Abstract

Background: Electronic health records (EHRs) have an enormous potential to advance medical research and practice through easily accessible and interpretable EHR-derived databases. Attainability of this potential is limited by issues with data quality (DQ) and performance assessment.

Objective: This review aims to streamline the current best practices on EHR DQ and performance assessments as a replicable standard for researchers in the field.

Methods: PubMed was systematically searched for original research articles assessing EHR DQ and performance from inception until May 7, 2023.

Results: Our search yielded 26 original research articles. Most articles had 1 or more significant limitations, including incomplete or inconsistent reporting (n=6, 30%), poor replicability (n=5, 25%), and limited generalizability of results (n=5, 25%). Completeness (n=21, 81%), conformance (n=18, 69%), and plausibility (n=16, 62%) were the most cited indicators of DQ, while correctness or accuracy (n=14, 54%) was most cited for data performance, with context-specific supplementation by recency (n=7, 27%), fairness (n=6, 23%), stability (n=4, 15%), and shareability (n=2, 8%) assessments. Artificial intelligence–based techniques, including natural language data extraction, data imputation, and fairness algorithms, were demonstrated to play a rising role in improving both dataset quality and performance.

Conclusions: This review highlights the need for incentivizing DQ and performance assessments and their standardization. The results suggest the usefulness of artificial intelligence–based techniques for enhancing DQ and performance to unlock the full potential of EHRs to improve medical research and practice.

Introduction

The adoption of electronic health records (EHRs) optimistically promises easily searchable databases as an accessible means for prospective and retrospective research applications [1]. EHRs often fall short of these promises due to limited local data and poor data quality (DQ) [2,3]. To overcome these limitations, several institutions have harmonized databases and model ontologies, including PCORnet (The National Patient-Centered Clinical Research Network), All of Us, MIRACUM (Medical Informatics in Research and Care in University Medicine), and the EHDEN Project [4-7]. These programs strive to offer high-quality data for research purposes [2]. However, EHR DQ remains highly variable, with some studies showing completeness in EHR parameter values ranging from 60% to 100% [8,9]. Similar inconsistencies present a significant limitation to the generalizability and applicability of lessons learned across these datasets for broader medical and research purposes.

Multiple initiatives have aimed to measure and improve EHR data [10,11]. Early efforts in DQ assessment (DQA) demonstrated inconsistent reporting and a need for universal

terminology standards in DQA efforts [11]. In response, attempts at a standardized ontology for DQA have been developed, such as through the efforts of the International Consortium for Health Outcomes Measurement, 3×3 DQA guidelines, and the terminologies proposed by Kahn et al [12] and Wang et al [8,12-15]. More recently, artificial intelligence (AI) and natural language processing techniques have automated quality initiatives, including data assessment and augmentation [16,17]. Nonetheless, these techniques introduce their own set of quality requirements, including fairness metrics, handling intolerable or lost data, and mitigating data drift [18]. Measuring the result of these techniques' application in real-world clinical contexts has given rise to another field that has become crucial for EHR improvement, namely, data performance assessment (DPA) [19].

In this review, we critically evaluate peer-reviewed literature on the intersection of DQA and DPA applications, as well as trends in their automation [10-13,20-22]. The purpose of this scoping review was to combine the 3 to formulate a more clear road map for evaluating EHR datasets for medical research and practice.

Methods

Overview

This scoping literature review was conducted according to the 2018 PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews), whose checklist is shown in Checklist 1 [23].

Literature Search

A search was performed for all full-text research articles published in English in PubMed from inception to May 7, 2023. A list of the exact search terms is included in Multimedia Appendix 1.

Article Selection

Four investigators (JB, RS, TRB, and YPP) reviewed the selected studies during the title and abstract screening. Further 4 investigators (ML, RS, TOB, and YPP) conducted the full-text review and final extraction of articles. Title or abstract screening, full-text review, and final extraction were based on the consensus opinion between 2 independent reviewers. Conflicts were resolved by a third reviewer. Article management and calculations of interrater reliability and Cohen κ were performed using Covidence systematic review software (Veritas Health Innovation).

Inclusion Criteria

Titles and abstracts were screened to include original research articles assessing the DQ and performance of all or part of a hospital's EHR system. We looked for studies reporting on 1 or more aspects of DQ (the assessment of EHR data without consideration of follow-up actions) and data performance (the assessment of EHR data applications) as defined (Table 1).

Table . Data quality and performance indicator definitions, mitigation strategies, and references.

	Definition	Mitigation strategies	Relevant studies
Data quality			
Completeness (or, conversely, missingness)	The absence of data points, without reference to data type or plausibility [12]	Automated data extraction; data imputation	[2-6,8,9,24-37]
Conformance	The compliance of data with expected formatting, relational, or absolute definitions [12]	Preemptively enforced data format standardization	[2-6,8,14,24-27,29-33,36,38]
Plausibility	The possibility that a value is true given the context of other variables or temporal sequences (ie, patient date of birth must precede date of treatment or diagnosis) [12]	Periodic realignment with logic rule sets or objective truth standards; thresholding	[4-6,8,14,25,27,28,30-33,35,37-39]
Uniqueness	The lack of duplicate data among other patient records [8]	Two-level encounter or visit data structure	[8]
Data performance			
Correctness or accuracy	Whether patient records are free from errors or inconsistencies when the information provided in them is true [10,13]	Periodic validation against internal and external gold standards	[2,7-9,14,23,24,28]
Currency or recency	Whether data were entered into the EHR[a] within a clinically relevant time frame and is representative of the patient state at a given time of interest [10,13]	Enforcing predetermined hard and soft rule sets for timeline of data entry	[2,4,9,27,32,34,36]
Fairness (or, conversely, bias)	The degree to which data collection, augmentation, and application are free from unwarranted over- or underrepresentation of individual data elements or characteristics	Periodic review against a predetermined internal gold standard or bias criterion	[3,19,22,24,27,35]
Stability (or, conversely, temporal variability)	Whether temporally dependent variables change according to predefined expectations [10,12]	Periodic measurement of data drift against a baseline standard of data distribution	[4,8,19,31]
Shareability	Whether data can be shared directly, easily, and with no information loss [3]	Preemptively enforced data standardization	[2,3]
Robustness	The percent of patient records with tolerable (eg, inaccurate, inconsistent, and outdated information) versus intolerable (eg, missing required information) data quality problems [24]	Timely identification of critical data quality issues	[24]

[a]EHR: electronic health record.

Data Quality

Conformance

Conformance refers to the compliance of data with expected formatting, relational, or absolute definitions [12].

Plausibility

Plausibility refers to the possibility that a value is true given the context of other variables or temporal sequences (ie, the patient's date of birth must precede the date of treatment or diagnosis) [12].

Uniqueness

Uniqueness refers to the lack of duplicated records [8].

Completeness (or Conversely, Missingness)

With regard to completeness, *missingness* is the absence of requested data points, without reference to conformance or plausibility as defined [12].

Data Performance

Correctness or Accuracy

Correctness or *accuracy* refers to whether patient records are free from errors or inconsistencies when the information provided in them is true [10,13].

Currency or Recency

Currency or *recency* refers to whether data were entered into the EHR within a clinically relevant time frame and are representative of the patient state at a given time of interest [10,13].

Fairness (or Conversely, Bias)

With regard to bias, *fairness* refers to the degree to which data collection, augmentation, and application are free from unwarranted over- or underrepresentation of individual data elements or characteristics.

Stability (or Conversely, Temporal Variability)

With regard to stability, *temporal variability* refers to whether temporally dependent variables change according to predefined expectations [10,12].

Shareability

Shareability refers to whether data can be shared directly, easily, and with no information loss [3].

Robustness

Robustness refers to the percent of patient records with tolerable (eg, inaccurate, inconsistent, and outdated information) versus intolerable (eg, missing required information) DQ problems [24].

We additionally included studies reporting on data imputation methods, defined as techniques used to fill in missing values in an EHR, such as through statistical approximation and the application of AI.

Exclusion Criteria

We excluded tangential analyses of DQ in articles focused primarily on clinical outcomes. As such, studies discussing data cleaning as part of quantifying clinical outcomes were excluded from our analysis. Proposals or study protocols with no results were also excluded during the screening process.

Article Quality Assessment

Full-text articles were additionally scored as having or missing the criteria for (1) data integrity: comprehensiveness for each main outcome, including attrition and exclusions from the analysis and reasons for them; (2) method clarity: a clear description of DQA data sources, analysis steps, and criteria; (3) outcome clarity: outcomes reporting in plain language, in their entirety, and without evidence for selective reporting; and (4) generalizability: applicability of DQ techniques described in the article to other clinical settings.

Results

Article Characteristics

The flow diagram for article selection is shown in Figure 1. A total of 154 records were identified using the search terms defined in Multimedia Appendix 1 using the PubMed library. After the removal of 31 duplicates and the 72 articles identified as irrelevant, 51 studies proceeded to full-text review. Full-text review excluded a further 25 articles owing to reasons listed in Figure 1, leaving a final total of 26 original research studies [2-6,8,9,14,19,22,24-39]. The Cohen κ between the different pairs of reviewers ranged from 0.28 to 0.54 during the screening process and from 0.54 to 1.00 during the full-text review.

Study characteristics are shown in Table 2 and Multimedia Appendix 2. Exactly half of the identified articles targeted general EHR DQ analysis [4-6,19,22,27-32,38,39], while the other half focused on a particular specialty or diagnosis (Table 2) [2,3,8,9,14,24-26,33-37]. The latter included primary care (n=3, 12%) [35-37], cardiovascular disease (n=3, 12%) [8,33,34], anesthesia or pain medicine (n=2, 8%) [14,26], intensive care units (n=2, 8%) [3,25], and pediatrics [24], oncology [2], and infectious disease (n=1 each, 4%) [9].

Article quality assessment conducted as part of our review process identified 14 (54%) of the articles [2-6,8,9,19,22,24-36,38,39] had at least 1 common study design or reporting limitation, with 5 of the articles having more than 1 [14,24,33,36,38]. Among these, 6 (30% of all errors) articles did not clearly state their methods [3,27,28,33,36,39], 5 (25%) had incomplete data [24,29,33,36,38], 5 were not generalizable to other settings [4,24-26,33], and 4 did not clearly state their outcomes (Table 2) [31,34,38,39].

Commonly referenced DQ and performance indicators are summarized in Table 3. Respective definitions, mitigation strategies, and references are listed in Table 1.

	Robustness	1 (4)

Data Quality Assessment

Completeness

Completeness was the most cited element of DQ analysis, with references in 21 (81%) of all articles [2-6,8,9,24-37]. Importantly, 19 (73%) studies integrated data from multiple clinical sites [2,4-6,9,19,22,24,26,30-39], which was associated with issues in data collection and missingness "across organizational structure, regulation, and data sourcing" [31]. Clinical domains reported to be prone to low data completeness included patient demographics, with Estiri et al [29] highlighting the issue for records of patient ethnicity and Thuraisingam et al [35] for mortality records (eg, missing year of death), and medication management, with Thuraisingam et al [35] highlighting the issue for dosage, strength, or frequency of prescriptions and Kiogou et al [34] for missing dates or reasons for discontinuation of medications.

To combat data missingness, Lee et al [22] used natural language processing algorithms to automatically extract data from patient records, while further 5 studies made use of data imputation techniques. Among the latter, 2 articles generated synthetic data, while another 3 supplemented datasets through information from external datasets. Fu et al [3] generated synthetic data by modeling providers' assessments of EHR data based on different information sources according to their individual characteristics (eg, tendency to ascertain delirium status based on Confusion

Assessment Method vs prior *International Statistical Classification of Diseases* coding or nursing flow sheet documentation), while Zhang et al [19] used a generative adversarial network (GAN) trained on real longitudinal EHR data to create single synthetic EHR episodes (eg, outpatient or inpatient visit). Meanwhile, Lee et al [33] supplemented existing EHR records on heart failure by aggregating data from open-source datasets of heart failure biomarkers (including the Database of Genotypes and Phenotypes and the Biologic Specimen and Data Repository Information Coordinating Center) and using literature guidelines to create a standard set of cardiovascular outcome measures, while Curtis et al [2] supplemented missing EHR mortality records with data from US Social Security Death Index and the National Death Index, and Mang et al [30] used a manually generated stand-alone synthetic dataset to test the development of a new software tool for DQ assessment.

Conformance

Conformance was the second most cited element of DQA, with references in 18 (69%) articles [2-6,8,14,24-27,29-33,36,38]. Similar to completeness, DQ checks on conformance were performed automatically across most studies. Mitigation strategies included enforcing strict formatting rules at the time of data entry, for example, by using *International Statistical Classification of Diseases* codes to define the cause of death or a diagnosis of delirium [2,3].

Plausibility

Plausibility was the third most cited element of DQA with references in 16 (62%) articles [4-6,8,14,25,27,28,30-33,35,37-39]. Clinical domains prone to issues with plausibility included patient baseline physical characteristics, medication, and laboratory records. Estiri et al [29] and Wang et al [39] reported significant rates of plausibility issues for baseline physical characteristics, with higher error rates for records of patient height as compared to weight, likely due to the multiple flow sheet fields for height, including "estimated," "reported," and "measured," which are generally averaged or selectively dropped. Pharmacologic data were prone to issues with plausibility due to timeliness (eg, antiretroviral therapy was dispensed before or more than 30 days after the visit date [9]) or discrepancies between diagnoses and drugs (eg, nonsteroidal anti-inflammatory drug prescription on the date of gastroduodenal ulcer diagnosis [6]). Finally, laboratory results were also prone to issues with plausibility due to value ranges, units, timing (eg, laboratory time was at an invalid time of day or in the future), and discrepancies between diagnoses and laboratory records (eg, drug was documented as present but there was no laboratory record) or drug prescriptions and laboratory records (eg, metformin was prescribed prior to a documented hemoglobin A_{1c} laboratory result, or warfarin was prescribed without a follow-up international normalized ratio laboratory result) [6]. Notably, this may reflect poorly integrated health care systems where laboratories are being drawn at disparate institutions.

A total of 18 (69%) studies used logic statements to assess plausibility [2,4-6,8,9,14,24,27,28,31-38], including rules to determine temporal plausibility (eg, laboratories drawn at an invalid time of day [eg, 10:65 AM] [6], extubation occurring prior to intubation [14], or death date occurring before birth date [32]), diagnostic or procedural plausibility (eg, a procedure marked as an outpatient when it is only performed on an inpatient basis [38] or an obstetric diagnosis given for a biologically male patient [6,9,38]), alignment with external standards or expectations (eg, laboratory result absent for diagnosis or drug [6] or demographic alignment of medication name and dose with expected value ranges [34]), and others. A total of 11 (42%) studies used thresholding to identify data of low or questionable quality [4,6,8,9,14,19,28,32,35,37,39], including clinical and physiological value ranges (eg, BMI between 12 and 90 kg/m^2 [35] or fraction of inspired oxygen between 10% and 100% [14]) and logical thresholds (eg, recorded date of arrival prior to the date of data collection initiation [8] or difference of >730 days when comparing age in years and date of birth fields [9]).

Uniqueness

Finally, 1 (4%) study reported on data uniqueness. Aerts et al [8] measured the frequency of patient record duplications (ie, when patient records were erroneously copied during data merging or reprocessing). To reduce the rate of record duplications, the researchers in the study suggest a 2-level data structure, with more general patient data being recorded at the encounter level (which can include multiple visits during a single clinical episode) and diagnosis or procedure-specific data at the level of the particular visit.

Data Performance Assessment

Correctness or Accuracy

Correctness or accuracy was the most cited element in data performance analysis, with references in 14 (54%) of all articles [2,8,9,14,19,25,26,32-37,39]. The metric was evaluated via manual review in 8 (57%) out of the 14 articles that reported the measure [2,8,14,25,26,34,36,39]. A total of 5 (36%) articles evaluated it in comparison to an external standard, including national registries [2,35], EHR case definitions based on billing codes [36], and literature guidelines with high research use [33], or, in the case of a newly proposed AI technique for synthetic data augmentation, comparison to a previously published GAN model performance [19]. A further 3 (21%) assessed correctness or accuracy against an internal standard by calculating the proportion of records satisfying internally predetermined rule sets [9,32,37]. Of note, Curtis et al [2] and Terry et al [36] used both manual review and comparison to an external gold standard for validation.

Currency or Recency

Recency was the second most cited data performance element, with references in 7 (27%) articles [2,4,9,27,32,34,36]. Among these, 5 (71%) studies evaluated the metric according to internally predetermined hard rule sets (eg, whether a patient who is obese had a weight recording within 1 year of the previous data point or whether data were entered into the EHR within 3 days of the clinical encounter [9,32,36]) or soft rule sets (eg, whether the data were entered into the EHR within a subjectively determined clinically actionable time limit [4,34]),

while 2 (29%) used external standards, including national registries and guidelines [2,27].

Fairness or Bias

The third most cited data performance element was fairness or bias, with references in 6 (23%) articles [3,19,22,24,27,35]. Among these, Lee et al [22], Thuraisingam et al [35], Tian et al [27], and García-de-León-Chocano et al [24] assessed fairness by manual review, while Fu et al [3] and Zhang et al [19] did so through automated review against a predetermined internal gold standard (ie, distribution of data characteristics within a real EHR dataset) or data bias criterion (ie, critic model measuring Jensen-Shannon divergence between real and synthetic data over time), respectively.

Stability

Data stability was the fourth most cited performance element, referenced in 4 (15%) articles [4,8,19,31]. All 4 articles that measured data stability did so via temporal statistical analyses of data drift according to a predetermined internal baseline standard of data distribution [8,9,32,37].

Shareability

Shareability was referenced in 2 (8%) articles from our analysis [2,3]. Both studies measured the performance metric by way of manual review in a pre- and posttest analysis of data standardization [2,3].

Robustness

Finally, García-de-León-Chocano et al [24] reported on information robustness by way of statistical estimation of critical (eg, missing or null required values) versus noncritical (all other) DQ issues that may obstruct subsequent data applications and performance measures.

Interventions for Improving DQ and Performance

Three articles included in our analysis reported effective interventions to improve DQ and performance [4,9,37]. In terms of DQ, Walker et al [37] reported an increase in compliance, with 155 completeness and plausibility data checks from 53% to 100% across 6 clinical sites after 3 rounds of DQA. In terms of DQ and performance, Puttkamer et al [9] reported both higher data completeness and recency following a continuous data reporting and feedback system implementation. Finally, Engel et al [4] reported increased shareability (concept success rate, ie, whether data partners converted information from their individual EHRs to the shared database)—an increase from 90% to 98.5%—and a notable reduction in the percentage of sites with over 3 DQ errors—a reduction from 67% to 35%—across 50+ clinical sites over 2 years.

Discussion

Principal Contributions and Comparison With Prior Work

This scoping review provides an overview of the most common and successful means of EHR DQ and performance analysis. The review adds to a growing body of literature on the subject, most recently supplemented by a systematic review by Lewis et al [40]. To our knowledge, ours is the first review of specialty-specific applications of DQ alongside performance assessments. We identified and analyzed a total of 26 original research articles recently published on the topic. The results serve to characterize the most common medical fields making use of such assessments, the methodologies they use for conducting them, and areas for specialty-specific, as well as generalizable, future improvement. Finally, the discussion proposes a set of 6 unique and practical recommendations for minimizing modifiable DQ and performance issues arising during data extraction and mapping.

Article Characteristics

Our review noted a paucity of DQ assessments within clinical specialties, where expert domain knowledge plays a key role in identifying logic inconsistencies. Half of all identified articles concerned general EHR data assessments, while the other half focused on medical fields such as primary care, cardiovascular diseases, or intensive care unit or anesthesia, with the notable absence of psychiatry, emergency medicine, and any of the surgical specialties. This points to a lack of peer-reviewed research and underuse of DQ and performance strategies across a wide spectrum of the medical field. There is a wide knowledge gap between how data are entered and acted upon clinically and how they appear in silico. Therefore, more efforts need to be directed toward supporting EHR data assessment initiatives in these specialties, with close collaboration between clinical users and data scientists.

More than half of the articles included in this scoping review had common limitations, including using or reporting incomplete data, methods, and outcomes. Among the articles scoring high for incomplete data, the chief issues include data attrition during extraction [24,29] and unclear or missing reporting [33,36,38], pointing to a need for higher information interoperability and reporting standards, such as those put forth by Kahn et al [12]. These standards recommend using a harmonized and inclusive framework for the reporting of DQ assessments, including standardized definitions for completeness, conformance, plausibility, and other measures as discussed previously.

Similar issues were observed with methods reporting, with several articles underreporting steps in their data extraction or analysis, thereby limiting the replicability and generalizability of their findings [3,27,28,33]. Unclear reporting or underreporting was a substantial issue for outcomes as well, with low-scoring articles reporting only partial or too high-level results suggesting selective reporting bias [14,31,34,38]. To align with the standards set forth by articles scoring high in reporting quality, we recommend stating all data sourcing, methods, and results according to predetermined definitions of DQ or performance (see above) in enough detail such that they would be easily replicated by researchers at an unrelated institution.

A final article quality pitfall concerned articles that were too specific to a particular health system or clinical context. The chief issues among original research articles that in house scored "low" in our generalizability assessment concerned their overreliance on internal DQ checks or measures that could only be implemented within their specific institutional EHR [4,24-26,33]. To increase generalizability, we recommend

relying on external DQ standards such as societal guidelines, previously published measures, or open-source databases, to the extent possible before resorting to the development of new in-house tools that impose limitations to generalizability outside the local clinical context [8,12-15].

Data Quality Assessment

The marked drop-off between the use of completeness, conformance, and plausibility versus other indicators (Table 3) demonstrates that the field has settled on these measures as the main components of EHR DQ analysis. Taking this into consideration, we recommend measuring all 3 for a general assessment of clinical DQ. Of note, there is a significant drop-off between 81% (n=21) of studies reporting on completeness versus 69% (n=18) on conformance and 62% (n=16) on plausibility, which indicates an opportunity for limited but quick DQ "checks" using completeness measures only. More specialized analyses may require further reporting, including uniqueness in the event of data merger with the possibility of duplicate results. These may be particularly important in the case of EHR DQ assessments following information reconciliation from the merger of multiple data sources, including patient demographics or baseline physical characteristics and laboratory or pharmacological data, which were shown to be particularly prone to errors in DQ.

Our review additionally demonstrates that issues with data completeness, conformance, and plausibility may be at least partially addressed with data imputation methods. While previously these methods were either too limited in scope (completeness only), crude (eg, augmenting missing data with the mean of the entire dataset or a value's k-nearest neighbor), or computationally expensive (eg, individual values calculated via regression models based on predetermined sets of correlated features), our review suggests that these tasks are being increasingly automated. Specifically, data attrition contributing to missingness and conformity at the extraction stage may be minimized with AI data extractor algorithms, such as the one described by Lee et al [22]. In cases where further extraction is no longer feasible, the dataset may be augmented by (1) using large language models for extracting structured data available in other formats (eg, laboratory values recorded in the text of media files from outside patient records); (2) incorporating or cross-referencing data from well-established outside data repositories (eg, the US Social Security Death Index for mortality records [2] or the Database of Genotypes and Phenotypes and the Biologic Specimen for biomarkers of heart failure and other conditions [33]); or (3) generating synthetic data, for example, by modeling providers' behaviors with respect to different information types or sources [3] and by using GANs to create synthetic care episodes based on longitudinal EHR observations [19].

Data Performance Assessment

Correctness or accuracy was by far the most reported measure among the data performance indicators examined in our review. While certainly integral to assessing a dataset's usability and potential for downstream clinical or research impact, correctness alone is insufficient to guarantee the success of said applications. A technically "correct" dataset may still be practically limited if it is outdated, biased, inconsistent, or entirely idiosyncratic. We, therefore, recommend that future data assessments consider including additional measures of recency, fairness, stability, and shareability, respectively, among their core set of performance indicators as they each contribute a unique measure of a dataset's applicability. Importantly, our review noted considerable heterogeneity in the definitions used for these additional measures (eg, by defining data recency in terms of whether the information was logged into the EHR within a set time or whether it represents a patient's state at a given time period [Table 1] [10,13]), suggesting that further efforts are needed to harmonize outcome definitions in the field of data performance analysis in particular. Nonetheless, the predominance of internal standard comparisons for measuring recency and stability in our review demonstrates that these indicators may be essential for individualized EHR DPAs and should, therefore, be considered on a case-by-case basis (eg, in epidemiology where the timing and consistency of reporting can be of essential importance, or quality improvement initiatives where a researcher might want to compare pre- vs postintervention results). Likewise, shareability ought to be considered in the case of assessing dataset performance for interoperability purposes (eg, with data integrations, sharing, and reporting).

As discussed previously, data fairness assessments can and should be considered for monitoring overall EHR bias, as well as the bias inherent to any data imputation methods as discussed above. Our review points to the fact that this is a rapidly developing field, with fairness assessments to date mostly requiring manual review against national guidelines or disease registries, or, in the case of synthetic data, real EHR datasets [41-43]. Nonetheless, such gold standards are not always readily available (eg, What is the standard distribution of age or race in the real world?), so tech-savvy researchers have more recently resorted to detecting fairness during the validation of machine learning models or algorithms instead of the data itself [41-43]. Several research articles from our analysis proposed ways of automating the process. Fu et al [3] present a straightforward way of measuring the agreement of AI-generated synthetic data against a gold standard dataset. Zhang et al [19] suggest that while such straightforward analysis may be valuable, it is insufficient to measure true fairness, and they go on to propose a method of measuring bias via Jansen-Shannon divergence, which can be calculated for comparisons of real-world and synthetic data. The latter article also suggests a way of preventing synthetic data drift through condition regularization (ie, minimizing contrastive loss by regularizing the synthetic dataset against a real dataset distribution) and fuzzying (ie, adding controlled noise to broaden the dataset distribution before the AI training phase). To our knowledge, this is the most recently proposed technique for fairness assessment in the field. More research is needed to validate and augment the technique. Whether through Jansen-Shannon divergence or alternative methods, we recommend that all future data assessment projects measure and report model performance and fairness for sensitive groups.

Finally, Garcia-a-de-Leon-Chocano et al [24] propose a way of calculating data robustness. The calculation draws on comparing

tolerable versus nontolerable issues with DQ, which may be particularly important prior to using the information. We highly suggest that DQ assessments conduct a robustness calculation immediately before calculating data performance measures for downstream applications, which will allow for timely intervention in the case of significant issues with data completeness, conformity, or plausibility that merit additional data collection, review, or imputation steps as discussed above. The above findings and recommendations are summarized in Table 4.

Table . Recommendations for future EHR[a] data quality and performance assessments.

Issue	Recommendation
Article characteristics	
Paucity of specialty-focused EHR data assessments	Incentivize (eg, through quality improvement initiatives and grants) more EHR data assessments, particularly in psychiatry, emergency medicine, and surgical specialties
Incomplete reporting	Use standardized frameworks for measuring and reporting data quality and performance assessments (eg, Table 1)
Poor replicability	Describe DQA[b] methods in enough details such that they could be replicated by a research team at a different institution
Limited generalizability	Use already available data quality tools and standards (eg, DQA Guidelines proposed by Weiskopf et al [21]) before developing proprietary methodologies
DQA	
Inconsistent methodologies	Analyze completeness, conformance, and plausibility at every DQA (completeness only may be applicable for quick data quality checks)
Data missingness and nonconformity	Use available AI-based data extraction algorithms (eg, Lee et al [22]), and augment data using external and synthetic datasets (eg, Zhang et al [19])
Data performance assessment	
Inconsistent methodologies	Augment correctness or accuracy measurement with recency, fairness, stability, and shareability performance metrics
EHR data bias	Automate data fairness assessments by measuring agreement of AI-extracted data against an gold standard dataset (eg, manually extracted data) and preventing drift via condition fuzzying and regularization (eg, Zhang et al [19])
Timeliness of analysis	Calculate dataset robustness prior to detailed data quality and performance analysis (eg, as described by García-de-León-Chocano et al [24])

[a]EHR: electronic health record.

[b]DQA: data quality assessment.

Further Recommendations

Based on the review and our team's experience with DQ improvement initiatives, we recommend that administrators minimize modifiable DQ and performance issues arising during extraction by first using Internet of Things devices (eg, "smart" patient beds and infusion pumps) that directly upload measurements or settings to the EHR instead of requiring manual data entry. Second, the EHR's interface should be anchored to a predefined data workflow and ontological structure agreed upon in collaboration with clinical and data administrators (eg, encounters start at the time of patient check-in instead of when a physician first sees the patient, and all encounter times are recorded in 1 location using standard units). Finally, the plausibility of automatically entered data should be periodically validated such that corrections can be made when necessary (eg, a minute-by-minute electrocardiogram plausibility check that can detect if an electrocardiography lead falls off a patient's chest and needs to be replaced to record accurate measurements). Wherever possible, a reference data format (eg, electrocardiogram voltage between 0.5 and 5 mV) for the validation should be provided.

To minimize modifiable issues arising during data mapping, we furthermore recommend first establishing rules for how to treat (1) "missing," (2) "modified," or (3) "overlapping" data, such as whether (1) fields with no value should be regarded as data points or artifacts; (2) data points that have been subsequently modified should be updated or retained; and (3) one data source should take precedence over another in case of duplicate records (eg, weight recordings measured by weighing scale should supersede those measured by a hospital bed). Finally, standards for parent-child encounters should be instituted (eg, if a postoperative outpatient clinic visit should be assigned as a unique encounter or as a child encounter of the parent surgery visit).

The provenance of outside facility records, which can be used to identify potential issues with externally collected data, should also be maintained (eg, keeping records of where and when outside laboratory measures were taken in order to identify

potential issues with more or less accurate laboratory techniques).

Limitations

While this scoping review provides valuable insight into the existing literature on EHR DQ analytics, it has several limitations. Foremost, it is important to acknowledge the limited sample size of 154 articles using our original search criteria, and consequently also the limited number of 26 original research articles which were included in our final analysis after full-text review. Among these articles, there was significant heterogeneity in settings and outcomes of interest, which may limit the validity of direct comparisons between the studies, as well as the generalizability of our findings. The review was furthermore restricted to articles available in the PubMed library, which may introduce a potential publication bias, as well as to articles available only in English, which may introduce a language bias to our study selection and subsequent analysis. Finally, while the review focused on EHR DQ and performance assessments, it did not include adjacent areas that may have a pronounced impact on clinical data recording and use such as EHR implementation or use. Future research should consider broader inclusion criteria and explore additional dimensions of EHR DQ to provide a more comprehensive understanding of this important topic.

Conclusions

The findings of this scoping review highlight the importance of EHR DQ analysis in ensuring the accuracy and reliability of clinical data. Our review identified a need for specialty-specific data assessment initiatives, particularly in the fields of psychiatry, emergency medicine, and surgery. We additionally identified a need for standardizing DQ reporting to enhance the replicability and generalizability of outcomes in the field. Based on our review of the existing literature, we recommend analyzing DQ in terms of completeness, conformance, and plausibility; data performance in terms of correctness; and use case–specific metrics such as recency, fairness, stability, and shareability. Notably, our review demonstrated several examples of DQ improvement with the use of AI-enhanced data extraction and supplementation techniques. Future efforts in augmenting DQ through AI should make use of data fairness assessments to prevent the introduction of synthetic data bias.

Abstract

Background: Electronic medical records (EMRs) contain large amounts of detailed clinical information. Using medical record review to identify conditions within large quantities of EMRs can be time-consuming and inefficient. EMR-based phenotyping using machine learning and natural language processing algorithms is a continually developing area of study that holds potential for numerous mental health disorders.

Objective: This review evaluates the current state of EMR-based case identification for depression and provides guidance on using current algorithms and constructing new ones.

Methods: A scoping review of EMR-based algorithms for phenotyping depression was completed. This research encompassed studies published from January 2000 to May 2023. The search involved 3 databases: Embase, MEDLINE, and APA PsycInfo. This was carried out using selected keywords that fell into 3 categories: terms connected with EMRs, terms connected to case identification, and terms pertaining to depression. This study adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines.

Results: A total of 20 papers were assessed and summarized in the review. Most of these studies were undertaken in the United States, accounting for 75% (15/20). The United Kingdom and Spain followed this, accounting for 15% (3/20) and 10% (2/20) of the studies, respectively. Both data-driven and clinical rule-based methodologies were identified. The development of EMR-based phenotypes and algorithms indicates the data accessibility permitted by each health system, which led to varying performance levels among different algorithms.

Conclusions: Better use of structured and unstructured EMR components through techniques such as machine learning and natural language processing has the potential to improve depression phenotyping. However, more validation must be carried out to have confidence in depression case identification algorithms in general.

(JMIR Med Inform 2024;12:e49781) doi:10.2196/49781

KEYWORDS

Introduction

Background

Depression is a significant factor contributing to the global burden of disease. It contributes significantly to the cost of health care services, with depression treatment services costing an average of CAD $550 (US $406.12) per patient in Alberta, Canada, in the 2007/2008 fiscal year [1]. Depression also carries a significantly higher mortality rate [2]. Surveillance of depression in the population is necessary to understand the needs of patients and allocate limited resources where they are most needed. This surveillance will ultimately allow health care professionals to make more targeted decisions when implementing population-level interventions.

Electronic medical records (EMRs) are a digitized collection of patient records documented by medical professionals. They contain various types of patient information, including test results, demographic data, and information about medication orders, recorded in structured data fields and free-text data, such as discharge summaries and nurses' notes [3-5]. EMRs were designed to aid individual patient care but are increasingly used for other purposes, such as research and gathering data for precision public health efforts, as they are compiled in large data warehouses [6-9]. An area that will be instrumental in

applying EMRs to public health is case phenotyping, which is developing case definitions to identify positive cases of a disorder in EMR data.

Accurate case identification in EMRs is an area where more research needs to be conducted. This is especially true for case identification of psychiatric disorders. Previous reviews of phenotyping algorithms for psychiatric disorders only considered primary care databases as their setting [10,11]. However, these are very different from inpatient EMR systems. For one, hospital inpatients are more likely to identify errors and omissions than patients in outpatient care or primary care [12]. EMR data have been used in research for psychiatric patients in various specific inpatient use cases, including assessing patient safety events in psychiatric inpatient units [13]. Research has also shown that hospitals with electronic psychiatric EMRs had lower readmission rates for psychiatric patients compared to hospitals without electronic records. Similarly, hospitals where psychiatric records were accessible to nonpsychiatric physicians had lower 14- and 30-day readmission rates [14]. In 2015, patients with a mental health diagnosis made up over 11% of hospital separations and 25% of hospital days [15]. Accurate case identification for inpatient stays for this at-risk population can help to identify what treatments have been most successful more efficiently than traditional research methods and could work in personalizing care for a more successful treatment plan.

Objectives

This study aims to provide an overview of existing algorithms for depression case identification in inpatient EMRs. It examines the performance of the algorithms and how they were constructed to provide guidance to those wishing to use an existing algorithm or to construct new ones.

Methods

Identifying Relevant Literature

This review followed the methodology outlined in the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) 2018 statement [16]. First, we used the *ICD-9-CM* (*International Classification of Diseases, Ninth Revision, Clinical Modification*) codes for depression provided by Elixhauser et al [17] to identify relevant terms, then developed a Boolean algorithm using these terms, as well as terms related to EMRs and terms related to case identification (Multimedia Appendix 1). Finally, we searched the following 3 databases: Embase (1974 to May 2023), Ovid MEDLINE (1946 to May 2023), and APA PsycInfo (1806 to May 2023) for peer-reviewed papers and exported the results of the search to a reference manager program (Zotero; Corporation for Digital Scholarship and Roy Rosenzweig Center for History and New Media).

Selecting Studies

Identified papers were screened in 2 stages. First, titles and abstracts were screened by 2 reviewers working independently to determine whether they met our established eligibility criteria. Papers were included if they were retrieved by the Boolean search and presented a case definition, involved depression and EMRs, were published between January 2000 and May 2023, and were written in English. We excluded papers that only used administrative databases, as this study focused on case phenotyping using EMR data. Next, full papers were reviewed for all abstracts that both reviewers identified as eligible. This review was carried out by 2 reviewers working independently. To be included, studies had to use EMRs for phenotyping and use inpatient data, and the case definition developed had to be for depression. The inpatient data source requirement was added because of differences in coding standards between primary care and inpatient settings. Disagreements at either screening stage were resolved by consensus, and if necessary, a third reviewer was consulted. We searched the references of all included papers for additional eligible papers, which we then screened using the same criteria. The search was designed to include all papers that used an algorithm phenotyping for depression with an EMR. The 2 most common methods were natural language processing (NLP) and machine learning, which were included but were not limited to. The search terms used to identify this category were not specific to a type of algorithm or method of case identification, as the purpose was to include a broad range of variations in phenotypic methodology (Multimedia Appendix 1).

Extracting Data

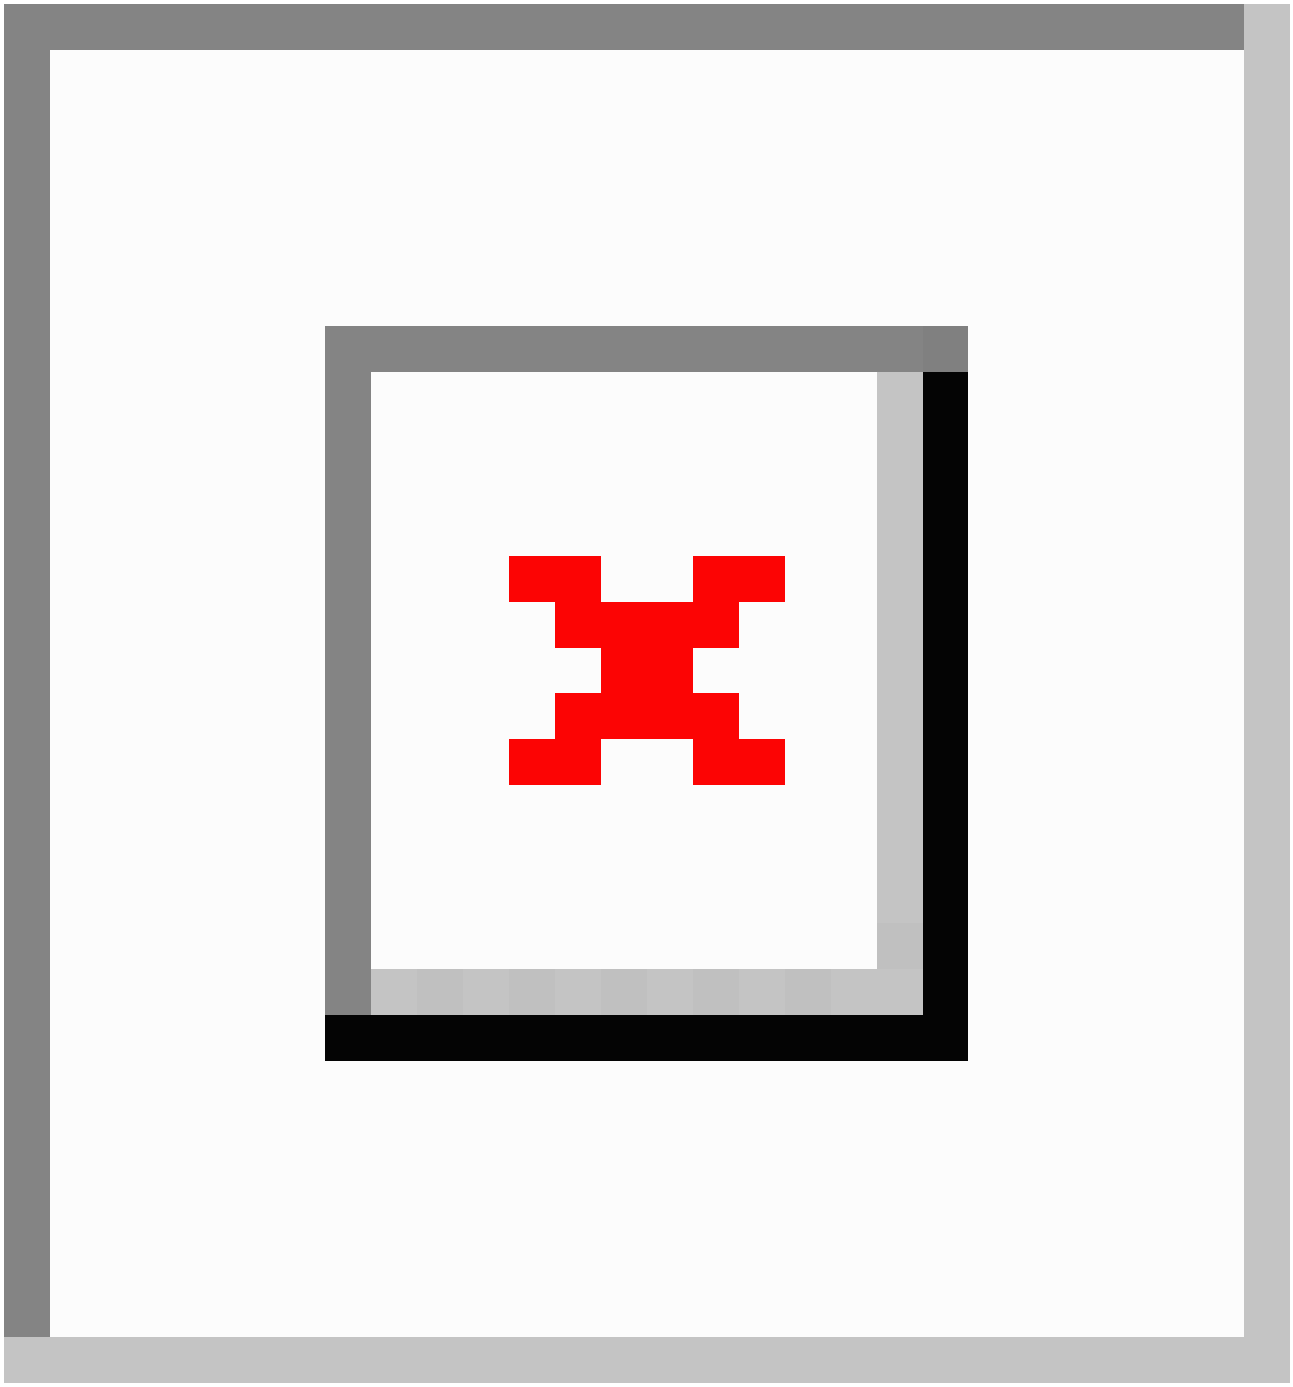
We adapted an existing data extraction form (Multimedia Appendix 2, Lee et al [18]) to collect the results of our review. Data were extracted by 1 reviewer and then confirmed by a second reviewer. Components we extracted included study characteristics (country, year, and inpatient or outpatient setting), the specific data source and details of the data, and the validation methodology (eg, medical record review), as well as detailed descriptions of the phenotype developed, the methods used, and the purpose for the case definition. We recorded the performance of the developed algorithms as reported in each study. We recorded the elements of EMRs used, whether other databases or diagnostic codes were used, and whether AI techniques (machine learning and NLP) were used as binary variables. Finally, based on this study's primary objective, we classified each study into 1 of 3 categories (algorithm development, outcome analysis, and comorbidity analysis).

Results

Paper Screening

The database search returned a total of 854 papers. After 257 duplicates were removed, 597 abstracts remained. Then, 522 abstracts were excluded in the title and abstract screening, leaving 75 papers for full-paper review. Of these, 20 papers could not be retrieved, and 36 were excluded based on the exclusion criteria. The 19 remaining papers met all eligibility criteria and were included in the review. Further, 1 additional paper was identified for inclusion from the references of the included papers, resulting in 20 papers for the review [6,19-37]. The PRISMA flow diagram illustrating these steps is shown in Figure 1.

Figure 1. PRISMA flow diagram. EMR: electronic medical record; PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.



Characterizing the Identified Literature

Of the 20 studies we identified, the majority occurred in the United States (15/20, 75%). The remaining studies were from the United Kingdom (3/20, 15%) and Spain (2/20, 10%). All the studies were published in 2005 or later.

Most studies looked at inpatient and outpatient data (16/20, 80%), while fewer focused solely on inpatient data (4/20, 20%). A few studies (4/20, 20%) linked EMR data to administrative databases. These studies used structured fields of EMRs and diagnostic codes found in administrative databases. They occurred in 3 countries (United States, United Kingdom, and Spain) and were all published in 2020 or later. Another 3 studies (3/20, 15%) linked EMRs to genomic data (the Partners HealthCare Biobank, United States; the Michigan Genomics Initiative, United States; and the pediatric biorepository database of the Center for Applied Genomics at the Children's Hospital of Philadelphia, United States). This linkage was conducted in an epidemiological analysis study to find genetic associations between conditions. These characteristics are shown in Table 1.

Table . Characteristics of included papers.

[a]EMR: electronic medical record.

Most of the identified studies (18/20, 90%) used diagnostic codes in their case definition for depression. The most common codes used were *ICD-9* (*International Classification of Diseases, Ninth Revision*), followed by *ICD-10* (*International Classification of Diseases, Tenth Revision*). In many studies, the diagnostic code case definitions were combined with structured data elements, such as patient demographics (sex, age, etc), laboratory results, medications, and procedures. For example, procedures were coded with Current Procedural Terminology codes and other types of classifications. Structured EMR data were used in 13/20 studies (65%). Fewer studies (8/20, 40%) incorporated unstructured data elements, such as clinical notes. To analyze these elements, some studies used standardized vocabularies, such as the Unified Medical Language System, to develop lists of keywords. Most studies using unstructured data used NLP techniques to analyze the free-text data in unstructured EMR fields (7/20, 35%). NLP is commonly used on free-text medical data to transform the data into a structured format that can be processed using statistical techniques and machine learning. A quarter of the identified studies (5/20, 25%) used machine learning to develop phenotyping algorithms. Machine learning models included logistic regression, random forest, and propositional rule learners. Table 2 contains details about the algorithms defined in each study.

Table . Summary of algorithms.

[a]EMR: electronic medical record.

[b]ML: machine learning.

[c]NLP: natural language processing.

[d]PPV: positive predictive value.

[e]AUC: area under the receiver operating characteristic curve.

[f]Not available.

[g]Area under the precision-recall curve and F_1 -score were only available for Hong et al [26]. The best algorithm in that paper had an area under the precision-recall curve of 0.90 and an F_1 -score of 0.81.

Only 9 studies (45%) conducted a medical record review to produce a reference standard to which to compare phenotyping results. Since most of the identified studies (14/20, 70%) were conducted with a larger goal of which phenotyping depression was a small part, many did not provide much information on the methods of their phenotyping. Most studies did not report any metrics measuring the diagnostic accuracy of developed phenotyping algorithms; only 8 studies (40%) reported at least one performance metric. The 6 metrics reported were sensitivity, specificity, positive predictive value (PPV), area under the receiver operating characteristic curve, area under the precision-recall curve, and F_1 -score. No studies reported negative predictive value. These metrics are displayed in Table 2.

We classified each study into 1 of 3 general purposes: algorithm development, comorbidity analysis, and outcome analysis. A small percentage of the identified studies (6/20, 30%) were conducted for algorithm development. These studies did not look at applications of the phenotyping algorithms developed; instead, they focused on phenotyping methods and algorithm performance. The rest of the studies used a case definition for depression as a step toward a larger goal. For 9 of these studies (9/20, 45%), this goal was outcome analysis or analyzing the effect of depression on patient outcomes, such as mortality, suicide attempts, and psychotherapy receipt. For the remaining studies (5/20, 25%), the goal was comorbidity analysis, examining the prevalence of depression as a comorbidity of other conditions. The comorbidities studied included HIV, hepatitis C, and cancer. Outcome analysis studies have become more prevalent in recent years. Further, 6 were published between 2020 and 2022, up from 3 between 2000 and 2019. In addition, algorithms used for depression phenotyping in EMRs have become more prevalent since 2017.

Discussion

Principal Results

In this review, we found 20 papers describing phenotyping algorithms for depression in inpatient EMR data. Most of these algorithms were case definitions using diagnostic codes, specifically *ICD-9*. This reflects that *ICD* (*International Classification of Diseases*) codes are commonly used for billing purposes in the United States and are the most frequently used diagnostic codes in EMRs worldwide [38]. *ICD*-coded data are thus widely available, making them a practical choice when developing a case definition. However, case definitions using diagnostic codes achieved worse sensitivity than algorithms that only used other fields of EMRs. Many algorithms also used structured EMR data [6,19,20,23,24,26-29,31,33,34,36], but fewer used unstructured data [6,19,28,29,33,34,36,37]. NLP and machine learning techniques were used by a minority of algorithms (NLP [19,28,33,34,36,37] and machine learning [19,26,29,37]). These types of machine learning applications are relatively new and are receiving much attention from researchers [39]. The algorithms that used machine learning performed well on all the metrics they reported (sensitivity 0.81 - 0.87, specificity 0.82, PPV 0.90, and area under the receiver operating characteristic curve 0.80 - 0.83). This suggests that the information in free-text EMR data is valuable for developing accurate phenotyping algorithms. It also supports the effectiveness of machine learning techniques for phenotyping of depression. This is likely an area that will be explored further in future research.

Many of the papers we found did not include a medical record review. If algorithms are not validated against a reference standard such as a medical record review, their accuracy remains unknown. Most papers also did not report metrics measuring the validity of the algorithms developed. This limits the potential of these algorithms for application in precision health care. Conducting validation studies on the algorithms presented in these papers would make them more rigorous. Of the papers that did report metrics, few reported sensitivity, specificity, and PPV together. This could result in skewed interpretations of phenotype performance, as a high sensitivity may come at the cost of a low PPV (or vice versa) for instance.

Based on the validity reported in these papers, an EMR appears promising as a phenotyping tool for depression; however, few studies have reported metrics of diagnostic accuracy of EMR algorithms, especially comprehensive metrics to fully assess performance. Future validation studies conducted on existing case definitions would be valuable in establishing their validity and bringing these types of phenotyping algorithms to the attention of medical professionals and public health analysts. Machine learning and NLP are small but growing areas within phenotyping research. More work could be carried out using these techniques on the unstructured fields in EMRs, alone or in combination with other fields. Finally, as most of the studies we found were performed in the United States on US EMR data, it is to be determined how generalizable the identified case definitions are to data recorded in other jurisdictions. Both the standards of care and the methods of reporting diagnoses vary widely between health care systems, which could result in an algorithm only being valid in the region in which it was developed. There is a need for further research validating existing case definitions across health care regions or creating new case definitions specific to the EMR systems of other countries.

Limitations

Some relevant papers may have been missed, as we only searched 3 databases. It is also possible that our search terms were not sufficiently broad to return every pertinent paper. We also only considered peer-reviewed papers, not gray literature.

However, we developed our search strategy in consultation with librarians and experts in the field with experience performing scoping reviews. For these reasons, we believe our search was sufficient to find papers for the review.

Conclusions

We examined current algorithms for phenotyping depression in inpatient EMRs. This is an area in which more research needs to be performed. It is difficult to accurately identify cases of depression in EMR data because depression is inconsistently coded, as there is some subjectivity in its diagnosis. Diagnostic codes are primarily used in the algorithms we found, but machine learning on free-text data has recently achieved promising results. Most of the algorithms were developed in the United States; how well they will perform on data from other jurisdictions is yet to be known. In addition, many identified algorithms have yet to be validated against a reference standard, or their performance was not reported. To be useful for public health research, case definitions must be validated; this is an area in which future work is needed. From this study, we conclude that EMRs have the potential to provide valuable insight into the indicators of depression, as well as its prevalence, common comorbidities, and associated outcomes. Future research into applying machine learning and NLP techniques on unstructured EMR data and studies to ascertain the validity and generalizability of existing phenotyping algorithms will be valuable in establishing EMR-based case phenotyping as a reliable tool in precision public health.

Acknowledgments

We are grateful to Natalie Wiebe, MSc, for her help developing the search strategy; to Seungwon Lee, PhD, for creating the data extraction form; and to Oliver Slater-Kinghorn for helping to screen papers. This work is supported by a Foundation Grant, led by HQ, through the Canadian Institutes of Health Research.

Abstract

Background: Some research has already reported the diagnostic value of artificial intelligence (AI) in different endoscopy outcomes. However, the evidence is confusing and of varying quality.

Objective: This review aimed to comprehensively evaluate the credibility of the evidence of AI's diagnostic accuracy in endoscopy.

Methods: Before the study began, the protocol was registered on PROSPERO (CRD42023483073). First, 2 researchers searched PubMed, Web of Science, Embase, and Cochrane Library using comprehensive search terms. Then, researchers screened the articles and extracted information. We used A Measurement Tool to Assess Systematic Reviews 2 (AMSTAR2) to evaluate the quality of the articles. When there were multiple studies aiming at the same result, we chose the study with higher-quality evaluations for further analysis. To ensure the reliability of the conclusions, we recalculated each outcome. Finally, the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) was used to evaluate the credibility of the outcomes.

Results: A total of 21 studies were included for analysis. Through AMSTAR2, it was found that 8 research methodologies were of moderate quality, while other studies were regarded as having low or critically low quality. The sensitivity and specificity of 17 different outcomes were analyzed. There were 4 studies on esophagus, 4 studies on stomach, and 4 studies on colorectal regions. Two studies were associated with capsule endoscopy, two were related to laryngoscopy, and one was related to ultrasonic endoscopy. In terms of sensitivity, gastroesophageal reflux disease had the highest accuracy rate, reaching 97%, while the invasion depth of colon neoplasia, with 71%, had the lowest accuracy rate. On the other hand, the specificity of colorectal cancer was the highest, reaching 98%, while the gastrointestinal stromal tumor, with only 80%, had the lowest specificity. The GRADE evaluation suggested that the reliability of most outcomes was low or very low.

Conclusions: AI proved valuabe in endoscopic diagnoses, especially in esophageal and colorectal diseases. These findings provide a theoretical basis for developing and evaluating AI-assisted systems, which are aimed at assisting endoscopists in carrying out examinations, leading to improved patient health outcomes. However, further high-quality research is needed in the future to fully validate AI's effectiveness.

KEYWORDS

endoscopy; artificial intelligence; umbrella review; meta-analyses; AI; diagnostic; researchers; researcher; tools; tool; assessment

Introduction

Gastrointestinal diseases impose a serious burden on health care systems worldwide. The data show that gastrointestinal diseases cause millions of deaths worldwide every year [1]. Endoscopy, as an efficient and convenient method, can effectively diagnose various gastrointestinal diseases [2]. Endoscopic intervention can also effectively treat early gastrointestinal cancers [3].

In recent years, with the rise of artificial intelligence (AI), numerous studies have been conducted to explore its application in the field of endoscopy, aiming to assist medical professionals in lesion identification and endoscopy quality control [4,5].

At present, some meta-analyses have reported the diagnostic value of AI in endoscopy [6-9]. Although AI has high sensitivity and specificity in identifying lesions in some studies, due to merger heterogeneity and sample size variations, the reliability of merger analysis outcomes needs further discussion [10-12].

In this study, an umbrella review methodology was used to elucidate current research directions and identify potential future research ideas by evaluating existing meta-analyses on AI in endoscopy. The meta-analyses of current studies were screened and extracted, and the quality of outcomes was assessed.

Methods

Registration

The protocol was registered on PROSPERO (CRD42023483073) before the study began. PROSPERO is an open access database of systematic reviews. Registration before the start of the study effectively reduced selective reporting [13,14]. This umbrella review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The details can be seen in Checklist 1.

Search Strategy

Two researchers searched PubMed, Web of Science, Embase, and Cochrane Library with a comprehensive search strategy up to November 2023. In addition, we searched "Google Scholar" to identify gray literature and searched for references of eligible articles. Two researchers independently screened the titles and abstracts and reviewed the full texts to identify eligible studies. Any discrepancies were resolved through consultation with a third researcher until a consensus was reached. The search strategy details are available in Table S1 in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

The inclusion criteria were as follows: (1) studies evaluating the diagnostic value of AI in endoscopy; (2) studies that provided at least one outcome data—sensitivity or specificity; (3) articles that had meta-analyses and were conducted by systematic methods; and (4) articles published in English.

We excluded studies that met the following criteria: (1) experiments not on humans, (2) unavailable full text, (3) duplicate studies, and (4) studies lacking critical information.

Data Extraction

Two researchers independently extracted data. The third researcher would extract data if there were any discrepancies. The following basic information was included: the first author, year of publication, country, kind of endoscopy, detection, followed guidelines, registered number, number of included studies in the meta-analyses, outcomes, included study types in the meta-analyses, and tools for assessing the risk of the Bias. Then, we collected outcome information, including sensitivity, specificity, positive likelihood ratio, negative likelihood ratio, diagnostic odds ratio, and area under the curve. We searched for missed information in primary studies if necessary.

Evaluation of Article Quality

Two reviewers independently evaluated the quality of the articles using A Measurement Tool to Assess Systematic Reviews 2 (AMSTAR2). AMSTAR is a tool for evaluating the systematic reviews of randomized trials [15,16]. In 2015, researchers introduced AMSTAR2, which expanded the application scope of AMSTAR to include the evaluation of systematic reviews of nonrandomized trials [17]. AMSTAR2 consists of a 16-item questionnaire prompting reviewers to respond with "yes," "partly yes," or "no" to each item. We viewed 2 "partly yes" answers as 1 "yes." In total, 7 items were considered important. If all the items were in conformity or only 1 unimportant item was out of conformity, the study was evaluated as having high quality. If more than 1 unimportant item did not fit, the study was rated as having moderate quality. If 1 important item did not conform, the study was rated as having low quality; the study was regarded as having critically low quality if more than 1 important item did not conform.

Data Analysis

We collected the outcome indicators of applying AI technology in different scenarios. This study evaluated the application of AI diagnostic techniques in different endoscopes. Considering that there are several studies analyzing the same issues, if there were multiple meta-analyses, we selected high-quality studies according to the AMSTAR2 criteria. If the quality of different studies was consistent, we chose the latest published study among them. After that, the most recent meta-analysis was collected and performed again to ensure that the most recent results were obtained. To make the results more reliable, we chose a more conservative method. Moreover, we used the random effect model to ensure the reliability of the result.

We calculated the effect quantity and 95% CI of each meta-analysis. In each meta-analysis, the *P* value of the Cochran Q test and the I^2 metric were used to evaluate the heterogeneity caused by the threshold effect. The Deek test was used to test publication bias. We used forest figures to show the diagnostic value of AI in endoscopy. We also used the bar accumulation charts to show the conformity of the included articles. In this study, we used R (version 4.3.2; R Foundation for Statistical Computing) for calculation. If the *P* value was more than .05, we considered that there was no statistically significant difference.

Grading of the Evidence

Using the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) principle, 2 reviewers evaluated the credibility of evidence independently. GRADE proposes 5 factors for downgrading certainty in the evidence (the risk of bias, inconsistency, indirectness, imprecision, and publication bias) and 2 factors for upgrading certainty in the evidence (large effect and dose-response). These factors were used to evaluate outcomes as being of high, moderate, low, or very low quality. The body of evidence for diagnostic test accuracy studies begins with high quality. There was no guidance on the up factors in the diagnostic test accuracy study; we only downgraded the evidence using the 5 downgrading factors. For the comparative study, we defined its initial reliability according to the results of AMSTAR2 and then adjusted it according to the above factors.

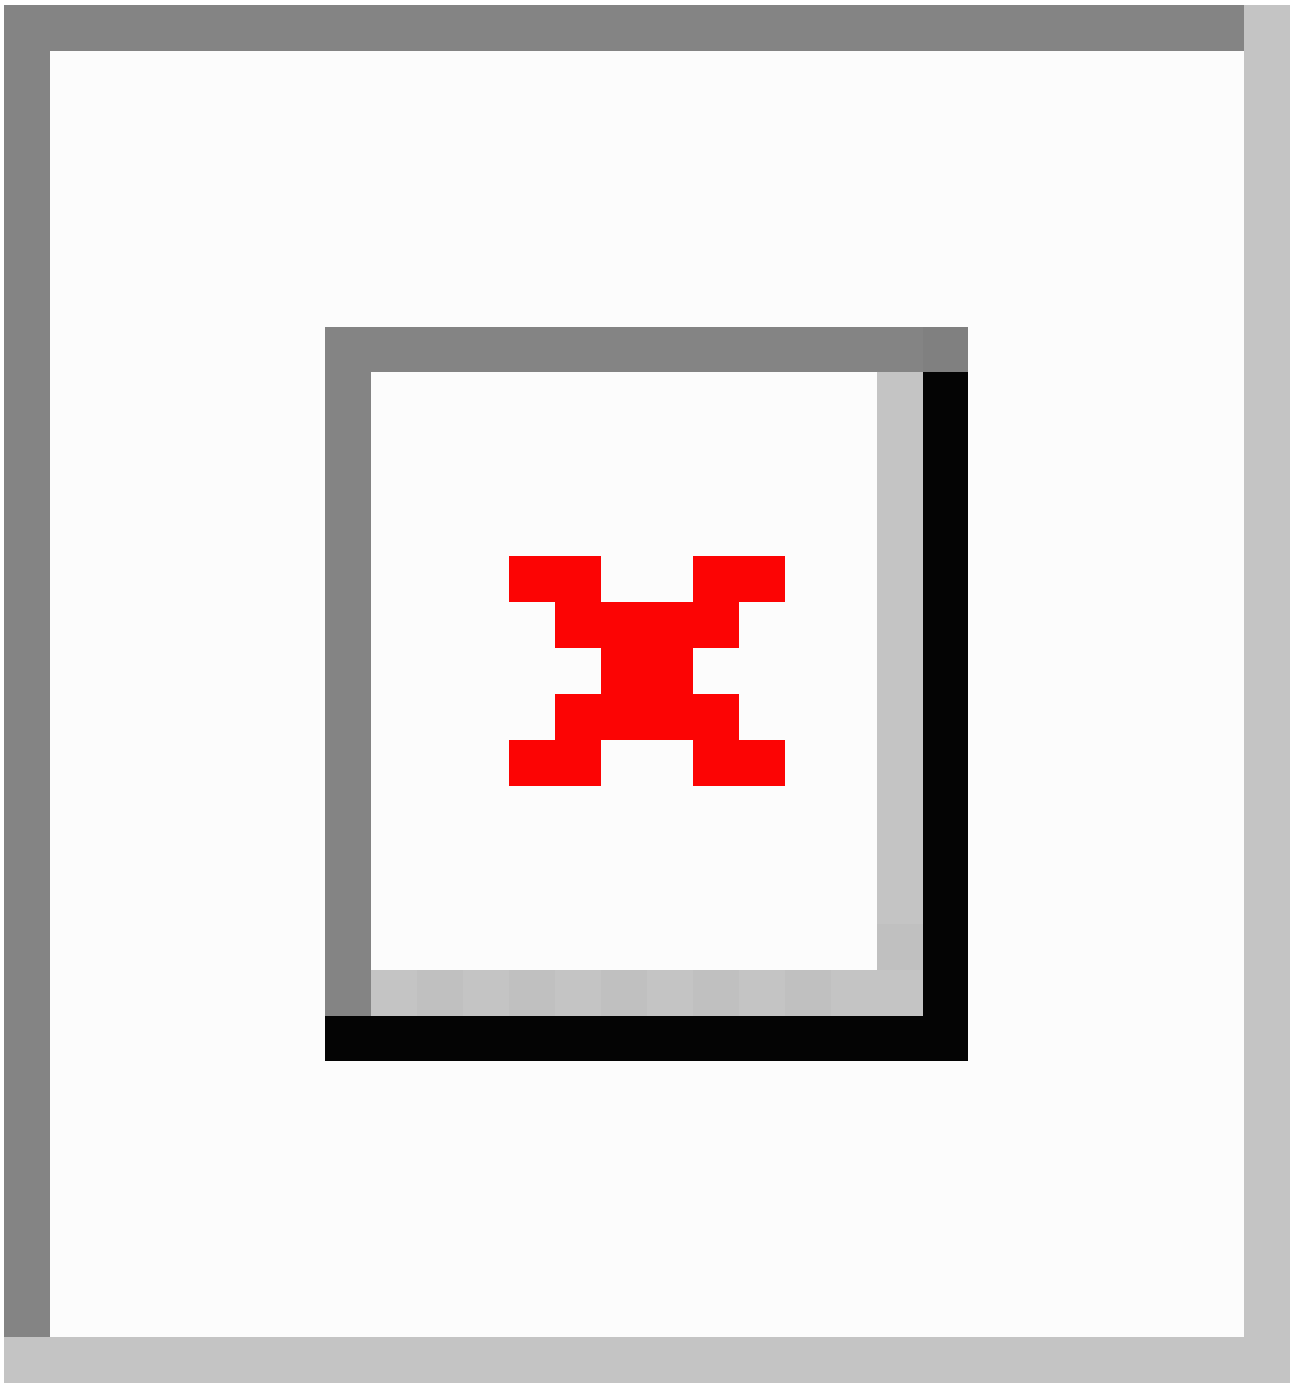
Results

Study Selection

We initially identified 3230 studies through the database and 208 studies through manual retrieval. After eliminating duplicates, we had 3013 studies. Then, the researchers eliminated 2897 studies that did not meet the criteria based on their titles and abstracts. After reading the full text of 116 studies, 80 irrelevant studies and 15 studies without

meta-analyses were excluded, and finally, 21 studies were included for statistical analysis and evaluation. These included 10 studies pertaining to upper gastrointestinal endoscopy[9,18-26], 5 studies focusing on colonoscopy [27-31], and 4 studies on capsule endoscopy [32-35]. Additionally, there was 1 study about endoscopic ultrasound (EUS) and 1 study about laryngoscopy [36,37]. Detail can be seen in Figure 1.

Figure 1. Search strategy and study screening.



Included Study Characteristics

A total of 10 studies reported the diagnostic value of AI technoloyg in upper gastrointestinal endoscopy. These studies encompassed various original research papers, ranging from 7 to 39 studies per investigation. These studies analyzed the diagnostic value of AI in various diseases, including esophageal and gastric neoplasia, Barrett esophagus, and *Helicobacter pylori* infection. In terms of research strategies, 9 research reports followed PRISMA guidelines, and 5 studies were registered on PROSPERO. With regard to evaluating bias, 8 studies used Quality Assessment of Diagnostic Accuracy Studies 2 (QUADAS-2), 1 study used QUADAS, and 1 study was not evaluated. QUADAS evaluates the diagnostic accuracy of the research system, including patient selection, index test, reference standard, flow, and timing. In 2011, researchers developed QUADAS-2 for better evaluation [38]. All studies were included in observational studies for diagnostic evaluation.

A total of 5 research studies on the diagnostic value of AI in colonoscopy were included. Among them, 1 study focused on ulcerative colitis, one focused on colon polyps and tumors, one used Prediction Model Risk of Bias Assessment Tool (PROBAST) to evaluate bias, 3 used QUADRAS-2, and one was not evaluated.

Of the remaining 6 included studies, 4 studies reported the value of AI in capsule endoscopy for diagnosing bleeding and ulcers; 2 studies reported AI's diagnostic value of laryngoscopes in examining normal or diseased throat structures and in EUS for diagnosing gastrointestinal stromal tumors separately; 5 studies were conducted according to the PRISMA guidelines; and 3 studies were registered in advance. All 6 studies were included in the observational study, and 5 of them used QUADRAS-2. The details can be seen in Table 1 and Table S2 in Multimedia Appendix 1.

[b]NR: not reported.

Methodological Quality of Included Studies

In all the included studies, methodological quality ranged from very low to moderate. Results show that the methodology was rated as moderate for 6 studies, low for 2 studies, and very critically low for the remaining 13 studies. Among the articles about upper endoscopy, it was found that 5 studies exhibited a moderate level of methodological quality. In comparison, 2 studies were deemed to have low quality, and 3 studies had were very low quality. The critical problems were the need for advanced registration and an incomplete retrieval strategy. The noncritical problem was that the original literature funding had not been reported. Besides, studies of moderate methodological quality were conducted on both the stomach and esophagus of the upper gastrointestinal tract. Three studies on colonoscopy were of moderate quality, 2 were of low quality, and the remaining 8 were of very low quality. The main problems were the meta-merging method and the evaluation of publication bias.

Regarding the application of AI in capsule endoscopy, 1 study was of moderate quality, and the other 3 had critically low quality. In addition, the research on applying EUS to identify gastrointestinal stromal tumors and laryngoscope to identify normal and pathological structures of the throat had critically low quality. The details can be seen in Table S3 and Table S4 in Multimedia Appendix 1.

Meta-Analyses

There were 4 outcomes for the esophagus. The sensitivity was 0.89 (95% CI 0.84-0.93) for esophageal neoplasia, 0.95 (95% CI 0.91-0.98) for esophageal squamous cell carcinoma, 0.94 (95% CI 0.67-0.99) for abnormal intrapapillary loops, and 0.97 (95% CI 0.67-1.00) for gastroesophageal reflux disease. Their specificity was 0.86 (95% CI 0.83-0.93) for esophageal neoplasia, 0.92 (95% CI 0.82-0.97) for esophageal squamous cell carcinoma, 0.94 (95% CI 0.84-0.98) for abnormal intrapapillary loops, and 0.97 (95% CI 0.75-1.00) for gastroesophageal reflux disease. The sensitivity of gastric cancer and chronic atrophic gastritis was 0.89 (95% CI 0.85-0.93) and 0.94 (95% CI 0.88-0.97), respectively. At the same time, their specificity was 0.93 (95% CI 0.88-0.97) and 0.96 (95% CI 0.88-0.98), respectively. The sensitivity and specificity of judging the invasion depth of gastric cancer were 0.82 (95% CI 0.78-0.85) and 0.90 (95% CI 0.82-0.95), respectively. The sensitivity and specificity of *Helicobacter pylori* infection were 0.87 (95% CI 0.72-0.94) and 0.86 (95% CI 0.72-0.96).

In colonoscopy, the sensitivity and specificity of colon polyps were 0.93 (95% CI 0.91-0.95) and 0.87 (95% CI 0.76-0.93), respectively. The sensitivity and specificity of colon neoplasia were 0.94 (95% CI 0.85-0.98) and 0.98 (95% CI 0.94-0.99), respectively. The sensitivity and specificity of ulcerative colitis were 0.83 (95% CI 0.78-0.87) and 0.92 (95% CI 0.89-0.95), respectively. For invasion depth of colon neoplasia, the sensitivity and specificity were 0.71 (95% CI 0.58-0.81) and 0.95 (95% CI 0.91-0.97), respectively.

For wireless capsule endoscopy, we got 2 results. The sensitivity and specificity of the diagnosis of gastrointestinal ulcer were 0.93 (95% CI 0.89-0.95) and 0.92 (95% CI 0.89-0.95), respectively. The sensitivity and specificity of the diagnosis of gastrointestinal bleeding were 0.96 (95% CI 0.94-0.97) and 0.97 (95% CI 0.95-0.99), respectively. The sensitivity and specificity of EUS in diagnosing gastrointestinal stromal tumors were 0.92 (95 % CI 0.89-0.95) and 0.80 (95 % CI 0.75-0.85), respectively. The sensitivity of healthy and diseased tissues in AI-identified laryngoscope was 0.91 (95 % CI 0.83-0.98) and 0.91 (95 % CI 0.86-0.96), respectively, and the specificity was 0.97 (95 % CI 0.96-0.99) and 0.95 (95 % CI 0.90-0.99), respectively. The details can be seen in Figure 2 and Table 2.

Grading of Evidence

We evaluated the reliability of each outcome through GRADE. Results showed that the quality was evaluated as very low for 44.1% of the outcomes and low for 55.9% of the outcomes. Our research found that the sensitivity and specificity of Barrett neoplasia, esophageal squamous cell carcinoma, *Helicobacter pylori* infection, chronological gastritis, colorectal polyp, gastrointestinal ulcer, and gastrointestinal hemorrhage had low credibility. The other outcomes had very low credibility. Generally speaking, the primary defects were indirectness and imprecision. These problems were caused by the different AI models and training methods used in the original literature, and there were also differences in the selection of recognition samples. Endoscopists in different regions used different samples and chose different AI algorithms to train and test the models, making the synthesized results less credible. Detail can be seen in Table S4 in Multimedia Appendix 1.

Discussion

Principal Findings

In this study, we conducted a systematic review of the current use of AI in endoscopic diagnosis, assessing the quality of

research and meta-analyses conducted in this field. AI has been studied and applied in upper gastrointestinal endoscopy, colorectal endoscopy, capsule endoscopy, and laryngoscopy. The meta-analysis results showed that AI has high sensitivity and specificity for these types of endoscopy. However, the overall evidence level of the outcomes was low.

In previous studies, AI could effectively assist in sedation and training in the operation process of upper digestive tract examination [39,40]. The earliest research we examined was conducted in 2007, when computers were trained to identify esophageal cancer [41]. At that time, the research only distinguished malignant and nonmalignant esophageal tissues in vitro.

With the rise of AI and the continuous upgrading of training methods, the application of AI in gastrointestinal endoscopy, including esophageal cancer, gastric cancer, and *Helicobacter pylori* infection, has been widely studied. In addition to the ordinary white light examination, computer-aided systems have shown a certain diagnostic value in stained and magnifying endoscopic imaging [42,43]. Moreover, some studies have found that trained models have research value in diagnosing gastric cancer's infiltration depth [44].

A study in 2022 compared the diagnostic value of computer-aided systems and professional endoscopists in gastric cancer images through retrospective data and found no significant difference in the diagnostic rate between the two groups [45]. This shows that AI aid is not inferior to endoscopists in image diagnosis. Wu conducted a single-center randomized controlled trial and found that the missed diagnosis rate of gastric adenoma could be significantly reduced using AI [46]. Multi-center randomized controlled studies are still needed for further analysis in the future.

AI has been widely studied in colorectal endoscopy. A meta-analysis showed that AI could effectively improve adenoma detection rate [7]. However, another meta-analysis based on real-world research reached the opposite conclusion [47]. The findings of our study proposed that AI has a noticeable effect in identifying intestinal lesions. However, many problems still need to be effectively addressed, particularly in terms of clinical implementation and practical translation.

In November 2023, the team at West China Hospital led a 12-center study with more than 10,000 patients [48]. This randomized controlled trial compared the relationship between AI-assisted and routine examinations in the missed diagnosis rate of esophageal lesions. The results showed that AI could not significantly improve the missed diagnosis rate of esophageal lesions. Many teams are constantly developing, improving and trying to use AI models in clinics. As mentioned above, although AI has been shown to have a significant effect in many studies, there has been an increase in research regarding the failure of AI to significantly improve the effectiveness of endoscopy in the clinical situation. In the application process, we found that the recognition threshold of AI greatly affected its application value. We are explored the possiblity of classifying patients according to some baseline information or endoscopic mucosal background images and then continuously optimized the AI recognition threshold according to the risk stratification of different patients. This approach aimed to achieve individualized endoscopic examinations and improve overall identification accuracy [49-51].

Moreover, the economic impact of a large-scale rollout of AI systems in clinical work on patients and health care institutions must be further studied. In addition, the differences in validation sets make it difficult to truly achieve accurate side-by-side comparisons when evaluating the capabilities of different AI models, which may lead to biased results. We believe it would be beneficial to produce an open platform that includes test data sets from different parts and different lesions of the gastrointestinal tract so that researchers can test the effectiveness of AI recognition in the future.

This study has several strengths. According to our preliminary understanding, the umbrella evaluation of using AI in endoscopic applications must be revised. To a certain extent, we have filled this blank. Second, we conducted a strict analysis and discussion following the PRISMA guidelines. Third, two researchers conducted all analyses, and the results were reliable.

There are also some limitations to this study. First, various computer-aid models have certain heterogeneity, and this could not be avoided in the analysis. Therefore, our results are a general summary of the current technology. Second, we could not gather the data of some unpublished studies. Third, the limited number of studies made it difficult to do further subgroup analyses. Fourth, we only included studies reported in English, which might have introduced some biases to our study.

Conclusions

This study found that AI has high diagnostic value in endoscopy. These findings provide a theoretical basis for the development and evaluation of AI-assisted systems, aimed at assisting endoscopists in conducting examinations, thereby improving patient health outcomes. However, it is worth noting that there is no convincing high-quality evidence in the existing research and further research is needed in the future.

Abstract

Background: With the increasing availability of data, computing resources, and easier-to-use software libraries, machine learning (ML) is increasingly used in disease detection and prediction, including for Parkinson disease (PD). Despite the large number of studies published every year, very few ML systems have been adopted for real-world use. In particular, a lack of external validity may result in poor performance of these systems in clinical practice. Additional methodological issues in ML design and reporting can also hinder clinical adoption, even for applications that would benefit from such data-driven systems.

Objective: To sample the current ML practices in PD applications, we conducted a systematic review of studies published in 2020 and 2021 that used ML models to diagnose PD or track PD progression.

Methods: We conducted a systematic literature review in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines in PubMed between January 2020 and April 2021, using the following exact string: “Parkinson’s” AND (“ML” OR “prediction” OR “classification” OR “detection” or “artificial intelligence” OR “AI”). The search resulted in 1085 publications. After a search query and review, we found 113 publications that used ML for the classification or regression-based prediction of PD or PD-related symptoms.

Results: Only 65.5% (74/113) of studies used a holdout test set to avoid potentially inflated accuracies, and approximately half (25/46, 54%) of the studies without a holdout test set did not state this as a potential concern. Surprisingly, 38.9% (44/113) of studies did not report on how or if models were tuned, and an additional 27.4% (31/113) used ad hoc model tuning, which is generally frowned upon in ML model optimization. Only 15% (17/113) of studies performed direct comparisons of results with other models, severely limiting the interpretation of results.

Conclusions: This review highlights the notable limitations of current ML systems and techniques that may contribute to a gap between reported performance in research and the real-life applicability of ML models aiming to detect and predict diseases such as PD.

Introduction

Parkinson disease (PD) is a progressive neurodegenerative disease that results in a loss of motor function with muscle weakness, tremors, and rigidity. Secondary symptoms include speech difficulties, sleep disorders, and cognitive changes. Research suggests that pathophysiological symptoms can be used to detect PD before the onset of the motor features [1]. For these reasons, multiple clinical assessments and analyses are required to diagnose PD and allow for early detection. However, clinical diagnosis of PD is an error-prone process [2]. A UK autopsy study found that the misdiagnosis rate of PD is 24% [3]. Early detection is especially important for PD since early neuroprotective treatment slows down the progression of the disease and lessens the symptoms, which improves the patient’s quality of life [4]. From diagnosis to treatment, each case of PD is unique [5,6]. Precision medicine using machine learning (ML) has the potential to better use the varied data of individuals. Therefore, ML-based solutions can play an important role in PD diagnosis [7,8].

Here, ML refers to the branch of artificial intelligence that uses computational methods to perform a specific task without being explicitly programmed, by learning from previous examples of data and making predictions about new data [9]. ML includes

a broad range of standard learning algorithms, such as decision trees, support vector machines, and linear or logistic regression, as well as the subfield of deep learning that uses sophisticated, biologically inspired learning algorithms called neural networks. Generally, supervised algorithms learn from labeled data (eg, classification or regression), whereas unsupervised algorithms learn from hidden patterns in the unlabeled data (eg, clustering).

In the medical field, ML is becoming an increasingly central technique. For example, ML-based prediction models are being developed to detect early signs of diseases, improve decision-making processes, and track rehabilitation efficacy. Fueled by advances in data-recording technology, the increasing availability of patient data, and more accessible databases and code libraries, these models can generate more accurate insights about patients from large, existing health data sets. Contreras and Vehi [10] showed that within a decade, the number of articles proposing artificial intelligence models in diabetes research grew by 500%. Despite the large number of promising studies reported in the literature, the adoption of ML models in real-life clinical practice is low [11]. A wide range of ML models have been proposed for the automatic detection of PD [12]. Searching with only 1 query related to ML and PD results in over 1000 publications in 1 year alone. Despite the rising popularity of ML in PD research, models are rarely deployed in the field due to their irreproducibility and are limited for research purposes [13]. Although there may be many explanations, one possibility is a disconnect between the models developed in research and real-life implementation.

In contrast to previous systematic reviews that primarily explored data types and model variations, the emphasis of this review lies in the critical context of model validation approaches to provide a comprehensive understanding of the strengths and limitations of ML models in the PD field. Previous reviews emphasized data types; for instance, Ramdhani et al [14] reviewed sensor-based ML algorithms for PD predictions, and Mei et al [15] provided a comprehensive overview of outcomes associated with the type and source of data for 209 studies that applied ML models for PD diagnosis. Mei et al [15] also noted concerns about insufficient descriptions of methods, results, and validation techniques. We focused on the critical evaluation of validation techniques that are instrumental for the clinical integration of ML.

In this review, we examined a cross-section of recent ML prediction models related to PD detection and progression. Our goal was to summarize the different ML practices in PD research and identify areas for improvement related to model design, training, validation, tuning, and evaluation. Implementing best ML practices would help researchers develop PD prediction models that are more reproducible and generalizable, which in turn would improve their impact on the entire landscape of patient care and outcomes.

Methods

Search Strategy

We conducted a systematic literature review in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Checklist 1) guidelines in PubMed between January 2020 and April 2021, using the following exact string: “Parkinson’s” AND (“ML” OR “prediction” OR “classification” OR “detection” or “artificial intelligence” OR “AI”). The search resulted in 1085 publications.

Inclusion and Exclusion

Inclusion criteria were studies (1) on ML applied for predicting PD, PD subscores or PD severity, and PD symptoms; (2) published between January 2020 and April 2021; (3) written in English; and (4) with an available title and abstract.

Questionnaire Design

We designed a customized questionnaire to easily parse the literature and extract characteristics of the different ML approaches. Textbox 1 summarizes the model details extracted from the questionnaire, and the exact questionnaire is provided in Multimedia Appendix 1. This questionnaire was not intended to extract exhaustive details about these models, but rather to target specific concepts that seem to be inconsistently reported in the PD modeling literature. Our rationale for each question, and how they were designed specifically for PD, is provided below.

PD is a progressive neurological disorder, and symptoms can vary widely for each individual. To categorize PD progression and assess patient status, clinicians use standardized metrics such as the Unified Parkinson’s Disease Rating Scale [16] and Hoehn and Yahr (H&Y) scores [17]. The first question is related to clearly defining the research objectives or target outcomes of a particular study. The challenge of classifying PD versus non-PD may depend on symptom severity, which can be more readily assessed when severity metrics are available. In certain stages of PD, symptoms can be controlled or lessened through careful medication regimens, such as levodopa. This medication’s *on* and *off* periods are essential components for clinicians and researchers to consider. *On* and *off* episodes can create a substantially different effect on symptoms [18,19], and these symptoms are being used in ML algorithms to classify or assess PD. For example, Jahanshahi et al [20] investigated the levodopa medication’s effect on PD probabilistic classification learning and demonstrated that learning is associated with the patient with PD being in an *on* or *off* state. Warmerdam et al [21] showed that the patient’s state relative to dopaminergic medication correlated with the arm-swing task during PD walking. PD characteristics are important while researching PD, and the application of the models might play different roles depending on the data. As a result, the questions regarding the severity and medication state of patients can play a crucial role. In addition, class imbalance, cross-validation techniques, and hyperparameter tuning are critical concepts in ML. Class imbalance can lead to biased models or misinterpretation of results. Cross-validation and hyperparameter tuning allow systematic exploring of models and are essential for assessing models’ generalization performance. Lastly, comparing model performance to benchmark data can be valuable for research goals, but this process is not always applicable or possible.

Textbox 1. Model details obtained during data extraction (n=113).

1. What have the authors classified using machine learning?
2. Was there any information about the participants being on or off medication prior to the experiment?
3. Of the study participants, how many were (1) individuals with Parkinson disease, (2) controls, and (3) individuals with other diseases?
4. Did the study mention the distribution of the Unified Parkinson's Disease Rating Scale and Hoehn and Yahr scores?
5. What class imbalance mitigation techniques did the authors perform?
6. How did the authors split or cross-validate the data set while training the model? If cross-validation was applied, which particular strategies were applied?
7. If applicable, have the authors made the reader aware of the potential overinflated performance results (eg, the model overfitting the training data)? If so, how?
8. How was the hyperparameter tuning done?
9. Did the authors analyze and discuss the models' errors or misclassifications?
10. How did they compare their model to other modeling approaches by themselves or other authors, directly or indirectly?
11. Did the authors use multiple evaluation metrics to measure the performance of the model(s)?

Data Extraction

Two authors assessed the inclusion criteria of 1085 studies based on the title and abstract. During the initial manual screening of the title and abstract, 155 studies that met the initial inclusion criteria were identified. A total of 42 studies were excluded after assessing the full text for eligibility. These authors also extracted data from the studies using the questionnaire described above. Ultimately, 113 studies and the corresponding questionnaire responses were rechecked independently by both reviewers, and disagreements were resolved through discussion to reach a consensus. Questionnaire data from each study are provided in in Multimedia Appendix 2.

For the multiple-choice and checkbox questions (ie, questions 1, 7, 8, 9, 10, 11, 13, 14, and 15), we counted the number of times each response occurred in the results.

Results

First, we provide a general overview of the study characteristics in each publication. Then, we examine specific results evaluating the ML modeling practices using the following categories: PD characteristics, class imbalance, data set splitting, overfitting, hyperparameter tuning, and model comparisons.

General Overview of Studies

Methods Applied

The most prevalent ML classification algorithms were support vector machines (53/113, 46.9%), boosting ensemble learning (48/113, 42.5%; eg, gradient boosting, extreme gradient boosting, and random forest), naive Bayes (4/113, 3.5%), decision tree (13/113, 11.5%), and *k*-nearest neighbor (22/113, 19.5%). In regression models, the most prevalent methods included multiple linear or logistic regression (32/113, 28.3%), regression trees, *k*-means clustering, and Bayesian regression (3/113, 2.6%). Deep learning methods included convolutional neural networks (10/113, 8.8%), variants of recurrent neural networks (4/113, 3.5%; eg, long short-term memory [LSTM] and bidirectional-LSTM), and fully connected neural networks (22/113, 19.5%).

Data Modalities and Sources

More than half of the studies (65/113, 57.5%) used data collected by the authors, whereas 38.9% (44/113) used a public data set and 3.6% (4/113) used a mixture of public and private data sets. The most common data modalities were magnetic resonance imaging, single-photon emission computerized tomography imaging, voice recordings or features, gait movements, handwriting movements, surveys, and cerebrospinal fluid features.

ML Modeling Practices

PD Prediction Target

We categorized the studies based on 5 ML outcomes for PD models: *PD versus non-PD classification*, *PD severity prediction*, *PD versus non-PD versus other diseases classification*, *PD symptoms quantification*, and *PD progression prediction*. A total of 10 studies fell into more than 1 category; among them, 8 (80%) studies examined both *PD versus non-PD classification* and *PD severity regression*, and 2 (20%) studies examined *PD versus non-PD classification* and *PD symptoms quantification*.

1. *PD versus non-PD classification* (59/113, 52.2%): studies that proposed ML methods to distinguish between individuals with PD from controls without PD
2. *PD severity prediction* (30/113, 26.5%): studies that proposed ML methods to predict the stages of Unified Parkinson's Disease Rating Scale scores or H&Y scores of PD
3. *PD versus non-PD versus other diseases classification* (24/113, 21.2%): studies that proposed ML methods to distinguish between PD, non-PD, and other diseases (eg, Alzheimer disease)
4. *PD symptoms quantification* (9/113, 8%): studies that proposed ML methods to distinguish between PD symptoms (eg, tremor and bradykinesia) from no symptoms or non-PD symptoms

5. *PD progression prediction* (1/113, 0.9%): studies that proposed ML methods to predict PD progression

PD versus non-PD classification and *PD versus non-PD versus other diseases classification* have target settings that are binary variable predictions, as these targets are mostly for predicting the presence or absence of PD. *PD severity prediction* can be categorical (multilabel classification) or continuous (regression), such as predicting the H&Y score. *PD symptoms quantification* can also be categorical, such as predicting the presence of resting tremors, rigidity, and bradykinesia, or continuous, such as predicting the degree of tremor intensity. *PD progression prediction* measures the changes in overall disease severity at multiple time points. We found that most studies (107/113, 94.6%) indicated PD severity. However, fewer than half (53/113, 46.9%) of the studies reported the patient medication status directly, with 38.9% (44/113) using public data sets.

Class Imbalance

Class imbalance occurs when 1 training class contains significantly fewer samples than another class. In this case, the learners tend to focus on the better performance of the majority group, making it difficult to interpret the evaluation metrics, such as accuracy, for groups with less representation. Prediction models can be significantly affected by the imbalance problem. ML models can be highly unstable with different imbalance ratios [22]. On predicting *PD versus non-PD classification*, performance can suffer significantly from an imbalanced data set and generate impaired results [23]. Class imbalance can impact model external validity, and either mitigating or at least reporting the potential concerns in the interpretability of outcomes due to imbalances would help the reader interpret the model's power for predicting each class.

There are multiple ways to handle a class imbalance in the training phase, such as using resampling techniques or weighted evaluation metrics. Resampling creates a more balanced training data set, such as by oversampling the minority class or undersampling the majority class [24,25]. Moreover, there are alternative evaluation metrics, for example, balanced accuracy and *F*-measure, but these improvements on the standard evaluation metrics are also affected by class imbalance [26]. We observed that among the studies that attempted to mitigate class imbalance, many of them adopted under- or oversampling methods and then applied class weights to the evaluation metrics. Other techniques were data augmentation and grouping data to use the same ratio of minority and majority classes. In the case of extreme class imbalance, Megahed et al [27] were not able to mitigate overfitting. Overall, there is no perfect solution to tackle this critical issue in ML; however, recognizing that the problem exists and investigating appropriate mitigation strategies should be standard practice. Our results found at least moderate class imbalance in more than two-thirds (77/113, 68.1%) of the studies, and only 18% (5/27), 31% (5/16), 27% (8/30), and 25% (1/4) of studies for the *PD versus non-PD classification*, *PD versus non-PD versus other diseases classification*, *PD severity prediction*, and *PD symptoms quantification and progression prediction* target categories applied strategies to mitigate the effects of class imbalance, respectively. In Figure 1, we illustrate the number of studies with more than 30% class imbalance and how many of them applied imbalance mitigation strategies.

In some cases, authors applied class imbalance strategies but found no significant improvement in their model performance. Reporting these cases still provides valuable perspectives. For instance, van den Goorbergh et al [28] illustrated that correcting for imbalance resulted in the model exhibiting strong miscalibration and did not improve the model's capability to distinguish between patients and controls. A total of 4 studies compared results when using imbalanced data compared to imbalance-mitigated data. Details of these studies are provided in Table 1.

Figure 1. Number of studies with more than 30% class imbalance and the percentage of studies that applied the class imbalance strategies, separated by PD prediction target. In the *PD versus non-PD classification*, *PD versus non-PD versus other diseases classification*, *PD severity prediction*, and *PD symptoms quantification and progression prediction* categories, 46% (27/59), 67% (16/24), 100% (30/30), and 40% (4/10) had class imbalance, but only 8% (5/59), 21% (8/30), 27% (8/30), and 10% (1/10) applied mitigation strategies, respectively. PD: Parkinson disease.

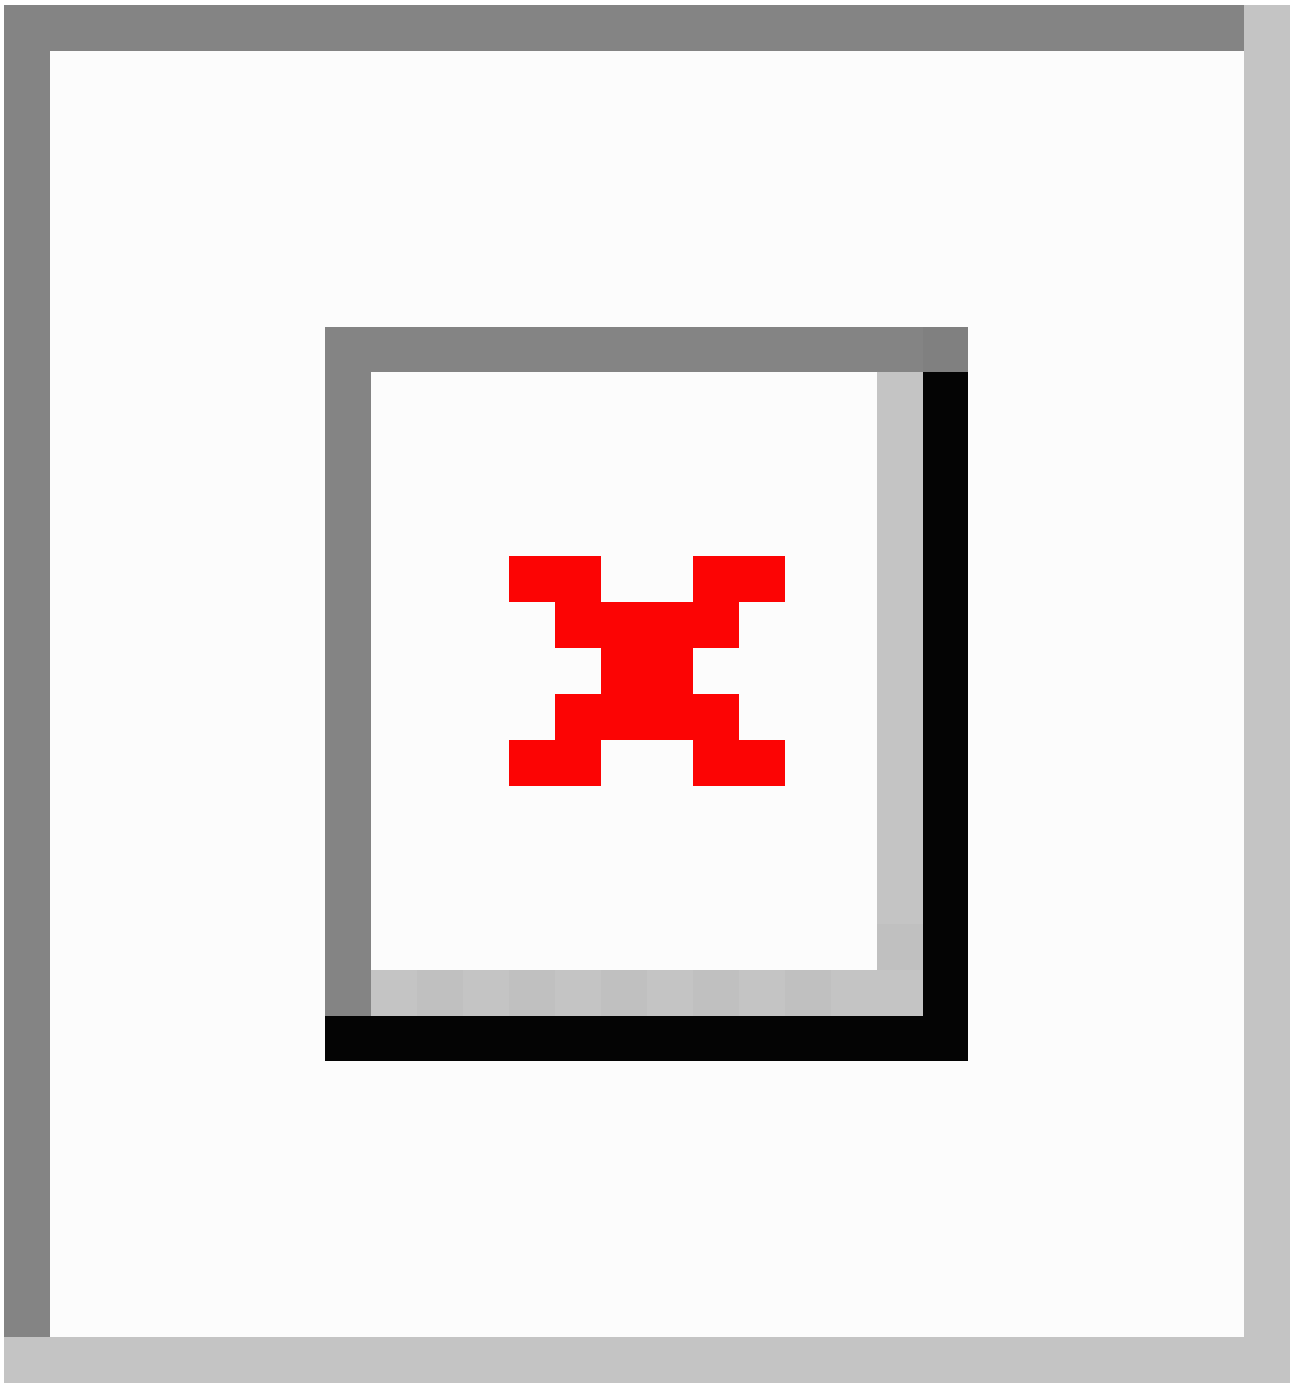

Table . Comparison between imbalanced data versus imbalance mitigation strategies.

Studies	Participant distribution	Techniques	Conclusion
Moon et al [29]	524 patients with PD[a] and 43 patients with essential tremor	• SMOTE[b]	• F_1-score improved
Veeraragavan et al [30]	93 patients with idiopathic PD and 73 controls; 10 patients with H&Y[c] 3; 28 patients with H&Y 2.5; and 55 patients with H&Y 2	• SMOTE	• Test accuracy improved
Falchetti et al [31]	388 patients with idiopathic PD and 323 controls	• Oversampling • Undersampling • Combination of oversampling and undersampling	• Without any sampling, the combination of oversampling and undersampling methods is comparable
Jeancolas et al [32]	115 patients with PD and 152 controls	• Data augmentation	• Performed better for free speech task • No consistent improvement in the sentence repetition task

[a]PD: Parkinson disease.

[b]SMOTE: synthetic minority oversampling technique.

[c]H&Y: Hoehn and Yahr.

Data Set Splitting

It is universally acknowledged that ML models can perform arbitrarily well on data that were used to create the model—that is, the training data set. This is why standard procedure in training models uses separate data sets to try different model variations and select the better variants. The confusion that sometimes occurs is when these separate data sets are used to select from a large number of model variants (validation set) or only used for the evaluation of selected variants (test set). The distinction in these 2 use cases of separate data is sometimes not clear and depends on the number of model variants tested. Critically, with modern ML practice, many model variants are often tested on provided data, which readily leads to overfitting on both the original training data and validation set used for evaluation. A separate holdout test set would be needed to properly evaluate model performance [33]. A single split can be error prone in estimating performance [34]. It is critical to have a holdout test set to provide better performance estimation. Additionally, cross-validation is a technique largely used to estimate and compare model performance or to optimize the hyperparameters [35]. Cross-validation divides the data into folds and iterates on these folds to test and train the models using different partitions of the data set. We found that 78.8% (89/113) of the studies used cross-validation; however, 5.3% (6/113) of the studies either did not mention the details of the validation procedure or did not do any splitting. A total of 9.7% (11/113) of the studies split the data set into only 2 sets, but it was not clear if the separate set was a validation set or a test set. Only 19.5% (22/113) of the studies applied cross-validation without a holdout test set (Table 2 and Figure S1 in Multimedia Appendix 3).

Table . Distribution of studies according to data set splitting techniques.

Data set splitting techniques	Studies (n=113), n (%)
Not mentioned	6 (5.3)
Split into 2 sets (training, test, or validation sets)	11 (9.7)
Only cross-validation	22 (19.5)
Split into 3 sets	7 (6.2)
Cross-validation and holdout test set	67 (59.3)

Cross-Validation

There are multiple types of cross-validation techniques. In *k*-fold cross-validation, the data set is divided into *k* equal folds randomly, and the model is trained and evaluated *k* times. Each time, the model is trained using *k*–1 folds and evaluated in the remaining fold. When the observations are independent and identically distributed, *k*-fold cross-validation works well. When the data are not identically distributed, *k*-fold cross-validation makes the model prone to overfitting and not generalize well [36]. For instance, multiple data samples from the same patient should generally not be present in both training and testing data sets. Subject-wise cross-validation separates folds according to the subject. Although Saeb et al [37] concluded that subject-wise methods are more clinically relevant compared to record-wise methods, Little et al [38] argued that subject-wise methods might not be the best in all use cases. However, Westerhuis et al [39] demonstrated that cross-validation can be overoptimistic and suggested that it is good practice to include a separate test set at the end to properly evaluate a model. To reduce bias in

model evaluation, nested cross-validation is another technique that involves 2 cross-validation loops [40]. The outer loop generates *k*-folds and iterates through them, so each fold is eventually used as a holdout test fold for a model developed using the remaining data. The inner loop uses a similar *k*-fold procedure to create a holdout validation fold that is used to select the best model during model tuning. Nested cross-validation is a more robust way to evaluate models than *k*-fold cross-validation alone, since using all available data to select the model architecture can lead to biased, overfitted results [40]. However, nested cross-validation is more computationally intensive, and these models can be difficult to interpret or implement (since they actually result in *k*-best models, so performance is usually averaged over all *k*-best models). In our analysis, we found that the most common cross-validation technique is *k*-fold cross-validation (68/113, 60.2%), whereas only 4.4% (5/113) of the studies adopted nested cross-validation (Table 3 and Figure S2 in Multimedia Appendix 3). Of the 113 studies, 20 (17.7%) adopted 2 types of cross-validation techniques, and 5 (4.4%) adopted 3 types of techniques.

Table . Distribution of studies that adopted cross-validation techniques.

Cross-validation techniques	Studies (n=113), n (%)
k-fold cross-validation	68 (60.2)
Leave-p-out cross-validation	25 (22.1)
Stratified or subject-wise cross-validation	21 (18.6)
Nested cross-validation	5 (4.4)
No cross-validation	24 (21.2)

Overfitting

We selected publications that did not evaluate their models with a holdout test set and then we analyzed if they mentioned that the proposed models could possibly be overfitting. Models can be overfitted for multiple reasons, such as an imbalanced data set or the lack of proper model selection and validation technique. Even with cross-validation, if a separate holdout set is not used, then the results can be inflated. Rao et al [41] demonstrated that leave-one-out cross-validation can achieve 100% sensitivity, but performance on a holdout test set can be significantly lower. Cross-validation alone is not sufficient model validation when the dimensionality of the data is high [41]. However, there are multiple ways to address or prevent overfitting, such as the examples provided by Ying [42]. Making the reader aware of overfitting concerns in the interpretability of results should be standard practice. Therefore, we searched to see if the authors mentioned that their model can suffer from overfitting. For this analysis, we excluded studies that applied the cross-validation technique with a holdout test set. We found that just over 54% (25/46) of the studies that likely suffer from overfitting did not mention it as a concern. Although 45% (21/46) of studies mentioned overfitting as a potential limitation, many of them did not have any detailed discussion about this.

Hyperparameters

While training a model, hyperparameters are selected to define the architecture of the model. These hyperparameters are often tuned so that the model gives the best performance. A common method of finding the best hyperparameters is by defining a range of parameters to test, then applying a grid search or random search on the fixed search space, and finally selecting parameters to minimize the model error [43]. These methods can be extremely computationally expensive and time-consuming depending on data complexity and available computation power [44]. Regardless of the method applied, it is considered good practice to make clear statements about the tuning process of hyperparameters to improve reproducibility [45]. This practice ensures parameters are properly selected and models are ready for direct comparison. Our results demonstrated that 38.9% (44/113) of studies did not report on hyperparameter tuning (Table 4 and Figure S3 in Multimedia Appendix 3). Of these, 2 adopted least absolute shrinkage and selection operator logistic regression, and 3 used a variant of logistic regression or linear regression, which typically have few or no hyperparameters to adjust.

Table . Distribution of studies according to hyperparameter tuning methods.

Hyperparameter tuning methods	Studies (n=113), n (%)
Not reported	44 (38.9)
Ad hoc	31 (27.4)
Random search	1 (0.9)
Grid search	27 (23.9)
Others	10 (8.8)

For many other models, there are inherently only a few hyperparameters that are usually adjusted; for instance, the major hyperparameter for the neighbor model is the number of neighbors, *k*. On the other hand, more complex models such as convolutional neural networks and LSTM require thorough tuning to achieve meaningful performance. Regardless of the

number of hyperparameters in a model, proper tuning would likely still contribute to achieving optimal performance. The choice of hyperparameters will impact model generalization, so it is worthwhile to examine changes in performance with different settings [46].

Model Comparison

In research domains that require complex deep learning models to achieve state-of-the-art performance, such as computer vision and natural language processing, it has become a regular practice to compare models with numeric benchmark data sets to contextualize their proposed model and provide insight into the model's relative performance to peers. Although such rigorous benchmarking and comparison is not possible given the heterogeneous data sets in PD research, it is important to contextualize a model's performance relative to other models, strategies, and data sets. We found that 66.4% (75/113) of studies compared results from multiple alternative models in their work, and 15% (17/113) of studies compared their results with previously published models. However, 18.6% (21/113) of studies only reported their single model performance and made no comparison to any other models or benchmarks (Table 5 and Figure S4 in Multimedia Appendix 3).

Table . Distribution of studies according to model comparison methods; 18.6% (21/113) of studies did not compare their model results to any alternative models or previously published models or benchmarks.

Model comparison methods	Studies (n=113), n (%)
Compared with their own multiple models	75 (66.4)
Compared with previous models or benchmarks	4 (3.5)
Compared with previous models and their own multiple models	13 (11.5)
No comparisons	21 (18.6)

Discussion

Principal Findings

In summary, we have comprehensively reviewed the general practices of ML research applied to PD in a recent cross-section of publications. We have identified several important areas of improvement for model building to reduce the disparity between in-the-lab research and real-world clinical applications. Standardizing the model reporting techniques and implementing best ML practices would increase the acceptability and reliability of these models to improve patient evaluation and care [47].

For the interoperability and usability of the models, clinicians need detailed information about the patients included in the model's training data, such as their medication state and PD progression stage. This information determines the predictive validity of a model to new patients and settings. We found that 94.7% (107/113) of the studies explained the PD severity of their patients, whereas only 46.9% (53/113) of studies reported the medication state of the patients. To incorporate data-driven algorithms in real life, the description of medication is significantly relevant to PD [48,49]. The overall representation of demographic samples in the training set should be accounted for as well. Our results show that 68.1% (77/113) of the studies had a class imbalance greater than 30% difference in their data set, and less than one-third (from 5/27, 18% to 5/16, 31%) of the studies addressed imbalance as a potential issue or considered its impact on the model results.

Another major finding is the lack of a standard reporting framework for a model's hyperparameter search and tuning. Hyperparameter tuning has a major impact on the model configuration and, by extension, its performance [50]. For example, Wong et al [51] demonstrated that a model using tuned (grid-searched) hyperparameters outperformed a model using default hyperparameters. Addressing hyperparameters is also essential for reproducibility, including a report on the final model configuration and how the authors made the decision. Although this is a considerably important aspect of ML model reporting, our study showed that 44 (38.9%) of the 113 studies did not report the hyperparameter tuning approach. Of these, 5 studies adopted logistic regression or linear regression. Traditional regression models are not expected to undergo significant hyperparameter tuning; however, variants that involve hyperparameters would likely still benefit from tuning. Consistent reporting of hyperparameter tuning practices will enhance the robustness and reliability of these models.

Moreover, to provide context to the results of model performance, comparisons of different models or with previously published models give a general idea of the quality of the proposed models. We found that 18.6% (21/113) of the studies only reported their proposed models; on the contrary, the reporting standard of proposed models in the computer vision and natural language processing fields is extensive. For instance, Wang et al [52] and Liu et al [53] proposed methods for visual recognition, and they reported large-scale experiment results with different data sets and compared their results with more than 10 previously proposed methods. Similarly, in natural language processing, to propose a task such as emotion cause extraction, Xia and Ding [54] compared around 8 methods with different evaluation metrics. These are a few cases to demonstrate that such comparisons are widely executed in the computer vision and natural language processing communities to propose a method. This systematic practice of comparison with previously published approaches results in reproducibility. Unfortunately, we found that only 15% (17/113) of the studies compared with previously proposed methods. However, in the medical field, due to the challenges of data availability, proper comparisons might not be possible.

There are several factors in ML and deep learning research that can create misleading results. One major factor is proper model validation, particularly in how the training and test data are separated. We found that 5.3% (6/113) of studies either did not

provide the details about data set splitting or did not do any splitting, and 15.9% (18/113) of studies performed static training, validation, and test set separation, which provides limited stability of scores. Cross-validation is a more stable validation method conducted while training the model and reduces the risk of overfitting [55]. The majority (89/113, 78.8%) of studies adopted some form of cross-validation, and the most common cross-validation technique adopted was *k*-fold (68/113, 60.2%). Nevertheless, the use case of different validation techniques depends on the data set and is problem specific. As powerful as cross-validation is in creating reliable models, applying simple cross-validation does not guarantee that the model is not overfitted [41]. For the studies that did not evaluate their results with a holdout test set in a cross-validation manner, we extracted information from their discussion sections. To be precise, we checked if they made their reader aware of how the study results might be overfitting. We found that 46% (21/46) of the studies that are potentially reporting overfitted scores did not mention this concern. The developed models should be reported with their limitations for transparency to allow for further improvement and real-world adoption.

In this systematic review, we sampled 113 recent studies on PD to summarize the standard ML practices and addressed broader concerns on reporting strategies. It is challenging for authors to always implement the best practices considering the practical realities of health care data, including limited sample sizes, noisy data, medical data privacy, etc. However, whenever possible, authors should consider these reporting practices, especially to acknowledge limitations in their data, model design, and performance. This will help to determine reasonable use cases for these models or to identify areas of improvement before they are ready for clinical translation. These considerations can also extend to other health care applications of ML.

Conclusion

Despite the increasing number of studies, our results demonstrate there are still many opportunities for improvement in reporting and implementing ML for applications in PD detection and progression. Studies should report detailed, standardized patient characteristics; use robust validation techniques to ensure the model's reliability; and justify choices of evaluation as well as hyperparameters. We found that 75% (58/77) of the studies sampled from 2020 to 2021 did not address class imbalance, and one-third (44/113, 38.9%) of studies did not report hyperparameter tuning. Reporting is the first step to understanding the usability and interpretation of models. By shifting the focus to the critical evaluation of these methods, we aim to improve the reporting and review of ML to strengthen the connection between research and real-world clinical applications. Ideally, the processes can be standardized, and clinical measurements can be leveraged more effectively for prediction models to improve the real-world impact on individuals with PD or other health conditions.

Data Availability

All data generated or analyzed during this study are included in this paper.

Authors' Contributions

TT, MVA, and MKO conceptualized the study. TT and RCS conducted the review, extracted the data, and conducted the analysis. TT wrote the paper. MKO and MVA revised the paper and supervised the study. All authors reviewed the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Ventilator-associated pneumonia (VAP) is a serious complication of mechanical ventilation therapy that affects patients' treatments and prognoses. Owing to its excellent data mining capabilities, artificial intelligence (AI) has been increasingly used to predict VAP.

Objective: This paper reviews VAP prediction models that are based on AI, providing a reference for the early identification of high-risk groups in future clinical practice.

Methods: A scoping review was conducted in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines. The Wanfang database, the Chinese Biomedical Literature Database, Cochrane Library, Web of Science, PubMed, MEDLINE, and Embase were searched to identify relevant articles. Study selection and data extraction were independently conducted by 2 reviewers. The data extracted from the included studies were synthesized narratively.

Results: Of the 137 publications retrieved, 11 were included in this scoping review. The included studies reported the use of AI for predicting VAP. All 11 studies predicted VAP occurrence, and studies on VAP prognosis were excluded. Further, these studies used text data, and none of them involved imaging data. Public databases were the primary sources of data for model building (studies: 6/11, 55%), and 5 studies had sample sizes of <1000. Machine learning was the primary algorithm for studying the VAP prediction models. However, deep learning and large language models were not used to construct VAP prediction models. The random forest model was the most commonly used model (studies: 5/11, 45%). All studies only performed internal validations, and none of them addressed how to implement and apply the final model in real-life clinical settings.

Conclusions: This review presents an overview of studies that used AI to predict and diagnose VAP. AI models have better predictive performance than traditional methods and are expected to provide indispensable tools for VAP risk prediction in the future. However, the current research is in the model construction and validation stage, and the implementation of and guidance for clinical VAP prediction require further research.

Introduction

Background

Ventilator-associated pneumonia (VAP) is a pulmonary infectious disease that occurs in patients who receive mechanical ventilation for more than 48 hours and is primarily caused by pathogens that are present in the hospital environment. VAP is one of the most common complications in patients who undergo invasive mechanical ventilation. The incidence of VAP among patients who undergo mechanical ventilation ranges from 5% to 40%, depending on the setting and diagnostic criteria. The estimated attributable mortality rate of VAP is approximately 10%, with higher mortality rates among surgical intensive care unit (ICU) patients and those with moderate severity scores at admission [1]. VAP seriously affects the treatments and prognoses of patients, resulting in prolonged hospital stays, increased medical costs, and increased mortality rates. The early identification of groups at high risk for VAP is important for reducing VAP incidence and mortality [2].

Artificial intelligence (AI) can contribute to significant developments in the medical field. With the popularity of electronic health records, advancements in hardware computing power, and the development of big data, AI has become the optimal tool [3]. Among predictive models, AI models perform better than traditional models in various ways [4]. Data mining of patient cases via AI technology is conducted to create tools

that can predict groups at high risk for VAP to help medical staff initiate preventive interventions early, which is critical for reducing VAP incidence and mortality. Therefore, we aimed to explore the application of AI technology in predicting VAP and report our findings to provide a reference for the future development of VAP prevention.

Research Problem and Objective

Many studies have been conducted on the application of AI to VAP prediction. However, there is a lack of integrated evidence describing the AI techniques and model features that have been used in existing research. Therefore, this review aims to explore the characteristics of AI models for VAP prediction to assist the scientific community in advancing research within this field by identifying gaps and planning for the future.

Methods

Overview

We conducted a scoping review of studies that used AI to predict and diagnose VAP. For a transparent review, the guidelines of the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [5] were followed.

Search Strategy

The following seven literature databases were searched for this study: the Wanfang database, the Chinese Biomedical Literature Database, Cochrane Library, Web of Science, PubMed, MEDLINE, and Embase. Databases were searched by using terms related to the target technology, population, and outcomes of interest. The search queries used for each database are listed in Table 1. In addition to searching the databases, backward citation screening was performed on the included studies to identify additional relevant studies. The search was conducted from January 12 to January 16, 2024.

Table . Search terms used to find studies.

Database	Hits, n	Search terms

Eligibility Criteria

This review included studies on AI technology for VAP diagnosis and risk prediction. However, this review excluded literature reviews and other articles that only summarized AI approaches to VAP analysis and studies that were based solely on clinical trials and experimental studies. We included only journal articles and conference papers and excluded case reports, reviews, white papers, conference abstracts, editorials, and gray literature. Studies that used non-AI techniques to predict VAP were excluded. Moreover, this review considered only studies that were written in English and Chinese and were published between the date of the establishment of the repository and January 2024. There were no constraints with regard to the study settings, study designs, study outcomes, publication months, or publication countries.

Study Selection

The screening process was performed by 2 researchers. First, we imported document titles into EndNote (Clarivate) software to eliminate duplicates. As per the inclusion criteria, irrelevant articles were further excluded by reading the titles and abstracts. Subsequently, the full texts were read to determine the final included articles. Any objections during screening were discussed with a third investigator.

Data Extraction and Synthesis

Two reviewers independently extracted the data from the included literature and discussed them with a third reviewer in cases of any objections. The extracted information included the authors; year of publication; study design; country; sample source; study population; sample size; positive outcomes; tool type; construction method; main evaluation content; model presentation form; verification method; and indicators related to reliability, validity, and predictive power.

Narrative synthesis was used to analyze the extracted data. The results included in this study were categorized as technical characteristics of the included studies (eg, AI models and algorithms used), AI model data (eg, data sources), and predictive performance indices.

Ethical Considerations

This study did not require ethical approval because we did not study any human or animal subjects and did not collect any personal information or sensitive data.

Results

Search Results

As shown in Figure 1, 137 studies were retrieved from the search, and 59 were duplicates. A total of 78 study titles and abstracts were screened, and 66 were excluded. Figure 1 presents the reasons for exclusion. Because the full text of 1 study could not be found, 11 studies were screened for eligibility; all of them met the criteria and were included in this review.

Characteristics of Included Studies

All included studies (11/11, 100%) were published in peer-reviewed journals. The studies were published between 2007 and 2023 (Table 1), with most (3/11, 27%) published in 2023. The included studies were from 4 countries but were predominantly from the United States (5/11, 45%), followed by China (4/11, 36%). In addition, ICU patients were the most frequently studied population (studies: 6/11, 55%), 2 studies involved neurosurgical ICU patients, 1 study involved patients with traumatic brain injury, 1 study involved pediatric ICU patients, and 1 study involved older patients (age≥65 y). Public databases were the most common sources of samples (studies: 6/11, 55%), with 4 studies using the MIMIC-III (Medical Information Mart for Intensive Care III) data set. The detailed characteristics of the included studies are summarized in Table 2.

AI Technical Characteristics of Included Studies

All 11 included studies used only machine learning algorithms, and none of them involved deep learning algorithms or large language models. The random forest model was the most commonly used model (studies: 5/11, 45%), followed by the XGBoost (extreme gradient boost) model (studies: 4/11, 36%) and neural networks (studies: 3/11, 27%). Only 4 studies mentioned the programming languages for model building (Python: 3/11, 27%; R: 1/11, 9%). Further, 3 studies used model-building software to develop predictive models (ie, Hugin, Tiberius, and SPSS Modeler 18.2). Further details are presented in Table 3.

Table . Basic characteristics, predictors, and performance of artificial intelligence models for ventilator-associated pneumonia prediction (studies: N=11).

Author	Model	Development methodology	Sample size, n	Positive outcome, n	Predictors	Application	Verification method	Prediction performance
Schurink et al [6]	BDSS[a]	Hugin	872	157	Body temperature: <36.5 °C or >38.5 °C; ICU[b] daily sputum score: none=+0, rarely=+1, moderate=+2, severe=+3; sputum score: >14; sputum color: yellow or green; PaO_2[c]/FiO_2[d]: ≤205 mm Hg or decrease of >35 mm Hg from the previous day; use of acetaminophen, nonsteroidal anti-inflammatory drugs, or steroid antipyretics; chest x-ray showing localized or diffuse infiltration of the lungs; WBC[e] count: <4×10^9/L or >11×10^9/L; MV[f] time: >48 h	—[g]	Not reported	AUC[h]: 0.846 (95% CI 0.794-0.899); sensitivity: 0.79; specificity: 0.79; positive predictive value: 0.87; negative predictive value: 0.66

[al]AUPRC: area under the precision-recall curve.

[am]LightGBM: light gradient boosting machine.

[an]COPD: chronic obstructive pulmonary disease.

Different types of data were used in the included studies, including laboratory data (eg, white blood cell count, neutrophil count, and bilirubin level), clinical data (including temperature, sputum volume, and ventilator parameters), and demographic data (eg, age, weight, and sex). Of note, 2 studies used sensor data to build predictive models, and the remaining 9 studies used clinical data. In addition, 67% (6/9) of these studies used laboratory data, with white blood cell count being the most commonly used laboratory data (studies: 4/9, 44%), followed by neutrophil count (studies: 1/9, 11%), bilirubin level (studies: 1/9, 11%), and blood urea nitrogen level (studies: 1/9, 11%). Demographic data were used in 56% (5/9) of the studies; age was used as a predictor in 4 studies, and weight and age were both included in only 1 study.

In terms of data set size, of the 11 studies, 6 (55%) had sample sizes of >1000; however, with regard to the data from the electronic nose sensors that were used in 2 studies, multiple sensors were placed on the electronic nose, and each sensor collected data more than once. Therefore, the actual sample sizes for these two studies were 1888 [9] and 3360 [12]. Nevertheless, because the data were collected by the same electronic nose sensor and came from the same patient, we did not include these two studies in the number of studies with sample sizes of >1000. Further, 3 studies used data sets with <1000 samples, and 4 studies had data sets with >10,000 samples. The AI performance index was mentioned in all 11 studies. The area under the curve (AUC) was the most commonly used predictive performance index (studies: 10/11, 90%), followed by sensitivity (studies: 6/11, 55%) and specificity (studies: 6/11, 55%). The AUC values, which were reported in 10 studies, averaged to 0.86 (SD 0.07) and ranged from 0.76 to 0.98. The sensitivity, which was reported in 6 studies, averaged to 0.74 (SD 0.18) and ranged from 0.43 to 0.97. The specificity, which was reported in 6 studies, averaged to 0.80 (SD 0.09) and ranged from 0.71 to 0.95. Additionally, 5 studies reported accuracy (mean 0.82, SD 0.07, range 0.77-0.95).

Discussion

Principal Findings

In this review, we explored AI techniques for the prediction of VAP. Of the 11 included studies, 9 (82%) were published in the past 5 years, and the number of studies has increased annually with the evolution of AI technology (1 in 2019, 1 in 2020, 2 in 2021, 2 in 2022, and 3 in 2023). Most (9/11, 82%) of the AI-based prediction model studies were published in the United States (5/11, 45%) and China (4/11, 36%). To explore the application of AI in predicting VAP, the results were divided into 3 categories, and each of them classified the included studies from a different perspective.

The first category included the technical characteristics of the studies. All studies used only machine learning algorithms, with the random forest model being the most commonly used model (studies: 5/11, 45%), followed by neural networks (studies: 4/11, 36%) and the XGBoost model (studies: 4/11, 36%). The second category focused on AI model data, in which we explored the data types, data sources, and data set sizes. Different types of data, including laboratory, clinical, and demographic data, were used in the included studies. In terms of data set size, apart from 2 studies that used electronic noses, 6 (55%) had sample sizes of >1000. Public databases were the most common sources of data (studies: 6/11, 55%). The third category focused on the predictive performance of AI models, including studies that used different performance validation indices, such as the AUC, accuracy, sensitivity, and specificity.

Implications for Practice and Research

This review highlights the most common AI models that have been used to predict VAP. Based on our findings, AI models can predict VAP by using various data types. In our review, no studies that used deep learning and large language models were found. A possible reason for this is that chest computed tomography data are not available in most public databases, and in clinical practice, patients who do not exhibit pneumonia symptoms do not undergo chest computed tomography examinations; therefore, such data are not available for research. The random forest and XGBoost models are the most frequently used machine learning–based VAP prediction models, probably because ensemble learning models exhibit better prediction performance and robustness when dealing with multiple types of data compared to other models [17].

Based on the data sources of the prediction models, the use of more data types for comprehensive predictions may be the main focus of future research. Current research may be constrained to using structured data, owing to the limitations of algorithms and data collection workloads, while electronic health records contain unstructured clinical text, such as admission records and progress notes. Furthermore, much data remain to be mined. Tsai et al [18] found that information extracted from unstructured clinical text could make predictive models more comprehensive and improve their predictive performance. In addition to unstructured clinical text, lung radiography and computed tomography can be used to predict the occurrence of pneumonia.

In terms of predictive tools, natural language processing and deep learning may be the direction of future research, and the development of large language models, such as ChatGPT, that are based on natural language processing is sufficient to prove the ability of natural language processing algorithms to process unstructured clinical text [19]. Traditional machine learning algorithms are not competent in the image recognition domain, while deep learning algorithms can analyze and process clinical

imaging data effectively. Lee et al [20] found that deep learning–based predictive models that used preoperative imaging data from patients could effectively predict the occurrence of postoperative pneumonia; however, no studies have used deep learning algorithms to construct VAP prediction models.

Of further note, the studies reviewed herein rarely mentioned nurse-related data, and it has been suggested that nursing is important for VAP prevention [21,22]. The potential of various data types in predicting VAP should be explored in future studies. Additionally, none of the studies included in this review considered the application of the final model. The deployment of feasible predictive models in clinical settings needs to be explored.

Strengths

This review discusses all of the AI techniques and study populations that have been used to date to predict VAP, with no major restrictions on paper status, research environment, and geographic location. In addition, the characteristics of each AI model and the data sets that were used to build the models were discussed in depth.

Based on our findings, Frondelius et al [4,23] explored diagnostic and prognostic models for VAP and performed a meta-analysis of the performance of machine learning–based predictive models for VAP. However, to the best of our knowledge, ours is the first review of all AI VAP prediction models that have been explored thus far, filling research gaps to improve understanding of prediction techniques rather than focusing solely on the final predictive performance of models. Moreover, in the literature search, we did not place any limitations on types of technology and included all branches of AI to gain insight into the research on different AI technologies for VAP prediction.

Finally, study selection and data extraction were performed independently by 2 evaluators to ensure minimal bias.

Limitations

This review has certain limitations. Reviews, conference abstracts, case reports, white papers, proposals, editorials, and gray literature were excluded to reduce the complexity of the results. We also included Chinese databases in our search but did not explore articles in languages other than English or Chinese, which might have reduced the comprehensiveness of our study.

Conclusions

This paper reviews the application of AI technology in VAP prediction and provides new evidence on the role of AI technology. We believe that the findings will help researchers better understand the application of AI technology in VAP prediction and provide a reference for future research on VAP prediction models. Lastly, we believe that advances in AI technology will provide further possibilities for predicting VAP and that interdisciplinary developments will improve the health care industry.

Data Availability

The data sets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

J Zhang implemented the research and drafted the manuscript. PY and LZ collected the data. SL made important revisions to the manuscript. J Zhou approved the final paper.

Conflicts of Interest

None declared.

Abstract

Background: Semantic interoperability facilitates the exchange of and access to health data that are being documented in electronic health records (EHRs) with various semantic features. The main goals of semantic interoperability development entail patient data availability and use in diverse EHRs without a loss of meaning. Internationally, current initiatives aim to enhance semantic development of EHR data and, consequently, the availability of patient data. Interoperability between health information systems is among the core goals of the European Health Data Space regulation proposal and the World Health Organization's *Global Strategy on Digital Health 2020-2025*.

Objective: To achieve integrated health data ecosystems, stakeholders need to overcome challenges of implementing semantic interoperability elements. To research the available scientific evidence on semantic interoperability development, we defined the following research questions: What are the key elements of and approaches for building semantic interoperability integrated in EHRs? What kinds of goals are driving the development? and What kinds of clinical benefits are perceived following this development?

Methods: Our research questions focused on key aspects and approaches for semantic interoperability and on possible clinical and semantic benefits of these choices in the context of EHRs. Therefore, we performed a systematic literature review in PubMed by defining our study framework based on previous research.

Results: Our analysis consisted of 14 studies where data models, ontologies, terminologies, classifications, and standards were applied for building interoperability. All articles reported clinical benefits of the selected approach to enhancing semantic interoperability. We identified 3 main categories: increasing the availability of data for clinicians (n=6, 43%), increasing the quality of care (n=4, 29%), and enhancing clinical data use and reuse for varied purposes (n=4, 29%). Regarding semantic development goals, data harmonization and developing semantic interoperability between different EHRs was the largest category (n=8, 57%). Enhancing health data quality through standardization (n=5, 36%) and developing EHR-integrated tools based on interoperable data (n=1, 7%) were the other identified categories. The results were closely coupled with the need to build usable and computable data out of heterogeneous medical information that is accessible through various EHRs and databases (eg, registers).

Conclusions: When heading toward semantic harmonization of clinical data, more experiences and analyses are needed to assess how applicable the chosen solutions are for semantic interoperability of health care data. Instead of promoting a single approach, semantic interoperability should be assessed through several levels of semantic requirements A dual model or multimodel approach is possibly usable to address different semantic interoperability issues during development. The objectives of semantic interoperability are to be achieved in diffuse and disconnected clinical care environments. Therefore, approaches for enhancing clinical data availability should be well prepared, thought out, and justified to meet economically sustainable and long-term outcomes.

Introduction

Over the past 2 decades, there has been growing interest in digital technologies and eHealth integration into national health care systems to promote health [1]. The World Health Organization (WHO) has launched the *Global Strategy on Digital Health 2020-2025* [2]. To implement digital health strategy objectives, a toolkit was set up to help countries to integrate eHealth into their health care systems [3]. The objectives of the WHO strategy include standards for interoperability. Another current large-scale international initiative is the European Health Data Space (EHDS) regulation proposal. EHDS is a health-specific ecosystem comprised of rules, common standards and practices, infrastructures, and a governance framework. It supports the use of health data for better health care delivery, research, innovation, and policy making. Moreover, it aims at empowering patients through increased digital access to and control of their personal health data [3-6].

Interoperability ensures health data availability and use. It is the ability of different organizations and professionals to interact and share information according to standards of data transfer and common protocols that support data exchange [4-8]. In clinical context, interoperable electronic health records (EHRs) help health care practitioners gather, store, and communicate essential health information reliably and securely across care settings. This aims to guarantee coordinated and patient-centered care while creating many efficiencies in the delivery of health care [9]. EHRs use health-related information pertinent to an individual patient, whereas registries are mainly focused on population management and are designed to obtain information on predefined health outcomes data and data for public health surveillance, for example. Although technological possibilities for using various types of data grow, new demands are placed on data quality and usability and, consequently, on interoperability [5,10,11].

Moreover, semantic interoperability enhances the unambiguous representation of clinical concepts, supported by the use of international standard reference systems and ontologies. Since there are different types of health information, such as data from EHRs, patient registries, genomics data, and data from health applications, the development of international data standardization, common guidelines, and recommendations are needed [4-8]. Without applying appropriate semantic standards, such as domain-relevant terminologies, interoperability will be limited. This may diminish the availability and potential value of data. The various parties involved have to address the importance of shared digital health standards and especially semantic interoperability features [12-15]. In the clinical context, interoperability is required to enhance the quality, efficiency, and effectiveness of the health care system by providing information in the appropriate format whenever and wherever it is needed by eliminating unnecessary replication [16].

Therefore, our study aims to provide readers with up-to-date information about the different types of approaches to resolve semantic interoperability in EHRs specifically and to summarize the benefits of these choices. We aimed to research the topic with an emphasis on patient data availability and use. Our research questions were as follows: What are the key elements of and approaches for building semantic interoperability integrated in EHRs? What kinds of goals are driving the development? and What kinds of clinical benefits are perceived following this development?

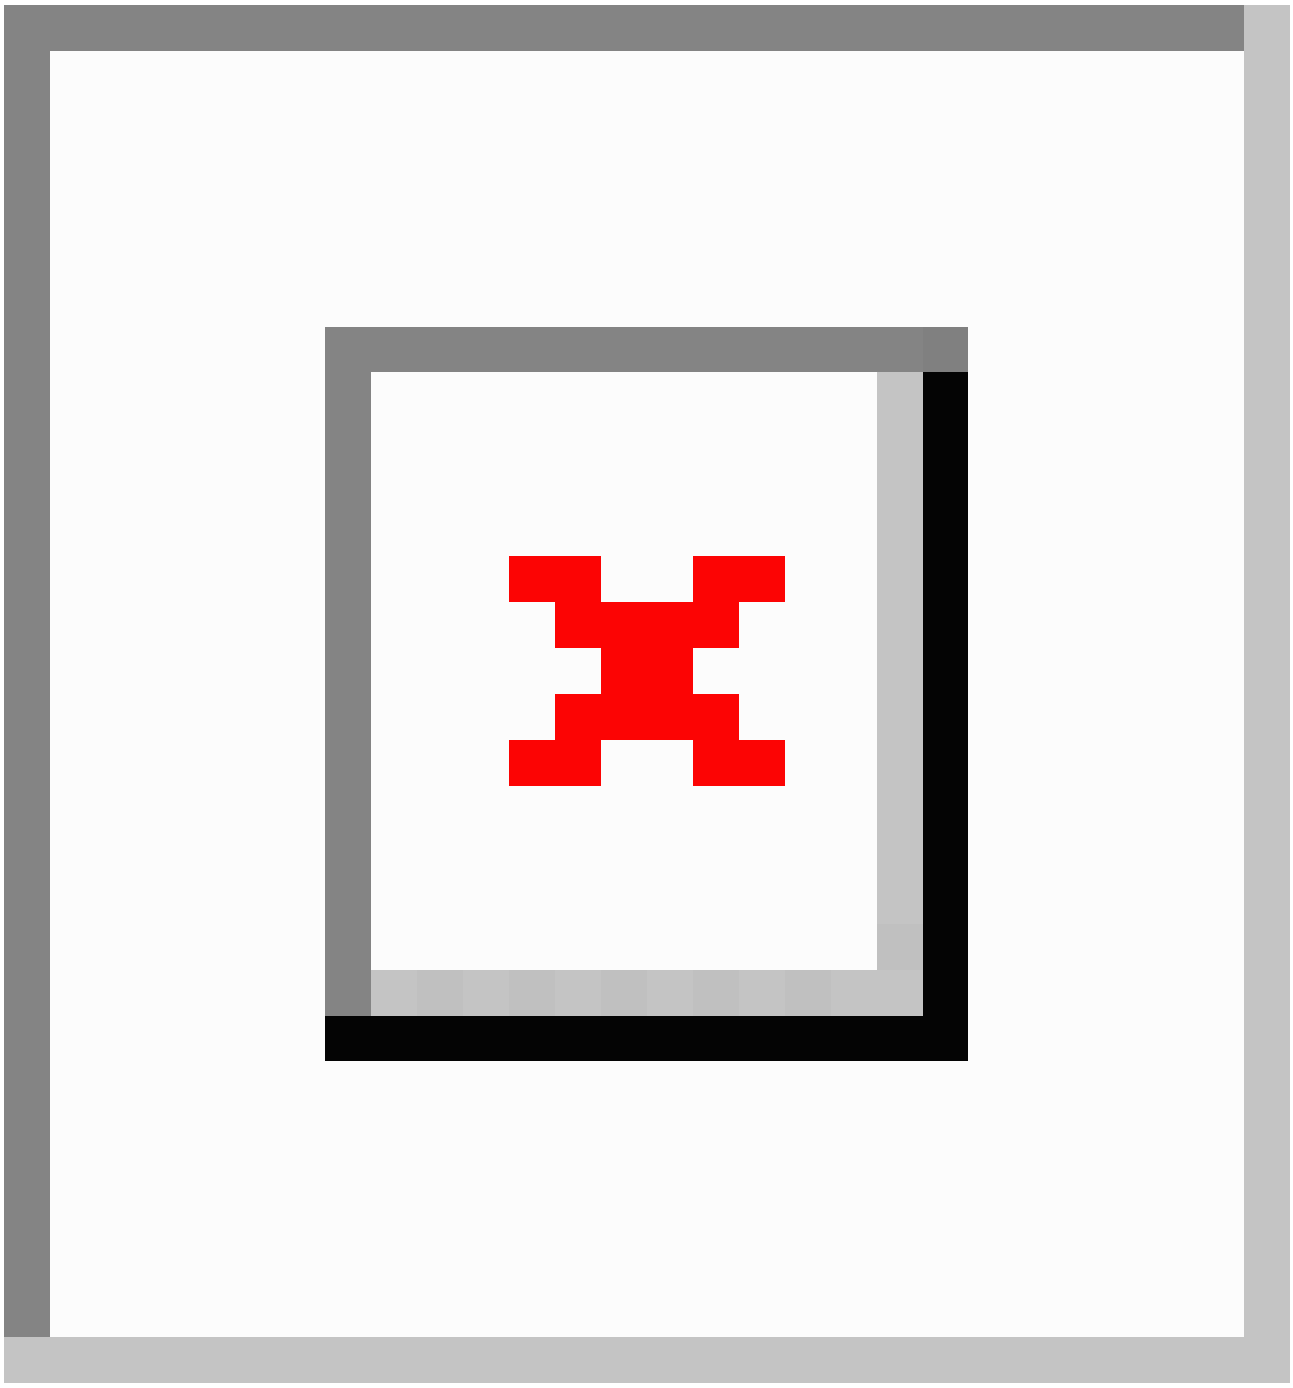
Methods

Methodological Framework

With our research questions as a starting point, we set out to perform a systematic literature review of semantic interoperability. Regarding different layers of interoperability, legal interoperability ensures overcoming potential barriers for data exchange. Interoperability agreements are made binding via international- or national-level legislation and via bilateral and multilateral agreements. Organizational interoperability defines, for example, business goals and processes. Semantic interoperability ensures that the precise meaning of exchanged information is understandable by any other application. It enables systems to combine received information with other information resources and process it in a meaningful manner. Technical interoperability covers various issues of linking computer systems and services, such as open interfaces, data integration, data presentation and exchange, accessibility, and security services [6,7].

For the study design, we first defined our core concepts to refine the literature search strategy. The scope of the review was semantic interoperability, that is, organizational, legal, and technical interoperability were excluded [7]. Semantic interoperability was apprehended based on the European Interoperability Framework (EIF) that provides a common set of principles and guidance for the design and development of interoperable digital services. In the EIF, semantic interoperability covers both semantic and syntactic aspects. The semantic aspect refers to the meaning of data elements and their relationships, whereas the syntactic aspect refers to the format of the information to be exchanged. With semantic interoperability, it is ensured that data can be shared in such a way that the meaning of data does not change [7,15,17,18]. There are also other models for analyzing interoperability layers [18]. For example, in comparison to the European approach [7], the Healthcare Information and Management Systems Society defines 4 levels of interoperability for health care technology: foundational, structural, semantic, and organizational [19,20]. Since the EIF is a well-established and largely applied framework [6], we chose the EIF definitions to primarily guide our review framework, as illustrated in Figure 1. Our review deals with semantic interoperability, which is highlighted in gray in the figure. Thus, we did not analyze, for example, standards that are related to processes or information quality.

Figure 1. Our framework for defining semantic interoperability elements for conducting the literature search and guiding our study design. ATC: Anatomical Therapeutic Chemical; CDA: Clinical Document Architecture; EHR: electronic health record; EMR: electronic medical record; FHIR: Fast Health Interoperability Resources; HL7: Health Level 7; *ICD-10: International Classification of Diseases, Tenth Revision*; *ICD-11: International Classification of Diseases, 11th Revision*; LOINC: Logical Observation Identifiers Names and Codes; RIM: reference information model; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terminology.



As shown in Figure 1, processing, storing, and exchanging health care data in EHRs and between EHRs or other clinical applications is, for example, governed and regulated at the legal layer. To continue, processes and workflows regarding information exchange are arranged at the organizational interoperability layer and resolved in the technical layer, for example, according to the principles of data protection and information security. To illustrate the point, for example, the EHDS proposal suggests that compliance with essential requirements on interoperability and data security may be demonstrated by the manufacturers of EHR systems through the implementation of common specifications. To that end, implementation can be grounded on common specifications, such as data sets, coding systems, technical specifications, standards, and profiles for data exchange, as well as requirements and principles related to security, confidentiality, integrity, patient safety, and he protection of personal data and so on [6].

The semantic interoperability layer in Figure 1 covers various approaches to resolve interoperability issues, such as more established international or domain-specific health care

classifications, clinical terminologies, and ontologies and applications of international standards for EHRs. In Figure 1, we provided some examples to illustrate various semantic aspects, but this is not an exhaustive list. Similarly, for other interoperability levels, real-world examples were given. Based on the EIF, semantic interoperability also covers syntactic features, such as data format and, for example, structured data content. We identified these key features of semantic interoperability based on previous research [8,16-19,21]. In our framework, a data model is a generic concept that describes various applications of data models from a reference information model (RIM) to a clinical information model. Data models define structures and semantics for storing, exchanging, querying, and processing health care data. Clinical information models can be implemented in an EHR, for example, as archetypes and templates, whereas RIMs refer to standards-based approaches to enable health care documentation and messages, such as the Health Level 7 (HL7) RIM or the International Organization for Standards' EN/ISO 13606 standard for EHR communication [19,22]. When designing EHRs, for semantic interoperability, a dual-level method can be applied to represent both information and knowledge levels of interoperability requirements, properties, and structures for data. This approach is used, for example, for representing the dual levels of knowledge by an archetype model and information structures by the chosen RIM [16,21,22].

Study Design

In the design of the review, we applied the Cochrane review protocol [23] to ensure the scientific reliability and validity of our review (Checklist 1). The search strategy (see Textbox 1) was defined based on the framework for semantic interoperability presented in Figure 1. We performed the search in the PubMed database in December 2022. To conduct a systematic literature review, PubMed is regarded as a comprehensive database [24]. Therefore, no further data searches were performed. We documented the search so that it can be reproduced (see Textbox 1). The search resulted in 131 unique articles. One article was removed because it did not include an abstract, and 1 was removed because it was not in English. In total, the authors screened 129 articles.

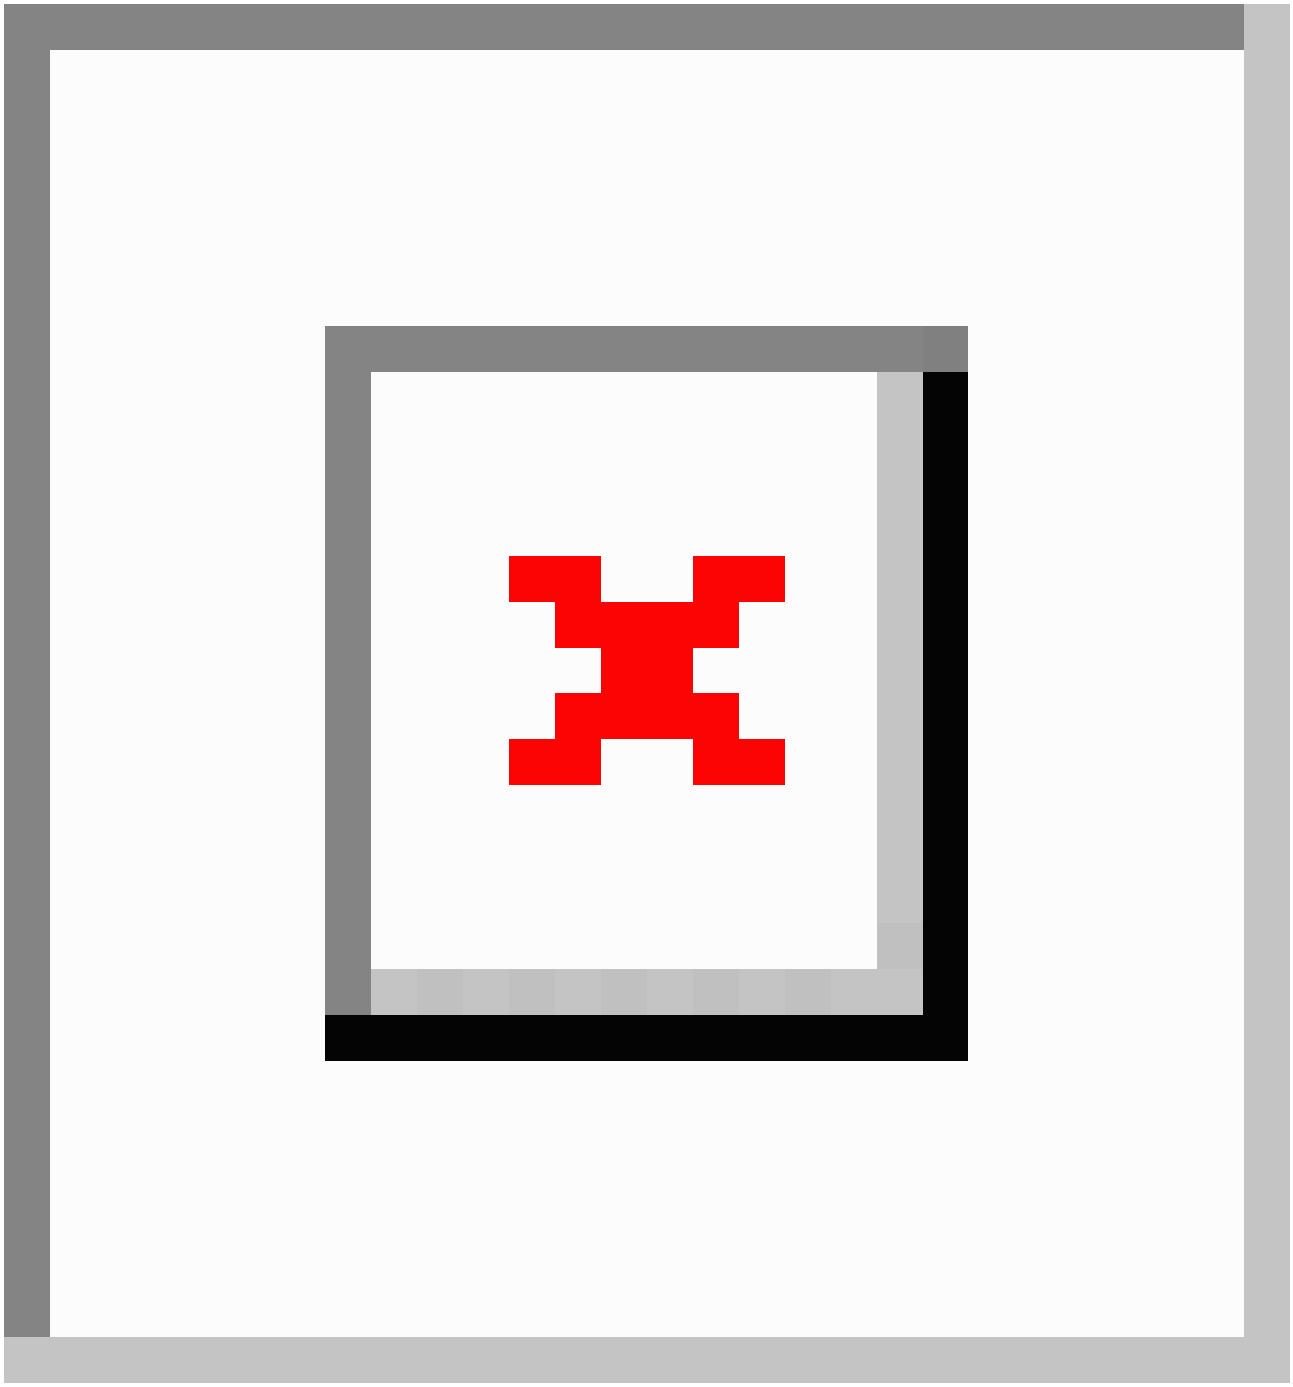
Textbox 1. Search strategy and filters used.

- Search terms: (((((EHR) OR (EMR)) OR ("Electronic Health Record")) OR ("Electronic Medical Record")) AND (((((“Semantic interoperability”) OR ((“data model”) AND (“Semantic interoperability”))) OR ((((“classification”) OR (ontology)) OR (terminology)) AND (“Semantic interoperability”))) OR (((“data content”) OR (“data format”)) AND (“Semantic interoperability”))) OR ((“Semantic interoperability”) AND (standard)))
- Filters used: abstract, full text, and English

The research team first screened all the remaining articles by title and abstract from January to March 2023. After the first test reading, the researchers discussed the inclusion and exclusion criteria and coherence of the understanding. Researchers were blinded and performed the analysis independently based on the inclusion and exclusion criteria and then compared the results. Selecting the same alternative created a match. Choosing a different alternative or failing to recognize the category at all was considered a nonmatch. In data-model cases, discussion was needed for alignment, but no complex situations developed. During the first screening, after discussion by the research team, 71 articles were excluded from the review for the following four reasons: (1) EHR was not a key factor but a contextual factor in the original research setting; (2) the original research did not focus on semantic interoperability but on another level of interoperability; (3) the original study did not entail practical implementation goals, but the focus was predominantly theoretical or methodological; and (4) the original research was not a research article but, for example, a poster. The remaining 58 articles were sought for retrieval. For 4 articles, the full text was not available. To evaluate eligibility, full texts of the 54 remaining articles were read by the research team. At this point, 17 articles were excluded because the original research was out of scope, that is, semantic interoperability was not developed with practical goals for advancing the availability and use of interoperable patient data. In addition, 15 articles were excluded as the semantic interoperability case did not involve EHR use or development, 3 articles were excluded due to the absence of semantic interoperability altogether, and 5 more were excluded because they were not research articles. After agreeing upon the final exclusion within our research team, 14 articles were analyzed for semantic interoperability in EHRs. Our final inclusion criteria were grounded on our research questions: the research article should explore an EHR use or development case with the focus on semantic interoperability of clinical data. Preferably, the case would document the stage of interoperability development or use, expected or realized clinical benefits, semantic development goals, and aspects of interoperability to be implemented, as well as the method of application.

The extraction and documentation of the information from the research articles was informed by our research questions, the review framework (Figure 1), and by previous research literature. At this stage, previous reviews [16-19,21] were especially used in compiling our study framework (see Figure 1). Based on our framework, the documentation of the review analysis included elements of interoperability already identified in the search strategy. Consequently, it was necessary to investigate which documented elements are typically examined in research and with what methods they are applied in EHRs [8,16-18]. Moreover, we deemed it important to document how semantic interoperability is described in the clinical use context, consisting of various EHRs, clinical applications, registers, and other data resources. Lastly, the information documentation had to include not only the semantic implementation, use goals, or intended benefits but also practical goals or benefits in the clinical use context (see Figure 2). We defined and agreed upon the information documentation categories within our research team to conduct a well-grounded analysis for the review.

Figure 2. Flowchart of article identification, screening, and final inclusion. EHR: electronic health record.



Results

Contextual Results

We identified 14 articles describing semantic interoperability in EHRs, published between 2011 and 2022, as shown in Multimedia Appendix 1 [24-37]. The results revealed predominantly European advances in the study topic. Most (n=11, 79%) of the research cases were affiliated with different types of institutions in the European Union member states or in European Economic Area countries. One of the publications was coproduced by authors from Columbia and Germany, and the authors of another article represented organizations from the United States, South Korea, China, and Egypt. We decided not to limit the included studies to a certain geographical area but to analyze any potential use case for enabling the interoperability of EHRs.

Two of the reported research cases focused on patients with heart failure [24,30], 1 focused on patients with neurosurgical tumors [28], 2 focused on patients in cancer care [33,37], and 1 focused on patients with type 1 diabetes [31]. Other clinical use domains described were a prehospital unit at the site of an incident or during transfer to the emergency department and a hospital emergency care unit where prehospital patient documentation must be reassessed. A primary care–related case documented experimental laboratory test results of a population of 230,000 patients. Examples of older adult medication care and multiprofessional health care were part of our sample. Two articles described multipurpose clinical use of physician's notes

and tertiary care data. One article concerned the domain of clinical research using data from different EHR systems, and another described semantic aspects for retrieval of medication, laboratory test, and diagnosis-related data.

Although all studies concerned data from the EHRs, some studies included more detailed descriptions on data sources. Heart failure summaries containing clinical situation data and diagnoses (severity and certainty), as well as heart failure summaries covering clinical situations and symptoms data (a symptom's presence, absence, and severity), were represented in the sample. One study regarded clinical history, observations, and findings during tumor control. One study focused on histories of patients with diabetes and diabetes care plans (eg, insulin regimen, diet, and exercise plans) and patients' self-monitoring of vital signs, and 1 study used self-monitoring data on daily activities, side effects, and patient-reported outcomes. One article reported results around diagnosis and laboratory data; 1 article reported on medication, laboratory, and diagnosis data; and another article reported on neurosurgical imaging and laboratory data, although the starting point in the paper was diagnosis and medication data. The remaining 4 studies generally applied prehospital patient case data, emergency care–related EHR data, laboratory data, and diagnosis data.

Interoperability Results

In our sample, data were transferred and shared between different EHRs and clinical applications with no loss of data or changes in their meaning (Multimedia Appendix 2 [24-37]). Half (7/14, 50%) of the studies were aimed at developing semantic interoperability between different EHRs or within different EHR modules, such as a medication module in 1 EHR system. One case concentrated specifically on an EHR and a clinical application. Two articles reported results about the interoperability between EHRs and personal health records. Interoperability with the laboratory system and the EHR was the focus of study in 2 cases. Two studies reported advances in interoperability development between EHR and clinical research resources or a clinical registry. Regarding the state of development, the largest number of studies were categorized as "in development" (n=5, 36%) and "in use" (n=6, 43%). Two articles reported results regarding the testing phase, and the remaining study was in an implementation stage.

All articles reported clinical benefits of the selected approach to enhancing semantic interoperability. We identified 3 main categories of clinical benefits within the articles: increasing the availability of data for clinicians (n=6, 43%), increasing the quality of care (n=4, 29%), and enhancing clinical data use and reuse for varied purposes (n=4, 29%). The first category describes use cases where patient care would benefit from better availability of data. This was to be achieved by enhancing interoperable data and its transfer from clinical applications (eg, a laboratory system) to a central EHR and between EHRs to increase accessible data for making informed clinical decisions. These advances were in implementation to enhance the quality and effectiveness of care. Moreover, developing better access to health data and providing homogeneous access to heterogeneous data sets may facilitate resource effectiveness; patient management; and overall, the optimization of data for different purposes. The second category included benefits for the quality of care. The category had largely been implemented in EHRs already. Benefits entail better resource effectiveness and optimization of patient care planning and monitoring and better patient management, as well as the continuity of care based on interoperable and accessible health data that facilitates informed decision-making by clinicians. One of these cases documented improved patient safety based on interoperable health data across EHRs. The third category, enhancing clinical data use and reuse, included 2 use cases where data were used across EHRs. One use case described data transfer between an EHR and a national oncology registry, where interoperability enhanced data integration and redesign of the systems in use. The other 2 cases documented the evidence of data use, where better availability of data provided a means for developing new EHR integrated tools, such as clinical alerts, dynamic patient lists, and clinical follow-up dashboards. In summary, semantic development goals emphasized better access to data regardless of underlying standards and data structures or EHRs in use. The underlying assumption is that with better access to data, it is possible to facilitate better communication between professionals and the continuity of care.

In our analysis, semantic development goals were divided in 3 categories. All of these were closely coupled with the need to build usable and available data based on heterogeneous medical information that is accessible through various EHRs and databases, such as registers. Data harmonization and developing semantic interoperability between different EHRs or between EHRs and clinical application was the largest category (n=8, 57%). Enhancing health data quality through standardization (n=5, 36%) and developing EHR-integrated tools based on interoperable data (n=1, 7%) were the other identified categories. Semantic development goals were described as harmonizing data or otherwise processing semantically equivalent data across different medical domains and among different clinical data sources including EHRs and applications, thus facilitating clinicians' availability of health data. One case included the formalization of data with a semantic converter to increase the interoperability of data. In 2 research cases, the main semantic development goals concentrated on advancing the interoperability of EHR data and patient-generated data or sensor data to monitor the situation of patients who are chronically ill. Regarding data standardization, 1 research case reported increasing data quality as the semantic interoperability development goal. Standardized data content decreased information overload of clinicians. Through data standardization, it was possible to increase conceptualization and, thus, access to data within an EHR regardless of the underlying standards and data structures, by providing a semantic standardized layer to facilitate clinicians' data use, or by otherwise ensuring complete and coherent information with no errors due to the loss of meaning or context. One of these research cases documented improvements for system-level efficiency for EHR functions and integrated tools based on advances of semantic interoperability.

Features of semantic interoperability were described in all 14 articles. Most (9/14, 64%) of the analyzed cases incorporated

1 or more semantic aspects. In more detail, the aspects of semantic interoperability were described as follows: ontologies were the chosen aspect in 3 research cases, terminologies in 6 cases, classifications in 4 cases, various clinical documentation standards in 8 cases, and different data models in 10 cases. In this categorization, data model refers to various semantic model layers, namely, the use of various types of data models that include, for example, data content specifications, RIMs, and clinical information models depending on the development context. A dual model was discussed in 2 of the cases for the application of data models.

Closely related to the aspects of interoperability, several interoperability standard solutions were named. Named ontology solutions included a top-domain ontology for the life sciences (BioTopLite) in 2 cases, a HL7 Fast Health Interoperability Resources (FHIR) and semantic sensor network–based type 1 diabetes ontology for type 1 diabetes data, and a system of several ontologies to be used for building EHR interoperability. Systematized Nomenclature of Medicine Clinical Terminology was the common terminology application in 7 cases, whereas classification systems were applied in more heterogeneous ways. The following international classifications were named: *International Classification of Diseases, Tenth Revision*; *International Classification of Diseases, Ninth Revision, Clinical Modification*; The Anatomical Therapeutic Chemical Classification System; and Logical Observation Identifiers Names and Codes. One article documented national classification use. Applied health care–specific standards included the open standard specification in health informatics (openEHR; n=6), Digital Imaging and Communications in Medicine (n=1), HL7 FHIR (n=5), and the HL7 Clinical Document Architecture (n=2). Regarding data models or reference information models, several types were applied for distinct use environments. These included the Observational Medical Outcomes Partnership common data model, an EHR-specific data component model, the i2b2 common data model for data warehouse development, the HL7 FHIR RIM, and the EN/ISO 13606 standard–based model. Moreover, 1 case reported using openEHR as a data model reference.

The method for applying an interoperability framework or approach is related to the overall design of the data use purposes and the needs driving the semantic development. The chosen methodology for semantic development was based on ontology development or the application of an ontology framework in 4 research cases, data model–based development in 5 cases, archetype development in 1 case, and clinical data warehouse development to enhance access and processing of data in 1 case. In data model–based approaches, use cases document a method's capability in separating different semantic levels of development, that is, system level, application level, clinical user interface level, or patient information level. The reusability of data model–based semantic approaches and related methods were assessed for resource savings in time and cost in development projects and, thus, to justify the choice of the approach. For example, clinical knowledge model–based development may allow recycling archetypes that further promote semantic interoperability.

Discussion

Principal Findings

Our results are related to the main goals of semantic interoperability development, such as enabling patient data use regardless of which EHR the data originated from and by which terminologies, classifications, or other semantic features they are supported [16-19,21]. Regarding key elements of semantic interoperability, of the documented terminologies, Systematized Nomenclature of Medicine Clinical Terminology seemed to prevail as the dominant choice for clinical terminology [24-30]. For international classifications that are typically integrated into EHRs, a selection of well-established classifications was documented [25,26,31,32]. Likewise, several health care specific standards [24-26,28,31,33], ontologies [21,24,32,33], and data models [25,27,28,30-36] were presented, albeit in a relatively small sample in this study. One possible factor affecting the selection of interoperability features such as international standards may be open availability and the level of cost of the standard-specific resources and their deployment. Consequently, shared implementation experiences and recommendations from previous projects or from collaboration in international communities may promote and facilitate decision-making concerning future implementations.

Our review illustrates several approaches for building sematic interoperability. For ontologies and data models, based on the review, several layers may be deployed to address semantic interoperability development needs. For ontologies, deploying a system of ontologies seeks to bridge, for example, domain-specific ontologies and application-specific ontologies. In our sample, a case with a data model–based development approach enhanced the communication of clinical information with the application. The application was used by the patients in self-monitoring, and the EHR served as a clinical data repository to avoid the loss of meaningful information. In general, when applying data model–based approaches, a dual model or multimodel approach may be needed to address different semantic interoperability issues during development—from the clinician as an EHR user to the system transaction level.

Our review highlights several clinical benefits of semantic interoperability. Primarily semantic interoperability fulfills the need to support the implementation of applications that enhance the continuity of care and ensure access to safe and high-quality health care. The reported clinical benefits of developing semantic interoperability reflect well common international goals [2,3,5]. The results in our sample show that an evident goal driving the development in these studies is the following assumption: through increased access to patient information, better quality and outcomes in care can be achieved [24,26,27,33,37]. Better communication based on easily accessible data across EHRs is facilitated not only between clinicians but also between professionals and patients [28,34,35]. Further advances are related to efficiency and subsequent economic factors, for example, reducing the clinicians' workload for documenting and evaluating extensive patient data, to avoid information overload and support multiprofessional care

[26,31-33,35]. In addition, interoperable patient data provide opportunities for a wide range of EHR-related clinical development, for example, regarding decision-making support, other EHR integrated tools, clinical research, or other types of secondary use [25,28-31,33,36]. Essentially, the interoperability cases in our review demonstrated a well-documented selection of development goals in EHRs, including considerations of patient-generated, self-monitoring data and related interoperability features.

Finally, when reflecting on the goal-related semantic interoperability results, there is evidently not one universal approach available to tackle all interoperability-related needs and challenges. One reason for this is that interoperability is to be achieved in diffuse and disconnected clinical care settings and in registry data use across borders. However, regulations and international recommendations can support the choosing of common tools and standards for building interoperability for patient data generated in various EHRs and clinical applications. This may be the strongest selling point for evolving international frameworks, such as the EHDS regulation proposal. If adopted, unified toolkits of the most crucial means can be achieved for building international eHealth interoperability. Through these mechanisms, common solutions and standards can be agreed upon to remedy existing inconsistencies and avoid possible future imparities that hinder the realization of the common goals. It is noteworthy that all member states have steps to take to meet the international requirements with a country-specific road map to achieve the common goal [3,5]. Moreover, it would require cooperation to align on which level of interoperability should be reached when the operating environment consists of a diverse set of clinical practices and related data needs, such as between public and private care or between primary and specialized care. Additionally, it may be worthwhile to consider whether instead of promoting a single approach, semantic interoperability requirements should be assessed through several levels of semantic requirements, such as standards, data models, classifications, and terminologies. Moreover, developing the necessary skills and increasing capabilities is an essential component of this development.

Specifically, regarding European development, one of the main goals is to support the use of health data for better health care delivery and better research. The comprehensive and timely availability of EHR data is known to improve the quality of care and patient safety [26,38]. Concurrently, the lack of not only technical or organizational but also semantic interoperability has been recognized as one of the barriers for the cross-border exchange of health data [2-8]. Therefore, commonly recognized interoperability approaches and standards for the harmonization of semantic interoperability are needed.

Limitations

Our goal was to ensure that we did not overlook any important studies and to minimize any potential biases by conducting a thorough and comprehensive search of the available literature. However, it is worth noting that our search was limited to a single database, PubMed. Nevertheless, recent literature suggests that PubMed can serve as a primary search tool. It possesses the necessary capabilities for systematic reviews, including the ability to formulate and interpret queries accurately, as well as ensuring search reproducibility. It is important to acknowledge that even a well-performing system such as PubMed might not always yield the desired results in different scenarios [23]. Our data set was limited by a small sample size of 14 articles. Therefore, findings can only be regarded as descriptive in nature. Relatively large heterogeneity in study environments and selected research approaches limit us from drawing strong conclusions. Despite these limitations, this review demonstrates potentially feasible approaches for promoting semantic interoperability toward harmonized approaches. Additional real-world studies accounting for semantic interoperability are needed to reinforce understanding of the most promising, scalable examples such as international reference models (eg, HL7 RIM). Moreover, it was challenging to determine the "development status" category for certain studies. This was due to varying levels of details in the study reports, where some of the studies provided a wealth of detail, whereas some were more restricted in their scope.

Suggestions for Future Research

Future research directions are 2-fold from the current development perspective. First, evidence-based recommendations on semantic interoperability features, for example, data models and terminologies, are needed. Initially, the applicability of international data models and standards such as HL7 V2 might be evaluated. Second, more experiences of interoperability development should be reported in the peer-reviewed research literature to contribute evidence around successful and not so successful experiences instead of leaning solely on individual expert opinions. Presumably, due to the evolving implementation status of semantic interoperability cases illustrated in the research literature, systematic research–based evaluation of benefits and outcomes is still scarce.

Conclusions

We conclude that based on our review, the research literature highlights valuable aspects in promoting semantic interoperability in terms of the efficiency and feasibility of solutions integrated in EHRs and possibly for enhancing care. However, when heading toward semantic harmonization, more data, pilot experiences, and analyses are needed to assess how applicable the chosen specific solutions are for the standardization and semantic interoperability of patient data. Instead of promoting a single approach, semantic interoperability could be assessed through several levels of semantic approaches. A dual model or multimodel approach is usable to address different semantic interoperability issues during development—from the clinician as an EHR user to the system transaction level. Since interoperability is being implemented in complex and disconnected clinical care environments, choices should be well prepared and justified to meet sustainable and long-term outcomes. From that point of view, it is possible to outline future directions in selecting semantic interoperability approaches for the realization of the international patient data–related goals.

Abstract

Background: Hypoxia is an important risk factor and indicator for the declining health of inpatients. Predicting future hypoxic events using machine learning is a prospective area of study to facilitate time-critical interventions to counter patient health deterioration.

Objective: This systematic review aims to summarize and compare previous efforts to predict hypoxic events in the hospital setting using machine learning with respect to their methodology, predictive performance, and assessed population.

Methods: A systematic literature search was performed using Web of Science, Ovid with Embase and MEDLINE, and Google Scholar. Studies that investigated hypoxia or hypoxemia of hospitalized patients using machine learning models were considered. Risk of bias was assessed using the Prediction Model Risk of Bias Assessment Tool.

Results: After screening, a total of 12 papers were eligible for analysis, from which 32 models were extracted. The included studies showed a variety of population, methodology, and outcome definition. Comparability was further limited due to unclear or high risk of bias for most studies (10/12, 83%). The overall predictive performance ranged from moderate to high. Based on classification metrics, deep learning models performed similar to or outperformed conventional machine learning models within the same studies. Models using only prior peripheral oxygen saturation as a clinical variable showed better performance than models based on multiple variables, with most of these studies (2/3, 67%) using a long short-term memory algorithm.

Conclusions: Machine learning models provide the potential to accurately predict the occurrence of hypoxic events based on retrospective data. The heterogeneity of the studies and limited generalizability of their results highlight the need for further validation studies to assess their predictive performance.

Introduction

A key factor in risk assessment for sequelae and mortality in hospitalized patients is hypoxia. It describes the decreased availability of oxygen in specific body regions (tissue hypoxia) or in the body as a whole (general hypoxia) [1-3]. To prevent general hypoxia and to detect deterioration quickly, hypoxemia monitoring is commonly performed using pulse oximetry as a continuous and noninvasive assessment, especially in the intensive care unit (ICU) and operating room (OR) [4]. Hypoxemia is defined as an abnormally low level of blood oxygen. In addition to pulse oximetry, it can be assessed through an arterial blood gas analysis or imaging techniques, which can additionally serve as reliable indicators of subsequent tissue damage [3]. A multinational, multicenter study including 117 ICUs found a hypoxemia prevalence of more than 50% among all ICU patients [5]. The severity of hypoxemia was shown to be a direct risk factor for mortality in patients with hypoxemia. Being able to validly assess the individual risk of future hypoxemic and ultimately hypoxic events is therefore highly relevant.

To determine the risk or stage of a disease, artificial intelligence (AI) has been increasingly introduced into clinical routine in recent years to exploit underlying causal mechanisms that may not be accessible to humans. As a prime example, machine learning (ML) as a discipline of AI is being successfully used

for cancer tissue classification in medical imaging [6,7]. ML is also already being applied for prognostic purposes, for example, in the examination of patient characteristics to identify an increased risk of deterioration tendencies such as atrial fibrillation and of developing sequelae of diabetes mellitus or hereditary diseases [8-10].

Efforts to date of using ML to predict hypoxic events are being conducted in a variety of settings and demonstrate diverse approaches and methodologies. Studies differ significantly in terms of the patient population assessed, definition of prediction outcome, features used to predict hypoxia, and ML algorithms used, thus increasing the difficulty to generalize the conclusions of individual studies. It is therefore challenging to compare and evaluate these studies comprehensively.

This review aimed to provide a systematic and structured overview of the existing approaches to predict hypoxic events in the hospital setting. Our specific objectives were to summarize the different populations, model details, and prediction performance to capture the current state of available models; identify gaps and limitations; highlight promising approaches and methodologies; and provide guidance for future research in this area.

Methods

Protocol

This review was reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement (Checklist 1) [11]. The protocol was registered in the International Prospective Register of Systematic Reviews (PROSPERO) prior to data extraction (reference CRD42023381710).

Search Strategy

Relevant literature was searched for using Ovid with Embase and MEDLINE, Web of Science, and Google Scholar. Although the prior 2 databases were searched via their web query interface, Google Scholar was searched using the software Publish or Perish, as it allows for more complex queries [12].

Publications on the topic of hypoxia prediction using ML were searched by creating 2 sets of search terms, with the first set addressing hypoxia (including hypoxemia) and the second set addressing ML. With the identified search engines, the intersection of these 2 groups was then searched for, adjusting the syntax according to the search logic of the respective search engine. If Medical Subject Headings or thesaurus entries were available, the selected terms were included in the search logic accordingly. For the searches using Ovid and Web of Science, the search results were filtered to only include studies that did not use wearables for data collection and that were published in the English and German languages. Those filters were not applicable for the search of Google Scholar using Publish or Perish.

