclature of Medicine–Clinical Terms.



Step 1: Define the Purpose and Scope of the Map

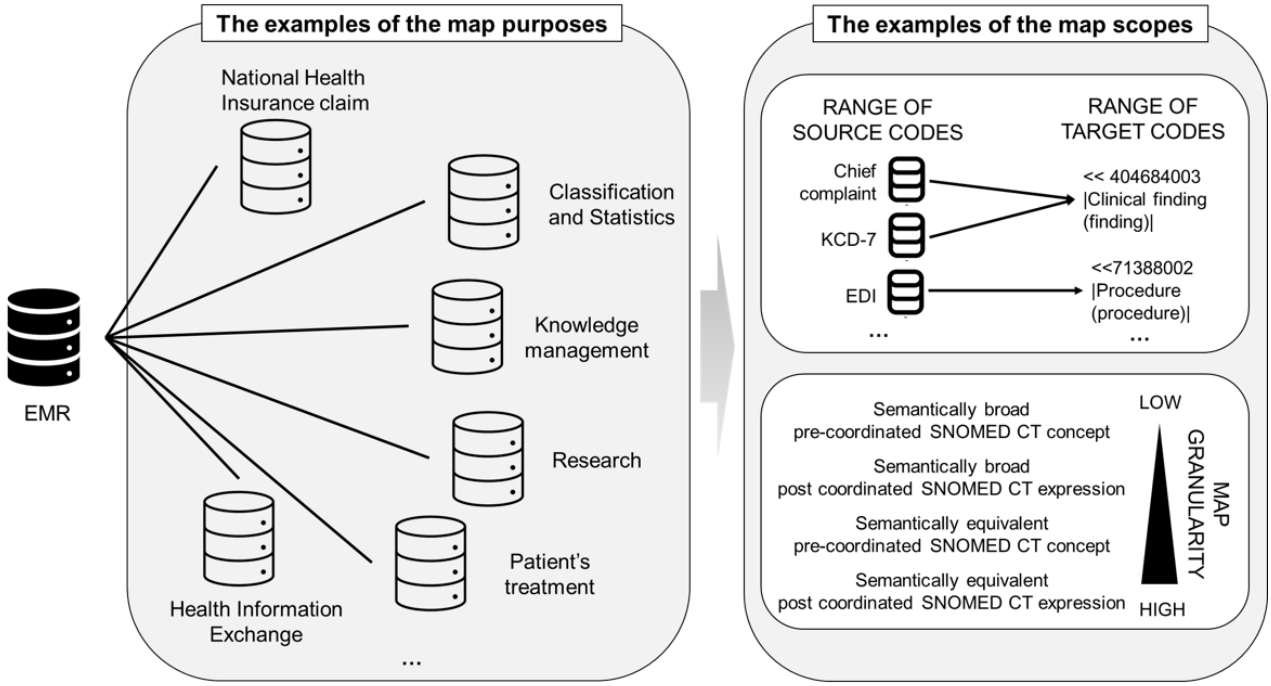
To proceed with mapping, the mapping specialists must first define the purpose and scope. The purpose of the map can be for national health insurance claims, classification and statistics (eg, mortality and prevalence of specific diseases), knowledge management (eg, decision support system), health information exchange among institutions, studies (eg, Common Data Model), and patient care. Figure 2 presents examples of map purposes and scopes.

The scope of the map refers to the range of source and target codes and granularity and may differ according to its purpose. For example, if the map's purpose is to provide prevalence

statistics for specific diseases, the source codes are restricted to KCD-7 in the clinical findings domain, and the range of target codes should be SNOMED CT concepts in the clinical findings, person, or event top-level hierarchy. If the map's purpose is for national health insurance claims, the source codes are restricted to the EDI codes in the procedure domain, and the range of target codes should be SNOMED CT concepts in the procedures' top-level hierarchy.

Map granularity can also vary according to the purpose of the map. For example, if the map is for national health insurance claims, the local term "alcohol-related seizure," mapped to KCD-7 code G40.5 (special epileptic syndromes), should be mapped to the abstract SNOMED CT concept 230431001 (situation-related seizures [disorder]). However, if the map is for exchanging health information among institutions, the source code should be mapped at the granular level to SNOMED CT concept 308742005 (alcohol withdrawal-induced convulsion [disorder]).

Figure 2. Examples of map purpose and scope. EDI: electronic data interchange; EMR: electronic medical record; KCD: Korean Classification of Disease; SNOMED CT: Systemized Nomenclature of Medicine–Clinical Terms.



Step 2: Extract Terms

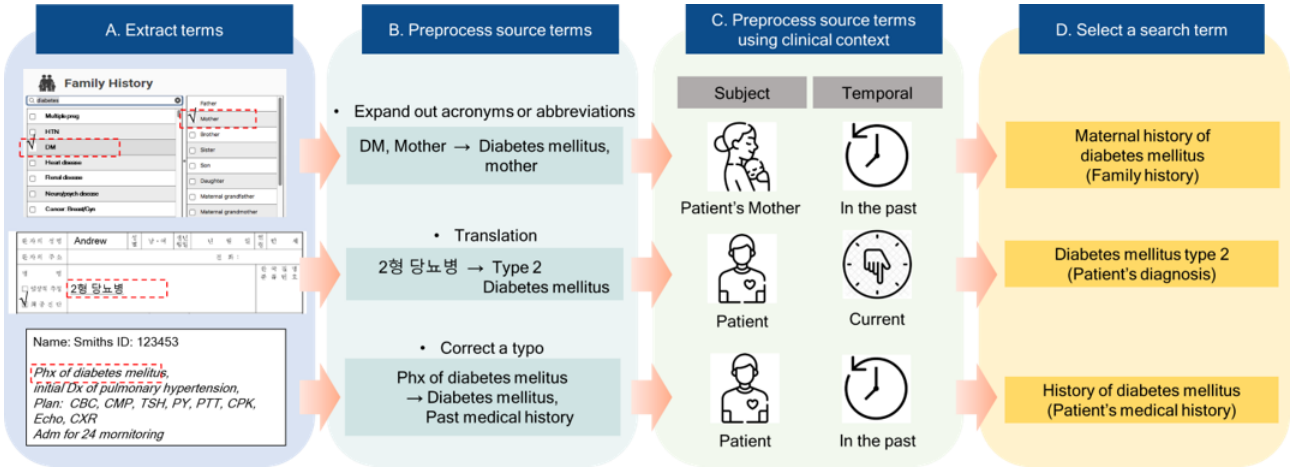
When the purpose and scope of the map are determined, mapping specialists should extract terms from EMRs while considering where and how clinical notes are documented. Patient diagnoses can be extracted from progress notes and other similar information sources. Family and past medical histories can be extracted from progress notes and initial nursing assessment records. Surgical procedure names can be extracted from surgical notes. Evaluation procedures can be extracted from laboratory documentation.

These data sources are either structured, semistructured, or unstructured medical records written in natural language; for example, as presented in step A of Figure 3, if we extract a "patient's mother diabetes mellitus type 2," first the interface terms from the family medical history sections in EMRs can be identified, and then the "DM" diagnosis and the "mother's family relationship" can be extracted. The terms written in free text from the semistructured family medical history records sections of EMRs can be identified, and then the diagnosis "2형 당뇨병 (diabetes mellitus, type 2)" can be extracted. We also can identify terms from unstructured records by reading all the documents and extracting the terms written in free text, such as "Past medical history of diabetes mellitus," which requires natural language processing (NLP).

When conducting automatic term extraction through NLP, word segmentation throughout semantic analysis is required using a corpus [33,34]. For example, the term "diabetes mellitus" should be extracted based on its meaning, not by extracting "diabetes" and "mellitus" separately. For this process to be possible, a Korean medical corpus can be used, such as the medical terminology database released by the Korean Medical Association [35] or the Korean Medical Library Engine [36]. The results of automatic terminology extraction should be reviewed manually.

Alternatively, terms can simply be extracted from code systems such as KCD-7, EDI, and local hospital codes. In these cases, it is sufficient to extract the terms mapped to the code system without duplication.

Figure 3. Examples of the process from term extraction to selecting a search term.



Step 3: Preprocess the Source Terms

Preprocessing takes daily English terms as the source terms, for instance, by translating Korean terms into English. These Korean English (Konglish) terms are then translated into native English terms, with acronyms or abbreviations defined and spelling or punctuation errors corrected. If terms are written in Korean, preprocessing starts with translating the Korean terms into English. For example, "당뇨" written in Korean must be translated into "diabetes mellitus." Konglish is often used in Korean clinical settings. It is necessary to change Konglish terms into proper English terms. In Korean clinical settings, for example, an evaluation procedure "초음파 검사" is represented by various English words such as in SONO and sonogram. SONO, or sonogram, is the image obtained using ultrasound. If it is the name of an evaluation procedure, it is, therefore, appropriate to translate it into "ultrasound."

If terms are written in acronyms or abbreviations, which are commonly used by health care providers, preprocessing may be required to rewrite them in complete words. The acronym ASD, used in departments of pediatric cardiology, was defined as "atrial septal defect." The abbreviation MMG used frequently in South Korea, must be rewritten to "mammography."

Terms should be corrected when misspelled. For example, "asceding aorta dilatation" should be corrected to "ascending aorta dilatation" to obtain the correct search results. Furthermore, if terms include incorrect punctuation, it is preferable to edit the spacing of the source terms. For example, the search for the source term "DeQuervain's disease, wrist, Rt." is missing a space, which must be added to produce "De Quervain." Other examples are presented in step B of Figure 3.

Step 4: Preprocess Source Terms Using Clinical Context

The terms preprocessed in the previous step can have different meanings depending on the clinical context, such as subject, temporal, or finding contexts. For example, the meaning of the preprocessed source term "diabetes mellitus" varies depending on which part of the EMR it is extracted from; it can be "diabetes mellitus," "past medical history of diabetes mellitus," "family history of diabetes mellitus," or "no family history of diabetes mellitus." "Past medical history of diabetes mellitus" means that the temporal context is in the past. "Family history of diabetes mellitus" means that the temporal context is current or in the past and that the subject is a person in the patient's family. "No family history of diabetes mellitus" means that the temporal and subject contexts are the same as "family history of diabetes mellitus," but the finding context is absent.

Clinical context can be inferred from the source of the structured or semistructured medical records or the text in which the source term is written. If the family history section is the source of the medical record, the subject is a family member of the patient, and the temporal context is the past or the present. If the past medical history section is the source, the subject is the patient, and the temporal context is the past or present. If the chief complaint section is the source, the subject is the patient, and the temporal context is the present. If the clinical context cannot be inferred from the structured or semistructured records, the mapping personnel should read the text in which the source term is written. Examples are presented in step C of Figure 3.

Step 5: Select a Search Term

To search for a target SNOMED CT concept, a search term comprising keywords of the source terms that have undergone preprocessing must be selected. The search success rate is increased if the mapping specialist understands the general naming convention used by SNOMED International [26]. For example, a diagnosis or chief complaint can be expressed as "finding or morphology + body structure," a surgery or procedure name can be expressed as "procedure + body structure," the past medical history can be expressed as "history + disease name," and the family medical history can be expressed as "family history + disease name." The body structure requires "structure" to be attached to its name. Most descriptions used singular rather than plural expressions.

Stop words in NLP, which are frequently used words with restricted semantic specificity, should be excluded from search terms to improve the success rate. These stop words include articles ("a," "an," "the"), prepositions ("in," "at," "with," "without"), conjunctions ("and," "as"), and ambiguous adjectives or adverbs ("other," "alone," "single," "side," etc). Examples are presented in step D of Figure 3.

Step 6: Use Search Strategies to Find SNOMED CT Concepts Using a Browser

Use the First 3 Characters of Words

Searches can start with the first 3 characters of search terms. With the first 3 characters, the mapping specialist can prevent search failures due to differences in the forms of various words, such as nouns, verbs, and the use of the passive voices and differences in singular and passive voices. For example, if the source term "perforated small intestine" is entered into the browser, equivalently matched concepts cannot be obtained. However, if 3 characters of each word—"per sma int"—are entered, the concept "235741002 |Perforation of small intestine (disorder)|" is matched.

When a SNOMED CT concept appears, the parent, child, and sibling concepts—higher, lower, or at the same level in the hierarchy—must be reviewed to determine if it is semantically correct.

Search With Synonyms of Source Terms

If the target SNOMED CT concept is not identified by search terms, synonyms should be used as search terms for the source term. The synonyms can be obtained by searching the medical terminology database released by the Korean Medical Association [34] or by searching the Korean Medical Library Engine [36]. Otherwise, the synonym can be found by including "synonym" in search terms on search engines such as Google, searching the thesaurus, reviewing websites of prestigious medical institutions, or from previous studies. In addition, conversational English terms should be changed so that different terms with equivalent meanings are also considered. For example, the conversational English phrase "removal of prostate stones" should be converted into the medically accurate phrase "removal of prostate calculus" for a successful search. Table 1 lists examples of using synonyms in a search term. If a concept is searched using synonyms, the parent, child, and sibling concepts must be reviewed in the final process to confirm whether the concept is semantically correct.

Table 1. Examples of using synonyms.

Source term	Search term
Removal of prostate *stones*	Removal of prostate *calculus*
Abdomen *sonogram*	*Ultrasonography* of abdomen
Operation of nystagmus	Nystagmus *surgery*
Extraction of nail	*Removal* of nail
Correction for rectocele	*Repair* of rectocele
Cervical mucus *test*	Cervical mucus *analysis*

Start With Broad or Narrow Terms

If the SNOMED CT concept is not found with synonyms of search terms, the target concept that is semantically equivalent to the source term can be searched by starting with broader or narrower terms. For example, "IUD ectopic" in the diagnosis means that an intrauterine device is in an abnormal place or position. If "intrauterine device ectopic" is entered as a search term, no search results are obtained. If "intrauterine device" (which is a broad term for a concept in the diagnosis) is searched for and the results are filtered through the "disorder" semantic tag, 16 disorder-related terms are retrieved. Among them, the "malposition of intrauterine contraceptive device" concept is semantically equivalent to the "IUD ectopic" concept. In this process, the parent, child, and sibling concepts must be reviewed to confirm whether the concept is semantically correct, as mentioned above in the final process.

Filter SNOMED CT Concept Using Semantic Tag

Critically, to map semantically equivalent target SNOMED CT concepts, the mapping specialist must filter results by semantic tag in the SNOMED CT browser when entering a search term. These tags are presented in Table 2. For example, if the source term "cold" in the diagnosis is entered in the browser without filters, 2 lexically matched concepts 82272006 (common cold [disorder]) and 84162001 (cold sensation quality [qualifier value]) with the same description "cold" are obtained. However, if the results are filtered through the semantic tag "disorder," the semantically equivalent concept, 82272006 (common cold [disorder]), is immediately obtained. The diagnosis "renal cell carcinoma" must be filtered through the "disorder" semantic tag, and mapped to 702391001 (renal cell carcinoma [disorder]), not 41607009 (renal cell carcinoma [morphologic abnormality]).

Table 2. SNOMED CT semantic tags according to the clinical domain of the source codes.

Clinical domain of source concepts	SNOMED CT[a] semantic tag
Chief complaint	finding
Diagnosis	disorder, finding
Past medical history, Family medical history	situation
Health-related behavior history	finding
Complication	finding
Procedure: (surgical procedure; evaluation procedure)	procedure, regime/therapy, observable entity
Pathologic diagnosis	morphologic abnormality
Medication	clinical drug, medicinal product, medicinal product form, substance

[a]SNOMED CT: Systematized Nomenclature of Medicine–Clinical Terms.

