diagnosis. The Jensen-Shannon divergence is shown in equation (2), in which *KL* is the KL divergence, *P* and *Q* are the 2 variable distributions being compared, and we compute na average of each possible KL divergence combination between the two distributions. Since the KL divergence is asymmetric, the calculation described can be interpreted as a symmetric divergence between the two distributions. This metric was tracked to evaluate whether the data distributions changed over time, how fast they changed, and whether the data shift was temporary.

$$JSD(P||Q) = 1/2\ KL(P||M) + 1/2\ \mathrm{KL}(Q||M) \quad \textbf{(2)}$$

In equation 2, *KL* is the KL divergence, *M* is 1/(*P* + *Q*), and *P* and *Q* are the distributions of the variables we compared.

Figure 4 presents the results of our drift detection metrics, applied to the various "anchor_year_groups" in the MIMIC-IV data set. The figure depicts the normalized magnitude of the drift signal calculated per "anchor_year_group." The drift signals were normalized in the 0 range for visualization, as shown in equation 2. The results for the Jensen-Shannon divergence, PCA reconstruction error, and centroid cosine distances revealed a trend toward increasing distance between the variable distributions over time, which did not revert to prior levels, suggesting a gradual temporal shift. As seen in Multimedia Appendix 2, this drift occurred gradually over several years, with a more pronounced change between the first 2 temporal chunks.

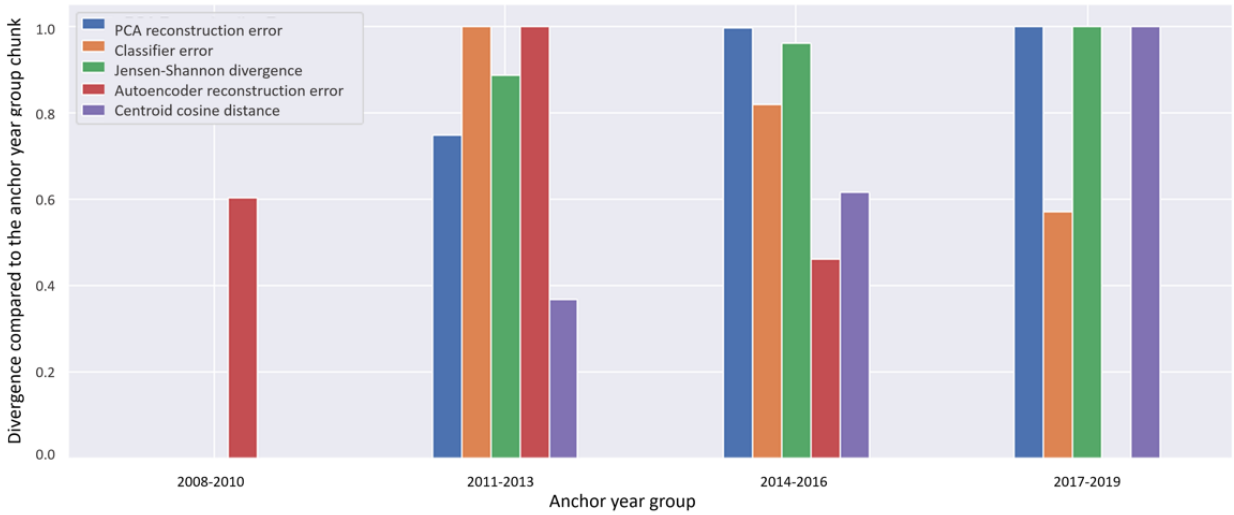
By contrast, when examining the autoencoder reconstruction error and classifier error metrics, a peak divergence was observed in the second time chunk (2011-2013), which gradually trended toward the baseline. As models with more parameters, these 2 drift metrics were sensitive to a combination of the data distribution, novel data points (ie, rare diseases or diseases not present in the reference time slice), and numerical outliers in the case of the autoencoder reconstruction error. For example, the disease codes appearing in the second chunk had the smallest intersection with the reference chunk, meaning they had the fewest diseases occurring concurrently in both chunks. This likely explains why the autoencoder reconstruction error and classifier error metrics exhibited their highest peaks in this slice.

In summary, the Jensen-Shannon divergence metric yielded more robust drift signals in our tests. It is important to note that the best metric depends on the most relevant type of drift for the data collection being analyzed. The Jensen-Shannon divergence is robust at detecting distribution changes, just as robust as the classifier error metric. If we are interested in detecting the occurrence of outliers or novel samples not seen before, the reconstruction errors might result in better detection. The choice of metric must be informed by the characteristics of the metrics themselves as well as the characteristics of the data stream being monitored.

$$\mathrm{NormalizedSignal} = (X - \min[X])/(\max[X] - \min[X]) \quad \textbf{(3)}$$

As show in equation 3, normalization is used to calculate the normalized magnitude of the drift signal.

Figure 4. Different drift detection metrics over time on the Medical Information Mart for Intensive Care, version IV (MIMIC-IV) data set, considering in-hospital International Classification of Diseases (ICD) diagnosis. PCA: principal component analysis.



DIS: Initial Characterization Step (MIMIC-IV)