The selection and deduplication process was performed using Covidence (Veritas Health Innovation Ltd), with undetected duplicates removed by hand [13]. The search results of all databases were included, and duplicates were removed. The abstracts of the remaining results were independently screened by 2 reviewers. Results that met the selection criteria were reviewed in their entirety for the assessment of eligibility by 2 reviewers. In addition, references of the included studies were also screened for studies that meet the inclusion criteria and were subsequently included where appropriate. The search strategy was developed by 1 team member and reviewed by another with expertise in conducting systematic reviews. The detailed search strategy can be found in Multimedia Appendix 1.

Selection Criteria

Primary outcomes were model features, definition of the prediction end point, and predictive performance. Studies developing ML models to predict hypoxia or hypoxemia in continuously monitored human inpatients were included. Both studies of patients who were mechanically ventilated and spontaneously breathing were included. Hypoxia could be a main outcome or an auxiliary goal.

Studies that assessed hypoxia only in specific tissues were excluded, as this review addresses the prediction of general hypoxia as an important indicator of critical illness for risk stratification and early detection of patients at risk of acute health deterioration. Additionally, studies focusing on a population <18 years of age were not included, since the distinct etiologies, risk factors, and clinical presentations of hypoxia in pediatric patients may limit the generalizability of the findings to the population of adult inpatients.

The definition of the end point of hypoxia prediction (eg, specific oximetry thresholds or time frames of prediction) was left unspecified due to the expected heterogeneity in the approaches. The patient population of the included studies was not limited to a specific hospital setting or ward.

Data Extraction and Risk of Bias

Data extracted included the data source; sample size and setting; model variables; prediction end point and time frame; type of model; and the predictive performance of each model, usually expressed as classification measures such as sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), or area under the receiver operating characteristics (AUROC). Missing values of performance measures and summary data influenced the risk-of-bias assessment.

A qualitative synthesis of the included studies was conducted. For this purpose, an overview of all studies was provided in a narrative summary by categorizing them into subgroups based on the population, model features, model types, and setting. For each study, the model with the highest performance according to performance metrics was selected to summarize AUROC, sensitivity, specificity, PPV, and NPV as the most reported performance measures. In the case of studies that examined multiple prediction outcomes, the outcome definition that is the most similar to those of the other studies was chosen for reporting. For studies reporting 1 performance value per patient, a mean value was calculated for each measure. Because of the heterogeneous study designs and characteristics of the data used, as well as missing summary data of model performances, conducting a meta-analysis was not feasible.

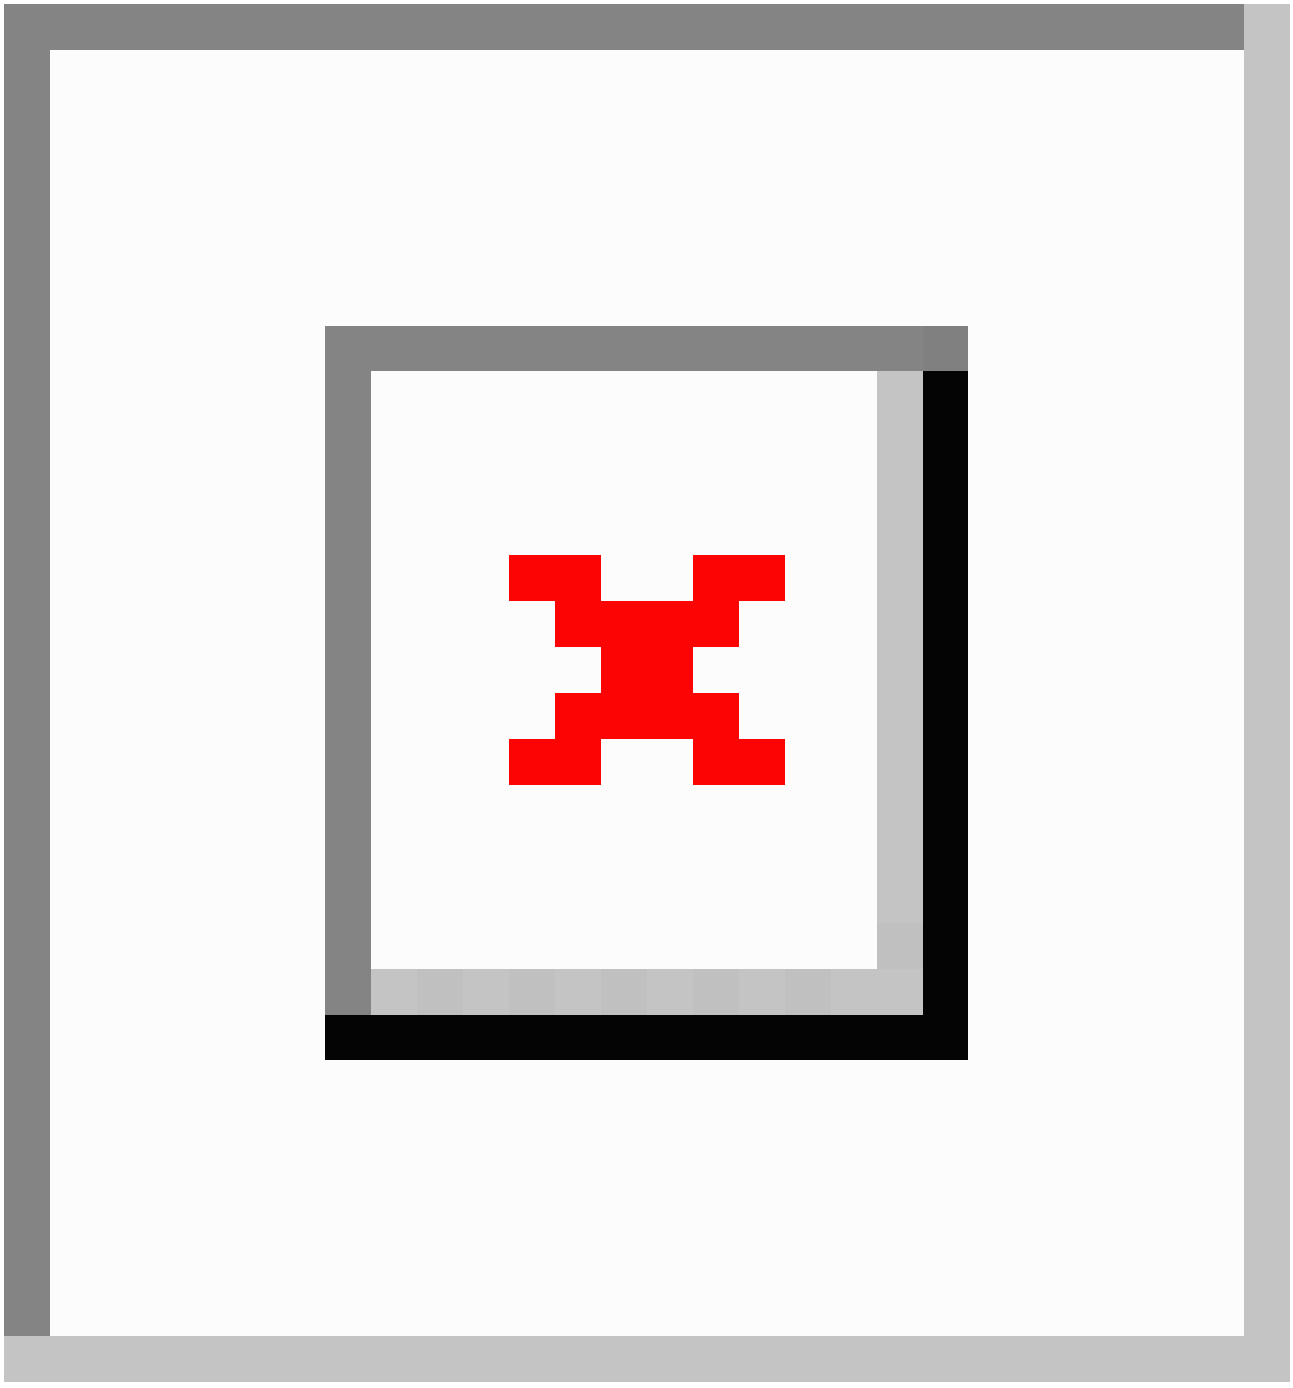
To assess the risk of bias, quality, and applicability of the studies included, Prediction Model Risk of Bias Assessment Tool (PROBAST) was used [14]. This tool is specifically designed to investigate the quality of prediction models and has become increasingly prevalent in systematic reviews in recent years. Assessment outcomes were evaluated based on 4 segments—participants, predictors, outcome, and analysis—and were determined by a comprehensive questionnaire. Risk of bias was rated as high, low, or unclear. If 1 domain suggested a high risk of bias, the overall risk of bias for that study was considered high. The assessment was conducted by a single researcher, with a second researcher reviewing the process independently.

Results

Literature Search

The initial search retrieved a total of 3734 studies (Figure 1). After removing a total of 700 duplicates, title and abstract screening identified the full texts of 31 studies for the assessment of eligibility. Of these, 19 studies were excluded due to not being a full study (n=6), not assessing a hypoxia outcome (n=4), not using machine learning (n=3), inability to obtain the full text (n=2), having an outpatient setting (n=2), having a pediatric patient population (n=1), and being in the Chinese language (n=1). The remaining 12 studies were included in the review.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.



Study Characteristics

Overview

Table 1 presents the characteristics of all included studies and gives an overview of the best-performing model in each study, divided into conventional ML and deep learning models for studies including both. The studies were conducted in the United States [15-22], China [23,24], Germany [25], and the United Arab Emirates [26]. Half (6/12, 50%) of them were published after 2020 [15,16,19,21,22,26]. In 3 (25%) of the 12 studies, the prediction of hypoxia was a side or auxiliary goal [17,19,21], whereas it was the main study aim for the other studies.

Table . Study characteristics of the reviewed studies (n=12). The model with the highest performance in each study is reported. For studies using both conventional machine learning and deep learning models, each best-performing model is reported. For studies examining multiple prediction outcomes, the outcome definition that is the most similar to those of other studies was chosen for reporting. For studies reporting 1 performance value per patient, a mean value was calculated.

[a]SpO_2: peripheral oxygen saturation.

[b]LSTM: long short-term memory.

[c]PPV: positive predictive value.

[d]SaO_2: arterial oxygen saturation.

[e]GBT: gradient boosted tree.

[f]AUROC: area under the receiver operating characteristics.

[g]Lin: linear regression.

[h]LR: logistic regression.

[i]ANN: artificial neural network.

[j]XGB: extreme gradient boosting.

[k]RNN: recurrent neural network.

[l]GBM: gradient boosting machine.

[m]PaO_2: partial pressure of oxygen.

[n]FiO_2: fraction of inspired oxygen.

[o]NN: neural network.

[p]RF: random forest.

[q]HR: heart rate.

[r]BR: breath rate.

[s]SBP: systolic blood pressure.

[t]DBP: diastolic blood pressure.

[u]AG: anion gap.

[v]CNN: convolutional neural network.

[w]MAE: mean averaged error to the range of values.

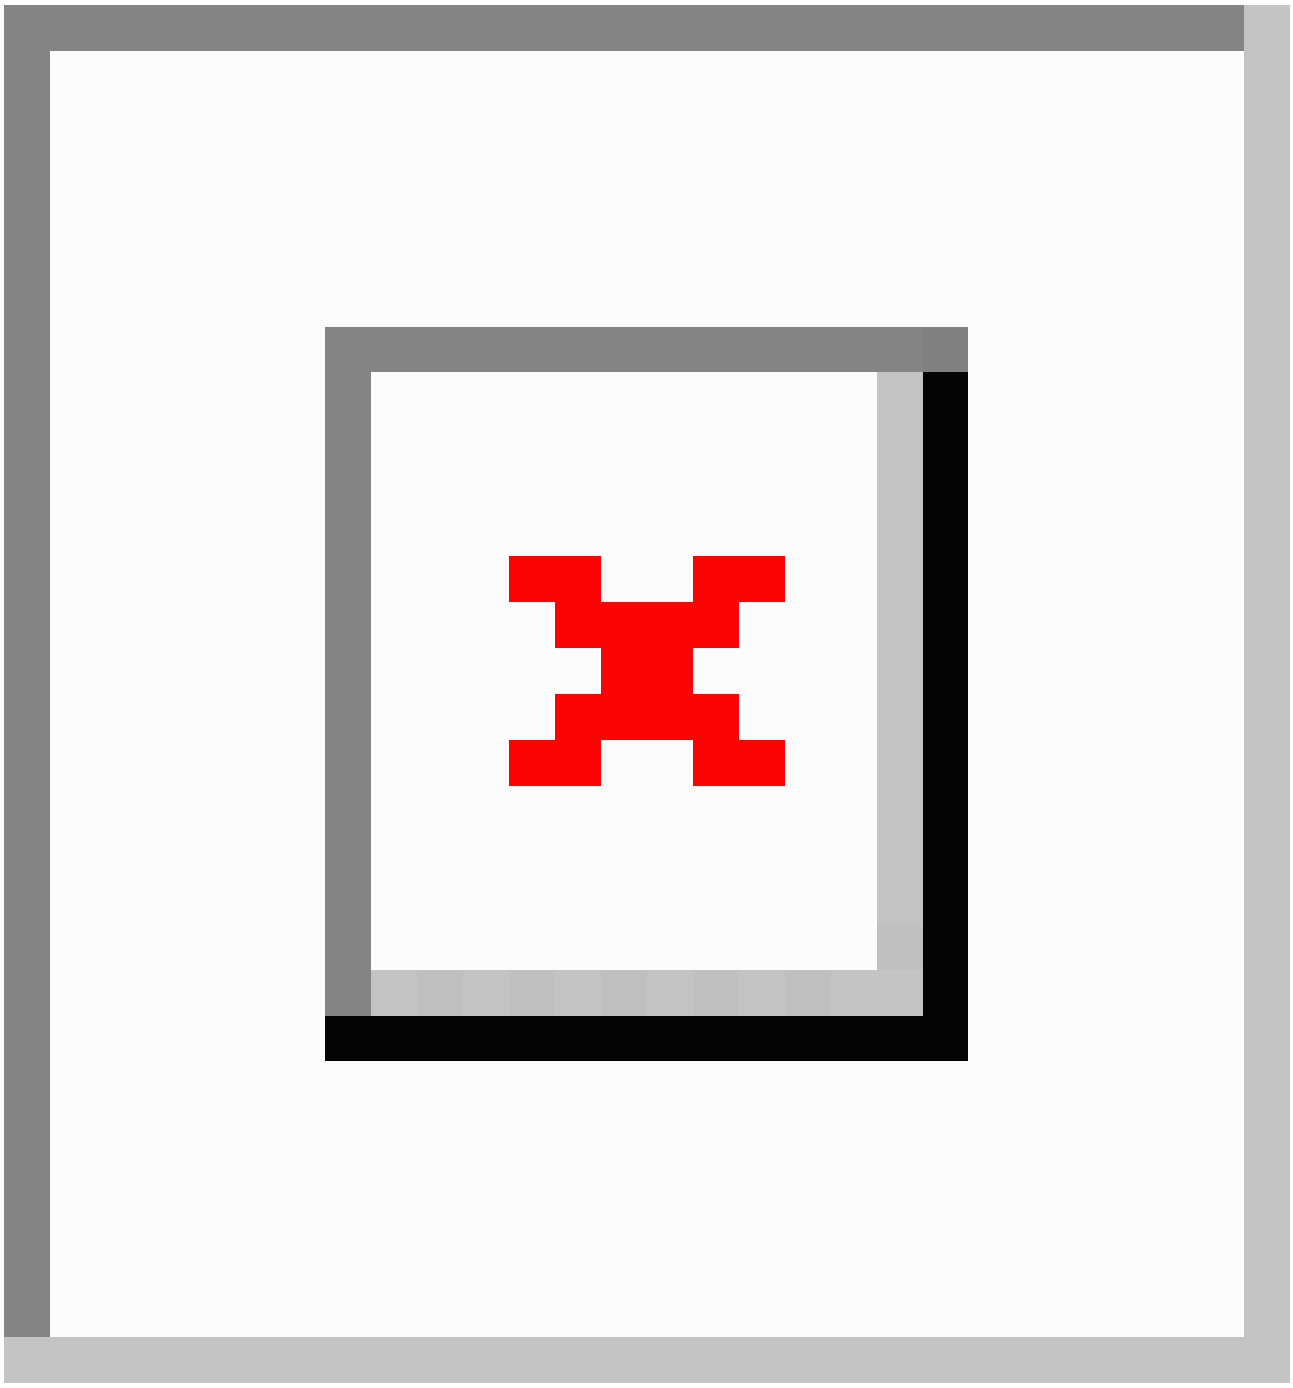
Data Sources and Population

Most studies (9/12, 75%) analyzed a large sample size of 500 or more patients [15,16,18-22,25,26]. Data from the publicly available databases Medical Information Mart for Intensive Care and eICU Collaborative Research Database were used in 4 of the studies [15,16,21,22], whereas 3 studies relied on data collected via an anesthesia information management system (AIMS) [16,18,20]. AIMSs are widely adopted hardware and software solutions that are integrated into a hospital's electronic health record system and are used to manage and document a patient's perioperative measurements [27,28]. The studies were set in the OR (n=5) [16,18,20,23,24], the ICU (n=3) [15,21,22], and mixed or general care units (n=4) [17,19,25,26]. Of the 12 studies analyzed, 10 (83%) did not include patients with COVID-19 [16-25], whereas the remaining 2 (17%) studies either were performed only on patients who tested positive for COVID-19 or were externally validated on a COVID-19 cohort [15,26].

ML Model Specifics

Figure 2 [15-26] gives an overview of the models and the number of variables used in each study. Exclusively conventional ML algorithms were applied in 5 of the identified studies [16,17,20,22,23], whereas 7 studies included deep learning algorithms [15,18,19,21,24-26]. Models based on logistic regression were used most often (n=4) [18,21-23], followed by artificial neural networks (n=3) [21,24,25].

Figure 2. Machine learning (ML) methods used by each study. ML methods (upper half) in gray: conventional ML; ML methods in black: deep learning. Studies are sorted by the number of clinical variables used. Studies in blue: 1 clinical variable; studies in green: 2-5 clinical variables; studies in yellow to red: >5 clinical variables. ANN: artificial neural network; Autoreg: autoregressive model; CNN: convolutional neural network; DTW: dynamic time warping; GBM: gradient boosting machine; GBT: gradient boosted tree; kNN: k-nearest neighbor; Lin: linear regression; LR: logistic regression; LSTM: long short-term memory; RF: random forest; RNN: recurrent neural network; SVM: support vector machine; XGB: extreme gradient boosting.



The number of clinical variables included ranged from 1 to over 65 different variables. The prediction of hypoxic events was based solely on prior peripheral oxygen saturation (SpO_2) values in 3 studies [15,17,18], whereas 4 studies used 2 or 3 clinical variables as input [21,23,24,26]. The remaining 5 studies relied on at least 6 variables [16,19,20,22,25]. The most frequently used variable sources were oximetry measurements (9/12, 75%) [15-22,25] and static patient characteristics such as age (5/12, 42%) [16,19,20,23,25]. Additionally, a single study relied on diagnostic images of the chest to make predictions [26].

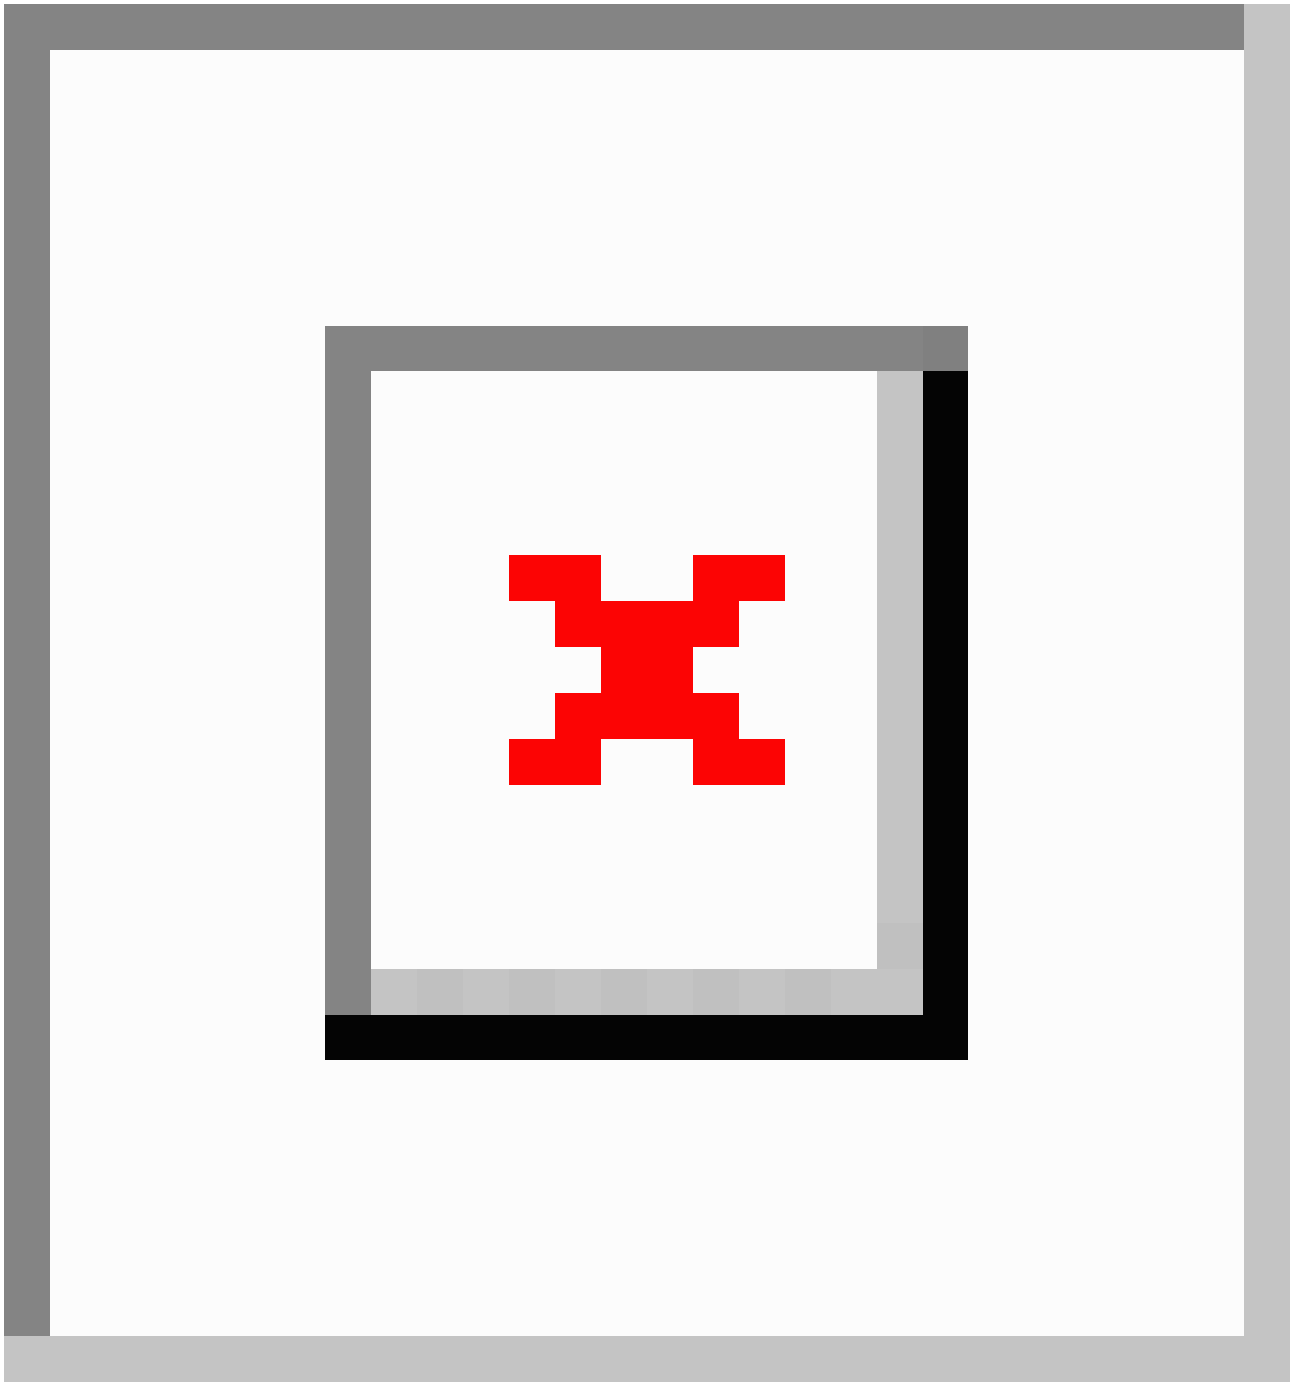
The prediction end point was defined by a threshold of SpO_2 between 89% and 92% for most of the studies (7/12, 58%) [15,17-20,23,24]. Thresholds of the partial pressure of oxygen, the arterial oxygen saturation, or the ratio of partial pressure of oxygen to the fraction of inspired oxygen were used in 3 other studies [16,21,22]. The remaining 2 studies assessed the presence and severity of hypoxia as defined by expert annotations and predicted functional markers of hypoxia, respectively [25,26]. Defined time frames for prediction included the length of a certain procedure [21,23-25], any time after

extubating [22], and a set time window of 5 to 30 minutes [15-18,20].

Performance

Most of the 12 studies reported sensitivity (n=9, 75%), specificity (n=8, 67%), or AUROC (n=9, 75%) as classification measures. Other performance indicators were PPV, NPV, area under the precision-recall curve, accuracy, and F_1-score. The most frequently reported performance measures of the best-performing model in each study are summarized in a heat map (Figure 3 [15-26]). The reported performance measures of 1 study were based on 10 individual patients since the focus of the study was to propose a performance metric and therefore have limited informative value [17]. One other study only reported the proportion of the mean averaged error to the range of values [26].

Figure 3. Heat map of performance measures, sorted by AUROC. The performance of the best-performing model in each study is presented. In the case of studies that examined multiple prediction outcomes, the outcome definition that is the most similar to the other studies was chosen for reporting. For studies stating 1 performance value per patient, the metrics represent the mean value. For 3 of the included studies, hypoxia prediction was not the main study aim [17,19,21]. The reported performance measures of 1 study were based on 10 individual patients and therefore have limited informative value. One study only reported the proportion of the mean averaged error to the range of values. AUROC: area under the receiver operating characteristics; NPV: negative predictive value; PPV: positive predictive value.



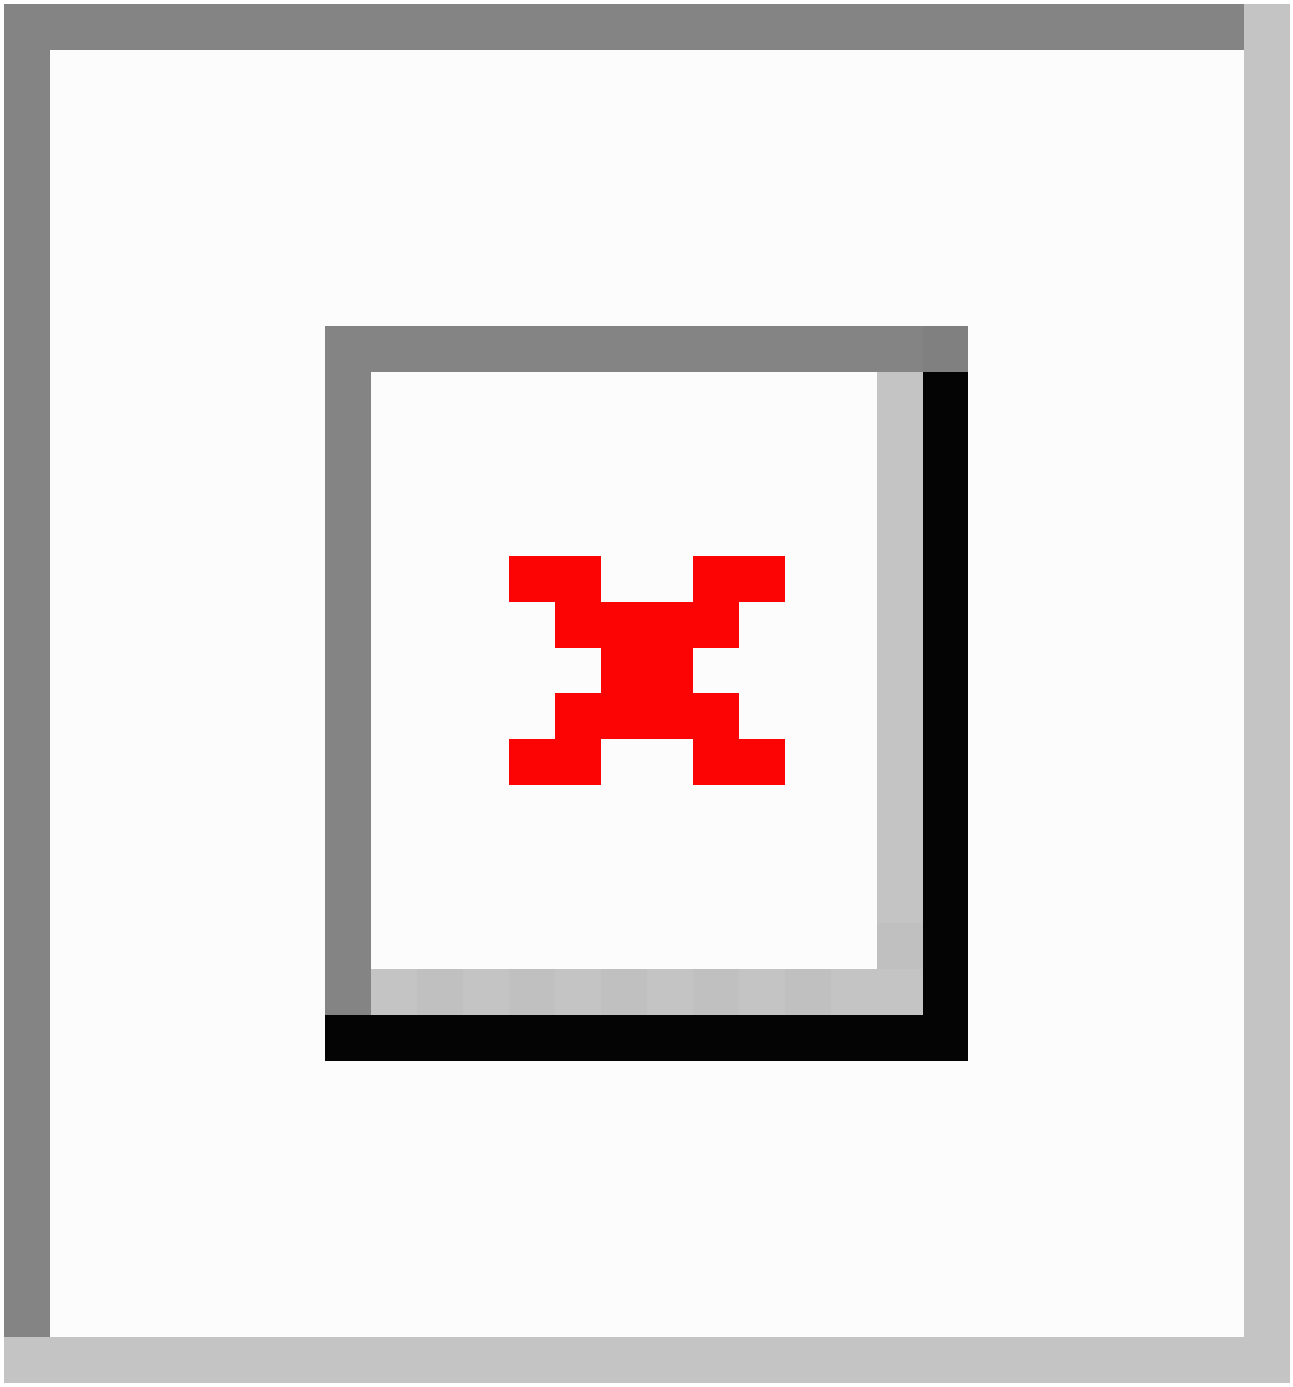
Of the 9 studies reporting AUROC, 8 (89%) showed a value higher than 0.75 [16-18,20-24]. This included 3 studies that showed a significant trade-off between sensitivity and specificity [17,21,24]. The overall performance was moderate or high with respect to classification metrics, both in studies performing the prediction task as the main study aim and in studies predicting hypoxia as a side or auxiliary goal. In studies drawing a comparison to anesthesiologist decisions, the prediction models alone or anesthesiologists using those models outperformed anesthesiologists without access to the model [18,20].

Deep learning and conventional ML are not directly comparable as they are not being applied on the same data set and the performance metrics are not consistently reported. However, in all studies comparing the 2 approaches, deep learning models showed similar or better performance than conventional ML models considering classification metrics [18,19,21,25]. Additionally, models only using prior SpO_2 data as a variable tended to outperform models using more clinical variables [15,17,18]. Two (67%) of the 3 studies only using prior SpO_2 data applied a long short-term memory (LSTM) algorithm, 1 of which was able to predict the detailed trend of the SpO_2 waveform [15,18]. Multitask learning for the prediction of related end points was implemented in 1 study, showing improved performance with an increasing number of tasks [19]. Approaches for providing explainability of their prediction outcome were presented in 2 studies, with 1 offering a real-time prediction tool displaying the contributing factors of an individual patient's hypoxemia risk within the next 5 minutes [16,20].

Risk-of-Bias Assessment

PROBAST was used to assess the risk of bias and applicability of each study. In the case of external validation, the assessment for that validation was performed separately. An overview of the overall and segment ratings of all 12 studies analyzed are shown in Figure 4. The overall risk of bias was rated as high or unclear for most of the studies (10/12, 83%) [16-21,23-26]. Unclear or high risk of bias ratings were mainly due to missing details of the procedure as well as unclear or unfitting timing of predictors or outcomes. External validation was only performed in 4 of the studies [15,16,19,21], whereas the other 8 studies relied on internal validation, primarily using random split samples and cross-validation [17,18,20,22-26].

Figure 4. Risk-of-bias assessment for all studies (n=12) based on 4 segments. The graph shows the number of studies with low, high, and unclear risk of bias by the author's assessment using PROBAST (Prediction Model Risk of Bias Assessment Tool).



Discussion

Principal Findings

In this systematic review, we identified and summarized 12 studies predicting hypoxic events or markers for hypoxia. The approaches proved to be highly diverse both in their assessment and definition of a hypoxic outcome as well as in the variables and model types used. Therefore, the comparability between studies was limited by the high variability of approaches, such as the variety of settings involving different influences on blood oxygen saturation (eg, sedation during surgery).

The data used to develop the models were primarily obtained from publicly available databases or directly from hospitals' AIMSs or electronic health record systems. Settings for the prediction included the OR, ICU, and general care units. The implemented ML models were based on both conventional ML and deep learning methods and assessed prediction end points defined as a threshold for blood oxygen measurements for most studies. Clinical variables used included patient characteristics, vital signs, and laboratory data. Blood oxygen data were the most applied model variables for hypoxia prediction.

The overall predictive performance of the presented models was moderate or high across the various settings. Deep learning approaches showed similar or better performance than

conventional ML approaches within the same studies. Models predicting hypoxia solely based on prior oximetry data tended to outperform models using more variables as inputs, with most of these studies using an LSTM algorithm.

The demonstrated trade-off between sensitivity and specificity of model performance highlights that it may be difficult to achieve both at the same time, especially when predicting medical events. This is a major caveat that holds true for a broad variety of diagnostic tests in medicine, such as D-dimers in investigating venous thromboembolism [29]. High specificity but low sensitivity, as demonstrated by 2 of the models, might, for example, result from missing relevant variables or an insufficient number of outcome events due to small sample sizes. An algorithm with high specificity may help to reduce unnecessary interventions, potentially leading to cost savings and minimizing patient inconvenience. However, in practice, an algorithm with that trade-off does not reliably detect patients with hypoxia who require immediate attention and may therefore be more appropriate as a decision support tool rather than a stand-alone diagnostic tool.

High sensitivity but low specificity on the other hand can, for example, be caused by the inclusion of variables that are highly associated with the presence of hypoxia but are not specific to hypoxia alone, or by the model being too sensitive and thus detecting subtle changes in nonhypoxic cases that are incorrectly classified as hypoxic. Practically, such a model could result in overalerting, disqualifying it for clinical application.

The informational value of many of the studies presented was limited due to a lack of external validation. In addition, more precise classification performance metrics were often not provided, thus not allowing for a meta-analysis. Unclear ratings were mostly due to missing information, particularly in the analysis segment. Comparability between studies was limited by the high variability of approaches, such as the variety of settings involving different influences on blood oxygen saturation (eg, sedation during surgery).

Applicability and Future Opportunities

The successful prediction of hypoxic events within a time frame of 5 or even 30 minutes into the future demonstrates the ability to provide sufficient lead time for crucial treatment interventions. Hence, these results suggest the potential of developing a helpful prediction tool, applicable in clinical practice, which complements the assessment of nurses and clinicians. Such a tool could be extended by a presentation and visualization of individual factors influencing the predicted outcome of hypoxia, as demonstrated by Lundberg et al [20]. The approach to make the model more understandable is useful both for more nuanced therapy strategies and for the general usability and acceptance of an ML tool for the prediction of hypoxia in the clinical setting.

While models with many features might have higher accuracy and might be able to capture more detailed and complex relationships between the features and the outcome of hypoxia, they also come with a higher complexity for use and are prone to overfitting [30]. Given the intended use of a predictive algorithm for making timely decisions that have immediate impact on the health status of patients, complex models with excessive features could impede their implementation in clinical practice. Additionally, utility might be reduced by patients missing 1 or more of these features. Therefore, the prediction results of LSTM models based only on previous SpO_2 values provide a foundation for further development and refinement of models using only a few, readily available, and noninvasive respiratory variables.

The results of Lam et al [19] suggest that multitask learning may contribute to higher predictive performance on related respiratory outcomes. Therefore, an approach for parallel prediction of several relevant intensive care parameters could provide a basis for further exploration. Opportunities for combined prediction include predictive models for the necessity of changes in ventilation, in airway pressure, or for increased risk of ventilation failure [31-33]. The prediction of hypoxia could also be embedded in a more general early warning score for related outcomes, for which ML mechanisms are already being applied [19,34-36]. In addition, the development of ML prediction models in a clinical context should include consideration of recent advances for the prediction of other unrelated health parameters and outcomes to avoid a complex system of different prediction systems, thus limiting the applicability and acceptability of these efforts. Forthcoming studies in this area should strive to accurately report performance details of their models, as well as to consistently define the end point of the prediction, to allow comparison with other approaches.

Limitations

This review focused on studies predicting hypoxic or hypoxemic events and therefore did not include studies predicting related outcomes (eg, blood oxygen saturation) without stating that aim of prediction. The comparability of predictive performance among the included studies was limited due to substantial differences in methodology, variables, and end point definition, precluding a meta-analysis from being conducted. An additional challenge arose from the fact that some studies, while including hypoxia predictions, did so as an auxiliary objective and not as their primary focus. Therefore, we focused on a qualitative summary and on demonstrating the variety of approaches taken. The generalizability of the results presented might be further restricted by the countries of origin being limited to the United States, Europe, and Asia.

Conclusion

Despite the large methodological variance of the studies presented, this review shows promising approaches for the prediction of hypoxia status, a factor that is highly informative for changes to a patient's state of health. Future studies must aim to improve the external validation of the predictive performance and, thus, verify the generalizability of the results to additional data sets. The applicability of validated predictive models for hypoxia risk should be proven by prospective studies in clinical practice.

Abstract

Background: Diabetes mellitus prevalence is increasing among adults and children around the world. Diabetes care is complex; examining the diet, type of medication, diabetes recognition, and willingness to use self-management tools are just a few of the challenges faced by diabetes clinicians who should make decisions about them. Making the appropriate decisions will reduce the cost of treatment, decrease the mortality rate of diabetes, and improve the life quality of patients with diabetes. Effective decision-making is within the realm of multicriteria decision-making (MCDM) techniques.

Objective: The central objective of this study is to evaluate the effectiveness and applicability of MCDM methods and then introduce a novel categorization framework for their use in this field.

Methods: The literature search was focused on publications from 2003 to 2023. Finally, by applying the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) method, 63 articles were selected and examined.

Results: The findings reveal that the use of MCDM methods in diabetes research can be categorized into 6 distinct groups: the selection of diabetes medications (19 publications), diabetes diagnosis (12 publications), meal recommendations (8 publications), diabetes management (14 publications), diabetes complication (7 publications), and estimation of diabetes prevalence (3 publications).

Conclusions: Our review showed a significant portion of the MCDM literature on diabetes. The research highlights the benefits of using MCDM techniques, which are practical and effective for a variety of diabetes challenges.

Introduction

Overview

Diabetes mellitus is a chronic disease that is characterized by impaired insulin production and action [1]. According to the etiopathology of diabetes, the 3 most common clinical categories are distinguished: type 1 diabetes, type 2 diabetes (T2D), and gestational diabetes mellitus [2,3]. In recent decades, diabetes prevalence has increased in both adults and children around the world. By 2035, there will be an estimated 592 million people worldwide with diabetes [4]. By 2040, this number is expected to rise to 642 million [5], and by 2045, there will be 783.2 million cases of diabetes worldwide [2]. According to the global

2021 findings of the International Diabetes Federation (IDF), 537 million adults are living with diabetes, and 3 in 4 of them reside in low- and middle-income countries. In 2021, a total of 6.7 million people died of diabetes, equating to 1 death every 5 seconds. The expenditure on diabetes-related health care is at least US $966 billion, and it has increased up to 316% over the last 15 years [2].

Diabetes is a chronic condition requiring continuous medical care and patient education to prevent severe complications and long-term risks. Managing diabetes involves addressing various aspects of the patient's health, including blood glucose monitoring, monitoring and managing carbohydrate intake, regular engagement in physical activity, and medication management. By understanding the disease's nuances and recognizing when it might become severe, people can take steps to protect their well-being. Thus, faster diagnosis of diabetes and its potential complications is crucial for both patients and health care providers [6]. General practitioners faced a significant problem when diagnosing diabetes, partly because patients displayed a wide range of signs and symptoms. This complex clinical environment confused general practitioners and changed the diagnostic procedure into a multiobjective health care decision-making challenge [7].

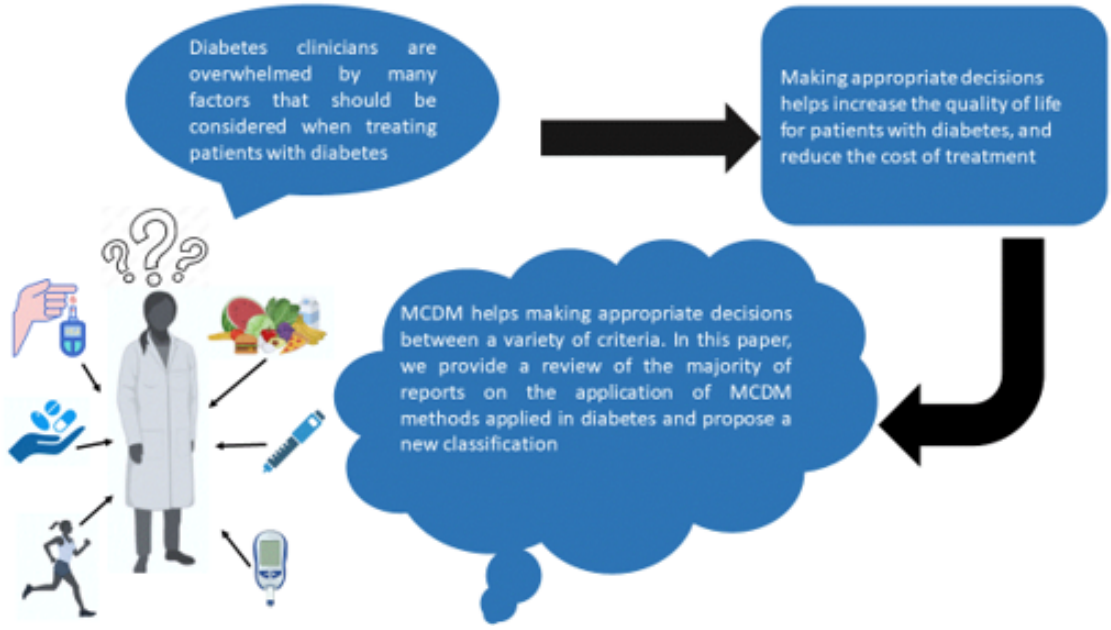
In addition to making informed decisions about the patient's health, endocrinologists and general practitioners should carefully assess various factors, including lifestyle choices, dietary habits, daily physical activity levels, insulin requirements, and the patient's willingness to embrace self-management technologies such as insulin pumps or pens, smart bracelets, continuous glucose monitoring, and mobile apps [8]. This comprehensive evaluation enables them to select the most appropriate treatment options. As an illustration, when it comes to managing hyperglycemia in patients with T2D, there is a diverse array of treatment options available. Currently, approximately 30 medications belonging to 9 distinct therapeutic categories have received approval for use, with ongoing research and development efforts yielding additional drugs and novel drug categories [9]. Due to the variety of options and guidelines from organizations such as the American Diabetes Association (ADA) [10], doctors often customize prescriptions using different doses and combinations for effective diabetes management [9]. The available medications vary in efficacy, safety, dosage, side effects, and cost. A lack of comparative information across these factors often leaves patients and physicians unable to make well-informed decisions [11]. The selection of diabetes medication presents itself as a multiobjective problem within the realm of health care decision-making [9].

Medical decision support could play a pivotal role in enhancing health care decision-making as it integrates pertinent, organized clinical knowledge and patient data into health-related decisions and processes [12]. Multiple stakeholders, including patients, health care providers, and those involved in patient care, can receive a mix of general clinical insights, patient-specific data, or both. Therefore, a quantitative approach that combines treatment benefits and drawbacks with individual preferences to effectively guide medical decisions could be multicriteria decision-making (MCDM) [13]. MCDM or multicriteria decision analysis (MCDA) is a valuable subdiscipline of operations research, particularly beneficial when dealing with multiple objectives, such as treatment-related outcomes, in benefit-risk analysis [14,15]. A typical MCDM problem consists of 4 key phases: option formulation, criteria selection, criteria weighting, and the decision-making process [16].

Objective

By considering the abovementioned factors, the primary aim of this research is to assess the use and practicality of MCDM methods in the context of diabetes. Our goal is to examine the various ways in which MCDM techniques have been used to study diabetes and present an innovative categorization of their applications in this field. Figure 1 demonstrates the graphical abstract of the paper.

Figure 1. Graphical abstract of the paper. MCDM: multicriteria decision-making.



Methods

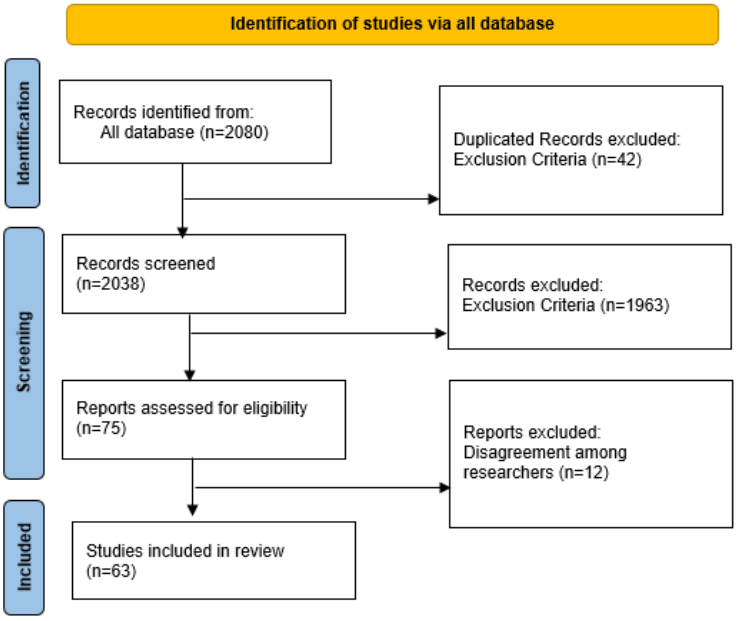
Search Strategies

A query was carried out on PubMed, Elsevier, Embase, MEDLINE, Scopus, MBC, Springer, IEEE, MDPI, Taylor and Francis Online, and Google Scholar based on published articles. The keywords for our paper were extracted from Medical Subject Headings (MeSH). The keywords “diabetes” and “glucose” were combined with MCDM techniques terms such as TOPSIS, AHP, and multi-criteria-decision-making using the Boolean operator AND/OR. The specific query searched was: ((diabetes OR glucose) AND (AHP OR TOPSIS OR MCDM OR multi-criteria-decision-making)).

Inclusion and Exclusion Criteria

We initially eliminated any duplicate articles from various sources after receiving the results of an initial collection of relevant articles and then manually inspected the remaining articles to assess them under the inclusion criteria. The inclusion criteria were any English papers published between 2003 and 2023. Research, review, conference, and case report articles with an abstract or full text were taken into account. Non-English articles and other research forms, such as letters to editors and brief messages, were excluded. Out of almost 2210 articles, only 63 were found and chosen based on keywords and all of our criteria. The article selection process was based on PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses; Figure 2) [17].

Figure 2. PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses) flowchart.



Results

Overview

Based on Figure 2, after removing duplicates and examining according to the inclusion and exclusion criteria, 63 publications were included in the final evaluation. Based on our investigation to reveal the frequency of publications in databases, it became clear that most of the publications were indexed in Google Scholar, with 60 publications; PubMed, with 17 publications; and Springer and IEEE, with 8 and 7 publications, respectively.

We initially provided a concise overview of MCDM and its techniques, followed by the presentation of our research findings gathered from reviewing publications.

MCDM Techniques Overview

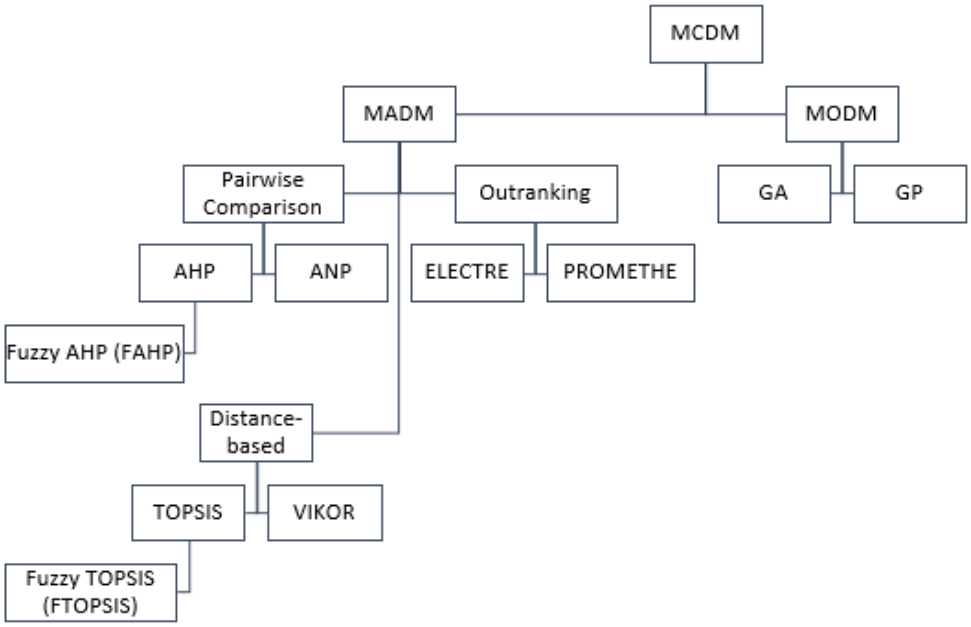
Since so many choices in our modern lives depend on a multitude of factors, the decision can be made by giving various criteria varying weights, which is done by expert groups. Determining the structure and explicitly evaluating several criteria is crucial. Therefore, constructing and resolving multicriteria planning and decision-making challenges is referred to as MCDM. As a result, MCDM is composed of a set of numerous criteria, a set of alternatives, and some sort of comparison between them [18-20].

No alternative optimizes all criteria uniformly in multicriteria optimization assignments. Any solution to the multicriteria task that enhances a specific criterion can be examined, but the task must ultimately have a preferred option. The decision maker must provide more details to select the best decision. Throughout its brief history of about 50 years, MCDM has been an interesting study topic [20]. There are 2 categories of MCDM approaches: multiattribute decision-making (MADM) and multiobjective decision-making (MODM) [19,20].

In order to find the optimal answer, decision makers in MADM choose to categorize, rank, or prioritize a limited number of choices. Pairwise comparison, outranking, and distance-based approaches are the 3 basic methods used in MADM. Pairwise comparison involves evaluating and contrasting the weights of several criteria using a base scale. Analytic hierarchy process (AHP) and analytical network process (ANP) are frequently used in pairwise comparison [21]. Outranking approaches offer a variety of options and determine whether one option has any sort of dominance over the others [22]; instances of outranking techniques include Elimination Et Choix Traduisant la Realité

(ELECTRE) and preference ranking organization method for enrichment of evaluations (PROMETHEE) [21]. The solution with the shortest distance to the ideal point is considered the best according to distance-based techniques, which measure the distance a solution is from the ideal point. The technique for order of preference by similarity to ideal solution (TOPSIS) and ViseKriterijumska Optimizacija I Kompromisno Resenje (VIKOR) are 2 popular distance-based methodologies [21]. Unlike MADM, MODM handles situations where there are many decision makers and an infinite number of possibilities. All of these MCDM methods are presented in Figure 3. The most efficient MCDM techniques are introduced in the following sections.

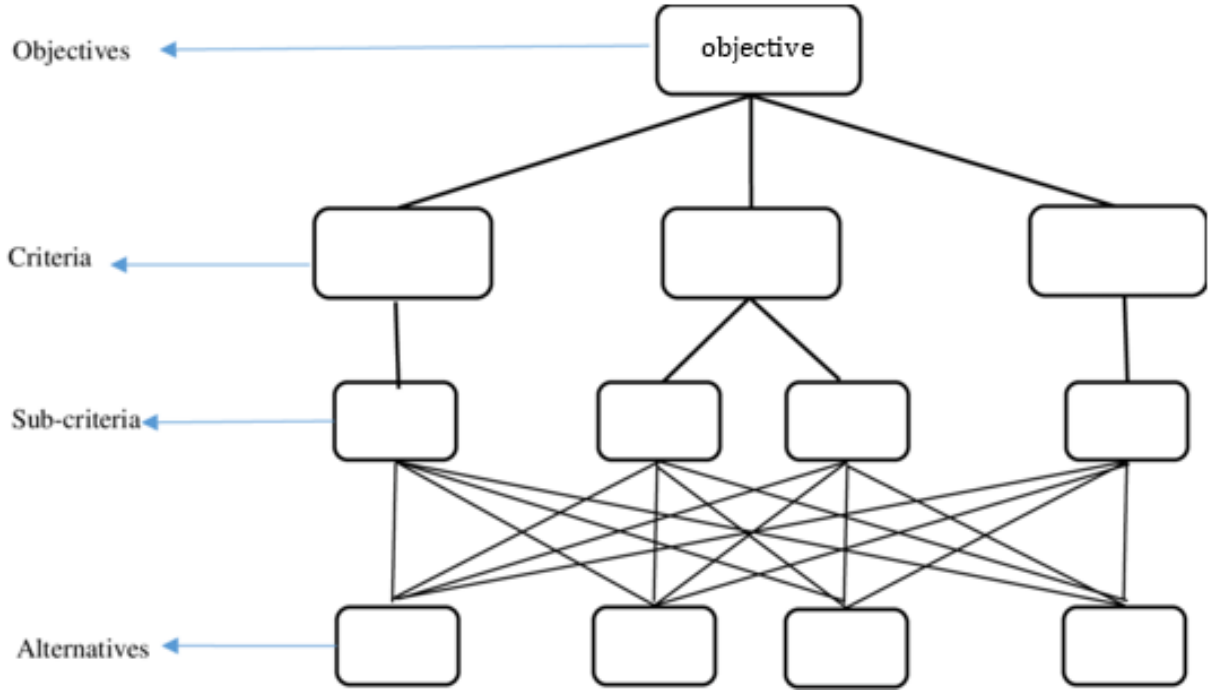
Figure 3. Hierarchical structures of MCDM methods. AHP: analytic hierarchy process; ANP: analytical network process; ELECTRE: Elimination Et Choix Traduisant la Realité; GA: genetic algorithm; GP: goal programming; MADM: multiattribute decision-making; MCDM: multicriteria decision-making; MODM: multiobjective decision-making; PROMETHEE: preference ranking organization method for enrichment of evaluations; TOPSIS: technique for order of preference by similarity to ideal solution; VIKOR: ViseKriterijumska Optimizacija I Kompromisno Resenje.



AHP Method

Saaty [23] was the first to introduce the AHP. As shown in Figure 4, AHP includes the decision's objective at the top, the criteria and subcriteria in the middle, and the collection of alternatives at the bottom [7]. The key benefits of AHP are its scalability and ease of usage. AHP can be applied using Excel (Microsoft) or web-based tools such as Transparent Choice, SpiceLogic, Decerns MCDA, MATLAB (MathWorks), R (R Core Team), and Super Decisions.

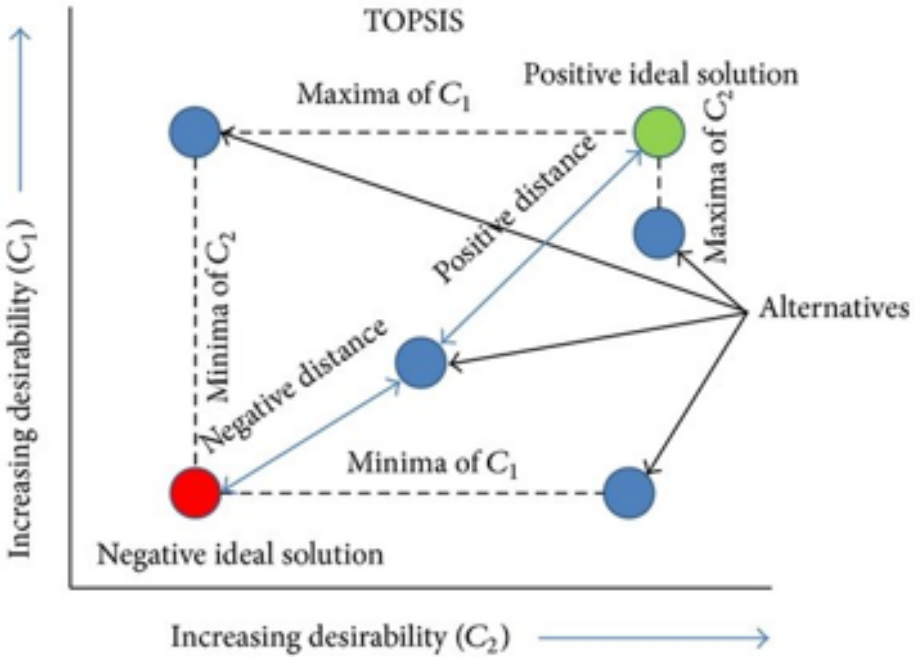
Figure 4. Hierarchical structure of analytic hierarchy process.



TOPSIS Method

As shown in Figure 5, TOPSIS is a distance-based technique that Hwang and Yoon [24] proposed in 1981. The TOPSIS technique makes it easy to define the positive and negative ideal solutions by presuming that each criterion tends to monotonically increase or reduce use. A Euclidean distance approach is suggested to assess how closely the alternatives resemble the ideal solution. The preferred order of the alternatives will be determined by a series of comparisons of their relative distances. The general principle behind this approach is that the optimal option should be closest to the ideal solution and the farthest distance from the negative ideal solution. In the ideal solution, the ideal solution has the best attribute values, maximizes the benefit criteria, and minimizes the cost criteria. In the negative ideal solution, the negative solution has the worst attribute values, maximizes the cost criteria, and minimizes the benefit criteria [19,21].

Figure 5. TOPSIS method. TOPSIS: technique for order of preference by similarity to ideal solution.



ANP Method

Due to the inability of AHP to produce an adequate rating with a limited number of possibilities, the majority of organizations do not use it often. Therefore, Saaty [25] suggested ANP as a continuation of AHP. Decision makers are capable of making

decisions in difficult situations, according to ANP's capability [21].

Weighting Methods

One of the crucial phases of MCDM problems is determining the weights of the criterion [26]. Several weighing techniques can be divided into the following groups: (1) subjective weighting method: AHP, Weighted Sum Model (WSM) [27], and Weighted Product Model (WPM) [27]; (2) objective weighting method: Entropy method [28] and Criteria Importance Through Intercriteria Correlation (CRITIC) [28]; and (3) integrated method: step-wise weigh assessment ratio analysis (SWARA) [29] and Weighted Aggregated Sum Product Assessment (WASPAS) [28].

Following a thorough analysis of all of the MCDM publications in the field of diabetes research during a 2-decade period, it was evident that, starting in 2016, the number of publications in this area has been steadily rising, reaching 10 in 2022.

Then, a new classification of the applications of MCDM approaches in diabetes was proposed: (1) selection of diabetes medication, (2) diagnosis of diabetes, (3) meal recommendation for diabetes, (4) diabetes management, (5) diabetes complication, and (6) estimation of diabetes prevalence.

Selection of Diabetes Medication

Table 1 shows that approximately 30% (n=19/63) of the publications focused on using MCDM techniques to determine the optimal diabetes medication among various options. Notably, AHP and fuzzy AHP, with 6 and 4 mentions, respectively, were the most frequently used methods.

Table 1. Diabetes medication publications.

Reference	Methods	Objective	Results
Maruthur et al [14]	AHP[a]	Select oral T2D[b] medications	Sitagliptin, sulfonylureas, and pioglitazone
Eghbali-Zarch et al [29]	SWARA[c] method, ratio analysis, and the FMULTIMOORA[d] method	Choose the pharmacological treatment for T2D	Metformin should be used as the first-line medication, followed by sulfonylurea, glucagon-like peptide-1 receptor agonist, dipeptidyl peptidase-4 inhibitor, and insulin
Eghbali-Zarch et al [28]	WASPAS[e], entropy, and CRITIC[f]	Determine the final ranking of the medications	Proposed a model to help endocrinologist to choose the best medicine
Zhang et al [30]	TOPSIS[g]	Ranking of diabetes medicines	CDSS[h] can assist young doctors and nonspecialty physicians with medication prescriptions
Maruthur et al [31]	AHP	Select oral T2D medications	AHP will aid, support, and enhance the ability of decision makers to make evidence-based informed decisions consistent with their values and preferences
Nag and Helal [32]	Fuzzy AHP and AHP	Classification of diabetic medications	Fuzzy AHP model can better handle the ambiguity of decision makers
Chen et al [33]	Entropy	Choose pharmaceuticals	AGI[i], DPP4[j], MET[k], Glinide, SU[l], and TZD[m]
Wang et al [34]	AHP and ANP[n]	Combine different clinical, economic, and medical decision-making elements	Modifying one's lifestyle, taking metformin, and receiving insulin injections
Bao et al [35]	MCDA[o]	Assess medicine for diabetes	Five DPP4 inhibitors was valuable
Onar and Ibil [36]	Fuzzy AHP	Considered the best oral antidiabetic	Proposed a decision support system
Zhang et al [37]	MCDA	Examine the Mudan Granules	The new medication was acceptable
Cai et al [38]	AHP	Evaluate strains of the efficacy of the LAB[p] with possible antidiabetic capabilities	Potential antidiabetic effect
Sekar et al [39]	Fuzzy PROMETHEE[q]	Choose the best course of therapy	Giving the high peace of treatment to the most affected people
Mühlbacher et al [40]	AHP and BWS[r]	Evaluate patients' preferences for various T2D treatment parameters	Proposed a model
Mahat and Ahmad [41]	Fuzzy AHP	Identify and choose the most efficient thermal massage treatment session	Number of therapy sessions (per day) was the most important factor
Pan et al [42]	Fuzzy AHP	Determine the weights of the various physiological factors	The mathematical model of exercise rehabilitation program for patients with diabetes was established
Rani et al [43]	COPRAS[s]	Select T2D medication treatment	Developed a new formula-based PFSs[t] and evaluated its feasibility by applying the model on selecting the T2D pharmacological therapy
Balubaid and Basheikh [44]	AHP	Developed a mathematical decision-making model that prioritizes the available diabetes medication based on criteria	Metformin, pioglitazone, sitagliptin, and glimepiride were ranked first, second, third, and fourth, respectively
Mühlbacher et al [45]	AHP and BWS	Examine the key patient-related decision criteria involved in the medicinal treatment of T2D	For oral antidiabetes-treated patient groups and insulin-treated patient groups, HbA1c[u] level, delay of insulin therapy, and occurrence of hypoglycemia were ranked first, second, and third, respectively

[a]AHP: analytic hierarchy process.

[b]T2D: type 2 diabetes.

[c]SWARA: step-wise weigh assessment ratio analysis.

[d]FMULTIMOORA: full multiplicative form.

[e]WASPAS: Weighted Aggregated Sum Product Assessment.

[f]CRITIC: Criteria Importance Through Intercriteria Correlation.

[g]TOPSIS: technique for order of preference by similarity to ideal solution.

[h]CDSS: clinical decision support system.
[i]AGI: α-glucosidase.
[j]DDP4: dipeptidyl peptidase-4.
[k]MET: meglitinide.
[l]SU: sulfonylureas.
[m]TZD: thiazolidinedione.
[n]ANP: analytical network process.
[o]MCDA: multicriteria decision analysis.
[p]LAB: lactic acid bacteria.
[q]PROMETHEE: preference ranking organization method for enrichment of evaluations.
[r]BWS: best–worst-scaling.
[s]COPRAS: Complex Proportional Assessment.
[t]PFS: Pythagorean Fuzzy Set.
[u]HbA1c: hemoglobin A1c.

Diagnosis of Diabetes

Table 2 displays that roughly 19% (12/63) of the publications centered on the application of MCDM techniques for aiding general practitioners and endocrinologists in diagnosing diabetes. Among these, AHP and TOPSIS were the most commonly cited methods, with 4 and 3 mentions, respectively.

Table 2. Diabetes diagnosis publications.

Reference	Methods	Objective	Risk factors	Results
Zulqarnain et al [6]	TOPSIS[a]	Investigate the prevalence of diabetes among women and men	Age, weight, height, BMI, systolic and diastolic BP[b], urine creatinine, albuminuria, and ACR[c]	Female patients were more likely to develop diabetes
Abdulkareem et al [7]	Fuzzy AHP[d]	Predict diabetes risks	Weakness, obesity, delayed healing, alopecia, muscle stiffness, polydipsia, polyuria, visual blurring, sudden weight loss, and itching	FAHP[e] model is an excellent tool for diagnosing medical disorders based on many criteria
Abbasi et al [46]	AHP	Identify the most significant risk factors for GDM[f]	A history of GDM or impaired glucose tolerance in previous pregnancies and a history of macrosomia in the infant	N/A[g]
Yas et al [47]	Fuzzy TOPSIS	Identify the symptoms of diabetes	Age, pregnancies, glucose, blood pressure, skin thickness, insulin, BMI, and diabetes pedigree function	Proposed a framework to recognize the symptoms of disease
Amin-Naseri and Neshat [48]	AHP	Determine the likelihood of developing T2D[h]	FBS[i] index, PRF[j], BMI, diet, age, BP, gender, family history, and smoking status	DIBAR[k], a knowledge-based expert system
El-Sappagh et al [49]	Fuzzy AHP	Diagnosis of diabetes	N/A	Created a new, systematically interpretable FRBS[l] framework
Baha et al [50]	AHP	Diagnosis of diabetes	Heredity, sex, ethnicity, age, impaired glucose tolerance, gestational diabetes, and so forth	Recognized top 3 most important risk factors: heredity, obesity, and physical inactivity
Sharma and Sharma [51]	EDAS[m]	Forecast diabetes	N/A	Combined MCDM[n] with machine-learning techniques to find the best forecasting model
Malapane et al [52]	WPM[o]	Forecast diabetes	N/A	Combined WPM method with machine learning to select the best model
Felix et al [53]	TOPSIS	Identification of the most important T2D risk factors in the Pima Indian database	Blood glucose, BP, blood cholesterol, obesity, blindness, physical inactivity	Blindness, obesity, and inactivity were the risk factors with greatest impact
Sankar and Jeyaraj [54]	AHP	Forecast diabetes in women	N/A	Propose a model for predicting diabetes among women
Bondor and Mureşan [55]	TOPSIS	Solve the problem of multicollinearity between criteria in diabetes diagnosis	N/A	Proposed a new algorithm which removed the multicollinearity among criteria

[a]TOPSIS: technique for order of preference by similarity to ideal solution.

[b]BP: blood pressure.

[c]ACR: albumin creatinine ratio.

[d]AHP: analytic hierarchy process.

[e]FAHP: fuzzy analytic hierarchy process.

[f]GDM: gestational diabetes mellitus.

[g]N/A: not applicable.

[h]T2D: type 2 diabetes.

[i]FBS: fasting blood sugar.

[j]PRF: physical risk factors.

[k]DIBAR: Created Diabetes Risk Assessment.

[l]FRBS: fuzzy rule-based systems.

[m]EDAS: evaluation based on distance for average solution.

[n]MCDM: multicriteria decision-making.

[o]WPM: Weighted Product Model.

Meal Recommendation for Diabetes

According to Table 3, a total of 8 (13%) out of 63 publications focused on using MCDM techniques to assist people with diabetes in making the healthiest food choices from their food options, considering factors such as fat content, carbohydrate content, and calorie count. Among these, AHP was mentioned most frequently, with 6 instances.

Table 3. Meal recommendation publications.

Reference	Methods	Objective	Criteria	Results
Gaikwad et al [56]	AHP[a]	Recommend a particular ice cream for patients with diabetes	Sugar, cholesterol, dietary fiber, and proteins	Ben & Jerry's Butter Pecan was enriched with all 4 criteria
Sharawat and Dubey [57]	AHP	Find out the best diet for a patient with diabetes among 3 alternatives: solid food, liquid food, and fluid food	Calories, body fat, healthy carbs, and dietary needs	Solid food was selected as the best
Santoso et al [58]	Fuzzy AHP	Designed a new yogurt product for patients with diabetes	N/A[b]	N/A
Zadeh et al [59]	AHP	Proposed a personalized meal-planning strategy	N/A	Proposed an affordable and culturally appropriate meals that would provide all the nutrition needed for a diabetic while still being mindful of calories and carbs
Gulint and Kadam [60]	AHP and TOPSIS[c]	Recommended shakes and ice cream for patients with diabetes	Sugar, cholesterol, carbs, fat, protein, and dietary fiber	Selected a type of ice cream that satisfies all criteria
Gaikwad et al [61]	ANP[d]	Recommendation of a particular ice cream	Sugar, calories, cholesterol, and proteins	Selected a type of ice cream that satisfies all criteria
Gaikwad et al [62]	AHP	Recommendation of a particular ice cream	N/A	Proposed a model combination of AHP-GA[e] and AHP-CI[f] to recommend an ice cream to patients with diabetes
Gaikwad et al [63]	AHP	Recommendation of a particular ice cream	Sugar, protein, cholesterol, and dietary fiber	Patient having a high sugar level of 262 mg/dl can consume an ice cream lower sugar like Breyers butter almond, also patient with low sugar level of 77 mg/dl can consume high sugar ice cream like Breyers

[a]AHP: analytic hierarchy process.

[b]N/A: not applicable.

[c]TOPSIS: technique for order of preference by similarity to ideal solution.

[d]ANP: analytical network process.

[e]AHP-CI: analytic hierarchy process–cohort intelligence.

[f]AHP-GA: analytic hierarchy process–genetic algorithm.

Diabetes Management

Based on Table 4, additional applications of MCDM techniques, particularly AHP methods, in diabetes management (14/63, 22%) encompass tasks such as identifying ideal locations for diabetes clinics, allocating resources for diabetes care, assessing the current diabetes applications, and constructing models to prioritize criteria that bolster the safety of the insulin supply chain.

Table 4. Diabetes management publications.

Reference	Method	Results
Gupta et al [64]	TOPSIS[a], VIKOR[b], PROMETHEE II[c]	Assess current mHealth[d] applications for T2D[e], including Glucose Buddy, mySugr, Diabetes: M, Blood Glucose Tracker, and OneTouch Reveal
Wang et al [65]	ANP[f] and CRITIC[g]	Assess the influence of social support on T2DM[h] self-management
Mishra et al [66]	AHP[i]	Created and used the SCP[j] assessment methodology for Indian diabetes clinic
Mishra [67]	AHP	Developed a customized service quality assessment model for diabetes care
Mishra [68]	Fuzzy TOPSIS	Proposed 3 alternatives for the placement of a diabetes clinic using the SLP[k] method
Byun et al [69]	AHP	Improving the treatment compliance of patients with diabetes
Mehrotra and Kim [70]	New multicriterion, robust weighted-sum methodology	Calculate the amount of funding allocated to diabetes preventive initiatives across the United States to reduce the weighted sum of diabetes prevalence and outcomes caused by improper health expenditure
Haji et al [71]	AHP and TOPSIS	Create a model that can prioritize and pick the optimal criterion for optimizing insulin safety
Suka et al [72]	AHP	Described a clinical decision support system that enhance dynamic decision-making
Fico et al [73]	AHP	Selected the best tool for screening and managing T2D
Long and Centor [74]	AHP	Assess the relative significance of 4 frequently used diabetes quality indicators: measuring HbA1c[l], measuring LDL[m], performing a dilated eye examination, and performing a foot examination
Gajdoš et al [75]	TOPSIS	Proposed a concept of chronic care management, which could increase effectiveness and reduce the cost of health care provided to patients with T2D
Gupta et al [76]	CODAS-FAHP[n] and MOORA-FAHP[o]	Assess the usability of mHealth applications to monitor T2D by developing 2 hybrid decision-making methods
Chang et al [77]	Delphi-AHP	Recommended a Delphi-AHP framework to establish agreement in creating a decision-making algorithm for evaluating the balance of benefits and risks associated with the use of complementary and alternative medicine for diabetes

[a]TOPSIS: technique for order of preference by similarity to ideal solution.

[b]VIKOR: ViseKriterijumska Optimizacija I Kompromisno Resenje.

[c]PROMETHEE II: preference ranking organization method for enrichment of evaluation II.

[d]mHealth: mobile health.

[e]T2D: type 2 diabetes.

[f]ANP: analytical network process.

[g]CRITIC: Criteria Importance Through Intercriteria Correlation

[h]T2DM: type 2 diabetes mellitus.

[i]AHP: analytic hierarchy process.

[j]SCP: Supply Chain Partnership.

[k]SLP: Systematic Layout Planning.

[l]HbA1c: hemoglobin A1c.

[m]LDL: low-density lipoprotein.

[n]CODAS-FAHP: combine distance-based assessment-fuzzy AHP.

[o]MOORA-FAHP: multiobjective optimization on the basis of ratio analysis-fuzzy AHP.

Diabetes Complication

T2D is a significant global public health issue, characterized by 2 categories of harm: macrovascular (involving large arteries) and microvascular (involving small blood vessels). Macrovascular disease such as strokes and microvascular diseases such as retinopathy, nephropathy, and neuropathy [7]. MCDM techniques, especially TOPSIS, as shown in Table 5, are used to assist endocrinologists and general practitioners in analyzing the severity of these complications, forecasting their likelihood of occurrence, and pinpointing the risk factors for them (n=7).

Table 5. Diabetes complication diagnosis publications.

Reference	Methods	Objective	Criteria	Complications	Results
Ebrahimi and Ahmadi [78]	Fuzzy TOPSIS[a]	Analyzed the severity caused by diabetes	High cholesterol, high BP[b], obesity, physical inactivity, smoking, family history, age, and sex	Neuropathy, diabetic retinopathy, cardiovascular disease, kidney disease, foot ulcer, and amputation	Cardiovascular disease was the most important complication in the problem
Ahmadi and Ebrahimi [79]	MCDM[c]	Assessed the severity of difficulties caused by diabetes	Ischemic heart disease, heart failure, heart stroke, ketoacidosis, diabetic ulcer, neuropathy, and lower extremely amputation	Cardiovascular disease, diabetic ketoacidosis, lower extremity complications, and lower extremity amputation	Proposed a new hybrid algorithm that calculate the severity of damage caused by diabetes
Bondor et al [80]	TOPSIS	Identification of the risk factors in kidney disease	Urinary albumin per creatinine ratio and glomerular filtration	Diabetic kidney	Rank the risk factors of microalbuminuria and eGFR[d] to evaluate the risk factor for CKD[e]
Ahmed et al [81]	TOPSIS and entropy	Detection of DR[f] through machine learning and TOPSIS models	Criteria of TOPSIS model: AUC[g], accuracy, precision, F1-score, recall, TPR[h], FNR[i], FPR[j], TNR[k], and time	DR	According to TOPSIS, Adaboost model ranks at the best model to detect DR
Bondor et al [82]	VIKOR[l]	Rank risk factors of diabetic kidney disease	Serum adiponectin, triglycerides, SBP, duration of diabetes and age, Malondialdehyde, and HDL[m]-cholesterol	Diabetic kidney	Identification of diabetic kidney disease risk factors
Alassery et al [83]	Fuzzy AHP[n] and Fuzzy TOPSIS	Determine the impact of mental health in patients with diabetes	BMI, SBP, DBP[o], age, height, exercise	Mental health	The model showed the applicability and impact of mental health in patients with diabetes
Wang et al [84]	AHP	Relieve the pain in patients with diabetes	N/A[p]	Diabetic neuropathy and foot ulcers	Selection of shoe lasts for footwear design to help relieve the pain associated with diabetic neuropathy and foot ulcers

[a]TOPSIS: technique for order of preference by similarity to ideal solution.

[b]BP: blood pressure.

[c]MCDM: multicriteria decision-making.

[d]GFR: estimated glomerular filtration rate.

[e]CKD: chronic kidney disease.

[f]DR: diabetic retinopathy.

[g]AUC: area under the curve.

[h]TPR: true positive rate.

[i]FNR: false negative rate.

[j]FPR: false positive rate.

[k]TNR: true negative rate.

[l]VIKOR: ViseKriterijumska Optimizacija I Kompromisno Resenje.

[m]HDL: high-density lipoprotein.

[n]AHP: analytic hierarchy process.

[o]DBP: diastolic blood pressure.

[p]N/A: not applicable.

Discussion

Principal Findings

Given the multitude of choices involved in selecting diabetes medication, meal planning, nutrient intake, diabetes management apps, and speedy diagnosis, endocrinologists, general practitioners, and individuals with diabetes, along with their caregivers, need guidance to make informed decisions. MCDM is a quantitative approach that effectively integrates treatment benefits and drawbacks, as well as individual preferences, to facilitate sound medical decision-making in these complex situations. Consequently, we embarked on an evaluation of the effectiveness of MCDM methods in the context of diabetes.

Based on a notable upward trend in publications within the realm of using MCDM methods in diabetes research over the last 2 decades, this underscores the growing interest among researchers in applying MCDM methods to address diabetes-related challenges. Furthermore, the majority of these publications (n=19) focus on diabetes treatment selection [14,28-45]. Diabetes management (n=14), diagnosis of diabetes (n=12), meal recommendation (n=8), diabetes complications (n=7), and global estimation (n=3) are in the later ranks. This outcome highlights the efficacy of using MCDM methods in the process of choosing diabetes medications.

All MCDM methods in diabetes are classified into 13 groups. AHP is ranked first, having been used in 25 articles. AHP is designed to help individuals and groups make complex decisions by breaking them into a hierarchical structure, comparing and weighting criteria and alternatives, and deriving a rational choice based on these comparisons [7,85,24]. AHP can be applied to diabetes issues and decision-making in several ways including treatment selection [14,31,32,34,36,38-42,44,45], diabetes diagnosis [46,48-50,54], dietary planning [56-60,62,63], diabetes management [66,67,69,71-74,77], complication diagnosis [84], and estimating diabetes prevalence [4,5]. TOPSIS and fuzzy AHP with 9 and 8 publications are in the next ranks, respectively.

As observed, 6 distinct weighting algorithms were recognized, with the Entropy approach ranking highest. The final component in our proposed classification pertains to estimating diabetes prevalence. In a 2013 study, researchers used logistic regression and AHP techniques to produce smoothed age-specific occurrence estimates for adults aged 20 to 79 years. These estimates were then used to calculate population projections for the years 2013 and 2035, foreseeing an increase in the number of individuals with diabetes to 592 million by 2035 [4]. In another investigation conducted by the IDF in 2015, AHP and logistic regression methods were used to estimate that there were 415 million people (ranging from 340 million to 536 million) with diabetes. Projections indicate that this figure is expected to reach 642 million (ranging from 521 million to 829 million) by 2040 [5].

Conclusions

One of the most serious health problems of the 21st century, whose prevalence is rapidly increasing, is diabetes mellitus. Almost all areas of diabetes research have seen significant progress to date, particularly in the areas of medication selection, meal selection, diabetes management applications, use of continuous glucose monitoring, and closed-loop system. The advancement of technology has expanded the scope of decision-making responsibilities for general practitioners in the initial stages of patient care. Determining the most optimal choice among numerous options falls within the domain of MCDM.

In this research, for the first time, we reviewed the majority of MCDM papers for diabetes and considered 2 important issues in the field of diabetes: examining the usability of MCDM techniques in diabetes and proposing a new classification of applications of MCDM methods in diabetes. Our study highlights that the use of MCDM techniques extends beyond the realm of diabetes medication selection. These methods hold promise for diverse applications, spanning meal planning, diabetes diagnosis, and addressing diabetes-related challenges. This includes tasks such as selecting optimal diabetes management applications from a wide range of options, identifying ideal locations for diabetes clinics, and efficiently allocating resources for diabetes care. Moreover, the analysis reveals that AHP is the preferred and widely embraced strategy and approach, primarily owing to its straightforward structure and user-friendliness. We firmly believe that the adoption of MCDM approaches offers advantages to a broad spectrum of stakeholders, including patients with diabetes, endocrinologists, general practitioners, caregivers, and health care policy makers. These techniques have the potential to serve as valuable tools for general practitioners, assisting in quicker diabetes diagnosis and more accurate medication selection, ultimately reducing patient costs and lifestyle concerns.

Abstract

Background: Health care has not reached the full potential of the secondary use of health data because of—among other issues—concerns about the quality of the data being used. The shift toward digital health has led to an increase in the volume of health data. However, this increase in quantity has not been matched by a proportional improvement in the quality of health data.

Objective: This review aims to offer a comprehensive overview of the existing frameworks for data quality dimensions and assessment methods for the secondary use of health data. In addition, it aims to consolidate the results into a unified framework.

Methods: A review of reviews was conducted including reviews describing frameworks of data quality dimensions and their assessment methods, specifically from a secondary use perspective. Reviews were excluded if they were not related to the health care ecosystem, lacked relevant information related to our research objective, and were published in languages other than English.

Results: A total of 22 reviews were included, comprising 22 frameworks, with 23 different terms for dimensions, and 62 definitions of dimensions. All dimensions were mapped toward the data quality framework of the European Institute for Innovation through Health Data. In total, 8 reviews mentioned 38 different assessment methods, pertaining to 31 definitions of the dimensions.

Conclusions: The findings in this review revealed a lack of consensus in the literature regarding the terminology, definitions, and assessment methods for data quality dimensions. This creates ambiguity and difficulties in developing specific assessment methods. This study goes a step further by assigning all observed definitions to a consolidated framework of 9 data quality dimensions.

KEYWORDS

data quality; data quality dimensions; data quality assessment; secondary use; data quality framework; fit for purpose

Introduction

To face the multiple challenges within our health care system, the secondary use of health data holds multiple advantages: it could increase patient safety, provide insights into person-centered care, and foster innovation and clinical research. To maximize these benefits, the health care ecosystem is investing rapidly in primary sources, such as electronic health records (EHRs) and personalized health monitoring, as well as in secondary sources, such as health registries, health information systems, and digital health technologies, to effectively manage illnesses and health risks and improve health care outcomes [1]. These investments have led to large volumes

of complex real-world data. However, health care is not obtaining the full potential of the secondary use of health data [2,3] because of—among other issues—concerns about the quality of the data being used [4,5]. Errors in the collection of health data are common. Studies have reported that at least half of EHR notes may contain an error leading to low-quality data [6-11]. The transition to digital health has produced more health data but not to the same extent as an increase in the quality of health data [12]. This will impede the potentially positive impact of digitalization on patient safety [13], patient care [14], decision-making [15], and clinical research [16].

The literature is replete with various definitions of data quality. One of the most used definitions for data quality comes from Juran et al [17], who defined data quality as "data that are fit for use in their intended operational, decision-making, planning, and strategic roles." According to the International Organization for Standardization (ISO) definition, quality is "the capacity of an ensemble of intrinsic characteristics to satisfy requirements" (ISO 9000-2015). DAMA International (The Global Data Management Community: a leading international association involving both business and technical data management professionals) adapts this definition to a data context: "data quality is the degree to which the data dimensions meet requirements." These definitions emphasize the subjectivity and context dependency of data quality [18]. Owing to this "fit for purpose" principle, the quality of data may be adequate when used for one specific task but not for another.

For example, when health data collected for primary use setting, such as blood pressure, are reused for different purposes, the adequacy of their quality can vary. For managing hypertension, the data's accuracy and completeness may be considered adequate. However, if the same data are reused for research, for example, in a clinical trial evaluating the effectiveness of an antihypertensive, more precise and standardized measurements methods are needed. From the perspective of secondary use, data are of sufficient quality when they serve the needs of the specific goals of the reuser [4].

To ensure that the data are of high quality, they must meet some fundamental measurable characteristics (eg, data must be complete, correct, and up to date). These characteristics are called data quality dimensions, and several authors have attempted to formulate a complex multidimensional framework of data quality. Kahn et al [19] developed a data quality framework containing conformance, completeness, and plausibility as the main data quality dimensions. This framework was the result of 2 stakeholder meetings in which data quality terms and definitions were grouped into an overall conceptual framework. The i~HD (European Institute for Innovation through Health Data) prioritized 9 data quality dimensions as most important to assess the quality of health data [20]. These dimensions were selected during a series of workshops with clinical care, clinical research, and ICT leads from 70 European hospitals. In addition, it is well known that there are several published reviews in which the results of individual quality assessment studies were collated into a new single framework of data quality dimensions. However, the results of these reviews have not yet been evaluated. Therefore, answering the "fit for purpose" question and establishing effective methods to assess data quality remain a challenge [21].

The primary objective of this review is to provide a thorough overview of data quality frameworks and their associated assessment methods, with a specific focus on the secondary use of health data, as presented in published reviews. As a secondary aim, we seek to align and consolidate the findings into a unified framework that captures the most crucial aspects of quality with a definition along with their corresponding assessment methods and requirements for testing.

Methods

Overview

We conducted a review of reviews to gain insights into data quality related to the secondary use of health data. In this review of reviews, we applied the Equator recommendations from the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines proposed by Page et al [22]. As our work is primarily a review of reviews, we included only the items from these guidelines that were applicable. Abstracts were sourced by searching the PubMed, Embase, Web of Science, and SAGE databases. The search was conducted in April 2023, and only reviews published between 1995 and April 2023 were included. We used specific search terms that were aligned with the aim of our study. To ensure comprehensiveness, the search terms were expanded by searching for synonyms and relevant key terms. The following concepts were used: "data quality" or "data accuracy," combined with "dimensions," "quality improvement," "data collection," "health information interoperability," "health information systems," "public health information," "quality assurance," and "delivery of health care." Textbox 1 illustrates an example of the search strategy used in PubMed. To ensure the completeness of the review, the literature search spanned multiple databases. All keywords and search queries were adapted and modified to suit the requirements of these various databases (Multimedia Appendix 1).

Textbox 1. Search query used.

("data quality" OR "Data Accuracy"[Mesh]) AND (dimensions OR "Quality Improvement"[Mesh] OR "Data Collection/standards"[Mesh] OR "Health Information Interoperability/standards"[Mesh] OR "Health Information Systems/standards"[Mesh] OR "Public Health Informatics/standards" OR "Quality Assurance, Health Care/standards"[Mesh] OR "Delivery of Health Care/standards"[Mesh]) Filters: Review, Systematic Review

Inclusion and Exclusion Criteria

We included review articles that described and discussed frameworks of data quality dimensions and their assessment methods, especially from a secondary use perspective. Reviews were excluded if they were (1) not specifically related to the health care ecosystem, (2) lacked relevant information related to our research objective (no definition of dimensions), or (3) published in languages other than English.

Selection of Articles

One reviewer (JD) screened the titles and abstracts of 982 articles from the literature searches and excluded 940 reviews. Two reviewers (RVS and JD) independently performed full-text screening of the remaining 42 reviews. Disagreements between the 2 reviewers were resolved by consulting a third reviewer (DK). After full-text screening, 20 articles were excluded because they did not meet the inclusion criteria. A total of 22 articles were included in this review.

Data Extraction

All included articles were imported into EndNote 20 (Clarivate). Data abstraction was conducted independently by 2 reviewers (RVS and JD). Disagreements between the 2 reviewers were resolved by consulting a third reviewer (DK). The information extracted from the reviews included various details, including the authors, publication year, research objectives, specific data source used, scope of secondary use, terminology used for the data quality dimensions, their corresponding definitions, and the measurement methods used.

Data Synthesis

To bring clarity to the diverse dimensions and definitions scattered throughout the literature, we labeled the observed definitions of dimensions from the reviews as “aspects.” We then used the framework of the i~HD. This framework underwent extensive validation through a large-scale exercise and was published [20]. It will now serve as a reference framework for mapping the diverse literature in the field. This overarching framework comprised 9 loosely delineated data quality dimensions (Textbox 2, [20]). Each observed definition of a data quality dimension was mapped onto a dimension of this reference framework. This mapping process was collaborative and required consensus among the reviewers. This consolidation is intended to offer a more coherent and unified perspective on data quality for secondary use.

Textbox 2. Consolidated data quality framework of the European Institute for Innovation through Health Data [20].

Data quality dimension and definition

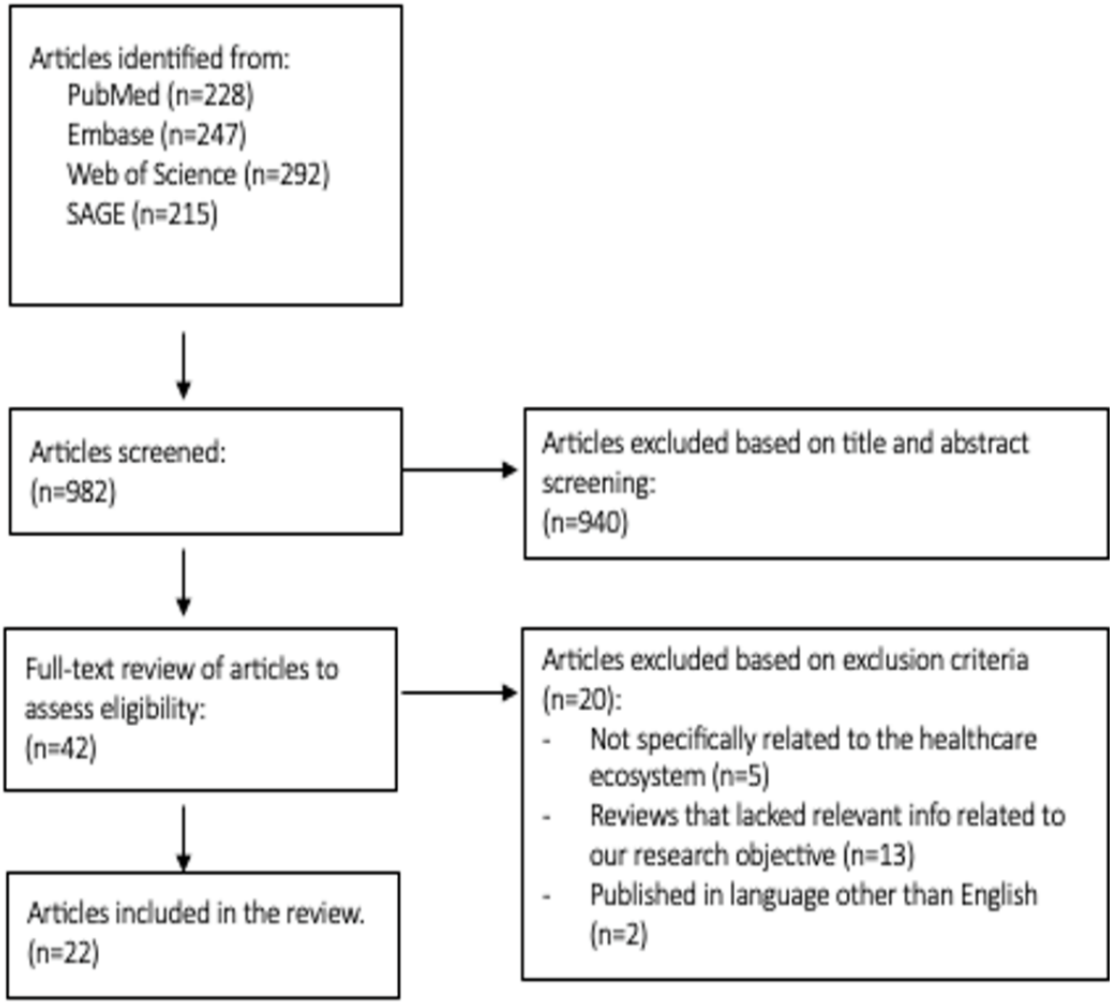
- Completeness: the extent to which data are present
- Consistency: the extent to which data satisfy constraints
- Correctness: the extent to which data are true and unbiased
- Timeliness: the extent to which data are promptly processed and up to date
- Stability: the extent to which data are comparable among sources and over time
- Contextualization: the extent to which data are annotated with acquisition context
- Representativeness: the extent to which data are representative of intended use
- Trustworthiness: the extent to which data can be trusted based on the owner’s reputation
- Uniqueness: the extent to which data are not duplicated

Results

Search Process

Figure 1 summarizes the literature review process and the articles included and excluded at every stage of the review using the PRISMA guidelines. It is important to note that this was not a systematic review of clinical trials; rather, it was an overview of existing reviews. As such, it synthesizes and analyzes the findings from multiple reviews on the topic of interest. A total of 22 articles were included in this review. The 22 reviews included systematic reviews (4/22, 18%) [23-26], scoping reviews (2/22, 9%) [27,28], and narrative reviews (16/22, 73%) [4,29-43]. All the reviews were published between 1995 and 2023. Of the 20 excluded reviews, 5 (25%) were excluded because they were not specific to the health care ecosystem [18,44-47], 13 (65%) lacked relevant information related to our research objective [6-18], and 2 (10%) were published in a language other than English [48,49].

Figure 1. The process of selecting articles.



Data Sources

Of the 22 reviews, 10 (45%) discussed data quality pertaining to a registry [25-27,34-36,40-43] and 4 (18%) to a network of EHRs [4,24,29,33]. Of the 22 reviews, 4 (18%) discussed the quality of public health informatics systems [37,38], real-world data repositories [31], and clinical research informatics tools [30]. Of the 22 reviews, 4 (18%) did not specify their data source [23,28,32,39].

Observed Frameworks for Data Quality Dimensions

In the initial phase of our study, we conducted a comprehensive review of 22 selected reviews, each presenting a distinct framework for understanding data quality dimensions. Across these reviews, the number of dimensions varied widely, ranging from 1 to 14 (median 4, IQR 2-5). The terminology used was diverse, yielding 23 different terms for dimensions and 62 unique definitions. A detailed overview, including data sources, data quality dimensions, and definitions, is provided in Multimedia Appendix 2 [4,23-43]. Figure S1 in Multimedia Appendix 3 presents the frequency of all dimensions in each review along with the variety of definitions associated with each dimension.

Data Synthesis: Constructing a Consolidated Data Quality Framework For Secondary Use

Overview

Table 1 presents all dimensions mentioned in the included reviews, with their definitions, mapped toward each of the 9 data quality dimensions in the framework of i~HD.

Table 1. Mapping of data quality aspects toward i~HD (European Institute for Innovation through Health Data) data quality framework.

i~HD data quality dimensions and aspects as mentioned in the reviews	Definition
Completeness	
Completeness [30,32,33,39]	The extent to which information is not missing and is of sufficient breadth and depth for the task at hand.
Completeness [24,29,39]	This focuses on features that describe the frequencies of data attributes present in a data set without reference to data values.
Completeness [27,35,42]	The extent to which all necessary data that could have been registered have been registered.
Completeness [34,41]	The extent to which all the incident cases occurring in the population are included in the registry database.
Completeness [43]	The completeness of data values can be divided between mandatory and optional data fields.
Completeness [23]	The absence of data at a single moment over time or when measured at multiple moments over time.
Completeness [4]	Is a truth of a patient present in the EHR[a]?
Completeness [26]	All necessary data are provided.
Completeness [25]	Defined as the presence of recorded data points for each variable.
Plausibility [31]	Focuses on features that describe the frequencies of data attributes present in a data set without reference to data values.
Capture [27,35]	The extent to which all necessary cases that could have been registered have been registered.
Consistency	
Accuracy [43]	The accuracy of data values can be divided into syntactic and semantic values.
Consistency [43]	Data inconsistencies occur when values in ≥2 data fields are in conflict.
Consistency [39]	Representation of data values is the same in all cases.
Consistency [26]	Data are logical across data points.
Consistency [32]	The degree to which data have attributes that are free from contradiction and are coherent with other data in a specific content of use.
Consistency [23]	Absence of differences between data items representing the same objects based on specific information requirements.
Consistency [30]	Refers to the extent to which data are applicable and helpful to the task at hand.
Correctness [26]	Data are within the specified value domains.
Comparability [34,40]	The extent to which coding and classification procedures at a registry, together with the definitions of recoding and reporting specific data terms, adhere to the agreed international guidelines.
Validity [30]	Refers to information that does not conform to a specific format or does not follow business rules.
Concordance [32]	The data are concordant when there was agreement or comparability between data elements.
Conformance [29,31]	Focuses on data quality features that describe the compliance of the representation of data against internal or external formatting, relational, or computational definitions.
Conformance [24]	Whether the values that are present meet syntactic or structural constraints.
Correctness	
Accuracy [27,35,42]	The extent to which registered data are in conformity to the truth.
Accuracy [32,33]	The extent to which data are correct and reliable.
Accuracy [23]	The degree to which data reveal the truth about the event being described.
Accuracy [26]	Data conform to a verifiable source.
Accuracy [30]	Refers to the degree to which information accurately reflects an event or object described.
Correctness [4,24]	Is an element that is present in the EHR true?
Correctness [39]	The free-of-error dimension.
Plausibility [4]	Does an element in the EHR makes sense in the light of other knowledge about what that element is measuring?

i~HD data quality dimensions and aspects as mentioned in the reviews	Definition
Plausibility [24]	This focuses on actual values as a representation of a real-world object or conceptual construct by examining the distribution and density of values or by comparing multiple values that have an expected relationship with each other.
Plausibility [29]	Focuses on features that describe the believability or truthfulness of data values.
Validity [34,40]	Defined as the proportion of cases in a data set with a given characteristic which truly have the attribute.
Uniqueness	
Redundancy [32]	Data contain no redundant values.
Stability	
Consistency [33]	Representations of data values remain the same in multiple data items in multiple locations.
Consistency [24]	Refers to the consistency of data at the specified level of detail for the study's purpose, both within individual databases and across multiple data sets.
Currency [43]	Data currency is important for those data fields that involve information that may change over time.
Comparability [24]	This is the similarity in data quality and availability for specific data elements used in measure across different entities, such as health plans, physicians, or data sources.
Concordance [4,24]	Is there agreement between elements in the EHR or between the EHR and another data source?
Information loss and degradation [24]	The loss and degradation of information content over time.
Timeliness	
Timeliness [30,33,39]	The extent to which information is up to date for the task at hand.
Timeliness [27,34,40]	Related to the rapidity at which a registry can collect, process, and report sufficiently reliable and complete data.
Timeliness [26]	Data are available when needed.
Currency [4]	Is an element in the EHR a relevant representation of the patient's state at a given point in time?
Currency [32]	The degree to which data have attributes that are of the right age in a specific context of use.
Currency [24]	Data were considered current if they were recorded in the EHR within a reasonable period following a measurement or if they were representative of the patient's state at a desired time of interest.
Currency [23]	The degree to which data represent reality from the required point in time.
Accessibility [33]	The extent to which data are available or easily and quickly retrievable.
Contextualization	
Understandability [24]	The ease with which a user can understand the data.
Understandability [30]	Refers to the degree to which the data can be comprehended.
Contextual validity [23]	Assessment of data quality is dependent on the task at hand.
Flexibility [24]	The extent to which data are expandable, adaptable, and easily applied to many tasks.
Trustworthiness	
Security [24,39]	Personal data are not corrupted, and access is suitably controlled to ensure privacy and confidentiality.
Representation	
Relevance [24,39]	The extent to which information is applicable and helpful for the task at hand.
Precision [26]	Data value is specific.

[a]EHR: electronic health record.

Completeness

The first data quality dimension relates to the completeness of data. Among the 22 reviews included, 20 (91%) highlighted the significance of completeness [4,23-27,29-35,39,41-43]. Of these 20 reviews, 17 (85%) used the term completeness to refer to this dimension [4,23-27,29-35,39,41-43], whereas the remaining 3 (15%) used the terms plausibility [31] and capture [27,35].

On the basis of the definitions of completeness, we can conclude that this dimension contains 2 main aspects. First, completeness related to the data level. The most used definition related to this aspect is the extent to which information is not missing [30,32,33,39]. Other reviews focused more on features that describe the frequencies of data attributes present in a data set without reference to data values [24,29,39]. Shivasabesan et al [25], for example, defined completeness as the presence of

recorded data points for each variable. A second aspect for completeness relates more to a case level, in which all the incident cases occurring in the population are included [27,34,35,41].

Consistency

The second data quality dimension concerns the consistency of the data. Among the 22 selected reviews, 11 (50%) highlighted the importance of consistency [23,24,26,29-32,34,39,40,43]. Although various frameworks acknowledge this as a crucial aspect of data quality, achieving a consensus on terminology and definition has proven challenging. Notably, some reviews used different terminologies to describe identical concepts associated with consistency [26,30,32,43]. Of the 11 reviews, 6 (55%) used the term consistency to describe this dimension [23,26,30,32,39,43], whereas 3 (27%) used conformance [24,29,31] and 2 (18%) referred to comparability [34,40]. Of the 11 reviews, 3 (27%) used distinct terms: accuracy [43], validity [30], and concordance [32]. Most definitions focus on data quality features that describe the compliance of the representation of data with internal or external formatting, relational, or computational definitions [29,31]. Of the 11 reviews, 2 (18%) provided a specific definition of consistency concerning registry data, concentrating on the extent to which coding and classification procedures, along with the definitions or recording and reporting of specific data terms, adhere to the agreed international guidelines [34,40]. Furthermore, Bian et al [24] concentrated on whether the values present meet syntactic or structural constraints in their definition, whereas Liaw et al [39] defined consistency as the extent to which the representation of data values is consistent across all cases.

Correctness

The third data quality dimension relates to the correctness of the data. Of the 22 reviews, 14 (64%) highlighted the importance of correctness [4,23,24,26,27,29,30,32-35,39,40,42]. Of the 14 reviews, 2 (14%) used 2 different dimensions to describe the same concept of correctness [4,24]. Accuracy was the most frequently used term within these frameworks [23,26,27,32,33,35,42]. In addition, other terms used included correctness [4,24,39], plausibility [4,24,29], and validity [34,40]. In general, this dimension assesses the degree to which the recorded data align with the truth [27,35,42], ensuring correctness and reliability [32,33]. Of the 14 reviews, 2 (14%) provided a specific definition of correctness concerning EHR data, emphasizing that the element collected is true [4,24]. Furthermore, of the 14 reviews, 2 (14%) defined correctness more at a data set level, defining it as the proportion of cases in a data set with a given characteristic that genuinely possess the attribute [34,40]. These reviews specifically referred to this measure as validity. Nevertheless, the use of the term validity was not consistent across the literature; it was also used to define consistency. For instance, AbuHalimeh [30] used validity to describe the degree to which information adheres to a predefined format or complies with the established business rules.

Timeliness

The fourth data quality dimension concerns the timeliness of the data. Among the 22 selected reviews, 11 (50%) underscored the importance of this data quality dimension [4,23,24,26,27,30,32-34,39,40]. Of the 11 reviews, 7 (64%) explicitly used the term timeliness [26,27,30,33,34,39,40], whereas 4 (36%) referred to it as currency [4,23,24,32]. Mashoufi et al [33] used the terms accessibility and timeliness to explain the same concept. Broadly, timeliness describes how promptly information is processed or how up to date the information is. Most reviews emphasized timeliness as the extent to which information is up to date for the task at hand [30,33,39]. For instance, Weiskopf and Weng [4] provided a specific definition for EHR data, stating that an element should be a relevant representation of the patient's state at a given point in time. Other reviews defined timeliness as the speed at which data can be collected, processed, and reported [27,34,40]. Similarly, Porgo et al [26] defined timeliness as the extent to which data are available when needed.

Stability

The fifth data quality dimension concerns the stability of the data. Among the 22 included reviews, 4 (18%) acknowledged the significance of stability [4,24,33,43]. The most frequently used terms for this dimension are consistency [24,33] and concordance [24]. In addition, other terms used include currency [43], comparability [24], and information loss and degradation [24]. Bian et al [24] explored this aspect of data quality by using multiple terminologies to capture its multifaceted nature: stability, consistency, concordance, and information loss and degradation. This dimension, in general, encompasses 2 distinct aspects. First, it underscores the importance of data values that remain consistent across multiple sources and locations [4,24,33]. Alternatively, as described by Bian et al [24], it refers to the similarity in data quality for specific data elements used in measurements across different entities, such as health plans, physicians, or other data sources. Second, it addresses temporal changes in data that are collected over time. For instance, Lindquist [43] highlighted the importance of stability in data fields that involve information that may change over time. The term consistency is used across different data quality dimensions, but it holds different meanings depending on the context. When discussing the dimension of stability, consistency refers to the comparability of data across different sources. This ensures that information remains uniform when aggregated or compared. Compared with the consistency dimension, the term relates to the internal coherence of data within a single data set, which relates to the absence of contradiction and compliance with certain constraints. The results indicate the same ambiguity in terms of currency. When associated with stability, currency refers to the longitudinal aspect of variables. In contrast, within the dimension of timeliness, currency is concerned with the aspect if data are up to date.

Contextualization

The sixth data quality dimension revolves around the context of the data. Of the 22 reviews analyzed, 3 (14%) specifically addressed this aspect within their framework [23,24,30]. The most used term was understandability [24,30]. In contrast, Syed et al [23] used the term contextual validity, and Bian et al [24] referred to flexibility and understandability for defining the same concept. Broadly speaking, contextualization pertains to

whether the data are annotated with their acquisition context, which is a crucial factor for the correct interpretation of results. As defined by Bian et al [24], this dimension relates to the ease with which a user can understand data. In addition, AbuHalimeh [30] refers to the degree to which data can be comprehended.

Representation

The seventh dimension of data quality focuses on the representation of the data. Of the 22 reviews examined, 3 (14%) specifically highlighted the importance of this dimension [24,26,39]. Of the 3 reviews, 2 (67%) used the term relevance [24,39], whereas Porgo et al [26] used the term precision. Broadly speaking, representativeness assesses whether the information is applicable and helpful for the task at hand [24,39]. In more specific terms, as defined by Porgo et al [26], representativeness relates to the extent to which data values are specific to the task at hand.

Trustworthiness

The eighth dimension of data quality relates to the trustworthiness of the data. Of the 22 reviews, only 2 (9%) considered this dimension in their review [24,39]. In both cases, trustworthiness was defined as the extent to which data are free from corruption, and access was appropriately controlled to ensure privacy and confidentiality.

Uniqueness

The final dimension of data quality relates to the uniqueness of the data. Of the 22 reviews, only 1 (5%) referred to this aspect [32]. Uniqueness is evaluated based on whether there are no duplications or redundant data present in a data set.

Observed Data Quality Assessment Methods

Overview

Of the 22 selected reviews, only 8 (36%) mentioned data quality assessment methods [4,24,32,34,35,39-41]. Assessment methods were defined for 15 (65%) of the 23 data quality dimensions. The number of assessment methods per dimension ranged from 1 to 15 (median 3, IQR 1-5). There was no consensus on which method to use for assessing data quality dimensions. Figure S2 in Multimedia Appendix 3 presents the frequency of the dimensions assessed in each review, along with the number of different data quality assessment methods.

In the following section, we harmonize these assessment methods with our consolidated framework. This provides a comprehensive overview linking the assessment methods to the primary data quality dimensions from the previous section. Table 2 provides an overview of all data quality assessment techniques and their definitions. Textbox 3 presents an overview of all assessment methods mentioned in the literature and mapped toward the i~HD data quality framework.

Table 2. Overview of all data quality assessment methods with definitions.

Assessment M[a]	Assessment technique in reviews	Explanation
M1	Linkages—other data sets	• Percentage of eligible population included in the data set.
M2	Comparison of distributions	• Difference in means and other statistics.
M3	Case duplication	• Number and percentage or cases with >1 record.
M4	Completeness of variables	• Percentage of cases with complete observations of each variable.
M5	Completeness of cases	• Percentage of cases with complete observations for all variables.
M6	Distribution comparison	• Distributions or summary statistics of aggregated data from the data set are compared with the expected distributions for the clinical concepts of interest.
M7	Gold standard	• A data set drawn from another source or multiple sources is used as a gold standard.
M8	Historic data methods	• Stability of incidence rates over time. • Comparison of incidence rates in different populations. • Shape of age-specific curves. • Incidence rates of childhood curves.
M9	M:I[b]	• Comparing the number of deaths, sourced independently from the registry, with the number of new cases recorded for a specific period.
M10	Number of sources and notifications per case	• Using many sources reduces the possibility of diagnoses going unreported, thus increasing the completeness of cases.
M11	Capture-recapture method	• A statistical method using multiple independent samples to estimate the size of an entire population.
M12	Death certificate method	• This method requires that death certificate cases can be explicitly identified by the data set and makes use of the M:I ratio to estimate the proportion of the initially unregistered cases.
M13	Histological verification of diagnosis	• The percentage of cases morphologically verified is a measure of the completeness of the diagnostic information.
M14	Independent case ascertainment	• Rescreening the sources used to detect any case missing during the registration process.
M15	Data element agreement	• Two or more elements within a data set are compared to check if they report the same or compatible information.
M16	Data source agreement	• Data from the data set are cross-referenced with another source to check for agreement.
M17	Conformance check	• Check the uniqueness of objects that should not be duplicated; the data set agreement with prespecified or additional structural constraints, and the agreement of object concepts and formats granularity between ≥2 data sources.
M18	Element presence	• A determination is made as to whether or not desired or expected data elements are present.
M19	Not specified	• Number of consistent values and number of total values.
M20	International standards for classification and coding	• For example, neoplasms, the International Classification of Diseases for Oncology provides coding of topography, morphology, behavior, and grade.
M21	Incidence rate	• Not specified
M22	Multiple primaries	• The extent that a distinction must be made between those that are new cases and those that represent an extension or recurrence of an existing one.
M23	Incidental diagnosis	• Screening aims to detect cases that are asymptomatic. • Autopsy diagnosis without any suspicion of diagnosed case before death.

Assessment M[a]	Assessment technique in reviews	Explanation
M24	Not specified	• 1=ratio of violations of specific consistency type to the total number of consistency checks.
M25	Validity check	• Data in the data set are assessed using various techniques that determine of the values "make sense."
M26	Reabstracting and recoding	• Reabstracting describes the process of independently reabstracting records from a given source, coding the data, and comparing the abstracted and coded data with the information recorded in the database. For each reabstracted data item, the auditor's codes are compared with the original codes to identify discrepancies. • Recoding involves independently reassigning codes to abstracted text information and evaluating the level of agreement with records already in the database.
M27	Missing information	• The proportion of registered cases with unknown values for various data items.
M28	Internal consistency	• The proportion of registered cases with unknown values for various data items.
M29	Domain check	• Proportion of observations outside plausible range (%).
M30	Interrater variability	• Proportion of observations in agreement (%). • Kappa statistics.
M31	Log review	• Information on the actual data entry practices (eg, dates, times, and edits) is examined.
M32	Syntactic accuracy	• Not specified.
M33	Log review	• Information on the actual data entry practices (eg, dates, times, and edits) is examined. • Time at which data are stored in the system. • Time of last update. • User survey.
M34	Not specified	• Ratio: number of reports sent on time divided by total reports.
M35	Not specified	• Ratio: number of data values divided by the overall number of values.
M36	Time to availability	• The interval between date of diagnosis (or date of incidence) and the date the case was available in the registry or data set.
M37	Security analyses	• Analyses of access reports.
M38	Not specified	• Descriptive qualitative measures with group interviews and interpreted with grounded theory.

[a]M: method.

[b]M:I: mortality:incidence ratio.

Completeness

Among the 20 reviews that defined data quality dimensions related to completeness, 6 (30%) incorporated data quality assessment methods into their framework [4,24,32,34,35,41]. These 6 reviews collectively introduced 17 different data quality assessment methods. Some reviews (4/6, 67%) mentioned multiple methods to evaluate completeness, which highlights the absence of a consensus within the literature regarding the most suitable approach. The most frequently used method in the literature for assessing completeness was the examination of variable completeness [4,24,32,35]. This method involved calculating the percentage of cases that had complete observations for each variable within the data set. In 3 reviews [4,24,32], researchers opted to compare the distributions or summary statistics of aggregated data from the data set with the expected distributions for the clinical concepts of interest. Another approach found in 3 reviews involved the use of a gold standard to evaluate completeness [4,24,32]. This method relied on external knowledge and entailed comparing the data set under examination with data drawn from other sources or multiple sources.

Consistency

Among the 15 reviews highlighting the significance of consistency, 6 (40%) defined data quality assessment methods [4,24,32,34,39,40]. In these 6 reviews, a total of 10 distinct data quality assessment methods were defined. The most used method involved calculating the ratio of violations of specific consistency types to the total number of consistency checks [32,39]. There were 2 categories established for this assessment. First, internal consistency, which focuses on the most commonly used data type, format, or label within the data set. Second, external consistency, which centered on whether data types, formats, or labels could be mapped to a relevant reference terminology or data dictionary. Another common assessment method was the implementation of international standards for classification and coding standards [34,40]. This addressed specific oncology and suggested coding for topography, morphology, behavior, and grade. Liaw et al [39] defined an assessment method in which ≥2 elements within a data set are compared to check if they report compatible information.

Correctness

Among the 16 reviews underscoring the importance of correctness, 6 (38%) detailed data quality assessment methods [4,24,32,34,35,40]. Collectively, these 6 reviews proposed 15 different techniques. Prominent among these were histological verification [34,40], where the percentage of morphologically verified values served as an indicator of diagnosis correctness. Another frequently used technique was the use of validity checks [4], involving various methods to assess whether the data set values “make sense.” Three additional reviews opted for a comparative approach, benchmarking data against a gold standard and calculating the sensitivity, specificity, and accuracy scores [4,32,35]. Interestingly, there is an overlap between consistency and completeness as data quality dimensions in the assessment of correctness. For instance, Weiskopf and Weng [4] defined data element agreement as an assessment for this dimension, whereas Bray and Parkin [40] evaluated the proportion of registered cases with unknown values for specific items as a correctness assessment method.

Stability

Among the 7 reviews emphasizing the importance of stability of the data, only 3 (43%) discussed assessment techniques that address this dimension [4,24,39]. These 3 reviews collectively outlined 5 different techniques. Notably, there was no predominant technique. Specifically, Weiskopf and Weng [4] used several techniques to assess data stability, including an overlap with other dimensions, by using data element agreement. Another technique introduced in the same review was data source agreement, involving the comparison of data from different data sets from distinct sources.

Timeliness

Of the 12 reviews focusing on the timeliness of data, 5 (42%) delved into assessment techniques for this data quality dimension [4,24,32,39,40]. Across these reviews, 5 distinct assessment techniques were discussed. The most commonly used technique was the use of a log review [4,39]. This method involved collecting information that provides details on data entry, the time of data storage, the last update of the data, or when the data were accessed. In addition, Bray and Parkin [40] assessed timeliness by calculating the interval between the date of diagnosis (or date of incidence) and the date the case was available in the registry or data set.

Trustworthiness

In the 2 reviews that considered trustworthiness as a data quality dimension, both used the same assessment technique [24,39]. This method involves the analysis of access reports as a security analysis, providing insight into the trustworthiness of the data.

Representation

In 1 review that addressed the representation dimension as a data quality aspect, only 1 assessment method was mentioned. Liaw et al [39] introduced descriptive qualitative measures through group interviews to determine whether the data accurately represented the intended use.

Uniqueness and Contextualization

No assessment methods were mentioned for these data quality dimensions.

Discussion

Principal Findings

This first review of reviews regarding the quality of health data for secondary use offers an overview of the frameworks of data quality dimensions and their assessment methods, as presented in published reviews. There is no consensus in the literature on the specific terminology and definitions of terms. Similarly, the methodologies used to assess these terms vary widely and are often not described in sufficient detail. Comparability, plausibility, validity, and concordance are the 4 aspects classified under different consolidated dimensions, depending on their definitions. This variability underscores the prevailing discrepancies and the urgent need for harmonized definitions. Almost none of the reviews explicitly refer to requirements of

quality for the context of the data collection. Building on the insights gathered from these reviews, our consolidated framework organizes the numerous observed definitions into 9 main data quality dimensions, aiming to bring coherence to the fragmented landscape.

Health data in primary sources refer to data produced in the process of providing real-time and direct care to an individual [50], with the purpose of improving the care process. A secondary source captures data collected by someone other than the primary user and can be used for other purposes (eg, research, quality measurement, and public health) [50]. The included reviews discussed data quality for secondary use. However, the quality of health data in secondary systems is a function of the primary sources from which they originate, the quality of the process to transfer and transform the primary data to the secondary source, and the quality of the secondary source itself. The transfer and transformation of primary data to secondary sources implies the standardization, aggregation, and streamlining of health data. This can be considered as an export-transform-load (ETL) process with its own data quality implications. When discussing data quality dimensions and assessment methods, research should consider these different stages within the data life cycle, a distinction seldom made in the literature. For example, Prang et al [27] defined completeness within the context of a registry, which can be regarded as a secondary source. In this context, completeness was defined as the degree to which all potentially registrable data had been registered. The definition for completeness by Bian et al [24] pertains to an EHR, which is considered a primary source. Here, the emphasis was on describing the frequencies of data attributes. Both papers emphasized the importance of completeness, but they approached this dimension from different perspectives within the data life cycle.

This fragmented landscape regarding terminology and definition of data quality dimensions, the lack of distinction between quality in primary and secondary data and in the ETL process, and the lack of consideration for the context allows room for interpretation, leading to difficulties in developing assessment methods. In our included articles, only 8 (36%) out of 22 reviews mentioned and defined assessment methods [4,24,32,34,35,39-41]. However, the results showed that the described assessment methods are limited by a lack of well-defined and standardized metrics that can quantitatively or qualitatively measure the quality of data across various dimensions and often suffer from inadequate translation of these dimensions into explicit requirements for primary and secondary data and the ETL process, considering the purpose of the data collection of the secondary source. Both the DAMA and ISO emphasize in their definition of data quality that requirements serve as the translation of dimensions. Data quality dimensions refer to a broad context or characteristics of data that are used to assess the quality of data. Data quality requirements are derived from data quality dimensions and specify the specific criteria or standards that data must meet to be considered high-quality data. These requirements define the specific thresholds that need to be achieved for each dimension. However, our results show that the focus of the literature lies in defining dimensions and frameworks, rather than adequately developing these essential data quality requirements.

To avoid further problems and ambiguities, it is important to understand the purpose, context, and limitations of the data and data sources to establish a comprehensive view on the quality of the data. Rather than pursuing an elusive quest in the literature for a rigid framework defined by a fixed number of dimensions and precise definitions, future research should shift its focus toward defining and developing specific data quality requirements tailored to each use case. This approach should consider various stages within the data life cycle. For example, when defining a specific completeness requirement for a secondary use case, it will impact the way data are generated at the primary source and how they are transformed and transferred between the primary and secondary sources. Creating explicit requirements that align with the purpose of each use case along with well-defined criteria and thresholds can foster the development of precise assessment methods for each dimension. Moreover, formulating these use case requirements will facilitate addressing the fundamental question of whether health data are fit for purpose, thus determining if they are of a sufficient quality.

Limitations

The strength of a review of reviews methodology is to provide a comprehensive overview of the current state of knowledge. However, it is important to acknowledge that this approach may have limitations, particularly in identifying new studies that have not yet undergone review or inclusion in the existing body of literature. Terms such as “information quality,” “error check,” “data check,” “data validation,” and “data cleaning” are commonly associated with the concept of data quality, particularly in older research papers. However, we did not include these terms in our search query because subsequent checking using these terms did not reveal any additional reviews that met our inclusion criteria. Furthermore, this overview focused on published reviews. Important information can also be found in grey literature [51,52] and in studies that collect stakeholders’ opinions on the quality of health data [20]. Finally, none of the included reviews discussed patient-generated data or data generated by wearables. Given the increasing adoption and use of these sources in health care, it is becoming important to consider their impact on data quality. Developing assessment methods that are applicable to these emerging data sources is an important area for further research.

Although having a consolidated reference framework of data quality dimensions and aspects is valuable, it is also of great importance to define specific data quality requirements for each relevant aspect within a single quality dimension. These requirements should specify the desired quality level to be achieved in a given percentage of the primary sources, based on the purpose of the data collection or a particular real-world data study. Once these requirements are clearly articulated, appropriate measurement methods can be determined, thereby ensuring the comprehensive analysis of secondary data collection for its suitability for a specific purpose.

Conclusions

The absence of a consensus in the literature regarding the precise terminology and definitions of data quality dimensions has resulted in ambiguity and challenges in creating specific assessment methods. This review of reviews offers an overview of data quality dimensions, along with the definitions and assessment methods used in these reviews. This study goes a step further by assigning all observed definitions to a consolidated framework of 9 data quality dimensions. Further research is needed to complete the collection of aspects within each quality dimension, with the elaboration of a full set of assessment methods, and the establishment of specific requirements to evaluate the suitability for the purpose of secondary data collection systems.

Abstract

Background: Therapeutic education and patient self-management are crucial in diabetes prevention and treatment. Improving diabetes self-management requires multidisciplinary team intervention, nutrition education that facilitates self-management, informed decision-making, and the organization and delivery of appropriate health care services. The emergence of telehealth services has provided the public with various tools for educating themselves and for evaluating, monitoring, and improving their health and nutrition-related behaviors. Combining health technologies with clinical expertise, social support, and health professional involvement could help persons living with diabetes improve their disease self-management skills and prevent its long-term consequences.

Objective: This scoping review's primary objective was to identify the key digital tool features of complex telehealth interventions used for type 2 diabetes or prediabetes self-management and monitoring with health professional involvement that help improve health outcomes. A secondary objective was to identify how these key features are developed and combined.

Methods: A 5-step scoping review methodology was used to map relevant literature published between January 1, 2010 and March 31, 2022. Electronic searches were performed in the MEDLINE, CINAHL, and Embase databases. The searches were limited to scientific publications in English and French that either described the conceptual development of a complex telehealth intervention that combined self-management and monitoring with health professional involvement or evaluated its effects on the therapeutic management of patients with type 2 diabetes or prediabetes. Three reviewers independently identified the articles and extracted the data.

Results: The results of 42 studies on complex telehealth interventions combining diabetes self-management and monitoring with the involvement of at least 1 health professional were synthesized. The health professionals participating in these studies were physicians, dietitians, nurses, and psychologists. The digital tools involved were smartphone apps or web-based interfaces that could be used with medical devices. We classified the features of these technologies into eight categories, depending on the intervention objective: (1) monitoring of glycemia levels, (2) physical activity monitoring, (3) medication monitoring, (4) diet

monitoring, (5) therapeutic education, (6) health professional support, (7) other health data monitoring, and (8) health care management. The patient-logged data revealed behavior patterns that should be modified to improve health outcomes. These technologies, used with health professional involvement, patient self-management, and therapeutic education, translate into better control of glycemia levels and the adoption of healthier lifestyles. Likewise, they seem to improve monitoring by health professionals and foster multidisciplinary collaboration through data sharing and the development of more concise automatically generated reports.

Conclusions: This scoping review synthesizes multiple studies that describe the development and evaluation of complex telehealth interventions used in combination with health professional support. It suggests that combining different digital tools that incorporate diabetes self-management and monitoring features with a health professional's advice and interaction results in more effective interventions and outcomes.

Introduction

Diabetes and Nutrition

The prevalence of diabetes in Canada is constantly rising, and related health expenditures are among the highest in the world. In 2018, approximately 8% of the Canadian population was living with this disease, and it is predicted that in 2025, a total of 5 million people will be affected (ie, 12.1% of the population) [1,2]. According to estimates, type 2 diabetes accounts for 90% of all diabetes diagnoses in the general population, type 1 diabetes accounts for 9%, and other kinds of diabetes account for 1% [3]. The prevalence of diabetes has been closely linked to dietary and lifestyle factors prevalent within the country, such as high rates of obesity and sedentary behavior coupled with a diet often rich in processed foods. However, best practice guidelines suggest that the onset of type 2 diabetes can be delayed or prevented using early lifestyle change interventions. As prediabetes is characterized by elevated blood glucose levels that do not yet meet the diagnostic criteria for diabetes, the therapeutic management of diabetes and prediabetes is similar [4,5]. In both cases, a comprehensive approach is required to better control glycemia levels [6,7]. Many factors are involved in preventing the disease and achieving better disease control, such as changing lifestyles through education, supporting self-management, and preventing the development and progression of complications [8]. The Diabetes Canada clinical practice guidelines recommend that individuals with diabetes receive personalized nutrition counseling by a registered dietitian to optimize glycemic control and weight management [3]. Strategies include caloric reduction for individuals who are overweight; the incorporation of low glycemic index carbohydrates; and the adoption of a Mediterranean, Nordic, Dietary Approaches to Stop Hypertension (DASH), or vegetarian diet because they are rich in protective foods [3]. These interventions are supported by evidence demonstrating improvements in glycated hemoglobin (HbA_{1c}) levels, metabolic outcomes, and reductions in hospitalization rates. As stated in the Diabetes Canada clinical practice guidelines, the care offered should be organized around the needs of people with diabetes (and of their families and close friends) because patients must be active participants for optimal engagement in self-managing their condition [4,8]. This active patient participation must be facilitated by a multidisciplinary team (nurses, dietitians, and physicians) that offers education and self-management support. Changing dietary behaviors poses a considerable challenge for people living with diabetes, yet it is a vital means of preventing the associated complications [4]. Monitoring with a dietitian's involvement has proven effective in supporting such behavior changes [4]. Again according to the Diabetes Canada clinical practice guidelines, all people living with diabetes should receive the services of a dietitian [4]. It has been shown that diet monitoring with a dietitian's involvement can alone reduce HbA_{1c} levels by 1% to 2% [4]. In addition, recent evidence underscores the advantages of using telehealth to foster adherence to medical recommendations and self-management [4,5,9]. Scientific literature has shown the benefits of telehealth in Canada for diabetes management [3,10]. These technological innovations facilitate patient monitoring and promote the use of different interventions that can support lifestyle changes through, for example, remote support, the telemonitoring of glycemia levels, reminders about taking medication, and the use of a food diary. These innovations also allow this information to be shared with the health care team. In 2018, the Diabetes Canada clinical practice guidelines advocated for the use of telehealth in disease management programs to improve self-management in underserved communities and to facilitate consultation with specialized teams, highlighting its effectiveness and the importance of integrating it into shared care models [3].

Telehealth and Diabetes Self-Management

Telehealth refers to "the use of communications and information technology to deliver health and health care services and information over large and small distances" [11]. In the same field of application, telemedicine refers to the exchange of medical information using information and communication technologies to improve a patient's health condition and is delivered by at least 1 health professional [12]. Telemedicine services are provided using various means, including the telephone, internet, email, mobile apps, SMS text messaging, photographs, and videos. New technologies are revolutionizing the health care field by creating new prospects for various care delivery modalities [13]. They are thus paving the way for

innovations and represent a real benefit in the face of new health care challenges, such as the aging population, rising health care costs, and the unprecedented challenges posed by pandemics such as the COVID-19 pandemic [6]. Particularly in Canada, the public health care system faces challenges often associated with overcrowded clinics, long wait times, and limited resources [7]. Through remote consultations and continuous monitoring, telehealth has the potential to relieve pressure on health care facilities, improving resource allocation and optimizing patient flow management in the public health care system. As such, telehealth would be a pertinent response to public health organizational challenges in the Canadian context, where the universal health care system aims to provide equitable and accessible care to all residents.

The day-to-day management of type 2 diabetes can be a complex challenge. Patients must monitor their blood glucose levels regularly, take medication on a precise schedule, adopt a balanced diet, and maintain adequate physical activity [7]. However, these requirements can be difficult to meet owing to time constraints, a lack of knowledge, or limited resources. In addition, fluctuations in blood glucose levels can occur unpredictably, increasing the risk of short- and long-term complications [7]. In particular, nutrition plays a fundamental role in diabetes management. Dietary monitoring, nutrition education, and the personalization of dietary recommendations are key aspects in optimizing health outcomes for patients with diabetes. Using digital technologies, it is possible to offer ongoing personalized nutrition support, enabling patients to make informed dietary decisions and maintain adequate glycemic control.

Recent evidence points to the enormous potential of using health technologies to facilitate access to care, patient adherence to their treatment plan, and self-management [14]. Many experts point out that diabetes is a chronic disease best adapted to self-management through telehealth [14-19]. Technological innovations have been developed to support lifestyle changes and facilitate patient monitoring. Telehealth offers a range of potential benefits for people with type 2 diabetes. Continuous monitoring of blood glucose levels using connected sensors enables patients to receive real-time information on their blood glucose levels and be alerted to abnormal variations [2,3]. This enables them to take immediate action to correct blood glucose levels and avoid complications. In addition, telehealth facilitates access to specialized care by enabling patients to consult health professionals remotely. This reduces geographic barriers and enables patients to receive personalized advice, education, and support tailored to their specific needs [9]. Regular monitoring and feedback as well as the use of digital tools encourage patients to better understand their condition, make informed decisions, and improve their quality of life [8]. According to recent systematic reviews and meta-analyses, these telehealth interventions involving everyday web-based and mobile technologies help reduce HbA_{1c} levels, allow for better daily glycemic control, promote an increase in physical activity, and improve dietary habits [20,21]. Connected blood glucose meters enable more convenient and accurate monitoring of blood glucose levels, whereas web-based platforms offer a web-based space for education, support, and communication with health professionals [14,15]. Teleconsultation enables patients to consult their physicians and specialists remotely, reducing travel and time constraints [15,16].

Combining self-management technologies with clinical expertise, social support, and health professional involvement can allow the development of telehealth solutions better adapted to the therapeutic management of patients with a chronic disease. Telehealth interventions using this combination are therefore expanding [22], but they present both advantages and limitations [12]. Telehealth enables improved care coordination, personalized interventions, and tailored patient education. However, it can lead to an increased workload for health care providers and raise data privacy concerns. The tension between interventions focused on service delivery and those involving health care providers highlights the importance of striking a balance between patient autonomy and medical expertise. An integrated collaborative approach involving both patients and health care providers may offer the best digital health outcomes. However, further studies are needed to fill the gaps in the literature, focusing on comparative studies with usual care, the evaluation of adherence, and long-term accessibility to optimize the use of telehealth in the self-management of type 2 diabetes.

To the best of our knowledge, no literature review has been conducted to identify the key digital tool features of such interventions. Nonetheless, improving knowledge on this subject could advance the development of more effective telehealth interventions for people with diabetes.

The primary objective of this scoping review was to identify the key digital tool features of complex telehealth interventions used for diabetes self-management and monitoring with health professional involvement that help improve health outcomes. The secondary objective was to identify how these key features should be developed and combined to optimize their contribution to improving health outcomes. Although our review draws from global scientific literature, the intent is to inform the future development of telehealth technologies, with a particular emphasis on the Canadian health care context. This focus stems from the recognition that although universal principles may guide the development of digital health tools, the specific features and their implementation must be tailored to meet the unique needs, regulations, and health care infrastructure of Canada. Our review aims to explicitly identify the characteristics of digital tools that have been shown to be effective in improving patient engagement, improving self-management, and leading to better health outcomes in diabetes care. By systematically cataloging these characteristics, we can provide a model for the design, development, and implementation of future telehealth interventions, provided we keep in mind specific requirements of the Canadian health care context, such as compliance with telehealth policies, local health care, patient privacy laws, and existing health IT infrastructure. In this study, *improving health outcomes* encompasses both the positive effects of the intervention on behavior changes (eg, eating healthier foods or performing physical activity) and the positive impacts on the health condition (eg, improved blood glucose levels or blood pressure).

Methods

Overview

Scoping reviews exhaustively synthesize the evidence to map a vast, complex, or emerging field of study and identify gaps in the literature, ultimately highlighting priorities for future studies in the field [23]. We chose this method because telehealth has emerged in different formats and offers solutions to various pathologies. We structured our scoping review according to the five steps developed by Arksey and O'Malley [24] and the revisions made by Levac et al [25]: (1) identifying the research question; (2) identifying relevant studies; (3) selecting the studies; (4) charting the data; and (5) collating, summarizing, and reporting the results. The procedure, which is described in the following subsections, was conducted in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist (Multimedia Appendix 1) to ensure rigorous and transparent reporting of the methodology and findings [26]. Several additional recommendations made by Levac et al [25] were also followed: clearly articulate the research question for the scoping review, have 2 researchers independently review the full articles to determine their inclusion, have the research team collectively develop the data-charting form, and continually extract data.

Identifying the Research Questions

This review seeks to answer the following research questions:

1. What are the key digital tool features of complex telehealth interventions used for diabetes self-management and monitoring with health professional involvement that help improve health outcomes?
2. How should these key features be developed and combined to help improve health outcomes?

These questions stem from the lack of consensus in scientific literature on the conceptual development, implementation, and evaluation of telehealth solutions. The research questions and objectives were developed based on the research team's expertise and a preliminary analysis of the literature on the subject. In accordance with scoping review methodology, this review included studies that used different approaches and research designs.

In this review, we applied the World Health Organization definition of telemedicine: "The delivery of health care services, where distance is a critical factor, by all health professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries, research and evaluation, and for the continuing education of health care providers, all in the interests of advancing the health of individuals and their communities." Furthermore, in the context of telehealth technology, the term *features* refers to the various components or tools that enable the various activities associated with remote health care delivery.

Identifying and Selecting the Studies

The search strategy was developed in collaboration with a Université de Montréal librarian specializing in health. The keywords based on *telehealth*, *nutrition*, and *diabetes* were identified by examining relevant articles, their references, and the associated keywords (Multimedia Appendix 2). A systematic search was performed in the MEDLINE, CINAHL, and Embase databases, covering the period from January1, 2010, to March 31, 2022. Our search efforts were focused on these databases because they are repositories where studies related to health and nutrition can be found. Only articles published since January 1, 2010, were selected to account for the widespread adoption of smartphones. By extending our review to cover more than a decade, we were able to capture the significant developments in mobile apps and smartphone use, which are pivotal in digital health. We also perused the bibliographies of the included articles to identify any additional studies. Only articles published in peer-reviewed scientific journals were examined. As proposed by the framework developed by Arksey and O'Malley [24], a quality assessment was not performed because it is not deemed essential for exploratory studies. The methodological rigor of the published articles was not an inclusion or exclusion criterion; instead, the articles were examined to substantiate the results and the discussion.

Given the rapid development of new technologies, only articles on complex telehealth interventions for managing diabetes published in the 12 years covering the period from January 1, 2010, to March 31, 2022, were retained. We used an iterative process to develop the inclusion and exclusion criteria during our searches to ensure a selection of studies more closely aligned with the research question. The searches were limited to scientific publications in English and French that either described the conceptual development of a complex telehealth intervention combining self-management and monitoring with health professional involvement or evaluated its effects on the therapeutic management of patients with type 2 diabetes or prediabetes. For inclusion in this review, the complex interventions had to be digital, have a patient interface, and concern type 2 diabetes or prediabetes self-management or monitoring. We excluded studies (1) not using a nutritional approach to investigate telehealth interventions, (2) involving a single component, (3) not integrating at least 1 health professional, (4) concerning type 1 diabetes or gestational diabetes, (5) involving populations aged <18 years, and (6) lacking empirical data (eg, literature reviews). All search results were imported into the Covidence reference management software (Veritas Health Innovation Ltd), and duplicates were removed [27].

The review team comprised CM, DG, KVM, and BV. These 4 researchers determined the inclusion of relevant studies based on the title and abstract; CM and BV determined the selection based on the full-text articles. Differences were discussed in detail until a consensus was reached. The full texts of the relevant articles were retrieved for more in-depth analysis (CM).

Charting the Data

The research team developed a data extraction table. It included the following information: study characteristics (eg, title,

participants, the results of interest, and effectiveness), intervention characteristics (eg, a brief description of the intervention, the components of self-management, and the components of monitoring with health professional involvement), and the benefits and limitations of both the intervention and the study according to the authors or reviewers.

Collecting, Summarizing, and Reporting the Results

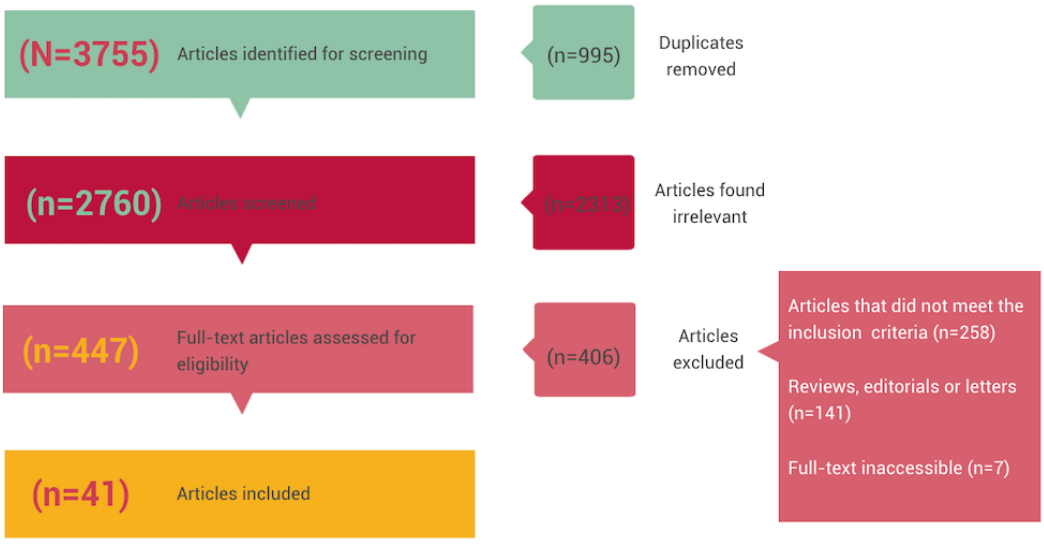
Again according to the framework developed by Arksey and O'Malley [24] and the revisions by Levac et al [25], descriptive web-based abstracts and thematic analyses performed with NVivo software (release 1.7; Lumivero) were used for data analysis, yielding an approach resembling that of a narrative review. In conducting our thematic analysis, we adopted a qualitative approach to discern the impact of telehealth interventions with health professionals on the health outcomes of patients with diabetes. Through meticulous data immersion and iterative coding, we identified recurring patterns that we then shaped into themes. An initial list of these codes, forming a codebook, was iteratively refined during the data analysis process [28]. Once the codes were established, it enabled a comprehensive review of their interrelationships, aiding in the identification of the key digital tool features of complex telehealth interventions used for diabetes self-management and monitoring with health professional involvement that help improve health outcomes. These themes were refined against the data set to ensure coherence and direct relation to our research objectives. By integrating concrete examples from the data, we were able to provide a rich, detailed description of the telehealth features, thereby adding depth to our findings and ensuring that they were both representative of real-world practices and aligned with our research questions.

Results

Overview

The database searches identified 3755 articles, from which 995 (26.5%) duplicates were removed. The 2760 remaining articles underwent an initial screening based on the abstract and title, after which 2313 (83.8%) were excluded. The full-text screening involved assessing 447 articles, of which 406 (90.8%) were deemed ineligible because the studies did not meet the inclusion criteria (n=258, 63.7%); were literature reviews, editorials, or letters (n=141, 34.8%); or the full texts were inaccessible (n=7, 1.7%; Figure 1). Thus, of the 3755 articles identified from the database searches, 42 (1.12%) were ultimately included in this scoping review (Multimedia Appendix 3 [29-70]). The qualitative analysis of the 42 articles using NVivo (release 1.7) yielded the coding of 1520 references, divided among 113 codes.

Figure 1. Flow diagram of study selection.



Characteristics of the Studies

The 42 studies were published between January 1, 2010, and March 31, 2022, with as many as 28 (67%) published within the past 6 years [29-56]. We found that, in 2021, nearly twice as many articles were published on the topic as in each of the previous 4 years (Figure 2).

Information on complex telehealth interventions used for diabetes self-management and monitoring with health professional involvement was obtained for 18 countries. Of the 42 studies, 11 (26%) were conducted in the United States [30,31,39,48-51,57-59]; 5 (12%) in South Korea [37,41,44,60,61]; 4 (10%) in Singapore [29,43,46,55]; 4 (10%) in Norway [32,62,63]; 3 (7%) in the United Kingdom [33,35,38]; 3 (7%) in Germany [40,45,56]; 2 (5%) in China [47,64]; and 1 (2%) each in Australia [54], South Africa [65], Spain [66], Iran [52], Italy [67], Japan [42], Lebanon [34], Slovenia [36], Switzerland, and Taiwan [68] (Figure 3).

Figure 2. Years in which the studies were published. Each circle represents 1 study.

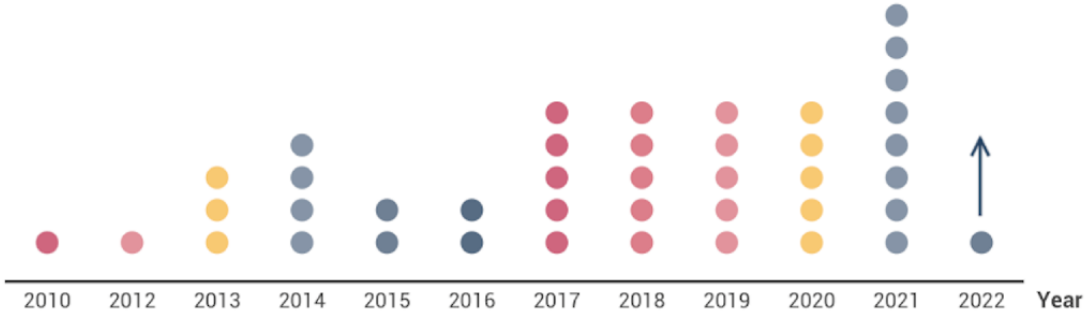


Figure 3. Countries in which the studies were published. The dots represent articles and the x-axis denotes the years.

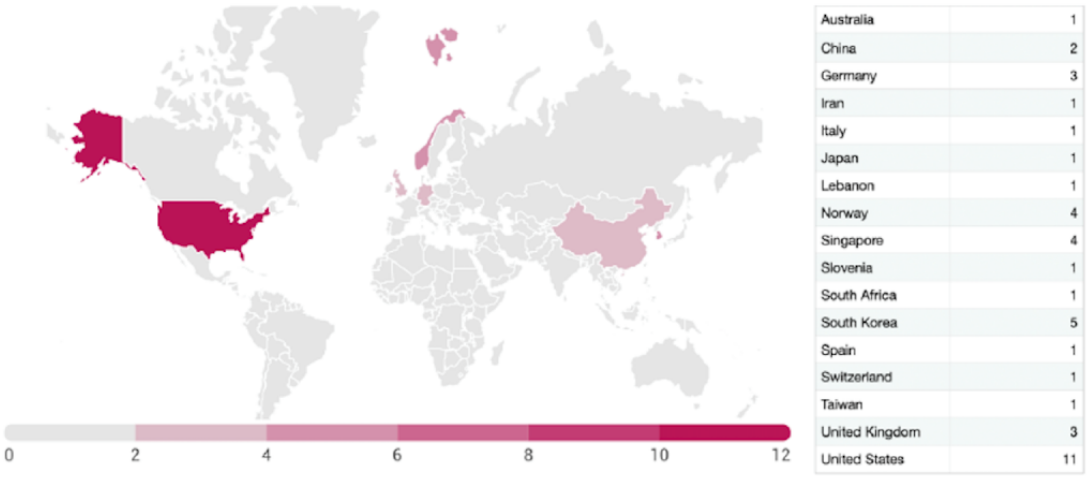
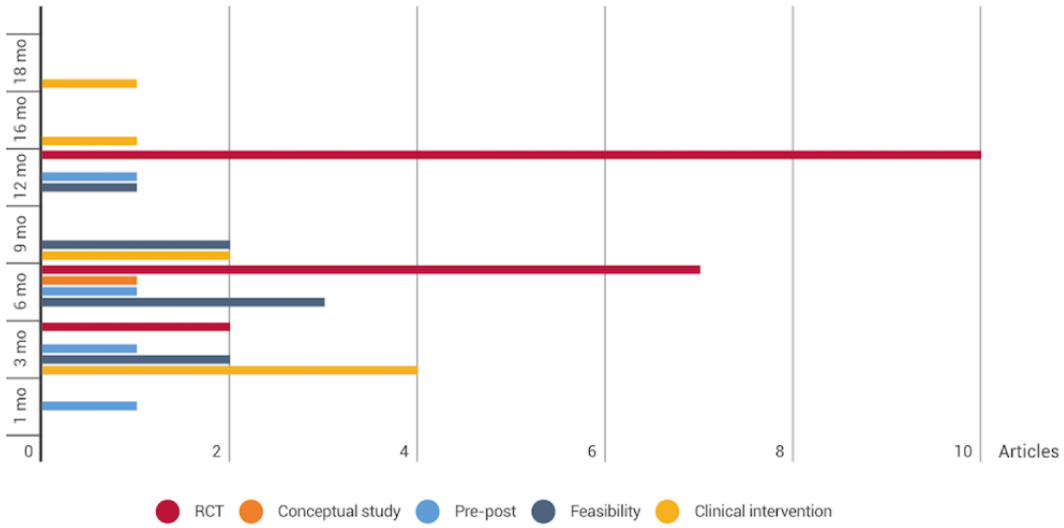


General Characteristics of the Intervention

One-third (14/42, 33%) of the studies were randomized controlled trials [35,36,40-42,46,47,55,57-59,62,64,67], with most of them (n=12, 86%) ranging from 6 months to 1 year in duration. Of the 42 studies, 9 (21%) were feasibility studies, with the interventions ranging from 3 months to 1 year in duration [33,38,39,43,44,51,53,56,71]; 8 (19%) were interventional studies, with the interventions ranging from 3 to 18 months in duration [30,31,34,48,50,54,63,68]; 5 (12%) were conceptual studies lasting 6 months [45,49,52,65,66]; and 4 (10%) were pre-post studies, in which the interventions ranged from 1 month to 1 year in duration [29,37,60,61] (Figure 4).

Figure 4. Durations of the interventions. RCT: randomized controlled trial.



Health Professional Involvement

Of the 42 studies, 21 (50%) included physicians [29-32,36,40-42,45,47-51,53,58,60,64,66,68,69], 16 (38%) involved dietitians [29,31,33,35,39,43,46,54,56,59,60,65,68-70,72], 12 (29%) involved nurses [31,32,36,41,55,58-62,68,69], 4 (10%) involved psychologists [31,33,67,69], 4 (10%) involved physical educators [29,33,35,60], and 3 (7%) involved case

managers [36,60,68]. Finally, of the 42 studies, 13 (31%) involved a multidisciplinary team [29,31-33,35,36,41,58-60,68,69,72], and 22 (52%) involved only 1 clinician [30,39,40,42,43,45-51,53-56,61,62,64-66,70] (Multimedia Appendix 4 [29-70]).

Characteristics of Digital Self-Management

The interventions under study involved the use of a mobile app [29-34,36-39,41-46,49,51-53,55,59-65,67,69,70] or a web portal [32,35,36,40-42,44,45,47,48,52,57,58,60,63,66-68,70], usually coupled with a blood glucose meter to optimize diabetes self-management [37,38,40,41,43,44,46,48-51,53,55,57,59-64,68,69]. Other Bluetooth-connected devices were used in some of the interventions (10/42, 24%), such as a Bluetooth-connected weight scale [31,40,42,43,46,48], a pedometer [40,43,45], an accelerometer [33,42], a Bluetooth-connected smartwatch [49], and a tensiometer [42].

The types of data collected concerned the monitoring of glycemia levels through, for example, the visualization of a blood sugar curve over time [29,32,37,38,41,43-49,51-53,55,59-66,68,69]; physical activity monitoring using, for example, a pedometer [33,35,40,43,45,46,56,61,67]; diet monitoring using, for example, a food diary [29-33,35,37,39,41,43-45,47,49,52,53,55,56,59,61-63,67-69]; medication monitoring through, for example, adherence monitoring or the possibility of issuing remote prescriptions [30,50]; and other health data monitoring (weight, BMI, and laboratory tests) [29,32,33,40,43,45-47,53,56,60,65,66]. Other features made it possible to ensure continuity of care by, for example, generating reports [34,38,42,45,47,52,60,66,67,70]; supporting therapeutic patient education; and ensuring support from a health professional to help patients learn and develop skills to independently manage their chronic disease and improve their quality of life [15,16].

On the basis of our analysis of the literature, we classified the key digital tool features that can have a positive impact on intervention outcomes into eight categories: (1) monitoring of glycemia levels, (2) diet monitoring, (3) physical activity monitoring, (4) medication monitoring, (5) therapeutic education, (6) health professional support, (7) other health data monitoring, and (8) health care management (Multimedia Appendix 5 [29-70]).

Key Digital Tool Features With Positive Impacts on the Health Condition

Monitoring of Glycemia Levels

Of the 42 studies, 22 (52%) incorporated a blood glucose meter to precisely monitor blood glucose levels during interventions; the blood glucose meter allowed the visual tracking of blood sugar curves by the patient and health professionals [37,38,40,41,43,44,46,48-51,53,55,57,59-64,68,69]. In addition, 3 (7%) of the 42 studies included blood glucose meters permitting real-time continuous blood glucose monitoring [29,30,50].

Of the 42 studies, 4 (10%) included an alert system [36,52,68,73]: "The online diabetes self-management system sent an SMS text message to care providers when the data exceeded the alerting range" [68]; "The application automatically sent users reminders by simple e-mail and SMS: 'Please enter your blood sugar/or other parameters into the eDiabetes application'" [36]. Of the 42 studies, 9 (21%) included a bolus dosing system [32,38,45,55,57-59,66,74]: "An optional bolus dosing feature was available as an algorithm on the e-diary that allowed the patient to generate a premeal bolus insulin dose" [57]. Of the 42 studies, 2 (5%) allowed the remote prescription of real-time continuous blood glucose monitoring devices [30,50].

The 42 studies used different indicators to collect glycemic control data, such as (1) HbA_{1c} levels in 27 (64%) studies, monitored through blood tests [29-34,36,40,41,43,44,46-48,51,54,55,57-60,62-64,67-69]; (2) blood glucose levels in 24 (57%) studies, monitored using data recorded by a blood glucose meter or a blood test [32-34,36,40,41,43,44,46-48,50,53-55,57-60,63,64,66,68,69]; and (3) hypoglycemia events in 4 (10%) studies [55,57,60,69], based on self-reports or alert systems after the recording of blood glucose levels with a blood glucose meter. All interventional studies included in the review reported a reduction of between 0.433 mmol/L and 1.554 mmol/L in fasting blood glucose levels. The studies reported a statistically significant decrease in HbA_{1c} levels ranging from 0.5% to 1.65% [34,40,41,57,68], as well as a drop of up to 1.554 mmol/L in blood glucose levels [29-31,36,41-44,46,48,56,57,59,61,62,68,69].

Diet Monitoring

Of the 42 studies, 13 (31%) included a meal planning system, with features such as generating shopping lists and recipes and calculating caloric intake [29,31,35,38,43,44,46,48,49,52,53,65,68]; and 27 (64%) included a food diary system that could be shared with the health professional for comment [29-33,35,37-39,41,43-47,49,52,53,55,56,59,61-63,67-69]. Patients logged their data using a list of foods or by taking photographs. A caloric intake–counting feature was available in 11 (26%) of the 42 studies [29,35,38,43,44,48,49,52,53,65,68]. Of the 42 studies, 5 (12%) included a carbohydrate-counting system [32,46,49,53,66]: "The app provided an automated individualized calorie limit which was computed based on body weight, gender, age and activity level. The total daily carbohydrate intake was restricted to 40% of total daily calories" [46]; "From the nutrition screen, the test persons manually entered carbohydrate values for their meals or scanned products to import the carbohydrate data into the app" [53]. Of the 42 studies, 18 (43%) included pedagogical material, particularly nutrition education and knowledge evaluation [31,33-37,46-48,51,52,55,59,60,63,64,66,69]. To collect data on diet, the studies used the data logged on mobile or internet platforms or obtained from food diaries, 24-hour reminders, or calorie counting [32,46,49,53,66]. The health professionals evaluated diet quality using the shared data or validated questionnaires (eg, the Healthy Eating Index). The studies reported a better understanding of nutritional issues, greater confidence in maintaining a healthy diet, and an improvement in dietary behavior [30,31,40,41,44,61,68,70].

Physical Activity Monitoring

Of the 42 studies, 6 (14%) monitored physical activity using a Bluetooth-connected device (Bluetooth-connected watch [49], pedometer [40,43,45], or accelerometer [33,42]), 8 (19%) used step counting via a Bluetooth-connected pedometer or a smartphone-integrated feature [33,35,40,45,46,56,61,67], and 16 (38%) included a graphic monitoring tool for monitoring physical activity [29,32,35,37,41,43-45,49,52,55,62-65,69]. These graphs were generated automatically using pedometer data or after patients' manual logging of their activities based on a list of predefined physical activities. A caloric expenditure–counting feature was often available: "Type, time, and intensity of any completed physical activity, which could be translated into calories burned. (BCT: prompt self-monitoring of behavior; provide feedback on performance)" [35]. The studies used data logged on mobile or internet platforms and obtained from pedometers, accelerometers, or self-reported physical activity diaries to collect physical activity data. These data made it possible to adjust the automated recommendation messages and the messages from the health professionals with whom the data were shared. The studies reported a trend toward increased weekly physical activity owing to the technology-motivated engagement (eg, Chen et al [68] report a significant increase in physical activity; $P<.001$) [30-38,41-47,50,54,55,57,60,62-64,66-69].

Medication Monitoring

Of the 42 studies, 16 (38%) included a medication adherence–tracking device [30,32,37,38,41,45,49,52,53,55,59,61,63-65,68], half of which (n=8, 50%) had a reminder feature [32,37,45,52,55,61,63,68]. Of the 42 studies, 6 (14%) included an insulin dose–adjustment device used by the health professional or patient (eg, using a bolus dose algorithm) [29,40,48,57,66,69]. Regarding the medication data collected, of the 42 studies, 6 (14%) reported medication adjustments [29,40,48,57,66,69], 7 (17%) analyzed the monitoring of prescribed insulin doses [30,32,55,57,58,66,68], and 5 (12%) administered questionnaires on medication adherence [31,34,50,57,67]. Finally, 4 (10%) of the 42 studies reported decreased oral antidiabetic doses after the interventions [31,40,48,68].

Therapeutic Education

Patients were provided various pedagogical tools to support their therapeutic education in 20 (48%) of the 42 studies [31,33-37,43,46-48,51,52,55,59,60,63,64,66,69,70]. Among these 20 studies, web-based course modules were used in 4 (20%) [43,48,63,66]. Other tools were used to advance nutritional literacy [31,35,46,59]; or the tools talked about or referred to relevant articles on topics such as using a blood glucose meter, diabetes complications, physical activity, and tobacco use [33,35,36,43,46,48,52,55,59,66,69]. Finally, 2 (10%) of the 20 studies proposed meditation or mindfulness exercises [51,55]. Personalized recommendation tools were used in 11 (26%) of the 42 studies [29,37,45-48,51,52,60,63,66]. These recommendations were either delivered by a health professional after an analysis of the patient's logged data, generated automatically by an artificial intelligence algorithm, or planned according to a therapeutic education protocol. The pedagogical materials were often supported by electronic notebook tools where patients could jot down topics to discuss with their health professionals [52,64,67].

Health Professional Involvement

Among the 42 studies, communication between the health professional and patient was ensured through a chat feature in 13 (31%) studies [31,35,43,46,47,49,51,52,59,60,63,66,68], by email in 7 (17%) studies [31,33,36,43,66,67,71], by SMS text messaging in 14 (33%) studies [29,36,37,41,42,44,48,54,58,62,63,67-69], by telephone calls in 13 (31%) studies [31,33,40,48,55-58,60,62,67-69], and by videoconferencing in 4 (10%) studies [55,60,67,68].

Of the 42 studies, 33 (79%) included a tool for displaying patient data [30,32-37,39,41-49,51-59,63-66,68-70], one-third of them (n=11, 33%) in real time, in the form of a graphic report. Of the 42 studies, 3 (7%) included a decision support tool [34,45,64], whereas 12 (29%) included a tool for setting and monitoring therapeutic goals that could be shared by the care provider and patient [29,32,33,37,45,46,53,59,61,63,68,69].

Other Health Data Monitoring

The monitoring of other health data concerned weight loss. Of the 42 studies, 16 (38%) monitored weight using a graphic representation over time [29,31-33,40,42,43,45-48,53,56,60,65,66]. Of these 16 studies, 6 (38%) collected automated data using a Bluetooth-connected weight scale [31,40,42,43,46,48]. In addition, 7 (17%) of the 42 studies enabled the sharing of blood test results [38,40,60,61,64,65,68]. Kobayashi et al [42] used a Bluetooth-connected tensiometer to transmit blood pressure readings to a cloud-based server, making it possible to summarize and present the data to patients and their primary care physicians to promote self-management, monitoring, and follow-up. The studies reported a statistically significant reduction in weight ranging from 3 to 6.2 kg [29,40,43,46,56,60] and in BMI ranging from 1.6 kg/m^2 to 4 kg/m^2 [29,34,42,48,56,60].

Health Care Management

Of the 42 studies, 20 (48%) included personal spaces in their technologies [31-35,38,40,42,45,47,49,51-53,61,63,66-68,70]. In these spaces, it was possible to view a dashboard summarizing the logged health data, monitor exchanges with health professionals, and generate reports that could be shared by the patient and downloaded by the health professionals for inclusion in the medical file [34,38,42,45,47,52,60,66,67,70]. Social support was promoted through links to social networks in 6 (14%) of the 42 studies [31,35,37,41,44,48]. Of the 42 studies, 6 (14%) included a web-based appointment scheduling tool, facilitating monitoring and follow-up by the health professionals [32,33,35,53,64,67]. Finally, Holmen et al [69] made technical support available 7 days a week to users of their technology.

Combination of Interventions

Studies showing significant positive results were those combining the involvement of a health professional with the monitoring of glycemia levels, diet, physical activity, and medication [41,57,61]. Of the 42 studies, 1 (2%) combined support from a health professional with the monitoring of

glycemia levels, diet, and physical activity; therapeutic education; and a follow-up of body weight [29]. Some of the studies (7/42, 17%) only added to the involvement of a health professional the monitoring of glycemia levels and physical activity (n=1, 14%) [40], the monitoring of glycemia levels alone (n=2, 29%) [51,58], diet and medication monitoring with therapeutic education (n=1, 14%) [31] or without therapeutic education (n=1, 14%) [35], diet monitoring and therapeutic education (n=1, 14%) [70], and physical activity and body weight monitoring (n=1, 14%) [42]. Of the 42 studies, 2 (5%) with positive significant results evaluated the combination of a health professional and the monitoring of glycemia levels, diet, and medication (n=1, 50%) [30] and therapeutic education and body weight follow-up (n=1, 50%) [34]. Most often (23/42, 55%), the combined strategies involved a health professional and the monitoring of glycemia levels and diet (Multimedia Appendix 6 [29-31,34,35,40-42,51,57,58,61,70]).

Discussion

Principal Findings

This study mapped telehealth interventions tailored to the needs of patients with type 2 diabetes supported by a health professional. This review—despite the range of scientific literature available; the complex nature of these interventions; and the heterogeneity of study designs, populations, organizational care contexts, measures, and result indicators used—revealed a trend suggesting the effectiveness of telehealth interventions with health professional involvement in improving health outcomes. The use of everyday technologies in these interventions could facilitate their accessibility and usability, which would facilitate their implementation in the longer term. On the basis of our exploration of the literature, we were able to classify the key features of digital tools that may have a positive effect on intervention outcomes into eight categories: (1) monitoring of glycemia levels, (2) diet monitoring, (3) physical activity monitoring, (4) medication monitoring, (5) therapeutic education, (6) health professional support, (7) other health data monitoring, and (8) health care management (Figure 5).

The duration of the interventions varied significantly among the studies, with interventions lasting 1 month to 18 months. A recent meta-analysis on the effectiveness of telemedicine application for chronic diseases found that for people living with type 2 diabetes, HbA_{1c} levels began to decrease after up to 12 months of telemedicine intervention compared with interventions lasting 6 months [75]. These results were also supported in a study by Timpel et al [76], where HbA_{1c} levels began to decrease in participants after 12 months of long-term telemedicine intervention. Given that the HbA_{1c} level is a recognized indicator of glycemic control over a retrospective period, reflecting average blood glucose levels over approximately 3 months, it is regarded as a standard for assessing the effectiveness of long-term diabetes interventions [77]. This measure offers a more stable view of a patient's glycemia levels than instantaneous measurements, which can be influenced by many immediate factors [77]. Longer interventions could allow for more accurate adjustments in treatments and disease management behaviors as well as provide enough time for these changes to result in improvements in glycemic control.

The health professionals involved in these studies were primarily physicians, dietitians, and nurses. Nearly half (19/42, 45%) of the studies involved a multidisciplinary care team [29,31,34,37,38,41,44,48,50,52-54,57-59,63,67,68,71] (Multimedia Appendix 4). The studies showed that health technologies could help optimize the therapeutic education and monitoring of people living with type 2 diabetes through collecting and sharing information between consultations. Care provider personnel would thus be better able to focus on other aspects of their practice during consultations. Some of the interventions (4/42, 10%) used a videoconferencing platform for consultations with the health professional to make the exchanges more natural and pleasant [55,60,67,68]. A recent narrative review that included 12 randomized controlled trials assessing the effectiveness of telemedicine versus conventional counseling, demonstrated that the counseling and monitoring of patients living with diabetes via telemedicine was more effective than conventional counseling [78]. Similarly, health technologies could help improve the efficiency of practical tasks performed by health professionals, for example, by producing more concise automatically generated reports that can be shared among the care team, thus fostering interdisciplinary monitoring and follow-up. They also offer the possibility of monitoring patients in real time and sharing targeted information with them, thereby facilitating timely adjustments. Telehealth tools enable the continuous monitoring of blood glucose levels, physical activity, diet, medication intake, and other health indicators. This enables patients and health care providers to quickly detect fluctuations in blood sugar levels and take appropriate action to maintain optimal control of blood sugar levels [1]. The features of telehealth tools can provide personalized recommendations and advice based on each patient's specific data [2]; for example, patients can receive medication reminders, nutritional advice tailored to their dietary preferences, and suggestions for physical activities based on their condition and health goals [2]. Telehealth tools offer educational resources and information on type 2 diabetes [3]. Patients can access educational materials, explanatory videos, meal plans, and tips to improve their understanding of the disease and its management [3]. This promotes patient empowerment by enabling them to actively participate in the management of their health [3-5]. Telehealth tools can include features such as appointment reminders, food diaries, and physical activity logs. These features help patients track their progress, stay engaged with their treatment, and maintain their motivation [3,5].

Our findings are in line with the chronic care model [79]. Telehealth interventions, as observed in our study, frequently incorporate goal-setting tools that empower patients to set and track health-related objectives, aligning with the model's emphasis on self-management support. In addition, our results underscore the vital role of health professional support within telehealth interventions, enabling remote monitoring and timely guidance, consistent with the model's focus on patient-centered care. Social support emerged in our findings, with patients benefiting from the encouragement of their social networks—a

concept aligned with the chronic care model's recognition of involving the patient's social support system. Finally, our research highlights the inclusion of educational materials in telehealth interventions, providing patients with essential knowledge about their condition, in line with the model's emphasis on patient education. Together, these elements within telehealth strategies contribute to patient empowerment, improved self-management, and enhanced outcomes for the management of chronic conditions such as diabetes, emphasizing the importance of a comprehensive approach to health care delivery, even in remote or web-based settings.

However, there are also potential limitations and challenges associated with the use of telehealth tools for the management of type 2 diabetes. The use of telehealth tools may be limited by internet access, technological skills, and the availability of the necessary devices [2,3]. Populations that have been historically marginalized or disadvantaged may face digital disparities, limiting their ability to benefit fully from these tools. It is thus essential to recognize that some patients may require additional human support. Interaction with health care providers may be necessary to obtain answers to questions, resolve problems, and receive emotional support. Furthermore, the use of telehealth tools involves the collection, storage, and sharing of sensitive health data. It is crucial to implement robust security measures to protect data confidentiality and prevent privacy breaches [2,8]. Telehealth tools use monitoring devices to collect data, such as blood glucose meters or continuous blood glucose monitoring sensors. However, these devices can have technical limitations and measurement errors, which can affect the accuracy of the data collected and potentially influence treatment decisions [5,8]. Given that diabetes management is characterized by a long process of therapeutic education, monitoring, and follow-up, technological support would be a helpful asset in primary health care because it would help maintain motivation [29,37,40,46,54,61,70] through the use of numerous tools (goal-setting tools and shared decision-making support tools, recipes, informational content, etc), by facilitating interactions with a health professional, and by promoting access to care (eg, with the possibility of using multilingual resources).

Figure 5. Classification of digital features for diabetes self-management and monitoring.

Recommendations for Future Designs

Telehealth offers many opportunities for diabetes self-management and monitoring, enabling patients to benefit from remote care, continuous monitoring, and personalized support. The use of continuous blood glucose monitoring devices, mobile apps, web-based platforms, and other technologies facilitates the collection and tracking of diabetes-related data [9]. The introduction of web-based educational resources, web-based learning modules, and self-help tools to help patients better understand their disease as well as manage their diet, physical activity, medication, and monitoring of blood glucose levels promotes patient self-management and empowerment [10,11]. In addition, web-based support via secure messaging to answer patients' questions and respond to their concerns supports therapeutic education and keeps them engaged. Indeed, technology developers will need to set up clear and effective communication channels between patients and health professionals. This may include web-based consultations, secure message exchanges, and regular reports on patient progress [11]. Finally, it will be important to consider the integration of these telehealth interventions into existing health care systems, ensuring coordination and continuity of care. It will be necessary to ensure that data collected by remote monitoring devices are accessible to health professionals and integrated into patients' medical records [12].

Limitations of Included Studies

The studies identified in this review involved voluntary patient participation. In particular, the studies favored individuals with good technology literacy. The selection bias inherent in voluntary patient participation and the preference for technology-literate individuals suggest that the findings might not be generalizable to the broader population of people with diabetes. The indicators used to assess the effectiveness of the interventions were primarily dietary intake; clinical indicators such as glycemia levels, HbA_{1c} levels, blood pressure, and cholesterol levels; physical activity; medication adherence; motivation; and the use of telehealth technology. Although positive changes in these indicators were noted in most clinical results, this may translate into something other than rigorous clinical parameters. Different strategies were used to collect data, notably involving innovative digital tools (although these

tools did not undergo a validation study). In addition, lifestyle changes (dietary planning and physical activity) were measured using the patient self-administered digital questionnaires, leaving the door open to all biases inherent in self-reporting. A meta-analysis of these data would help inform a position in this regard.