Step 7: Classify Mapping Correlations

The mapping results can be classified according to the correlation between the source concepts and SNOMED CT concepts or according to map cardinality, depending on the number of concepts.

Mapping Classification According to the Correlation

According to the correlation, the mapping results can be classified as "1193548004 |Exact match between map source and map target (foundation metadata concept)|," "1193549007 |Narrow map source to broad map target (foundation metadata concept)|," or "1193551006 |Map source not mappable to map target (foundation metadata concept)|." When the source term is matched to the equivalent SNOMED CT concept, the map is classified as a "1193548004 |Exact match between map source and map target (foundation metadata concept)|." When the source term is matched to broader SNOMED CT concepts, the map is classified as a "1193549007 |Narrow map source to broad map target (foundation metadata concept)|." When no concept broadly matches a source term, the map is classified as "1193551006 |Map source not mappable to map target (foundation metadata concept)|."

As an example, the source term "breast cancer, upper inner quadrant" in a diagnosis is equivalently matched to 373082000 (malignant neoplasm of breast upper inner quadrant [disorder]), and the map is classified as "1193548004 |Exact match between map source and map target (foundation metadata concept)|." Another example is that the source term "aortic valve stenosis occurred after mitral valve replacement" in the diagnosis has no equivalent SNOMED CT concept that can be equivalently mapped, so it can be mapped to the broadly matching "703223000 |Postprocedural aortic valve stenosis (disorder)|." In this case, the map is classified as "1193549007 |Narrow map source to broad map target (foundation metadata concept)|."

Classify Mapping According to Map Cardinality

If a single source code does not map to a single SNOMED CT concept, it is necessary to classify the map's cardinality using a complex map. The mapping results can be classified as either "one to one" or "one to many" according to their cardinality. When a single source code is mapped to a single SNOMED CT concept, the map is classified as a "one to one." When a single source code with broad or multiple meanings is mapped to multiple SNOMED CT concepts, it is classified as "one to many." For example, the source term "right or left hemicolectomy" has 2 meanings: "right hemicolectomy" and "left hemicolectomy." The source term is mapped to "359571009 |Right colectomy (procedure)|" and "82619000 |Left colectomy (procedure)|," respectively, and the map is classified as "one to many."

Step 8: Validate the Map

The map is validated with internal and external validation. Internal validation may vary depending on how many individuals participated in the mapping and validation processes. When 2 mapping experts are involved, one maps the source terms and the other reviews the mapping results. Otherwise, both mapping experts could map the same source terms and then compare the maps constructed by each other. When more than 2 mapping experts are involved, a validation can be conducted by dividing them into 2 groups—mapping and reviewing groups. The map is deemed to be correct if the mappers and reviewers select the same results. If the maps differ, the results should be evaluated in a group discussion with the other mapper to agree on which SNOMED CT concept to use.

External validation can also be used, in which clinical or mapping experts who were not involved in the mapping process verify the validity of the mapping results. Methods for performing external validation include reviewing the sample mapping results and obtaining mapping results that were difficult to map or that were not agreed upon in an internal group discussion.

Step 9: Build the Final Map Format

There are 2 types of maps—simple and complex maps. A simple map is a representation of mapping from a term in other code systems to a SNOMED CT concept; this is comprised of the source code (id, term), target SNOMED CT (id, fully specified name), and map correlation. A complex map is a representation of mapping from a term in other code systems to one or more SNOMED CT concepts; this is comprised of the source code (id, term), target SNOMED CT (id, fully specified name), map correlation, and cardinality. If map cardinality is 2 or more, rows are added to the final map. When documenting the final map, versions of source codes and SNOMED CTs, mapping

dates, and mapper information must be included. Figure 4 presents examples of the mapping format.

Figure 4. Examples of final map formats. SNOMED CT: Systemized Nomenclature of Medicine–Clinical Terms.

[Simple map]

Source code		Target SNOMED CT		Map correlation	Mapping date	Mapper
ID	Term	ID	Fully Specified Name			
B02	Zoster [herpes zoster]	4740000	Herpes zoster (disorder)	1193548004 |Exact match between map source and map target (foundation metadata concept)|	YYYYMMDD	SS, HJ
B05	Measles	14189004	Measles (disorder)	1193548004 |Exact match between map source and map target (foundation metadata concept)|	YYYYMMDD	SS, HJ
A18	Tuberculosis of other organs	56717001	Tuberculosis	1193549007 |Narrow map source to broad map target (foundation metadata concept)|	YYYYMMDD	HJ, HK

[Complex map]

Source code		Target SNOMED CT		Map correlation	Map Cardinality	Mapping date	Mapper
ID	Term	ID	Fully Specified Name				
D00	Carcinoma in situ of oral cavity, oesophagus and stomach	78579800 2	Carcinoma in situ of oral cavity (disorder)	1193548004 |Exact match between map source and map target (foundation metadata concept)|	3	YYYYMMDD	SS, HJ
		92585006	Carcinoma in situ of esophagus (disorder)				
		92756002	Carcinoma in situ of stomach (disorder)				

Discussion

Principal Results

A SNOMED CT mapping guideline has been developed for the terms used to document clinical findings and procedures in EMRs. It was developed based on a review of previous mapping guidelines and the literature and the experiences of the authors and the map guideline development committee members. During the development of this mapping guideline, we reflected on the methods of resolving the difficulties experienced in KCD-7 and EDI code mapping, such as preprocessing the source terms and selecting search terms. We also reflected on the methods and examples identified while teaching mapping specialists working in local institutions to map the terms used to document clinical findings and procedures in EMRs to the SNOMED CT at the Korea Human Resource Development Institute of South Korea since 2019 [37]. The mapping training program was evaluated as having high satisfaction among mapping specialists with an average of 4.25 out of 5 points in 2021 (1=very low to 5=very high) and was reported as helpful in conducting mapping during work when they returned to their job with 3.75 out of 5 points in 2021 (1=not helpful to 5=very helpful). The guideline developed in this study will therefore be useful for local mapping specialists to map the terms used to document clinical findings and procedures in EMRs to the SNOMED CT. The guideline will improve the mapping quality performed at each medical institution.

The guidelines developed in this study contain detailed mapping steps from the Korean perspective, not only in the new steps such as term extraction, syntactic and semantic preprocessing, search term selection, and searching strategies in the SNOMED International browser but also in the steps adopted from previous mapping guidelines and studies [19,27,38]. For example, South Korean EMRs are written in both English and Korean. When written in Korean, translation is mandatory during preprocessing, and even when written in English, the Korean way of expressing a medical concept in English differs from that in English-speaking countries, so additional preprocessing is also required. Since Korean mapping specialists are limited by their knowledge of English synonyms, examples of synonyms were included to make the guideline easier to understand. The guideline can, therefore, be applied in local medical institutions to map Korean terms used to document clinical findings and procedures in EMRs to SNOMED CT. They can also be used to develop SNOMED CT mapping guidelines in other countries.

Limitations

This study had some limitations. Since the guideline focused on specific clinical domains, other clinical domains, such as medicine, were not included. Future studies are required on the development of mapping guidelines for terms used to document other clinical domains. In addition, this guideline does not include a guideline for mapping to SNOMED CT post-coordinated expression. The post-coordinated expressions frequently used in South Korea can be added as a new concept in the Korean extension of SNOMED CT.

Conclusions

This study developed a SNOMED CT mapping guideline for the terms used to document clinical findings and procedures in EMRs at local institutions in South Korea. The guideline was based on existing mapping guidelines, the findings of previous studies, and the mapping and teaching experiences of the authors. The mapping guideline developed in this study consisted of the following nine steps: (1) define the purpose and scope of the map, (2) extract terms, (3) preprocess source terms, (4) preprocess source terms using clinical context, (5) select a search term, (6) use search strategies to find SNOMED CT concepts using a browser, (7) classify mapping correlations, (8) validate the map, and (9) build the final map format. The new guideline can be published on the website of the Korea Health Information Service. The guideline can be applied to local medical institutions when mapping Korean terms used to document clinical findings and procedures in EMRs to SNOMED CT. It will also support local medical institutions in standardizing their local code systems using SNOMED CT. Ultimately, the data quality of each local medical institution will be improved, allowing the data to be fully used in clinical

decision support systems, health information exchange, and clinical research.

Acknowledgments

This study was supported by the Korea Health Information Service, and by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare and Ministry of Science and ICT, Republic of Korea (grant HU22C0168).

Abstract

Experts have noted a concerning gap between clinical natural language processing (NLP) research and real-world applications, such as clinical decision support. To help address this gap, in this viewpoint, we enumerate a set of practical considerations for developing an NLP system to support real-world clinical needs and improve health outcomes. They include determining (1) the readiness of the data and compute resources for NLP, (2) the organizational incentives to use and maintain the NLP systems, and (3) the feasibility of implementation and continued monitoring. These considerations are intended to benefit the design of future clinical NLP projects and can be applied across a variety of settings, including large health systems or smaller clinical practices that have adopted electronic medical records in the United States and globally.

clinical natural language processing; electronic health records; population health science; clinical decision support; information extraction

Introduction

Natural Language Processing (NLP) has the potential to improve the delivery, quality, and safety of health care [1-7]. There have been numerous research applications, including the extraction of disorders, drugs, and procedures. Moreover, NLP methods have automated the extraction of information that is likely to be undercoded or not coded in a patient's record, such as the severity of a disorder, their functional status, or social determinants of health [4,6-8]. However, examples of health systems operationalizing clinical NLP tools for real-world clinical decision-making, as well as population health management and quality measurement, are limited. This is a missed opportunity to turn rich, unstructured data into structured information that can be used for quality and performance initiatives within a health system or a professional field, or to make national-level comparisons [2,9-12].

To address the challenges translating research tools to clinical practice, we present practical considerations for NLP system stakeholders that can be used to position an early-stage research project for use in real-world decision-making and to eventually demonstrate institutional value. Our practical considerations are informed by prior literature and reports that describe a chiasm rather than a synergy between clinical NLP research and clinical practice. For example, Wen et al [13] share the Mayo Clinic's Desiderata for the implementation of an NLP development delivery platform derived from 2 decades of implementing clinical NLP in their health system. Lederman et al [14] describe how existing clinical NLP systems "have delivered marginal practical utility and are rarely deployed into

health care settings" and call for a new paradigm of clinical NLP research for real-world decision support. Similarly, Newman-Griffis et al [15] call for a new paradigm and general principles for clinical NLP research that are focused on challenges posed by application needs and describe how these challenges can drive innovation in basic science and technology design. Referring to artificial intelligence systems in medicine more broadly, Topol et al [16] have also observed that "deployment of medical AI systems in routine clinical care provides an important yet largely unfulfilled opportunity". We also draw from our own collective experience developing clinical NLP systems for research studies and in an operational capacity.

Our practical considerations can be used to support the development of applications that can push forward advances in clinical medicine right now. We also assess the current landscape of Clinical NLP tools and techniques on our adjoining public GitHub site, which can be updated by the research community as clinical NLP technologies evolve [17].

Practical Consideration #1: Are Data and Compute Infrastructure Ready for NLP?

"Garbage in, garbage out" refers to low-quality data, or "garbage," that can result in misinformation. It was first used by US Army scientists to provide the intuition that computers cannot think for themselves, and that "sloppily programmed" inputs inevitably lead to incorrect outputs. Although this saying is over a half century old, it applies even more today, when powerful computers can record large amounts of data that are not fit for the intended use in a short amount of time.

Key questions that will help to determine NLP readiness of a new clinical corpus includes the following: (1) Are notes and note metadata reported in a timely way and with reasonable quality? (2) Is the unstructured free-text data ready for NLP techniques (eg, can the data be used to extract clinical concepts with an accuracy that is fit for the indented use)? And (3) Are the NLP algorithms feasible to execute in the production environment?

Assessing the quality of textual data—or "Data Readiness"—confronts on the problem of data quality by providing empirical findings about syntactic and semantic aspects of a clinical corpus as well as the associated note metadata such as patient identifiers, the date and time of the note, and the type of note. We define "quality" within the context defined by Kahn et al [18] where three dimensions are considered, including plausibility, conformance, and completeness. The results of a Data Readiness assessment help to predict the difficulty of building an NLP system for those data. The quality of free-text data can vary significantly between different note types within the same or across different electronic medical record (EMR) systems. For example, discharge summaries typically contain complete sentences and clearly demarcated sections. By contrast, intensive care unit (ICU) progress notes typically contain large quantities of digits that are not explicitly labelled as to whether they are vital signs, ventilator settings, or any of the many other quantitative measures that are monitored in critically ill patients. ICU progress notes also frequently contain large amounts of information in just one or two grammatically unstructured sentences. Ambulatory progress reports can range from a few sentences to longer documents with standardized formats.

In some cases, data sets that do not initially appear to be ready for NLP on an intended task can be further processed or sampled so that the data are more amenable to their intended use. For example, a data source can be preprocessed to remove notes that do not fit predetermined plausibility criteria, such as the known range of system availability to identify notes that have a plausible date, or notes that do not have an indicated date. However, this may not always result in data that are ready for NLP; in these cases, investigators should work with an organization leadership to improve data collection before undertaking an NLP project.

The institutional nuances of EMR clinical documentation processes require clinical NLP systems developed at other institutions to be customized to a new local data set. This uses specific preprocessing steps related to the provenance and structure of the source data. In prior work funded by the Agency for Healthcare Research and Quality that was based on the Rheumatology Informatics System for Effectiveness (RISE) registry, we found that simple summary statistics on note length in characters and words ("tokens") were helpful to assess the quality of clinical notes from rheumatology practices across the United States [12]. The RISE registry began operation in 2014, and the free-text extraction covered the period between 2014 and 2018. It combines data from over 260 ambulatory outpatient rheumatology practices that collectively use more than 20 different EMR products. To assess the data readiness of RISE for health services research and to better understand the epidemiology of chronic rheumatic diseases, we first used note metadata. For example, we calculated the number of unique clinical notes recorded by year, as indicated by the time stamp of the patient note. Unique notes were determined by each entry of a textual document within the RISE database. We found that many notes had an invalid timestamp, with dates as early as 1800 and as far out as 8018. This suggested an opportunity to improve the quality of these data. We also found that simple summary statistics describing the textual data helped determine the potential informativeness of RISE for scientific and practical applications. Table 1 suggests that RISE contains many relatively short patient notes (mean of 34.57 tokens in 2018) as well as some longer, more traditional patient notes and letters (SD 203.01 tokens). These types of summary statistics are an important first step in NLP data readiness assessments.

Table 1. Mean, SD, minimum, mode, and maximum note length[a] and word count[b] for free-text patient Rheumatology Notes submitted to the American College of Rheumatology's data registry, by year.