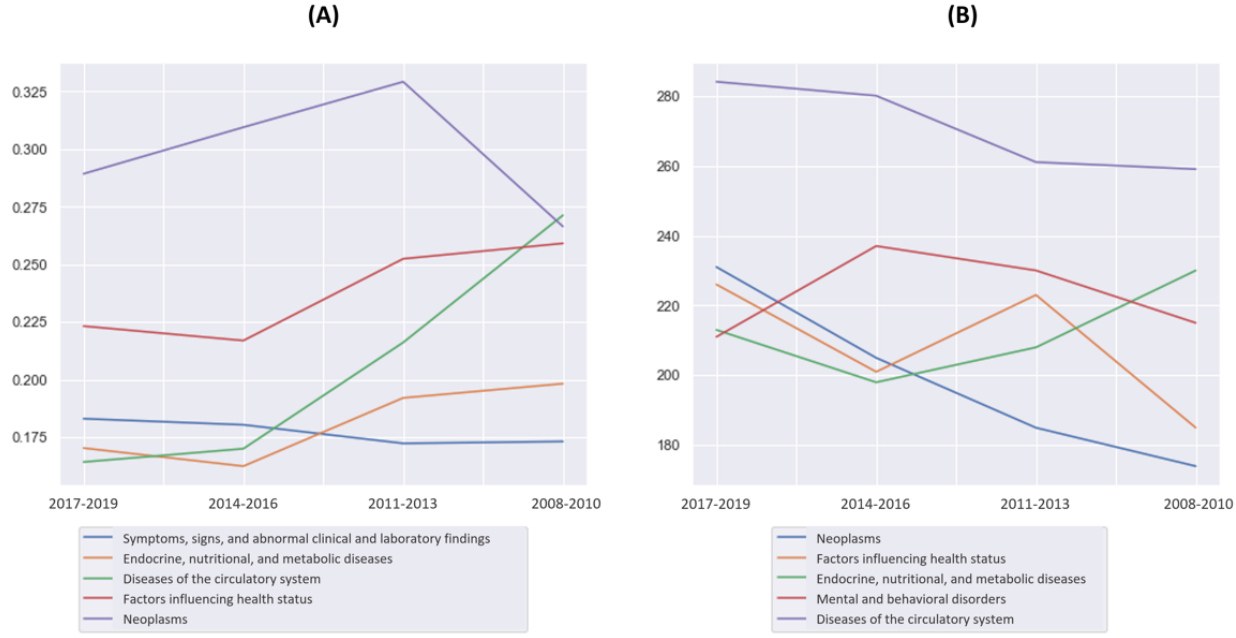
After establishing that a drift has indeed occurred, especially based on the results of the most accurate method, the Jensen-Shannon divergence, we proceeded to *step 2*. In this step, we strived to understand how the independent variables (*P*(*X*)) affect the outcome, which is our *dependent variable (P(y|X))*, and how the relationship between dependent and independent variables changes over time. This analysis can be accomplished by examining changes in correlations and feature importance over time, as well as by characterizing the distribution of different features over time. For instance, in Multimedia Appendix 3, we show how the relative distribution of the "death" outcome has changed over time in this data set. This means that our data exhibit a consistent trend toward in-hospital mortality reduction over time, which indicates a change in the relative distribution of the 2 possible categories (deceased × not deceased) for this outcome.

In Figure 5, we show the correlations and feature importance variations of the top 5 most correlated and the top 5 most

predictive *ICD* chapters (according to *ICD-10*) and the "death" outcome (according to feature importance). For instance, Figure 5A shows some expressive variations, such as how circulatory system diseases seem to grow more correlated with death over time, Figure 5B shows how neoplasms seem to become less predictive of death over time.

In Multimedia Appendix 4, we show how the different outcome groups behave over time from given baseline, in particular the patterns of independent variables given the outcome categories P(y|X) observed in the first temporal chunk. To obtain this result, we computed the arithmetic mean of each class's features in each "anchor_year_group" and calculated the cosine distance between these means over time, taking the first chunk as a reference to compare all other chunks against it. In this particular figure, we represent each patient as a "corpus" containing all their health care events (such as diseases and medications used during the hospital stay), then encode each feature as a 1-hot sparse matrix (each event can have the value "0," if it did not happen for a particular patient, or "1," if it did), and subsequently average these features. Notably, this representation treats each patient as a "bag of health care events," disregarding the order of precedence between those events, unlike what we did in our semantic characterization step. In the specific case, we show how the "death" outcome exhibits greater temporal drifts over the available time chunks in both data sets compared to the overall hospitalized patient population.

Figure 5. (A) Pearson correlations between the top 5 International Classification of Diseases (ICD) chapters (according to ICD-10) most correlated with the death outcome over time. (B) Feature importance among the top 5 ICD chapters most predictive of the death outcome over time.



DIS: Semantic Characterization (MIMIC-IV)

In Table 2, we show the top 5 *ICD-10* chapters that have become more and less similar to the "death" outcome over time. Notably, certain diseases, such as neoplasms, have become less similar, while others, such as malformations and circulatory system diseases, have become more similar. That is consistent with the findings in step 2, and over the next few paragraphs, we describe the procedure to obtain this similarity score. We explain the token-level vectorization process for both dependent and independent variables in Figure 6. First, we compiled a temporally ordered list of patient data, consisting of discrete data points such as items consumed during hospital stay (antibiotics, anti-inflammatories, etc), disease codes (using *ICD*), and procedures. At the end of each patient's sequence, we appended the outcome category for that patient. To classify the outcome, we divided binary outcomes into distinct tokens, such as "deceased" and "not deceased," and used the corresponding token to generate our training corpus. Continuous outcomes and dependent variables could be binarized using a simple histogram binarization scheme, as demonstrated in the next analysis. Following the corpus generation, we used it to train token embeddings with Word2Vec [26]. This method produced embedding vectors for both dependent and independent variables, allowing semantic comparisons between different entities, such as the "death" outcome and different disease codes. We created 1 outcome token for each outcome category and temporal chunk in our data set. This allowed us to evaluate how an outcome such as "death" may have drifted closer to or farther from certain diseases or procedures over time.

In Multimedia Appendix 5, we show the top 5 conditions that became more similar to the "death" token and the top 5 conditions that became less similar when comparing the first and last time chunks. Since every entity is a "token," we could evaluate similarities between diseases and disease chapters, between patients and diseases they have not yet been diagnosed with, and between outcomes and diseases (Multimedia Appendix 5). In particular, in Multimedia Appendix 6, we demonstrate changes in similarity for the "dysphagia following stroke" *ICD* code within the MIMIC-IV data set [18]. Our analysis revealed a rise in the simultaneous appearance of ICD codes related to obesity between the periods of 2011 to 2013 and 2017 to 2019.

This trend aligns with broader observations indicating an uptick in obesity rates across the United States. Importantly, it is essential to recognize that this method does not permit the establishment of causal relationships; rather, it emphasizes changes in correlation and cooccurrence.