The heterogeneity of the included studies posed a real challenge in interpreting the results. Aside from the various methods used, which yielded different levels of evidence, the interventions were based mainly on effecting behavior changes through therapeutic education supported by digital tools and a health professional; yet, none of the studies assessed the impact on the results of the context within which these technologies were used, such as concurrent public health policies (eg, diabetes or obesity prevention campaigns, the promotion of a balanced diet, physical activity, or tobacco use).

Moreover, the literature states that 90% of people with diabetes have at least 1 other chronic disease. Nonetheless, few interventions have provided the integrated management of diabetes and other pathologies. Specifically, renal and cardiac risks have not always been assessed. The multipathological context should be systematically considered when designing studies because multiple medication use (eg, sulfonylureas and insulin) can cause iatrogenic hypoglycemia and influence the clinical parameters [80-82]. Similarly, the different stages of diabetes severity should be documented to foster a more accurate interpretation of the results.

The varying durations of the interventions, ranging from 1 month to 18 months, and the differing technologies used emphasize that outcomes such as improvements in HbA_{1c} levels are not uniform across all studies. The positive association observed with longer interventions and the reduction in HbA_{1c} levels may not hold true in every context or for every patient demographic. The role of health professionals in these interventions is undoubtedly significant, but the translation of these findings into practice must consider the individual needs and circumstances of diverse patient populations, including access issues and technological literacy. The integration of everyday technologies seems promising for broader implementation; however, this assumption requires careful consideration of the digital disparities that may exist, particularly among groups that have been historically marginalized or disadvantaged.

Strengths and Limitations of This Review

To further leverage the qualitative nature of the content analyzed in the studies, we performed a descriptive content analysis of the data using NVivo (release 1.7). This allowed us to supplement our research with a narrative account of the selected studies. The abundance of literature on the subject attests to a worldwide questioning of digital health policies. The COVID-19 pandemic led to a doubling of the number of annual publications on the topic of telehealth interventions used for type 2 diabetes or prediabetes self-management and monitoring with health professional involvement. Given the rapid development of technologies and research, which has only escalated in recent years, a systematic review would help provide invaluable data on the effectiveness of these interventions. This scoping review included studies published in peer-reviewed journals and is thus subject to publication bias owing to the well-documented notion that researchers and journals tend to publish positive results. In addition, we limited ourselves to selecting studies published in French or English from 2010 given the rapid pace of technological development and the consequent rapid increase in the literature. Future researchers should consider more inclusive approaches, such as conducting systematic reviews that encompass gray literature and unpublished studies. This ensures a more comprehensive and unbiased overview of existing literature on the topic.

The results of this review did not allow us to identify how the 8 key digital tool features should be developed and combined to help improve health outcomes. However, the strategy most often combined with telehealth interventions facilitating interaction with health professionals was the monitoring of glycemia levels, diet, and physical activity. A few of the studies (7/42, 17%) also included medication monitoring and therapeutic education. Future studies should perform in-depth analyses of the usability and acceptability of these technologies to highlight the design issues and shed light on health policies.

The diversity of the interventions analyzed underscores the necessity to acknowledge the unique challenges and issues inherent to each specific population. Such issues can encompass socioeconomic factors, cultural differences, accessibility to health services, and varying levels of health literacy, all of which can significantly influence the effectiveness of interventions; for instance, interventions that succeed in urban environments with high connectivity and technologically savvy populations may not yield identical results in rural or low-income areas where internet access is scarce and digital literacy is an issue. Moreover, the cultural context may impact patient engagement and the suitability of educational materials. Each population may hold distinct health beliefs, practices, and priorities, which must be considered during the design and implementation of health interventions. Recognizing these disparities is critical to understanding why results from 1 group cannot be generalized to another. Public health strategies must develop resource allocation policies and create interventions focused on the users' needs. Hence, although telehealth presents a promising avenue for improving diabetes management, its application must be nuanced and considerate of the public health challenges unique to each specific population to be truly effective and equitable.

Future Research Prospects

With regard to gaps in the literature, some questions require further research. This scoping review revealed a need for long-term implementation studies, possibly because telehealth programs require a less-structured time commitment and could be used over extended periods. Long-term evaluation studies are also needed to facilitate the implementation of telehealth interventions. Further studies on adherence and engagement could explore the factors that influence patients' adherence to telehealth interventions and their engagement in diabetes self-management. These studies will also help to identify effective strategies for encouraging patients' active participation and maintaining their motivation over the long term. Evaluation

frameworks should incorporate reports on participant engagement and satisfaction, acceptability, security, and costs into future telehealth interventions because these will facilitate their translation into clinical practice. In addition, the measurement of the effects of interventions should include measures other than clinical data, such as patient-reported experience measures and patient-reported outcome measures to ensure that these interventions are meeting the needs of patients. In addition, multimorbidity was mentioned by only a few of the included studies (7/42, 17%) and warrants further research to assess the impact of these interventions on health [34,49,54,56,65,67,70]. Additional studies could define standardized assessment criteria for telehealth interventions that support the therapeutic management of patients with diabetes and multiple comorbidities. The impact of equity of access to care on the use of telehealth interventions for populations considered vulnerable, including populations with low-income status, rural or remote populations, and culturally diverse groups, will need to be studied. A better understanding of these impacts will help identify potential barriers and strategies to reduce disparities and improve equitable access to telehealth [12]. Finally, it will be vital to evaluate the effectiveness of integrating telehealth interventions into existing health care systems, including collaboration among health professionals, data sharing, and care coordination. This will help distinguish best practices for the successful integration of telehealth into clinical care and existing health care systems [12]. Of the 42 studies, 3 (7%) assessed the impact on the cost of care [48,58,64]. The macroeconomic implications of these telehealth interventions for health care systems warrant future studies to shed clearer light on health policies. Finally, the COVID-19 pandemic has revealed the various structural and organizational shortcomings of health care around the globe. It has also accelerated the dissemination and adoption of digital tools and advanced the digital ambitions of governments worldwide. The abundance of publications means that future studies can perform a meta-analysis of randomized controlled trials. Our analysis underscores the critical role of multidisciplinary health care teams and promotes the integration of ubiquitous technologies into daily health management practices to achieve superior patient outcomes. Furthermore, this review stresses the necessity of considering the long-term viability of telehealth solutions, patient adherence, and the seamless incorporation of these solutions into current health care frameworks in subsequent research.

Finally, although we included studies conducted in different parts of the world in this scoping review, we did not find relevant studies conducted in Canada, indicating an opportunity for research tailored to the Canadian context. For the implementation of future telehealth interventions to improve diabetes management in Canada, it is recommended to consider the specificities of the Canadian health care system, such as the heterogeneity of its organization across different provinces, the diversity of its population, and its varied health resources. It would be wise to design personalized interventions that address the unique needs of patients with diabetes within the Canadian population, particularly in Indigenous communities that are disproportionately affected by diabetes, including linguistic and cultural considerations. Strategies for equitable access to telehealth technologies for populations that have been historically marginalized or those living in remote areas should also be considered. Training health professionals in telehealth tools and best practices for web-based care is equally essential. Moreover, interdisciplinary and intersectoral collaboration would be beneficial to effectively integrate telehealth into primary care, allowing for coordinated and consistent follow-up. Finally, by anticipating challenges related to privacy and data security, interventions should incorporate robust security measures to protect sensitive patient information while focusing on a personalized approach and the development of patient-centered interventions and technologies.

Conclusions

This review systematically maps out the effectiveness of telehealth interventions for managing type 2 diabetes, with a focus on the enhanced outcomes gained through the involvement of health professionals. It presents a detailed categorization of the pivotal characteristics of digital tools into 8 distinct areas that significantly influence the success of these interventions. The evidence-based data suggest that participation in sustained telehealth interventions with health professional involvement helps improve health outcomes and type 2 diabetes–related behavior, reducing the risks of complications. However, despite our identification of the key digital tool features of these interventions, it remains to be seen how to combine and translate them into long-term usable components in specific care contexts. Nonetheless, the results are promising for future health care because they point to consolidating care through a single platform, which could improve patients' quality of life while encouraging active self-management. They also shed light on developing evidence-based telehealth programs that can be adapted to specific care contexts and offer decision makers more effective options for funding diabetes management programs. Ultimately, this review aims to enrich the understanding of telehealth's role in diabetes care and to outline specific domains for future research that will inform policy making and the advancement of telehealth practices.

Abstract

Background: The use of social media for disseminating health care information has become increasingly prevalent, making the expanding role of artificial intelligence (AI) and machine learning in this process both significant and inevitable. This development raises numerous ethical concerns. This study explored the ethical use of AI and machine learning in the context of health care information on social media platforms (SMPs). It critically examined these technologies from the perspectives of fairness, accountability, transparency, and ethics (FATE), emphasizing computational and methodological approaches that ensure their responsible application.

Objective: This study aims to identify, compare, and synthesize existing solutions that address the components of FATE in AI applications in health care on SMPs. Through an in-depth exploration of computational methods, approaches, and evaluation metrics used in various initiatives, we sought to elucidate the current state of the art and identify existing gaps. Furthermore, we assessed the strength of the evidence supporting each identified solution and discussed the implications of our findings for future research and practice. In doing so, we made a unique contribution to the field by highlighting areas that require further exploration and innovation.

Methods: Our research methodology involved a comprehensive literature search across PubMed, Web of Science, and Google Scholar. We used strategic searches through specific filters to identify relevant research papers published since 2012 focusing on the intersection and union of different literature sets. The inclusion criteria were centered on studies that primarily addressed FATE in health care discussions on SMPs; those presenting empirical results; and those covering definitions, computational methods, approaches, and evaluation metrics.

Results: Our findings present a nuanced breakdown of the FATE principles, aligning them where applicable with the American Medical Informatics Association ethical guidelines. By dividing these principles into dedicated sections, we detailed specific computational methods and conceptual approaches tailored to enforcing FATE in AI-driven health care on SMPs. This segmentation facilitated a deeper understanding of the intricate relationship among the FATE principles and highlighted the practical challenges encountered in their application. It underscored the pioneering contributions of our study to the discourse on ethical AI in health care on SMPs, emphasizing the complex interplay and the limitations faced in implementing these principles effectively.

Conclusions: Despite the existence of diverse approaches and metrics to address FATE issues in AI for health care on SMPs, challenges persist. The application of these approaches often intersects with additional ethical considerations, occasionally leading to conflicts. Our review highlights the lack of a unified, comprehensive solution for fully and effectively integrating FATE principles in this domain. This gap necessitates careful consideration of the ethical trade-offs involved in deploying existing methods and underscores the need for ongoing research.

fairness, accountability, transparency, and ethics; artificial intelligence; social media; health care

Introduction

Background

Machine learning (ML) algorithms have become pervasive in today's world, influencing a wide range of fields, from governance and financial decision-making to medical diagnosis and security assessment. These technologies depend on artificial intelligence (AI) and ML to provide results, offering clear advantages in terms of speed and cost-effectiveness for businesses over time [1]. However, as AI research progresses rapidly, the importance of ensuring that its development and deployment adhere to ethical principles has become paramount.

User data on social media platforms (SMPs) can reveal patterns, trends, and behaviors. Platforms such as Twitter (X Corp) are predominantly used by younger individuals and those residing in urban areas [2]. These platforms often impose age restrictions, leading to a potential bias in algorithms trained on their data toward younger, urban demographics. Social media presents a rich source of data invaluable for health research [3], yet using these data without proper consent poses ethical concerns. Furthermore, social media content is influenced by various social factors and should not always be interpreted at face value. For example, certain topics may engage users from specific regions or demographic groups more than others [4], rendering the data less universally applicable. An additional challenge is the trustworthiness of these data. The issue of bias is further exacerbated when AI or ML software is proprietary with a closed source code, making it challenging to analyze and understand the reasons behind biased decisions [3].

The spread of both misinformation and disinformation is a significant concern on social media [5,6], a problem that became particularly acute during the COVID-19 pandemic. False claims about vaccine safety contributed to public mistrust and hesitancy, undermining efforts to control the virus. In tackling this issue, AI tools have been deployed to sift through information and spotlight reliable content for users [7]. These AI systems are trained using health data from trustworthy sources, ensuring the dissemination of scientifically sound information. On the bright side, social media provides a venue for disseminating new health information, offering valuable insights for the health sector [8]. However, the inherent challenges of social media, such as verifying information authenticity and the risk of spreading misinformation, require careful management to guarantee that the health information shared is accurate and reliable.

Fairness, accountability, transparency, and ethics (FATE) research focuses on evaluating the fairness and transparency of AI and ML models, developing accountability metrics, and designing ethical frameworks [9]. Incorporating a human in the loop is one approach to upholding ethical principles in algorithmic processes. For example, in the case of the Correctional Offender Management Profiling for Alternative Sanctions system used within the US judicial system to predict the likelihood of a prisoner reoffending after release, it is recommended that a judge first review the AI's decision to ensure its accuracy. In summary, recognizing the inherent biases in AI and ML, the implementation of systematic models is crucial for maintaining accountability. Efforts in computer science are directed toward enhancing the transparency of AI and ML, which helps uncover the decision-making processes, identify biases, and hold systems accountable for failures [10,11].

Motivation

The American Medical Informatics Association (AMIA) has delineated a comprehensive set of ethical principles for the governance of AI [12] building on the foundations laid out in the Belmont Report [13]: autonomy, beneficence, nonmaleficence, and justice. These principles are critical for the responsible application of AI in monitoring health care–related data on SMPs [7]. The AMIA expanded these principles to include 6 technical aspects—explainability, interpretability, fairness, dependability, auditability, and knowledge management—as well as 3 organizational principles: benevolence, transparency, and accountability. Furthermore, it incorporated special considerations for vulnerable populations, AI research, and user education [12]. Our review emphasized the concept of FATE, which is prevalent in the AI and ML community [14], and discussed its alignment with the principles outlined by the AMIA.

The discourse on AI ethics is notably influenced by geographic and socioeconomic contexts [15]. There has been extensive debate regarding the best practices for evaluating work produced by explanatory AI and conducting gap analyses on model interpretability in AI [16,17]. Recent advancements in ML interpretability have also been subject to review [18]. Table 1 provides a summary of existing studies that discuss FATE in various contexts. These studies reveal a substantial research gap in understanding how the principles of FATE are integrated within the realm of AI in health care on SMPs. Notably, none of the studies have thoroughly investigated the computational methods commonly used to assess the components of FATE and their intricate interrelationships in this domain.

To bridge the identified research gap, this study focused on three pivotal research questions (RQs):

1. What existing solutions address FATE in the context of health care on SMPs? (RQ 1)
2. How do these solutions identified in response to RQ 1 compare with each other in terms of computational methods, approaches, and evaluation metrics? (RQ 2)
3. What is the strength of the evidence supporting these various solutions? (RQ 3)

Our aim was to enrich the domain of FATE by exploring the array of techniques, methods, and solutions that facilitate social media interventions in health care settings while pinpointing gaps in the current body of literature. This study encompassed the definitions, computational methods, approaches, and evaluation metrics pertinent to FATE in AI along with an

examination of FATE in data sets. The novelty of our research lies in delivering a comprehensive analysis of metrics, computational solutions, and the application of FATE principles specifically within the realm of SMPs. This includes a focus on uncovering further research directions and challenges at the confluence of health care, computer science, and social science.

Methods

Research Methodology

Our research methodology was grounded in the approach presented by Kofod-Petersen [24] and adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [25]. We used 2 search databases, PubMed and Web of Science, to ensure the reproducibility of the search results in the identification of records. PubMed was chosen for its comprehensive coverage of biomedical literature, providing direct access to the most recent research in health care and its intersections with AI, rendering it indispensable for studies focused on the FATE principles in the domain. Web of Science was selected for its interdisciplinary scope, diversity of publication sources, and rigorous citation analysis, offering a broad and authoritative overview of global research trends and impacts across computer science, social sciences, and health care. In addition, we used Google Scholar, which is recognized as the most comprehensive repository of scholarly articles [26], known for its inclusivity and extensive coverage across multiple disciplines. However, due to the lack of reproducibility of the search results on Google Scholar, we classified it as *other source* for record identification, as shown in Figure 1. Our search across these databases was conducted without any language restrictions, ensuring a comprehensive and inclusive review of the relevant literature.

We conducted a strategic search using Table 2 as a filter to identify research papers pertinent to our review. The table was designed to allow for customization of groups for retrieving varied sets of literature, aiming to find the intersection among these sets. For group 1, we selected "fairness," "accountability," "transparency," and "ethics." These keywords, being integral components of the FATE framework, were an obvious choice for our search queries. In group 2, we identified "natural language processing" and "artificial intelligence" as our keywords. The selection of "natural language processing" was justified by the predominance of textual data on SMPs, necessitating algorithms adept at processing natural language. The inclusion of "artificial intelligence" reflected its broad applicability beyond traditional ML applications. Given that AI encompasses a wide range of advanced technologies, including sophisticated natural language processing (NLP) techniques, its inclusion ensured the comprehensive coverage of relevant studies. Finally, the terms "social media" and "healthcare" were directly pertinent to our review, making their inclusion essential. Consequently, our aim was to encompass a wide spectrum of studies relevant to the topic of our review.

On the basis of Table 1, our initial strategy involved using the intersection of groups as follows: ([group 1, search term 1 ∩ group 2, search term 1] AND [group 1, search term 1 ∩ group 2, search term 2]) ∩ ([group 1, search term 1 ∩ group 3, search term 1] AND [group 1, search term 1 ∩ group 3, search term 2]), which, for simplicity, we condensed to (group 1, search term 1 ∩ group 2, search term 1 ∩ group 2, search term 2 ∩ group 3, search term 1 ∩ group 3, search term 2), as outlined in the search query presented in Textbox 1.

For our queries, we implemented year-based filtering in PubMed and conducted a parallel topic search in Web of Science, limiting the results to articles published since 2012. However, this approach yielded only 2 publications from each database, a tally considered inadequate for our purposes. Consequently, we opted to broaden our search by applying the union of 2 intersections. The initial formula ([group 1, search term 1 ∩ group 2, search

term 1] AND [group 1, search term 1 ∩ group 2, search term 2]) ∪ ([group 1, search term 1 ∩ group 3, search term 1] AND [group 1, search term 1 ∩ group 3, search term 2]) was streamlined to group 1, search term 1 ∩ ([group 2, search term 1 ∩ group 2, search term 2] ∪ [group 3, search term 1 ∩ group 3, search term 2]), as detailed in the search query in Textbox 2, while maintaining the same year range.

Our search queries resulted in 442 records from PubMed and 327 records from Web of Science, as shown in Figure 1. Subsequently, we eliminated duplicates across the 3 sources, consolidating the findings into 672 records for initial screening. During the screening phase, we applied specific inclusion criteria based on an analysis of titles and abstracts to refine the selection: (1) the study primarily addressed FATE principles in the context of health care on SMPs (inclusion criterion 1); (2) the study reported empirical findings (inclusion criterion 2); (3) the study elaborated on definitions, computational methods, approaches, and evaluation metrics (inclusion criterion 3).

This process narrowed down the field to 172 records eligible for full-text assessment. At this stage, we applied our quality criteria to further assess eligibility: (1) we confirmed through full-text screening that the study adhered to inclusion criteria 1, 2, and 3 (quality criterion 1); (2) the study articulated a clear research objective (quality criterion 2).

Ultimately, this led to the selection of 135 articles for inclusion in our review. The complete list of these articles is available in Multimedia Appendix 1 [1-3,5-11,15-23,26-141].

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram for record selection.

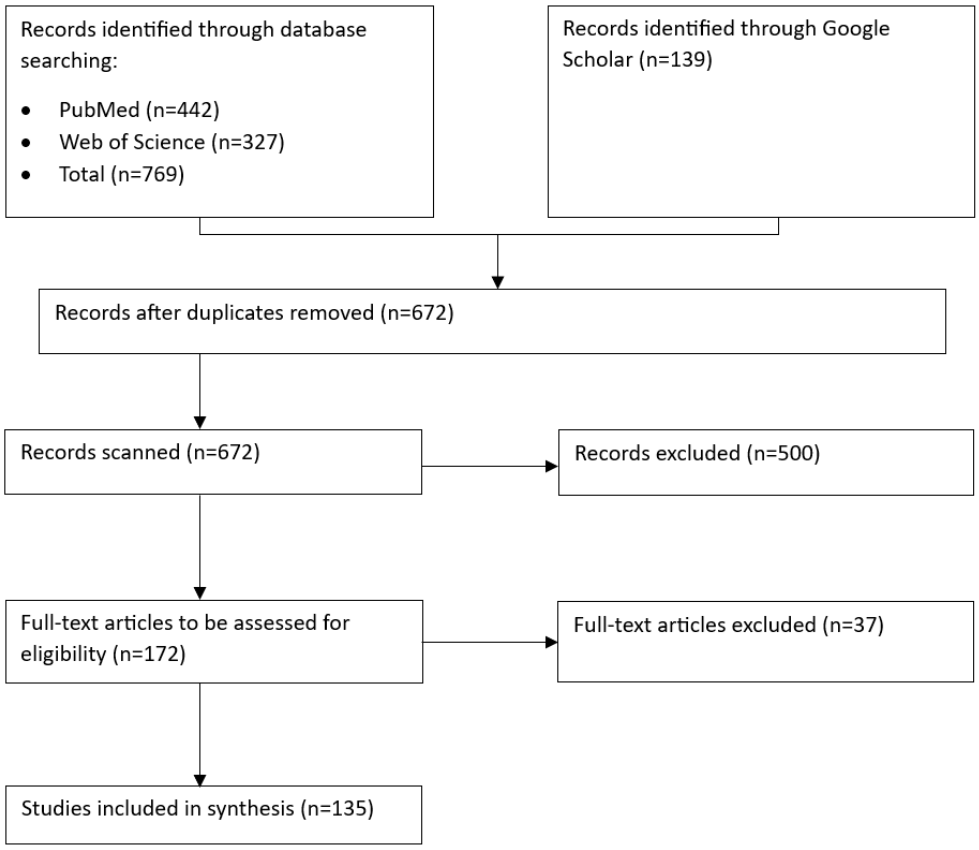

Table 2. Search strategy for finding research articles.

	G1[a]	G2[b]	G3[c]
T1[d]	Quality[e]	Natural language processing	Social media
T2[f]	N/A[g]	Artificial intelligence	Health care

[a]G1: group 1.

[b]G2: group 2.

[c]G3: group 3.

[d]T1: search term 1.

[e]{Fairness, Accountability, Transparency, Ethics}

[f]T2: search term 2.

Textbox 1. The initial query to the databases.

- ("Fairness" OR "Accountability" OR "Transparency" OR "Ethics") AND ("NLP" or "Natural Language Processing") AND ("AI" OR "Artificial Intelligence") AND ("Healthcare" AND "Social Media")

Textbox 2. Modified query to the databases.

- ("Fairness" OR "Accountability" OR "Transparency" OR "Ethics") AND ((("NLP" or "Natural Language Processing") AND ("AI" OR "Artificial Intelligence")) OR ("Healthcare" AND "Social Media"))

Data Items and Data-Charting

In our review, we incorporated the following data items: (1) approaches and definitions related to each component of FATE; (2) mathematical formulations and algorithms designed to address FATE; (3) methodologies for the integration of FATE principles into AI and ML systems, particularly within health care settings on SMPs; (4) characteristics of the AI or ML systems under study, encompassing their type, application areas within health care, and the specific roles that SMPs play in these systems; (5) outcomes from the formal evaluation or assessment of FATE aspects within the studies, such as their impact on decision-making processes; (6) challenges and barriers reported in the implementation of FATE principles in AI or ML systems; (7) use of frameworks or tools developed to support or evaluate FATE in AI and ML systems; and (8) engagement of stakeholders throughout the AI and ML system's life cycle, including their perspectives on FATE.

The data-charting process involved 3 researchers, each independently extracting pertinent data from the selected sources with a particular focus on the aforementioned data items. For methodical organization and analysis, the extracted information was documented in Microsoft Excel spreadsheets (Microsoft Corp). These spreadsheets were organized alphabetically by the last name of the first author of each article and included references to the corresponding data items as presented in the studies. To consolidate the compiled data, one researcher was tasked with merging the information from these spreadsheets. This step aimed to synthesize the data and ensure a coherent presentation of our findings. The merging process entailed a thorough review and amalgamation of the data charted by each researcher, emphasizing the consolidation of similar approaches and methodologies as identified in the studies.

Results

Definitions, Computational Methods, and Approaches to Fairness

Overview

The understanding of fairness among the public is diverse [26]. The AMIA classifies fairness as a technical principle, emphasizing its importance in creating AI systems that are free from bias and discrimination [12]. This study reviewed various approaches to achieving fairness, with a particular focus on perspectives that facilitate the quantification of fairness in the context of AI for health care on SMPs. The mathematical formulations used to measure fairness are presented in Multimedia Appendix 2 [27-32,142,143]. The following subsections offer a comprehensive examination of approaches to ensure fairness.

Calibrated Fairness

Calibrated fairness seeks to balance providing equal opportunities for all individuals with accommodating their distinct differences and needs [33]. For instance, in the context of social media, a calibrated fair algorithm aims to ensure equal access to opportunities, such as visibility for all users, while also considering specific factors, such as language or location, to offer a personalized experience. In health care, such an algorithm would ensure that all patients have access to the same standard of care yet take into account variables such as age and health status to tailor the best possible treatment plan. The objective is to find a balance between treating everyone equally and acknowledging individual differences to achieve the most equitable outcomes. Fairness metrics, including the false positive rate difference [29] and the equal opportunity difference [34], are used to evaluate the degree of calibrated fairness. Common computational methods used to achieve calibrated fairness include the following: (1) preprocessing—modifying the original data set to diminish or eliminate the impact of sensitive attributes (eg, gender and ethnic background) on the outcome of an ML model [35]; (2) in-processing—integrating fairness constraints into the model's training process to ensure calibration with respect to sensitive attributes [35]; (3) postprocessing—adjusting the model's output after training to calibrate it in relation to sensitive attributes [35]; (3) adversarial training—training the model on adversarial examples, which are designed to test the model's fairness in predictions [36].

Each of the approaches to achieving calibrated fairness in AI systems has a specific application context that is influenced by various factors. Preprocessing aims to directly mitigate biases in the data before the model's training phase but may present challenges in preserving the integrity of the original data, potentially resulting in the loss of important information. In contrast, in-processing involves the integration of fairness constraints during the model's learning process, which, while aiming to ensure fairness, might compromise model performance due to the added constraints. Postprocessing, which adjusts the model's outputs after training, may appear as a straightforward solution but often falls short in addressing the root causes of bias, thus providing a superficial fix. Adversarial training stands out as a promising approach by challenging the model's fairness through specially designed examples; however, its effective implementation can be complex and resource intensive. Each method has inherent trade-offs between fairness, accuracy, and complexity. The choice among them depends on the specific

circumstances of the application, including the nature of the data, the criticality of the decision-making context, and the specific fairness objectives.

Statistical Fairness

Statistical fairness considers various factors, including demographic information, that may be pertinent to the concept of fairness within a specific context. Among the widely recognized statistical definitions of fairness are demographic parity, equal opportunity, and equal treatment [37]. The measure of "demographic parity" is used to reduce data bias by incorporating penalty functions into matrix-factorization objectives [38], whereas the "equal opportunity" metric is crucial for ensuring that decisions are devoid of bias [39]. In the realm of social media, individual notions of fairness might encompass issues such as unbiased content moderation, equitable representation of diverse perspectives and voices, and transparency in the algorithms used for content curation and ranking. Common approaches for measuring statistical fairness include the following: (1) equalized odds—this approach evaluates fairness by examining the differences in true positive and false positive rates across various groups [40]; (2) theorem of equal treatment—this approach assesses fairness by comparing how similar individuals from different groups are treated [41].

Moreover, several toolkits have been developed for measuring statistical fairness in ML and AI models. For instance, Aequitas, as introduced by Saleiro et al [42], generates reports aiding in equitable decision-making by policy makers and ML researchers. The AI Fairness 360 toolkit [43] provides metrics and algorithms designed to reduce statistical biases that lead to the unfair treatment of various groups by ML models [44]. Another toolkit, Fairlearn [45], offers algorithms aimed at addressing disparities in the treatment of different demographic groups by an ML model.

Intersectional Fairness

This approach integrates multiple intersecting identity facets, such as race, gender, and socioeconomic status, into decision-making processes concerning individuals [46]. Its objective is to guarantee equitable treatment for all stakeholders, recognizing that the confluence of these identities may exacerbate marginalization and discrimination. Within the realm of social media, an algorithm designed with intersectional fairness in mind ensures that content is neither recommended nor censored in a manner that is prejudiced against a user's race, gender, or socioeconomic status. Similarly, in health care, an algorithm that incorporates intersectional fairness aims to prevent the disproportionate allocation of medical treatments and resources. Intersectional fairness can be operationalized using the worst-case disparity method, which involves evaluating each subgroup individually and comparing the best and worst outcomes to ascertain the precision of the fairness score. Subsequently, the ratio of the maximum to minimum scores is calculated, with a ratio nearing 1 indicating a more equitable outcome [46]. Other prevalent methods and strategies for achieving intersectional fairness include the following: (1) constraint-based methods—these are designed to honor specific fairness constraints, such as providing equal treatment to different groups identified by multiple attributes, through mathematical optimization [47]; (2) causal inference methods—these aim to ensure that the algorithm's outputs are unbiased by examining the causal relationships between inputs and outputs [48]; (3) decision trees and rule-based systems—these are used to guarantee that the algorithm's decisions are informed by relevant factors and free from bias [49].

Constraint-based methods are adept at enforcing predefined fairness goals; however, the complexity of defining and optimizing these goals poses a significant challenge. In contrast to constraint-based methods, causal inference methods do not necessitate predefined fairness constraints but require a thorough comprehension of the data at hand. Erroneous assumptions regarding causality can result in flawed assessments of fairness. Decision trees and rule-based systems, owing to their interpretability, facilitate the understanding of algorithmic decisions. However, their simplicity may be a limitation as they may not adequately address the complexities inherent in various data sets. To mitigate some of the discussed shortcomings, supervised ranking, unsupervised regression, and reinforcement in fairness evaluation can be approached through pairwise evaluation [50]. This technique involves assessing an AI model's performance by comparing its outputs against a preselected set of input data pairs.

Definitions, Computational Methods, and Approaches to Accountability

Overview

The AMIA considers accountability a fundamental organizational principle, stressing that organizations should bear the responsibility for continuously monitoring AI systems. This includes identifying, reporting, and managing potential risks. Furthermore, organizations are expected to implement strategies for risk mitigation and establish a system for the submission and resolution of complaints related to AI operations [12]. In the following subsections, we explore prevalent views on accountability within the ML and AI community. In addition, we provide summaries of the measurements for different accountability components as identified in the reviewed literature, which can be found in Multimedia Appendix 3 [51-54,144].

Legal Accountability

Legal accountability encompasses the obligations of entities involved in designing, developing, deploying, and using AI systems for health care purposes on social media [55]. This responsibility includes ensuring that AI systems are developed and used in compliance with relevant laws and regulations in addition to addressing any adverse effects or impacts that might arise from their use. Legal accountability also covers issues such as data protection and privacy along with the duty to prevent the use of AI systems for discriminatory or unethical purposes. Commonly used conceptual methods for achieving legal accountability include the following: (1) transparency—this method involves making AI systems transparent, ensuring that their decision-making processes are explainable and comprehensible [56] (there are existing

frameworks designed to enhance transparency in the accountability of textual models [57]); (2) documentation—this involves maintaining detailed records of the systems' design, development, and testing processes, as well as documenting the data used for training them [58] (an initiative toward accountability is the implementation of model cards, which are intended to outline an ML model's limitations and disclose any biases that it may be susceptible to [59]); (3) adjudication—this refers to the creation of procedures for addressing disputes and grievances associated with the use of ML and AI systems [60].

Overall, the pursuit of legal accountability should be carefully balanced with the autonomy of stakeholders and must not hinder innovation.

Ethical Accountability

Ethical accountability ensures that AI systems make decisions that are transparent, justifiable, and aligned with societal values [61]. This encompasses addressing data privacy, securing informed consent, and preventing the perpetuation of existing biases and discrimination. Ethical concerns specific to the use of AI in health care include safeguarding patient privacy, handling sensitive health data responsibly, and avoiding the reinforcement of existing health disparities [62]. Common strategies for achieving ethical accountability include the following: (1) ethical impact assessment—this approach entails assessing the ethical risks and benefits of the system and weighing the trade-offs between them [63]; (2) value alignment—this strategy involves embedding ethical principles and values into the design and development of the system, ensuring that its operations are in harmony with these values [64]; (3) transparency and explanation—this is accomplished by offering clear, understandable explanations of the system's functionality and making its data and algorithms openly available [65]; (4) stakeholder engagement—this involves the active participation of a diverse group of stakeholders, including users, developers, and experts, in all phases of the AI or ML system's life cycle [66].

When crafting ethical AI for disseminating health care–related information on social media, the application of these methodologies varies according to specific tasks. Ethical impact assessments, for instance, are valuable for evaluating the potential advantages, such as enhanced patient engagement via personalized dissemination of health care information, against risks, including privacy breaches and the spread of misinformation. The value alignment method plays a crucial role in pinpointing essential ethical values such as patient privacy, information accuracy, nondiscrimination, and accessibility. This method also supports the performance of regular audits to verify that AI systems continuously reflect these ethical standards. Finally, approaches to stakeholder engagement establish a platform for transparent and continuous communication between stakeholders and developers, thereby promoting a cooperative atmosphere in development.

Technical Accountability

Technical accountability ensures that developers and designers of AI and ML systems are held responsible for maintaining standards of security, privacy, and functionality [67]. This responsibility encompasses the implementation of adequate mechanisms to monitor and manage AI algorithms and address arising technical issues. Within the realms of social media and health care, technical accountability further entails the use of AI technologies to foster ethical decision-making, safeguard user privacy, and ensure that decisions are made fairly and transparently [68]. Common strategies for achieving technical accountability include the following: (1) logging—the practice of recording all inputs, outputs, and decisions to trace the system's performance and pinpoint potential problems [69]; (2) auditing—conducting evaluations to check the system's performance, detect biases, and ensure compliance with ethical and legal standards [70].

Both logging and auditing play critical roles in the development of ethical AI for health care information on social media, each with its unique benefits and challenges. Logging, which captures the inputs, outputs, and decisions of an AI system, is vital for tracking system performance. Nonetheless, the retention of detailed logs, especially those involving sensitive health care information, may introduce privacy concerns and necessitate careful consideration of data protection strategies. Auditing, essential for upholding ethical and legal norms, demands expertise and considerable time to effectively scrutinize complex AI systems. In addition, frameworks designed to enhance AI system accountability are in use. An example is Pandora [71], representing a significant move toward achieving a holistic approach to accountable AI systems.

Societal Accountability

Societal accountability entails the obligation of stakeholders to ensure that their AI systems align with societal values and interests [72]. This encompasses addressing privacy, transparency, and fairness issues, along with considering the wider social, cultural, and economic impacts that AI systems may have. Achieving societal accountability may require stakeholders to participate in public consultations, develop ethical and transparent regulations and standards for AI use, and enhance public understanding of AI system functionalities and applications. Essentially, it advocates for the development and use of AI systems under the principles of responsible innovation, with society's interests considered at every life cycle stage.

Methods for ensuring societal accountability include the following: (1) regulation and standardization—creating regulations and standards for AI system design and use can help hold these systems accountable to society, safeguarding the rights and interests of all stakeholders [73]; (2) public-private partnerships—fostering collaboration among government agencies, private-sector companies, and other entities to promote the societal accountability of AI and ML systems [74].

To ensure accountability, integrating transparency and fairness into algorithms, designing systems with privacy considerations, and conducting regular audits and evaluations to review AI system performance is critical. Researchers have suggested approaches for holding companies accountable for their AI-related actions [9]. They emphasize the importance of pinpointing specific decision makers within a company responsible for any errors, a crucial step for ensuring equitable

accountability. The entity or individuals determining accountability should possess comprehensive knowledge of legal, political, administrative, professional, and social viewpoints regarding the error to guarantee fair and unbiased judgments. Moreover, the consequences imposed on decision makers should be appropriately matched to their areas of responsibility, considering each individual's level of responsibility within the company's hierarchy when deciding on these consequences.

Definitions, Computational Methods, and Approaches to Transparency

Overview

According to the AMIA, transparency is an organizational principle that asserts that an AI system must operate impartially, not favoring its host organization. This principle ensures fairness, treating all stakeholders equally without privileging any party. Moreover, transparency requires stakeholders to be clearly informed that they are interacting with an AI system and not a human [12]. Adadi and Berrada [22] presented a nuanced view on transparency, defining it as the degree to which the workings of an AI system are comprehensible to humans. This definition encompasses providing explanations for the system's decision-making processes, clarifying the data used for system training, and certifying the system's neutrality and nondiscriminatory nature. The balancing act between transparency and privacy presents challenges. For instance, in the analysis of mental health data on SMPs, the difficulty does not lie in pinpointing user-specific attributes (as data are often aggregated) but in the application of these data [75]. Here, transparency intersects with the ethical principle of autonomy, which demands that systems protect individual independence, treat users respectfully, and secure informed consent [12]. Guaranteeing autonomy is particularly crucial in the deployment of AI-powered depression detection systems on social networks [76]. The following subsections will delve into the nuances of transparency in AI, emphasizing the importance of openness in data and algorithmic procedures. This focus is particularly critical in the context of data derived from SMPs. We also introduce some metrics for assessing transparency in Multimedia Appendix 4 [77-81].

Algorithmic Transparency

Algorithmic transparency is the clarity with which one can comprehend the manner in which an AI algorithm or model produces its outputs or decisions [82]. Within the context of AI for health care on SMPs, transparency entails the ability to lucidly grasp the processes and methodologies used in the creation, dissemination, and evaluation of social media interventions for health care objectives [83]. This encompasses an understanding of the data sources that inform these interventions, the algorithms or models that analyze the data and generate the interventions, and the criteria for assessing intervention effectiveness. Algorithmic transparency is crucial for identifying and addressing potential biases or errors in interventions and fostering trust among stakeholders, including patients, health care providers, and regulatory bodies. Several computational techniques can enhance algorithmic transparency: (1) feature importance analysis—this technique identifies the most impactful features or variables in the model's output, shedding light on the decision-making process [84]; (2) model interpretability—this involves designing models whose outputs are easily understood and interpreted by humans [85] (for instance, decision trees and logistic regression models are more interpretable compared to more complex models [86]; detailed discussions of model interpretability will follow in a dedicated subsection); (3) explanation generation—this technique produces explanations for a model's outputs, offering insights into its decision-making process through visualizations or natural language descriptions [87].

Feature importance analysis enhances the comprehension of a model's decision-making process, yet it may not fully elucidate the complex interactions among features or their combined effect on the model's decisions, especially in the case of sophisticated deep neural networks. Models that are inherently interpretable, such as decision trees and logistic regression, promote user trust and facilitate the validation of model behaviors. However, these models might not offer the same level of power and precision as more complex models such as deep neural networks, which restricts their effectiveness in analyzing health care–related social media interactions. On the other hand, explanation generation seeks to clarify the model's reasoning for stakeholders. Nonetheless, guaranteeing that these explanations are both accurate and reflective of the model's inner workings poses a considerable challenge.

Data Transparency

Data transparency pertains to the comprehensibility of how data are collected, stored, and used in the development of an AI system [88]. Within the realm of AI for health care on SMPs, data transparency delineates the degree to which health care organizations and providers maintain openness and clarity regarding the collection, storage, and use of patient data [89]. This aspect is critical to the design and implementation of social media campaigns, encompassing the provision of explicit information to patients about the nature of the data being collected, their intended uses, the entities granted access, and the measures in place for their protection. By adopting a transparent approach to data collection and use, health care organizations can foster trust among patients and encourage more robust engagement in social media–driven health interventions. Such transparency can significantly enhance patient health outcomes as individuals are more inclined to engage in interventions in which they feel informed, comfortable, and confident. Examples of computational methods to enhance data transparency include the following: (1) data visualization—this method entails the creation of graphical representations of data to simplify user understanding and interpretation [90]; (2) data profiling—this process analyzes data to ascertain their structure, quality, and content, aiding in the identification of issues such as missing values and inconsistencies [91]; (3) data lineage analysis and provenance tracking—this approach tracks the movement of data through various systems and processes to verify their accuracy and reliability [81,92].

A critical consideration in implementing any of the data transparency methods is ensuring that the autonomy and privacy of all stakeholders are upheld.

Process Transparency

Process transparency denotes the capability to comprehend the procedures involved in the development and deployment of an AI system, including the testing and validation methodologies used [93]. Within the sphere of social media and health care, this notion extends to the clarity of decision-making processes that govern the prioritization, display, and dissemination of health-related information on SMPs. This encompasses transparency regarding the algorithms and computational methods used to curate and showcase health-related content as well as the policies and guidelines governing the moderation of user-generated content pertaining to health. Enhancing process transparency allows users to place greater trust in the information and interventions presented to them and affords researchers increased confidence in the data they examine. Several computational techniques can facilitate enhanced process transparency in AI systems: (1) auditability and monitoring—this involves integrating auditing and monitoring functions within the AI system, including tracking the system's performance, detecting biases or other ethical concerns, and pinpointing instances of underperformance [94]; (2) open-source development—this entails the open and transparent creation of AI systems, where the code, data, and models are made accessible to the public. Such transparency fosters enhanced scrutiny and accountability of the system by external parties, including regulators and the general public [95].

Adopting these methods while recognizing their limitations and taking into account additional ethical considerations can foster greater transparency in AI applications for health care interventions on SMPs.

Explainability and Interpretability

According to the AMIA, the concepts of explainability and interpretability in AI are closely intertwined in the context of transparency. Explainability necessitates that AI developers articulate the functions of AI systems using language appropriate to the context, ensuring that users have a clear understanding of the system's intended use, scope, and limitations. Conversely, interpretability concentrates on the system's capability to elucidate its decision-making processes [12]. It is common for researchers to use the terms explainability and interpretability interchangeably [18,96].

In the realm of social media interventions for health care, explainability and interpretability pertain to comprehending how an AI system processes social media data, identifies pertinent information, and bases its recommendations or decisions on those data [97]. Research conducted by Amann et al [98] delves into the explainability aspects of AI in health care from 4 perspectives: technological, medical, legal, and that of the patient. The authors highlighted the critical role of explainability in the medical domain, arguing that its absence could compromise fundamental ethical values in medicine and public health. The pursuit of explainability and interpretability in AI systems remains a vibrant area of research. For AI systems that apply social media interventions in health care, various methods, including feature selection techniques and visualizations, can facilitate a deeper understanding among health care professionals of the AI system's underlying mechanisms and the factors influencing its decision-making process. As Barredo Arrieta et al [99] noted, techniques for interpretability in AI involve the design of models with clear and comprehensible features, which can aid in identifying the factors that impact the AI's decisions, thus simplifying the understanding and explanation of the outcomes. The existing computational approaches to achieving explainability and interpretability include the following: (1) partial dependence plots (PDPs) [98,100]—PDPs elucidate the relationship between specific input variables and the predicted outcome, offering insights into the rationale behind an AI model's decisions; (2) local interpretable model-agnostic explanations (LIME)—LIME elucidates the outputs of ML models by creating a simpler, interpretable model that approximates the behavior of the original model [101]; (3) Shapley additive explanations (SHAP)—unlike LIME, SHAP explains the outputs of ML models by calculating the contribution of each input feature to the final output [102]; (4) counterfactual explanations—this approach identifies the minimal changes required in the input features to alter the model's output, providing insights into alternative decision pathways [103]; (5) using mathematical structures for analyzing ML model parameters—techniques such as concept activation vectors, t-distributed stochastic neighbor embedding, and singular vector canonical correlation analysis are used for this purpose [104]; (6) attention visualization [105]—techniques for visualizing attention in transformer-based language models used across various NLP tasks on SMPs help reveal the models' inner workings and potential biases; (7) explanation generation—this involves creating natural language or visual explanations for an AI system's decisions (using techniques such as saliency maps, LIME [101], and SHAP [102] in conjunction with NLP methods enhances the generation of comprehensible explanations); (8) applying inherently interpretable models—models such as fuzzy decision trees, which graphically depict the decision-making process akin to standard decision trees, clarify how decisions are made and identify the most influential factors [106]; (9) model distillation—this technique trains a simpler model to approximate the decision boundaries of a more complex model, thereby facilitating the creation of an interpretable model while maintaining the original's performance [107].

While all the aforementioned methods significantly contribute to the explainability and interpretability of AI and ML systems in this domain, it is crucial to recognize their inherent limitations in practical applications. Specifically, PDPs may face challenges with complex unstructured data such as natural language. SHAP can become computationally intensive when dealing with a large number of input features, which is typical in complex models. LIME might yield inconsistent outcomes, and the interpretations from attention visualization techniques necessitate detailed analysis by experts. Explanation generation, which is often dependent on the aforementioned methods, can inherit their flaws, potentially resulting in misleading explanations. Finally, models that are inherently interpretable or refined through distillation techniques might oversimplify,

failing to fully encapsulate the complexities of health care interventions on SMPs.

Definitions, Computational Methods, and Approaches to Ethics

Overview

Ethics encompasses a wide range of considerations, many of which align with the AI principles recognized by the AMIA. In the realm of AI, ethics generally pertains to the study and practice of crafting and applying AI technologies in ways that are fair, transparent, and advantageous to all stakeholders [108]. The objective of ethical AI is to ensure that AI systems and their decisions are in harmony with human values, uphold fundamental human rights, and do not cause harm or discrimination to individuals or groups. This encompasses issues related to privacy, data protection, bias, accountability, and explainability [109].

Within the sphere of social media, the digital surveillance of public health data from SMPs should adhere to several key principles: (1) beneficence, ensuring that surveillance contributes to better public health outcomes; (2) nonmaleficence, ensuring that the use of data does not undermine public trust; (3) autonomy, either through the informed consent of users or by anonymizing personal details; (4) equity, ensuring equal access for individuals to public health interventions; and (5) efficiency, advocating for legal frameworks that guarantee continuous access to web platforms and the algorithms that guide decision-making [110]. AI-mediated health care interventions must consider affordability and equity across the wider population. In addition, health-related data gathered from social platforms need to be scrutinized for various biases such as population and behavioral biases using appropriate metrics [111]. The following subsections offer insights into different ethical viewpoints and the methods used to evaluate how well AI systems align with these ethical standards. We also present summaries of quantifications of key ethical elements in Multimedia Appendix 5 [112-115].

Philosophical Ethics

Our review concentrated primarily on the practical application of ethical principles in AI rather than exploring the purely philosophical dimensions of ethics. Consequently, this subsection focuses on a set of general ethical principles directly pertinent to AI. Kazim and Koshiyama [116] examined various philosophical aspects of ethics and supported a human-centric approach to AI. This perspective underscores the significance of designing and using AI systems in ways that uphold human autonomy, dignity, and privacy [116]. Within the realm of health care interventions on social media, the philosophical ethics of AI can be specifically perceived as the application of ethical principles and values to the development and use of AI-powered tools and technologies [117]. This entails scrutinizing the potential benefits and risks associated with using AI to gather, analyze, and interpret health-related data from SMPs. It also involves ensuring that the deployment of such technologies adheres to the ethical principles recognized by the AMIA, including autonomy, beneficence, and nonmaleficence [12]. The ultimate goal is to foster the development and use of AI technologies that enhance health outcomes while minimizing the potential risks and harms that could emerge from their application. Examples of computational methods and models for addressing philosophical ethics include the following: (1) Methods and models focused on the simulation and modeling of ethical dilemmas, such as those using model-based control and Pavlovian mechanisms, are instrumental. These approaches offer valuable insights into the likely outcomes of diverse ethical decisions [118]. (2) Game theory experiments serve as a pivotal means to model and analyze decision-making processes in social contexts, encompassing ethical dilemmas. Notable examples of these experiments include the ultimatum game, the trust game, and the prisoner's dilemma [119]. (3) The field of data analytics provides methods and models that leverage statistical methods and ML algorithms to scrutinize data. This analysis aims to unearth patterns or insights pertinent to ethical questions or dilemmas [120].

Overall, while methods and models for simulating and modeling ethical dilemmas are capable of effectively representing various scenarios and predicting outcomes, there is a risk that they might oversimplify the complexities inherent in real-world ethics and fail to fully encapsulate the nuances of human ethical reasoning. Although game theory experiments provide insightful perspectives on human behavior in ethical dilemmas, they possess an abstract nature that may limit their practical applicability in realistic situations. Moreover, the efficacy of data analytics methods is heavily dependent on the quality and quantity of the available data. Thus, the application of these methodologies in AI for health care–related interventions on social media should be approached with caution. It is essential to ensure that such applications are in alignment with broader ethical principles.

Professional Ethics

In the context of health care interventions via social media, professional ethics refers to a set of guidelines and principles that guide the behavior of health care professionals engaging with social media as part of their practice [121]. These guidelines may cover aspects such as patient privacy; confidentiality; informed consent; and the appropriate use of SMPs for disseminating health information, which includes avoiding conflicts of interest or biased behavior [122]. Algorithms that are designed to detect and flag fraudulent behavior among stakeholders can play a crucial role in identifying potential breaches of professional ethics [123]. Various modeling approaches, such as the living laboratory model, can support the development of health care professional ethics on SMPs [124]. Some researchers call for the development and implementation of local policies at health care organizations to govern the social media activities of health care professionals, highlighting the significant risks associated with the dissemination of information in health care–related social media endeavors [125].

While enforcing professional ethics is vital, it poses challenges, particularly when the methods used may infringe on the autonomy of stakeholders. The strategies mentioned, although essential for upholding ethics, could inadvertently overstep

boundaries, thus eliciting concerns regarding the autonomy and privacy of the individuals involved.

Legal Ethics

Legal ethics refers to the ethical considerations related to complying with the laws, regulations, and policies surrounding health care data privacy and security. This encompasses safeguarding the confidentiality of patient data, adhering to informed consent and data-sharing agreements, and complying with relevant legal and ethical standards [126,127]. Furthermore, it necessitates ensuring that AI models used in social media interventions for health care are developed and used in conformity with applicable regulations and standards. The existing regulatory and ethical oversight frameworks include the following: (1) the Health Insurance Portability and Accountability Act (HIPAA)—this framework is dedicated to implementing privacy regulations for health care data [145]; (2) the General Data Protection Regulation (GDPR)—it mandates compliance with data protection laws and adherence to other relevant legal and regulatory frameworks governing the use of AI in health care and social media interventions [128]; (3) ethical review boards—advocating for Ethics by Design, this approach involves integrating the services of an ethical review board into the development process of any product within an organization [129].

Both HIPAA and the GDPR are pivotal in the realm of data protection; however, they face intrinsic limitations, with HIPAA being constrained by jurisdictional reach and the GDPR being constrained by the specific subjects it safeguards. The Ethics by Design concept encourages the responsible and ethical development of AI. Nonetheless, this approach could potentially decelerate the innovation process due to the additional layer of review and oversight required during the deployment phase.

Other Ethical Considerations

Guttman [130] highlighted a range of ethical concerns tied to health promotion and communication interventions, including issues related to autonomy, equity, the digital divide, consent, and the risk of unintended adverse effects such as stigmatization of certain groups through the use of derogatory terms to describe their medical conditions. The author stressed the importance of identifying and addressing these issues in the context of health care–related communication interventions [130]. This involves safeguarding the privacy and confidentiality of patient data, respecting patient autonomy and consent, and ensuring that the use of SMPs does not harm the patient [131]. Gagnon and Sabus [132] recognized the concerns that health care professionals may have regarding the use of SMPs due to potential factual inaccuracies. Nevertheless, they argued that using social media in health care does not inherently breach ethical principles as long as evidence-based practices are followed, digital professionalism is upheld through controlled information sharing, and the potential benefits of disseminated information outweigh the risks [132].

Bhatia-Lin et al [133] suggested a rubric approach for the ethical use of SMPs in research that is applicable to health care–associated research involving social media surveillance. Wright [63] introduced a framework for assessing the ethical implications of a wide range of technologies whose comprehensiveness renders it a suitable baseline for evaluating the ethical implications of using AI in social media and health care contexts. Various tools, methods, and approaches can aid in ensuring the ethical use of AI within the health care domain on SMPs: (1) data visualization tools—these tools are designed to present complex ethical data in a clear and accessible manner, thus aiding health care professionals and other stakeholders in understanding and making informed decisions [134]; (2) sentiment analysis of social media posts related to health care interventions—this technique identifies ethical issues and concerns, such as biases or stigmatization of certain patient groups, by analyzing the sentiment of social media content [135]; (3) crowdsourcing platforms for ethical feedback—these platforms are developed to gather insights from a wide range of individuals on the ethical implications of AI systems and their recommendations, ensuring the inclusion of diverse perspectives and values (this approach highlights potential ethical concerns that development teams may otherwise overlook [136]); (4) fairness-aware ML algorithms—these algorithms are designed to address and mitigate unfairness in both the training data and the algorithmic decision-making process with the goal of promoting equity [137]; (5) privacy-preserving data analysis—this method emphasizes the protection of sensitive data from unauthorized access while enabling meaningful analysis, thus balancing privacy with utility [138,139]; (6) human-in-the-loop approaches by incorporating human oversight and decision-making into AI systems, these approaches aim to ensure that technology aligns with social values and ethical principles, thereby promoting responsible use [140]; (7) value-sensitive design—this approach focuses on identifying and integrating social values and ethical principles into the design and development of AI systems, thereby promoting their alignment with societal ethics [141].

In summary, each method has distinct applications and limitations. For instance, sentiment analysis of health care–related social media posts is effective in identifying ethical issues such as biases or stigmatization, yet it is susceptible to misinterpretation due to the inherent ambiguity of natural language. On the other hand, human-in-the-loop approaches may introduce subjectivity and diminish the efficiency of automated systems. Consequently, stakeholders involved in applying AI in social media within the health care domain should be cognizant of these methods' inherent limitations before implementation.

Discussion

Principal Findings and Future Research Directions

Overview

Health care providers leverage social media to advertise their services, engage with individuals, and cultivate community bonds [146]. SMPs enable medical professionals to interact with patients and gather feedback, thereby enhancing patient care. Moreover, social media acts as a medium for health promotion via peer support and disease awareness initiatives and enabling web-based consultations between physicians and patients [147]. To combat misinformation, implementing

rigorous fact-checking measures is imperative for the dissemination of accurate health information. It is also vital to oversee the use of these platforms by health professionals to ensure the protection of patient confidentiality.

The key findings of this study are outlined in the following sections.

RQ 1: What Existing Solutions Address FATE in the Context of Health Care on SMPs?

There are 4 identified solutions to FATE in health care discussions on SMPs. First, fairness in this domain is tackled through calibrated, statistical, and intersectional approaches. Calibrated fairness seeks to balance equal opportunities with individual differences, such as language or location. Statistical fairness uses demographic data to prevent biases. Intersectional fairness examines various aspects of an individual's identity. Second, accountability in health care on SMPs is ensured by adhering to legal standards, incorporating ethical principles into system design, and maintaining technical functionality and privacy, as well as through societal regulation and standardization. These measures include protecting data privacy, preventing discriminatory or unethical use of AI systems, conducting ethical impact assessments, enhancing transparency, involving stakeholders, carrying out audits and evaluations, and holding decision makers responsible. Third, transparency in AI within health care on social media emphasizes the importance of understanding AI systems, including their algorithms, data sources, and decision-making processes. Transparency is vital for comprehending how interventions are crafted, disseminated, and assessed, playing a significant role in identifying and rectifying biases or errors, fostering trust among stakeholders, and improving participation in social media–based health interventions. Fourth, ethics in health care on SMPs focuses on the development of AI technologies that are fair, transparent, and beneficial. This encompasses considerations of privacy, data protection, bias, accountability, and explainability. Upholding professional and social ethics, such as ensuring patient privacy and autonomy, is crucial. The primary aim is to guarantee the ethical use of AI in health care on SMPs while reducing potential risks and adverse effects.

RQ 2: How Do the Different Solutions Identified in Response to RQ 1 Compare to Each Other in Terms of Computational Methods, Approaches, and Evaluation Metrics?

The various solutions identified in response to RQ 1 can be compared based on computational methods, approaches, and evaluation metrics. These solutions encompass strategies for achieving calibrated, statistical, and intersectional fairness through a variety of computational methods, including data preprocessing, postprocessing, adversarial training, and decision tree use. Key evaluation metrics for assessing these solutions are equal opportunity and equalized odds. Accountability can be examined from multiple perspectives: legal accountability, achieved through regulatory measures and public-private partnerships; technical accountability, emphasizing logging and auditing; and ethical accountability, focusing on the identification of ethical risks through methods such as ethical impact assessments, value alignment, and stakeholder engagement. Transparency is attainable through several strategies: algorithmic transparency, data transparency, process transparency, and the interpretability and explainability of models. Enhancements in algorithmic transparency can be achieved through feature importance analysis, interpretability techniques for models, and the generation of explanations. Data transparency improvements are facilitated by data visualization, profiling, lineage analysis, and provenance tracking. Process transparency can be bolstered by auditability, monitoring, and adoption of open-source development practices. Although interpretability and explainability remain burgeoning research areas, there is a diverse range of methods for attaining these goals, each suitable for specific contexts. The promotion of ethics in health care on SMPs involves the use of simulation, modeling, data analytics, sentiment analysis, crowdsourcing, and automated systems considering both professional and social ethics.

RQ 3: What Is the Strength of the Evidence Supporting the Different Solutions?

The strength of the evidence supporting the solutions is variable and influenced by research quality, methodology, and the statistical significance of the findings. Concepts such as calibrated, statistical, and intersectional fairness are grounded in substantial research. Computational methods, including data preprocessing, adversarial training, and the use of decision trees, are widely adopted, although the extent of evidence supporting their efficacy varies. Evaluation metrics such as equal opportunity and equalized odds rely on well-established statistical measures, but their applicability and effectiveness can differ across studies. Within the ethics domain of health care on SMPs, the principles of privacy protection and bias mitigation are robustly supported by research; however, the evidence for the effectiveness of specific solutions may vary. Techniques such as simulation, modeling, data analytics, and crowdsourcing are commonly used, with their success dependent on the specific application context. Due to the rapidly evolving nature of this field, consulting current and reputable sources is essential for accessing the latest research findings.

The findings from this study contribute to the evolving landscape of AI applications within health care on SMPs by enhancing the understanding of the ethical considerations essential for deploying AI in health care. They delineate practical pathways for leveraging social media to improve patient care and engagement. This study offers insights into achieving fairness in this domain through calibrated, statistical, and intersectional approaches, presenting methodologies that balance personalized care with broader demographic considerations and effectively address biases. It identifies accountability measures such as transparency, documentation, adjudication, stakeholder engagement, logging, and auditing as essential for the design and regulation of AI, ensuring its responsible use in health care contexts. Achieving public transparency presents technical and practical challenges; however, entities involved in AI applications within health care should provide comprehensive reports on decision-making factors, data origins and use, and solid scientific evidence supporting their decisions to stakeholders upon request. Finally, ethical considerations,

encompassing philosophical, professional, and legal dimensions, should drive the implementation of the 3 core components of FATE: fairness, accountability, and transparency.

Our study identified several research gaps in AI systems within health care on SMPs. First, primary challenge in the integration of AI and health care on SMPs is the collection and use of data that accurately represent diverse populations without inherent biases. Trustworthy data sets are crucial for training large language models for clinical applications, yet these data sets often lack diversity in key demographics such as age, ethnicity, or medical history. This shortfall can result in AI predictions that disproportionately benefit certain groups. Moreover, the process of obtaining informed consent on SMPs is complicated by the limited understanding users have of how their data might be used for health care research. A common scenario involves the use of patient-generated data from web-based health forums or social media support groups where consent is ambiguously defined, thereby raising ethical and privacy concerns. Second, the operationalization of the broad set of ethical principles defined by the AMIA into a cohesive FATE framework presents significant challenges. The pursuit of a unified approach that addresses the components of FATE simultaneously is hampered by potential conflicts among these principles. For example, increasing transparency by making AI decision-making processes more comprehensible can inadvertently risk patient privacy and system security by exposing sensitive data or proprietary algorithms. Third, the application of FATE principles in real-world health care interventions on SMPs is critically underdocumented. There is a notable absence of comprehensive case studies that detail the implementation, challenges, and outcomes of ethical frameworks in practice. Such documentation is essential for grasping how theoretical ethical considerations are translated into practical impacts and for pinpointing areas that need adjustment when applying these principles. The effectiveness and ethical considerations of AI-driven public health campaigns on platforms such as Twitter and Facebook, for instance, are largely unexplored in a manner that would provide actionable insights into their real-world impact and ethical ramifications. Fourth, the current landscape of evaluating FATE in AI systems, particularly at the intersection of health care and social media, is characterized by a lack of methods that can be universally applied across different models and data types. The specific challenges of the health care domain on SMPs, which include the necessity to analyze diverse data formats in real time, call for the development of model-agnostic tools for ethical assessment. Most existing methods are designed for particular models or data types and do not comprehensively address the wide range of health care applications on social media. Furthermore, there is an absence of a clear strategy for assessing the impact of various AI-assisted interactions between health care and social media domains.

Given the identified gaps, our study proposes 5 research directions. First, research should focus on the development of comprehensive models that integrate the FATE framework with the broader ethical principles outlined by the AMIA. This involves pioneering methodologies that ensure a balanced consideration of all ethical dimensions, aiming to uphold each without compromising the significance or effectiveness of the others. For medical professionals and researchers, this direction represents a shift toward creating AI systems in health care that are both technologically advanced and ethically robust, ensuring equitable and responsible AI use in patient care and data management. Second, investigations are needed into merging computational methods with ethical evaluations to devise sophisticated mathematical formulations capable of quantitatively assessing ethical components in AI applications within health care on SMPs. By developing robust metrics and evaluation frameworks, researchers can bridge the theoretical ethical considerations with practical computational methods. This effort aims to facilitate the integration of ethical principles into the design and evaluation of AI technologies, ensuring that they meet the highest standards of medical ethics and patient care. Third, exploration is required into ethical trade-offs by focusing on understanding and mitigating inherent conflicts between different ethical components within the FATE framework. By systematically examining these trade-offs, research could aim to find innovative solutions that minimize conflicts, such as between transparency and privacy or between fairness and accountability. For the medical and research community, acknowledging and navigating these trade-offs is crucial for the development and implementation of AI systems that are both ethically responsible and effective in achieving health care goals. Fourth, investigation is necessary into the application of FATE principles in real health care interventions on SMPs. This direction seeks to understand the ethical impact of these technologies on users and society. Focusing on the ethical implications of AI-driven health care solutions, from patient engagement strategies to public health campaigns on social media, this research direction aims to ensure that they positively contribute to user well-being and societal health standards. Fifth, a strategic approach should be identified to evaluate the impact of AI-assisted interactions within health care and social media from a FATE perspective. This includes analyzing these interactions to develop universal, model-agnostic metrics that assess the ethical dimensions of AI applications across various platforms. Once established, such metrics could be integrated into social networks, guiding the regulation of AI use in health care on SMPs. For medical professionals and researchers, these metrics would provide a framework for consistently evaluating and ensuring the ethical integrity of AI technologies, promoting safer and more beneficial health care interactions on social media.

Limitations

The primary limitation of our study stems from the scarcity of comprehensive research that thoroughly explores all dimensions of FATE in the context of AI applications in health care on SMPs. This scarcity reflects not only existing research gaps but also the early stage of scholarly inquiry in this interdisciplinary area. Consequently, our review may not fully encapsulate the complex and multidimensional nature of how FATE intersect and manifest in the deployment of AI within health care settings on social media. This limitation is significant because it suggests that our understanding of FATE issues in this context may rely on an incomplete picture, thus impacting the generalizability of our findings across all potential AI applications in health care on social media.

In addition, identifying the precise population of studies relevant to FATE in AI and health care on SMPs is made more challenging by the heterogeneity and dynamism of SMPs as well as the diversity of AI applications within health care. SMPs are rapidly evolving, introducing new functionalities and altering user interactions, which in turn influences how AI technologies can be applied and examined within these contexts. The challenge of compiling a representative collection of studies that fully encompasses this range contributes to potential gaps in our review, limiting the degree to which our findings can be seen as representative of the field as a whole.

Moreover, the fast-paced advancement of technology, along with the continual evolution of both SMPs and AI, imposes a temporal limitation on our study. Research that was up-to-date at the time of our review may soon become outdated as new technologies emerge and existing ones advance. This swift pace of change implies that the ethical challenges identified today may evolve, new challenges may surface, and previously proposed solutions may become obsolete or less applicable. Therefore, the applicability of our findings is inherently limited by this temporal aspect, underscoring the necessity for ongoing research to continuously refresh our understanding of FATE within AI in health care on SMPs.

Conclusions

Our review sheds light on the current state of FATE in health care AI as applied to SMPs. It offers a critical analysis of the methodologies, computational techniques, and evaluative strategies used in various studies. By examining the successes and identifying the shortcomings of current practices, this review stimulates further innovation in the field. It challenges existing paradigms on how AI technologies can be both technologically advanced and ethically robust, ensuring fairness, accountability, and transparency in their application.

The practical implications of this work are substantial. First, it guides future research by identifying recent trends and research gaps, suggesting that researchers focus on creating more robust, fair, and ethical AI systems. This includes using diverse data sets that more accurately represent the global population and using evaluation metrics that comprehensively assess the systems' impacts on all stakeholders. Second, this review underscores the importance of integrating FATE principles throughout the AI system development life cycle, from conceptualization to deployment. For practitioners in health care and technology, this signifies a move toward more inclusive, transparent, and ethically guided development processes. Such a transition not only addresses biases and accountability issues but also boosts patient trust and engagement with AI-driven health care solutions on social media.

Third, the insights from this review are invaluable for policy makers and regulatory bodies, aiding in the creation of nuanced regulations and guidelines that ensure that AI technologies positively contribute to health care outcomes without compromising ethical standards or patient rights. Furthermore, by simplifying complex concepts, this review acts as an educational tool for a broad audience, including health care providers, AI developers, patients, and the general public. Raising awareness about the importance of FATE in health care AI fosters more informed participation in discussions and decision-making regarding AI use in health care, particularly on SMPs.

Ultimately, this study aids in the pursuit of ethical development and deployment of AI systems in health care. By providing an in-depth analysis of the current achievements and future directions for FATE in health care AI on social media, it advocates for the adoption of best practices that balance ethical considerations with technological innovations. The implications of this study extend beyond academia, affecting how AI technologies are conceptualized, developed, and implemented in health care on social media, thereby shaping a future where AI-driven health care solutions are not only effective and innovative but also ethically responsible, equitable, and transparent. This ensures that these technologies serve the best interests of society.

Abstract

Background: Burnout among health care professionals is a significant concern, with detrimental effects on health care service quality and patient outcomes. The use of the electronic health record (EHR) system has been identified as a significant contributor to burnout among health care professionals.

Objective: This systematic review and meta-analysis aims to assess the prevalence of burnout among health care professionals associated with the use of the EHR system, thereby providing evidence to improve health information systems and develop strategies to measure and mitigate burnout.

Methods: We conducted a comprehensive search of the PubMed, Embase, and Web of Science databases for English-language peer-reviewed articles published between January 1, 2009, and December 31, 2022. Two independent reviewers applied inclusion and exclusion criteria, and study quality was assessed using the Joanna Briggs Institute checklist and the Newcastle-Ottawa Scale. Meta-analyses were performed using R (version 4.1.3; R Foundation for Statistical Computing), with EndNote X7 (Clarivate) for reference management.

Results: The review included 32 cross-sectional studies and 5 case-control studies with a total of 66,556 participants, mainly physicians and registered nurses. The pooled prevalence of burnout among health care professionals in cross-sectional studies was 40.4% (95% CI 37.5%-43.2%). Case-control studies indicated a higher likelihood of burnout among health care professionals who spent more time on EHR-related tasks outside work (odds ratio 2.43, 95% CI 2.31-2.57).

Conclusions: The findings highlight the association between the increased use of the EHR system and burnout among health care professionals. Potential solutions include optimizing EHR systems, implementing automated dictation or note-taking, employing scribes to reduce documentation burden, and leveraging artificial intelligence to enhance EHR system efficiency and reduce the risk of burnout.

Introduction

The integration of electronic health record (EHR) into health care systems marks the beginning of a new era in medical information management, with significant potential benefits for patient care, clinical decision-making, and administrative efficiency [1,2]. EHR systems are central to the modern health care infrastructure [3]. Along with these benefits, however, the widespread adoption of EHR systems has raised concerns about the well-being of health care professionals [4,5]. Unintended consequences, such as burnout among health care professionals, technology-related errors, and increased safety risks, have been associated with EHR use [4,6,7]. In addition, a notable part of the problems with EHR systems in the United States is the need to provide additional documentation for insurance companies [8].

Within the realm of EHR use, burnout among health care professionals, characterized by emotional exhaustion, depersonalization, and a diminished sense of personal accomplishment, has emerged as a critical concern [9,10]. Burnout among health care professionals has become a pressing public health concern [11-13]. Some studies have reported an average burnout prevalence of 44% [2], with rates exceeding 80% in some specific settings and departments [4,5] such as primary care and emergency departments. This pervasive problem affects not only health care professionals but also patients, with negative consequences such as reduced quality of care and increased medical errors and psychological problems [14-17]. The estimated annual cost of burnout among health care professionals due to medical negligence and staff turnover exceeds US $4 billion [18].

The phenomenon of burnout among health care professionals goes beyond individual distress and has significant implications for patient safety, quality of care, and overall health system performance [14,15,19]. Understanding the prevalence and underlying factors of EHR-related burnout among health care professionals is critical to developing effective interventions and policy adaptations. These interventions are essential to mitigate this burden and ensure the long-term sustainability of EHR implementation in health care [19,20]. The increase in EHR-related burnout among health care professionals reflects a multifaceted interplay of factors, including increased documentation requirements, cumbersome user interfaces, and the rapid pace of technological development [9,16,18].

This systematic review and meta-analysis aims to provide a comprehensive assessment of the existing literature on EHR-related provider burnout. It seeks to capture the full extent of burnout, identify its causes, and provide evidence-based support and recommendations to alleviate this pervasive problem. In addition, we hypothesize that specific features of EHR systems, such as user interface design or increased documentation requirements, may contribute to provider burnout. We hope that this work will serve as a guide for health care organizations, policy makers, and EHR developers in developing interventions and technological improvements that prioritize the well-being of health care professionals. In doing so, we can promote a sustainable and resilient health care system while harnessing the potential benefits of EHR systems to improve patient care.

Methods

Study Guidelines

We focused on studies that directly measured burnout, as it is often considered in existing research to be a distinct emotional state, separate from depression or anxiety. This systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) guidelines [21] and was registered with PROSPERO (CRD42021281173). Details of the guidelines and registration can be found in Multimedia Appendices 1 and 2, respectively.

Definitions

Our definitions of burnout were based on the Maslach Burnout Inventory-Human Services Survey instrument (MBI-HSS) [13,22], which characterizes burnout with high emotional exhaustion as a score ≥27, high depersonalization as >10, and low personal accomplishment as <33. Across the included studies, burnout was defined inconsistently, with definitions ranging from any one of the 3 items to all 3 items. In cases where the same study examined multiple definitions of burnout, we used the most common definition (high emotional exhaustion, high depersonalization, and low personal accomplishment) for the meta-analysis. For alternative definitions, such as those from the Stanford Physician Wellness Survey [23] or mini-Z [24], only outcomes explicitly described as burnout were documented. We categorized studies according to the measurement tool and definition of burnout.

Search Strategy

We systematically searched PubMed, Embase, and Web of Science to identify relevant peer-reviewed English language studies published between January 1, 2009, and December 31, 2022. We used several search terms to capture EHR systems, including “electronic health record” and its abbreviation “EHR,” as well as “electronic medical record (EMR)” and “computerized physician order entry (CPOE).” To capture the phenomenon of burnout, we used terms such as “burnout,” “alert fatigue,” and “exhaustion.” In defining our study participants, we considered a spectrum of health care professionals, including “doctor,” “clinician,” “physician,” “surgeon,” “medical staff,” and “health care provider.” On June 30, 2023, the researchers conducted a literature search in databases such as PubMed, Embase, and Web of Science, following the previously established search strategy. No papers were found that met the inclusion criteria for this review.

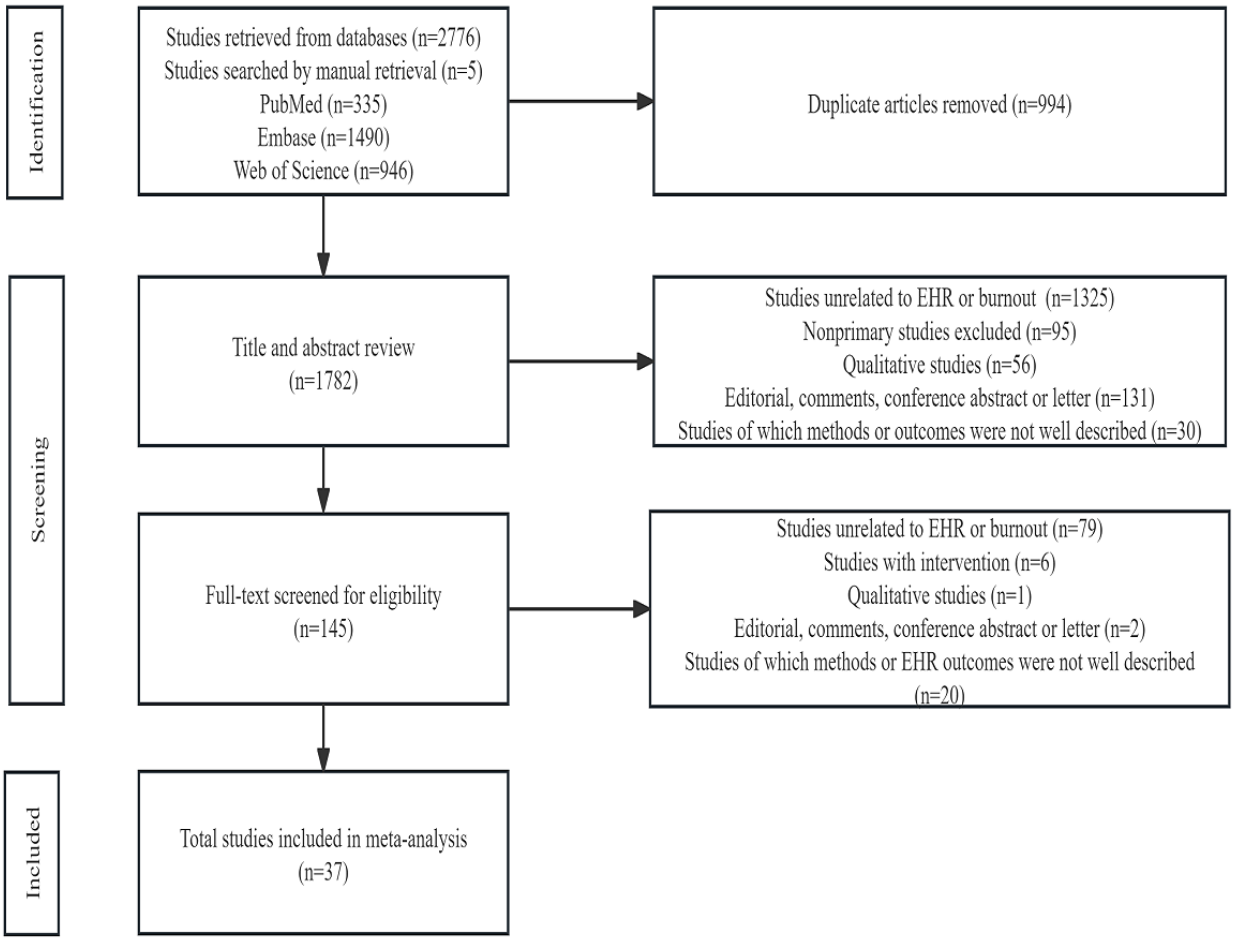
The terms were combined using Boolean logic and then filtered by publication date and language (English). A full description of the search strategy can be found in Multimedia Appendix 3. In addition, we carefully examined the references of each article and manually added 5 relevant references to our review list. Duplicate studies were systematically excluded from consideration.

Inclusion and Exclusion Criteria

Figure 1 shows the search and selection process. We applied strict inclusion and exclusion criteria to identify original and observational studies relevant to our research objectives. We included studies that examined general EHR use or specific supporting systems such as computerized physician order entry. We focused on studies that directly assessed burnout among health care professionals and individual psychological responses to EHR systems. Our review included the following types of research: cohort studies, case-control studies, and cross-sectional studies. EHR-related burnout was assessed using validated tools such as the MBI-HSS, the mini-Z, or other similar measures. The following publication types were excluded: abstracts, editorials, letters, reviews, commentaries, guidelines, and studies by non–health care professionals. In addition, studies were excluded if the necessary data could not be obtained from the corresponding author. We also excluded studies that repeated data already published in the literature.

Two reviewers independently screened all titles and abstracts to assess for relevance. Full texts of articles identified for further review were then assessed against the inclusion criteria. In cases of disagreement about the study eligibility of studies, a third reviewer was consulted for resolution.

Figure 1. Flowchart of study selection. EHR: electronic health record.



Data Extraction and Synthesis

For the included studies, we extracted relevant information including study design, geographical region, study duration, medical specialties involved, sample size, and relevant outcomes. The main outcomes included the prevalence of burnout in cross-sectional studies, the odds ratio (OR) along with its 95% CI in case-control studies, and the factors influencing burnout. We also documented the specific tools or measures used to assess these outcomes.

Risk of Bias Assessment

Two reviewers assessed the integrity, confirmability, and quality of the cross-sectional studies using the Joanna Briggs Institute (JBI) checklist [25] and the Newcastle-Ottawa Scale (NOS) [26] for the included case-control studies. Details of these assessments can be found in Multimedia Appendices 4-6, respectively.

Statistical Analysis

Meta-analysis was performed using R software (version 4.1.3; R Foundation for Statistical Computing). Heterogeneity was

calculated using the Cochran *Q* test, and statistical significance was set at $P<.05$. If there was no statistical heterogeneity ($I^2<50\%$), the fixed-effects model was used to pool results; otherwise ($I^2>50\%$) the random-effects model was used [27,28]. We grouped the main outcomes according to the predictor and moderator factors described by the participants and derived from the outcome reports. Continuous variables were summarized using the mean and standardized mean difference, whereas rates were extracted for categorical variables. For cross-sectional studies, the effect size measure was the prevalence of burnout and its corresponding 95% CI. For case-control studies, the effect of EHR was assessed using the pooled OR and its 95% CI. Publication bias was analyzed using the Egger test [29] and the trim-fill funnel plot. A sensitivity analysis was performed for each omitted method to determine the robustness and reliability of the results.

Results

Characteristics of the Included Studies

After reviewing a total of 2776 studies, 37 were selected for inclusion in our analysis (Figure 1) according to the predefined criteria and after elimination of duplicates. The baseline characteristics of the selected studies are summarized in Tables 1 and 2. For further details see Multimedia Appendix 7 [6,30-60].

The studies included in our review covered the period from 2009 to 2022 and included regions in both Canada and the United States. They involved a total of 66,556 health care professionals. The sample sizes of these studies varied widely from 84 to 25,018 participants, and the response rates ranged from 8.9% to 73.0%.

The primary measure used to assess burnout in the majority of studies was the MBI-HSS, which was used in 17 of 37 studies (46%). In addition, the mini-Z scale was used in 10 studies (27%). Notably, 2 studies using the MBI-HSS used cutoff definitions for burnout subcomponents that followed the standardized recommendations of the MBI-HSS.

[a]OR: odds ratio.

[b]EHR: electronic health record.

Quality of Included Studies

The quality of the cross-sectional studies was assessed using the JBI checklist. Of the cross-sectional studies reviewed, only 16 had a response rate of more than 50%. In addition, 24 studies provided a clear and precise description of their inclusion and exclusion criteria for participants. Additionally, 32 cross-sectional studies provided a detailed and thorough statistical analysis of their data and results.

We used the NOS to assess the risk of bias and the overall quality of the case-control studies. In particular, one study failed to clarify its selection criteria for the control group and comparability with the exposed group, which resulted in a high risk of selection bias. Furthermore, none of the 5 case-control studies reported information on the nonresponse population, indicating a high risk of nonresponse bias. Overall, the risk of bias in the case-control studies was assessed as moderate. A full breakdown of the quality assessment for each study can be found in Multimedia Appendices 4 [6,30-60] and 5 [61-65].

In our meta-analysis, we examined 37 studies that focused on identifying the prevalence of burnout associated with EHR use, involving a total of 66,556 health care professionals. The internal heterogeneity of 37 cross-sectional studies was evident in all included cross-sectional studies (I^2=98.3%). Using random-effects models, we calculated the combined overall prevalence of EHR-related burnout of 40.4% (95% CI 37.6%-43.2%). Subgroup analysis showed that studies using the MBI-HSS reported a higher pooled prevalence of burnout (41.4%) than those using the mini-Z (35.1%) but lower than those using other instruments (43.2%). However, these differences were not statistically significant (Figures 2 and 3).

Figure 2. Forest plot of the pooled prevalence of burnout among health care professionals across cross-sectional studies [6,30-60]. IV: inverse variance methods.

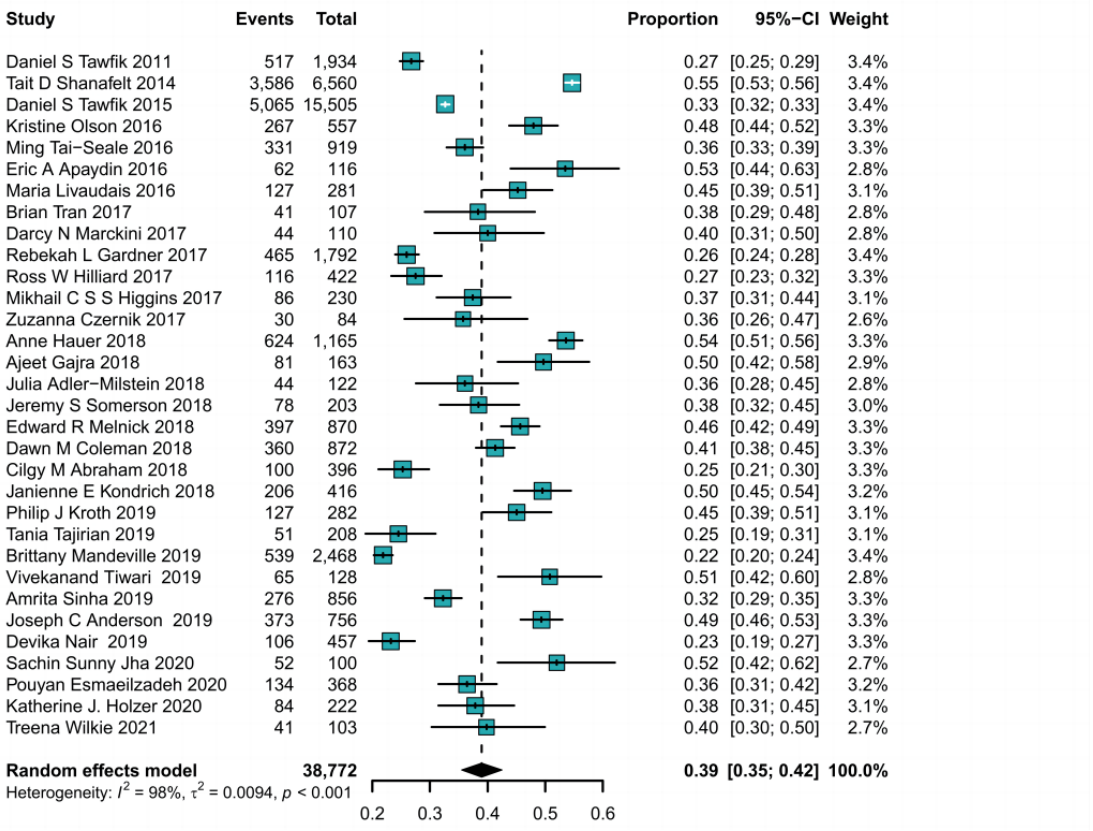

Figure 3. Measurement tool subgroup analysis of the pooled prevalence of burnout among health care professionals in cross-sectional studies [6,30-60]. IV: inverse variance methods; MBI: Maslach Burnout Inventory.

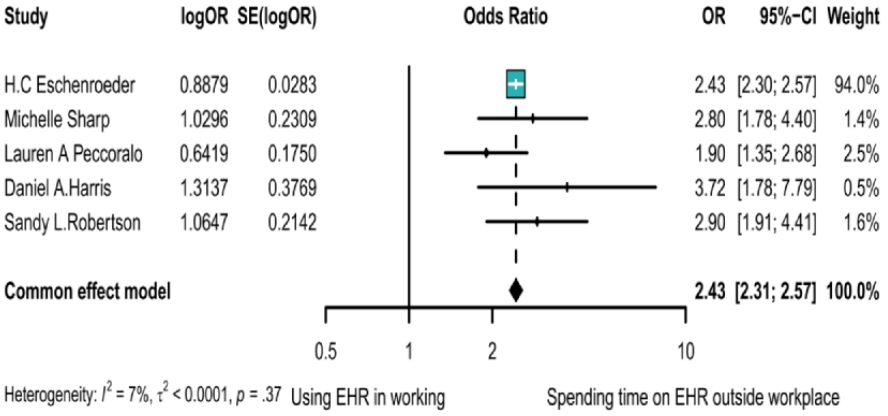


Publication Bias

The Egger test and the funnel plot were used to estimate the publication bias in the included studies (t=1.35, P=.18), indicating no significant publication bias. The distribution of the points in the funnel plot is symmetric. There was no statistical difference in publication bias. The results are available in Multimedia Appendices 8 and 9.

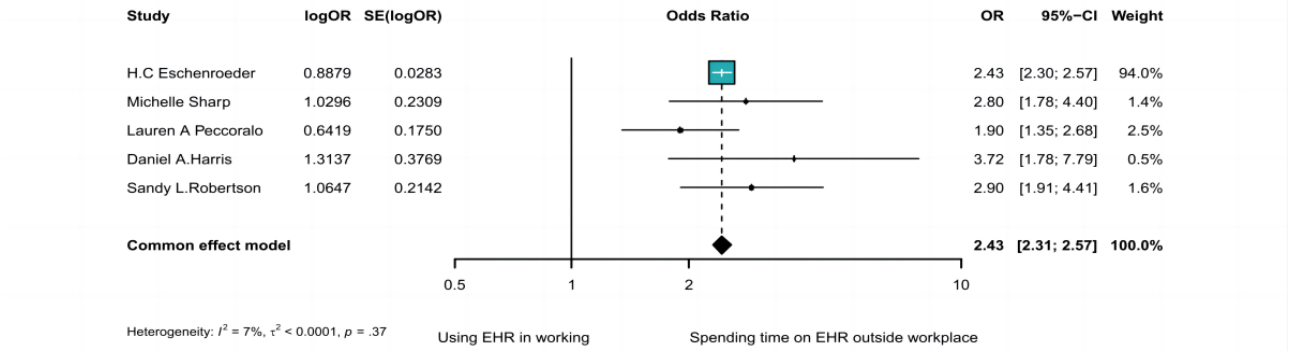
Sensitivity Analysis

Sensitivity analysis was performed using the individual omission method. The results showed that no single study had a significant effect on the pooled prevalence of burnout. The results of the sensitivity analysis indicated that the meta-analysis was robust.

The Association Between Time Spent on the EHR and Burnout

Data from 5 case-control studies with 27,784 participants were available for the meta-analysis of the time spent on EHR and burnout prevalence. There was no significant within-study heterogeneity (I^2=7.2%, P=.37), and a longer duration of EHR use was associated with a higher prevalence of burnout (OR 2.43, 95% CI 2.31-2.57) (Figure 4).

Figure 4. Forest plot of the association between the time spent using EHR and the risk of burnout [61-65]. EHR: electronic health record; IV: inverse variance methods; OR: odds ratio; SE: standard error of the TE; TE: take the logarithm of the effect value.



Main Causes of Burnout and Proposed Solutions

We have summarized the factors contributing to burnout among health care professionals in relation to EHR use in Table 3. Among these, challenges related to the design and availability of EHR systems were identified as the most significant contributors, as evidenced by 32 studies. Complaints from EHR users focused on several key issues: disruption to workflow [33]; cumbersome data entry (copy and paste) [59]; reduced direct communication with patients [38]; and annoyance with redundant, repetitive, or irrelevant alerts [52]. Poor EHR design has been shown to reduce work productivity and lead to prolonged EHR use [51,64]. This prolonged use has a negative impact on work-life balance of health care professionals and increasing burnout [42,57,65,66]. Workload factors, identified in 18 of the 32 studies, further exacerbate this problem. Specific aspects of workload that contribute to burnout include the number of hours worked per week [62-64], the frequency of night shifts [46,60], administrative documentation tasks [33,35,38,48,64], the volume of patient admissions [30,35,56], and the amount of information to manage in the EHR inbox [34,37,40]. Together, these factors exacerbate provider fatigue and increase the risk of burnout.

EHR usability, recognized as a contributing factor to burnout, relates to issues of accessibility and functionality of the system. This includes instances where the system is frequently unavailable due to maintenance, updates, or technical failures, as well as situations where the system is not user-friendly and requires excessive time to navigate and use effectively, potentially leading to burnout among health care professionals.

The factors contributing to burnout identified in the reviewed studies fall into 3 main categories: EHR use, work environment and organizational support, and the personal factors. Table 4 provides a summary of strategies to address these contributing factors. For example, the burden of medical clerical tasks imposed by EHR systems suggests the need to employ assistants or scribes to reduce the workload of health care professionals [31,67]. Evidence suggests that the EHR system itself can be improved by involving clinical staff in the design process [33], optimizing the user interface [39,64], minimizing the number of clicks required [52], and actively soliciting and incorporating user feedback [32]. In addition, some practitioners may not fully use health information technology in their roles and may be frustrated with EHR systems or similar systems [32]. To address this, health care organizations are advised to establish clear policies and procedures before implementing an EHR system and to provide ongoing health information technology education to reduce technology-related anxiety among users [32,52,68]. Finally, comprehensive and systematic initiatives are essential to effectively reduce burnout. Health care professionals are encouraged to work together to advocate for legislative and regulatory changes that ensure reasonable working hours, mandatory breaks, and safeguards against burnout [36,42,43,58,62].

Moreover, research also suggests that sociodemographic characteristics, interpersonal dynamics, and the work environment have a significant impact on the prevalence of burnout. In particular, factors such as being female, younger, and less experienced correlate with higher rates of burnout [34,48,55]. Conversely, high levels of satisfaction or positive perspectives on the use of EHR systems may reduce burnout [36,42,58].

Table 3. The influencing factors of burnout for studies.

Author	Design	Risk factors for burnout	Protective factors against burnout	Main EHR[a] factors influencing burnout
Tawfik et al [30]	Cross-sectional	NICU[b] with ≥10 weekly admissions, nursing care workload, and patient mortality	Burnout recognition education; implementation of burnout interventions at the individual and institutional level	Using EHR outside working or at home; time on using EHR
Shanafelt et al [31]	Cross-sectional	Using CPOE[c], female gender, emergency medicine, each additional hour per week	Assistant order entry; documentation support	Time spent on clerical tasks
Tawfik et al [32]	Cross-sectional	HIT[d] frustration, difficulty in falling asleep	Supplemental EHR training; scribes to assist documentation； team-based documentation and inbox management； automating data-entry tasks	Frustrated or stressed by EHR
Olson et al [33]	Cross-sectional	Poor control over workload, inefficient teamwork, lack of value alignment with leadership, and hectic-chaotic work atmosphere	Improve professional satisfaction; nonphysician order entry	Using EHR outside working or at home; insufficient documentation time
Tai-Seale et al [34]	Cross-sectional	Female gender and poor control over work schedule	Feeling highly valued; having good control over work schedule; working in a quiet or busy but reasonable environment; assist physician with email work; limit desktop medical work outside working hours (except in emergencies)	Using EHR outside working or at home; number of EHR system-generated in basket messages
Apaydin et al [35]	Cross-sectional	Managing unscheduled or same-day patients, lack of pharmacist support, administrative work, excessive overall workload, difficulty communicating with other professionals, inadequate care coordination, and answering patient emails	Interventions to facilitate provider-led quality improvement	Managing in-basket messages generated by EHR; responding to EHR alerts
Livaudais et al [36]	Cross-sectional	Negative perceptions of EHR	Perceiving positive effect of EHR in practice； technical support for EHR when using systems; EHR optimization program	Managing in-basket messages generated by EHR; poor EHR design; dealing with patient-call messages in systems
Tran et al [37]	Cross-sectional	Clinical full-time equivalents >0.9 and more incomplete messages in inbox	Perception positive attitudes about the effect of EHR or satisfied with EHR	Average additional 10 minutes spent on EHR after each visit; less efficient at completing EHR and inbox information
Marckini et al [38]	Cross-sectional	Female gender and dissatisfaction for clerical tasks	EHR optimization; improve physician efficiency; and job satisfaction	Managing in-basket messages generated by EHR; dissatisfaction with EHR
Gardner et al [39]	Cross-sectional	Primary care specialties, female gender, and reporting poor or marginal time for documentation	Perception positive attitudes about the effect of EHR or satisfied with EHR	Excessive data inputting in EHR; using EHR at home; frustrated with EHR
Hilliard et al [40]	Cross-sectional	High volume of patient call messages in the system and lack of control over workload	Copy and paste used in EHR documentation; assist with inbox tasks and create 2 administrative “desktops”	Using EHR outside working or at home; excessive data inputting in EHR; managing in-basket messages generated by EHR
Higgins et al [41]	Cross-sectional	Self-compassion, sleep disorder, lacking support from leaders, and poor control over schedules	Peer support, perceived appreciation and meaningfulness in work; maintaining values consistent with practice institution	Poor EHR usability; perception negative attitudes about the effect of EHR
Czernik et al [42]	Cross-sectional	Frustrated or stressed by EHR	Reducing the burden of documentation tasks; improving EHR usability; interventions to improve the EHR	Poor usability of EHR; information overload; degradation of medical documentation
Hauer et al [43]	Cross-sectional	Loss of practicing autonomy, female gender, frustrated with EHR, and increasing insurance and government regulation	Improve the functionality of EHR; enhance physician leadership and involvement; create a center for physician empowerment; create a physician health program	Using EHR outside workday

Author	Design	Risk factors for burnout	Protective factors against burnout	Main EHR[a] factors influencing burnout
Gajra et al [44]	Cross-sectional	Variable reimbursement models, interactions with payers, and increasing treating and caring demands	Use advanced practice providers; hire additional administrative staff; invest in information technology	Excessive data inputting in EHR; frustrated or stressed by EHR; using EHR outside workday
Adler-Milstein et al [45]	Cross-sectional	Poor self-rated EHR skills	Improve EHR design; scribe or team documentation; reduce documentation requirements	Using EHR outside working or at home; time spent on EHR; system-generated in-basket messages (>114) per week
Somerson et al [46]	Cross-sectional	Working >80 hours per week, verbal abuse from faculty, educational debt, “scut” work >10 hours per week	Nursing support; duty-hour restrictions; improve EHR functionality and efficiency; adequate, personalized training and support; adequate social work support	Time spent on EHR per week; used EHR >20 hours per week
Melnick et al [47]	Cross-sectional	Practice location (academic medical center) and medical specialty	Improve EHR usability	Using EHR outside working or at home; poor EHR usability
Coleman et al [48]	Cross-sectional	Work-related physical pain, work-home conflict, and younger age	Build personal resilience, enhance wellness; peer support; reduce administrative or EHR burden	Using EHR outside working or at home; increased EHR or documentation requirement
Abraham et al [49]	Cross-sectional	Intraorganizational factors	EHR with multifunctional; reduce high EHR workload; work with supportive colleagues; improve team communication	High EHR workload
Kondrich et al [50]	Cross-sectional	Feeling undervalued by patients, lacking superior support, little promotion chances, perceived unfair clinical working schedule, and nonacademic environment	Improve physician well-being	Feeling that the EHR detracts from patient care
Kroth et al [51]	Cross-sectional	Overall stress	Improve EHR design; clinician training; scribes to assist documentation; work at home boundaries; exercise, taking breaks	Information overloading; slow system response; excessive data inputting； fail to navigate quickly; note bloat; patient-clinician relationship interference; fear of missing something; billing oriented notes.
Tajirian et al [6]	Cross-sectional	Workflow issues	Reduce the administrative burden of EHR； improve EHR	Lower satisfaction and higher frustration with the EHR； poor intuitiveness and usability of EHR
Mandeville et al [52]	Cross-sectional	HIT-related stress and burnout and emergency medicine	Improved workflow	Daily frustration added by EHR； using EHR outside working or at home
Tiwari et al [53]	Cross-sectional	Lack of physical exercise and weekly working hours	Teamwork and working satisfaction; self-care training	Poor EHR usability; dissatisfaction with EHR
Sinha et al [54]	Cross-sectional	Interpersonal disengagement	Lower CLOC[e] ratio (total CLOC time to allocated appointment time); well-established personal resources	Using EHR outside working
Anderson et al [55]	Cross-sectional	Female gender, younger age, shorter practicing years, and having children at home	Taking 20 days or more of vacation time	Using EHR at home; ≥2-hour patient administration
Nair et al [56]	Cross-sectional	Working long hours, weekly number of nursing patients, practice environment, disinterested health systems, and dissatisfaction with remuneration	Caring for fewer patients per week	Using EHR outside working or at home; EHR requirements
Jha et al [57]	Cross-sectional	COVID-19 pandemic and in-house billing	Stay positive; improved EHR design	Documentation through EHR
Esmaeilzadeh and Mirzaei [58]	Cross-sectional	Less direct communication with patients, inadequate training for using HIT, and increasing computerization at work	Positive perceptions of EHR; more policy and legal interventions to ensure meaningful use of EHR	Poor EHR usability; time spent entering data
Holzer et al [59]	Cross-sectional	Receive COVID-19 patients	Using EHR to streamline clinical care activities; physician task relief	Using EHR outside work; increased EHR workload

Author	Design	Risk factors for burnout	Protective factors against burnout	Main EHR[a] factors influencing burnout
Wilkie et al [60]	Cross-sectional	High workload and insufficient resources	Good leadership; prioritize work-life balance	Poor EHR usability
Eschenroeder et al [61]	Case-control	Specialty	Organizational support for EHR	After-hours EHR charting time per week >6 hours; time-consuming data entry
Sharp et al [62]	Case-control	Working hours per week >70 hours	Report system to cover personal illness or emergency; access to mental health services; reduce EHR and clerical burden	>90 minutes on the EHR outside of the workday
Peccoralo et al [63]	Case-control	Clerical work time (>60 minutes/day) and poorer work-life integration	Reducing time spent on EHR and clerical tasks	Using EHR outside working (>90 minutes/day); EHR adds to daily work frustration
Harris et al [64]	Case-control	Insufficient time for documentation	Improve EHR usability; documentation practices optimization	Using EHR outside working or at home; EHR adding to daily frustration
Robertson et al [65]	Case-control	Dissatisfaction with work-life balance and female gender	EHR proficiency training	Extra time spent on EHR per week >6 hours

[a]EHR: electronic health record.

[b]NICU: neonatal intensive care unit.

[c]CPOE: computerized physician order entry.

[d]HIT: health information technology.

[e]CLOC: clinician logged-in outside clinic time.

Table 4. Proposed solutions for burnout mentioned.

Perspectives/solutions and suggestions	Measures
EHR[a]	
Improve EHR usability and performance	Enhance EHR user interface and design to reduce health care professionals to use
Institutions provide timely technical support during EHR use	Improving the effectiveness and efficiency of technological responses
Institutions should offer comprehensive training courses for EHR users	Ensure users master EHR skills to reduce burnout from technological issue
Working environment and organizational support	
Institutions introduce mechanisms for regular assessment of EHR efficacy	Regularly optimize and update the system based on user feedback
Establish a schedule, routine, and workflow	Design and optimize the workflow to ensure that the EHR aligns with the health care professional's actual work, reducing unnecessary steps and improving work efficiency
Enhance peer, managerial, and technical support	Provide appropriate human resources, such as medical assistants, scribes, and improving teamwork to distribute workload among health care professionals
Development of transparent policies and objectives	Establish clear policies and legislation to define the purpose, scope, and duration of EHR use, to delineate the responsibilities and obligations of health care professionals, and to reduce confusion and burnout
Personal	
Use of mental health resources and services	Counseling services and mindfulness meditation therapy help health care professionals better manage work stress and reduce their psychological distress
Encourage academic and career development	Plan career paths and training programs and create an environment for career development and learning

[a]EHR: electronic health record.

Discussion

Key Findings

This study explores the relationship between burnout and health care professionals. Our analysis revealed several key findings. First, the prevalence of burnout differs between assessment instruments, with the MBI-HSS indicating higher levels of burnout. However, this difference was not statistically significant. Second, there was a positive association between the average daily duration of EHR use and the risk of burnout. In particular, reducing the administrative burnout emerged as an effective strategy to reduce the risk of burnout [63]. Third, positive perceptions of the EHR and constructive work attitudes were correlated with the reduction in burnout.

The MBI-HSS is valued for its extensive validation and widespread acceptance as an essential tool for assessing burnout. Our findings suggest that the MBI-HSS may report higher rates of burnout due to several factors: sensitivity to burnout constructs—unlike self-report measures, which may rely predominantly on respondents' respondents' subjective feelings, the MBI-HSS comprehensively assesses burnout across multiple dimensions: emotional exhaustion, depersonalization, and personal accomplishment. This multidimensional assessment provides a nuanced perception of burnout, encompassing both its physical and psychological facets. These include the following: standardized cut-off scores—the MBI-HSS delineates specific cut-off scores for its dimensions, establishing clear criteria for identifying significant levels of burnout. This standardization promotes a consistent classification framework for burnout, which may contribute to the higher prevalence rates reported. Comprehensive assessment—the multidimensional approach of the MBI-HSS allows for a comprehensive assessment of burnout, including emotional exhaustion, depersonalization, and personal accomplishment. This thorough assessment is able to uncover more precise and detailed manifestations of burnout, thereby increasing detection rates. Benchmark for comparison—the MBI-HSS is often used as a benchmark for validating alternative burnout measures, and differences in results when compared with other instruments do not necessarily indicate a variance in prevalence. Rather, these differences underscore the accuracy of the MBI-HSS and the comprehensive scope of its assessment. The use of different instruments underlines the heterogeneity observed in our study results.

Solutions

This study demonstrates a robust relationship between workload, time spent using EHR, and burnout. Through a systematic review, we outline several pragmatic recommendations aimed at mitigating these problems.

Reduce Documentation and EHR Workload

A key strategy for alleviating workload concerns is to adopt a rational task allocation and effective teamwork model. Previous research highlights the effectiveness of this approach in reducing workload pressures [33,53]. By integrating medical assistants and scribes into the health care team, it is possible to distribute clerical tasks more evenly, thereby reducing the burden on health care professionals. This redistribution not only reduces workload but also increases overall operational efficiency [53,69,70]. In addition, the provision of targeted training is critical to improving teamwork dynamics, communication skills, and workflow efficiency. Such training efforts aim to cultivate a competent team capable of optimizing and streamlining workflow processes. The ultimate goal is to minimize documentation and EHR-related workloads, thereby making a significant contribution to reducing burnout among health care professionals [58,63].

Optimizing EHR and Training Courses

Continuous refinement of EHR systems through improved design, functionality, and integration of predesigned templates and phrases effectively increases system efficiency. The elimination of redundant steps and interactions further improves the user experience [32,71]. For example, customizing templates to include commonly used medical advice and alerts tailored to the specific needs of different departments significantly increases EHR efficiency [48,72]. Numerous studies have highlighted the critical role of improving user interaction with the EHR system. Developing a user-friendly interface that minimizes unnecessary clicks and reduces redundant and irrelevant data entry has been shown to significantly improve the user experience. Such improvements also significantly reduce the cognitive burden on health care professionals, resulting in a more streamlined and efficient health care delivery process [32,39,42]. In addition, comprehensive training and strong technical support are critical to improving the efficiency and effectiveness of EHR use. Systematic training aimed at promoting EHR proficiency among health care professionals can significantly improve operational efficiency and mitigate the effects of technology stress [46,58]. Research emphasizes the importance of training health care professionals to enhance EHR use and tailoring templates to specific clinical workflows.

Artificial Intelligence–Based Solutions

The integration of artificial intelligence (AI) into EHR systems represents a significant frontier for improvement. Innovations in machine learning, natural language processing (NLP), and large language models (LLMs) are poised to significantly increase the intelligence and automation capabilities of EHR systems [73,74]. Incorporating speech recognition and automated dictation or note-taking into hospital workflows can streamline the creation of medical documents, thereby increasing operational efficiency [75]. NLP is characterized by its ability to efficiently organize both unstructured and semistructured textual records, thereby facilitating a reduction in paperwork [76,77]. Recent research has highlighted the utility of LLMs, such as GPT-4, as powerful tools for medical documentation [78,79]. The use of technologies such as GPT-4 as a linguistic assistant or the use of intelligent templates can significantly speed up the medical documentation process for health care professionals, while improving the accuracy of documentation [79]. In addition, the researchers developed a data-driven method to generate recommendations for refining alert criteria through an explainable AI framework [80]. This advancement directly addresses the issue of overalerting in clinical decision support systems, which has been identified as a potential contributor to

burnout among health care professionals. By reducing unnecessary alerts, this approach promises to reduce the cognitive and operational workload of health care professionals, thereby improving both the quality of patient care and the work-life balance of health care staff. While AI technology could potentially help reduce burnout, it is important to recognize that the causes of burnout are complex and require further research.

Implications for Future Research

There is considerable evidence to support the need for comprehensive redesign of EHR systems to improve efficiency [32,51,53,81]. However, the literature reveals a paucity of published empirical research quantifying EHR limitations, user fatigue and burnout. While some studies have indirectly demonstrated the poor usability of EHR by measuring pupillary reflex and cognitive fatigue [82,83], claims of inefficiency are primarily based on subjective perceptions of users. Thus, there is a need for more studies that objectively assess usability and user experience. Future research should aim to quantitatively assess the usability of EHR systems and their impact on the physical and mental well-being of health care professionals.

Furthermore, the incorporation of AI, specifically LLMs, into EHR systems is an important future research direction to reduce burnout among health care professionals. Such research could include, but is not limited to, (1) reducing the amount of time health care professionals spend on nonclinical tasks by automating administrative tasks, including data entry, scheduling, and patient history taking; (2) using LLMs to efficiently generate and review medical documentation to ensure high quality and consistency of documentation while saving time; (3) improving the interpretability and transparency of clinical decision support to provide clinicians with trustworthy decision support to reduce their cognitive load; and (4) ensuring the ethical use of AI to guarantee that AI systems are used ethically and that algorithms are unbiased. The integration of AI into EHR systems must comply with strict privacy regulations to protect patient privacy [84]. Exploring the potential of AI could make a significant contribution to creating a more supportive and efficient health care ecosystem [73,79,85].

Limitations

This review has several limitations. First, it has a language bias by including only peer-reviewed literature published in English. This limitation may introduce information and selection bias by omitting non-English studies that may provide valuable insights or alternative viewpoints on the topic. Second, the internal heterogeneity of the included studies is remarkably high, with significant differences in methodology, participant demographics, and outcome measures between studies, which may bias the synthesis of findings. In addition, the geographical distribution of the selected studies is dominated by North American research, with only 1 study from Iran. This distribution may introduce regional bias, as health care practices and experiences in these areas may not accurately reflect global patterns.

In addition, the temporal scope of the study, covering the years 2020 to 2022, was significantly influenced by the COVID-19 pandemic. Data collected during this period may be subject to bias or inaccuracy due to the unprecedented impact of the pandemic on global health systems. Additionally, the pandemic introduced new stressors and challenges for health care professionals, which may have influenced the incidence and manifestation of their burnout. These factors should be carefully considered when interpreting the study results, as they may limit the generalizability and significance of the findings beyond the specific context and timeframe of the pandemic.

Conclusions

This review highlights the significant impact of the EHR and the workload of health care professionals on burnout and emphasizes the need for targeted solutions such as workflow optimization, improved training, and the use of medical scribes. It also identifies that the potential of AI to improve EHR efficiency is a promising direction. Despite these findings, there remains a critical need for empirical research to accurately quantify the challenges associated with EHR use and their impact on provider well-being. Future studies are encouraged to explore innovative solutions to foster a more supportive health care environment.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files.

Authors' Contributions

J Liu, J Lin, and SL conceived and designed the study. YW, SL, MW, J Liu, and J Lin developed the methods. YW, SL, CW, J Lin, and J Liu developed the search strategy. Abstract

Background: The integration of artificial intelligence and chatbot technology in health care has attracted significant attention due to its potential to improve patient care and streamline history-taking. As artificial intelligence–driven conversational agents, chatbots offer the opportunity to revolutionize history-taking, necessitating a comprehensive examination of their impact on medical practice.

Objective: This systematic review aims to assess the role, effectiveness, usability, and patient acceptance of chatbots in medical history–taking. It also examines potential challenges and future opportunities for integration into clinical practice.

Methods: A systematic search included PubMed, Embase, MEDLINE (via Ovid), CENTRAL, Scopus, and Open Science and covered studies through July 2024. The inclusion and exclusion criteria for the studies reviewed were based on the PICOS (participants, interventions, comparators, outcomes, and study design) framework. The population included individuals using health care chatbots for medical history–taking. Interventions focused on chatbots designed to facilitate medical history–taking. The outcomes of interest were the feasibility, acceptance, and usability of chatbot-based medical history–taking. Studies not reporting on these outcomes were excluded. All study designs except conference papers were eligible for inclusion. Only English-language studies were considered. There were no specific restrictions on study duration. Key search terms included "chatbot*," "conversational agent*," "virtual assistant," "artificial intelligence chatbot," "medical history," and "history-taking." The quality of observational studies was classified using the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) criteria (eg, sample size, design, data collection, and follow-up). The RoB 2 (Risk of Bias) tool assessed areas and the levels of bias in randomized controlled trials (RCTs).

Results: The review included 15 observational studies and 3 RCTs and synthesized evidence from different medical fields and populations. Chatbots systematically collect information through targeted queries and data retrieval, improving patient engagement and satisfaction. The results show that chatbots have great potential for history-taking and that the efficiency and accessibility of the health care system can be improved by 24/7 automated data collection. Bias assessments revealed that of the 15 observational studies, 5 (33%) studies were of high quality, 5 (33%) studies were of moderate quality, and 5 (33%) studies were of low quality. Of the RCTs, 2 had a low risk of bias, while 1 had a high risk.

Conclusions: This systematic review provides critical insights into the potential benefits and challenges of using chatbots for medical history–taking. The included studies showed that chatbots can increase patient engagement, streamline data collection, and improve health care decision-making. For effective integration into clinical practice, it is crucial to design user-friendly

interfaces, ensure robust data security, and maintain empathetic patient-physician interactions. Future research should focus on refining chatbot algorithms, improving their emotional intelligence, and extending their application to different health care settings to realize their full potential in modern medicine.

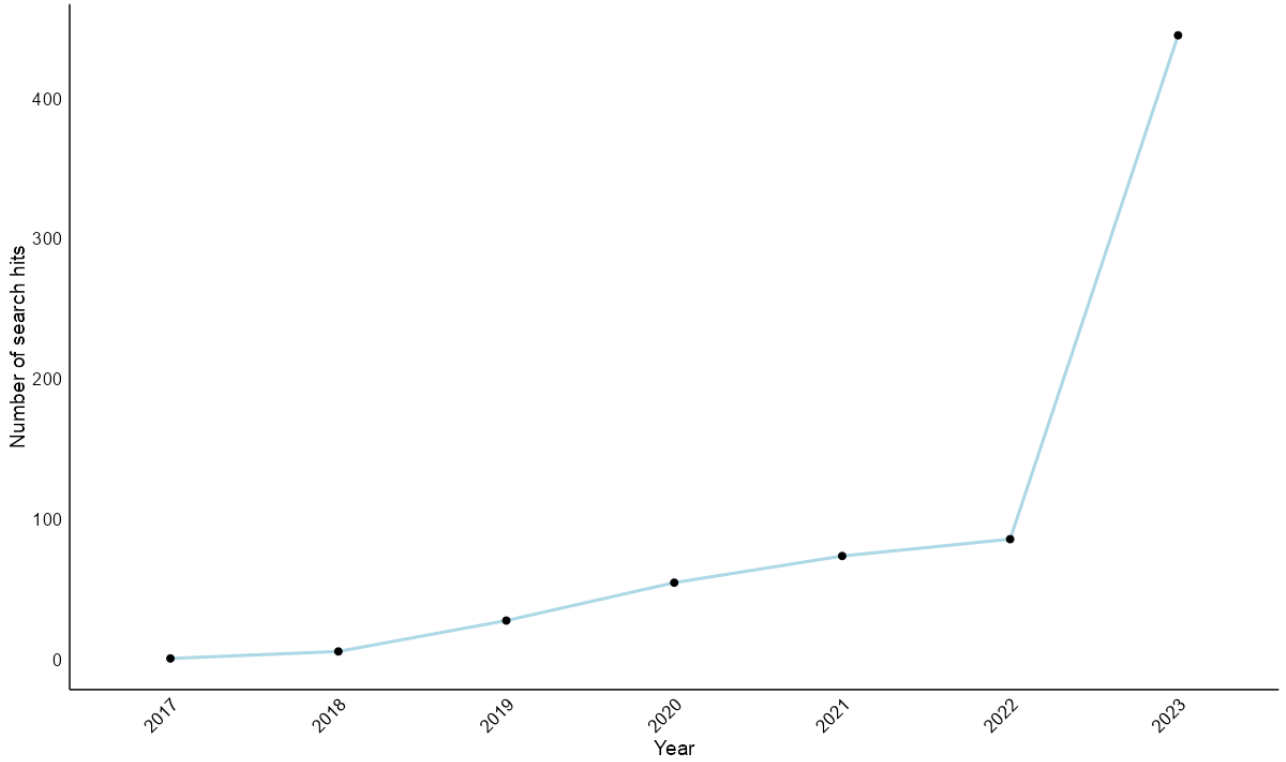
Introduction

Taking a patient's medical history is of central importance in the health care sector. Collecting comprehensive data is essential for accurate diagnosis and customized treatment [1]. Traditionally, clinicians have relied on interviews or questionnaires to gather this important information, but these methods can lack efficiency and accuracy, potentially leading to incomplete records and low patient engagement [2]. New technologies have brought about innovative solutions to streamline documentation, such as chatbots, with their ability to digitally transform data collection [3]. Chatbots can use artificial intelligence (AI) and natural language processing (NLP) to simulate conversations and minimize the limitations of paper-based processes [4-6]. The integration of chatbots promises significant improvements in care by enabling accurate, streamlined documentation that supports personalized, evidence-based clinical decision-making and greater patient engagement [7,8]. While chatbots are widely used in other areas, such as entertainment, customer service [9], security systems, and emergency communications [10-12], there is a lack of thorough research evaluating their effectiveness, usability, and acceptability of chatbots specifically for health care data collection. Research has focused on a narrow area without contextualizing the broader implications. To date, few people have had access to sophisticated AI due to its cost and complexity. However, new publicly available models, such as ChatGPT, are making these capabilities accessible to a wide audience by analyzing large amounts of literature and data in seconds to make time-critical decisions in a more data-driven and accurate way [13-17]. For interactions in the health care sector, specific and individual patient profiles can be addressed in order to improve documentation and the associated health outcomes. In addition, continued adoption will ensure that counseling by health care professionals remains widely accessible, especially in underserved communities [18]. In addition, their ability to work continuously and remotely can improve health care by ensuring that expert-level advice is always available, improving access to quality care, especially in underserved areas [18,19]. However, these benefits must be balanced by robust measures to ensure that the use of AI in health care improves, rather than undermines, patient care and trust [20].

Despite the promise of chatbots, important considerations are taken into account, particularly in health care. Cybersecurity is paramount, as chatbots handle sensitive medical information that must be protected from unauthorized access or data breaches [21,22]. Furthermore, despite the remarkable capabilities of chatbots in effectively processing and generating responses through predefined algorithms, they often lack the empathetic understanding and emotional intelligence inherent in human interactions [23]. This limitation can affect relationship-building and patient trust, especially during sensitive medical conversations [20].

Recent data highlighted the growing interest in the interplay between chatbots and medicine. An analysis of studies from the first study in 2017 to 2024 with the search query "chatbot*" AND "medicine" shows a significant increase, especially in 2022, with the trend rising from a single study in 2017 to 445 in 2023 (Figure 1).

Figure 1. Number of studies over recent years: "chatbot*" AND "medicine." This chart shows the increasing trend in publications on chatbots in medicine from 2017 to 2023. In 2022, there was an exponential increase in published studies, indicating a growing research interest and progress in chatbots in medicine.



Chatbots rely on advanced algorithms and AI-supported NLP for their technical function. These techniques enable chatbots to examine user input, provide applicable data in the form of feedback, and modify their interactions depending on context and user behavior, which can be refined through machine learning approaches, including information-driven learning and pattern recognition [24-26].

Considering the potential benefits and problems associated with chatbots, a thorough investigation is essential to assess their impact on the process of medical history–taking. While existing studies have examined the practicality and acceptability of chatbots in specific medical areas, such as psychological well-being or genetic counseling, a systematic literature review is needed for a complete understanding of chatbot-based history-taking [27-29].

The primary objective of this systematic review is to provide a comprehensive assessment of the role, effectiveness, usability, and patient acceptance of chatbots in medical history–taking. This systematic review also aims to explore the impact and future directions of integrating chatbots into clinical settings by assessing data accuracy, level of patient interaction, health care provider efficiency, and patient outcomes. Chatbots could transform the process of taking medical histories by supporting the accurate capture of patient information. In addition, this has the potential to increase productivity and improve the quality and delivery of health care services.

Methods

Overview

The systematic analysis was conducted in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for reporting systematic reviews to ensure transparency [30]. The protocol was registered under registration number CRD42023410312 in the PROSPERO database of the National Institute for Health Research [31].

Eligibility Criteria

Eligibility criteria for the studies were based on the PICOS (participants, interventions, comparators, outcomes, study design) framework for assessing participant demographics, types of interventions assessed, study designs, and outcome of interest [32]. We aimed to identify research investigating chatbots to facilitate medical history–taking to support physicians in diagnosis and treatment planning. The scope was limited to chatbots that facilitate patient disclosure of personal health information to improve accuracy and support clinical decision-making. In contrast, chatbots designed exclusively as "symptom-checkers," such as stand-alone apps providing rapid assessments and potential diagnoses, were excluded. This exclusion was made to focus on tools that facilitate comprehensive medical history–taking rather than immediate symptom-based advice. There were no limitations on the modality of chatbot input and output. The comparators were not subjected to any specific restrictions. The outcomes of interest included the feasibility, acceptability, and efficacy of chatbot-based history-taking interventions. There were no restrictions on study design, except for conference papers, which

were excluded to ensure the inclusion of studies with rigorous peer review and substantial data reporting. The review was limited to English-language studies because resources were limited.

Information Sources

PubMed, CENTRAL, Embase, MEDLINE (through Ovid), Scopus, and Open Science were searched to identify relevant studies. In addition, reference lists of relevant studies were screened manually.

Search Strategy

For each database, we developed a search strategy that included keywords, subject headings, mesh terms (in PubMed), filters, and restrictions to find relevant studies. The search terms focused on chatbots, anamnesis, history-taking, and related concepts: ("chatbot*" OR "conversational agent*" OR "chatterbot*" OR "virtual assistant" OR "intelligent virtual agent" OR "artificial intelligence chatbot" OR "AI chatbot" OR "conversational AI" OR "dialogue system") AND ("anamnesis" OR "medical history" OR "history-taking" OR "medical interview" OR "patient interview" OR "medical questionnaire" OR "patient questionnaire"). The last search was done in July 2024 (Multimedia Appendix 1). Additionally, a reference list search was conducted.

Selection Process

The selection process was done by 2 authors (MH and SS) independently screening the titles and abstracts of the identified studies based on the predetermined eligibility criteria. Potentially relevant studies were retrieved in full text and further assessed for eligibility. The full-text assessment was also performed independently (MH and SS). Any disagreements between the 2 authors were resolved through discussion, focusing on the eligibility criteria and study relevance. If consensus could not be reached, the involvement of a third author (AZ) was sought when necessary.

Data Collection Process

Data from the selected studies were extracted independently (MH and SS) using a data extraction form based on the PICO criteria (STROBE [Strengthening the Reporting of Observational Studies in Epidemiology]) [32,33]. The extracted data included information such as the first author, number of authors, country, year, title of the scientific journal, topics and type of journal, impact factor, and main results focused on history-taking (anamnesis). Additional data collected encompassed study design, setting, sample size, type of participants, female percentage, mean age (range), and results. Outcomes extracted focused on key aspects such as feasibility, acceptability, and efficacy. When full-text access was unavailable, the corresponding author was contacted by email. Data were visualized using the R-package for creating alluvial diagrams [34]. Any discrepancies in data extraction were resolved through a discussion between the 2 authors (MH and SS).

Quality Assessment

The methodological quality of the included observational studies was assessed using the STROBE criteria [33]. Each study was evaluated based on the fulfillment of the STROBE criteria. The studies were categorized into 3 categories: category A, if more than 80% of the STROBE criteria were fulfilled; category B, if 50%-80% were met; and category C if less than 50% of the criteria were fulfilled [35]. For example, category A studies provided comprehensive details on study objectives, participant selection, and statistical analysis. Category B had adequate but incomplete information. Category C studies frequently lacked critical details such as clear definitions of eligibility criteria or thorough data collection methods.

In addition, the RCTs included in this review were evaluated for risk of bias using the Risk of Bias tool and the robvis R-package [36,37]. The RoB 2 tool assesses various domains of bias, including randomization, allocation concealment, blinding, incomplete outcome data, selective reporting, and other potential sources of bias. The overall risk of bias score was determined for each study based on the number of criteria for high risk of bias met. Studies are considered to have a low risk of bias if no domains are rated as high risk and most domains are rated as low risk. Studies with some concerns in one or more domains but no high-risk ratings are considered to have some concerns. If any domain is rated as high risk, the study is considered to have a high risk of bias.

Software and Tools

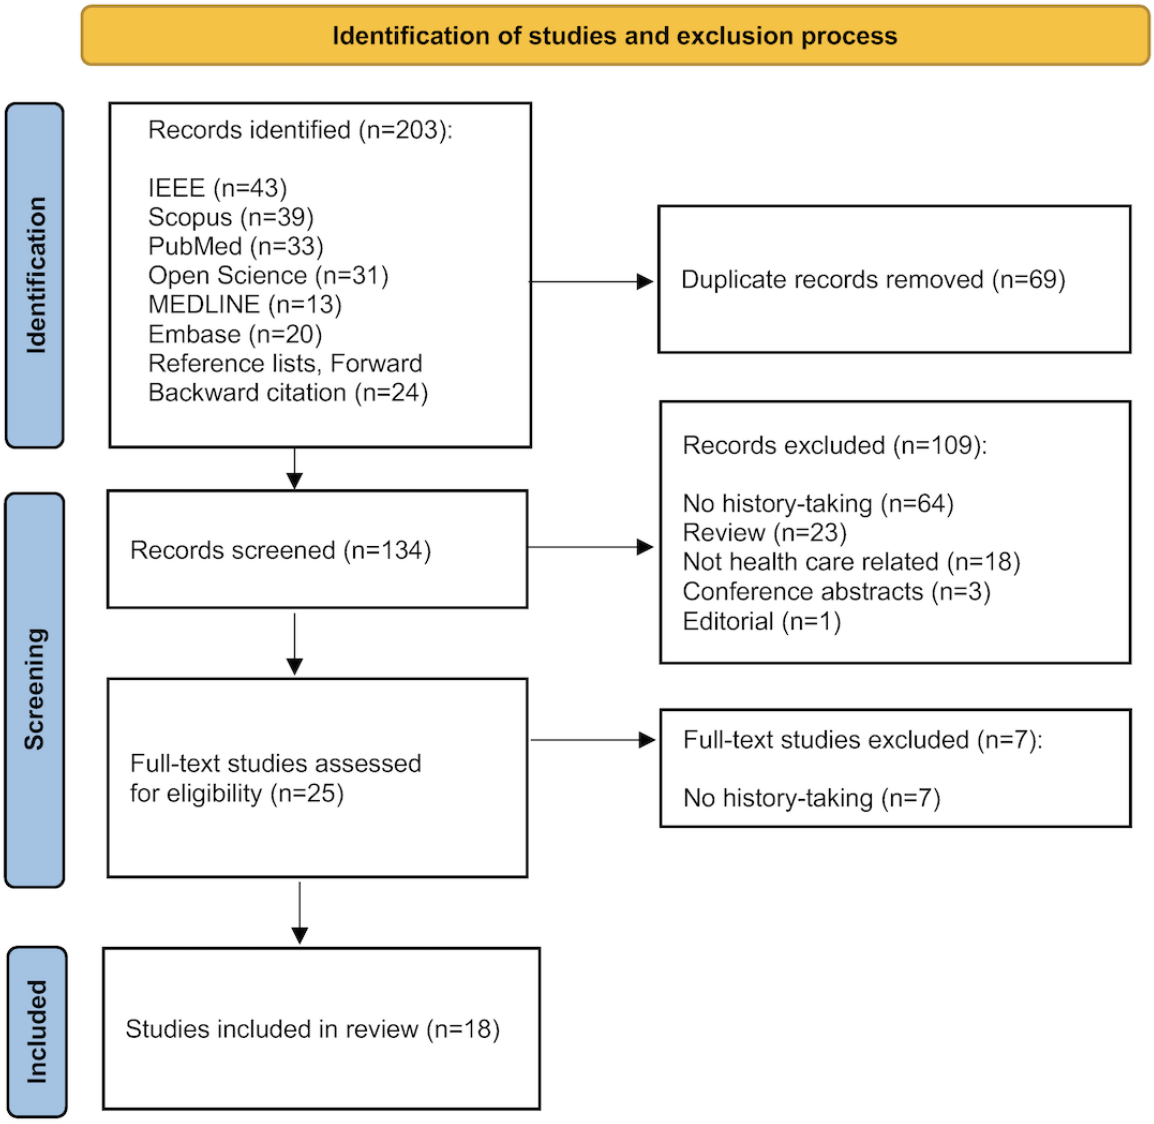
Data were managed and analyzed using R (version 4.2.1; The R Foundation). The ggplot2 package [38] was used for data visualization and the robvis R-package was used for risk of bias charts [37]. The alluvial R package [34] was used to create alluvial diagrams.

Results

Study Selection

The initial literature search yielded 203 records. After removing 69 duplicate studies, a total of 134 unique records were screened based on titles and abstracts. Of these, 109 studies did not meet the eligibility criteria and were excluded. Subsequently, 25 full-text studies were screened, resulting in 18 studies being included in the review (Figure 2).

Figure 2. Flowchart of the study search and inclusion. This flowchart details the systematic process of selecting studies for the review, starting from 203 records and narrowing down to 18 studies after removing duplicates and applying eligibility criteria. IEEE: Institute of Electrical and Electronic Engineers.



Study Characteristics

The studies investigated the use of chatbots for history-taking across diverse patient populations and sample sizes (range: n=5-61,070) and were mostly published in scientific health technology journals with varying impact factors (mean 4.52, SD 4.49; range: 0.14-14.71; Table 1). The studies used different research designs, including 9 cross-sectional studies, 3 case-control studies, 2 observational studies, and 3 RCTs (Multimedia Appendix 1 and Tables 1-3).

Table 1. General characteristics of the included studies. This table summarizes the number of authors, countries, and journal topics of the studies, showing most research from Germany and the United States, and a focus on Health Informatics and Technology.

	Count, n (%)
Numbers of authors	
1-3	4 (22)
4-6	8 (44)
>6	6 (33)

Surgical Procedures and Techniques	1 (6)
Mental Health and Psychology	1 (6)

Table 2. Study characteristics. This table details study characteristics, including author, year, design, sample size, participant type, and key findings, highlighting diverse participant demographics and study outcomes.

Reference		Participants				Methods and result	
Authors (year)	Study design	n	Type of participants	Female (%)	Mean age (years)	Type of measurement	Relevant results
Denecke et al (2018) [39]	Cross-sectional study	22	Music therapy patients	41	39 (range 19-73)	Usability test of the tool and corresponding questionnaire	CUI[a]-based self-anamnesis app well-received, potential for collecting anamnesis data.
Denecke et al (2022) [40]	Cross-sectional study	5	Radiology patients	40	39.2 (range 17-73)	System usability scale	Digital medical interview assistant with good usability.
Faqar-Uz-Zaman et al (2022) [41]	RCT[b]	450	Patients with abdominal pain in ER[c]	52.2	44 (range 18-97)	Accuracy of diagnosis by ER doctor and Ada app according to the final diagnosis	Classic patient-physician interaction superior to AI[d]-based tool, but AI benefits diagnostic efficacy.
Frick et al (2021) [42]	Cross-sectional study	148	German participants	53	33.32 (SD 12.59)	Scales for disclosure and concealment of medical information	Patients prefer disclosing to physicians over chatbots. No significant difference in concealment.
Gashi et al (2021) [43]	Cross-sectional study	N/A[e]	N/A	N/A	N/A	N/A	AnCha chatbot improves patient-doctor communication, enhances diagnostic process.
Ghosh et al (2018) [44]	Case-control study	30 scenarios	Not specified	N/A	N/A	True positives and false positives, precision	Medical chatbot helps with automated patient preassessment.
Heald et al (2021) [27]	Feasibility study	506	Various types of care	58	56.6 (SD 12.5)	Colon cancer risk assessment tool	Chatbot feasible for increasing genetic screening in at-risk individuals.
Hennemann et al (2022) [45]	Observational study	49	Adult patients from an outpatient psychotherapy clinic	61	33.41 (SD 12.79)	Interviews, questionnaires, diagnostic software	Chatbot shows moderate to good accuracy for condition suggestions.
Hong et al (2022) [46]	Cross-sectional study	20	Primary care patients	60	50	Web-based survey	Patients believe chatbot helps clinicians better understand their health.
Ireland et al (2021) [28]	Cross-sectional study	83	Adults who had whole exome sequencing for genetic condition diagnosis	53	range 23.2-80.4	Transcript analysis	Chatbot enhances genetic counseling by providing genomic information.
Jungmann et al (2019) [47]	Case-control study	6	Psychotherapists, psychology students, and laypersons	50	40 (therapists) 22 (students)	Case vignettes, health app comparison	Chatbot shows moderate diagnostic agreement, improvement needed for childhood disorders.
Nazareth et al (2021) [48]	Retrospective, observational study	61,070	Women's health	96	N/A	Genetic testing results	Chatbot helps identify patients at high risk for hereditary cancer syndromes.
Ni et al (2017) [49]	Cross-sectional study or proof-of-concept	11	Patients with chest pain, respiratory infections, headaches, and dizziness	N/A	N/A	Question accuracy, prediction accuracy	Chatbot generates medical reports with varying accuracy based on disease category.

Reference		Participants				Methods and result	
Authors (year)	Study design	n	Type of participants	Female (%)	Mean age (years)	Type of measurement	Relevant results
Ponathil et al (2020) [50]	Cross-sectional study	50	Adults	50	N/A	NASA Task Load Index workload instrument IBM Usability Questionnaire Technology Acceptance Model Questionnaire	Chatbot interface saves time, preferred for collecting family health history.
Reis et al (2020) [51]	Case-control study	16	Physicians	35	35.51	N/A	Failure of cognitive agent highlights need for managing resistance and transparency.
Schneider et al (2023) [52]	RCT	30	Hymenoptera venom allergic patients	N/A	38.93 (SD 12.56)	Standardized questionnaire	Chatbot-supported anamnesis saves time, potential for allergology assessments.
Wang et al (2015) [29]	RCT, hospital	70	Majority of patients from underserved populations (low-income families, elders, people with disabilities, and immigrants)	60	Majority in age group 45-54	Interview, questions	Technological support for documenting family history risks is accepted and feasible.
Welch et al (2020) [53]	Cross-sectional study	3204	General population	100	49.4 (SD 7.1)	Standardized questionnaire	Chatbot engages users, potential for gathering family health history at population level.

[d]AI: artificial intelligence.

[e]Not applicable.

Table 3. Chatbot characteristics. This table outlines the chatbots used in the studies, including their name, goal, modality, techniques, outcomes, user preferences, and challenges, showcasing varied applications and technological approaches in health care. Table format based on Schachner et al [54].

Authors (year)	Name	Goal	Modality	Techniques	Main outcomes	User preference	Challenges
Denecke et al (2018) [39]	Ana	Collect medical history for music therapy	Mobile app: Text input	AIML[a], rule-based	Comprehensive data collection, usability	Engaging, intuitive	Integration, diverse interactions, data completeness
Denecke et al (2022) [40]	Not specified	Improve radiological diagnostics	Telegram CUI[b]	RiveScript (rule-based)	Enhanced knowledgeability, diagnostic quality	User-friendly	Clinical workflow integration, data security
Faqar-Uz-Zaman et al (2022) [41]	Ada	Evaluate diagnostic accuracy in ER[c]	iPad app	AI[d] questionnaire, ML[e]	Increased diagnostic accuracy	Not specified	Physician integration, diagnostic variability
Frick et al (2021) [42]	Not specified	Elicit truthful medical disclosure	Digital survey	Common CA[f] technologies	Disclosure versus concealment	Prefer physicians	Information accuracy, privacy
Gashi et al (2021) [43]	AnCha	Collect previsit medical history	IBM Watson, web-based	Rule-based tree	Efficient data collection	Reduces previsit anxiety	Clinical integration, data security
Ghosh et al (2018) [44]	Quro	User symptom check, personalized assessments	Web interface	NLP[g], ML	Precision in condition prediction	High engagement	Data complexity, accurate predictions
Heald et al (2021) [27]	Not specified	Screen for heritable cancer syndromes	Web-based, text-based	AI conversation, NLP	Efficient risk assessment, facilitated testing	High engagement, completion rates	Workflow integration, genetic risk understanding
Hennemann et al (2022) [45]	Ada	Diagnose mental disorders	App-based symptom checker	AI analysis, NLP	Moderate diagnostic accuracy	Mixed preferences	Diagnostic performance, user input dependency
Hong et al (2022) [46]	Genie	Collect detailed medical histories	Web-based, AI speech-to-text	AI, NLP	Improved history collection	Helpful for PCPs[h]	Ease of use, AI use concerns
Ireland et al (2021) [28]	Edna	Support genomic findings decision-making	Mobile, tablet, PC	NLP, Sentiment Analysis	Enhanced patient agency, informed decisions	Ease of access, supports consent	Empathy, complex interactions, data privacy
Jungmann et al (2019) [47]	Ada	Diagnose mental disorders	Mobile app	AI symptom analysis	Moderate diagnostic agreement	Not specified	Accuracy for complex cases
Nazareth et al (2021) [48]	Gia	Hereditary cancer risk triage	Web-based, mobile	NLP	Automated risk triage, educational interactions	High engagement	Workflow integration, privacy, diverse needs
Ni et al (2017) [49]	Mandy	Automate patient intake	Mobile app	NLP, data-driven analysis	Reduced staff workload, privacy maintenance	Improves physician efficiency	Full clinical integration, privacy, diverse interactions
Ponathil et al (2020) [50]	VCA	Collect family health history	Web-based chat	Not specified	Higher satisfaction, lower workload	Preferred by most users	Multiple clicks, extensive interaction
Reis et al (2020) [51]	Cognitive Agent	Automate anamnesis-diagnosis-treatment	Voice-based AI chatbot	ML, NLP, speech recognition	Reduced documentation time	Reduces nonbillable activities	Physician resistance, legal concerns, oversimplification
Schneider et al (2023) [52]	Not specified	Standardize allergy history-taking	HTML-based, digital	HTML, Java scripting	Time-efficient, accurate history-taking	High satisfaction	Question clarity, specificity
Wang et al (2015) [29]	VICKY	Collect family health histories	Touchscreen tablet	Speech recognition, decision trees	High satisfaction, effective identification	Easy to use, recommended	Data entry issues, complex questions
Welch et al (2020) [53]	It Runs In My Family	Assess hereditary cancer risk	Web-based chatbot	NLP	High engagement, thorough assessments	Prefer chatbot to web forms	Data accuracy, interface design, demographic reach

[a]AIML: artificial intelligence markup language.

The alluvial diagram (Figure 3 [27,29,39-53]) shows an overview of the literature over time, indicating the year, the country of origin, and the medical area of focus for each study. The included studies were published from 2015 to 2023. Most of the studies were published in 2020 and 2022. The included studies (Figures 3 [27,29,39-53] and 4) were conducted in Switzerland [39,40,43], Germany [41,42,45,47,51,52], the United States [27,29,46,48,50,53], Australia [28,44], and New Zealand [49]. The studies cover a diverse range of medical areas: general medicine [42-44,49,51] genetics [28,29,48,50] cancer research [27,53], family medicine [46], mental health [45,47], radiology [40], surgery [41], allergy [52], and music therapy [39].

Figure 3. Alluvial diagram of the publication date, country, and area of studies. The alluvial diagram illustrates the distribution of studies by year, country, and medical area from 2015 to 2023, highlighting increased publications in 2020 and 2022, with contributions from Germany, the United States, and Switzerland across various medical fields.

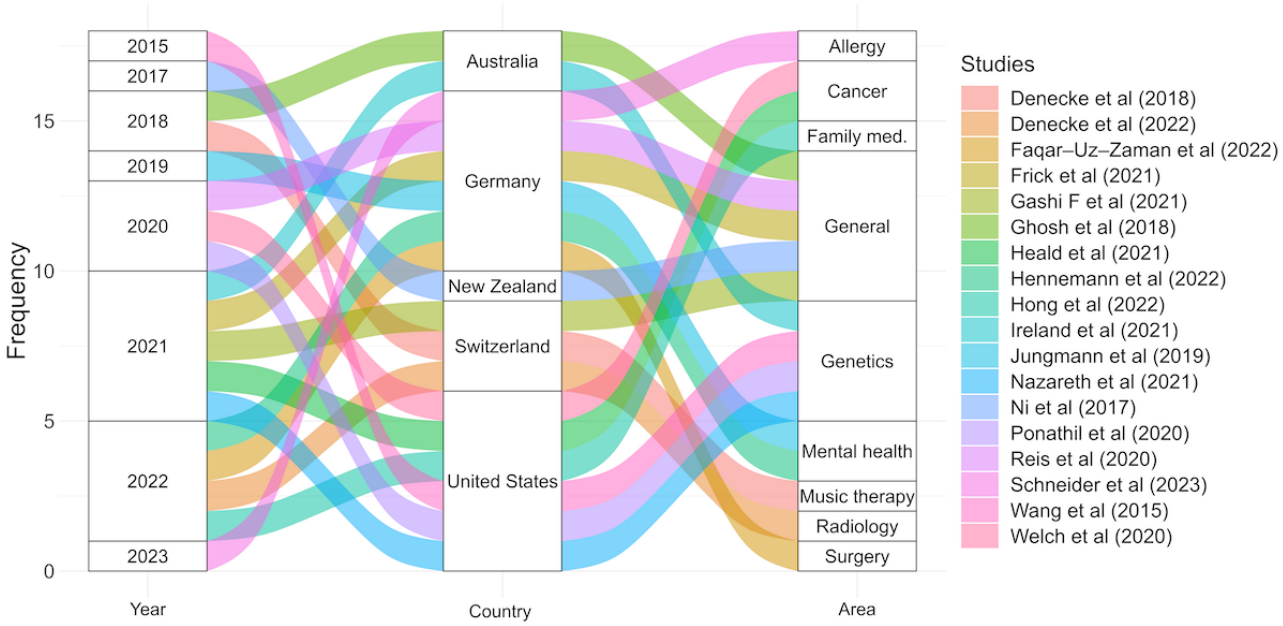

Figure 4. World map showing the number of studies published in each country. This map shows the geographical distribution of the studies, with most research originating from Germany and the United States. Created with MapChart [55].

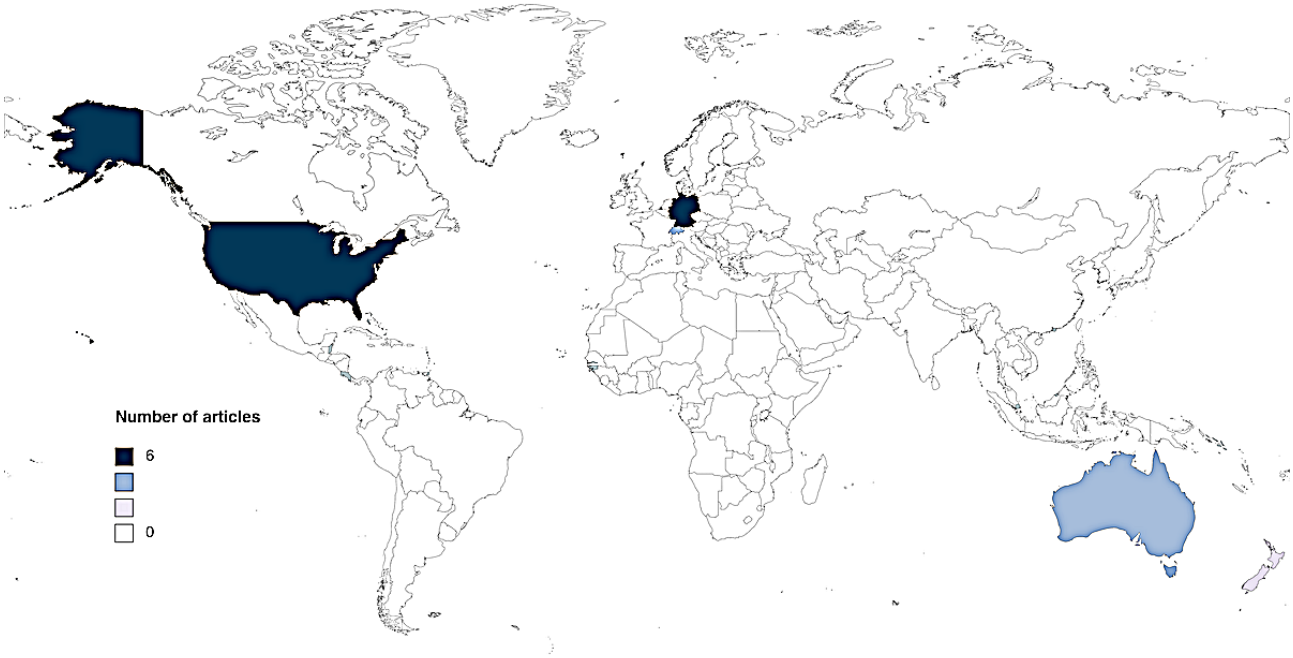
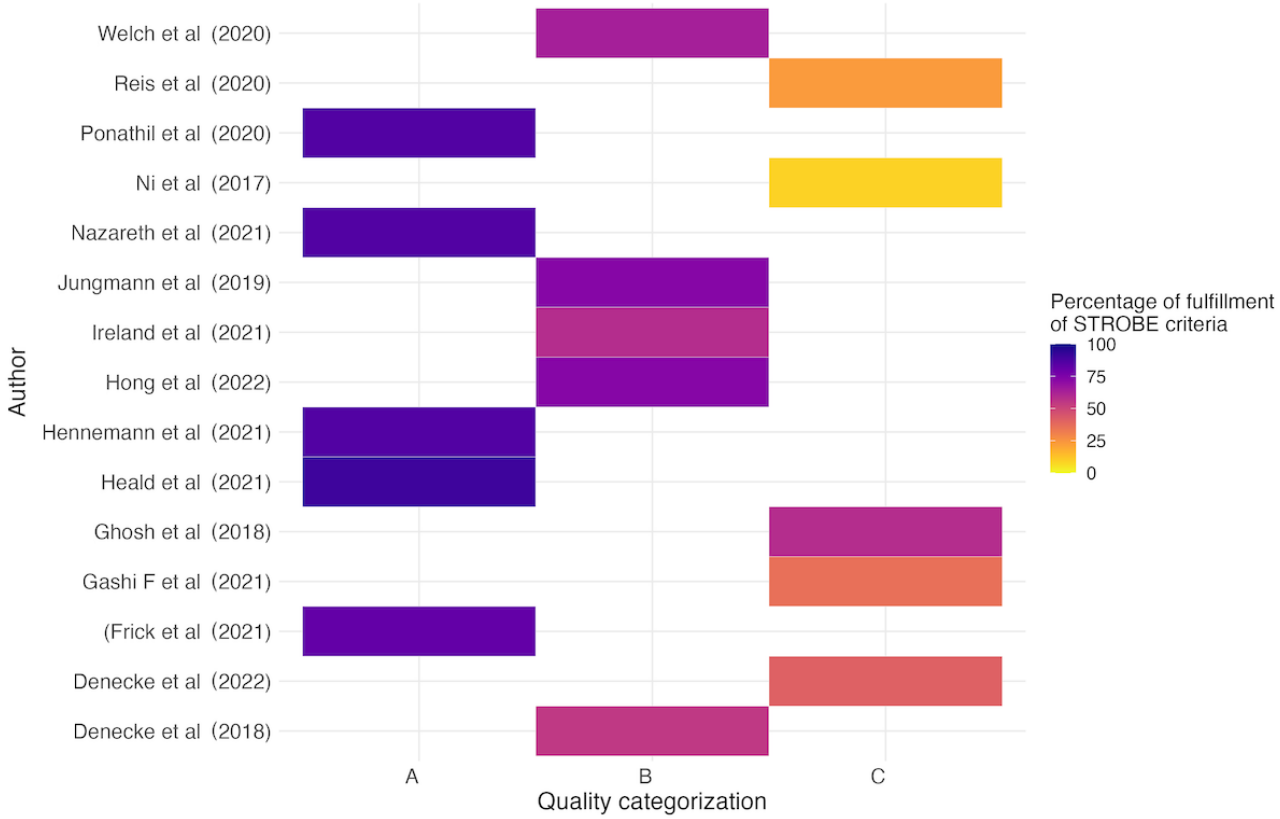


Quality Appraisal of the Included Studies

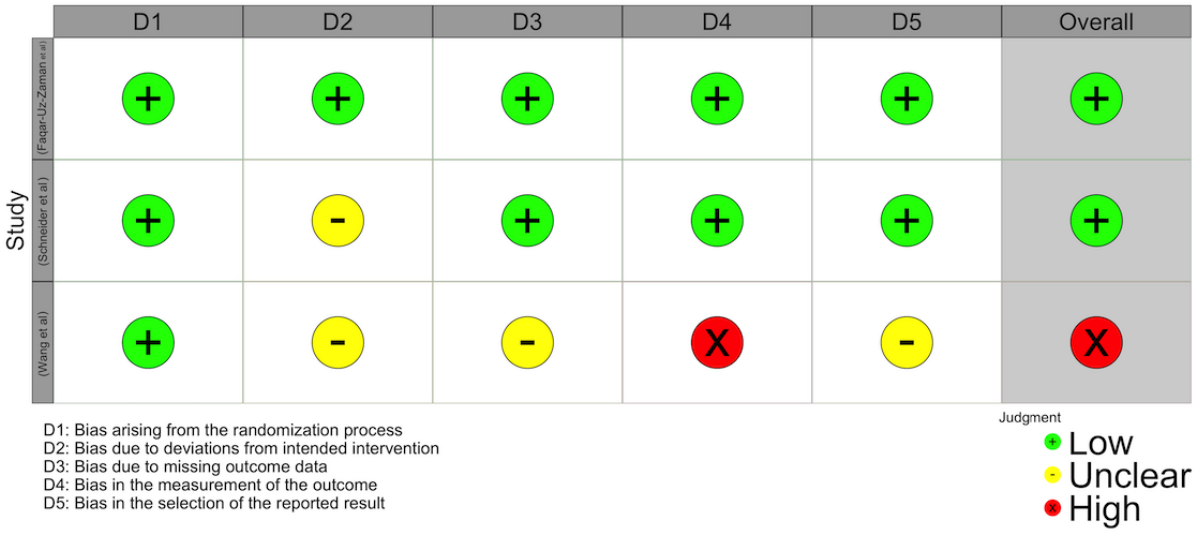
Among the 16 observational studies, 6 (38%) studies were classified as category A [27,42,45,48,50], indicating high methodological quality with more than 80% of the STROBE criteria fulfilled (Multimedia Appendix 1). A total of 5 (31%) studies were classified as category B [28,39,46,47,53], meeting 50%-80% of the STROBE criteria, and 5 (31%) studies were classified as category C [40,43,44,49,51], meeting less than 50% of the STROBE criteria (Figure 5 [27,28,39,40,42-51,53]). The lack of adherence to STROBE criteria in observational studies can have a significant impact on the quality. Missing elements, such as clear definitions of eligibility criteria or participants or detailed methods, lead to biases that reduce validity and reliability. For example, the study of Denecke et al [40] showed a high risk of selection bias due to a small, nonrepresentative sample and lack of eligibility criteria, limiting the generalizability of their findings. Gashi et al [43] faced biases from the absence of a control group and unclear eligibility criteria. This could impact the validity of the effectiveness results. Ghosh et al [44] showed high bias from simulated scenarios without real patient interactions. This could lead to overestimated accuracy and applicability in real-world settings.

Figure 5. Fulfillment of STROBE criteria and categorization. This bar chart categorizes observational studies by their adherence to STROBE criteria, showing 37.5% of high-quality (category A), and an even split between moderate (category B) and lower quality (category C). STROBE: Strengthening the Reporting of Observational Studies in Epidemiology.



The studies by Schneider et al [52] and Faqar-Uz-Zaman et al [41] showed a low risk of bias according to the RoB tool, with detailed methodology and statistical analysis. In contrast, the study by Wang et al [29] showed a risk of bias due to the absence of intention-to-treat analysis and participants being aware of the intervention (Multimedia Appendix 1 and Figure 6), which could skew results by excluding noncompleters and altering participant behavior.

Figure 6. Risk of bias domains (RoB-tool) for randomized controlled trials.



Summary of Statistical Analyses

The studies included in this systematic review used a variety of statistical methods. Descriptive statistics summarized demographics and usability ratings. Comparative analyses used 2-tailed *t* tests and chi-square tests to compare diagnostic accuracy and user engagement. κ statistics measured agreement between chatbot and expert diagnoses. Precision and accuracy metrics were assessed using precision, recall, and F_1-scores. Nonparametric tests, such as the Mann-Whitney *U* test showed significant reductions in anamnesis duration. CIs and *P* values were reported where relevant to clarify the strength of the evidence.

Usability and User Experience of Chatbots

Five studies focused on the usability and user experience of chatbots in history-taking (Tables 2 and 3). Denecke et al [39,40] found that chatbots were well-received by participants and showed potential for history-taking. Usability scores were high, between 90 and 100 (average 96). Ponathil et al [50] found that using a voice-controlled assistant interface for taking family health history significantly reduced history-taking duration. Ghosh et al [44] implemented a medical chatbot that assists with automated patient preassessment through symptom analysis, demonstrating the possibility of avoiding form-based data entry. The chatbot correctly identified at least one of the top three conditions in 83% (n=25) of cases and two out of three conditions in 67% (n=20) of cases. Welch et al [53] found high engagement and interest in chatbots, suggesting the potential for gathering family health history information at the population level in the United States. Of the over 14,000 who participated in the assessment of the study, 54.4% (n=7616) of users went beyond the consent step, and 22.7% (n=3178) of users completed the full assessment.

Chatbots and Patient-Doctor Communication

One study highlighted the potential of chatbots to improve patient-doctor communication. Gashi et al [43] reported that using a chatbot could reduce patient nervousness, allow patients to respond more thoughtfully, and give physicians a more comprehensive picture of the patient's condition.

Diagnostic Accuracy and Efficacy of Chatbots

Nazareth et al [48] found that a chatbot can help identify high-risk patients for hereditary cancer syndromes. A total of 27.2% (n=14,850) of the chatbot users met the criteria for genetic testing, and 5.6% (n=73) of the chatbot users had a pathogenic variant. Ni et al [49] reported that Mandy, a chatbot, automates history-taking, understands symptoms expressed in natural language, and generates comprehensive reports for further medical investigations, with varying degrees of accuracy depending on the disease category. Hennemann et al [45] reported that the app-based symptom checker with an AI chatbot showed agreement with therapist diagnoses in 51% (n=25) of cases for the first condition suggestion and in 69% (n=34) of cases for the top five condition suggestions. Jungmann et al [47] tested a health app's diagnostic agreement with case vignettes for mental disorders, pointing to the need for improvement in diagnostic accuracy, especially for mental disorders in childhood and adolescence.

Patient Perceptions and Acceptance of Chatbots

Hong et al [46] reported that most primary care patients believed that chatbots could help clinicians better understand their health and identify health risks. Ireland et al [28] found that the development of the Edna tool, an AI-based chatbot that interacts with patients via speech-to-text, signifies progress toward creating digital health processes that are accessible, acceptable, and well-supported, enabling patients to make informed decisions about additional findings. Heald et al [27] highlighted the feasibility of using chatbots for increasing genetic screening and testing in individuals at risk of hereditary colorectal cancer syndromes.

Challenges and Limitations of Chatbots

Reis et al [51] noted the importance of managing user resistance and fostering realistic expectations when implementing AI-based history-taking tools. Frick et al [42] found that patients preferred to disclose medical information to a physician rather than a conversational agent.

Effectiveness on Chatbots

Faqar-Uz-Zaman et al [41] found that classic patient-physician interaction was superior to an AI-based diagnostic tool applied by patients. However, they also noted that AI tools can benefit clinicians' diagnostic efficacy and improve the quality of care. Schneider et al [52] found that a chatbot-supported anamnesis could save significant time by 57.3%, in assessing Hymenoptera venom allergies with high completeness (73.3%) and patient satisfaction (75%). Wang et al [29] demonstrated that technological support for documenting family history risks can be highly accepted, feasible, and effective.

Discussion

Principal Results

This systematic review highlights that the use of chatbots can improve medical history–taking. Results of the included studies have shown that chatbots can facilitate data collection while increasing patient engagement and satisfaction [39,49]. Chatbots show value, especially in collecting structured data such as family history [29,50,53]. As highlighted, the collection of family history benefits significantly from chatbot automation due to the simple nature of their queries, which typically require binary responses. This area contrasts with the challenges of collecting data on undiagnosed symptoms, where patient responses are inherently more nuanced and variable. The inherent abilities of chatbots to handle yes or no questions efficiently and without misinterpretation make them particularly valuable in this context, minimizing human error and optimizing the data collection process. Several studies have highlighted that chatbots provide a more engaging patient interaction, often perceived as less intimidating than traditional face-to-face conversations [27,46]. This interaction is crucial as it motivates patients to disclose more comprehensive health information, which can lead to better health outcomes. While chatbots excel at retrieving and conveying information through interactions that require limited context, their capabilities remain limited when it comes to more nuanced understanding and complex emotions. Research has shown that specific sensitive topics are best-discussed face-to-face with a human, where building trust is paramount [42]. Chatbots, on the other hand, offer relief through constant availability and allow patients to share details from any location and at any time, which can expand access—especially for urgent needs that require quick access to medical history [41,53]. This expanded access aims to improve care, especially in cases where timely data can make the difference between outcomes. In addition, chatbots support overburdened care providers by systematically presenting summarized patient data, potentially enabling faster and more accurate decisions [43,52]. Such support is invaluable in high-pressure situations requiring rapid action based on comprehensive information. These findings are consistent with

previous research that emphasizes the ability of chatbots to capture patient reports in a structured, comprehensive way [3,22]. Their conversational design facilitates higher engagement and satisfaction through interactive discussions [4,50]. This contributes to improved documentation of patient histories. Furthermore, automated information capture has been confirmed to increase both the efficiency and accessibility of health care by simplifying reporting processes [21,39].

While chatbots already promise success in supporting diagnostic processes, the required level of accuracy must be achieved for complex medical scenarios that require in-depth understanding and sound clinical judgment. The limitations of current systems are highlighted in the studies by Hennemann et al [45] and Jungmann et al [47], highlighting the need to improve the algorithms and decision-making processes to manage complex health conditions.

While the seamless integration of conversational agents into clinical workflows requires robust data infrastructures and user-friendly interfaces, such integration can drive adoption among care providers and patients if done in a secure manner [48]. Customized chatbots are required to serve different patient audiences and different facilities. Addressing these needs can increase patient engagement and satisfaction [48,50].

However, the development of such technologies requires careful consideration [56]. Rushing to release chatbots without thorough refinement and validation can lead to inaccuracies and potentially detrimental outcomes. These hastily deployed chatbots run the risk of failing to understand complex medical situations and recommending incorrect diagnoses or treatments. The use of chatbots requires caution and rigorous testing or validation to minimize the risks [57-59].

Limitations

Although this systematic review provided useful insights, certain limitations must be acknowledged. As we only considered papers published in English, we may have overlooked important work published in other languages. In the future, a more comprehensive review that includes multilingual research could promote a more complete understanding of chatbots worldwide. The variability of study designs, patient groups, and health care contexts makes it difficult to draw definitive conclusions. Different studies, such as those by Denecke et al [39] and Faqar-Uz-Zaman et al [41], focused on different settings and patient groups, which influenced the results. Cross-sectional studies provide snapshots of usability, while RCTs provide robust evidence. Heterogeneity in demographics and health status also affects generalizability, as seen in the studies by Welch et al [53] and Wang et al [29]. Bias assessment frequently showed unmet STROBE criteria. Clear eligibility criteria and detailed methods could influence reliability. For example, Gashi et al [43] lacked defined selection criteria, and Jungmann et al [47] had a selection bias. Inconsistent reporting and lack of blinding in some RCTs, such as Wang et al [29], impaired internal validity.

The methodological quality of the included studies varied. At the same time, most observational studies demonstrated satisfactory quality, and a significant proportion fulfilled only some of the STROBE criteria. Additionally, the risk of bias assessment of the RCTs revealed a high risk of bias in one of the studies [41]. It is important to consider these limitations when interpreting the data and trying to understand how they relate to clinical practice. In addition, only published research has been included in this systematic review, which may lead to publication bias as studies with positive results are more likely to be published [41].

Future Directions

Based on the findings and limitations of this systematic review, future research should focus on conducting more standardized and well-designed studies in this field. Emphasizing rigorous study designs, such as RCTs, with larger sample sizes and standardized outcome measures will enhance the scientific validity of the research and provide more substantial evidence of the effectiveness of chatbots in history-taking. Standardized outcome measures between studies are crucial for better comparability. Future studies should use measures such as diagnostic accuracy, patient satisfaction, engagement, and usability ratings. Instruments, such as the system usability scale or the technology acceptance model, could be used. Further investigation is needed to explore the specific contexts and patient populations where chatbots for history-taking may be most effective [29,50,53]. Different medical areas and health situations may present special considerations and challenges that could influence the implementation and acceptance of chatbot-based systems for taking medical histories, such as in the case of older people due to a more limited technical affinity or long medical histories in people with chronic illnesses.

Moreover, future research should address the challenges and limitations identified in this review. Efforts should be made to minimize bias and improve the methodological quality of studies. Conducting studies with more homogeneous patient populations and using consistent outcome measures would enhance the comparability and generalizability of the findings [39].

Finally, it would be valuable to explore the integration of chatbots with other technologies or interventions to optimize the history-taking process. The integration of chatbots with modern technologies, such as NLP, machine learning algorithms, and decision support systems, has the potential to significantly improve history-taking [21,46,51]. NLP could improve the ability to understand and interpret patient responses to the chatbot. The interactions will be more fluid and intuitive. Machine learning algorithms can be used to continuously improve chatbot responses based on patient interactions. This could lead to more accurate and personalized information. The integration of decision support systems can provide health care providers with real-time evidence-based recommendations. Research designs to investigate these integrations could include comparative studies for measuring differences in diagnostic accuracy, patient satisfaction, and efficiency between 2 groups. One group could use a simple chatbot, and another group could use an advanced chatbot with integrated NLP and machine learning.

Conclusions

The systematic review provides an insightful overview of the use of chatbots in medical history–taking. The results show that chatbots can increase data completeness and user satisfaction. This can encourage patient engagement, and more accurate assessment can be achieved in a reduced timeframe. Chatbots can be used in primary care before the face-to-face visit. This would not only reduce the workload of medical staff but also enable more targeted interaction between patients and physicians. Future research should focus on different areas to improve the use of chatbots for medical history–taking. Larger studies and RCTs are essential for adequate validation. The use of chatbots needs to be investigated in different health care settings and with different patient groups, for example, in patients with chronic diseases, mental illness, or older patients and in people who are not tech-savvy. Another area that needs to be considered is analyzing the impact of chatbots on workflows in clinics or practices and the change in the doctor-patient relationship. In addition, data protection and security issues must be clarified to ensure the protection of patient data, especially considering the latest developments in AI models. These offer new opportunities for more precise and personalized interactions. Research should optimize these models for history-taking and integrate them into decision support systems for real-time evidence-based recommendations. If these areas are addressed, chatbots can significantly transform health care by improving efficiency, accuracy, and patient engagement, especially for underserved patient populations, as well as chronic disease management and real-time symptom assessment.

Acknowledgments

This systematic review was funded by the Department of Dermatology and Allergology of the Technical University of Munich, Germany. Funding did not influence the review process or results.

Data Availability

All data generated or analyzed during this study are included in this published article. All aggregate data collected for this review are available from the corresponding author upon reasonable request.

Authors' Contributions

MH conceptualized and designed the analysis, collected the data, performed the screening and analysis, and was the primary author of the article. SS served as the second reviewer for screening and quality appraisal. AZ critically reviewed and provided feedback on the paper.

Conflicts of Interest

None declared.

Abstract

Background: Postoperative infections remain a crucial challenge in health care, resulting in high morbidity, mortality, and costs. Accurate identification and labeling of patients with postoperative bacterial infections is crucial for developing prediction models, validating biomarkers, and implementing surveillance systems in clinical practice.

Objective: This scoping review aimed to explore methods for identifying patients with postoperative infections using electronic health record (EHR) data to go beyond the reference standard of manual chart review.

Methods: We performed a systematic search strategy across PubMed, Embase, Web of Science (Core Collection), the Cochrane Library, and Emcare (Ovid), targeting studies addressing the prediction and fully automated surveillance (ie, without manual check) of diverse bacterial infections in the postoperative setting. For prediction modeling studies, we assessed the labeling methods used, categorizing them as either manual or automated. We evaluated the different types of EHR data needed for the surveillance and labeling of postoperative infections, as well as the performance of fully automated surveillance systems compared with manual chart review.

Results: We identified 75 different methods and definitions used to identify patients with postoperative infections in studies published between 2003 and 2023. Manual labeling was the predominant method in prediction modeling research, 65% (49/75) of the identified methods use structured data, and 45% (34/75) use free text and clinical notes as one of their data sources. Fully automated surveillance systems should be used with caution because the reported positive predictive values are between 0.31 and 0.76.

Conclusions: There is currently no evidence to support fully automated labeling and identification of patients with infections based solely on structured EHR data. Future research should focus on defining uniform definitions, as well as prioritizing the development of more scalable, automated methods for infection detection using structured EHR data.

Introduction

Postoperative bacterial infections, including deep or superficial surgical site infections (SSIs), urinary tract infections (UTIs), and pneumonia, are the most frequent complications after surgery. Postoperative infections can be categorized into subtypes, usually based on location or severity according to the Clavien-Dindo classification [1]. The overall incidence of postoperative infections within 30 days of surgery varies between 6.5% and 25% [2-4]. Considering the 313 million patients undergoing surgery globally each year, these postoperative infections have an enormous impact on population health and overall health care costs [5]. Effective postoperative infection prevention and management require early detection of high-risk patients through prediction and data-driven surveillance. It is imperative for developing and validating prediction and surveillance systems to be able to accurately identify patients who have postoperative infections. Machine learning modeling practices use the term “labeling” for the identification of patients with the outcome of interest. Labeling and surveillance are both challenges due to underreporting in (hospital) complication registries, ranging from 38% to 77% when compared with a manual chart review [6,7]. Consequently, the current reference standard for identifying patients with postoperative infections relies on labor-intensive manual chart review, with an estimated 1.5 full-time equivalents per 10,000 admissions [8,9]. Furthermore, manual surveillance and labeling are prone to interobserver variability [10,11] and human errors [12], highlighting the need for more robust methods to address this devastating postoperative problem.

To achieve a more objective, cost-effective, and resource-efficient identification of patients with postoperative infections, it is imperative to leverage the electronic health records (EHRs) to automatically detect patients with infections without human checking on high-risk patients based on readily available EHR data. Different types of data are present within the EHR, including structured, tabular, and free-text records in which diagnoses and clinical symptoms are reported. A previously performed systematic review identified semiautomated and fully automated surveillance methods for hospital-acquired infections (HAIs) [13]. As more than 90% of the included systems required manual checking of infectious cases, it was concluded that fully automated surveillance of HAIs cannot be routinely used yet in health care settings.

To go beyond manual labeling and manual surveillance and to explore the current methods and criteria used in prediction modeling studies, the aim of this study was to perform a scoping review on available labeling methods for postoperative infections and fully automated surveillance systems (ie, not requiring manual checking). We aimed to (1) evaluate the current methods and criteria used to label patients with postoperative infections in prediction modeling and biomarker validation studies, (2) explore available automated surveillance methods and their performance (sensitivity, specificity, positive predictive value [PPV], and negative predictive value [NPV]) in comparison with reference standard manual chart review, and (3) determine the necessary data types and sources needed to perform automated detection of postoperative infections.

Methods

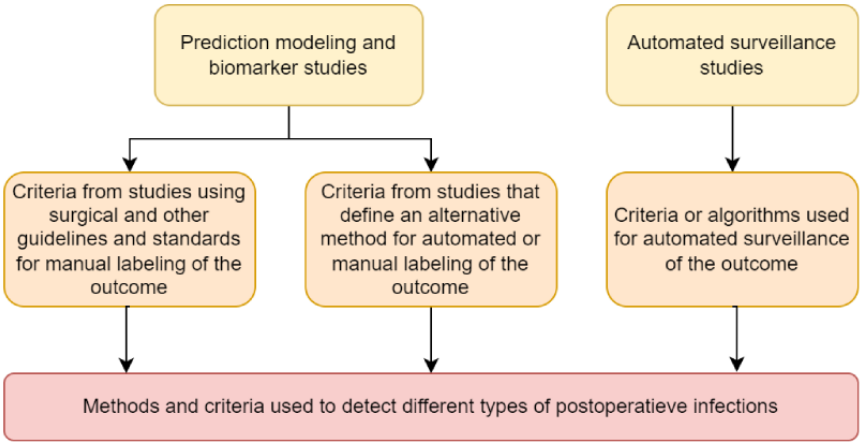
Overview

This scoping review combined 2 literature searches to evaluate current methods used by prediction modeling and biomarker validation studies to label patients with postoperative infections and the use of automated surveillance systems to identify patients with postoperative infections based on EHR data. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist was used. The protocol was registered on Open Science Framework [14].

Search Strategy

First, prediction modeling validation studies using machine learning methods, statistical models, and biomarkers to predict postoperative infections were identified. Second, a separate search was performed to identify studies on automated surveillance for postoperative and other hospital-acquired infections (Figure 1). Surveillance studies focusing on surgical populations often only investigate SSIs. As we aimed to study all bacterial infections that may occur after surgery, surveillance studies in a hospital-wide setting were also included. Both searches were performed in PubMed, Embase (OVID), Web of Science (Core Collection), the Cochrane Library, and Emcare (OVID). Studies were included from inception (ie, 1966) to August 1, 2023. The search queries were generated with help from an information specialist (JWS) from the Leiden University Medical Center. The details of the search queries are provided in Appendix A of Multimedia Appendix 1.