Year	Note count	Length of note				Word count			
		Mean (SD)	Min[c]	Mode	Max[d]	Mean (SD)	Min	Mode	Max
2010	891,837	96 (353)	1	17	18,774	16 (54)	__[e]	2	2549
2011	1,238,711	128 (554)	4	17	40,295	20 (80)	1	2	5713
2012	2,412,737	118 (559)	3	19	23,370	18 (81)	1	2	3496
2013	3,409,806	120 (597)	3	19	23,921	18 (87)	1	2	3567
2014	5,394,083	209 (1069)	1	19	614,356	31 (160)	—	2	107,498
2015	7,715,894	211 (1547)	1	19	2,179,227	31 (224)	—	2	375,620
2016	9,812,735	233 (1356)	1	19	425,503	34 (186)	—	2	75,844
2017	11,685,000	242 (1468)	1	19	570,721	35 (204)	—	2	100,311
2018	5,301,039	239 (1415)	1	19	192,570	35 (203)	—	2	31,852
Total	50,222,840	205 (1271)	1	19	2,179,227	30 (180)	—	2	375,620

[a]Please note that 2018 is a partial year. Note length is indicated by non–whitespace characters and symbols.

[b]Word count was estimated after deidentification of the Rheumatology Informatics System for Effectiveness corpus.

[c]Min: minimum.

[d]Max: maximum.

[e]Not available.

To assess the readiness of data for specific linguistic analysis tasks, such as part-of-speech tagging or named-entity recognition, there are a variety of other descriptive statistics based on corpus linguistics that can be used to assess the quality of textual data. Some of these focus on gross characteristics of the data, such as the extent to which documents have clearly identifiable sections and the nature of the data in those sections. For example, lists such as diagnoses and medications usually have relatively clear boundaries, while family and individual medical histories may not. The presence or absence of sentence boundaries, as well as the length of sentences, are also important predictors of the effort required to build high-performing language processing tools. Other descriptive statistics assess textual data on the level of individual words. For example, textual genres with high levels of repeated word use (eg, fever and pain) can be easier to process than textual genres with high levels of words that only appear once (eg, misspellings and typographic errors).

In addition to data that are ready for NLP, automated information extraction algorithms require infrastructure that will allow for the efficient processing of large volumes of new patient notes. There must be discussions at the design phase of the project to ensure that any research products can be operationally tested, and if warranted, translated to operational infrastructure. It is also important for the product to be updated and maintained if being used longitudinally with routine updates of notes.

If a project has no feasible pathway to operationalize the NLP system for real-world decision support, it might be possible that new resources, including institutional computing infrastructure, could be recommended and acquired.

Practical Consideration #2: What are the Incentives for Adopting the NLP System?

Key questions that will help determine if the proper incentives are in place to support a Clinical NLP system are as follows: (1) will the NLP help to address an existing clinical need? (2) is there support from clinical leadership for the ongoing use of the NLP system? and (3) is there a financial incentive to adopting the NLP system?

Reporting from structured data has been the mainstay in health care practice for decades. The Sentinel active surveillance system for medical products and Observational Medical Outcomes Partnership (OMOP) initiatives helped to pioneer the use of common data models to support regulatory initiatives [19,20]. Building on OMOP's common data models, the Observation Health Data Science Initiative's extension has extended the OMOP schema to incorporate unstructured data with the "NOTE" and "NOTE_NLP" tables. It is likely that EMR databases will become even more powerful for regulatory initiatives when they can jointly leverage various data modalities such as patient notes or images for the purpose of improved patient care. However, in the absence of a specific clinical need that a system is designed to address, and without the proper incentives to use the system, it is unlikely that a system will be adopted for clinical uses such as decision support, regardless of performance on a research task. A successful system for population and precision health must be innovative, pragmatic enough to be deployed in a production environment and directly aligned with organizational incentives and clinical leadership's priorities. It should support interoperability but also allow for customization to the nuances of different health systems. We discuss some of these challenges in the next section.

In cases where there is little or no organizational incentive to adopt a clinical NLP system, it is unlikely to succeed past the research phase. Therefore, working with leadership to identify the potential value to a health system and finding possible incentives to adopt such a system are important first steps.

Practical Consideration #3: Feasibility of Implementation and Evaluation

Key questions that will help to determine the feasibility of implementing and evaluating a clinical NLP system include the following: (1) What is the task (ie, clinical need) that this system seeks to address? (2) Are the clinical concepts of interest captured in structured data? If so, are there limitations to what can be extracted? (3) If NLP is justified, are simple NLP techniques enough or are more complex algorithms warranted? (4) Can the Clinical NLP tool be developed and implemented in a reasonable timeline to fulfill stakeholder needs? (5) What are potential sources of bias, considering factors such as the NLP approach, the data used to train the NLP tool, and the population to which it is applied?

An important early consideration is regarding the target population. In cross-validation over random folds, models are trained and tested over the same population. However, in practice, models are often developed in a training data set but applied to novel data that may originate from a different underlying population of patients or clinicians. Differences in clinical practice and workflow patterns, as well as lack of homogeneity in clinical language (as described above), can have large impacts on the transportability of models from where they were developed to a given target population. This is important to factor into the training assessment (eg, being aware of overfitting) and possibly also into model development. If an available external test set exists that represents the target population, it should be tested as part of the model development process to ensure that the NLP tool is portable and externally valid. Ideally, performance metric reporting should be required for all tools meant to be transportable outside of their training corpus.

There are multiple strategies for mitigating bias and improving portability of NLP tools. One source of bias may arise from the specific type of note used to develop a model; for example, an NLP tool developed only on ICU notes, pathology reports, or notes within a certain specialty may not generalize to other note types or clinical settings. Therefore, different note types should be incorporated into the training corpus, if in fact, the target corpus is intended to involve multiple types. Additionally, as previously described, incorporating a secondary data set that represents the target population for testing, apart from the primary data set used for training, can help ensure that the model is transportable and performs well across health care settings, EMRs, and patient populations.

To evaluate model performance, one must decide at which level the assessment should occur, that is, at the mention, document, or patient level. NLP models can be evaluated by their precision (positive predictive value), recall (sensitivity), specificity, F_1-score (harmonic mean of precision and recall) and overall accuracy compared to a "gold-standard" test set of reviewed text [5,9]. However, the text-specific evaluation may not be as important as the document or even patient-level performance, especially if multiple mentions per patient occur, or structured data fields are being incorporated into the evaluation in conjunction with NLP annotations. Therefore, although at the mention level, the NLP model may correctly identify a patient as positive, it may be that it is only when combined with the additional information (other mentions, lab results, etc) that the output and model performance are clinically important.

As important as model performance at the time of development is, more crucial may be the model performance over time. Validation of NLP models is key both retrospectively and prospectively, as data change longitudinally. It is important for models to be evaluated continually to determine whether they should be fine-tuned and updated, and whether any biases exist. For example, this may involve updating rule-based code to reflect changes in language representation or reevaluating or redeveloping deep learning–based NLP models.

If a clinical NLP system does not address a known and ideally high-priority clinical need, it is less likely to be adopted into practice. However, it may be possible to adapt the system to address a need identified by organizational leadership. If it does not initially show good performance, continued development may help to improve the clinical systems accuracy, especially if linguistic annotation data can be generated and made available for training a better model. Lastly, in some cases where additional expertise can be used for a project, it may be possible to meet a project deadline that would otherwise not be possible. Importantly, having a strategy, including a business plan, for maintaining deployed models is important to ensuring that their clinical application is sustained.

The Potential Role of NLP in Real-World Decision Support

NLP has the potential to improve population health outcomes in the United States. For example, in the inpatient care setting, NLP systems could reliably identify individuals with symptoms of diarrhea reported in progress notes and feed these data into algorithms for *Clostridioides difficile* testing. Inpatients with falls documented in clinical notes could trigger alerts to discontinue sedatives or narcotics. In the outpatient setting, NLP can be used to assess the severity of a disease or a postoperative complication. The NLP of free-text patient notes also creates opportunities for national, routine quality and performance measurement, which can support improvement in the value of health care delivered to patients at highest risk for poor outcomes [9-12,21-23]. As health systems across the United States move toward whole-person care paradigms, NLP systems can also be used to identify important clinical decision support factors that are undercoded or altogether absent from structured data sources in patient records, such as the presence of behavioral, psychosocial, and economic risk factors.

Predictive analytics is another area where incorporating clinical text has the potential to improve population health [5-7,24]. Most models for population-level risk stratification that use

health care data have exclusively relied on structured data, but several groups have demonstrated that in certain domains, adding information from clinical text can improve performance. Studies in this area reflect a wide range of tasks from predicting hospital readmissions to identifying patients at risk for suicide [2-13,17,21,22,24,25]. Such models can be used operationally to more accurately target a subset of a population for specific interventions designed to address modifiable risk factors.

Applications of NLP to streamline and facilitate quality and safety reporting are also emerging [9-12]. Federal reporting of quality and safety measures often places considerable burden on clinicians, sometimes requiring duplicate entry of similar concepts in the text of clinical notes as well as in structured fields that can be queried to calculate performance. Reliable extraction of relevant information from clinical notes would not only alleviate burdensome data entry but also greatly expand the types of concepts included in reporting programs. For example, guidelines in rheumatology support the routine collection of disease activity scores for patients with rheumatoid arthritis, but not all EMRs have structured fields to input these scores. Electronic quality measures that extract this information automatically from structured fields might miss scores that are documented only in clinical notes. NLP could be used to extract these scores and improve the validity and reliability of such quality measures[9-12].

While these and other applications of NLP have the potential to improve health care and population health, the successful deployment and dissemination of these applications has been limited. Given these barriers, how should the field move forward? In addition to our three considerations, we think it is critical that multiple stakeholders provide input from the start of NLP projects. Practicing clinicians can ensure the focus of the work is clinically relevant, fulfills an unmet need, and is aligned with current clinical workflows; clinical informaticians can provide insight into whether data systems are available to scale valid NLP algorithms, and health care administrators can lend insight into IT resources required and the feasibility of scaling and sustaining systems. Until there is stakeholder alignment and investment in a project, impact and scalability are likely to be limited. Similar to many new technologies in medicine, alignment often requires the development of the NLP program as a value proposition that either clearly impacts operational efficiency, revenue, quality and safety, or patient outcomes. Moreover, stakeholders need to be integrated into the software development life cycle to ensure the product's ongoing implementation is successful.

Conclusion

The analysis of unstructured free-text patient data enables new ways in which scientific questions can be studied and health care can be delivered. Although such uses are promising, leveraging the clinical text data collected in the EMR and using these data in health care operations are not without substantial caveats. Opportunities to better align state-of-the-art systems developed by researchers to support the measurement of patient-reported outcomes and to support high-quality health care delivery can likely lead to improved outcomes. With a focus on designing practical applications that are aligned with clinical requirements and organizational incentives, the considerations listed here can be used to design a project-specific checklist for a variety of stakeholders. We also summarized the procedures for considering appropriate use of NLP in health and survey the current landscape of Clinical NLP tools. To support future work in this area, we have provided software and data set summaries, license, and other access requirements on our adjoining GitHub site, which we hope will serve as a continuously updated resource for the research community as technologies evolve.

Abstract

Background: Medical coding is the process that converts clinical documentation into standard medical codes. Codes are used for several key purposes in a hospital (eg, insurance reimbursement and performance analysis); therefore, their optimization is crucial. With the rapid growth of natural language processing technologies, several solutions based on artificial intelligence have been proposed to aid in medical coding by automatically suggesting relevant codes for clinical documents. However, their effectiveness is still limited to simple cases, and it is not yet clear how much value they can bring in improving coding efficiency and accuracy.

Objective: This study aimed to bring more efficiency to the coding process to improve the selection of codes by medical coders. To achieve this, we developed an innovative multimodal machine learning–based solution that, instead of predicting codes, detects the degree of coding complexity before coding is performed. The notion of coding complexity was used to better dispatch work among medical coders to eventually minimize errors and improve throughput.

Methods: To train and evaluate our approach, we collected 2060 cases rated by coders in terms of coding complexity from 1 (simplest) to 4 (most complex). We asked 2 expert coders to rate 3.01% (62/2060) of the cases as the gold standard. The agreements between experts were used as benchmarks for model evaluation. A case contains both clinical text and patient metadata from the hospital electronic health record. We extracted both text features and metadata features, then concatenated and fed them into several machine learning models. Finally, we selected 2 models. The first used cross-validated training on 1751 cases and testing on 309 cases aiming to assess the predictive power of the proposed approach and its generalizability. The second model was trained on 1998 cases and tested on the gold standard to validate the best model performance against human benchmarks.

Results: Our first model achieved a macro–F_1-score of 0.51 and an accuracy of 0.59 on classifying the 4-scale complexity. The model distinguished well between the simple (combined complexity 1-2) and complex (combined complexity 3-4) cases with a macro–F_1-score of 0.65 and an accuracy of 0.71. Our second model achieved 61% agreement with experts' ratings and a macro–F_1-score of 0.62 on the gold standard, whereas the 2 experts had a 66% (41/62) agreement ratio with a macro–F_1-score of 0.67.

Conclusions: We propose a multimodal machine learning approach that leverages information from both clinical text and patient metadata to predict the complexity of coding a case in the precoding phase. By integrating this model into the hospital coding

system, distribution of cases among coders can be done automatically with performance comparable with that of human expert coders, thus improving coding efficiency and accuracy at scale.

Introduction

Background

Medical coding [1] is the translation of health care diagnoses and procedures into standard diagnosis and procedure codes using medical classifications and controlled terminologies. It is a strategic activity for funding hospitals and, therefore, its optimization is a priority in health care systems under financial pressure. In many countries worldwide, including Switzerland, hospital funding is based on the so-called *Prospective Payment System* [2,3] mechanism. In the Swiss Prospective Payment System, for example, inpatient stays are assigned to diagnosis-related groups [4] according to diagnosis and procedure codes derived from medical documentation, and each hospital stay is paid according to the diagnosis-related group to which it is assigned. Therefore, medical coding is closely linked, on the one hand, to medical documentation, and on the other hand, to hospital revenues. In addition to establishing reimbursement claims, medical codes are used for several other goals, such as setting budgets for planned hospitalizations or evaluating the quality of care by means of indicators such as complication rates after surgery.

The diagnosis and procedure codes of a specific case (ie, inpatient stay) are derived from clinical documentation such as discharge letters, surgical reports, physicians' and nurses' notes, and laboratory and radiologic results. The International Statistical Classification of Diseases and Related Health Problems, 10th Revision (ICD-10) [5], is usually used for coding diagnoses, whereas the classification system used to code procedures can vary from country to country [6].

Codes are manually entered into a hospital information system. In Switzerland, there are >200 coding rules that govern code entry and must be applied by medical coders. The latter are health care professionals who have undergone specific training for this purpose. However, despite training, medical coding remains a complex, quickly evolving, time-consuming, and error-prone task. In our tertiary academic medical center, medical coding staff have been divided into specialty teams since 2018. In a batch of cases, 50% are distributed to a "common pot," and the other 50% are distributed to the corresponding specialty teams of medical coders. The cases in the "common pot" are distributed randomly to each team. A higher percentage of cases for the specialty teams is not envisaged for 3 reasons. First, it could lead to a loss of knowledge in general coding. Second, it could cause boredom for medical coders. Third, it will not always be possible to guarantee a sufficient number of cases for certain teams. Thus, a way to increase the efficiency of the current distribution of work without going toward a counterproductive overspecialization [7] is to force cases requiring high expertise to be assigned to experienced and specialist coders. This approach is only possible by detecting the complexity of the cases in advance before they are distributed and coded.