The *step 3* analysis can also be conducted at different levels of granularity to gain a deeper understanding of the observed changes. From step *2*, it can be inferred that mortality has been decreasing and has some relationship with particular disease groups. If *step 3* is performed at the disease code level, as shown in Multimedia Appendix 6, chapters that had considerable shifts in their similarity to the "death" outcome, either increasing or decreasing similarity, can be identified. For instance, the findings confirm what is illustrated in Figure 6, where "cancer" shows a decreasing similarity to the outcome, while the variable "circulatory diseases" exhibits an increasing similarity to the outcome. This observation is further supported by the results shown in Multimedia Appendix 7, where an absolute increase in the number of patients with cancer over time is shown, associated with a relative decrease in in-hospital cancer-related deaths between 2008 and 2019.

To further illustrate how the proposed DIS semantic analysis based on embedding distances among entities of interest can help in better comprehending the reasons for the drifts, we contrasted the previous analyses of our third step with a traditional clustering analysis for the MIMIC-IV data set. This analysis used a syntactically oriented term frequency–inverse document frequency (TF-IDF) [28] representation for the entities, built from the same corpus of clinical entities. In a TF-IDF representation, each dimension corresponds to a unique term (word) in the document corpus. The value in each dimension reflects the importance of that term in a specific document, calculated by multiplying the term's frequency in the document (term frequency) by the inverse frequency of the term across all documents (inverse document frequency). In our case, each "document" was a patient, and each "word" was a health care event, such as the identification of a novel disease. We applied a spectral clustering [29] procedure to the TF-IDF representation of the entities to create the clusters. The results are shown in Figure S8. To obtain the 4 clusters displayed in Multimedia Appendix 8, we used a silhouette analysis using 2 to 15 clusters.

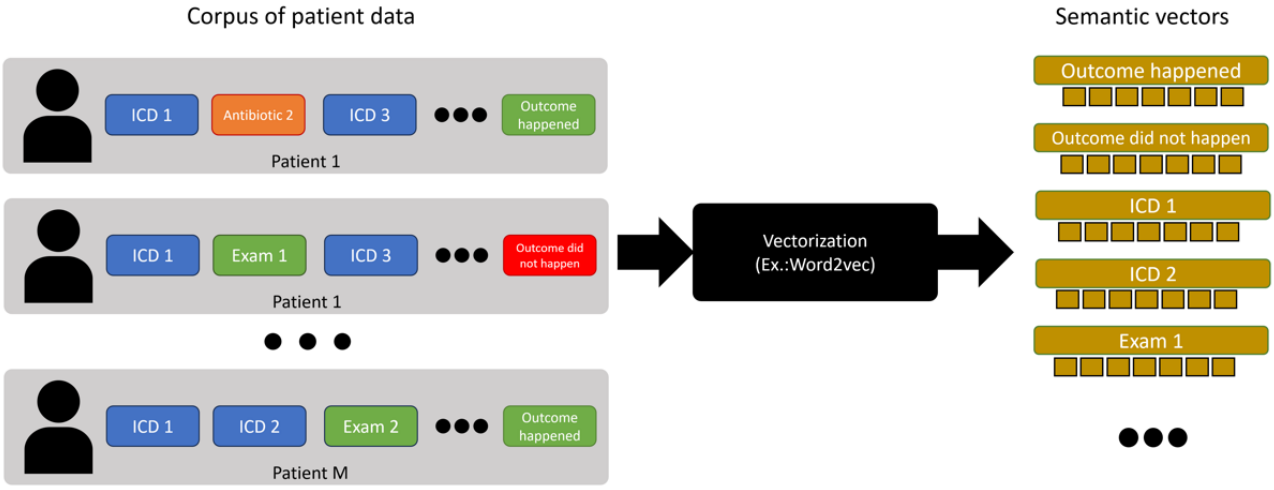
Multimedia Appendix 8 shows the top 5 most frequent diseases for each of the 4 clusters (y-axis). On the x-axis, we present the index of each cluster. Multimedia Appendix 8 shows how the relative frequency of each cluster changed over each "anchor_year_group." A few points stood out from the clustering analysis illustrated in Multimedia Appendix 8. As it can be observed, the cluster analysis using syntactically oriented vectors made it harder to interpret the drivers of a data drift when compared to DIS. For instance, some semantically similar diseases, such as "other and unspecified hyperlipidemia" and "hyperlipidemia, unspecified," may have very distinct profiles in different clusters, such as in clusters 0 and 2, each having a high concentration of patients with either one of these diseases. The main problem of this particular cluster analysis based on syntactically oriented representation is the separation of semantically similar entities into distinct clusters. In DIS, similar entities will be represented similarly and thus analyzed in conjunction.

Table 2. Change in similarity by ICD[a] chapter.

ICD chapter	Change in similarity	Direction
Diseases of the nervous system	–0.14	Less similar
Diseases of the musculoskeletal system	–0.12	Less similar
External causes of morbidity and mortality	–0.10	Less similar
Diseases of the digestive system	–0.08	Less similar
Neoplasms	–0.02	Less similar
Congenital malformations	+0.40	More similar
Diseases of the circulatory system	+0.35	More similar
Diseases of the genitourinary system	+0.30	More similar
Endocrine, nutritional, and metabolic diseases	+0.25	More similar
Diseases of the skin and subcutaneous tissue	+0.20	More similar

[a]ICD: International Classification of Diseases.

Figure 6. How to generate semantic vectors? We start by generating a corpus of temporally ordered patient discrete data points. Then, we vectorize the tokens of this corpus using Word2Vec to obtain semantic vectors for dependent and independent variables. ICD: International Classification of Diseases.



DIS Instantiation for the Brazilian COVID-19 Registry Data Set

The median age was 60 (IQR 48-71) years, and 21.72% (2367/10,898) were women (5012 patients). In this data set, 21% of registered patients died, yielding an unbalanced classification problem when predicting future deaths. The data set has low temporal granularity, with only 1 data point per patient, which precludes time tracking during hospital stays. Consequently, we could measure time only at the populational level. In other words, unlike the previous case study, there was a single "snapshot" for each patient, with no temporal evolution at the individual level.