Figure 1. Data sources from the literature for identifying infections in prediction modeling or biomarker studies and automated surveillance studies.



Selection Criteria

The selection of studies was performed in Covidence, a program used to manage systematic literature searches. The inclusion and exclusion criteria used are presented in Table S1 in Multimedia Appendix 1. All titles and abstracts were screened by 2 independent reviewers (AMVB and BFG for prediction models; SLVDM and BFG for surveillance studies). The full texts of all potentially relevant studies were retrieved and assessed by 2 reviewers (SLVDM and BFG) for eligibility. Any disagreement on the inclusion or exclusion of studies was resolved through reassessment and discussion with a third reviewer (MSA). The data from the different reports were collected by 1 researcher (AMVB or SLVDM), and inconsistencies were checked for by a second researcher (BFG).

Data Extraction and Definitions

The following data were extracted for the prediction modeling studies: name of the prediction tool, type of prediction tool (machine learning, biomarker, and statistical model), surgical subpopulations, type of postoperative infection predicted, and criteria and guidelines used to manually or automatically label patients with infections. Manual labeling involves individuals conducting EHR chart reviews and applying specific criteria, often derived from surgical guidelines, to determine the presence or absence of infections in patient records. The criteria for diagnosing patients with an infection, for example, from a reference guideline from the literature, were identified and extracted.

For automated surveillance studies, the population, study design, years of data collection, type of infection surveyed, type of algorithm used, definition used to automatically detect infections, reference standard used to compare the automated method with, type of validation performed, and performance metrics reported compared with the reference standard were collected. The main metrics used to assess performance were the method's sensitivity, specificity, PPV, and NPV. Other metrics extracted are presented in Table S17 in Multimedia Appendix 1, including the area under the receiver operating characteristic curve, accuracy, F_1-score, κ score, Pearson correlation coefficient, and agreement percentage. Only performance metrics were assessed for surveillance studies, as for prediction modeling studies, and no accuracy of the labeling method compared with a reference standard was determined.

Data Synthesis

For each method to identify and label patients with infections, the data type categories needed from the EHR were assessed to identify infections based on the definition used. These could be structured EHR data (type A), including tabular information stored, such as complication registries, medication information, and vital signs; free-text clinical notes (type B), including all clinical information stored in free-text, such as discharge letters and daily reports; microbiology results (type C), which is seen as a separate category, as it differs per hospital how well-structured this information is stored [15]; and an additional interpretation layer (whether the results are positive) is needed to use this information; or imaging results (type D), or a combination of these categories. The definitions were further differentiated based on the data types and criteria needed to adhere to the definitions in Appendix E in Multimedia Appendix 1.

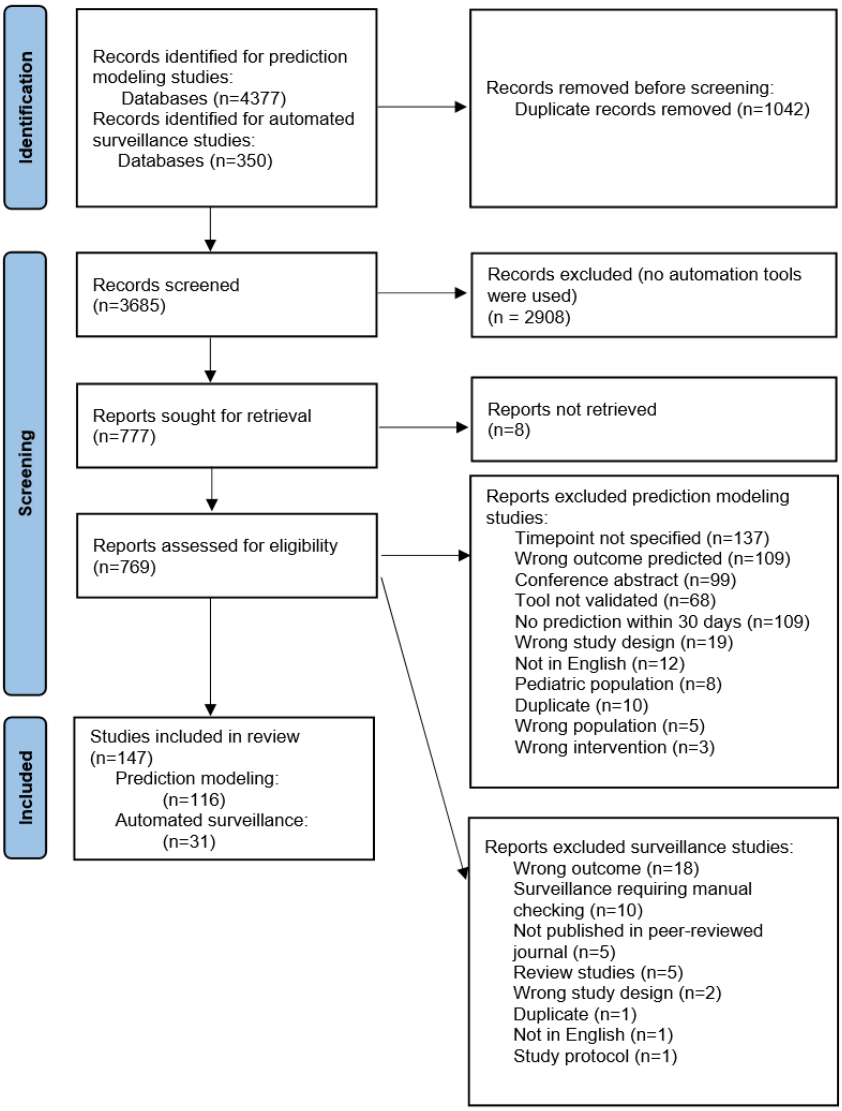
Some prediction models and surveillance systems are focused on predicting or detecting all severity types of bacterial infections, while others focus only on infections requiring pharmacological or surgical treatment. For example, some definitions include the prescription of antibiotics as one of the criteria, while others base their criteria on clinical symptoms only. As the severity of the infections surveyed or predicted influences the intended use case and number of infections identified, we classified the definitions according to the Clavien-Dindo scale [1]. Finally, the performance of the automated infection surveillance systems compared with that of the reference standard manual review was visualized per subtype of infection. The results were grouped according to the type of infection, such as HAI (type not further specified), SSI, pneumonia, anastomotic leakage and abdominal infections, bloodstream infections (including central venous catheter-related infections and sepsis), and UTIs. Infections that did not belong to one of these groups were categorized as "other."

Results

Overview

We included a total of 147 studies published between 2003 and 2023 (Figure 2). Of these, 116 studies focused on the prediction of postoperative infections; either the development and validation of prediction models or a predictive biomarker were performed, or validation was performed of preexisting risk scores. These included the American College of Surgeons National Surgical Quality Improvement Program surgical risk calculator (ACS NSQIP; 33/116 studies), the National Nosocomial Infection Surveillance System (NNIS; 4/116 studies), and the Surgical Risk Preoperative Assessment System (SURPAS; 5/116 studies).

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram.



Out of 116 studies, 4 did not report the methodology used to determine which patients had the outcome of interest (ie, postoperative infection). In 83% (97/116) of prediction modeling studies, manual labeling based on diagnostic guidelines was performed, or a publicly available, manually labeled database was used, such as the participant use data file from the ACS NSQIP program (Table 1). A total of 13% (15/116) of studies used an alternative, non–guideline-based method to label patients with infections, 11 of whom used manual labeling, 3 of whom did not explicitly mention manual or automatic labeling, and 1 of whom used automatic labeling. In total, 93% (108/116) of the prediction modeling studies used manual labeling to determine the outcome of interest or a manually labeled, publicly available data set to perform their research.

[l]MRSA: Methicillin-resistant *Staphylococcus aureus*.

[m]PJI: prosthetic joint infection.

Automated Surveillance

We included 31 automated surveillance studies for bacterial infections. Surveillance was performed and reported per patient, admission, procedure, patient days, or culture. Different types of surveillance systems were studied, and some studies have reported on more than 1 method. Most often (21/31, 68%), a set of criteria or rules was defined to automatically detect infections based on EHR data, followed by natural language processing (NLP) algorithms for free-text from the EHR (7/31, 23%) and other classification algorithms such as logistic regression (3/31, 10%). Except for one study [25], all the studies validated their automated surveillance algorithms against a reference standard (manual chart review, often according to one of the established diagnostic guidelines). Comparing the automated surveillance algorithm to manual chart review according to the established guidelines resulted in a range of sensitivity (0.79-0.96), specificity (0.81-0.96), PPV (0.31-0.76), and NPV (0.96-1.00) estimates for the different types of infection (Figure 3). The performance of all the combinations of postoperative infection data needed to run the automated surveillance algorithm varied (Figure 4). Reported performance per surveillance algorithm is provided in Table S17 in Multimedia Appendix 1.

Figure 3. Performance of automated surveillance of postoperative infections compared with manual reference standard chart review. Panel A is the sensitivity, B is the specificity, C is the PPV, and D is the NPV. HAI: hospital-acquired infection; NPV: negative predictive value; PPV: positive predictive value; SSI: surgical site infection; UTI: urinary tract infection.

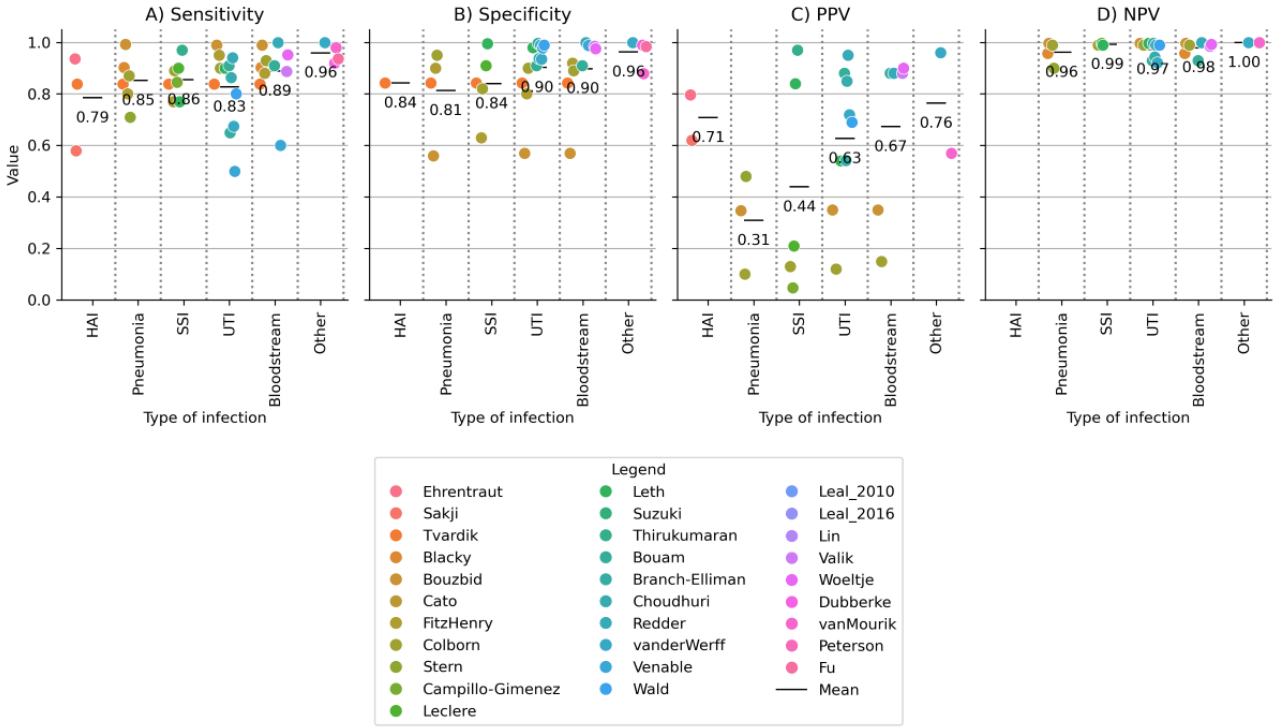

Figure 4. Performance per data type category used in automated surveillance algorithms. A=Structured electronic health record data only (eg, registrations and medication), B=Free-text clinical notes, C=microbiology results. Panel A is the sensitivity, B is the specificity, C is the PPV and D is the NPV. HAI: hospital-acquired infection; NPV: negative predictive value; PPV: positive predictive value; SSI: surgical site infection; UTI: urinary tract infection.

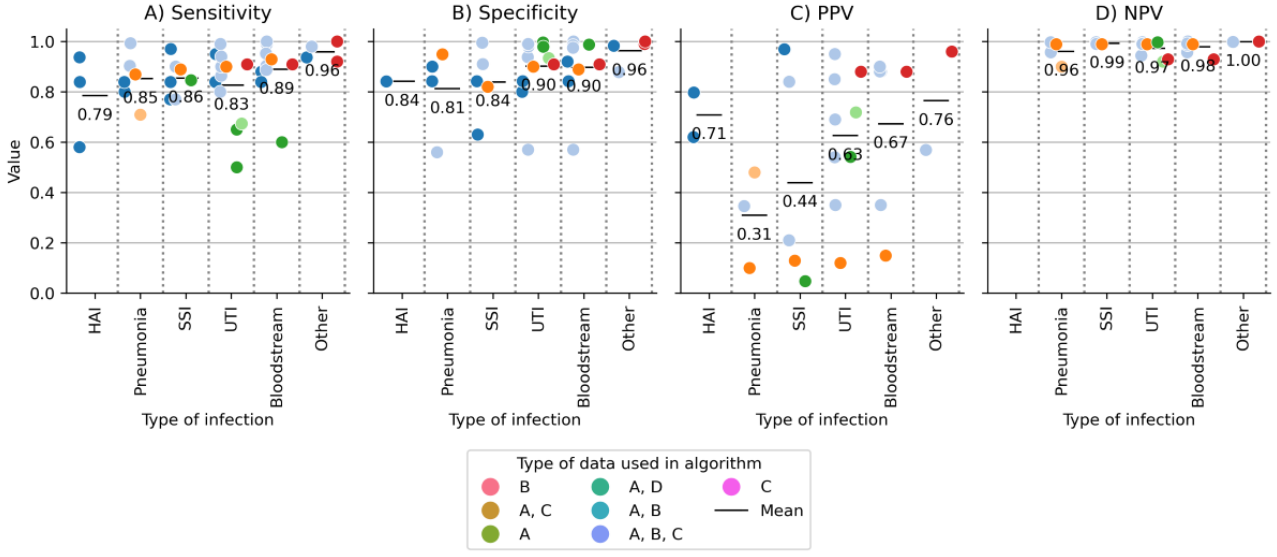
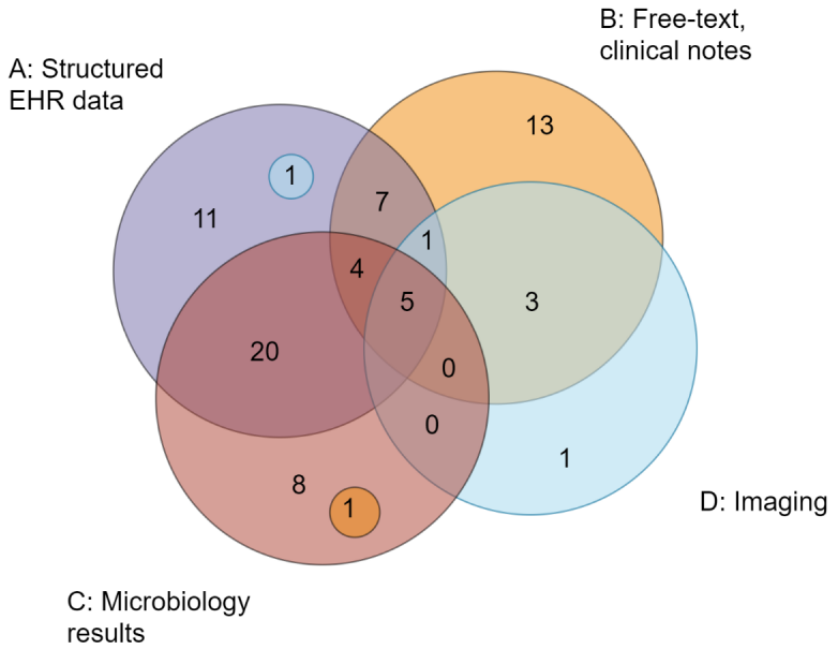


Electronic Health Record Data for Automated Identification and Surveillance

In the 147 included studies, 75 different methods and definitions were used to identify different types of bacterial infections. A total of 56% (42/75) used 2 or more datatypes to label, diagnose, or surveil infections, and 45% (34/75) required free-text and clinical notes as at least one of their data sources. In Table 1, the different types of data from the EHR needed to automatically detect patients with an infection are specified for each diagnostic guideline or infection definition used in the different prediction modeling studies or automated surveillance methods. Figure 5 shows the total number of methods used to identify patients with bacterial infections and the different data categories used. Most frequently (20/75, 27%), a combination of microbiology results and structured EHR data was used, followed by free-text (13/75, 17%) and structured EHR data (11/75, 15%). In total, 45% (34/75) of the identified methods used free text and clinical notes as one of their data sources.

Figure 5. Venn diagram of the types of data used to identify bacterial infections in the included studies and guidelines. The data were divided into structured electronic health record data, free-text and clinical notes, microbiology results, and imaging. In total, 75 unique definitions were identified for different types of bacterial infections. EHR: electronic health record.



For hospital-acquired infections (no specification of subtype), free-text information was needed for all definitions and methods, limiting the ability to detect patients with an infection based on structured EHR data. For pneumonia, some automated surveillance studies have identified patients without the need for free-text information [24,25], but they did include culture results in their definition. For SSIs and UTIs, a wide range of criteria were used compared with other types of infections. Abdominal surgery-related anastomotic leakage and abdominal infections were identified based on antibiotic treatment or surgical reinterventions supplemented with free-text data or imaging results. Bacterial culture data, in combination with structured EHR parameters, are used in most methods for detecting bloodstream infections. For *Clostridium difficile* infections, cerebral extraventricular and lumbar drain-related meningitis, methicillin-resistant *Staphylococcus aureus*, and prosthetic joint infection, the authors used a maximum of 2 criteria from different categories to define infection. Prediction modeling studies that did not use manual chart review for labeling patients in the data set relied on the registration of infections or the performance of surgical interventions, sometimes in combination with antibiotic administration [32].

When assessing infection severity according to the different Clavien-Dindo definitions, most (64%, 48/75) were based on identifying infections according to a Clavien-Dindo score of 1 or more. This indicates that, based on the registration of infection or clinical criteria only, infections were surveyed and predicted. In 23% of definitions (17/75), the prescription of antibiotic therapy or surgical intervention was included as the criterion, resulting in a Clavien-Dindo score of 2 or higher.

Discussion

This scoping review assessed the methods and criteria used for identifying postoperative bacterial infections in prediction modeling and fully automated surveillance studies. We identified a total of 75 different methods and definitions from 147 included studies to identify patients with different types of bacterial infections. We found that 45% (34/75) used unstructured free-text and clinical notes as at least one of their data sources. Furthermore, out of 116 postoperative infection prediction studies, 108 (93%) used manual labeling based on self-defined criteria or diagnostic guidelines or used publicly available manually labeled databases. In addition, among the 31 automated surveillance studies, various methods, such as NLP, classification algorithms, and predefined criteria or rules on structured data, were used to automatically detect infections. Compared with manual chart review, automated surveillance systems have reported sensitivities for different types of infections ranging from 0.79 to 0.96, specificities from 0.81 to 0.96, PPVs from 0.31 to 0.76, and NPVs from 0.96 to 1.00. Finally, we found that different criteria were used among both prediction and surveillance studies to identify patients with infections, indicating that there is no uniform definition being used. Given the current use of different types of criteria and data used in prediction and surveillance studies, we were not able to identify or formulate a uniform and reliable method to automatically label patients with infections based on structured EHR data.

Prediction and surveillance of postoperative infections are crucial for early detection and assessment of the impact of preventative interventions but are currently hindered because the labeling of these cases is performed by resource-intensive manual chart review. In contrast to a previous study on semiautomated surveillance where high-risk patients were manually checked [13], we included only fully automated surveillance systems that were built to avoid requiring any human intervention. However, human intervention might still be required to incorporate the systems as well as to clean and

preprocess the EHR data. Furthermore, we broadened the scope by assessing current labeling methods for prediction modeling studies, which, with some exceptions, were based on manual labeling according to established guidelines. In line with our findings, the predominant use of manual labeling was reported in a meta-analysis on the predictive performance of machine learning algorithms for SSI prediction [71]. Although manual labeling based on chart review is still the predominant method and is considered the reference standard, it must be noted that manual labeling may be flawed due to human errors and interobserver variability [9,10,12]. Furthermore, validating models only on national registries and databases limits the generalizability of developed prediction models and surveillance systems to other settings [72].

We extensively researched different definitions and methods from prediction modeling studies, guidelines, and surveillance studies to identify patients with bacterial infections that may occur after surgery and summarized different types of data needed to adhere to the different definitions. This study has several limitations. First, heterogeneity between studies (eg, differences in study design) prevented a meta-analysis, making it difficult to draw generalizable conclusions on optimal labeling methods. However, combining different types of studies allowed us to generate insight into the current methods of labeling and identifying patients with infections. Second, the distinction between structured and unstructured data may differ according to hospital data set and region (eg, microbiology results can be registered as free-text or tabular data). Despite these limitations, we could identify a lack of uniform definitions for labeling of postoperative infections exists, and that manual labeling is currently the predominant method. Third, pre-existing infections could have impacted the performance of surveillance algorithms and prediction models as well as label reliability [73]. This could explain the relatively lower PPVs and warrants further research before reliable implementation of automated surveillance systems.

Different types of data were used among the definitions and methods, including structured tabular data, microbiological data, free-text data, and imaging results. The importance of reliable, high-quality outcome data is essential for the reliable use of artificial intelligence and surveillance systems [74]. Using structured EHR data is preferable, as free text is often subject to misinterpretation and contains personal patient-specific data that conflict with privacy legislation and thus have restrictions on data use [75]. By extracting free-text information, NLP shows promise in uncovering postoperative infections from free-text data. However, challenges remain with respect to generalizability [76], transparency, reliability, and potential biases, including concerns about accuracy or unintended errors [77,78]. Furthermore, NLP methods can be computationally expensive, depend on the quality of the input data, and are influenced by nuances in language, dialects, and medical jargon. Considering that NLP methods can vary significantly in complexity, ranging from simple string searches to advanced neural networks, future research should investigate whether increased complexity leads to improved surveillance accuracy. The use of microbiology results in definitions is prevalent, despite their occasional unreliability due to the possibility of false negatives or positives, causing under- or overreporting of infections [13], and heterogeneous storage practices. This reliance on microbiology results could lead to errors or inconsistencies in infection identification.

Accurately identifying patients with infections based on an automated analysis of EHR data remains a challenge, and validation is difficult owing to the limitations of manual chart review, which until now has remained the reference standard for postoperative infections and other relevant patient outcomes. Manual labeling based on manual EHR chart review is unfeasible when scaling artificial intelligence–based or statistical prediction models to more than one hospital, with 100,000 patient records each. In some of the included studies, alternative approaches were identified that relied on treatments and other structured data sources [27,31-33,41-43]. For future prediction model development and surveillance, alternative approaches to identifying patients with infection should be explored, such as focusing on pharmacological and interventional treatments performed by clinicians, as these approaches are often stored in a structured format in the EHR system [27]. Emphasis should be placed on the consensus on the definition and whether it is worse to miss infections that do not require treatment compared with those that do. Compared with sensitivity, specificity, and NPV, automated surveillance systems have a lower PPV where heterogeneity is observed between the different types of infections. The PPV to detect pneumonia and SSIs is lower compared with other types of infections. This could be due to variations in clinical presentation, differences in diagnostic criteria, or the inherent complexity and variability of these particular infections. A lower PPV in general could be due to the use of low classification cutoffs to not miss any cases, but it could also indicate that the reference standard manual labeling may have resulted in erroneous labels and that the systems found infections where the human annotator did not [79]. In addition to detecting individual patients with infections, automated surveillance systems hold promise for assessing hospital incidence rates, predicting rates of complications, and evaluating the effectiveness of quality improvement initiatives, where the emphasis may shift from high PPVs to broader statistical insights.

In conclusion, there is currently no evidence to support fully automated labeling and identification of patients with infections based solely on structured EHR data. This is due to the diverse definitions of postoperative infection and the need for unstructured data types, such as free text and clinical notes, which were required as data sources in nearly half of the instances to assess an infection. Furthermore, manual labeling was still the predominant method in prediction modeling studies. Fully automatic surveillance methods may result in overreporting due to a relatively low PPV and heavy reliance on free-text data. Future research must focus on defining uniform or globally accepted definitions of postoperative infection that use criteria that can be extracted from the EHR, as well as prioritizing the development of more scalable automated methods for infection detection using EHR data.

Acknowledgments

This research was partially funded by the Recovery Assistance for Cohesion and the Territories of Europe grant provided by the European Regional Development Fund (ERDF; grant KVW-00351).

Authors' Contributions

SLVDM, AMVB, MSA, BFG, RGHHN, EWS, MGJDB, and HVG contributed to the conception of the study. SLVDM, BFG, and MSA designed the study. JWS assisted in conducting the literature searches. SLVDM, BFG, AMVB, and MSA conducted the literature search and selection of the studies. SLVDM and MSA performed the data synthesis and data analyses. SLVDM wrote the initial draft of the paper. AMVB, MSA, BFG, RGHHN, EWS, MGJDB, and HVG reviewed and corrected the paper. All the authors read and approved the final paper.

Conflicts of Interest

BFG is currently the chief executive officer and majority shareholder of healthplus.ai BV and its subsidiaries. BFG has also consulted for and received research grants from Philips NV and Edwards Lifesciences LLC. SLVDM works as a data scientist and PhD candidate at Healthplus.ai and LUMC. SLVDM owns share options in Healthplus.ai. The rest of the authors declare no competing interests.

Abstract

Background: Data models are crucial for clinical research as they enable researchers to fully use the vast amount of clinical data stored in medical systems. Standardized data and well-defined relationships between data points are necessary to guarantee semantic interoperability. Using the Fast Healthcare Interoperability Resources (FHIR) standard for clinical data representation would be a practical methodology to enhance and accelerate interoperability and data availability for research.

Objective: This research aims to provide a comprehensive overview of the state-of-the-art and current landscape in FHIR-based data models and structures. In addition, we intend to identify and discuss the tools, resources, limitations, and other critical aspects mentioned in the selected research papers.

Methods: To ensure the extraction of reliable results, we followed the instructions of the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. We analyzed the indexed articles in PubMed, Scopus, Web of Science, IEEE Xplore, the ACM Digital Library, and Google Scholar. After identifying, extracting, and assessing the quality and relevance of the articles, we synthesized the extracted data to identify common patterns, themes, and variations in the use of FHIR-based data models and structures across different studies.

Results: On the basis of the reviewed articles, we could identify 2 main themes: dynamic (pipeline-based) and static data models. The articles were also categorized into health care use cases, including chronic diseases, COVID-19 and infectious diseases, cancer research, acute or intensive care, random and general medical notes, and other conditions. Furthermore, we summarized the important or common tools and approaches of the selected papers. These items included FHIR-based tools and frameworks, machine learning approaches, and data storage and security. The most common resource was “Observation” followed by “Condition” and “Patient.” The limitations and challenges of developing data models were categorized based on the issues of data integration, interoperability, standardization, performance, and scalability or generalizability.

Conclusions: FHIR serves as a highly promising interoperability standard for developing real-world health care apps. The implementation of FHIR modeling for electronic health record data facilitates the integration, transmission, and analysis of data while also advancing translational research and phenotyping. Generally, FHIR-based exports of local data repositories improve data interoperability for systems and data warehouses across different settings. However, ongoing efforts to address existing limitations and challenges are essential for the successful implementation and integration of FHIR data models.

KEYWORDS

data model; Fast Healthcare Interoperability Resources; FHIR; interoperability; modeling; PRISMA

Introduction

Background

In informatics, operations and data structures can be described by a set of concepts called data models. Because structures and data points need to be connected to represent connections, data modeling offers a visual representation of the system, in a whole or in some parts. For instance, one of the most used conceptual data models is the entity relationship model which is generally linked to a relational database [1]. Data modeling is a process that defines how the data should be maintained in a database. Data types, constraints, relationships, and metadata definitions are among the features specified by a data model [2]. Data models are also crucial for clinical research as they enable researchers to fully use the vast amount of clinical data stored in medical systems. Standardized data and well-defined relationships between data points are necessary to "guarantee reproducible research findings" [3].

Furthermore, data modeling can facilitate interoperability between medical systems. Interoperability refers to the ability to exchange information between computer systems, which is essential in various fields, such as artificial intelligence (AI), big data research and analytics, medical communication, and multinational collaboration. In the medical field, interoperable systems can reduce errors and documentation workload, empower patients, and facilitate information retrieval. In research, real-world information can be collected and used for data mining and AI to generate new hypotheses [4]. The management board of the Healthcare Information and Management Systems Society (HIMSS) defined 3 levels of interoperability: fundamental, structural, and semantic. Fundamental interoperability refers to the communication method between IT firms and devices, while structural interoperability is the format and structure of data being communicated. Semantic interoperability, by contrast, involves the ability of disparate and heterogeneous systems to not only exchange information but also interpret and use it autonomously [5]. Developing a data model would enhance structural and semantic interoperability between medical information systems. Furthermore, efficient data exchange contributes to the reduction of time and financial resources [6].

Health Level 7 (HL7) is a standard-developing organization focused on enhancing information exchange among health care systems. These standards are fundamental in the adoption of electronic health records (EHRs). Fast Healthcare Interoperability Resources (FHIR) is the most recent interoperability standard, preceded by HL7 version 2 and HL7 version 3 [7]. FHIR aims to advance messaging standards to enhance semantic interoperability [8]. Using this standard for clinical data representation is a practical methodology to enhance and accelerate data availability for research. These models can also have the potential to be transformed into other models for analytics purposes [9]. FHIR mapping is the process of identifying the corresponding FHIR resources to real-world data elements. This is an essential step in the FHIR data modeling procedure [10]. When the objective is to maintain semantic interoperability with legacy applications, performing manual data transformations and mappings is necessary to guarantee that the exchanged data are interpreted properly and as expected by all end points [8].

Because not all health care information is structured, there is a need to use other approaches for mapping and FHIR modeling. Natural language processing (NLP) is a branch of AI that deals with the computerized interpretation, representation, and analysis of natural (human) language. In the health care domain, this technology is widely used to interpret and analyze unstructured health data, such as diagnostic reports, medical notes, and prescriptions [11]. The extracted information can then be represented in a structured format, such as a FHIR-based model. In general, it is possible to formalize and integrate unstructured and structured EHR data through a FHIR-based framework [12].

FHIR-based data normalization pipelines are valuable tools in data capture and EHR phenotyping [13]. For instance, a pipeline called NLP2FHIR standardizes unstructured EHR data [14]. Concerning the big data domain, workflows of data harmonization pipelines integrated with FHIR would present a scalable data modeling of large data sets [15]. It is also feasible to use FHIR data models to standardize heterogeneous annotation corpora [16]. All the mentioned potentials will lead to better semantic interoperability between medical systems. To the best of our knowledge, no research has been done so far to comprehensively assess the practical implementations of FHIR-based models and infrastructures. Thus, in this research, we aim to review recent advancements in this field, focusing on the functional data model or structure implementations using this standard. More specifically, this scoping review focused on addressing the question, "What insights can be gained from analyzing the state-of-the-art FHIR-based data modeling approaches considering technological advancements, application in the medical domain, and potential limitations?"

Objectives

The research objectives are as follows: (1) to provide a comprehensive overview of FHIR-based data models in the context of interoperability, structure, and functionality and summarize the state of the art for developing FHIR-based data models and (2) to highlight limitations, challenges, advantages, and opportunities brought about by FHIR-based data models

Methods

Overview

This review was conducted according to the instructions of the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist [17]. This checklist aims to facilitate the development of a deeper comprehension of pertinent terminology, fundamental concepts, and essential items to report for scoping reviews [17]. The checklist is available in Multimedia Appendix 1.

Study Protocol

We used the PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols) 2015 checklist

to formulate and draft the review protocol. Protocols for systematic reviews facilitate the organization and recording of review procedures, ensuring the reproducibility of research. In addition, they serve as a safeguard against indecisive judgment during the review process and allow the readers to determine whether selective reporting has been applied [18]. The full checklist and the review protocol are available in Multimedia Appendix 2.

Eligibility Criteria

To select the papers, we considered the articles that encompass the FHIR standard in the data model development or infrastructure design. The inclusion and exclusion criteria were defined in more detail in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Original articles and case studies from journals and conferences
- Articles related to the Fast Healthcare Interoperability Resources (FHIR)-based data models and structures focusing on a health care condition or using real-world patient data, registries, or data sets
- Articles with high-quality and detailed workflow processes with at least one architecture or data model diagram
- Articles that discuss the barriers, challenges, or limitations of developing FHIR-based data models and infrastructures in a health care domain

Exclusion criteria

- Not written in English
- Not accessible
- Letter to the editors, reviews, editorials, commentary articles, short papers without detailed implementation information, posters, and preprint articles
- Not relevant to research questions and objectives; in other words, articles not focusing on FHIR-based data model development or not providing practical and detailed insights into the development or use of FHIR-based data models by a schematic approach
- Papers lacking specific use cases or real-world data sources (practical implementations) or without discussion of limitations and challenges

Information Sources and Search Strategy

We searched academic databases, such as PubMed, Scopus, Web of Science (standard selection of databases—Web of Science Core Collection), IEEE Xplore, and the ACM Digital Library in May 2023.

The search was conducted using database-specific variants of the basic search term ([“fhir”] AND [“data model” OR “modelling” OR “minimum data set” OR “data element”]) with their synonyms, variations, and full forms.

It is worth mentioning that no time limit was applied to the search to obtain a comprehensive overview of all published articles in this field. We should clarify that the initial pages of Google Scholar (9-10 pages) were investigated as a supplement to the mentioned academic libraries to retrieve additional papers. Full searches are available in Multimedia Appendix 3.

Study Selection

In a stepwise process, 2 coauthors (PT and MDR) independently screened the retrieved articles and selected the initial studies by applying the inclusion and exclusion criteria to the titles or abstracts or, in some cases, full texts (by rapid skimming). Inconsistencies in the selection were discussed with other coauthors until a consensus was reached. EndNote (Endnote X9; Bld 12062) software was used for article screening and investigation in each step. The full texts of the initially selected articles were assessed in the next phase to check compliance with the eligibility criteria. PT thoroughly reviewed the articles and then discussed with other authors about inclusions. Disagreements were resolved after group discussions.

Each selected study was thoroughly investigated for the appropriateness and clarity of the research methodology and design. We also assessed them to ensure alignment with the study objectives. The rigor of the methods, tools, and techniques used for FHIR-based architectural design was considered in this phase. The presentation of results and the coherence of model interpretation were also closely examined.

Data Charting Process and Data Items

Two coauthors (PT and MDR) extracted and analyzed the selected articles and charted the data. The final analysis was thoroughly reviewed and confirmed by other coauthors to ensure reliability and rigor. The collaborative review process among coauthors further enhanced the robustness of the results’ interpretation, ensuring a comprehensive and well-rounded analysis of the gathered evidence. The following information was extracted and collected in a spreadsheet: (1) bibliographic information, such as title, authors, and year of publication; (2) data sources; (3) FHIR resources; (4) data transformation and mapping; (5) standards, tools, terminologies, and models; (6) data validation and evaluation; (7) use case.

Synthesis of the Results

After extraction, we assessed the information to find themes or categories. Subsequently, we performed a general analysis of the papers, based on the overall technical themes and the medical domains. In addition, any important technologies used most in the included articles were comprehensively presented and

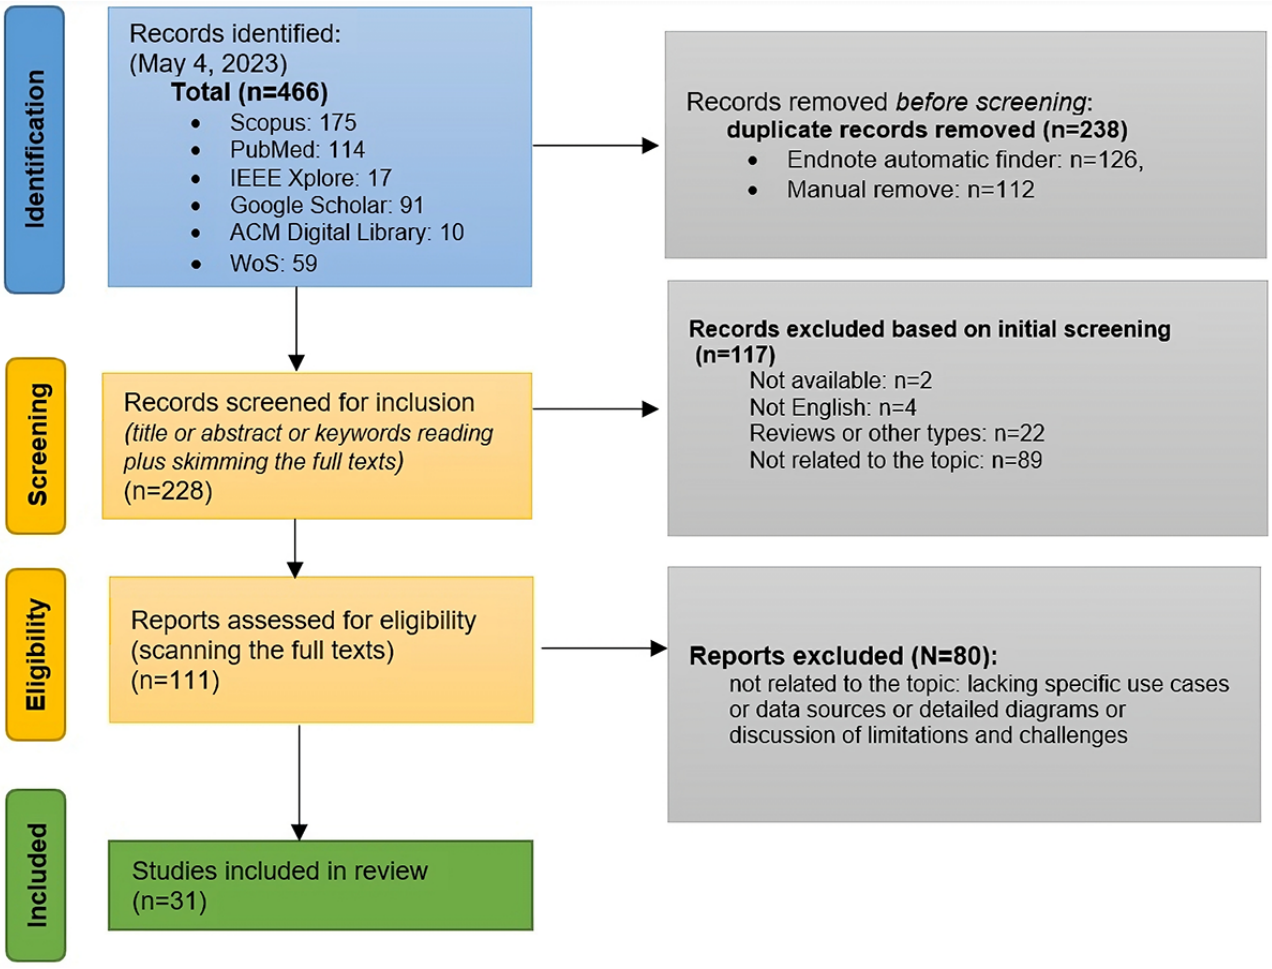
discussed afterward. Resource frequency analysis was performed via the investigation and counting of FHIR resources used in each data model and infrastructure to find out which resources were more common in system developments. One of the most important aims of our research was to extract and categorize the implementation limitations mentioned by the researchers. Therefore, these aspects were also addressed subsequently to provide a thorough viewpoint of challenges that future scientists may face.

Results

Selection of Sources of Evidence

Of the overall 466 articles found during the comprehensive search, 238 (51.1%) studies were duplicates. Of the remaining 228 articles, 117 (51.3%) were excluded based on reading titles or abstracts or skimming some full texts. Of the remaining 111 articles for the next phase (full-text assessment), 31 (27.9%) articles were eventually selected to be included in this review. Figure 1 illustrates the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) chart of this study.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for study selection. WoS: Web of Science.



Structural Categorization

After analyzing the full texts of the 31 articles, we categorized them based on 2 models: dynamic (pipeline-based) and static data models.

Dynamic Data Models

Data pipelines are chains of functions and activities that lead the input to the output in an attempt for the flow of data to be smooth and automated from source to destination [19]. Dynamic or pipeline-based data models deal with moving, transforming, and analyzing the data using the FHIR standard in their approach. In this category, the FHIR standard has been used as a canonical data model to develop dynamic models. This group encompasses the articles with processes that go beyond static representation and include the movement and transformation of data. Of the 31 articles included, 25 (81%) were related to the development of dynamic data models using the FHIR standard. Table 1 summarizes the extracted information about this category.

Table 1. Dynamic models.

Study	FHIR[a] resources	Data source	Data transformation and mapping	Standards, tools, terminologies, and models	Validation and evaluation	Use case
Lenert et al [9]	Patient, Encounter, Condition, Procedure, MedicationRequest, MedicationAdministration, and Observation	Epic EHR[b], large academic institution	Flat file to FHIR, FHIR to OMOP[c], FHIR to PCORnet[d]	HL7[e] version 2.X, OMOP, PCORnet, Flat file, FHIR CDR[f], and CDM[g]	By published quality assessment tools	Health care research, especially in the context of COVID-19
Wen et al [20]	Composition and ValueSet	i2b2[h] Obesity Challenge data set, MIMIC[i] III obesity discharge summaries	FHIR-based NLP[j] extensions to CQL[k], FHIR extensions to NLP2FHIR pipeline	NLP2FHIR pipeline, CQL, NLP engines (cTAKES[l], MEDXN[m], MedTime) and PheKB[n]	Phenotype algorithms in PheKB and obesity phenotyping algorithm plus 2 obesity data sets	Obesity
Hong et al [13]	Composition, Condition, MedicationStatement, Procedure and FamilyMemberHistory	i2b2 obesity challenge (discharge summaries)	EHR data to FHIR resources	NLP tools (cTAKES, MedXN, MedTime) and NLP2FHIR pipeline, machine learning algorithms (logistic regression, support vector machine, decision tree, and random forest)	Using MIMIC-III obesity data set as a second data set, evaluation measures (precision, recall, and F_1-score) for performance evaluation	Obesity
Hong et al [14]	Composition, Condition, Observation, Procedure, MedicationStatement, Medication and FamilyMemberHistory	Mayo Clinic's unstructured EHR data	Unstructured and structured EHR data to FHIR resources	NLP2FHIR pipeline, UIMA[o] clinical NLP tools (cTAKES, MedXN, MedTime), LOINC[p], SNOMED CT[q], RxNorm[r], and ATC[s]	Reusing annotation corpora, standardizing annotation corpora, NLP2FHIR performance evaluation by precision, recall, and F_1-score	Random notes from EHR
Zong et al [21]	Questionnaire and QuestionnaireResponse	Mayo Clinic patients with colorectal cancer and ACP[t]	Unstructured reports to structured reports and synoptic report to ACP, and ACP FHIR model to CRF[u]	NLP tools and UDP[v] data sources	Precision, recall, F_1-score, and accuracy	Colorectal cancer
Hong et al [12]	MedicationStatement	Medication data from Mayo Clinic's EHR	Unstructured EHR data to FHIR, structured data to FHIR resource, and FHIR resources to annotation schemas	NLP tools (cTAKES, MedXN, MedTime), rule-based approach, SNOMED CT, CAS[w], RxNorm, UIMA, and protégé	Precision, recall, and F_1-score	Random notes from EHR
Williams et al [15]	Patient, Encounter, Observation, Procedure, MedicationRequest, MedicationAdministration, and Condition	MIMIC-IV database for validation	Raw hospital records to AI[x]-friendly and harmonized representation, and database tables to FHIR standard	ETL[y] framework and Postgres	Openly available MIMIC-IV database to test FHIR-DHP[z] and syntactic validation of FHIR mapping	Intensive care
Fischer et al [22]	Patient, Encounter, and Observation	German Pulmonary Hypertension registry	CSV file to FHIR bundle collection, source filed names to standard terminology (SNOMED CT, LOINC, ATC, and *ICD*[aa]*-10*) and source data to OMOP schema	ETL process, XSLT[ab], XPath, OMOP CDM, SNOMED CT, LOINC, ATC, and *ICD-10*	Feasibility assessment by computation time and source data coverage in the target CDM	Pulmonary Hypertension registry
Pfaff et al [23]	Patient, Encounter, Condition, Procedure, Observation, MedicationRequest, and Practitioner	i2b2	CDM to FHIR	CDM and FHIR PIT[ac]	Comparison of generated data by the pipeline and equivalent clinical data of CDWH[ad] warehouse	Asthma

Study	FHIR[a] resources	Data source	Data transformation and mapping	Standards, tools, terminologies, and models	Validation and evaluation	Use case
Rosenau et al [24]	Condition, Observation, Procedure, MedicationStatement, Immunization, DiagnosticReport, and Specimen	GECCO[ae]	Clinical data to FHIR, structured query to FHIR search, and CQL requests	SNOMED CT, LOINC, *ICD-10*-GM[af], ATC, CQL, and ETL processes	Create test patients and automated and manual test	COVID-19
Zong et al [25]	Observation, Condition, Medication, FamilyMemberHistory, and Patient	Mayo Clinic clinical data warehouse	Clinical entries to FHIR resources, FHIR to RDF[ag]	RDF, classification, machine learning and deep learning, cTAKES, MedXN, MedTime, NLP2FHIR, bag of features, Node2vec, *ICD-9*, RxNorm, and LOINC	Conventional 10-fold cross-validation, AUROC[ah], and AUPRC[ai]	Cancer
Bennett et al [26]	CodeSystem, ValueSet, MedicationRequest, MedicationDispense, and MedicationAdministration	MIMIC-IV	MIMIC-IV to FHIR	FSH[aj], py mimic FHIR package, PostgreSQL, and SNOMED CT	Validation by open-source FHIR server (HAPI[ak] FHIR) by bundles	Intensive care (ED[al] data)
El-Sappagh et al [27]	Patient, Practitioner, RelatedPerson, Observation, Condition, AdverseEvent, AllergyIntolerance, Location, FamilyMemberHistory, CarePlan, Goal, NutritionOrder, Medication, MedicationRequest, MedicationStatement, Device, Encounter, EpisodeOfCare, CareTeam, and Procedure	WBAN[am], patient profiles in EHR, and manual data sent by patients	RDB[an] to FHIR, FHIR to RDB, EHR data to FHIR, and direct mapping of historical data to FASTO[ao] ontology	FASTO ontology (using FHIR, SSN[ap], BFO[aq], and CPG[ar]), OWL[as] 2, WBAN, CDSS[at], Protégé, PHR[au], ISO IEEE 11073, LOINC, SNOMED CT, UoM[av], FHRBase database, FHIR RESTful[aw], OAuth2[ax], SPARQL[ay], D2RQ platform, Jena API[az], and Pallet and HermiT reasoners	Ontology is evaluated (assessment of correctness, consistency, and completeness of ontology knowledge) and manual evaluation by experts	Type 1 diabetes mellitus
Zong et al [28]	DiagnosticReport and Observation	ACP and clinical records of Mayo Clinic's patients	Structured and unstructured data to FHIR-based data profile and directly-inherited data element mapping	CRF, DMM[ba] model, ETL process, and topic modeling	Precision, recall, and F_1-score	Cancer clinical trials-colorectal
Hong et al [29]	Patient, Observation, Condition, and Procedure	Ovarian cancer database, laboratory test database, and CDM database	Local code to standard code, laboratory test codes to LOINC codes, and mapping between local identifiers and FHIR resource identifiers	Shiny web framework, Shiny apps library, R packages for FHIR data visualization, HAPI FHIR API, LOINC, ICD, and CPT[bb]	Feasibility and adaptability test using public FHIR servers	Ovarian cancer
Hong et al [16]	Condition, FamilyMemberHistory, Procedure, Observation, MedicationStatement, and Medication	Three annotated corpora from SHARPn project, MedXN project, and active Mayo's clinical NLP project (Family History NLP Project)	Source annotation schemas and FHIR annotation schema	UMLS[bc], SNOMED CT, LOINC, RxNorm, NLP tasks, support vector machine, annotation tools (Knowtator and Anafora), Protégé ontology editor, and HAPI FHIR API	Evaluation with annotation corpora, calculated precision, recall, and F_1-score	Annotated clinical notes
Marteau et al [30]	Not defined	SHC[bd] data repositories and Synthea Patient Generator	Map OMOP CDM concepts to FHIR resources by OMOP-on-FHIR (a novel clinical infrastructure)	ETL processes, OMOP CDM, OMOP-on-FHIR, PostgreSQL, psql[be], SMART[bf] on FHIR, and Synthea Patient Generator	Qualitative feedback collection and SUS[bg]	Pediatric musculoskeletal disorders
Ismail et al [31]	Patient, Observation, Condition, and Practitioner	MCHHJ[bh] and CRMHIS[bi]	Data elements to FHIR resources	MongoDB, FHIR RESTful web services, DAO[bj], Google's REST console app	User study and questionnaires, generate requests and view responses	Maternal health

Study	FHIR[a] resources	Data source	Data transformation and mapping	Standards, tools, terminologies, and models	Validation and evaluation	Use case
Guinez-Molinos et al [32]	Patient, Specimen, DiagnosticReport, and Observation	UC Christus laboratory	Minimum data set fields to FHIR	HAPI FHIR libraries, BPMN[bk], Cawemo, clinFHIR graphBuilder, JWT[bl], and MySQL	Performance evaluation (response time, throughput, process management time, main memory storage, secondary storage), and usability test	PCR[bm] SARS-CoV-2 tests
Burkhardt et al [33]	Patient, Organization, Communication Consent, Questionnaire, QuestionnaireResponse, and CarePlan	Requirement analysis outputs (undergraduate students were surveyed)	Data elements to FHIR	FHIR RESTful API, FHIR Search API, Google's Flutter, Keycloak, HAPI FHIR, AWS[bn], Docker, Postgres DB, JWT, and Apache web server	Not stated	COVID-19 symptom tracking
De et al [34]	Patient, Practitioner, RelatedPerson, Organization, HealthcareService, Appointment, Device, Encounter, DocumentReference, AllergyIntolerance, AdverseEvent, BodyStructure, Specimen, Procedure, FamilyMemberHistory, Observation, Condition, Medication, Immunization, CarePlan, ExplanationOfBenefit, and Account	The web-based patient portal at the Mayo Clinic Rochester	Biomedical text to UMLS and patient secure messages to hidden microconcepts	MetaMap, LDA[bo], multipurpose Annotation Environment, and FHIR definitions	F_1-score to check the consistency between annotators	Random samples of secure patient messages
Liu et al [35]	Condition, Procedure, MedicationStatement, FamilyMemberHistory, Composition, and Bundle	i2b2 2008 obesity data set and MIMIC III data set	Clinical text to FHIR bundle	Deep learning models (text GCN[bp], GRU[bq], and CNN[br]), scikit-learn, TensorFlow, Keras, text classification, NLP2FHIR pipeline, cTAKES, and SNOMED CT codes	Accuracy and macroaveraged precision, F_1-score, and recall	Obesity and random notes from discharge summaries
Zong et al [36]	Observation, Condition	Mayo Clinic's UDP (a clinical data warehouse)	Mappings of report data to 3 data elements (patient clinic number, name, and date of birth) and mappings between elements of PheWAS[bs] profile and FHIR	UML[bt], (*ICD-9* and *ICD-10*) codes, LOINC, phecode, Forge editor, FHIR profiling, cross- validation, chi-square distribution associated allelic *P* value, and KS[bu] test	Cross-validation and FHIR specifications and IGs[bv]	Cancer
Xiao et al [37]	Patient, Encounter, Location, Condition, MedicationStatement, Observation, Procedure, Practitioner, and ConceptMap	MIMIC-III data set (OMOP CDM-based)	OMOP to RDF mappings and OMOP-FHIR mappings	OWL, Protégé, FHIR ShEx[bw], FHIR RDF, VKG[bx] (also known as OBDA[by]), MIMIC-OMOP ETL tool, OMOP CDM, Ontop toolkits, SQL, and SPARQL	Using OMOP CDM-based MIMIC-III data set for system evaluation and comparing patient counts identified over MIMIC database and virtual CKG[bz]	Intensive care

Study	FHIR[a] resources	Data source	Data transformation and mapping	Standards, tools, terminologies, and models	Validation and evaluation	Use case
Kukhareva et al [38]	Patient, Encounter, Observation, Procedure, and Related Person	Epic EHR	Local codes to LOINC, local codes to standard codes, and QUICK[ca] to different FHIR versions and profiles	EHR web services, FHIR services, Authorization services, SMART-on-FHIR, native EHR FHIR APIs, SNOMED, and LOINC	Feasibility check by clinicians	Neonatal bilirubin management

Static Data Models

Static models do not follow a sequential or linear flow of data processing; instead, they capture and integrate data in broader aspects and mainly consider data mappings rather than the flow of data. These models are more likely to focus on capturing relationships between variables. They focus on the representation and organization of data within the FHIR standard without necessarily addressing the dynamic aspects of data flow or processing. Out of 31 included articles, 6 (19%) studies were related to the development of static data models. Table 2 summarizes the important information of the articles that presented these data models.

Table 2. Static models.

Study	FHIR[a] resources	Data source	Data transformation and mapping	Standards, tools, terminologies, and models	Validation and evaluation	Use case
González-Castro et al [10]	Observation, Device, Questionnaire, QuestionnaireResponse, FamilyMemberHistory, AllergyIntolerance, Patient, Procedure, MedicationStatement, Condition, and Encounter	Patient medical records, PGD[b]	Map data elements to FHIR resources	SNOMED[c], and LOINC[d]	Mapping possibilities check	Cancer survivorship (colon and breast cancers)
Montazeri et al [39]	Patient, Observation, Condition, Medication, ServiceRequest, and Practitioner	CPOE[e] systems, Shafa Hospital (Kerman, Iran)	Data elements to FHIR	CPOE, DigiSurvey platform	Expert panel	Cardiovascular
Shivers et al [40]	AllergyIntolerance, Appointment, CarePlan, Communication, Condition, Consent, CoverageEncounter, HealthcareService, Medication, MedicationAdministration, MedicationStatement, Observation, Patient, Practitioner, Procedure, and ServiceRequest	DAK[f] data dictionaries that contain core data elements for recommendations about family planning and sexually transmitted infections	Data mappings to FHIR and semantic terminologies (*ICD*[g]*-10*, SNOMED CT[h], LOINC, and RxNorm[i])	*ICD-10*, SNOMED CT, LOINC, RxNorm, IG[j], UMLS[k], and IPS[l]	Iterative validation of mappings to identify discrepancies gaps, and errors	Family planning and sexually transmitted infections
Lambarki et al [41]	Patient, Organization, Condition, ClinicalImpression, ServiceRequest, Encounter, Observation, Procedure, and MedicationRequest	DKTK[m]	FHIR data elements to corresponding ADT[n] and ISO standard (11179-3 fields)	*ICD-10*, *ICD*-O-3[o], TNM[p], Forge, Simplifier, FHIR validator, clinFHIR, LOINC, ADT/GEKID schema, and OID[q]	FHIR validator to validate FHIR profiles	Oncology

Medical Use Case–Specific Summary of Papers

In this phase, we tried to maintain the medical domain consistency in summarizing the articles, and there may be some overlaps between the categories of each article's health care domain. In the following sections, the included papers are summarized and ordered by specific medical use cases and health care applications.

Chronic Diseases

A standard-driven methodology called Clinical Quality Language (CQL) 4NLP was developed to integrate a collection of NLP extensions represented in the HL7 FHIR standard, into the CQL to enhance EHR-driven phenotyping. Using the FHIR standard, specifically the FHIRPath system, enhanced metadata handling and querying by allowing the integration of NLP-derived metadata (such as hypotheticals and negation) into queries. The use case of this research was obesity comorbidities [20]. Another study in the obesity domain used a normalization pipeline to automatically analyze and understand the information in medical records. This FHIR-based approach could detect different sections of medical records and identify important concepts and states of obesity using discharge summaries. The methodology enhanced precise data extraction and portable EHR phenotyping [13]. A similar approach was followed to conduct a case study with obesity data sets. The objective was to predict this condition and the related comorbidities. The sample of adults was categorized into 2 groups called obesity and nonobesity considering their BMI. The design allowed the sharing of deidentified data because only higher-level concepts from knowledge bases and clinical ontologies were included in the FHIR components [35].

In another study, heterogeneous data from a pulmonary hypertension registry were integrated into the Observational Medical Outcomes Partnership–Common Data Model (OMOP CDM) data standard. Common parameters were first identified and mapped to Logical Observation Identifiers Names and Codes (LOINC) and Systemized Nomenclature of Medicine–Clinical Terms (SNOMED CT) as standard terminologies. Extracted data in the form of FHIR bundles were then transformed to OMOP CDM using the Extensible Stylesheet Language Transformations (XSLT). The researchers claimed that FHIR bundles and XSLT can be efficiently and simply used as components of an Extract, Transform, and Load (ETL) process, which can eventually increase data interoperability and applicability [22]. The goal of another research in this area was to map source variables and the value sets to FHIR data elements. The researchers developed a tool called Clinical Asset Mapping Program for FHIR to read Common Data Models (such as informatics for integrating biology and the bedside and Patient-Centered Outcomes Research Network data models) and map the items to FHIR. Using FHIR as a Common Data Model can enhance collaboration, interoperability, and data sharing among health care centers. The clinical use case in the mentioned study was "Asthma" [23].

OMOP-on-FHIR is a technology to convert data elements in OMOP CDM format to the FHIR standard. The researchers used this framework to implement 2 apps to facilitate cohort administration in the context of pediatric musculoskeletal disease research. Accordingly, FHIR can facilitate data access from OMOP CDM databases, support practical integration into health care systems, and enable the development of interoperable clinical applications [30]. For type 1 diabetes mellitus, research presented an ontology-based Clinical Decision Support System based on FHIR and Semantic Sensor Network-Based Type 1 Diabetes Ontology (FASTO). The researchers integrated the FHIR standard, clinical practice guidelines (CPGs), Basic

Formal Ontology, and Semantic Sensor Network and implemented a cloud-based interoperable mobile health system for monitoring and managing patients with this condition. Broader adoption and seamless integration within existing EHRs can be achieved through using FHIR and ontology semantics [27]. A multimethod approach involving the development of a Minimum Data Set for cardiovascular computerized physician order entry was presented in another study. The researchers identified and classified critical data elements by reviewing the content of medical records and then mapped them to the FHIR standard. The FHIR standard was used to maintain interoperability between EHR and computerized physician order entry, which can eventually avoid duplicate data entries and redundancies [39].

COVID-19 and Infectious Diseases

In the context of COVID-19, clinical data across sites were federated by maintaining a single master patient identifier and consistent demographic information. In addition, this proposed methodology was used to distribute data across networks and maintain common data elements, such as mortality status and social determinants of health data. In the aforementioned approach, the data were loaded into an FHIR Clinical Data Repository, which finally produced real-time linked repositories, including FHIR, OMOP, and Patient-Centered Outcomes Research Network. The researchers found that using FHIR as the initial canonical data model and FHIR subscription protocols for transformation and synchronization of multiple data models has potential benefits for health care research, including the automated creation of research data marts for COVID-19 research [9]. An interoperable platform based on the FHIR standard was developed for convenient reporting and sharing of the polymerase chain reaction SARS-CoV-2 tests across countries. The aim was to create a Minimum Data Set for the tests, followed by modeling associated processes and end points. Implementation continued with standards and interoperability design, software development, testing, and implementation [32]. Another COVID-19–related tool called StayHome was developed for collecting patient-reported outcomes. This reusable mobile app was designed to collect COVID-19 symptoms and share them with health care organizations. The FHIR standard was used to ensure interoperability [33]. In another study on COVID-19, the automatic generation of research ontologies through a terminology server and FHIR profiles was analyzed. The researchers also investigated the process of translating user inputs into FHIR queries. On the basis of the results, it is possible to automatically generate mapping files and ontologies for FHIR-based data and profiles [24]. FHIR-based and evidence-based CPG recommendations for patients with COVID-19 were outlined in another approach. Iterative consensus-based mapping of model elements and links to FHIR correspondences along with modeling of recommendations were covered in the mentioned framework. According to the CPG-on-FHIR architecture, the generated guideline recommendations were represented using FHIR profiles. Using this FHIR-based architecture facilitates the creation of computerized guidelines and their seamless integration into EHR systems [42]. In the fields of family planning and sexually transmitted infections, the researchers structured data dictionaries to improve the mapping procedures to FHIR and multiple terminologies, such as the International Classification of Diseases 10th Revision. The corresponding FHIR resources and codes were then identified and mapped to each data dictionary term. The goal was to prepare inputs (mappings and data dictionaries) for an implementation guide (IG) generation tool and enhance the creation of machine-interpretable guidelines [40]. To clarify, FHIR IG is a collection of guidelines and rules designed to facilitate the adaptation of profiles to align with specific care contexts and promote the standardization of information exchange [44].

Cancer Research

In the context of research in cancer clinical trials, FHIR-based pipelines can be used to automatically populate the case report forms (CRFs). The Electronic Data Capture framework was developed in a study to model colorectal cancer trials as a case study. With this strategy, real-world trials can be supported using EHR data [21]. Classification of cancer types and prediction of cancers from unknown primaries were the aims of another research in this field. In the mentioned study [25], genetic data elements (from the oncology reports of patients with cancer) and the associated phenotyping data (from an EHR) were extracted. Researchers presented a network-based infrastructure that modeled the EHR and genetic data with FHIR and Resource Description Framework (RDF) to enhance cancer prediction. In this respect, the performance of different machine learning and deep learning techniques was compared and analyzed [25]. In a paper related to colorectal cancer, data elements were extracted from the CRFs of cancer clinical trials using a data population application. The information was then mapped to an equivalent element in the FHIR cancer profile [28]. An interactive statistics and analysis platform called Shiny FHIR was implemented for ovarian cancer. The system included related R packages (R Foundation for Statistical Computing), FHIR resources, and Shiny (a web application framework). In the FHIR data modeling phase, the ovarian cancer data elements were mapped to corresponding FHIR resources. On the basis of the findings, Shiny can be used in parallel with FHIR to perform interactive analysis [29]. Another interoperable data model called Cancer Survivorship Interoperable Data Elements (CASIDE) was developed in the context of cancer survivorship. The researchers defined data elements and then mapped them to the corresponding FHIR resources. Patient information was illustrated by a collection of FHIR resources to enhance secondary use and sharing of medical data. The research declared the benefits of using FHIR-based models in conjunction with machine learning techniques. In addition, data entry tools can be seamlessly integrated with FHIR-based EHRs [10]. A harmonized data model was also developed in the context of cancer research based on FHIR. German cancer care providers are generally required to report patient data to cancer registries using a specific schema called ADT/GEKID. Therefore, in the mentioned research, the XML representation was compared to the extended version in the German Cancer Consortium (DKTK), and a codification of the cancer life cycle was created. The DKTK FHIR-based data model was represented, and the FHIR resources were identified. Other oncology FHIR profiling efforts were analyzed for reuse in DKTK. It was proved that

multiple health care domains can be efficiently modeled using the FHIR standard and that using embedded mapping annotations, FHIR can be smoothly integrated with other standards [41]. The integration of genetic data from heterogeneous sources, including EHR data and genetic reports, was provided using another FHIR-based data model. The objective was to enable the validation of the Phenome-Wide Association Studies results across different institutions using the FHIR-based data profile. The researchers used the developed model to identify cancer genotype-phenotype associations, followed by validation of the associations according to a literature review [36].

Random and General Medical Notes

The modeling capability of a data normalization pipeline (NLP2FHIR) was assessed in a study focusing on core clinical resources and unstructured EHR data. The researchers attempted to integrate the unstructured elements to develop an FHIR-based model that successfully standardized the annotated corpora [14]. Another framework was designed to integrate unstructured and structured data into an interoperable format by implementing an NLP-based pipeline using the FHIR-type system. On the basis of the results, the model facilitates the integration of NLP-driven EHR data into a standard FHIR format, supports diverse NLP tools, and provides strong extension capacities [12]. A framework presented in another research for standardizing heterogeneous annotation corpora included 2 main modules (automatic schema mapping module and expert-based annotation and verification module). The system used annotated clinical notes and proved that using FHIR with this kind of heterogeneous data can enhance data reuse as well as integration in medical NLP research [16]. A data model in the context of secure patient messages was developed based on FHIR concepts (related to base, foundation, clinical, and financial categories). The objective was to define significant information contained in these sources. After annotating the sentences and creating a huge corpus, the researchers extracted hidden topics related to 3 microconcepts (fatigue, patient visit, and prednisone as highly discussed topics) through topic modeling. The presented data model could distinguish critical concepts in messages and can be used to identify other narratives on multiple platforms [34].

Acute or Intensive Care

In the field of intensive care, researchers aimed to convert the Medical Information Mart for Intensive Care (MIMIC)-IV database elements to FHIR. This database contains patient data from intensive care departments. To support the use of MIMIC-IV on FHIR, a resource demo and a FHIR IG were also created. The benefits of using the FHIR data model are claimed to be its extensive details, which facilitate mappings and conversions of data elements [26]. A FHIR Data Harmonization Pipeline was developed in another study based on an ETL framework. The harmonization of EHR data was performed in 5 phases, including querying the hospital database, mapping the retrieved data to the FHIR format, validating the mapping, transferring the FHIR resources to the patient model database, and exporting the data to the JSON format. Consequently, raw clinical records were transformed into AI-friendly and harmonized representations of data because the hierarchical structure of FHIR may not be sufficiently accessible and standard for AI frameworks. The data could then provide the fast and generic integration of cohort identification methods, facilitating big data processing [15]. In an application for the management of bilirubin in neonates, custom FHIR interfaces were included. After extensive intrainstitutional use, several strategies were explored to modify the app for cross-institutional transfer. Adapting the app for cross-institutional dissemination included clinician-specific implementation using custom FHIR application programming interfaces (APIs), gathering user feedback, differentiating functionality based on FHIR capabilities, implementing gradual replacement with native FHIR interfaces, and using the HL7 Quality Improvement and Clinical Knowledge (QUICK) logical data model for mapping to different FHIR versions and profiles [38]. The QUICK model encapsulates specific details of FHIR (eg, the differences between elements and extensions), enabling a more focused approach to the attributes and classes. This allows for the logical data model specifications to be identified with greater clarity [45]. Another research focused on knowledge graphs (KGs) and semantic modeling. In the mentioned research, the relational databases of the OMOP were used to develop the FHIR-Ontop-OMOP system. The aim was to generate virtual KGs from the databases. The generated KGs were evaluated for the accuracy of data transformation and compatibility with FHIR RDF using an intensive care data set (including medications, vital signs, observations, survival data, and so on). This semantic system could fully represent an OMOP database as an FHIR-compliant representation using KGs, thus enhancing the interoperability of OMOP CDM and FHIR [37].

Other Conditions

A study aimed at implementing a maternal health record system with a data access model based on RESTful web services. In the proposed data model, important data elements were mapped to FHIR resources. Maintaining the related data as FHIR resources enhanced interoperability, efficient data exchange, and evidence-based decision-making [31]. Another article dealt with genetic laboratory tests. The researchers aimed to map the test elements to FHIR format based on an IG. FHIR clinical genomic IG is a beneficial and almost comprehensive tool for sharing genetic test results [43].

Technical Approaches

Overview

Concerning developing data models or infrastructures using the FHIR standard, several tools have been used in the reviewed research articles. This section summarizes the important or common tools and approaches. These items include FHIR-based tools and frameworks, machine learning approaches, and data storage and security.

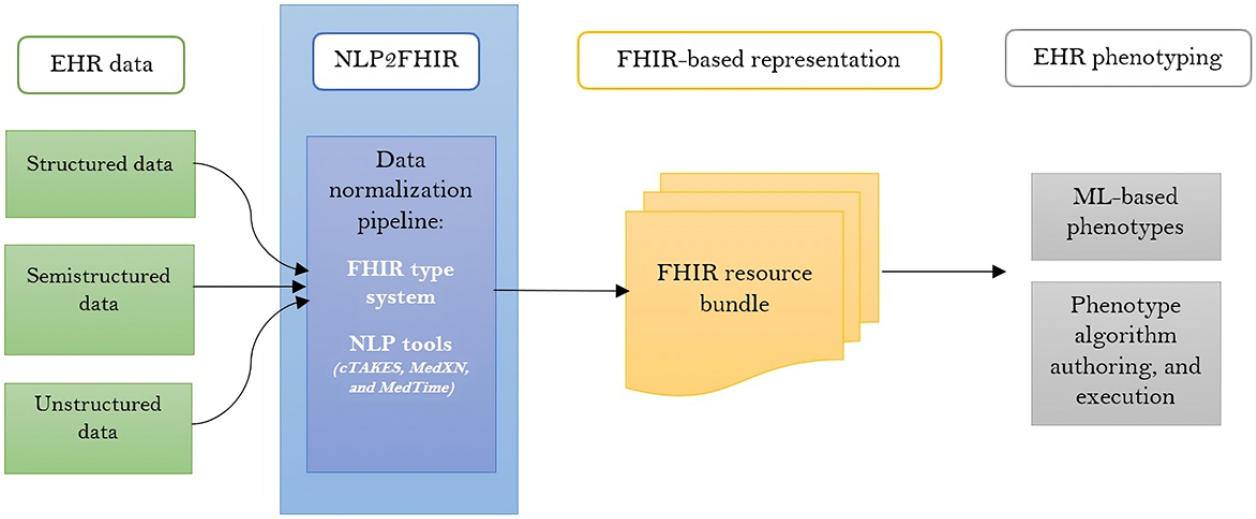
FHIR-Based Tools and Frameworks

NLP2FHIR Pipeline

In the field of NLP, there is a FHIR-related clinical data normalization pipeline called NLP2FHIR for EHR data modeling. This pipeline can be used to standardize and integrate structured and unstructured data stored in EHRs. In other words,

it can make unstructured EHR data consistent and integrate it with structured data. This procedure facilitates portable EHR-driven phenotyping and large-scale data-driven analytics. Several studies used NLP tools as part of the data model's implementation. The NLP2FHIR pipeline was used in 5 articles [13,14,20,25,35]. As shown in Figure 2, this pipeline receives the EHR data in various formats (structured, semistructured, and unstructured) as input. The pipeline itself uses the FHIR-type system as well as NLP tools. The binaries required to run this pipeline are MedTagger, clinical Text Analysis and Knowledge Extraction System (cTAKES), MedTime, Medication Extraction and Normalization (MedXN), and Unified Medical Language System Vocabulary and Terminology Service. The raw clinical data are then transformed into FHIR bundles. Phenotypes can be created based on FHIR bundles, and finally, the FHIR-based data are easily integrated into EHR systems [46].

Figure 2. NLP2FHIR data normalization pipeline and its applications [46]. cTAKES: Clinical Text Analysis and Knowledge Extraction System; EHR: Electronic Health Record; FHIR: Fast Healthcare Interoperability Resources; MedXN: Medication Extraction and Normalization; ML: Machine Learning; NLP: Natural Language Processing.



To elaborate more, MedTagger is an open-source NLP pipeline that underpins the implementation and handling of unstructured clinical data. The system differentiates between general NLP processes and task-specific NLP knowledge, enabling experts to directly encode clinical information using relevant terms and phrases [47]. cTAKES is another open-source NLP system that extracts free-text and narrative information from EHRs and enables semantic processing of this information. It is developed based on the OpenNLP toolkit and a framework called Unstructured Information Management Architecture [48]. MedTime is a hybrid framework containing both machine learning and rule-based approaches for the extraction of temporal information from unstructured clinical text. This system has a high performance in recognizing temporal expressions and clinical incidents [49]. MedXN is a system for extracting pharmaceutical information from clinical notes, making it compatible with RxNorm representation with high accuracy [50]. Unified Medical Language System Vocabulary and Terminology Service enables the interaction of the Unified Medical Language System and the different source vocabularies [51].

Using this pipeline, the data contained in discharge summaries can be transformed into FHIR resources [13]. In addition, normalization and mapping rules as well as NLP-based FHIR extensions can be implemented through NLP2FHIR. It is proven that this pipeline can be a practical tool for modeling unstructured data to eventually integrate the structured elements into models [14]. When NLP-derived artifacts are stored as FHIR extension metadata fields through NLP2FHIR, these elements can be seamlessly incorporated into queries. This integration supports more comprehensive and precise querying by including clinically relevant metadata extracted from unstructured data [20]. In a study conducted by Zong et al [25], each entry in family history records was processed by the NLP2FHIR pipeline, which involved identifying and normalizing medical concepts with MedXN, cTAKES, and MedTime tools. Liu et al [35] followed a workflow of tokenizing documents from 2 data sets and improved the embedding performance by preprocessing (eg, removing less frequent words as well as stop words). The JSON-formatted FHIR resources from the NLP2FHIR pipeline were then transferred into token-like representations categorized into FHIR resources and bundles. cTAKES was also used for concept normalization. The researchers compared the performance of models based on the information in this pipeline with models with original texts.

Substitutable Medical Apps, Reusable Technology–on-FHIR

This specification can be used for data and security requirements for health-related applications. Substitutable Medical Apps, Reusable Technology (SMART)-on-FHIR defines a workflow of secure requests for data access, as well as receiving and using that data [52]. In other words, this specification is a framework that includes web standards that are used to define health applications based on the FHIR-based data stored in an FHIR server. Marteau et al [30] developed a SMART-on-FHIR application, including a query and an upload page to enhance data organization and accessibility. The research highlights that clinicians and health care professionals can query health care applications through FHIR APIs [30]. The applications

containing SMART-on-FHIR can interact and integrate with EHR systems through APIs and provide efficient "plug and play interoperability." Kukhareva et al [38] discussed the balance between portability and functionality of SMART on the FHIR applications and how the developers should consider this balance. A comprehensive approach with the integration of user-centered and technical methods is needed to optimize this balance.

Evidence-Based Medicine–on-FHIR and CPG-on-FHIR

Evidence-Based Medicine–on-FHIR (EBMonFHIR) is a knowledge asset project on FHIR resources for EBM. The objective of EBMonFHIR is to offer interoperability for people who generate, analyze, synthesize, disseminate, and implement clinical evidence and CPGs [53]. CPG-on-FHIR is an IG that uses FHIR resources to build computable and interoperable representations of clinical guideline contents [54]. Lichtner et al [42] developed an IG that used the resources developed by EBMonFHIR to represent primary evidence and the evidence-to-decision process. These resources were eventually integrated into the CPG-on-FHIR framework. Both EBMonFHIR and CPG-on-FHIR are supported by the HL7 Clinical Decision Support staff and represent different aspects of evidence-based guideline recommendations. The former focuses on the justification aspects of the recommendations, while the latter focuses on the implementation aspects of the recommendations.

clinFHIR

clinFHIR is a web-based, open-source educational environment that also allows developers to create or search FHIR-based resources [55]. ClinFHIR graphBuilder is used to model the relationships between resources. This tool also assembles resource instances into a graph with related resources to specify a scenario using FHIR [32]. Accordingly, the structure of models can be visualized using clinFHIR software [41].

HL7 Application Programming Interface FHIR

HL7 API (HAPI) FHIR is a comprehensive implementation of FHIR in the Java language [56]. The API is available for both FHIR clients and servers [57]. Several studies used HAPI FHIR in the data model implementation process. Bennett et al [26] used the HAPI FHIR server in the process of validation, bulk export, and writing data to NDJSON files. Hong et al [29] used the API to put ovarian cancer data into FHIR resources. They also used the client API to upload structured FHIR data elements to the FHIR server. HAPI was one of the test servers that was used to assess data quality and server stability. The API can also be used in the NLP domain. Hong et al [16] used HAPI FHIR for annotation serialization; they converted the annotations to FHIR XML and JSON formats that were eventually represented in an FHIR-consistent format. The HAPI FHIR resource validator API was also used to validate the resources for compliance with the FHIR specification. In the model presented by Guinez-Molinos et al [32], the HAPI FHIR database was used to store resources, and the HAPI server was responsible for the interoperability layer of the model. The HAPI libraries were also used to construct resources, messages, and end points. For persistent storage of FHIR-based data and as an API server, Burkhardt et al [33] used HAPI FHIR V4.2.0. HAPI generally offers standard functionalities, such as create, read, update, and delete APIs, along with specialized domain-specific tools, including CQL. This capability enables developers to concentrate more on the specific needs of their app.

Machine Learning Approaches

Apart from the use of the NLP2FHIR pipeline discussed in the previous section, some other articles used simple NLP tools and algorithms to convert unstructured data into structured data elements adhering to a specific schema for better data description [21]. Hong et al [12] used Unstructured Information Management Architecture NLP tools such as MedXN and MedTime in the normalization phase to enhance interoperability. MedXN was used to extract medication extraction concepts, and MedTime was used to extract FHIR-defined temporal elements. Separate NLP extraction modules were developed to extract information directly from free text for those entities that cannot be extracted by current NLP tools. In a classification system developed by Hong et al [13], 4 machine learning algorithms, including support vector machine (SVM), random forest, logistic regression, and decision tree, were implemented to train the classifiers of the disease prediction module; the features that were used by the system were extracted from FHIR resources as well as terminology extensions. Among all methods, the random forest approach had the best performance. Zong et al [25] analyzed some deep learning and machine learning backbone models to compare the performance of cancer prediction. The bag of features (or bag of words) was used in their research based on the values of attributes in the FHIR model. A graph embedding method called Node2vec was used to learn the patient's features (a vector). Generally, 3 methods of feature generation were compared, including the bag of features, Node2vec, and the bag of features combined with Node2vec. Moreover, 7 classification algorithms were analyzed and compared (random forest, logistic regression, naive Bayes, deep neural network, SVM, graph convolutional network [GCN], and convolutional neural network). Node2vec+bag of features and random forest classifier showed the best performance. To analyze the potential of integrating the unstructured FHIR data representations into deep learning methods, Liu et al [35] used Gated Recurrent Unit, CNN, Text GCN on NLP2FHIR inputs, and raw text. The results highlighted that the best performance was achieved by using the Text GCN classifier in NLP2FHIR input. Therefore, this combination can enhance interoperable EHR phenotyping.

In the data model presented by Zong et al [28], NLP tools were used to provide structured data for the ETL process from unstructured data (such as surgical reports). To cluster each patient in the patient subgrouping process, a model called Dirichlet Multinomial Mixture was used. In the Dirichlet Multinomial Mixture model, one document represents a single topic, which makes it suitable for clustering short texts. The genetic relationship extractor that was developed by Hong et al [16] used SVM as a learning model; the goal was to extract the "FamilyMemberHistory.relationship" FHIR element. Eventually, the NLP performance of the corpora was analyzed. On the basis of the results, an NLP engine can be developed on a pooled corpora that offers enough annotations to train a model. To learn the concealed topics of patient messages, De et al [34] used

latent Dirichlet allocation, an unsupervised topic-learning model. It was claimed that latent Dirichlet allocation is effective in finding common topics with well-known terms but, at the same time, tends to overlook less frequent yet important topics in patient messages.

Data Storage and Security

Several studies used PostgreSQL (also known as Postgres) as the database management system [15,26,30,33]. This system is an SQL-based open-source relational database management system that is compatible with JSON document storage. In the study of Williams et al [15], data storage was based on FHIR resource type, and each resource was mapped to a separate JSON structure. Bennett et al [26] used the MIMIC-IV database; the data contained in the data source was loaded into Postgres and the HAPI FHIR server. The data elements were then mapped to JSON within that system. The research indicated a substantial increase in storage requirements when data is converted to FHIR and further when inserted into HAPI FHIR. Specifically, the HAPI FHIR format required significantly more storage space compared to the basic relational structure. To store the "OMOP CDM database" generated by the Synthea synthetic patient generator, Marteau et al [30] used Postgres. The database was then modified to incorporate additional data needed for OMOP-on-FHIR. A PostgreSQL client application (psql) was subsequently used to interact with the database.

Burkhardt et al [33] also used this system along with the Apache web server in their proposed architecture. By contrast, Ismail et al [31] used MongoDB (NoSQL, or nonrelational data storage) for efficient data record manipulation processes. MongoDB can conveniently handle JSON structure, which is the format of the FHIR resources sent and received by servers. Using MongoDB provides a straightforward transformation of JSON objects into JSON documents, making storage and management more efficient. The database can handle FHIR resource searches based on specified criteria. This is facilitated by the MongoDB Data Access Object component that is responsible for validating the JSON strings received from clients.

Some researchers implemented OAuth for security purposes [27] and used Keycloak as an identity provider [33]. JSON Web Token was also used in other studies [32,33] to provide authentication services. This token securely shares information between end points by a JSON object.

Resource Frequencies

Table 3 illustrates the frequency of each resource in the included articles. It should be mentioned that in this section, we only discuss the official base FHIR resources, and the items mainly considered as profiles, extensions, or domain-specific resources are not illustrated here (eg, "LabTest, Imaging, Referral, Risk, CoverageEligibility, ClaimPayment, ProcedureRequest, Dosage, and DeviceUseStatement" [27,34,38,40]).

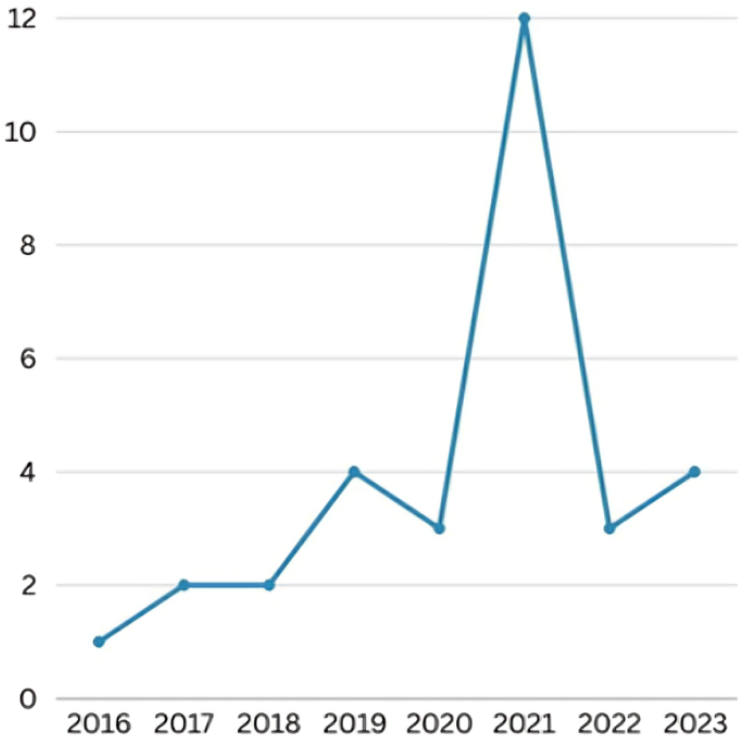
Table 3. Frequency of Fast Healthcare Interoperability Resources (FHIR) resources mentions in the included articles (n=31).

FHIR resources	Articles, n (%)
Observation	21 (68)
Condition	19 (61)
Patient	18 (58)
Procedure	16 (52)
Encounter	11 (35)
MedicationStatement	10 (32)
FamilyMemberHistory and Practitioner	8 (26)
MedicationRequest and Medication	7 (23)
Composition and CarePlan	5 (16)
MedicationAdministration, Questionnaire, AllergyIntolerance, Organization, and ServiceRequest	4 (13)
QuestionnaireResponse, DiagnosticReport, Specimen, RelatedPerson, Device	3 (10)
ValueSet, Immunization, AdverseEvent, Location, NutritionOrder, Communication, Consent, HealthcareService, and Appointment	2 (6)
CodeSystem, MedicationDispense, Goal, EpisodeOfCare, CareTeam, DocumentReference, BodyStructure, ExplanationOfBenefit, Account, Coverage, ClinicalImpression, EvidenceVariable, PlanDefinition, ActivityDefinition, Citation, ArtifactAssessment, Evidence, Group, Bundle, ConceptMap, PractitionerRole, RiskAssessment, Task, DeviceRequest, and SupplyRequest	1 (3)

Publication Distribution

Figure 3 illustrates the distribution of included studies according to the publication year. As shown in the figure, the year 2021 encompassed the highest number of publications.

Figure 3. Yearly distribution of reviewed articles.



Limitations and Challenges of Developing Data Models

Overview

Data model development can present many challenges and constraints arising from issues of data integration, interoperability, standardization, performance, scalability, generalizability, etc. In this section, we discuss the significant challenges and limitations identified in the reviewed papers, which researchers should take into account when developing FHIR-based data models and architectures. It is worth noting that there would be overlaps in the categorization of limitations and challenges.

Data Integration

It is the process of combining data from multiple sources and creating a unified data set. The initial stage of working on data analysis, reporting, and forecasting is data integration [69].

Regarding data integration, the problems mentioned in the analyzed papers include requiring some manual ETL processes [9], manual download of FHIR resources [12], reproducibility issues [20], maintaining robustness [9,20], using only 2 data sets and information loss [13], challenging content normalization [14], single CRF with limited data elements and inadequate questions [21], quality and completeness of the database documentation and nonautomatic concept recognition and considerable data preparation process [15], using incomplete synthetic database [30], no data curation during transformation, bias in database [26], storage space costs [26,33], maintaining inadequate aspects of data [27], synchronization issues and hard-coded mapping [22], privacy and confidentiality issues and limited corpora reuse [16], ignoring continuous changing of values over time [25], lack of comprehensive use of health care records due to lack of education and awareness [31], mapping rules based on only 2 use cases and not including information about generic data [10], manual FHIR mapping and reviewing data of only 1 setting [39], the requirement to implement a structured information model to an existing data dictionary [40], issues with ADT data set as a national reference (completeness and accuracy) [41], and no robust mapping [37].

Interoperability

Interoperability issues are related to the limitations in the seamless transfer and exchange of information between medical systems or applications [70].

Interoperability issues mentioned in the papers include reproducibility concerns [20], organizational interoperability issues [24], privacy and confidentiality issues [16], synchronization issues and hard-coded mapping [22], no evidence to attain a balance of functionality and portability and dissemination barriers due to development and integration costs [38], and extra mapping effort, which affects flexibility and adaptability of the framework [36].

Data Standardization

It is a crucial step in transforming data into a uniform format to enable the shared use of advanced tools and techniques, large-scale analytics, and collaborative research [9,71]. Therefore, standardization issues are related to challenges in attaining standard and consistent data representation across different medical systems.

The issues that could be categorized into the data standardization challenges include difficult rule-changing in compiled java code

for data transformation [9]; semantic gaps between NLP system's data model and FHIR specification [14]; no adequate standardization [12]; mapping accuracy issues [15]; handling valid source system data with no match in FHIR [23]; SNOMED CT postcoordination limitations [24]; not mapping to the US Core as standard ontology, not mapping other databases linked to MIMIC-IV, and not covering some clinical modifiers and qualifiers by FHIR redefinitions [16]; SNOMED coverage restrictions [10]; manual FHIR mapping [39]; duplication of the mapping terms and the necessity to assess the need for a new FHIR profile versus continuing with the existing one [40]; LOINC codes for some observations (SNOMED could be used instead), no available code systems for many value sets, and lack of ubiquitous adoption of FHIR profiles due to the issues with SNOMED license [41]; requiring constant synchronization to the updates because the model was based on EBMonFHIR resources (have low maturity level and subject to changes) and impossibility of showing all guideline information in the FHIR resource format [42]; no textual structure due to lack of gold standard labels, not using syntax-based features for semantic representation, and elimination of some contextual information [35]; translation issues (from OMOP to preferred code systems of FHIR) [37].

Performance

Performance issues are related to obstacles in the efficient processing and retrieval of data that can compromise system performance, for example, the data are not processed within an acceptable response time [72].

According to the analyzed papers, performance issues include integration speed limitations due to transactional EHR [9], performance limitations [13], lack of sophisticated evaluation method [21], limited implementation assessment [30], performance validation issues and no validation for real questions [28], technical challenges [29], model's limited functionality and lack of comprehensive specification [10], no evidence to attain a balance of functionality and portability [38], reduced response rate due to using a web-based questionnaire [39], no execution engine available for representation format [42], evaluation and validation [34], performance rate lower than others and low F_1-score [35], evaluation issues (one instance of MIMIC-III OMOP CDM, no rigorous evaluation) and no comprehensive assessment [43].

Scalability

Scalability limitations can be considered as the data model's weakness in handling increasing data volume or workload.

Generalizability

Generalizability problems are challenges in the applicability of the data model to other aspects or settings.

Considering the selected papers, scalability and generalizability limitations include few resources being used [15]; limited corpora reuse [16]; not enough compatibility and generalizability experiments [15]; not using a real environment [27]; possible bias when conducting a similar study and challenging generalizability for other types of a disease (in this case other cancers) [28]; restriction in the adaptability of the best-performing prediction model and requiring more complex methods to empower prediction and cover diversity [25]; the generalizability issues of the platform [32]; no broad adoption of the app due to issues related to resources and expertise, the best performance for specific programs [33]; few data models are used with no exhaustive evaluation [35]; low contribution to the medical field, failure to distinguish differences in genetic data, low resources for evaluation, and lack of comprehensive data modeling comparisons [36]; and not studying other test types and small sample size [43].

Discussion

Principal Findings

In this review, we aimed to provide a comprehensive PRISMA-based overview of data models using FHIR in the context of interoperability, structure, and functionality and summarize the state of the art for developing FHIR-based data models. In addition, we highlighted limitations, challenges, advantages, and opportunities brought about by FHIR data models. On the basis of the reviewed papers, the most common resources were from the "Clinical" (Observation and Condition) and "Base" (Patient resource) categories of FHIR resources. To develop the models, researchers focused more on the use cases, such as chronic diseases, cancer, COVID-19 and infectious diseases, and intensive care. The reason may be the availability of data in these fields. For instance, Mayo Clinic's clinical data warehouses provide cancer data for researchers. Moreover, i2b2 and MIMIC offer health care data sets about chronic diseases such as obesity. MIMIC-IV on FHIR is also accessible for research in critical care, which provides deidentified FHIR-based data [26].

In terms of limitations, data integration issues are among the most significant challenges in developing data models. The necessity for manual ETL processes, the potential for information loss, and the use of constrained and incomplete data sets can impede the data integration process. Furthermore, organizational differences and hard-coded mappings complicate the seamless exchange of data, affecting interoperability. Issues, such as speed limitations and a lack of robust evaluation metrics, negatively impact performance. In addition, scalability and generalizability are further hindered by limited resources, insufficient compatibility experiments, and small sample sizes.

However, apart from the limitations and challenges, there are numerous advantages to using FHIR-based data models. This standard uses a set of resources and attributes (either common or unique) that enhance data modeling procedures. Constraining the attributes based on an adaptation of clinically relevant ontologies, such as *International Classification of Diseases, Ninth Revision (ICD-9)*, and *International Classification of Diseases, Tenth Revision (ICD-10)*, LOINC, and SNOMED CT, is done through common data types (eg, codeable concepts and string). FHIR can be integrated with other data models, such as RDF, to provide a network-based model for disease prediction. It also supports feature generation and network population in these frameworks [25].

The use of the FHIR models provides the potential to significantly enhance the efficiency and effectiveness of health care research [9,15,29]. CRFs can be automatically populated with FHIR-based EHR data [21], and this automation can identify patient subgroups by topic modeling [28]. EHR data can also be harmonized and mapped to FHIR elements to enhance interoperability and quality of care [15]. Therefore, accessing health-related data for research would be more efficiently achieved when the data are in the FHIR format. Researchers and practitioners can access FHIR app galleries through FHIR APIs and SMART-on-FHIR applications, which can promote health care research and quality of care. FHIR also enables health care professionals to create use case–specific and customized applications [30]. However, implementing SMART-on-FHIR apps poses multiple dissemination challenges and barriers because FHIR-based APIs are not generally considered in the initial stages of implementation in some EHRs [38]. By contrast, as more EHRs choose FHIR as a data exchange standard, nonacademic health care settings will also tend to produce FHIR-formatted data with their EHR systems using FHIR APIs [23]. Maintaining health care data in the format of FHIR resources and using RESTful APIs provide more efficient data transmission compared to conventional record-keeping methods [31].

Another possibility is to use patient messages in web-based portals for health care research. In this respect, a FHIR data model can be developed to extract essential information and concepts from this type of data; FHIR is a beneficial option because it encapsulates modular actions and concepts in health information sharing [34]. Moreover, FHIR exports of local data repositories increase data interoperability for systems and data warehouses [22]. Using FHIR ensures standardized data representation, supports data quality through validation tools (eg, IGs and FHIR specifications), offers flexible adaptation, and benefits from strong community support [35]. The transition of traditional medical guidelines to machine-readable FHIR IGs is a sophisticated and advancing process and needs validation approaches. These use case–specific IGs can eventually enhance real-world application and interoperability of the clinical guidelines [40], considering the constant feedback and inputs from related health care communities [43]. Furthermore, it is crucial to thoroughly follow domain-specific FHIR IGs to gain optimal semantic interoperability. However, even with this guidance provided by IGs, developers still have to make numerous representation and implementation decisions, which may not always be ideal [33].

Evidence-based and computer-interpretable guidelines can be developed using structured data from frameworks' evidence and reviews, followed by mapping the derived items to EBM-on-FHIR resources. This approach aligns with the CPG-on-FHIR framework and includes FHIR profiles and IGs [42].

On the basis of the results of a research paper on using the FHIR standard in oncology, specific health care domains can also be modeled with minimal gaps between FHIR and other standards using annotations of embedded mappings [41]. In addition, in the field of EHR phenotyping and data capture, using FHIR-based data normalization pipelines is considered valuable and beneficial [13]. Using FHIR-based NLP extensions and FHIR composition resources represents NLP components in phenotyping algorithms [20]. Inherently, as mentioned earlier, FHIR resources have granular and atomic characteristics that enable them to share only the required elements for specific use cases and purposes rather than a wide range of elements. This feature is useful for developing specialized AI platforms and interpreting machine learning algorithms [10]. By contrast, this multilayer and complex structure of FHIR may cause some accessibility issues for AI algorithms. To be useful for AI, FHIR data often need to be transformed into a simpler format with a higher level of abstraction, making it more compatible with typical data preprocessing tools. This transformation seems to be necessary to make the data more manageable and easier to analyze by AI systems [15].

Using machine learning algorithms and NLP models is advantageous when integrating with FHIR data models and structures [12] in cases such as standardizing heterogeneous corpora [16]. FHIR modeling for EHR data enhances data integration, data transmission, translational research, and phenotyping [12]. Similarly, the NLP2FHIR pipeline can be used to enhance the standardization of unstructured EHR data [14]. The researchers illustrated how deep learning models can be effectively transferred and used across different settings or systems when dealing with data that have been processed using NLP2FHIR representations. This pipeline performed better in text classification in comparison with models using original texts [35].

Limitations

This review has some limitations. First, we focused only on the articles that dealt with specific use cases with real-world data. By contrast, this approach enabled us to gain insight into the practical applications of the subject matter in real-world contexts rather than merely theoretical ones. In this review, we may have some generalizability issues or biases, especially in the resources and methodologies used and with ontological, general, and theoretical data models. Second, we did not analyze articles published in languages other than English, so we potentially missed some articles due to this criterion. Third, because we did not thoroughly analyze the gray literature and preprints, and due to the relatively small number of included articles, some results may not be generalizable to the entire field of FHIR data modeling.

Comparison With Prior Work

There are some valuable review studies considering the FHIR standard (Table 4). In a scoping review, Balch et al [58] investigated machine learning–based clinical information systems that used the FHIR standard. The focus of the review was to analyze analytics and data management platforms, CDSSs, and APIs and assess the systems' functionalities as well as strengths and weaknesses. Then, the researchers proposed a clinical structure that integrated FHIR and machine learning techniques.

Table 4. The summary of previous reviews considering FHIR[a].

Study, year	Title	Items included in the review
Balch et al [58], 2023	Machine Learning–Enabled Clinical Information Systems Using Fast Healthcare Interoperability Resources Data Standards: Scoping Review	• Investigation of FHIR-based systems using machine learning methods focusing on decision support, data analytics, and APIs[b] • PRISMA-ScR[c] guideline's steps • Categorization of the articles based on functionalities, limitations, and strengths • Proposing a machine learning–based system using FHIR
Nan and Xu [59], 2023	Designing Interoperable Health Care Services Based on Fast Healthcare Interoperability Resources: Literature Review	• Reviewing FHIR-based studies about interoperable health services • Study year and country distributions and charts • Flowchart of paper selection • Clinical categorization of studies and corresponding FHIR resources • Data model migrations to FHIR • Data management methods • Data integration modes • Presenting a FHIR practice design and its development architecture • Commonly used tools
Pimenta et al [60], 2023	Interoperability of Clinical Data through FHIR: A review	• Some selected examples and applications of FHIR (data standards, analysis, API implementations, and research) • PRISMA[d] chart
Pavão et al [61], 2023	The Fast Health Interoperability Resources (FHIR) Standard and Homecare, a Scoping Review	• Home care research studies focusing on FHIR • Screening and inclusion details • FHIR resources • Technological tools in the implementation phase • Privacy and security measures
Ayaz et al [62], 2021	The Fast Health Interoperability Resources (FHIR) Standard: Systematic Literature Review of Implementations, Applications, Challenges and Opportunities	• Focusing on FHIR and EHR[e]; all articles dealt with FHIR related to research questions • Screening and inclusion details • Study year, type, and country distributions • Primary subject categories over time • FHIR resource list • Types of applications that leverage FHIR • Data mappings form or to FHIR • Objectives of using FHIR • Challenges of using FHIR
Vorisek et al [63], 2022	Fast Healthcare Interoperability Resources (FHIR) for Interoperability in Health Research: Systematic Review	• FHIR-based implementations in health care research • PRISMA flowchart for article inclusion • Study year distribution and coauthorship network chart • Research domains • FHIR applications, international standards, and medical domain • FHIR resources • Items mapped to FHIR • Objectives of using FHIR • Limitations of using FHIR
Duda et al [64], 2022	HL7[f] FHIR-based tools and initiatives to support clinical research: a scoping review	• Trends and gaps in using FHIR in health care research • PRISMA flowchart for article and project inclusion • The expansion of Marquis-Gravel categorization [43] of FHIR-based projects contributing to research, in the categories of preparation, prestudy, study setup, recruitment, study conduct, and poststudy activities • Gaps in using FHIR in clinical research
Lehne et al [65], 2019	The Use of FHIR in Digital Health - A Review of the Scientific Literature	• Investigation of using FHIR in digital health care • Article selection flowchart • Study year and article category distribution charts • Abstract text mining for most frequent words
Yogesh and Karthikeyan [66], 2022	Health Informatics: Engaging Modern Healthcare Units: A Brief Overview	• FHIR architecture in health care units • Narrative explanation of FHIR definitions, FHIR data layers and resources, and workflow relations • Health informatics challenges, some related to FHIR

Study, year	Title	Items included in the review
Schweitzer et al [67], 2022	Data Exchange Standards in Teleophthalmology: Current and Future Developments	• Interoperability standards in the field of store-and-forward ophthalmology • Reviewing IHE[g], HL7 standards, DICOM[h], and health care terminologies
Torab-Miandoab et al [68], 2023	Interoperability of heterogeneous health information systems: a systematic literature review	• Interoperability in heterogeneous health care systems • PRISMA flowchart for article selection • Charts and figures for frequencies and trends of interoperability articles • Summary and categorization of interoperability standards and architecture components • Word cloud figures for frequent standards and platforms • Interoperability levels

[h]DICOM: Digital Imaging and Communications in Medicine.

Nan and Xu [59] reviewed FHIR-related papers on designing and building interoperable health care services with a focus on data standardization, management, and integration. The researchers analyzed detailed processes and techniques for each group, resulting in a comprehensive FHIR practice guideline. Similar to our research, Nan and Xu [59] reviewed important techniques and FHIR resources for developing health care services. The difference between this research and our study is the focus of the research; they [59] investigated a broader range of FHIR-based studies and services, while we focused more on data models and infrastructures.

Pavão et al [61] reviewed research articles using the FHIR standard in home care services. The researchers aimed to analyze FHIR resources, types of home care applications, privacy and security considerations, and deployment tools. Pimenta et al [60] reviewed interoperability with FHIR and summarized some important points and examples. The researchers selected some articles and extracted FHIR applications in each study. Ayaz et al [62] in 2021 reviewed all aspects of FHIR in the articles published from January 2012 to December 2019. Our study also considered more recent articles from 2020 to 2023. The main objective of their study was to analyze the articles according to the implementation, challenges, future applications, and opportunities of this standard. The researchers reviewed articles that focused on all categories, including apps, FHIR implementation models, FHIR resources, FHIR framework, mapping framework and data model, challenges, and FHIR goals. The researchers also summarized the resources used in the included articles; "Observation" and "Patient" resources, respectively, were the most commonly used resources in the included articles. We also performed this analysis and had close results; as we mentioned earlier in our study, "Observation," "Condition," and "Patient" resources were used more frequently. The mentioned researchers also discussed the mapping approaches from other techniques or methods to FHIR. The focus of the study by Vorisek et al [63] was to review the FHIR standard from a "health research" perspective. The researchers analyzed the studies that used FHIR in any aspect of the research process, such as data collection, recruitment, data standardization, analysis, and consent management. In addition, they categorized the articles with generic or specific clinical specialty approaches. We also categorized our articles based on the medical field. In the mentioned research, it was reported that most studies used other terminologies and data models besides FHIR, which included SNOMED CT, LOINC, International Classification of Diseases 10th Revision, OMOP CDM, and more. It was reported that among "data capture–related" studies, the "Questionnaire" resource was used more frequently, as expected. In addition to the scientific aspects, the limitations of using FHIR were similarly discussed. They highlighted that the limitations may include the evolving contents of FHIR resources, legal issues, safety, and the need to have an FHIR server. In our study, by contrast, we categorized the limitations into other aspects.

Regarding the medical research aspects of FHIR, Duda et al [64] also presented a literature review. The study extended the "Marquis-Gravel categories" [73], in which it is possible to categorize the way each project contributes to research tasks. The FHIR projects focused on research were investigated, which included the activities of preparation (eg, mapping to and from FHIR), prestudy (eg, defining or refining of cohorts), study design (eg, data collection for research), recruitment (eg, including screening criteria in EHR), study conduct (eg, patient data collection), and poststudy (eg, data sharing). Most projects focused on "general research preparation" (eg, infrastructure and data pipeline development). Lehne et al [65] reviewed the application of FHIR in digital health. On the basis of their research, the reviewed articles were mostly related to data models, mobile or web applications, and medical devices. Yogesh and Karthikeyan [66] reviewed the FHIR architectural specifications, such as the linkages, workflow state, health informatics, and public health safety approaches using this standard. The researchers also highlighted the likely challenges with health care data standards, including coding speed and accuracy issues, code mappings, compatibility issues between

new and legacy systems, and communication concerns between EHRs and patients.

Some other articles reviewed general interoperability and data exchange standards. In the research conducted by Schweitzer et al [67], the researchers narratively described and compared exchange approaches, such as Digital Imaging and Communications in Medicine (DICOM), the Integrating the Health Care Enterprise initiative, and clinical terminologies (such as SNOMED CT) as well as FHIR in the field of teleophthalmology. In their research, the ophthalmology-related FHIR resource, which is "VisionPrescription," as well as the current proposal of the related IG were discussed. Torab-Miandoab et al [68] reviewed interoperability approaches and requirements for semantic interoperability between heterogeneous health information systems. It was found that FHIR, Clinical Document Architecture (CDA), Service-Oriented Architecture, Reference Information Model, Health Insurance Portability and Accountability Act security act, SNOMED CT, XML, JAVA, SQL, and API can be considered the most important requirements to implement semantic interoperability. On the basis of the results, a summary of interoperability standards in the context of terminology, content, transport, and security was also presented. The researchers highlighted the categorization of interoperability architecture components with the main categories of service-oriented architecture, archetype-based, web-based, client-server, multiagent, blockchain-based, XML-based, cloud-based, ontology-based, object-oriented, and local network.

Future Directions and Recommendations

In the course of this study, we encountered some ideas and recommendations for future research. These included the following: (1). a comparison of health care data models with the use of FHIR and other standards, including earlier versions of HL7 interoperability standards (such as HL7-version 2 and version 3 and CDA), OpenEHR, and OMOP CDM. The aim would be to provide a detailed analysis of the models created with these standards, focusing on the methodological aspects, limitations, strengths, and maintenance of interoperability. (2). an examination of the ontological aspects of data models and a discussion of how they represent medical terminologies and concepts.

Conclusions

FHIR serves as a highly promising interoperability standard for developing real-world health care applications. The integration of FHIR with other data models facilitates the development of more interoperable domain-specific solutions and improves research efficiency. In addition, the implementation of FHIR modeling for EHR data facilitates the integration, transmission, and analysis of data while also advancing translational research and phenotyping. Several FHIR data models have been developed to enhance the extraction of essential information and concepts from unstructured data such as patient summaries retrieved from EHRs. Generally, FHIR-based exports of local data repositories improve data interoperability for systems and data warehouses across different settings. However, ongoing efforts to address existing limitations and challenges are essential for the successful implementation and integration of FHIR data models.

Abstract

Background: Large language models (LLMs) have substantially advanced natural language processing (NLP) capabilities but often struggle with knowledge-driven tasks in specialized domains such as biomedicine. Integrating biomedical knowledge sources such as SNOMED CT into LLMs may enhance their performance on biomedical tasks. However, the methodologies and effectiveness of incorporating SNOMED CT into LLMs have not been systematically reviewed.

Objective: This scoping review aims to examine how SNOMED CT is integrated into LLMs, focusing on (1) the types and components of LLMs being integrated with SNOMED CT, (2) which contents of SNOMED CT are being integrated, and (3) whether this integration improves LLM performance on NLP tasks.

Methods: Following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines, we searched ACM Digital Library, ACL Anthology, IEEE Xplore, PubMed, and Embase for relevant studies published from 2018 to 2023. Studies were included if they incorporated SNOMED CT into LLM pipelines for natural language understanding or generation tasks. Data on LLM types, SNOMED CT integration methods, end tasks, and performance metrics were extracted and synthesized.

Results: The review included 37 studies. Bidirectional Encoder Representations from Transformers and its biomedical variants were the most commonly used LLMs. Three main approaches for integrating SNOMED CT were identified: (1) incorporating SNOMED CT into LLM inputs (28/37, 76%), primarily using concept descriptions to expand training corpora; (2) integrating SNOMED CT into additional fusion modules (5/37, 14%); and (3) using SNOMED CT as an external knowledge retriever during inference (5/37, 14%). The most frequent end task was medical concept normalization (15/37, 41%), followed by entity extraction or typing and classification. While most studies (17/19, 89%) reported performance improvements after SNOMED CT integration, only a small fraction (19/37, 51%) provided direct comparisons. The reported gains varied widely across different metrics and tasks, ranging from 0.87% to 131.66%. However, some studies showed either no improvement or a decline in certain performance metrics.

Conclusions: This review demonstrates diverse approaches for integrating SNOMED CT into LLMs, with a focus on using concept descriptions to enhance biomedical language understanding and generation. While the results suggest potential benefits of SNOMED CT integration, the lack of standardized evaluation methods and comprehensive performance reporting hinders definitive conclusions about its effectiveness. Future research should prioritize consistent reporting of performance comparisons and explore more sophisticated methods for incorporating SNOMED CT's relational structure into LLMs. In addition, the biomedical NLP community should develop standardized evaluation frameworks to better assess the impact of ontology integration on LLM performance.

KEYWORDS

SNOMED CT; ontology; knowledge graph; large language models; natural language processing; language models

Introduction

Background

The recent emergence of large language models (LLMs), exemplified by Bidirectional Encoder Representations from Transformers (BERT) [1] and GPT [2], has significantly advanced the capabilities of machines in natural language understanding (NLU) and natural language generation (NLG). Despite achieving state-of-the-art performance on a range of natural language processing (NLP) tasks, LLMs exhibit a deficiency in knowledge when confronted with knowledge-driven tasks [3]. These models acquire factual information from extensive text corpora during training, embedding this knowledge implicitly within their numerous parameters and consequently posing challenges in terms of verification and manipulation [4]. Moreover, numerous studies have demonstrated that LLMs struggle to recall facts and frequently encounter hallucinations, generating factually inaccurate statements [5,6]. This poses a significant obstacle to the effective application of LLMs in critical scenarios, such as medical diagnosis and legal judgment [7].

Efforts have been made to address the black box nature of LLMs and mitigate potential hallucination problems. Approaches include enhancing language model (LM) veracity through strategies such as retrieval chain-of-thought prompting [8] and retrieval-augmented generation [9]. Another significant avenue involves integrating knowledge graphs (KGs) or ontologies into LMs using triple relations or KG subgraphs [7,10]. KGs, renowned for their excellence in representing knowledge within a domain, can provide answers when combined with LMs [11], making them valuable for common sense–based reasoning and fact-checking models [12]. However, LLMs often face challenges when trained and tested predominantly on general-domain datasets or KGs, such as Wikipedia and WordNet [13], making it difficult to gauge their performance on datasets containing biomedical texts. The differing word distributions in general and biomedical corpora pose challenges for biomedical text mining models [14].

Biomedicine-specific KGs may be a potential solution to the abovementioned problems. In the biomedical domain, KGs, also known as ontologies, are relatively abundant, with the Unified Medical Language System (UMLS) [15] being one of the most frequently used ontologies [16]. The UMLS serves as a thesaurus for biomedical terminology systems such as the Medical Subject Headings, International Classification of Diseases, Gene Ontology, Human Phenotype Ontology, and SNOMED CT, all curated and managed by the United States National Library of Medicine.

Among UMLS member terminologies, SNOMED CT stands out as the most comprehensive biomedical ontology, encompassing a wide range of biomedical and clinical entities, including signs, symptoms, diseases, procedures, and social contexts [17]. These entities are represented by concepts (clinical ideas), descriptions (human-readable terms linked to concepts), and relations (comprising hierarchical *is-a* relations and horizontal attribute relations). As SNOMED CT is increasingly integrated into electronic health record (EHR) systems, as required by the Fast Healthcare Interoperability Resource (FHIR) to ensure interoperability among health care institutions [18], terminology servers supporting SNOMED CT have become ubiquitous. With its ready availability across health care institutions, SNOMED CT has gained attention as a knowledge source or ontology for representing biomedical and clinical knowledge [17]. In this case, the abstract model of SNOMED CT is used to describe and store biomedical facts in a hierarchical and structured manner, readily available across health care institutions.

Integrating SNOMED CT into LLMs holds significant potential for advancing various aspects of health care and biomedical research. By incorporating the comprehensive and structured biomedical knowledge from SNOMED CT, LLMs can better understand medical terminology, relationships between clinical concepts, and domain-specific context, potentially reducing errors and hallucinations when understanding or generating biomedical texts. This integration could enhance clinical decision support systems, improve the accuracy of automated coding and billing processes, facilitate more precise information retrieval from medical literature, and support the development of personalized medicine approaches. Furthermore, it may enable more accurate NLP of clinical notes and medical records, potentially leading to improved patient care and outcomes through better data analysis and insights.

Objectives

This scoping review aimed to examine the use of SNOMED CT as a knowledge source to be incorporated into LLMs, specifically focusing on the methodology of integrating these 2 modalities. This review sought to answer the following research questions: (1) What are the dominant types and components of LLMs being integrated with SNOMED CT? (2) Which contents of SNOMED CT (ie, descriptions, relations, or entity classes) are being integrated into LLMs? and (3) Does the integration of SNOMED CT into LLMs improve the performance on NLP tasks in terms of NLU and NLG? Answers to these questions could suggest future methodological approaches for more effectively integrating human-engineered knowledge into LLMs.

Methods

This scoping review was guided by the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) framework, which outlines the recommended steps and reporting standards for conducting scoping reviews (Multimedia Appendix 1) [19].

Study Identification

We defined LLMs as transformer-based LMs pretrained on large-scale corpora [20] (Multimedia Appendix 2). Given that transformer-based models currently dominate in the field and

are likely to continue doing so in the coming years, reviewing other LMs, such as recurrent neural networks and more conventional statistical models, does not hold scientific significance for current and future applications. Therefore, focusing on transformer-based models allows a more cohesive and in-depth analysis of the most relevant and cutting-edge techniques in the field.

To explore scientific literature describing transformer-based models, we conducted our literature search on ACM Digital Library, ACL Anthology, IEEE Xplore, PubMed, and Embase on March 12, 2024, using the following query terms: (1) ("language *model" OR "pretrained *model" OR "language processing" OR "embedding") AND ("SNOMED" OR "Unified Medical Language System" OR "UMLS" OR "*medical") AND ("knowledge graph" OR "ontolog*" OR "knowledge*base" OR "knowledge infusion") and (2) ("SNOMED") AND ("large language model" OR "BERT" OR "GPT"). Queries were modified according to the bibliographic databases when necessary. Queries were designed to search for articles published from 2018 to 2023. The start date of the query was set to 2018 when BERT, the first transformer-based LM to gain widespread adoption, was introduced, marking the beginning of significant research into transformer-based LLMs.

Study Selection

Articles were extracted from ACM Digital Library, ACL Anthology, IEEE Xplore, PubMed, and Embase. Duplicates were removed, and 2 authors (SS and EC) examined the full text of the retrieved articles for the presence of the term "SNOMED." We prioritized a full-text search first before title and abstract review because many potentially eligible papers do not explicitly mention "SNOMED" in their titles or abstracts. To be eligible for our review, articles had to have SNOMED CT incorporated into NLP pipelines, which encompass processes from text cleansing through pretraining and inference to model evaluation, specifically for tasks involving NLU and NLG. We then further excluded studies that met ≥1 of the following criteria: (1) published in languages other than English; (2) categorized as reviews, surveys, keynotes, or editorial articles; (3) did not incorporate SNOMED CT at any stage of the NLP pipeline; (4) aimed to create, develop, enrich, or enhance ontologies or graphs; (5) did not involve the processing of natural language (NL) text; or (6) solely used SNOMED CT codes for retrieving patients of interest from EHRs or for annotating instances with SNOMED CT codes as gold-standard target labels for LM training.

Result Synthesis

Through discussions and qualitative assessments, we analyzed the included articles according to the following characteristics: chronological and geographic publication trends, baseline LLM and its output, dataset used for training and testing the model, methods for integrating SNOMED CT into the LLM, and the model's end task and performance (Textbox 1).

Textbox 1. Methods for synthesizing the review.

Synthesis of results

- Chronological and geographic publication trends
- Baseline large language model (LLM) and its output
- Dataset used for training and testing the model
- Methods for integrating SNOMED CT into the LLM (methodologies for knowledge graph [KG]–enhanced LLMs [7])
  - KG-enhanced LLM pretraining: works that apply KGs during the pretraining stage and improve the knowledge expression of LLMs
  - KG-enhanced LLM interpretability: works that use KGs to understand the knowledge learned by LLMs and interpret the reasoning process of LLMs
  - KG-enhanced LLM inference: research that uses KGs during the inference stage of LLMs, which enables LLMs to access the latest knowledge without retraining
- End task and performance
  - End task natural language understanding: entity recognition or typing, entity or relation extraction, document classification, question answering (multiple choice), and inference End task natural language generation: text summarization, question answering (short or essay answers), translation, and dialogue generation Performance analysis: nominal percentage gains in performance after SNOMED CT integration

We elucidated the methodology for incorporating SNOMED CT into NLP pipelines following the categorization methods previously outlined by Pan et al [7]. These methods categorized methodologies for KG-enhanced LLMs into three distinctive types: (1) KG-enhanced LLM pretraining, (2) KG-enhanced LLM interpretability, and (3) KG-enhanced LLM inference. The end tasks of LLMs after SNOMED CT integration included NLU and NLG. Regarding the performance analysis, we presented the nominal percentage gains in performance after SNOMED CT integration without analyzing their statistical significance, as most studies did not perform statistical significance testing. We refrained from conducting direct study-to-study comparisons due to concerns about the heterogeneity of testing corpora and evaluation metrics across different studies.

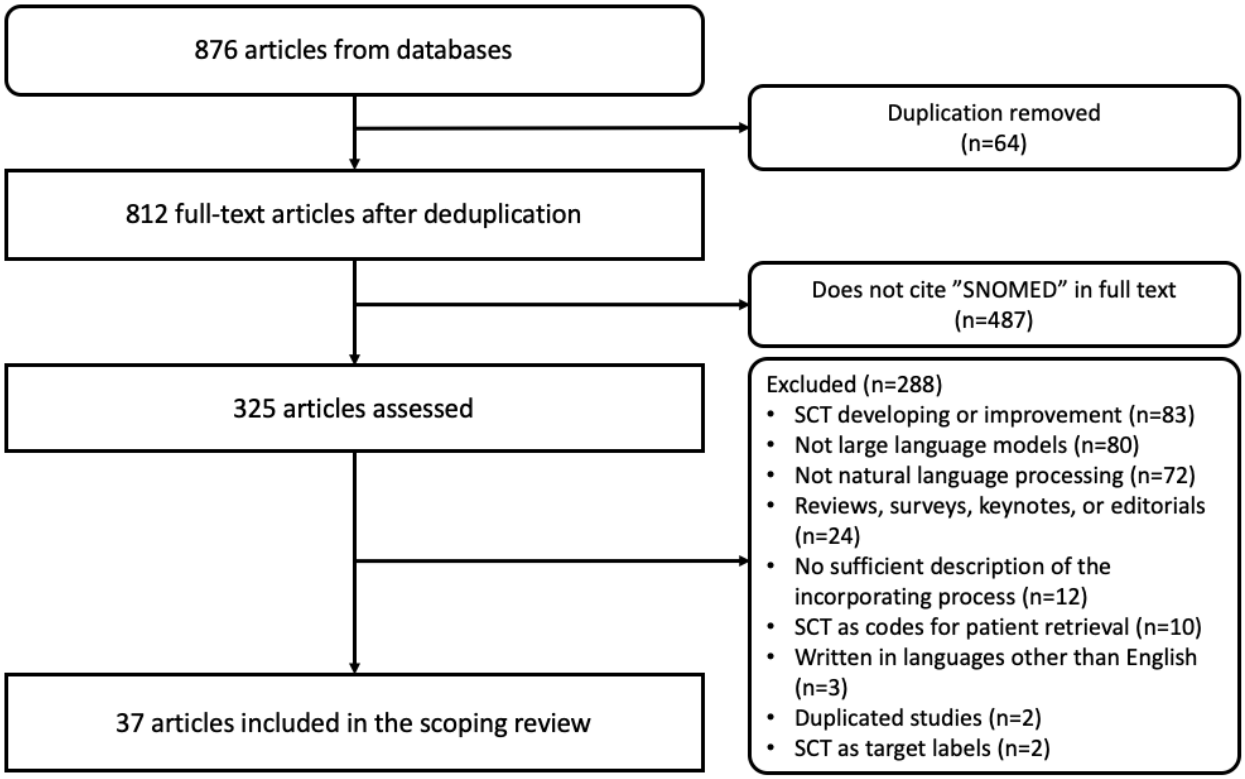
Results

Selected Papers

The query yielded 876 articles from the 5 bibliographic databases, with 634 (72.4%) obtained from the first query and

242 (27.6%) from the second query (Figure 1). After the removal of duplicates, 812 (92.7%) articles were reviewed to check whether the term "SNOMED" was mentioned in their full texts. A total of 325 (37.1%) articles were then reviewed according to the inclusion and exclusion criteria. Consequently, 37 (4.2%) publications were finally selected for the scoping review (Figure 1). The characteristics of the individual papers and other features, including the language of used datasets and SNOMED CT descriptions, other ontologies used, and the types of entities represented by SNOMED CT, are detailed in Multimedia Appendix 3.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of article selection. SCT: SNOMED CT.



Chronological and Geographic Publication Trends

Table 1 presents the publication trends noted in the review. Although our literature search covered publications from 2018 onward, no studies published in 2018 were included in the final review. The largest volume of studies was published in 2022 (13/37, 35%), followed by those published in 2020 (10/37, 27%).

When the number of countries was counted according to the first authors' institutional affiliations, the largest number of studies was noted to originate from the United States (10/37, 27%). While most of the studies (26/37, 70%) were conducted in countries that are members of SNOMED International, some were performed in nonmember countries such as Bulgaria and China, where separate license fees and in-house translation of SNOMED CT descriptions to the local language were required.

Table 1. Chronological and geographic publication trends among the included studies.

Baseline LLMs and Their Outputs

Most of the included studies (27/37, 73%) used BERT and its variants as the baseline LLMs for NLU and NLG tasks. Variants such as RoBERTa [58] and ALBERT [59] were also used to address BERT's relatively small training corpora and long training time [31,37,38,50,53]. To overcome the limited applicability of these general-purpose LLMs to biomedical texts, many studies (13/37, 35%) used LLMs trained on large-scale biomedical corpora, such as BioBERT [14] and PubMedBERT [60], which were trained on PubMed articles, and ClinicalBERT [61] and EHRBERT [23], which were trained on clinical notes. SapBERT [62], initialized by PubMedBERT, was further fine-tuned using contrastive learning with UMLS synonyms to better accommodate SNOMED CT synonym descriptions [44,47]. To support biomedical NLP tasks in languages other than English, LLMs trained on corpora in those languages were also adopted, such as medBERT.de [63], designed specifically for the German medical domain [51], and ERNIE-health, pretrained from Chinese medical records [41]. Aside from these BERT-based models, GPT emerged as a new baseline LLM since 2023. Makhervaks et al [53] used BioGPT [64], whose decoder was pretrained on biomedical corpora, to enhance the generation of artificial sentences. In addition, Xu et al [55] used GPT-3.5 for ranking suggested annotation terms in their study (Table 2).

A primary assertive role of LLMs was representing biomedical entities from text data. While most proposed methods produced embedding vectors to convey contextual information about the biomedical entities that appeared in texts, Kalyan and Sangeetha [31] introduced a Siamese RoBERTa model to generate concept vectors from synonym relationships defined by SNOMED CT. These basic outputs of LLMs might undergo additional task-specific layers to perform desired end tasks, which will be discussed later. Beyond producing embedding representations of entities, some studies required LLMs to perform classification or ranking tasks after fine-tuning, predicting the most likely relevant standard concepts [23,24,26,34,41,55], entity types [35,38,51], sentences [49,53], or matched foreign language words, enabling machine translation [28-30,39]. LLMs with encoder-decoder architectures, such as BART [65], were used for dedicated NLG tasks [32,57].

Data for Training and Testing Models

When using general-domain LLMs, authors deployed additional fine-tuning or pretraining on biomedical corpora to better adapt their models for biomedical NLP tasks. The pretraining corpora included PubMed or MEDLINE articles [28,30,38,39,46] and other publicly available datasets, such as Wikipedia articles [29] and tweets [37] related to biomedical topics. Synthetic sentences were also used to address data scarcity, which was generated based on SNOMED CT descriptions or relations [21,29].

While some studies (8/37, 22%) used real-world clinical narrative records [21,30,48,52] or customized (ie, manually annotated by researchers) data [25,27,41,56] for testing their models, most of the studies (29/37, 78%) used publicly available datasets, especially when researchers were participating in shared task competitions or dealing with English texts. CADEC [66] and PsySTAR [67], open datasets built from drug review posts in which concept mentions were mapped to SNOMED CT concepts, were used for validating and testing concept normalization models [31,45]. The Medical Concept Normalization (MCN) corpus, drawn from discharge summaries annotated using SNOMED CT and RxNorm concepts, was experimented on by concept normalization models [24,26]. The WMT corpora, provided by the annual Conference on Machine Translation Shared Tasks, were used to test multilingual machine translation tasks by participating researchers [28,29,39]. Makhervaks et al [53] and Chopra et al [22] used sentence pairs in the MedNLI corpus [68], annotated by medical doctors into 3 categories—contradictory, entailing, and neutral—for NL inference tasks. The MedMentions corpus [69] identifies >350,000 mentions from >4000 PubMed abstracts, linking them to the UMLS concepts; it was used in the studies by Zotova et al [40] and Dong et al [54], in which SNOMED CT was loaded onto the UMLS. The ShARe/CLEF 2013 corpus [70] consists of deidentified clinical notes annotated with disease mentions using the SNOMED CT subset of the UMLS; it was used for testing concept normalization tasks [44,54].

SNOMED CT Content Integration Into NLP Pipelines

Overview

While the categorization methods by Pan et al [7] pertained to the integration of LLMs with general-purpose KGs, we treated SNOMED CT as a specified form of KG. Their third category—KG-enhanced LLM interpretability—was omitted due to the lack of relevant studies in our review. In addition, we found no studies that fit into the subcategories "Integrating KGs into Training Objectives" (under "KG-enhanced LLM pretraining") and "Dynamic Knowledge Fusion" (under "SNOMED CT–enhanced LLM inference"). The overarching categorization of all included methods is shown in Textbox 2.

Textbox 2. Summarized categorizations of SNOMED CT–incorporated large language model (LLM) methods (allowed duplicated counting of studies).

Category and subcategory

- SNOMED CT–enhanced LLM pretraining
  - Integrating SNOMED CT into LLM inputs (n=28, 76%)
  - Integrating SNOMED CT into additional fusion modules (n=5, 14%)
- SNOMED CT–enhanced LLM inference
  - Retrieval-augmented knowledge fusion (n=5, 14%)

Integration of SNOMED CT Into LLM Inputs

Overview

Research in this area concentrated on developing new training objectives for LLMs that incorporate knowledge awareness. More specifically, this line of research aimed to incorporate relevant portions or subsets of SNOMED CT as additional input to LLMs during training. Because a disproportionately large number of included studies (28/37, 76%) fell into this category, we analyzed the methodology by two additional themes: (1) the content of SNOMED CT that was integrated into an LLM and (2) the part of the NLP pipeline into which the aforementioned content was incorporated. After qualitative analysis of the included articles and heuristic discussions among reviewers, we categorized the former theme into descriptions (including descriptions of synonyms), relations, and entity types (classes) and the latter theme into encoders and training data. SNOMED CT contents could be incorporated into LLM encoders either as embedding vectors or as annotations or tags when incorporated into the training corpus.

Table 3 shows the distribution of models across SNOMED CT contents and NLP pipelines, allowing for duplicated counting of a single study if it adopted ≥2 methods.

Table 3. Distributions of models across SNOMED CT contents and natural language processing (NLP) pipelines.

SNOMED CT content integrated into the NLP pipeline	Part of the NLP pipeline where SNOMED CT contents were integrated into	
	Encoder (as vector embedding)	Training corpora (as annotated text)
Description	[31,35,41,43,44,54]	[21,23,24,28-30,32,34,39,40,47-50,52,54,57]
Relation	[31,45]	[21,34,40,52,53]
Entity type (class)	—[a]	[25,38,42,51]

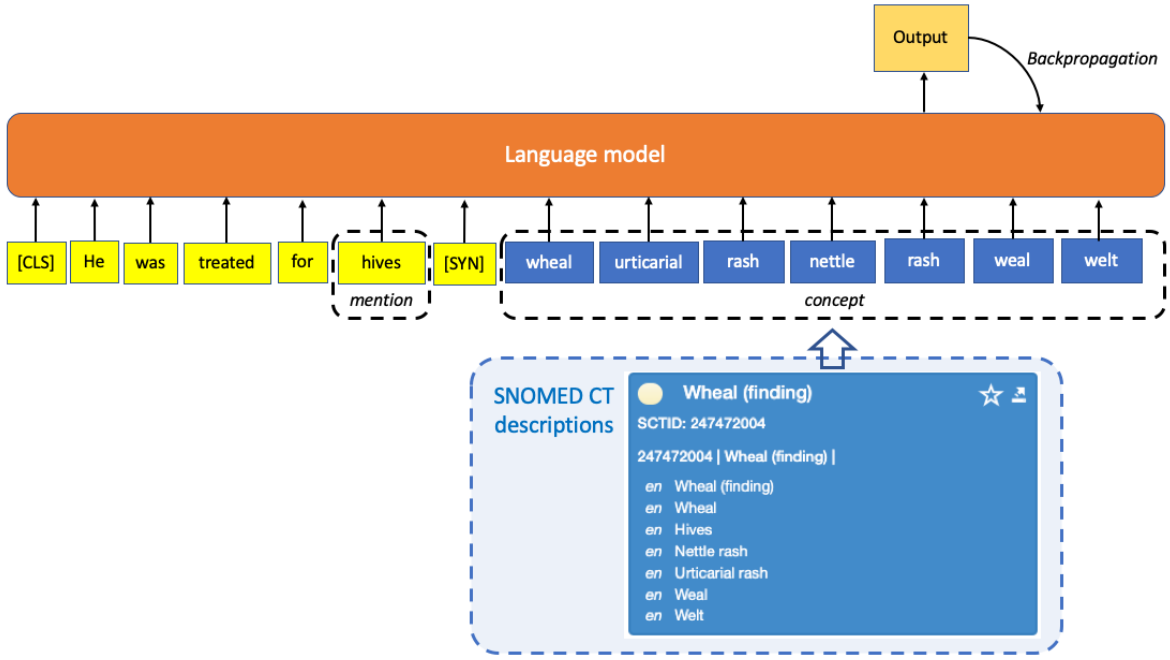
[a]Not available.

Integration of SNOMED CT Descriptions

Vector representations of SNOMED CT concept descriptions were created to facilitate seamless fusion into LLM encoders. The vectors for SNOMED CT description embeddings were used to calculate cosine similarity between the original mentions and SNOMED CT descriptions for concept normalization tasks [35,41,43,54].

Instead of transforming text descriptions into vector embeddings, NL description texts were directly added to training corpora to expand the size of in-domain vocabulary (Figure 2). The description texts of synonyms were either concatenated in the training corpora before being input into an LLM for pretraining [24,47,49,54,57] or they replaced the original entity mentions in the text with standardized terms [32,48]. The descriptions of SNOMED CT codes were also prepended to the word sequences as classifier tokens for LLM pretraining [23]. The multilingual feature of SNOMED CT descriptions was exploited to address the limited availability of training datasets in foreign languages by adding the translated SNOMED CT descriptions into the training corpora [28-30,39,50].

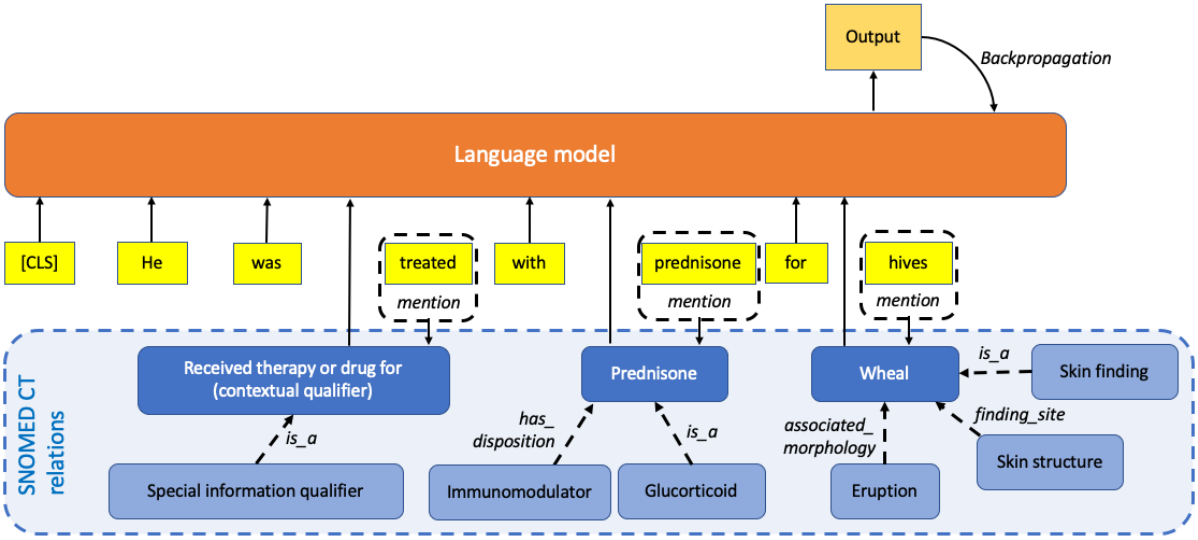
Figure 2. Integrating SNOMED CT descriptions into large language models. CLS: classification; SYN: synonym.



Integration of SNOMED CT Relations

This line of research introduced relevant subgraph information of SNOMED CT, representing SNOMED CT relations as graph edges, into LLMs (Figure 3). Kalyan and Sangeetha [31] encoded SNOMED CT concept descriptions to generate concept embedding vectors and learn representation vectors of concept mentions in the text, further improving the representations by retrofitting the target concept vectors with SNOMED CT synonym relations. CODER [45] used KG embedding methods such as DistMult and ANALOGY [71] to learn relational knowledge from SNOMED CT, enabling the quantification of term-relation-term similarity as well as term-term similarity.

Figure 3. Integrating SNOMED CT relations into large language models. CLS: classification.

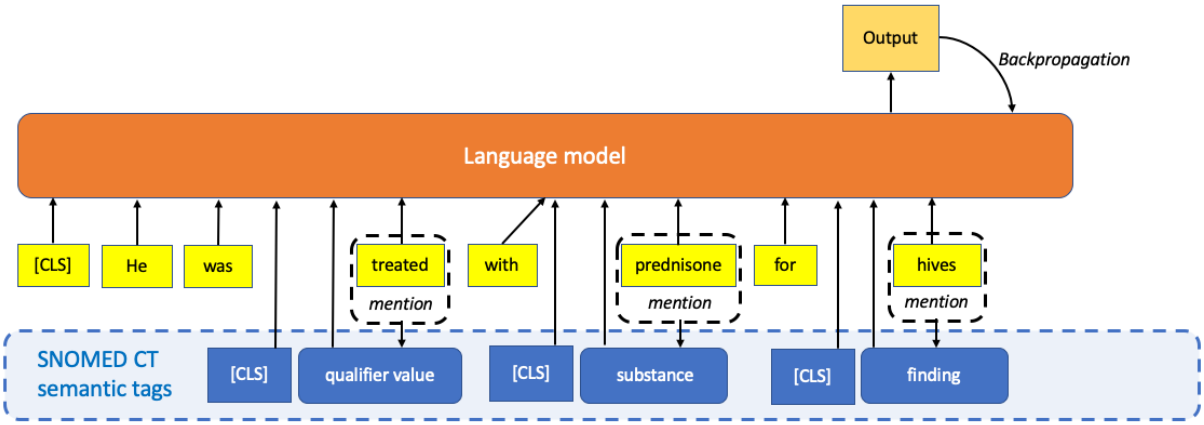


A different approach was taken to introduce textual relation triplets defined by SNOMED CT to expand the size of training corpora. Soto et al [21] exploited the relations defined in SNOMED CT, such as *is_a* and *occurs_in*, to generate synthetic training corpora. Relations defined in SNOMED CT were also used to apply weak supervision to sentence pairs extracted from PubMed to establish contradiction labels in the dataset [53]. Other authors exploited the existing mappings to other ontologies (eg, International Classification of Diseases-10 and UMLS) to enrich the training corpus with the description texts from the linked ontology concepts [34,40,52].

Integration of SNOMED CT Entity Types

The type of entities was incorporated into training corpora by distantly labeling the identified entities with SNOMED CT semantic tags (eg, diseases and chemicals; Figure 4) [25,38]. In other studies, training corpora were annotated with SNOMED CT top-level hierarchies [51] or subclasses of top-level hierarchies [42] to label sentences per their respective tasks.

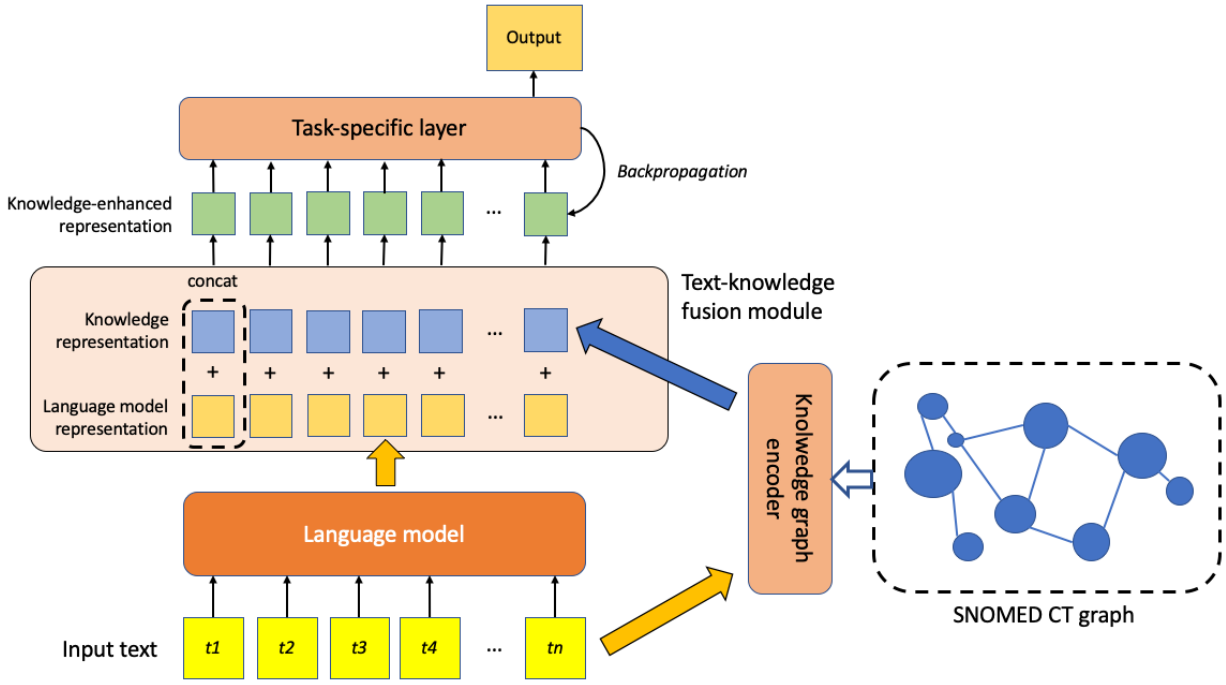
Figure 4. Integrating SNOMED CT entity type information into large language models. CLS: classification.



Integration of SNOMED CT Into Additional Fusion Modules

In this approach, concept information was processed separately before being concatenated and fused with the LLM embedding output (Figure 5). Authors created knowledge-directed embeddings using SNOMED CT graphs, where concepts were represented as nodes and relations as edges, and concatenated them with the LLM contextual embeddings. The merged representations of text and graph embeddings were then passed through a task-specific knowledge fusion module to achieve end tasks such as semantic similarity measurement [36,46], classification [22,27], and question answering [33,46]. To represent the graph information of SNOMED CT concepts, Chang et al [36] used a graph convolutional network [72] for encoding node features and edges. Chopra et al [22] proposed the Bio-MTDDN model, which introduced the shortest path information between corresponding SNOMED CT concepts into knowledge-directed embeddings.

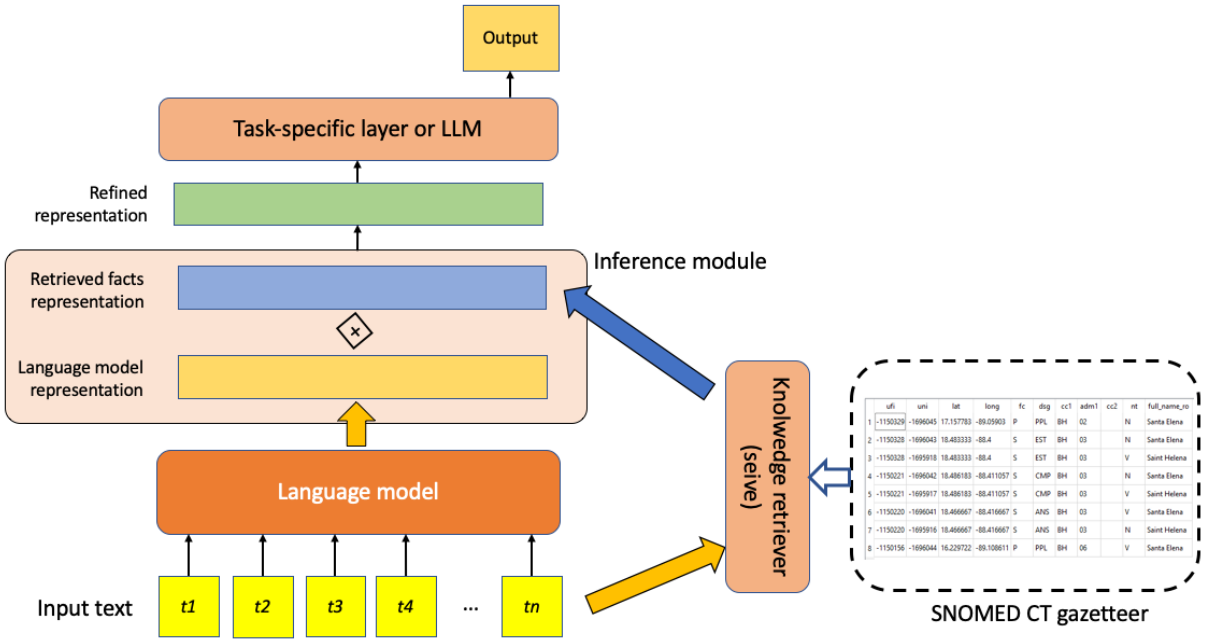
Figure 5. Integrating SNOMED CT into additional fusion modules.



Retrieval-Augmented Knowledge Fusion

In this approach, SNOMED CT was located outside LLMs as a fact-consulting knowledge base, injecting knowledge during inference (Figure 6). The module functioned as a gazetteer (dictionary), matching mentions in texts against the dictionary of SNOMED CT descriptions to filter out irrelevant entities from the models and map textual mentions to the most likely SNOMED CT concepts [24,26,37,55,56]. These methods primarily concentrated on entity recognition and question answering, capturing both textual semantic meanings and up-to-date real-world knowledge.

Figure 6. Retrieval-augmented knowledge fusion. LLM: large language model.



End Task and Performance Gain After SNOMED CT Integration

Overview

Most of the included studies (30/37, 81%) focused on NLU tasks, such as entity typing and classification. NLG tasks, including translation and summarization, were also attempted by a substantial number of studies (9/37, 24%), often involving various NLU pipelines before producing the final text output. Therefore, notably, works on NLU may also appear in the NLG category. Herein, we also compared the performance of models integrated with SNOMED CT to that of their counterparts without SNOMED CT integration.

NLU Tasks

Entity Extraction and Typing

Entity typing or named entity recognition tasks aim to detect specific types of entities by identifying the spans of their mentions in the text. These can be regarded as multiclassification tasks, where the number of classes is arbitrarily chosen by researchers. To fine-tune LLMs for type classification, authors annotated entities in texts by matching domain gazetteer strings (eg, "BIO" tagging scheme) [37,38,49] or using off-the-shelf automatic concept extractors [27]. The identified entities were then classified into human-annotated entity types [37,38] or topmost nodes in the SNOMED CT hierarchies [27,51]. In addition to typing individual entities, extraction and typing of relations between 2 entities were also attempted to align the detected entities with FHIR resources [25], such as protein to chemical and gene to disease [46] as well as disease to inflicted family members [35].

Many researchers did not conduct a comparative performance analysis of their SNOMED CT–integrated models against out-of-domain vanilla models. Among the few researchers who reported such comparisons, Jha and Zhang [46] demonstrated a gain in the F_1-score after the integration of SNOMED CT, while Montañés-Salas et al [37] found a positive impact only on recall (Table 4).

Table 4. Percentage performance gain in biomedical entity typing tasks after SNOMED CT integration into large language models.

Studies	F_1-score gain (%)	Precision gain (%)	Recall gain (%)	AUC[a] gain (%)
Montañés-Salas et al [37] (Best 2 model)	−0.11 (0.899→0.898)	−7.97 (0.928→0.854)	+8.60 (0.872→0.947)	—[b]
Jha and Zhang [46] (PubMedBERT on BC2GM)	+4.08 (0.80982→0.84287)	—	—	—

[a]AUC: area under the receiver operating characteristic curve.

[b]Not available.

Classification

We defined classification tasks as occurring at the sentence or document level, rather than at the word, entity, or phrase level. When classification tasks were implemented, semantic similarity [36] or the conditional probability of a positive case [22,33,53] was calculated, and the case was categorized as positive if the probability exceeded a threshold. Binary classification was performed to determine whether a sentence pair was entailed [33], contradictory [22,53], or similar [36]. Multilabel classification was conducted to categorize utterances by clinical

encounter components, such as symptoms, complaints, and medications [27]; social determinants of health [42]; or narrators' intent [48].

Table 5 shows the percentage performance gain after SNOMED CT integration in classification tasks. While Yadav et al [33] and Zhang et al [48] estimated the performance of their models based on the F_1-score, precision, and recall, Khosla et al [27] and Makhervaks et al [53] measured performance in terms of the area under the receiver operating characteristic curve, which improved by 0.87% to 14.83% after the integration of SNOMED CT. Chang et al [36] reported the Pearson correlation to assess clinical semantic textual similarity, and the incorporation of SNOMED CT into ClinicalBERT improved the performance of the model by 1.77% and 2.36% using cui2vec [73] and KG embeddings, respectively.

Table 5. Percentage performance gain in classification tasks after SNOMED CT integration into large language models.

Studies	F_1-score gain (%)	Precision gain (%)	Recall gain (%)	AUC[a] gain (%)	Accuracy gain (%)

[a]AUC: area under the receiver operating characteristic curve.

[b]Not available.

MCN Tasks

The most prominent end task in NLU was MCN, with 15 studies involved. MCN, the task of linking textual mentions to concepts in an ontology, provides a solution for unifying different ways of referring to the same concept. All the studies approached concept recognition as a multilabel classification task involving entity extraction and entity typing from words, phrases, or sentences. Models were trained on corpora annotated with SNOMED CT concepts and semantic types to identify concept mentions and generate a list of candidate SNOMED CT concepts that best match those mentions from testing texts. When training from annotated corpora was not available, MetaMap [74] was used to extract biomedical entities mentioned in free texts and map them to ontology concepts [25,26,35,50]. When candidate concepts were ranked, representation vectors of mentions and concept descriptions were generated, and their similarity was calculated using cosine similarity [31,35,44,45,54], linear transformation such as support vector classifiers [52], or softmax function [23,41,43]. In a more rule-oriented approach, Borchert and Schapranow [47] calculated weights based on semantic type and preferred term status from a gazetteer to reorder candidate lists. In other studies [24,26,50], sieve-based multipass entity linking systems [75] were used to rank the most likely concepts and achieved superior performance compared to neural classifiers.

Most of the studies observed positive gains in accuracy in MCN tasks after SNOMED CT integration (Table 6). Two authors reported the pre- and postintegration F_1-scores, recall values, and precision values and observed inconsistent results, with one reporting positive gains in the F_1-score and precision value and the other demonstrating a loss in the F_1-score and precision value after the integration of SNOMED CT.

[b]The training data dictionary was constructed based on the Medical Concept Normalization corpus data. The SNOMED CT dictionary included the RxNorm dictionary.

NLG Tasks

Machine Translation

Several studies that participated in the WMT Biomedical Shared Task [76] described their methods for translating biomedical texts from various foreign languages, such as Spanish, French, German, and Chinese, as well as less-resourced languages, such as Basque, into English or vice versa. Transformer-based multilingual neural machine translation systems were the mainstream architectures, which were trained on dictionaries derived from SNOMED CT [28,30,39] or clinical notes artificially generated from SNOMED CT terminology contents [21,29].

The translation performance was reported using the Bilingual Evaluation Understudy (BLEU) score [77]. While most studies (4/5, 80%) presented improved BLEU scores by up to 131.66% [21] compared to their out-of-domain models, some studies (1/5, 20%) reported nonsuperior results [30] (Table 7).

Table 7. Performance comparison of biomedical translation tasks with and without SNOMED CT integration into large language models (LLMs).

[a]BLEU: Bilingual Evaluation Understudy.

Text Summarization

For medical text summarization, encoder-decoder LLMs were used to process input embeddings and produce simplified texts. Pattisapu et al [32] primarily focused on the simplification of verbose sentences. They substituted biomedical mentions with UMLS-preferred names and tokenized them at the subword level to produce noisy input sentences for training. In contrast, Searle et al [57] summarized entire hospital encounters into a few sentences by ranking the most salient ones to constitute the summary. To address the hallucination problem arising from LLMs, authors used SNOMED CT semantic tags of the extracted biomedical terms to configure guidance signals for clinical problems and interventions.

Recall-Oriented Understudy for Gisting Evaluation recall [78] measures how many n-grams in the source text appear in the summarization. Pattisapu et al [32] reported no gain in ROUGE recall when incorporating SNOMED CT into NLP pipelines. Searle et al [57] presented ROUGE-F_1, a harmonized measure of the recall and precision for ROUGE, and observed improvements by 3.6% (from 11.1 to 11.5) and 48.84% (from 8.6 to 12.8) on the Medical Information Mart for Intensive Care III and King's College Hospital corpora, respectively, after incorporating SNOMED CT.

Question Answering and Generation

Generating answers for short-answer or essay questions, as opposed to multiple-choice questions, can be classified as NLG. The task of question answering may involve preliminary NLU pipelines, such as intent and content recognition. Zhang et al [48] developed a clinical communication training dialogue system incorporated with SNOMED CT synonyms for the augmentation of textual data and BioBERT for intent recognition. They qualitatively evaluated the performance of the conversation system using scales rated by physicians from 29 training records, which indicated a comparable precision as clinical experts.

Discussion

LLMs and SNOMED CT

In this scoping review, we observed that BERT was the mainstream LLM integrated with SNOMED CT. Considering the significant time required to publish state-of-the-art methodologies, especially in peer-reviewed journals [79], it is unsurprising that more recent inventions, such as GPT-3.5 and BART, were less prevalent in articles published from 2018 to 2023. Researchers in this field exploited biomedically oriented BERT variants, such as BioBERT and PubMedBERT, reflecting the need for biomedical tasks to be trained or fine-tuned on specialized corpora [16]. However, due to privacy and confidentiality concerns, there is a dearth of clinical documents and patient notes, making it difficult to sufficiently train biomedical LLMs to an extent comparable to those in the general domain [80]. SNOMED CT can supplement or even substitute biomedical pretraining corpora, addressing the chronic shortage, as noted in this review. A substantial number of studies included in this review used SNOMED CT to expand pretraining corpora by concatenating synonyms or relations in documents or generating synthetic texts based on SNOMED CT descriptions or relations.

We identified 3 approaches to incorporating SNOMED CT into LLMs: LLM input, additional fusion modules, and knowledge retriever, with the former 2 intervening in the pretraining process of LLMs. While either lexical or graph information from SNOMED CT could be incorporated into the pretraining stage, the lexicon of SNOMED CT descriptions was the predominant form of integration. This underscores that SNOMED CT chiefly introduces synonym information to LLMs, yet relation information remains underused in NLP research. The advantage of SNOMED CT in defining relations between biomedical entities through semantic networks needs to be adopted for more sophisticated tasks such as knowledge inference and validation and highlighted within the biomedical NLP research community.

End Tasks and Performance Reports

A significant number of studies included in this review engaged in the concept recognition process from free texts, whether as the final task or an intermediate step for subsequent tasks. Recognizing and extracting SNOMED CT concepts from the unstructured sections of EHRs is becoming crucial in clinical settings, where substantial patient information, such as social history and socioeconomic status, remains untapped in free-text clinical notes [81]. Leveraging previously unrepresented SNOMED CT concepts from free-text clinical data holds great potential in significantly enhancing clinical care and research, especially in the era of smart applications where patient-generated data can be integrated into EHRs through the representation of patient-authored texts with SNOMED CT concepts [82].

Only a small fraction of the included models disclosed performance comparisons before and after SNOMED CT integration. For example, only 6 (40%) out of 15 studies on MCN tasks provided information about the gain in the F_1-scores or accuracy after SNOMED CT incorporation. This suggests that many biomedical NLP researchers do not focus on the role of SNOMED CT or other ontologies in improving their models. Moreover, some authors chose to demonstrate only selected metrics, potentially leading to publication bias that favors improved performance at first glance. In our review, we identified 7 studies that presented only 1 metric without disclosing others (excluding those that reported only the BLEU score, which is widely recognized as the best metric for measuring translation performance). This focus on a single metric may encourage researchers to optimize their models for that metric, potentially leading to underperformance in other areas. The NLP community needs to propose standardized methods for presenting performance and, if possible, develop new metrics that better reflect the specifics of NLU and NLG tasks performed by LLMs.

Implications for Future Endeavors

The knowledge-intensive approaches to enhancing LMs, which are often renounced by those favoring deep learning–based approaches, still comprise a small portion of the artificial intelligence research community. However, in the face of immense computational power and the availability of data

required by LLMs and deep learning–based systems, an increasing number of researchers now advocate the harmonization of the 2 approaches [83], and a plethora of KG-enhanced LLMs is developed in the general domain [10,84]. In addition to improving the performance of artificial intelligence models, ontologies and human-curated knowledge bases can address the explainability and controllability of artificial intelligence, probing facts within the human-interpretable form of system architectures [85]. Exploring the trade-offs in combining the 2 approaches is anticipated to contribute toward trustworthy and reliable artificial intelligence.

Among various biomedical terminology systems and ontologies, SNOMED CT was the primary focus in this review as a KG integrated with LLMs. Although the UMLS continues to dominate NLP research in the biomedical domain [16], SNOMED CT has the potential to expand its influence, given its governance over the health care industry. Consequently, the use of SNOMED CT as a reliable knowledge source becomes more feasible, considering its presence in various EHR systems or common data models. While this review did not identify real-world SNOMED CT–incorporated LLM applications directly tied to EHR systems, SNOMED CT is implicitly expected to support these systems as a standardized terminology system bound to syntactic interoperability structures such as FHIR and OpenEHR. In addition, medical institutions already implementing SNOMED CT in their EHR systems are anticipated to incorporate LLM applications and use SNOMED CT at the point of care [86]. Explicit descriptions of SNOMED CT in technical specifications or scientific papers by developers of these applications would have been valuable to include in this review.

Limitations

One of the limitations of this scoping review is that we examined LLMs that accepted SNOMED CT only as a working ontology, leaving other biomedical ontologies out of our scope. To the best of our knowledge, however, there is no comprehensive review of the use of other biomedical ontologies within LLMs. The queries used in this review, especially the first one, retrieved articles that used a variety of biomedical ontologies, such as the UMLS, Medical Subject Headings, Gene Ontology, and Medical Wikidata. We chose to limit the scope of our review to SNOMED CT due to the heterogeneity of components among different ontology systems and the difficulty in delineating the contributions of each ontology in a standardized way. A more consolidated analysis of different ontologies used within LLMs awaits more comprehensive work.

A significant proportion of the included studies (23/37, 62%) were retrieved from conference proceedings. While we excluded short abstract articles and included only those that provided sufficient information to be categorized by our preset features, interested readers might find it challenging to delve into detailed methodologies from these proceedings articles. However, many of these papers refer to additional materials, such as GitHub (GitHub, Inc) repositories, to provide raw data and source codes; for example, Khosla et al [27] provided the source code of their system on GitHub [87]. We encourage more studies to share additional materials on open developer platforms to enhance methodology transparency and accelerate NLP research.

Another limitation of this review is that we could not conclude on how the integration of SNOMED CT improved the performance of LLMs. While most of the studies (14/18, 78%) observed a positive impact on performance after SNOMED CT integration, their statistical significance was not indicated. Moreover, the diversity of evaluation methods prevented us from performing a meta-analysis across all the included studies. While we examined whether SNOMED CT integration improved LLM performance by presenting percentage gains across various metrics, these results are prone to being misleading due to potential publication bias and the insufficient number of included studies. Nevertheless, this before-and-after comparison method, often adopted for comparative studies, effectively measures the effect of interventions (SNOMED CT in our case) within a single group or entity [88]. To control for confounding factors, we excluded models whose performance differences could be attributable to modalities other than SNOMED CT integration. For example, we excluded the study by Zotova et al [40] from our analysis because their performance might have been affected by the use of a different testing corpus. An evenhanded testing bed, such as a shared task competition under a single testing method requiring all participants to report performance differences before and after KG integration, could provide a controlled evaluation to reliably and objectively measure the contributions of KGs.

Conclusions

In conclusion, this scoping review explored the methodologies and effectiveness of integrating SNOMED CT into LLMs. The predominant approach involved using SNOMED CT concept descriptions or graph embeddings as inputs for LM encoders, many of which were involved in MCN tasks. The endeavor to identify and extract SNOMED CT concepts from free texts was proven to be instrumental in enhancing the understanding and generation of NL texts for downstream tasks in the biomedical realm. However, our study revealed both a lack of standardized methods for assessing KG integration into LLMs and a scarcity of explicit performance reporting in existing research, highlighting significant gaps in current evaluation practices. These findings underline the need for more consistent reporting and evaluation practices in this field of research. Future research is anticipated to be more aware of the advantage of SNOMED CT when incorporating it into LLMs and to report findings in a manner that facilitates comparison across different works.

Abstract

Background: Electronic health records (EHRs) commonly contain patient addresses that provide valuable data for geocoding and spatial analysis, enabling more comprehensive descriptions of individual patients for clinical purposes. Despite the widespread use of EHRs in clinical decision support and interventions, no systematic review has examined the extent to which spatial analysis is used to characterize patient phenotypes.

Objective: This study reviews advanced spatial analyses that used individual-level health data from EHRs within the United States to characterize patient phenotypes.

Methods: We systematically evaluated English-language, peer-reviewed studies from the PubMed/MEDLINE, Scopus, Web of Science, and Google Scholar databases from inception to August 20, 2023, without imposing constraints on study design or specific health domains.

Results: A substantial proportion of studies (>85%) were limited to geocoding or basic mapping without implementing advanced spatial statistical analysis, leaving only 49 studies that met the eligibility criteria. These studies used diverse spatial methods, with a predominant focus on clustering techniques, while spatiotemporal analysis (frequentist and Bayesian) and modeling were less common. A noteworthy surge (n=42, 86%) in publications was observed after 2017. The publications investigated a variety of adult and pediatric clinical areas, including infectious disease, endocrinology, and cardiology, using phenotypes defined over a range of data domains such as demographics, diagnoses, and visits. The primary health outcomes investigated were asthma, hypertension, and diabetes. Notably, patient phenotypes involving genomics, imaging, and notes were limited.

Conclusions: This review underscores the growing interest in spatial analysis of EHR-derived data and highlights knowledge gaps in clinical health, phenotype domains, and spatial methodologies. We suggest that future research should focus on addressing these gaps and harnessing spatial analysis to enhance individual patient contexts and clinical decision support.

KEYWORDS

clinical phenotypes; electronic health records; geocoding; geographic information systems; patient phenotypes; spatial analysis

Introduction

Electronic health records (EHRs) have significantly enriched clinical decision support by providing relatively cost-effective, time-efficient, and convenient sources of a large population of patient records [1,2]. Because EHRs often contain patient addresses, spatial analysis can enable value addition via high-resolution geocoding. The simplest of such analyses may be mapping, which can promote a better understanding of health disparities. Further, patient geocoding can link external data such as environmental, demographic, and socioeconomic factors for more refined patient phenotyping and a more profound

understanding of patient exposures for targeted interventions [3].

The possibilities for applying spatial analysis on individual-level, EHR-derived data are beyond geocoding, basic mapping, or external data linkage. For instance, spatial network analysis examines proximity to the sources of pollution [4], measures accessibility to health care facilities [5], and optimizes resource allocations to mitigate health disparities [6]. Spatial clustering pinpoints statistically significant spatial and spatiotemporal hotspots and cold spots [7], especially when considering longitudinal EHRs data. Moreover, spatial and spatiotemporal modeling can identify localized patterns, trends, and relationships within a specific region [8,9]. Identifying underserved communities through spatial analysis can enhance clinical decision support to implement targeted interventions such as screening, vaccination, or health education campaigns.

Despite the availability of advanced spatial analysis methods, most studies primarily focus on basic mapping or geocoding. Moreover, while these methodologies have the potential to better describe the context of individual patients in biomedical studies, there is a need for their improved application to derive more meaningful insights. To accurately address medical conditions, identify a disease in a patient, and scale that to cohorts of patients, phenotyping is required [10]. Phenotypes are a combination of observable traits, symptoms, and characteristics. They can contain inclusion and exclusion criteria (eg, diagnoses, procedures, laboratory reports, and medications) and can be used to recruit patients who fit the necessary criteria for clinical trials.

A prior systematic review used spatially linked EHRs data to investigate the effects of social, physical, and built environments on health outcomes [11]. Another study highlighted the need to integrate spatial data related to individual patients into health care decision-making and practice [12]. Nonetheless, this is the first comprehensive study that systematically reviews US-based studies that used spatial analysis for analyzing EHR-derived data in characterizing patient phenotypes for clinical decision support and interventions. This review collates and synthesizes existing literature that used individual-level health data from EHRs in conjunction with advanced spatial analyses and patient phenotyping. Thus, the main objectives of this review are (1) to evaluate the degree to which advanced spatial methods are currently being used with individual-level data sourced from EHRs in the United States, (2) to identify areas of spatial analyses most applicable to biomedical studies, (3) to categorize publications concerning their biomedical and clinical areas and the specific patient phenotypes they target, and (4) to highlight knowledge gaps and propose future research directions for harnessing the potential of spatial analysis to enhance the context of individual-level data sourced from EHRs for biomedical studies.

Methods

Overview

This systematic review was performed using the protocols outlined by the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) to identify the studies that satisfy the eligibility criteria for subsequent data extraction and synthesis (Multimedia Appendix 1).

Data Source

A comprehensive search for peer-reviewed studies was carried out using abstracts and titles screening within the PubMed/MEDLINE, Scopus, and Web of Science databases using the search terms in Table 1. The search was conducted on August 29, 2023, without limitations on study design or specific health domains.

Table 1. The search strategy key terms.

Theme[a]	Key terms
Spatial analysis	(“Geospatial*” OR “Geo-spatial*” OR “Spatio-Temporal” OR “Spatial Temporal” OR “Space-Time” OR “Space Time” OR “Spatiotemporal” OR “Geocod*” OR “ Spatial Autocorrelation” OR “Spatial Interpolation” OR “Spatial Epidemiology” OR “Spatial Data” OR “Spatial Modeling” OR “Spatial Modelling” OR “Spatial Mapping” OR “Geographic Mapping” OR “Georeferenc*” OR “Spatial Analys*” OR “Spatial Inequalit*” OR “Spatial Disparit*” OR “Spatial Dependenc*” OR “Spatial Access*” OR “Geographical Mapping” OR “Geographical Visualization” OR “Geographic Visualization” OR “Geovisualization” OR “Geographical Information System*” OR “Geographic Information System*” OR “Geofencing” OR “Geographical Distribution*” OR “Geographic Distribution*” OR “Spatial Statistic*” OR “Spatial Bayesian” OR “Spatial Hotspot*” OR “Spatial Cluster*” OR “Geographic Cluster*” OR “Geographic Hotspot*” OR “Remote Sensing” OR “Global Positioning System” OR “Spatial Pattern*” OR “Spatial Data Mining” OR “Spatial Variabilit*” OR “Spatial Heterogeneit*” OR “Geostatistic*” OR “Spatial Covariance” OR “Spatial Regression” OR “Spatial Uncertaint*” OR “Spatial Point Pattern*” OR “Kriging” OR “Cartography” OR “Spatial Decision Support System*” OR “OpenStreetMap” OR “Location-Based Services” OR “Spatial Quer*” OR “GIS” OR “Web GIS” OR “Satellite Imager*” OR “ArcGIS” OR “QGIS” OR “Risk Mapping”) AND
EHR[b]	(“EHR” OR “EMR” OR “EPR” OR “Electronic Health Record*” OR “Electronic Medical Record*” OR “Electronic Patient Record*” OR “EDW” OR “Enterprise Data Warehouse” OR “RDW” OR “Research Data Warehouse”)

[a]The selected studies that used spatial analysis of EHR data were manually excluded if they lacked patient phenotype characteristics or were not conducted based on the US data.

[b]EHR: electronic health record.

Search Strategy

The initial search comprised 2 main categories. The first category included a broad set of key terms related to spatial analysis. The second category used the key terms associated with EHR. Henceforth, our reference to EHRs will also encompass electronic medical records (EMRs), electronic patient records (EPRs), enterprise data warehouses (EDWs), and research data warehouses (RDWs). The Boolean operator AND was applied to synthesize the 2 categories.

For PubMed/MEDLINE, Scopus, and Web of Science, we used a consistent search strategy tailored to the specific features and functionalities of each platform. We used the advanced search options available on these databases to input the key terms from Table 1. The search was conducted across titles and abstracts. For Google Scholar, due to its distinct search engine and more limited filtering options compared to the other databases, we conducted broad search queries with the same key terms. We then manually reviewed the results to identify and include relevant studies that met our criteria.

Study Selection

The retrieved abstracts and titles were imported into Covidence systematic review software (Veritas Health Innovation), where duplicate records between original databases are automatically eliminated. Two reviewers (AM and BH) independently assessed the eligibility of the studies based on the following inclusion and exclusion criteria.

The studies were eligible for primary inclusion if they (1) were composed in English; (2) were original peer-reviewed studies; (3) used individual-level patient data derived from EHRs, EMRs, EPRs, EDWs, or RDW; and (4) incorporated at least 1 form of spatial methods. Conversely, the studies were excluded if they (1) were not peer-reviewed (eg, letters, editorials, reviews, case reports, abstracts, and grey literature), (2) solely geocoded addresses or generated basic visualizations (eg, dot map and choropleth map) without any spatial analysis, and (3) not based on the US data.

The reviewers (AM and BH) independently reviewed the full texts of all remaining studies. The studies also were excluded if they lacked phenotype characteristics. Further, we manually checked the references for all the selected studies for possible inclusion. A third reviewer (AVA) was consulted to break ties.

Data Extraction

Upon identifying studies that satisfied all inclusion criteria, two reviewers (AM and BH) extracted the following items for each study: title, publication year, country and region, sample size, study period, spatial methodologies, and key findings from the spatial methods. Moreover, studies were assessed to identify clinical domains (including primary and secondary when applicable), health conditions or problems, and themes (including social determinants of health [SDOH], environmental factors, ecological aspects, climate, microbiome, genomics, and clinical phenotypic characteristics). Previous publications have emphasized the importance of data domain sources in phenotyping, underscoring the need for validating the created phenotype [13] and using multiple data sources. Thus, in cases where the included publications did not provide details of data sources but instead referenced previously published works, referenced publications were reviewed. Additionally, we cataloged the types of EHRs that served as the sources.

Narrative Synthesis

There is no universally accepted classification for spatial analysis methods. In this review, we have adopted and refined a classification framework based on the study of Nazia et al [14], which initially categorized methods into frequentist and Bayesian approaches and spatial and spatiotemporal methods. This classification was further broken down into descriptive, clustering, and modeling techniques [15]. Therefore, following data extraction, the studies were categorized into the following spatial methodology classifications: descriptive, clustering, modeling (frequentist), spatiotemporal (frequentist), and Bayesian. The phenotype characteristics were extracted and recorded as free text. It should be noted that the categories were not mutually exclusive.