In recent years, artificial intelligence (AI) methods have been increasingly proposed to improve the efficiency and accuracy of medical coding. Their main goal has been to support medical coders in finding the most appropriate diagnosis and procedure codes for a given medical documentation. Conventional models, deep learning models such as convolutional neural networks and long short-term memory, and transformers have been trained and tested on automatic coding tasks using publicly available data sets in English [8-13]. Recently, this work has also been expanded to non-English corpora such as the French corpus [14,15]. In addition to the academic approach, commercial software for automatic coding has also been developed and introduced to the market. For example, commercial software such as ID SUISSE [16] applies rule-based algorithms to perform automatic coding. Their principle is to use a prebuilt dictionary of ICD-10 codes and their text labels, try to find clinical text that matches the labels, and then convert the text to ICD-10 codes. More recent tools such as Collective Thinking [17] and 360 Encompass (3M) [18] have improved the rule-based algorithms with machine learning (ML) techniques. Finally, solutions such as Sumex [19] rely on statistical methods to analyze the distributions and combinations of ICD-10 codes to identify possible inconsistencies in the coding patterns.

Despite the increasing number of available solutions, the effectiveness of automatic coding is still limited. Among the best-performing ML models, although precision can reach approximately 75%, the macro–F_1-score could only achieve 10% to 12% [12,20,21]. The results indicate that even the best models can only capture a small portion of medical codes from free text. Therefore, the improvement of medical coding using AI-assisted strategies remains an open challenge (Kaur R, unpublished data, July 2021).

Objectives

The purpose of our study was not to find a way to predict ICD-10 codes from medical records. Instead, it was to improve coding quality and efficiency by predicting coding complexity before the coding process. Our primary objective was to bring more efficiency to the coding process to improve the quality of coding by medical coders, and the means to achieve this is an innovative solution using ML. The innovation is to use ML to detect complexity, which is then used to better dispatch the work among medical coders. To the best of our knowledge, this

approach has never been used before. It allows for a more efficient distribution of cases according to coders' abilities and experience. As such, we will be able to minimize potential human errors because of random assignment and uneven distributions of coding expertise within hospitals' coding divisions or units. Eventually, by knowing the coding complexity up front, simple cases can be assigned to beginners or nonspecialist coders or AI-assisted systems to maximize their utility while complex cases for which AI-assisted tools are still inefficient are assigned to coding specialists or at least to experienced medical coders.

Depending on the amount of clinical documentation to be examined and other factors such as the length of stay or the diversity of medical specialists involved in the treatment of a patient, coding a case may be a simple or a really complex task. Once a case has been coded, it is typically easy for the person who has done so to classify the case into a complexity level, which represents the complexity of the coding activity. However, predicting the complexity level of a case up front is very time-consuming for a human coder as it requires a deep analysis of the entire documentation, which eventually is equivalent to conducting the coding process directly.

To predict the complexity of a coding task in the precoding phase in an automatic way, we used advanced natural language processing (NLP) techniques to analyze clinical texts and extract features that are predictive of the complexity of cases. We proposed an end-to-end approach that integrates the NLP and ML model into the hospital clinical data warehouse and end-user coding system. Our NLP and ML model predicts case complexity with an accuracy comparable with that achieved by expert human coders. Its beta version is currently under deployment at Lausanne University Hospital. To the best of our knowledge, we are the first to propose and develop this innovative approach.

The remainder of the paper is organized as follows. The application details are presented in the *Methods* section, and the performance and analysis are presented in the *Results* section. In the *Discussion* section, we discuss the values and importance of our application as well as the use of NLP in health care.

Methods

Ethics Approval

The Cantonal Ethics Commission for research on human beings of Canton Vaud granted a full waiver for this study given the its retrospective and quality assurance nature under Req-2022-00677.

Overview

We describe a typical medical coding workflow in Figure 1. After an inpatient (patient who is hospitalized overnight) is treated in the hospital, a discharge letter is produced. Medical coders analyze the diagnosis in the discharge letter and translate the diagnosis into International Statistical Classification of Diseases and Related Health Problems, 10th Revision (ICD-10) codes. Sometimes the coders need to refer to other clinical documents (eg, intervention protocol and laboratory reports) to translate the information accurately. The diagnosis-related group codes are computed based on the ICD-10 codes and are sent to the insurance companies for billing. The insurance companies reimburse the bills to the hospital based on the received diagnosis-related group codes. If the insurance companies find mistakes in the codes, they ask for revisions from the coding service. We provide an overview of our decision support system in Figure 2 and describe its integration into the hospital information system in Figure 3.

Figure 1. The general coding procedure in hospitals. DRG: diagnosis-related group; ICD-10: International Statistical Classification of Diseases and Related Health Problems, 10th Revision.

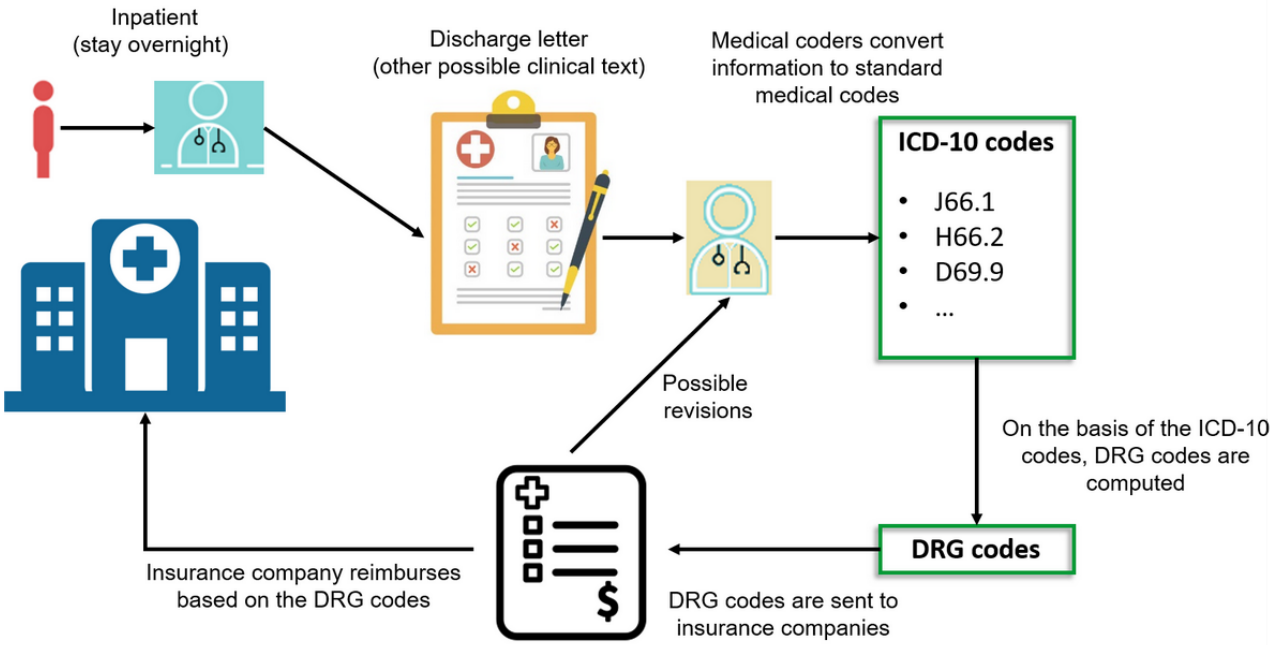

Figure 2. Workflow of this study. (A) We extracted 2060 cases from the clinical data warehouse at Lausanne University Hospital (CHUV). The cases are rated by coders (B) with complexity ranging from 1 (simplest) to 4 (most complex). (C) We performed feature engineering and trained models on the labeled cases. (D) The final model can produce both predictions of the complexity and its confidence in the predictions.

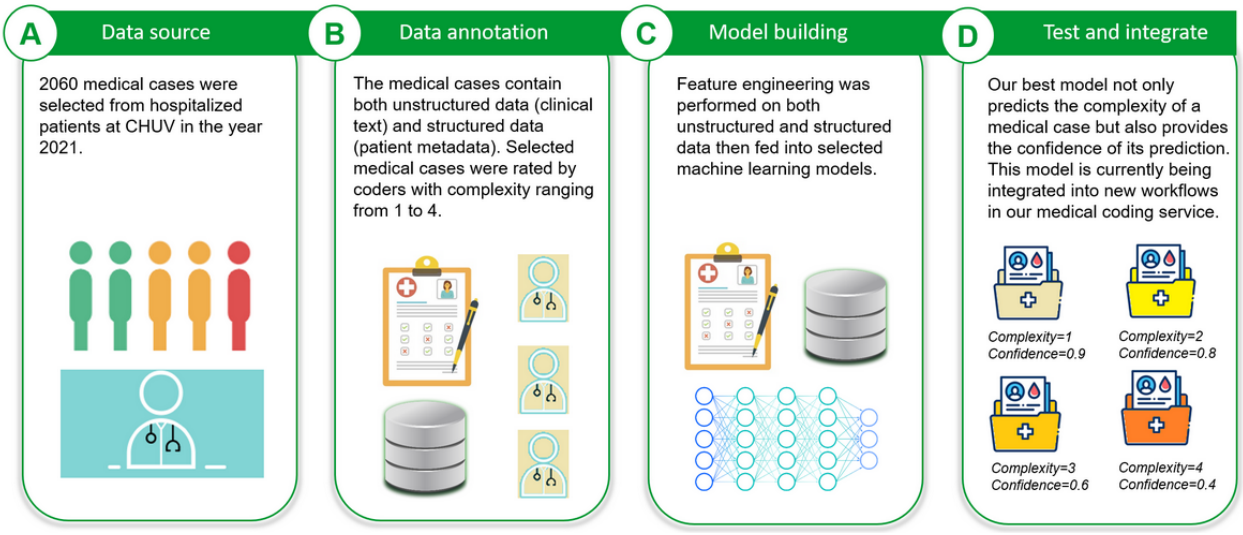

Figure 3. Integration of our model into the coding service. (A) When an inpatient visits the hospital and their medical case has been produced, the clinical text and patient metadata are stored in our clinical data warehouse. (B) A workflow manager will extract new medical cases regularly and send the data to our model. (C) Our model is containerized and deployed to an execution environment, where it performs the prediction for received cases. (D) Model predictions, together with the confidence of the predictions, are presented to the end users through a user interface to support task distribution in the coding service.

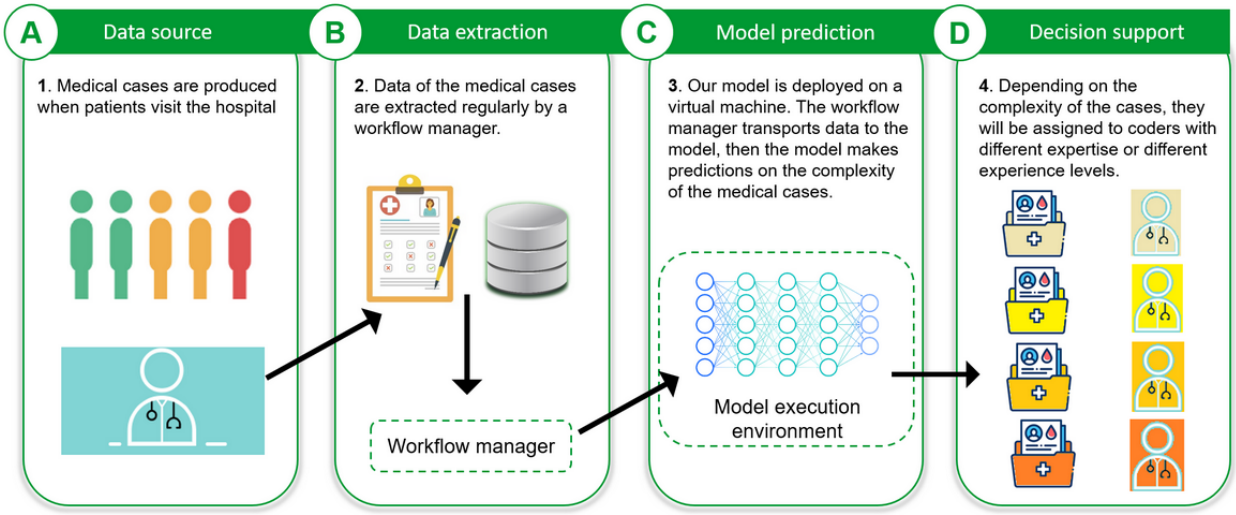


Definition of Complexity

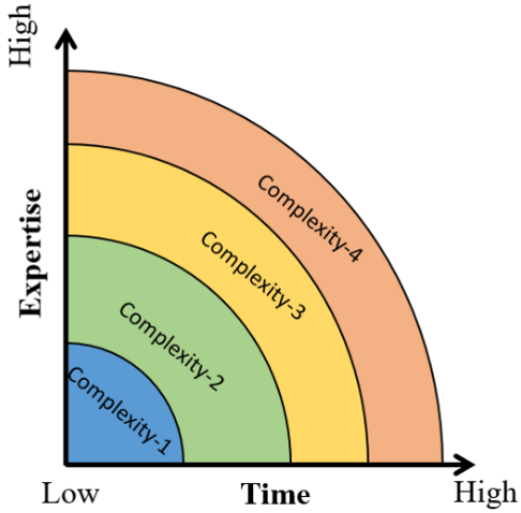
We use the term “coding complexity” to characterize the time and expertise required of medical coders to assign diagnostic codes to medical cases.

Expertise can be defined as the level of experience, medical knowledge, and mastery of coding rules. Therefore, a medical case can be complex by applying many coding rules without being difficult but increasing the possibility of attention errors. Other cases may be complex and difficult because of the medical knowledge they require for proper coding. Therefore, complexity was the measure chosen to categorize the cases.

If coding a medical case does not require much time and deep expertise, the coding complexity is low (level 1; Figure 4). Conversely, if coding a medical case requires a lot of time and deep expertise, the coding complexity is high (level 4; Figure 4).

Coding complexity, similar to pain or satisfaction, is a subjective quantity. A potential objective way of defining coding complexity can be provided by the automatic coding models. By passing the medical cases through automatic coding models and manually examining the confidence score and the completion and accuracy of ICD-10 code predictions, we could divide the cases into simple and complex groups. However, owing to the limited performance (ie, the very low recall score) of current automatic coding models regardless of language [12,20,21], this approach will not bring much value to our situation. Furthermore, if coding complexity could be measured using simple objective data (eg, similar to blood pressure), our multimodal modeling approach would be useless. Thus, in this study, our definition of coding complexity will focus on the subjective ratings provided by medical coders, aiming to minimize subjectivity by using ML approaches and to predict the subjective scores of complexity.

Figure 4. Intuitive representation of coding complexity regarding the time and expertise required of a coder.



To train our ML model, we extracted 2060 medical cases from hospitalized patients (inpatients) in 2021. We organized 2 annotation phases, each lasting 1 week, for 28 coders to rate the cases' complexity. During each annotation phase, the coders rated the complexity of the given cases based on an evaluation grid (Figure 4).

Data Collection and Preprocessing

Data Source and Data Annotation

A medical case contains 2 types of data: a patient's medical dossier and patient metadata (Textbox 1). We collected 2060 cases in total from the annotation phases. We note that the coding team at our hospital consisted of coders specialized in different medical domains. Hence, during annotation, we also kept track of whether a case was coded by a specialist. For example, if the responsible unit for a case was the internal medicine unit and the coder who coded this case was specialized in cardiology cases, the case was considered as not coded by its specialist coder.