DIS: Detection Step (Brazilian COVID-19 Registry Data Set)

As in the previous case study scenario, we evaluated the same 5 alternative techniques, namely the PCA reconstruction error, autoencoder reconstruction error, classifier error (in separating past vs future), and Jensen-Shannon divergence. All these metrics measure the drift compared to a reference temporal slice and do not require setting a specific outcome or using labeled data.

The outcomes of this procedure are illustrated in Figure 7, where the divergence sharply increases starting from the final quarter of 2020, based on the Jensen-Shannon divergence metric. Numerically, a drift is indicated in this interval as the divergence levels surpass a user-defined threshold, such as a fixed threshold of 2 SDs or a threshold informed by domain expertise. As depicted in the figure, the PCA reconstruction error, autoencoder reconstruction error, and centroid cosine distances indicate positive drift signals in the quarter starting from April 2020. During this semester, the Brazilian COVID-19 Registry data set exhibited a small number of numeric outliers, which were identified by these methods. Conversely, the Jensen-Shannon method signaled a data drift in the quarter starting from October 2020, which aligns with the "official" start of the second wave in Brazil in November 2020. Meanwhile, the classifier error method indicated a drift in July 2020, which falls between the identification of numeric outliers and the actual distribution change from the first wave to the second wave. Both the Jensen-Shannon method and the classifier error method signaled drift closer to known actual changes, while the other, more reconstruction-based methods were more sensitive to numeric shifts, which were not necessarily associated with changes in the underlying distributions.

Figure 7. Different drift detection metrics over time in the Brazilian COVID-19 Registry data set. PCA: principal component analysis.

DIS: Initial Characterization Step (COVID-19)

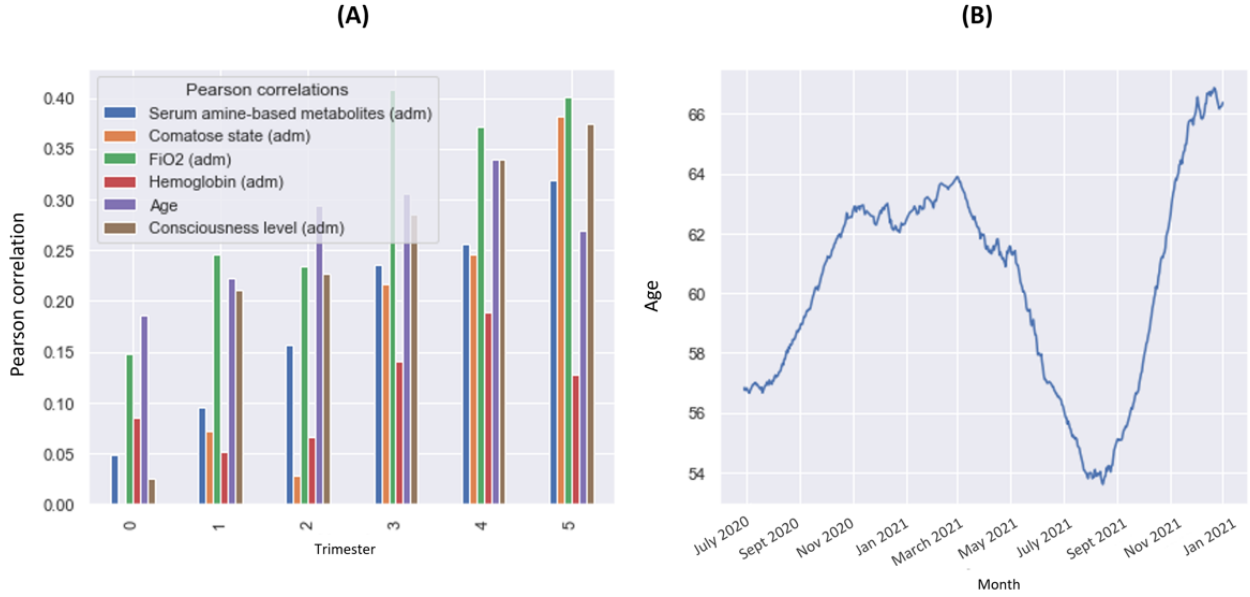
Once a drift was detected, we proceeded with the second DIS step, initial characterization. This step aims to understand the main drivers ("what") of changes during the considered period and "how" they affect the underlying outcomes. At a high level, this begins with the characterization of the changes in the outcome (the independent variable) over time. In Figure 7, we illustrate this upon evaluating the variation in COVID-19–related mortality in our data set. This example displays a trend toward a reduction in the death outcome over time. At the initial characterization step, it is expedient to examine the distribution of the outcome of interest (death, ICU admissions, etc) as well as those of the most predictive independent variables (eg, those with the highest correlation with the desired outcomes or higher feature importance in a tree-based classifier).

To guide the next steps, it is helpful to check how much each outcome category's properties (such as the mean age of the deceased patient population or the prevalence of hypertension) have changed over time. In particular, focusing on which outcomes have changed the most helps target specific subsets of the data that could better explain the observed phenomena. We show an example in Multimedia Appendix 9, where we analyzed such variations in the Brazilian COVID-19 Registry data set. To build the graphs in this figure, we split our data set into time chunks. For each chunk, we separated all patients into classes according to their outcome (eg, dividing the population into deceased and nondeceased and then representing the chunk by averaging all of the patient's features in each category). For each subgroup of patients within the same time chunk and sharing the same outcome, we computed the centroid of that class (the arithmetic mean of all attributes). We then took the first chunk as a reference and compared each class's chunk arithmetic mean to the reference using a cosine distance. Multimedia Appendix 9 shows how much the deceased patients' characteristics changed more than those of the overall population during the same period.