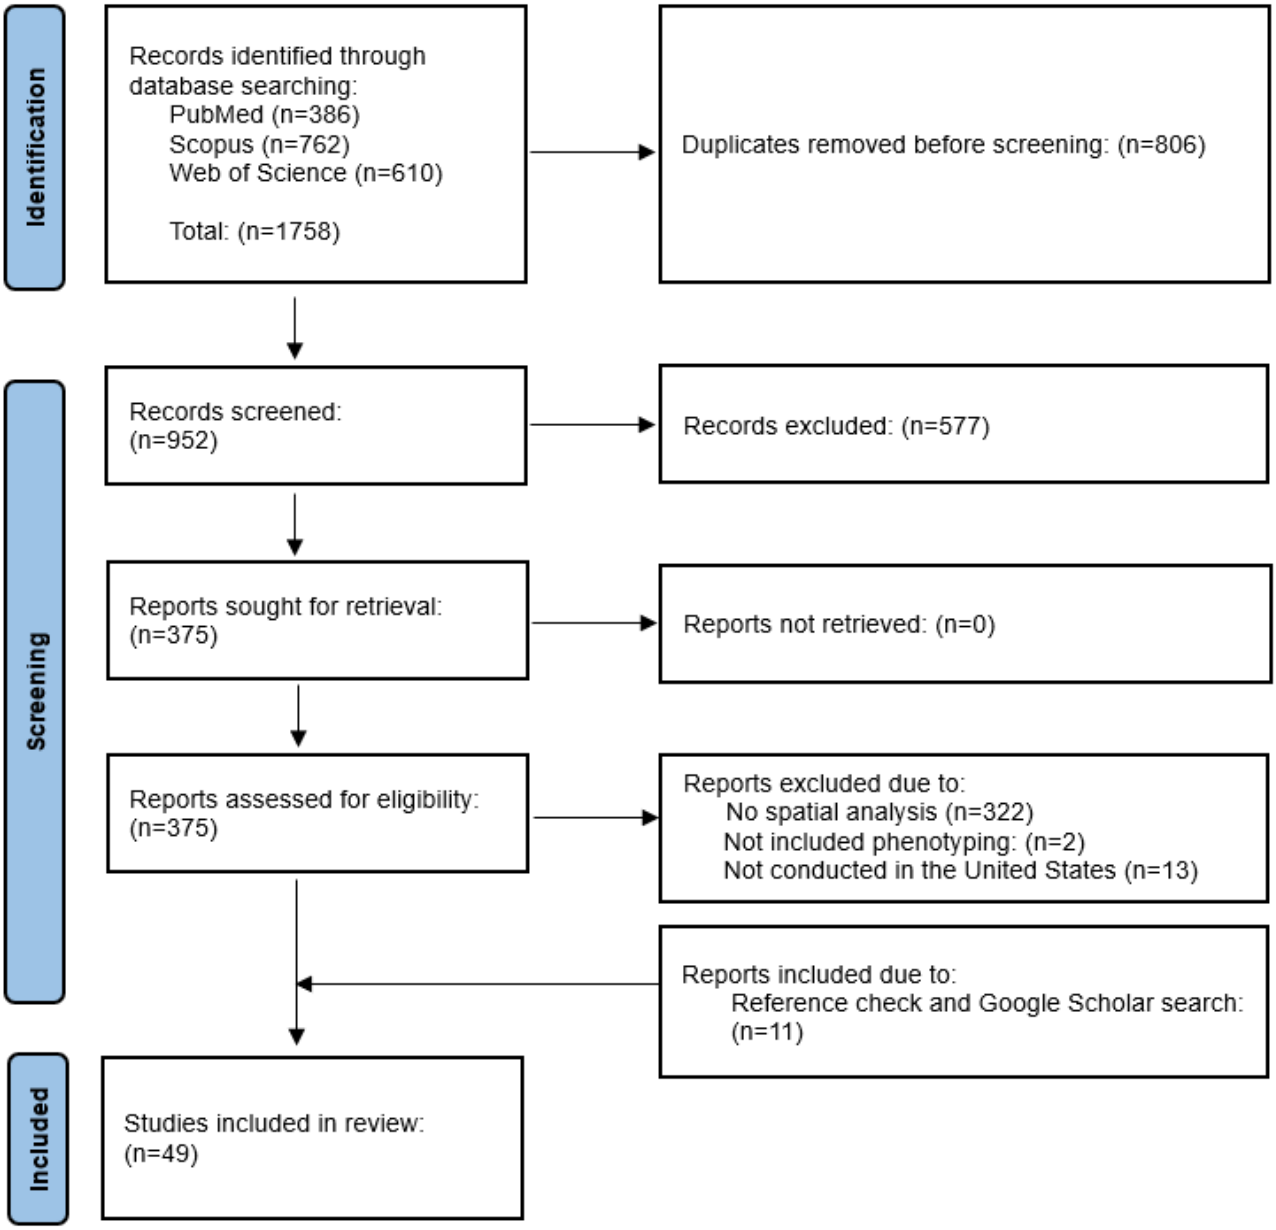
The quality appraisal of the studies was not feasible due to the substantial heterogeneity in spatial methodologies and health domains. The geospatial distribution of the included studies was visualized using ArcGIS Pro software (version 3.0; ESRI).

Results

Study Selection

The initial search yielded 1758 references. After removing duplicate records, we identified 952 studies for abstract and title screening, from which 375 were selected for full-text review. Of these, 322 studies were excluded as they only contained geocoding or basic mapping without any spatial analysis. Additionally, 15 studies were omitted due to the absence of patient phenotype characteristics (n=2) or were not based on US data (n=13). We further manually searched references and Google Scholar and found 11 new studies that met the eligibility criteria. Therefore, 49 studies that fulfilled the inclusion criteria were retained for data extraction and synthesis. Figure 1 depicts the PRISMA flowchart for the study selection process.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) study selection flowchart.



Temporal and Geographic Distribution of Studies

Of the 49 included studies, a limited number (n=7, 14%) were published prior to 2017. The earliest study included in this study was published in 2011, and the publication frequency has experienced a significant upsurge since 2017 (n=42, 86%), likely due to increased adoption of EHR systems and growing familiarity with spatial analysis techniques among researchers. There was only one study [16] at the national level. General characteristics of the included studies are presented in Table 2. Most studies were concentrated in North Carolina (n=8, 16%), Pennsylvania (n=6, 12%), California (n=6, 12%), and Illinois (n=4, 8%). Figure 2 illustrates the geospatial distribution of studies at the state level in the United States.

Table 2. General characteristics of the included studies.

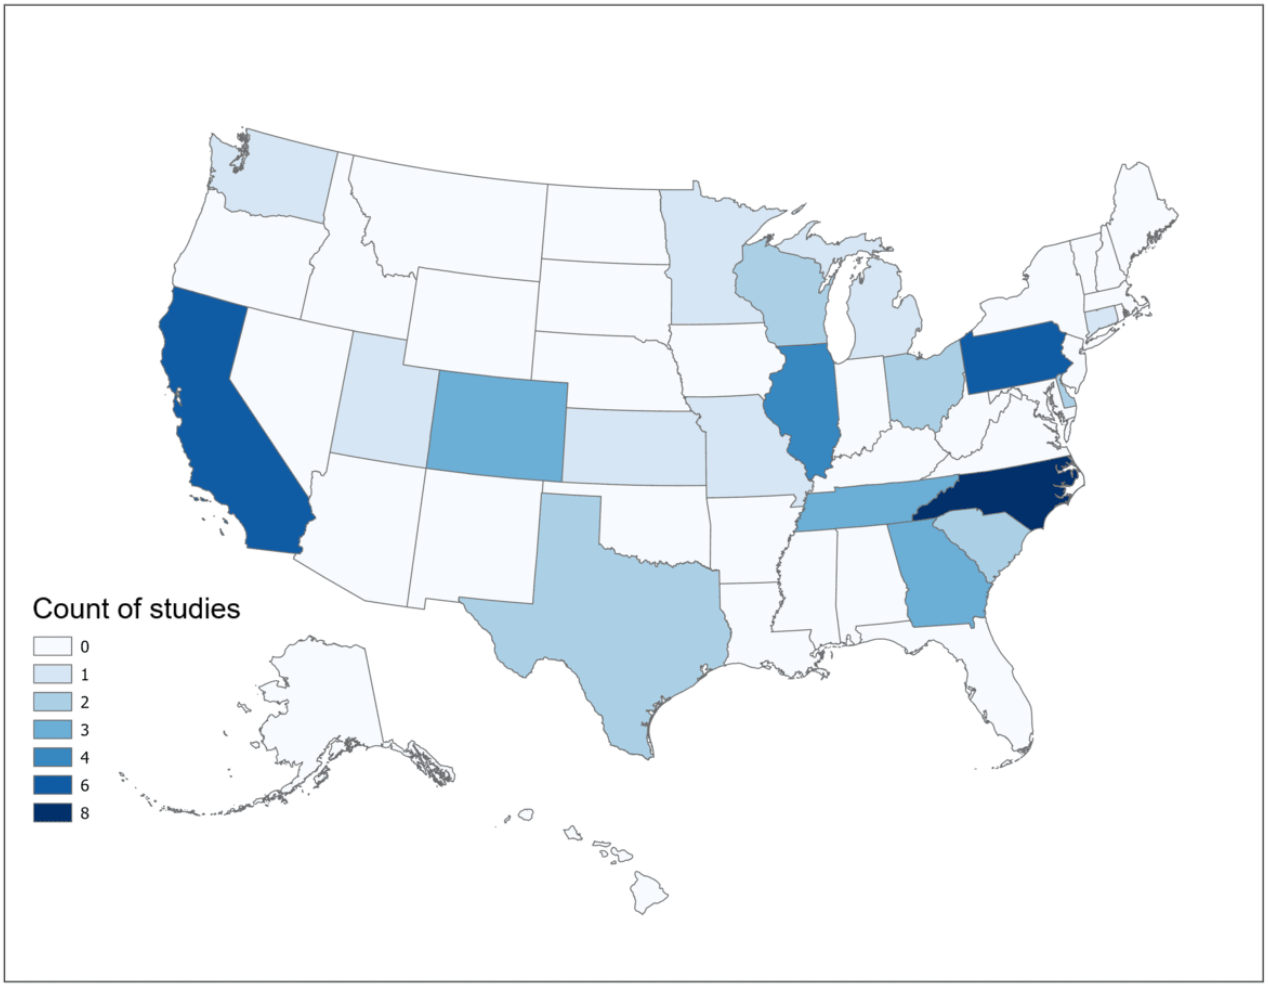
Figure 2. Geospatial distribution of the included studies at the state level in the United States.



Spatial Methodologies

Overview

Most studies focused on frequentist methods compared to the Bayesian methods. Among frequentist methods, the most prevalent category was clustering (n=29), followed by descriptive (n=12), modeling (n=6), and spatiotemporal analyses (n=2). More detailed explanations of the spatial methods used in this study are provided in Multimedia Appendix 2.

Descriptive Analyses

Descriptive analyses were categorized into four groups: spatial sampling (n=2), spatial overlay (n=2), proximity analysis (n=4), and spatial interpolation (n=4).

Spatial Sampling

A 2 SD ellipse method is used to optimize spatial sampling density. This ellipse contains almost 95% of the locations of patients and is used to ensure that the collected samples reflect the underlying spatial pattern in data, particularly when resources are limited [61]. Lantos et al [38] and Lantos et al [39] adopted this approach when sampling women who

underwent cytomegalovirus antibody testing during pregnancy, especially in peripheral areas with limited subject representation.

Spatial Overlay

Spatial overlay integrates various spatial data sources, often maps, to represent their shared features. Wakefield et al [55] overlaid the map of major radiation treatment interruptions based on race onto the map of median household income. Their analysis implied that regions with higher income levels experienced lower rates of radiation treatment interruption. Samuels et al [48] spatially joined patient addresses to the nearest city parcels and computed an estimate of the incidence of emergency department visits for asthma for each parcel [48].

Proximity Analysis

Proximity analysis includes measuring distances between geographic features to identify nearby features within a defined distance or buffer zone to uncover proximity patterns [62]. Wilson et al [56] created temporal and spatial buffers to assess the correlation between individual exposure to violent crime and blood pressure. Schwartz et al [49] evaluated the associations between environmental factors and BMI within a 0.5-mile network buffer from the place of residence. Casey et al [23] investigated the associations between prenatal residential greenness and birth outcomes within 250-m and 1250-m buffers. Using a geographic information system service area network analysis, Jilcott et al [35] examined BMI percentile and proximity to fast-food and pizza establishments among adolescents within 0.25-mile Euclidean and network buffer zones.

Spatial Interpolation

Ordinary Kriging is one of the most widely used spatial interpolation techniques that leverages the spatial autocorrelation structure of observed locations to estimate values at unmeasured locations [63]. Hanna-Attisha et al [33] applied ordinary Kriging with a spherical semivariogram model based on observations of the children's elevated blood lead level geocoded to the home address to visualize blood lead level variations before and after water source changes. Mayne et al [44] interpolated the levels of neighborhood physical disorder based on an exponential variogram. Patterson and Grossman [16] demonstrated spatial variations for the incidence rates of each *International Classification of Diseases, Ninth Revision* diagnostic code based on an exponential variogram. Sun et al [53] estimated monthly average concentrations of fine particulate matter to investigate the associations between air pollution exposure during pregnancy and gestational diabetes mellitus.

Spatial Clustering

Overview

Spatial clustering techniques assess whether health outcomes are random, uniform, or clustered and pinpoint the locations of clusters [64]. Spatial clustering was the most widely used category (n=29) among all studied categories. Moran *I* clustering and cluster detection were the most frequent techniques (n=10), followed by kernel/point density estimation (n=5), spatial scan statistics (n=4), and Getis-Ord Gi* statistics (n=4).

Kernel/Point Density Estimation

Kernel density estimation generates a smooth surface to visualize areas of the most significant spatial intensity by calculating a distance-weighted count of events within a specified radius per unit area [65]. Several studies adopted kernel density estimation to analyze patterns, including cholera hospitalization [58], comparison of the spatial intensity of chronic kidney disease with nonchronic kidney disease patients [30], and comparison of the spatial intensity of breast cancer and nonbreast cancer [52]. Using the point density function, Beck et al [17] pinpointed hotspots of inpatient bed-day rates within a 2-mile radius of a medical center, and Kane et al [36] estimated the number of participants per square mile.

Global and Local Moran I

Global Moran *I* (GMI) evaluates the overall pattern for spatial autocorrelation [66] by inferring if a variable is spatially clustered or overdispersed versus being randomly distributed under the null hypothesis [66]. Local Moran *I* (LISA) is used to locate statistically significant clusters including hotspots, cold spots, and outliers [67]. GMI has been adopted to analyze spatial clustering of health outcomes including gestational diabetes mellitus [53], day-of-surgery cancellation [43], obesity [54], and COVID-19 [51]. All exhibited clustered patterns. Xie et al [58] analyzed 3 groups: depression, obesity, and comorbid cases, confirmed clustering for all outcomes, and identified spatial clusters and outliers. Pearson and Werth [47] found random distributions for dermatomyositis (DM) and subtypes, classic DM, and clinically amyopathic DM. Meanwhile, Davidson et al [25] pinpointed clusters with higher or lower depression prevalence, and Winckler et al [57] identified a cluster of low use of acute pediatric mental health interventions in less-densely populated rural border areas.

GMI and semivariograms or variograms can also identify spatial autocorrelation in model residuals. If detected, the models are adjusted accordingly to avoid biased estimates. For example, Lipner et al [42] modeled nontuberculous mycobacteria disease, shifting the use from a nonspatial Bayesian model to a spatial model when spatial autocorrelation was found in residuals. Similarly, Georgantopoulos et al [29] incorporated spatial random effects into a prostate cancer model due to significant autocorrelation in the residuals. Sharif-Askary et al [50] used variograms to assess spatial dependency in cleft lip or palate, leading to a geostatistical model over standard logistic regression. Conversely, Casey et al [23] found no spatial autocorrelation in nonspatial model residuals.

The bivariate GMI quantifies the overall spatial dependence between two distinct variables (positive value indicates high values of one variable are surrounded by high values of the other or low values are surrounded by low values, while negative value implies high values of one variable are surrounded by low values of the other) [68]. Bivariate LISA assesses the relationship between the two variables at the local level. Pearson and Werth [47] used bivariate GMI for the prevalence of DM, classic DM, and clinically amyopathic DM with airborne toxics but found no overall spatial dependencies. However, bivariate LISA identified local dependencies at the zip code level. Garg et al [31] applied bivariate GMI and found significant overall

associations between longer (average) distances to the nearest supermarket and higher incidence of diabetes, and bivariate LISA identified significant "high-high" relationships at the zip code level. Gaudio et al [28] used bivariate LISA and found no local association between radiation therapy interruption and social vulnerability index at the zip code level.

Getis-Ord Gi*

The Getis-Ord Gi* statistic identifies high- or low-value clusters (hotspots and cold spots) by assessing deviations of health outcomes at locations from the average within a defined neighborhood [69]. Lê-Scherban et al [40] measured racial residential segregation by examining the deviations in the African American residents in each census tract from the mean of neighboring tracts. Similarly, Mayne et al [45] measured racial residential segregation for the percentage of non-Hispanic Black residents. Ali et al [7] identified significant community-onset methicillin-resistant Staphylococcus aureus (CO-MRSA) hotspots with distinct patterns between cases and controls. Kersten et al [37] detected the high- and low-value clusters for the child opportunity index and median household income.

Spatial Scan Statistics

The spatial scan statistics technique identifies high- and low-risk clusters and estimates their relative risks [70]. It also can incorporate covariates to characterize underlying patterns [71]. Lipner et al [42] found that people living in zip codes within the primary cluster had an almost 2.5 times greater risk of nontuberculous mycobacteria disease. Lieu et al [41] identified clusters of underimmunization and vaccine refusal among children, with rates ranging from 18% to 23% inside the clusters compared to 11% outside.

The technique can also pinpoint cold spots. Brooks et al [21] identified areas with significantly lower COVID-19 testing than expected, indicating a need for interventions. Zhan et al [59] observed significantly low rates of up-to-date colorectal cancer screening.

Spatial Modeling (Frequentist)

Among the included studies, the generalized additive models (GAMs) emerged as the most frequently used spatial models. GAMs can account for spatial autocorrelation by incorporating smooth functions (such as thin-plate regression) of spatial coordinates [72], allowing the estimate of geographic variation with or without covariate adjustments. GAMs were used to identify the spatial variabilities in asthma prevalence [3,8] and cytomegalovirus [38,39], although such variations often diminished when adjusted for demographic factors such as race and age. Less commonly used geospatial models were generalized linear mixed effects [51] and spatial error [43] models.

Spatiotemporal Analysis

Only 2 studies explored spatiotemporal patterns, and no spatiotemporal modeling was conducted. Oyana et al [46] used space-time scan statistics to study the spatiotemporal patterns of childhood asthma and found a significant frequency increase (2009-2013) and a rising trend from 4 to 16 per 1000 children (2005-2015). Ali et al [7] used the space-time cube tool and emerging hotspot analysis to analyze the spatial-temporal trends and evolving patterns of CO-MRSA from 2002 to 2010. They identified several types of space-time hotspots of CO-MRSA including new, consecutive, intensifying, sporadic, and oscillating hotspots.

Bayesian Analysis

The studies using Bayesian methods were categorized into empirical Bayes smoothing (n=5) and Bayesian modeling (n=6).]

Empirical Bayes Smoothing

The empirical Bayes smoothing was used by Lê-Scherban et al [40], Liu et al [43], Tabano et al [54], and Xie et al [58] to stabilize estimated rates in areas with limited data points by borrowing information from the overall population [73]. Zhao et al [60] used nonparametric kernel smoothing to estimate the prevalence of childhood obesity in areas with sparse observations (n<20 individuals) [60].

Bayesian Modeling

Bayesian modeling can account for spatial and temporal dependencies and quantify uncertainty by specifying prior distributions [74]. Among the studies, the conditional autoregressive (CAR) prior emerged as the most used, with 2 variants: intrinsic and multivariate CAR. Intrinsic CAR was used to assess the spatial variations in diabetes in relationship with racial isolation [18], hypertension related to racial isolation [19], and type 2 diabetes mellitus with the built environment [20]. Multivariate CAR was used to identify areas with higher or lower-than-expected prostate cancer while controlling for risk factors [29]. Moreover, hierarchical Bayesian that can incorporate hierarchical structures for modeling [75] was used to investigate spatial distributions of patients admitted for drug-related reasons concerning the area deprivation index [24]. Bayesian negative binomial hurdle models that can account for excessive zeros and overdispersion were used to examine spatial variation between patient responses to the questions concerning unhealthy home environments and the mean number of emergency department visits after screening [26].

Phenotyping

Clinical Domain Characteristics and Themes

The largest category of studies was classified under the infectious disease (n=7), endocrinology (n=7), and oncology (n=6) domains. Additionally, 19 studies had a pediatric domain or focus, as noted with an additional column in Table 3. Maternal and newborn care was classified as its own domain (n=8), but it overlapped with other domains such as nephrology, endocrinology, and infectious disease.

Table 3. Clinical domains and condition or problem of focus for each publication.

Condition by clinical domain[a]	Secondary clinical domain[b]	Pediatric population involved
Pediatric		
DoSC[c] [43]	—[d]	✓
EBLL[e] [33]	—	✓
Disparities in inpatient bed-day rates [17]	—	✓
Maternal and newborn care

[a]Condition or problem of focus column displays the general condition of the study and may not directly correspond to the phenotype.
[b]Publications with more than 1 clinical domain and those with a pediatric component are noted as such.
[c]DoSC: day-of-surgery cancellation.
[d]Not applicable.
[e]EBLL: elevated blood lead levels.
[f]CKD: chronic kidney disease.
[g]GDM: gestational diabetes mellitus.
[h]T2DM: diabetes mellitus, type 2.
[i]PICU: pediatric intensive care unit.
[j]MRSA: methicillin-resistant Staphylococcus aureus.
[k]CMV: cytomegalovirus.
[l]RTI: radiation treatment interruption.
[m]TNBC: triple-negative breast cancer.

The relationship between the clinical domains and the "conditions or problems of focus" in each study was examined (Table 3). In some cases, direct correspondence was observed, while in other instances, the "condition or problems of focus" differed from the phenotype of the patient cohort. In many studies, one or more overlapping domains were observed (eg, rheumatology, neurology, and dermatology for the study of DM). Asthma (n=5), hypertension (n=5), and diabetes (n=4) were studied most frequently. Three studies did not focus on any health condition but rather on examining disparities in either a data source or a specific domain or cohort (eg, disparities in the use of pediatric intensive care units).

Every study was attributed to at least one prominent theme, with the possibility of multiple themes. SDOH themes were prevalent in many studies. To organize and present this information, we used the domains defined by the Healthy People 2030 framework [76]. There are 5 domains in the SDOH framework (Table 4), with the corresponding counts of these domains being seen as themes of the studies. Most studies had 1 or more SDOH themes (n=42). Many studies focused either on all the domains or SDOH holistically without particular focus on any specific domain (n=32). However, some studies contained prominent themes that were not directly related to SDOH, which were phenotypic features (n=4), followed by

environmental (n=3), and ecological (n=2), with climate, genomics, and microbiome, each contributing one study.

Table 4. SDOH[a] themes examined within the framework of Healthy People 2030 SDOH domains [76].

Labels and SDOH domains	Counts, n
SDOH 1	
Economic stability (employment, food insecurity, housing instability, poverty)	2
SDOH 2	
Education access and quality (early childhood development and education, enrollment in higher education, high school graduation, language, and literacy)	N/A[b]
SDOH 3	
Health access and quality (access to health services, access to primary care, health literacy)	5
SDOH 4	
Neighborhood and built environment (access to foods that support healthy dietary patterns, crime and violence, environmental conditions, quality of housing)	14
SDOH 5	
Social and community context (civic participation, discrimination, incarceration, social cohesion)	5
All 5 SDOH domains or SDOH as a whole	36
Non-SDOH focus	8

[a]SDOH: social determinants of health.

[b]Not applicable.

Clinical Phenotype Features

For each publication, clinical phenotype definitions were extracted (Multimedia Appendix 3). In almost all studies, phenotype definitions included demographic details such as patient age, race, and gender, along with some diagnostic characteristics (eg, asthma diagnosis). Only a limited number of phenotypes were observed to be validated (n=8). The most frequently observed method for phenotype validation was a manual chart review of all matches or a sample of matched charts. None of the studies with chart review as a validation method shared information on the match rate. Additionally, only two studies [20,58] were observed to use validated eMERGE Network computable phenotypes from the Phenotype Knowledgebase [77-79].

Discussion

Principal Findings

This systematic review is the first comprehensive investigation of spatial methodologies within EHR-derived data in the United States. The findings reveal that a considerable portion of studies predominantly focus on basic mapping or geocoding, with a limited use of advanced spatial analysis methods. Spatial clustering and descriptive analysis were the most used methods, while space-time modeling, either frequentist or Bayesian, was not widely applied. The diverse use of spatial analysis for EHR-derived data in different health domains highlights the potential to incorporate spatial methods to enhance the context of individual patients for future biomedical research. We found limited use of EHR-derived data for spatial analysis, probably due to the challenge of safeguarding patient privacy. Address data, crucial for spatial analysis, is highly confidential and often restricted from sharing. Researchers and institutions often use geographic masking techniques [6,80] to balance data use and privacy protection by altering the precise geographic coordinates while preserving the overall spatial characteristics of data. Encouraging the adoption of spatial analysis could promote biomedical knowledge sharing and collaboration.

The use of EHRs data for spatial analysis can present several challenges, particularly in accurately geocoding patient addresses. Issues, such as address formatting errors, incomplete or outdated addresses, and potential inaccuracies in geocoding services, can influence the outcome of spatial analysis [81]. Advanced geocoding algorithms and manual verification processes can mitigate these issues. For instance, Goldberg et al [82] developed a web-based system for rapid manual intervention of previously geocoded data, significantly improving the match rate and quality of individual geocodes with minimal time and effort. Additionally, when addresses are only available at the zip code level, additional nuances arise as zip code boundaries are often not well-defined and can change over time [83]. Spatial smoothing techniques and zip code centroids can mitigate some of these challenges. We recommend standardizing address formats before geocoding (using tools like the US Postal Service address verification), using advanced geocoding services, leveraging higher-resolution geographical data when possible, and integrating multiple spatial scales to enhance the accuracy and reliability of spatial analysis using EHRs data.

We acknowledge that not all patient phenotypes are inherently suited for spatial analysis, and integrating genomics, imaging, and clinical notes phenotypes can be particularly challenging. However, evidence suggests that spatial techniques can provide valuable insights even in these areas where their application may initially appear challenging. For instance, Baker et al [84] demonstrated the effectiveness of spatial analysis in genomics

by combining single-nucleotide polymorphism genotyping with geospatial K-function analysis. Their study of typhoid in Nepal found significant geographic clustering of cases. Canino [85] developed a robust framework that integrated biological data with geographic information from EMRs. Their system identified correlations between patient profiles and geographic factors such as environmental exposures related to pollution. Future interdisciplinary studies can explore developing frameworks that integrate genomics or notes with geospatial datasets to reveal complex relationships and patterns.

The application of spatiotemporal analysis of EHR-derived data was mainly limited to exploring spatiotemporal clusters with no spatiotemporal modeling. This might be due to the technical expertise required for analysis, data complexity, availability of longitudinal data, and computational challenges. The Bayesian framework offers a more adaptable framework to handle complex spatial and temporal dependencies, control confounding variables [86], and incorporate prior information, such as existing medical literature and expert opinions, resulting in more interpretable results [87,88]. Moreover, spatiotemporal Bayesian modeling can aid in understanding disease trends and progressions, seasonality, and long-term shifts at the local levels [89]. Bayesian modeling can also account for uncertainty in parameter estimates and predictions to assess the reliability of findings before implementing interventions [90]. Thus, future research should delve into spatial and spatiotemporal modeling, focusing on Bayesian approaches. Moreover, ignoring spatial dependence in modeling can bias parameter estimates [9,91,92]. Additional state-of-the-art methods, such as space-time autoregressive models and generalized additive models for location scale and shape, also provide flexibility in modeling complex relationships. Spatiotemporal point process models also contribute by analyzing the distribution of health events and underlying states over space and time.

Among the health conditions studied, chronic and infectious diseases emerged as the most frequently investigated domains compared to others. This disparity may be attributed to the pressing public health concerns posed by diseases with immediate impacts that often attract more funding and resources for research initiatives [93,94]. The historically high mortality rates of these conditions likely led to continuous research. Furthermore, the nature of spatial contamination and the spread of infectious diseases has historically driven the development of spatial analysis for clinical purposes, exemplified by John Snow's seminal cholera investigation. Surprisingly, despite the plethora of funding in cancer research, we only found a small number of studies within the cancer domain, which may likewise be attributed to and indicative of the pressing needs of other domains such as infectious disease.

We observed recurring and prominent themes related to the SDOH. This emphasis may result from the growing maturity and increased awareness within the biomedical informatics community regarding the significant influence of social, economic, and environmental factors on health outcomes. Understanding the roles of SDOH in health disparities will likely lead to the implementation of integrative health interventions that address the needs of individuals affected by these health disparities. These interventions can likewise be enhanced by incorporating spatial perspectives.

Another missed opportunity is the limited use of computable phenotypes—automated algorithms designed for characterizing diseases and enrolling patients in studies. Most studies primarily depended on the manual application of inclusion and exclusion criteria to define phenotypes. While this method may be suitable in certain scenarios, it often necessitates greater depth and granularity to consistently and accurately capture the intended patient cohorts. The accuracy and precision of the manual approach can vary depending on the data sources and clinical domains. Notably, only 2 of the studies in this review used computable phenotypes, indicating a limited adoption of this essential and potentially transformative approach, highlighting a noteworthy area for growth. Furthermore, only 5 studies carried out any form of chart review validation. Validation methods, including chart reviews, genetic markers, and clinical variables, are indispensable in phenotyping to guarantee the accurate characterization of the desired cohorts. This applies even to computable phenotypes within specific medical domains [95].

Limitations

This study has several main limitations. First, we only considered English-language studies, possibly introducing language bias. Additionally, selection bias is possible due to database availability. However, we mitigated these limitations by searching Google Scholar and conducting backward reference checking to identify relevant studies that might yet be identified through our initial search strategy. Finally, we used a query search strategy with limited keywords, which inherently restricted the scope of studies we could retrieve, potentially omitting studies that did not use these specific terms in their abstract or title.

Our rationale to focus exclusively on US data was driven by our familiarity with the reliability and availability of EHR-based systems within the country. Moreover, we recognize that spatial analyses of health data in regions, such as Europe, Asia, Australia, and Canada, use different terminologies and labels for their systems, which might not align with our search terms for EHRs or EMRs. For instance, Canada's national administrative databases and electronic discharge records could encompass significant work not captured by our key terms, a situation that can be generalized to other countries. To avoid inconsistencies arising from varying data labeling and storage systems across different regions, we opted to concentrate on the United States. Nevertheless, future research should endeavor to include and explore contributions from these regions to provide a more comprehensive understanding of emerging trends in spatial analysis in characterizing patient phenotypes.

Conclusions

This systematic review provided a comprehensive overview of the current use of spatial analysis in EHR-based research in the United States and underscored the pivotal role that spatial analysis can play in clinical decision support and interventions. The use of EHR-derived spatial analysis is on an upward trajectory, parallel with the widespread adoption of EHR

systems. The volume of studies on this topic is anticipated to continue to grow. The primary health outcomes investigated were asthma, hypertension, and diabetes. Notably, patient phenotypes involving genomics, imaging, and notes that are notoriously high-dimensional and add to the computational intensity of spatial methods were limited. This review also highlighted the need for additional exploration of spatial analysis techniques, including but not limited to spatiotemporal Bayesian analysis and modeling, particularly in computable phenotypes or patient phenotypes involving genomics, imaging, and notes.

Acknowledgments

We would like to express our gratitude to Professor Gregory Glass from the University of Florida for his constructive review of the earlier version of the manuscript. We would also like to thank Clemson University librarian Karen Burton and Medical University of South Carolina librarian Ayaba Logan, MPH, MLIS, whose expertise in library and information sciences facilitated our systematic review. AM, BH, and AVA are supported by the South Carolina SmartState Endowed Center for Environmental and Biomedical Panomics (CEABP). AVA is supported by South Carolina Cancer Disparities Research Center (SC CADRE) from NIH/NCI U54 CA210962. BH is a trainee supported by the SC Biomedical Informatics and Data Science for Health Equity Research Training (SC BIDS4HEALTH) from NIH/NLM T15 LM013977.

Abstract

Before deploying a clinical prediction model (CPM) in clinical practice, its performance needs to be demonstrated in the population of intended use. This is also called "targeted validation." Many CPMs developed in tertiary settings may be most useful in secondary care, where the patient case mix is broad and practitioners need to triage patients efficiently. However, since structured or rich datasets of sufficient quality from secondary to assess the performance of a CPM are scarce, a validation gap exists that hampers the implementation of CPMs in secondary care settings. In this viewpoint, we highlight the importance of targeted validation and the use of CPMs in secondary care settings and discuss the potential and challenges of using electronic health record (EHR) data to overcome the existing validation gap. The introduction of software applications for text mining of EHRs allows the generation of structured "big" datasets, but the imperfection of EHRs as a research database requires careful validation of data quality. When using EHR data for the development and validation of CPMs, in addition to widely accepted checklists, we propose considering three additional practical steps: (1) involve a local EHR expert (clinician or nurse) in the data extraction process, (2) perform validity checks on the generated datasets, and (3) provide metadata on how variables were constructed from EHRs. These steps help to generate EHR datasets that are statistically powerful, of sufficient quality and replicable, and enable targeted development and validation of CPMs in secondary care settings. This approach can fill a major gap in prediction modeling research and appropriately advance CPMs into clinical practice.

Background

In health care, distinct tiers of care, namely primary, secondary, and tertiary care, play vital roles in addressing patients' diverse medical needs. Patients requiring specialized medical attention or hospital care are generally treated in secondary care settings. Approximately one-third of primary care patients are referred to secondary care, and the majority of these patients are treated and monitored in this setting [1]. Tertiary care consists of highly specialized services for highly complex diseases. Less than 5% of patients require care in a tertiary setting. The distribution of patients across primary and secondary care settings may differ between countries and health care systems; some countries require a referral from primary care to enter secondary care, while in other countries patients have direct access to medical specialists without a referral. While there can be significant variability in primary and secondary care structures, variablity in tertiary care structures are generally less pronounced. This is because tertiary care focuses on highly specialized and complex conditions that are often standardized based on international research and protocols. Academic hospitals and specialized centers provide similar highly specialized care worldwide.

Due to the complexity of care, strong research facilities, and involvement in clinical trials, most clinical understanding and knowledge of medical conditions come from patients treated in tertiary settings [2,3]. Similarly, in this setting many clinical prediction models (CPMs) are developed. A CPM is a statistical or artificial intelligence-based tool used in health care to predict future health events in individual patients using a set of predictors or risk factors. CPMs have the potential to combine and weigh large amounts of patient information, enabling the

stratification of patients based on their risk of future health events. This informs decision-making processes and may guide the allocation of resources and interventions. While such models are also developed in primary and secondary settings, CPMs developed in tertiary settings may have great potential to be useful in secondary care, where the patient case mix is broad and practitioners need to triage patients efficiently.

However, the usefulness of such CPMs depends significantly on their quality in the population of intended use. Recent discussions emphasize the importance of targeted validation, which is the assessment of a CPM's quality in the specific population for which it is intended. Yet, this specification of the population of intended use is often lacking in publications [4]. Secondary health care settings, where large numbers of patients with specialized medical needs are treated, accumulate vast amounts of data in electronic health records (EHR) on a daily basis. Despite this potential, CPMs are often not developed or validated on data from secondary care populations due to the scarcity of appropriate datasets. This is known as the "validation gap." In this viewpoint, we discuss the opportunities and challenges faced when considering EHR data from secondary health care settings for the development or validation of CPMs.

Importance of Targeted Validation of CPMs

The performance of CPMs is significantly influenced by the case mix of patients (ie, baseline characteristics of the patients) and the prevalence of the outcome [5-7]. The case mix of a secondary care population is essentially different from a tertiary care population. Due to these case mix differences, a CPM developed in tertiary care often performs poorly in secondary care populations [8].

For instance, in cardiovascular risk prediction models, such disparities in patient characteristics and outcomes between tertiary and secondary care settings substantially impact model performance. Research by Wynants et al [3] highlights the challenges of model transportability and generalizability. In a review, they showed that 23 out of 50 studies did not describe the population of intended use. In those studies that reported health care setting, all participating centers were in tertiary or academic settings. One of the studies applied a tertiary CPM in a secondary care setting. In this secondary care setting, patients were older, the outcome was less prevalent, and patients more often had (multiple) risk factors such as diabetes and hypertension. Under these circumstances, the CPM severely overestimated event probabilities when applied to secondary care. Similarly, in chronic obstructive pulmonary disease management, the use of CPMs is complicated by variations in patient profiles across health care settings. While primary and secondary care cohorts exhibit marked heterogeneity in health status, tertiary care cohorts tend to comprise more homogeneous samples [2].

These examples, along with many others in medical literature [9,10], demonstrate poor model performance, specifically poor calibration, of tertiary CPMs in the population of intended use. Arguably, these prediction models are most useful at lower levels of care, where the patient case mix is broad and practitioners need to triage patients efficiently [11]. More concretely, an overestimation of event probabilities means that patients could be incorrectly categorized as high-risk based on a CPM that is poorly calibrated to the target population. Such inaccurate risk prediction can be misleading and may negatively influence clinical practice; it may lead to false expectations from the patientor professional, or patients may make personal decisions in anticipation (or absence) of an event [12]. CPM specialists argue that poor calibration may render an algorithm less clinically useful than a competing model with lower discriminative ability but is well calibrated [9].

While checklists exist to improve reporting quality [13,14] and assess the risk of bias [15] in CPM development and validation, targeted validation remains an uncommon practice. Sperrin et al [4] rightly argue that we should report the intended population of use more explicitly. This means that if, for example, a CPM is intended to aid decision-making in a secondary care setting in the Netherlands, then it should be developed and validated in a secondary care setting in the Netherlands. Such targeted validation requires data from the population of intended use. The difficulty lies in the scarcity of structured or rich datasets from secondary settings available to assess the quality of a CPM. Addressing this validation gap remains a challenge in CPM literature and hampers the implementation of CPMs in clinical practice, emphasizing the importance of leveraging EHR data from secondary health care settings for CPM development and validation.

EHR Datasets and Text Mining Tools

Every day, hospitals collect an enormous amount of health information in EHRs. Data in these EHRs have structured and unstructured formats. Structured EHR data comprise data in fixed numerical or categorical areas, such as diagnoses, prescriptions, and laboratory values, while unstructured data includes clinical documentation such as notes, referral letters, or discharge summaries produced by health care personnel [16]. These documents are inputted as free text into EHRs and offer a complete picture of a patient's condition. It is estimated that more than 70% of EHR data is stored as free text. Even information that seems structured, such as a total score from a questionnaire, is often stored as free text in the EHR in letters or notes. To conduct good research in general, this data should be converted into structured formats and datasets. Specifically, to validate a CPM, it is required that a certain predictor, which is part of the CPM, is collected and recorded in a consistent manner. Leveraging the value of unstructured data is key to generating meaningful insights from clinical data [16-18].

Text mining tools and natural language processing (NLP) techniques allow us to transform unstructured documents into a structured format to enable analysis and the generation of high-quality CPMs [19]. Text mining applications are increasingly used in research and computational settings, but are now also commercialized in software applications (for example, CTcue from IQVIA or Amazon Comprehend Medical from Amazon Web Services) that allow hospitals to generate structured data and subsequently cohorts of patients with a

specific disease more efficiently from their electronic medical files.

With respect to targeted development and validation of CPMs, specific predictors can be found more easily, especially when the CPM is based on commonly used clinical measures and data. These datasets are often very large and are therefore statistically powerful [16].

EHR Data Quality

Overview

Leveraging EHR data for research brings challenges with regard to data quality. These records are prone to ascertainment bias and missingness [18,20], especially concerning free text data, where semantic and context understanding are required to correctly classify types of information. Furthermore, data quality depends on how and if a clinician records information in the EHR [19]. This may be even more problematic in secondary teaching hospitals, which have a higher turnover of personnel. Another challenge is information overload, which poses a substantial problem in accessing a particular, significant piece of information from vast datasets. A recent systematic review shows additional technical challenges such as lack of labeled data, spelling correction, medical abbreviation, negation detection, and clinical entity recognition [21].

Data quality is a key contributor to the quality and success of developed CPMs: “rubbish in, rubbish out.” While NLP software is developing rapidly and their quality improves, their output needs to be checked and validated carefully. When using EHR data for the development and validation of CPMs, alongside the widely accepted checklists, we propose additionally considering the following steps in the data extraction process:

Step 1: Include a Clinician, Nurse, or Health Care Professional as the Local EHR Expert and in the EHR Data Extraction Process

This is not always the case, as data extraction may be conducted by supporting staff, business intelligence specialists, or students and interns. However, clinicians have firsthand knowledge of their patients’ conditions, treatments, and histories. Clinicians and health care professionals may be aware of certain patient details that are not well-documented in the EHR, such as informal diagnoses or symptoms not coded in the system. Including this information helps create a more comprehensive and accurate dataset, informing the EHR data capturing process. With regard to unstructured data; discuss the clinical workflow and how and when specific clinical notes are made. As a simple example: when extracting data from the “medical history” part of medical notes, you might find “Hypertension: -.” Does this mean that information on hypertension for this patient is missing, is not applicable, or is absent?

With regard to structured data, check (if applicable) whether protocol changes occurred in the period of interest. Unlike research databases, major protocol changes are not documented in EHRs. In a hospital setting, system updates are regularly performed, new equipment is purchased, or measurement methods are changed. This is not documented in the EHR of individual patients. When using EHR data for research purposes, such as developing or validating a CPM, these organizational factors should be considered. For example, if the clinical chemistry laboratory first measured thyroid hormone FT4 with a Beckman Coulter analyzer with normal values between 7 - 16 pmol/L and later switched to Siemens with normal values between 11 - 21 pmol/L, this significantly influences the outcome of CPMs including FT4. Another example is the measurement of the tumor marker carcinoembryonic antigen, where levels of carcinoembryonic antigen measured with Siemens are approximately 25% lower compared to those measured with Beckman Coulter. Harmonization of such laboratory results within a hospital, but also between hospitals, is therefore important and requires knowledge of protocol changes over time.

Step 2: Perform Validity Checks on the Generated Dataset

Data validation and verification are broadly accepted exercises in research settings. It is the process of checking whether entered data is accurate and consistent. This may encompass the crosschecking of data in a random set of cases, which may be even more relevant in research where data is derived from EHRs. EHR data are complex and heterogeneous, originating from different systems, formats, and medical practices. This variability can introduce inconsistencies and errors. Validation and verification processes are essential to standardize the data, correct inconsistencies, and ensure uniformity in the data used for research.

In addition to checking the data quality of specific variables extracted from EHRs, we advise also executing a crosscheck on the included cases. Specifically, if software is used to compose a cohort, let a clinician provide a list of patients that they believe should be included in the generated dataset, and check whether that is indeed the case (ie, do I find the cases that I should find?). This is important for a number of reasons. First, clinicians can identify patients who meet specific criteria based on nuances that may not be captured in the EHR data alone. This clinical insight is invaluable for ensuring that the correct patients are included in the research cohort. Second, automated systems rely on predefined algorithms to identify patients, but these algorithms can sometimes miss relevant cases or include irrelevant ones. Lastly, clinicians can provide supplementary information to fill gaps in the EHR data, enhancing the completeness and richness of the dataset. This additional information can improve the robustness of the research outcomes.

Step 3: Deliver Information or Metadata on How Certain Variables Are Constructed

Information should be provided and made publicly available on whether a variable is composed from structured codes or from a search in unstructured free-text (for example, reports) and include a list of search terms used (or excluded). Delivering detailed information or metadata on how certain variables are constructed, and understanding whether these variables come from structured or unstructured electronic patient record data, enhances data quality and integrity during the data extraction process and is crucial for transparency and reproducibility [22].

Knowing whether a variable comes from structured (eg, coded fields or predefined formats) or unstructured (eg, free-text notes or narratives) data is essential as they have different characteristics. Structured data is generally more reliable, easier to analyze, and in some cases similar across hospitals (eg, Anatomical Therapeutic Chemical Classification System codes). It follows a predefined format, making it straightforward to extract and use in statistical analyses. Unstructured data, on the other hand, is rich in detailed information but more challenging to analyze due to variability and complexity. NLP and other sophisticated methods are often required to extract meaningful information from unstructured data. Clear documentation of variable construction enhances the impact and credibility of research findings, making it easier for clinicians and policy makers to apply the results in real-world settings.

Conclusion

CPMs may be particularly valuable in secondary care settings, and the introduction of software applications for text mining of EHRs allows the generation of structured "big" datasets. However, the imperfection of EHRs as a research database requires careful validation of data quality. On using EHR data for the development and validation of CPMs, alongside the widely accepted checklists, we propose to additionally consider three practical steps: (1) let a local EHR expert (clinician or nurse) be involved in the data extraction process, (2) perform validity checks on the generated datasets, and (3) provide metadata on how variables were constructed from EHRs. If successful, such datasets are statistically powerful and enable targeted development and validation of CPMs in secondary care settings, filling a major gap in prediction modeling research.

Abstract

Interoperability has been designed to improve the quality and efficiency of health care. It allows the Centers for Medicare and Medicaid Services to collect data on quality measures as a part of the Meaningful Use program. Covered providers who fail to provide data have lower rates of reimbursement. Unintended consequences also arise at each step of the data collection process: (1) providers are not reimbursed for the extra time required to generate data; (2) patients do not have control over when and how their data are provided to or used by the government; and (3) large datasets increase the chances of an accidental data breach or intentional hacker attack. After detailing the issues, we describe several solutions, including an appropriate data use review board, which is designed to oversee certain aspects of the process and ensure accountability and transparency.

Introduction

Background

Interoperability has been an overarching goal of the American health care industry since the American Recovery and Reinvestment Act in 2009. Provider-to-provider sharing of patient information was designed to improve the safety, quality, and efficiency of patient care. The next target for interoperability was provider-to-patient sharing of information. The 21st Century Cures Act called for patients to have electronic access to their health care record [1]. Health Level 7 Fast Healthcare Interoperability Resources was developed for secure data exchange between computer systems using different information storage methods [2].

Interoperability is a prerequisite for meaningful use (MU). The Health Information Technology for Economic and Clinical Health Act, a component of the American Recovery and Reinvestment Act, included incentives for providers to adopt electronic health records (EHRs) as well as penalties for failing MU [3]. The Meaningful Use program requires providers to share data with the Centers for Medicare and Medicaid Services (CMS) to ensure satisfactory health care quality. Using the Quality Reporting Document Architecture [4], providers are required to submit data in support of the quality measures applicable to their practice. If covered providers do not submit data, their rate of reimbursement is reduced.

Although interoperability has been designed to improve the quality and efficiency of patient care, there are unintended consequences of data sharing. To date, few articles have examined the negative consequences of data sharing by providers to governmental entities [5,6]. Data must be generated before it can be shared, so this article begins with clinical data generation.

Ethical Considerations

This study does not include human subject research (no human subject experimentation or intervention was conducted) and so does not require institutional review board (IRB) approval.

Data Generation

Data are generated by both providers and patients during a visit. While most data are generated to serve clinical needs, some are generated solely to satisfy later MU reporting.

Uniform Data Generation

The criteria for satisfying a particular MU requirement do not consider differences in specialty. For example, annual screening for depression is one MU measure (Centers for Medicare and Medicaid Services 2, version 12, 2023) [7]. Patients with depression are frequently undiagnosed in general medicine settings and therefore remain untreated. Explicit screening for depression in these settings is important to identify patients and offer appropriate treatment [8,9]. Administering a validated screening instrument is one way to satisfy the screening portion of the MU requirement.

In contrast, psychiatrists screen patients for depression using implicit methods such as interviewing the patient [10,11]. Requiring them to report an instrument score for each patient

does not further the goal of identifying and treating patients with depression. It does, however, increase the burden of data collection and documentation on both the provider and patient.

Proposed Solution: Broader Criteria for Meeting MU Requirements

Instead of forcing all providers to perform the same task to meet a particular MU requirement, providers should be allowed limited flexibility to decide how best to meet the intent of the requirement.

Free-Rider Problem

In the broadest definition, a free rider receives a benefit without contributing to the cost of that benefit's production [12]. Billing codes determine the provider's compensation for a given patient visit. These codes in part represent the amount of time spent on a given activity. However, there is no billing code for collecting data only required for CMS reporting. Providers are penalized for not providing the data but are not compensated for their time spent; thus, the CMS is acting as a free rider.

Proposed Solution: Current Procedural Terminology Code Modifiers

Current Procedural Terminology code modifiers further describe a procedure code without changing its definition [13]. Creating a modifier specifically for MU data collection would allow providers to bill for the time spent on clinical data collection. Additional payment for data collection should be made by the CMS, since it receives the reports.

Data Ownership

Access to Data

Ownership of data has philosophical implications that differ from ownership of real property [14,15]. A more useful framework for understanding the consequences of MU data collection may be access to data. Patients have a compelling interest in managing their own data. Patients who do not trust their provider with safeguarding their data may withhold information, leading to adverse outcomes [6]. This is especially true for marginalized groups [16].

Despite advances in interoperability and data-sharing mandates [1], neither providers nor patients can usually access all data pertaining to their role. Health care entities create data silos and deny access to patients and providers who are not, or are no longer, part of the entity. Data do not commonly follow patients who are seen by multiple providers. Outside of closed systems such as the Veterans Affairs, in which patients receive all care within the system, data do not follow providers who work in multiple health care settings, or who change jobs.

Proposed Solution: Improved Interoperability Processes

While interoperability is constantly improving, the process of data sharing continues to be cumbersome. We propose the following process: When a patient begins receiving care at a particular entity, the consent form should include data sharing with providers outside of the entity. If the patient does not opt out, any provider who has the patient's demographics and certifies that they need access to protected health information (PHI) should receive it. Allowing patients to consent ahead of time lowers the burden on both the patients and the providers.

Data Sharing

Overview

Data can be shared with the CMS either by a provider via EHRs or by an insurance company. The CMS receives complete charts, including all PHI. Neither providers nor patients are directly involved in this process, and they may not know when or how often data sharing occurs.

Calculating Compliance

Many MU measures include a numerical criterion. To calculate the percentage of patients who have had a particular test or screening requires collecting not only the charts of patients satisfying the measure (the numerator) but also the charts of patients not satisfying the measure (the denominator). In practice, this means that any chart may be included in any dataset, and that many charts are included in multiple datasets. Patients and providers have no control over this process and no way of knowing which charts are included in which dataset.

Lack of Patient Consent

Patient consent forms include consent for sharing data with other members of their health care team, designated family members, and insurance companies. Currently, consent forms do not include sharing data with the CMS as part of MU requirements. Patients are unaware that their data are shared with the CMS, via their providers and their insurance companies, and have no mechanism to give or deny consent.

Proposed Solution: Updated Consent Forms and Opt Outs

Including a section on data sharing with the CMS in patient consent forms is straightforward. Both providers and insurance companies can include a section explaining that PHI may be shared with the CMS and allow patients to opt out.

However, opting out could have unintended consequences. Some patients may hesitate to share any health data with the CMS. More patients may hesitate to share sensitive data, such as mental health or substance misuse data, with the CMS. Therefore, the CMS would need to decide how to handle compliance calculations. Giving patients the opportunity to opt out of data sharing also requires changes to EHR programming.

Data Use and Potential Misuse

The intent of MU data collection is to improve the efficiency and effectiveness of health care. However, once collected, data can be used for any number of other purposes. At present, it is unclear what safeguards are in place to prevent other branches of government from accessing the data for their own purposes. For example, California allows a person to obtain a driver's license without proof of legal immigration status. The personal data collected can then be accessed by the Department of Homeland Security to perform civil immigration enforcement [17].

Data Breaches

The US government has experienced multiple data breaches over the last 15 years, both accidental and through hacking [18-21]. Improvements in processes at least partially address accidental breaches. Hacking by sophisticated foreign entities is more difficult to prevent. Hackers may be attracted by the combination of the volume of data and its potential sensitivity [22,23].

Proposed Solution: An Appropriate Data Use Review Board

We propose the creation of an independent board, modeled after an IRB, to address many of the concerns related to data collection and use. Research on human subjects requires the approval of an IRB [24,25]. This requirement was put in place in the United States after a series of egregiously unethical experiments was conducted. Each IRB is required to have at least 5 members, with at least one whose main concern is scientific, one whose main concern is nonscientific, and one who is not affiliated with the academic institution in which the proposed research would take place.

As the data recipient is the CMS, a part of the federal government, we propose the following composition for an appropriate data use review board, made up of a minimum of 6 members to allow for group decision-making:

- At least one member who is employed at the CMS
- At least one member who is a clinician providing data
- At least one member who represents patients
- At least one member with communication experience
- At least one member who is a biomedical informatician with big data expertise
- At least one member who owns and operates a small market-share EHR software company

Each of the members of the appropriate data use review board has a critical role to play. As the data recipient, the CMS needs to lay out both the data required and the rationale behind collecting the data. The clinician and EHR owner provide important insight into the impact of data collection on workflows, as well as the feasibility of modifying software to streamline data collection and reporting. The patient representative provides the patients' perspective as well as communication guidance. As any decision reached by the review board needs to be communicated clearly and effectively to patients, the communication specialist and patient representative would work together to craft and disseminate necessary information. The biomedical informatician can assist the CMS with deciding on data needs as well as suggest the most current data analysis methods. They can also help the patient representative and communication specialist explain different ways to protect patient data from unauthorized disclosure.

After an open application and vetting process, members to the board should be appointed by a bipartisan committee of the US House. Their term of service should be 4-5 years to allow members to become proficient in their roles.

Proposed uses of data should be approved by the committee and communicated to the public. Public input should be sought through a variety of means and become an important aspect of decision-making. Disclosure of data use and data breaches should be prompt and effective, without further compromising data security.

Effect of MU on the EHR Ecosystem

MU requirements affect not only patients and providers but also EHR companies. MU certification and recertification is time consuming and costly. While EHR companies with a large market share can justify the expense and pass the cost on to their customers, companies with a smaller market share cannot. Lack of certification leads to decreased market share, thereby encouraging consolidation across the industry.

Consolidation may be advantageous to the government because it is easier to negotiate with fewer companies. However, consolidation leads to increased costs for providers and less competition. It makes independent, autonomous practice, away from corporate monocultures, very difficult. Customer service also suffers because customers have fewer choices.

Customer service is not the only casualty; innovation is also affected. Smaller companies are more likely to produce innovative products. However, given the high bar of MU certification, bringing these innovations to the market often proves to be cost prohibitive. Similarly, though open-source software has also driven down costs and spurred innovation [26], given the expense associated with MU certification, many companies committed to open-source software have stopped providing their code freely.

Conclusion

MU was made possible by progressive advances in interoperability. While CMS data collection has the potential to advance health care, it leads to the aggregation of large datasets that are vulnerable to unintentional data breaches and data misuse. Since the data collection is largely invisible to both providers and patients, an appropriate data use review board is needed to protect all participants.

Acknowledgments

We want to thank Ross Koppel for insightful comments on an early draft of this paper.

Abstract

With the popularization of large language models (LLMs), strategies for their effective and safe usage in health care and research have become increasingly pertinent. Despite the growing interest and eagerness among health care professionals and scientists to exploit the potential of LLMs, initial attempts may yield suboptimal results due to a lack of user experience, thus complicating the integration of artificial intelligence (AI) tools into workplace routine. Focusing on scientists and health care professionals with limited LLM experience, this viewpoint article highlights and discusses 6 easy-to-implement use cases of practical relevance. These encompass customizing translations, refining text and extracting information, generating comprehensive overviews and specialized insights, compiling ideas into cohesive narratives, crafting personalized educational materials, and facilitating intellectual sparring. Additionally, we discuss general prompting strategies and precautions for the implementation of AI tools in biomedicine. Despite various hurdles and challenges, the integration of LLMs into daily routines of physicians and researchers promises heightened workplace productivity and efficiency.

Introduction

Large language models (LLMs), exemplified by OpenAI's ChatGPT, have garnered significant attention as text-based artificial intelligence (AI) tools in record time [1]. While they excel in mimicking natural language patterns, LLMs lack inherent factual accuracy and struggle with tasks requiring, for instance, mathematical reasoning at the graduate level [2]. Current research explores the association between LLMs and external databases [3], as well as the combination of LLMs with preexisting data and software tools as seen in ChatGPT's incorporation within Microsoft Copilot. This facilitates the step toward retrieving and articulating coherent responses using factual information from web-based sources, which is particularly relevant in fields like health care and the natural sciences where supplementation with external and up-to-date data is an essential prerequisite for meeting professional standards. ChatGPT, for instance, already demonstrates versatile applications in the medical domain, spanning from the identification of research topics, aiding in medical education, and supporting clinical and laboratory diagnosis to enhancing knowledge dissemination among health care professionals, extracting medical knowledge, and engaging in medical consultation [4,5]. However, despite LLMs' seemingly ideal suitability for enhancing personal productivity and keeping up to date with latest research, many professionals in our personal circle, including one of the coauthors, report discouragement after a few initial experiences with widely available LLMs. From our experience, criticism that dampens the enthusiasm of inexperienced users for adopting LLMs in work routine includes (1) superficial responses from chatbots, which read well but fail to capture the level of factual detail often expected in professional context; (2) confabulated information that is factually wrong or has no factual basis (also called "hallucination"); (3) lack of citation and source disclosure; (4) limited control over output format; and (5) failure to implement adaptation requests or criticism. Fortunately, for many use cases, these limitations can be effectively overcome by precisely instructing the LLM. These input instructions, known as "prompts," can be formulated in natural language rather than code, thus enabling intuitive usage. Nevertheless, there are several recommendations on how to effectively interact with

an LLM to obtain the desired output. This viewpoint article provides practical guidance along with an overview of potential LLM applications in the everyday work of health care professionals and scientists who have limited experience with LLMs so far. Selected examples will illustrate why LLMs offer added value for these applications and how they can be used effectively. Finally, we will discuss overarching aspects to consider when using LLMs.

General Recommendations for Using LLMs

Before delving into specific use cases within the medical and scientific context, let us first introduce some universally applicable suggestions for optimizing prompts. Drawing from our experience, prevalent recommendations can be broadly categorized into specifying the precise task for the LLM, elucidating relevant contextual factors, and delineating the desired output (Multimedia Appendix 1).

To align the outcome closely with personal expectations, it can be advantageous to construct one or more exemplary outcomes and append them as explicitly classified examples to the prompt, separated by quotation marks or parentheses. Based on our usage experience, the choice of language itself also influences output quality; hence, formulating the prompt in a widely used language, ideally English, is recommended, as it enables the LLM to draw from a wider database. To refine the desired output, unambiguous language should be used, preferably using positive rather than negative formulations. Particularly with complex tasks, the "Chain of Thought Prompting" technique can yield improved results [6]. This technique enhances the reasoning capabilities of LLMs by breaking down multistep problems into a series of intermediate reasoning steps. For generating suitable prompts, it is also feasible to integrate the LLM by providing the program with relevant instructions and subsequently request feedback to iteratively refine the desired prompt. Further guidance on optimizing prompts can be found within the realm of "Prompt Engineering" and on websites of various popular LLM providers.

Use Cases

There are numerous opportunities for the use of LLMs in the professional environment of scientists and health care professionals [eg, 4,5]. The use cases presented in this viewpoint, therefore, only provide a spotlight on this broad field and by no means an all-encompassing overview. Based on personal experience, our reasons for selecting the applications presented in the following sections are that they are easy to implement also for individuals with limited prior LLM experience, quickly yield satisfactory results, and are transferable to similar application scenarios (Table 1).

Table . Overview of presented use cases in this article and the complexity of their corresponding prompts. For each category of prompt complexity, at least 1 illustrative example with the original prompt and output is given in the course of this article.

	Use case	Description	Prompt complexity
1	Translation	Executing customizable translations	Low
2	Text editing	Refining text and extracting information	Low
3	Information compilation	Constructing comprehensive overviews and specialized insights	Medium
4	Idea elaboration	Integrating ideas into cohesive narratives	Medium
5	Training and education	Developing personalized learning schedules and crafting educational materials	Medium
6	Personalized sparring partner	Facilitating intellectual sparring and creative brainstorming	High

Customizing Translations

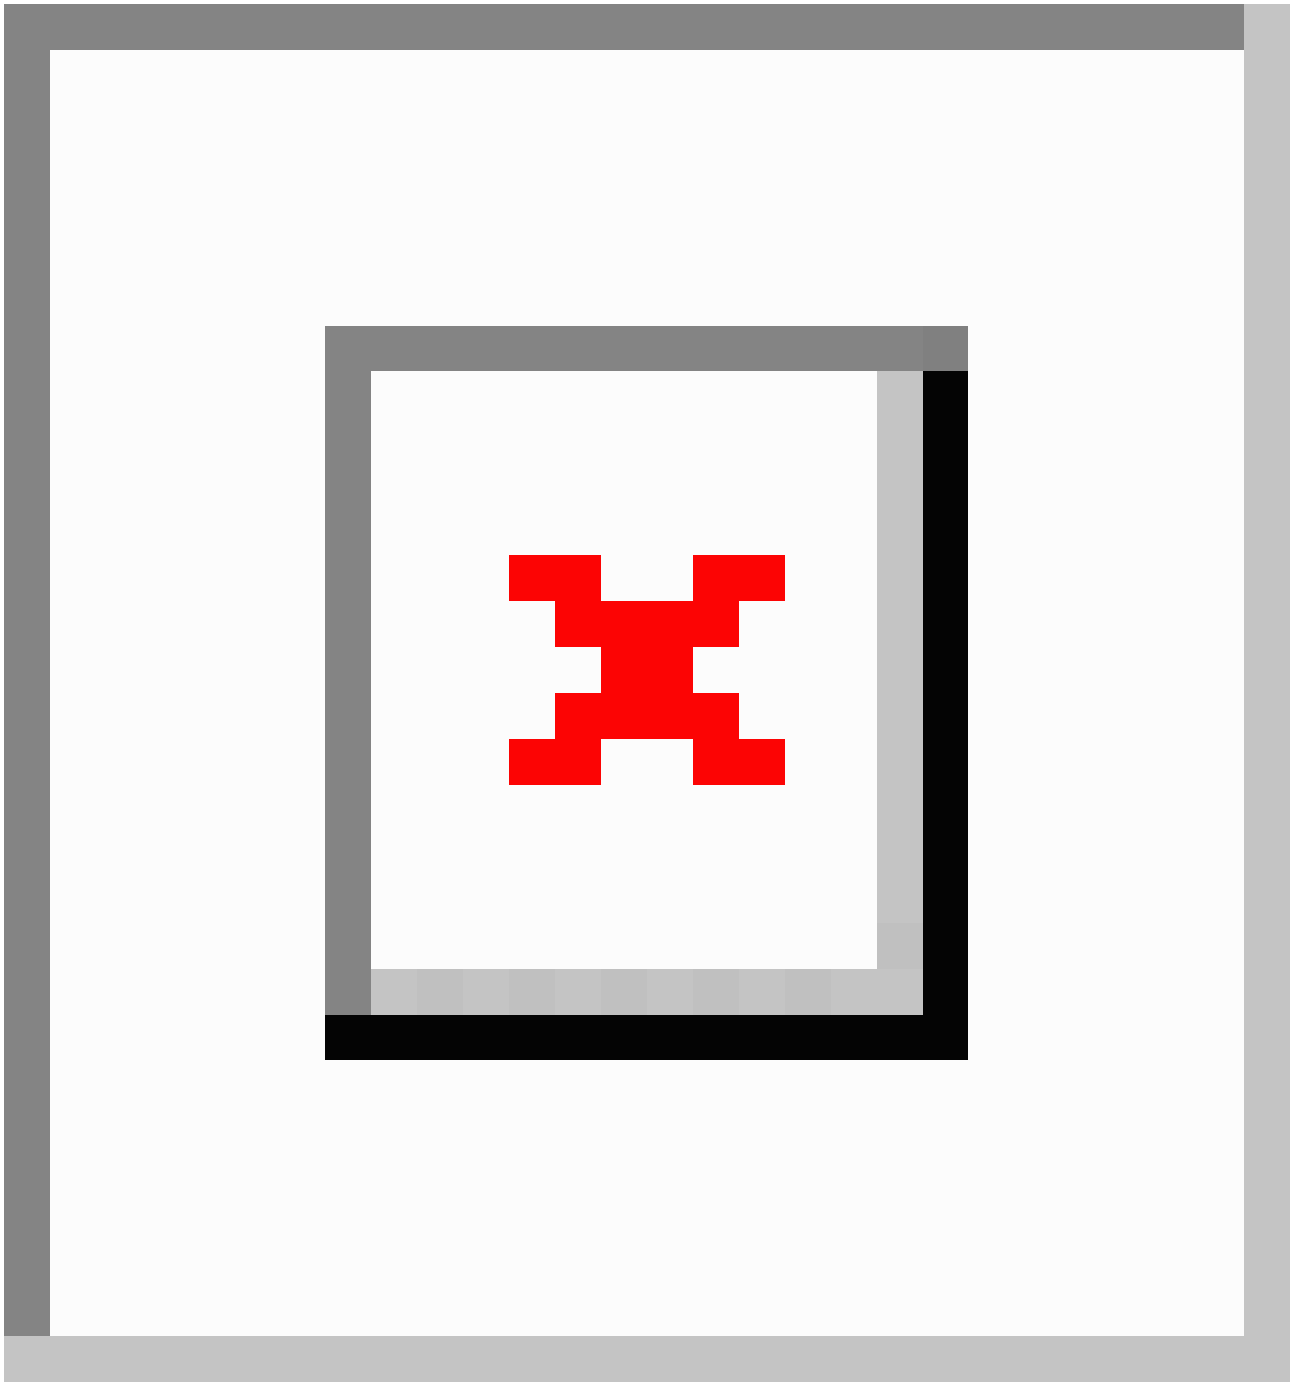
For widely spoken languages, the milestone of ensuring a translation quality comparable to that of translation software has been achieved, for instance, by ChatGPT [7]. In contrast with dedicated translation tools, leveraging an LLM provides diverse customization opportunities for vocabulary, tone, and style, combining general benefits of a proficient translation software with specific strengths inherent in an LLM. A translation prompt should encompass details on the target language, desired degree of alignment with the original text (literal vs freely translated), intended target audience (eg, PhD vs elementary school students), and writing style (formal vs informal). A noteworthy application involves the analysis of scientific information, wherein an LLM not only translates but also succinctly condenses and linguistically adjusts the content to the recipient while retaining its meaning. This facilitates communication and understanding not only across language barriers but also across diverse backgrounds and levels of education, which is particularly crucial in medical and scientific communication with laypeople.

An example for a translation prompt could look like the following: "Translate the following text given in quotation marks into Spanish. Stick closely to the original text. Adopt a formal writing style. Make sure the text is understandable for an adult layperson without medical training."

Editing Text and Extracting Information

One of the core strengths of LLMs lies in handling text, such as summarizing and efficiently organizing written information. For this use case, the text to be summarized or edited can be either typed or uploaded to the LLM as a document, with the latter feature, for instance, available from ChatGPT version 4.0 onwards. The output length, format, and style can be tailored by a precise prompt, as shown in Figure 1. By specifying the audience or assigning a writer persona, the output style and depth of factual detail can be adjusted.

Figure 1. Tailored summaries of an uploaded document depending on the intended target audience. Two different prompts asking for a summary of the same uploaded document (blue). A full-length PDF of one of the authors' open access scientific articles was uploaded as the input [8]. The prompt on the left specifies word count, output format, and audience for a summary to be used in a professional context. The prompt on the right exemplifies how large language models can be used to extract key information and make the content widely accessible for any audience. Answers given by OpenAI's ChatGPT-4 are shown in gray.



Information Compilation: Creating Comprehensive Overviews and Specialized Insights

As the body of available knowledge grows both in depth and breadth, LLMs are a helpful tool to gain specialized insights or general overviews over topics of interest. However, when LLMs are confronted with factual questions, hallucination can occur, meaning that the returned information is syntactically and grammatically accurate but factually incorrect. Special attention should be paid to this matter by meticulously verifying all facts,

references, sources, and links provided by the LLM. Furthermore, while LLMs without internet access often explicitly mention that their "knowledge" is limited to a specific time period, from our practical usage experience, there has rarely been an indication that the prompt's answer might be beyond the capabilities of the program. For the current version (4.0) of OpenAI's ChatGPT, which has internet access, allowing it to execute a web search and mine information, it has been demonstrated that the incidence of hallucinations is significantly lower than that of the previous version (ChatGPT-3.5) [9]. By summarizing and comparing findings from various sources, LLMs are especially useful for exploring a topic in which the user may not be an expert yet. They can also aid in highlighting trends across different sources or extracting divergent positions on a debated topic. However, performing a thorough web search with the help of LLMs often requires specific instructions.

For instance, while the prompt "What are the latest developments in quantum computing?" triggered a web search and quoted 3 sources, the more detailed prompt, "Search the web for research on quantum computing from 2023. What are the latest developments in the field?" yielded results based on 6 sources and a link leading to the web search. Adding "Include your level of confidence, sources and date of answer, and whether your answer is speculative. Make it a markdown table at the end of your answer" returned a long answer based on 5 references and included a statement on research confidence and speculation, as well as a tabular summary of the results and sources. Asking the AI chatbot to "Consider at least 10 sources" returned 8 brief paragraphs based on 12 different sources (Multimedia Appendix 2).

Elaborating Ideas: Integrating Bullet Points Into Flowing Text

Standardized documentation tasks are a frequent requirement in medical-scientific fields. A substantial amount of time is dedicated to formulating individual pieces of information into full-text narratives. By acquainting an LLM with one's preferred or desired writing style, it becomes possible to transform bullet-pointed information into full text. Initially, this involves providing the LLM with examples of target frameworks in terms of structure, content, and style. Once an example is established, additional information can be incorporated and processed with reference to this example. This approach thus represents the opposing process to condensing an extensive text to fewer key points. A specific application in the medical field might be the generation of discharge summaries and medical reports [10]. Initially, structural layout and linguistic style need to be defined. Subsequently, information needed for generating a medical summary report can be listed in bullet points as a prompt and transformed into full text by the LLM.

An exemplary prompt for this use case could appear as follows:

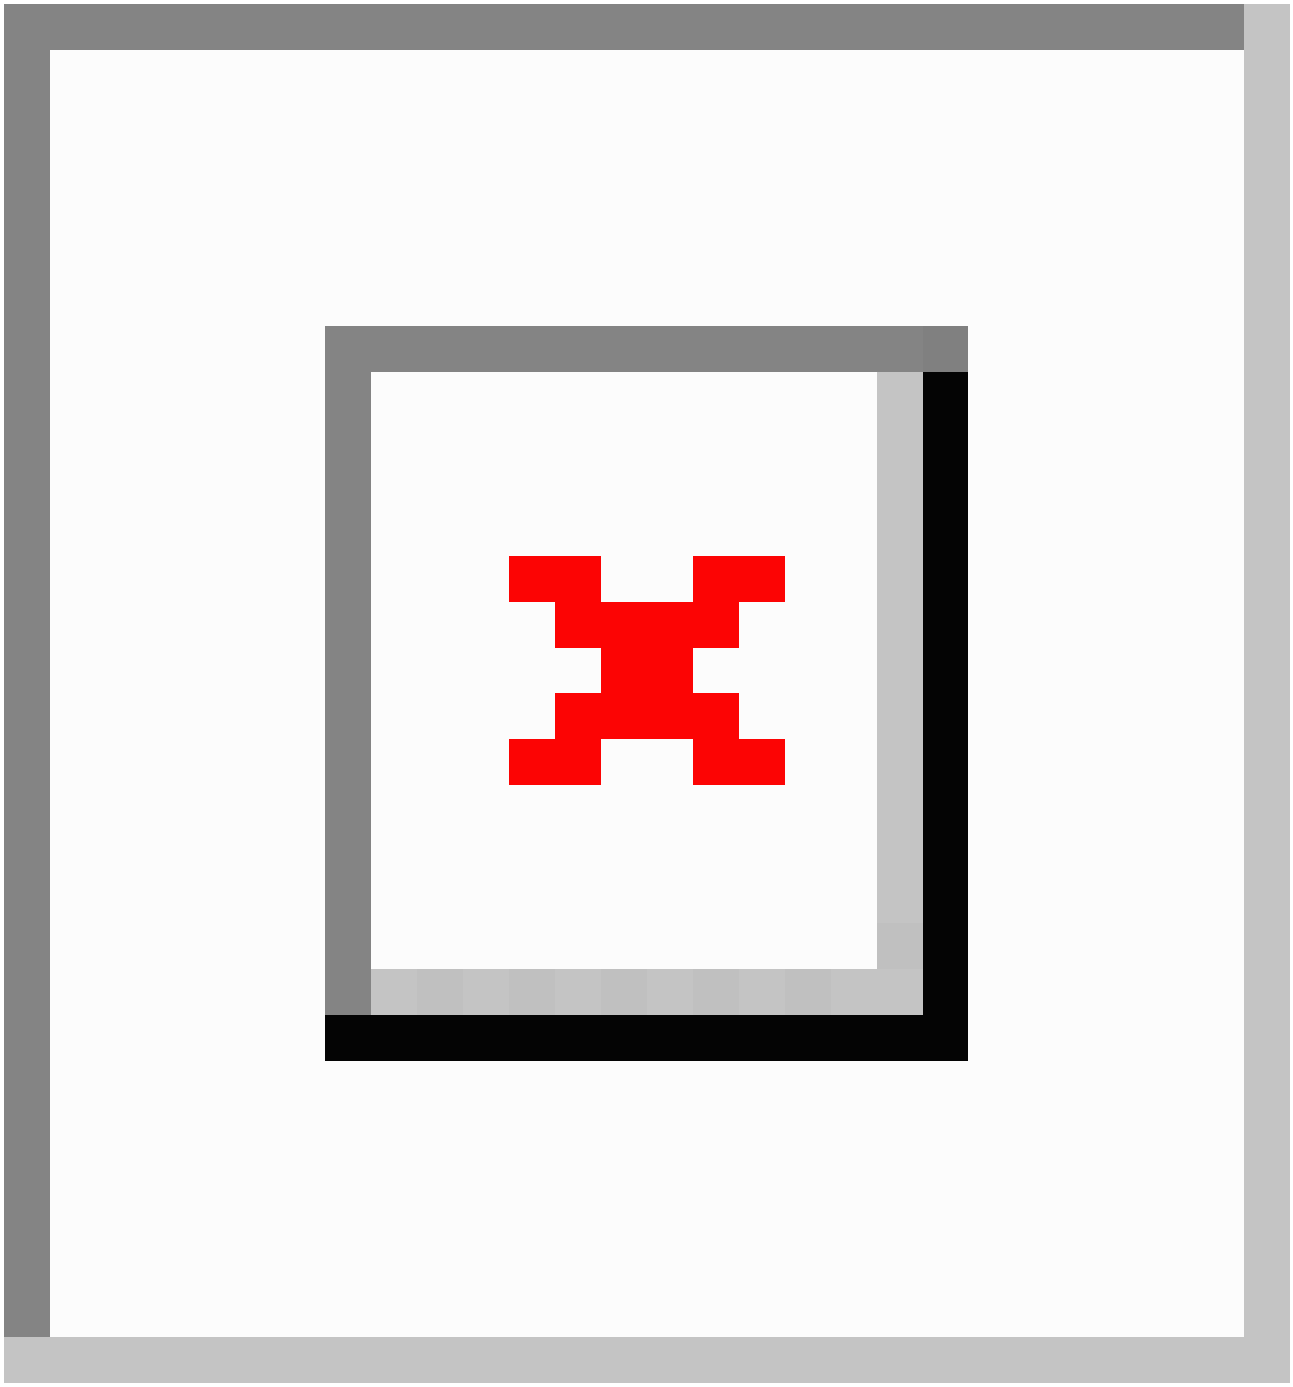
> *Here are two examples (named Example 1 and 2, each in quotation marks) demonstrating the structural and content-based layout of an epicrisis authored by me: ("Example 1," "Example 2"). Now, utilize the following pieces of information to compose a coherent text and align them linguistically and structurally to the two examples mentioned above: (pieces of information in bullet-point style)*

For such applications, special precautions, such as anonymizing all data that could be used to identify a person, must be strictly observed.

Training and Education: Developing Customized Learning Schedules and Teaching Material for Students

Leveraging LLMs in the medical domain also offers applications to training and education. Their adaptive learning capabilities hold promise, for instance, in crafting personalized learning plans for medical professionals. LLMs can also harness vast repositories of medical information and scientific data to curate tailored educational materials. By analyzing a learner's proficiency level, preferred learning modality, areas of interest along with requirements and demands, LLMs can generate personalized curricula and suggest resources, textbooks, or web-based courses. In the context of student education, LLMs present opportunities for the development and structuring of seminars that optimize learning outcomes. By aggregating and analyzing diverse sources of medical and scientific information, LLMs can assist educators in designing seminars that align with specific learning objectives and curriculum requirements [11]. As shown in Figure 2, LLMs can aid in crafting and structuring seminar topics, designing interactive presentations, and suggesting clinical scenarios for case studies, following a single prompt.

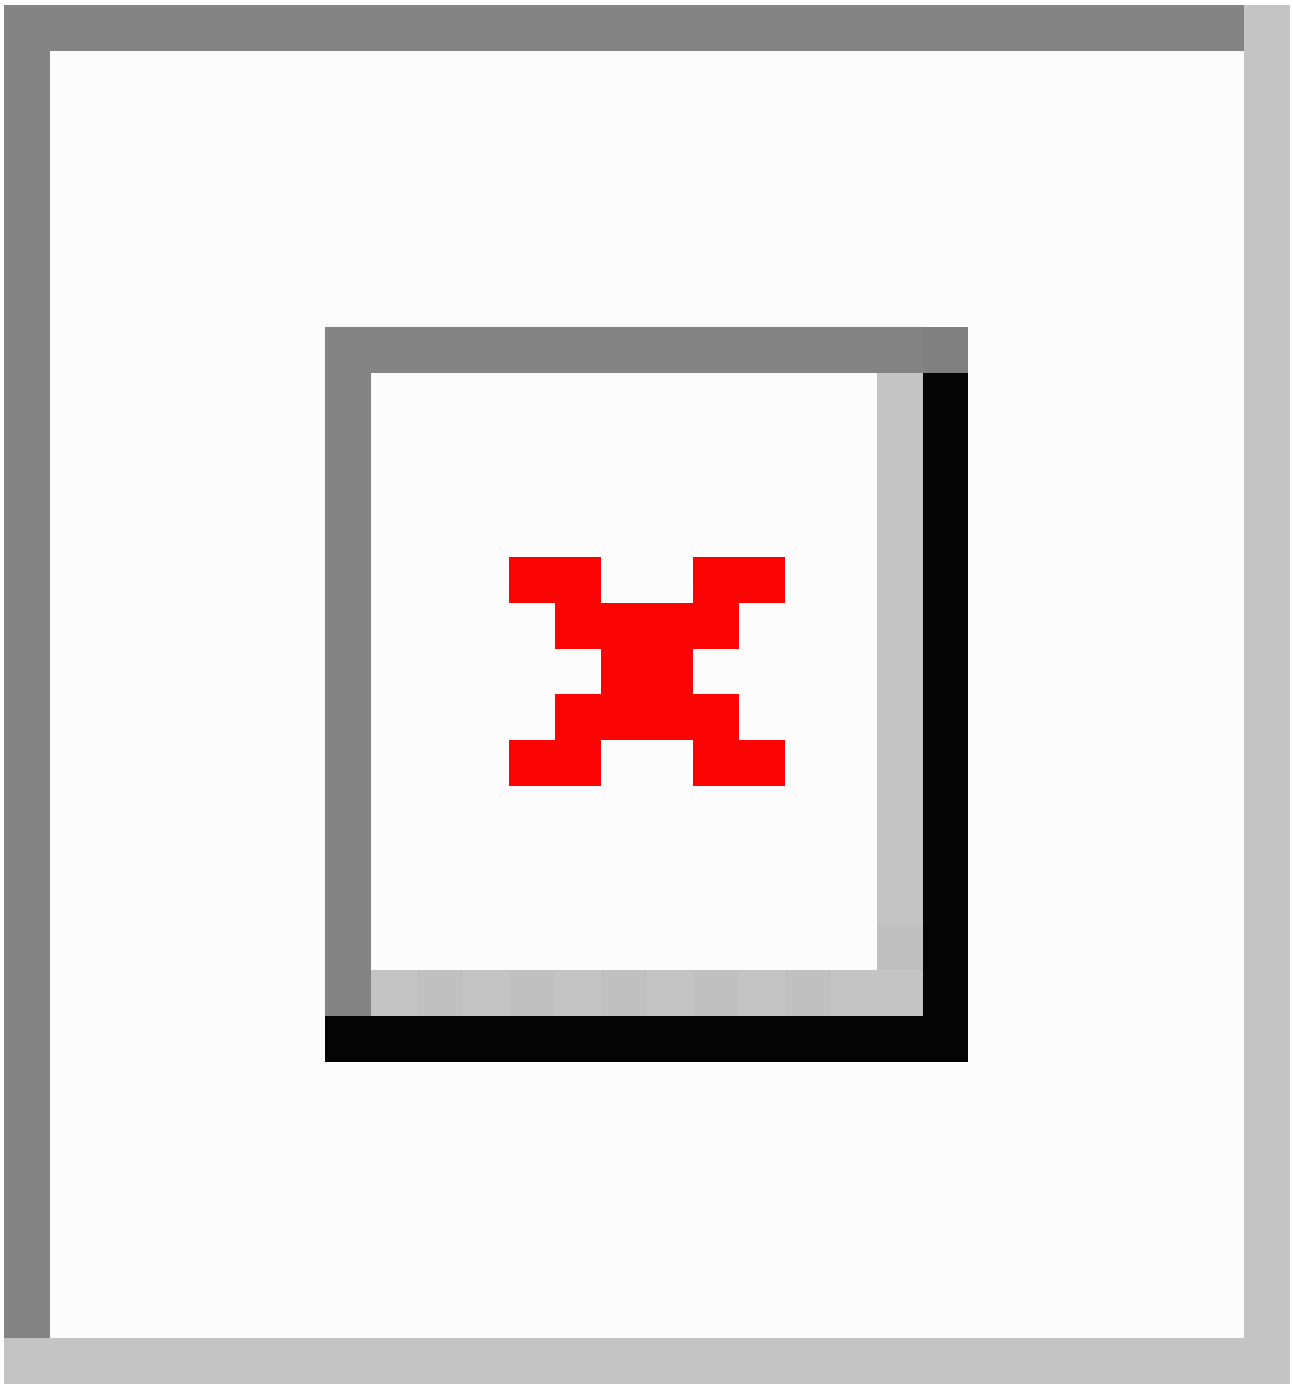
Figure 2. Designing customized teaching material to facilitate medical education. An example prompt asking for a course schedule on a given topic for a specific audience (blue). The response by ChatGPT-4 is shown in gray. The output is presented in tabular format.



Personalized Sparring Partner: Challenging Ideas, Supporting Brainstorming, and Being Queried

This chapter delineates the transformative potential of LLMs as cognitive partners, elucidating their ability to challenge preconceived notions, fuel imaginative thinking, foster structured brainstorming, and provide feedback on the user's theories or hypotheses. Thus, using LLMs as personalized assistants might help researchers overcome writer's block and break out of their creative rut by providing diverse perspectives. The iterative dialogue with an LLM facilitates a reflective process for individuals, compelling them to articulate their ideas cogently. This fosters a deeper understanding of the proposed concepts and enables refinement through robust debate and structured discourse. This feature can be used, for instance, by prompting the LLM to be queried on a specific topic, as shown in Figure 3. It is helpful to first introduce the setting and specify the desired output. To help the LLM process the task, the respective prompt can be subdivided into several shorter inputs.

Figure 3. Using ChatGPT as a personal sparring partner to simulate interactions and discussions. Exemplary prompts asking for a study plan on rheumatology (blue) and then to be tested on the contents of the proposed plan. The task is broken down into 2 prompts, resulting in a conversational interaction. First, ChatGPT-4 replies with a detailed schedule and specific advice for 21 study sessions over the course of 1 week (gray). The first answer is truncated and shown in smaller font due to limited space. Next, ChatGPT-4 is asked to test the user on the proposed topics. Upon receiving an answer, the large language model first corrects the user's answer and then proceeds to pose the next question, thus correctly referring to the previously defined task. EULAR: European Alliance of Associations for Rheumatology.



Technical Hurdles and Challenges

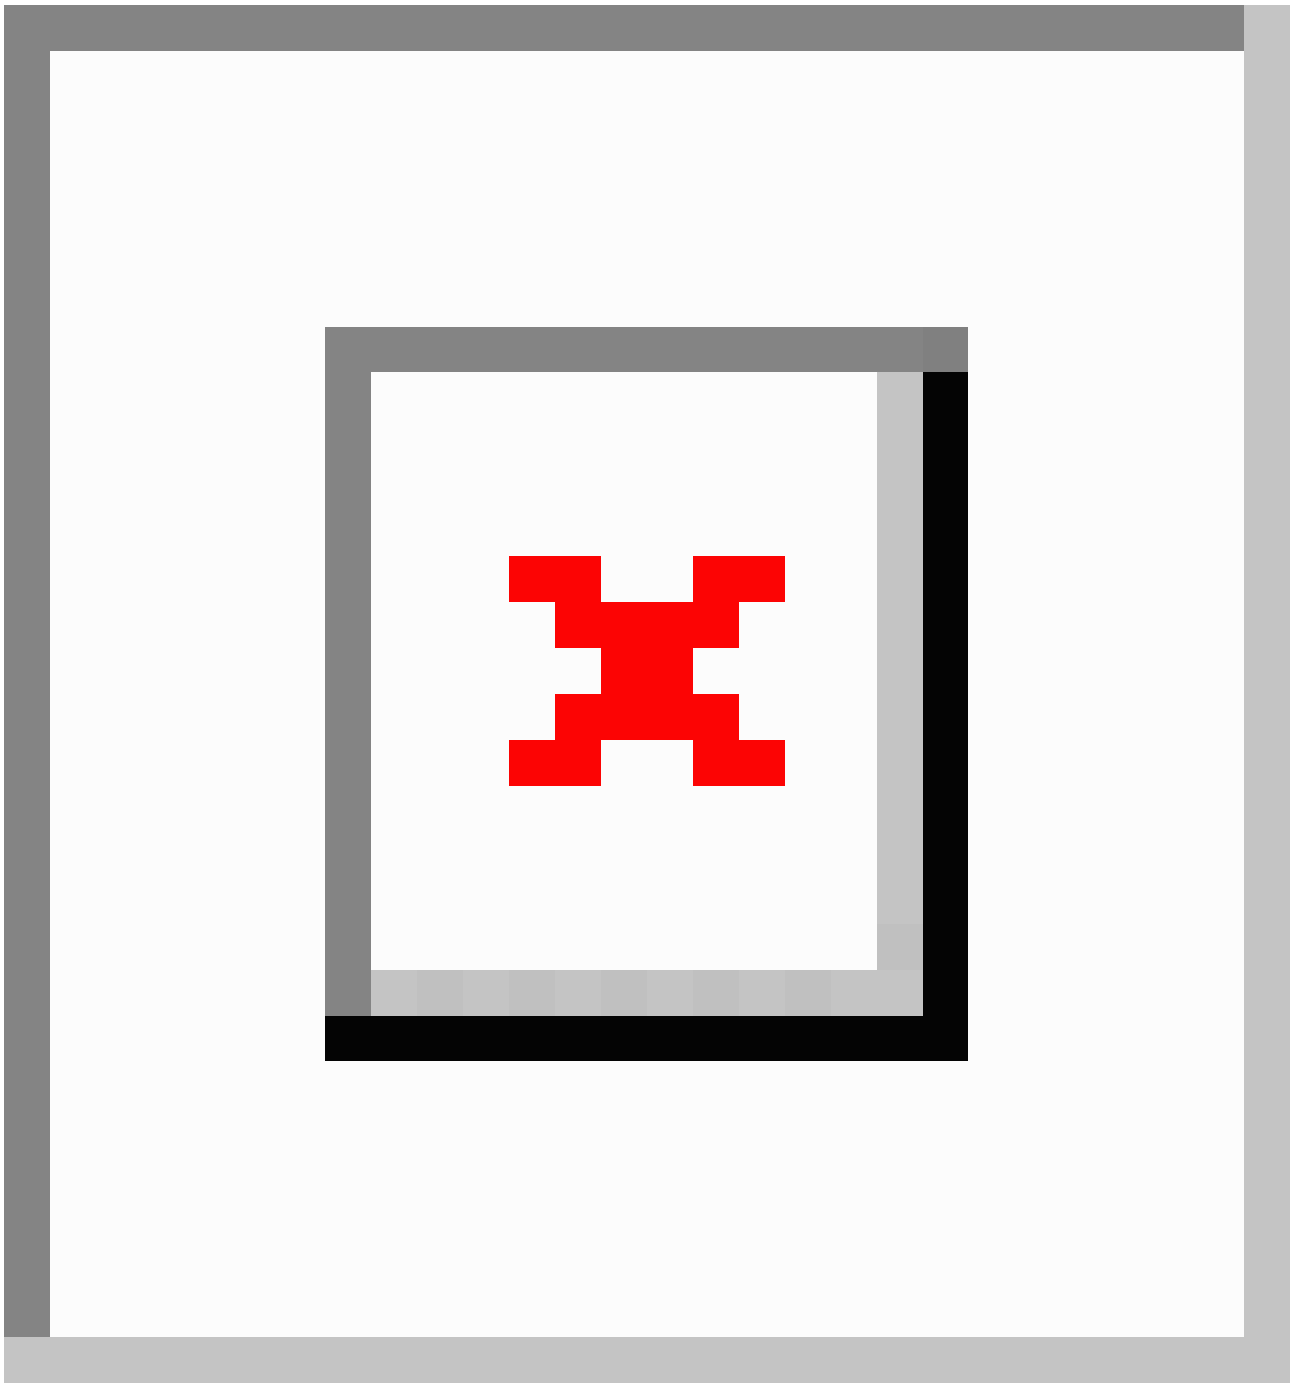
Regarding LLMs, the generation of factually incorrect responses or an output that may be well worded but disconnected from the input is known as a hallucination and may discourage further use of LLMs, particularly among professional users who rely on a high level of output accuracy. Consequently, using LLMs as mere fact-finding tools not only carries substantial risks of misinformation but also fails to fully exploit the actual strength of LLMs in handling extensive volumes of text. Therefore, we do not recommend using LLMs for looking up hard facts or for conducting rigorous literature searches. While completely preventing hallucinations is likely unattainable, various prompting strategies, such as the previously mentioned chain-of-thought prompting, specifying concrete example outputs (few-shot prompting), or uploading reference documents (retrieval-augmented generation) offer empirical evidence for reducing hallucinations [12] and can also be applied by novice users. On a broader level, another technical hurdle to achieving a meaningful impact in health care is the seamless integration

of LLMs into existing systems and workflows [13]. Resource constraints, a lack of clinical validation for these tools, and opaqueness in decision-making are exemplary barriers in this regard, which could be overcome in the future when more practical application experience has been gained and clear regulatory guidelines and frameworks have been established.

Random Versus Deterministic Responses

A limitation of the ChatGPT web interface is the randomness of the responses, meaning that the model may provide a slightly different reply for each new prompt. This is particularly evident with long and complex outputs, which can vary greatly in length, tone, and overall quality, even when the same prompt has been used. The use of an application programming interface (API) offers the same GPT models and functionalities as regular web chats but comes with expanded features for users who wish to purchase a customized model and integrate it into their business software. The API not only enables users to integrate the various available GPT models into their own applications and products, but also allows for more precise customization of the LLM, including a temperature setting. This parameter controls the randomness of the LLM's responses, with a low temperature setting resulting in a more consistent and deterministic output, while a higher temperature generates more varied and creative responses. To demonstrate this, we asked GPT-4 to tell a joke, as shown in Figure 4. At a temperature of 0, the model repeated the same joke on scientists and atoms 3 times, varying its response by only 1 word. With increasing temperature, the program responded less often with its usual atom joke. A low temperature setting may be useful to produce replicable outputs of similar length, style, or structure. A high temperature setting would potentially be useful, when similar prompts are used for repetitive tasks, but a varying output is required, such as when composing invitation emails for recurring professional events without reusing identical content every time.

Figure 4. Setting the output temperature via the application programming interface (API) to generate deterministic results. An identical prompt was entered into the OpenAI API 3 times using the GPT-4 model (chat was cleared between prompts). When the temperature (Temp) was set to 0, the output showed only minimal variation as the model behaved deterministically. At higher values of Temp=1 or Temp=2, the output variety also increased.



Responsible Use of LLMs

The transformative potential of using and integrating LLMs into clinical workflows and health care systems must be approached with caution and guided by rigorous ethical principles and regulatory oversight. One of the foremost challenges lies in patient privacy and data security. As LLMs rely on vast amounts of patient data for training, there are major concerns regarding privacy breaches and unauthorized access [13]. Robust data anonymization, secure storage, and adherence to privacy regulations are essential. Consent for data use must be transparently obtained. From an ethical perspective, LLMs may inadvertently perpetuate biases present in their training data, leading to unequal treatment recommendations [14]. Rigorous bias detection and model fine-tuning are necessary, while legal frameworks should ensure algorithmic fairness and accountability. Lastly, transparency of decision-making processes is crucial, as clinicians need insights into how LLMs arrive at their recommendations [15]. All these limitations should be considered when LLMs are used by health care professionals or scientists. Striking a balance between technological advancement and human safety, multiple governments, companies, and institutions have established guidelines for responsible LLM use. The World Health Organization, for instance, emphasizes the significance of

adhering to ethical principles when using LLMs in health by outlining 6 core principles: protecting autonomy, promoting human well-being, ensuring transparency, fostering responsibility, ensuring inclusiveness, and promoting sustainable AI [16].

Conclusion

LLMs are potent tools, providing immediate and user-friendly access to substantial computational capabilities for a broad range of individuals, while bypassing the necessity for programming skills. Despite certain technical, legal, and ethical challenges, the integration of LLMs into the daily practices of medical professionals and researchers holds potential for significant enhancements in productivity and efficiency. However, as for any tool, the impact of LLMs will be shaped by their intended application. In summary, to address the various challenges arising from the use of LLMs, we believe that a multistage evaluation process is indicated: first, it should be determined which tasks can be appropriately outsourced to such a tool and weighed up against potential implementation hurdles [17,18]. Issues with regulatory, ethical, and legal requirements also need to be examined. Subsequently, the generated material must be thoroughly checked for content accuracy and appropriate references to mitigate the risk of hallucinations or plagiarism [18,19]. Finally, any use of these tools must be transparently disclosed, with accountability always resting with the human user [20]. Overall, the orientation toward a bioethical framework composed of the principles of beneficence, nonmaleficence, autonomy, and justice provides valuable guidance for the deployment of LLMs in a medical context [21]. We advocate for responsible LLM usage, necessitating a comprehensive understanding of their limitations, an awareness of potential data biases, and a consistent adherence to ethical standards.

Acknowledgments

No external funding in the preparation of this paper. When preparing this manuscript, the authors used OpenAI's ChatGPT-4 to translate expressions and suggest vocabulary for improved readability (search prompts shown in Multimedia Appendix 2). After using this tool, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

Authors' Contributions

Abstract

The growing adoption and use of health information technology has generated a wealth of clinical data in electronic format, offering opportunities for data reuse beyond direct patient care. However, as data are distributed across multiple software, it becomes challenging to cross-reference information between sources due to differences in formats, vocabularies, and technologies and the absence of common identifiers among software. To address these challenges, hospitals have adopted data warehouses to consolidate and standardize these data for research. Additionally, as a complement or alternative, data lakes store both source data and metadata in a detailed and unprocessed format, empowering exploration, manipulation, and adaptation of the data to meet specific analytical needs. Subsequently, datamarts are used to further refine data into usable information tailored to specific research questions. However, for efficient analysis, a feature store is essential to pivot and denormalize the data, simplifying queries. In conclusion, while data warehouses are crucial, data lakes, datamarts, and feature stores play essential and complementary roles in facilitating data reuse for research and analysis in health care.

KEYWORDS

data reuse; data lake; data warehouse; feature extraction; datamart; feature store

Introduction

Over the last few decades, the widespread adoption and use of health information systems (HISs) have transitioned a substantial amount of clinical data from manual to electronic format [1]. HISs collect and deliver data for care, administrative, or billing purposes. In addition to these initial uses, HISs also offer opportunities for data reuse, defined as “non-direct care use of personal health information” [2], such as research, quality of care, activity management, or public health [3]. Hospitals have gradually adopted data warehouses to facilitate data reuse [4,5]. Even if the data warehouse is a popular concept, data reuse is not limited to feeding and querying a data warehouse. In this viewpoint, our objective is to outline the different components of the data reuse pipeline and how they complement and interconnect with each other. This definition is derived from our personal experiences and insights gained through collaboration with colleagues at various institutions [5-8]. Additionally, we draw on the collective experiences shared by professionals in the field, contributing to a comprehensive understanding of data reuse practices in diverse health care settings. The pipeline is illustrated in Figure 1 and detailed below. Table 1 compares characteristics of each component. Last, Multimedia Appendix 1 provides examples of data, structures, and architectures for each component of the data reuse pipeline.

Figure 1. Components of the complete pipeline for data reuse. EHR: electronic health records; ETL: extract-transform-load.

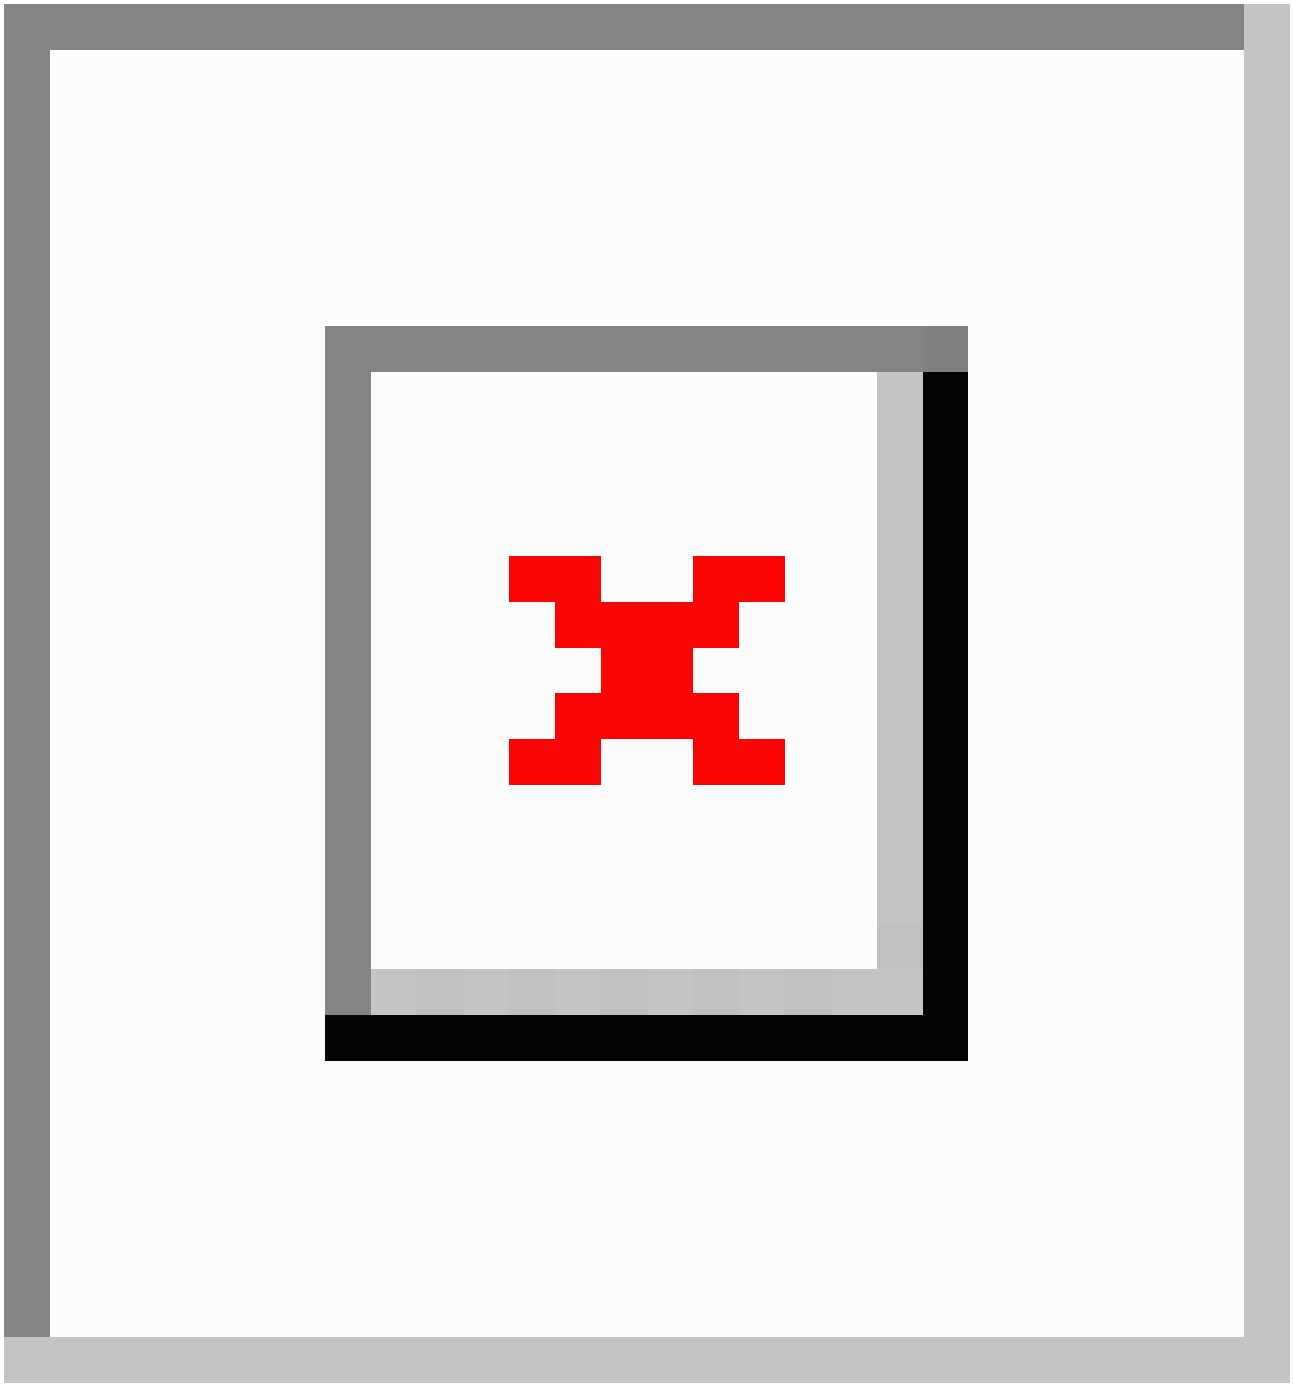

Table . Characteristics of each component of the data reuse pipeline.

Characteristics	Software	Data lake	Data warehouse	Datamarts	Feature store
Content	Data and metadata	Data and metadata	Data	Features	Features and metadata about feature
Architecture	Distributed	Centralized	Centralized	Centralized	Centralized
Detail level	Fine-grained	Fine-grained	Fine-grained	Aggregated	Aggregated
Data	Raw	Raw	Cleaned	Cleaned	Cleaned
Nomenclature	Heterogeneous	Heterogeneous	Standardized	Standardized	Standardized
Data model	Normalized	Normalized	Normalized	Normalized	Denormalized
Data structure	Row-oriented	Row-oriented	Row-oriented	Row-oriented	Column-oriented
Purpose	Transactional software purpose	Ad hoc exploratory queries	All purposes	Prespecified purpose	Prespecified purpose

Ethical Considerations

This study does not include human participants research (no human participants experimentation or intervention was conducted) and so does not require institutional review board approval.

Health Information System

The raw data stored in the HIS are distributed across multiple software, making it impossible to cross-reference information between sources due to variations in data formats, ranging from tabular to hierarchical structures and free text [9]. Different technologies and distinct identification schemes for patients, admissions, or any other records compound the complexity. Additionally, direct write access to the software databases is typically unavailable, as software editors rarely grant such privileges to prevent any potential disruption to routine software operation. In transactional software databases, data consist of meticulously organized and highly accurate records presented in rows. These records are collected with great precision to fulfill the specific functions of the software. Alongside the data, a wealth of metadata is also present, including information regarding data collection (eg, information on the individuals inputting data, record timestamps, and biomedical equipment identifiers), as well as software configurations. Notably, a significant portion of these metadata may not be directly relevant to our research purposes, as they primarily support the routine functioning of the software.

The Data Lake

An optional first component of a comprehensive data reuse pipeline is the data lake [10-14]. A data lake is a centralized, flexible, and scalable data storage system that ingests and stores raw data from multiple heterogeneous sources in its original format [12,15]. Data are stored in a fine-grained, row-oriented, and raw format, in a secure and cost-effective environment. These raw data still encompass diverse formats, from structured data to unstructured text documents, images, songs, videos, and sensor data, ensuring that a wide spectrum of information is readily available for various data analytics endeavors [12].

The technologies implemented for the data lake can include the usual relational databases, such as PostgreSQL or Oracle, but also NoSQL databases and big data technologies, such as the Hadoop Distributed File System or Apache Hudi for the storage and Apache Spark, Hadoop MapReduce, or Apache Kudu for the data processing.

Unlike structured data typically integrated into data warehouses, the data lake refrains from immediate structuring or transformation, allowing for a more agile and adaptable approach. This flexibility enables exploration, manipulation, and, if necessary, transformation of the data to fulfill specific research or analytical requirements. By delaying the application of predefined data models, the data lake cultivates an environment where information can be uncovered without predetermined hypotheses. This includes insights that may not have been evident during the initial phases of data collection and storage. The system further facilitates on-the-fly query processing and data analysis [12,15].

In a data pipeline without a data lake, it is essential to finalize the extract-transform-load (ETL) process before leveraging the data. This introduces a time delay, as it necessitates identifying relevant data in the HIS, updating the data warehouse data model for their accommodation, and subsequently designing and implementing the ETL.

In addition, when interpreting the results, if it becomes apparent that relevant data are missing for the analysis, it requires updating both the ETL process and the data model to incorporate the missing data. This iterative cycle of identifying, modifying, and reimplementing can lead to prolonged timelines and may hinder the agility of the data analysis process. Therefore, a data lake approach proves advantageous in providing a more flexible and dynamic environment for data exploration and analysis, potentially avoiding some of these challenges encountered in a traditional pipeline.

The Data Warehouse

The data warehouse stands as the most prevalent component of the pipeline and acts as a centralized repository of integrated data from 1 or more disparate sources [5,8,16-19]. It stores historical and current fine-grained data in a format optimized for further use. This involves a single storage technology, a

consistent naming convention for tables and fields, and coherent identifiers across data sources. This is a departure from the data lake where all these elements varied between sources.

The data warehouse is supplied through an ETL process [9,18]. The primary objective of this process is to select and extract relevant data from the HIS or other external resources [19]. During this initial phase, the majority of metadata linked to software operations (such as usage logs or interface settings), monitors, and individuals inputting data are usually excluded. Indeed, these types of metadata do not relate to patient care information and would introduce an unnecessary volume of data. Subsequently, the ETL process enhances the raw data by identifying and correcting any abnormal or erroneous information. Following this refinement, data are integrated into a unified data model independent of the source software [9,19]. Notably, there is a strong focus on harmonizing identifiers from diverse data sources to ensure data integrity and streamline queries involving information from multiple origins. The ETL process is also responsible for regularly updating the data warehouse with new information recorded in the original data sources.

The data warehouse, as a relational database, is typically implemented using systems like PostgreSQL, Oracle, SQL Server, Apache Impala, or Netezza. However, for a data warehouse, exploring NoSQL technologies such as MongoDB, Cassandra, or Couchbase can also be interesting, offering advantages in handling unstructured or semistructured data, and providing scalability for large-scale data storage and retrieval [20]. The ETL process can be developed using 2 types of technologies. The first one, with programming languages such as R (R Core Team), Python (Python Software Foundation), or Java (Oracle Corporation), can be used, coupled with a scheduler like Apache Airflow (Apache Software Foundation), to organize the execution of scripts and retrieval of logs and error messages. The second kind of application is graphical user interface software, such as Talend (Talend) or Pentaho (Hitachi Vantara). They do not require programming capacities, because graphical components, corresponding to data management operations, are organized through a drag-and-drop interface.

To foster collaboration among institutions and facilitate the sharing of tools, methods, and results, several initiatives have emerged to offer common data models (CDM). As a result, table and field names are standardized following a common nomenclature, and local vocabularies and terminologies are mapped to a shared vocabulary. Among these CDMs, the Observational Medical Outcomes Partnership CDM was developed by the Observational Health Data Sciences and Informatics community, which brings together multiple countries and thousands of users [21] and led to methodological and practical advancements [22,23].

As a result, the data warehouse functions as a unified, centralized, and normalized repository, for both fined-grained historical data and metadata, and continues to present information in a row-oriented format. The modeling approach presented by Inmon [24] and described as a “subject-oriented, nonvolatile, integrated, time-variant collection of data” implies that data are stored persistently without any assumptions as to their future use, thus remaining open-ended in their usage.

The Datamarts

While the data warehouse serves as a unique standardized repository, primarily dedicated to data storage, querying these data can be time-consuming due to the volume and distribution of data in the relational model. Furthermore, raw data integrated into the data warehouse may not be readily aligned with specific research or analytical questions, as these data lack the necessary aggregated features. For instance, the data warehouse retains all biological measurements (eg, potassium and sodium), while what will be stored in the datamart are the features related to the biology values, such as the occurrence of hypokalemia, hyperkalemia, hyponatremia, or hypernatremia. Thus, the datamart acts as a dedicated resource for transforming the data into usable and meaningful information [19,25,26]. This transformation process involves feature extraction, achieved through the application of algorithms and domain-specific rules [6,7]. The outcome is data that are tailored to address specific research questions or analytical needs. For instance, within a clinical setting, the datamart can convert raw mean arterial pressure values into a format suitable for detecting perioperative hypotension [5].

Moreover, datamarts can be organized in the form of online analytical processing (OLAP) cubes, offering a multidimensional view of the data [27]. This cubical structure allows for in-depth analysis, enabling users to efficiently explore and navigate across various dimensions such as time, geography, or specific categories, gaining profound and contextualized insights. These datamarts are often modeled in either a snowflake or star schema, optimizing their structure for the creation of OLAP cubes. The star schema, with its central fact table surrounded by dimension tables, or the snowflake schema, which further normalizes dimension tables to minimize data redundancy, both serve to facilitate the creation of these OLAP cubes. Such schemas play a pivotal role in enhancing the efficiency of multidimensional data analysis within the OLAP environment, providing a structured framework for faster and more comprehensive insights.

In the context of health care, an example of an OLAP cube could encompass dimensions such as patient (eg, age and gender); time (eg, admission and discharge dates); medical conditions (eg, primary and secondary diagnoses and medical procedures); hospital unit (eg, information on services, departments, and bed types); health care provider (eg, physicians); and outcome (eg, length of stay, treatment outcomes, and medical costs). The cube would include various facts, such as the number of patients, average length of stay, and average treatment costs. This multidimensional structure allows health care professionals to conduct in-depth analyses, explore trends over time, compare costs across different hospital units, and assess the impact of medical interventions on patient outcomes [19,28].

Datamarts, owing to the structured nature of their data, are typically stored on relational databases (eg, PostgreSQL, Oracle, and SQL Server) [25]. In the case of OLAP cubes, this may

include Apache Kylin or other proprietary OLAP tools built on relational databases [28,29].

In contrast to Inmon's [24] approach, the Kimball [9] bottom-up approach places datamarts at the core, with their design driven primarily by business requirements. However, by directly developing datamarts, the Kimball approach may overlook some crucial data that were not initially identified as relevant during the business requirements phase.

As a result, the datamart stands as a centralized component for cleaned and aggregated features for dedicated purposes, still stored in row-oriented structure.

The Feature Store

The feature store addresses the limitations of the traditional row-oriented, relational database structure typically used in datamarts. This architecture, which relies on multiple tables, may not fully meet various analytical requirements. For instance, effective statistical analysis often necessitates a single, flat file with column-oriented variables, mandating the transformation of data from a row-based to a column-based format within the feature store. This process streamlines data access, simplifying complex queries into straightforward selections from a single table. Consequently, the feature store emerges as a centralized repository housing well-documented, curated, and access-controlled features. In addition to features extracted from datamarts, which are often calculated by algorithms derived from business rules, the feature store can also receive features generated by machine learning algorithms [30].

The design of the feature store aims to provide data scientists with direct access to these features, eliminating the need for additional data cleaning, aggregation, or pivoting [31]. This specialized role enhances efficiency and promotes the use of high-quality, analysis-ready data, significantly contributing to the effectiveness of data-driven research in the health care organization. Notably, the feature store not only stores the features themselves but also their associated metadata, documenting how they were calculated and used [31]. It ensures the preservation of all feature versions, guaranteeing the reproducibility of analyses.

When derived from business rules, features are stored in relational databases (eg, PostgreSQL, Oracle, and SQL Server) or in a NoSQL data store such as MongoDB to also store metadata. When features originate from machine learning models, they are stored and shared from big data platforms such as Databricks or Hopsworks [30,32].

As the final component of the data reuse pipeline, the feature store plays a pivotal role in various analytical applications within the health care organization. It significantly contributes to the creation of insightful dashboards and automated reports, delivering real-time and historical information. In research, its most crucial contribution lies in generating denormalized flat tables, similar to questionnaire data tailored for statistical analyses.

Conclusions

In this opinion paper, we propose standardized nomenclature and definitions for the components of a data reuse pipeline. Table 2 summarizes the advantages and limitations of each component in this pipeline.

While the data warehouse serves as a necessary initial stage, the integration of datamarts and a feature store enhances its effectiveness. Datamarts compute pertinent information from raw data, while the feature store organizes it into columns, streamlining data set construction. Additionally, the data lake emerges as a valuable resource for storing raw data in a single location, allowing for exploitation without having to wait for the entire pipeline to be developed.

Notably, in a data pipeline without a data lake, the requirement to complete the ETL process before analysis introduces delays. This involves identifying relevant data in the HIS, adapting the data warehouse data model, and implementing the ETL. Additionally, discovering missing data during result interpretation prompts iterative updates to both the ETL process and the data model, potentially prolonging timelines and hindering data analysis agility.

It is important to emphasize that the specific components and their characteristics described here are not rigidly fixed and can vary based on the unique organizational needs and configurations. For instance, the inclusion of a data lake and feature store is often discretionary, influenced by factors such as the scale and intricacy of source data, the quantity of features, the scope of research projects, the team's size, and the imperative for study reproducibility over time.

Table . Advantages and disadvantages of the components of the data reuse pipeline.

Component	Advantages	Disadvantages
Data lake	• All data sources on the same server • Independence from source software • On-the-fly query processing and data analysis without the need for the complete development of an extract-transform-load (ETL) process	• Inconsistencies in data formats and structures • Lack of standard schema can make querying complex • Analyses reproducibility
Data warehouse	• Querying data from both administrative and biology systems is facilitated by the unified data model (ie, data from both systems are linked, and the model conventions are consistent) • Relevant data are retained at the finest level of detail (eg, dates, diagnoses, and all biology values), enabling the answering of numerous questions without necessarily identifying them beforehand	• ETL process must be implemented to standardize the data • Multidimensional data model with several statistical units • Fine-grained data is not directly usable and adapted for statistical analysis or decision-making
Datamarts	• Features are ready to be used directly	• Features are still organized with a row-format (ie, 1 feature per row) in several datamarts
Feature store	• Using features directly, without the need for data management tasks such as joining datamarts or pivoting to reorganize features into columns	• Having developed the entire pipeline beforehand

Conflicts of Interest

None declared.

Abstract

This viewpoint article explores the transformative role of large language models (LLMs) in the field of medical education, highlighting their potential to enhance teaching quality, promote personalized learning paths, strengthen clinical skills training, optimize teaching assessment processes, boost the efficiency of medical research, and support continuing medical education. However, the use of LLMs entails certain challenges, such as questions regarding the accuracy of information, the risk of overreliance on technology, a lack of emotional recognition capabilities, and concerns related to ethics, privacy, and data security. This article emphasizes that to maximize the potential of LLMs and overcome these challenges, educators must exhibit leadership in medical education, adjust their teaching strategies flexibly, cultivate students' critical thinking, and emphasize the importance of practical experience, thus ensuring that students can use LLMs correctly and effectively. By adopting such a comprehensive and balanced approach, educators can train health care professionals who are proficient in the use of advanced technologies and who exhibit solid professional ethics and practical skills, thus laying a strong foundation for these professionals to overcome future challenges in the health care sector.

large language models; medical education; opportunities; challenges; critical thinking; educator

Introduction

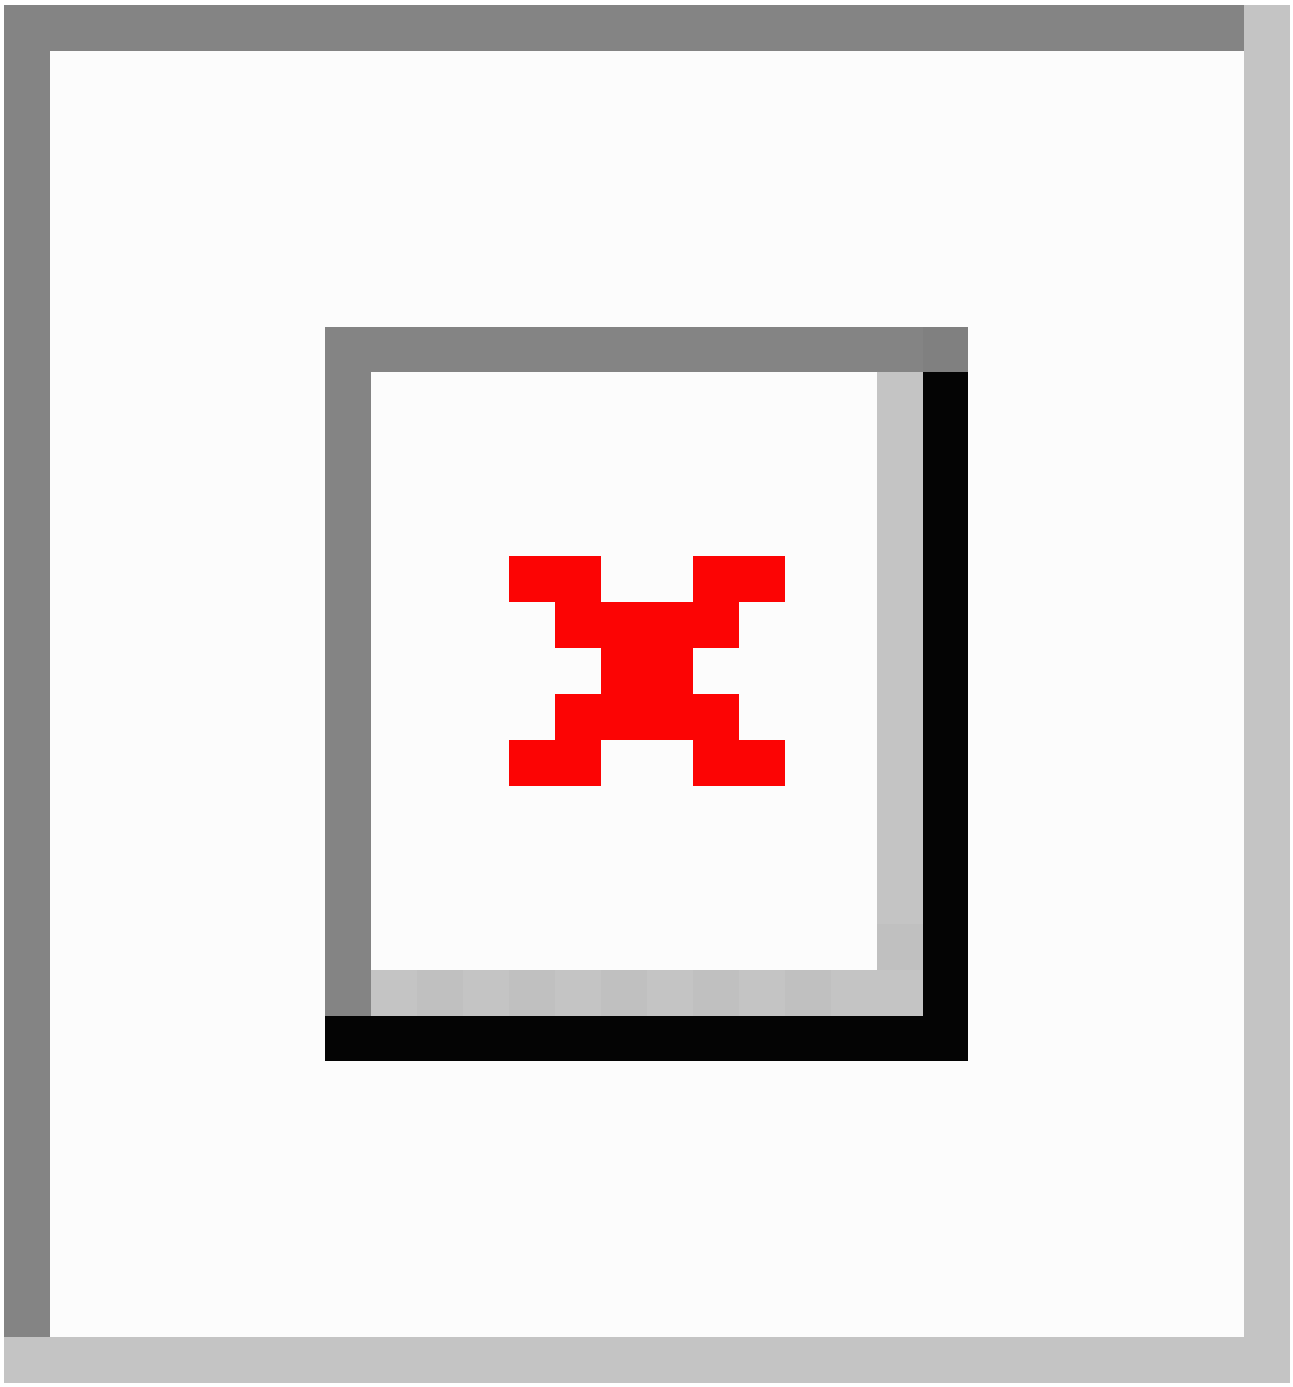
Technological advancements have significantly shaped medical education, leading to transformative shifts in approaches to teaching and learning. The recent rapid evolution of artificial intelligence (AI) technology has entailed unprecedented changes and challenges in this field, particularly due to the emergence of large language models (LLMs). LLMs, which are extensively trained on vast text data sets, are advanced AI systems best exemplified by OpenAI's GPT series, Google's Gemini, and Twitter's Grok [1]. By using complex neural network architectures, especially those based on transformer design, LLMs can identify and replicate subtle linguistic nuances. Their capabilities extend beyond the generation of text; they can also produce corresponding images or even videos based on text inputs, thereby addressing a wide variety of linguistic tasks. Notably, the use of LLMs in medical education is increasingly becoming a focal point of global research and discussion [2,3]. In the context of medical education, LLMs can answer questions regarding medical concepts, generate simulated cases, assist researchers, and support clinical decision-making [4,5]. These applications not only optimize the efficiency of teaching but also offer students a more personalized, digital, and adaptable learning experience [6]. However, as this tool is integrated into medical education, challenges pertaining to the accuracy of information, privacy, potential overreliance on such technology, and academic integrity have emerged [7].

This viewpoint article, which is based on current international research, thoroughly explores the impacts associated with the integration of LLMs into medical education. The article also analyzes in depth the adaptive changes that teaching methods should make in response to these opportunities and challenges. The primary goal of this article is to provide a nuanced perspective on the use of technological innovation in medical education and to serve as a reference for future teaching practices and strategies.

Opportunities in Medical Education

The various uses of LLMs are gradually changing traditional medical education. The opportunities presented by LLMs in the context of medical education are illustrated in Figure 1.

Figure 1. Opportunities associated with the use of large language models in medical education. CME: continuing medical education.



Enhancing the Efficiency and Quality of Teaching

The integration of LLMs into medical education heralds a transformative advance in the efficiency and quality of instruction. A study that focused on the ChatGPT 3.5 platform in the context of a problem-based learning teaching model revealed that the application of ChatGPT significantly enhanced collaboration and participation among members of learning groups. This approach also increased students' motivation, encouraging them to pose questions more actively [8]. A randomized controlled study that compared ChatGPT-assisted learning with traditional literature-based learning reported that students' examination scores significantly improved as a result of ChatGPT-assisted learning [9]. By leveraging these advanced tools, educators can swiftly craft comprehensive syllabi, develop engaging lecture materials, and create detailed textbooks. This approach is particularly effective within the frameworks of case-based learning and problem-based learning, which emphasize contextual and practical learning [10,11]. LLMs offer 2 advantages in educational settings. First, they can

generate visual content, such as illustrative diagrams to depict disease progression or 3D models of anatomical structures, and they can even source existing educational imagery on the internet to meet specific learning objectives. This capability not only enriches teaching materials but also caters to diverse learning styles, thus facilitating students' retention and understanding of complex concepts. Second, LLMs excel in the tasks of analyzing and interpreting visual data. They can help educators and students decipher complex medical images such as computed tomography (CT) or magnetic resonance imaging (MRI) images. Through such digital and visually driven learning experiences, LLMs significantly enhance students' comprehension and retention of information regarding challenging medical subjects, such as pathology or clinical diagnosis. The use of LLMs in medical education substantially improves the efficiency of preparing instructional material as well as the quality of the material itself. By enhancing students' collaboration skills and learning motivation, this approach effectively improves learning outcomes.

Facilitating Personalized Learning

Personalized learning involves tailoring instructional content and strategies to the specific needs, abilities, interests, and learning styles of students. Compared to traditional educational models, LLMs offer a more flexible, digital, and immediate approach to learning [12]. Traditional education often relies on standardized curriculum structures and educator guidance, while LLMs can adapt to each student's unique learning needs and style, thereby providing students with customized guidance and feedback. Such assistance not only enhances student engagement but also helps students grasp knowledge at their own pace [13,14].

Xu et al [15], who conducted interviews with 6 higher education professors and 3experts in information and communication technology, revealed that ChatGPT significantly improves students' cognitive skills, such as their ability to process information, solve problems, and understand concepts. It also enhances students' noncognitive skills, such as motivation and self-efficacy, and facilitates their development of metacognitive skills, thus helping students plan and adjust their learning. These improvements are crucial for enhancing personalized and interdisciplinary education in higher education [15]. This support is particularly crucial for students in dynamic fields such as medicine, in which context triggering intrinsic motivation for self-learning and offering a timely understanding of the latest research findings in depth are essential.

Moreover, ChatGPT facilitates a discussion-based learning approach that is closely connected to real-world scenarios. This type of interaction not only facilitates knowledge acquisition but also serves as a platform through which students can engage LLMs as debate partners, thereby fostering the development of critical thinking skills by enabling students to present and evaluate different viewpoints [16]. Accordingly, students can use LLMs to create a tailored learning journey based on their own interests, knowledge gaps, and learning pace, thereby crafting a personalized educational path that aligns with their individual needs. Additionally, a study that evaluated students' reasoning abilities by referencing published case reports and simulated clinical cases revealed that ChatGPT significantly enhances the clinical reasoning abilities of medical professionals [17]. This kind of reasoning ability is developed through personalized feedback based on the individual learning progress and needs of each person. Through these digital and customized teaching solutions, LLMs effectively meet the personalized learning needs of students. This approach can enhance students' engagement and promote the development of crucial skills such as critical thinking and logical reasoning, thereby helping students overcome the challenges entailed by an ever-evolving knowledge landscape effectively.

Reinforcing Clinical Skills

Traditional clinical skills training relies heavily on real clinical cases or standardized patients (SPs), which can allow students to interact with patients and address authentic clinical challenges directly. However, this approach has significant drawbacks, including high costs, temporal and spatial constraints, the inclusion of only a limited variety of medical conditions, issues related to patient privacy, and the inability to provide timely feedback regarding learning outcomes.

The integration of LLMs into clinical skills training can effectively address these limitations, as demonstrated by a pioneering study conducted in China. The use of ChatGPT to simulate SPs not only addresses the scarcity of SPs but also obviates the need for supplementary training, thereby conserving substantial human and material resources. Crucially, LLMs such as ChatGPT can emulate a diverse array of SPs, thereby delivering intelligent, articulate, and vivid responses that are tailored to specific scenarios [18]. This innovation enables students to engage in repetitive practice in a low-risk environment that can obviate concerns regarding patient welfare and privacy, thereby enhancing students' diagnostic reasoning and communication skills [19].

The use of LLMs to simulate clinical patients offers other significant advantages. First, given that the accessibility of LLMs—for instance, ChatGPT 3.5 and Microsoft Gemini—do not require registration and can be seamlessly integrated into browsers—clinical simulation exercises can become ubiquitous, thus transcending the traditional confines of clinical settings. This flexibility significantly enhances the adaptability of learning [12]. Second, the ability of LLMs to replicate a spectrum of diseases, ranging from common ailments to rare conditions, broadens the scope of educational content and experiences, thereby addressing students' lack of exposure to rare clinical cases. According to Scherr et al [5], LLM simulations facilitate the early development of independent diagnostic and therapeutic reasoning among medical students. Furthermore, LLMs can adaptively refine their responses based on student interactions, thereby offering a more authentic reflection of real-world patient-provider communication than is possible using conventional, static simulation models. Moreover, LLMs provide an inexhaustible supply of free simulation opportunities, thus democratizing access to medical education, particularly for students from economically

disadvantaged backgrounds or for institutions with limited resources [5].

Although LLMs currently do not extend to procedural skill training in medical education, such as training in surgical tasks, including debridement and suturing, the prospective integration of LLMs with virtual reality and augmented reality technologies could represent a transformative advance in this regard. This combination could facilitate the establishment of a multidimensional, digital, and highly authentic simulation learning environment, thereby leading to the advent of a new era of innovative teaching methodologies and content in the context of medical education. Such advancements can address students' diverse educational needs, enrich the learning landscape, and imbue the domain with fresh momentum.

Improving Medical Teaching Assessments and Examinations

Traditional medical education assessments, which include standardized examinations, interviews, and clinical skills evaluations, require considerable preparation, detailed grading, and extensive time to compile students' scores. In contrast, LLMs such as ChatGPT represent a dynamic shift in this context by streamlining the creation of diverse, integrated assessment questions; they are, thus, closely aligned with instructors' needs. A study conducted in Hong Kong, Singapore, and the United Kingdom highlighted the ability of the ChatGPT to generate 50 multiple-choice questions rapidly, with the questions thus generated exhibiting a quality comparable to that of questions developed by university professors while offering a significant reduction in preparation time [20]. This efficiency extends to case-based questions, in which context the outputs of ChatGPT have been reported to be equally robust [21].

The evolving research on LLMs has focused on their precision regarding addressing a spectrum of medical questions, thus highlighting their ability to enhance educational assessments. The success of the ChatGPT in passing rigorous examinations regarding medical theory, such as the United States Medical Licensing Examination and the Objective Structured Clinical Examination in Singapore, highlights the proficiency of this LLM in domain-specific knowledge and its potential applicability across a variety of medical assessments [22,23]. In addition to generating questions, LLMs excel in the tasks of delivering immediate, detailed feedback, identifying student errors, and highlighting areas for improvement [24]. Furthermore, LLMs provide deep insights into examination results, thereby offering educators real-time insights into the learning challenges faced by students. This analytical capability fosters a more nuanced understanding of student performance, thus enabling educators to tailor their teaching strategies effectively [25].

The integration of LLMs into medical education heralds a more efficient, personalized assessment process, thereby decreasing educators' workloads while providing students with a clearer comprehension of their academic progress. This innovative approach enriches the educational experience, shifting from a conventional focus on scores to a more holistic perspective on the efficacy of learning and teaching.

Enhancing the Efficiency of Medical Research

Information retrieval in the context of medical research has long been associated with challenges such as information overload, time-consuming classification processes, and a lack of personalized suggestions. Due to their intelligent information retrieval capabilities, LLMs can offer more precise and personalized literature search suggestions based on researchers' queries. This technology can help researchers swiftly locate relevant information and effectively mitigate issues pertaining to information overload [26]. Moreover, LLMs can summarize lengthy papers and offer reasonable advice regarding research methods, experimental design, and statistical analysis, thereby accelerating the research process and enhancing the efficiency of research [27]. Additionally, LLMs can facilitate data analysis and visualization, enabling researchers to interpret and summarize research results efficiently and streamlining the research workflow [2].

LLMs also provide cross-lingual assistance to researchers from non-English-speaking countries, thereby improving the quality of research [28-30]. Numerous studies have indicated that ChatGPT can help researchers refine papers and that the ability of LLMs to write abstracts is comparable to that of humans, thus highlighting the potential of this technology regarding providing support for academic writing [31-33]. Indeed, scholar King [34] successfully published a paper produced with ChatGPT that required no further language editing. Additionally, ChatGPT can help researchers draft cover letters, thus enabling them to convey the significance and relevance of their research effectively when submitting papers to journals [35,36]. The combined impact of these capabilities can significantly boost the ability of researchers from non-English-speaking backgrounds to engage in international academic communication and support the results of their research.

Support for Continuing Medical Education and Professional Development

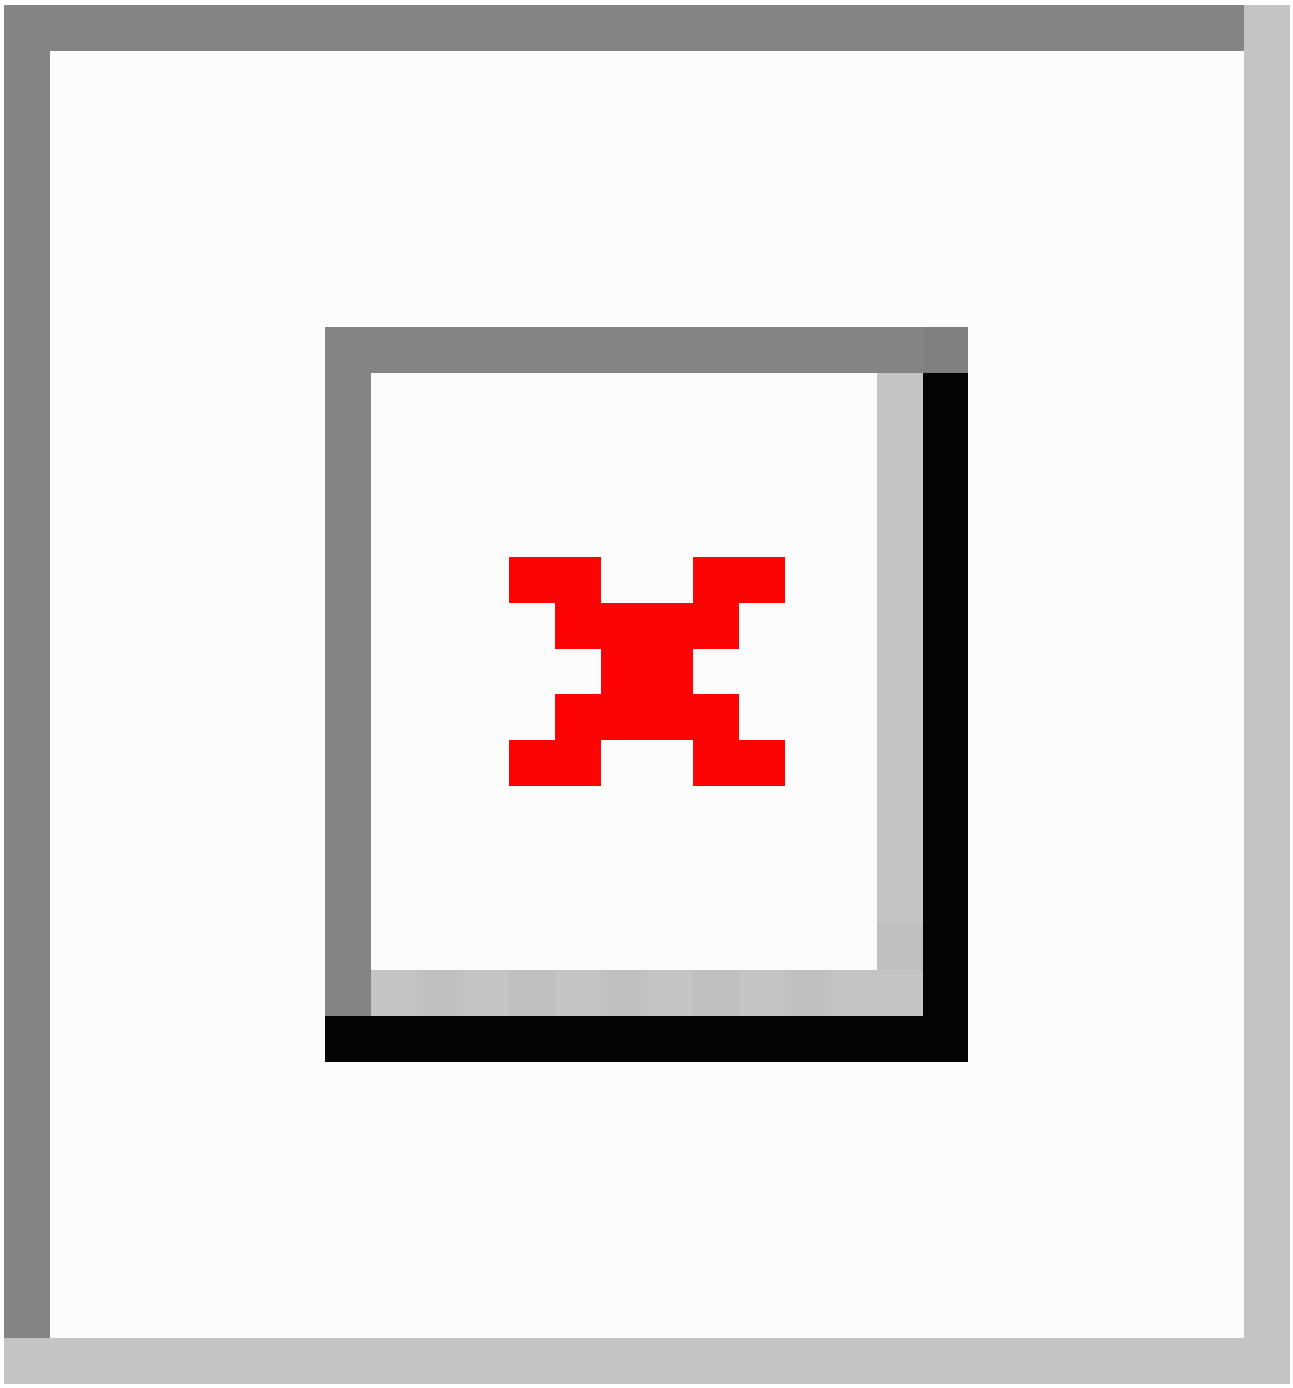
Rapid advancements in the field of medicine require health care professionals to engage in lifelong learning to enhance their professional competence continuously. In this context, LLMs represent an efficient, convenient, and flexible approach to continuing medical education. For instance, LLMs can systematically and specifically help medical professionals remain up-to-date regarding the most recent developments in medical research, treatment guidelines, and clinical practices [24]. Several comparative studies focusing on various LLMs and search engines have consistently revealed that LLMs can generate evidence-based medical recommendations tailored to specific topics [37,38]. The experience of clinical doctors is often limited due to their frequent encounters with common and prevalent cases, which often causes them to lack sufficient expertise regarding rare diseases or emerging epidemics, as was observed at the onset of the COVID-19 pandemic. In this regard,

LLMs can address the knowledge gaps of health care professionals by collecting global medical information or providing clinical experiences with respect to the diagnosis and treatment of specific diseases. By using LLMs, health care professionals can pursue continuing education in a manner that requires minimal economic and time investments, thereby enhancing their clinical decision-making capabilities. This approach ensures that professionals in the field of health care can effortlessly remain up-to-date in terms of their knowledge and skills despite their demanding clinical schedules [39].

Challenges Associated With Medical Education

Despite the numerous opportunities in the field of medical education associated with the use of LLMs, this approach also entails a series of challenges and limitations. The challenges posed by LLMs in the context of medical education are summarized in Figure 2.

Figure 2. Challenges associated with the use of large language models in medical education. AI: artificial intelligence.



Concerns Pertaining to the Accuracy of Information

In medical education, the accuracy of knowledge is of paramount importance, as even minor errors can threaten patient safety. For students who have only limited background knowledge, identifying inaccuracies or misleading information can be particularly challenging. Alkaissi and McFarlane [40] reported that ChatGPT can generate fabricated data, cite nonexistent literature, and provide incorrect citations, a phenomenon known as AI hallucination. Additionally, LLMs may sometimes provide varying responses to identical queries [40,41]. Therefore, the current LLMs cannot yet be fully relied upon in education or research fields. A detailed evaluation of 180 questions answered by the ChatGPT, which was conducted by 33 doctors from 17 medical specialties, revealed that while some responses were highly accurate, significant errors occurred in response to more complex questions [42].Other studies in the medical field have also confirmed this, showing that the ambiguities or errors in LLMs' responses to complex questions stem from their limited depth of understanding and reasoning capabilities [43,44]. Furthermore, the levels of accuracy exhibited by different language models varied. A study of the accuracy of multiple LLMs in the context of generating answers to dental questions revealed that ChatGPT-4 was significantly more accurate than ChatGPT 3.5, Google Bard, and Microsoft Bing Chat. However, all these LLMs provided irrelevant information, vague answers, or even entirely incorrect responses [38]. Similar conclusions have been reported in several other studies [45-47]. This limitation is primarily due to the training data used for LLMs, which are largely drawn from the internet and often lack rigorous screening and quality control. Consequently, the inclusion of errors, biases, or outdated information directly impacts the accuracy of the outputs of LLMs. Additionally, while current LLMs such as Google Gemini can directly incorporate references from open-access journals into their responses, thus significantly enhancing confidence in the accuracy of the information, access to the subscription sections of certain authoritative databases, such as PubMed, remains limited. This constraint continues to impede the accuracy and comprehensiveness of their responses [48,49].

Concerns Pertaining to Overreliance and Academic Integrity

Students may depend excessively on LLMs to perform learning tasks, such as writing papers or preparing for examinations. While the content generated by LLMs is original, students who submit text generated by LLMs directly as their own work might engage in plagiarism and academic dishonesty [34,50]. In particular, the integration of LLMs with search engines, which allow direct access to original texts and multimedia, significantly increases the risk of plagiarism. One study indicated that when university professors are presented with abstracts generated by LLMs and those written by humans, they struggle to determine whether these abstracts were authored by a machine or by a human [31]. In a study conducted in 2023, reviewers were able to identify only 63% of fabricated abstracts generated by ChatGPT [27]. This finding suggests that the quality of the text produced by LLMs has equaled or exceeded the quality of the text produced by professionals, thereby providing opportunities for students to engage in academic misconduct by using LLMs to generate summaries, data, or even complete drafts of papers. Furthermore, the ability of LLMs to achieve high scores on exams such as the United States Medical Licensing Exam, as mentioned previously, inevitably raises the possibility of students using them to cheat on exams. Overreliance on LLMs not only entails the risk of academic misconduct but also may impair students' development of independent research and critical thinking abilities, causing them to have only a shallow grasp of topics and affecting their ability to accurately diagnose complex medical conditions. According to a survey of 370 undergraduate medical students in India, more than 53% of these medical students expressed concerns about the possibility that the widespread application of LLMs might lead to such overreliance, which could hinder their development of clinical reasoning skills [51]. Mechanically extracting answers from LLMs inevitably deprives students of invaluable face-to-face engagement with teachers and peers, thus impeding the development of critical thinking skills, which must be refined through dynamic and diverse intellectual exchanges. Therefore, while LLMs offer significant reference value in medical education, it is crucial to establish appropriate guidelines and balanced strategies to ensure that students can develop independent thinking skills and clinical judgment.

Bias and Transparency

In medical education, when LLMs are employed, it is essential to scrutinize potential biases in the training data and algorithms underlying these LLMs as well as to address the opacity of the models' decision-making processes [52]. If an LLM overemphasizes a specific treatment while neglecting others, it might bias students' perceptions, potentially instilling in them a narrow view of patient care. In January 2024, Zack et al [53] used the Azure OpenAI application interface to evaluate ChatGPT-4 and discovered that the model inadequately represented demographic diversity in terms of medical conditions. It consistently generated clinical vignettes that reinforced stereotypes associated with specific demographic groups. Furthermore, the differential diagnoses produced by the ChatGPT-4 regarding standardized clinical vignettes tended to include stereotypical biases pertaining to certain races, ethnicities, and genders. The assessments and plans generated by the model were significantly linked to demographic attributes; the model thus often recommended more costly procedures and exhibited disparities in terms of patients' perceptions. This widespread unfair response primarily arises from training data and algorithmic biases. Even if the training data are unbiased, bias in the algorithmic design of LLMs can still lead to biased outputs [54]. The harm of LLMs that output-biased information lies not only in the decline of teaching quality but also in their potential to distort medical students' ethical principles, leading to unfair treatment of clinical patients and even endangering their health and lives.

When faced with responses from LLMs, users often struggle to understand how these responses are generated or the underlying

logic, a phenomenon known as the "black box" effect, indicating a lack of transparency in the model [55]. In medical education, the lack of transparency in LLMs may prevent teachers and students from accurately assessing the accuracy of information, posing risks to patient safety in clinical practice [56]. Additionally, failure to comprehend the logic behind LLMs' responses may lead to rigid thinking among students, overlooking the importance of logical thinking in medical curriculum learning and thereby weakening the cultivation of critical thinking.

Risks Pertaining to Privacy and Data Security

AI has long been used to assist in facilitating the diagnosis and treatment of diseases by examining patients' medical histories and examination images [36]. In medical education, when sensitive patient information such as names, ages, diagnoses, and other details is input for case-based teaching simulations or even as raw data for training LLMs, as well as CT or MR images containing patient information for image interpretation or diagnostic purposes, LLMs may inadvertently disclose patient privacy during the reasoning process or through their "memory" effects [52,57]. Even more concerning, current research has shown that even anonymized information could lead to privacy breaches through cross-referencing with other available web-based data, resulting in the reidentification of personal information [57]. Studies have demonstrated that with only 15 demographic characteristics, 99.98% of personal information can be reidentified [58]. As a cloud-based service, LLMs face various cybersecurity risks regarding data storage and processing, including hacking attacks or the infiltration of malicious software. Any such security vulnerabilities could lead to the leakage of sensitive data, thereby leading to significant risks and legal liabilities [59]. Companies that develop chatbots, such as OpenAI, may employ users' personal information for various purposes, including service analysis, improvement, and research. Such companies also reserve the right to share users' personal information with third parties without prior notification or explicit consent from users [60]. All these factors introduce risks pertaining to privacy and data security to the process of medical education.

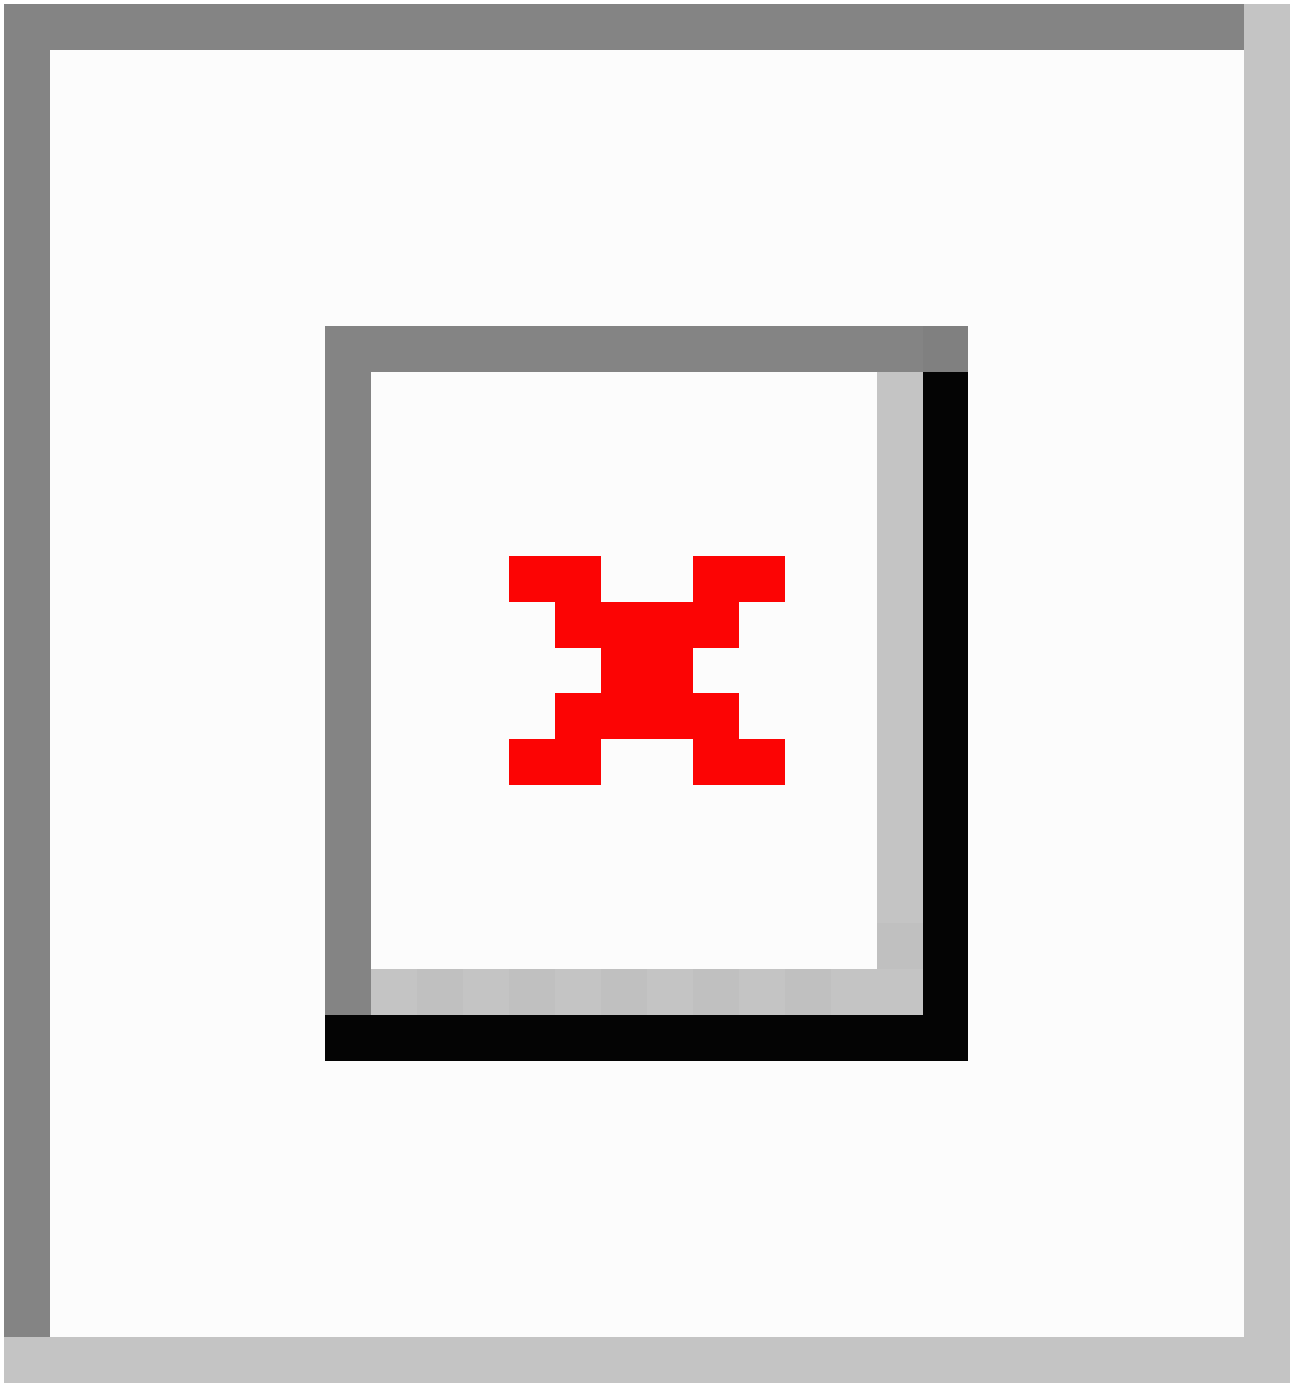
Lack of Emotional Intelligence

Cultivating empathy is a cornerstone of medical education. Although language models such as the ChatGPT can be trained to mimic empathetic language and used to facilitate patient communication [61], artificial empathy cannot replicate genuine, subtle empathy on the part of health care providers, which is crucial for patient care and can easily be identified by patients [62]. Prof Marc Succi from Harvard University believes that excessive reliance on artificial emotional communication in medical settings can exacerbate societal loneliness [63]. The subtlety, profundity, and diversity of empathy that is expressed in the context of human-to-human interactions are currently irreplaceable in LLMs. When LLMs simulate patients, all the emotional responses they exhibit are expressed as textual descriptions, thus preventing the student from interpreting or responding to nonverbal cues such as facial expressions, tone of voice, and gestures. These cues are even more crucial for genuine human empathy than verbal expressions [64]. The empathy conveyed through the programmed responses of LLMs poses a challenge for medical students' attempts to acquire the basic experience necessary to engage in interpersonal relationships by interacting with these models. The establishment and development of empathy also involve addressing the inherent complexity and uncertainty associated with real interactions, in which context the diverse backgrounds, beliefs, and values of real patients lead to a wide range of emotional expressions in interpersonal communication. LLMs struggle to simulate such personalized and diverse emotional responses. Furthermore, cultivating empathy requires ongoing practice over time. LLMs are static models that cannot engage in long-term interaction and provide personalized feedback; accordingly, they are unable to facilitate the deep practices necessary for students to develop empathy.

Changes in Teaching Methods

LLMs are currently revolutionizing numerous aspects of medical education. As we exploit the power of these advanced technologies to promote innovation in medical education, we must also address the various challenges they entail. In the context of teaching activities, educators must continue to play a leadership role in the classroom, emphasize the value of traditional classroom settings, enhance students' critical thinking abilities, and highlight the crucial role of practical experience. In this manner, we can not only benefit from the advantages of LLMs but also ensure the comprehensiveness and effectiveness of the educational process. The specific content of the adaptive changes made by educators in response to the challenges entailed by LLMs is summarized in Figure 3.

Figure 3. Main content of adaptive changes in educators' teaching methods. LLM: large language model.



To ensure the reliability of the information imparted during medical education, educators must exercise critical scrutiny, especially in light of students' tendency to trust their teachers to a considerable extent. Compared to one-on-one human-machine interactions, one-to-many scenarios during teaching may exacerbate the adverse effects of misinformation transmission. When using chatbots such as Microsoft's Copilot or Google's Gemini, which can access and cite real-time data directly from the internet, it is crucial to recognize that medical students may lack the necessary skills to evaluate the authenticity of such information. Therefore, employing multiple methods to verify information and teaching students how to discern the truthfulness of information has become an urgent and important educational need. Educators should corroborate AI-generated content by providing references to trusted sources such as PubMed, the Cochrane Library, or UpToDate. Additionally, seeking insights from subject matter experts can provide valuable perspectives on complex or nuanced medical topics. Cross-verification, which involves comparing the responses provided by various language models, serves as another means of such validation, which can lead to further investigation of discrepancies. This not only involves effectively transmitting precise knowledge but also helps in developing students' critical thinking skills.

Simply prohibiting the use of language models to address challenges pertaining to academic integrity is not a practical solution. Educational institutions must establish explicit policies regarding academic misconduct in the context of these

technologies. Educators should clearly define how assignments should be completed and inform students of the consequences of academic dishonesty. Just as the response to King's [34] inquiry to ChatGPT about the strategies college professors should use to prevent students from cheating with ChatGPT suggested, designing assignments that incorporate a variety of assessment methods is an effective approach. This approach includes changing traditional homework methods and supervising students' independent completion of assignments related to specific topics in class. The introduction of classroom presentations, group discussions, practical activities, and video productions, which are tasks that LLMs cannot complete independently, can highlight students' knowledge and skills. Additionally, when students inevitably use LLMs to complete assignments, they should be required to clarify the role of LLMs in their work and provide examples of such human-computer interactions for reference. Educators can also use plagiarism detection software to identify copied or unoriginal content in submitted papers [34]. These changes in teaching methods can not only foster critical thinking but also prevent overreliance on AI as well as academic dishonesty.

The development of critical thinking skills is also essential in light of the biases and unfairness entailed by LLMs. Although educators may not have the capacity to alter the biases inherent in training data or LLM algorithms, it is imperative for us to scrutinize the outputs of LLMs critically and to cultivate a similar critical perspective on the part of our students. When case-based instruction is employed, inclusivity should be ensured in terms of diverse populations and medical scenarios to avoid reinforcing stereotypical associations with specific demographic groups or medical conditions. LLM-generated clinical vignettes should be used as pedagogical tools by prompting students to engage in structured activities such as group discussions, role-playing, or debates. These activities should focus on dissecting the reasoning process, diagnostic conclusions, and therapeutic recommendations presented in the cases in question, thus emphasizing the process of identifying and critiquing potential biases and logical inconsistencies. Additionally, the broader ethical, societal, and cultural ramifications of the deployment of LLM-generated insights in medical decision-making should be explored. Students should be encouraged to engage in reflective practices after interacting with LLMs, thus prompting them to assess their decision-making trajectory and outcomes introspectively and to recognize and address their inherent biases and cognitive patterns.

Educators should prioritize hands-on experience and advocate for experiential learning anchored in authentic clinical settings. Regarding data privacy and security, it is crucial to adhere strictly to legal standards regarding patient confidentiality. Educators should aim to minimize the use of actual patient data in LLMs and prefer to use synthetic or hypothetical scenarios to avert any potential privacy breaches. In cases in which it is necessary to input patient-specific medical history, examination images, and other sensitive information into LLMs, it is imperative for students to obtain informed consent from the patient, obtain the necessary approval from an ethics committee, and implement appropriate data anonymization measures. Additionally, it is vital to provide medical students with comprehensive education and training regarding patient privacy protection, including lawful and ethical procedures for the collection, use, and storage of patient information. By actively engaging in clinical practices that emphasize the importance of patient privacy and preventing data leakages, medical students can cultivate a profound understanding of the legal and ethical responsibilities associated with patient privacy protection.

An emphasis on clinical practice is essential for the development of fundamental clinical skills and the promotion of profound empathic connections, both of which are rooted in medical practice. To cultivate empathy, practical teaching methods such as role-playing and simulated patient interactions can be used to enhance students' effective doctor-patient communication skills. These skills include listening techniques, nonverbal communication, and appropriate expressions of empathy and care. Engaging with real patients allows medical students to observe, learn from, and emulate the empathetic behaviors of experienced instructors and to apply these insights to patient care. Accumulating experiences in empathy by engaging in diverse patient interactions and a process of immersive reflection can enable students to understand and empathize with patients deeply, thereby equipping them to address the complexities of patient care effectively. Moreover, the incorporation of disciplines such as psychology and other disciplines in the humanities into medical curricula can provide students with a theoretical foundation for understanding patients' emotional and psychological states, thereby enriching the practical application of their skills in clinical settings.

We must acknowledge the positive role played by LLMs in education, and educators must ensure that this technology can complement traditional teaching methods rather than replace them. Teachers should respond to the opportunities and challenges associated with the use of LLMs by adapting their teaching methods and content, promoting critical thinking among students, and emphasizing the importance of practical experience to ensure that teachers continue to play a leading role in medical education. In the future, establishing unified ethical principles or guidelines for the application of LLMs in medical education could better guide educators and students on how to effectively and safely use LLMs. Such a balanced approach can ensure that future medical professionals are better equipped by combining technological advancements with the enduring values of medical education.

Conclusion

We explored the diverse opportunities and challenges associated with the use of LLMs in medical education. While LLMs offer new avenues for exploration and innovation in the context of medical education, educators must recognize that these technologies serve as supplementary tools to traditional teaching methodologies. The expertise and foresight of educators remain paramount regarding safeguarding the quality of teaching. Educators must possess the ability to exploit these emerging technologies while continuing to play a guiding role in student learning, nurture critical thinking skills, and consistently emphasize the significance of clinical practice in medical education, thus ensuring that students use LLMs judiciously

and efficaciously. By obtaining a comprehensive understanding of the strengths and limitations of LLMs and making corresponding adjustments to their teaching approaches, educators can steer medical education toward a more innovative, intelligent, and practice-oriented future.

Acknowledgments

We appreciate Ms Ding Ding for her assistance in the literature search.

Authors' Contributions

LZ and RW contributed to the conceptual design, data collection, drafting, final revision, and final submission of this article; NY, LL, and WZ contributed to the data collection, language correction, and revision; and XZ and YX contributed to the data collection and drafting. CH and LX contributed to the language correction and final revision. All authors read and approved the final version of the manuscript.

Abstract

The extensive utilization of personal health data is one of the key success factors of modern medical research. Obtaining consent to the use of such data during clinical care, however, bears the risk of low and unequal approval rates and risk of consequent methodological problems in the scientific use of the data. In view of these shortcomings, and of the proven willingness of people to contribute to medical research by sharing personal health data, the paradigm of informed consent needs to be reconsidered. The European General Data Protection Regulation gives the European member states considerable leeway with regard to permitting the research use of health data without consent. Following this approach would however require alternative offers of information that compensate for the lack of direct communication with experts during medical care. We therefore introduce the concept of "health data literacy," defined as the capacity to find, understand, and evaluate information about the risks and benefits of the research use of personal health data and to act accordingly. Specifically, health data literacy includes basic knowledge about the goals and methods of data-rich medical research and about the possibilities and limits of data protection. Although the responsibility for developing the necessary resources lies primarily with those directly involved in data-rich medical research, improving health data literacy should ultimately be of concern to everyone interested in the success of this type of research.

KEYWORDS

health data literacy; informed consent; broad consent; data sharing; data collection; data donation; data linkage; personal health data

Data-Rich Research, Broad Consent, and Informedness

Various initiatives around the world are currently working on the technical and organizational requirements to make data from different sources and contexts usable for medical research (eg, MyHealthRecord in Australia, FINDATA in Finland, and the Medical Informatics Initiative in Germany). The starting points of these endeavors often are local, regional, or national health care data repositories that must nevertheless be highly linkable to allow full exploitation of their scientific value. This connectivity requirement implies that the data cannot be fully anonymized before being moved into the research domain.

One of the ethical prerequisites for research on humans—and thus for research using identifiable personal health data—is the informed consent of the data subjects. However, being properly informed requires that those affected (1) are capable of making self-determined decisions in the first place; (2) were informed about the nature, benefits, and risks of the research in question; (3) have understood the importance of this information; and (4) are able to decide voluntarily and without coercion for or against participation.

Not least because of the increasing relevance of hypotheses-free research approaches (keyword: big data), the storage and use of data for future, currently undeterminable purposes also play an increasingly important role in medical research. Recent studies have shown that patients and members of the general public are very willing to share personal health data for research (eg, [1]), even if no information about the purposes and aims of the research can be provided at the time consent is given. Notably, this attitude turned out to be mainly motivated by altruism, solidarity, and the idea of reciprocity. Since the paradigm of project-related informed consent is difficult to transfer to such unspecific practice, the World Medical Association changed its regulations on research with identifiable data when revising the Declaration of Helsinki in 2013 [2]. There was no longer a requirement for specific information about the subjects of future research, thereby paving the way for a new form of "broad consent."

In essence, "broad consent" means the one-off, unspecific agreement to the use of one's personal data for medical research without knowing who will access the data when and to what end. However, since the data in question are usually collected in a clinical care context, the suitability and practicality of broad

consent as a legitimation for their research use is limited. First, the temporal and spatial linking of the consent process to care measures can lead to incorrect therapeutic [3] and diagnostic [4] assumptions on the side of the patient. Second, in the time available, it is hardly possible to create sufficient understanding of the benefits and risks of the envisaged research, despite great efforts to ensure that the corresponding information and consent documents are legible. Finally, asking for consent during clinical care bears a substantial risk of low and unequal approval rates, which can lead to methodological problems in the scientific use of the data.

In view of these shortcomings, and of the proven willingness of people to contribute to medical research by sharing personal health data, the means to achieve practically feasible and truly informed consent needs to be reconsidered. In particular, is consent-free data use for medical research, combined with the possibility of straightforward opt-out by the data subjects after thorough consideration, a better option for legitimizing the secondary use of health data? This question is all the more justified as numerous studies in the United Kingdom, Iceland, Norway, Sweden, and Germany, among others, have shown a generally positive attitude of people toward such a regulation (eg, United Kingdom [5]; United Kingdom, Iceland, Norway, and Sweden [1]; Norway [6]; and Germany [7,8]).

In the following, we will first introduce “data donation” as an opt-out approach to legitimizing the secondary research use of personal medical data. Since opt-out would imply that patients are no longer informed directly about the research-associated risks and benefits, alternative ways of information provision must be explored in the context of data donation if the paradigm of informedness was to be maintained. We therefore also introduce the concept of “health data literacy,” defined as the capacity to find, understand, and evaluate information about data-rich medical research. Although a case for general health data literacy can be made independently of the issue of patient consent, its consideration becomes particularly urgent for the latter if the framework of consenting was to change from opt-in to opt-out.

Data Donation: Consent-Free Research Use of Medical Data Plus Opt-Out

The European General Data Protection Regulation (EU-GDPR) gives European member states considerable leeway with regard to permitting the research use of health data without consent. While Article 9 Paragraph 1 of the EU-GDPR clearly prohibits the processing of personal genetic, biometric, or health data, Article 9 Paragraph 2(j) explicitly exempts processing for scientific research purposes [9]. In addition, Article 89 allows national legislation to provide for this exception, subject to appropriate safeguards for the rights and freedom of the data subjects.

In Germany, the ethical, legal, technological, and organizational framework of the consent-free use of health data was examined in 2020 in a detailed report to the Federal Ministry of Health [10]. In addition to its legal admissibility, the report addressed the scientific benefits of such an approach, its impact upon the right of informational self-determination, and the necessity and possibilities for fair involvement of the data subjects. The authors concluded that it would be possible in Germany to replace the requirement for explicit consent for research with personal medical data by an equivalent legal permission, combined with an easy-to-exercise opt-out. Under certain conditions, such “data donation” (as it was termed in the report) would be both legally possible and ethically reasonable.

The above notwithstanding, the authors were also unequivocal that the actual process of data access by potential users should be independent of whether access is legitimized by opt-in or opt-out. The involvement of an ethics board or a use-and-access committee that reviews and decides data applications remains essential in both cases. Notably, such institutions also play an important role in weighing the potential risks and benefits of individual research projects, a legitimation mechanism that was deliberately placed on the same level as consent by the EU-GDPR.

Importantly with a view to the following considerations, the report clarified that, in addition to technical and organizational protective measures, one prerequisite for the acceptability of data donation would be that patients and citizens were sufficiently well informed about it. This proviso inevitably leads to the question of how sufficient knowledgeability can be achieved if the decision about sharing one’s data for research purposes is no longer made actively, following thorough verbal explanation, but passively by exercising or not exercising a right of objection.