Of the 2060 collected cases, 1998 (96.99%) were annotated by 28 medical coders, with each case coded by only 1 coder to maximize the size of the annotation set. As different medical coders may have different perceptions of the complexity of the same case, we evaluated the interrater reliability by asking 2 expert coders to code another 3.01% (62/2060) of cases. These 62 cases also represented our gold standard to create benchmarks for the models' performance. For case selection, we first trained several models using the 1998 cases; then used the best model's prediction to predict the complexity of several cases from our data warehouse; and, finally, randomly selected 62 out of the predicted cases while making sure that the complexity distribution of these 62 cases followed the same complexity distribution as the annotated data set. Each of the 62 cases was rated by each of the expert coders, and they were considered specialists for all cases. These 62 cases are referred to as the gold-standard set.

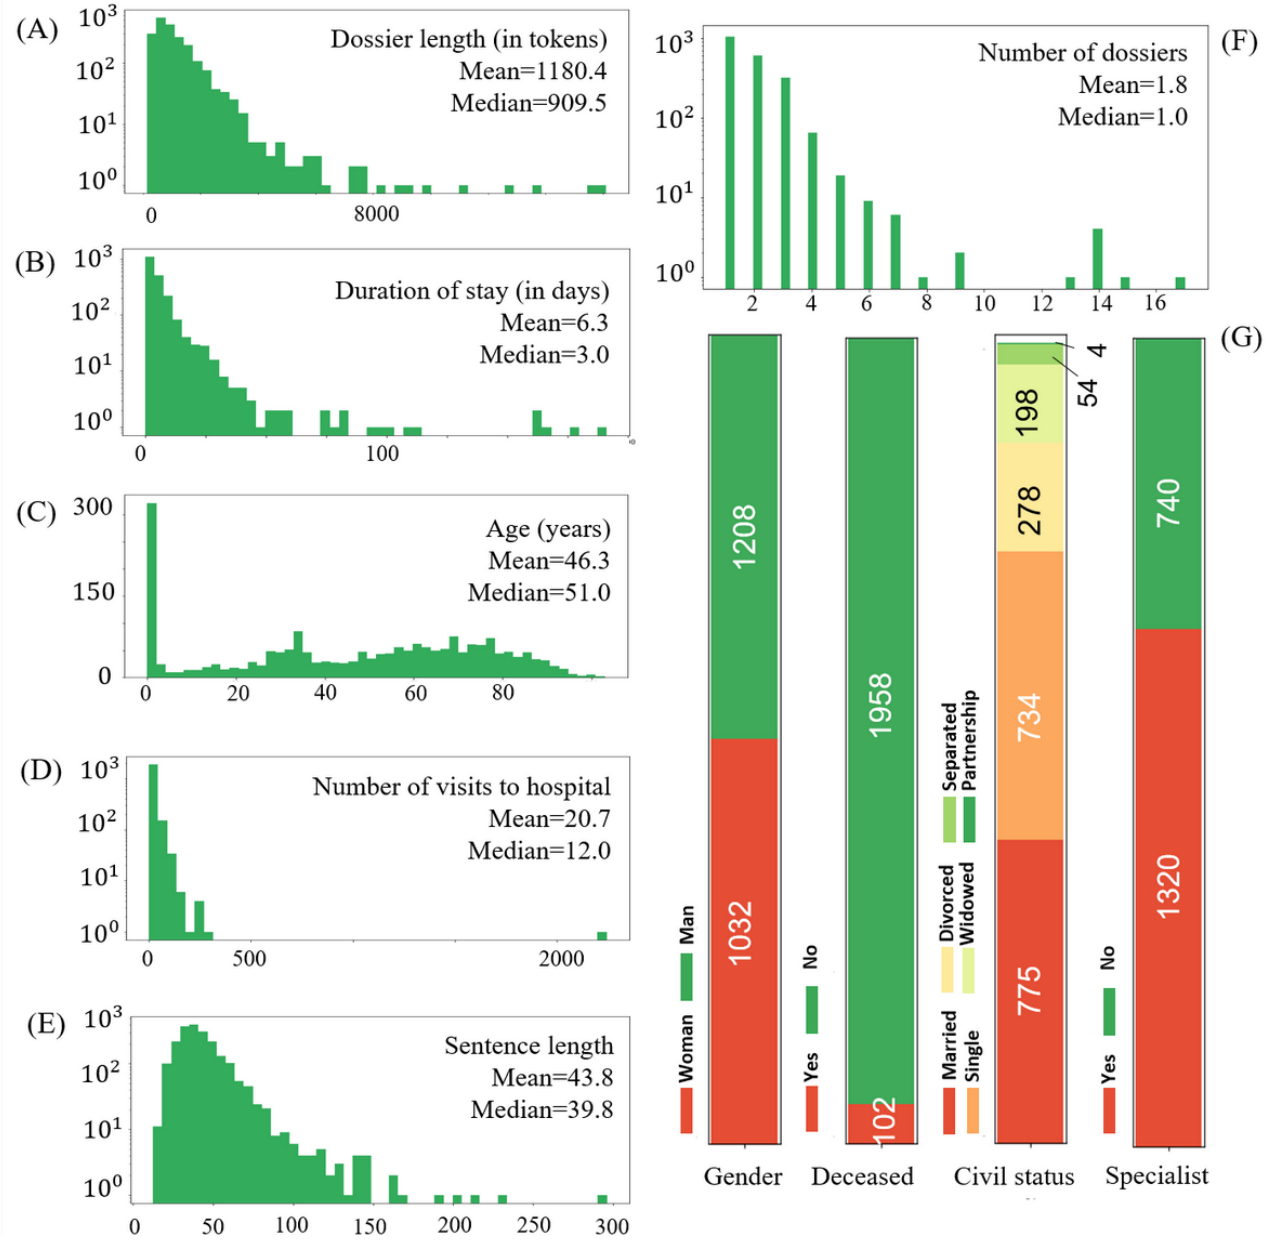
Textbox 1. Data collected for training and testing the model.

- Patient metadata: responsible medical service, number of movements between medical services, age, gender, civil status, whether the patient was deceased, length of stay, and whether the case was coded by a specialist
- Medical dossier: discharge letter of each service, operating procedure, intervention reports, and death letter

Metadata Preprocessing

The missing patients' metadata were imputed based on the nature of the data. For numerical values such as age and length of stay, the missing values were imputed with the median of the existing values because of their skewed distributions (Figure 5). For categorical values such as gender and civil status, the missing values were imputed with the mode of existing values.

Figure 5. An overview of the distribution of patient metadata per stay. Document length and sentence length are counted in terms of tokens (words and punctuation marks). The distributions on A, B, D, and E are heavily skewed. Note that the distributions on A, B, D, E, and F are log-scaled. The rightmost column of G is deduced from the coder's team specializations. The age=0 cases in C represent newborn cases.



Text Data Preprocessing

We tested both classic term frequency-inverse document frequency (TF-IDF)–based text encoding and ML-based text encoding, and different text preprocessing steps were applied accordingly. For TF-IDF text encoding, we first tokenized the text; then removed the stop words; and, finally, replaced the entities with their entity type. The second and third steps were used to reduce the noise and increase the frequency of important words to provide a better signal for the model. An example of processed text is presented in Textbox 2.

For ML-based text encoding such as fastText (Facebook AI Research lab) and transformers, no preprocessing was applied.

Textbox 2. An example of text preprocessing results.

- *Processed text: ["patient," "susnommé," "séjourné," "service," "<date>," "<date>," "date," "domicile," "."]*

Model Design

Overview

The overall approach of the model design was as follows. First, we extracted features from the preprocessed metadata and text data. Second, we tested 2 modeling approaches: framing the problem as a classification problem or as a regression problem. On the basis of the modeling approach, we used different metrics to evaluate the model performance.

Feature Engineering

As the values for the patients' metadata have different scales, we applied standardization (*z* score) to the numerical data and one-hot encoding to the categorical data.

To extract features from free text, we used 2 methods: TF-IDF and word embeddings.

TF-IDF provides a numerical weight of how important a word is to a collection of documents (Multimedia Appendix 1). We tested 2 configurations of the TF-IDF method: using the top 10,000 frequent terms or using the top 1000 frequent terms. We found that, using the top 10,000 frequent terms, the models performed better than using only the top 1000 frequent terms. Thus, in the following sections, we only report the results from the TF-IDF vector using the top 10,000 frequent terms.

Word embeddings provide the vectorized representation of a word based on the context in which it appears. We tested three types of word embeddings: (1) word2vec [22,23] embeddings trained on 2.5 million clinical texts (12 GB) collected from the hospital's clinical data warehouse; (2) the pooled output (CLS tokens) of the state-of-the-art French-language transformer model French-Language Understanding via Bidirectional Encoder Representations from Transformers (FlauBERT) [24], which was pretrained on 71 GB of French text collected from the internet; (3) the fastText supervised approach [25] with embeddings initialized with the pretrained word2vec embeddings of (1)—we tested fastText as it provided the subword approach that could reduce the impact of the out-of-vocabulary (OOV) issue. A detailed analysis of OOV for this study is provided in Multimedia Appendix 1.

Textbox 3 shows the sizes of the vectors extracted using the different methods. The detailed conversion methods are presented in Multimedia Appendix 1.

Textbox 3. Vector sizes of text feature engineering.

- Term frequency-inverse document frequency (vectors were extracted using scikit-learn [version 1.0.1]): 10,000
- fastText (initialized with customized embedding; fastText embeddings were extracted using fastText [version 0.9.2; Facebook Artificial Intelligence Research lab]): 100
- word2vec (customized; word2vec embeddings were trained using Gensim [version 4.0.0; RARE Technologies, Ltd]): 100
- French-Language Understanding via Bidirectional Encoder Representations from Transformers (FlauBERT; the FlauBERT embeddings and fine-tuned model were implemented using Hugging Face [version 4.17.0; Hugging Face, Inc]): 768

Model Architecture

The complexity of cases ranges from 1 to 4 with discrete values; thus, we can treat it as either a multi-class classification problem or as a regression problem. The tested models are presented in Figure 6.

For both classification and regression, we used different feature combinations as inputs to train the models. The combinations were as follows: (1) metadata only, (2) word embeddings only, (3) TF-IDF vectors only, and (4) TF-IDF concatenated with metadata.

The overall process of model implementation is summarized in Figure 7. During training, we applied 5-fold cross-validation to reduce overfitting. As the labels were unbalanced, we used stratified sampling for cross-validation in the classification models. We performed hyperparameter tuning of the most promising features and models. For TF-IDF, we optimized the number of words considered in the vocabulary (topmost frequent words) and text preprocessing (lower case, lemmatization, removal of stop words, and removal of nonalphanumeric tokens). For the gradient-boosted trees model, we tuned the number of estimators, learning rate, and maximum depth. Hyperparameters were tuned based on the average performance over all folds in the cross-validation sets using Bayesian optimization.

In addition, we tested the fine-tuning of the FlauBERT sequence classification model using the Hugging Face transformer library [26]. The FlaubertForSequenceClassification application programming interface provides a pretrained FlauBERT model with a classification layer of size 1024 on top. It takes raw text as input and outputs the predicted classes (in our case, which is the complexity level). Among all our experiments, our best results were obtained using the fine-tuned FlauBERT-base uncased model. Notably, we froze the first 11 encoder layers and trained the last encoder layer and the classification layer to limit overfitting. We also weighted each class differently in the cross-entropy loss to account for imbalance. We used the maximum sequence length of 512 tokens and a batch size of 32. In this manuscript, we only report the fine-tuned FlauBERT results obtained using this configuration.

Figure 6. Comparison of performance using different models and input features on the 5-fold–cross-validated training data set (1751 cases) and the best model performance on the test set (309 cases). Dashed vertical lines represent the baseline model results. Models are ranked based on the classification macro–F1-score in the figure. *Average per service: for a given case in a given service, it always predicts the average complexity of cases in this service. A total of 29 services have an average complexity of 2, a total of 5 services have an average complexity of 3, and a total of 1 service has an average complexity of 1. **Majority vote: always predicts the majority class (in our case, complexity 2) and serves as a baseline for model prediction performance. FlauBERT: French-Language Understanding via Bidirectional Encoder Representations from Transformers; TF-IDF: term frequency-inverse document frequency.

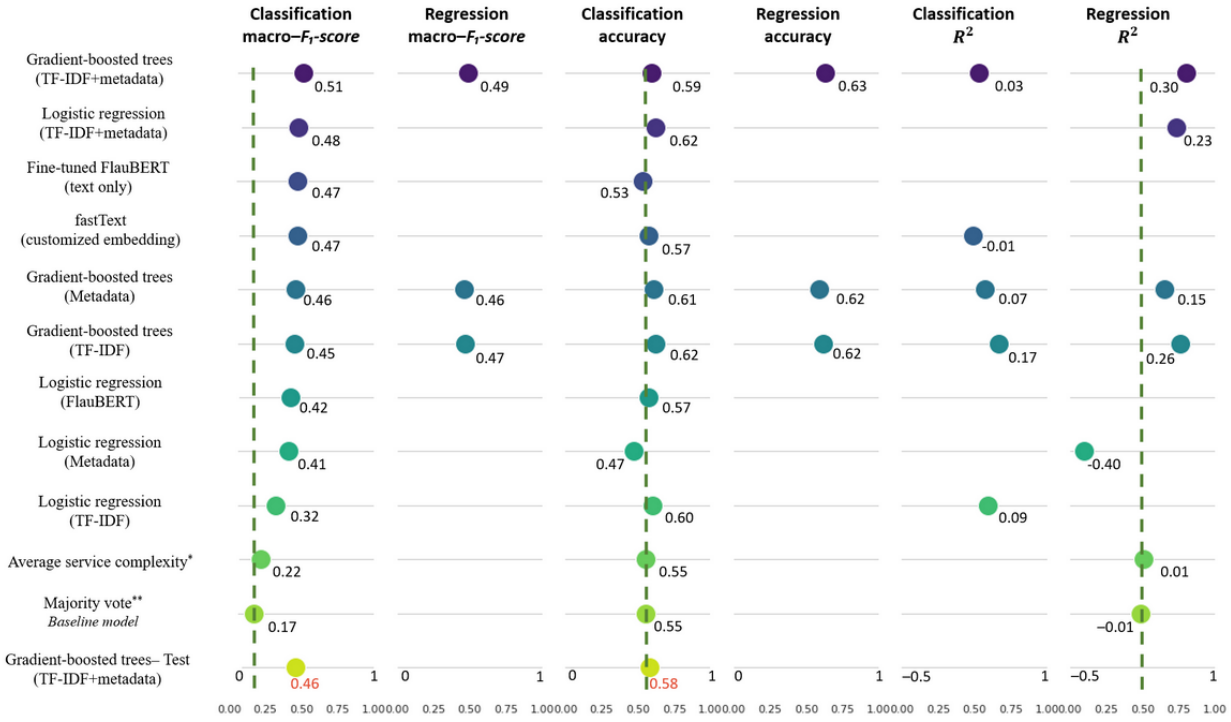

Figure 7. Feature engineering and modeling approach using word embeddings and patient metadata as model inputs. The fine-tuned French-Language Understanding via Bidirectional Encoder Representations from Transformers text classification model is not included in this flow.