A better comprehension of the drift drivers during the COVID-19 pandemic emerges from Figure 8. As shown in Figure 8A, we observed how the overall best predictors of death changed over time through Pearson correlation analysis conducted each trimester on the data set. At the beginning of the pandemic, age was the single best predictor of death, in trimesters 0 and 2. As the vaccination campaign started, older adults were prioritized and received immunization first. This led to a progressive deterioration of the predictive value of age, as well as an overall decrease in mortality (Multimedia Appendix 10), culminating in the latest trimester, where age was the worst predictor among the top 5 variables. In Figure 8B, it can be seen that the median age of the deceased patient population over time.

In summary, the second step revealed that the COVID-19 data showed a progressive decrease in patient mortality (Multimedia Appendix 10), with a more pronounced change in the group of deceased patients (Multimedia Appendix 9). It was also possible to notice that the overall characteristics of the patients who were dying changed abruptly (Figure 8). From the remaining characterization steps in Figure 8, we can see that age lost its predictive capacity (Figure 8A) over time, while clinical features such as the patients' fraction of inspired oxygen (FiO_2) became better predictors of death. Concurrently, there was a reduction in the median age of patients who were dying (Figure 8B).

Figure 8. (A) Pearson correlations over time for the overall top 6 most predictive variables in the Brazilian COVID-19 Registry data set. (B) Median age of hospitalized patients dying from COVID-19.



DIS: Semantic Characterization (COVID-19)

Following the conclusions from the previous step, we moved further into the semantic characterization step. As the Brazilian COVID-19 Registry data have low temporal granularity and most of their features are continuous, what requires data categorization to enable the use of NLP techniques to treat words and other semantic units.

Subsequently, due to low granularity at the individual level, we needed to model relationships between these now-discrete entities. In more detail, we assumed that the temporal precedence between events imposes a relationship between them and that this relationship can be learned and embedded into a distributional representation. The issue with low temporal granularity data is that the order of precedence is not known; hence, it is not possible to model it directly. Therefore, we modeled all health events (from the perspective of a single individual) as if they happened simultaneously. Therefore, in this setting, we modeled the passing of time only from the perspective of the population and not from the perspective of the individual. This means that we only knew, for instance, that a given patient had events (such as new diseases or use of medications) 1, 2, and 3, but we did not know the order of precedence between these attributes, something that was explicit in the MIMIC-IV data due to high temporal granularity. We began by discretizing the continuous features with a histogram discretizer, which essentially breaks the data intervals into "equal width segments" and then assigns a "token" (ie, a string or integer value) that is unique to patients having that attribute in that specific range of values.

After that, we created a graph with patients, discretized continuous attributes, discrete attributes, and outcomes, such as the one in Figure 9. To build this graph, we connected each patient to their attribute tokens and outcomes while creating one outcome token for each time chunk under analysis. Finally, we embedded the graph using a node embedding algorithm such as Node2Vec [30]. We contrasted this procedure with the one adopted to characterize the MIMIC-IV data set (Figure 10). As discussed before, in MIMIC-IV, the temporal order is defined at the individual level, with entity relationships determined by the timeline. By contrast, the Brazilian COVID-19 Registry data set presents events as occurring "simultaneously" at the patient level, limiting the understanding of relationships between events and patients. In this case, to derive semantic vectors representing entity relationships, we approached it as a graph vectorization problem.

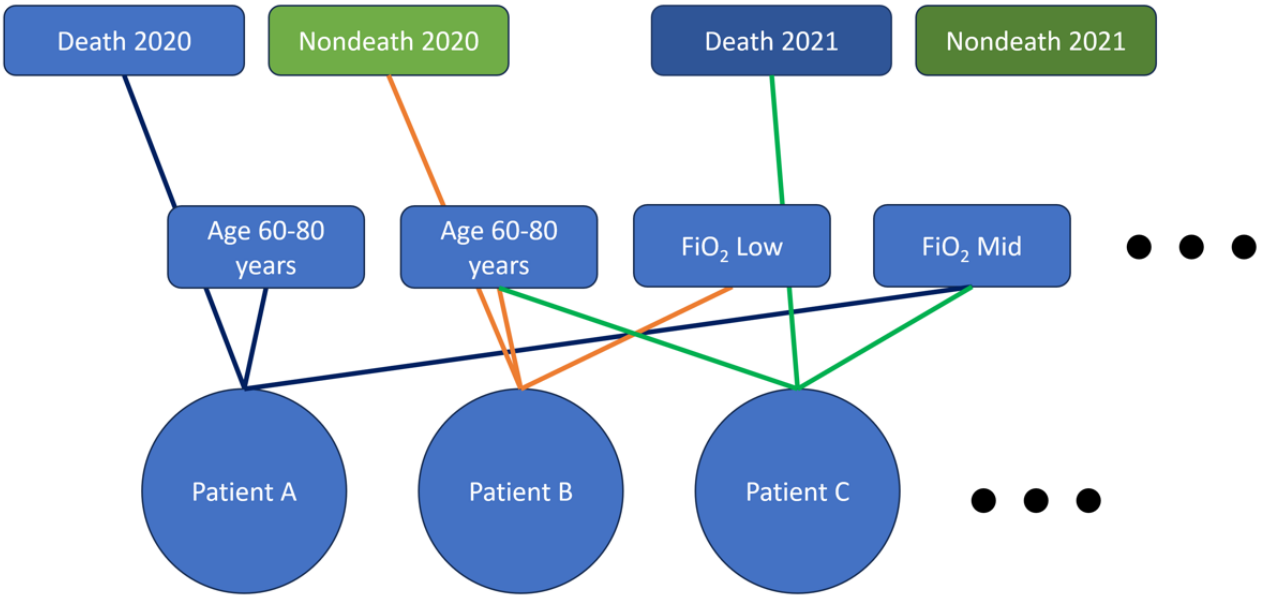
To analyze the resulting model, we compared the outcome embedding vectors to evaluate their similarity to each other and to other patient attributes. We show the results of this procedure in Multimedia Appendix 11. From that, it is evident that the 2021 death outcome token increased in similarity to lower age groups, such as age groups 18 to 39 years and 40 to 61 years, while decreasing in similarity to older age groups, such as age groups 62 to 83 years and 84 to 105 years. This observation further validates the previous findings and introduces new elements not captured in earlier steps. We could also see an increase in similarity to lower admission heart rates and lower admission serum sodium values, as well as lower FiO_2 at admission, showing a shift in disease severity markers over this time frame.