Limits of Top-Down “Informability”: the COVID-19 Infodemic as an Example

Since data donation, in the above sense, would be temporally and spatially decoupled from medical care and instead be anchored in everyday life, alternative offers of information would have to compensate for the lack of direct communication with medical or scientific experts [11]. Yet, the COVID-19 pandemic recently highlighted that the expansion of top-down media campaigns alone is not sufficient to adequately convey the complex aspects of medical research to the general public. Instead, it turned out that, despite the general increase in information provided, many people who opposed vaccination in the first place still were not sufficiently receptive to scientific facts [12]. Moreover, even some kind of social grouping occurred along people’s vaccination status, and the COSMO study carried out in Germany and Austria revealed that the stronger the identification with being unvaccinated, the lower the inclination to change this status, and the greater the feeling of discrimination [13]. Obviously, the ability to become informed (“informability”) had reached its limits in view of the amount of information available, a paradox that lamentably also had a negative impact upon the effectiveness of public health measures taken.

In connection with the COVID-19 pandemic, the World Health Organization (WHO) coined the term “infodemic” for the increasingly observed susceptibility of people to fake news as a result of reduced informability. According to the WHO, the

infodemic caused a high degree of uncertainty in the population, a greater willingness to engage in health-damaging and risk-taking behavior, and an increased distrust of the health authorities [14]. The "Infodemic Management" called for by the WHO aimed to enable the population to better understand information from health experts and to become more resistant to misinformation [15].

Ways to Better Informability?

In view of its complexity, it seems unrealistic to convey all relevant information about the research use of personal health data at once. We therefore propose "health data literacy" as a basis for better informability of the general population and, hence, as a means to uphold the paradigm of informed consent even in the context of data donation in the above sense. For a well-informed general public, data donation would indeed mean nothing more than a change in decision format—from opt-in to opt-out.

In a narrower sense, the word "literacy" stands for the ability to read and, thereby, to acquire education and knowledge. According to the Organisation for Economic Co-operation and Development (OECD), understanding and interpreting written material should enable citizens to develop their own potential and to fully participate in societal affairs [16]. The starting point of our considerations on health data literacy therefore will be a class of communication models that focus upon the possible causes of limited informability.

One decisive factor for the success of communication is the thought system of the recipient. Since we often have little time to consider large amounts of everyday information, we believe statements that we have heard very often to be more credible than others [17]. This effect is reinforced by the phenomenon of group polarization: those who share a widespread opinion on complex issues are more likely to be reserved about new information and tend to believe whatever confirms their own viewpoint rather than information that does not fit. This selective form of information intake can, for example, increase polarization in social disputes even in the presence of reliable evidence and information [18]. The concept of health data literacy picks up on the basic idea of these communication models and aims to create anchor points in the knowledge base of people, where information on the benefits and risks of data-rich medical research can be stored and evaluated.

Value congruence approaches aim in a similar direction, in that they try to increase trust in certain institutions [19,20]. Such trust will be greater when more individuals perceive that their interests and values are shared by the institution in question, because trust is also largely based upon the perception of common values. This applies all the more to institutions that use health data for research, and it is therefore in the best interest of such institutions to develop and represent values that are highly rated by the public [19,20]. In this context, widespread health data literacy could form the breeding ground for the perception of a congruence of values and, thus, for greater trust in the recipients and beneficiaries of data donation.

The Concept of "Health Data Literacy"

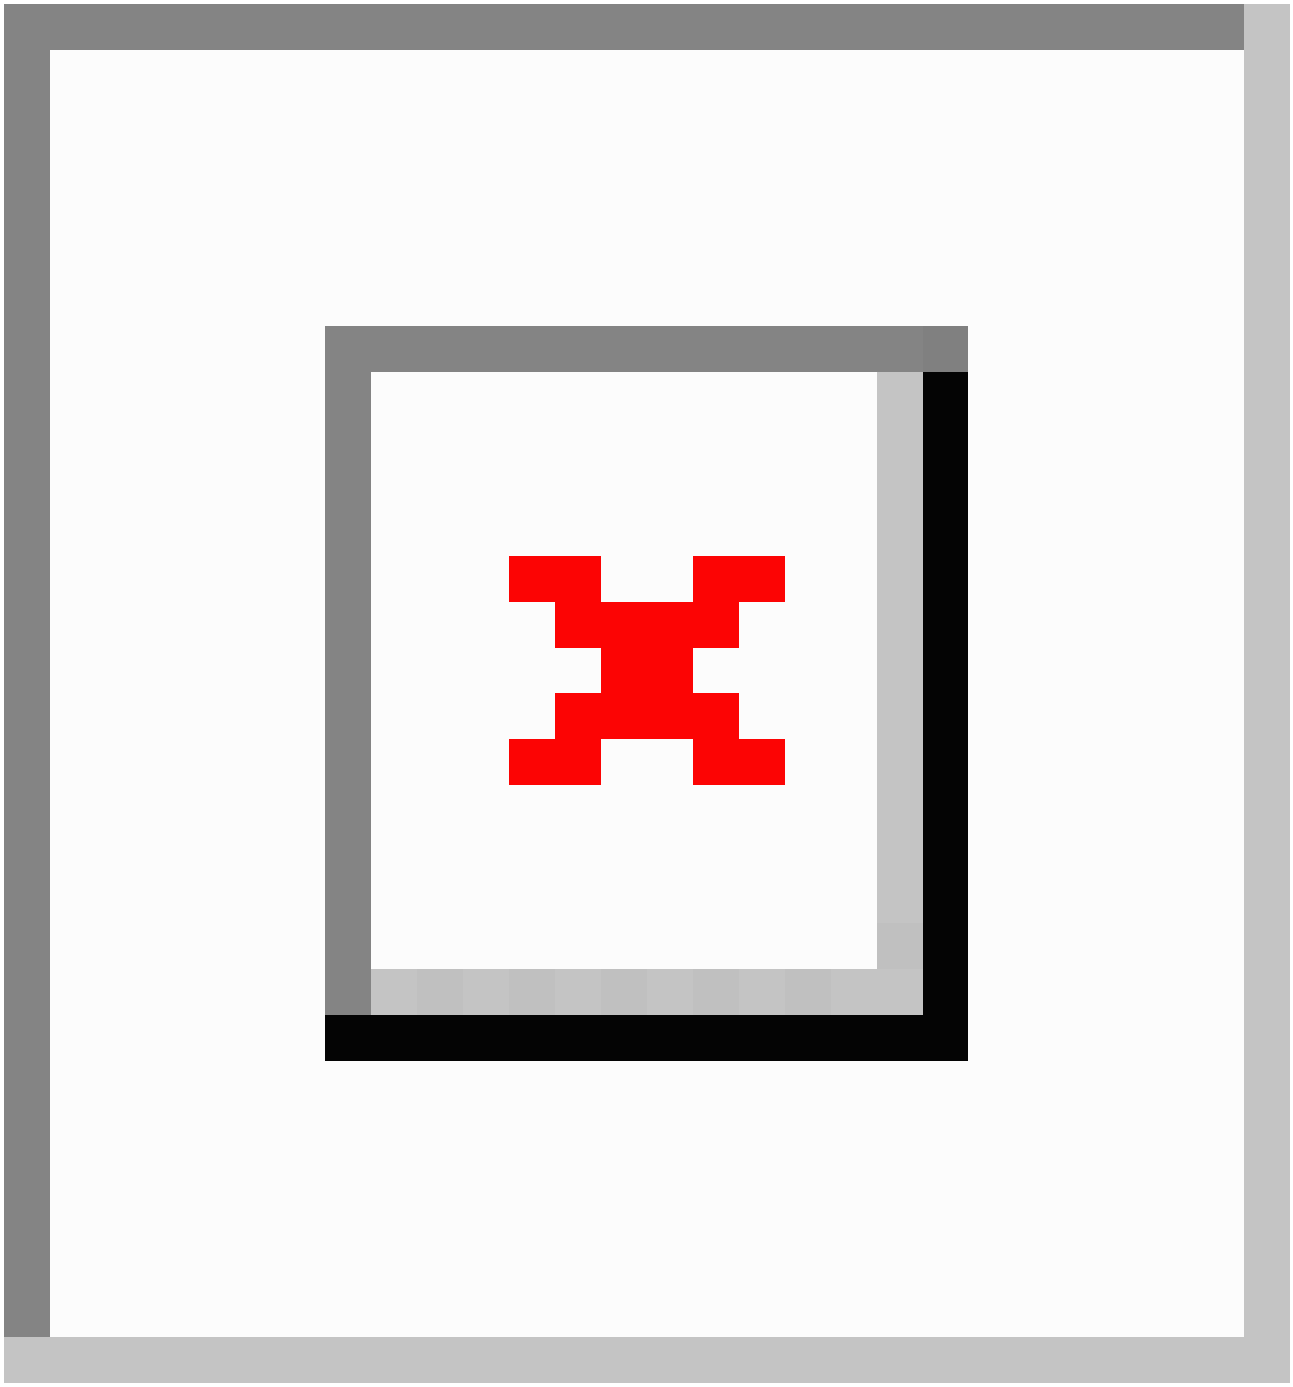
An individual's health data literacy is positioned between their health literacy and their data literacy, where the latter in particular has been promoted politically, for example, by the data strategy of the German federal government [21].

- In view of the increasingly specific treatment options promised by so-called "precision medicine," citizens would be well advised to take an interest in issues related to disease prevention and medical care [22]. The associated term "health literacy" summarizes both the motivation and the ability to find, understand, evaluate, and apply the information underlying personal health–related decisions [23]. Numerous international studies have measured and compared the level of health literacy in different populations (eg, [24]), as well as spurring considerations as to how health literacy can be increased (eg, [25]).
- The term "data literacy" refers to knowledge about data and their use in general, including legal, ethical, and social aspects. Data literacy thus forms the basis of personal self-determination in an increasingly digitalized society [26]. The aim of data literacy is an ability to weigh one's own personal rights against the potential benefits of making personal data available to others [27].

In combining both abovementioned terms, "health data literacy" stands for the capacity to find, understand, and evaluate information about the risks and benefits of medical research with personal health data; to compare this information with one's own values; and to act accordingly. Health data literacy is thus a transformer of information into informed action, aimed at a level of thematic familiarity that enables self-determined decision-making about the sharing of one's own health data with the research community. Specifically, health data literacy should at the very least include basic knowledge about the goals and methods of data-rich medical research and about the possibilities and limits of data protection.

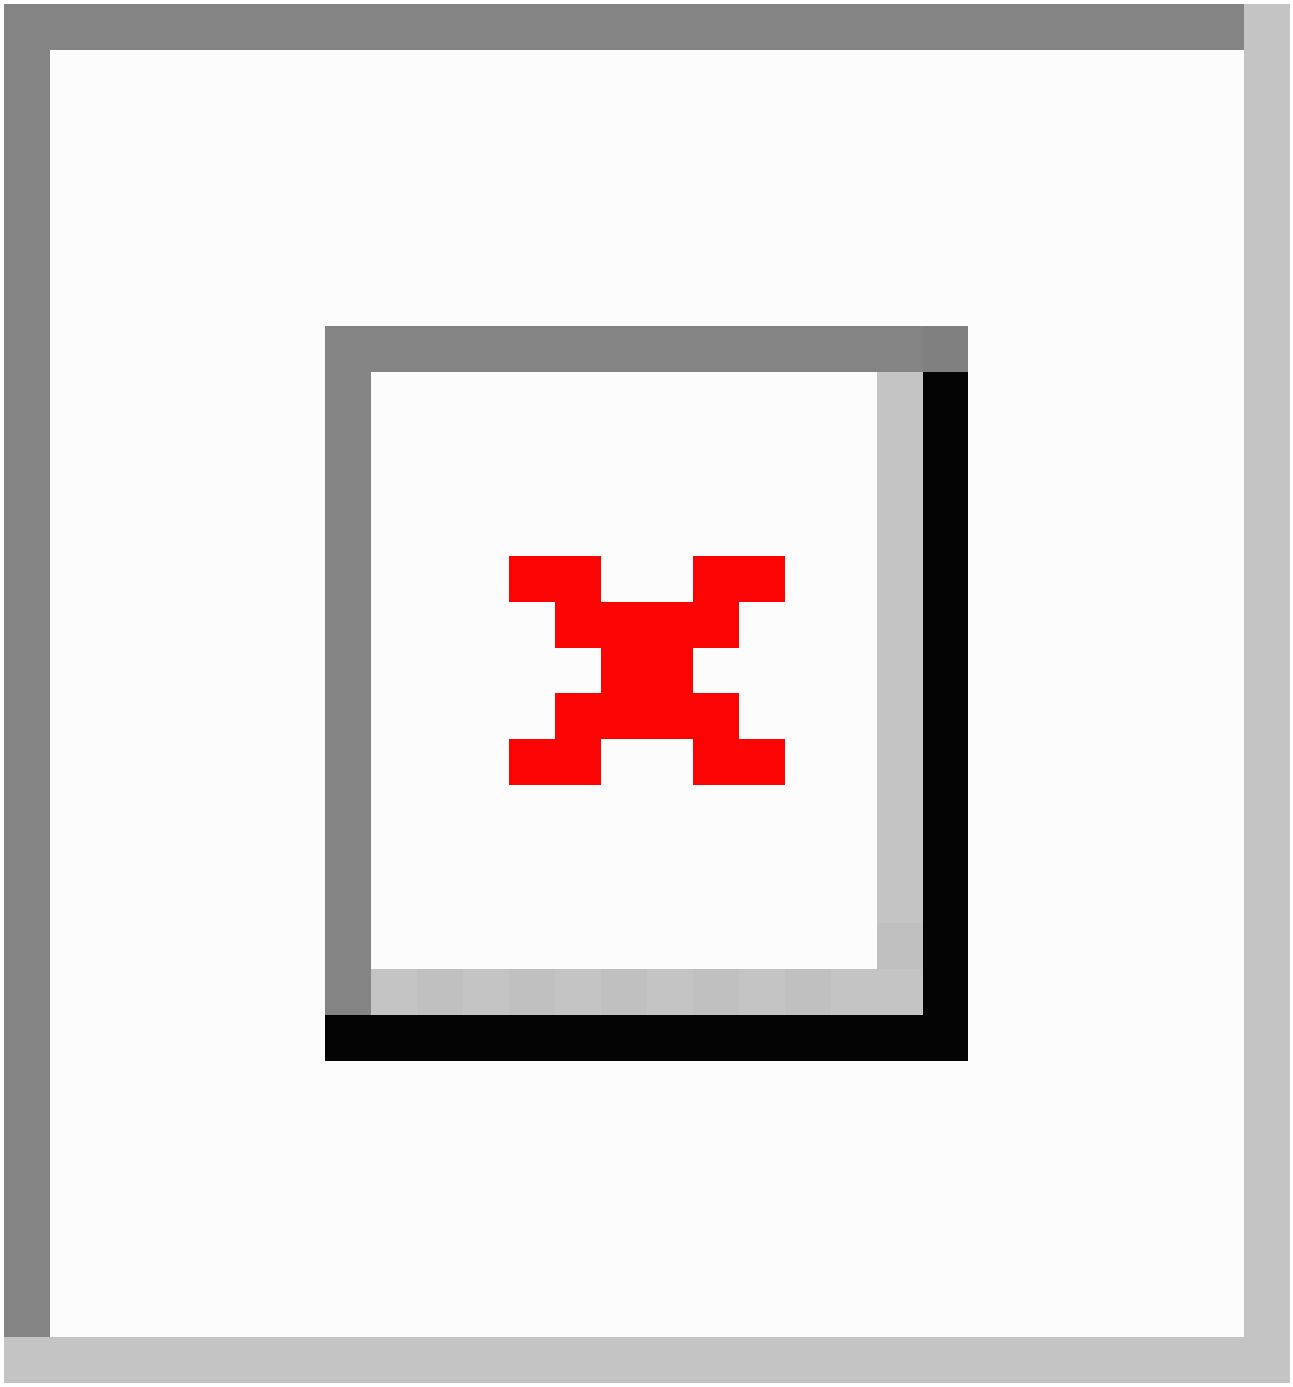
The increasing relevance of personal health data for medical research has led to a large number of measures to increase the societal acceptance of the use of such data. However, legislative regulations on data governance and data protection, as well as efforts to increase patient involvement and public information, are likely to have greater impact when they are met with more adequate prior knowledge in the sense of health data literacy (Figure 1).

Figure 1. Health data literacy as a breeding ground for the societal acceptance of data donation.



When the mental anchor points set by health data literacy receive information on scientific successes, new technical and organizational developments, as well as possible setbacks of data-rich medical research (keyword: transparency), this information can be evaluated competently by the recipient and compared to their own expectations. In the aftermath of such reflections, informed self-determination and sufficient trust in regulations and institutions can develop (Figure 2).

Figure 2. Transparency nourishes confidence and trust in data-rich medical research.



Outlook: Feasibility and Implementation of Health Data Literacy

Numerous international studies among patients and in the general population have revealed a broad positive attitude toward the provision of personal health data to medical research (eg, [28]). This approval was consistently found to be driven by a sense of reciprocity, that is, a wish to give something back after benefiting from research (eg, [29,30]). Evidence also emerged for the widespread belief in a social duty of citizens to contribute their own data to research, independent of their personal benefit [31,32]. At the same time, however, a craving for more detailed information was observed, up to and including the view that every individual is responsible themselves to find out about the nature and benefits of research with personal health data (eg, [33]).

In summary, we are thus in a situation where (1) there is little doubt about the need to utilize personal health data from different contexts to achieve the goals of modern medical research, (2) the consent-free use of such data meets broad approval by the general public, and (3) there is a widespread willingness of people to acquire the knowledge necessary to make a self-determined decision about data donation. The most compelling argument for general health data literacy is therefore self-evident: widespread background knowledge of the risks and benefits of data-rich medical research would allow the paradigm of informedness to be maintained even if consent to

participation in research is implement by opt-out, rather than opt-in.

However, the appeal of general health data literacy undoubtedly goes beyond the issue of data donation. Its necessity arises from the increasing complexity of data-rich medical research, which can no longer be explained adequately via waiting room leaflets or doctor consultations. We are also aware that improved health data literacy could, in principle, help to reduce some of the misunderstandings of patients that we somehow held against broad consent when advocating data donation. However, in view of the many advantages of data donation summarized above, we think that only little importance should be attached to this possibility.

Attempts to establish general health data literacy should strive for a certain level of competence across as broad a proportion of the population as possible. This goal not only expresses fairness and ensures equal representation of different societal groups in medical research but can also help to reduce the vulnerability to fake information as a potential threat to public health, as observed during the COVID-19 pandemic. Achieving equity in practice will require the development and provision of target group–specific offers of information and education. One particularly efficient way to increase health data literacy across the board would be to start this process in school, as suggested previously to strengthen health literacy [25]. This approach is not only easy to implement in practice; it would also offer the opportunity to use children as multipliers among friends and family.

Further research is needed to determine exactly what kind of information should be communicated, in what form, and to whom to improve health data literacy in a given population. These questions are ideally answered through cocreation research involving representatives of different target groups to enhance the credibility of the education curriculum and content among end users. However, although the responsibility for developing the necessary resources lies primarily with those directly involved in data-rich medical research, improving health data literacy should ultimately be of concern to everyone interested in the success of this type of research.

Acknowledgments

We acknowledge financial support by Deutsche Forschungsgemeinschaft (DFG) within the funding program Open Access-Publikationskosten. We are most grateful to Claudia Bozzaro, Kiel University, for discussing health data literacy with us.

Authors' Contributions

The idea of health data literacy was first conceived by GR; GR and MK jointly developed the concept further and authored the manuscript.

Abstract

Implementing artificial intelligence to extract insights from large, real-world clinical data sets can supplement and enhance knowledge management efforts for health sciences research and clinical care. At Vanderbilt University Medical Center (VUMC), the in-house developed Word Cloud natural language processing system extracts coded concepts from patient records in VUMC's electronic health record repository using the Unified Medical Language System terminology. Through this process, the Word Cloud extracts the most prominent concepts found in the clinical documentation of a specific patient or population. The Word Cloud provides added value for clinical care decision-making and research. This viewpoint paper describes a use case for how the VUMC Center for Knowledge Management leverages the condition-disease associations represented by the Word Cloud to aid in the knowledge generation needed to inform the interpretation of phenome-wide association studies.

Introduction

The rapid advancement and availability of artificial intelligence (AI) approaches provide biomedical informatics groups with opportunities for exploring and generating insights from internal and external data at scale to enhance health sciences research and clinical care [1,2]. One such opportunity is using natural language processing (NLP) to extract usable knowledge from the vast amounts of structured and unstructured clinical data captured daily via the electronic health record (EHR). Insights from this process can be used to inform patient care, target information provision, and generate research hypotheses. This paper presents some of the activities that such usable knowledge makes possible.

Vanderbilt University Medical Center (VUMC) maintains an electronic health repository containing data for over 4.6 million individuals, going back to 1995, which includes structured data (eg, laboratory results and vital signs), textual data (eg, provider notes and radiology interpretations), reports (eg, electrocardiograms and pulmonary function test results), and image data. Included in this vendor-agnostic repository are all VUMC patient data captured from the in-house developed StarPanel EHR (VUMC) dating back to 2001 [3] and VUMC's current vendor-based EHR (Epic; Epic Systems Corporation), which was implemented in 2017 [4]. Roughly 850,000 new documents are added daily.

To identify and quickly represent the most critical information about a particular patient or population from this large data set, VUMC established the Word Cloud, a real-time and at-scale concept extraction tool that uses NLP to create a visual, time-oriented representation of clinical data [5-7]. The Word Cloud NLP uses a rules-based, finite-state machine approach

to process all nonimage incoming documents in real time and extract coded concepts using the Unified Medical Language System (UMLS) terminology [8]. With a processing speed of more than 50,000 documents per minute, the Word Cloud NLP is faster than currently available concept extraction NLP tools such as Apache cTakes (50,000 documents per hour; Apache Software Foundation, Mayo Clinic) [9] and MetaMap (22 citations per minute; National Library of Medicine) [10]. The rapid speed allows for better integration into the clinical workflow as real time–generated Word Cloud concepts are immediately presented to health care providers as they access the feature in the medical chart. The system handles all linguistic phenomena in clinical text, including acronyms, abbreviations, misspellings, negation, family history, uncertainty, and differential diagnosis. Excluding image data, the entire EHR repository is included in the Word Cloud NLP database, which uses close to 14,000 UMLS concepts to index 1.7 billion documents. In addition to the individual patient concepts, which include pointers to the original documents, the database also includes population-level associations of any pair of concepts.

The original purpose of the Word Cloud data was to provide a user interface that displays all concepts extracted from a patient's clinical documents in a word cloud display, with the size of each concept indicating how often the concept was documented for the patient. This interface is available to all users of the EHR. The Word Cloud data have been used since 2019 to generate clinical alerts for a variety of situations, such as flagging patients with implanted cardiac devices and a positive blood culture, patients with signs of serious inflammation due to immune checkpoint inhibitors, or patients with Andersen-Tawil syndrome who might be candidates for enrollment into a research study. The Word Cloud data drive real-time decision support by injecting detected concepts back into the VUMC EHR [11]. Because all the concepts extracted by the Word Cloud NLP are stored in the enterprise data lake, these data are also available for retrospective research and can be easily combined with other data such as the International Statistical Classification of Diseases codes or coded medications data [11].

The Center for Knowledge Management (CKM) has explored how the Word Cloud can be leveraged by information scientists engaged in EHR projects. The CKM facilitates the discovery and integration of external knowledge into medical practice and promotes curation, archiving, and reuse of internal knowledge across VUMC [12-15]. This viewpoint paper details how the CKM's innovative application of the Word Cloud enhances knowledge generation processes and describes future directions for NLP in knowledge management.

Case Description

Collaborations with medical center researchers comprise the majority of the CKM's partnership activities. A recent project to inform the interpretation of phenome-wide association studies (PheWASs) using evidence-linked knowledge bases illustrates these types of partnerships [16]. PheWASs examine relationships between markers (genetic or nongenetic) and phenotypes, producing extensive lists of possibly relevant marker-phenotype associations [17,18]. A methodological approach to compare known associations with PheWAS results can make it easier to identify potentially novel PheWAS outcomes [16]. Knowledge bases—created in part from synthesized evidence sources and primary literature documenting disease causes, risks, and complications—can be used for these comparisons.

For this research collaboration, the CKM created a "condition flowchart" with the causes, risk factors, and complications of a given medical condition. The sources consulted to create the flowchart include evidence synthesis resources (eg, UpToDate; UpToDate, Inc), medical textbooks (eg, Goldman-Cecil Medicine), and consumer health websites (eg, MedlinePlus; National Library of Medicine). From each source, the CKM team identified all causes, risk factors, and complications for the condition of interest and added them to the flowchart. Our collaborators then used the flowchart to create a knowledge base of phecodes for the PheWAS analysis. During flowchart creation, the CKM leveraged the Word Cloud to identify meaningful disease-condition associations—based on real-world population-level data—and target appropriate primary literature to substantiate the observed linkages.

Identifying Meaningful Condition Associations From the EHR

Each flowchart focuses on a specific clinical condition (eg, hypertension and hypotension), which is searched against the Word Cloud. Using a population-level analysis feature, the Word Cloud returns a list of all UMLS concepts represented in the EHR records of patients with the specified condition. The expected value is calculated for each UMLS concept [19] and the ratio of actual-to-expected patient cases (ie, strength of association) is then used to rank the list of causes, risk factors, and complications on the flowchart. This ranking thus provides our team with rapid knowledge acquisition of what is associated with the condition of interest. The actual-to-expected ratio for concept 1 and concept 2 is computed as follows:

where T=total population size, $a_{1,2}$=number of patients with both concept 1 and concept 2, n_1=number of patients with concept 1, and n_2=number of patients with concept 2.

A strength of association ratio of 15 or higher indicates that the concept occurs more often than expected by chance and signifies a meaningful relationship between the UMLS concept and the condition. Figure 1 provides an example of the UMLS concepts most associated with orthostatic hypotension in 71,996 patients.

Figure 1. Snapshot of the Word Cloud population-level list of UMLS concepts associated with orthostatic hypotension. Concepts are listed in descending order by the strength-of-association ratio, that is, the ratio of actual to expected number of cases in the VUMC EHR with the pairwise association of UMLS concepts. The population frequency of each term is also displayed. The ratio is used to rank the condition flowchart. CUI: concept unique identifier; EHR: electronic health record; Misc.: miscellaneous; MsgBskts: message baskets; NewRes: new results; Pop. Freq.: population frequency; Pt.Chart: patient chart; Pt.Lists: patient lists; StNotes: Star Notes; UMLS: Unified Medical Language System; VUMC: Vanderbilt University Medical Center; WhBoards: white boards.

The Word Cloud also aids in identifying concepts most applicable to guide the ranking by displaying each term's UMLS semantic type. In the UMLS Metathesaurus, each concept term is assigned to 1 or more of 127 types in the vocabulary's hierarchical semantic network [20]. Semantic types most relevant for comparison with the condition flowchart include disease or syndrome, injury or poisoning, mental or behavioral dysfunction, sign or symptom, finding, and congenital abnormality. The Word Cloud provides a filter to exclude concepts with semantic types nonrelevant to this task (eg, procedures).

The Word Cloud often lists multiple UMLS concepts that can be grouped to correspond with a single term on the condition flowchart. For example, the Word Cloud concepts associated with orthostatic hypotension include Shy-Drager syndrome, multisystem degeneration of autonomic nervous system, and multisystem atrophy (Figure 1). In 1998, Shy-Drager syndrome was newly categorized as a multisystem atrophy and is no longer the preferred term [21]; the UMLS also lists it as a narrower concept of the term "multiple system atrophy" [8]. In the UMLS, the relationship between "multiple system atrophy" and "multisystem degeneration of autonomic nervous system" is vaguely and imprecisely defined as an "RO" relationship type. RO relationships are described as "other than synonymous, narrower, or broader," however, in this case, the RO determination in the UMLS lacks the relationship attribute that is normally included [8]. The phecodeX map, the term mapping table used for the CKM collaborator's PheWAS, matches "multisystem atrophy" to the phecode "multi-system degeneration of the autonomic nervous system" [22]. Given the evolution of the Shy-Drager syndrome terminology, the UMLS, and the phecodeX mapping, we subsequently considered all 3 of the Word Cloud concepts as a group of related terms; the highest ratio within the group was then used to rank order the condition flowchart.

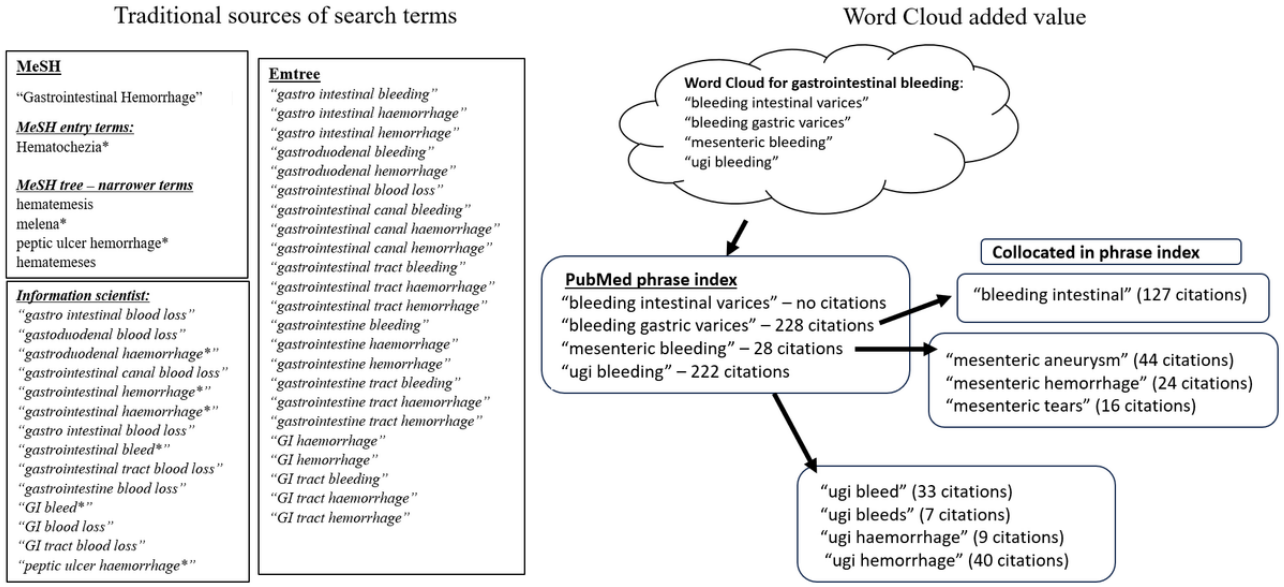
Through the combined processes of documenting actual-to-expected case ratios of the Word Cloud's relevant UMLS concepts, excluding nonrelevant semantic types, and grouping related concepts, our team creates rank-ordered lists of disease causes, risk factors, and complications reflecting our medical center's real-world clinical data.

Substantiating Disease-Condition Associations With Evidence

Providing primary literature to substantiate the associations on the condition flowchart is a key component of our research collaboration. CKM information scientists derive synonyms from the Word Cloud to strengthen the search strategy. When conducting a search, they first compile controlled vocabulary and synonyms from Medical Subject Headings and Emtree [23,24]. Next, they brainstorm additional permutations and extract terms from a scan of the literature; these keywords are subsequently checked for inclusion in the PubMed phrase index.

Figure 2 shows an example of this process for the UMLS concept "gastrointestinal bleeding." Consulting the Word Cloud identified 4 phrases that were not in the initial list of search strategy terms; 3 were found in the PubMed phrase index. Additional terminology was found by scanning collocated terms in the phrase index.

Figure 2. Word Cloud concepts leading to supplemental terminology for a search strategy on gastrointestinal hemorrhage. An asterisk denotes the truncation of a term or phrase to capture permutations. GI: gastrointestinal; MeSH: Medical Subject Headings; UGI: upper gastrointestinal.



In addition to aiding with identifying terminology and concepts to build upon our search strategies, we increasingly realize the importance of the Word Cloud's actual-to-expected patient case ratio for locating appropriate evidence. When creating the condition flowchart, our team may encounter associations for which it is difficult to locate substantiating evidence. In these cases, a Word Cloud ratio that is nonexistent, or lower than 15, can aid in validating literature scarcity. For example, snake bites can lead to nonseptic distributive shock [25]. In the Word Cloud, the association between snake bite and distributive shock has a low ratio of 5.38. Substantiating evidence for the association was found only in case reports and case series (ie, studies with few patients). Similarly, searching for literature to support hypertrophic cardiomyopathy as a cause of obstructive shock yielded only case reports as the best available evidence. A review of the Word Cloud UMLS concepts revealed a ratio of 8.7. In these instances, the evidence may still be used, but the low ranking, due to the low ratio, aids in understanding the strength of association when compared with other causes, risk factors, and complications listed on the condition flowchart.

Conclusions

This viewpoint paper describes a novel use of an institution's AI-driven, large-scale aggregation of condition-specific patient data extracted from free-text clinical documents. The Word Cloud NLP system can inform and guide knowledge generation processes by enhancing our ability to represent, substantiate, and prioritize condition associations for use in PheWAS interpretation.

The VUMC Word Cloud NLP is a valuable resource that provides real-time concept extraction from all clinical documentation and makes the resulting data viewable interactively, available for real-time decision support and alerting, and available as a rich source of coded data for research. An important limitation, however, is that this type of resource would be expensive and difficult to port directly to other institutions, thus limiting its generalizability. The emergence of generative AI, and in particular large language models, makes it conceivable that some of these limitations might be reduced in the near future; for example, large language models might be used to perform a significant portion of the concept extraction task, turning clinical free text into sets of terms which might then be mapped to coded terminologies (such as the UMLS). This possibility is still largely hypothetical and will need to be investigated to evaluate whether it is feasible, performant, and economically viable.

It is also worth noting that in addition to the population-level analysis features offered by the Word Cloud as described in our research collaboration for PheWAS analysis, the CKM also uses its capability of providing summary views of individual patient charts for other projects, such as our synthesized evidence provision services [14,26]. In response to providers' complex clinical questions, information scientists consult the visual display of the Word Cloud to gain a holistic understanding of each patient's comorbidities, medications, and other prominent clinical history. This greatly facilitates our ability to generate tailored syntheses of the published evidence that are personalized to each specific patient case [26]. Additional applications of the Word Cloud and other AI tools are also under exploration at our center, including the use of AI for scaling the maintenance of evidence syntheses over time [27-29]. Through both of these approaches—leveraging the Word Cloud NLP for population-level concept analysis and individual patient-level assessment—the CKM achieves the rapid knowledge acquisition strategy critical for informing clinical health care and research at our institution.

Abstract

Background: In the 21st century, Chinese hospitals have witnessed innovative medical business models, such as online diagnosis and treatment, cross-regional multidepartment consultation, and real-time sharing of medical test results, that surpass traditional hospital information systems (HISs). The introduction of cloud computing provides an excellent opportunity for hospitals to address these challenges. However, there is currently no comprehensive research assessing the cloud migration of HISs in China. This lack may hinder the widespread adoption and secure implementation of cloud computing in hospitals.

Objective: The objective of this study is to comprehensively assess external and internal factors influencing the cloud migration of HISs in China and propose promotional strategies.

Methods: Academic articles from January 1, 2007, to February 21, 2023, on the topic were searched in PubMed and HuiyiMd databases, and relevant documents such as national policy documents, white papers, and survey reports were collected from authoritative sources for analysis. A systematic assessment of factors influencing cloud migration of HISs in China was conducted by combining a Strengths, Weaknesses, Opportunities, and Threats (SWOT) analysis and literature review methods. Then, various promotional strategies based on different combinations of external and internal factors were proposed.

Results: After conducting a thorough search and review, this study included 94 academic articles and 37 relevant documents. The analysis of these documents reveals the increasing application of and research on cloud computing in Chinese hospitals, and that it has expanded to 22 disciplinary domains. However, more than half (n=49, 52%) of the documents primarily focused on task-specific cloud-based systems in hospitals, while only 22% (n=21 articles) discussed integrated cloud platforms shared across the entire hospital, medical alliance, or region. The SWOT analysis showed that cloud computing adoption in Chinese hospitals benefits from policy support, capital investment, and social demand for new technology. However, it also faces threats like loss of digital sovereignty, supplier competition, cyber risks, and insufficient supervision. Factors driving cloud migration for HISs include medical big data analytics and use, interdisciplinary collaboration, health-centered medical service provision, and successful cases. Barriers include system complexity, security threats, lack of strategic planning and resource allocation, relevant personnel shortages, and inadequate investment. This study proposes 4 promotional strategies: encouraging more hospitals to migrate, enhancing hospitals' capabilities for migration, establishing a provincial-level unified medical hybrid multi-cloud platform, strengthening legal frameworks, and providing robust technical support.

Conclusions: Cloud computing is an innovative technology that has gained significant attention from both the Chinese government and the global community. In order to effectively support the rapid growth of a novel, health-centered medical industry, it is imperative for Chinese health authorities and hospitals to seize this opportunity by implementing comprehensive strategies aimed at encouraging hospitals to migrate their HISs to the cloud.

(JMIR Med Inform 2024;12:e52080) doi:10.2196/52080

KEYWORDS

hospital information system; HIS; cloud computing; cloud migration; Strengths, Weaknesses, Opportunities, and Threats analysis

Introduction

In the 21st century, innovative business models have emerged in Chinese hospitals, such as online diagnosis and treatment, cross-regional multidepartment consultation, real-time sharing of medical test results, and continuous public health surveillance. However, most hospitals still rely on traditional hospital information systems (HISs) designed for in-hospital management that are inadequate to support the development of these new business models [1]. Cloud computing has emerged as a promising global information technology recognized as a new infrastructure for future economic growth [2,3]. Since 2010, it has also been prioritized by the Chinese government as a "national strategic emerging industry" [4]. The adoption of cloud computing technologies can significantly reduce hospitals' costs associated with system construction and maintenance [5], expand medical services to partner institutions or patients outside the hospital [6], provide more secure network protection than self-built data centers [7], and facilitate large-scale collection and analysis of clinical data essential for scientific clinical decision-making [8]. Based on these advantages, there has been a surge in China's medical cloud service market and application research in recent years [9].

However, despite the increased attention given to cloud computing in various disciplinary domains such as disease monitoring, health surveillance, and clinical diagnosis, there is a lack of research on the cloud migration of HISs. A comprehensive review of the PubMed and HuiyiMd databases only yielded 3 relevant studies: an Iranian study that identified key driving factors for hospitals adopting cloud computing [10], a Greek study that proposed a method for migrating clinical and laboratory data based on local hospital conditions [11], and an American study that focused on essential considerations for chief financial officers before venturing into the cloud [12]. However, none of these studies have adequately addressed the aforementioned issue. Without conducting prior assessments, hospitals may struggle to fully comprehend the external environment, internal conditions, and potential opportunities and risks, thus failing to ensure prudent decision-making. Blindly following trends could pose significant threats to the security, operational efficiency, and maintenance costs of already deployed cloud-based information systems and existing hospital networks [13]. Therefore, this study aims to systematically assess factors influencing the cloud migration of HISs in China, identify associated challenges, and propose corresponding strategies for advancement. It can assist hospitals in gaining a comprehensive understanding of this work while safely implementing their cloud-based medical services. Additionally, it serves as a foundation for formulating policies aligned with Chinese hospital informatization development in the new era by health authorities while being referenced by other countries or regions facing similar challenges.

Methods

Information Sources

The primary data source for this study was obtained from literature databases to understand the practical applications of cloud technology in Chinese hospitals. The articles published between January 1, 2007, and February 21, 2023, were selected from MEDLINE (accessible through PubMed) and HuiyiMd (accessible through the Huiyi Medical Literature Express Service System).

In order to overcome the inherent limitations of academic articles, this study augmented a wealth of pertinent internal and external environmental information by extensively consulting authoritative sources such as government agencies, industry organizations, academic institutions, and market research companies. These sources of information included national policies, action plans, white papers, implementation guidelines, survey reports, and statistical data from the past 10 years.

Search Strategies

The search strategy for PubMed: (((cloud [Title/Abstract]) OR (cloud-based [Title/Abstract])) AND (hospital [Title/Abstract]) AND ("2007/01/01" [Date-Publication]: "2023/02/21" [Date-Publication])). The search strategy for HuiyiMd: ([TI] (cloud AND hospital) OR [AB] (cloud AND hospital) OR [MH] (cloud AND hospital)) AND ([PY]>=2007). The search strategy for authoritative sources involves entering the keywords "hospital" AND "cloud" in the search box on websites.

Inclusion and Exclusion Criteria

Based on specified inclusion and exclusion criteria (Textbox 1), irrelevant articles or those covering the same topic from the same institution were excluded. Subsequently, an Excel (Microsoft) spreadsheet (Multimedia Appendix 1) and a reference list (Multimedia Appendix 2 [1,2,6,8,14-26]) were generated for literature review and Strengths, Weaknesses, Opportunities, and Threats (SWOT) analysis.

Textbox 1. Inclusion and exclusion criteria for literature review.

Inclusion criteria

- Article type: fully retrievable
- Language: English, Chinese
- Nationality of the first author: Chinese (including Hong Kong and Taiwan)
- Article topic: the research, development, and application of cloud technology in Chinese hospitals
- Publication date: from January 1, 2007, to February 21, 2023

Exclusion criteria

- Article type: nonretrievable
- Language: other languages
- Nationality of the first author: other countries
- Article topic: other topics
- Publication date: before January 1, 2007; after February 21, 2023

Information Extraction

The accessible articles were assessed based on the following criteria: title, authors, first author, first author affiliation, publication year, journal name, digital object identifier (DOI), PubMed unique identifier (PMID), first author nationality, abstract, and conclusion. Furthermore, the positive and negative impacts, research methods, disciplinary domains, cloud service models, and institutional affiliations were taken into account for further in-depth analysis purposes. The findings were documented and statistically analyzed in Excel.

Analysis Methods

The SWOT analysis is a systematic assessment of strengths (S), weaknesses (W), opportunities (O), threats (T), and other factors that influence a specific topic, objectively describing the current situation of an organization or enterprise and formulating corresponding strategies [14]. It is widely used in strategic decision-making and competitor analysis within organizations or businesses due to its ability to simplify complex problems into essential issues, enabling more focused problem-solving. This study uses the SWOT method to assess the factors impacting China's cloud migration of HISs and proposes promotional strategies.

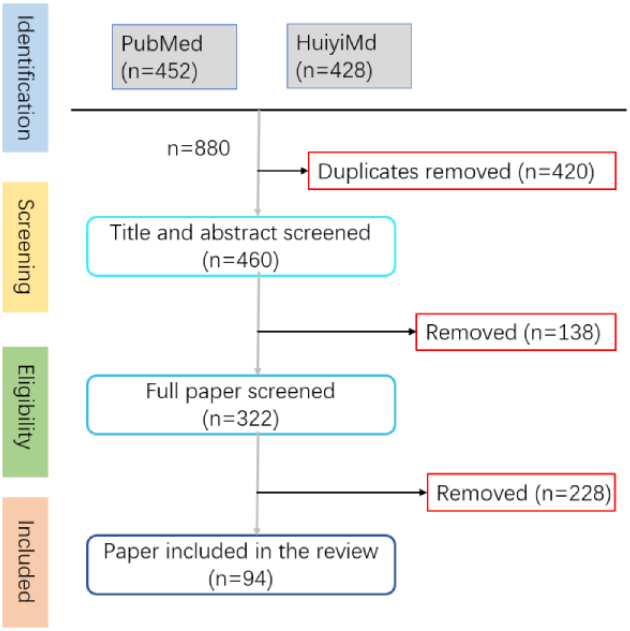
Results

Literature Review

Identification Process

The identification process in this study consists of four steps (Figure 1): (1) A total of 880 articles were retrieved from PubMed and HuiyiMd databases. (2) The search results were amalgamated, resulting in 460 deduplicated articles. (3) Screening the titles and abstracts eliminated 138 irrelevant articles based on the exclusion criteria. (4) The full text of the remaining articles was meticulously examined against predefined inclusion and exclusion criteria, resulting in a final selection of 94 relevant articles.

Figure 1. Flow diagram for the identification process.

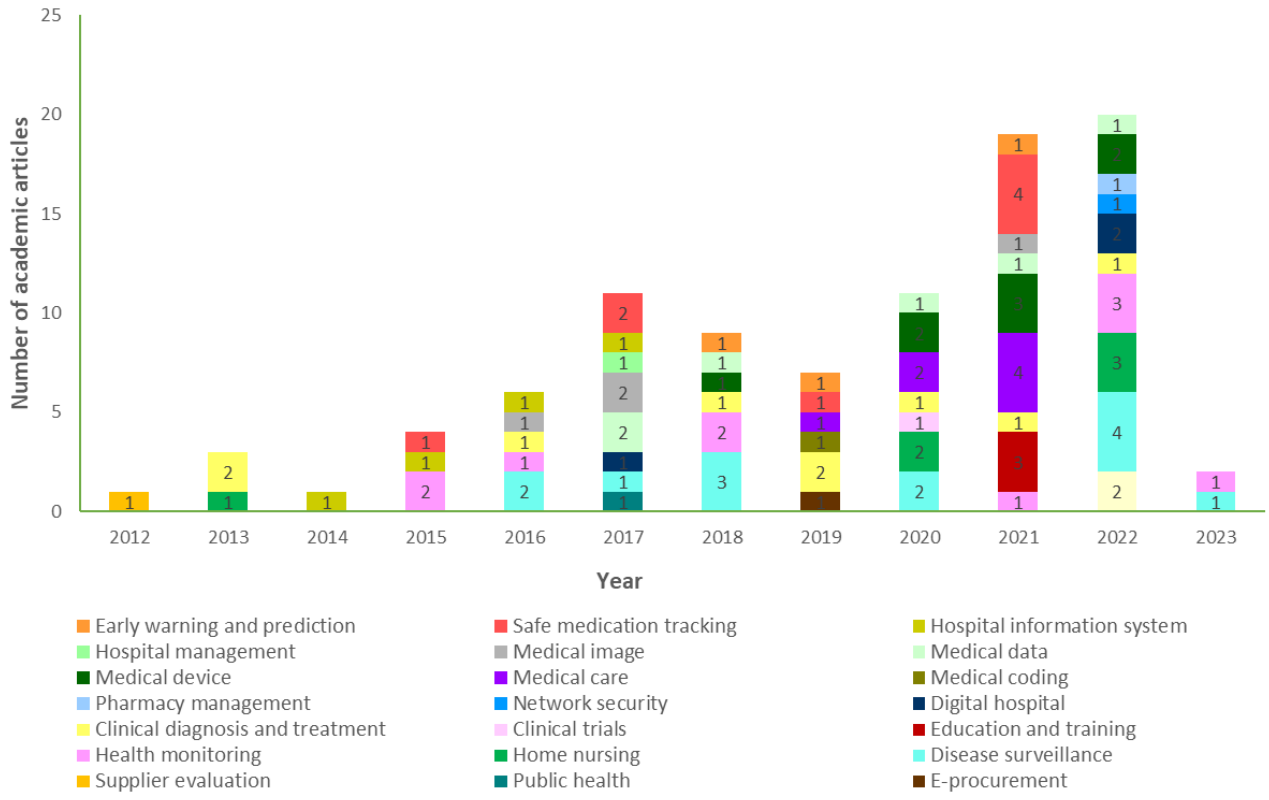


Comprehensive Description of the Literature

Research and Application of Cloud Technology in Hospitals Has Grown Rapidly and Continuously Expanded in Disciplinary Domains

In terms of time line, there was a gradual step-like increase in the number of articles starting in 2012 and reaching its peak at 20 articles in 2022. The compound annual growth rate (CAGR) was approximately 35%, highlighting the escalating quantity of research into and application of cloud technology in hospitals, as shown in Figure 2. The number of disciplines involved has increased from 1 in 2012 to 10 in 2022, encompassing a total of 22 domains. Specifically, research and application are predominantly observed in the domains of disease monitoring, health surveillance, clinical diagnosis and treatment, safe medication tracking, and medical devices, constituting 51% (48/94) of the overall distribution.

Figure 2. Time distribution of disciplinary domains involved in academic articles.



Implementation of Cloud Technology Can Yield Favorable Outcomes for Hospitals to a Certain Extent

The analysis of 94 articles identified 3 categories and 9 research methods (Table 1). The "technology" category was the most prevalent, with 47 (50%) articles focusing on information systems, cloud platforms, and associated technologies. The "experience" category followed closely, with 40 (43%) articles, primarily validating the performance of or applying cloud-based information systems through empirical research, case-control studies, experience sharing, and cohort studies. Finally, the "literature" category consisted of only 7 literature reviews on this subject matter. The consistent findings of these studies demonstrate the implementation of cloud technology in hospitals can yield positive impact to some extent, such as enhancing precision in management practices, expanding disease monitoring capabilities, reducing workload for medical personnel, and providing convenient and cost-effective health care services for patients. However, 5% (n=5) of the articles also acknowledged certain negative impacts, such as underdevelopment of digital methods in hospitals, cybersecurity risks, and low satisfaction rates among physicians and community pharmacists.

Table 1. The correlation between research methods used in academic articles and the institutional affiliations of their first authors.

Research methods	Hospitals, n (%)	Universities or colleges, n (%)	Associations or companies, n (%)
Technology			
System research and development	13 (14)	14 (15)	N/A[a]
Cloud platform construction	5 (5)	5 (5)	N/A
Technical research	2 (2)	8 (9)	N/A

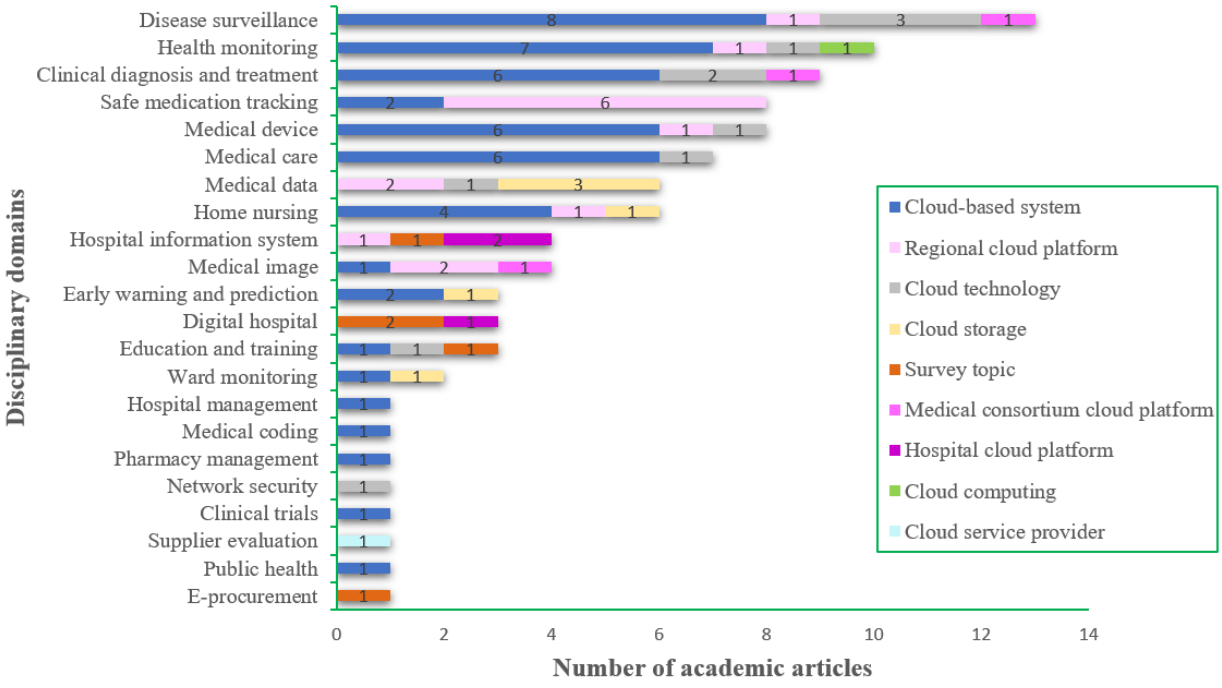
More Than Half of the Studies Focused on Task-Specific Cloud-Based Systems, While Only 1 in 5 Addressed Integrated Cloud Platforms

Out of the 94 articles analyzed, the majority (n=49, 52%) focused on task-specific cloud-based systems in hospitals. In contrast, only 21 (22%) articles discussed or developed integrated cloud platforms for sharing within a region, medical alliance, or hospital. Furthermore, as shown in Figure 3, 67% (n=33) of task-specific cloud-based systems were used in patient-related domains such as disease monitoring, health surveillance, clinical diagnosis and treatment, medical care, and medical devices. A total of 15 regional cloud platforms (16%) were commonly used for safe medication tracking, data storage, and medical imaging. A total of 3 medical alliance cloud platforms (3%) found use in disease treatment-related domains such as disease monitoring, clinical diagnosis, and treatment along with medical imaging. A total of 3 hospital cloud platforms (3%) primarily originated from digital hospitals or HIS upgrades.

Figure 3. The cross-distribution of cloud service models and disciplinary domains covered in academic articles.



More Supplementary Materials Were Collected to Support the SWOT Analysis for This Study

Because the literature review provided insufficient information to support the analysis of internal and external factors for this study, supplementary materials were collected, including national policies, action plans, white papers, implementation guidelines, research reports, and statistical reports from authoritative websites, such as government agencies, industry organizations, academic institutions, and market research companies. In total, 37 supplementary documents were included in the SWOT analysis: 4 policy papers, 11 industry reports, 15 academic articles, 2 dissertations, 2 official bulletins, and 3 news articles. All of them were recorded in an Excel file (Multimedia Appendix 2).

SWOT Analysis

External Opportunities (O)

Politics: Governments Worldwide Prioritize Cloud Technology and Have Implemented Supportive Policies

The United States introduced the Cloud First policy [2] and the CLOUD Act [15]. Similarly, the European Union aims for digital sovereignty through initiatives like the Gaia-X Association and the EU Cloud Computing Strategy [27]. China also prioritized cloud computing as a "national strategic emerging industry" in 2010 and implemented policies to promote its adoption by the government and businesses [28]. Consequently, China has rapidly developed in this field and ranks among global leaders [29].

Economy: Both Nations and Enterprises Have Made Substantial Capital Investments to Foster Its Development

According to Gartner's data from 2011 to 2022, the market scale increased from US $95.24 billion to US $491 billion with a CAGR exceeding 16% [30]. The global medical cloud computing market reached US $39.4 billion, with Asia-Pacific exhibiting the fastest growth rate at 22% per year; China and India are significant contributors to this expansion [9]. In China, the market size has surged from less than US $270 million in 2011 to US $66.91 billion in 2022, with a consistent CAGR surpassing 40%, and will exceed US $150 billion by 2025 [30].

Social: Online Health Care Has Become a Norm in Modern Life

According to the National Telemedicine and Connected Healthcare Center of China, as of June 2021, there were 239 million users accessing health care services online and more than 1600 internet-based hospitals in China [31]. Another survey revealed that approximately 63% (n=465) of the surveyed hospitals (738 hospitals across 30 provinces) used cloud services to some extent in 2022 [32]. Moreover, the COVID-19 pandemic has further fueled the demand for online health care services [6]. Consequently, these services have become as commonplace in our lives as online shopping.

Older Adult Care: The Older Adult Care Industry Urgently Needs Advanced Technological Support

By the end of November 2020, China's population of people aged 60 years and older was 264,018,766, accounting for 19% of the total population, making it the country with both the largest older population and the fastest-aging society worldwide [33]. Consequently, relying solely on their children, nursing homes, or communities to provide older adult care services has become increasingly impractical. Recognizing this challenge, the National Health Commission of China issued a document in October 2019 emphasizing the need to fully harness modern technologies such as cloud computing, artificial intelligence (AI), and the Internet of Things to develop an intelligent service model known as "Internet plus Healthy Aging" [34].

External Threats (T)

Market: Technological Monopolies Pose a Significant Threat to the Digital Autonomy of Nations

A total of 81 (81%) of the Forbes Top 100 cloud computing companies are American [35], and they possess significant technological and capital advantages. They continuously expand their global market share; they captured 60%-70% (JPY ¥1,725-¥2,012 billion [US $11.6-$13.6 million]) of the Japanese cloud market in 2020 [36] and 69% of the European cloud market in 2021 [37]. The passage of the Clarifying Lawful Use of Data Abroad Act (CLOUD Act) by the US Congress in March 2018 caused European countries to feel threatened due to the potential loss of digital sovereignty [15], which prompted them to initiate their "European cloud" project in 2020 [27]. Other nations may face similar challenges.

Competition: Fierce Competition May Lead to Uncertain Levels of Service Quality

In November 2021, 5 bidders for a public cloud service project in Shijiazhuang City, China, submitted bids of CNY ¥0, sparking concerns among stakeholders [38]. The intense competition may lead to unpredictable service performance issues for users, such as limiting hospitals' access to better pricing and a wider range of choices by restricting the interoperability and portability of HISs or causing sudden disruptions in cloud-based medical services after winning the bid, which poses significant risks to patient safety [16].

Security: Hospitals Express Apprehensions Regarding Diverse Cyber-Attacks Targeting Cloud Infrastructure

Security is the primary challenge for cloud-based systems due to various cyberattacks faced by current cloud environments, especially in the health care sector where sensitive data such as personal privacy, health records, diagnostics, and treatments are stored [13]. Even prominent cloud providers like Azure (Microsoft), Docker Hub (Docker), and Everis (NTT DATA) have experienced malicious intrusions [30], while both the United Kingdom's National Health Service (NHS) in 2017 and Ireland's Department of Health information system in 2021 were both targeted and resulted in a complete paralysis [39,40].

Legislation: The Lack of Precise Legislation Hinders the Efficient Implementation and Enforcement of Regulatory Measures

To support the implementation of the "Cloud Normal" and "Internet Plus" strategies, the Chinese government has enacted laws, regulations, and management measures. However, there are limited directly applicable legal provisions for cloud migration of HISs. Imperfect laws and regulations, insufficient safety standards, unclear legal liabilities, and the absence of a damage assessment mechanism hinder the proper development of cloud services. As a result, doctors and patients may encounter challenges in protecting their rights during disputes [17].

Internal Strengths (S)

Data: Hospitals Generate Substantial Volumes of Medical Data on a Daily Basis

Hospitals are natural suppliers of big data. For instance, the Chinese National Cloud-Based Telepathology System (CNCTPS) has collected 23,167 cases and served 9240 users in 4 years (2016-2019), providing comprehensive details from whole-slide images to diagnostic reports [5]. Additionally, medical big data can provide substantial value to both hospitals and patients. For example, the aforementioned CNCTPS application can save patients around US $300,000 per year [5]. Abundant electronic health and care records in the United Kingdom's NHS can reduce hospital operational costs by approximately £5 billion (US $ 3.9 billion) annually and save patient welfare expenses by roughly £4.6 billion (US $3.6 billion) [41]. Furthermore, traditional computing tools are unable to handle the processing and analysis of such massive amounts of data—this is exactly where cloud computing technology excels [18].

Business: The Provision of Comprehensive Medical Services Necessitates Extensive Interdisciplinary Collaboration

Medical services are complex and innovative, requiring synchronization of knowledge, technology, experience, and resources from diverse disciplines. Cloud computing provides extensive connectivity, offering robust support for these tasks, including interdisciplinary expert consultations, collaborative surgeries, and integrating medicine and care [19]. The Huashan Hospital, affiliated with Fudan University, uses a medical consortium cloud platform where experts from higher-level hospitals offer diagnostic advice to lower-level hospitals for subsequent care and daily treatment, ensuring positive outcomes for patients with epilepsy [42].

Application: Multiple Cloud Technology Applications Have Been Effectively Implemented Across Various Medical Domains

As shown in Figure 2, cloud technology is receiving increasingly extensive research and application in the medical field, and even some regional or medical alliances have constructed their own medical cloud platforms to store health data, share medical images, and facilitate collaboration. Furthermore, a national survey conducted in 2022 also confirmed these findings by revealing that out of the 738 surveyed hospitals, 63% (n=465) partially used cloud services across nearly 20 different medical business scenarios [32]. These effective practices can serve as valuable references and support for other hospitals yet to implement such initiatives.

Demand: The Provision of Health-Centered Medical Services Necessitates Advanced Technological Support

The transition from disease-centered to health-centered hospital development in the new era has rendered traditional HISs increasingly inadequate as they were previously designed solely for managing information within hospitals. Cloud computing can significantly expand hospitals' medical services beyond their physical premises, enabling online chronic disease management, individual life-cycle health surveillance, and remote diagnosis for patients in remote areas. This enhancement

empowers hospitals to provide health-centered medical services [20]. The findings of this study also strongly support this notion. As depicted in Figure 3, cloud technology has been extensively used in closely associated domains with patients, encompassing disease monitoring, health surveillance, clinical diagnosis and treatment, and safe medication tracking.

Internal Weaknesses (W)

System: The Complexity of HISs Poses Challenges for Hospitals When Migrating Them to the Cloud

The HISs are the most complex organizational information management systems developed by various contractors in diverse environments, covering a wide range of business functions and user groups [21], as depicted in Figure 3, with only 94 articles included but spanning across 22 distinct disciplinary domains as well. Therefore, the cloud migration of HISs presents significant challenges, particularly for those systems abandoned by development companies due to insolvency or insufficient technical support. Nevertheless, if there existed an all-encompassing and authoritative medical cloud platform enabling hospitals to tailor services based on their specific requirements, it would undoubtedly expedite the overall migration process.

Security: The Security of Existing Hospital Networks Still Faces Numerous Risks

Currently, most HISs still operate in self-constructed networks instead of using cloud-based solutions, which poses information security challenges due to insufficient infrastructure, overreliance on a single protective measure, incomplete regulatory frameworks, and potential vulnerabilities from privilege abuse [22]. For example, the 2019-2020 China Hospital Informatization Survey Report revealed that around 28% (n=282) of surveyed hospitals experienced unplanned core system failures lasting more than 30 minutes [43]. To effectively address these concerns, proficient IT teams like reputable cloud vendors or organizations equipped with advanced technologies such as cloud computing should collaborate rather than solely rely on in-house hospital IT capabilities.

Plan: Strategic Planning and Resource Allocation in Hospitals Exhibit Certain Deficiencies

According to Figure 3, more than half of the research articles focused on hospital-specific systems for various tasks. These systems still adhered to traditional information system designs, had limited scalability and functionality, and operated independently. As a result, there were significant challenges in effectively using cloud computing's computing capabilities, storage capacity, and integrated analysis to generate valuable information supporting government scientific decision-making. The survey results from China's National Health Commission also confirmed this point as many internet hospitals were not fully developed yet and encountered diverse issues [44]. Moreover, only 14% (n=101) of hospitals had migrated their core business operations to the cloud with a mere 13% (n=100) planning to do so in the next 3-5 years [32]. Therefore, it is crucial for hospitals to reorganize and integrate their operations and resources before incorporating their HISs into the cloud in order to meet the demands of cloud capabilities and new health care models.

Personnel: The Allocation of Information Personnel Is Inadequate and Lacks Specialization Levels

With the increasing integration of cloud computing, AI, and robotics, hospitals urgently require highly skilled IT professionals to effectively implement these new technologies [23]. However, a national survey in 2021 revealed that the average number of information department personnel in 9376 secondary and tertiary hospitals was only 6. Most of these personnel held undergraduate or junior college computer degrees and possessed limited interdisciplinary expertise. This falls significantly below national standards [24], particularly for hospitals below grade 2 or in economically underdeveloped areas [45].

Investment: Primary Hospitals Lack Sufficient Investment in Information Technology and Cloud Services

According to a 2020 survey by the National Health Commission of China, most primary hospitals allocated less than 1% of their budgets to HIS development, facing challenges such as unstable funding and support [25]. A nationwide survey conducted in 2022 revealed that only 53% of the surveyed 738 hospitals had expenses related to public cloud services in the previous 2 years, with 54% spending less than US $14,000. Particularly for primary hospitals, establishing a cloud service system is even more financially challenging [32]. Clearly, these primary hospitals require more reliable financial guarantees for the smooth operation of their HISs and cloud services.

Discussion

Principal Findings

Extensive literature review and systematic SWOT analysis indicate that cloud computing is increasingly being applied in nearly 22 discipline domains in Chinese hospitals; it plays a crucial role in monitoring patient-related diseases, health surveillance, clinical diagnosis and treatment, and safe medication tracking. However, more than half of the research and applications are limited to cloud-based systems for specific hospital tasks, which fail to fully leverage the robust integrated analytical capabilities of cloud computing due to limited data scale and functionality that could otherwise generate valuable information supporting hospital or government decision-making processes. Additionally, challenges such as market sovereignty disputes, intense industry competition, network attacks, inadequate regulation, and hospitals' internal weaknesses like complexity of HISs, insufficient resource integration, and limited manpower and investment, hinder widespread adoption of cloud technology among most hospitals that exhibit a relatively weak willingness to migrate their core operations to the cloud within the next 3-5 years. Nevertheless, cloud computing is widely recognized as a novel infrastructure driving global economic growth. Integrating cloud technology in hospitals can enhance medical service quality, foster interdisciplinary collaboration and remote consultations, and promote coordinated development within regional health care economies. Consequently, it is imperative for hospitals and health authorities to pay special

attention to this matter and actively implement diverse strategies to facilitate its advancement. Based on the aforementioned research findings, this study proposes a set of promotional strategies for collective deliberation among peers. The overall framework depicting these proposed strategies is illustrated in Figure 4, which will be further elucidated in subsequent sections.

Figure 4. SWOT analysis and response strategies diagram for cloud migration of HISs. HIS: hospital information system; SWOT: Strengths, Weaknesses, Opportunities, and Threats.

Internal factors / External factors	Strengths (S)	Weaknesses (W)
	1. Data: Hospitals generate substantial volumes of medical data on a daily basis. 2. Business: The provision of comprehensive medical services necessitates extensive interdisciplinary collaboration. 3. Application: Multiple cloud technology applications have been effectively implemented across various medical domains. 4. Demand: The provision of health-centered medical services necessitates advanced technological support.	1. System: The complexity of HISs poses challenges for hospitals when migrating them to the cloud. 2. Security: The security of existing hospital networks still faces numerous risks. 3. Plan: The strategic planning and resource allocation in hospitals exhibit certain deficiencies. 4. Personnel: The allocation of information personnel is inadequate and lacks specialization levels. 5. Investment: Primary hospitals lack sufficient investment in information technology and cloud services.
Opportunities (O)	**OS strategy**	**OW strategy**
1. Politics: Governments worldwide prioritize cloud technology and have implemented supportive policies. 2. Economy: Both nations and enterprises have made substantial capital investments to foster its development. 3. Social: Online health care has become a norm in modern life. 4. Older adult care: The older adult care industry urgently needs advanced technological support.	**Implementing multiple initiatives to encourage more hospitals to migrate their HISs to the cloud.** 1. Taking multiple initiatives to encourage more hospitals to migrate their HISs to the cloud. 2. Guiding hospitals in safely and effectively migrating their systems to the cloud.	**Enhancing hospitals' overall capability for cloud migration of HISs.** 1. Improving the medical information literacy and capabilities of all staff in hospitals. 2. Reengineering hospital's business processes and integrating them into one organic HIS. 3. Increasing investment in and application of cloud technology in primary hospitals.
Threats (T)	**TS strategy**	**TW strategy**
1. Market: Technological monopolies pose a significant threat to the digital autonomy of nations. 2. Competition: Fierce competition may lead to uncertain levels of service quality. 3. Security: Hospitals express apprehensions regarding diverse cyber-attacks targeting cloud infrastructure. 4. Legislation: The lack of precise legislation hinders the efficient implementation and enforcement of regulatory measures.	**Establishing a provincial-level unified medical hybrid multicloud platform.** 1. Selecting the most suitable cloud deployment model for hospitals. 2. Establishing a unified medical cloud platform at the provincial or municipal level.	**Enhancing legal framework and technical support for cloud-based HISs.** 1. Establishing a solid and reliable legal foundation. 2. Providing comprehensive and efficient technical support.

Implementing Multiple Initiatives to Encourage More Hospitals to Migrate Their HISs to the Cloud

The primary objective of this strategy is to address the issue of "whether or not to adopt cloud technology." Based on the outcomes of the SWOT analysis, despite the pressing need for cloud technology to enhance health-centered medical service delivery today, hospitals remain cautious about its implementation due to external threats and internal weaknesses. Furthermore, providing cloud-based medical services has brought about a significant transformation within the medical industry that exceeds traditional independent operations and self-financing models used by hospitals. Therefore, governments should make greater efforts by implementing more active measures such as policy guidance, training planning, demonstration projects, or provision of cloud vouchers, in order to encourage more hospitals to securely migrate their HISs onto the cloud and meet demands for innovative medical services in this modern era.

Enhancing Hospitals' Overall Capability for Cloud Migration of HISs

The strategy aims to address the issue of "what preparations are necessary." As previously mentioned, cloud migration of HISs is a highly intricate system engineering project that requires hospitals to be fully prepared for its successful implementation. These preparations encompass various aspects including, but not limited to the following. First, human resources: hospitals should enhance employees' medical information literacy and application skills through comprehensive training programs, specialized lectures, or successful case studies. Second, material resources: hospitals should redesign and integrate existing systems and resources based on future development, existing foundations, and expert recommendations in order to optimize the use of cloud resources for acquiring more valuable information. Third, financial resources: hospitals require long-term financial investment planning to support the provision of cloud-based medical services. Moreover, health authorities should acknowledge that primary hospitals serve as both frontline institutions addressing medical needs and significant sources of authentic data. Therefore, moderate increases in investment in HIS construction of primary hospitals are necessary to ensure a continuous input of firsthand authentic data. Fourth, tools: a hospital that has robust IT capabilities can leverage free cloud migration consultation and tools provided by major cloud providers such as Alibaba, Tencent, Google, Microsoft, and Amazon Web Services, which can expedite the process of migrating information systems. However, it should be noted that the cloud services used (eg, computing and storage) may incur charges.

Establishing a Provincial-Level Unified Medical Hybrid Multi-Cloud Platform

The strategy aims to address the issue of "how to implement changes efficiently." In response to numerous complex internal and external situations, this study proposes a coping strategy: establishing a unified medical hybrid multi-cloud platform in each province or municipality.

First, the hybrid multi-cloud platform highly aligns with hospital operations. Hospitals require private clouds for storing sensitive and core data, nonpublic community clouds for internal consultations and other collaborations, public clouds for providing more extensive medical services to the public, and adopting a "multi-cloud" strategy to reduce risks such as vendor lock-in or declining service quality.

Second, a medical cloud platform at the provincial or municipal level can achieve maintainable security and more highly effective cloud migration. In comparison to hospitals, health authorities at this level possess stronger technological expertise, greater manpower resources, maintainable financial support, and relevant assets for constructing comprehensive platforms while effectively mitigating internal and external risks. Moreover, this approach can also foster overall advancements in cloud migration and system function quality of hospitals (particularly primary ones), as well as minimize redundant construction and maintenance expenses.

Last but most importantly, the scale of data possessed by one or several individual hospitals is insufficient to constitute true big data, limiting the opportunities for leveraging cloud computing's powerful intelligent analysis capabilities in uncovering hidden objective laws that can support the government to make scientific decisions. Considering factors such as data scale, cloud computing capabilities, and government economic support capacity, a provincial or municipal regional medical cloud platform is a more suitable choice.

Enhancing Legal Framework and Technical Support for Cloud-Based HISs

The primary goal of this strategy is to address the issue of "how to create a supportive environment." As an ancient Chinese proverb states, "A single log cannot support a crumbling building," indicating that relying solely on a provincial-level medical cloud platform is still insufficient to counter all external threats and internal risks faced by hospitals. Therefore, it requires a more proactive role from the government, which strengthens cooperation with relevant departments and enterprises to build a more robust and secure supporting environment for medical cloud platforms. Specifically, 2 aspects of support are necessary. First, credible legal support: although the Chinese government has been improving laws regarding cybersecurity, personal information protection, and data security, its support for cloud-based medical services remains inadequate. For example, in resolving disputes related to cloud medical services, health authorities still rely on laws such as the Physician Practice Law and Regulations on Prevention and Handling of Medical Disputes in China. However, these regulations have not explicitly defined the status and responsibilities of all parties involved in cloud-based medical services, which poses challenges in terms of judgments and penalties [26]. Therefore, it is essential to further refine relevant legislation and update existing regulations regarding doctors' practice rights, insurance responsibility, and reimbursement for medical insurance, ensuring doctors and patients can confidently participate in cloud-based medical services. Second, holistic technical support: as indicated by SWOT analysis results, hospitals often lack professionals with deep knowledge of cutting-edge technologies like cloud computing, AI, and big data. Therefore, establishing an organization like a medical cloud technology association becomes necessary. This organization should consist of experts from various relevant fields, including IT, communication, engineering, cryptography, medicine, and more. Their responsibilities would include devising unified long-term plans and action plans, standardizing contracts between hospitals and cloud service providers, reviewing hospitals' cloud migration plans and contracts, and conducting regular evaluations of the construction and operation of cloud-based HISs.

Conclusions

In conclusion, cloud computing is prioritized by the Chinese government as a "national strategic emerging industry." Despite encountering numerous challenges, the cloud migration of HISs in China exemplifies a prevailing development trend. Therefore, hospitals should adopt an open mindset and focus on enhancing their capabilities to develop medical services based on the cloud. Health authorities should also use more effective strategies to incentivize hospitals to migrate their HISs safely to the cloud, thereby fostering the flourishing growth of a novel health-centered medical industry.

The main contribution of this study is a comprehensive literature review and systematic SWOT analysis on the current status of cloud migration of HISs in China, and corresponding strategies for different combinations of internal and external influencing factors. It can help hospitals gain a clearer understanding of the overall situation while having more specific goals and methods when planning and implementing related work. Moreover, it can serve as a foundation for health authorities to develop policies aligned with the development of hospital informatization in the new era, as well as provide references for other countries or regions facing similar challenges.

There are 2 limitations in this study: first, not all personnel from hospitals contribute to writing papers, thus limiting the comprehensiveness of literature information; second, the SWOT analysis method assumes a distinction between internal and external factors, as well as a differentiation between strengths and weaknesses, overlooking the interrelated effects among influencing factors. To supplement and improve these aspects, more empirical investigation data are needed, along with a more rigorous analysis of the interactions among influencing factors. This will be the focus of my future research.

Abstract

Inhaled corticosteroid (ICS) is a mainstay treatment for controlling asthma and preventing exacerbations in patients with persistent asthma. Many types of ICS drugs are used, either alone or in combination with other controller medications. Despite the widespread use of ICSs, asthma control remains suboptimal in many people with asthma. Suboptimal control leads to recurrent exacerbations, causes frequent ER visits and inpatient stays, and is due to multiple factors. One such factor is the inappropriate ICS choice for the patient. While many interventions targeting other factors exist, less attention is given to inappropriate ICS choice. Asthma is a heterogeneous disease with variable underlying inflammations and biomarkers. Up to 50% of people with asthma exhibit some degree of resistance or insensitivity to certain ICSs due to genetic variations in ICS metabolizing enzymes, leading to variable responses to ICSs. Yet, ICS choice, especially in the primary care setting, is often not tailored to the patient's characteristics. Instead, ICS choice is largely by trial and error and often dictated by insurance reimbursement, organizational prescribing policies, or cost, leading to a one-size-fits-all approach with many patients not achieving optimal control. There is a pressing need for a decision support tool that can predict an effective ICS at the point of care and guide providers to select the ICS that will most likely and quickly ease patient symptoms and improve asthma control. To date, no such tool exists. Predicting which patient will respond well to which ICS is the first step toward developing such a tool. However, no study has predicted ICS response, forming a gap. While the biologic heterogeneity of asthma is vast, few, if any, biomarkers and genotypes can be used to systematically profile all patients with asthma and predict ICS response. As endotyping or genotyping all patients is infeasible, readily available electronic health record data collected during clinical care offer a low-cost, reliable, and more holistic way to profile all patients. In this paper, we point out the need for developing a decision support tool to guide ICS selection and the gap in fulfilling the need. Then we outline an approach to close this gap via creating a machine learning model and applying causal inference to predict a patient's ICS response in the next year based on the patient's characteristics. The model uses electronic health record data to characterize all patients and extract patterns that could mirror endotype or genotype. This paper supplies a roadmap for future research, with the eventual goal of shifting asthma care from one-size-fits-all to personalized care, improve outcomes, and save health care resources.

Introduction

Asthma is a chronic disease characterized by inflammation, narrowing, and hyperactivity of the airways causing shortness of breath, chest tightness, coughing, and wheezing [1]. Asthma affects about 25 million people in the United States [2]. In 2021, there were 9.8 million exacerbations of asthma symptoms (or asthma attacks) leading to over 980,000 emergency room (ER) visits and over 94,500 hospitalizations [2]. Asthma costs the US economy over US $80 billion in health care expenses each year, work and school absenteeism, and deaths [3].

Inhaled corticosteroid (ICS) is a mainstay treatment for controlling asthma and preventing exacerbations in patients with persistent asthma [4] accounting for over 60% of people with asthma [5,6]. Many types of ICS drugs are used, either alone like fluticasone (Flovent, Arnuity, and Aller-flo), budesonide (Pulmicort, Entocort, and Rhinocort), mometasone (Asmanex), beclomethasone (Beclovent, Qvar, Vancenase, Beconase, Vanceril, and Qnasl), ciclesonide (Alvesco), and so forth, or in combination with a long-acting beta2 agonist like fluticasone/salmeterol (Advair), budesonide/formoterol (Symbicort), mometasone/formoterol (Dulera), and fluticasone/vilanterol (Breo), and so forth [4]. Regular use of appropriate ICSs improves asthma control and reduces airway inflammation, symptoms, exacerbations, ER visits, and inpatient stays [7-9].

Despite the widespread use of ICSs, asthma control remains suboptimal in many people with asthma [10-13] including 44% of children and 60% of adults based on asthma exacerbations in the past year [14,15], 72% of patients based on asthma control test [10], 53% of children and 44% of adults based on asthma attacks in the past year [16], and 59% of children based on the 2007-2013 Medical Expenditure Panel Survey [17]. Suboptimal control leads to recurrent exacerbations, causes frequent ER visits and inpatient stays, and is projected to have an economic burden of US $963.5 billion over the next 20 years [18]. Suboptimal control is due to multiple factors [19-23] including (1) failure to recognize and act on early signs of declining control [24,25], (2) lack of self-management skills, (3) nonadherence to therapy [26], and (4) inappropriate ICS choice for the patient [27-32]. While interventions targeting other factors exist, less attention has been given to inappropriate ICS choice.

Asthma is heterogeneous with variable profiles in terms of clinical presentations (phenotypes) and underlying mechanisms (endotypes) [33,34]. Molecular techniques have revealed a few phenotype and endotype relationships, allowing the categorization of asthma into two main groups (1) T-helper type 2 (Th2)-high (eg, atopic and late onset) and (2) Th2-low (eg, nonatopic, smoking-related, and obesity-related) [33,34]. It is known that within the 2 groups, there are many subgroups [33,35] with different biomarker expressions (eg, immunoglobulin E [IgE], fractional exhaled nitric oxide [FeNO], interleukin [IL]-4, IL-5, and IL-13) [36]. So far, only a few biomarkers have been characterized for use in clinical practice. Despite a few successes using biomarkers for targeted therapy, ICS choice, especially in the primary care setting, is largely by trial and error and many patients remain uncontrolled [37-42].

Besides patient nonadherence and environmental factors, response to ICS treatment is affected by genetic variations in ICS metabolizing enzymes [43,44], regardless of whether the ICS is used alone or is combined with another asthma medication like a long-acting beta2 agonist. Single nucleotide polymorphisms in cap methyltransferase 1 (CMTR1), tripartite motif containing 24 (TRIM24), and membrane associated guanylate kinase, WW and PDZ domain containing 2 (MAGI2) genes were found to be associated with variability in asthma exacerbations [43]. Additional evidence supports that these genes also cause variability in ICS response [44]. Due to genetic variations in cytochrome P (CYP) 450 enzymes that metabolize over 80% of drugs including ICS, up to 50% of people with asthma have altered metabolism to certain ICSs [45-51] impacting asthma control [52,53]. CYP3A5*3/*3 and CYP3A4*22 genotypes were found to be linked to ICS response [54,55]. These studies provide evidence that genetic variations greatly affect ICS responsiveness, although the exact relationships between genetic variations and ICS response remain largely unknown [36,56,57]. Currently, many candidate genes are being studied, and pharmacogenetics has not yet reached routine clinical practice in asthma care.

ICS choice for patients is often dictated by insurance reimbursement, organizational policies, or cost, leading to a one-size-fits-all approach [37-42]. Some insurers require patients to first fail on a cheaper ICS before authorizing a more expensive ICS [39]. Nonmedical switch due to preferred drug formulary change is common and leads to bad outcomes, with 70% of patients reporting more exacerbations after the switch [39]. Patients also often report that they tried a few different ICSs before ending up with the drug that gave them the most relief, with 60% reporting it was hard for their providers to find the effective drug [37-39]. Cycling through various ICSs delays the start of an effective ICS and is neither efficient nor cost-effective [39]. New strategies are needed to allow a faster and more efficient way to tailor ICS selection to each patient's characteristics [36].

While the biologic heterogeneity of asthma is vast, few, if any, biomarkers or genotypes can currently be used to systematically profile all patients with asthma and predict ICS response [36,58,59]. Readily available electronic health record (EHR) data collected during clinical care offer a low-cost, reliable, and more holistic way to profile all patients [36,60]. With a high accuracy of 87%-95% [36], machine learning models using EHR data have been used to profile patients in various areas, for example, to develop a phenotype for patients with Turner syndrome [61], identify low medication adherence profiles [62], find variable COVID-19 treatment response profiles [63], and predict hypertension treatment response [64]. Yet, while machine learning has helped find various asthma profiles [65-72], no prior study has predicted ICS response. Also, prior

studies are mostly from single centers with small sample sizes and have not moved the needle of precision treatment for asthma [58,60].

A decision support tool is greatly needed, especially in the primary care setting, to guide providers to select at the point of care the ICS that will most likely and quickly ease patient symptoms and improve asthma control. Forecasting which patient will respond well to which ICS is the first step toward creating this tool, but no prior study has predicted ICS response, forming a gap.

To shift asthma care from one-size-fits-all to personalized care, improve outcomes, and save health care resources, we make three contributions in this paper, supplying a roadmap for future research: (1) we point out the above-mentioned need for creating a decision support tool to guide ICS selection; (2) we point out the above-mentioned gap in fulfilling this need; and (3) to close this gap, we outline an approach to create a machine learning model and apply causal inference to predict a patient's ICS response in the next year based on the patient's characteristics. We present the central ideas of this approach in the following sections.

Creating a Machine Learning Model and Applying Causal Inference to Predict ICS Response

Overview of Our Approach

We use EHR data from a large health care system to develop a machine learning model and apply casual inference to predict a patient's ICS response based on the patient's characteristics. As endotyping or genotyping all patients is infeasible, our model uses EHR data to characterize all patients and extract patterns that could mirror endotype or genotype. Our model is trained on historical data, and can then be applied to new patients to guide ICS selection during an initial or early encounter for asthma care. The optimal ICS choice identified by our approach can be either an ICS (generic name and dosage) alone or an ICS combined with another asthma medication like a long-acting beta2 agonist.

Both pediatric and adult patients with asthma are treated by primary care providers (PCPs) who are mostly generalists and asthma specialists including allergists, immunologists, and pulmonologists. Large differences exist between PCPs and specialists in terms of knowledge, care patterns, and asthma outcomes, with asthma specialists adhering more often to guideline recommendations [73-76]. A greater difference exists between PCPs and specialists in controller medication use [76]. Compared to PCPs, asthma specialists tend to achieve better outcomes [77], including higher physical functioning [78], better patient-reported care [78], and fewer ER visits and inpatient stays [78-84]. As over 60% of people with asthma are cared for by PCPs [85], our machine learning model primarily targets PCPs, although asthma specialists could also benefit from this model.

The asthma medication ratio (AMR) is the total number of units of asthma controller medications dispensed divided by the total number of units of asthma medications (controllers + relievers) dispensed [86,87]. Higher AMR (≥0.5) is associated with less oral corticosteroid use (a surrogate measure for asthma exacerbations), fewer ER visits and inpatient stays, and lower costs [87-89]. Lower AMR (<0.5) is associated with more exacerbations, ER visits, and inpatient stays [90,91]. Approved by Healthcare Effectiveness Data and Information Set (HEDIS) as a quality measure, AMR is widely used by health care systems [89]. AMR is a reliable reflection of asthma control and gives an accurate assessment of asthma exacerbation risk [92]. We use change in AMR as the prediction target of our model for predicting ICS response, as AMR can be calculated on all patients. In comparison, neither asthma control nor acute outcomes (eg, ER visits, inpatient stays, or oral corticosteroid use) is used as the prediction target, as the former is often missing in EHRs and the latter does not occur in all patients. An effective ICS will lead to less reliever use and increased AMR. An ineffective ICS will lead to more reliever use and reduced AMR. We formerly used EHR data to build accurate models to predict hospital use (ER visit or inpatient stay) for asthma [93-95]. We expect EHR data to have great predictive power for AMR, which is associated with hospital use for asthma [87-91]. Using the AMR can facilitate the dissemination of our approach across health care systems.

We outline the individual steps of our approach in the following sections.

Step 1: Building a Machine Learning Model to Predict a Patient's ICS Response Defined by Changes in AMR

We focus on patients with persistent asthma for whom ICSs are mainly used. We use the HEDIS case definition of persistent asthma [96,97], the already validated [98] and the most commonly used administrative data marker of persistent asthma [97]. A patient is deemed to have persistent asthma if in each of 2 consecutive years, the patient meets at least one of the following criteria: (1) at least 1 ER visit or inpatient stay with a principal diagnosis code of asthma (*ICD-9* [*International Classification of Diseases, Ninth Revision*] 493.0x, 493.1x, 493.8x, 493.9x; *ICD-10* [*International Classification of Diseases, Tenth Revision*] J45.x), (2) at least 2 asthma medication dispensing and at least 4 outpatient visits, each with a diagnosis code of asthma, and (3) at least 4 asthma medication dispensing. In the rest of this paper, we always use patients with asthma to refer to patients with persistent asthma. The prediction target or outcome is the amount of change in a patient's AMR after 1 year. The AMR is computed over a 1-year period [86,87].

We combine patient, air quality, and weather features computed on the raw variables to build the model to predict ICS response. Existing predictive models for asthma outcomes [93-95,99-110] rarely use air quality and weather variables, but these variables impact asthma outcomes [111-117] (eg, short-term exposure to air pollution, even if measured at the regional level, is associated with asthma exacerbations [113-117]). For each such variable, we examine multiple features (eg, mean, maximum, SD, and slope). We examine over 200 patient features listed in our papers' [93-95] appendices and formerly used to predict hospital use for asthma, which is associated with AMR [87-91]. Several examples of these features are comorbidities, allergies, the

number of the patient's asthma-related ER visits in the prior 12 months, the total number of units of systemic corticosteroids ordered for the patient in the prior 12 months, and the number of primary or principal asthma diagnoses of the patient in the prior 12 months. We also use as features the patient's current AMR computed over the prior 12 months [86,87], the generic name and the dosage of the ICS that the patient currently uses, and those of the long-acting beta2 agonist, leukotriene receptor antagonist, biologic or another asthma medication, if any, that is combined with the ICS.

Step 2: Conducting Causal Machine Learning to Identify Optimal ICS Choice

Our goal is to integrate machine learning and G-computation to develop a method to estimate the causal effects of various ICS choices on AMR for patients with specific characteristics. This causal machine learning method [118] processes large data sets by capturing complex nonlinear relationships between features, thereby revealing the cause-and-effect relationships between ICS choice and change in AMR. We use the machine learning model built in step 1. Using G-computation [119,120], an imputation-based causal inference method, we estimate the potential effects of hypothetical ICS choices with specific dosages on changes in AMR after 1 year. G-computation builds on the machine learning model of the outcome as a function of ICS indicators, ICS dosages, and other features to predict AMR outcomes under different counterfactual ICS choice scenarios. CIs are estimated through 10,000 bootstrap resampling with replacement [121].

We apply causal machine learning to estimate the impact of ICS choices on patients with specific characteristics by averaging predicted AMR after 1 year for a given ICS and these characteristics across all participants. This estimation is contrasted with the averaged predicted outcome in the absence of any ICS choice. The ICS choice with the highest and statistically significant contrast estimation is identified as the optimal choice for patients with these characteristics. All hypotheses can be tested at a significance level of .05.

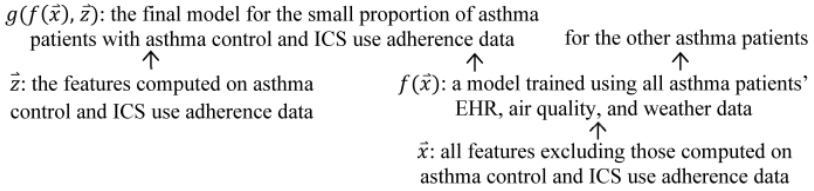
Step 3: Assessing the Impact of Adding External Patient-Reported Asthma Control and ICS Use Adherence Data on the Model's Predictions

EHRs have limitations regarding patient-reported data with extra predictive power such as asthma control and ICS use adherence. For asthma, asthma control and ICS use adherence are critical variables, as (1) a patient's asthma control fluctuates over time and drives the provider's decision to prescribe or adjust ICSs and (2) ICS use adherence impacts the patient's asthma control and helps assess whether the patient is actually responding to an ICS. However, despite their high predictive power for patient outcomes, these variables are not routinely collected or included in EHRs in clinical practice. At Intermountain Healthcare, the largest health care system in Utah, we pioneered the electronic AsthmaTracker, a mobile health (mHealth) app used weekly to assess, collect, and monitor patients' asthma control and actual ICS use adherence [122]. Like most patient-reported data, these patient-reported variables have been collected on only a small proportion of patients with asthma. To date, 1380 patients with asthma have used the app and produced about 45,000 records of weekly asthma control scores and ICS use adherence data (eg, the ICS' name and the number of days an ICS is actually used by the patient in that week). If we train a predictive model using EHR and patient-reported data limited to this small proportion of patients, the model will be inaccurate due to insufficient training data. Yet, for these patients, combining their patient-reported data with the outputs of a model built on all patients' EHR data can help raise the prediction accuracy for them. To realize this, we propose the first method to combine external patient-reported data available on a small proportion of patients with the outputs of a model built on all patients' EHR data to raise prediction accuracy for the small proportion of patients while maintaining prediction accuracy for the other patients.

To illustrate how our method works, we consider the case that the model created in step 1 is built using Intermountain Healthcare EHR data. The weekly asthma control scores and ICS use adherence data collected from the 1380 patients with asthma are unused in step 1. Now we add features (eg, mean, SD, and slope) computed on patient-reported asthma control and ICS use adherence data to raise prediction accuracy for these patients. Among all patients with asthma, only 1% have asthma control and ICS use adherence data. We use the method shown in Figure 1 to combine the asthma control and ICS use adherence data from this small proportion of patients with the outputs of a model trained on EHR, air quality, and weather data of all patients with asthma. We start from the original model built in step 1. This model is reasonably accurate, as it is trained using EHR, air quality, and weather data of all patients with asthma and all features excluding those computed on asthma control and ICS use adherence data. For each patient with asthma control and ICS use adherence data, we apply the model to the patient, obtain a prediction result, and use this result as a feature. We then combine this new feature with the features computed on asthma control and ICS use adherence data to train a second model for these patients using their data. The second model is built upon and thus tends to be more accurate than the original model for these patients. The original model is used for the other patients. Our method is general, works for all kinds of features, and is not limited to any specific disease, prediction target, cohort, or health care system. Whenever a small proportion of patients have extra predictive variables, we could use this method to raise prediction accuracy for these patients while maintaining prediction accuracy for the other patients.

For the patients with asthma control and ICS use adherence data, we compare the mean squared and the mean absolute prediction errors gained by the model built in step 1 and the second model built here. We expect adding asthma control and ICS use adherence data to the model to lower both prediction errors. The error drop rates help reveal the value of routinely collecting asthma control and ICS use adherence data in clinical care to lower prediction errors. Currently, such data are rarely collected.

Figure 1. Our method to raise prediction accuracy for the small proportion of patients with asthma and asthma control and ICS use adherence data while maintaining prediction accuracy for the other patients with asthma. EHR: electronic health record; ICS: inhaled corticosteroid.



Discussion

Principal Findings

Besides the variables mentioned in the "Step 1: Building a machine learning model to predict a patient's ICS response defined by changes in AMR" section, environmental variables beyond air quality and weather and many other factors can impact patient outcomes. Moreover, there are almost infinite possible features. For any first future study that one will do along the direction pointed out in this paper, a realistic goal is to show that using our methods can build decent models and improve asthma care rather than to exhaust all possible useful variables and features and obtain the theoretically highest possible model performance. Not accounting for all possible factors limits the generalizability of these models to medication selection for other diseases.

We use the G-computation method to conduct causal inference. This method relies heavily on correctly specifying the predictive model for ICS response, including accurately identifying all relevant confounders and interactions and incorporating them into the model. Misspecification of the model can lead to biased estimated effects of various ICS choices on AMR. To address this issue, we can adopt several preventive strategies during model development. We engage with subject matter experts to ensure that the model includes all relevant variables and reflects the underlying process. To guide model development and help identify potential sources of bias, we construct a directed acyclic graph that lays out the relationships among the independent and dependent variables. We use machine learning techniques that provide flexible modeling approaches to capture complex relationships among variables. When reporting our findings, we keep transparent about the final model specification and the rationale behind our model building process. We believe using these strategies will mitigate the risk of model misspecification and strengthen the reliability of our estimated effects of various ICS choices on AMR.

AMR is reported to be a reliable reflection of asthma control and of asthma exacerbation risk [92]. In a future study that we plan to do along the direction pointed out in this paper, we can use Intermountain Healthcare data to validate this relationship. Specifically, we use multivariable linear regression to assess the relationship between the AMR computed on EHR data and the patient's asthma control level obtained from the external patient-reported data, while controlling for other factors. We expect to see a strong and positive association between the AMR and the patient's asthma control level.

When creating the model in step 1, we can include medication persistence measures computed on insurance claim data [123], such as the proportion of days covered for ICS, as features. However, this does not obviate the need to examine patient-reported ICS use adherence data in step 3. ICS persistence measures give information on the possession of ICS, but not on actual use of ICS. Each ICS persistence measure is computed at a coarse time granularity as an average value over a long period. In comparison, our patient-reported ICS use adherence data offer information on the actual use of ICS. The data are at a fine time granularity, with 1 set of values per week for a patient. This enables us to compute features on various patterns and trends that can be useful for making predictions.

Conclusions

In asthma care, ICS choice is largely by trial and error and often made by a one-size-fits-all approach with many patients not achieving optimal outcomes. In this paper, we point out the need for creating a decision support tool to guide ICS selection and a gap in fulfilling this need. Then we outline an approach to close this gap via creating a machine learning model and applying causal inference to predict a patient's ICS response in the next year based on the patient's characteristics. This supplies a roadmap for future research.

Authors' Contributions

FLN and GL are co-senior authors mainly responsible for the paper. They conceptualized the presentation approach, performed literature review, and wrote the paper. BLS provided feedback on various medical issues, contributed to conceptualizing the presentation, and revised the paper. YZ wrote the causal inference section. All authors read and approved the final paper.

Conflicts of Interest

GL is an editorial board member of *JMIR AI*. The other authors declare no conflicts of interest.

Abbreviations

AMR: asthma medication ratio
CMTR1: cap methyltransferase 1
CYP: cytochrome P
EHR: electronic health record
ER: emergency room
FeNO: fractional exhaled nitric oxide
HEDIS: Healthcare Effectiveness Data and Information Set
***ICD-9*:** *International Classification of Diseases, Ninth Revision*
***ICD-10*:** *International Classification of Diseases, Tenth Revision*
ICS: inhaled corticosteroid
IgE: immunoglobulin E
IL: interleukin
MAGI2: membrane associated guanylate kinase, WW and PDZ domain containing 2
mHealth: mobile health
PCP: primary care provider
Th2: T-helper type 2
TRIM24: tripartite motif containing 24

Abstract

The pursuit of groundbreaking health care innovations has led to the convergence of artificial intelligence (AI) and traditional Chinese medicine (TCM), thus marking a new frontier that demonstrates the promise of combining the advantages of ancient healing practices with cutting-edge advancements in modern technology. TCM, which is a holistic medical system with >2000 years of empirical support, uses unique diagnostic methods such as inspection, auscultation and olfaction, inquiry, and palpation. AI is the simulation of human intelligence processes by machines, especially via computer systems. TCM is experience oriented, holistic, and subjective, and its combination with AI has beneficial effects, which presumably arises from the perspectives of diagnostic accuracy, treatment efficacy, and prognostic veracity. The role of AI in TCM is highlighted by its use in diagnostics, with machine learning enhancing the precision of treatment through complex pattern recognition. This is exemplified by the greater accuracy of TCM syndrome differentiation via tongue images that are analyzed by AI. However, integrating AI into TCM also presents multifaceted challenges, such as data quality and ethical issues; thus, a unified strategy, such as the use of standardized data sets, is required to improve AI understanding and application of TCM principles. The evolution of TCM through the integration of AI is a key factor for elucidating new horizons in health care. As research continues to evolve, it is imperative that technologists and TCM practitioners collaborate to drive innovative solutions that push the boundaries of medical science and honor the profound legacy of TCM. We can chart a future course wherein AI-augmented TCM practices contribute to more systematic, effective, and accessible health care systems for all individuals.

(JMIR Med Inform 2024;12:e58491) doi:10.2196/58491

KEYWORDS

traditional Chinese medicine; TCM; artificial intelligence; AI; diagnosis

Introduction

Traditional Chinese medicine (TCM) is a vibrant and enduring medical system that has been refined for thousands of years, thus offering a rich tapestry of health and healing practices [1]. With its roots deeply embedded in Chinese philosophy and a profound understanding of the human body's relationship with the natural world, TCM has developed a unique set of diagnostic and therapeutic methodologies. These methodologies include herbal medicine, acupuncture, and the identification of syndrome patterns, which are grounded in the fundamental concepts of yin and yang and the 5-element theory, thus providing a holistic approach to health that addresses the body, mind, and spirit. As a traditional medical system, TCM primarily depends on personal experience and lacks standardized and systematic diagnosis and treatment procedures, which potentially discourages its more widespread adoption. Thus, the rapid expansion of artificial intelligence (AI) can significantly improve the reliability and accuracy of TCM diagnostics, thereby increasing the effective use of therapeutic methods for patients [2]. AI is currently being used in diagnostics to detect abnormalities in medical imaging, such as identifying lung nodules or other suspicious lesions in early cancer screening

[3]. These tools can assist physicians in making an initial diagnosis by analyzing large amounts of imaging data to identify potential signs of cancer and can also help physicians more accurately characterize suspicious lesions, including their shape, volume, histopathological diagnosis, disease stage, and molecular features. AI also has potential therapeutic value for the diagnosis of mental disorders such as major depressive disorder by successfully distinguishing patients from healthy controls through machine learning [4,5]. This characterization is critical for determining treatment options and predicting disease progression. However, applying AI to TCM exhibits a range of both opportunities and challenges. AI can enhance the diagnostic process by enabling physicians to make more accurate assessments of diseases and patient constitutions through the analysis of extensive TCM clinical data. It can also be instrumental in creating personalized treatment plans that are tailored to the unique conditions of each patient. Concurrently, the integration of AI into TCM raises significant concerns about patient privacy and data security. Although the establishment and learning of classification criteria still cannot eliminate subjectivity, efforts must be made to refine these processes. Addressing these issues necessitates the establishment of stringent ethical standards and robust privacy measures.

The successful integration of AI into TCM is contingent upon collaborative efforts across various disciplines, including medicine, computer science, and data science. Building interdisciplinary teams and fostering effective communication are crucial for driving innovation in this field. As technology evolves, it possesses the potential to revolutionize TCM practices provided that it is implemented with careful consideration of the ethical implications and needs of the TCM community. In the realm of TCM, diagnosis is a pivotal element wherein practitioners engage in comprehensive inquiry and conduct head-to-toe examinations of patients. This process is central to collecting health-related data. Such a diagnostic approach facilitates an in-depth evaluation of the patient's overall health status coupled with a nuanced understanding of the fundamental characteristics of the disease. TCM diagnosis is based on a holistic perspective and involves a comprehensive assessment of both physiological and psychological aspects of health rather than relying solely on objective diagnostic criteria such as molecular markers and physiological indicators. There are generally 4 main diagnostic methods in TCM: inspection, auscultation and olfaction, inquiry, and palpation. These facets of TCM have been widely accepted by TCM practitioners worldwide. This aspect of TCM is particularly pronounced for highly skilled physicians who are able to derive diagnostic insights through visual inspection alone, often without an explicit need for detailed procedural explication. Moreover, they believe that nonrational thinking, which encompasses implicit meanings, intuition, inspiration, and imagination, plays a vital role in TCM diagnosis and treatment [6]. In conjunction with the concept of the 4 diagnostic methods, practitioners assess and integrate various clinical data to investigate evidence, identify a disease's root causes, establish treatment strategies, assess treatment efficacy, and anticipate healing progress [7]. The integration of AI into TCM diagnosis respects and uses the intuition and experience of practitioners, thus serving as an auxiliary means of clinical research to evaluate and verify diagnostic results rather than replace human judgment. AI can be designed to analyze complex patterns in patient data, thereby augmenting traditional diagnostic methods. For example, machine learning models can be trained to recognize subtleties in patient inquiry responses, thus enhancing the practitioner's ability to identify the root causes of diseases and tailor treatment strategies. AI systems can be developed to consider the holistic approach that is inherent in TCM. By analyzing a wide range of clinical data, AI can provide a more comprehensive health assessment that aligns with the TCM concept of integrating various aspects of a patient's condition. This not only supports the practitioner's diagnostic process but also aids in anticipating healing progress and the efficacy of treatments. In addition, AI can tailor treatments to patients' individual needs and conditions by considering their unique body states and responses to various therapeutic interventions, thus leveraging the ability of AI to process and learn from large data sets as well as the enormous potential for personalized treatment in TCM. The role of AI in TCM is to augment the expertise of physicians, thus providing insights and analytics that support the holistic and personalized approach to health care that is at the heart of TCM. By doing so, AI can contribute to enhancing patient care and ensuring that the rich heritage of TCM is carried forward and developed in the modern health care era.

AI in TCM Diagnosis

Inspection

In the practice of TCM, the method of inspection primarily focuses on the acquisition of diagnostic information through direct observation. This approach involves assessing the patient's condition by scrutinizing various physical changes across the body. Distinct from the paradigm of Western medicine, which predominantly relies on objective, empirical evidence, TCM tends to base its diagnostic conclusions on subjective interpretations by medical practitioners [8]. The scope of inspection for diagnosis is quite broad. Although the methods comprise craniofacial observations, tongue and face diagnoses are the primary methods used for inspection. An inspection of the tongue's shape, size, color, and texture aids in the assessment of organ function and the development of medical conditions. Facial expression analysis is a diagnostic method that aligns with the theory of 5 zang organs, corresponding to 5 elements and colors. It involves distinguishing different changes in facial color, such as green, red, yellow, white, and black, based on the principles of yin and yang and the 5-element theory [9]. Building on this traditional foundation, technological advancements have introduced new methods to enhance TCM diagnostics. For example, the development by Chen [10] of a neural network–based system marked a significant advancement in this research. This innovative platform automates the diagnostic and treatment process in TCM with a focus on symptom analysis. It empowers physicians to efficiently access crucial medical records, thus providing valuable insights into the effectiveness of TCM treatments for similar conditions. Furthermore, the system streamlines the prescription process, thus enabling precise electronic prescriptions to be quickly dispatched to relevant departments and patients. This integration of AI with TCM improves diagnostic accuracy and facilitates

the sharing of expertise among practitioners, thus ultimately enhancing the standard of care in TCM. AI is currently one of the most discussed topics in medical imaging research. It serves as a significant enabler for handling vast amounts of medical images, thereby deciphering disease features that may be imperceptible to the human eye. Similarly, AI-based facial diagnosis and tongue diagnosis hold promise for further development. Recently, Liu et al [11] reviewed AI methods in the field of tongue diagnosis. They identified two main challenges that hinder development in this field: (1) the authority of data sets and (2) a misconception about a sole reliance on single features for diagnosis in traditional Chinese tongue diagnosis [11]. The combination of AI with this field overcomes the inherent subjectivity of TCM diagnosis and provides a more objective and standardized approach to tongue diagnosis. Technological advances such as multiscale features and the incorporation of previous knowledge have been successfully applied to improve the accuracy and reliability of AI-assisted tongue analysis. In addition, robust data sets and reliable performance evaluations are still needed to address existing problems in the field. The future of intelligent tongue diagnosis is promising, with potential breakthroughs in self-supervised methods, multimodal information fusion, and tongue pathology research that are expected to have a significant impact on research and clinical practice. On the basis of this scenario, we propose potential solutions to address these issues. First, standardizing data sets for tongue diagnosis should be a collaborative effort that involves experts in TCM. Second, leveraging multimodal data in AI is a crucial approach for the AI-driven transformation of TCM.

The future of AI in the inspection component of TCM is poised to transform traditional diagnostic practices through innovative research and practical applications. One of the primary research directions is the development of sophisticated AI algorithms that can analyze and interpret tongue and facial diagnostics at a level of detail that surpasses human perception. By training these algorithms on diverse and high-quality data sets, AI systems can learn to identify subtle patterns and changes that indicate underlying health conditions, thus complementing the expertise of TCM practitioners.

Auscultation and Olfaction

Auscultation and olfaction in TCM involve the use of a physician's hearing to detect changes in a patient's voice and sounds. Olfaction relies on the physician's sense of smell to detect changes in odors. The theoretical basis for these practices in TCM is the belief that a patient's speech sounds and body odors can reflect the physiological and psychological states of their internal organs. Consequently, auscultation and olfaction have long been highly regarded in the field of TCM. However, objective studies and literature on auscultation and olfaction are scarce, which may be attributed to the complex acoustic properties of sounds, including a plethora of natural noises, similar acoustic signals, and diverse chemical compositions of thousands of volatile organic compounds in exhaled gases. These factors have hindered the development of objective research on TCM auscultation and olfaction. Chiu et al [12] introduced quantifiable parameters for TCM auscultation, which allowed for the identification of nonvacuity, qi vacuity, and yin vacuity characteristics in participants. This quantification process enhances the practice of TCM auscultation. There is still a need for more quantitative data on auscultation and further advancements in the application of AI to analyze such quantitative data. The integration of AI into this method is facilitated through the use of advanced sensor technologies and audio analysis algorithms. For example, digital stethoscopes can capture and record bodily sounds with greater clarity. These sounds are then processed by AI algorithms that can filter out background noise and enhance the relevant audio signals. With regard to objective olfactory analysis, there have been several recent studies from a TCM perspective. A recent study introduced a new odor map with the ability to characterize odor quality that was comparable to that of highly skilled human "sniffers" [13]. The algorithms of these odor detection tools have significant potential for quantifying olfactory diagnosis in TCM. AI algorithms are then applied to data generated by these devices to identify specific volatile organic compound profiles that are associated with different health conditions. This is a complex task given the vast number of potential volatile organic compounds and their concentrations; however, machine learning models have shown the ability to handle this complexity and provide objective data for diagnosis. Therefore, the primary focus should be on building an AI odor monitoring system. Such a detection system can be developed by selecting specific biomarker reagents [14]. The development of diagnostic molecular biomarkers for olfaction diagnosis in TCM is also a substantial task. These biomarkers should be capable of quantifying the olfactory diagnostic process in TCM more accurately.

However, there are still some challenges in the application of AI to auscultation and olfaction, including challenges regarding data quality and standardization. The collection of auditory and olfactory data requires highly accurate sensors and devices. Data quality and standardization are critical for training accurate AI models. Inaccurate or inconsistent data can lead to misjudgments by the AI system. The second challenge involves the recognition of extremely complex sound and smell patterns that can be perceived differently among individuals. AI needs to be able to recognize and understand these complexities, which places high demands on the design and training of algorithms. We need to explore and develop more advanced sensor technologies to improve the accuracy and consistency of data collection and use deep learning techniques to improve the ability of AI models to recognize complex sound and odor patterns.

Inquiry

Interrogation diagnosis (or inquiry diagnosis) directly asks patients questions about various physiological and psychological feelings. This methodology includes gathering information about the patient's family history, primary complaints, living conditions, dietary habits, sleep patterns, and other physical condition characteristics. This process allows the practitioner to gain a comprehensive understanding of the patient's overall health, including factors that may contribute to their current condition. A thorough understanding of a patient can also avoid the influence of a previous medical history on treatment. The inquiry aims to provide a holistic view of the patient in

consideration of not only physical symptoms but also lifestyle and environmental factors that could impact their health. The content of TCM inquiries is mainly based on the "Ten Brief Inquiries"; however, at present, TCM inquiries also incorporate past history, allergy history, and family history from modern medical records [15]. The GatorTron system, which was developed by Yang et al [16], enhances the use of clinical narratives in the creation of various medical AI systems, thus ultimately leading to better health care delivery and health outcomes. However, electronic health record (EHR) analysis for TCM inquiry is not yet well developed and primarily relies on natural language extraction techniques to extract electronic medical record data, which are then used to establish a knowledge repository for traditional Chinese clinical cases. For example, AI systems are capable of identifying TCM-specific symptoms such as "fatigue" and "dry mouth" from patient narratives, thus correlating these symptoms with associated internal organ imbalances. This sophisticated recognition aids physicians in assessing patients' constitutions and developing personalized treatment plans. For individuals with chronic conditions, AI facilitates a more in-depth analysis by sifting through extensive health records to forecast disease progression, thereby providing physicians with a solid foundation for accurate diagnoses. Moreover, AI extends its support to patients who require ongoing care by offering tailored advice on diet and exercise, thus significantly contributing to the enhancement of their quality of life and the mitigation of relapse risks. The advent of smart wearables has further empowered AI by enabling real-time health data collection, which is swiftly relayed to AI for analysis. This system proactively notifies health care providers and patients about emerging health concerns, thus exemplifying the potential of AI in diagnostics and proactive patient care within the framework of TCM.

In the future, it will be essential to confirm the accuracy of large language models (LLMs) such as GPT-3.5 and GPT-4 in TCM diagnosis [17]. This process requires a nuanced approach that acknowledges the complexity and richness of TCM terminology. The first step is to collect comprehensive patient data, including symptoms, medical history, lifestyle factors, and any other relevant information. These data must be preprocessed to ensure that they are suitable for AI analysis. AI models, especially LLMs, are trained in neurolinguistic programming to understand and interpret human language. In the context of TCM, this involves training models to recognize and analyze specific terminology that is used in patient inquiries. Afterward, AI models must be trained to understand the context in which TCM terms are used. This includes recognizing relationships between different symptoms and their implications with regard to overall health according to TCM principles. However, TCM is practiced worldwide, and patient inquiries may also be in various languages or dialects. AI models need to be trained on diverse data sets to ensure that they can handle different languages and cultural interpretations of TCM terms. A significant amount of labeled data and expert input are subsequently required for validation. Collaborations with TCM practitioners to annotate and validate data can improve the model's accuracy. In summary, although AI with LLMs shows significant promise for managing EHRs, TCM inquiry demonstrates a unique knowledge system. The fine-tuning of LLMs is essential for transforming these general-purpose models into specialized models that are adept at handling TCM EHRs [18]. Future efforts should entail constructing a knowledge system for TCM diagnosis. It will then be necessary to fine-tune LLMs for TCM diagnosis based on existing LLM data models, thus providing AI tools for case analysis in TCM diagnosis. The integration of AI into the TCM inquiry process is a complex task that requires the careful consideration of unique aspects of TCM terminology and practice. With the right approach, including ongoing research and collaboration with TCM experts, AI can be effectively used to analyze patient data and enhance the diagnostic process in TCM.

Palpation

Pulse diagnosis is one of the 4 main pillars of TCM assessment. By palpating the pulse at 3 specific positions on the wrists ("cun," "guan," and "chi"), practitioners can gain a comprehensive understanding of a person's overall health and the state of specific organs. TCM pulse diagnosis consists of approximately 29 different pulse types that encompass a range of descriptors, including floating pulses and scattered pulses [19]. The intersection of pulse diagnosis and AI presents 2 main challenges. TCM pulse detection has historically relied on manually palpating the arteries beneath the skin to detect the pulse, thus lacking objective standards. In the process of AI-driven traditional Chinese pulse diagnosis, 2 critical issues need to be addressed: the development of pulse measurement devices and the standardization of pulse detection data. Lan et al [20] created a sensing device that features a multipoint sensor to measure pulse. Due to the complexity of pulse detection, previous methods that have primarily relied on multipoint sensors have only offered a limited scope of information. The development of pulse measurement devices has led to significant technological advances in recent years, and these advances are mainly reflected in innovations in sensor technology and the application of AI algorithms. Photovoltaic volumetric pulse wave sensors, which are based on photoplethysmography, are among the most common types of sensors used in pulse measurement devices. Pulse waves are measured by detecting the flow of blood in the microvasculature to obtain physiological parameters such as heart rate [21]. Photoplethysmographic sensors, such as smartwatches and fitness trackers, are widely used in consumer electronics. Some devices use pressure sensors to measure pulse waves, especially in continuous blood pressure monitoring. These sensors are often embedded in wearable devices that can monitor changes in blood pressure over time. To address the challenge of normalizing pulse data, AI algorithms preprocess the data before analysis, including filtering, denoising, and normalization, to ensure data quality. AI technology that is currently under development is working to improve the cross-device compatibility of algorithms so that data from devices from different manufacturers and models can be consistently analyzed, thus promoting data standardization and interoperability. The standardization of TCM pulse diagnosis is key to promoting the use of AI technology in TCM pulse measurements. It is necessary to establish unified pulse data and diagnostic standards along with integrating more diagnostic methods such as tongue diagnosis and diagnostic observation, from which we can develop an integrated TCM

diagnostic platform and improve the comprehensiveness and accuracy of diagnosis.

In the future, more powerful multipoint sensing devices and multimodal detection devices will be needed to comprehensively examine pulse data and achieve better quantification. A challenge still remains in determining whether pulse data from these detectors can adequately reflect the characteristics of pulse diagnosis and in improving the classification of pulse patterns. To address the challenge of enhancing the precision of AI in interpreting pulse data for future research and development, noncontact pulse measurement techniques have demonstrated significant advancements. These methods eliminate the need for physical contact with the patient, which is particularly crucial for monitoring in unique or sensitive situations. For instance, the polarized multispectral imaging technique for noncontact heart rate measurement has refined the accuracy of data acquisition by pioneering new methods for extracting pulse waves from the palm [22]. This innovation contributes to the establishment of a standardized framework for pulse data, thus facilitating seamless data sharing and comparisons across various devices and systems. However, the attainment of high-quality data hinges on precise labeling, which is a process that can be both labor intensive and costly. In the context of electrocardiogram data annotation, the requirement for specialized physicians introduces variability, in which different medical professionals may offer conflicting assessments. This reality compounds the complexity and challenges associated with data preprocessing. To overcome these obstacles, it is imperative to refine data annotation protocols and invest in the development of more efficient and accurate labeling tools. By doing so, we can ensure that AI systems are trained on the most reliable data, thereby improving their diagnostic capabilities and contributing to the advancement of AI in health care. In summary, the development of detection methods and quantification of detection-based data are bottlenecks in the process of AI-driven pulse diagnosis.

AI-Powered Tuina Massage Robot

Tuina massage (also known as Chinese medical massage) is a traditional hands-on manipulation treatment that is guided by the principles of TCM. It is widely used to treat various ailments, such as knee osteoarthritis, chronic neck pain, and insomnia [23-25]. The tuina massage serves 3 primary functions: facilitating the circulation of meridians, harmonizing qi and blood circulation, and augmenting the immune system [26-28]. These functions are essential for disease prevention and treatment and overall well-being. The integration of AI into tuina massage therapy is in its early stages. Efforts are underway to develop highly intelligent massage equipment and robotics based on TCM tuina to enhance its effectiveness, with a focus on improving the comfort, intelligence, and safety of massage robots [29]. Vibration and percussion are the 2 main types of tuina massage robotics. These devices offer acupressure techniques; however, manual massage from experienced physiotherapists provides additional popular movements, such as light stroking, stretching, and advanced kneading techniques, that machines cannot replicate. Therefore, the development of massage robots is a significant research focus for greater health care demands. Challenges mainly exist in their control, structure, and path planning; however, ongoing efforts aim to optimize their design and functionality. For example, the incorporation of a series-parallel hybrid structure may enhance flexibility while maintaining stiffness and precision [30]. Future research should focus on ergonomics to design high-performance massage robots that integrate advanced AI technologies for better control, sensing, and essential functions.

In current TCM tuina practice, the Expert Manipulative Massage Automation (EMMA) electronic massager, which was developed by AiTreat Pte Ltd in Singapore, is widely used. To deliver precise and effective massage based on muscle feedback, EMMA uses advanced sensor-based technology to identify focus points and adjust pressure levels. By detecting stiffness and resistance, EMMA can pinpoint muscle knots and tension points, thus applying varying pressure levels based on feedback and user preferences. In addition, EMMA incorporates Internet of Things technology for remote control, programming, and updates, thus enhancing its functionality in “green” Internet of Things applications. In EMMA technology, machine learning algorithms (especially convolutional neural networks in deep learning) are used to identify and analyze muscle tension patterns, acupuncture point locations, and physiological responses of patients. Through training, these algorithms are able to identify specific treatment points from sensor data to provide a customized massage solution for the patient. This pattern recognition capability allows the robotic massage therapist to pinpoint the area to be treated, thus mimicking the diagnostic process of an experienced massage therapist. The robotic masseur is able to adjust the intensity and speed of the massage based on real-time feedback from the patient. For example, if the sensors detect that a patient is experiencing discomfort at a certain pressure level, then the AI system can immediately adjust the intensity to ensure the comfort and effectiveness of the treatment. Through its advanced data analytics and learning capabilities, the AI application in EMMA technology is able to accurately identify treatment points and adjust massage intensity based on the patient’s real-time feedback. The EMMA massager has garnered high levels of acceptability and satisfaction among healthy volunteers, thus demonstrating its feasibility [31]. Nonetheless, research on massage robots still faces challenges, particularly regarding their clinical effectiveness. In addition, massage robots are categorized as class-I medical devices that do not require Food and Drug Administration approval for marketing in the United States [32]. Traditional medical device classification focuses on physical and biological characteristics, whereas the functionality of AI devices relies more on software and algorithms. Therefore, new classification criteria need to be developed that consider the specificities and potential risks of AI technologies. In the future, there will be a need for more standardized regulations to oversee research on massage robots [33]. Medical devices process and analyze large amounts of patient data, which requires regulations to include stringent requirements for data security and privacy protection. Medical device regulations need to incorporate specifications for data collection, storage, processing, and transmission to ensure the security and confidentiality of patients’ information, including the validation and clinical testing of AI algorithms. The use of AI medical devices involves the collection and analysis of large

amounts of personal health information, which can threaten patients' privacy. Regulations must ensure that the collection and use of patient information comply with privacy protection standards to prevent unauthorized access and data breaches. This will entail validating the functionality and therapeutic efficacy of medical devices to guarantee their safety and efficacy for users.

We propose the following perspective on the development of tuina robots. First, the overall stability of the tuina technique involves the stability of variable mechanical parameters and resulting morphological changes in mechanical effects during technique operation. These factors include mechanical characteristics such as force; speed; frequency; displacement; and kinematic features such as limb range of motion, joint angles, and overall movement amplitude. For example, the dexterity of the robotic arm is key to achieving an accurate simulation of a human masseur's maneuvers; however, it requires sophisticated mechanical design, including joint flexibility, end-effector versatility, and overall structural stability. The robot arm's control system also needs to process large amounts of data and make decisions in real time. This includes trajectory planning, motion control, and complex algorithms for force and position control. To ensure safety, collision detection and response mechanisms also need to be implemented. Consequently, tuina has significant limitations and subjectivity, thus making it difficult to objectively quantify and accurately assess efficacy. AI offers unique advantages in addressing this issue, which is primarily manifested in the digitization of tuina techniques (ie, the development of precision and flexibility in massage robots). Addressing the accuracy of the tuina technique is a prominent issue that may require more diverse AI algorithms to digitize massage techniques and analyze the clinical effects of different massage methods. The accuracy of Chinese massage largely depends on the precise positioning of acupoints. Researchers are developing a human body model based on the mechanism of "bone degree and minutes" in Chinese medicine, which realizes the calculation of 3D coordinate values of acupoints through robotics as well as identifying and tracking human body features by using such sensor technologies as depth cameras, thus realizing the precise positioning of acupoints. Second, another advantage of AI includes personalized health care services. The personalized parameter settings of massage robots are core parameters for future tuina robots. There are significant differences in individuals' sensitivity and tolerance to pressure. The comfort and pain thresholds of people can vary, thus significantly affecting their experience with massage robots. AI can analyze the user's physical condition, health data, and personal preferences to design a personalized massage program. Through the integration of advanced intelligent sensors, massage robots can monitor users' physiological responses, such as muscle tension and body temperature, in real time. According to these data, massage robots can adjust their massage strength, speed, and focus area to overcome the "subhealth pain problem" of accurate positioning and efficient massage. At present, there are few studies on the clinical effectiveness of AI nudging robots, and patient self-reported changes in pain level, duration of pain relief, reduction in drug dependence, and objective measures of mobility (such as gait analysis) will be important indicators for evaluating their effectiveness in the future. When considering factors such as safety and comfort, AI data recording and analysis can also be used to measure the clinical efficacy of tuina robots.

AI-Directed Acupuncture Manipulation

Acupuncture, which is a therapeutic technique in TCM that has been practiced for thousands of years, has gained widespread global acceptance and demonstrated significant efficacy for various chronic diseases, particularly pain-related conditions. This therapeutic approach involves stimulating specific areas, known as acupoints, on the patient's body, thus eliciting sensations such as soreness, numbness, fullness, or heaviness, which is commonly referred to as "De Qi" or achieving qi [34]. Due to the inherent subjectivity and reliance on experience in traditional acupuncture practices, there is growing interest in parameter-based electroacupuncture to address these limitations [35]. By setting different parameters using an electroacupuncture device, clinical efficacy can be enhanced, thus facilitating further research. However, the efficacy of acupuncture is still not universally recognized [36], possibly for 2 main reasons. First, the inadequate design and implementation of past clinical research methods have led to a lack of clinical evidence. Second, the mechanism of acupuncture remains unclear, thus necessitating more high-quality evidence to elucidate its biological mechanisms for informed clinical decision-making [37]. The integration of AI and acupuncture shows great potential for substantially improving the precision of acupuncture prescriptions and treatment techniques. A bibliometric study by Zhou et al [38] demonstrated substantial progress in AI research within the acupuncture field over the past 2 decades, with significant contributions from the United States and China. However, the application of AI in acupuncture lacks a clear framework, with a scarcity of systematic research and a lack of organization of relevant technologies and application approaches.

Given the unique characteristics of AI and the importance of data mining in clinical acupuncture practice and manipulation, further research is needed [39]. Clinical trials are costly and limited, and most articles that analyze the safety and efficacy of acupuncture are of low quality and lack comprehensive analyses. There is still a lack of standardized acupuncture point selection protocols for many diseases [40]. Therefore, future efforts should focus on standardizing TCM while improving the quality of randomized controlled trials on acupuncture to obtain more and higher-quality clinical data, thus providing a foundation for AI-based clinical data mining. AI can analyze a patient's symptoms, signs, and physiological data and compare them to a large body of medical knowledge. Through machine learning and pattern recognition algorithms, AI can help clinicians interpret diagnostic data and provide potential pathological patterns or disease classifications that can help acupuncturists in developing treatment strategies. AI can then be used to analyze large amounts of clinical data and research the literature to determine the most effective point selection for a particular condition or disease situation. A recent study "linked" original studies and 332 systematic evaluations of evidence in 20 disease areas by using AI analysis techniques to

comprehensively improve clinical evidence for acupuncture therapy in the Epistemonikos database, which constructed a total of 77 evidence matrices [41]. This will facilitate the development of a machine learning framework to predict the efficacy of acupuncture and patient prognosis. Acupuncture manipulation techniques are crucial components of acupuncture therapy, and their efficacy is paramount [42]. However, the determination of the optimal stimulation intensity in clinical research is often challenging because of technique selection, treatment duration, needling speed, and force [43-45]. Therefore, the quantification and standardization of acupuncture manipulation, such as needle insertion force, duration, and direction, are essential for achieving clinical efficacy and AI-guided acupuncture manipulation. In response to the problems in standardizing operation techniques, AI technologies, especially machine learning models and sensor technologies, are being used to capture and analyze the nuances of manual needling operations. Acupuncture robots that are currently under development can accurately gauge the location of acupuncture points by measuring a person's height and sebum thickness and use ultrasound sensors to control the depth and speed of needling. These sensors and machine learning models are able to identify key parameters such as the needling force, speed, and angle to ensure the standardization and consistency of treatment. The application of sensor technology in acupuncture focuses on the precise control and measurement of the depth, force, and speed of needling. This robot uses an ultrasound sensor to control the depth and speed of needling. By emitting ultrasonic waves and receiving their echoes, the ultrasonic sensor can accurately measure the distance between the tip of the needle and the surface of the tissue to ensure that the depth of the needles is appropriate and avoid unnecessary injury to the patient. Through built-in mechanical sensors, the robot can also automatically adjust the needle insertion process according to changes in needle insertion resistance to ensure safe needle insertion.

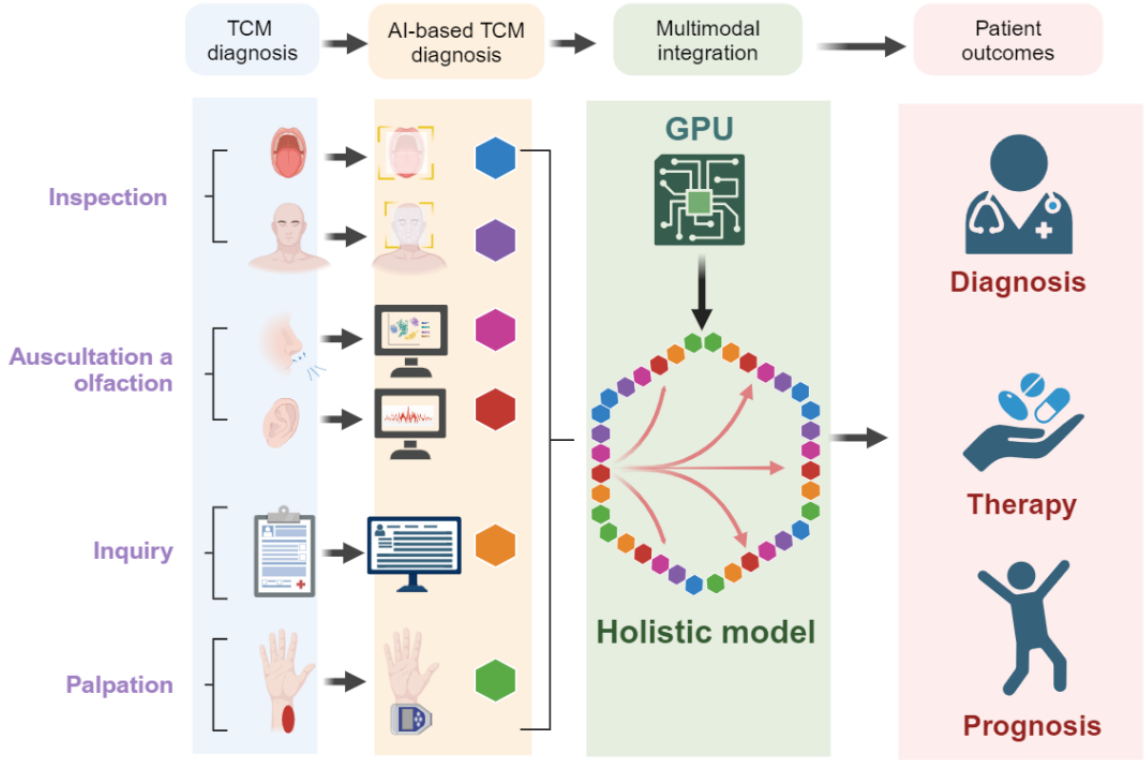
The standardization of acupuncture manipulation forms the basis of the use of AI in acupuncture. With AI technology, we propose three different ways to help standardize acupuncture: (1) imaging recognition–based standardization of acupuncture practitioners' techniques, (2) analysis of parameters derived from acupuncture practitioners' lifting and thrusting techniques using neural network image analysis systems, and (3) extraction of spatiotemporal features from video images of acupuncture operations by using computer vision technology [46]. In addition, a hybrid model that combines 3D convolutional neural networks and neural networks is used to recognize and classify dynamic hand gestures in acupuncture operation videos, thus enabling quantitative analyses and technical inheritance research for various techniques. Another approach involves recording acupuncture practitioners' movements and mechanical parameters during acupuncture procedures by using 3-axis posture sensors. Davis et al [47] developed force and motion sensor technology (acusensors) to quantify the linear and rotational movements of acupuncture needles and the force and torque that are generated during manual needle manipulation. A standardized TCM acupuncture manipulation database was established for the quantification of motion and force patterns. These data serve as a crucial tool for future AI applications in acupuncture. Finally, acupuncture parameters based on other electrophysiological signals have been recorded, thus showing significant differences in electrophysiological signals between acupuncture points and nearby nonacupuncture points and highlighting the electrical specificity of acupoints [48,49]. This finding serves as compelling evidence for TCM theory and provides parameters for the standardization of acupuncture stimulation. In addition, collaboration between AI experts, acupuncturists, and biomedical engineers is essential for developing and improving acupuncture-related technologies. The data analysis and intelligent algorithms that are provided by AI experts can help acupuncturists better understand treatment effects and optimize treatment plans. The clinical experience and theoretical knowledge of acupuncturists can guide AI experts in developing intelligent systems that better meet clinical needs. Moreover, there are some prominent conditions or events existing outside of normal circumstances that exist beyond the abilities of AI. In such cases, acupuncturists can make judgments based on their own experience and knowledge. Technical support from biomedical engineers subsequently ensures that these intelligent systems can be effectively applied in practice. Close collaboration among the 3 factors is the key to promoting technological innovation in acupuncture, improving treatment outcomes, and standardizing and popularizing acupuncture techniques. Through this interdisciplinary collaboration, modern technology can be better used to enhance the value and impact of traditional acupuncture medicine. AI technology can be used to simulate acupuncture operations and provide support for learning and training. For example, through virtual reality and augmented reality technologies, AI can create simulated acupuncture treatment scenarios that allow learners to practice acupuncture techniques and decision-making processes in a virtual environment. This approach improves learning efficiency and reduces risks in actual practice.

Outlook

The future is promising for the integration of AI into TCM diagnosis (Figure 1). The core of TCM diagnosis involves 4 fundamental methods: inspection, auscultation and olfaction, inquiry, and palpation. First, through inspection, we can explore the application of AI in facial and tongue diagnosis. By leveraging image processing techniques, we anticipate groundbreaking innovations in these areas. Due to the low contrast and noisy nature of ultrasound images, which require extensive knowledge of tongue structure and ultrasound data interpretation, it can be challenging for medical professionals to accurately diagnose various conditions. To overcome these challenges, researchers have proposed new deep neural networks, referred to as BowNet models [50]. These models leverage the global prediction capabilities of encoder-decoder fully convolutional neural networks and the high-resolution extraction features of dilated convolutions. The models are designed to automatically extract and track the tongue contour in real-time ultrasound data. By providing more accurate and objective tongue contour tracking, AI can assist TCM practitioners in making more informed diagnoses and treatment decisions. However, the digitization of valuable empirical data

from TCM facial and tongue diagnosis remains a challenge, although unsupervised machine learning may provide a solution. First, addressing the challenge of digitizing TCM experience data often requires seamless collaboration among diverse teams, which encompasses TCM practitioners, AI experts, and health care institutions. This initiative involves partnering with medical facilities to meticulously gather and curate a rich array of TCM clinical case data, thus encompassing detailed patient complaints, symptomatic expressions, tongue diagnoses, and pulse assessments. Subsequently, synergy between TCM professionals and AI researchers has extended to the intricate task of knowledge structuring. The translation of the profound insights of TCM theories, herbal formulas, and medicinal properties into a web-based knowledge graph can greatly enhance the accessibility and utility of this ancient medical wisdom. This graph facilitates a nuanced understanding of intricate relationships within TCM, underpins the development of intelligent recommendation systems, and assists in informed decision-making within the realm of TCM. Through these collaborative efforts, the rich tapestry of TCM experience data is meticulously incorporated into accessible, digital formats, thereby bridging the gap between ancient wisdom and modern technological advancements. These initiatives have propelled the modernization and globalization of TCM and significantly contributed to the broader landscape of health care innovation. Second, TCM diagnosis through auscultation and olfaction provides new avenues for development. We can develop specialized AI tools for auditory and olfactory systems that can complement TCM diagnosis. Third, the analysis of inquiry in TCM diagnosis presents an exciting frontier. There has been significant progress in Western medicine in this area with regard to LLMs, and TCM EHRs contain unique knowledge graphs that are specific to TCM diagnosis. Therefore, fine-tuning is necessary for the analysis of TCM EHRs. Fourth, pulse diagnosis is a cornerstone of TCM diagnosis and requires the development of more advanced pulse detection tools. By obtaining substantial pulse data, we can standardize objective pulse analysis. By leveraging machine learning and classification techniques, we can align these data with TCM pulse patterns, thus ultimately achieving AI-driven pulse diagnosis. Quantifiable metrics or benchmarks are instrumental in ensuring the high performance of AI systems, establishing unambiguous objectives, and measuring advancements in the integration of AI technologies. For example, metrics such as diagnostic accuracy and generalization capability can assess AI systems' proficiency in managing patient data across varying regions, age groups, and sexes, thereby ensuring their efficacy across a wide array of populations. By juxtaposing outcomes that are generated by AI systems with diagnoses that are rendered by seasoned TCM experts, the precision of AI systems in pinpointing specific conditions can be quantified. This quantification is facilitated through the computation of statistical indicators such as sensitivity (true positive rate), specificity (true negative rate), precision, and the F_1-score. These benchmarks serve as a foundation for the continuous refinement of AI systems, thus ensuring their optimal integration and application within the sphere of TCM. These directions of development have the potential to revolutionize TCM diagnosis, thus enhancing its accuracy and efficiency.

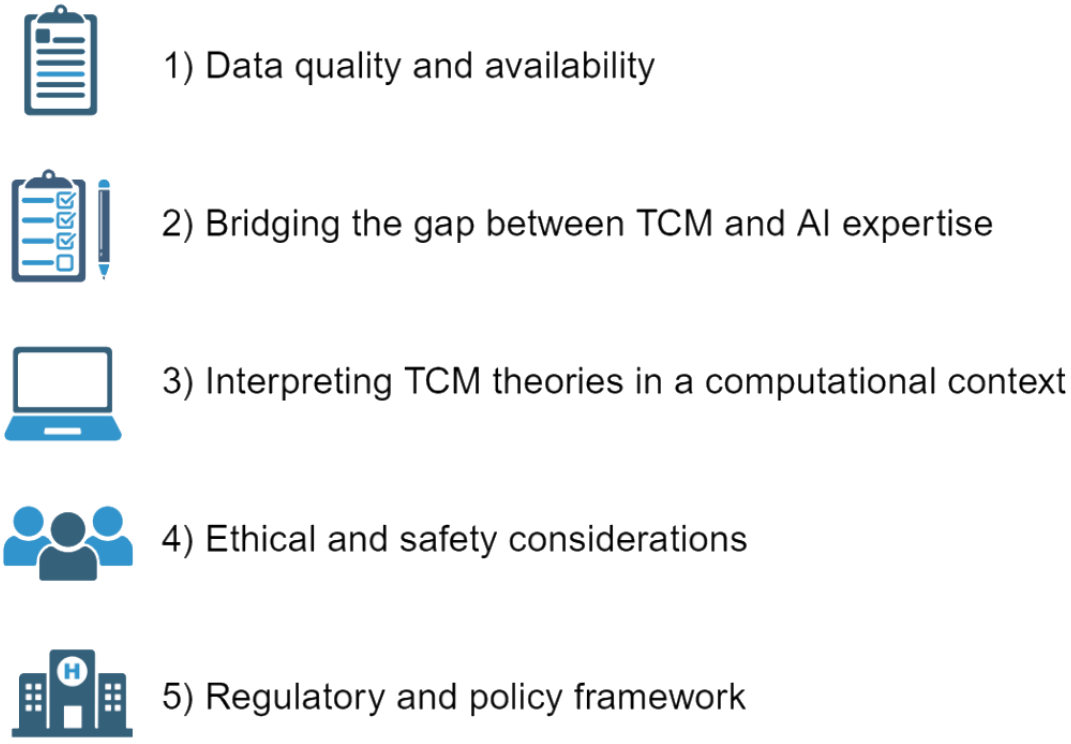
Figure 1. Overview of artificial intelligence (AI) development strategies based on traditional Chinese medicine (TCM) diagnosis. The acquisition and standardization of unimodal data through TCM diagnostic techniques is followed by the integration of multimodal data using a comprehensive model. This approach aids in enhancing predictions and supports TCM diagnoses for treatment and prognosis. GPU: graphics processing unit.



Challenges

There are unique challenges to the use of AI in TCM (Figure 2). First, regarding data quality and availability, the successful implementation of AI in TCM relies on access to reliable and standardized data sets. High-quality data can potentially promote clinical diagnosis and treatment in precision TCM. However, data collection and digitization efforts in TCM can be challenging, and the quality and interoperability of existing data sets may vary. Varied interpretations of identical conditions among TCM practitioners can result in divergent diagnostic criteria and terminological applications. Such disparities, coupled with the potential for errors and biases in manually entered data, can significantly impact the learning efficacy of AI systems. Consequently, the establishment of standardized TCM diagnostic criteria and terminology glossaries, in addition to the implementation of uniform data entry protocols for TCM practitioners, is essential for mitigating interpractitioner discrepancies. Furthermore, the use of advanced automated data collection techniques, including image recognition and natural language processing, is instrumental in enhancing the quality and precision of the collected data. These measures collectively contribute to the refinement of the analytical capabilities of AI within the realm of TCM, thus ensuring a more accurate and reliable diagnostic process. Second, to bridge the gap between TCM and AI expertise, the integration of AI technologies into TCM requires collaboration and communication among TCM practitioners and AI experts. Bridging the gap between these domains is crucial for developing AI algorithms that align with TCM principles and meet specific clinical needs. Measures could be taken to promote collaboration between TCM organizations and technology companies, as well as higher-education institutions, to facilitate the development of AI-driven TCM diagnostic and therapeutic tools. These collaborations will foster innovation and create platforms for TCM students and practitioners to perform internships in the technology industry. In addition, the provision of scholarships and research grants is critical for incentivizing and sustaining interdisciplinary scholarship. By allowing students and researchers to delve into the convergence of TCM and AI, we can accelerate the digitization of TCM knowledge. Third, TCM theories must be interpreted in a computational context. TCM theories are often complex and based on holistic and individualized perspectives. The translation of this knowledge into AI algorithms and computational models is a significant challenge that requires careful consideration of cultural, philosophical, and theoretical aspects. Many concepts in Chinese medicine, such as qi, yin and yang, and the 5 elements, are abstract and ambiguous, and it is difficult to describe these concepts in precise mathematical language; therefore, ambiguous logic can be used to address ambiguous concepts in TCM, and Bayesian networks can be used to simulate causality and uncertainty in the theory of Chinese medicine. Fourth, there are notable ethical and safety considerations regarding this scenario, as with any implementation of AI in health care [51]. Ensuring patient privacy, data security, and transparency in algorithm decision-making is essential for building trust and ethical practices in AI-supported TCM. Informed patient consent must be obtained before collecting and using patient data. This includes a full explanation of the purpose of data collection, how the data will be used, how long they will be stored, and potential risks. To protect patients' privacy, all the data sets that are used for machine learning should be anonymized by removing or encrypting any personally identifiable information. During the development and deployment of AI systems, ethical review committees need to be established to ethically review the design, implementation, and evaluation of AI systems to ensure that all the activities meet ethical standards. Fifth, the integration of AI into TCM necessitates clear regulatory frameworks and policies that govern its implementation, including issues related to data protection, algorithm validation, and clinical decision-making. Sixth, the function and efficacy of TCM are broadly accepted worldwide; however, the underlying mechanism has remained enigmatic, thus limiting people's confidence in TCM and precision therapy that is learned by AI. In summary, the process of implementing and validating AI tools in a clinical setting requires careful planning and rigorous execution. Representative and actionable clinical environments are selected to develop pilot projects. These projects should focus on specific TCM diagnostic tasks, such as tongue analysis, pulse recognition, and symptom assessment. Clinical trials need to be designed and executed to evaluate the performance of AI tools in real clinical settings. This includes randomized controlled trials and prospective cohort studies to assess the impact of AI tools on patient outcomes. Finally, the results and experiences will be published and shared through academic journals and conferences to promote communication and learning within the industry.

Figure 2. Summary of the challenges of integrating artificial intelligence (AI) into traditional Chinese medicine (TCM) diagnosis.



Conclusions

In conclusion, the integration of AI into TCM exhibits immense promise for improving diagnosis, including inspection, auscultation and olfaction, inquiry, and palpation. The successful integration of AI into TCM is evident through advancements in areas such as image analysis for tongue diagnosis, the development of intelligent tuina massage systems, and the application of machine learning to refine treatment protocols based on individual patient data. Addressing the challenges of data quality, the standardization of data sets, interdisciplinary collaboration, the interpretation of TCM theories, ethical considerations, and regulatory frameworks is crucial for the successful and responsible implementation of AI in TCM. By overcoming these challenges, we can leverage the power of AI to enhance patient care, personalize treatments, and advance our understanding of TCM. Moreover, we can develop more precise AI models that are tailored to TCM, thus creating a positive cycle of problem-solving and progress that ultimately leads to better patient care. By combining the wisdom of TCM with the power of AI technology, we can improve patient outcomes and promote the integration of TCM into modern health care systems. It is imperative to conduct more research into AI's ability to decode complex diagnostic patterns that are inherent to TCM. The validation of AI-enhanced TCM treatment methods through clinical trials is essential to ensure their safety and efficacy, thus providing empirical support for their widespread adoption. As we advance the integration of AI into TCM, it is vital to uphold ethical standards that prioritize patient rights, cultural integrity, and data privacy. The responsible use of AI will ensure that technological advancements align with the principles and practices of TCM, thus safeguarding the well-being of patients and respecting the cultural significance of this ancient medical system. The fusion of AI with TCM has the potential to bridge traditional and modern medical practices, enrich global health, and foster cultural exchange. By integrating these 2 domains, we can create a more comprehensive health care system that is both innovative and respectful of historical practices.

Finally, a call to action is made to all stakeholders (practitioners, researchers, policy makers, and investors) to collaborate and support the integration of AI into TCM. Through collective efforts, we can harness AI to transform patient care, broaden our understanding of TCM on a global scale, and identify new horizons in health care that are both deeply rooted in tradition and boldly futuristic.

Abstract

Integrating machine learning (ML) models into clinical practice presents a challenge of maintaining their efficacy over time. While existing literature offers valuable strategies for detecting declining model performance, there is a need to document the broader challenges and solutions associated with the real-world development and integration of model monitoring solutions. This work details the development and use of a platform for monitoring the performance of a production-level ML model operating in Mayo Clinic. In this paper, we aimed to provide a series of considerations and guidelines necessary for integrating such a platform into a team's technical infrastructure and workflow. We have documented our experiences with this integration process, discussed the broader challenges encountered with real-world implementation and maintenance, and included the source code for the platform. Our monitoring platform was built as an R shiny application, developed and implemented over the course of 6 months. The platform has been used and maintained for 2 years and is still in use as of July 2023. The considerations necessary for the implementation of the monitoring platform center around 4 pillars: feasibility (what resources can be used for platform development?); design (through what statistics or models will the model be monitored, and how will these results be efficiently displayed to the end user?); implementation (how will this platform be built, and where will it exist within the IT ecosystem?); and policy (based on monitoring feedback, when and what actions will be taken to fix problems, and how will these problems be translated to clinical staff?). While much of the literature surrounding ML performance monitoring emphasizes methodological approaches for capturing changes in performance, there remains a battery of other challenges and considerations that must be addressed for successful real-world implementation.

Introduction

As machine learning (ML) models integrate into clinical practice, ensuring their continued efficacy becomes a critical task. A pervasive limitation in ML is the inability of most models to adapt to changes in their environment over time. As a result, a model that may have performed exceptionally in its development environment can become gradually or immediately less accurate while in production [1,2]. This problem has been well studied by the ML community, with current literature offering invaluable methodological strategies for the detection of declining model performance and the ethical implications of such declines [3-7]. However, the proper choice of monitoring algorithm is only one step in the larger series of problems and considerations surrounding the sustained maintenance of these models in a real-world scenario. While some authors address the wider set of problems encountered in the long-term maintenance strategy of a deployed model, it is typically only an acknowledgment of these problems, rather than the personal experiences and solutions developed to solve them [8,9]. As

such, we aimed to supplement current literature with an alternative approach in which we provided an in-depth review of the experiences and challenges encountered when integrating our ML monitoring solution into clinical practice.

This paper focuses on an ML model implemented into Mayo Clinic's practice in 2018. The model, known as "Control Tower," is a fully integrated health care delivery model that predicts the need for inpatient palliative care through modeling palliative care consultation. The model runs automatically on all inpatients at Mayo Clinic's St Marys and Methodist Hospitals in Rochester, Minnesota, with patient scores monitored by the palliative care practice [10]. The approach was to treat the palliative care consult as a time-to-event outcome. Some of the features used are static (patient demographics and prior history), while others are time varying or dynamic (such as laboratory values, vitals, and in-hospital events). To capture the time-varying nature of these covariates, we used a heterogeneous Poisson process. Furthermore, it was crucial to account for nonlinearity and interactions; as a result, we used a gradient boosting machine. The model was validated through a clinical trial conducted from 2019 to 2022 to assess real-world effectiveness and is still in use by the palliative care practice as of July 2023 [11,12]. The study by Murphree et al [10] provides a complete methodological overview of the ML model and validation procedure. The Control Tower monitoring platform was developed and implemented over the course of 6 months. The platform has been used and maintained for 2 years and is still in use as of July 2023.

This paper provides a series of guidelines for developing and integrating ML performance monitoring into a team's workflow. Guidelines were developed from real-world experiences and challenges encountered throughout this process by a data science team at Mayo Clinic. In addition, a comprehensive overview of the developed monitoring platform is provided, as well as the accompanying source code for demonstration purposes (Multimedia Appendix 1). Overall, this paper serves as a primer for considerations that must be made when implementing and maintaining a model-monitoring system in a clinical setting, coupled with the corresponding solutions that our team had used.

Development of the Model Monitoring Platform

Overview

Traditionally, guidelines are developed through expert-driven processes, such as the Delphi method that seeks to provide standards through initial conceptions followed by several rounds of revisions until ultimately converging to an agreed-upon set [13]. However, in emerging areas where expertise is sparse, expert-driven approaches are often costly when seeking consensus of multiple experts through multiple rounds of responses [14]. An alternative to the expert-driven approach is experience-driven methodologies, which emphasize the personal experiences and observations of individuals who have directly encountered the phenomena. Normally these methodologies focus on practical knowledge through the explication of the "real world." Our team opted to derive a set of guidelines based on our specific real-world experiences and the challenges faced when designing, implementing, and integrating the Control Tower monitoring platform. Our specific methodologies used throughout this process are documented here and later generalized into a series of guidelines in the *Design Considerations* section.

Establishing the Team and Responsibilities

When planning the phases of Control Tower, it was decided that the role of monitoring the model would remain with the model development team. The task of monitoring was divided among 4 team members, rotating the responsibility of monitoring, monthly. This approach ensured monitoring would not significantly inhibit the bandwidth of any 1 team member. Monitoring responsibilities did not fall to the team member who developed the model, as their primary task in monitoring would be to retrain the model when necessary. The monitoring platform was checked biweekly, Mondays and Thursdays, to balance coverage and analyst time. The Monday check ensured immediate response to any issues that may have occurred during the previous weekend, and the Thursday check provided enough time before the upcoming weekend to identify and resolve any errors that may have occurred during the week. Typically, a single-model monitoring session would take approximately 5 to 10 minutes, assuming no problems were encountered.

Platform Development

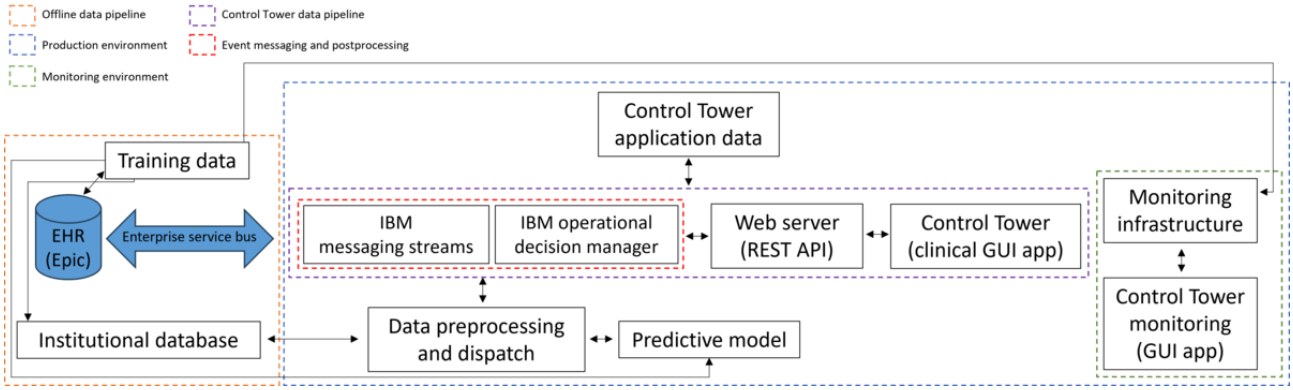
Overview

Performance monitoring of Control Tower was accomplished through the development of an R Shiny web application that comprised data visualizations and interactive tables. The goal was to create a centralized, user-friendly platform for all team members to check model performance. The platform consisted of 5 different tabs addressing different types of data shift, providing multiple degrees of granularity depending on the depth of investigation required. The model used a set of 126 features, measured daily, and was called an average of 80,000 times per day. Daily metrics collected for performance monitoring included mean and scale covariate shifts per feature, predicted probabilities, and the number of daily predictions made by the model. The resulting data size of these collected performance monitoring metrics was trivial; however, capturing patient-generated data resulted in data creation on the order of GB per day, requiring a dedicated storage space.

Figure 1 provides an overview of the system architecture for the Control Tower model and monitoring platform. The figure details the offline data pipeline used for the initial training of the Control Tower model; the components of the broader production environment and pipelines necessary for the predictive model and clinical graphical user interface (GUI) app; and finally, the components necessary for monitoring the performance of the Control Tower model. A more detailed visualization and comprehensive description of the system architecture is provided by Murphree et al [10]. Briefly, they outlined our deployment strategy which integrates a Representational State Transfer application programming interface within a Docker container, enabling the integration of

predictive models into the Control Tower GUI. The data ingestion and preprocessing pipeline, integrated with IBM Streams and Operational Decision Manager, facilitates real-time prediction processing triggered by updates to institutional health records (Health Level Seven messages by our electronic health record). The Control Tower GUI application is built with Angular (Google LLC).

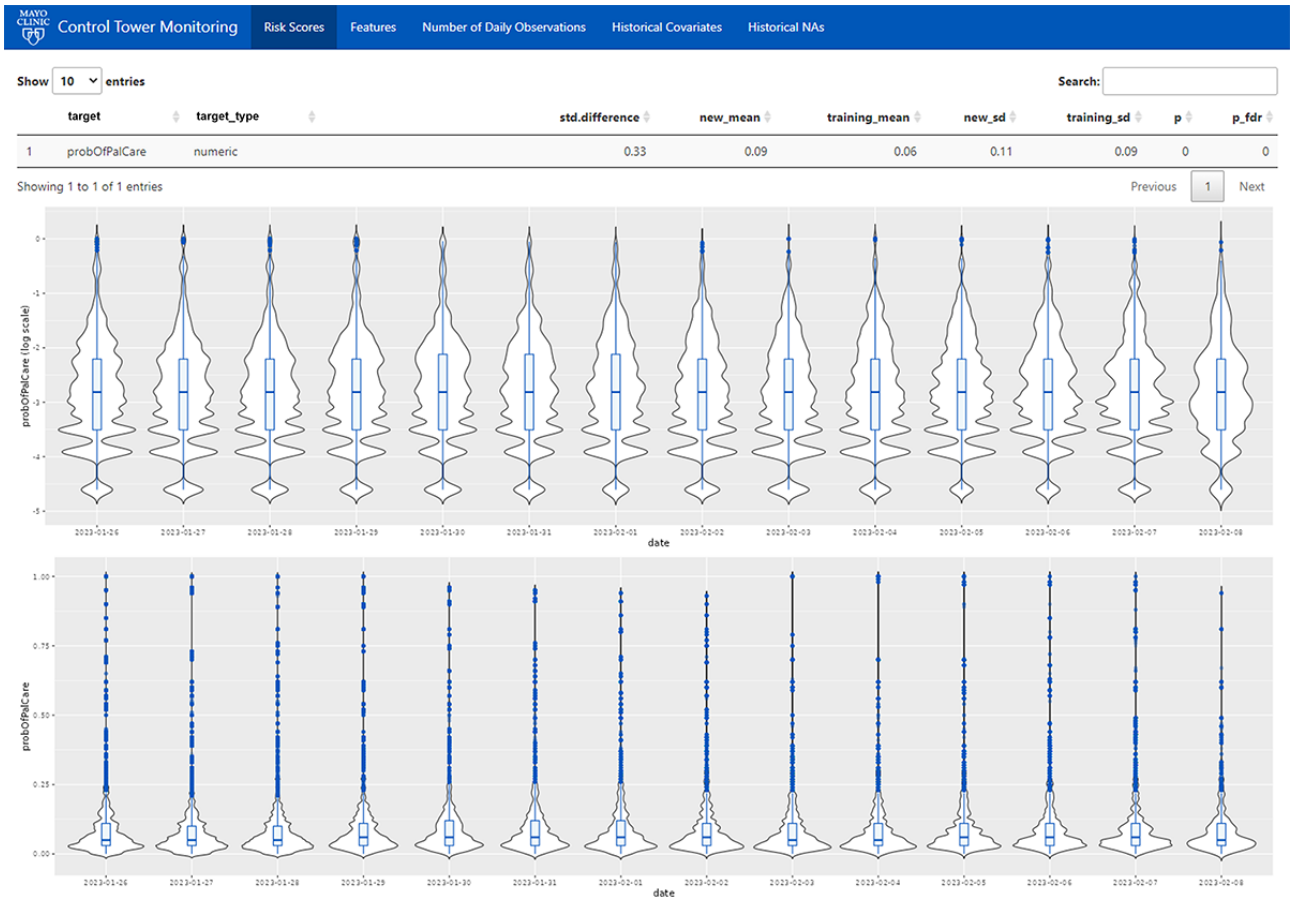
Figure 1. System architecture for Control Tower. For the Control Tower monitoring platform, we have 3 parent processes (training, production, and monitoring) that constitute our deployment. Child processes include the orchestration of the streams, events, and the prediction pipeline, which sends scores to the graphical user interface (GUI). EHR: electronic health record; REST API: Representational State Transfer application programming interface.



Monitoring Model Probabilities

In the absence of ground truth labels, predicted probabilities from the model were monitored as an alternative to evaluating model performance. The platform visualizes these predicted probabilities as distributions of daily risk scores (Figure 2). Distributions are plotted on probability and logarithmic scales, allowing for easier detection of shifts when most predicted probabilities are low, considering that most patients will not be "high risk." Historical daily distributions extend back 2 weeks, which is considered an optimal amount of time to notice shifts without overwhelming the user with data. Alongside these visualizations, several statistics are presented for comparing the prior 2 weeks data against the original training data. Means and SDs for the incoming and training distributions, the standard difference, and a *P* value for the Kolmogorov-Smirnov test of differences between the 2 distributions are provided. These statistics allow the user to detect gradual, more long-term changes that may go unnoticed when surveying 2 weeks of historic data. Overall, the tab shown in Figure 2 provides an overview of model predictions, allowing the user to quickly gauge whether a sudden or gradual probability shift has occurred.

Figure 2. The startup screen of the Control Tower performance monitoring platform. This screen provides the user a quick overview of the model's predicted probabilities over the past 2 weeks. The table near the top provides several statistics comparing the distribution of predicted probabilities over the last 2 weeks with the predicted probabilities on the training data. The 2 graphs contain a series of violin plots featuring the daily distribution of predicted probabilities. Given that the predicted probabilities cluster near 0, the distributions are also displayed on the log scale for easier visual inspection.



Monitoring Covariate Shift

Covariate shift was addressed in Control Tower by creating an interactive table containing all features included in the model (Figure 3) [4]. The table lists feature names and type, that is, continuous or discrete, and displays different statistical tests and plots, dependent on the feature type. To assess the impact of a feature with drift, the team included global feature importance scores from the originally trained model, in this case, the gradient boosting machine's relative influence rank statistic. Providing a ranking of features based on the extent of error reduction in the model enables the user to triage different drifts. All other things being equal, a drifting feature with higher importance to the model than another feature would indicate a higher priority need of a fix. Similar to the predicted probability tab, the previous 2 weeks of incoming data are compared with the training data, with standard differences, means, and SDs provided. To accommodate for the discrete variables present, the distributional Kolmogorov-Smirnov test is changed to the chi-square test. The user can sort the table by column, allowing them to quickly pinpoint features, for example, with high standard difference. Clicking on a feature's row in the table generates 2 plots underneath the table: the first is a line graph visualizing the daily standard differences, spanning back 2 weeks, and the second plot is dependent on the feature type. For continuous variables, the plot compares the feature's daily distributions over the past 2 weeks with the distribution of the training data, using box plots. For discrete variables, bar plots are displayed in a similar fashion indicating the percentage of patients where the discrete feature was present or "True." In tandem with the interactive table, these plots provide an efficient means of investigating a feature's historic values at a glance.

When a deeper investigation into a feature is necessary, the 2-week "look-back" may be insufficient. Therefore, the platform also keeps a log of the full historic feature trends, spanning back to when the model was deployed (Figure 4). Feature plots are sorted by the model's global feature importance and color-coded "green" or "red" to indicate whether the feature significantly drifted from the initial training distribution. Significance was determined via a nonparametric test developed by Capizzi and Masarotto [15], using a *P* value of .05. A nonparametric model was used because a moderate number of features were highly skewed, making traditional methods that assume normal distributions unworkable. Each feature contains plots for the location (level) and dispersion (scale) of the distribution. Overall, this tab, in addition to serving as a historical reference, provides a simple way to spot check for gradual shifts. Finally, an additional tab (Figure 5) is provided to assess the proportion of missing values over time, using the same visualizations and tests.

The final tab of the platform provides a simple line graph displaying the number of daily calls made to the model within the previous 2 weeks (Figure 6). Monitoring the number of daily

calls can provide quick insight into whether the model is performing appropriately. For example, an abnormal number of model calls in a day, such as 0, may indicate an error in the data pipeline or model environment.

Figure 3. The "Features" screen of the platform details the distributions of all features used by the model. The distribution of each feature based on the last 2 weeks of data is compared with the feature's distribution from the training data. These comparisons are provided via statistics in the table near the top, which can be sorted by each statistic to quickly find features with potential drift. Clicking on a feature populates 2 graphs, which are displayed below the table. The first graph displays the standardized difference between the feature's distribution for that day against the distribution from the training data. Below this graph, one of the 2 graphs will be displayed depending on whether the selected feature was binary or continuous. These graphs display the daily distributions of the feature, using bar graphs for binary features (red outline) or box plots for continuous features (yellow outline).

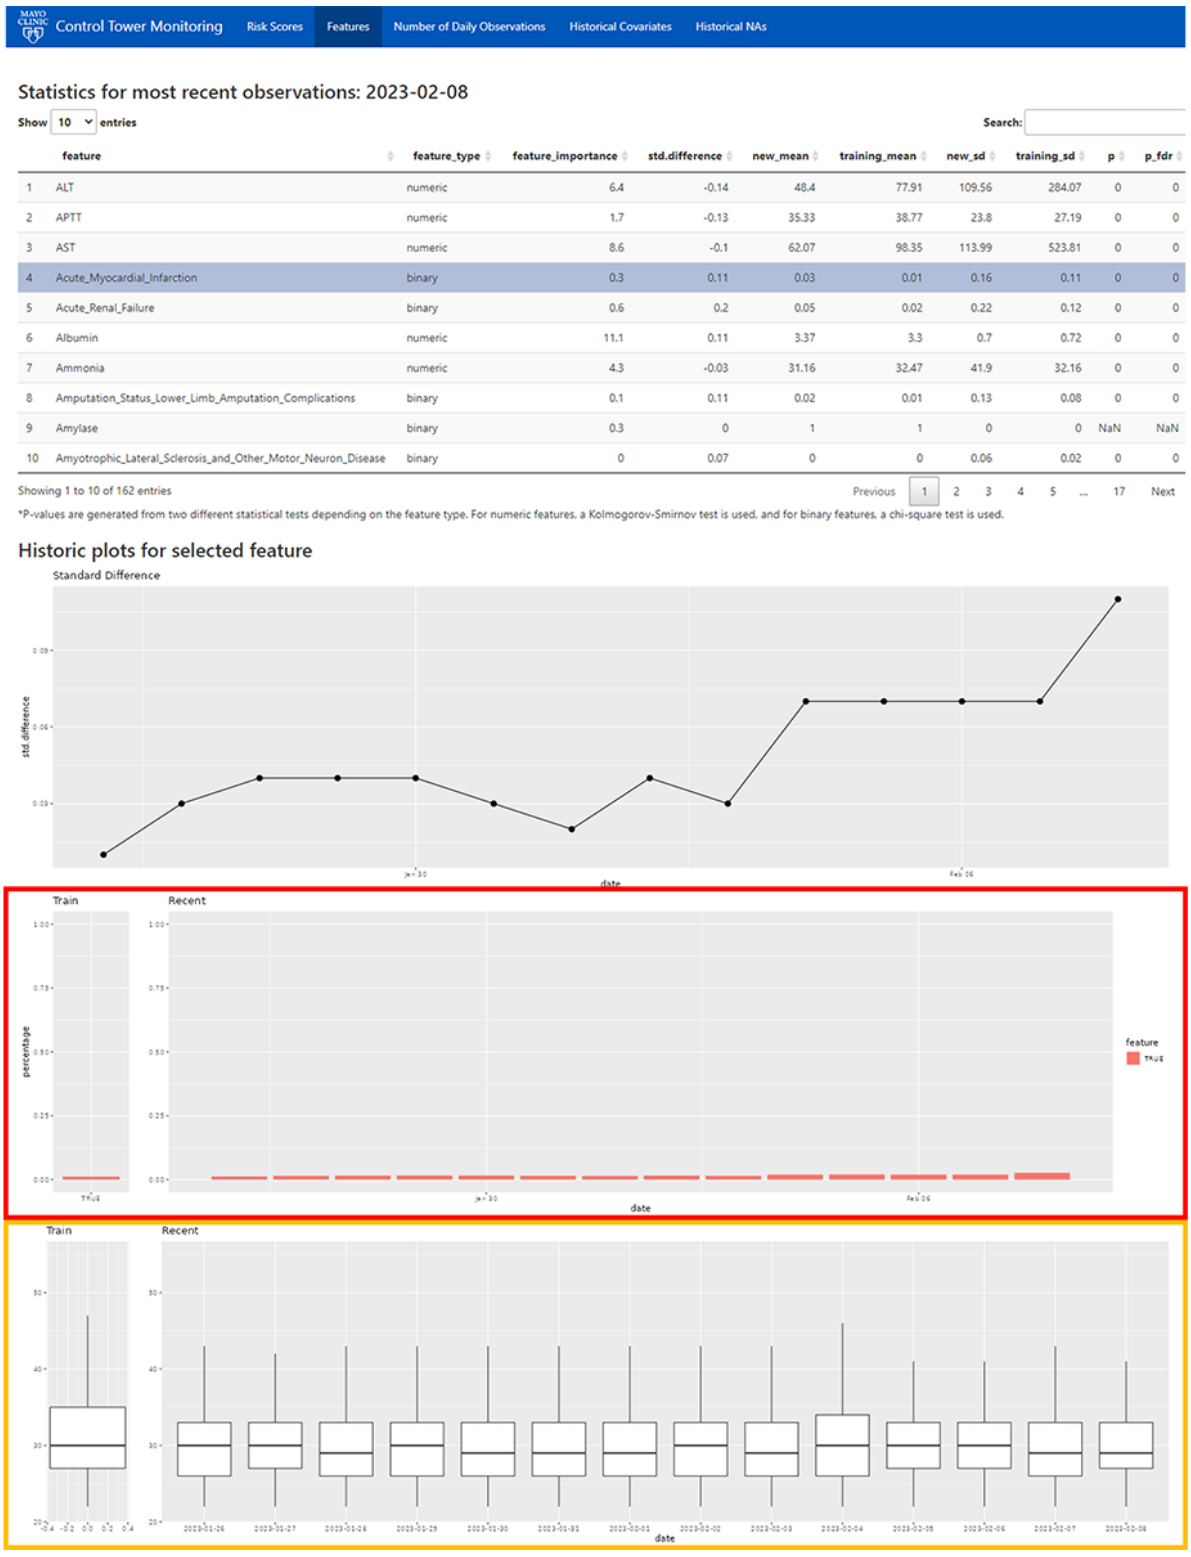


Figure 4. The "Historical Covariates" screen of the platform visualizes each feature's daily distribution, beginning with the training data and then spanning from the day the model was deployed and onward. Each feature contains plots for the location (level) and dispersion (scale) of the nonparametric distribution. Each feature's graph is color-coded "green" or "red" to indicate whether the feature's distribution has significantly drifted from the initial training distribution, with red indicating significant drift.

Figure 5. The "Historical NA's" screen of the platform visualizes each feature's historical missingness, beginning with the training data and then spanning from the day the model was deployed and onward. Each feature contains plots for the location (level) and dispersion (scale) of the nonparametric distribution. Each feature's graph is color-coded "green" or "red" to indicate whether the feature's missingness has significantly drifted from the initial training distribution, with red indicating significant drift. NA: not available.