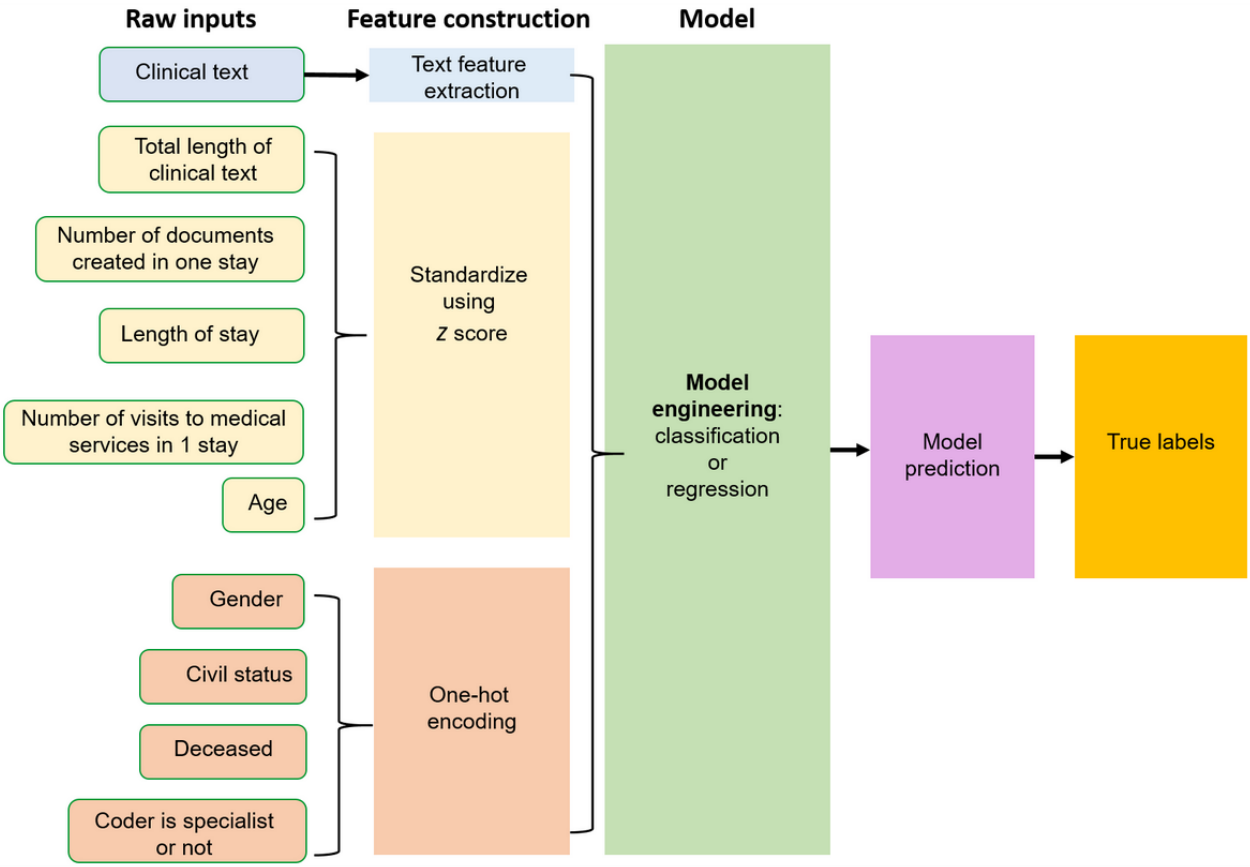

Data Imbalance

Our data labels were strongly imbalanced, and we tried to overcome this issue by using oversampling and undersampling techniques. Our best model was trained using Synthetic Minority Oversampling Technique [27] for oversampling underrepresented classes followed by random undersampling for overrepresented classes. We also chose metrics to penalize models that did not predict underrepresented classes, such as the macro–F_1-score. Ordinal classification can also be an interesting "hybrid" approach. However, we leave trying more sophisticated classification approaches for future work.

Technological Stack

The ML pipeline leverages spaCy (version 3.1; Explosion AI) for preprocessing texts (using the French-language model "fr_core_news_md"), scikit-learn (version 1.0.1) to build complex pipelines that can work with cross-validation, and Optuna (version 2.10.0; Preferred Networks, Inc) to conduct hyperparameter searches. It also eases the deployment of the selected model as preprocessing is part of a single serialized pipeline. The other tools used to try other approaches were fastText for document classification, Gensim (RARE Technologies, Ltd) to manipulate pretrained word embeddings, and Hugging Face Transformers (Hugging Face, Inc) to use pretrained transformer models. Training was performed on a virtual machine with 64 central processing unit cores, allowing us to parallelize training, and an Nvidia RTX 3090 graphics processing unit for larger deep learning models.

The first version of the selected model is being deployed with Machine Learning Model Operationalization Management infrastructure in our medical coding service. The deployment details are presented in Multimedia Appendix 1.

Results

Metadata Analysis

Each team of coders had a set of medical specialties. We considered that a case was annotated by a specialist if the annotator was part of a team from one of the specialties involved in the case. Following this logic, 63.98% (1318/2060) of the cases were annotated by a specialist. We used this as a feature during training. At inference time, we could choose to request a prediction for whether the case would be coded by a specialist.

The distribution of the numerical metadata and categorical metadata is presented in Figure 5. To check if any of the metadata had significant predictive power on coding complexity, we performed Pearson correlations between the numerical metadata features and the complexity ratings; we also performed statistical tests on categorical features such as patient gender and marital status (Table 1). The results show that, in the precoding phase, features such as sentence length and number of medical services visited during a stay did not have strong effects on coding complexity. In the postcoding phase, the number of ICD-10 codes and Swiss Classification of Surgical Procedures codes showed correlations with coding complexity. With these results, we propose that a future direction of NLP-

or AI-assisted coding could use the metadata and clinical text to predict the number of codes that a case may produce and then compare it with the actual codes obtained after the coding process to perform quality checks in the postcoding phase.

Table 1. Pearson correlations between the numerical metadata features and the complexity ratings in both the pre- and postcoding phases and statistical tests of the categorical features and complexity ratings in the precoding phase.

	Correlation or statistical test	*P* value
Numerical features		
Number of tokens from all documents in a stay	0.44	<.001
Number of documents produced in a stay	0.33	<.001
Number of medical services visited during a stay	0.02	.35
Duration of the stay	0.41	<.001
Age	0.25	<.001
Sentence length	0.003	.83
Categorical features		
Marital status	$F_{5, 2054}=14.05$	<.001
Gender	$t_{2058}=-3.70$	<.001
Other metadata available after coding		
Number of ICD-10[a] codes	0.55	<.001
Number of CHOP[b] codes	0.46	<.001
DRG[c] cost	0.34	<.001

[a]ICD-10: International Statistical Classification of Diseases and Related Health Problems, 10th Revision.

[b]CHOP: Swiss Classification of Surgical Procedures.

[c]DRG: diagnosis-related group.

Coder Rating Analysis

The complexity ratings of the cases are shown in Figure 8A. The most common rating was complexity 2 (1127/2060, 54.71% of cases), and the least common rating was complexity 4 (58/2060, 2.82% of cases). We used stratified sampling to select the training and test sets; hence, their distributions were nearly identical to the true distribution shown in Figure 8A.

The original medical service of a case may also affect its complexity. Figure 8B shows that the cases from the Department of Palliative Care have the highest average complexity, whereas cases from the Department of Thoracic Surgery have the lowest average complexity.

By analyzing the gold-standard set, where all cases were rated by 2 experts, we found that even the expert coders did not always agree with each other. Of the 62 cases, the 2 experts agreed on 41 (66%). However, they disagreed by more than one complexity level in only 3% (2/62) of cases (Table 2). The interrater reliability (Cohen κ score) was 0.49 between the 2 expert coders. If we consider one expert as the ground truth and the other expert as a predictive model, the macro–F_1-score of this "predictive model" can only achieve 0.67 (Figure 9), a moderately good score showing that the task can be learned but models will not achieve a very high performance.

The reason why coders rate the same case with different complexity levels is mainly subjectivity. This is also a reminder that subjective-rated labels are often noisy, and no model can achieve a perfect performance. The ratio of agreement between 2 expert coders gives us an idea of the performance we could expect from a model. If we consider one expert as the model that predicts complexities and the other expert gives true complexity labels, then the highest accuracy that this model (the former expert) can achieve is 66%. In this sense, when later analyzing our model's performance, the 66% accuracy can be considered as one of the benchmarks. However, given the strong imbalance in the complexity labels, we should rely as well on the confusion matrix to compare the annotator-annotator agreement with the model-annotator agreement.

However, as mentioned in the Model Design section, our samples were highly imbalanced, and the accuracy metric lacked the ability to measure the model's performance comprehensively according to the sample distribution. As there were 54.71% (1127/2060) of cases rated with a complexity of 2, a naive model that predicts 2 all the time could reach an accuracy of 54.71%, but it provides no value for solving our problem. To consider the imbalanced sample distribution, we used the macro–F_1-score together with accuracy to measure the model performance. The macro–F_1-score between the 2 coders was 0.67, which was considered as the other benchmark that we used to evaluate the model's performance.

Figure 8. (A) The distribution of complexity ratings over all 2060 cases. (B) Average complexity rating by service. The green bars show the top 5 services, and the red bars show the bottom 5 services. CHT: thoracic surgery; ION: immuno-oncology; MIN: infectious diseases; OBS: obstetrics; PED: pediatrics; RHU: rheumatology; SIA: adult intensive care; SIP: pediatric intensive care; SPL: palliative care; URG: emergency department.

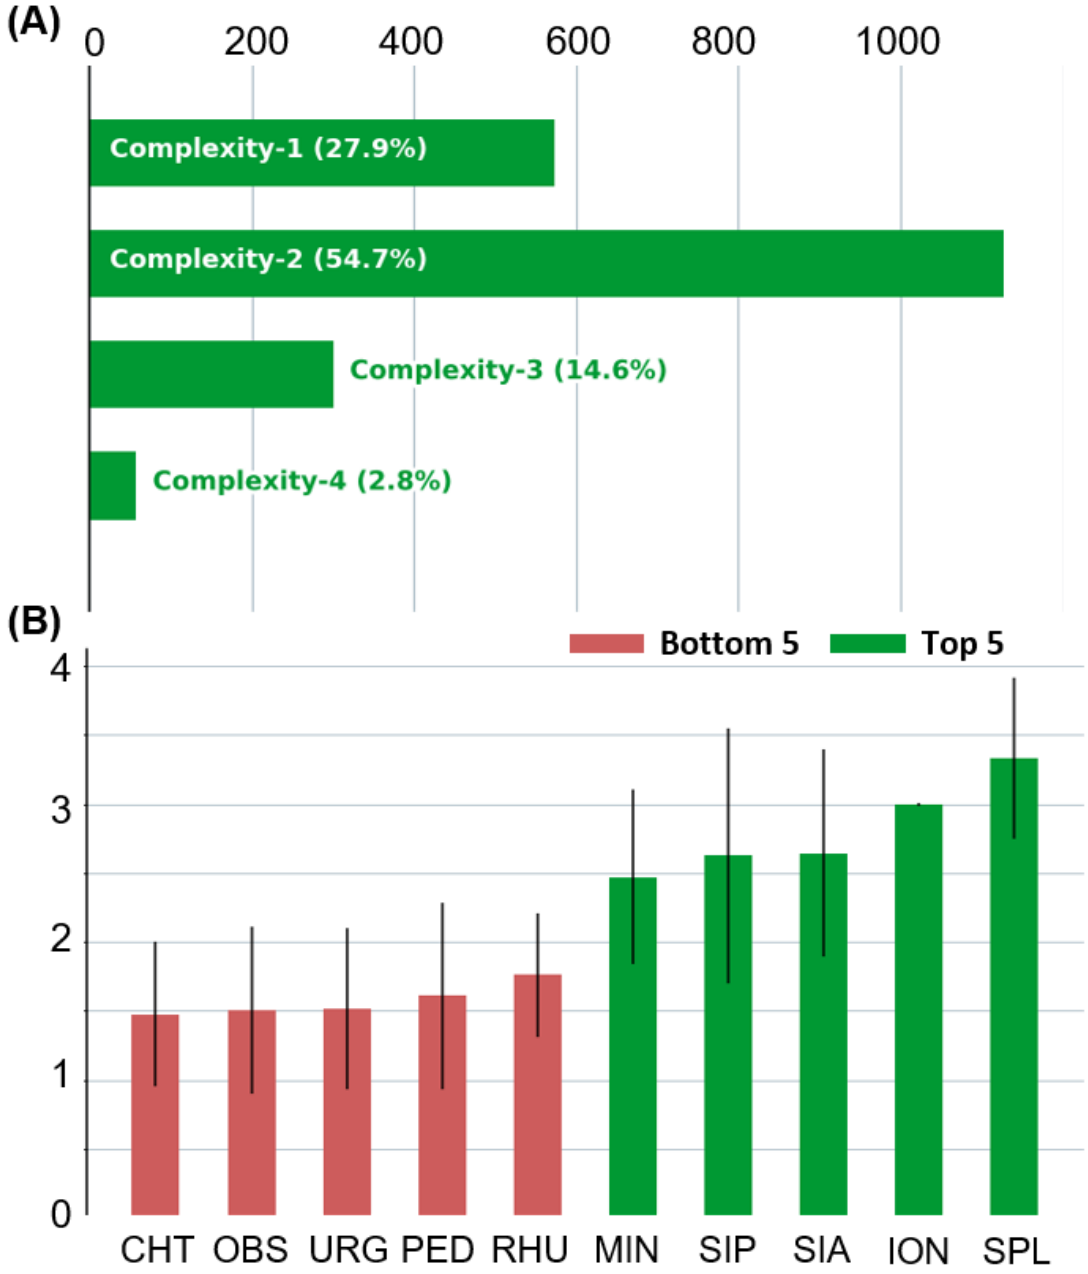

Figure 9. (A) The complexity rating comparison between 2 expert coders on the gold-standard set. (B) The comparison between the validation model's predictions and average expert ratings on the gold-standard set. (C) The comparison between 2 expert coders' ratings on the gold-standard set when grouping into simple (complexity 1 and 2) and complex (complexity 3 and 4) cases. (D) The comparison between average expert ratings and the validation model's predictions on the gold-standard set when grouping into simple and complex cases. The average expert ratings are rounded up to the next largest integer.