As mentioned earlier, for comparative purposes, to emphasize the semantic capabilities of the proposed DIS procedures, we compared our semantic-step results with those obtained through traditional clustering analysis for the Brazilian COVID-19 Registry data set (Multimedia Appendix 12). In this analysis, entities were represented by a syntactically oriented TF-IDF representation. In Multimedia Appendix 12, we show the top 5 highest-value features for each of the 6 clusters selected using the silhouette analysis, as was done for the MIMIC-IV case. In Multimedia Appendix 12, we show how the relative frequency of each cluster changed over time in each trimester.

Similar to the MIMIC-IV case, the clustering analysis of the COVID-19 data was not as straightforward to interpret as the

DIS analysis when searching for the drivers of data drift. For example, we identified a cluster of patients who underwent a "transplant" and another cluster of patients with diabetes mellitus type 2, but the reasons why these particular clusters were selected and the reasons for the drifts could not be easily derived through a straightforward analysis of these syntactically oriented clusters.

Figure 9. Example of how to create a patient graph with tokenized dependent variables and temporal outcome tokens.



Discussion

Comparison With Prior Work

Multiple studies have analyzed variations observed over time in class distributions and model effectiveness and their overall impacts. Studies such as Salles et al [31] and Mouro et al [32], for instance, performed a detailed characterization of such effects in textual data sets of documents organized into topics. Health care data, however, are quite different from simple text data [31,32]. To begin with, this type of data is multimodal, including tabular and sequential information in the form of vital measurements, disease code diagnosis, and items consumed during a hospital stay, as well as common text, images, wave forms, and sometimes even sound waves. Furthermore, the data may experience sudden and specific drifts driven by new medications, vaccines, surgeries, and public policies [9]. For example, an effective vaccine may cause the eradication of a disease, resulting in a subsequent data drift [33]. While most studies on health care data focus on either drift detection or drift adaptation [33,34], our work is unique in that it focused on drift detection, monitoring, and characterization. We advanced the existing literature by leveraging these 3 steps to pursue explanations for health care data drifts.

Concerning terminologies and problem-setting definitions, Gama et al [35] defined data changes as being related to the distribution of the independent variables P(X) and dependent variables P(y) or the conditional probability of dependent variables for given independent variables P(y|X). Works unified and consolidated some of the underlying terminologies [21,36]. As defined by Lu et al [36], data and concept drifts can be categorized based on how they behave over time, being (1) sudden (ie, 1 event permanently changes the "meaning" of a concept), (2) incremental (ie, 1 event incrementally generates gradual changes to the "meaning" of a concept), (3) gradual (ie, the concepts interchange gradually until the complete shift occurs), or (4) reoccurring (ie, a transient concept drift).

Approaches to detect and learn in the presence of concept drifts do exist. However, in most contexts, naively monitoring data drifts may be expensive, as it often requires data labeling. As an alternative approach, Haque et al [37] used an ensemble of classifiers to report their prediction confidences and monitor changes in their confidence distribution to detect when a concept drift occurred. In the data sets used in this paper, however, deaths are readily available labeled data, which means that our main issue was related to learning in the presence of a data drift.

A common approach to drift detection is monitoring model outputs, as in the study by Sahiner et al [38]. These "model monitoring" approaches are not always possible or desirable; for instance, Tiwari and Agarwal [39] argued that labels are a resource that is not always available and suggested exploring other options, such as detecting drifts by monitoring changes in the underlying data distributions. Following this idea, we propose a *drift monitoring* procedure that is independent of labels and focuses on distribution changes over time. Additionally, Tiwari and Agarwal [39] provide a comprehensive review of useful health care data type classification and data drift management strategies in data streaming scenarios. Textbox 2 details the categorization of health care data proposed by these authors.

In addition to the categorization mentioned in Textbox 2, Tiwari and Agarwal [39] discussed the use of sampling in diverse forms to handle data streams and drifts. In health care data, it is common to encounter massive data sets encompassing multiple years and thousands of patients. For such cases, sampling may

be a viable option. Given the size and nature of our data sources, we opted to work with the complete data set available instead of using sampling. The decision to use sampling should be evaluated depending on the type of ML algorithm used, the available computing capabilities, and the data set size.

Drift detection has multiple beneficial impacts on health care. Once detected and treated, a drift can be used to help maintain and enhance model effectiveness. Additionally, it can be useful to detect whether a new treatment is changing the outcomes of a disease in a meaningful manner or even understand populational trends to derive health policies. A recent example is the COVID-19 pandemic. This topic was explored in the studies by Jung et al [41] and Jassat et al [42], which showed differences in hospitalized patient profiles as new COVID-19 waves spread. Another study has explored how the death prediction task evolved throughout the pandemic, showing that factors such as vaccination changed the profile of patients who were severely ill [4]. These characterizations can help in the detection of important pandemic events, such as the impacts of vaccination, the emergence of new COVID-19 strains, and the emergence of new viral strains resistant to current therapies. In this context, we focused our characterization efforts on technology evaluation through the lens of data drifts in a health care setting.

Some solutions have been reported in the literature to address the challenge of learning in the presence of data drifts, and most of these solutions focused on sample selection or sample weighting, with variations on how they derive the final weighting or sampling. Klinkenberg [43], for instance, tackled the problem by using support vector machines for both sample selection and sample weighting, using an iterative process that sequentially trains support vector machines to find the training instances that constitute the model's support vectors [43]. Kolter and Maloof [44] used a special weighted ensemble to learn in the presence of such drifts. Salles et al [6,31,45] used a temporal weighting function that can be automatically learned to select relevant samples for each training window. Finally, Rocha et al [7] tackled the problem using temporal contexts. The authors analyzed document collections that evolved over time and defined a temporal context as portions of documents that minimize the temporal effects of class distribution, term distribution, and class similarity over time. This method is used to devise a greedy strategy to optimize the trade-off between undersampling and temporal effects. We were inspired by this latter work in our methodology. Most of these approaches, however, are not applied to the health care setting, focusing mostly on common text data.