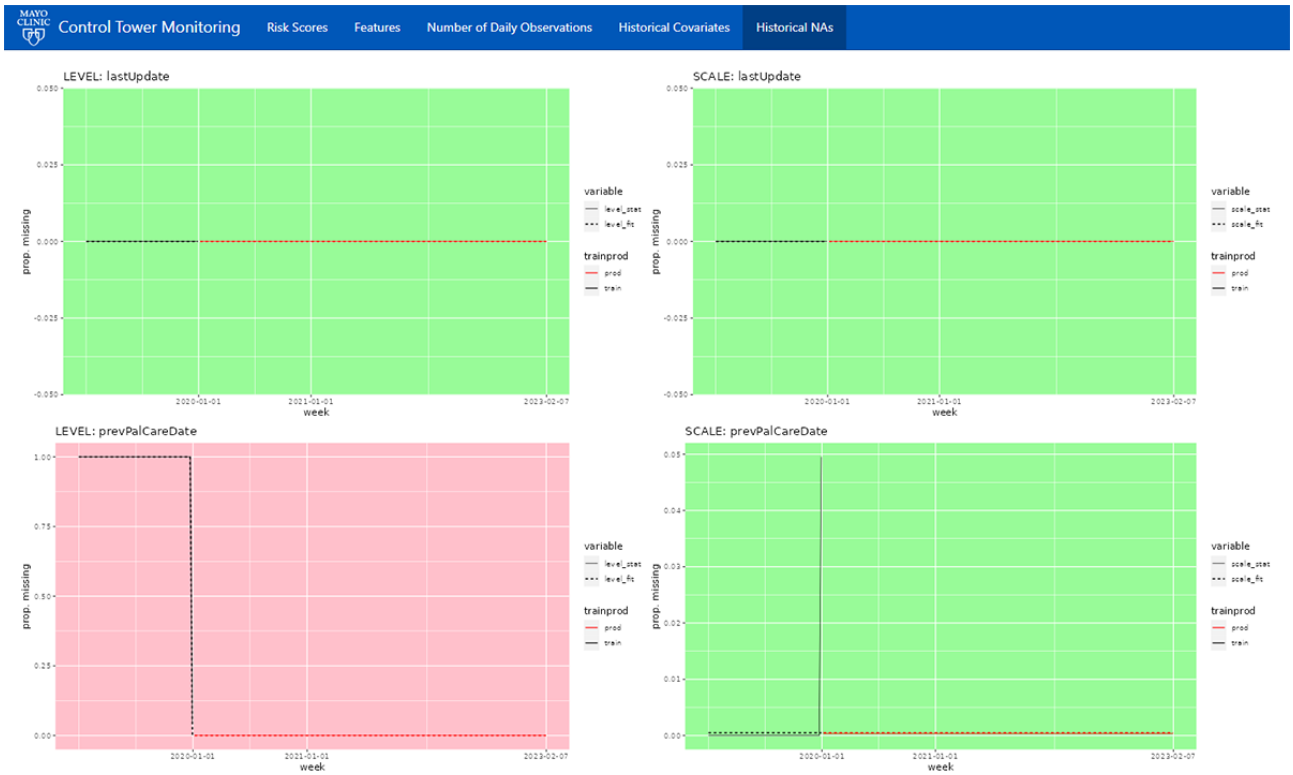

Figure 6. The “Number of Daily Observations” screen visualizes the number of model calls or predictions made each day over the past 2 weeks.

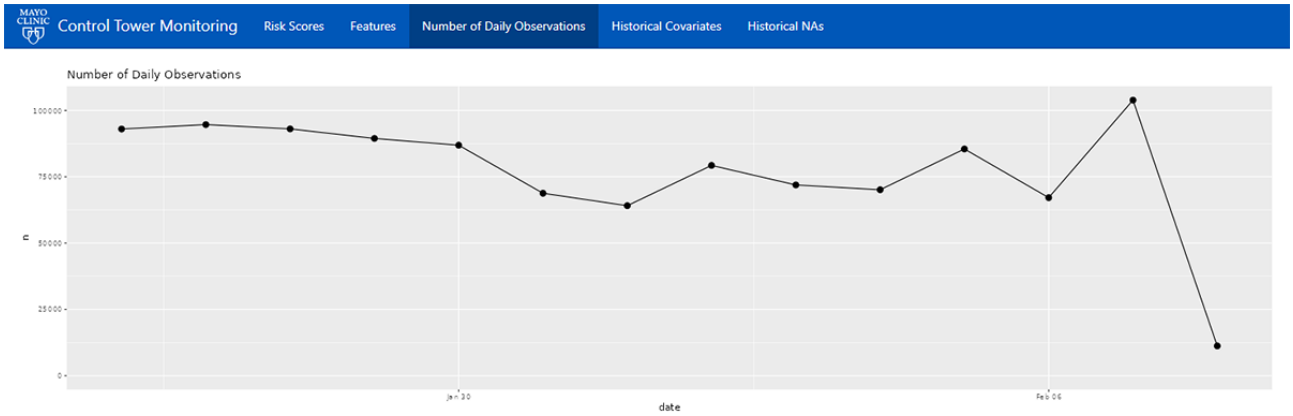


Error Classification

Any production-level model is susceptible to various errors, and Control Tower was no exception. Most errors primarily revolved around technical infrastructure, particularly issues with databases being inaccessible due to nightly processing or a high influx of requests. In Textbox 1, a sample of encountered errors while monitoring Control Tower is presented. Although some errors were seemingly random occurrences, such as server reboots or expired certificates, others were more frequent and persistent. For instance, every night at specific hours, the database that supplies data to Control Tower, called Clarity, became unresponsive due to data updates. On January 5, 2022, this process was delayed and caused errors in the morning scores. In addition, updates to our electronic health record (Epic, Epic Systems Corporation), often resulted in Clarity being temporarily unavailable. In such cases, most issues were resolved on the same day, requiring no further action besides acknowledging the possibility of outdated or missing scores. However, a few errors necessitated intervention. On November 7, 2022, a data mart containing diagnosis codes underwent structural changes, breaking a Control Tower query. Furthermore, the team identified a covariate shift where they observed a gradual decrease in troponin blood tests. This error was traced back to a change in laboratory codes used for troponin; the clinical practice had adopted a new laboratory code that was not present in the training data. To address this, the error was rectified by associating the new codes with the “Troponin” feature on the platform’s back end.

Textbox 1. Error logging: A convenience sample of encountered errors while monitoring Control Tower is presented. This was constructed through email chains of discussions between IT personnel who oversaw the Control Tower system and the data scientists who oversaw model delivery.

Date and error

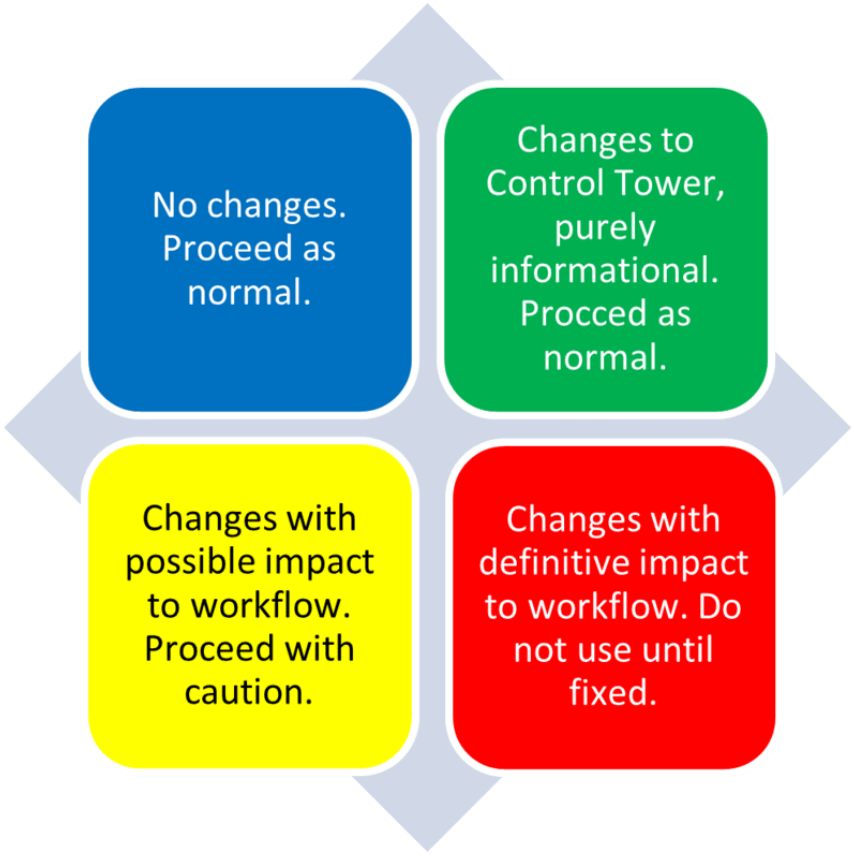
- August 26, 2019
  - Multiple errors in logs. It looks like calls were during 1:45 AM to 6:00 AM. During the period 1:45 AM to 6:00 AM, all messages are failing due to Clarity Refresh.
- November 27, 2019
  - Server reboot schedule, Control Tower team was not notified of schedule leading to unexpected downtime.
- July 24, 2020
  - Increase in FHIR (Fast Healthcare Interoperability Resources) API (application programming interface) for real-time observation calls leading to timeouts of model predictions.
- February 15, 2021
  - Generic FHIR API error call: “HTTP error code: 500.”
- April 8, 2021
  - Model errors after Epic upgrade.
- July 30, 2021
  - Troponin issues fixed causing covariate drift in model scores.
- September 15, 2021
  - Production system competed for resources requiring scale back of Control Tower scores updates. Errors created and schedule has now been updated for processing.
- January 5, 2022
  - Nightly Clarity Database delay causing morning score errors.
- May 16, 2022
  - IBM queue server certificate update causing server errors.
- November 7, 2022
  - Data mart for diagnoses codes update causing pipeline to break down.
- November 8, 2022
  - Issues with Clarity Database slowing down Control Tower queues.
- March 21, 2023
  - Control Tower FHIR API for real-time unit changes failing for a single request, causing payload slowdown.
- April 5, 2023
  - JSON structure changing causing model error (unintended repo change).
- May 1, 2023
  - An unplanned issue impacting Enterprise API Services, who manages real-time data feeds, resulting in internal server error.

Monitoring Protocol

Actions prompted by model monitoring feedback were synthesized into a protocol to communicate model failures and downtimes with clinical staff. The Control Tower protocol used a triage system, consisting of 4 stages in which each stage prompts a message to the clinical team, as outlined in Figure 7. The first stage (blue) was reserved for when everything was operating as expected. Stage 2 (green) indicated a minor change in the layout of the tool, such as a user interface change. These first 2 stages delivered informational prompts to the user, notifying them of the tool’s status and requiring no action from the user. The third stage (yellow) indicated possible performance degradation, such as when patient scores from the model were

not up-to-date, that is, a day old. The day-old scores can still provide evidence for action, but the clinical team may need to be cautious, as updated scores can change the patient's risk. As such, users were notified of these issues and asked to use the tool at their discretion. The last stage (red) indicated a significant error within the tool, such as a covariate completely missing from the model's input. This stage would notify staff not to use the tool until a fix was implemented.

Figure 7. Communication triage protocol for Control Tower. The protocol's stages are color-coded to signify different statuses and recommendations: blue for normal operation, green for minor layout changes, yellow for potential performance issues, and red for significant errors.



Design Considerations

Overview

From our experience of developing and implementing the Control Tower monitoring platform, we have derived a series of broader considerations necessary for model monitoring to serve as generalized guidelines for future implementations. Central to these guidelines arose themes of feasibility, design, implementation, and policy. While existing frameworks have proven successful in managing long-term IT infrastructure projects in health care, ML models are experimental and inherently open systems, entailing costly development and maintenance. As such, they demand additional considerations due to their reliance not solely on technical data but also on statistical and clinical assessments to identify errors. Consequently, there is no unequivocal, predetermined signal that can be provided to an IT group lacking clinical or data science expertise to detect these errors. Identifying them often necessitates the accumulation of statistical data over time. While readily available and accessible data may be used to identify some errors, others may require weeks or months of new data collection to draw inferences. Furthermore, in traditional software operations, refinements can be implemented more quickly. Responding to user feedback can often be met with bug fixes or minor feature requests. However, implementing refinements to an ML model often requires a longer development cycle, as many changes will require a complete retraining of the model or the acquisition of novel data. Such complications in model maintenance underscore the need for input from multiple teams, alongside established structures and policies, to ensure effective orchestration of model maintenance.

Feasibility: Are the Resources to Facilitate Productive Monitoring Available?

Successful real-world implementation of models must consider the present and *future* bandwidth limitations of a team. In an ideal scenario, a team would be provided ongoing dedicated time or personnel to ensure the upkeep of deployed models. However, this is not always feasible, and the responsibility of maintenance competes with a team's constant stream of new projects and tasks. As such, it is important to first determine how long-term monitoring of a model (or eventually, *models*) will be integrated into the team's workflow. For example, who will check in on the model and with what frequency? If and when the model requires retraining, who will perform the retraining, and how will they be guaranteed the flexibility to shift from their current projects to accomplish this?

In addition to personnel, computational resources must also be considered for long-term monitoring. Regarding storage requirements, the amount of data produced from monitoring

depends on a variety of factors, including the model's feature set, the frequency of calls made to the model, and the number of feature and performance metrics that will be tracked. For example, a model that delivers constant, real-time feedback in a critical care setting may, in turn, require constant monitoring to ensure performance does not suddenly degrade, resulting in performance metrics and feature distribution logs needing to be generated continuously.

When assessing the feasibility of long-term monitoring, an attractive option to consider is automated monitoring: developing models that detect whether a significant change has occurred in a deployed model's predictions or its incoming data. While our team chose a "hands-on" approach, others have found success in implementing an additional model for performance monitoring to notify the team of data shifts and, in some cases, automatically retrain the original model [16]. Ultimately, the decision to use an automated monitoring model comes down to the type of model deployed, the bandwidth of the team, and the reliability of the data to support automatically retraining the deployed model. In any case, even an automated monitoring model will still require some human monitoring as well. Our team is currently working on an automated monitoring system for this purpose.

Design: Deciding What and How to Monitor?

Overview

The design of an investigative platform to facilitate model monitoring may range from dynamic and interactive interfaces to static reports, the choice of which is dependent on feasibility factors and nuances of the particular scenario, but design should ultimately enable rapid and comprehensive assessment. Furthermore, there are standard functionalities each platform should feature to appropriately assess long-term model performance.

Deployed models encounter performance declines through distributional and relational shifts in the underlying data [17]. These shifts are the crux of why postdeployment monitoring is necessary, and no model is immune to them, regardless of how well it performed in its testing environment [18]. This impediment has received a wealth of attention from the ML community and has been synthesized into 3 types of distinct shifts.

Prior Probability Shift

The distribution of the target variable Y changes between the training data and incoming data, but not P (X|Y) [19]. This can occur when the prevalence of a disease changes over time in the target population; however, the underlying factors that cause the disease remain constant, for example, a spike in influenza rates during the influenza season. Prior probability shift is assessed by monitoring the distribution of the target variable over time, measuring for any sudden or gradual changes.

Covariate Shift

Distributions of input data diverge between training data and new incoming data [4]. Such shifts may occur in the clinical setting, for example, when diagnostic screenings are updated. This procedural change may decrease the specific laboratory values, which are heavily relied upon by the model. Conversely, diagnostic variables that were initially infrequent may become more prevalent over time. This can result in situations where the model, which had limited instances of these variables during training, struggles to fully capture, and therefore use, their predictive signals.

Concept Drift

The relationship between the incoming input data and target variable changes over time, drifting from the original relationship captured in the training data [20]. The COVID-19 pandemic provided a real-world example of concept drift, as hospital census models were affected by admissions that drastically moved toward higher-risk patients due to increases in complications from the COVID-19 disease and decreases in hospital use among people with a milder spectrum of illness [21].

Usability

A successful UI will take into consideration the professional backgrounds of those using the platform. However, when the responsibilities of monitoring are handed to a different group, the new group's level of familiarity with the model should guide the design. For example, guidelines for what is acceptable variance should be established and implemented. One method for accomplishing this may be through using control charts, allowing the modeling team to prespecify a simple and visual approximation of how much drift is tolerable before action must be taken [22].

Implementation: How Will the Platform Be Built and Sustained?

When implementing a monitoring platform, it is necessary to consider how the back end of the platform will process and store the necessary data elements. The efficiency of this task is critical and must accommodate the model's scale and responsiveness. Data can amass quickly as large feature sets are monitored, and the model may be called frequently to predict on many patients throughout the day. Furthermore, the back end must be capable of efficiently parsing, formatting, and, if necessary, compressing the data into clean data sets for the platform to analyze and visualize. For Control Tower, many of these data storage requirements were already in place for capturing and storing the necessary patient elements. This will likely be the case for many clinical scenarios, as patient data must be securely and efficiently housed. Instead, implementation efforts are more apt to center around ensuring these data elements are efficiently piped to the monitoring platform.

Using a web application for model monitoring provides a dynamic interface, allowing any user with log-in permissions to view the real-time status of the model and the surrounding data. This investigation mechanism can eliminate potential confusion, which may arise from a routine generation and sharing of static technical reports, such as accidentally referencing outdated documents. When selecting a programming language to build the app, preference should be given to those languages that facilitate efficient app development. For Control Tower, R Shiny was used given the team's previous experience with the package and strong background in R. The R package

provides a user-friendly environment for quickly creating, testing, and publishing web applications. Similar web application tools exist across multiple programming languages including Python and Java, and as such, teams are likely to find a web application package in a language they are familiar with.

When coding the app, modular coding practices should be adopted to ensure flexibility and scalability. Such adoption promotes versatility of the app to incorporate additional statistical measures or visualizations and allows the app to be easily translated for other monitoring use cases. Leveraging modular coding practices at the onset of app development allows for future additions, revisions, and ports to be made with minimal effort. For Control Tower, modular coding practices were primarily used to better facilitate development across multiple team members. This practice allowed for functions to be easily repurposed by other team members to avoid duplication of work and to allow the app to be easily extended to other ML models within Mayo Clinic.

The number of programming languages used in the data pipeline plays a significant role in shaping the development process and the overall efficiency of the monitoring. To facilitate this, minimizing the number of programming languages used across the various tasks can streamline development and maintenance through ease of interpretability and integration. This can reduce maintenance costs and overhead by reducing interoperability concerns and decreasing the learning curve for new team members. Minimizing these ongoing costs is a necessity when considering the model will ideally be in production long term. However, if the development team is proficient in multiple languages, leveraging the strengths of each may have its advantages, such as reducing bottlenecks in development or data transfer, while increasing the flexibility of a system. In the case of Control Tower, R (R Foundation for Statistical Computing), Python (Python Software Foundation), and shell scripts were used, favoring R for app development, Python for data processing, and shell scripts for scheduling various model and platform tasks.

In addition, upstream problems will inevitably manifest; therefore, implementing a notification system for these errors can proactively address disruptions, minimizing the downtime of the pipeline. One method for accomplishing this is to incorporate error logging and alerts into cron jobs, which can immediately notify the team of any failures. Such notifications are critical for model monitoring, as some errors may be undetectable to the end user, resulting in the continued use of inaccurate information. As such, it is vital for monitoring teams to identify, communicate, and resolve errors as soon as possible.

Finally, integrating regular checking of the platform into the team workflow allowed the team to not only stay abreast of model performance but also maintain an intuitive sense of potential broader complications surrounding the model. For example, monitoring the probability distributions of the model ultimately provided the team with a sense of whether further investigations into the model would be necessary. However, investigations into the distributions of the individual features allowed for potential diagnoses as to why the model may begin to degrade in performance, as well as alluded to data pipeline errors that may be present. By maintaining a sense of these wider issues, shifts in the outcome could be more easily prevented and diagnosed

Policy: What Is the Response to Platform Feedback?

Overview

Once the monitoring platform is deployed and available, the next stage of considerations surrounds how knowledge provided by the platform will be used. A set of policies must be developed to determine which actions will be taken based on monitoring feedback, addressing such questions as “At what point is a data shift significant enough to prompt retraining?” and “How will errors be communicated with technical and clinical staff?” Generally, such a policy should cover error designation and response, when to retrain, and how to communicate failures. In addition, a well-defined policy allows for the task of monitoring to more easily be extended across various teams and roles.

Error Designation and Response

It is essential to establish and define a process that determines when a specific degree of shift or drift in the model qualifies as an error warranting a response. The question *“How much drift is necessary to take action?”* represents one of the more subjective aspects of model monitoring. In scenarios where multiple team members are tasked with overseeing model performance or possess limited familiarity with the model, substantial interrater variability becomes a concern. For example, one team member might observe a 5% shift in the distribution of a feature and consider it inconsequential, while another member might view it as a reason for immediate action. To address this variability, the Control Tower team would send email updates to other team members detailing any shifts that were noticed; this would allow for a collective discussion on whether to take action as well as allow for a convenient forum to keep all team members updated on the model’s status. Regardless of the criteria used to identify shifted covariates or outcomes, team members must communicate and establish agreement on the minimal drift threshold requiring action, while ensuring that utmost priority is placed on maintaining optimal model accuracy.

Even with consensus on the magnitude of a shift, several contextual factors can influence the team’s risk tolerance toward these shifts. Significant changes may occur without sustained trends, indicating a regression to the mean. Alternatively, a dramatic shift might happen for a variable with minimal contribution to the risk score. While predefined cutoff points could be considered to standardize investigations, these benchmarks may still necessitate ongoing human review and could vary for each feature, making it impractical to define for every feature in large feature sets.

Even if an error is defined with a certain level of risk in mind, there are considerations in the response to the error and the amount of time one needs to allocate for remediation. A deployed model is prone to errors from a variety of sources, ranging from data shifts to IT scheme modifications. Given the diversity of potential errors, an effective policy will include guidelines for the categorization of errors along with the

appropriate responses to each. The errors encountered with Control Tower fell broadly into 4 categories.

1. Technical infrastructure: database issues, expiration of certificates, and password updates often causing the pipeline to fail
2. Explained shift: a significant data shift with an identified root cause
3. Unexplained shift: a significant data shift with an unidentified root cause
4. Performance loss: a decrease in the model's performance metrics, which may manifest with or without data shift

Categorizing errors for appropriate response is crucial, as it establishes a standardized knowledge base for reporting, ultimately enhancing the efficiency of troubleshooting. Categorization often leads to the discovery of similar strategies for mitigating similar error types. For instance, errors related to database refreshing or password expiration typically do not require immediate intervention, while performance losses in accuracy or calibration often necessitate retraining of the model. Appropriate categorization also offers the advantage of reducing risk tolerance while enhancing response efficiency. Having encountered an error previously increases the likelihood of streamlining investigations, enabling the examination of lower-risk shifts or drifts.

When ongoing outcomes data are available, performance loss can be detected by looking for significant shifts across a variety of classification performance metrics including area under the receiver operating characteristic, area under the precision-recall curve, calibration, subgroup differences, and so on. When such data are absent, as in the case of Control Tower, performance loss can only be inferred by looking for significant shifts in the distribution of predicted probabilities of the model. To supplement assessing predicted probabilities, potential performance loss may also be identified by looking for significant shifts in the features of the model. While significant shifts may occur in these features without significant shifts in the model's output, drifts in feature distributions can signal other potential problems necessary to address. While performance loss may be resolved or mitigated through upstream pipeline errors, some instances may require the model to be retrained.

Model Retraining

The circumstances for when to retrain a model will vary across teams and platforms, often dependent on the cost of retraining. As such, it is necessary for a platform policy to clearly state when, and when not, to retrain. For example, many errors will not require model retraining such as simple pipeline errors or data shifts due to changes in medical coding, requiring only a small update to the pipeline. Therefore, it is important to first identify and fix any upstream errors before considering retraining. There are even instances of significant shifts that do not warrant retraining. For example, one could have several shifted covariates in the model with trivial importance scores, effectively having no impact on predictive performance. From the perspective of model importance, one may bin covariates that have little impact and essentially treat them as nuisance variables.

Assuming no upstream errors are present, a model should always be retrained when significant and sustained performance loss is encountered. Defining *significant* and *sustained* will be specific to each scenario, depending on the algorithm and health care delivery model. However, it is incumbent upon the team to define an appropriate window for performance to vary, with a lower limit triggering retraining.

It is important to note that retraining does not have to be used sparingly, assuming the bandwidth is available. When feasible, it may be good practice to routinely retrain the model with the expectation that updated data are more current with clinical practice. Such versioning of the model would allow for new features, incremental improvements, and technical debt management. For Control Tower, versioning allowed us to spot potential bugs or fixes and investigate new features.

Communicating With Clinical Staff

The clinical team using the model's outputs must be consistently informed about the model's status due to its significance to their workflow and overall trust in the model. The model's standard operating procedure outlines how the clinical team should use the model and details communication protocols between IT, data science, and the clinical users. Protocols should consist of dedicated contacts for various issues and plans for how to operate during model performance shifts and downtime.

Discussion

Principal Findings

As ML models require consistent monitoring to ensure sustained accuracy, a series of decisions must be made for how best to integrate model monitoring into a team's workflow. Problems, considerations, and solutions that arise from this process can vary greatly depending on the setting, nature of the model, and available bandwidth, both from the technical team and their computational resources. While prior work has established the importance of monitoring and corresponding statistical solutions, this paper provides specific considerations and solutions derived from the real-world implementation and day-to-day use [23,24]. Throughout the integration of Control Tower, our team found that these considerations centered around 4 phases that serve as a road map when planning a long-term modeling strategy: feasibility, design, implementation, and policy.

Experiences

Development and implementation of the platform faced several obstacles, which we attribute to the inherent realities of integrating real-world applications. First, the team was unable to complete the platform by the time the associated clinical trial for the Control Tower model began recruitment. This required the team to omit crucial features from the platform, such as monitoring for concept drift. Monitoring concept drift required collecting ground truth outcomes, that is, whether patients actually received palliative care. Collecting these patient outcomes required building a separate data pipeline, which was the team's original intent, but as the team took on additional tasks, the pipeline was passed over in favor of monitoring predicted probabilities. While omitted from Control Tower in scenarios where outcomes data are tracked, we direct the readers

to literature providing a more comprehensive understanding of concept drift [25-27].

The original intention for Control Tower was to have the model run any time a patient's laboratory values were updated, ensuring that the patient's risk scores were always reflective of current data. While the model was originally deployed using this dynamic system, it, unfortunately, proved too taxing for the IT infrastructure in which it was hosted. To alleviate this problem, the model and platform were switched to running on a batch schedule, updating patient risk scores and the monitoring platform every 4 hours. While this delivery schedule proved more manageable, model calls made between these 4-hour updates ran the risk of using outdated patient data, potentially impacting performance. Given that the workload imposed by the original schedule was infeasible, this was considered a fair compromise. Finally, the implementation of the platform occurred during the COVID-19 pandemic, which affected staffing and resulted in IT furloughs. Unfortunately, this meant that technical infrastructure problems, which could typically be fixed by IT on the same day, instead, took up to 1 week to fix, resulting in prolonged downtime for the model.

Despite these challenges, there were several positive experiences to highlight. First, a significant amount of collaboration occurred within the data science team in order to have the monitoring platform in a usable state by the time of the model's clinical trial. This required analysts to tend to a variety of tasks, often on a moment's notice. Following deployment, there was also sufficient bandwidth from the team members to continue monitoring the platform as they took on additional projects. Second, IT furloughs as a result of the pandemic were resolved within 6 months, allowing routine technical infrastructure issues to once again be resolved on the day of occurrence, resulting in less model downtime. Finally, the model's predicted probabilities remained, for the most part, consistent, making for a stable tool throughout the documented 2 years of use. Using a simple linear regression model, we examined the relationship between daily predicted probabilities (dependent variable) and time since deployment (independent variable), observing a slope of 0.005 at a P value of <.001, suggesting a statistically significant, but functionally small trend, with the mean probability increasing .005% each day.

Limitations

Despite a thorough detailing of our experiences, it is important to note that this paper covers only a single implementation. While we have recounted the challenges and considerations necessary for Control Tower, this is not an exhaustive list, and other teams and platforms may encounter challenges foreign to ours.

Future Considerations

The Control Tower platform allowed our team to successfully monitor performance and maintain our deployed model for 2 years. Moving forward, our team is planning to automate parts of this task, for example, by implementing an automated email notification system, notifying the team when the number of model calls, predicted probabilities, and incoming data streams shift beyond their respective significance thresholds. While this modification is not intended to outright replace the manual checks of the platform, it will allow the team to check the platform at a lesser frequency. This system will serve as a placeholder while the team develops a new model to monitoring the performance of Control Tower, leveraging supervised learning to detect shifts in the probability and multivariate covariate distributions [28,29].

The team also considered an online or continuous learning model to automatically address data drift. In continuous learning, the algorithm would update its predictions as new data come in and alleviates the need to manually retrain the data [30]. Although appealing, an automated system, in this sense, would require more policy changes and would bring with it a number of issues. First, there are several cost and computing issues that could make an implementation difficult, as entire systems would need to know when to train and to do it without interrupting the current pipeline, as well as a validation step to ensure sustained, if not improved, accuracy. Second, the algorithm must remain trustworthy for clinicians. Did the algorithm *unlearn* anything important? Did it learn anything irrelevant or incorrect? As an example, if a covariate shift occurred due to a missing laboratory code, resulting in increasingly missing values of that laboratory, we would not want the model to learn a new relationship with the missingness; instead, we would make an update to the data pipeline to resolve the missingness. Finally, all continuous learning models require ready access to the gold-standard outcome, which might not be feasible in all cases.

Conclusions

Once an ML model has been successfully developed and deployed, it must be continuously monitored to ensure its efficacy amidst an ever-evolving practice and stream of patients. While a variety of methods have been proposed to statistically monitor the performance of models, this is only one factor to consider when implementing a long-term modeling strategy. By disseminating the broader experiences of integrating ML monitoring platforms into clinical practice, readers will be better equipped for the considerations and challenges encountered during their own implementations.

Abstract

The economic trend and the health care landscape are rapidly evolving across Asia. Effective real-world data (RWD) for regulatory and clinical decision-making is a crucial milestone associated with this evolution. This necessitates a critical evaluation of RWD generation within distinct nations for the use of various RWD warehouses in the generation of real-world evidence (RWE). In this article, we outline the RWD generation trends for 2 contrasting nation archetypes: “Solo Scholars”—nations with relatively self-sufficient RWD research systems—and “Global Collaborators”—countries largely reliant on international infrastructures for RWD generation. The key trends and patterns in RWD generation, country-specific insights into the predominant databases used in each country to produce RWE, and insights into the broader landscape of RWD database use across these countries are discussed. Conclusively, the data point out the heterogeneous nature of RWD generation practices across 10 different Asian nations and advocate for strategic enhancements in data harmonization. The evidence highlights the imperative for improved database integration and the establishment of standardized protocols and infrastructure for leveraging electronic medical records (EMR) in streamlining RWD acquisition. The clinical data analysis and reporting system of Hong Kong is an excellent example of a successful EMR system that showcases the capacity of integrated robust EMR platforms to consolidate and produce diverse RWE. This, in turn, can potentially reduce the necessity for reliance on numerous condition-specific local and global registries or limited and largely unavailable medical insurance or claims databases in most Asian nations. Linking health technology assessment processes with open data initiatives such as the Observational Medical Outcomes Partnership Common Data Model and the Observational Health Data Sciences and Informatics could enable the leveraging of global data resources to inform local decision-making. Advancing such initiatives is crucial for reinforcing health care frameworks in resource-limited settings and advancing toward cohesive, evidence-driven health care policy and improved patient outcomes in the region.

KEYWORDS

Asia; electronic medical records; EMR; health care databases; health technology assessment; HTA; real-world data; real-world evidence

Introduction

Real-world data (RWD) in medical and health research describes data relating to patients’ health status or the delivery of health care in an environment outside of conventional clinical trials. This includes data routinely collected for treatment and disease registries, electronic medical records (EMRs), insurance claims, and other health databases that collect information reported by patients or health care professionals [1,2]. Extending from this concept of RWD is real-world evidence (RWE), which is the analyses produced from appropriate, well-designed studies using RWD [3].

In randomized controlled trials, patients with severe forms of disease or multiple comorbidities are typically excluded from

participating due to potential risks or adverse events [2]. This leads to a large number of underrepresented patients, reducing the generalizability of interventions in the population, particularly for those who may need it most. RWD can provide the external validity needed when exploring different interventions and treatment strategies across the health care system [2]. To provide external validity for different interventions and disease management strategies, different study styles are used for RWD generation. These can be broadly categorized as comparative effectiveness research (CER) and descriptive studies (non-CER) [4]. CER can be defined as studies that primarily compare interventions and strategies, while non-CER are observational studies that aim to provide a descriptive overview of factors such as disease prevalence or treatment patterns [4,5].

Two scoping reviews have been conducted to explore the spectrum of RWE from linked databases in Asia and their possible impact on health care evolution, strategy, and policy [6,7]. The literature search for these reviews was conducted on PubMed in September 2022 and May 2023, and analysis of RWD publications across these countries assumed a linear distribution of studies [6,7]. In the initial scoping review, the trends and research warehouses for RWD-published studies from 3 countries in Asia with varying health care systems, Taiwan, India, and Thailand, were evaluated. The second scoping review continued this explorative research in 7 other diverse Asian health care systems using the established protocol from the prior review [4,7]. This study aimed to understand the evolving landscape of RWD use and its implications across Hong Kong, Indonesia, Malaysia, Pakistan, the Philippines, Singapore, and Vietnam. The number of total publications and single-country studies (SCS) and cross-country collaboration studies (CCCS) from all the countries in these scoping reviews was used to archetype them as either “Solo Scholars” if they published predominantly SCS with relatively higher number of studies published in last 5 years or “Global Collaborators” if they published less numbers and predominantly CCCS [7]. Hong Kong, India, Malaysia, Singapore, Taiwan, and Thailand were categorized as Solo Scholars, and Indonesia, Pakistan, the Philippines, and Vietnam were categorized as Global Collaborators (Multimedia Appendix 1).

Using these archetypes generated from the 2 scoping reviews, this viewpoint review intends to evaluate evolving trends and patterns in the use of various RWD warehouses and contextualize these findings within the broader health care and economic trends. Studying these evolving trends is crucial as it helps understand how RWD warehouses are generating RWE, which in turn informs health care policy and economic decisions [8]. Health technology assessment (HTA) organizations evaluate the clinical and economic aspects of medicines and health care technologies and recommend reimbursement and other policy criteria. Country HTAs are increasingly incorporating RWE for crucial complementary evidence, particularly in cost-effectiveness analyses [8,9]. However, data accessibility issues, lack of knowledge on robust methodologies, and a shortage of qualified researchers limit the generation of RWE for regulatory and reimbursement decision-making [10]. Our selection of countries for this scoping review was strategically based on the contrasting spectrum of HTA expertise at different timelines of development, from relatively mature systems in Taiwan, Singapore, Hong Kong, Malaysia, and Thailand to emerging frameworks in India, Indonesia, the Philippines, and Vietnam, and nascent systems in Pakistan (Figure 1).

Country Trends and Key Identified Databases for 10 Asian Countries

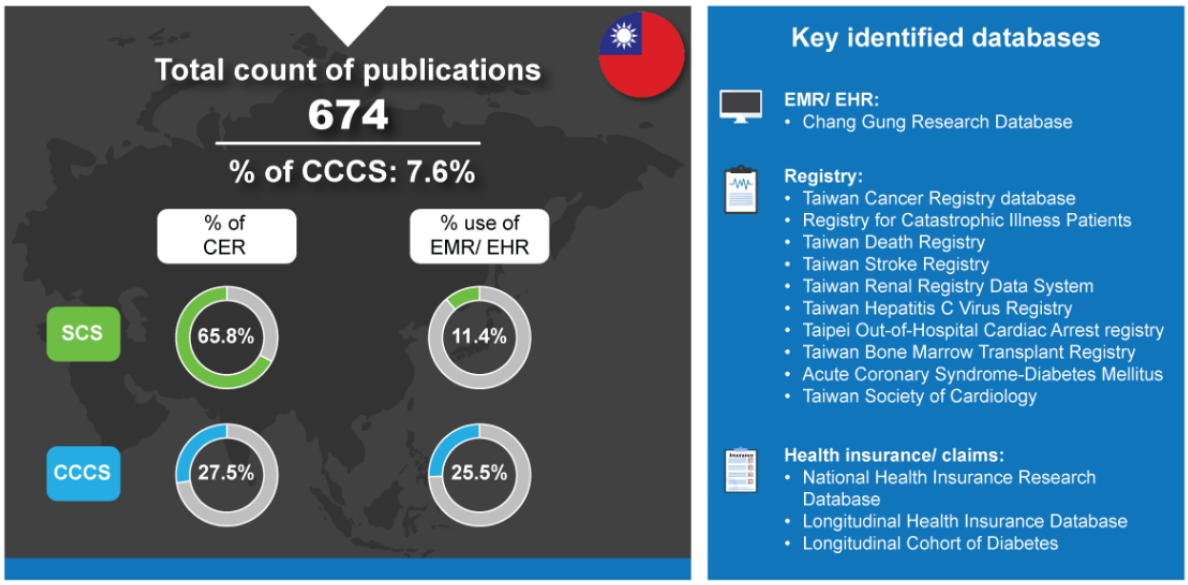
Harnessing RWD is pivotal for improving health care outcomes, and understanding country-specific trends and the databases that underpin this research is crucial [11,12]. The following section provides a granular view of the health care and RWD landscape across 10 Asian countries, dissecting the trends in research publications and the key linked databases that have been pivotal in generating RWE (Multimedia Appendix 2 [13-20]). Countries are listed in order of highest to lowest counts of generated RWD publications in the last few years [6,7].

Solo Scholars

Taiwan

Taiwan is a thriving democracy with a population of 23.3 million and a prosperous market economy. Taiwan's gross domestic product (GDP) grew by 2.45% in 2022 [21]. Development of the digital infrastructure in health care is one of the Taiwan government's major goals in the next few years [22]. Although there seems a lower overall usage of EMRs or electronic health records (EHRs) in SCS for Taiwan (71/623, 11.4%) (Figure 2), there was a noticeable increase in their usage from 2.8% (1/36) to 19.4% (20/103) from 2017 to 2022 [6]. As shown in Figure 2, Taiwan has a high percentage of CER in their SCS (410/623, 65.8%). Inversely, the trend for higher CER is not seen in the CCCS (14/51, 27.5%).

Figure 2. Real-world data landscape for Taiwan (2017-2022). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



Taiwan has a robust health care system, which is reflected in the percentages describing their RWD publications. Following the creation of the National Health Insurance (NHI) in 1995, Taiwan has set a benchmark in the region with a successful universal health coverage (UHC) scheme in their health care system [23]. Enrollment in the NHI provides coverage for essential medical care and pharmaceuticals for all residents [24]. The success of this system is exemplified in Taiwan's favorable result on the world's health and health systems ranking in 2023 [25], on which they were placed fourth (based on the Legatum Prosperity Index that also accounts for economic and social well-being). Furthermore, most health care facilities in Taiwan upload the claims data of each visit to NHI, including patient visits, drug prescriptions, surgeries, and examinations [23]. However, Taiwan's NHI has changed since its creation in 1995 and continues to evolve [26]. In 2007, Taiwan implemented its HTA within their Centre for Drug Evaluation to evaluate the financial suitability and clinical effectiveness of new drugs for reimbursement decisions [27]. This evolved into the formation of the Division of HTA in 2008 [28]. The high proportion of NHI drug expenses was a huge burden on Taiwan's health care system, and there were general recommendations to have a reduction in drug expenditure [29]. As such, with this goal of reducing drug expenditures, some behind-the-counter products were delisted from Taiwan's national Drug Reimbursement Scheme [23]. Along with this, coverage change was aimed at reshaping patient expectations and attitudes toward health. Taiwan's vision for 2030 includes "precision health," which places an important focus on health promotion. This concept of precision health involves using data to gather sufficient information that can be used to predict health risks and prevent diseases at the population level [30]. This vision relies on adopting descriptive RWD to produce RWE that can aid in the refinement of specific health policies that contribute to precision health and less comparative research. This also partially explains why there was a decrease in the publication of CER studies most notably from 75% in 2018 to 60% in 2022 [6]. It is worth noting that the literature search on the publication of RWE from linked databases in Taiwan was conducted in September 2022 on PubMed, and the analysis assumed a linear distribution for studies in 2017 and 2022.

Taiwan stands out as a significant contributor to RWD studies in Asia, predominantly through SCS, because it employs a diverse array of databases and holds a wealth of insurance claims data.

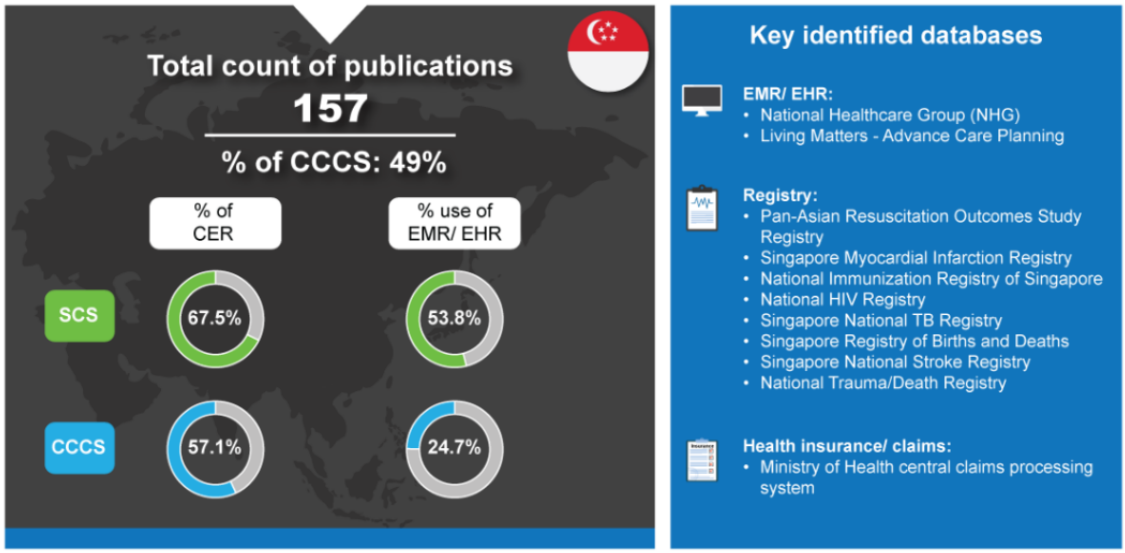
The key identified databases contributing to RWD publications included the following [6]:

- *Chang Gung Research Database (CGRD)*: CGRD is a multi-institutional EMR database collected from the Chang Gung Memorial Hospital system, which is the largest medical system in Taiwan [31]. Except for 2 municipal hospitals, all EMR data from Chang Gung Memorial Hospital are included in the CGRD. The database includes approximately 6%-20% outpatient and 10%-12% inpatient claims records [32,33].
- *Taiwan Cancer Registry (TCR) Database*: TCR was developed to monitor cancer incidence at the national level. The TCR holds basic information on patients with newly diagnosed cancer from hospitals with >50 beds throughout the country [34].
- *Registry for Catastrophic Illness Patients*: It is associated with the National Health Insurance Research Database (NHIRD) and is used to identify patients with catastrophic illness in the Taiwan health insurance system [35].
- *Taiwan Death Registry*: It contains information on accurate causes of death and dates for all residents of Taiwan [36].
- *Taiwan Stroke Registry*: This is a nationwide hospital-based registry that enrolls patients with stroke from 19 academic medical centers, 37 regional hospitals, and 8 district hospitals. The data are collected prospectively by trained neurologists and study nurses [37].
- *Taiwan Renal Registry Data System*: It collects patients' clinical and laboratory information from all dialysis units in Taiwan [38].
- *Taiwan Hepatitis C Virus Registry*: This registry program is a nationwide hepatitis C virus platform implemented by the Taiwan Association for the Study of the Liver [39].
- *Taipei Out-of-Hospital Cardiac Arrest Registry*: It includes prehospital and hospital information on patients with out-of-hospital cardiac arrest in Taipei [40].
- *Taiwan Bone Marrow Transplant Registry*: This registry holds clinical data from consecutive allogeneic hematopoietic cell transplant recipients from 15 transplant centers in Taiwan [41].
- *Acute Coronary Syndrome-Diabetes Mellitus Registry*: It is a nationwide registry of patients with acute coronary syndrome in Taiwan that collects real-world clinical practices and outcomes data [42].
- *Taiwan Society of Cardiology Registry*: This registry collects data from patients at 21 medical centers or teaching hospitals in Taiwan from patients who are hospitalized with acute new-onset heart failure or acute decompensated chronic heart failure with a reduced ejection fraction [43].
- *NHIRD*: It covers >99.6% of the Taiwanese population and collects claims data from outpatient and inpatient hospital care settings [26].
- *Longitudinal Health Insurance Database*: This database is derived from the NHI system and includes the registration files and original reimbursement claims of a million randomly selected beneficiaries, under the NHI program [44].
- *Longitudinal Cohort of Diabetes*: This is a de-identified subset of data from the NHIRD [45].

Singapore

Singapore is a prosperous nation with one of the highest GDP per capita in Asia. In 2022, Singapore's GDP grew by 3.6% [46]. In 2023, the Singapore government announced the plan to spend US $2.5 billion on info-communications technology with the redevelopment of major hospitals [47]. Compared with Taiwan, Singapore relies on higher use of EMRs or EHRs for real-world SCS (43/80, 53.8%), which is balanced with their use of clinical registries (46/80, 57.5%) [7]. Although Singapore SCS was predominantly in CER style (54/80, 67.5%), unlike Taiwan, the percentage of CCCS publications remained relatively high (57/77, 57.1%; Figure 3).

Figure 3. Real-world data landscape for Singapore (2018-2023). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies; TB: tuberculosis.



In 2023, Singapore was regarded as top-ranking in the world's health and health systems, 3 places ahead of Taiwan [25]. Despite emerging issues surrounding health care services and the affordability of health care, Singapore is able to achieve good health outcomes with a health index score of 86.9 through a hybrid public and private health care model that is dominated by public hospitals in the hospital sector and private clinics in the outpatient sector [25,48]. Trusted Research and Real World Data Utilization or TRUST platform stands as the cornerstone for national data exchange in Singapore by facilitating the secure and anonymized sharing of health-related RWD between public and private health care sectors [49]. The Ministry of Health (MOH) aimed to increase health care capacity to enhance health care affordability in the Healthcare 2020 Masterplan [50]. Within the MOH, the Agency for Care Effectiveness was established in 2015 as the national HTA agency with the aim of evaluating drugs for subsidization and medical technologies [51,52]. This may partially explain Singapore's relatively high percentage of CER publications in both SCS and CCCS, particularly as these types of studies enable a comparison of different medications and health management strategies. This is further magnified by the observation that the percentage of SCS CER publications from Singapore increased from 2018 to 2023 (analysis of these publications assumed a linear distribution for studies in 2018 and 2023) [7].

The key identified databases contributing to RWD publications from Singapore included the following [7]:

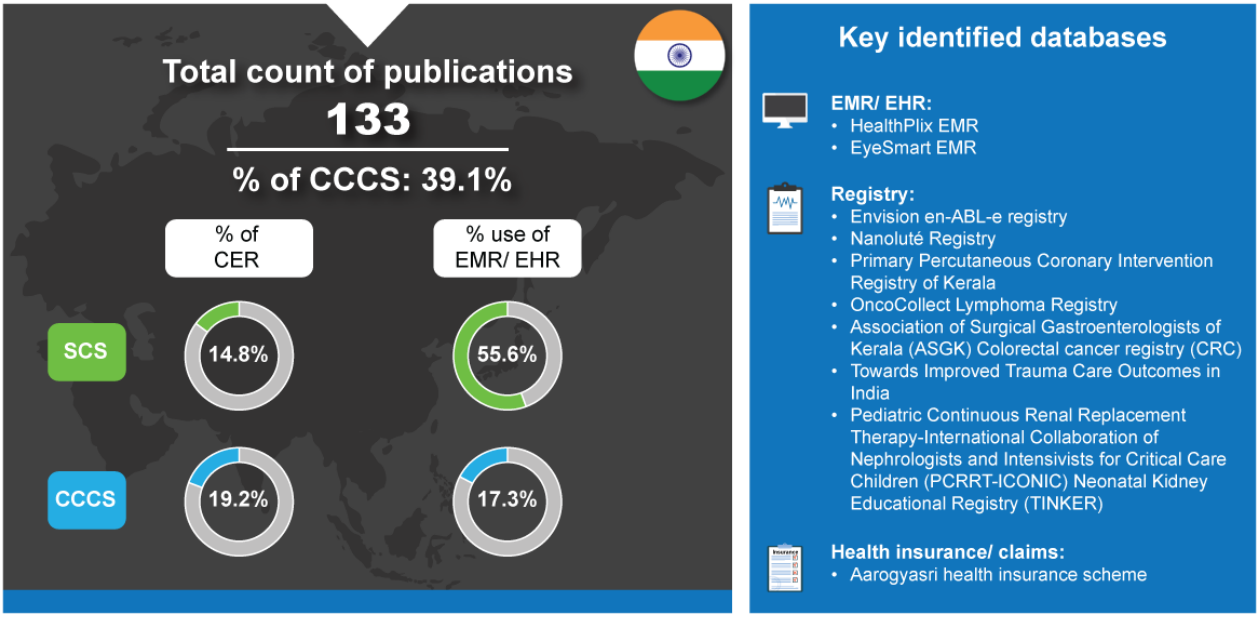
- *National Healthcare Group*: This record links key administrative and clinical information from a group of National Healthcare Group health care institutions for patients with chronic diseases such as diabetes mellitus, hypertension, dyslipidemia, stroke, cardiovascular diseases, and chronic renal disease [53].
- *Living Matters—Advance Care Planning (ACP)*: This framework provides a comprehensive web-based resource about ACP, including options for documenting patients' care preferences, particularly valuable in emergencies or when making critical care decisions. ACP details are also integrated into EMR or EHR, and all health care providers involved in patient care can easily access and understand a patient's end-of-life care preferences [54].
- *Pan-Asian Resuscitation Outcomes Study Registry*: The Pan-Asian Resuscitation Outcomes Study registry contains information from dispatch centers, ambulances, and hospitals from 7 countries in the Asia Pacific region (Japan, South Korea, Taiwan, Thailand, United Arab Emirates-Dubai, Singapore, and Malaysia) [55].
- *Singapore Myocardial Infarction Registry*: It is an island-wide registry that is being managed by the National Registry of Diseases Office that contains epidemiological data on acute myocardial infarction cases diagnosed in public and private sector hospitals and some out-of-hospital deaths certified by medical practitioners in Singapore [56].
- *National Immunization Registry of Singapore*: This registry collects and maintains accurate, complete, and current vaccination records of children and adults living in Singapore [57].
- *National Human Immunodeficiency Virus Registry*: This registry is a name - based system that holds identifiable data for known human immunodeficiency virus cases in Singapore, as well as contacts of cases that were reported [58].
- *Singapore National Tuberculosis Registry*: This registry is electronically linked to the 2 mycobacterial culture laboratories in Singapore and captures all positive Mycobacterium tuberculosis complex culture results in the country [59].
- *Singapore Registry of Births and Deaths*: This death registry is maintained by the Ministry of Home Affairs Immigration and Checkpoints Authority. It collects data on the cause and date of death of all Singaporeans and permanent residents in Singapore [60].
- *Singapore National Stroke Registry*: This is a countrywide registry of risk factors, stroke subtypes, management, and outcomes of incident and recurrent stroke in Singapore [61].
- *National Trauma/Death Registry*: This is a registry that contains anatomical injury codes, indicators of physiological response to injury, and patient demographics [62].
- *MOH's Central Claims Processing System*: It is used in Singapore to process the patient's MediSave and MediShield claims [63].

India

India is the largest lower-middle-income country in the world and accounts for around 18% of the total population [64]. According to Nexdigm, the Indian health care industry is expected to reach more than US $610 billion by 2026, as there is a growing demand for specialized and higher-quality health care facilities [65]. Hospitals, clinical trials, telemedicine, medical tourism, medical devices, medical and diagnostic equipment, and health insurance are among the key products and services that would drive this growth [66].

Compared with Taiwan and Singapore, India has a less extensive health care system [25], which is also reflected in its comparatively lower percentage of SCS (12/81, 14.8%) and CCCS (10/52, 19.2%; Figure 4). India attracts a growing medical tourism market with a growth of 22%-25% from 2014 and advocacy for adoption of EMR across the country [67]. Among RWD databases, the studies primarily use EHR or EMR (45/81, 55.6%), with an increasing trend from 20% in 2017 to 48% in 2022 [6]. Its usage is expected to continue to rise with the National Digital Health Mission, since 2020 [68]. India has made commitments toward achieving UHC and has been producing policies and institutional changes that are directed toward increasing health coverage and access to health services [69]. Government-funded health care sector is the provider of health care to lower-income populations; however, the private health care sector is the dominant health care provider [70]. In 2020, 70% of hospital market share was controlled by private sector providers, and 63% of hospital beds were provided by the hospital sector [71,72].

Figure 4. Real-world data landscape for India (2017-2022). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



India launched Ayushman Bharat—one of the most ambitious health missions ever to achieve UHC in 2018 [73]. Ayushman Bharat encompasses 2 complementary schemes, Health and Wellness Centres and the National Health Protection Scheme [69]. Along with this, there have been other initiatives to achieve UHC [69]. The Pradhan Mantri Jan Arogya Yojana scheme provides secondary and tertiary hospital care insurance to the bottom 40% of the population [68]. Previously called the "Medical Technology Assessment Board," HTAIn, founded in 2017, is the HTA agency within the Ministry of Health and Family Welfare tasked with developing an HTA system to aid in decision-making for resource allocation at the national and state levels [74,75]. Reflecting these policy aims, the proportion of CER for SCS and CCCS was low in India but increased from 2017 to 2022 (12/81, 14.8% and 10/52, 19.2%, respectively, Figure 4), assuming a linear distribution for studies in 2017 and 2022 [6].

The key identified databases contributing to RWD publications from India included the following [6]:

- *HealthPlix EMR*: This is an artificial intelligence–powered electronic medical software system in India [76].
- *EyeSmart EMR*: This is an EMR and Hospital Management System in India that integrates the clinical, surgical, financial, and operational functions of the LV Prasad Eye Institute on a single platform [77].
- *Envision en-ABL-e Registry*: This was a multicenter registry that enrolled 2500 patients treated with 3286 Abluminus DES (Envision Scientific, Surat, India) across 31 centers across the country from June 2012 to December 2018 [78].
- *Nanoluté Registry*: Nanoluté registry was used to observe the clinical performance of a novel sirolimus-coated balloon (Concept Medical Research Private Limited, India) for treating coronary de novo and restenotic lesions [79].
- *Primary Percutaneous Coronary Intervention Registry of Kerala*: This registry is a large multicenter primary percutaneous coronary intervention registry from Kerala, India. It reports long‐term outcomes of patients presenting with ST‐segment–elevation myocardial infarction to percutaneous coronary intervention–capable hospitals or facilities [80].
- *OncoCollect Lymphoma Registry*: This registry was set up in 2017 as a collaborative group effort to evaluate current practices for managing diffuse large B-cell lymphoma in middle-income countries [81].
- *Association of Surgical Gastroenterologists of Kerala Colorectal Cancer Registry*: This registry collects demographics and perioperative outcomes of colorectal cancer in Kerala from volunteer members of the Association of Surgical Gastroenterologists of Kerala [82].
- *Towards Improved Trauma Care Outcomes in India*: It is a multicenter trauma registry that contains data on trauma patients admitted to 4 public university hospitals in Mumbai, Delhi, and Kolkata from October 1, 2013, to September 30, 2015 [83].
- *The Indian Pediatric Continuous Renal Replacement Therapy-International Collaboration of Nephrologists and Intensivists for Critical Care Children Neonatal Kidney Educational Registry*: This registry is a database of all admitted neonates ≤28 days who received intravenous fluids for at least 48 hours [84].
- *Aarogyasri Health Insurance Scheme*: This is a social insurance scheme with a private-public partnership model to deal with the problems of medical expenditures for poor households [85].

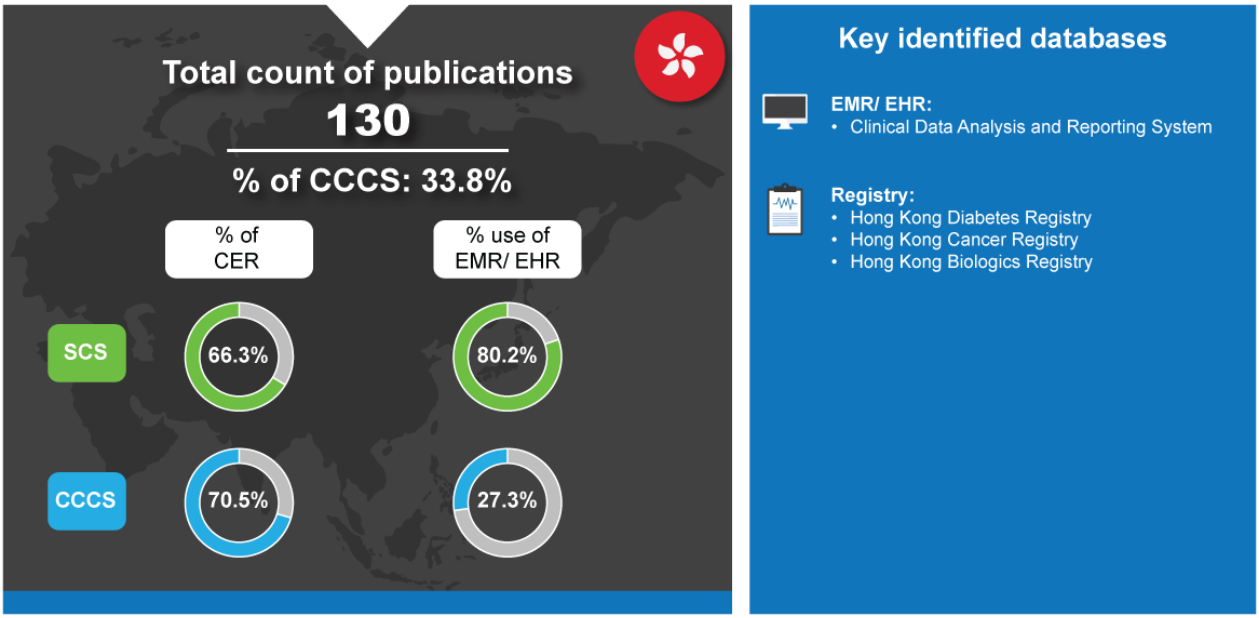
Hong Kong

Health care services in Hong Kong are provided by both private and government-funded public sectors, with public medical services provided by the Department of Health and the Hong Kong Hospital Authority (HA) [86]. Hong Kong has a well-developed health care system that ranked 14th among the health and health systems ranking of countries worldwide in 2023 [25]. Hong Kong's system is a parallel, segmented public

and private financed and provided health care, where the public sector accounted for 51% of total health expenditure and the private sector accounted for 49% in 2017/18 [87]. With the government's commitment to provide UHC, the Drug Advisory Committee is used to evaluate and advise on new drugs listed on the Hospital Authority Drug Formulary, which is the largest public health care service provider in Hong Kong. One of the missions of the Drug Advisory Committee is to ensure equal access of patients to cost-effective drugs with proven safety and efficacy [88].

As shown in Figure 5, CER publications made up 66.3% (57/86) of SCS publications and 70.5% (31/44) of CCCS. To put these high percentages into context, the drug appraisal and review process involves an assessment of clinical evidence and health economic evidence that is then used to make recommendations on reimbursement of new drugs [89]. In Hong Kong, there has been an increase in the requirement for a systematic HTA, placing emphasis on the value and comparison of emerging and conventional drugs [88]. In line with this, there is an upward trend in the percentage of SCS CER publications for Hong Kong from 2018 to 2023, assuming a linear distribution for studies in 2018 and 2023 [7].

Figure 5. Real-world data landscape for Hong Kong (2018-2023). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



The key identified databases contributing to RWD publications from Hong Kong included the following [7]:

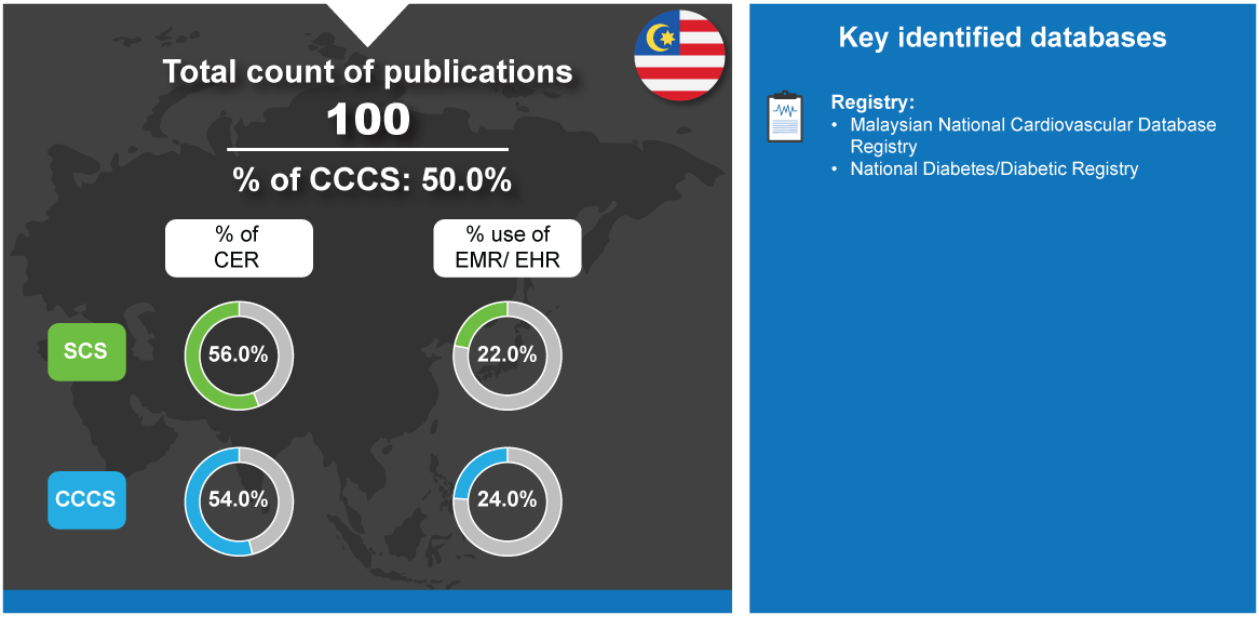
- *Clinical Data Analysis and Reporting System (CDARS)*: CDARS is a centralized database developed for research and audit purposes. It is managed by the HA. It collects anonymized records of demographics, admission, prescription, diagnosis, procedure, laboratory test, and death information [90].
- *Hong Kong Diabetes Registry*: This is a diabetes registry used for quality assurance and risk stratification to facilitate subsequent triage of patients to different clinic settings [91].
- *Hong Kong Cancer Registry*: This is a population-based registry committed to collecting and conducting analyses on data from all cancer cases in Hong Kong [92].
- *Hong Kong Biologics Registry*: This is a registry that was established in December 2005 by The Hong Kong Society of Rheumatology to capture efficacy and safety data regarding the use of biological agents for the treatment of rheumatic disease [93].

Malaysia

Malaysia is an upper-middle-income country with a population of about 34 million [94]. It is located at the heart of Southeast Asia and represents one of the regional hubs for information and communication technology and medical travel [95]. Digitalization of information forms across major industrial sectors will help secure Malaysia's role in the future global economy. As of 2023, Malaysia was ranked 42nd on the health and health systems of countries worldwide [25]. Malaysia's health care system consists of tax-funded and highly subsidized government-led services, with a fast-growing private sector [96]. Their dual-tier system consists of a government-led public sector with an existing private sector, and in 2019, their public health expenditure amounted to 52% of their total health expenditure.

Malaysia's 2023 Health White Paper outlines a transformative masterplan for health management information and data system [97]. They aim to improve the health outcomes and well-being of Malaysians and the use of the Malaysian Health Technology Assessment, also termed as MaHTAS. HTA has been formalized in Malaysia as a central structure within the MOH since 1995 and is a trusted medical evidence source [97]. Their generation of RWD publication used registries, with no, or low contributions from other database types [7] (Figure 6). In line with other countries that use HTA, 56% (28/50) of SCS were CER, as were 54% (27/50) of the CCCS [7].

Figure 6. Real-world data landscape for Malaysia (2018-2023). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



The key identified databases contributing to RWD publications from Malaysia included the following [7]:

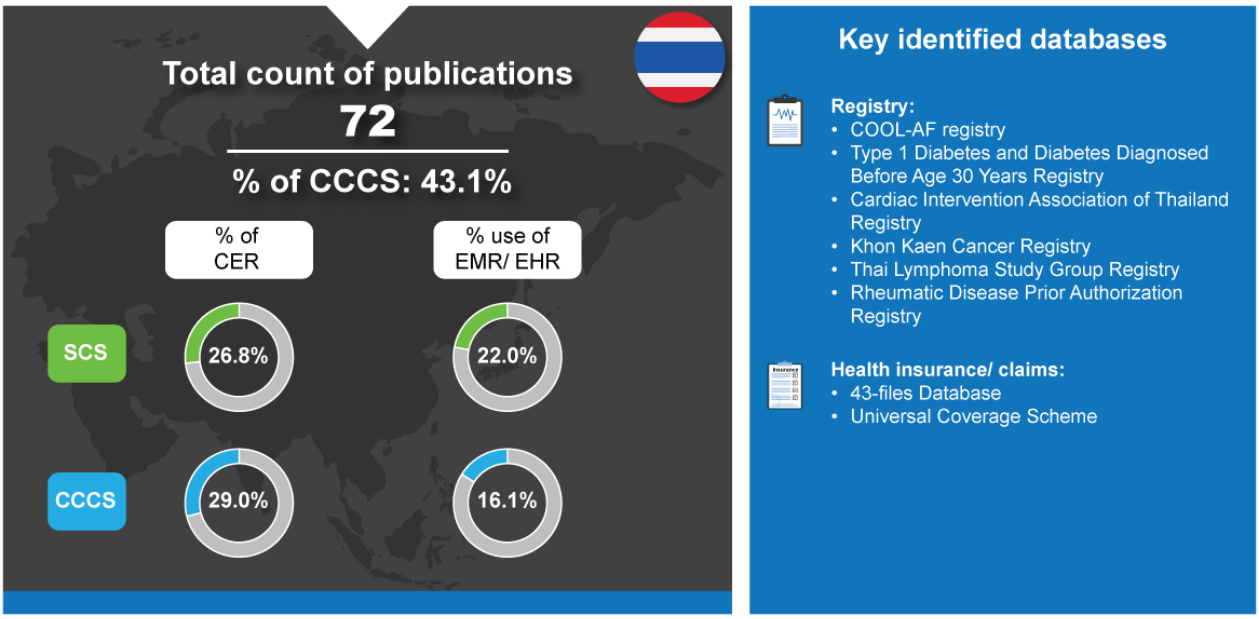
- *Malaysian National Cardiovascular Database Registry*: This is a service supported by the Malaysian MOH to collect information about cardiovascular diseases [98].
- *National Diabetes/Diabetic Registry*: This is a registry used to enable tracking of glycemic control and clinical outcomes of patients with diabetes managed at MOH health clinics [99].

Thailand

Thailand is also an upper-middle-income country but with the second largest economy (after Indonesia) in the Association of Southeast Asian Nations (ASEAN). Its GDP in 2022 was US $526 billion [100]. Thailand has the fourth greatest number of Joint Commission International accreditation–certified hospitals after Saudi Arabia, the United Arab Emirates, and Brazil. Yet the medical expenses in Thailand are 50%-80% lower than those in Europe, the United States, and Canada [101].

On the health and health systems ranking of countries worldwide in 2023, Thailand was ranked 13th [25]. In 2020, the private health expenditure in Thailand accounted for about 71.2% of the total health expenditure [102]. Furthermore, Thailand has become internationally known for its success with UHC policy since its development in 2002 [103]. The National List of Essential Medicines is a drug reimbursement list for the public health insurance schemes in Thailand, and the Health Intervention and Technology Assessment Program is a Thai HTA agency established in 2007 that supports reimbursement decisions [104]. Thailand used a relatively low percentage of EHR or EMR warehouses in their RWD publications, with only 22% contribution in SCS publications and 16.1% in CCCS publications (Figure 7). Surprisingly, they also had a relatively low percentage of CER publications with 26.5% of their SCS being CER publications and 29% of the CCCS being CER publications [6].

Figure 7. Real-world data landscape for Thailand (2017-2022). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; COOL-AF: Cohort of Antithrombotic Use and Optimal International Normalized Ratio Levels in Patients with Atrial Fibrillation; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



The key identified databases contributing to RWD publications from Thailand included the following [6]:

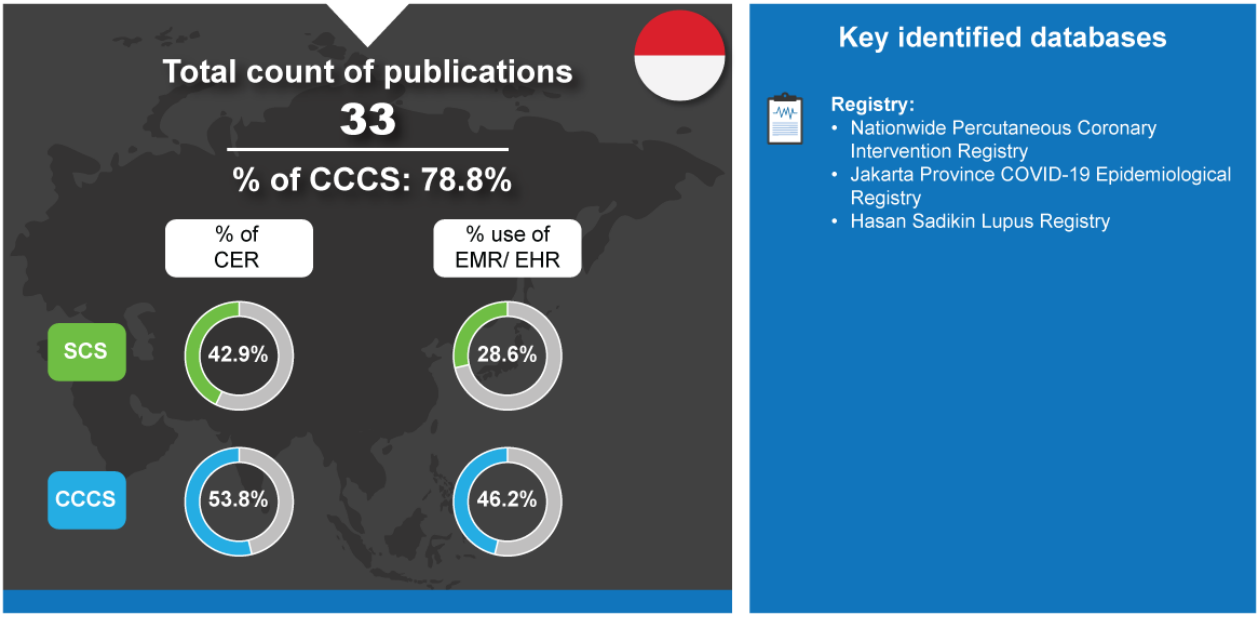
- *COOL-AF Registry*: The "Cohort of Antithrombotic Use and Optimal International Normalized Ratio Levels in Patients with Atrial Fibrillation (COOL-AF)" registry is a database of patients with atrial fibrillation in Thailand [105].
- *Type 1 Diabetes and Diabetes Diagnosed Before Age 30 Years Registry*: This registry was established in 2014 and involves 31 hospitals to evaluate glycemic control and complications in patients with type 1 diabetes [106].
- *Cardiac Intervention Association of Thailand Registry*: This nationwide registry was an initiative of the Cardiac Intervention Association of Thailand. All cardiac catheterization laboratories in Thailand were invited to participate [107].
- *Khon Kaen Cancer Registry*: This is a population-based cancer registry of Khon Kaen that covers 26 districts in Northeastern Thailand [108].
- *Thai Lymphoma Study Group Registry*: This is a web-based nationwide lymphoma registry from the Thai Lymphoma Study Group [109].
- *Rheumatic Disease Prior Authorization Registry*: This is a national registry used for government reimbursement in the Rheumatic Disease Prior Authorization system. This registry contains data on patients' demographic and clinical characteristics at baseline, data-related disease activity, and type of biologic medication prescribed [110].
- *43-Files Database*: These are administrative data collected by the Thai Ministry of Public Health for the purpose of reimbursement and health service use [111].
- *Universal Coverage Scheme*: This health coverage scheme consists of 3 main public insurance schemes that offer full-service coverage. The 3 schemes are the Civil Servants Medical Benefits Scheme for civil servants and their dependents, Social Health Insurance for private sector employees, and the Universal Coverage Scheme that covers 70% of the population in Thailand [112,113].

Global Collaborators

Indonesia

Indonesia is a country of 279.5 million people and is South East Asia's largest economy with a GDP of ~US $1.32 trillion in 2022. Ranked 97th in the 2023 health and systems ranking, Indonesia is progressing their UHC through the expansion of NHI (Jaminan Kesehatan Nasional scheme) [25,114,115]. The Indonesian government established the Indonesian Health Technology and Assessment Committee as an HTA committee in 2014 to be the center of HTA activity, and as a starting point for the development of HTA [116]. Similar to the other Solo Scholars in this study, Indonesia was responsible for a relatively low number of RWD publications [7]. Of their SCS, 28.6% (2/7) used EMR and 42.9% (3/7) were CER (Figure 8).

Figure 8. Real-world data landscape for Indonesia (2018-2023). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



The key identified databases contributing to RWD publications from Indonesia included the following [7]:

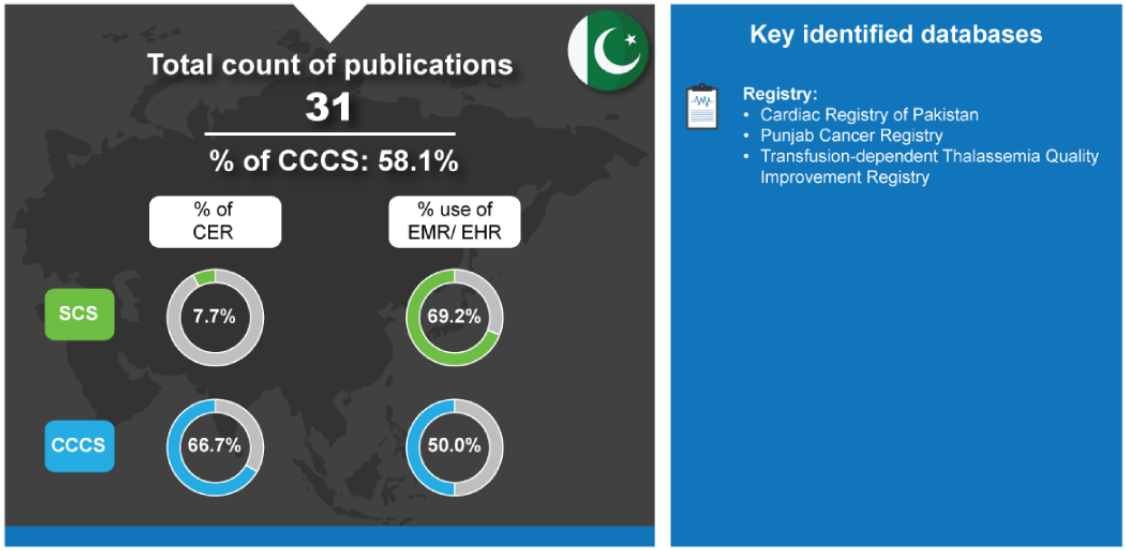
- *Nationwide Percutaneous Coronary Intervention Registry*: This is a multicenter registry of interventional cardiology projects involving 9 centers across Indonesia [117].
- *Jakarta Province COVID-19 Epidemiological Registry*: This is a database of patients with confirmed COVID-19 cases from Jakarta province [118].
- *Hasan Sadikin Lupus Registry*: This is a registry created in January 2016 that reports the medical records of patients with systemic lupus erythematosus from the Dr Hasan Sadikin General Hospital [119].

Pakistan

Health care has been identified as one of the best industry prospects for Pakistan, a country with a population of more than 240 million and a GDP growth rate of 0.29% in 2023 [120]. Ranked 124th on the health and health systems ranking of countries in 2023, Pakistan's health care comprises a 3-tier system of primary, secondary, and tertiary levels. The public and private sectors work together to provide the best possible care, but there have been tremendous concerns about the failure of the delivery of quality care due to various factors, ranging from inadequate infrastructure to inequitable distribution of health care facilities [121]. Of note, to our knowledge, there are currently no formal HTA programs in Pakistan [122].

These challenges are reflected in their low number of publications and, more specifically, their low number of SCS. Among the SCS, only 7.7% (1/13) were CER studies. Alternatively, due to their inadequate infrastructure, more CER was conducted in CCCS (12/18, 66.7%) (Figure 9).

Figure 9. Real-world data landscape for Pakistan (2018-2023). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



The key identified databases contributing to RWD publications from Pakistan included the following [7]:

- *Cardiac Registry of Pakistan*: This is a cardiac registry that includes 25 facilities from 3 provinces of Pakistan. Standardized data are collected every 3 weeks for this database [123].
- *Punjab Cancer Registry*: This registry collects population-level cancer statistics in Pakistan [124].
- *Transfusion-Dependent Thalassemia Quality Improvement Registry*: It is a database comprising patients with transfusion-dependent thalassemia from 4 centers in Karachi, Pakistan [125].

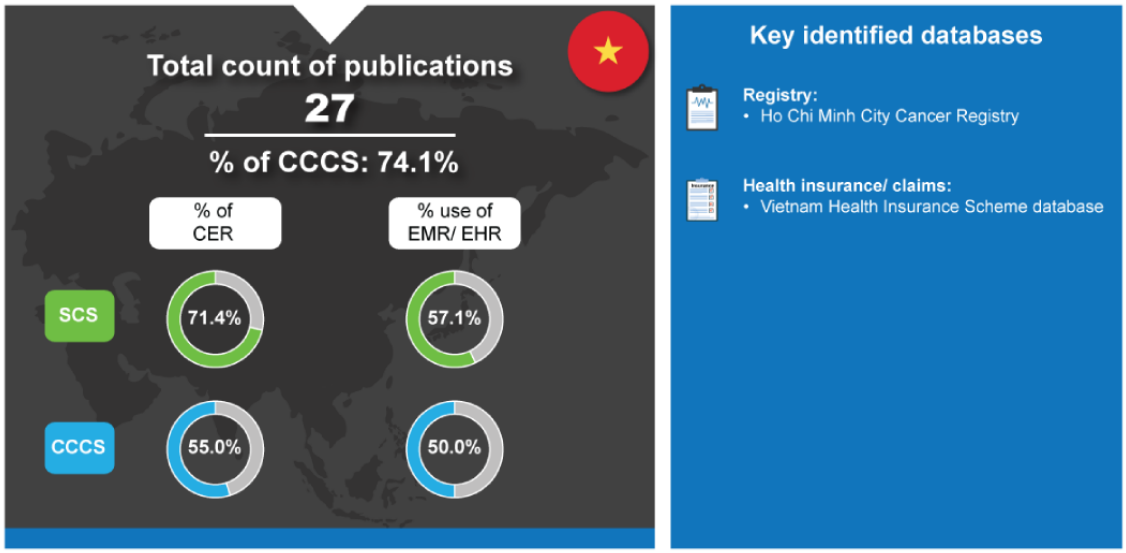
Vietnam

In the 2022 ASEAN Business Outlook Survey, AmCham Singapore members indicated Vietnam as the top Asia Pacific country (30%), where companies are considering expansion, followed by Malaysia (25%), Thailand (24%), and Indonesia (23%) [126]. The per capita GDP for Vietnam was US $4086 in 2022 and is meant to increase to at least US $18,000 by 2035. A large population of almost 100 million (half of which are younger than 30 years), consistent strong economic growth, and ongoing reform have created a dynamic and rapidly evolving commercial environment in Vietnam [126].

Vietnam was ranked 44th on the health and health systems ranking of countries in 2023 [25]. The Vietnamese MOH manages 3 levels of health service delivery: primary level in districts and communes, secondary level in provinces, and tertiary level in national institutions under central government control. Working within this hierarchical system, Vietnam aims to build a solid health care infrastructure from the grassroots [127]. Despite the significant progress, the health care system still faces challenges to keeping ahead of the country's escalating population [127]. Vietnam is making significant progress toward achieving UHC and is committed to delivering UHC [127]. In 2014, Vietnam introduced the HTA, working closely with the Health Strategy and Planning Institute to facilitate its institutionalization [128].

Similar to the other Global Collaborators, Vietnam generated a low percentage of publications. However, 71.4% (5/7) of SCS and 55% (11/20) of CCCS were CER (Figure 10). Based on the literature search of RWE publications from linked databases in Vietnam conducted in May 2023 on PubMed where the analysis assumed a linear distribution for studies in 2019 and 2023, Vietnam also exhibited the most significant increase with a growth rate of 24.5% in RWD publications in the last 5 years [7].

Figure 10. Real-world data landscape for Vietnam (2018-2023). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



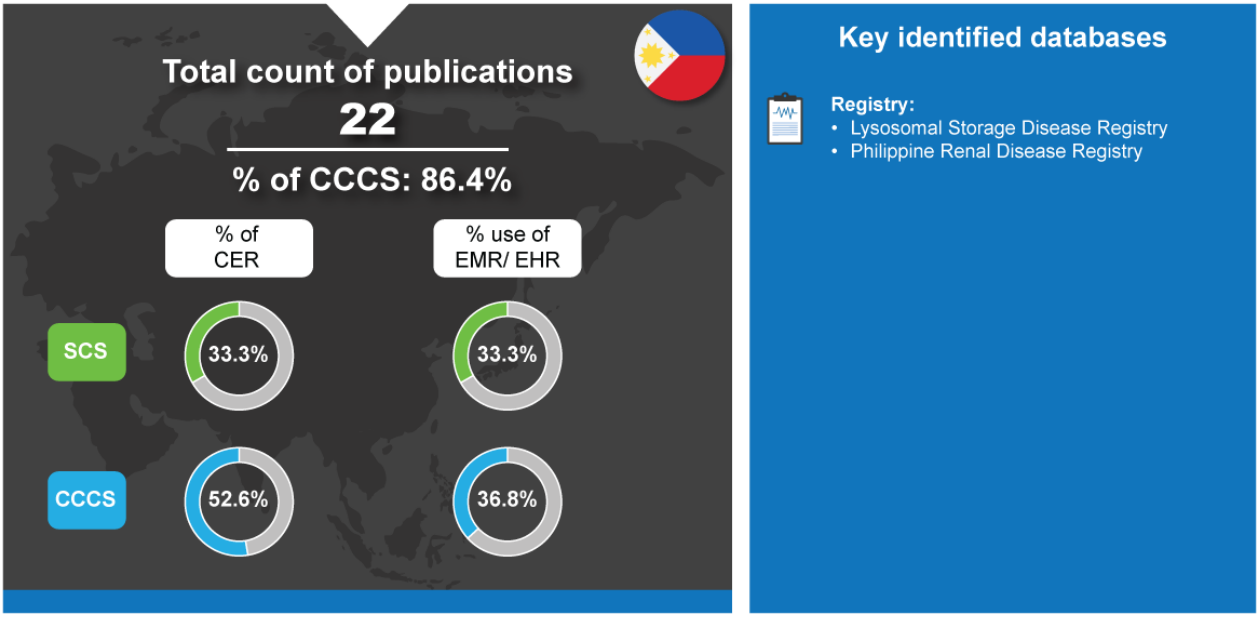
The key identified databases contributing to RWD publications from Vietnam included the following [7]:

- *Ho Chi Minh City Cancer Registry*: This registry documents all diagnosed cancer cases in Ho Chi Minh City [129].
- *Vietnam Health Insurance Scheme Database*: This claims database is managed by the Vietnam Social Security Service and it contains medical examinations and care, preventive care, rehabilitation, maternity care, and prescribed medications [130].

Philippines

The health care system is shared between the public and private sectors in Philippines and was ranked 96th on the health and health systems ranking of countries worldwide in 2023 [25]. To respond to health financing gaps, the Philippines made major reforms including the passage of the Universal Health Care Law in 2019; however, there are ongoing issues with expenditure [131]. Following this passage, there were increased efforts to institutionalize HTA in the Philippines and as a result, a health technology assessment unit was set up and is under development [52]. During the time period of 2018-2023, the majority of the Philippines' RWD publications were CCCS (19/22, 86.4%) and only 33.3% (1/3) each of SCS were CER and used EMR (Figure 11). Although the adoption of EMR for research is low and the publication count has been scanty in the last 5 years [7], the Philippines is estimated to spend approximately US $4.4 billion on digital infrastructure over the next 6 years [132].

Figure 11. Real-world data landscape for Philippines (2018-2023). CCCS: cross-country collaboration studies; CER: comparative effectiveness research; EHR: electronic health record; EMR: electronic medical record; SCS: single-country studies.



The key identified databases contributing to RWD publications from the Philippines included the following [7]:

- *Lysosomal Storage Disease Registry*: It is a registry of Filipinos diagnosed with any lysosomal storage disease [133].
- *Philippine Renal Disease Registry*: This is a registry consisting of 2 major components: The Chronic Renal Disease Registry and the End Stage Renal Disease Registry. The Chronic Renal Disease Registry is composed of the Renal Biopsy Registry, and the End Stage Renal Disease Registry is composed of Haemodialysis, Peritoneal Dialysis, and Transplant Registries [134].

Discussion

RWD is used to inform policies in different capacities across the countries. Focusing on the types and sources of RWD, we noted key differences across the countries. For example, Taiwan has a strong market economy [21], with a robust and successful health care system [25]. It was noted that they had fewer publications using EHR or EMR and more so used health insurance or administrative claims for their numerous publications. They also had many identified databases and, as such, were able to access several data sources to generate RWE (Figure 1). Taiwan exemplifies a country with the infrastructure and resources to comfortably produce RWE. A trend in Solo Scholar countries such as Taiwan was that they are prolific in the publication of SCS, with a general decrease in CER studies over time [6,7]. Typically, Global Collaborators have less robust economies and health care systems. These were countries that had less variety in data sources within their health system and a lack of standardized or integrated databases. These countries published more CCCS with a general increasing trend in the percentage of CER studies [7].

For Global Collaborators, CCCS are important for the generation of RWE. This highlights the necessity for data-sharing strategies and a need for the development of data-sharing frameworks, particularly to aid countries that have weaker health care systems and less established infrastructure for RWD [7]. It also underscores the potential benefits of opening data initiatives, where governments play a pivotal role [135]. Opening these data resources to a broader spectrum of stakeholders, including academic institutions, can spur innovation, improve public health outcomes, and foster a more collaborative ecosystem [136]. Such initiatives not only democratize access to valuable health data but also pave the way for a more inclusive approach to tackling global health challenges. This reflects a growing recognition of the importance of transparency and collaboration between the public sector and external entities in enhancing health care delivery and research [137]. Indeed, many nations such as Vietnam leverage regional and global studies conducted in a CER style to match their requirements for HTA. HTA agencies across Asia could contribute to these types of developments as this may be beneficial to them. In 2011, the HTAsiaLink Network was set up as a collaborative network for HTA agencies in Asia [138]. There is also the International Network of Agencies for Health Technology Assessment, which is an international HTA community, though to our knowledge, Taiwan, Singapore, and Malaysia are the only countries discussed that are part of this network [139]. Cross-sectoral partnerships through HTAsiaLink Network and International Network of Agencies for Health Technology Assessment could help address challenges related to RWE generation, which are much more common in lesser developed countries, and support country HTA and regulatory decision makers in decision-making [140,141]. However, there is also a need to improve database identification and integration across countries as there is no consistent naming of the databases, resulting in difficulty in identifying and analyzing RWD publications across Asia. Outside of reimbursement decisions, these improvements would be helpful for a range of groups including health professionals and researchers, health system managers, researchers, policy makers, and investors. Along with these improvements, there

is a need for focused use of EMR to streamline the process of generating RWD for disease surveillance and management [142].

In recent years, an increasing number of Asian countries have begun to recognize the importance of HTA in making informed pricing and reimbursement decisions for health care technologies [143]. This shift toward evidence-based health care policy is critical to ensure that decisions around health care technologies are transparent and equitable [144]. To further enhance the transparency and effectiveness of the HTA process, it is crucial to involve all stakeholders at every step of the implementation. In this context, global observational networks such as the Observational Health Data Sciences and Informatics (OHDSI) program offer a promising avenue for enriching HTA processes with robust RWE. Countries such as Taiwan, Singapore, and India already participate in OHDSI, although the global presence remains limited [145]. By aligning governmental initiatives with the Observational Medical Outcomes Partnership Common Data Model used by OHDSI, there is a unique opportunity to rapidly scale up the generation and use of RWE [146]. Such collaboration broadens the evidence base for HTA and facilitates international cooperation and benchmarking in health care technology assessment. Moreover, linking HTA processes with Observational and Medical Outcomes Partnerships or OHDSI could serve as a catalyst for developing sophisticated and evidence-driven health care policies.

In the Hong Kong government's 2021-2022 budget, an increase of US $480 million was allotted to the HA to meet increasing demand for health care services [86]. One such service is the CDARS, which emerged as the key EMR database for Hong Kong [7]. It is a database developed by HA, which is readily used in Hong Kong for RWD [90]. Among all 10 countries, Hong Kong leveraged EMR for most of its RWD SCS (80.2%) (Figure 4). Streamlined use of EMRs has the potential to collect a variety of RWD, which reduces the need to set up multiple disease-specific clinical registries for generating non–cost-related RWE. The CDARS database is a good example of this as it has been established for research purposes and contains necessary medical information, including patient demographics, details on admission, diagnosis, and prescription and laboratory tests [90].

Conclusions

RWD plays a significant role in informing policy decisions across Asia. There are differing trends and patterns in the use of databases for published RWD across Asia and clear gaps in usage of warehouses across countries. However, based on the economic and health care development trends, there seems a great potential in generating fit-for-purpose RWE across distinct health care systems. Global Collaborators demonstrate a reliance on international partnerships for CCCS, due to a strategic drive to overcome infrastructural limitations. The review stresses the necessity for enhanced data-sharing strategies and more robust database integration, which are critical for countries with limited health care system resources. Furthermore, the consistent naming and use of databases, especially EMRs, are pivotal for advancing disease surveillance and RWD generation across Asia. The findings call for joint efforts by HTA agencies and stakeholders to fortify RWD frameworks, which would not only aid reimbursement decisions but also support the broader spectrum of health care stakeholders.

Acknowledgments

Desktop research and medical writing for this article were funded by Pfizer and were conducted by Transform Medical Communications Limited (Transform Medcomms), New Zealand. The authors thank Ms Dansoa Tabi-Amponsah from Transform Medcomms for editorial assistance.

Data Availability

Data generated or analyzed during this study are included in Multimedia Appendices 1 and 2.

Authors' Contributions

All the authors were involved in the idea's conception, design, and interpretation of the facts and data. SS led the manuscript writing, and all authors were engaged in revising it for scientific content and final approval before submission for publication.

Abstract

Background: Computerized clinical decision support systems (CDSSs) enhance patient care through real-time, evidence-based guidance for health care professionals. Despite this, the effective implementation of these systems for health services presents multifaceted challenges, leading to inappropriate use and abandonment over the course of time. Using the Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) framework, this qualitative study examined CDSS adoption in a metropolitan health service, identifying determinants across implementation stages to optimize CDSS integration into health care practice.

Objective: This study aims to identify the theory-informed (NASSS) determinants, which included multiple CDSS interventions across a 2-year period, both at the health-service level and at the individual hospital setting, that either facilitate or hinder the application of CDSSs within a metropolitan health service. In addition, this study aimed to map these determinants onto specific stages of the implementation process, thereby developing a system-level understanding of CDSS application across implementation stages.

Methods: Participants involved in various stages of the implementation process were recruited (N=30). Participants took part in interviews and focus groups. We used a hybrid inductive-deductive qualitative content analysis and a framework mapping approach to categorize findings into barriers, enablers, or neutral determinants aligned to NASSS framework domains. These determinants were also mapped to implementation stages using the *Active Implementation Framework stages* approach.

Results: Participants comprised clinical adopters (14/30, 47%), organizational champions (5/30, 16%), and those with roles in organizational clinical informatics (5/30, 16%). Most determinants were mapped to the organization level, technology, and adopter subdomains. However, the study findings also demonstrated a relative lack of long-term implementation planning. Consequently, determinants were not uniformly distributed across the stages of implementation, with 61.1% (77/126) identified in the exploration stage, 30.9% (39/126) in the full implementation stage, and 4.7% (6/126) in the installation stages. Stakeholders engaged in more preimplementation and full-scale implementation activities, with fewer cycles of monitoring and iteration activities identified.

Conclusions: These findings addressed a substantial knowledge gap in the literature using systems thinking principles to identify the interdependent dynamics of CDSS implementation. A lack of sustained implementation strategies (ie, training and longer-term, adopter-level championing) weakened the sociotechnical network between developers and adopters, leading to communication barriers. More rigorous implementation planning, encompassing all 4 implementation stages, may, in a way, help in addressing the barriers identified and enhancing enablers.

Introduction

Background

The integration of digital technologies in health care services, especially the implementation of computerized clinical decision support systems (CDSSs), promises to enhance the quality, safety, and efficiency of patient care [1]. Evidence continues to build in favor of implementing CDSS for the optimization of clinical management decisions [2], thereby enabling more effective risk-based decision-making and the delivery of personalized care within the realm of acute health care [3]. Noteworthy applications include the adoption of computerized provider order entry systems [4], the deployment of point-of-care alerts to enhance patient safety [5], and the integration of electronic health record data and artificial intelligence (AI) for decision support [6,7].

Indeed, CDSSs are increasingly incorporating AI and machine learning to realize several critical benefits to clinical decision-making [8]. AI and machine learning techniques facilitate rapid analysis of extensive clinical data, including patient records and medical literature, surpassing traditional rule-based systems in swiftly generating insights and recommendations [1,8]. These technologies excel in identifying intricate patterns and relationships within data, enhancing diagnostic accuracy and treatment recommendations [1]. The relevance of AI and machine learning to CDSS adopters, such as health care providers, lies in the ability to tailor recommendations and predictions to specific scenarios [9]. For instance, machine learning can enhance diagnostic accuracy for common medical conditions by learning from large datasets, which directly benefits the adopters by providing more precise and actionable insights [10]. Although AI-enhanced CDSSs promise more precise, timely, and personalized clinical support, they are designed to complement rather than replace human judgment, necessitating careful consideration of implementation risks and limitations to optimize patient care and outcomes [11].

Despite these considerable potential benefits, the effective implementation of these systems within health services presents multifaceted challenges [1,12]. These include managing diverse stakeholder expectations, emergent clinical and sociopolitical contexts, and changing strategic priorities [13,14]. Failing to address these challenges may give rise to unanticipated outcomes related to low adoption rates [15,16], inappropriate use [17,18], unforeseen consequences [19,20], and long-term technology abandonment [21].

CDSSs can be valuable tools in health care, offering guidance to professionals; however, these systems can face limitations in practice. For example, CDSSs may struggle to accommodate patients with complex comorbidities, potentially leading to treatment recommendations that inadvertently worsen certain conditions such as prescribing heart disease medication that could harm kidneys [1]. Furthermore, CDSSs often do not incorporate patient preferences, cultural beliefs, or financial constraints as these data sources are not considered, necessitating personalized adjustments by clinicians to ensure treatment adherence and efficacy [1]. In acute care settings, CDSS may not keep pace with rapidly evolving clinical conditions, requiring clinicians to rely on their real-time assessments rather than potentially outdated CDSS guidance [1,9]. Moreover, there are high costs associated with the implementation, adoption, and maintenance of CDSSs [22,23]. These limitations of CDSSs underscore the critical role of effective implementation so that the right CDSS can provide the right information at the right time to the right patient [1].

Examining the factors that drive the successful adoption of CDSSs and those that impede its progress contributes to a deeper understanding of the dynamic interplay between technology and health care delivery [24-26]. This can be approached systematically [1,12-21] with guidance from well-established theories within the discipline of implementation science, which also accounts for organizational complexity [27,28]. A recent scoping review found that models, rather than theories or frameworks (18/42, 43% of the included studies), were most frequently used to guide CDSS adoption and evaluation strategies [29]. Unlike frameworks, models can be limited in examining the complexity of sustained implementation, acceptability, and adoption of technology across organizational and system levels [29,30]. The Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) framework uses a complex systems approach, which encapsulates the determinants NASSS of technological adoption overtime in health care settings [24]. This framework serves as a conceptual lens through which technological interventions are viewed as part of a complex system consisting of many processes and components. The utility of the NASSS framework lies in its ability to identify contextually appropriate determinants and inform implementation strategies, thereby shedding light on the factors that impact the success of digital health implementations [31-33]. Contextually informed implementation strategies tailored to influence clinician behavior could have a greater influence on CDSS adoption than technological design and content features [15,24-26,34].

Objectives

As such, this research was characterized by 2 principal aims. First, we aimed to identify the NASSS theory-informed determinants that either facilitate or hinder the application of CDSSs within a metropolitan health service. These include multiple CDSS interventions at the health-service level and at a single hospital setting spanning for 2 years. Second, this study aimed to map these determinants into specific stages of the implementation process, thereby developing a systems-level understanding of CDSS application across implementation stages. A stage-specific mapping approach allows for more nuanced and tailored strategies for CDSS integration, ensuring that the unique challenges and opportunities associated with each implementation stage are addressed [35-37].

Methods

Ethical Considerations

The Metro South Health Human Research Ethics Committee granted ethical clearance for this research (HREC/2020/QMS/64807). All participants provided written and verbal informed consent before participating in the study. Participation was voluntary and participants could withdraw at any time. All data were deidentified and handled in accordance with the Metro South Human Research Ethics Committee guidelines.

Study Design and Theoretical Framework

This qualitative study used a hybrid inductive-deductive approach [38]. The deductive approach was informed by the NASSS framework to identify contextually specific determinants associated with the use of CDSS technology in a large metropolitan health service across discrete implementation cycles during a 2-year period. The NASSS framework positions technological interventions as part of a complex system and has been used to guide implementation efforts and identify factors that influence technology implementation success in health services [24,31-33].

Study Setting

This study was conducted in a metropolitan health service comprising 5 hospitals, which serve a large catchment area (3856 km^2) in Australia. Consequently, those employed by the health service within the digital health and informatics portfolio were recruited to take part in the study. It must be noted that this department operates at both a health-service level and a facility level. In addition, clinicians who worked at either of the 2 largest hospitals within the health service were also recruited. With a facility of 1033 beds, hospital 1 is the largest teaching and training university hospital and is equipped with all major medical specialties except maternity services and pediatrics. Hospital 2 comprises most medical specialties, with 459 beds, including maternity services and pediatrics. Both hospitals (and the health service at large) used the same integrated electronic medical record system that had been implemented before the commencement of the study.

Participant Recruitment and Sample

The participants sampled in this study included staff from the clinical informatics unit, which operated at the health-service level. In addition, clinical staff who worked within the 2 largest (defined according to the number of available beds) hospitals within this health service were also recruited to participate in the study. In this study, CDSSs were defined as any electronic system or interface designed to provide health system users with tailored information to inform decision-making within a particular context or situation [1,31]. The participants who met the following selection criteria were recruited for this study: experience with decision-making, governance, purchasing, design, and implementation of CDSS initiatives within the health service. This could include those with roles in informatics, governance, and management, as well as frontline clinical staff. The researchers used purposive sampling throughout the study, seeking representativeness of participants who were involved in using or implementing CDSS. The researchers also sought representativeness across a range of implementer roles, that is involved in making decisions or engaging in CDSS procurement, rollout, and upgrades, and adopter roles, that is clinician users of the CDSS [39,40]. To obtain this representativeness, the researchers estimated a sample size of 30 to 40 participants.

Acting as a knowledge broker, SM, an academician who is also embedded in the health service, used a knowledge brokering process [41] to identify potential participants during informal discussions with health-service staff. Those identified were then formally invited to the study using internal memos and emails sent from SM, with participants given a week to respond. Nonresponders were followed up one more time within a fortnight of the initial email. Saturation was deemed to be achieved when no new concepts or understanding were identified after 3 consecutive interviews following purposive sampling [39].

Study Materials and Data Collection

The reporting of findings was guided by the Standards for Reporting Qualitative Research checklist (Multimedia Appendix 1). A semistructured, NASSS framework–informed interview guide, which focused on the availability, development, and perceptions of CDSS within the participants' health system (Multimedia Appendix 2), was developed. Questions also explored decisions around the implementation of CDSS as well as their adoption, use, and sustainment in the course of time.

Data collection was conducted between March 2021 and March 2023. On the basis of the participants' preferences and availability, data were collected through one-on-one interviews or through focus group discussions among groups consisting of 6 participants. This was done through in-person and web-based (Teams; Microsoft Corporation) techniques. Interviews and focus group discussions were led by SM, an experienced digital health and health services researcher (male, PhD qualified, embedded in health service, and familiar to a few participants), and SN, an experienced mixed methods health services researcher (male and PhD qualified). The interview duration was approximately 1 hour, while focus group discussions were conducted for up to 2 hours. The interviews and focus group discussions were audio recorded and transcribed

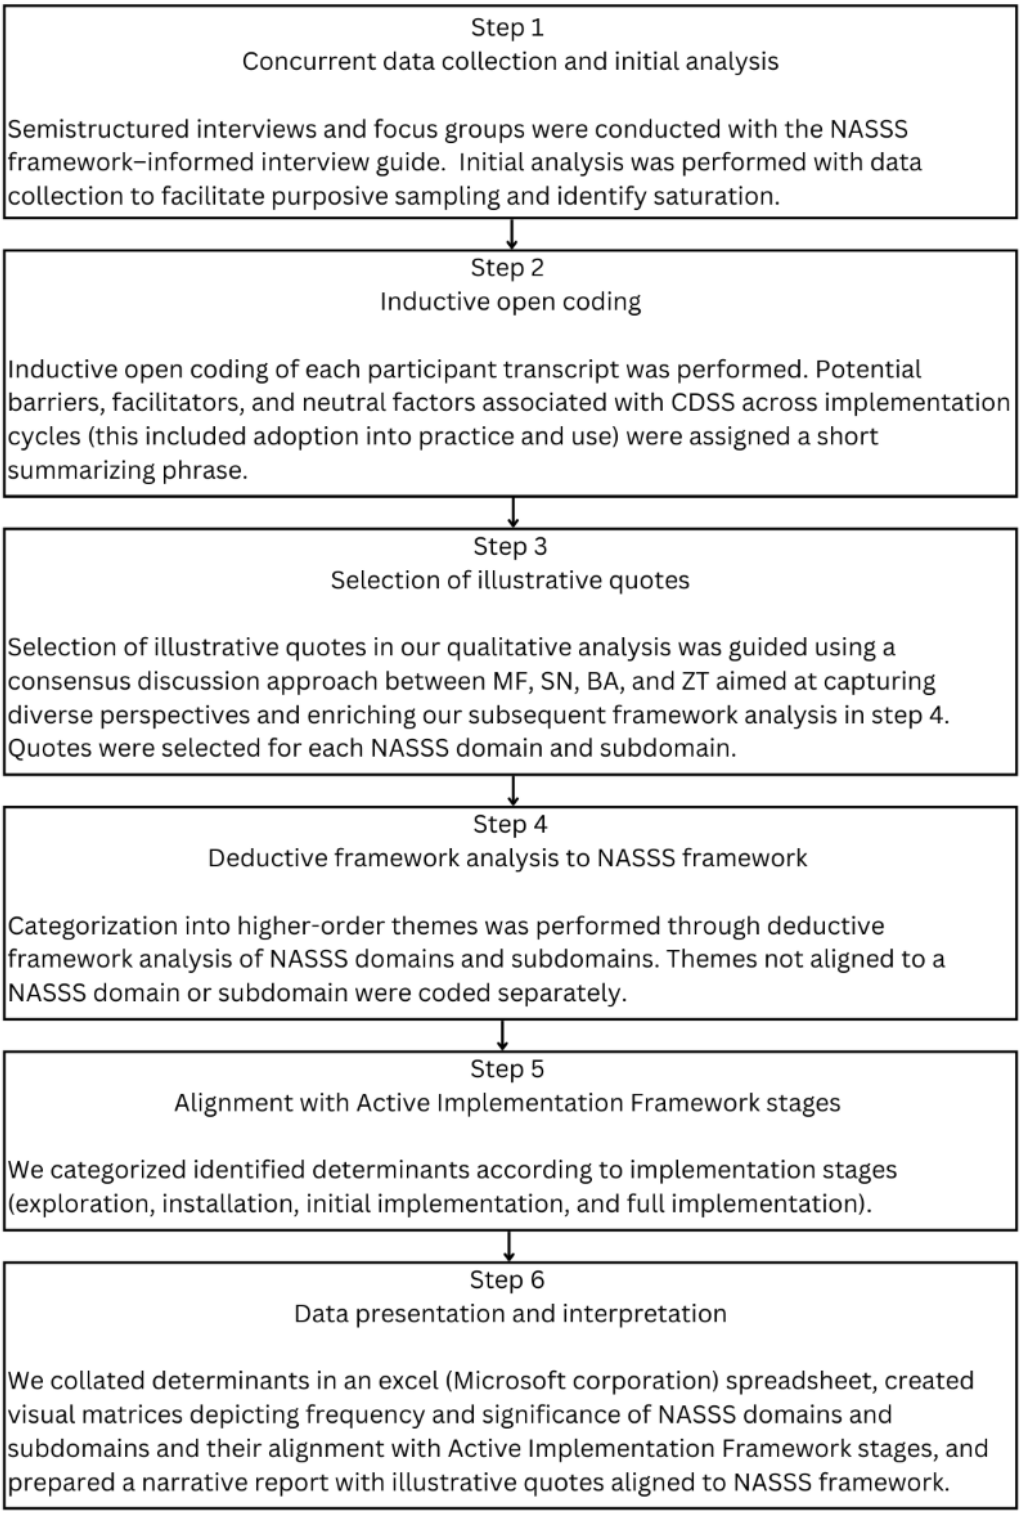
verbatim. Preliminary findings were monitored and discussed with the research team. This information was used to guide recruitment until saturation was reached [33,42].

Obtaining Saturation

Initially, SN analyzed the transcripts thematically and concurrently with data collection to facilitate purposive sampling and identify saturation. Early analysis of transcripts allowed us to identify preliminary themes and gaps, informing subsequent interviews and ensuring that a diverse range of perspectives were explored [33,42,43]. This iterative process of concurrent analysis and interviewing was integral to refining our understanding and ensuring the trustworthiness of the findings [42,44]. At the completion of the interviews and focus group discussions, MF and SN analyzed data using qualitative content analysis [31] and framework analysis [31,45-47]. Framework analysis is a systematic qualitative analysis widely used in health and social care research to organize and analyze large volumes of textual data, enabling comparison by case and theme [48].

The data analysis process is outlined in Figure 1. First, barriers, facilitators, and neutral factors associated with CDSS across implementation cycles were assigned a short summarizing phrase [31,42]. This was done through inductive open coding of each transcript. These initial phrases were discussed and revised, with a few being discarded, amended, or subsumed to create higher-order codes [31]. Through an initial inductive analysis of codes, the researchers aimed to capture the context-specific elements of the data without prematurely applying a predefined framework [38,46]. This approach enabled the discovery of preliminary themes and patterns, which were subsequently aligned with the NASSS domains and subdomains during the deductive phase of the analysis [33,38,46].

Figure 1. Analytic process used in data analysis. CDSS: clinical decision support system; NASSS: Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability.



Alignment With the NASSS and Active Implementation Stages Frameworks

As a part of this process, where appropriate, illustrative quotes were extracted for each of these codes [42]. The selection of illustrative quotes during qualitative analysis was guided using a consensus approach after discussion with MF, SN, BA, and ZT. The selection of quotes aimed to capture diverse perspectives and enrich subsequent mapping to the NASSS framework to showcase the variations within each theme and subtheme, ensuring that findings were both grounded in the data collected and demonstrative of the range of perspectives expressed by the participants [33,45,46,48-50]. The outcome of this process was to reflexively map each of the higher-order themes onto ≥1 of the NASSS domains and subdomains with which they were aligned [31]. This analysis was primarily

deductive, with the intent to align barriers, facilitators, and neutral factors identified in our inductive analysis with preexisting domains within the NASSS framework [31]. It is important to note that, in the analysis, no restriction was placed on the number of domains or subdomains with which an individual-coded barrier, facilitator, or neutral factor could align [31]. This was not only to categorize using the NASSS framework but to reflect on the role of the theoretical framework in capturing the complexity of CDSS implementation within a real-world health service [31,51]. Themes not aligned to an NASSS domain or subdomain were coded separately [46]. Finally, the Active Implementation Framework [35,36] was used to categorize and display identified determinants according to the stages for digital health implementation. These stages include exploration, which is focused on the feasibility and organizational readiness, installation, which is centered on the organizational preparation, initial implementation, which covers implementation-initiation techniques such as training, and full implementation, which emphasizes sustainment [35-37].

Data Presentation and Interpretation

A descriptive numerical summary of the identified determinants was collated in an Excel (Microsoft Corporation) spreadsheet, mapping determinants to the NASSS framework domains and the Active Implementation Framework stages [31,42]. To illustrate the alignment of barriers, facilitators, and neutral factors with the NASSS framework and the Active Implementation Framework, the researchers developed visual matrices to depict the frequency and salience of the identified themes and their association with various implementation phases [31]. This visual and numerical representation aimed to demonstrate common findings across the NASSS domains relating to CDSS implementation and to identify gaps in the implementation of CDSS across different phases.

Trustworthiness

Throughout the analysis, the researchers maintained trustworthiness and reflexivity by reflecting on the research process through discussion as a research team and considering how their perspectives and the chosen frameworks may have influenced data interpretation [45-47,49]. This study provided a narrative report of the framework mapping to each NASSS domain and subdomain supported by direct quotes from the interviews and focus groups [33,45,46] and discussed the implications for practice.

Results

Participant Characteristics and Implementation Roles

A total of 30 participants, including implementers, decision makers, and CDSS end users, across several departments took part in this study. Table 1 provides comprehensive demographic information about the participants.

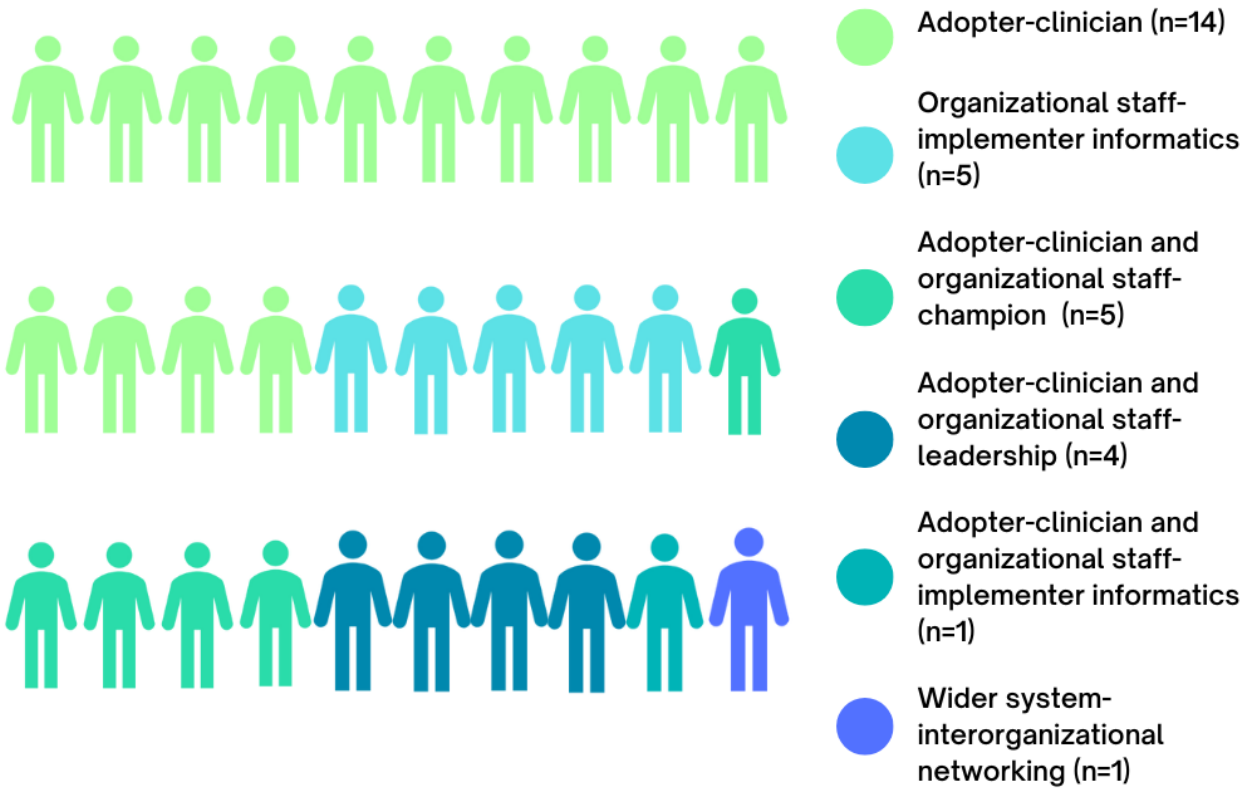
Table 1. Participant demographics (N=30).

Position and categories	Participants, n (%)
Sex	
Female	13 (43)
Male	17 (57)
Portfolio[a]	
Medical specialty (ie, radiology, pharmacy, and cardiology)	16 (53)
Digital health and informatics directorate	8 (27)
Nursing and allied health	6 (20)
Job role	
Physician (ie, residents, junior physicians, consultants, specialists, and directors)	18 (60)
Clinical informatics (ie, project manager, senior management, and data analyst)	6 (20)
Allied health and nursing (ie, physiotherapist and triage nurse)	6 (20)
Implementation role	
Adopter-clinician (ie, physicians, allied health staff, and nursing staff)	14 (47)
Organizational staff–implementer informatics	5 (17)
Adopter-clinician and organizational staff champion	5 (17)
Adopter-clinician and organizational staff leadership	4 (13)
Adopter-clinician and organizational staff-implementer informatics	1 (3)
Wider system–interorganizational networker	1 (3)

[a]Portfolio refers to the health service department associated with the participant, recognizing that some participants had a clinical background, that is, physician, but were experienced at a department level with decision-making, governance, purchasing, design, and/or implementation of clinical decision support system initiatives within this health service.

Participants were mapped to NASSS-informed implementation roles, highlighting their level of decision-making within the hospital systems of interest, as shown in Figure 2. Of the 30 participants, 14 (47%) clinical staff identified solely as adopters of CDSS tools. In addition, 17% (5/30) of clinical staff took on the role of organizational staff champions, that is, clinicians who advocate for the technology and its use [52,53]. Overall, 17% (5/30) of participants were informatics professionals, 13% (4/30) of participants acted in dual roles of organizational staff leadership and clinical adopters, that is, as clinical directors. Only 1 (3%) participant encompassed adopter-clinician and organizational staff–implementer informatics roles, that is, as a clinician who worked within the digital health and informatics directorate portfolio. Only 1 (3%) participant was considered a wider system–interorganizational networker.

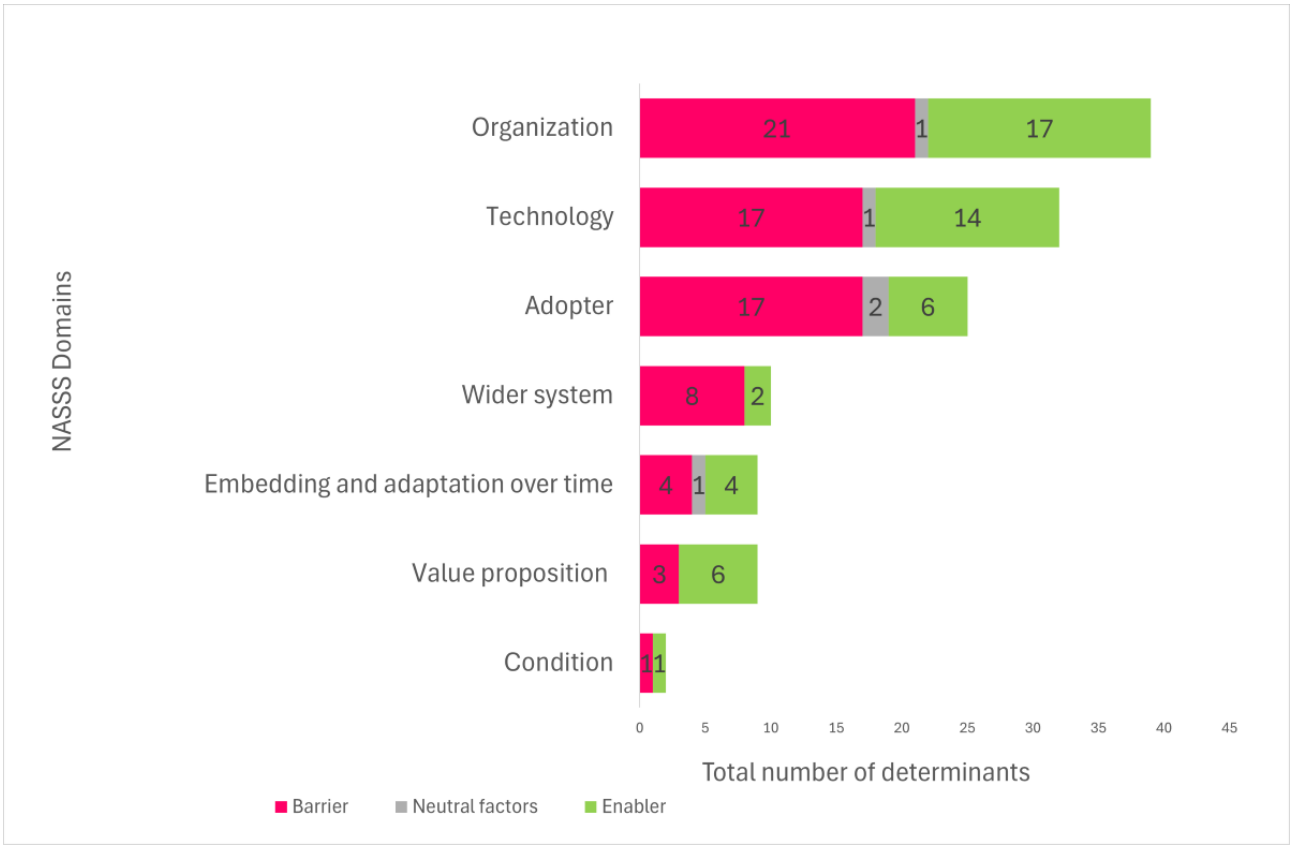
Figure 2. Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) framework–informed implementation roles of participants (N=30).



Key Determinants Associated with CDSS Implementation

The identified determinants encompass specific elements pertinent to CDSS implementation. These elements were classified into barriers, enablers, and neutral factors. For a comprehensive breakdown of these determinants, refer to Multimedia Appendix 3. The findings were mapped to the NASSS domains and subdomains, as shown in Figure 3. Barriers (71/126, 56.3%), enablers (50/126, 39.6%), and neutral factors (5/126, 3.9%) associated with CDSS implementation were identified in this study. Most determinants were mapped to the organization (39/126, 30.9%), technology (32/126, 25.3%), and adopter (25/126, 19.8%) domains.

Figure 3. Key determinants associated with clinical decision support system (CDSS) implementation mapped to the Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) domains.



Framework Analysis of NASSS Domains and Subdomains

Organizational Domain

Key organizational level determinants were mapped to the following NASSS subdomains. The barriers included limited implementation capacity stemming from a lack of longer-term implementation planning know-how:

> *That's something that's a little bit vague for me, do we plough on? With a state that shows it works. Then you bring in your usability. Or do you bring in your app and then do your study?...And so that, that design of the next phase sort of up here, but I don't know the best way to do it would be...how I'd explain it.* [Clinical adopter, senior management]

The participant highlights a concern on whether to continue with existing approaches that show some amount of success (eg, *state that shows it works*) or to introduce new technologies (eg, apps) and evaluate their impact. This decision-making process ties into limited implementation capacity, underscoring the importance of strategic planning and expertise in guiding successful implementation efforts. This may have flow-on effects, resulting in inappropriate resource prioritization, which is identified as a barrier that needs to be worked on:

> *Generally, they will provide support for when they're rolling out something new. But often you don't actually discover issues or problems with that new process or software until you're using it.* [Clinical adopter]

Furthermore, this impacted *technological readiness* as a barrier, as stated by a participant:

> *I think [Health Service] really hasn't accommodated us because...if you're on a VPN connection, you're throttled down to three or four megabits per second.* [Clinical adopter]

While not every clinician in the hospital may always be on a virtual private network (VPN), VPN throttling affects system performance in hospitals by limiting bandwidth, thereby hindering the speed and efficiency of accessing critical systems or data. This can negatively impact workflow efficiency and user satisfaction for those required to use a VPN. This quote also reflects participant's concerns about organizational readiness to adopt new technologies effectively in comparison to existing organization infrastructure and practices. Conversely, the organization appeared well- equipped to support initial or early-stage CDSS implementation activities, including training:

> *Champions are trained, they've done validation, then it's a case of, OK, now we go live with that product.* [Informatics staff, senior management]

The organization has also established a highly skilled clinical informatics workforce, as stated by a participant:

> *They're the only group that has a clinical informatics solution. So, you can do a training...in clinical informatics. So, it's nice because they have some*

> *champions now integrated.* [Clinical adopter, digital consultant]

This workforce ensures ongoing maintenance and support in navigating the digital ecosystem:

> *There is a department in place to help you navigate all the things you need to do. Whether that's from an IT procurement perspective, whether or not that's from a cybersecurity perspective...* [Informatics staff]

These enablers were mapped to the subdomain of work needed to plan, implement and monitor change. It must also be noted that the inclusion of organizational champions across clinical contexts was a significant enabler in the adoption of several CDSSs across this hospital system. This was a key factor in enabling the initial work needed to plan, implement, and monitor change.

The informatics team has a close familial culture due to the team members working together for a long time:

> *All of us have been working together for 10 plus years, some of them 15. Very close-knit team. So that is what holds us together.* [Informatics staff]

The tight-knit nature of the informatics team can be seen as part of the organizational culture, impacting how the team works together, their ability to innovate, and their readiness to implement changes in the organization. Although mapped to the organizational domain of the NASSS framework, given that the primary focus of this culture was not strictly covered by standard organizational structures or leadership theories associated with the NASSS framework's *general capacity to innovate* [54] but instead highlighted the unique interpersonal dynamics within the team, we coded this separately from the NASSS framework.

Technology Domain

In the hospital system, the most common technological barrier was associated with the interoperability of CDSSs, which was mapped to the material properties subdomain:

> *Sometimes, the lack of interface between the systems...they run a parallel system.* [Clinical adopter]

Participants also shared that they were not always fully aware of CDSS modifications:

> *There used to be a feature in the IEMR where you could taper medication doses...I don't know what ever happened to it and it just wasn't there anymore.* [Clinical adopter]

In addition, users were not always aware of the best ways to optimize using CDSS technology in this hospital system:

> *I know as someone who works in digital health and informatics, there is...a little button to the side of that that says, Click to see the 'information. But I don't think a lot of people realize that...* [Clinical adopter, digital consultant]

However, when participants were able to experience how CDSS supported effective practice, they were more likely to engage and use the technology:

> *If you're not too familiar with this medication or you've forgot what the maximum dose should be or you were distracted by something else, the power plan [CDSS] has it there and says you shouldn't be going above this...so I think that's good from a patient safety perspective.* [Clinical adopter]

> *I would imagine ease of use for a start...if it's too clunky, they won't go anywhere, you know, even introducing a new app into the system if it...takes 10 minutes to set it up.* [Clinical adopter, senior management]

> *Ease of use drives clinicians' confidence.* [Clinical adopter, senior management]

These quotes are illustrative of how *ease of use* can enhance clinicians' overall confidence and proficiency in using the technology effectively. This aspect minimizes the learning curve and allows users to operate the CDSS with minimal training or interruption. This can lead to increased confidence among clinicians because they are able to interact with the system more efficiently and focus more on patient care rather than struggling with the technology. Therefore, this enabler mapped to the NASSS subdomains of knowledge generated by the technology and knowledge to use it.

Adopter and Condition

Despite some participants viewing technology as supportive of effective practice, others expressed concerns with machine learning found in modern CDSSs. These concerns were about limiting the capacity for critical thinking, professional autonomy, and personal legal ramifications:

> *The threat of machine learning would be that you could become reliant on, you know, what an algorithm is telling you and directing you to do, and you might lose that art of being able to, like, go well...I recognise this issue because I've seen it before.* [Clinical adopter]

> *This is where I think it's something we're going to have to have to work out and develop some protections around it...I want to make sure this thing is safe.* [Clinical adopter]

Conversely, adopters expressed positive perceptions of CDSS technology when there was a clear lived experience of improved workflow:

> *From a workflow perspective, it reduces the number of clicks and the number of individual actions you need to do to...So I think it makes things a lot easier in that respect.* [Clinical adopter]

This was also the case for patient-centered care observed through improved outcomes:

> *I think that's...the excitement of machine learning is learning more...individualising the dose for a patient.* [Clinical adopter]

Effective adaptation to the local clinical context was also an enabler, as stated by a participant:

> *One sort of springs to mind that we do use as a screening tool...It's helpful to do it, sort of pops up for every patient during your initial clinical assessment...it's just like three little questions that you ask...it is an incentive for me to do a complete set of vitals each time...I feel like I do it more often because I've got that incentive to get that score.* [Clinical adopter]

Participants emphasized the importance of adapting CDSSs to local clinical environments. CDSS was viewed positively when demonstratively relevant adaptations were made in contrast to a clear lack of clinically contextual adaptation:

> *Sometimes it can be a bit too rigid, and if you're wanting to do something that falls out of the power plan, they sometimes can make the job harder...* [Clinical adopter]

> *The warfarin one works well and I think it's a better example of how our plans would be used.* [Clinical adopter]

Consequently, this determinant was also mapped to the condition domain.

Value Proposition

CDSS using AI was seen as valuable to adopters by enabling efficiency in protocolized tasks with predefined workflows:

> *So, it's really saving time on things that can very well be done by sort of an artificial intelligence...it won't replace the reporting.* [Clinical adopter, senior management]

In contrast, when considering the relationship between demand-side value (to adopters) and supply-side value (to developers), different priorities can create misalignment regarding the value proposition of a CDSS initiative. This misalignment may lead to communication barriers:

> *I think our clients and customers, they think they're things really important. Because they have no visibility of the strokes that we're managing at the moment, yeah so. For them, it's hard to say what do you mean. My initiative in one tiny little ward, which means so much to me...you can't help me. And I think, because truthfully, they don't have visibility of all the other things that we're doing.* [Informatics staff]

Wider System

The lack of clear and consistent governance surrounding the application of CDSSs within the hospital context was perceived as a major wider system barrier by most participants:

> *But it's also really raised a lot or highlighted a lot of the areas where there could be more maturity...I guess, operating in terms of making sure that whatever processes need to be in place for governance and decision-making, ethics, liability.* [Informatics staff, senior management]

However, participants also noted that the experience of the COVID-19 pandemic showed that wider system decision-making to facilitate the appropriate use of digital technology could be streamlined in an effective and efficient manner:

> *I think COVID certainly showed us that we can streamline a lot of our decision making...* [Clinical adopter, digital consultant]

Embedding and Adaption With Time

Participants noted the resilience of this hospital system in adapting to and accommodating the application of technology as a key strength. This stemmed from an innovation culture and recognition of the importance of evaluating technology across implementation cycles, even if they did not currently have the resources or exact know-how to do so:

> *I'm a massive champion of that whole point of we do go through a cycle, right? Where you plan your budget, you deliver, you maintain most systems...go to that next step, which is to evaluate and more importantly, evaluate does this thing still deliver the same value statement that we thought it would at the start.* [Informatics staff]

A noted barrier was the acknowledgment that adapting complex CDSSs, particularly AI, to contextual changes in the system in the course of time was specialized and labor intensive:

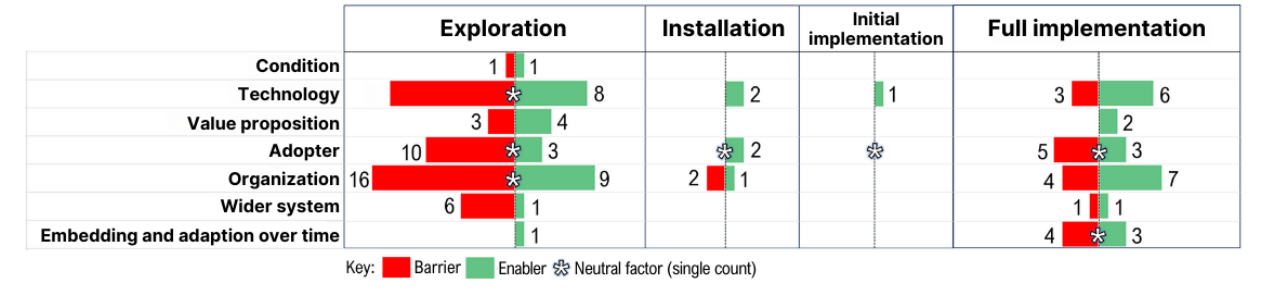
> *So, we need to optimise it...how do we then make sure that the tool stays accurate over time? No one really has, I think, quite worked out, I think "that's going to be the challenge."* [Clinical adopter, senior management]

Mapping NASSS-Informed Determinants to Implementation Stages Across the Health Service

Overview

It must be noted that when mapped to Active Implementation Framework stages [35-37], there was an uneven distribution of determinants across implementation stages, with most determinants falling in the scope of the exploration and full implementation stages. This highlighted a tendency of stakeholders to engage in the frequent preimplementation or exploration activity and full-scale adoption activity. In contrast, fewer determinants were associated with identifying contextual drivers, developing adopter readiness, and facilitating contextual capacity building to sustain ongoing adaption within an established feedback and monitoring strategy. Figure 4 illustrates the uneven distribution of the 126 identified determinants; Out of the identified determinants, 77 (61%) were solely associated with the *exploration* stage, 39 (31%) with the *full implementation* stage, and 6 (5%) with the *middle installation* stage.

Figure 4. A tabular diagram illustrating the Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) determinants mapped to implementation stages.



Exploration

Most determinants described in this study were identified during the preimplementation stage, which is associated with assessing organizational readiness and technological procurement (exploration stage). Enablers in this stage included mapping CDSS procurement to the clinical context and recognizing the importance of involving diverse stakeholders. Conversely, there were several barriers relating to the organizational, technological, and wider system within the exploration stage. This included a lack of streamlined executive decision-making for CDSS procurement and adaption and navigating complex governance processes.

Installation and Initial Implementation

These stages describe actions associated with identifying contextual factors, which may facilitate the integration of a CDSS into a system to inform an initial smaller-scale rollout or pilot. The organization appeared to have engaged in fewer installation-stage piloting activities; however, the key enabling determinants were identified. Among these adopter-level factors associated with enhancing clinician trust in CDSSs through education, training, and leveraging peer champions were noted. Conversely, barriers in this stage included a lack of targeted resourcing to facilitate full-cycle CDSS implementation planning.

Full Implementation

This stage represents a state of full technological integration across an entire system or organization. This involves activities associated with ongoing monitoring and iteration, scalability, and replicability. Several enablers were identified within this phase, particularly at an organizational and technological level, when considered in the context of adaption and embedment in the course of time. This included decision makers recognizing the need for ongoing investment in capacity building to sustain a digitally informed workforce and the need for ongoing iteration of CDSSs to support effective practice in the course of time. The barriers identified included the lack of sustained organizational champions postadoption and insufficient training and information on technology upgrades which occurred over time.

Multistage Implementation Activities

Four determinants spanned multiple stages. Organizational-level training of champions supported CDSS adoption in both exploration and installation stages. A notable barrier was the lack of knowledge and guidance for implementation planning, affecting organizational readiness. Trust in CDSS was recognized as varying among clinicians and was not systemically evaluated across all implementation stages. Inbuilt tracking mechanisms to measure uptake and patterns of CDSS were seen as beneficial for transparency and user fidelity throughout implementation cycles but were not uniformly explored or applied.

Discussion

Principal Findings

By mapping NASSS-informed determinants influencing CDSS implementation cycles using the Active Implementation Framework stages [35-37], our research provides pragmatic insights to inform tailored integration strategies of these technologies into large hospital systems. Despite encountering limitations in implementation capacity and planning know-how, the institution demonstrated strength through a well-equipped clinical informatics workforce and early-stage training of its adopter workforce. This finding aligns with existing literature, emphasizing the critical role of organizational culture and support structures in successful technology adoption [13,31]. Second, CDSS implementation faced technological hurdles, including interoperability and interface issues, a frequently reported CDSS engagement barrier [15,22,55]. However, positive user experiences emerged as a significant factor influencing CDSS use, particularly when adopters could directly experience improved efficiency and better patient outcomes for themselves. This underscores the importance of user-centric design and showcases the practical impact of CDSS on health care workflows, aligning with the broader pattern of emphasizing end user perspectives in technology adoption [12,15,17]. The presence of peer champions among clinicians emerged as a significant enabler. Peer-to-peer support and advocacy played a crucial role in enhancing clinician confidence and acceptance of CDSSs, contributing to a smoother initial implementation process. Moreover, the study reveals wider systemic barriers, such as a lack of clear governance for CDSS applications, aligning with the ongoing discourse on the necessity for robust regulatory frameworks in the broader implementation of digital health care technologies [25,56]. This finding emphasizes the need for a systemic approach to address governance gaps and ensure the effective integration of CDSSs into health care systems. These findings strongly align with our recent scoping review, which mapped reported CDSS

implementation barriers and enablers to NASSS domains [31]. Although further empirical evidence from successful implementation is required, this further highlights the reliability of the NASSS framework as a pragmatic tool to identify meaningful domain-level determinants associated with the implementation of technology within health systems [24,54].

When determinants were mapped to the *Active Implementation Framework stages* [35-37], a clear pattern emerged highlighting implementation activities most notable in the early stage of *exploration* and the later stage of *full implementation*. The absence of planned piloting and process evaluation was not unexpected, given a lack of evaluation and implementation planning *know-how* was identified as a key organizational readiness barrier.

This may be addressed through the application of theory-informed approaches to implementation planning [27,30]. This finding aligns with the gaps identified in our recent scoping review examining the use of theories, models, and frameworks to support CDSS implementation within hospital systems [29]. This review [29] reported an inconsistent application of systematic approaches to implementation planning within hospital systems in several countries.

Furthermore, while organizational-level training of champions was crucial and supported CDSS adoption in both the exploration and installation stages, this was not sustained throughout the implementation life cycle. This weakening of the informatics-adopter sociotechnical network during the course of time may have contributed to the communication issues adopters frequently highlighted. This study identified 3 key communication issues in the implementation of CDSSs. First is the challenges in effectively communicating and coordinating within the complicated web of governance structures, potentially impeding the progression of CDSS implementation. Second, the limitations in ongoing communication about system updates and advancements may lead to adopters being unaware of improvements, impacting their ability to fully use the CDSS. Third, trust in CDSSs was recognized as varying among clinicians, indicating a potential communication challenge in conveying the benefits and reliability of the system uniformly across all CDSS adopters. More rigorous implementation planning, encompassing all 4 stages, may go some way in addressing the identified communication gaps [27,29,30,35,36].

Furthermore, this study identified the need for ongoing adopter support and planned evaluation strategies encompassing the full implementation cycle [36,56]. Evidence indicates that sustained cycles of monitoring and iteration may lead to sustained integration of CDSS in health care systems [21,34,57]. For example, planned mechanisms for user tracking allow for real-time assessment of uptake, which may impact the choice and delivery of implementation strategies to facilitate the continuous adoption of the innovation in practice [10,58].

Strengths and Limitations

The study's strengths lie in its holistic systems thinking approach, which provides a comprehensive understanding of the challenges and enablers within each implementation stage and across implementation cycles for complex systems such as CDSS. The researchers acknowledge that the final phase, defined as *full implementation* within the *Active Implementation Framework*, does not fully address all components of sustainability, which can include factors such as changing legislation, government (federal and state) budgets, and workforce capacity [35,36,57,59]. However, this framework does acknowledge factors that bridge the policy gap within an organization, including clear governance pathways and longer-term resourcing, in addition to recognizing embedded behavior change and ongoing monitoring and iteration as parts of full implementation cycles [35].

It must be noted that while this study was intentionally designed for a 2-year period, there may have been specific events (including the COVID-19 pandemic) that may have influenced participant perceptions. However, it was not within the study's scope to contextualize a comprehensive list of events that could have impacted perceptions. Nonetheless, our questions were designed to probe reasons behind participant perceptions when interviewed; early analysis of transcripts allowed us to identify preliminary themes and gaps, ensuring that a diverse range of perspectives were explored and stopped when no new insights were gained [33,42,44]. The participants' roles can influence their perceptions and experiences with CDSS implementation. Clinical adopters might focus more on usability and patient impact, whereas senior management or informatics professionals may prioritize technical challenges and integration issues [60]. Findings may not fully generalize to other health care settings with different organizational structures, levels of technological maturity, or cultural contexts [10]. It must be noted that patient perspectives were outside the study scope, which focused on clinicians as end users within an acute-care (hospital) setting. Recommendations and insights derived from this study may need to be interpreted cautiously in broader contexts and may apply more directly to the study settings where similar participant distributions and roles are prevalent [10,61]. Future work should also consider examining patient perspectives to enhance insights.

The study was conducted within a specific health care system, potentially limiting the generalizability of some findings. However, the use of the NASSS framework has identified multilevel determinants that align with trends in contemporary research findings across the health care system [31,62,63]. Moreover, the study's participant population represents a broad spectrum of stakeholders involved in CDSS implementation, including clinical staff adopters, organizational champions, and informatics professionals. This diversity ensured the representativeness of perspectives needed to understand the broader contextual factors applicable beyond this study's settings [63,64]. By including individuals from various departments and decision-making levels, the study captures a holistic view of the challenges and facilitators influencing CDSS adoption, contributing to a nuanced understanding of implementation dynamics within the hospital system. Furthermore, this qualitative study was exploratory in nature and enabled us to unpack the intersectionality of multiple determinants in influencing a range of implementation outcomes.

Future research could extend the use of the NASSS framework to the application of CDSS in different health care environments

or medical conditions such as in rural hospitals or mental health care [31,34]. Furthermore, investigations might integrate a systems-level framework, such as the NASSS framework, using behavioral assessments, standardized psychological tests, or multimodal methodologies to explore individual emotional reactivity for CDSS adoption [13,65]. Such endeavors may deepen insights into health care professionals' emotional responses, such as stress levels, satisfaction, and confidence [13], to CDSS use. The insights gained could contribute to broader knowledge about technology implementation across diverse health care contexts, informing tailored strategies for improved adoption, long-term viability, and best practices to enhance CDSS adoption in various health care settings [31,66]. Additional quantitative data and further empirical application of the NASSS framework may be beneficial in further exploring specific qualitative findings identified in this study. Future research could explore the longitudinal aspects of CDSS adoption to capture changes and adaptations over extended periods by conducting trials with integral process evaluations to test the identified implementation factors across diverse populations and settings [53,60,63].

Conclusions

These findings address a significant knowledge gap in the literature using system thinking principles to identify the interdependent dynamics of CDSS implementation. In moving forward, this study serves as a catalyst for informed decision-making in CDSS implementation, offering actionable insights for practitioners and researchers alike. As technology continues to evolve and health care landscapes transform, the lessons gleaned from this study provide a foundation for refining CDSS implementation strategies and advancing patient-centered, efficient, and ethically sound health care practices.

Acknowledgments

The authors would like to gratefully acknowledge the study participants who gave their valuable time to participate in this study.

Data Availability

The dataset (which includes individual transcripts) is not publicly available due to confidentiality policies.

Authors' Contributions

MF, SM, and SN were involved in the conceptualization of the study. MF and SN were involved in the methodology, and MF, BA, and SN were involved in the validation. Formal analysis was performed by MF and SN, visualization was performed by MF and BA, and investigation was performed by SM and SN. The study was supervised by BA, SM, ZT, and SN. Writing the original draft involved MF and SN, and the writing was reviewed and edited by MF, BA, SM, ZT, AT, and SN.

Conflicts of Interest

MF reports that financial support and paper publishing charges were provided by the Digital Health Cooperative Research Centre (DHCRC-0058). SM reports that financial support was provided by fellowships administered by the National Health and Medical Research Council administered (#1181138). Other authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Abstract

In the rapidly advancing landscape of artificial intelligence (AI) within integrative health care (IHC), the issue of data ownership has become pivotal. This study explores the intricate dynamics of data ownership in the context of IHC and the AI era, presenting the novel Collaborative Healthcare Data Ownership (CHDO) framework. The analysis delves into the multifaceted nature of data ownership, involving patients, providers, researchers, and AI developers, and addresses challenges such as ambiguous consent, attribution of insights, and international inconsistencies. Examining various ownership models, including privatization and communization postulates, as well as distributed access control, data trusts, and blockchain technology, the study assesses their potential and limitations. The proposed CHDO framework emphasizes shared ownership, defined access and control, and transparent governance, providing a promising avenue for responsible and collaborative AI integration in IHC. This comprehensive analysis offers valuable insights into the complex landscape of data ownership in IHC and the AI era, potentially paving the way for ethical and sustainable advancements in data-driven health care.

KEYWORDS

data ownership; integrative healthcare; artificial intelligence; AI; ownership; data science; governance; consent; privacy; security; access; model; framework; transparency

Introduction

Integrative health care (IHC), which emphasizes a holistic approach to patient well-being [1], increasingly incorporates artificial intelligence (AI) to enhance health care delivery. Within this intersection, questions regarding data ownership become pivotal [2]. The wealth of patient data created during the practice of IHC and processed by AI includes medical history, social determinants of health (SDOHs), lifestyle factors, and treatment responses. These underscore the importance of clarifying ownership and control over this sensitive information. Varied legal and ethical perspectives on health data ownership have emerged. These include individuals retaining certain rights and interests in the data, leading to the dilemma of data ownership in health care [3], especially in the age of AI. For instance, in common law countries like the United States, health care providers typically own physical patient records, not patients. While patients have access rights under privacy or freedom of information laws (and health information laws in some regions), these do not equate to ownership. Similarly, government agencies (eg, disease registry administrators) own patient data stored in their databases. In this context, we focus on a detailed exploration of data ownership in the IHC and AI era, discussing its implications and challenges in the United States.

Many countries grapple with data ownership frameworks, particularly in health care. Some, like those with national electronic health records, prioritize centralized accessibility [4,5]. Others, with federalized health care systems, navigate the division of responsibility between national and regional

governments [6]. This complexity underscores the need to examine the US context. Within the United States itself, data ownership can also vary significantly. Just like the health care example, some regions might have more centralized data access, while others operate with a more fragmented system. This internal diversity emphasizes the importance of exploring such frameworks across the US landscape.

This study aims to evaluate common data ownership models that apply to the IHC setting, scrutinizing their appropriateness based on the purpose of law and ethics. Through this exploration, we intend to contribute to the ongoing dialogue surrounding the responsible integration of AI in IHC. The study sheds light on the significance of patient-centric data governance, providing insights into the legal and ethical implications and considerations for ensuring responsible and transparent AI implementation within integrative health (IH).

IH Model

IHC embraces a holistic approach to wellness and centers on the interconnectedness of the mind, body, and spirit, advocating for comprehensive healing that addresses all facets of an individual's health [1]. IHC often adopts an interdisciplinary modality, fostering collaboration among practitioners from diverse fields to deliver optimal care. This integrative team may include medical doctors, nurses, acupuncturists, chiropractors, and other health care professionals [7]. The IHC model has gained significant momentum in recent years. The United States National Institutes of Health established a dedicated center, the National Center for Complementary and Integrative Health, for IHC research. Additionally, the Veteran's Health Administration's Whole Health System [8] exemplifies its implementation within large health care systems. This growing recognition positions IHC as a key component of the learning health system, aiming to continuously improve patient-centered care through data-driven insights [9].

At the core of IHC is integrating conventional and complementary approaches, forming a coordinated health care ecosystem. This approach emphasizes multimodal interventions, combining conventional health care practices (medication, physical rehabilitation, and psychotherapy) with complementary health approaches (such as acupuncture, yoga, massage, lifestyle coaching, and so on) [1]. These tailored interventions address the entire individual rather than focusing solely on a specific organ system. IHC seeks to deliver comprehensive health care that addresses an individual's well-being by promoting well-coordinated care among diverse providers and institutions.

Incorporating integrative approaches to health and wellness is gaining momentum within health care settings in the United States [10]. Researchers are actively investigating the potential benefits of IHC in diverse contexts, such as pain management for military personnel and veterans, symptom alleviation for patients with cancer and survivors, and programs promoting healthy behaviors [11]. These ongoing investigations seek to shed light on the transformative potential of IHC in enhancing patients' overall well-being, and patient and provider-generated data often appear through the processes.

An IH practice process typically involves the following steps:

1. The patient consults with an IH practitioner to discuss their health concerns and goals.
2. The IH practitioner assesses the patient's health and devises a treatment plan that may incorporate a blend of conventional and IH practices.
3. The IH practitioner may recommend the patient to other providers, such as chiropractors, acupuncturists, or nutritionists.
4. The patient collaborates with these additional providers to develop a more comprehensive treatment plan.
5. The health care providers work together to offer the patient the best possible care, focusing on the specific condition and overall well-being and long-term health outcomes improvement.

For instance, a patient experiencing chronic pain might consult an IH practitioner who crafts a treatment plan encompassing physical therapy, acupuncture, and herbal supplements. The practitioner may also recommend a nutritionist to guide the patient in making dietary changes, supporting their healing, and using food as medicine [12] to ease the mental response to the body changes. The IH model is increasingly embraced in health care, reflecting a growing interest in holistic approaches to address health concerns. The interdisciplinary collaboration among IHC practitioners enables patients to receive comprehensive and effective care. However, it is worth noting that the data generated by patients, providers, and other stakeholders throughout this process can be substantial on a large scale, covering a wide range of data fields and categories (Table 1).

In addition to the 3 main categories mentioned earlier, IH clinical practice may also generate data on the following:

1. Patient-reported outcomes (PROs): Include assessments such as pain scales, mood evaluations, and sleep diaries
2. Clinical laboratory tests: Involve procedures like blood work and imaging studies
3. Patient engagement and adherence to treatment plans: Monitoring how actively and consistently patients participate in and follow their treatment plans
4. Cost-effectiveness of IH interventions: Evaluating IH approaches' economic efficiency and value
5. Adverse events or side effects: Tracking any negative reactions or undesirable effects resulting from IH therapies

IHC represents a paradigm shift in the health care model, moving from a disease-centered approach to a holistic one that prioritizes patient's well-being by incorporating a wider range of data sources, fostering interdisciplinary collaboration, and potentially leveraging AI for personalized insights. IHC's strength lies in its interdisciplinary nature, where various providers (doctors, therapists, and nutritionists) collaborate and continuously learn from patient data. This collaborative approach, while fostering innovation and new interventions, creates a complex data landscape. Since IHC collects a wide range of data—medical history, behaviors, SDOHs, and even patient-developed wellness plans (and often uses AI to analyze it), the ownership of these combined datasets and the potential new knowledge derived from them becomes unclear.

Furthermore, the very process of AI analysis creates additional complexities. As AI identifies patterns and trends within this rich patient data, new knowledge may be generated. Who owns these "derived data"? Does the ownership lie with the patient who provided the original information or with the platform that developed the AI creating the insights?

These uncertainties around data ownership can discourage patients from fully engaging with IH programs, fearing a loss of control over their personal health information. Clear data ownership policies and legal frameworks are essential to navigate these complexities. The health care stakeholders, including patients, caregivers, providers, and health care systems, need to understand how their data are being used, who has access to it, and for what purposes. Only then can IHC unlock its full potential for holistic and personalized medicine and improved health outcomes while ensuring patient trust and privacy. Next, we will dissect the data ownership issues from the practice perspective.

Table 1. Data types generated in the clinical practice.

Category	Examples
Patient information	This type of data can include demographic details, medical history, family history, lifestyle factors, and SDOHs[a].
Treatment details	This encompasses integrative health therapies provided, including acupuncture, massage therapy, herbal medicine, nutritional counseling, and mindfulness practices. It also includes information on these treatments' frequency, duration, and intensity.
Patient outcomes	This involves assessing the impact of integrative health interventions on patient health and well-being. Relevant outcome measures include symptom management, quality of life, functional status, and overall satisfaction with care.

[a]SDOH: social determinant of health.

Data Ownership Issues Rooted in the IHC Practice

Data ownership issues can arise at all stages of health care, including the IHC practice process, from the initial assessment to developing a treatment plan to monitoring the patient's progress.

Assessment Phase

During the assessment phase, the IHC practitioner may collect data from the patient's electronic medical records (EMRs), diagnostic tests, and questionnaires. Like other medical fields, data collected from EMRs and tests are often used to plan treatment options. In the IHC settings, PRO data, or real-world data, have more essential roles than traditional models, as PRO data may assist shared decision-making [13] and are associated with the enrollment of IHC approaches [14]. However, from the data ownership perspective, these data may contain sensitive information about the patient's health condition and lifestyle.

For example, an IHC practitioner may ask patients about their diet, exercise habits, sleep patterns, stress levels, and use of herbs and other supplements that the local policy or law may not regulate. The sensitivity of this information may burden some providers when certain patients have situations that they may not want to share with other stakeholders to avoid potential troubles. For instance, a patient might be hesitant to disclose a history of substance abuse or mental health concerns, fearing discrimination from employers or insurers. This is especially concerning in the context of IHC, where expanded access to data raises the stakes for patients who could face negative consequences for past medical decisions, such as declining to seek treatment or noncompliance. These data are essential for the practitioner to develop an accurate and effective treatment plan for the patient Determining how these data can be used for medical diagnosis, how patients can authorize providers to access them, and how patients can control or participate in data transfer and usage raises significant challenges. However, it is also important to note that these data are sensitive and confidential. The patient has a right to know how their data are being used and to control who has access to it.

Treatment Plan Development

Once the practitioner has assessed the patient's health, they will develop a treatment plan. This plan may include a combination of conventional and IH practices, as discussed above. For example, an IHC practitioner may recommend that a patient with chronic pain take a combination of over-the-counter pain relievers, acupuncture, and yoga. The practitioner may also suggest dietary changes and stress management techniques.

The treatment plan may require the patient to share additional data with the practitioner, such as their treatment response or progress. Many of these data may not be categorized or can be innovative exploratory work that no other medical field has touched, which reflects the whole person-based care model. These data can be generated through new interventions, while the treatment plan outcomes formulated between patients and interdisciplinary providers may not have standard end point criteria. Another challenging part here is understanding the different data levels related to a person's life. Beyond that, much data can be associated with SDOH [15] and other measurements that have yet to be invented or discovered, which could pose future privacy challenges. For instance, the integration of genetic data or continuous environmental monitoring could create more detailed profiles, raising new questions about who has access, how it can be used, and the potential for discrimination [16].

Monitoring Phase

During the monitoring phase, the practitioner will track the patient's progress and adjust the treatment plan as needed. This may involve collecting additional data from the patient, such as their symptoms, quality of life, and satisfaction with the treatment.

These data are essential for the practitioner to ensure that the patient receives the best possible care. However, it is also

important to note that these data are personal, sensitive, and confidential; like the data generated during the treatment phase, they can be collected by multiple providers. It may also contain health data collected from the patient's family member and caregiver, including qualitative data that may have the patient's family member's personal information. Thus, the patient has a right to know how their data are being used and to control who has access to it.

AI in the IH Setting

AI technologies have proven to be powerful tools in many health care fields, leading a shift in health care delivery focusing on the patient and their overall well-being [17]. AI holds immense potential to revolutionize the IHC [2] by enhancing patient outcomes, boosting efficiency, and transforming health care delivery [18]. One of AI's key contributions lies in enabling personalized medicine. By analyzing patient data encompassing medical history, genetics, lifestyle, and environmental factors, AI can assist IHC providers in tailoring treatment plans to individual needs, ensuring optimal care [19-21]. In addition, AI can analyze patient data to identify patterns or markers indicative of underlying health conditions, facilitating earlier and more accurate diagnoses [22]. AI's capabilities extend to improving treatment outcomes by providing real-time analysis of patient data and presenting relevant treatment options, empowering IHC practitioners to make informed decisions [23]. Furthermore, AI can automate routine tasks, such as scheduling appointments and managing patient records, alleviating the administrative burden on practitioners and allowing them to devote more time to patient care [24,25].

Significant breakthroughs in AI and IHC primarily focus on optimizing therapeutic models, including AI-assisted acupuncture [26], traditional Chinese medicine diagnoses through tongue and lip analysis [19], and traditional Chinese medicine syndrome identifications [27]. In addition, the research explores the use of AI in mindfulness practices [28] and medication adherence [29], leveraging EMR and natural language processing to improve the syndrome pattern diagnosis of lung diseases in integrative medicine [19]. While these clinical trials and applications demonstrate promising progress, other endeavors strive to leverage AI's advantages in IHC beyond improving existing models, such as patient education and AI-powered symptom analysis. To summarize, the potential applications of AI in IHC can be followed by the 3 phases of IHC—assessment, treatment, and monitoring.

Assessment Phase

Personalized Risk Assessment

AI can analyze vast patient data, including genetic, lifestyle, and environmental factors, to identify individuals at higher risk of developing chronic diseases or adverse health outcomes [30]. This personalized risk assessment can guide preventive health care measures and early interventions.

Symptom Analysis and Pattern Recognition

AI-powered tools can analyze patient-reported symptoms, medical history, and clinical data to identify patterns and potential underlying conditions [31]. This can help clinicians make more accurate diagnoses and tailor treatment plans accordingly.

Mental Health Assessment and Screening

AI-based chatbots and virtual assistants can engage in conversations with patients to assess their mental health status and identify potential signs of depression, anxiety, or other mental health concerns. This can facilitate early intervention and support [32].

Treatment Phase

Personalized Treatment Planning

AI can analyze patient data and clinical guidelines to generate personalized treatment plans considering individual factors, including genetic predispositions, past treatments, and coexisting conditions [30,33]. This can optimize treatment efficacy and minimize side effects.

Drug Dosage Optimization

AI can analyze patient data and medication profiles to determine the optimal dosage for prescribed medications, reducing the risk of adverse drug reactions and improving treatment outcomes [34,35].

Nutritional Guidance and Meal Planning

AI-powered tools can analyze individual dietary needs, preferences, and health goals to provide personalized nutritional guidance and meal planning recommendations, supporting a healthy lifestyle and disease management [36].

Monitoring Phase

Real-Time Remote Monitoring

AI-enabled wearable devices and sensors can continuously collect patient data, such as vital signs, activity levels, and sleep patterns, and transmit it to health care providers for real-time monitoring [37]. This allows for early detection of potential health concerns and timely interventions.

Predictive Analytics for Disease Exacerbation

AI can analyze patient data and identify patterns that predict potential disease exacerbations or adverse health events, enabling proactive interventions and preventing complications [24,30].

Patient Engagement and Adherence support

AI-powered chatbots and virtual assistants can engage with patients, provide reminders, and offer personalized support to improve medication adherence and lifestyle modifications, enhancing treatment outcomes [38,39].

Data Generated in AI-Incorporated IHC

With the potential applications of AI in IH clinical practice, the types of data generated can expand beyond traditional patient information and treatment details. Here are some examples of data that can be created with AI integration:

1. Patient-generated health data: AI can analyze data from wearable devices, fitness trackers, and patient-reported

symptom trackers to provide insights into patient lifestyle, sleep patterns, and overall health status. These data can be used to personalize treatment plans and monitor patient progress [40,41].
2. Real-time biofeedback data: AI can analyze biofeedback data from devices that measure heart rate variability, skin conductance, and other physiological signals [42]. These data can be used to assess patient stress levels, anxiety, and pain, allowing for real-time adjustments to IH interventions.
3. Genomic and proteomic data: AI can analyze genetic and protein expression data to identify individual variations in drug metabolism, disease susceptibility, and response to IH therapies [43]. This information can tailor treatment plans and predict potential adverse reactions.
4. Predictive analytics: AI can analyze historical data and patient characteristics to predict the likelihood of future health events or treatment outcomes [44]. This information can be used to proactively identify patients at risk and tailor preventive care or treatment plans.
5. AI-driven treatment recommendations: AI can analyze patient data and clinical guidelines to provide personalized treatment recommendations, including the type, dosage, and frequency of IH therapies [30,45]. This can streamline treatment planning and improve patient adherence.
6. AI-powered clinical decision support: AI can provide real-time clinical decision support to health care providers, suggesting appropriate IH therapies based on patient data and evidence-based guidelines. This can enhance clinical decision-making and improve patient care [30,46,47].
7. AI-powered research and clinical trials: AI can facilitate the design, analysis, and interpretation of clinical trials in IH, leading to faster advancements in evidence-based practice [48,49].

Data Ownership Issues in the IHC or AI Setting

IHC and AI data collection raise complex ownership concerns due to several factors. First, individual contributions to these systems are often intertwined, making it unclear who truly "owns" the resulting data. Second, machine-generated data and AI-derived insights introduce new questions about who holds rights to these intellectual creations. Finally, traditional legal frameworks like copyright and privacy struggle to adapt to the unique dynamics of IHC and AI, leaving ownership ambiguous and potentially sparking disputes. Furthermore, there are several other challenges:

1. Ambiguity around consent and control: Individuals interacting with IHC and AI systems may struggle to understand how their data are collected, used, and shared. Consent mechanisms might be opaque, leaving users unsure if they retain any control over their information [50].
2. Difficulty attributing authorship and creativity: As AI systems increasingly contribute to data generation and analysis, it becomes challenging to determine who deserves credit for the resulting insights [51-53]. Is it the human who provided the initial data, the developer who created the AI, or the AI itself?
3. Balancing individual rights with collective benefits: While data collected through IHC and AI can offer societal benefits like improved health care or personalized services, these advantages can come at the cost of individual privacy and autonomy. Striking a balance between these competing interests remains a significant challenge [50,54].
4. Exploitation and bias risks: Unethical actors might exploit data ownership ambiguities to manipulate or discriminate against individuals [55]. Biased algorithms trained on skewed datasets can further perpetuate such injustices.
5. International complexities: Data ownership laws and regulations vary significantly across jurisdictions, creating challenges for global IHC and AI projects [56]. This can lead to confusion and hinder responsible data governance.

Addressing these complex issues requires ongoing collaboration between technology developers, policy makers, legal experts, and the public. We can ensure equitable data ownership and responsible AI development that benefits all through open dialogue and innovative solutions.

Who Has the Right to Own the Data?

Data are more critical than ever in the AI and machine learning era. This is especially true in IHC, where AI or machine learning can be used to develop new treatments, improve patient care, and conduct research. However, the ownership of IHC data is a complex issue. There are several stakeholders who may claim ownership of IHC data.

First, patients may argue that they own their data, including data derived from their medical records and diagnostic tests. Traditionally speaking, patients have limited control over the data once the deidentified data are shared with a broader audience. Due to legislation mandating patient privacy, health care providers, institutions, and governing bodies establish policies and practices that determine patients' ability to access and control their personal health information [57].

Second, IHC providers may argue that they own data derived from their patient interactions, such as data from clinical notes and patient portals. Furthermore, a provider can claim the data ownership if collected from a new intervention or clinical trial. The interaction between patients and providers is also meaningful, as patients can refuse to share the data in any research capacity. While data privacy laws allow patients to control who has their data and how they are used, limited knowledge about existing data holdings creates an informational asymmetry, hindering their ability to fully exercise these rights [58]. Thus, health care providers may proactively opt patients out of broad research programs at the outset to address limited patient control over data reuse [59]. While opting out can prevent future data collection, it does not necessarily erase existing data held by researchers, government agencies, or private entities. This creates a situation where patients may struggle to exercise their data privacy rights due to limited knowledge of which entities hold their data.

Third, researchers may argue that they own data from their research, including data derived from IHC patient data and interventions. Many clinical providers are involved in linear

research activities, which often follow the health care stream from identifying diseases to developing interventions. When considering the application of AI in clinical practice, the researchers may claim ownership of the developed algorithm (through a patent); however, in some circumstances, they may claim ownership of the data being used in the research trials and projects.

Fourth, AI and machine learning developers may argue that they own the data to train AI or machine learning algorithms, including IHC patient data, as some deidentified personal data can be purchased or licensed for research depending on its availability and approval processes. However, access to other sensitive health data, particularly from IHC settings, is often more restricted. These datasets may require specific approval from research ethics committees before access is granted [60,61].

Finally, technology companies may argue that they own data collected through their wearable devices and other health-tracking apps, including IHC patient data. Multiple companies can claim over the same data collected at the same time.

Data Ownership Models Related to IHC

Data ownership models in health care are a complex and evolving topic. There are a variety of different models, each with its advantages and disadvantages. Some of the most common data ownership models in health care are described in this section.

Privatization Postulate

Originating from John Locke's natural rights theory, the privatization postulate in health care data ownership asserts that data are a valuable private asset owned and controlled by individuals or organizations [62,63]. Within the context of IHC and AI collaboration, this model raises concerns about private entities' potential monetization of IHC data. This practice could hinder interdisciplinary collaboration, as apprehensions regarding data protection might limit information sharing among health care providers. Furthermore, developing AI under the privatization postulate may lead to proprietary algorithms, restricting their accessibility and hindering the collective advancement of IHC treatments. The focus on individual or organizational ownership may create barriers to the seamless sharing of insights and innovations, impeding the collaborative potential of IHC in the era of AI.

Despite these challenges, the privatization postulate does offer advantages. It recognizes the economic value of health care data, potentially incentivizing individuals, and organizations to invest in data collection and analysis. This could lead to advancements in personalized health care solutions and tailored treatment plans. However, the drawbacks lie in the potential negative impact on collaboration, data accessibility, and collective progress in the IHC landscape. Striking a balance between recognizing the value of data as an asset and fostering collaborative efforts is crucial for successfully integrating AI in health care under this ownership model.

Communization Postulate

Unlike the privatization postulate, the communization postulate views data as a public good to be shared openly, and data can be used simultaneously and legally [63-65]. In the context of IHC and AI, this model emphasizes collaboration and coordination among interdisciplinary health care providers, researchers, and patients. The concept of shared data platforms and open-source AI aligns to improve resource use and, consequently, patient outcomes. Challenges may arise while this model envisions a more inclusive and collective approach to health care data. Concerns about responsible and ethical AI use and the equitable sharing of benefits necessitate careful consideration. Achieving a balance between open collaboration and addressing ethical concerns becomes imperative to realize the positive outcomes envisioned fully under the communization postulate.

The advantages of the communization postulate lie in its potential to break down data silos, promoting seamless data sharing and accessibility among health care providers. This collaborative environment can foster innovation, leading to more effective IHC treatments. However, the model also raises ethical considerations, such as ensuring data are used responsibly and equitably [63]. Striking this balance is crucial for successfully implementing the communization postulate in IHC, ensuring that the benefits of shared data extend to all stakeholders while upholding ethical standards.

Intellectual Property

Ownership of health data can be both tangible and intangible property [66]. Regarding tangible property rights, the answer is sometimes for sure. For example, it is likely to be said that medical providers, rather than patients, typically own physical medical records in the United States [3]. Meanwhile, health data are intangible information. Relevant stakeholders can own health information based on different types of laws in the field of intellectual property, including patent law, copyright law and copyright in databases, trademark law, and trade secrets. However, such ownership protection must meet various criteria, leading to clarity and incomplete or partial ownership protection of health data [66]. For example, health data should be patent eligible in order to enjoy patent protection [67]. Also, trade secrets or relevant confidential information laws apply to limited types of health data and several questions are still open concerning ownership of health data [68]. Furthermore, conferring ownership rights through intellectual property law is even more complicated in the AI background, such as AI's capacity to claim intellectual property rights, determining contributions between humans and AI, and so forth. Therefore, answering ownership questions concerning AI-generated health data in the context of intellectual property law is highly complex and uncertain.

Next, we will discuss the current data ownership models in health care data that are related to IHC. Understanding the advantages and disadvantages of these models can help to address the rising issues and conflicts in the data ownership of IHC in the AI era.

Distributed Access Control Model

The distributed access control (DAC) [69] model presents a decentralized approach to data ownership, providing individual health care providers or organizations more control over their data, especially in the context of IHC and AI. This model addresses critical concerns related to privacy and security in health care data. By allowing entities to control access to their data through mechanisms such as role-based access control or attribute-based access control, the DAC model aims to safeguard sensitive patient information. However, the emphasis on individual control may lead to challenges in data sharing between providers, resulting in fragmented care and potentially hindering medical research progress within the interdisciplinary landscape of IHC.

While the DAC model helps mitigate privacy and security concerns, it introduces complexities related to data silos and barriers to efficient information exchange. The fragmented nature of data ownership under DAC can hinder collaborative efforts in IHC, limiting the comprehensive understanding of patient health and potentially compromising the effectiveness of treatments. In addition, difficulties in research access may arise, as researchers need permission from each provider or organization that owns the data. Balancing individual control with the need for seamless collaboration and research access becomes essential in implementing the DAC model effectively within IHC, particularly in the era of AI.

Data Trusts

Data trusts, as legal entities holding data for multiple stakeholders, offer an alternative to the DAC and communization models in the landscape of IHC and AI [26]. In this context, data trusts provide increased control over data for stakeholders, promoting responsible and ethical use. Establishing a neutral and trusted third party to manage data helps address data ownership, privacy, and security concerns. However, challenges persist, particularly regarding the complexity and cost of setting up and maintaining data trusts in IHC. The intricacies involved in creating and maintaining these legal entities may not be feasible for all IHC providers, limiting the universal adoption of this model.

Despite the potential advantages, such as improved data sharing and collaboration, data trusts may face difficulties aligning the interests of the trust and stakeholders. Conflicts over data ownership and use could arise, highlighting the importance of establishing clear guidelines and frameworks for the functioning of data trusts in the realm of IHC and AI. In addition, holding data trusts accountable for their actions may prove challenging due to their complex and opaque nature. Striking a balance between the benefits and challenges of data trusts becomes crucial for their effective integration into the IHC landscape, ensuring that they contribute positively to data management and use in the era of AI.

Blockchain Technology

Blockchain technology emerges as a promising solution for secure and transparent data ownership records, particularly in the context of IHC and AI. In health care, blockchain could enhance transparency, accountability, and data sharing, reducing the risk of breaches and other security incidents [70]. However, concerns persist about the scalability and reliability of blockchain technology, mainly when applied to manage large amounts of health care data within the interdisciplinary collaboration inherent in IHC. The relatively new nature of blockchain introduces uncertainties about its widespread implementation and integration into existing health care systems.

The advantages of blockchain in IHC include its potential to create an immutable and tamper-proof ledger, ensuring the integrity of health care data. This can be particularly beneficial in maintaining accurate patient records and supporting collaborative efforts among health care providers. However, the complexity and cost of implementing blockchain technology may pose challenges, especially for smaller IHC providers with limited resources. The lack of a clear regulatory framework adds to the complexity, introducing uncertainties about data ownership and usage within the IHC landscape. Furthermore, data privacy laws, both common law and civil, are often incompatible with public blockchains because anyone can see the information stored on them. This transparency can be a major issue for sensitive data. To help developers navigate this challenge, the National Institute of Standards and Technology has created a flowchart to identify suitable blockchain use cases. Striking a balance between leveraging the benefits of blockchain and addressing the challenges is essential for its successful integration into the evolving landscape of IHC and AI.

Rethinking the Data Ownership Framework of IHC Practice in the AI Era

While IH offers a promising shift toward holistic patient well-being through collaboration and AI-powered insights, the complex data landscape it creates necessitates a robust data-sharing model. The current lack of clarity around ownership of combined datasets and AI-derived knowledge discourages patient participation and hinders progress. Addressing these concerns involves more than just technical solutions; it requires a data ownership model to safeguard data ownership rights.

Further clarification and specification of data ownership from a legal perspective is essential to consider the recommendations and legal action. Property is not the object itself but rather the ability to assert control through aggregated legal interests as McGuire et al [3] pointed out [71]. Ownership encompasses legal rights, including but not limited to possession, access, and control. Despite opposing views on establishing property rights in data for reasons such as public good, lack of market failure, fundamental rights, and transaction costs [64], it is crucial to promptly assign health data ownership. This step is necessary to actively incentivize the high-quality, efficient generation, dissemination, and use of medical data, thus energizing AI development in IH settings.

Simultaneously, the bestowed ownership of health data should be limited to strike a balance among various stakeholders' interests and appropriately reduce transaction costs. Limiting ownership for different entities aligns with the law's purpose of promoting societal progress and maintaining balance. As discussed earlier, patients, IHC providers, researchers, and AI

or machine learning developers all contribute to IHC practice data in the AI era. Co-ownership among these interested parties is essential, but granting full ownership rights to each stakeholder could significantly increase transactional costs, potentially hindering the application of health data in clinical settings, research, and AI fields. Due to the complexity involving numerous rights and interest holders, providing recommendations is challenging.