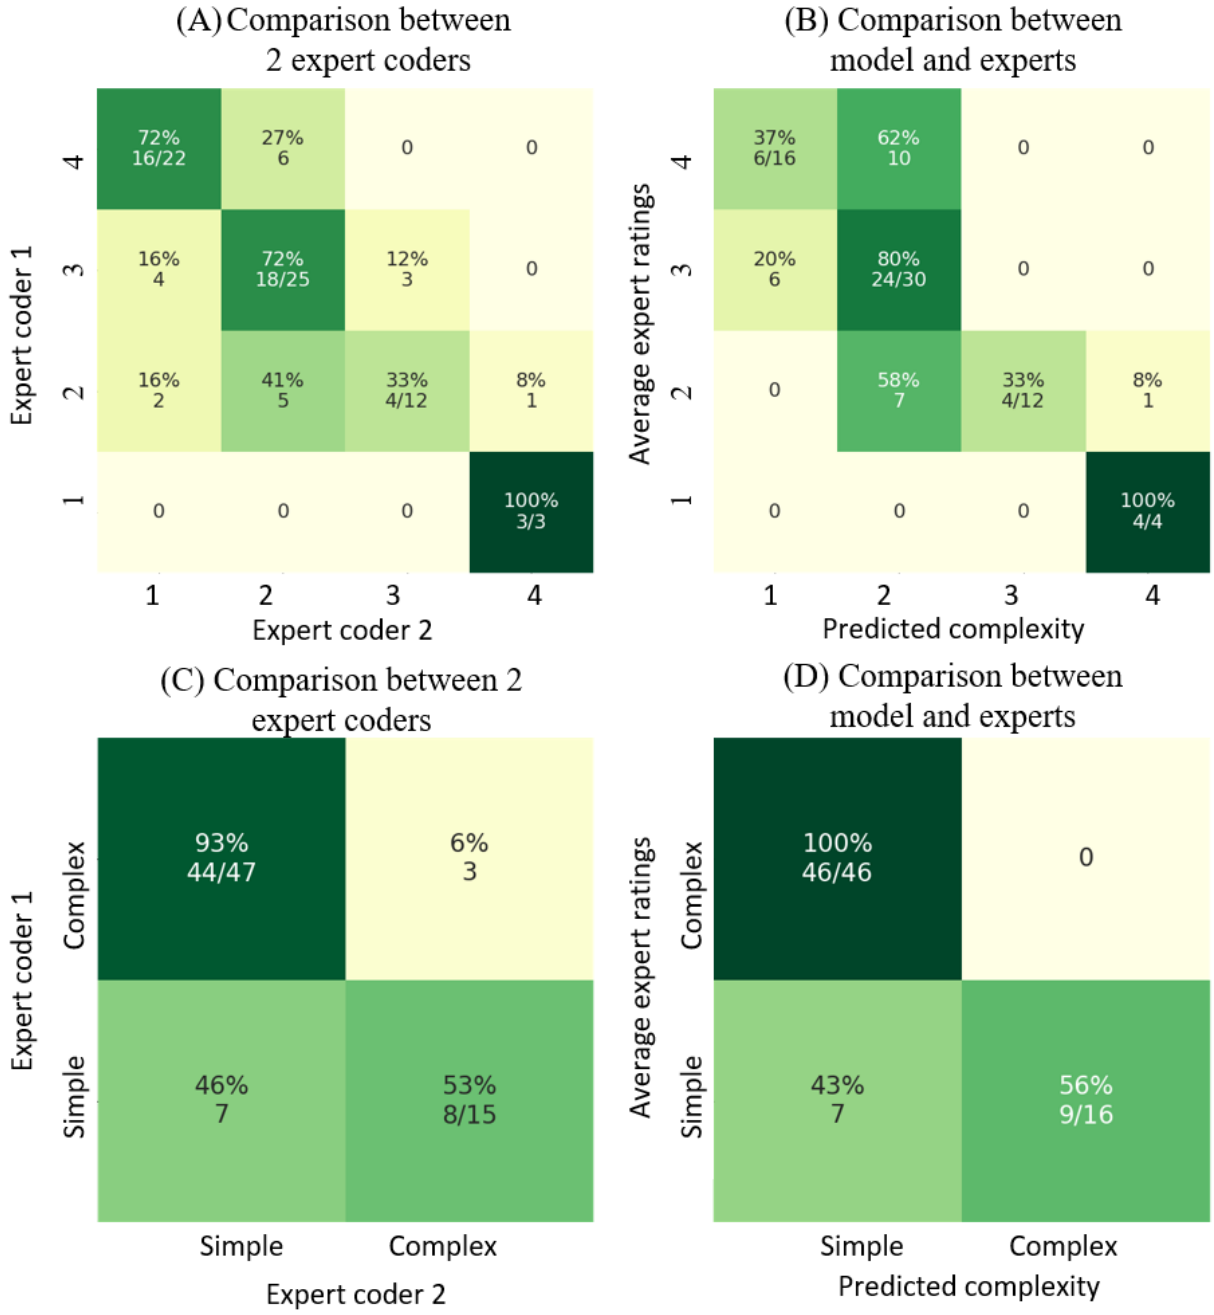

Table 2. Absolute difference between expert 1 and expert 2 complexity ratings. The accuracy reached by expert coders was approximately 66% (41/62; N=62).

Absolute difference in complexity ratings between expert coders 1 and 2 (number of complexity levels)	Cases, n (%)
0	41 (66)
1	19 (31)
2	2 (3)
3	0 (0)

Model Analysis

Overview

First, we wanted to study whether our approach worked on predicting coding complexity for medical cases. We made use of all the 2060 annotated cases (n=1998, 96.99% 1-coder–rated and n=62, 3.01% gold-standard cases). We split the 2060 cases into a training set (n=1751, 85% of cases) and a test set (n=309, 15% of cases) and tested our model architecture. Then, to validate the model's performance with expert coders' benchmarks, we left the 3.01% (62/2060) of gold-standard cases out as the test set and trained a model with the same architecture but with more training data (1998/2060, 96.99% of cases).

The Main Model

To train the models, we started by using either patient metadata only or word embeddings or TF-IDF vectors only as input features. The best-performing model using patient metadata was gradient-boosted trees (macro−F_1-score=0.46; accuracy=0.61 for classification; R^2=0.15 for regression). The best-performing model using word embeddings was the fastText classification model (macro−F_1-score=0.47; accuracy=0.57; initialized with customized embeddings), and the best-performing model using TF-IDF vectors was gradient-boosted trees (macro−F_1-score=0.45; accuracy=0.62 for classification; R^2=0.26 for regression).

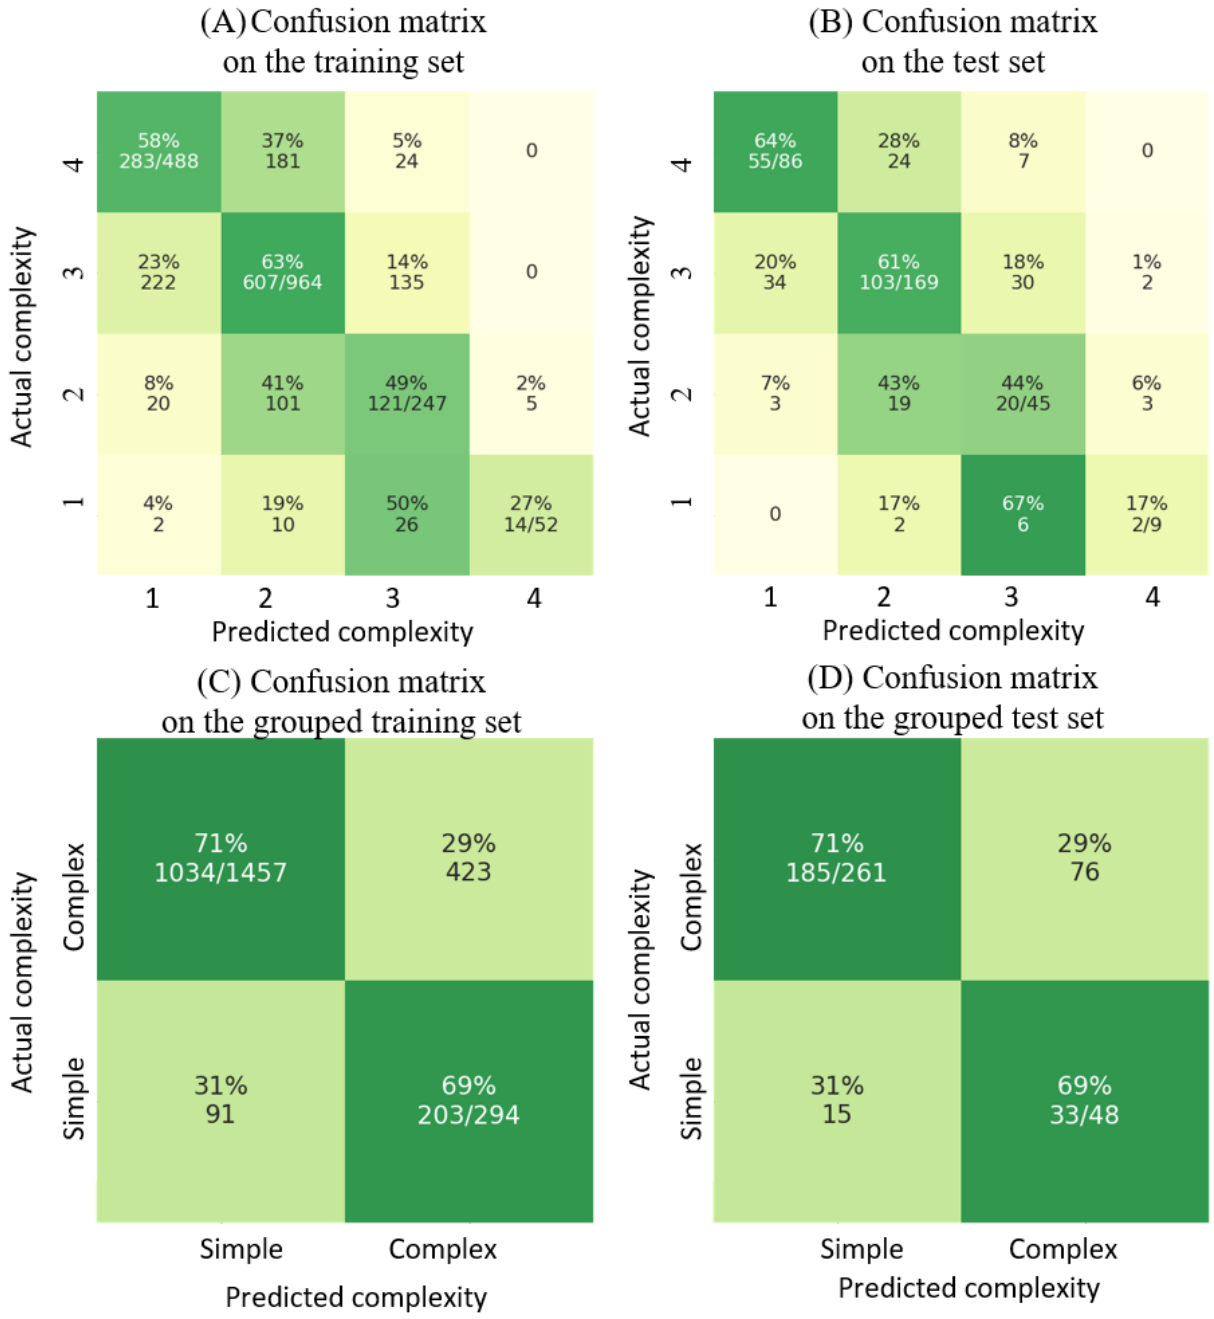
The model using word embeddings did not outperform the model using TF-IDF vectors. Thus, we combined the TF-IDF vectors with metadata as input features to integrate information from both patient metadata and medical dossiers. The best-performing model used gradient-boosted trees and achieved a macro−F_1-score of 0.51 and accuracy of 0.59 on the cross-validated training set and a macro−F_1-score of 0.46 and accuracy of 0.58 on the test set. Figure 6 shows the performance comparison between different models on the 5-fold–cross-validated training data set and the test set. The detailed numbers can be found in Multimedia Appendix 1.

As performing well on underrepresented classes is important in our case, we report the macro–F_1-score as the first metric. Macro–F_1-score is the average of the F_1-score per class and is not weighted by the number of instances in the class. Unlike accuracy, this metric penalizes each class equally. On the basis of the macro–F_1-score, we selected our best model as the gradient-boosted trees trained with the combined TF-IDF and metadata features (referred to as the main model).

The confusion matrix (Figures 10A and 10B) shows that our main model confused complexity-2 and complexity-3 cases during training and testing. Figure 9A shows that, even for expert coders, there was no clear distinction when rating complexity 2 and 3 for a case. The difficulty to distinguish between complexity 2 and 3 could be due to the similarity between the 2 classes of cases. We noticed that our main model also had difficulties distinguishing between complexity 3 and 4 during training and testing. This performance could be due to the lack of examples. Although we performed oversampling using Synthetic Minority Oversampling Technique on cases with a complexity of 3 and 4, it still lacked variability in complexity-4 cases.

We then tried to merge complexity-1 and complexity-2 cases as "simple" cases and complexity-3 and complexity-4 cases as "complex" cases and tested the model as a binary classifier. The results (Figures 10C and 10D) show that the model performed well on distinguishing between simple and complex cases. On the training set, the model achieved a macro–F_1-score of 0.62 with an accuracy of 0.71. On the test set, the model achieved a macro–F_1-score of 0.65 with an accuracy of 0.71.

Figure 10. (A) and (B) The main model's performance on the training set (1751 cases) and the test set (309 cases). (C) and (D) The main model's performance on the grouped training set (1457 cases as simple and 294 cases as complex) and the test set (261 cases as simple and 48 cases as complex).



The Validation Model

To validate our model approach and compare it with experts' benchmarks, we trained a validation model using the 96.99% (1998/2060) of 1-coder–rated cases and tested it on the 3.01% (62/2060) of gold-standard cases. The architecture of the validation model was the same as that of the main model.

The comparison between the 2 expert coders' ratings (Figure 9A) shows that most of the expert coders' disagreements were on complexity-2 and complexity-3 cases, and the overall agreement ratio between the 2 coders was 66% (41/62), with a macro–F_1-score of 0.67. Table 3 and Figure 9B show the comparison between our validation model and the 2 experts' ratings on the gold-standard set. The model agreed on 53% (33/62) of the cases with expert coder 1 and in 63% (39/62) of the cases with expert coder 2. The validation model achieved a 61% agreement ratio with the average ratings of both experts, with a macro–F_1-score of 0.62.

Table 3. Comparison between our validation model's predictions and 2 expert coders' ratings on the gold-standard set.

	Percentage of agreement	Pearson correlation
Expert coder 1 vs expert coder 2	66	0.70[a]
Model vs expert coder 1	53	N/A[b]
Model vs expert coder 2	63	N/A
Model vs ceiled mean of 2 expert coders	61	0.70[a]

[a]$P<.001$.

[b]N/A: not applicable.

When merging the 4 complexity levels into 2 (simple vs complex; Figures 10C and 10D), the agreement ratio between the 2 coders became 84% (52/62) with a macro–F_1-score of 0.76, and the agreement ratio between model predictions and average expert ratings became 0.89 with a macro–F_1-score of 0.82. The results indicate that the model is comparable with human experts' performance and predicts in a very similar manner to that of human experts (Figures 9A and 9B).

Interestingly, for the gold-standard cases, our validation model managed to predict complexity-4 cases 100% correctly, which was different from the main model's performance during training and testing (Figures 10A and 10B). As there were only 4 selected cases with a complexity of 4 owing to the sampling for expert cases, these cases could be extremely complex and, thus, easy for the model to identify.

Compared with other models that can provide higher accuracy but lower F_1-score, both the main model and the validation model were more practical in our concrete use case as it is important to predict diverse complexity levels rather than keep predicting a complexity of 2 for all cases (Multimedia Appendix 1).