Another relevant setting is detecting drifts in data streams. This is potentially relevant to some health care data, especially sensor data, which are most commonly obtained from hospitalized patients but also streamed from personal health devices such as smartwatches and heart rate sensors. Zliobaite et al [46], for instance, proposed a continuous loop of labeling new samples under a labeling budget and used active learning to detect data drifts.

Class imbalance is another important aspect of detecting data drifts in health care data. Disease occurrence is naturally unbalanced, with common diseases such as diabetes or hypertension affecting between 5% and 30% of the population [47,48]. Rare diseases, by contrast, have a prevalence in the order of <10 patients per 100,000 or 1,000,000 inhabitants, with combined prevalence among all rare diseases being estimated to be between 3.5% and 5% [49]. Most approaches to handling such class imbalances in the data drift literature focus on oversampling, undersampling, or a combination of both. Gao et al [50], for instance, proposed oversampling the minority class over multiple time slices while undersampling the majority class using only the most recent slice. Ditzler and Polikar [51], by contrast, focused on using incremental learning combined with the synthetic minority oversampling technique [52] to learn a classification ensemble that can deal with both the class imbalance and concept drifts in streamed data. In particular, the combination of models and data sets used in our work was robust to such class imbalance issues and did not require using these types of techniques, as discussed in the following sections.

Textbox 2. Categorization of health care data.

Categories

1. Clinical data, such as the records in Medical Information Mart for Intensive Care, version IV (MIMIC-IV) [18] and the Brazilian COVID-19 Registry [17], are desirable if the goal is to describe data drifts related to the impact of specific interventions, such as the introduction of a new drug or therapy.
2. Self-administered data, obtained from questionnaires, usually investigate lifestyle variables, such as smoking or alcohol consumption habits.
3. Biological data, usually obtained by measuring parameters in biological samples such as blood and urine, are often the result of a laboratory study.
4. Molecular data are the kind of data encoded in protein databases such as UniProt [40], genome databases, or even drug-to-molecule interaction databases.
5. Exposure data encode patients' exposure to given events, drugs, or interventions.
6. Modeling data are data generated from models, including estimated risks given the patient's exposure.

Summary of the Main Results of Applying DIS to the MIMIC-IV Data Set

The instantiation of the drift detection step using several distribution comparison metrics showed the flexibility of the methodology. It also demonstrated that, for the purpose of separating the temporal chunks in this particular scenario, metrics such as the Jensen-Shannon divergence or the classifier errors capture the underlying distributions better than particular outliers or novel samples. Higher values in these metrics imply more significant "populational" changes, such as a gradual shift in the composition of the in-hospital population's disease burden.

As seen in the drift detection step (Table 2), there is a gradual but persistent pattern in MIMIC-IV, happening over several years. This gradual change may be caused by various factors, such as an increased tendency for patients who are terminally ill to receive end-of-life care at home or advancements in therapeutic techniques for certain diseases. The nature of the expected data change can be hypothesized based on characteristics such as the suddenness or gradualness of the drift, its persistence, and its duration, along with the results from the next analytical steps in DIS. This difference becomes evident when comparing the MIMIC-IV and the Brazilian COVID-19 Registry data sets.

The initial characterization step (Figure 5) revealed a trend toward a decrease in overall mortality over time, and this is the "context" in which we interpreted subsequent findings. Additionally, Figure 6 indicates that the overall characteristics of the deceased patients changed more than those of the overall in-hospital population over the observed time frame. This means that the reduction in overall mortality is due to changes in the characteristics of the patients who died. The findings in Figure 5 show how different diseases impacted mortality predictions over time. Figure 5 shows that 2 *ICD-10* chapters, "diseases of the circulatory system" and "cancer," had important changes during this period. By associating the findings of step 1 with those of *step 2*, we can begin to understand the factors contributing to decreased mortality over time, but it does not provide the "full picture."

The DIS semantic characterization step, which measures how the contexts of the independent variables relate to those of the dependent variables over time at a more semantic level, yields interesting results that complement the previous ones. Multimedia Appendix 6 shows an example of such a result, that is, changes in similarity for the "dysphagia following stroke" ICD-10 code within the MIMIC-IV data set [18]. There has been an increase in the cooccurrence of many obesity-related ICD codes between the 2011 and 2013 and 2017 and 2019 time slices. This is aligned with general observations of the increase in obesity prevalence in the overall US population. It is worth noting that this technique does not allow us to draw causal conclusions but instead focuses on the correlation and cooccurrence changes. The cooccurrence of death and "cancer," as well as the presence of "external causes," has decreased over the period, possibly indicating a reduction in iatrogenic events, improved cancer treatment leading to lower lethality, or that patients with cancer are receiving more end-of-life care at home. This may be an explanation as to why overall in-hospital mortality has decreased in this data set.

As overall mortality decreases, patterns affecting the decrease of similarities between entities, such as the lethality of circulatory diseases, unchanged. This means that increases in similarity with the outcome may be simply due to the decrease in the lethality of other groups. To investigate this, we filtered the data only for cancer disease codes, as in Multimedia Appendix 5. The figure reveals important decreases in mortality in mostly severe and hard-to-treat cancers, such as brain, colon, lung, and secondary (metastatic) tumors.

It is also possible that the observed patterns may be attributed to multiple factors at the same time. For instance, recent policy changes favoring home care for patients who are terminally ill may influence who dies in the hospital. If these patients are more likely to die at home, we might have a "survivorship bias," where mostly the ones who did not die received hospital care and the patients who were terminally ill were sent back home. Over this time frame, there were important advances in immunobiological therapies for tumors, such as lung cancer, as well as early diagnostic techniques that have made it possible to cure some early cases when the tumor is still resectable. Combining these factors yields a lower lethality, which has decreased over time despite an increase in the total number of patients with neoplasm, as shown in Figure 6.