One suggested framework is to grant patients ownership only over their personal health data. Since health data without personal information have less connection to patients and dealing with numerous patients would dramatically increase transactional costs, restricting ownership to personal health data is a prudent choice. Furthermore, specific legal rules for ownership rights concerning patients' personal data can be explored with reference to Articles 5-22 of the General Data Protection Regulation (GDPR) [72]. Under GDPR, patients can request access to their own data and have some level of control (eg, delete the data or ask not to be shared with third parties). However, they do not have data ownership, which is similar to other privacy frameworks. Another crucial aspect is to establish limitations or exceptions regarding health data ownership for stakeholders like patients, IHC providers, researchers, and AI or machine learning developers. These limitations and exceptions help balance the interests among stakeholders, drawing inspiration from various fair use models in intellectual property law.

Defining ownership rights and limitations for stakeholders in the context of IHC in the AI age is challenging, especially with the emergence of AI. Identifying and allocating data ownership rights, such as determining ownership based on proportion or primary contributors, present ongoing challenges. Consideration must be given to patients' rights and privacy, physicians' efforts, AI practitioners' involvement and time commitment, and public interests. Only through this comprehensive approach can medical development and the balance of various interests be promoted, aligning with the purpose and spirit of legal regulations. While this is just 1 aspect of many possible recommendations, it is crucial as legal clarity on these issues will directly impact the establishment and implementation of other suggestions to address data ownership in IHC practice in the AI era.

In summary, we propose the Collaborative Healthcare Data Ownership (CHDO) framework. The CHDO emphasizes the collective power of data when stakeholders work together. It acknowledges that various parties contribute valuable insights to health care data, from patients to providers, researchers, and AI developers. The CHDO framework addresses this by proposing three key features:

1. Shared ownership: The CHDO framework goes beyond traditional ownership models, where one entity holds exclusive rights. Instead, it advocates for co-ownership, granting stakeholders specific rights and responsibilities over the data based on their contributions. This fosters trust and incentivizes collaboration, unlocking the full potential of data for research, development, and personalized care.
2. Defined access and control: The CHDO framework advocates the establishment of clear guidelines for accessing and using data. Patients retain control over their personal health information, while other stakeholders can access anonymized or aggregated data for approved purposes. This balance ensures individual privacy while enabling collective advancements in health care.
3. Fair and transparent governance: The CHDO framework recognizes the need for robust governance structures. Transparent policies and procedures ensure equitable access, prevent misuse, and address potential conflicts. This fosters trust and accountability among all stakeholders, creating a sustainable environment for data-driven health care progress.

Based on the analysis of various data ownership models in the context of IHC and AI presented in the previous sections, the CDHO co-ownership model offers several advantages over other frameworks. It addresses the concerns raised by the privatization postulate regarding the impact on public interest by granting patients ownership over their personal health data. In addition, it mitigates the ethical issues that may arise from the communization postulate and the stand-alone DAC model, such as privacy and security concerns. Furthermore, the CDHO model avoids limited ownership protections based on patent law, trade secrets or relevant confidential information laws, copyright law, and trademark law in the context of IHC and AI. It is important to note that the other 2 models, data trusts and blockchain technology, are primarily concerned with the management and storage of health care data and can incur significant costs. In these models, conflicts between stakeholders can persist in the absence of clear ownership rights, and there is no clear guidance for resolving them. Whether trusts or blockchains are used, a prerequisite for their establishment is the clear identification of the party with ownership rights to establish the trust or blockchain. The CHDO model effectively addresses this issue by clearly defining and balancing the interests of all parties, ensuring individual privacy and security, and promoting the realization of public interest.

These advantages are particularly significant in the context of IHC and AI. IHC's collaborative nature and focus on patient-centered care necessitate a data ownership model that fosters trust and incentivizes collaboration (shared ownership). Furthermore, the need to balance individual privacy with the potential of data for research and development aligns well with the CHDO framework's defined access and control mechanisms. Finally, the CHDO framework's emphasis on fair and transparent governance is crucial for navigating the complex ethical considerations surrounding AI use in health care. By implementing these principles, the CHDO framework unlocks a new era of collaboration, empowering stakeholders and fostering a healthier future for all, ultimately propelling the health care industry toward a data-driven and AI-integrated future that prioritizes both individual rights and collective progress.

Conclusion

While a universal solution may be elusive, navigating data ownership challenges in AI-powered IHC requires tailoring approaches to specific stakeholder needs and regulations. By ensuring that data use benefits individual patients, adheres to legal frameworks, and contributes to societal well-being, this collaboration can unlock the full potential of AI in IHC while mitigating legal risks. In essence, addressing data ownership in IHC can pave the way for a more streamlined, effective, and ethical integration of AI in health care, ultimately amplifying its benefits for the whole society.

Abstract

Background: Corneal transplantation, also known as keratoplasty, is a widely performed surgical procedure that aims to restore vision in patients with corneal damage. The success of corneal transplantation relies on the accurate and timely management of patient information, which can be enhanced using electronic health records (EHRs). However, conventional EHRs are often fragmented and lack standardization, leading to difficulties in information access and sharing, increased medical errors, and decreased patient safety. In the wake of these problems, there is a growing demand for standardized EHRs that can ensure the accuracy and consistency of patient data across health care organizations.

Objective: This paper proposes the use of openEHR structures for standardizing corneal transplantation records. The main objective of this research was to improve the quality and interoperability of EHRs in corneal transplantation, making it easier for health care providers to capture, share, and analyze clinical information.

Methods: A series of sequential steps were carried out in this study to implement standardized clinical records using openEHR specifications. These specifications furnish a methodical approach that ascertains the development of high-quality clinical records. In broad terms, the methodology followed encompasses the conduction of meetings with health care professionals and the modeling of archetypes, templates, forms, decision rules, and work plans.

Results: This research resulted in a tailored solution that streamlines health care delivery and meets the needs of medical professionals involved in the corneal transplantation process while seamlessly aligning with contemporary clinical practices. The proposed solution culminated in the successful integration within a Portuguese hospital of 3 key components of openEHR specifications: forms, Decision Logic Modules, and Work Plans. A statistical analysis of data collected from May 1, 2022, to March 31, 2023, allowed for the perception of the use of the new technologies within the corneal transplantation workflow. Despite the completion rate being only 63.9% (530/830), which can be explained by external factors such as patient health and availability of donor organs, there was an overall improvement in terms of task control and follow-up of the patients' clinical process.

Conclusions: This study shows that the adoption of openEHR structures represents a significant step forward in the standardization and optimization of corneal transplantation records. It offers a detailed demonstration of how to implement openEHR specifications and highlights the different advantages of standardizing EHRs in the field of corneal transplantation. Furthermore, it serves as a valuable reference for researchers and practitioners who are interested in advancing and improving the exploitation of EHRs in health care.

Introduction

Background

The eye is a highly evolved and complex sensory organ possessed by a wide range of species, enabling organisms to perceive and interpret visual information from their surroundings. Vision is one of the most valuable senses for humans and plays a critical role in every facet of an individual's life [1]. The sense of vision is the result of an intricate interaction among the eyes, the brain, and the nervous system [2].

Visual impairment occurs when a pathological condition disrupts the visual system and one or more of its associated functions [1]. Blindness is a major public health issue, particularly in low- and middle-income countries where access to health care and resources is scarce [3,4]. The loss of sight can severely impact an individual's daily life, hindering their ability to perform routine tasks, interact with others, and preserve their independence [5]. On many occasions, blindness can also lead to social isolation, depression, and decreased quality of life [1,5].

In 2019, the World Health Organization estimated in the World Report on Vision that there were approximately 2.2 billion people worldwide with vision impairment or blindness [1]. The prevalence of visual disability is alarming and a source of growing global concern.

The apprehension surrounding blindness is rooted not only in the physical limitations it imposes but also in its social and economic consequences [3]. From an economic point of view, the loss of sight can cause reduced workforce participation, decreased productivity, and increased health expenses [5]. Consequently, the loss of income and the higher health care costs can drain governments with additional financial pressures, exacerbating poverty and slowing economic growth [1]. Hence, the impacts of blindness are far reaching, affecting not only the individual but also their families, communities, and society as a whole.

Without more assertive measures, the escalating demand for eye care services worldwide is projected to persist and intensify in the next few decades, posing a meaningful challenge to the health care industry and requiring innovative solutions to meet the increasing pressure for quality eye care services [6,7].

The eye is a complex organ composed of several structures that work together in the perception of the world in all its lights, colors, shapes, and movements [2]. One of the most vital structures of the visual system is the cornea, which is the clear outermost layer located at the front of the eye [8]. A transparent cornea acts as a clear window to allow light to enter the eye and reach the retina, a layer of neural tissue at the back of the eye where light is converted into electrical signals and transmitted to the brain for interpretation as visual information [2]. For an individual to have clear vision, the cornea must be transparent and free of any obstructions, such as scars or opacities, to allow light to cross the eye and access the retina [8,9].

The main causes of visual impairment are cataract, glaucoma, macular degeneration, detached retina, diabetic retinopathy, and retrolental fibroplasia [3,7,10,11]. Some of these eye conditions, such as cataract, diabetic retinopathy, and retrolental fibroplasia, can negatively impact the clarity of the cornea and lead to vision impairment [2,9]. According to the World Health Organization, corneal opacities are the fourth leading cause of blindness on a global scale [9].

In many cases, visual rehabilitation is possible with corneal transplantation [4,8]. Corneal blindness can be effectively reversed with a cornea transplant from a healthy donor. Because the cornea lacks blood vessels, the risk of graft rejection is significantly reduced, making corneal transplantation one of the most successful forms of organ transplantation in the human body [8]. Corneal transplantation, also known as keratoplasty, is a surgical procedure that replaces a damaged or diseased cornea with a healthy one to restore vision and improve the quality of life of patients [4].

The success of corneal transplantation heavily relies on the accurate and timely management of patient data, including preoperative evaluation, surgical planning, and postoperative care. Electronic health records (EHRs) have evolved as indispensable means for handling clinical information, providing a centralized repository for patient records, and facilitating communication between health care providers [12,13]. The appropriate use of EHRs can substantially bolster the positive outcomes of corneal transplant surgeries, culminating in improved patient results and a more seamless and efficient care journey. By minimizing errors and inconsistencies in patient data management, EHRs can further diminish the likelihood of unfavorable events, ultimately improving the success of corneal transplants.

Despite their widespread use, traditional EHRs are prone to lack of standardization and consistency [12]. As a consequence, inconsistency and fragmentation plague the management and documentation of corneal transplantation records, causing difficulties in accessing and sharing information, increased medical errors, and decreased patient safety. Furthermore, the lack of standardization and organization creates an obstacle for health care professionals to access complete and accurate information about patients who are due to undergo or have undergone corneal transplantation, resulting in inefficiencies and suboptimal patient care.

To address these issues, there is a growing need for standardized EHRs that can ensure the accuracy and consistency of patient data across health care organizations and locations [14,15] to ultimately improve the management and documentation processes of corneal transplantation records.

One promising approach for standardizing EHRs is the use of openEHR structures [16,17]. openEHR is an open-source

standard that provides a set of specifications and tools to support the creation of interoperable data structures and the long-term management of health data [18]. A foundational paradigm on which the openEHR framework is based is the 2-level modeling, separating domain semantics from software. Under the model-driven approach, a stable reference information model constitutes the first level of modeling, whereas formal definitions of clinical content in the form of archetypes and templates constitute the second level. Overall, the adaptability, flexibility, and scalability of openEHR's modular methodology provide a powerful solution to the challenges facing the health care industry, and it is an ideal approach for health care systems of all sizes [16-19].

Objectives

Hence, this study sought to explore the implementation of openEHR structures as a means of standardizing records in the field of corneal transplantation. In addition, this manuscript expounds upon the potential benefits that may arise from the use of openEHR specifications for standardizing corneal transplantation records, including improved data consistency and completeness and increased data accessibility and sharing, alongside the mitigation of errors and inefficiencies in data management. This paper will also delve into the challenges and limitations of implementing openEHR in the context of corneal transplantation.

Through the evaluation of the potential benefits and hurdles of using openEHR specifications, this study provides an informative resource and a valuable reference for researchers and practitioners interested in improving the use of EHRs in health care, extending beyond the field of ophthalmology and encompassing other medical disciplines as well.

One of this research's objectives was to contribute to the ongoing efforts to improve the quality and safety of patient care through the disclosure of insights into the potential of using openEHR structures for the advancement of EHRs in health care, particularly in the field of corneal transplantation.

As health care continues to evolve, the authors believe that the standardization of clinical records using openEHR structures holds great potential for ensuring that patients receive safe, effective, and high-quality care.

Methods

Overview

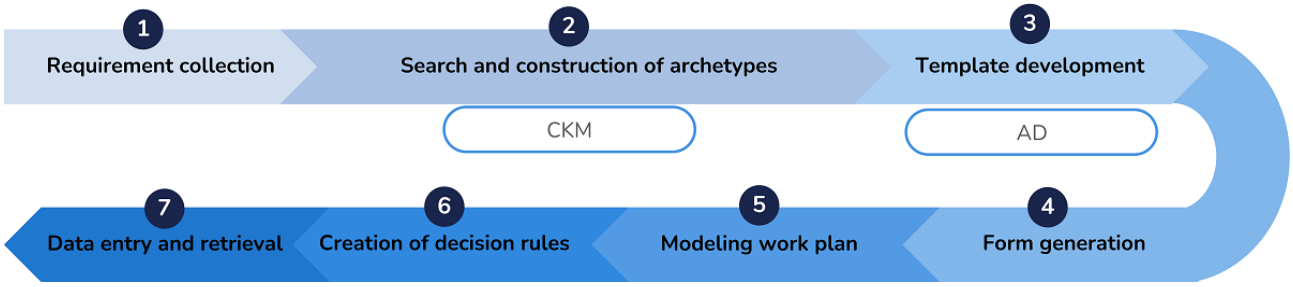
In this study, a specific methodology was defined that outlines the sequential steps involved in transforming the corneal transplantation records of a Portuguese hospital using the openEHR specifications.

In contrast to traditional approaches, openEHR's advanced modular approach separates data from applications and services, providing a level of flexibility that is unmatched in the industry [20]. This approach enables an easier adaptation to constantly evolving requirements, technological changes, health care policies, and other external factors. Moreover, by separating the data layer from the application layer, openEHR can integrate a wide range of health-related data from various sources regardless of the format in which they are stored [20].

By using archetypes and templates as a means of ensuring the consistency and accuracy of clinical data, openEHR is more supple compared to conventional approaches to clinical documentation, which often rely on free-text entries that can be arduous to comprehend and interpret across different patients and clinical settings [20]. The use of archetypes and templates allows health care institutions to minimize variability and fragmentation, which contrasts with the current uncoordinated methods. It provides a framework that allows health care professionals to customize patient-specific information in a more dynamic and structured way [19]. In addition, it ensures that clinical data remain consistently structured and semantically interoperable, leading to more precise interpretation and sharing of clinical data among different clinical systems.

In this sense, the methodology adopted in this study uses openEHR to contribute to the ongoing efforts to improve the quality and safety of patient care through the implementation of standardized EHRs. Figure 1 represents in a simplified way the different stages of the methodology carried out in this study.

Figure 1. Methodological approach followed in the standardization of corneal transplantation electronic health records using openEHR specifications. AD: Archetype Designer; CKM: Clinical Knowledge Manager.



Initially, as the objective was to develop a case study on the transformation of the corneal transplantation records of a particular hospital institution, a direct line of communication with the medical team was deemed indispensable to conduct an in-depth inquiry on the necessary requirements.

After collecting the requirements, the modeling of the openEHR structures that will support the registration and management of corneal transplantation records and the timely execution of associated tasks of corneal transplantation records began, which includes archetypes, templates, forms, decision rules, and work plans.

In the next subsections, the characterization of the work developed in each of the stages that compounds the methodology represented in Figure 1 will be described in detail.

Requirement Collection

Requirement collection is a crucial step in the development of health care systems and applications as it lays the foundation to ensure that the needs and expectations of all parties involved are understood and incorporated into the final solution.

Accordingly, the first step of the methodology started with stakeholder identification, including health care professionals and IT personnel. Overall, the process of collecting requirements for enhancing the corneal transplantation records using openEHR was a collaborative effort between medical staff, the IT personnel of the hospital's information systems department, and the developers.

After identifying a work group, a series of meetings were organized to initiate the requirement-gathering phase. This stage entailed the active participation of stakeholders, who served as the primary source of knowledge for modeling, guiding the design and development of the openEHR structures. During these collaborative meetings, a thorough analysis of the current documentation processes and data management practices was conducted to identify areas for improvement. The meetings were structured to stimulate an active feedback process from the stakeholders regarding existing workflows, specific needs and preferences, and any identified pain points and suggestions for improvement.

Over the course of these conversations, it became apparent that the information system that the hospital used for the management of corneal transplantation records was plagued by significant shortcomings, including the possibility of errors in data entry, loss of information, difficulty sharing data between health care providers, and lack of standardization.

Therefore, the main goal was to address these issues and implement a more reliable and comprehensive information management system that used openEHR structures to mitigate the problems acknowledged. Through a collaborative effort, the stakeholders were able to delimit the scope and define the requirements and use cases of the clinical domain to be modeled.

The work group identified 5 key events in the corneal transplantation process in which data-recording actions could take place. These moments were carefully analyzed to ensure that all necessary data are captured with the highest level of accuracy and consistency. Textbox 1 provides a description of each key event.

Textbox 1. Description of the 5 key events identified within the corneal transplantation process.

Key event and description

- Corneal transplantation proposal: to insert the data concerning the corneal transplantation proposal, such as type of transplant, laterality, diagnosis, priority, and motive, among others
- Contact for corneal transplantation: to record the 3 possible contact attempts for corneal transplantation, including information such as phone number, date of contact, result, reason, and date of next contact
- Schedule anesthesia consultation: to enter data regarding the scheduling of the anesthesia consultation; it contains the requesting service, the date of the appointment, the motive, and additional information
- Perform anesthesia consultation: to record the result of the anesthesia consultation, the executing service, the execution date of the appointment, and observations
- Manage suspended proposal: to register the result of the decision regarding suspended corneal transplantation proposals, either to reinstate to the list or to abandon, and the corresponding reason

Modeling and Development of Archetypes, Templates, and Forms

Archetypes, templates, and forms are interconnected concepts in openEHR that work together to ensure that clinical data are consistently collected, stored in a structured and meaningful way, and retrievable in a usable format [18,21]. By providing a standard, flexible, and scalable manner to manage clinical data, they also serve as a foundation for data sharing and exchange among different health systems and organizations, thereby promoting interoperability [22].

Archetypes are reusable, modular building blocks that describe the structure and content of clinical data elements. They define the data types, units, constraints, and other properties of specific clinical concepts, such as patient demographics, test results, and medication information [19,22].

In turn, templates are collections of archetypes that define a specific clinical record, such as a patient's progress notes, a medication prescription, or a diagnostic test result. Templates provide standardized structure and content for clinical records, ensuring that data are collected consistently in a usable and meaningful format [19].

Forms, on the other hand, provide a user-friendly interface based on templates for the input and retrieval of clinical data, supporting the entry and display of structured, semistructured, and unstructured data [23]. Forms can be customized and configured to meet the unique requirements of various clinical scenarios.

In summary, archetypes provide the building blocks for clinical data structures, templates define the standard structures for specific clinical records, and forms serve as a user-friendly interface for the input and retrieval of clinical data.

The development process of the openEHR forms in which data can be introduced in some tasks of the corneal transplantation workflow involves transforming archetypes into templates and

later into forms. For representation purposes, and to simplify the demonstration of the development process, from now on the description will focus on illustrating the development of the openEHR structures, archetypes, templates, and forms related to the corneal transplantation proposal.

As previously stated, the first step involved meetings with domain experts to define the scope of the clinical domain to be modeled and collect data requirements as specified by the archetype modeling methodology [24]. The main stakeholders involved in this process were health care professionals who were familiar with openEHR, the archetype development process, and clinical terminologies.

After determining the scope of the modeling process and identifying the clinical concepts and information elements involved, the second step entailed searching the Clinical Knowledge Manager for existing archetypes that fit the scope of the modeling scenario under consideration. The Clinical Knowledge Manager is an openEHR community pillar that enables worldwide governance of domain knowledge artifacts as well as collaborative development, management, and publishing [25]. It is an open-source library of openEHR archetypes and templates that lays the foundation for both semantic and syntactic interoperability [26].

Some archetypes were used directly, whereas others did not fully represent the data elements and had to be adapted through specialization. When no corresponding archetypes existed, new ones were created. The openEHR Reference Model defines 4 major categories of archetypes: COMPOSITION, SECTION, ENTRY, and CLUSTER. A COMPOSITION is a container class, whereas a SECTION is an organizing class, both of which contain ENTRY objects [27]. The ENTRY class is further specialized into ADMIN_ENTRY, OBSERVATION, EVALUATION, INSTRUCTION, and ACTION subclasses, of which the latter 4 are kinds of CARE_ENTRY. CLUSTERS are reusable archetypes that can be used within any ENTRY or CLUSTER [16].

For the corneal transplantation proposal, 2 archetypes were found suitable for use, namely, the service request (Figure 2), which is part of openEHR's INSTRUCTION subclass of the ENTRY class, and the anatomical location (Figure 3), which is part of openEHR's CLUSTER class.

In addition, a third archetype was created to contemplate some procedure aspects, namely, the risk, complexity, number of previous surgeries, and need for anesthesia consultation. This archetype was named "Eye Surgery Details" and belongs to the CLUSTER class. Figure 4 depicts the archetype's mind map.

At the end of this step, information concerning applicable data constraints, such as data types, cardinality, occurrences, and specific data values (eg, terminologies for coded values and ranges for numerical values), was stipulated for each archetype.

It is worth mentioning the use of Systematized Nomenclature of Medicine–Clinical Terms terminologies for mapping the coded values of the "Laterality" item belonging to the "Anatomical Location" archetype. Local terms were used for the remaining coded text items. Table 1 provides a description of the coded values used for each coded text item.

After the discovery and development of the required archetypes, the Archetype Designer tool was used to assemble and constrain the archetypes into a template that represents the requirements of the corneal transplantation proposal. A template of the COMPOSITION type was created using the "Request for Service" archetype and named "Corneal Transplantation Proposal." To begin, the "Service Request" archetype was incorporated into the content attribute. The template was then modified to remove items that were irrelevant to the clinical context being modeled, such as "Service Type," "Order Detail," and "Intent." Both the "Anatomical Location" and "Eye Surgery Details" archetypes were imported into the "Specific Details" cluster. The items "Aspect," "Anatomical Line," and "Description" of the "Anatomical Location" archetype were also excluded from the template. Subsequently, some items were assigned specific default values, the content of which can be found in Table 2.

Figure 2. Mind map view of the “Service Request” archetype. EHR: electronic health record.

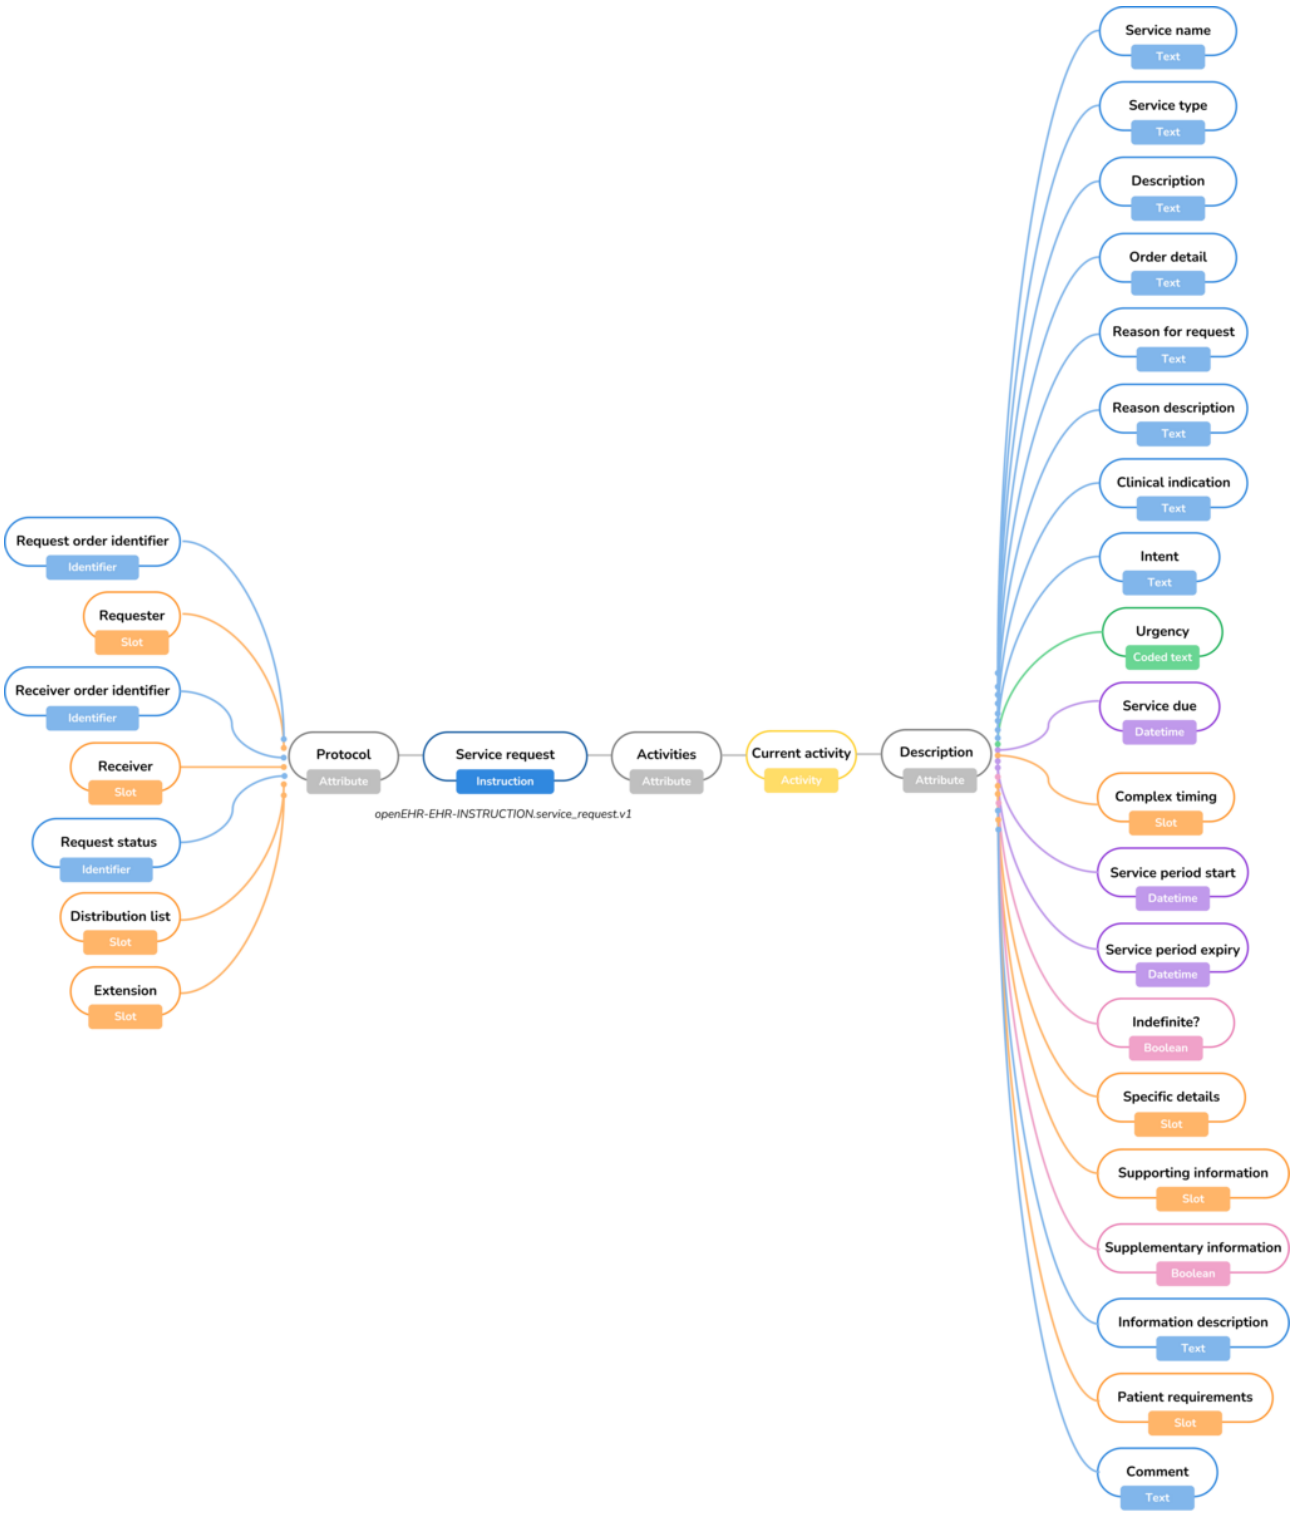


Figure 3. Mind map view of the “Anatomical Location” archetype. EHR: electronic health record.

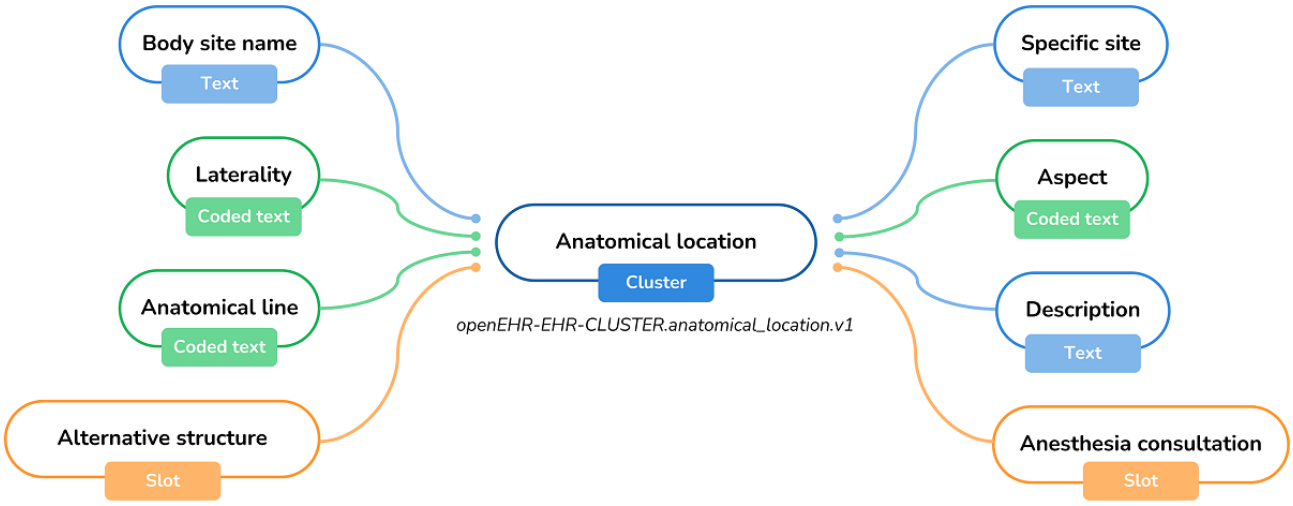

Figure 4. Mind map view of the “Eye Surgery Details” archetype. EHR: electronic health record.

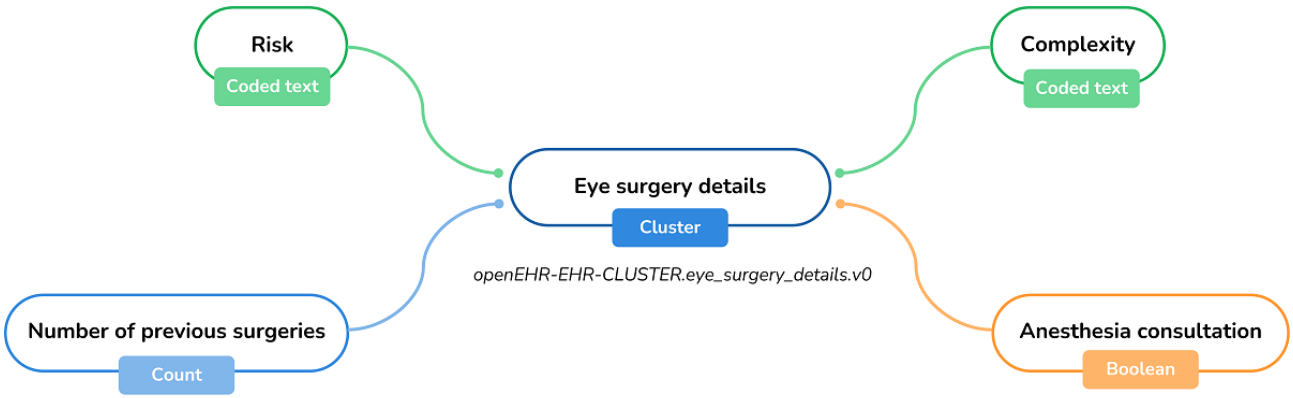

Table 1. Description of the coded values assigned to each coded text item.

Archetype	Item	Code	Value
Anatomical location	Laterality	SNOMED-CT[a]::362503005	Left eye
Anatomical location	Laterality	SNOMED-CT::362502000	Right eye
Anatomical location	Laterality	SNOMED-CT::362508001	Both eyes
Eye surgery details	Risk	at0004	High
Eye surgery details	Risk	at0005	Moderate
Eye surgery details	Risk	at0006	Low
Eye surgery details	Complexity	at0007	High
Eye surgery details	Complexity	at0008	Moderate
Eye surgery details	Complexity	at0009	Low
Service request	Diagnosis	H16319	Corneal abscess
Service request	Diagnosis	H1830	Corneal membrane alterations
Service request	Diagnosis	H52219	Irregular astigmatism
Service request	Diagnosis	H18739	Descemetocele
Service request	Diagnosis	H18519	Corneal endothelial dystrophy
Service request	Diagnosis	H18719	Corneal ectasia
Service request	Diagnosis	H1820	Corneal edema
Service request	Diagnosis	T868499	Corneal graft (complication)
Service request	Type of transplant	08R83KZ_tt_d	Total transplantation (right eye)
Service request	Type of transplant	08R83KZ_tt_e	Total transplantation (left eye)
Service request	Type of transplant	08R83KZ_dalk_d	Anterior transplantation—DALK[b] (right eye)
Service request	Type of transplant	08R83KZ_dalk_e	Anterior transplantation—DALK (left eye)

Service request	Type of transplant	08R83KZ_dmek_e	Anterior transplantation—DMEK (left eye)
Service request	Urgency	at0136	Emergency
Service request	Urgency	at0137	Urgent
Service request	Urgency	at0138	Routine

[a]SNOMED-CT: Systematized Nomenclature of Medicine–Clinical Terms.

[b]DALK: deep anterior lamellar keratoplasty.

[c]DSAEK: Descemet stripping endothelial keratoplasty.

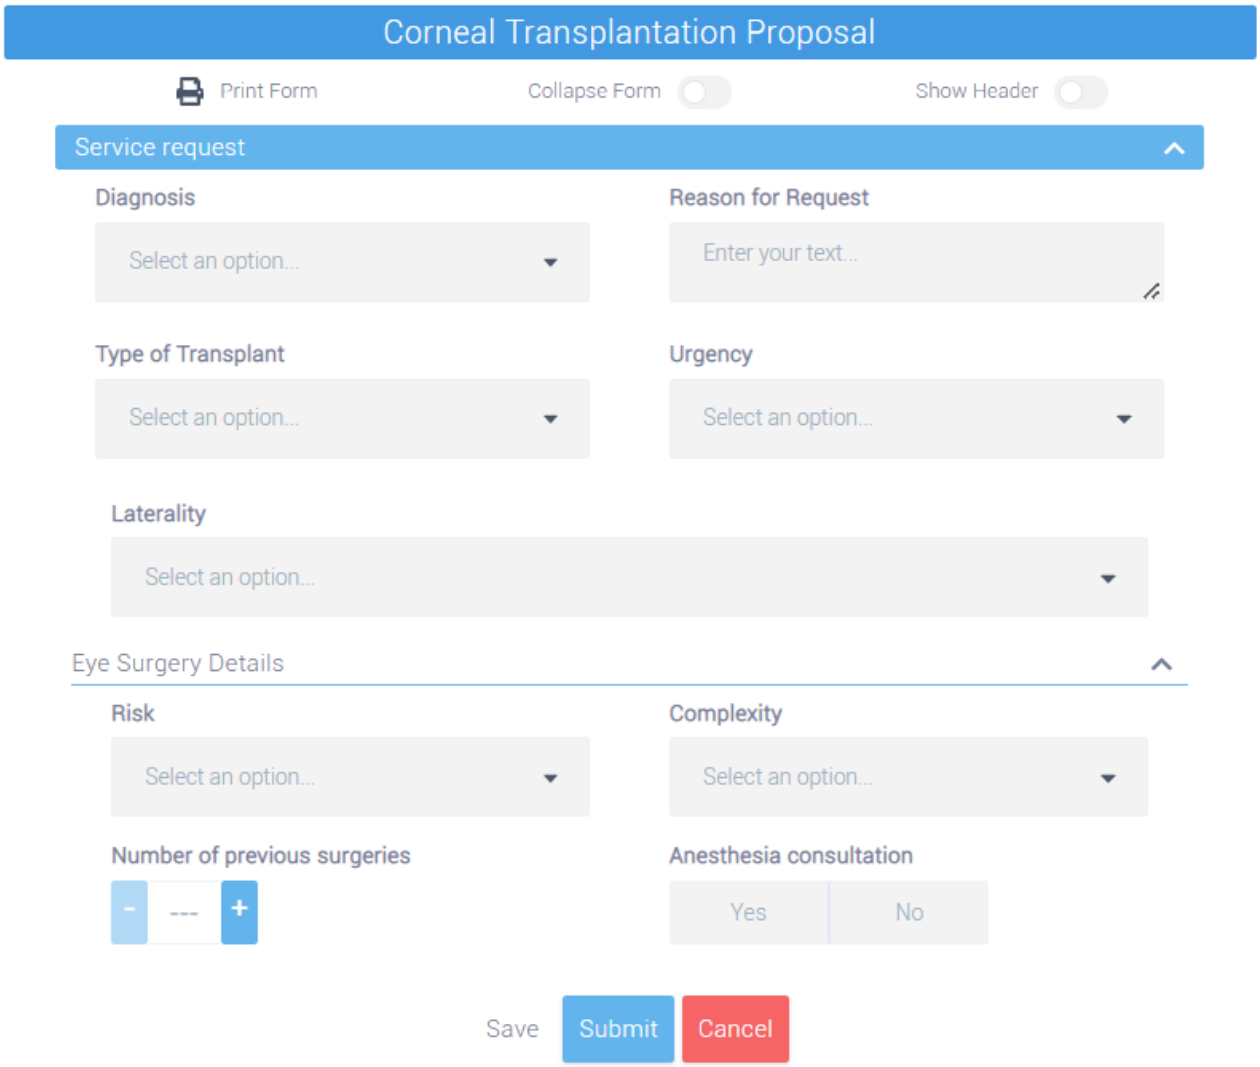
[d]DMEK: Descemet membrane endothelial keratoplasty.

Table 2. Description of the default values assigned.

Archetype	Item	Default value
Service request	Service name	Corneal transplantation
Anatomical location	Body site name	Eye
Anatomical location	Specific site	Cornea

To facilitate interpretation and manipulation, the template was exported in the Operational Template structure and later converted into the JSON Data Template structure. Finally, the JSON Data Template was injected into the Form Builder tool to format the user interface form, which can be consulted in Figure 5.

Figure 5. Graphic representation of the user interface form generated from the "Corneal Transplantation Proposal" template.



At the end of this stage, 5 forms were created. To simplify the identification of each form, Textbox 2 assigns an identification label to each form. Following that, each of these forms will be associated with specific tasks in the corneal transplantation workflow, acting as storage schemes for different patient tasks. A more detailed description of the deployment will be provided later in this paper.

Textbox 2. Forms developed for the corneal transplantation workflow.

ID and form

- F1: corneal transplantation proposal
- F2: contact for corneal transplantation
- F3: schedule anesthesia consultation
- F4: perform anesthesia consultation
- F5: manage suspended proposal

Work Plan Modeling

In recent years, a major extension has been incorporated into the openEHR specifications for addressing requirements in the area of clinical process automation, known as Task Planning [18]. Task Planning allows for the management of standardized Task Plans (TPs) and clinical workflows. The main concept of Task Planning is centered on a plan, or set of plans, that is devised to accomplish a specific goal and pertains to an active subject [28].

Within the Task Planning specification, in terms of conceptual elements, the formal concept at the highest level of hierarchy is the Work Plan (WP), which encompasses one or more TPs [29]. A WP defines a series of tasks that need to be performed in a specific order to achieve a clinical goal with respect to a

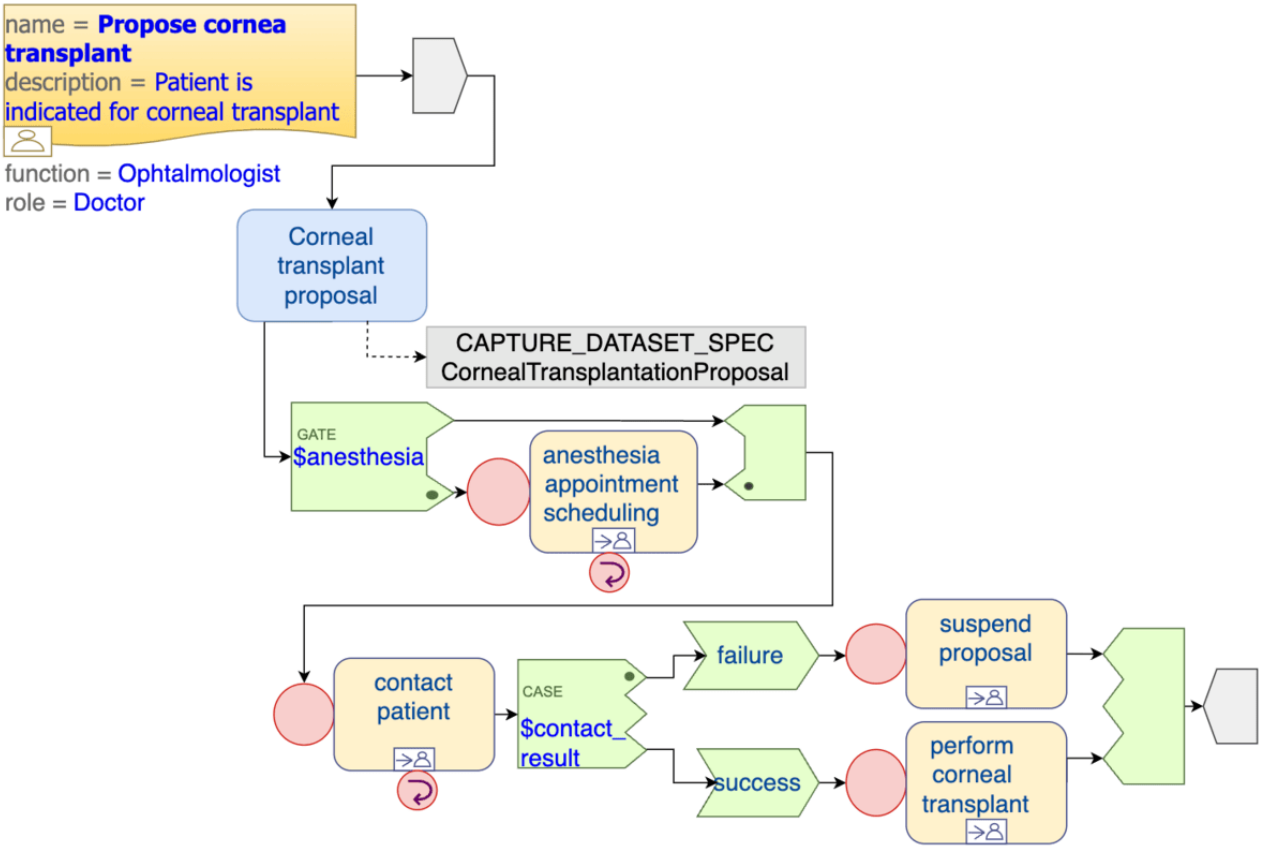
subject, human, or other subject of care [18]. It is worth noting that, as the WP is subject-centric, each subject requires a unique instance of a WP. WPs can organize and monitor the progress of clinical tasks, ensuring that all necessary steps are taken in a timely and efficient manner [29]. In turn, each TP incorporated within a WP is an explicit depiction of the work that must be performed in a particular work context by the principal performer, along with other possible participants [18]. In openEHR, the principal performer refers to the individual or entity responsible for carrying out a specific clinical action, which enables the tracking of clinical actions back to their responsible parties. The data collected through forms and the decision support provided by Decision Logic Modules (DLMs) can be used to define and update WPs in real time.

In this study, a WP regarding corneal transplantation was modeled to ensure that the implementation of the solution proceeds smoothly and is completed within the specified timeline.

The first TP defined in this WP concerns the corneal transplantation proposal. This task is available to certain ophthalmologists in specific contexts. In total, 2 TPs related to the anesthesia consultation were also included: scheduling and carrying out the consultation, which are assigned to different groups of professionals. Finally, 2 more TPs were modeled: one related to the contact for transplantation carried out by administrative staff and one related to the performance of the transplant, which is allocated to the physician who submitted the proposal in the first instance.

Figure 6 shows the first TP in a simplified way. It is interesting to note that, in this first TP, the proposal form for a corneal transplant is completed in the first performable task. After submission, the execution of the anesthesia consultation relies on the value assigned to the DV_BOOLEAN field labeled "Anesthesia Consultation" within the "Corneal Transplantation Proposal" form. If this field indicates a true value, the subsequent steps for that patient involve scheduling the anesthesia consultation; conducting the consultation; and, eventually, establishing contact for the transplantation procedure. On the contrary, if the anesthesia consultation is not necessary, the patient goes to the active waiting list represented by the cornea transplant contact tasks. If the contact is successful, the patient proceeds to undergo the transplant; if not, the proposal is suspended, and the suspension management task becomes available. All dispatchable tasks presented in this example are connected to other TPs, which mainly have a performable task with one of the associated modeled forms.

Figure 6. Representation of the top-level Task Plan.



Later in this paper, the main decisions that need to be made in the course of the WP will be explained.

Construction of Decision Rules

Overview

Clinical decision support is a key component of the openEHR architecture, responsible for automating and enhancing decision-making. The openEHR community defines decision

rules and guidelines using a specific syntax, the Decision Language (DL) [30]. DL is a formal language for representing clinical knowledge in decision-making and expressing decision support logic through rulesets.

DLMs are multisectioned modules with a specific structure for defining rules, encompassed in DL. DLMs are computerized decision-making instructions that provide a standardized and automated way to apply decision rules to patient data within the EHR in real time [30,31].

DLMs enable health care organizations to implement algorithms and rules to determine the best course of action for a given patient [32]. The output from a DLM can be used to guide clinical decision-making; provide alerts or notifications to health care providers; or drive automated actions within the EHR, such as ordering tests or medications [18].

To ensure the efficiency of the solution, decision rules were established for forms and TPs to define the logic and actions that should be taken based on specific data inputs. The rules are stored in a standardized structure that can be applied to patient data at runtime.

Overall, by automating the application of decision rules, DLMs can help reduce the risk of errors and variability in decision-making, providing more consistent care [33].

Form Decision Rules

The DLMs allow the forms to automatically adapt to the specific constraints for a given patient or scenario and to the responses of the health care professional filling in the form fields, ensuring that the information entered is always consistent with established clinical guidelines and best practices. The data collected through the forms are used as input for DLMs to support the delivery of real-time decision support.

By automating the process of adjusting forms to specific scenarios and inputs, the solution can provide decision support to health care providers, guiding them through the process of entering data and making clinical decisions.

Hence, according to the requirements gathered in the first stage of the methodology, 2 DLMs were created for guiding health care professionals in the process of filling in the forms F1—“Corneal Transplantation Proposal” and F2—“Contact for Corneal Transplantation.” Table 3 describes the association among the forms, DLMs, and rules.

Table 3. Association among forms, Decision Logic Modules (DLMs), and rules.

Form	DLM	Rule	Rule description
F1	1	1	If the patient’s age is ≥75 years, anesthesia is mandatory.
F2	2	1	If the patient intends to leave the transplant list, the motive is mandatory.
F2	2	2	If the patient needs to postpone the contact, the next contact is mandatory.

The rules associated with each DLM, including the conditions necessary to trigger a certain action, are described below.

For the “Contact for Corneal Transplantation” form, the decision logic operates as follows: If the “Result” field is set to “Cancellation,” the “Motive” field becomes mandatory. Similarly, if the “Result” field is set to “Postpone contact,” the “Next contact” field becomes mandatory.

Regarding the “Perform Anesthesia Consultation” form, the logic dictates that if the “Age” field has a value of 75 or greater, the “Anesthesia” field must be set to “Yes.”

WP Decision Rules

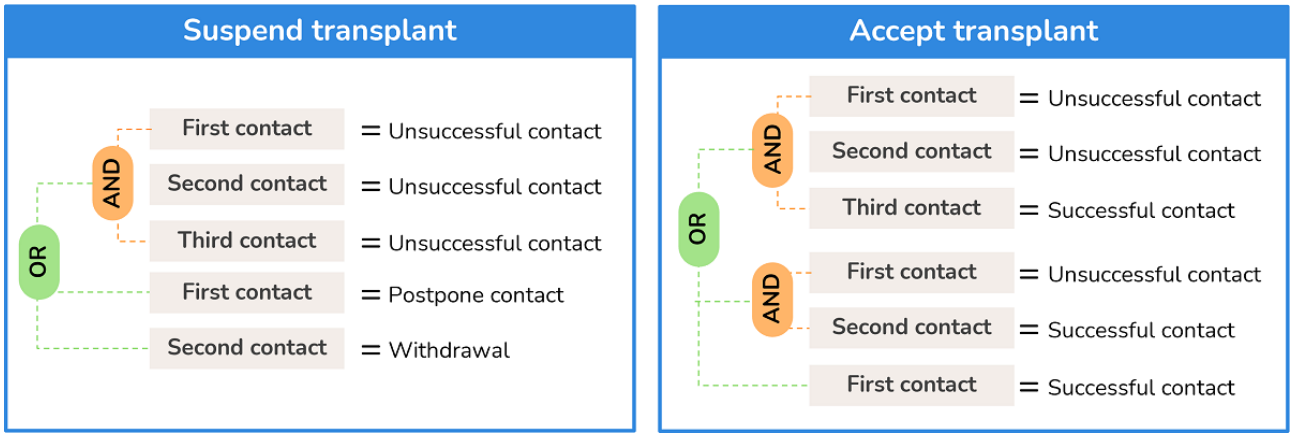
The DLM rules built to support the necessary decisions in the modeled WP were crucial for the correct functioning of the respective materializations.

The first rule to be processed concerns the decision whether the patient should proceed to an anesthesia appointment. If the priority of the proposal is urgent, the patient does not need an anesthesia appointment. If it is not urgent, the need for an anesthesia consultation is decided by the “Anesthesia” field filled in by the physician in the “Corneal Transplantation Proposal” form.

Regarding the anesthesia consultation, a rule was created to verify the success of the consultation and, thus, decide whether the patient goes to the contact for transplantation. This rule uses the data entered by the anesthesiologist in the respective form.

Then, the most complex rule was built to support the decision after the patient is called for transplant. Figure 7 represents the logic behind the decision to be made after the transplant contact, where up to 3 contacts with the patient can be registered.

Figure 7. Decision logic associated with the Work Plan.



Finally, there is still a decision that is made for suspended patients, which is based on whether they are removed from the transplant waiting list and the WP ends or the patient is reinserted into the transplant contact list, making the respective performable task available.

Ethical Considerations

In this study, all patient demographic information was anonymized through the use of the openEHR separation of the Demographic Information Model and Clinical Information Model. This approach ensures that personal identifiers are not linked to clinical data, thereby maintaining patient confidentiality and minimizing the risk of reidentification. Furthermore, the data analysis conducted in this study focused on performing statistical analyses at an administrative level. This includes examining the quantity of tasks available, the completion rate of these tasks, and referencing solely the number of patients enrolled in the study. The analysis was restricted to aggregate data, ensuring that individual patient identifiers and clinical details were not disclosed. This methodological approach allowed for a comprehensive evaluation of the operational aspects of the study without compromising patient confidentiality or violating ethical standards. The data structure of the generated forms can be found [34]. Given these protections, this study qualified for an exemption from ethical review, as per the Code of Ethical Conduct of the University of Minho.

Results

Deployment and Architecture Overview

The openEHR ecosystem provides a comprehensive solution for managing health care data by combining different tools and technologies. In openEHR, forms, DLMs, and WPs interact in a complementary manner to support the provision of effective and efficient clinical care. These modules ensure that patient data are accurate, consistent, and accessible and provide data validation, automated actions, and real-time decision support to ensure that the best course of action is taken for each individual patient. Furthermore, the integration of these modules allows for the organization and tracking of the progress of clinical tasks to ensure that all necessary clinical tasks are performed in a timely and efficient manner.

Once the modeling and validation of all openEHR structures supporting corneal transplantation EHRs were concluded, it was necessary to integrate them into an automated solution. The implementation step involved the integration of a set of tools from the openEHR ecosystem, which include Form Builder, the TP engine, and the DLM engine.

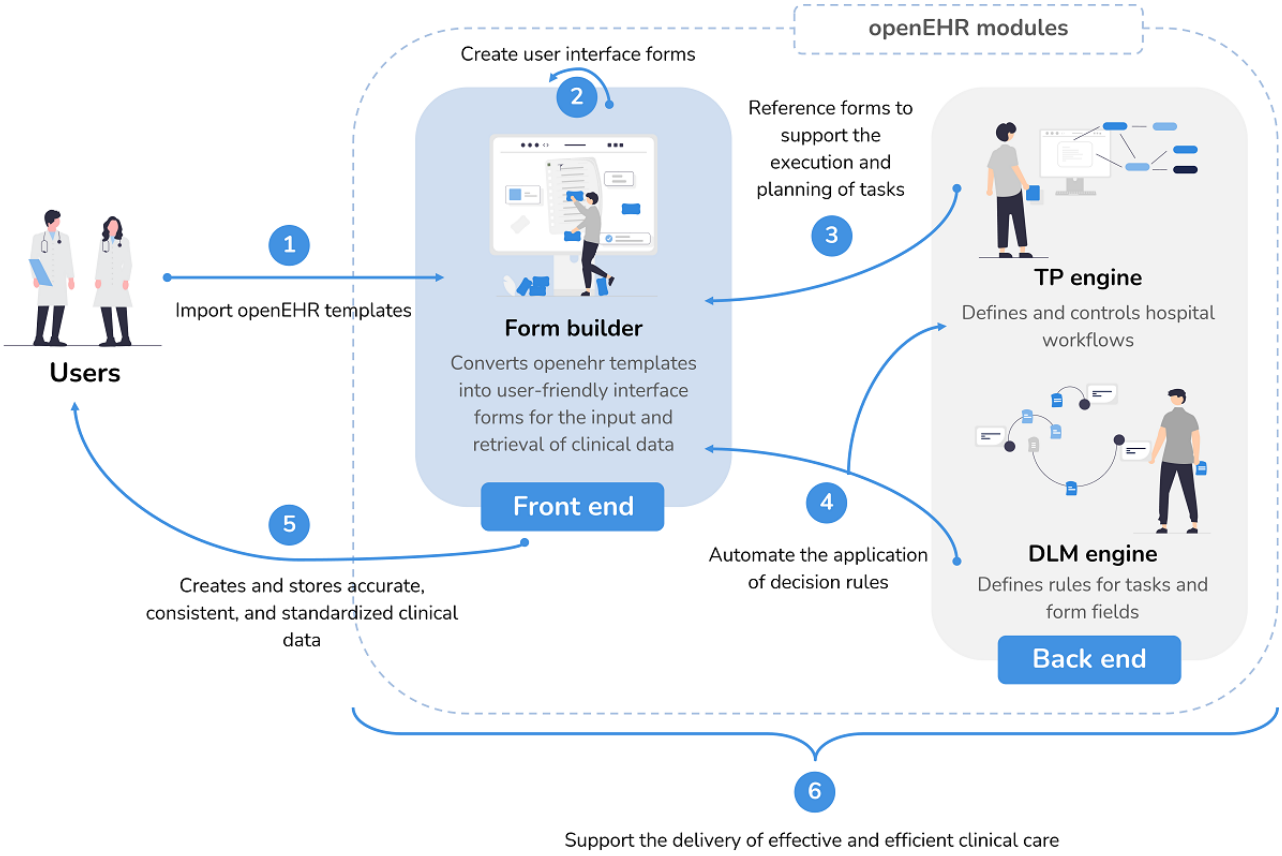
Form Builder is a web application that is designed to generate user interface forms from openEHR templates. It provides a platform for health care professionals who possess modeling knowledge to customize the user interface forms by adjusting the formatting, such as choosing colors and fonts and determining whether fields should be shown or hidden. In addition, it allows for the association of functions and refsets to form fields, which can add further functionality to the form. Using Form Builder, health care professionals can streamline the process of data entry by creating forms that are intuitive and optimized for their specific clinical workflows.

In turn, the TP engine is a tool that manages all workflows modeled by the professionals, including materialization, task status, decision management, and allocation of performers. To accomplish this, the TP module defines a formal model for processing tasks and workflows. This tool is designed to translate graphical workflow models into executable models of an organized plan that, when carried out by an engine, notifies employees of tasks. Overall, the TP engine provides an automated solution for managing and executing complex workflows in the health care setting.

The DLM engine, on the other hand, is a decision logic engine that is responsible for processing clinical or operational rules and triggering specified events based on predefined conditions. This engine plays a crucial role in supporting the logic of forms and TPs. Accordingly, it receives requests from both Form Builder and the TP engine. It ensures that decision rules are executed correctly and consistently, leading to improved patient care and outcomes.

Figure 8 illustrates the different interactions that occur among these openEHR modules.

Figure 8. Representation of openEHR modules and their interactions. DLM: Decision Logic Module; TP: Task Plan.



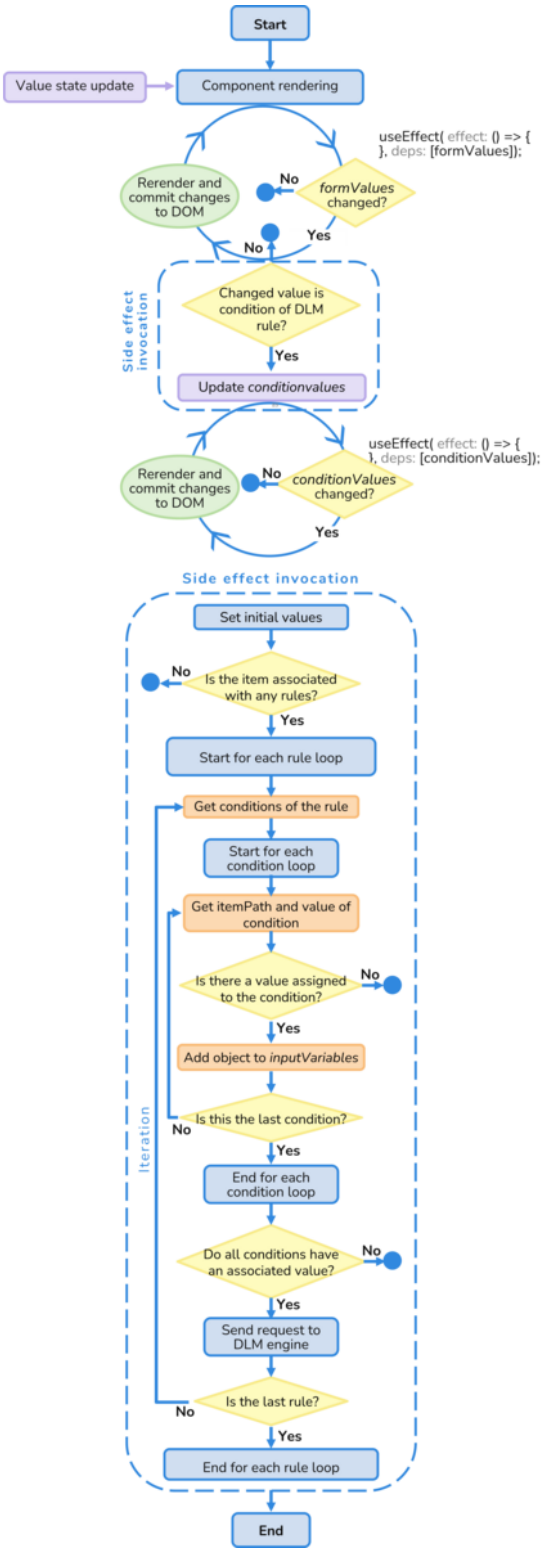
The integration of all these components was also explored in this research.

Regarding the integration of Form Builder and the DLM engine, the process starts when a health care professional updates a form field. Whenever the value of a field changes, Form Builder performs an internal processing to check whether that field is a condition of any rule within the DLM associated with the current form. If so, Form Builder identifies each associated rule and, for each of them, verifies whether there are more associated conditions that already have a value assigned to them. When all the conditions of a rule have an assigned value, Form Builder triggers a POST request to the DLM engine with the input variables. This is a well-defined sequence of computational tasks that need to be followed to properly implement the specific set of rules that have been modeled for each form. For better understanding, a graphical representation of the processing that occurs in Form Builder to verify the need to trigger any rule requests is presented in Figure 9.

Upon receiving the input variables, the DLM engine checks whether the conditions are met for executing a given rule. If the values assigned to the form fields do not fulfill a rule, an empty object is returned. On the other hand, if the values meet the conditions for executing a rule, the engine returns the path of the affected field and the type of event to execute. Form Builder then triggers the necessary actions for each field depending on the response. Figure 10 serves as an exemplification of the HTTP requests that are exchanged between Form Builder (front-end server) and the DLM engine (back-end server) in 2 distinct scenarios. In the first scenario, the health professional enters a value that triggers the execution of a rule, whereas the second scenario does not involve the activation of any rule. This diagram provides a clear representation of the data flow and communication between the 2 servers during the execution of the rule-based system.

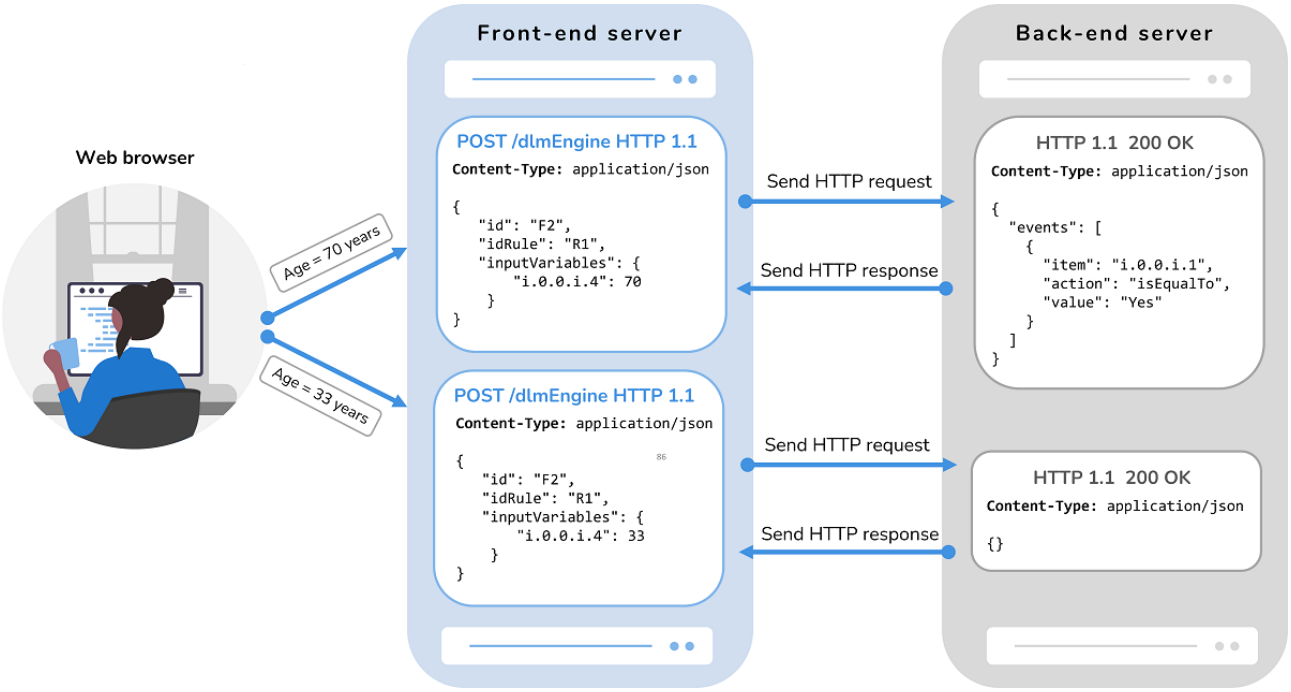
The integration of the DLM engine with the TP engine represents a remarkable achievement in the openEHR ecosystem. The successful interaction between the 2 enables the handling of all conditional structures encompassed in a WP, including condition groups, decision groups, and event groups, with the support of the DLM engine. In general, when the path of a WP materialization reaches a decision point, a request is issued to an application programming interface provided by the DLM engine with the variable associated with that point. In turn, the DLM engine processes the rules and conditions associated with the request that was made and returns a response. Through the response received, the TP engine manages to associate it with the respective branch (decision branch, condition branch, or event branch) and proceed with its execution.

Figure 9. A schematic illustration of the logic flow that occurs in the Form Builder process responsible for initiating rule requests. DLM: Decision Logic Module; DOM: Document Object Model.



In the openEHR ecosystem, the TP engine can refer openEHR forms to support the planning and execution of hospital tasks. By providing a user-friendly interface for entering and retrieving data, Form Builder makes forms available to health care professionals that can be used to collect data required for various tasks, and it ensures that the collected data are accurate and standardized. Furthermore, the responses given by health care professionals in certain fields of the form can be determinant to define which path should be triggered after submitting the form. By integrating the TP engine and Form Builder, health care providers can ensure that relevant information is captured and acted upon as part of the patient's care plan, leading to improved patient outcomes and increased efficiency in health care delivery. This integration enhances the quality of care provided to patients and enables health care professionals to make informed decisions based on accurate and timely data.

Figure 10. Diagram of HTTP request and response interactions between Form Builder, which acts as the front-end server, and the Decision Logic Module (DLM) engine, which serves as the back-end server, in 2 distinct settings.



After successfully integrating these components in a symbiotic IT environment, it was possible to install the solutions in the Portuguese hospital to implement and evaluate them in a real-world setting.

For several years, this hospital has maintained a collaborative relationship with the research center where the working group is based. Given this existing partnership, the hospital was deemed an ideal site to deploy and assess the newly developed solution.

Considering the current IT infrastructure of the hospital, the amalgamation of the proposed solution was not hampered by any intricate integration challenges and unfolded as a straightforward process. To streamline the workflow and improve efficiency, Form Builder was integrated into a web application already implemented in the hospital that presents a detailed listing of the tasks assigned to a certain user. This integration enables health care professionals to view a comprehensive list of assigned tasks and submit completed forms directly through the portal. The TP engine is the mechanism that controls and triggers the tasks made available to the medical team on the professional portal. As a result, the professional portal serves as a centralized hub for task management and data collection, enhancing the overall clinical workflow.

To ensure that only authorized health care professionals had access to corneal transplantation tasks, it was necessary to create specific members for this purpose within the demographic of professionals with their respective capabilities, roles, and functions. Once the members of each team were established, they were associated with the corresponding tasks. By establishing a clear hierarchy of roles and responsibilities, the hospital was able to ensure that the tasks related to corneal transplantation were being accessed and completed by qualified and authorized personnel.

The collaboration between the health care institution and the research center has paved the way for the exchange of knowledge and resources, allowing for a more efficient and effective implementation of the solution. Furthermore, this cooperation has fostered a culture of innovation and continuous improvement in the hospital's clinical practices, ultimately yielding beneficial outcomes for the patients.

The main challenges encountered during deployment were related to the lack of health care professionals with knowledge of openEHR and modeling skills. As a result, the team conducted several demonstrations and provided comprehensive documentation to facilitate the users' adoption of the tools. Despite these challenges, the feedback and acceptance from medical staff were generally positive as they reported ease of adaptation and expressed satisfaction with the provided tools.

Statistical Analysis

In a data-driven world, statistical analysis has become critical to gain insights and draw conclusions that may not be immediately apparent through simple visual inspections. It holds particular significance in the realm of health research, where it can be used to evaluate the effectiveness and efficiency of IT solutions such as EHRs, telemedicine platforms, and other digital health tools. In this way, health care professionals can identify areas for improvement, including the streamlining of workflows, the enhancement of usability, and the resolution of technical glitches, ultimately leading to improved patient outcomes and enhanced quality of care.

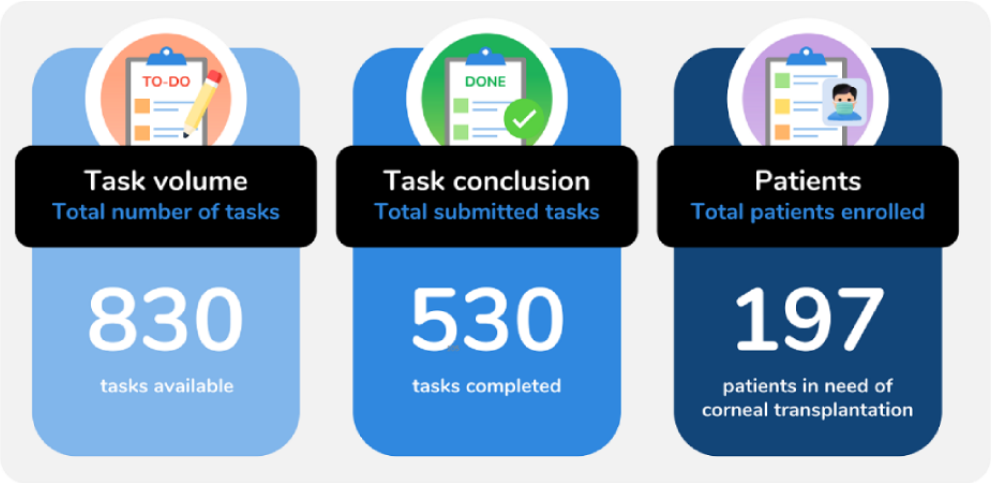
Overall, the importance of data analytics in the health care domain cannot be overstated as it has the potential to significantly impact the lives and well-being of countless individuals. Hence, to verify the efficiency and performance of the solutions offered to manage the corneal transplantation process, this section presents an analysis of the data gathered

over the period of study from May 1, 2022, to March 31, 2023. This analysis will include relevant indicators and charts. Before presenting the data analysis, a brief overview of the data collection process will be provided.

The data collection process for this study required careful planning, attention to detail, and adherence to ethical guidelines to ensure the accuracy and validity of the data. First, the databases and tables of interest were selected. Then, an anonymization process was carried out to preserve the identity and privacy of the patients, which involved removing any personal identifying information from the data. Once the data had been anonymized, the relevant SQL queries were developed to extract the data required. Finally, after the data had been extracted, they were meticulously organized into descriptive statistics in the form of indicators, charts, and graphs to ease interpretation and help convey the findings.

Figure 11 shows the graphical representation of key indicators in the corneal transplantation process, including task volume, task conclusion, and patients enrolled. The task volume represents the number of tasks available for health care professionals to fill out the corresponding forms, whereas the task conclusion corresponds to the number of tasks successfully submitted by health care professionals. On the other hand, patient enrollment indicates the number of patients registered in the corneal transplantation list.

Figure 11. Single-number indicators of the corneal transplantation process, including task volume, task conclusion, and patient enrollment.



The proportion of concluded tasks in comparison to the number of available tasks provides a clear and concise overview of the overall task completion rate and offers a general picture of how well tasks are being managed and completed. The number of available and completed tasks can help gauge the workload of health care professionals and assess the capacity of the system to handle the demands of the workflow. A higher number of completed tasks relative to available tasks indicates that the system is functioning efficiently and effectively. Meanwhile, a lower completion rate could suggest potential bottlenecks or areas for improvement in the system's design or implementation. In this study, there is 63.9% (530/830) of concluded tasks and 36.1% (300/830) of available tasks.

The total number of corneal transplantation forms submitted by health care professionals over time can be consulted in Table 4, allowing for the identification of trends and patterns in form submission and providing insights into the volume and frequency of tasks completed.

Table 4. Total number of corneal transplantation tasks submitted over time (n=530).

Month and year	Corneal transplantation tasks submitted, n (%)
March 2023	33 (6.2)
February 2023	19 (3.6)
January 2023	79 (14.9)
December 2022	53 (10)
November 2022	32 (6)
October 2022	87 (16.4)
September 2022	39 (7.4)
August 2022	49 (9.3)
July 2022	30 (5.7)
June 2022	58 (10.9)
May 2022	51 (9.6)

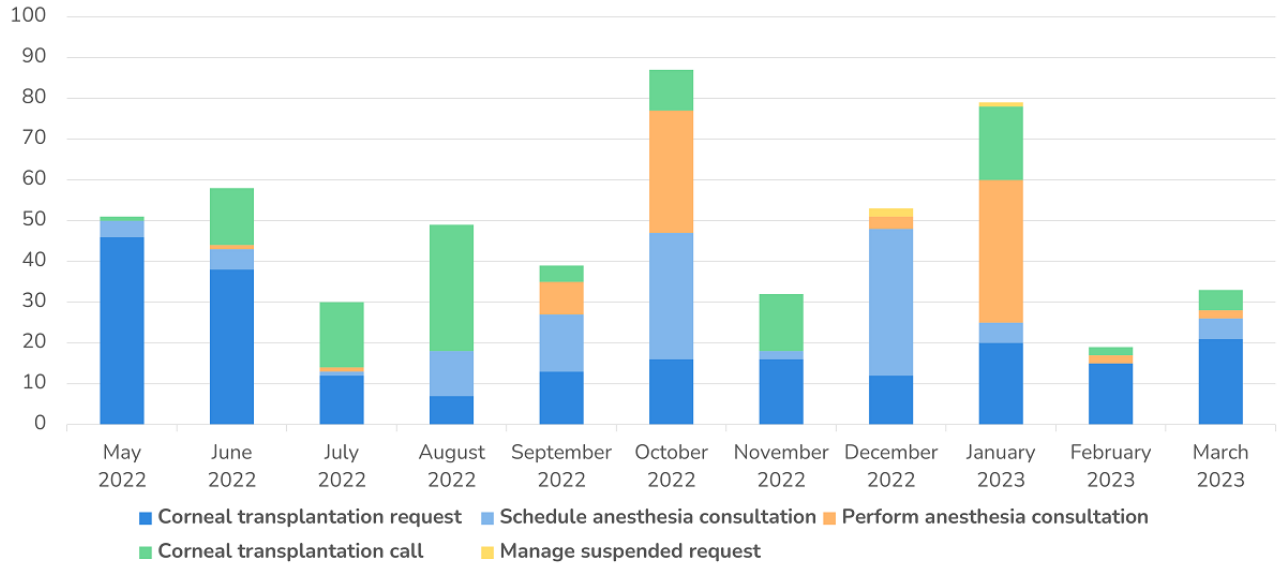
As the corneal transplantation workflow is a complex process involving the completion of a variety of tasks, Table 5 helps visualize the distribution of these tasks across the different form categories. This table displays both the numerical and percentage distribution of submitted tasks according to each form category.

Table 5. Total number of corneal transplantation tasks submitted over time (n=530).

Tasks	Corneal transplantation tasks submitted, n (%)
Corneal transplantation request	216 (40.8)
Schedule anesthesia consultation	114 (21.5)
Perform anesthesia consultation	82 (15.5)
Corneal transplantation call	115 (21.7)
Manage suspended requests	3 (0.6)

Finally, to provide a comprehensive visualization of the number of tasks submitted over time for each form category, a stacked bar chart was used in Figure 12. This chart displays the total number of tasks completed and submitted for each form category over the period under consideration, helping assess the relative contributions of each form category to the overall workflow.

Figure 12. Number of submitted tasks within the corneal transplantation workflow for each form over time.



Discussion

Principal Findings

The findings of this study offer a comprehensive and in-depth overview of the incorporation of various components of openEHR specifications, particularly the interaction of openEHR forms, WPs, and DLMs, which have not yet been fully covered in scientific literature.

To evaluate the impact of the solution, the openEHR structures were incorporated into a workflow and integrated into a health care institution. This study demonstrated the effects of the intervention on the corneal transplantation workflow, which was previously characterized by inadequate automation and an intensified risk of data loss. The use of the new technologies has the potential to substantially influence the workload of health care professionals and, consequently, affect patient care outcomes. Therefore, in addition to providing a thorough description of the implementation process, this paper also presented a statistical analysis of its effects.

The indicators presented in the *Statistical Analysis* section, which are shown in Figure 11, show the number of available tasks, completed tasks, and patients enrolled in the corneal transplantation list during the time frame of this study.

The number of available tasks was 830, which represents the total number of tasks that need to be completed. Of these tasks, 530 were completed, indicating that the completion rate of the tasks was 63.9% (530/830).

The number of available and completed tasks can help gauge the workload of health care professionals and assess the capacity of the system to handle the demands of the workflow. A higher ratio of completed tasks to available tasks indicates that the system is working efficiently and effectively. A lower completion rate, on the other hand, may suggest potential bottlenecks or areas for improvement in the system's design or implementation.

As a result, a 63.9% (530/830) completion rate falls short of expectations. This lower rate could be explained by a number of factors. First, the hospital may have limited resources to complete the tasks within the workflow, leading to delays in

completing the tasks. Furthermore, the health care professionals responsible for completing the tasks within the workflow may not have received enough training or may be inexperienced, which may imply some reluctance in adopting the new technologies.

Because most of the available tasks within the studied workflow regarded the "Contact for Corneal Transplantation," which represents the active waiting list for corneal transplantation, the workflow completion depended on external factors such as patient health and availability of donor organs. These dependencies directly affected the time required to complete the tasks and, consequently, the total workflow.

Due to the complexity of the corneal transplantation process, a multidisciplinary service team is required, namely, the anesthesia team and the ophthalmology team, which can cause communication issues between the teams and, as a result, delays in task completion.

These factors may also explain the fluctuations in the number of task submissions over time depicted in Table 4. Hence, as a result of the influence of these factors, it was not possible to establish patterns in the data over time as expected given the nonseasonal nature of the data.

Furthermore, the enrollment of 197 patients is a significant aspect of the data as it serves as a critical contextual element in assessing the workload. However, it should be noted that the number of enrolled patients, as previously mentioned, does not accurately reflect the total number of corneal transplantation proposals submitted. This is because a single patient may be registered multiple times to undergo different procedures. As a result, the number of enrolled patients may not be a direct indicator of the workload or the number of tasks that need to be completed in a corneal transplantation workflow.

In this sense, to gain a more comprehensive understanding of workload management within a hospital setting, a more specific study on the different types of tasks available was required. This analysis enables more detailed scrutiny of the specific challenges and constraints associated with each task type and allows for the identification of more targeted solutions to enhance efficiency and productivity.

A quick look into Table 5 reveals a higher rate, 40.8% (216/530), of completed tasks associated with the "Corneal Transplantation Proposal" form in comparison to the remaining tasks. This rate can be explained by the lack of resources to perform the transplants at a quicker pace. It is also worth noting that the form with the lowest submission rate was "Management of Suspended Proposal," indicating the fewer cases in which the corneal transplantation proposals were suspended.

Finally, Figure 12 depicts the number of submitted tasks according to each form over time. In the first months, it is possible to observe that the tasks associated with the "Contact for Corneal Transplantation" form increased, whereas the number of "Corneal Transplantation Proposal" tasks decreased. Since August 2022, a higher number of submitted tasks pertaining to the "Schedule Anesthesia Consultation" form can be observed. As a result, a month later, it is possible to observe an increase in the number of tasks pertaining to the "Perform Anesthesia Consultation" form.

The findings of this analysis emphasize the importance of effective workload management within a hospital setting. By monitoring and analyzing the number of tasks available and completed, hospitals can identify areas for improvement and ensure that patient care is not jeopardized. In addition, this study can help identify potential bottlenecks and areas of inefficiency in current workflows, informing the design and implementation of targeted interventions to enhance the effectiveness of health care operations.

Limitations

A paper outlining the implementation steps of clinical standards in a hospital setting is a valuable resource for identifying best practices and areas for improvement, as well as for advancing patient care. However, it is important to acknowledge its potential limitations to fully understand its impact on health care.

Resource limitations are an important concern to consider as the implementation of openEHR specifications requires staff time and training, which can pose additional challenges for health care organizations. One difficulty encountered in this study was the staff workload as the implementation of the solution presented in this paper required them to attend training sessions and meetings, as well as review new policies and procedures. Changes in work processes and team dynamics were an additional threat to the implementation of the solution as it was necessary to update team members' permissions and roles.

Training was another area in which difficulties were encountered as health care providers had to learn new skills and competencies to use the specifications effectively, which involved becoming accustomed to new technology and tools. This was particularly challenging for those who were less comfortable with technology, limiting their willingness to adopt new practices and posing resistance to change.

Finally, it was essential to consider time constraints because the findings discussed in this paper pertain to the duration of the study. The adoption of clinical standards is an ongoing process, and this paper may not be able to fully capture the long-term effects of the implementation.

Conclusions

Traditional health care is plagued by the use of disparate systems for managing patient data, leading to a fragmented view of medical records as well as inconsistencies and gaps in clinical information. Without standardized and efficient systems in place, there is a higher risk of medical errors, miscommunication, delayed or inadequate diagnoses, and suboptimal treatment decisions, which can ultimately compromise patient safety and health care quality. In addition, this issue underscores the importance of interoperability in health care.

In the case of corneal transplantation, accurate and timely management of patient information is critical for the success of the procedure and the well-being of the patient. Hence, this

study proposed the adoption of clinical standards, specifically openEHR, to address these challenges by enabling the creation of a comprehensive and shared patient record. This paper provides insights into the use of openEHR in health care and contributes to the incessant efforts to improve the quality and safety of patient care.

The implementation of openEHR specifications to standardize corneal transplantation records and streamline its workflow can yield significant benefits to patients, health care providers, and the health care system as a whole. Standardized EHRs can ensure the accuracy, consistency, and completeness of data entry and management, leading to increased patient safety and reduced medical errors. Furthermore, it serves as a centralized repository for clinical data, enabling health care providers to access information more easily and facilitating the seamless exchange of data between different health care systems. openEHR can also support clinical decision-making by providing real-time access to patient data and enabling clinicians to make more informed decisions about patient care.

In summary, the process that connects openEHR forms, WPs, and DLMs ensures that the best course of action for a given patient is taken by providing real-time decision support, data validation, and automated actions and ensuring that patient data are accurate, consistent, and accessible, as well as that all necessary clinical tasks are performed in a timely and efficient manner.

Although this study focused on the implementation of clinical standards in a specific health care setting, the principles and strategies used to implement openEHR specifications remain relevant and applicable in other health care contexts. Hence, the findings of this study hold considerable value for health care professionals, hospital administrators, and technology developers, providing critical insights into the implementation of openEHR specifications within a hospital setting and paving the way for the development of innovative solutions to optimize health care operations.

In light of these benefits, it is clear that the adoption of openEHR structures for the standardization of corneal transplantation records represents a critical step forward in the pursuit of safer, more effective, and higher-quality care. Hence, the authors believe that using openEHR specifications will become standard practice in the health care industry in the near future.

Future research could focus on the application of artificial intelligence algorithms to data extracted from standardized EHRs as training algorithms on reliable, consistent, and high-quality data leads to more robust and trustworthy results. This can enable a more efficient and effective clinical data analysis, maximizing the potential of openEHR to drive meaningful improvements in health care outcomes.

Abstract

Background: Coprescribing naloxone with opioid analgesics is a Centers for Disease Control and Prevention (CDC) best practice to mitigate the risk of fatal opioid overdose, yet coprescription by emergency medicine clinicians is rare, occurring less than 5% of the time it is indicated. Clinical decision support (CDS) has been associated with increased naloxone prescribing; however, key CDS design characteristics and pragmatic outcome measures necessary to understand replicability and effectiveness have not been reported.

Objective: This study aimed to rigorously evaluate and quantify the impact of CDS designed to improve emergency department (ED) naloxone coprescribing. We hypothesized CDS would increase naloxone coprescribing and the number of naloxone prescriptions filled by patients discharged from EDs in a large health care system.

Methods: Following user-centered design principles, we designed and implemented a fully automated, interruptive, electronic health record–based CDS to nudge clinicians to coprescribe naloxone with high-risk opioid prescriptions. “High-risk” opioid prescriptions were defined as any opioid analgesic prescription ≥90 total morphine milligram equivalents per day or for patients with a prior diagnosis of opioid use disorder or opioid overdose. The Reach, Effectiveness, Adoption, Implementation, and Maintenance (RE-AIM) framework was used to evaluate pragmatic CDS outcomes of reach, effectiveness, adoption, implementation, and maintenance. Effectiveness was the primary outcome of interest and was assessed by (1) constructing a Bayesian structural time-series model of the number of ED visits with naloxone coprescriptions before and after CDS implementation and (2) calculating the percentage of naloxone prescriptions associated with CDS that were filled at an outpatient pharmacy. Mann-Kendall tests were used to evaluate longitudinal trends in CDS adoption. All outcomes were analyzed in R (version 4.2.2; R Core Team).

Implementation (Results): Between November 2019 and July 2023, there were 1,994,994 ED visits. CDS reached clinicians in 0.83% (16,566/1,994,994) of all visits and 15.99% (16,566/103,606) of ED visits where an opioid was prescribed at discharge. Clinicians adopted CDS, coprescribing naloxone in 34.36% (6613/19,246) of alerts. CDS was effective, increasing naloxone coprescribing from baseline by 18.1 (95% CI 17.9 - 18.3) coprescriptions per week or 2,327% (95% CI 3390 - 3490). Patients filled 43.80% (1989/4541) of naloxone coprescriptions. The CDS was implemented simultaneously at every ED and no adaptations were made to CDS postimplementation. CDS was maintained beyond the study period and maintained its effect, with adoption increasing over time (τ=0.454; P<.001).

Conclusions: Our findings advance the evidence that electronic health record–based CDS increases the number of naloxone coprescriptions and improves the distribution of naloxone. Our time series analysis controls for secular trends and strongly suggests that minimally interruptive CDS significantly improves process outcomes.

Introduction

Overdose (OD) deaths decreased in the United States from 2022 to 2023, but 81,083 people still died from opioids in 2023 [1]. Almost 10 million adults misused prescription opioids in 2019 [2], making opioids the most misused prescription drug [3]. Up to 20% of emergency department (ED) visits result in an opioid prescription, and ED opioid prescribing has been associated with increased opioid misuse, abuse, and death [4-10], underscoring the need for ED harm reduction.

Naloxone is an opioid antagonist capable of reversing opioid OD. Naloxone distribution has been associated with reductions in population-level opioid mortality [11,12]. Prescribing naloxone with opioids (naloxone coprescribing) is a Centers for Disease Control and Prevention (CDC) best practice and has been mandated in some states [13,14]. Yet, naloxone coprescribing remains rare [15-17], only occurring 2.3% of the time when >90 morphine milligram equivalents of opioids are ordered from the ED and 7.4% of the time after an ED visit for suspected opioid OD (vs epinephrine which is prescribed in 49% of ED visits for anaphylaxis) [16,17]. Stigma, workload, and time pressures may explain these gaps [18-21].

Health systems have begun implementing strategies to facilitate naloxone coprescribing [22]. Computerized clinical decision support (CDS) is a strategy to assist decision-making and improve health care quality [23,24]. When designed well, CDS have been shown to improve evidence-based prescribing [25-27], as well as opioid OD education and naloxone distribution [28-33]. CDS best practices include increasing specificity and sensitivity, triggering at the right time, making the evidence-based choice the easiest option, and tracking patient outcomes [24,34,35]. Effective CDS implementation requires attention to choice architecture, setting, and best practices to reduce bias and improve adoption [36-38].

We aimed to improve the evidence-based delivery of naloxone by developing and deploying an ED clinician-facing, electronic health record (EHR)–based CDS. We quantified the impact of CDS according to the Reach, Effectiveness, Adoption, Implementation, and Maintenance (RE-AIM) framework [39]. By specifying the users targeted, including workflow events that triggered CDS, and describing lessons learned, we hope to encourage the deployment and testing of similar CDS beyond our health system.

Methods

Intervention

Following user-centered design (UCD) principles [40], a multidisciplinary team including 5 physicians, 2 pharmacists, and several EHR builders, with expertise in implementation science, informatics, behavioral economics, and health services research, designed a fully automated, EHR-embedded, interruptive, provider-facing CDS. The intervention was beta-tested by several ED clinicians in a practice setting for 6 months before the systemwide rollout. CDS did not interface with any technologies beyond the EHR and fired within typical workflow to recommend and facilitate the addition of a naloxone prescription before the e-signing of any high-risk opioid analgesic prescription order (Multimedia Appendix 1). High-risk criteria were adapted from the 2016 CDC guidelines for chronic pain and defined as any opioid prescription (1) resulting in >90 morphine milligram equivalents per day, (2) for a patient with an opioid use disorder (OUD) diagnosis, or (3) prior opioid OD [41]. CDS searched for Systematized Nomenclature of Medicine Clinical Terms in the "Problem List Diagnosis," "Encounter Diagnosis," and "Hospital Problem Diagnosis" lists. Alerts were suppressed if the patient had an active naloxone prescription or if the patient was discharged to hospice, given patients on end-of-life care are excluded from CDC guidelines [41]. Naloxone prescriptions stayed on the patient's medication list for 1 year.

Key design principles followed were that CDS be intuitive, trigger only when indicated, and default to a preselected naloxone order that was the least expensive option in the health care system's retail pharmacies [24,34,35]. Any provider with prescribing privileges could encounter the alert. Default selection was chosen to decrease work (clicking "Accept" added naloxone to the existing order) and because "opt-out" approaches increase the uptake of target clinical behaviors [42-45].

Accepting CDS was the path of least resistance. However, consistent with nudge theory, clinicians could bypass CDS by (1) selecting "Do Not Order" then "Accept" (2 clicks); (2) selecting prepopulated bypass options ("Doesn't meet criteria," going to "Hospice/SNF," "Already has naloxone") then "Accept" (2 clicks);" or (3) commenting (≥2 clicks) [46]. "Already has naloxone" was included to account for naloxone outside the EHR. Clinicians were returned to their prior workflow after any action.

Clinicians were educated on CDS via departmental meetings and email. Educational materials included (1) CDS rationale, (2) instructions for use, and (3) suggested patient communication. No ongoing education was provided, and no changes were made to CDS after implementation.

Study Design and Setting

This was a retrospective, observational study of ED visits in a large, not-for-profit university-affiliated, nongovernmental health care system. Located in the Rocky Mountain Region, the system has >500,000 total ED visits per year and includes 12 EDs—1 urban-academic level 1 trauma center, 2 urban community hospitals (1 a level 1 trauma center), 2 suburban community level 2 trauma centers, and 7 community free-standing EDs. The study was approved and informed consent was waived by the Colorado Multiple Institutional Review Board (COMIRB). The Guidelines and Checklist for the Reporting on Digital Health Implementations (iCHECK-DH) were followed (Multimedia Appendix 2) [47].

Data Collection, Measurements, and Outcomes

Naloxone coprescribing was defined as a clinician prescribing opioids and naloxone during the same ED visit. Deidentified patient characteristics (age, sex, race, ethnicity, preferred language, and insurance), CDS data (reasons for firing, number of firings per visit, clinician actions, and bypass reasons), and

clinical variables (whether naloxone was prescribed via CDS and the prescription was filled) were extracted monthly from the shared EHR (Epic Systems). Research data governance was linked to EHR data governance. Clinicians entered data into Epic Hyperspace and CDS responses were automatically registered in real time. Extract, transform, and load processes transferred all patient data into relational databases hosted on private virtually protected servers nightly, and a Microsoft SQL Server Management Studio query was run to further clean and filter research data into Microsoft Excel.

The RE-AIM framework was used to determine the impact of CDS [39]. More explicitly, reach was measured by examining the proportion of ED visits where CDS was triggered and whether patients' characteristics influenced opioid prescribing (and high-risk opioid prescribing, ie, CDS triggering) and naloxone coprescribing. Effectiveness (primary outcome) was assessed by evaluating the number of ED discharges with naloxone coprescriptions per week across the system before and after CDS implementation. Effectiveness was also measured by quantifying the naloxone prescription fill rate (naloxone prescription fills per naloxone orders via CDS vs other workflows) at a 24-hour ED outpatient retail pharmacy in the largest urban academic ED. This subgroup analysis was performed to determine whether increased naloxone orders translated to more naloxone reaching patients and to compare whether patients prescribed naloxone via CDS were more likely to fill their prescriptions than patients prescribed naloxone via other workflows. All prescriptions written at this ED defaulted to the ED's outpatient pharmacy—unless specifically requested by the patient—thus prescription fill data were available in the pharmacy EHR. Adoption was defined as the number of naloxone prescriptions from CDS per number of CDS firings. Due to EHR limitations, we could not measure CDS suppression. The process of implementation is described. Finally, maintenance was judged by whether CDS was maintained after the study period and by modeling changes in adoption over time.

Ethical Considerations

All data releases were cleared by a Research Services Manager who ensured the data being released were compliant with the Health Insurance Portability and Accountability Act (HIPAA) and the corresponding institutional review board exemption (#23-0458). No continuing review was required because this was secondary research and all data were deidentified. Results were shared via secure email. Individual informed patient consent was waived and no compensation was offered, given no patient participation or protected health information was shared.

Data Analysis

There is a documented need for rigorous, pragmatic evaluation when implementing new CDS [34]. Interrupted time series analyses are suggested for CDS evaluation because they control for confounding secular trends [34,48-50]. We used a Bayesian structural time-series model controlling for the number of ED visits to evaluate the impact of CDS on naloxone coprescribing (CausalImpact package; version 1.3.0; Brodersen et al) [51], Mann-Kendall tests to model longitudinal changes in CDS adoption, and chi-square tests to compare the proportions of individuals who triggered CDS and were prescribed either an opioid or opioid with naloxone across demographic categories. Equity of RE-AIM outcomes was evaluated based on patient characteristics because prior research has demonstrated an increased likelihood of opioid prescribing for White patients and increased naloxone prescribing (and coprescribing) for Black and Latine patients [52-58]. Otherwise, frequencies and percentages are reported for categorical variables. All statistical analyses were conducted in R (version 4.2.2; R Core Team) [59].

Study Sample

All ED visits with a discharge opioid prescription between March 2013 and July 2023 were included. Effectiveness was assessed by comparing weekly aggregated counts of ED visits, opioid prescriptions, and naloxone coprescriptions between the pre- (March 2013-November 2019) and postimplementation periods (November 2019-July 2023). Adoption was assessed using only post-period data. The accuracy of synthetic control models, like the Bayesian structural time-series model used, is generally improved by including more pre-period data [51]. Therefore, we extracted enough data to provide a 2:1 pre-to post-period ratio. We did not perform a prospective power calculation. Patients younger than 18 years or older than 90 years old and those who were admitted to the hospital were excluded from both periods.

Implementation (Results)

Demographics

After implementation, between November 2019 and July 2023, there were 1,994,994 eligible ED discharges. Of these, 5.19% (103,606/1,994,994) included an opioid analgesic prescription and 0.83% (16,566/1,994,994) of prescriptions met high-risk criteria. Most visits included female (n=1,083,973, 54.33%), White (n=1,357,153, 68.03%), non-Latine (n=1,519,584, 76.17%), English-speaking (n=1,866,744, 93.57%), and publicly insured (n=1,146,781, 57.48%) patients (Table 1). White, non-Latine, English-speaking, privately insured patients were prescribed opioids a greater proportion of the time compared to Black, Latine, non–English-speaking, and publicly insured patients (P<.001).

Table . Postimplementation visit demographics stratified by visit type.

[a]ED: emergency department.

[b]CDS: clinical decision support.

Reach

CDS fired in 0.83% (16,566/1,994,994) of all ED visits. A total of 15.99% (16,566/103,606) of visits with a discharge opioid prescription met high-risk criteria and triggered CDS. CDS fired multiple times in 13.17% (2182/16,566) of visits (mean 1; median 1); ED clinicians interacted with CDS 19,246 times overall. Visits triggering CDS most often involved patients who were female (n=8670, 52.34%), White (n=12,724, 76.81%), non-Latine (n=13,818, 83.41%), spoke English (n=15,934, 96.18%), and had Medicaid or Medicare (n=10,193, 61.53%; Table 1). However, adjusting for the number of visits with an opioid prescription (a prerequisite for CDS triggering), CDS was more likely to trigger in visits with male, Latine, English speaking, and publicly insured patients (P<.001).

Effectiveness

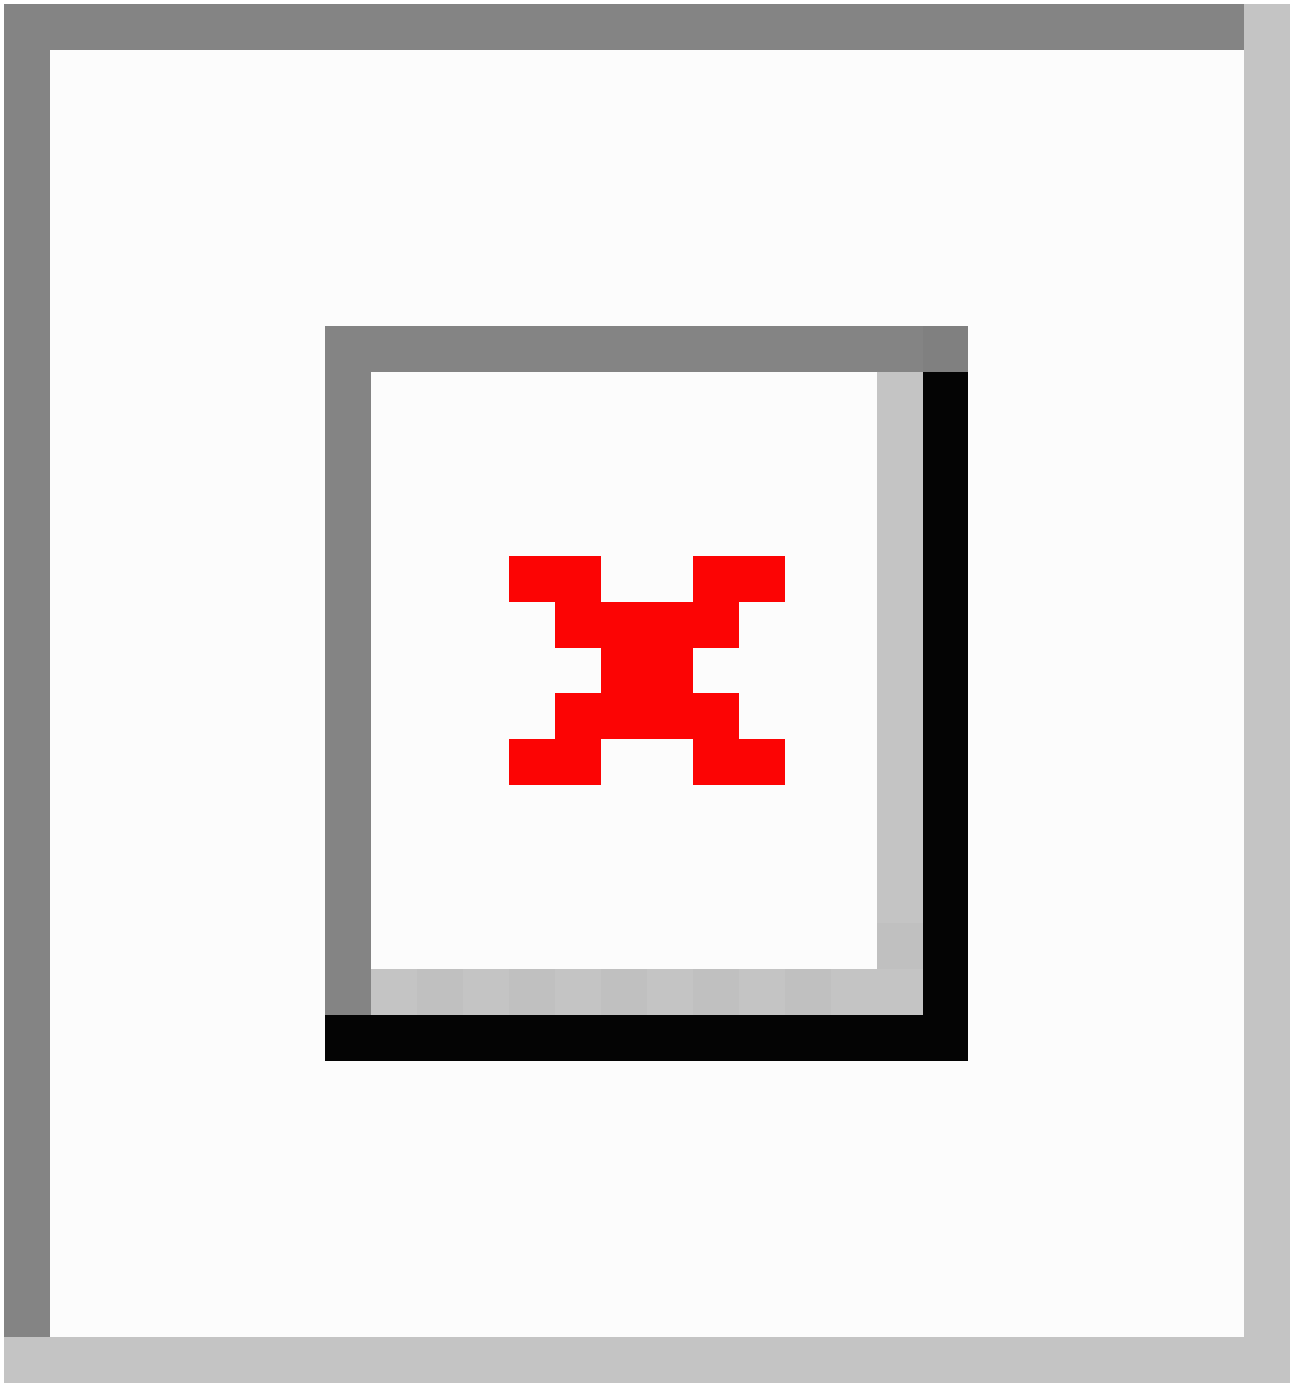
Before CDS implementation, clinicians coprescribed naloxone in 0.05% (156/318,216) of ED visits when an opioid analgesic was prescribed. After CDS implementation, ED clinicians coprescribed naloxone in 3.49% (3616/103,606) of ED visits when an opioid analgesic was prescribed. In the postimplementation period, 85.09% (3077/3616) of naloxone coprescriptions originated from CDS.

Using the number of ED visits as a covariate, the CausalImpact package predicted 0.80 (95% CI 0.55 - 1.05) ED visits with

naloxone coprescriptions per week and 150 (95% CI 100 - 200) ED visits with naloxone coprescriptions in the postimplementation period. After CDS go-live there was an immediate increase in the number of ED visits with naloxone coprescriptions each week—18.9 ED visits with naloxone coprescriptions observed on average weekly and 3616 ED visits with naloxone coprescriptions in the entire postimplementation period (Figure 1). In other words, CDS increased ED naloxone coprescribing by 18.1 (95% CI 17.85 - 18.34) naloxone coprescriptions per week or 2327% (95% CI 1702 - 3335). Black and non-Latine patients were more likely to have naloxone coprescribed when CDS triggered compared to White and Latine patients (P<.001).

During the postimplementation period, there were 4541 naloxone coprescriptions with opioid analgesics written at the urban, academic ED (mean 1.2; median 1 per visit) and 3308 (72.85%) were ordered from a CDS alert. Patients filled 49.42% (2134/4318) of their opioid prescriptions and 43.80% (1989/4541) of naloxone coprescriptions. Patients coprescribed naloxone via CDS filled their prescriptions less often than patients coprescribed naloxone via other workflows (35.64%, 1179/3308 vs 65.69%, 810/1233).

Figure 1. The CausalImpact plot of naloxone coprescribing. CDS: clinical decision support.



Adoption

ED clinicians adopted CDS, following the recommendation to coprescribe naloxone in 34.36% (6613/19,246) of alerts. Clinicians at the academic ED adopted CDS at a higher rate 61.62% (2005/3254) than at community EDs 34.70% (4608/13,280).

Implementation

This CDS was implemented simultaneously at every ED and no changes were made to CDS postimplementation. All EDs used the same EHR, and it took a CDS builder 70 hours (including meetings, communications, and build time) to design and implement CDS.

Maintenance

According to the Mann-Kendall test, CDS adoption increased over time (τ=0.454; P<.001). Because no changes were made to CDS, there were no obvious sustainability costs beyond what our health system regularly paid for EHR access. CDS is still active and currently being scaled to outpatient clinics. Sustainability decisions are made by local governance based on naloxone prescribing because it was defined as a CDC best practice. CDS are reviewed ad hoc based on technical issues and yearly otherwise.

Lessons Learned

The implementation process benefitted from the makeup of the study team, who were able to provide local context for design, identify key workflow needs, address local barriers, and serve as champions during implementation. Beta testing and CDS-specific data analytics were prioritized to identify technical and efficiency issues early. Having data analytics built and collecting data during testing was key for providing estimates on workflow interruptiveness and informing iterative improvements. For example, monitoring revealed CDS initially only searched the current visit diagnosis, failing to identify histories of OUD and OD. The trigger algorithm was changed to include any EHR documented history of OUD or OD before going live, with a significant increase in case identification. Additionally, because clinicians told champions that CDS were firing "too late," CDS were modified to trigger when clinicians entered as opposed to signed orders, facilitating clinician-patient communication before prescribing.

This project began as quality improvement, which was important for local buy-in. Also, the health system is funded, and therefore, owns the intervention. It would have been ideal to prospectively track implementation to elucidate system and per-patient costing and inform decisions about CDS maintenance. Future studies should formally evaluate patient-centered outcomes to confirm CDS as an effective and equitable implementation strategy.

Discussion

Principal Findings

A minimally interruptive CDS was readily adopted, showed a sustained effect, and significantly increased the number of ED naloxone coprescriptions. These findings support CDS as an effective implementation strategy to increase clinician uptake of naloxone best practices.

The high rate of adoption supports the need for user-centered CDS development, monitoring, and evaluation as the impact of CDS is often limited by low adoption and frequent workflow interruptions resulting in "alert fatigue" (the desensitization to important safety warnings) [24,60-64]. A Cochrane review of 122 CDS trials showed that CDS, on average, only increases the proportion of patients receiving desired care by 5.8% (95% CI 4.0% to 7.6%) [36]. The impact is variable, with the top quartile of reported improvements ranging from 10% to 62% [36]. With an adoption rate of 34.36% and a 2327% increase in the number of ED visits with naloxone coprescriptions, this CDS falls well within the top quartile of CDS improvements [36]. Interestingly, adoption increased over time. This finding differs from most other CDS literature reporting a decrease in adoption over time [65], and mirrors one other CDS study that reported a similar effect after UCD [66], perhaps suggesting that UCD improves initial and sustained adoption [66].

ED clinicians face increasingly complex workflow challenges that require validated solutions [67,68]. Previous evaluations of naloxone coprescribing CDS have not always aligned with best practices for designing, conducting, and reporting CDS interventions [28-31,34]. Prior studies have not discussed the rationale for CDS design (such as choice architecture) and have excluded key operational details (supplements and alert screenshots), making it challenging to reproduce or scale CDS [28-31,34]. The default order design of our CDS may have contributed to CDS acceptability by making choice architecture less burdensome to clinicians [34]. CDS adoption may also reflect actions in line with clinicians' and patients' positive attitudes toward naloxone prescribing and use [15,34,62].

Our Bayesian structural time series model, without a statutory mandate, offers robust evidence to support claims that CDS increases ED naloxone coprescribing. Our methods address the gap from prior studies that relied on pre-post designs and inferential statistics (logistic regression, t tests, and χ^2 tests) [30,31], which increase the risk of confounding by organizational policies, regulations, or reimbursement rules [34].

The fact that White, non-Latine, English-speaking, and privately insured patients were significantly more likely to have an opioid prescribed is concerning but consistent with prior literature [52-58]. Demographic differences in opioid and naloxone prescribing have been widely reported [52-58]. It is notable that Black and non-Hispanic patients were more likely to have naloxone coprescribed after CDS was triggered. This is the first study to report demographic differences in clinicians' responses to CDS designed to increase naloxone coprescribing. Although, Black and Latine patients are coprescribed naloxone more often at baseline. Thus, it is possible CDS increased naloxone coprescribing equally and simply failed to reduce the influence of racial and ethnic bias on opioid or naloxone prescribing [57,58]. Other CDS designers should consider these differences when implementing and evaluating CDS to ensure they do not inadvertently maintain or widen existing disparities.

Limitations

No clinical outcomes were measured, so we do not know if practice changes impacted care such as ED readmissions. No statutory mandates were implemented during this study, but we cannot be sure local educational efforts were not made to encourage naloxone coprescribing. Larger trends in opioid prescribing were not examined but are unlikely to have impacted the rate of naloxone coprescribing.

The availability of a 24-hour ED pharmacy at the academic site was another potential operational confounder in measuring naloxone fill rates. Discharged patients had to pass the pharmacy to exit the ED. This is an important consideration for sustainability since we do not compare naloxone coprescribing versus take-home naloxone (THN). THN has been reported to improve naloxone distribution by removing the need to stop at a pharmacy and may alleviate patient costs but shift medication costs to systems or public health organizations. Prior work, evaluating THN programs, has reported naloxone distribution rates as high as 87.3% [69]. However, THN programs are resource intensive [69,70], thus, might still be improved by CDS that improve the recognition of patients at risk for OD [71].

Conclusions

An EHR-based CDS encouraging ED naloxone coprescribing with opioid analgesics increased alert-based naloxone orders and overall system rates of naloxone coprescribing. The CDS had a low rate of interruption, a high rate of adoption [36], and significantly increased ED naloxone coprescribing across 12 EDs. There were no obvious sustainability costs beyond what the health system regularly paid for EHR access. These findings support claims that health care system leaders should consider CDS as an implementation strategy to address the significant gap in naloxone coprescribing [28-33].

Acknowledgments

The authors would also like to thank Natalia Truszczynski for their help editing the paper. They would like to thank Wyatt Tarter, Zhixin Lun, and the Center for Innovative Design and Analysis (CIDA) for their help in validating the statistical analyses.

Authors' Contributions

CGJ, SVE, CLD, and ATW designed and implemented the clinical decision support (CDS). SWS, HJT, and JAH conceived and operationalized the trial. SWS and HJT analyzed the data. SWS drafted the paper with contributions from JAH, HJT, CGJ, SVE, CLD, KET, and ATW. SWS takes responsibility for the paper as a whole.

Conflicts of Interest

None declared.

Abstract

Background: Collecting the medical history during a first outpatient consultation plays an important role in making a diagnosis. However, it is a time-consuming process, and time is scarce in today's health care environment. The computer-assisted history taking (CAHT) systems allow patients to share their medical history electronically before their visit. Although multiple advantages of CAHT have been demonstrated, adoption in everyday medical practice remains low, which has been attributed to various barriers.

Objective: This study aimed to implement a CAHT questionnaire for orthopedic patients in preparation for their first outpatient consultation and analyze its completion rate and added value.

Methods: A multicenter implementation study was conducted in which all patients who were referred to the orthopedic department were invited to self-complete the CAHT questionnaire. The primary outcome of the study is the completion rate of the questionnaire. Secondary outcomes included patient and physician satisfaction. These were assessed via surveys and semistructured interviews.

Implementation (Results): In total, 5321 patients were invited, and 4932 (92.7%) fully completed the CAHT questionnaire between April 2022 and July 2022. On average, participants (n=224) rated the easiness of completing the questionnaire at 8.0 (SD 1.9; 0 - 10 scale) and the satisfaction of the consult at 8.0 (SD 1.7; 0 - 10 scale). Satisfaction with the outpatient consultation was higher in cases where the given answers were used by the orthopedic surgeon during this consultation (median 8.3, IQR 8.0 - 9.1 vs median 8.0, IQR 7.0 - 8.5; *P*<.001). Physicians (n=15) scored the average added value as 7.8 (SD 1.7; 0 - 10 scale) and unanimously recognized increased efficiency, better patient engagement, and better medical record completeness. Implementing the patient's answers into the electronic health record was deemed necessary.

Conclusions: In this study, we have shown that previously recognized barriers to implementing and adapting CAHT can now be effectively overcome. We demonstrated that almost all patients completed the CAHT questionnaire. This results in reported improvements in both the efficiency and personalization of outpatient consultations. Given the pressing need for personalized health care delivery in today's time-constrained medical environment, we recommend implementing CAHT systems in routine medical practice.

Introduction

Background

The patient's medical history plays a crucial role in establishing an accurate diagnosis [1-3]. However, collecting the medical history during a first consultation is time-consuming, and time is scarce in today's health care environment. In addition, the first consultation can be a stressful event for a patient, resulting in anxiety and misinterpretation of the questions asked during a medical encounter [4]. Subsequently, this can potentially result in incomplete and invalid information, hindering a patient's ability to participate in shared decision-making [4].

Computer-assisted history taking (CAHT) systems, also known as digital medical interview assistant systems, are software programs that allow patients to present their medical history electronically before an outpatient consultation. For instance, this can be done remotely via a web-based portal or smartphone app prior to the scheduled consultation [5]. CAHT was first introduced in the early 1970s as an additional channel to collect highly relevant, comprehensive, and accurate patient information [6]. Multiple advantages of CAHT have been demonstrated, including saving face-to-face consultation time spent on history taking and empowering patients to be active in their own care [7]. Moreover, CAHT might enhance the comprehensiveness of patient history taking by employing standardized algorithms that expand questioning depth based on the participant's responses [8]. This approach holds the potential to uncover psychosocial and psychiatric issues potentially associated with the presenting complaint [9].

Although these findings are promising, the adoption rate of CAHT within health care remains low. This is attributed to various barriers for both health care professionals (HCPs) and patients [6]. The accessibility of health care for all comes into question while digitalizing health care. Additionally, concerns arise regarding the interoperability of data that is fragmented across multiple compartments. The ability of patients to provide accurate answers is also brought into focus when they are consulted via an online survey rather than an in-person consultation [10].

Despite these barriers in integrating CAHT into everyday medical practice, the current pressure on the health care system demands action. Since the projected growth of multiple patient populations by far exceeds the number of available HCPs in the near future, the time spent on each patient needs to be as efficient and effective as possible, without reducing (perceived) health care quality. Given the number of patients that nowadays have access to email, websites, and smart devices, and the unprecedented advances in technologies in recent years, a more successful implementation of CAHT in clinical practice could be expected. However, no research has been published about achieving this goal.

Objectives

The aims of this study were to implement an online orthopedic CAHT questionnaire that enables patients to provide their medical history prior to their first outpatient consultation and to integrate the CAHT system into the electronic health records (EHRs) of two Dutch hospitals. We subsequently analyzed the completion rate of the CAHT questionnaire, as well as HCPs' satisfaction with the collected information, its accessibility, and its added value.

Methods

Study Design and Setting

This multicenter implementation study was conducted at the orthopedic departments of the Anna Hospital (Geldrop, The Netherlands) and Elisabeth-Tweesteden Hospital (Tilburg, The Netherlands). No changes were made to the design after the study was commenced. We followed the implementation guidelines for the reporting on digital health implementations [11].

Ethical Considerations

Approval was obtained from the medical ethics committees of Anna Hospital and Elisabeth-Tweesteden Hospital. The study was exempted from the Medical Research Involving Human Subjects Act (WMO, N23.090). Patients were informed about data usage for research and publication purposes at the start of the CAHT questionnaire, with participation being voluntary.

Participant Selection

All patients aged 18 years and older who were referred to the orthopedic departments of the participating centers for their first in-hospital consultation were invited to participate in the study. Patients needed to have an email address and sufficient command of the Dutch language. Patients with a cognitive disorder and patients specifically referred for pediatric orthopedics were excluded. Inclusion criteria were assessed by hospital staff when they contacted the patients to schedule their appointment.

All physicians and orthopedic residents (n=24) working in the participating hospitals and who have had scheduled initial consultations with patients during the study period were invited to participate in the study as well [12].

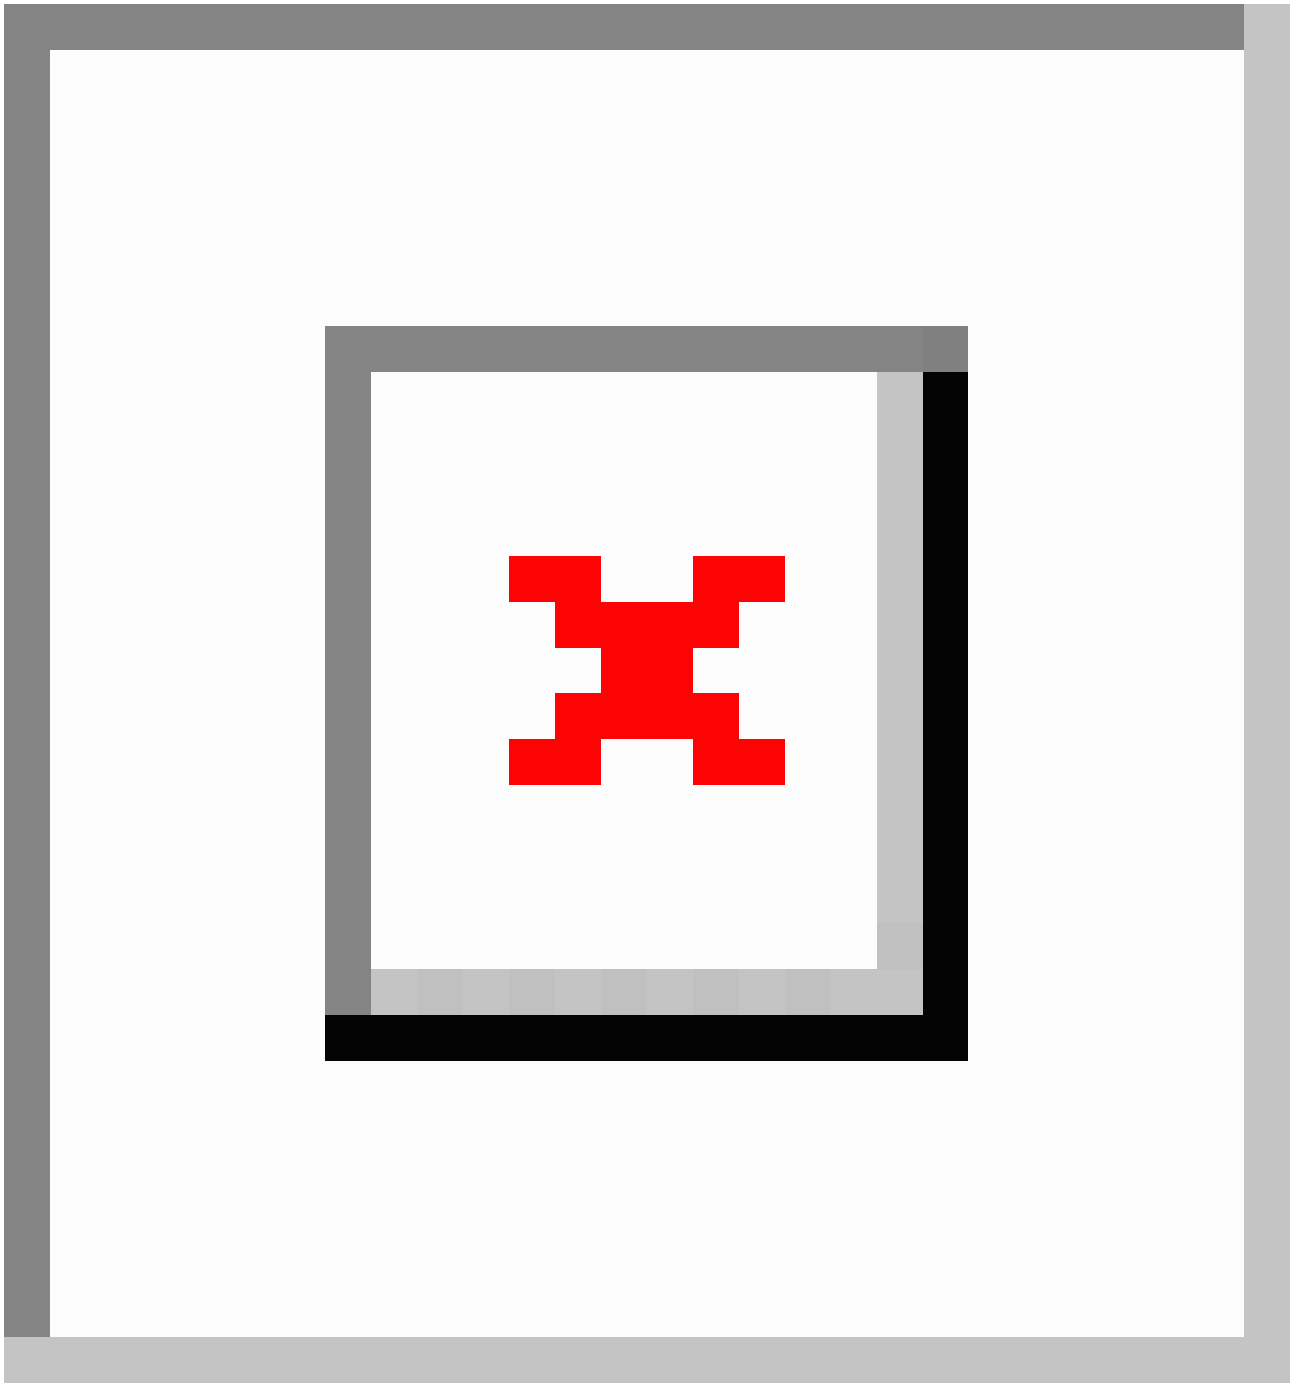
The CAHT Questionnaire

The CAHT questionnaire aimed to collect the patients' medical condition, in preparation for their first outpatient consultation. The questionnaire included several topics in the following order: affected joint, previous diagnoses or treatments, health status, personal care needs or preferences, and patient characteristics (Table 1). Some questions were generic, but most were joint-specific. Depending on the answers given by the patient on specific questions, standardized algorithms expand questioning depth using branching logic without using artificial intelligence (eg, in the case of trauma, more information was requested about the trauma origin). The online questionnaire was offered to patients in a design consistent with the hospital's branding, and some questions were supported with illustrations and instructions (Figure 1).

Table . Example of covered subjects and related questions for patients with knee complaints. Questions are translated from Dutch (the language used in the study) to English.

Topic	Question
History	• Have you ever received a diagnosis**,** by a physician or general practitioner, due to complaints in your knee and/or your lower back? • Have you ever undergone a surgical procedure for your knee and/or lower back?
Main complaint	• For which knee do you have complaints? • For how long have you experienced knee complaints? • On a scale of 0 to 10, how severe is your knee pain at rest?
Main complaint in relation to social activities	• Are you limited in playing sports or executing your hobby due to your knee complaints? • Are you limited in your job due to your knee complaints?
Personal care needs and preferences	• Your orthopedic surgeon would like to know what your main worry or question is regarding your complaints. This way the consultation can be about what's important to you. • If necessary, to what extent are you willing to undergo a surgical procedure to get rid of your knee complaints?
Effect of conservative therapies	• Have you tried muscle-strengthening physical training for a period of 4 to 6 weeks?

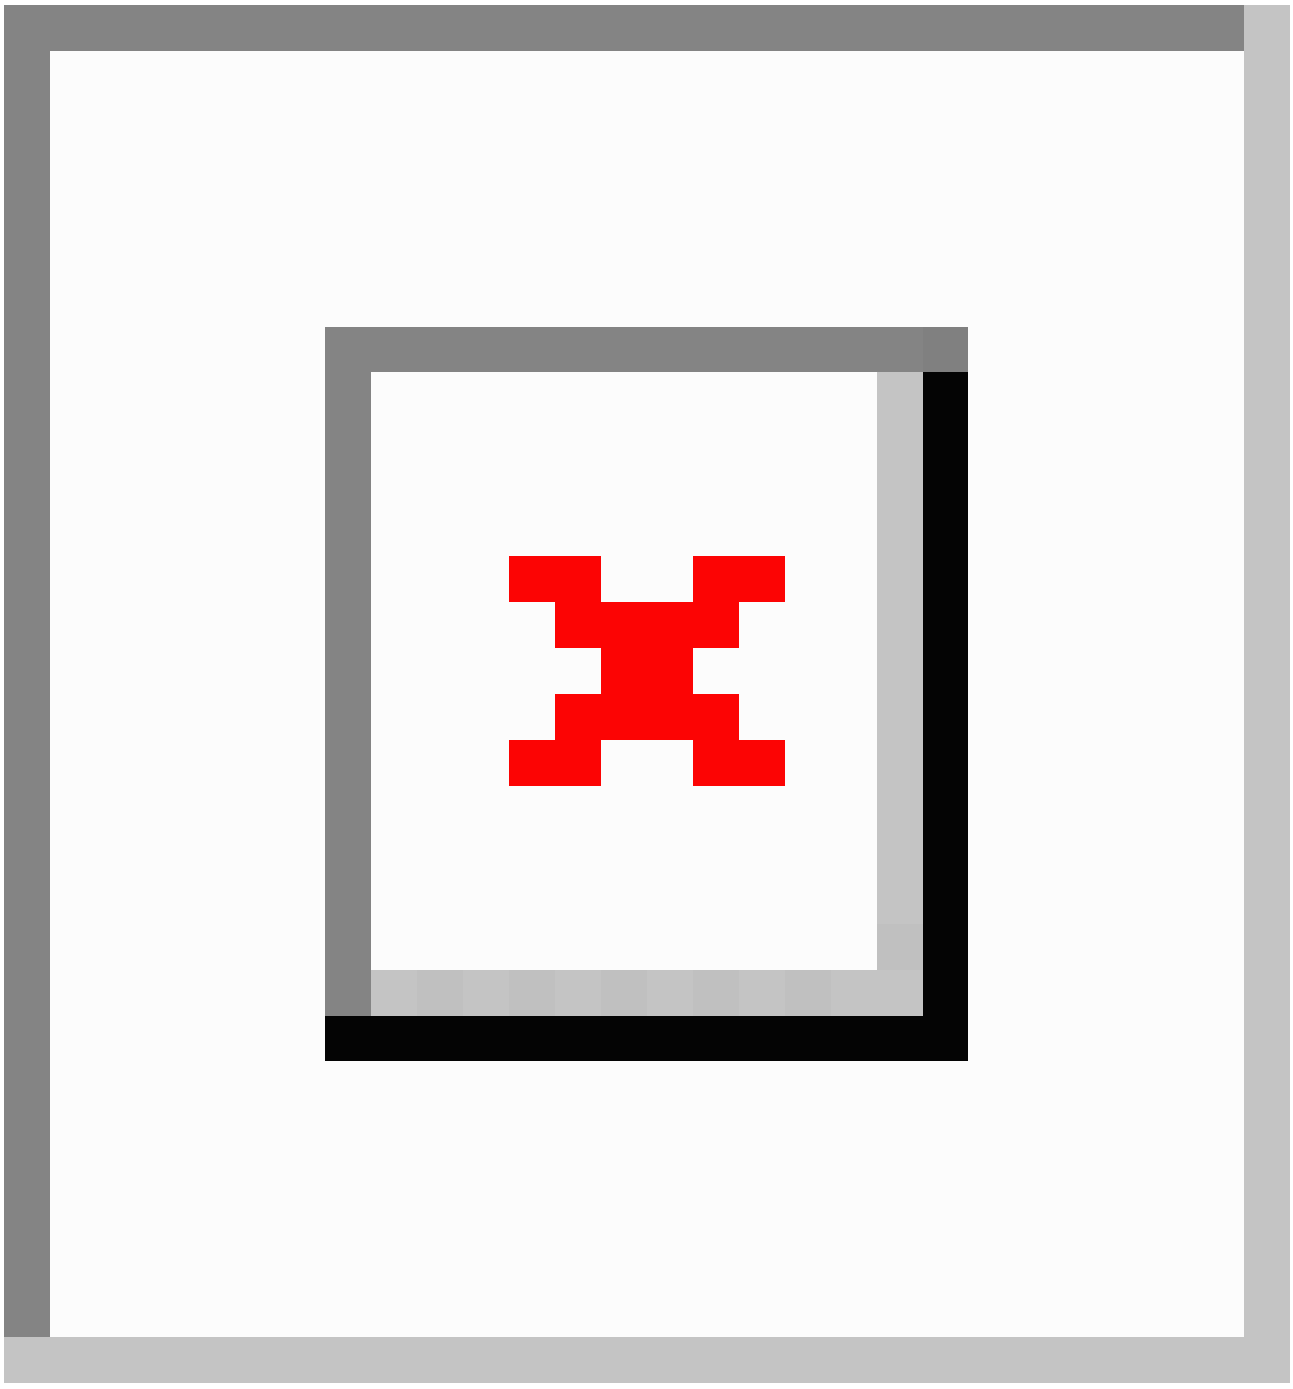
Figure 1. Example of the computer-assisted history taking questionnaire for patients with hip complaints. Patients can indicate the location of their hip pain using an illustration. Questions are translated from Dutch (the language used in the study) to English.



Development of the CAHT Questionnaire

The CAHT questionnaire and its output were developed between January 2022 and March 2022. An expert panel was created for the development of the CAHT questionnaire and its output and consisted of three experienced orthopedic surgeons from both hospitals. First, the input from the physicians at Anna Hospital was obtained, offering insights from the perspective of their professional focus area. Subsequently, the draft version was developed and internally reviewed before undergoing external assessment by three orthopedic surgeons from the Elisabeth Tweesteden Hospital. The answers to the CAHT questionnaire were automatically presented as a coherent summary in a format designed by the expert panel, without providing a differential diagnosis (Figure 2). A web link from the CAHT platform with single sign-on was integrated with the two EHRs used by the participating hospitals in March 2022. This allowed the physicians to read and interpret the data, and to alter it when deemed necessary during the consultation. All feedback on the questionnaire and its output were processed before the study commenced.

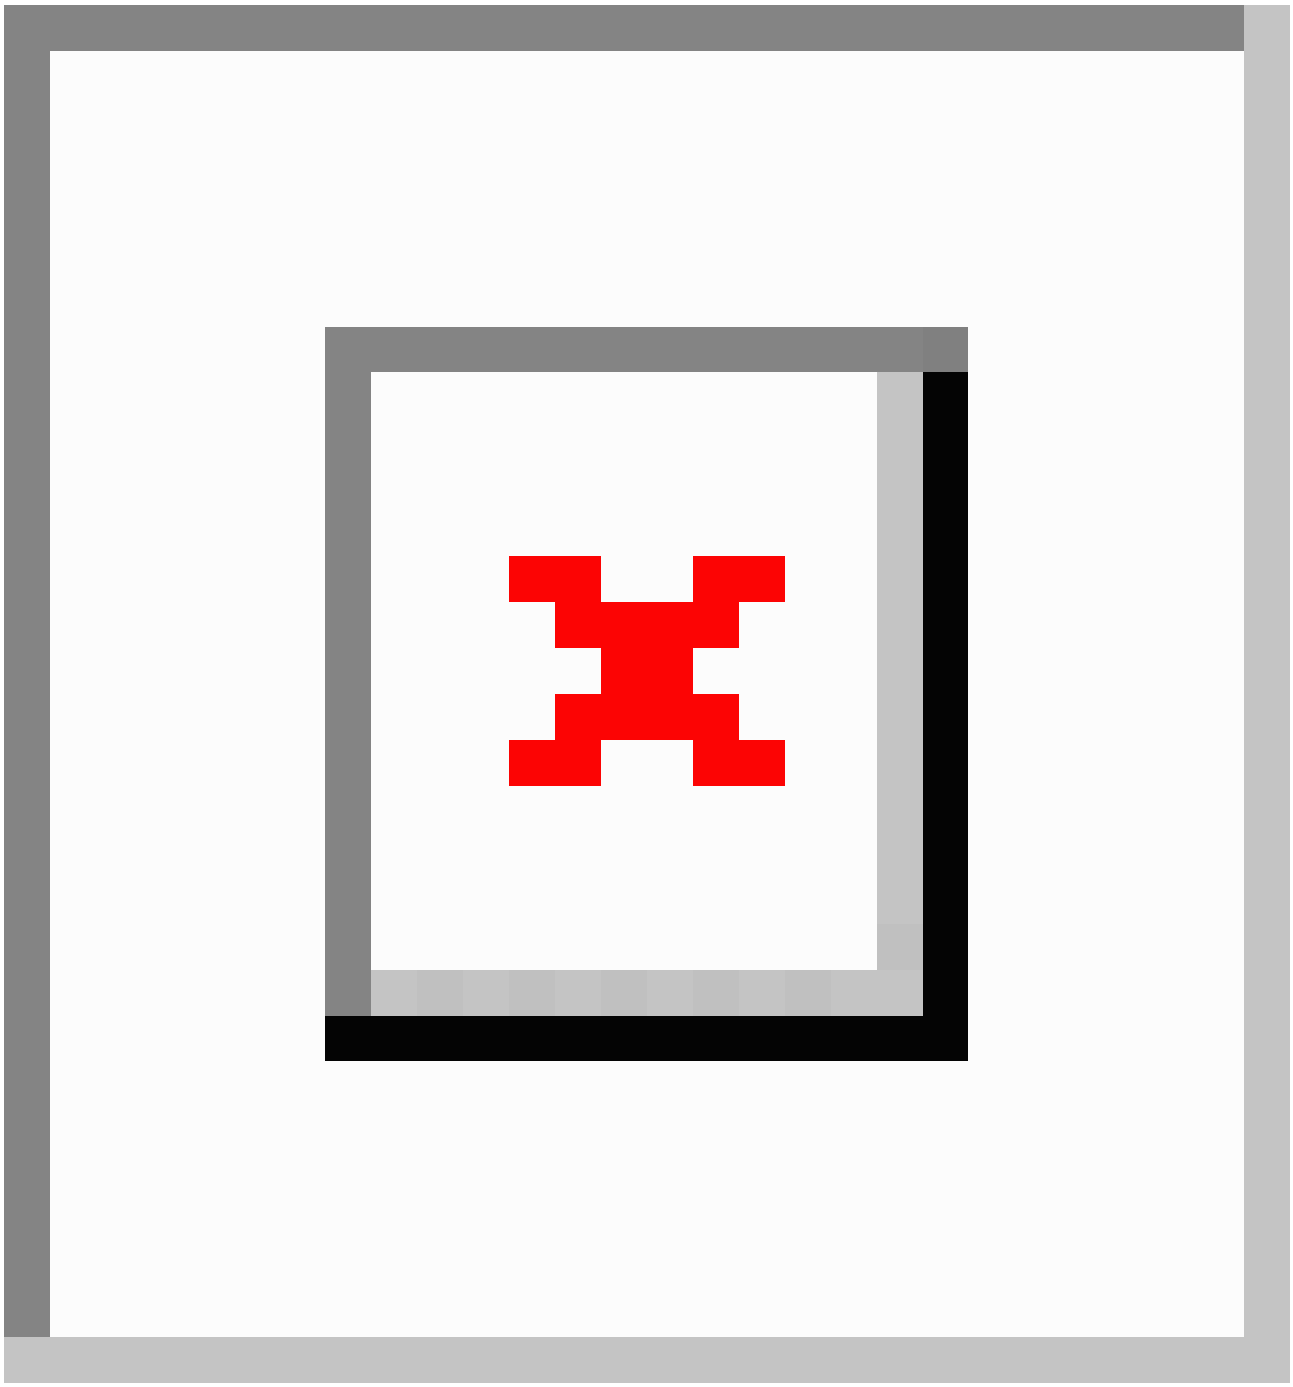
Figure 2. Example of the answers to the computer-assisted history taking questionnaire, presented as a coherent summary of a patient indicating the knee as the affected joint. The summary is translated from Dutch (the language used in the study) to English. AB: antibiotics; ACL: anterior cruciate ligament; NRS: numeric rating scale.



The CAHT Platform

OnlinePROMS (Interactive Studios, ‘s-Hertogenbosch, The Netherlands) was used as the CAHT platform. Interactive Studios has been active in the Dutch health care market for over a decade, providing sustainable solutions for remote patient monitoring. The platform meets European regulations for the privacy and security of patient-reported health data. Invitations to answer the CAHT questionnaire were automatically sent by email when a patient was added to the platform by hospital administration staff. The CAHT questionnaire became accessible to the patient after a two-factor authentication code was entered. The platform allowed hospitals to send two reminders by either email or SMS text messaging if the patient did not complete the questionnaire. Participants of Anna Hospital were reminded 1 and 2 days after the initial invitation at 9 AM via SMS text messaging or email if the phone number was unknown. The ETZ Hospital was chosen to send automated reminders 5 and 10 days after the initial invitation at 9 AM (Figure 3).

Figure 3. Flowchart of the computer-assisted history taking (CAHT) platform. After a patient was referred to the hospital and got in contact with the hospital staff, patients were included, and subsequently, an automated invitation was sent. If the patient did not respond to the invitation, a first and a second reminder were sent based on the response schedule. If the patient completed the questionnaire, a coherent summary of the answers was generated automatically from the available data and was eventually accessible from the electronic health record (EHR).



Study Outcomes

The percentage of patients who completed the CAHT questionnaire was the primary outcome. The usage statistics were collected as secondary outcomes, including the time needed to complete the CAHT questionnaire and the number of necessary reminders. Patient demographic data were collected from the CAHT questionnaire (age, sex, BMI, and affected joint). In addition, in July 2022, all patients were invited to answer a questionnaire on the usage of the CAHT questionnaire. After reaching a convenience sample (n=224), this invitation was deactivated. All physicians of the participating hospitals were asked to rate their satisfaction with the information collected with the CAHT system as well as its accessibility and added value. An overview of the study outcomes is presented in Table 2. All data were collected for the duration of the study via the OnlinePROMS platform.

Table . Overview of the study outcomes.

Outcome	Description
Completion percentage[a]	The percentage of patients who completed the CAHT[b] questionnaire in preparation for their outpatient consultation.
Duration to complete[c]	Time (in minutes) needed to complete the CAHT questionnaire.
First reminders sent[c]	The number of first reminders automatically sent by the CAHT platform in case the CAHT questionnaire was not completed yet.
Second reminders sent[c]	The number of second reminders automatically sent by the CAHT platform in case the CAHT questionnaire was not completed yet.
Patient demographics[a]	Age, sex, BMI, and affected joint.
Easiness of the CAHT questionnaire[d]	Easiness of the CAHT questionnaire on a 10-point Likert scale.
Patient satisfaction[d]	Satisfaction of the consultation on a 10-point Likert scale.
Usage by the physician[d]	The number of patients reporting that the CAHT questionnaire summary was used by the physician during consultation.
Added value[d]	The added value of a CAHT questionnaire supported medical history taking during consultation on a 10-point Likert scale.
HCP[e] data accessibility[f]	Experienced easiness for data accessibility. Satisfaction is rated on a 10-point Likert scale.
Added value for HCP[f]	The added value of a completed CAHT questionnaire during outpatient consultation on a 10-point Likert scale.

[a]Collected prior to consultation.

[b]CAHT: computer-assisted history taking.

[c]Derived from platform user statistics.

[d]Collected 1 day after consultation.

[e]HCP: health care professional.

[f]Collected at the end of the study.

Statistical Methods

Categorical variables are presented as numbers and percentages. Normally distributed continuous variables are presented as means (with the SD). Nonnormally distributed variables are presented as the median value (with the IQR). To analyze satisfaction between groups, data were considered statistically significant at $P<.05$. In case of normal distribution and variances, an independent *t* test was used. For nonnormal distributions, a nonparametric test was used. All data was analyzed using IBM SPSS Statistics for Macintosh, version 29.0 (IBM Corp).

Budget Planning

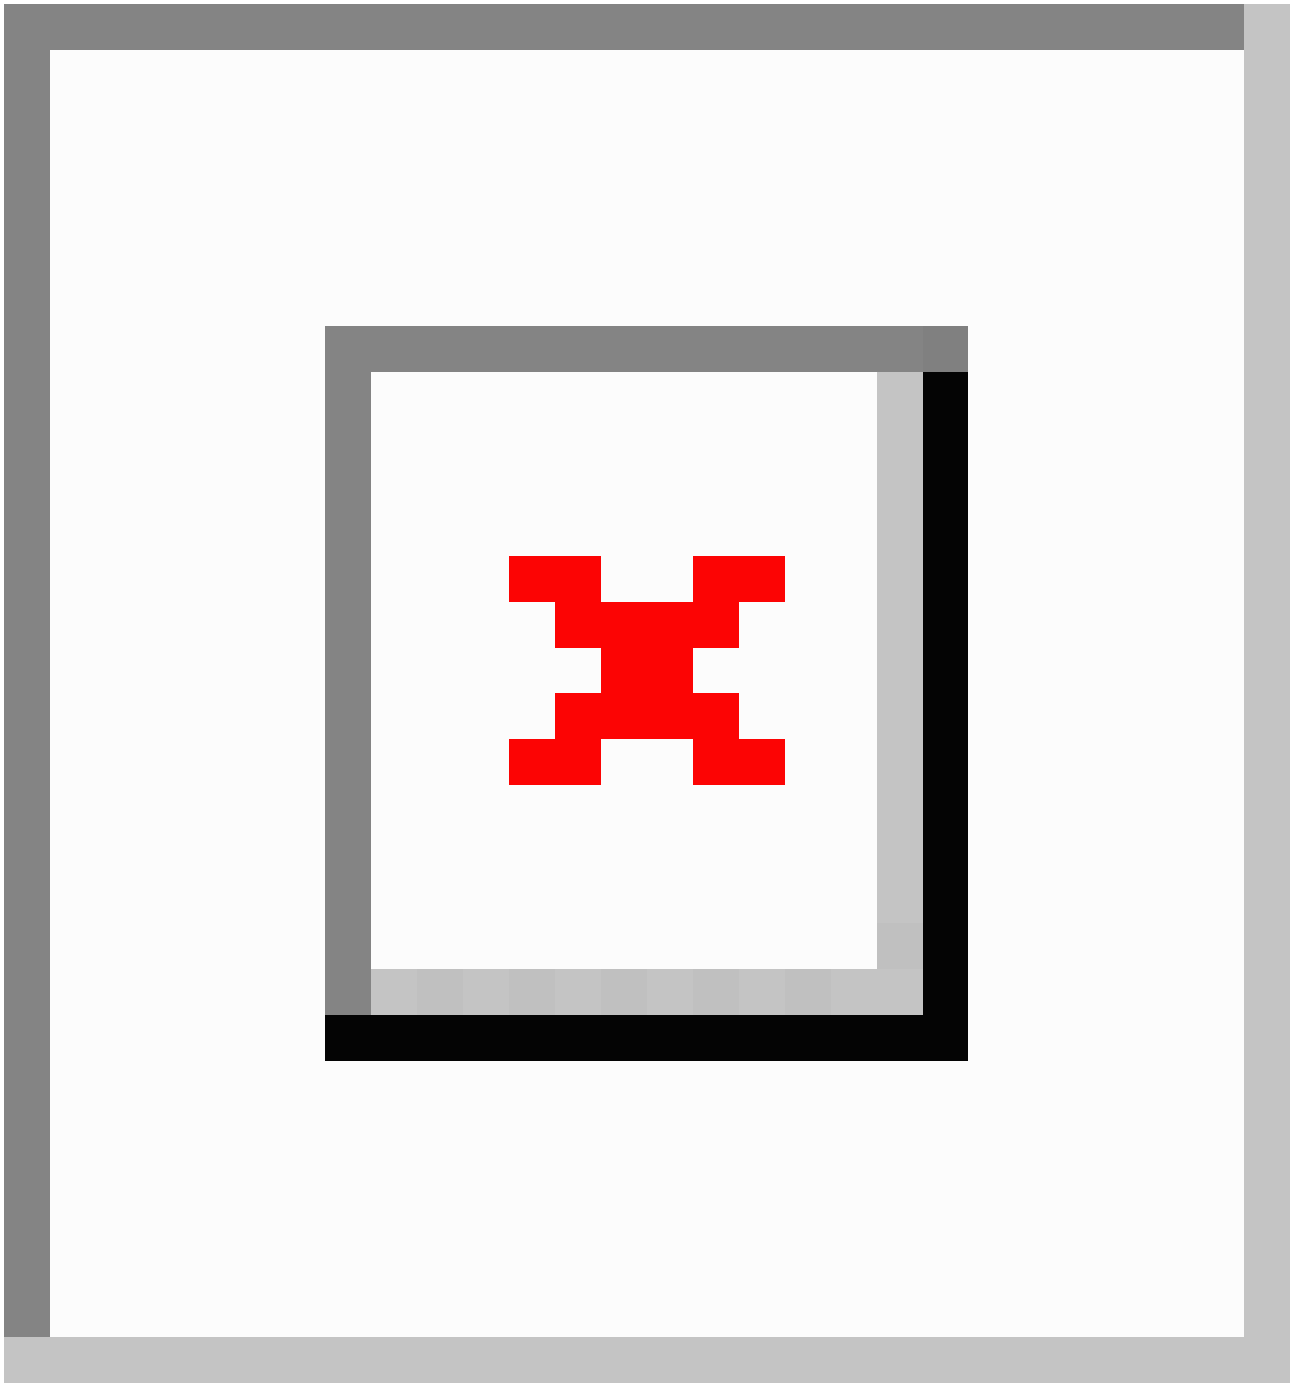
The license fee of the CAHT platform was estimated to be €1000 (US $1085) per month regardless of the number of patients included and health care providers involved. In addition, a one-time setup fee for the questionnaire was estimated to be €4000 (US $4343). Finally, a one-time setup fee for the integration with the EHR was estimated to be €4000 (US $4343).

Implementation (Results)

Study Sample

Between April 2022 and July 2022, a total of 7065 patients were scheduled to have a first consultation with an orthopedic surgeon in 1 of the 2 participating hospitals. Of these, 5321 (75.3%) met the study's inclusion criteria. In addition, a usability questionnaire was sent to 414 participants, of whom 224 (54.1%) responded (Figure 4). Semistructured interviews were performed with 15 orthopedic surgeons from the participating hospitals.

Figure 4. Flow diagram showing the inclusion and exclusion of patients. Anna: Anna Hospital; CAHT: computer-assisted history taking; ETZ: Elisabeth Tweesteden Hospital.



Completed CAHT Questionnaires

In total, 5321 patients were invited to complete the CAHT questionnaire. Out of these, 4932 (92.7%) participants fully completed the questionnaire. Anna Hospital invited 2620 patients, of whom 2516 (96.0%) completed the CAHT questionnaire. ETZ Hospital invited 2701 patients, of whom 2416 (89.4%) completed the CAHT questionnaire (Table 3).

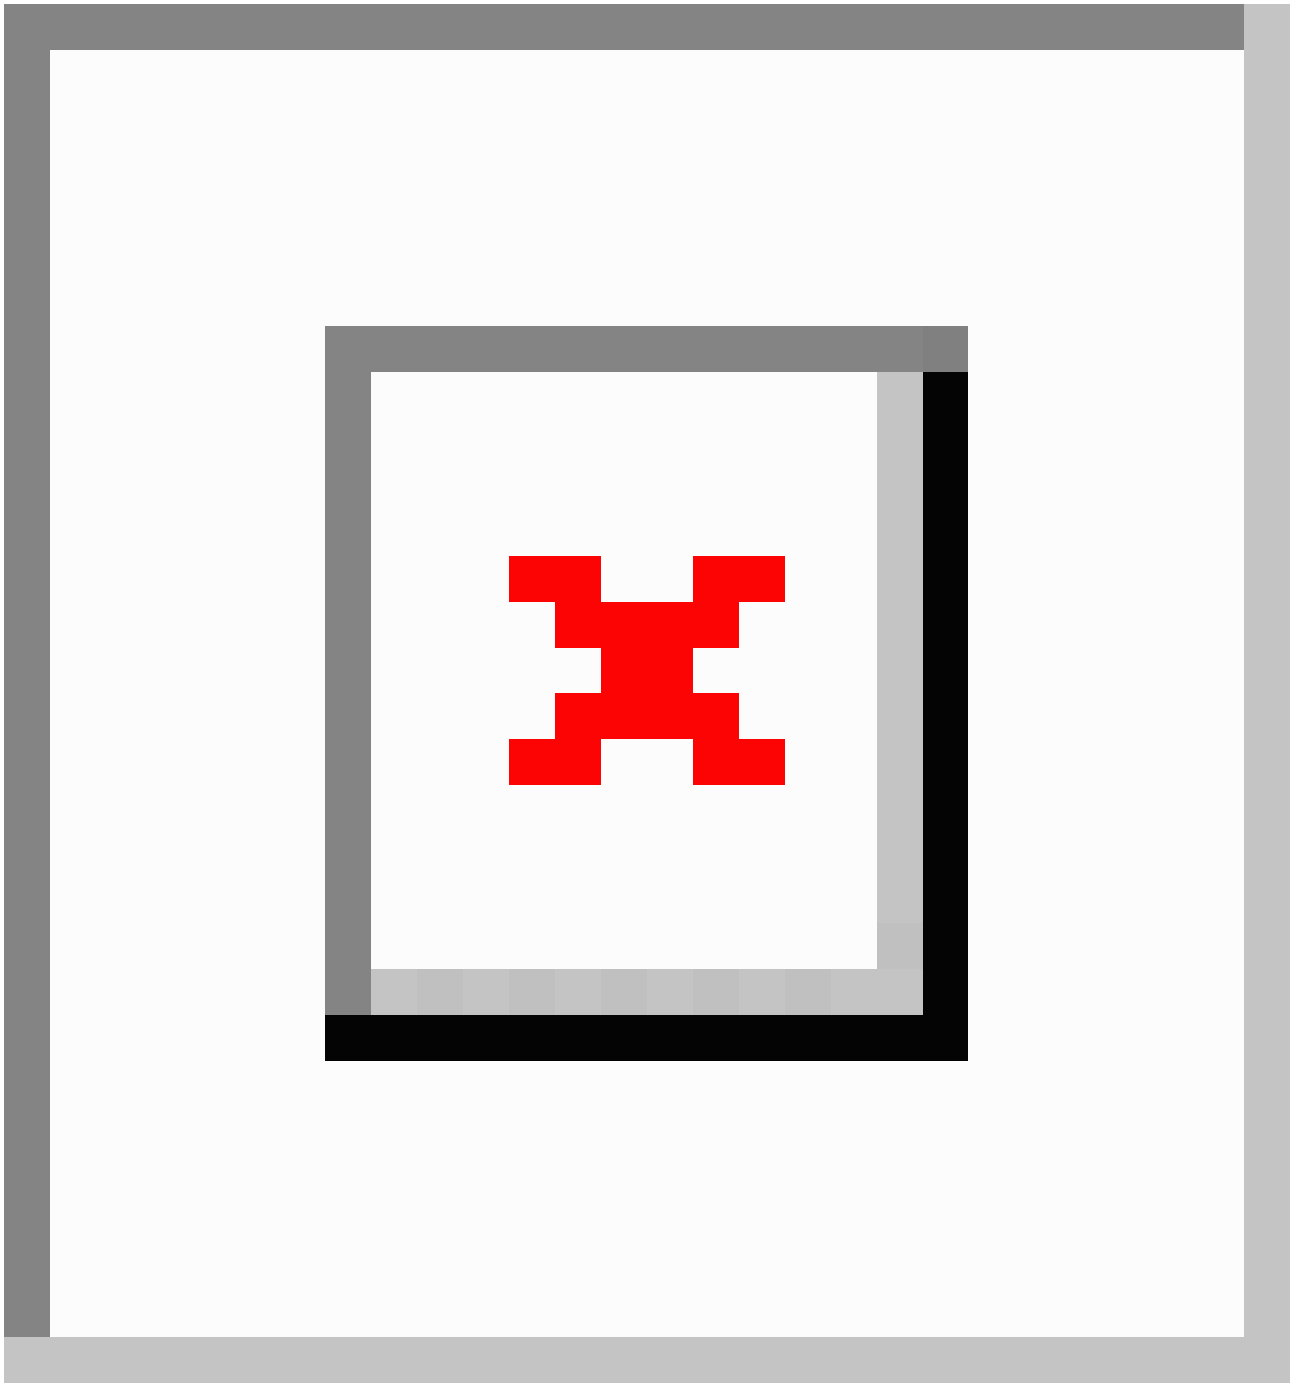
Table . Number of invitations sent and completed computer-assisted history taking questionnaires, divided by hospital.

	Invitations sent, n (%)	Completed, n (%)
Anna Hospital	2620 (49.3)	2516 (96.0)
Elisabeth Tweesteden Hospital	2701 (50.8)	2416 (89.4)
Total	5321 (100)	4932 (92.7)

Usage Statistics

The duration to complete the questionnaire for participants who started and completed the questionnaire on the same day displayed a median value of 16.2 (IQR 11.4 - 26.1) minutes. In addition to the initial invitation, Anna Hospital needed 1846 first and 707 second reminders and ETZ needed 796 first and 323 second reminders, respectively (Figure 5).

Figure 5. Flow diagram showing the response to automated sent invitations and reminders. Anna: Anna Hospital; ETZ: Elisabeth Tweesteden Hospital.



Patient Characteristics

Table 4 shows the patient characteristics. The mean participant age was 56.5 (SD 16.8) years, and 2208 out of 4932 (44.8%) participants were men with a mean BMI of 27.4 (SD 5.1) kg/m^2. The three joints most often selected as affected by the 4932 participants were the knee (n=2205, 44.7%), hip (n=962, 19.5%), and ankle/foot (n=908, 18.4%).

Table . Participant characteristics.

Characteristic	Patients from Anna Hospital (n=2516)	Patients from Elisabeth Tweesteden Hospital (n=2416)
Age (years), mean (SD)	55.4 (16.9)	57.5 (16.7)
18 - 27, n (%)	239 (9.5)	165 (6.8)
28 - 37, n (%)	206 (8.2)	190 (7.9)
38 - 47, n (%)	254 (10.1)	272 (11.3)
48 - 57, n (%)	548 (21.8)	468 (19.4)
58 - 67, n (%)	592 (23.5)	552 (22.8)
68 - 77, n (%)	511 (20.3)	529 (21.9)
78 - 87, n (%)	156 (6.2)	220 (9.1)
88 - 97, n (%)	10 (0.4)	20 (0.8)
Sex (male), n (%)	1157 (46)	1051 (43.5)
BMI (kg/m^2), mean (SD)	27.2 (16.8)	27.6 (5.2)
Affected joint[a], n (%)		
Knee	1205 (47.9)	1000 (41.4)
Hip	437 (17.4)	525 (21.7)
Ankle/foot	423 (16.8)	485 (20.1)
Shoulder	409 (16.3)	310 (12.8)
Elbow	34 (1.4)	48 (2.0)
Wrist/hand	57 (2.3)	116 (4.8)
Spine	183 (7.3)	349 (14.4)

[a]The computer-assisted history taking questionnaire allowed patients to select multiple affected joints.

Patient Satisfaction

Participants included were asked to rate the CAHT questionnaire usability (n=224); on average, they rated it an 8.0 (SD 1.9) out of 10 on easiness to complete the questionnaire and an 8.0 (SD 1.7) out of 10 considering the satisfaction of the consult. Satisfaction with the outpatient consultation was higher in cases where the given answers were used by the orthopedic surgeon during this consultation (median 8.3, IQR 8.0 - 9.1 vs median 8.0, IQR 7.0 - 8.5; *P*<.001). Out of 224 participants, 145 (64.7%) reported that the CAHT questionnaire was used by the physician during the consultation and 157 out of 224 (70.4%) participants had the feeling that their physician had a better understanding of their complaint due to the CAHT questionnaire.

Physician Satisfaction

On average, physicians (n=15) scored the added value of using the CAHT questionnaires during their consultation as 7.8 (0 - 10 scale, SD 1.7). One physician reported not using the answers at all during the consultation. Physicians' unanimously recognized benefits during outpatient consultations, such as increased efficiency, better patient engagement, and better medical record completeness. This was more the case in patients with hip or knee complaints, and less in those with foot and ankle complaints, most likely due to the foot and ankle's more complex anatomy, making it harder for patients to pinpoint the exact location of their symptoms. Physicians highlighted the questionnaire's value in eliciting pertinent information, aiding diagnosis, and providing a framework for informed decision-making. Implementing the summary generated from patients' answers in the EHR was deemed necessary to achieve this with direct access to the information from their own workspace.

Discussion

Principal Findings

This study demonstrates the feasibility of the implementation and clinical adaptation of CAHT for orthopedic patients scheduled for their first consultation in a hospital. The completion rate to answer a CAHT questionnaire before the first consultation was very high: 4932 out of 5321 (92.7%). Patients found the questionnaire easy to understand and complete. Additionally, they were more satisfied with their outpatient consultation when the summary of the CAHT questionnaire was taken into consideration by their physician. Physicians rated the CAHT questionnaire to be a useful addition to standard outpatient consultations, as insight into the personal care needs and preferences allowed them to address the main concern of the patient directly.

To achieve a high completion rate of the CAHT questionnaire, we took implementation barriers addressed in previous studies (accessibility, accuracy, and acceptability) into consideration [6]. For accessibility, linked with interoperability [13], we integrated a single sign-on web link that displayed a

comprehensive summary (and the entire questionnaire when needed) of the answers directly in the EHR. From a patient perspective, the CAHT questionnaire was easily accessible from their email inbox with a two-factor authentication code. Regarding the accuracy, there is conflicting evidence [10,14]. We aimed to obtain accurate answers by enriching some questions with illustrations or a short instruction and using easy/informal language where possible. For data acceptance [15], we created an expert panel to develop and design the CAHT questionnaire and its output. This method is underlined by research, addressing the improvement in quality and acceptance of data [16].

Examining the impact resulting from the implementation of CAHT in a multicenter study design represents a major strength of this study. By incorporating 2 hospitals (1 nonacademic teaching hospital and 1 general hospital), we were able to include a high number of patients, strengthening the generalizability and robustness of our findings. This is confirmed by the similarity of the data between hospitals in terms of demographics, completion rate, and satisfaction.

This study is not without limitations. In this study, we implemented CAHT within orthopedic departments only, limiting the generalizability to other medical departments. The study population's age and sex distribution might, however, indicate usability within other departments as well. Another limitation is the absence of nonverbal communication that occurs in face-to-face conversations. In contrast, CAHT completion allows for more time to think about the answers and fact-check them, without the stress and shortage of time experienced during outpatient visits. The reported median time of 16 minutes for completion supports this.

Lessons Learned

Our study demonstrates that implementing CAHT in the daily routine of an orthopedic department is feasible and can lead to good clinical adaptations but does require the necessary steps to be taken. Requirements are that the patients have an email address, and hospital staff must be available to invite patients to the CAHT platform. The latter would ideally be done through an automated connection with the EHR. Making the results of the questionnaire available in the EHR can be done through a single sign-on web link, offered by almost all EHR suppliers. In addition, the development of the CAHT questionnaire by an expert panel was considered important to ensure usability for HCPs. The integration of the CAHT system with the EHRs and the presentation of the CAHT questionnaire answers as a coherent summary in a format designed by the expert panel were crucial elements for its adoption as well. We hypothesize that key factors contributing to a high completion rate among patients include the predefinition of questions in a standardized order, the inclusion of smart dependencies to avoid unnecessary questions, and the presentation of the online questionnaire in a design consistent with the hospital's branding.

Future Research

Today's health care system is facing an immense burden. Time is limited, but personalized health care needs to be maintained or even improved. Increased consultation duration is associated with better health outcomes, fewer prescriptions, and better recognition of long-term and psychosocial problems [17,18], but this is simply impossible in most health care systems. Nevertheless, a physician who is supported by CAHT results might optimize consultation time in a friendly manner while improving patient-centered communication (ie, signposting, summarization, and repetition of the medical history) [19]. This may lead to more accurate diagnoses, enhanced shared decision-making, and increased patient satisfaction [20,21]. Future research should aim to study the effect of optimized face-to-face consultation time with the support of CAHT and its effect on satisfaction and cost-effectiveness.

Conclusion

Previously reported barriers to implementing and adapting CAHT in clinical practice can nowadays be resolved. In this study, we demonstrated that almost all patients completed the CAHT questionnaire before their outpatient consultation. Both patients and HCPs reported a more efficient and personalized consultation when the answers to the questionnaire were used. Given the pressing need for personalized health care delivery in today's time-constrained medical environment, we recommend implementing CAHT systems in routine medical practice.

Acknowledgments

The authors would like to thank all the health care professionals from Anna Hospital in Geldrop and Elisabeth-Tweesteden Hospital in Tilburg for their time and energy in turning this project from an idea into this manuscript. Furthermore, they would like to thank the team of Interactive Studios for creating the computer-assisted history taking platform. Finally, they would like to thank all patients who were willing to participate in the study.

Authors' Contributions

CC, TT, MS, and WVDW conceived the study and designed the trial. WVDW and TG supervised the data collection. CC managed the data. CC, TT, and WVDW provided statistical analysis. CC drafted the manuscript. All authors contributed to its revision.

Conflicts of Interest

CC and TT work at the research and development department of Interactive Studios. Interactive Studios is the company that developed the computer-assisted history taking platform platform used in this study. Interactive Studios offered the computer-assisted history taking platform used in this study free of charge. The other coauthors declare that the research was conducted in the

absence of any other commercial or financial relationships that could be construed as a potential conflict of interest. Moreover, all authors have completed the International Committee of Medical Journal Editors uniform disclosure form and declare the following: no support from any organization for the submitted work, no financial relationships with any organizations that might have an interest in the submitted work in the previous 3 years, and no other relationships or activities that could appear to have influenced the submitted work.

Abstract

Background: Biomedical data warehouses (BDWs) have become an essential tool to facilitate the reuse of health data for both research and decisional applications. Beyond technical issues, the implementation of BDWs requires strong institutional data governance and operational knowledge of the European and national legal framework for the management of research data access and use.

Objective: In this paper, we describe the compound process of implementation and the contents of a regional university hospital BDW.

Methods: We present the actions and challenges regarding organizational changes, technical architecture, and shared governance that took place to develop the Nantes BDW. We describe the process to access clinical contents, give details about patient data protection, and use examples to illustrate merging clinical insights.

Implementation (Results): More than 68 million textual documents and 543 million pieces of coded information concerning approximately 1.5 million patients admitted to CHUN between 2002 and 2022 can be queried and transformed to be made available to investigators. Since its creation in 2018, 269 projects have benefited from the Nantes BDW. Access to data is organized according to data use and regulatory requirements.

Conclusions: Data use is entirely determined by the scientific question posed. It is the vector of legitimacy of data access for secondary use. Enabling access to a BDW is a game changer for research and all operational situations in need of data. Finally, data governance must prevail over technical issues in institution data strategy vis-à-vis care professionals and patients alike.

Introduction

The increasing use of electronic health records in research settings presents physicians with the systematic yet secondary use of data collected from multiple sources [1-3]. Indeed, hospital information systems (HISs) face a technical challenge to harmonize and integrate application systems and clinical databases that are highly heterogeneous, are based on editor-specific software formats, and use nonstandardized terminologies [3,4].

Moreover, institutions must face the legal and ethical challenge of granting secondary access to data due to national and international laws vis-à-vis patient privacy [5-7]. The reuse of data produced during the care process implies operational knowledge of ethics and legacy concepts that must be solved through well-defined data governance and access policies [7].

Repositories must ensure not only the technical aspects to data access but also the decision criteria granting access [6]. Indeed, institutional data governance is also pivotal when considering legal and ethical principles such as patient informed consent and privacy data protection [2,8,9]. Last but not least, following the line of traditional epidemiology, clinical data reuse requires treatment within a validated and standardized methodological framework to ensure a qualitative result from a scientific and clinical point of view [9].

Despite these difficulties, the rise of biomedical data warehouses (BDWs) is transforming research processes for epidemiology and clinical studies [5,10-12]. Patient data constitute well-defined profiles that can be used to facilitate the enrichment of cohorts [13,14], patient selection and follow-up for clinical trials [15], phenotypic detection, and detailed descriptions of symptoms. BDWs can facilitate the development and performance of personalized and precision medicine, including through the use of big data and artificial intelligence methods.

The implementation of BDWs is conducted at various geographical levels in France. To our knowledge, 24 active hospital BDWs were set up between 2008 and 2023 [16-21]. Regional coordination often occurs within specialized networks of BDWs such as the "Ouest Data Hub," which is specifically designed for university hospitals in Western France [22]. This can take place in thematic networks and is well advanced in cancer data [23]. National or European Union–wide initiatives also propose a development and coordination framework to deal with the different challenges of implementation. In particular, France initiated in 2019 a national project called "Health Data Hub" [24,25] that promotes centralized coordination and increases the visibility of data sources on a nationwide level.

In this paper we report our 5-year experience regarding organizational changes, technical architecture, and governance, supporting the implementation of the Nantes University Hospital Biomedical Data Warehouse (NBDW). We describe the process to access clinical content. We also give figures concerning sources and contents included in the repository, and provide some insight into the projects to which the NBDW contributed. Finally, we propose three indicators to measure the effectiveness of the setting up operation.

Methods

Overview

In 2018, Centre Hospitalo-Universitaire de Nantes (CHUN; University Hospital of Nantes) implemented a BDW to facilitate secondary use of personal health data originally collected in the context of patient care for research and to offer single secure access to up-to-date data from different sources within the CHUN HIS, accommodating a wide range of data types, including demographic and clinical information, consultations, billing codes, diagnoses, laboratory results, medical notes, and drug administration in a unified view.

The focal point of the intervention geared toward implementing the NBDW entailed orchestrating the reorganization across the involved hospital research entities. This restructuring initiative encompassed not only the resolution of technical hurdles but also the delineation of governance structures, regulatory frameworks, and parameters governing data access.

This implementation report adheres to the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) reporting guidelines [26].

From Blueprint to the Functional Organization of the NBDW

Implementation of the NBDW required the de novo organization of a functional research network within a 3-fold structure (Figure 1). First, enforcement of the governance policy and NBDW legal framework was achieved by the Research Administration Department (RAD), which assumed legal and ethical responsibility. Second, the creation of a clinical data center (CDC) took charge of the scientific question and the potential need for NBDW data to coassume scientific responsibility with project investigators. The last layer of technical responsibility was established by the hospital's Information Technology Department (ITD). IT priorities are defined by legal and governance constraints, and address the data needs of each project. The new organization allows the distribution of tasks and responsibilities in the implementation and management of the NBDW.

Figure 1. A functional framework dedicated to the CHUN NBDW. A 3-fold governance structure constitutes the functional research framework accompanying the development of the NBDW. The ITD ensures the IT infrastructure's quality, transparency, and data deidentification. Through an ETL process, data flows are extracted and loaded to the NBDW. The RAD is an administrative department that assumes legal and ethical responsibility, and lays the regulatory framework that will define data use and access policies. The CDC assumes scientific data stewardship, is in charge of scientific responsibility, supports the methodology of the study, and grants data access. Those three structures are organized and structured to ensure research quality, ethics, and technical transparency. White arrows represent the data request and access process undertaken by investigators. CDC: clinical data center; CHUN: Centre Hospitalo-Universitaire de Nantes; ETL: extract, transform, and load; ITD: Information Technology Department; NBDW: Nantes Biomedical Data Warehouse; NLP: natural language processing; RAD: Research Administration Department.