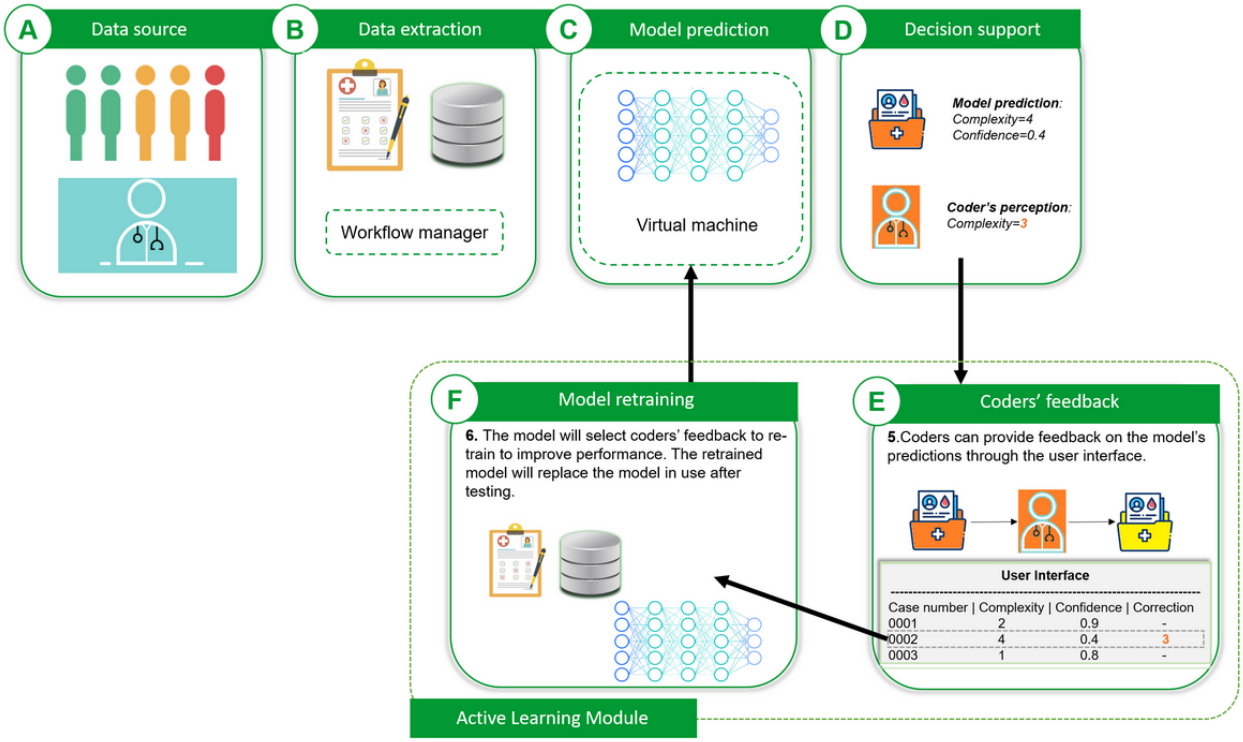
Classification Versus Regression

We summarize the pros and cons of both approaches given our use case in Textbox 4.

Textbox 4. Pros and cons of the classification and regression approaches.

- *Prediction confidence*: many classification models output the confidence in the predicted class as a probability, whereas regression models typically do not provide such information out of the box (although CIs are sometimes possible). Confidence is useful for end users, meaning that they can disregard predictions with low confidence. It can also be used in the active learning module (Figure 11) to select new cases (with low prediction confidence and strong disagreement between prediction and coder perception) to retrain the model.
- *Interpretability of results*: using a classification approach enables the computation of F_1-scores, accuracy, and confusion matrices. These are more intuitive for end users. Note that, for regression, it is still possible to round prediction to apply these metrics.
- *Order of labels*: complexity scores are naturally ordered. Therefore, given a case annotated with a complexity of 4, a model should be penalized more for predicting a complexity of 1 than for predicting a complexity of 3. Regression methods consider order, whereas classification methods do not.

Figure 11. Use of active learning module to collect coders' feedback and improve model performance. The workflow manager in (B) can be any software or platform that provides automatic scheduling for designated work (eg, a script for data extraction).



Discussion

Principal Findings

We presented different ML models that can predict the complexity of coding medical cases with 4 complexity levels. We first trained the models on all 2060 annotated cases. When only using patient metadata, the best model (gradient-boosted trees) could achieve a macro−F_1-score of 0.46, an accuracy of 0.61 for classification, and an R^2 of 0.15 for regression. By applying NLP methods to extract information from clinical text, the best model (fastText initialized with customized embeddings) could achieve a macro−F_1-score of 0.47 and an accuracy of 0.57 for classification. When combining patient metadata and NLP-extracted information, the best model (the main model in the Model Analysis section) achieved a macro−F_1-score of 0.51 and an accuracy of 0.59 on the cross-validated training set and a macro−F_1-score of 0.46 and an accuracy of 0.58 on the test set.

To evaluate our model approach with experts' benchmarks, we trained our validation model using the same architecture as the main model on all except the gold-standard cases. Our validation model achieved an accuracy of 0.61 with a macro−F_1-score of 0.62 on the gold-standard cases. When merging the 4 complexity levels into "simple" (complexity 1-2) and "complex" (complexity 3-4) cases, our validation model could achieve an accuracy of 0.89 and a macro−F_1-score of 0.82. The results indicate that the model performance is highly comparable with that of human experts.

To the best of our knowledge, this is the first study to apply NLP and ML models to help differentiate the complexity of coding medical cases.

Clinical Importance

Lausanne University Hospital in Switzerland has 2 missions: guaranteeing medical services in an area and serving as a referral hospital. The dominance of cases with a complexity level of 2 (referred to as case 2) in the labeled sample cases can be explained by this double activity as the hospital not only concentrates on university or referred complex cases but also receives normal cases similar to other hospitals.

In our current medical coding service, the cases to be coded are distributed 50% to the team of the specialty and 50% to a "common pot." This team versus common pot distribution is done randomly without considering the complexity of the cases, leaving complex cases in the common pot and, conversely, depriving the common pot of "simple" cases of specialized resources. Note that, in our case, coders can still choose complex cases from the common pot even if the case is not in their specialty. Many coders care about diversity or learning other types of cases. The integration of this model enables them to choose the complexity consciously.

The dominance of cases 2 will have the effect of pushing a lot of cases into the common pot, reducing the number of cases arriving to teams of different specialties and, hence, reducing the ratio of common pot to specialists. The quality of coding of complexity-3 and complexity-4 cases will be improved as they will be redirected to the specialty teams or senior coders. However, this will also be at the risk of lowering the quality of coding of cases 2, which will end up in the common pot. Therefore, it will be necessary to maintain a 50/50 ratio between

the common pot and the teams or senior coders and force cases 2 to be coded by teams or seniors as well. This adjustment will enhance the quality of coding of cases 3 and 4 and a maximum of cases 2. After our system is deployed, the new distribution considering the complexity predicted by our NLP and ML model will be monitored in terms of satisfaction of the coding teams and accuracy of coding. Furthermore, we will analyze the accuracy of coding in relation to the predicted case complexity to adjust the model design and more efficiently allocate the case distribution to coders.

In our current model, the complexity of the cases is defined by the coders from our medical service and is rated subjectively. By analyzing the model predictions for a variety of cases, it is possible to summarize the common features shared by the high-complexity cases and those shared by the low-complexity cases. The summarized features can be used to build a set of objective rules that can be shared with other clinical services or the medical coding services of other hospitals. For small hospitals or clinical services, which do not always have sufficient resources to train and build their own ML models, this set of rules can help them distribute the cases more efficiently. In contrast, if the summarized features could not distinguish well between the simple and complex cases, it may reflect that the case complexity is a subjective rather than objective measure. In this situation, the best way to generalize this subjective measure is to build a model, such as in our approach, to learn the highly nonlinear subjective measures.

The complexity of coding a medical case can approximately reflect the complexity of the corresponding clinical case. Our application can not only improve resource allocation in medical coding services but also be generalized to other clinical services. Indeed, coding complexity levels can also be used in decision-making processes to help arbitrate resource allocation among professionals in the same department but affiliated with different clinical services within the department. For example, in the surgery department, a similar approach can be applied to help study the need for resources for different subspecialties based on the volume of treated cases but also on their relative complexity. The generalized application can be integrated into different digital health care systems for automatic task assignment to avoid conflicts in an unfair workload distribution.

Technical Importance

OOV is an issue that can impair model performance. Although the word2vec embeddings used in this study were trained on our own clinical data, OOV was still present as the corpus we used to train the embeddings might not have been sufficient to cover all the clinical terms used in the medical discharge documentation. To mitigate the impact of OOV, we tested the fastText subword approach. However, as shown in the Model Analysis section, the model performance was not much improved because of the low OOV ratio of our data set, which was only approximately 8% in the 2060 selected cases for this study. We provide a detailed analysis of OOV in our corpus in Multimedia Appendix 1.

As new clinical documents are produced every day, our deployed model could also face the impaired performance caused by the OOV issue. The solution we propose in this paper to reduce the impact is to monitor the evolution of new OOV with respect to the training data set and retrain the word embeddings when needed. During the retraining phase, we will not only retrain the word embeddings but also retrain the models with coder feedback to further improve the model performance from the perspective of both feature engineering and model engineering.

In our study, we used FlauBERT, which is a pretrained French-language transformer, in 2 different ways. The first way to use it is to generate word embeddings as text features for model inputs. We then also tested a Hugging Face [26] implementation of the sequence classification model using FlauBERT. A detailed description of this approach is presented in Multimedia Appendix 1. The best performance using the transformer model directly achieved a macro–F_1-score of 0.47, which is similar to other models that only receive text as features. The model performance did not improve as much as expected. The reason could be that our data set was too small (only 2060 cases) compared with the size of the transformer model. Regarding this, we will continue collecting coder feedback on the predicted cases and use them to train the model continuously. With these approaches, we hope to improve the transformer model performance in the future.

We found that using TF-IDF vectors as text features provided better prediction performance than using word embeddings as text features. The fastText and FlauBERT embeddings were pretrained on a nonclinical corpus; thus, the represented context of the word could deviate from the context used in the clinical text. As shown in the Metadata Analysis section, the median document length per stay was 909 tokens. Common pretrained transformer-based models handle up to 512 tokens, and it is not obvious which subset of the document should be selected to pass to the model. Although it is possible to overcome this limitation by embedding each chunk of 512 tokens and averaging their embeddings, we believe that a substantial improvement over other methods is needed to justify the computation cost. Furthermore, fastText and word embeddings both perform averaging over all vectors of each document, which may dilute the signal too much given the number of tokens. In contrast, TF-IDF can preserve some of this information, which could be the reason why TF-IDF vectors outperformed word embeddings in our task. A future direction to improve the model performance could be to combine TF-IDF vectors with word embeddings as text features. TF-IDF vectors can be used as a weight of importance for the words, whereas word embeddings can represent the contexts of the words. By combining the two, we could obtain vectors that represent both the importance and context of the words comprehensively. Another possible approach to improve the model performance is to build a rule-based model from coders' experiences and then combine the rule-based model with the ML model, which can increase both the interpretability and flexibility of the prediction. As the complex cases are more likely to have multiple laboratory tests and clinical examinations, we could also include this structured clinical information for future feature engineering.

By comparing our model's predictions with the expert coders' ratings, we found that the model could achieve an expert performance level (Figure 9). As rating case complexity is relatively subjective, even expert coders do not always agree with each other. This introduced another level of complexity to our study. However, by learning 1998 cases from the training set, our model's performance became comparable with that of the experts.

One of the advantages of our model is that we used a multimodal approach. Structured data such as patient metadata can provide quantitative information about patients' status. Clinical text can provide rich information on diagnostic and other assessments of patients, which are not usually presented in the structured data. By combining the two, we are able to maximize the information needed to evaluate the complexity of a clinical case. Our study used 1 model to process data of different modalities and make predictions. In future work, we propose using dedicated models for each data modality and combining the predictions of multiple models using another ML model to make the final prediction. The benefits of using multiple models are that (1) it is easy to plug in new data and new models into the architecture, which makes the model flexible to extend, and (2) it is easier to perform feature engineering and interpret the model's prediction.

The advantage of classification models over regression models in our study was that classification models allowed us to produce the confidence of the predictions. By showing both the predicted complexity level and the confidence of the prediction, we are able to provide comprehensive information to end users. However, there are also limitations to our model. Of the 2060 cases we collected for this project, 54.71% (1127/2060) were labeled as complexity-2, and only 2.82% (58/2060) were labeled as complexity-4. The unbalanced data set affects the performance of the classification models, meaning that the models have a higher tendency to predict complexity 2 for a given case. This problem was tackled by oversampling the underrepresented cases and undersampling the overrepresented cases. The results showed that the model performed better with oversampling and undersampling techniques (Multimedia Appendix 1).

Our model will be integrated into our current coding system with an active learning module. Figure 11 shows the integration architecture. The model reads patient metadata and medical dossiers regularly from our clinical data warehouse through a workflow manager. The predictions are presented in the user interface of the coding software. When coders find that the prediction deviates from the perceived complexity, they can put their corrections in a feedback field. Coders' feedback is stored and sent to the model for retraining. This integration architecture allows us to track and continuously improve the performance of the model.

Future Work

Future work can be carried out on different aspects. To improve the model prediction performance, we can continue working on feature and model engineering. In addition to the data we used in this study, there could be other patient data that can be useful to predict the complexity of cases. Regarding the text features, we could try different combinations of NLP tools to maximize the information extraction from clinical text. We will also continue working on reducing the OOV impact by retraining the word embeddings (both word2vec and fastText) and TF-IDF vectors every 6 months and use coder feedback as new training samples to retrain the models. To make full use of the advanced transformer models, we will not only keep training using the new samples but also explore ways to incorporate patient metadata into the model design. We will also work together with coders to establish a sound and interpretable rule-based model and then combine it with the ML model. The hybrid model can provide both flexibility and good reasoning in distinguishing cases.

Currently, most NLP applications focus on AI-assisted coding using rule-based or ML models. As stated before, the rules framing medical coding complexity are dynamic and change over time, preventing the rapid learning of the tool. Instead of using AI-assisted tools only for coding, it is possible to extend the AI-assisted scope from case preselection to postcoding quality checks. Our approach provides a possibility to preselect cases that are suitable for automatic coding and other cases for manual coding. After a case is coded, AI-assisted tools can provide a post hoc analysis of the code categories and combinations, aiming to find possible mistakes in the codes. This can be done by studying previous coded cases using statistical and NLP analysis.

We also aim to continuously evaluate the application's impact on our medical coding service. After the integration, we will monitor the average time a coder spends coding a case and the average number of mistakes a coder makes for each case. By comparing the time and accuracy before and after the integration, we can obtain a quantitative measure of how much improvement the model can bring to the coders' daily work.

In addition to monitoring the quality of coding, we will keep tracking the coders' user experience. With the help of the active learning module, we are able to collect coders' feedback on the model's predictions. The model will be retrained based on coders' feedback through iterations to improve the prediction performance. As discussed in the Clinical Importance section, our application can not only help with task distribution to current coders but also be used to select cases for training junior coders. Junior coders will receive simple cases at the beginning and gradually receive more complex cases. This approach can give junior coders enough exposure to a variety of cases with respect to their capabilities as well as evoke their interests in medical coding.

Acknowledgments

The authors thank the 2 expert coders, Mireille Nya Buvelot and Lionel Comment, and all coders in the Coding Division for their contribution to complexity annotations. They also thank Dr Mostafa Ajalloeian for providing advice on this project.