In summary, the application of the DIS methodology to the MIMIC-IV data set allowed us to determine important trends that help understand certain phenomena observed in the data. Moreover, it facilitates the formulation of interesting hypotheses, which are harder to validate based only on the data themselves. Nevertheless, in a real-world scenario, such hypotheses could be the subject of further investigation using other data sources, such as official policy implementation records, country-wide demographic records, or even published literature.

Summary of the Main Results of Applying DIS to the Brazilian COVID-19 Registry Data Set

The *drift detection* step, especially using the Jensen-Shannon divergence, revealed important data drifts in the Brazilian COVID-19 Registry data set, which commenced approximately at the same time interval as the vaccination rollout in Brazil, between late 2020 and early 2021 [14]. The initial characterization revealed a trend toward decreasing mortality over time, with the steepest decrease closely matching our drift detection. This means that thus far, there has been an important variable distribution shift as well as a change in the distribution of the outcome itself.

We analyzed how the top 5 highest Pearson correlation variables behaved over time (Figure 8). Figure 8A shows how the relative ranking and correlation of the best predictors of death changed over the course of the pandemic, with features such as "age" being the strongest predictors at the early stages and gradually becoming less predictive over time. Figure 8A also shows how patient severity markers, such as "FiO_2" and "altered level of consciousness," gradually became more important predictors over time, hinting at the change from "older patients dying from

COVID-19" to "patients who were severely ill at admission dying from COVID-19." From our analysis, the patient's age is shown to be a consistently robust predictor of COVID-19–related hospitalization and death. In Figure 8B, we show the median age of the patients who died from COVID-19. This shows how one of the most predictive features in this data set has changed over time, with the median dying age decreasing from approximately 63 years at the peak of the pandemic to approximately55 years in a time frame coinciding with the start of the vaccination campaign in Brazil [5]. However, the median age starts to rise again, possibly relating to another drift, such as the emergence of new viral strains that can disproportionately affect the older adult population. This fluctuation in the median age of deceased patients leads to the aforementioned deterioration of the correlation scores. Furthermore, this pattern with the age variable decreasing over time is consistent with how the vaccines were rolled out to the public, with older age groups being prioritized for vaccination [46]. If these groups received vaccines earlier and consequently reduced their probability of death, this would likely reduce the median and mean deceased patients' ages.

The main results of the semantic characterization step (Multimedia Appendices 10-12 and Figures 8-10), where we compared the semantic vectors for the "death" outcome in 2020 and 2021, validate several findings from the initial characterization step and introduce new findings. For instance, the results show a decrease in similarity between the outcome and older groups (eg, the age groups "84-105" years vs "62-83" years) with an increase in similarity between the outcome and younger groups. This validates the findings in Figure 8A, where median age declines steadily up until roughly September 2021. Figure 8A also shows how the "death" outcome had an increase in similarity to several disease severity markers, such as lower admission serum sodium, lower admission arterial blood pressure, fewer comorbidities, and lower FiO_2. This potentially indicates that, when compared to 2020, patients who died in 2021 were more severely ill at admission, had fewer comorbidities, and were younger (presumably unvaccinated). This is a significant pattern change, especially compared to the bulk of deceased patients in the initial chunk, who were mostly older adults with lower severity at admission. This change in pattern implies that, at the analyzed time frame, patients who were young and severely ill at admission were more common among patients who were dying. However, this should be analyzed in conjunction with the previous findings from the other steps. For instance, we know that the overall mortality has decreased, and this patient profile (young and severely ill at admission) could also be present in the first temporal chunk. What possibly happened was the removal of a significant portion of older patients who were dying from the population through events such as vaccination, as evidenced by the reduced mortality and diminished predictive power of age.

To conclude, the DIS analysis hints at the central role of vaccination in the COVID-19 pandemic, which reduced the odds of older patients dying from the disease following the rollout of the vaccines. This hypothesis was raised by the alignment between the detected data drift and mortality reduction during the vaccination period. Additionally, the observed decrease in the median age of the patients who were dying corresponded to the age-stratified vaccination strategy. Furthermore, the shift of mortality burden to patients who were young and severely ill upon admission, who were likely unvaccinated, demonstrates how they possibly kept dying while this process unfolded.

Limitations

We have proposed a methodology to discover and interpret temporal shifts in health care data. While our approach provides valuable insights by uncovering many correlations and semantic connections, DIS still cannot establish causal relationships outcomes and semantic units. The causal part is only hypothesized and inferred, but the methodology does not go so far as to return causal links for arbitrary outcomes. Furthermore, we have not applied the methodology to certain relevant health care domains, such as images (eg, x-rays, computed tomography, or ultrasound) and wavelets (eg, electrocardiograms or electroencephalograms).

That said, here, we offer some insights into how we could apply DIS to handle temporal shifts in nonquantitative data or raw magnetic resonance imaging data. For this, we would first need to obtain a distributed representation of the data in such a manner that samples from similar patients have similar embedding vectors. For instance, we could use DINOv2 embeddings or contrastive language-image pretraining embeddings in images. This type of pretrained neural network exists for multiple data types, which facilitates its application to multiple domains. From the embeddings, we can apply the first step of our methodology as applied to tabular data, computing Jensen-Shannon divergence (or autoencoder errors, classifier errors, etc) to detect whether a drift exists in the data. Exploring these data in the second step presents some challenges, as it might involve exploring both the embedding and raw data spaces. For instance, we can use clustering and centroid analysis (applied to the embeddings) to find samples where the drift is particularly pronounced. Then, we can go back to the raw data and analyze the samples to check for patterns. In essence, the third step remains similar in nature. The idea is to train a neural network model such that the embeddings of the samples closely resemble the embeddings of the outcomes experienced by those patients over time. One such way to obtain these embeddings, starting from pretrained ones, is to use losses such as the triplet loss to approximate patient sample embeddings from outcome embeddings. The interpretation of the triplet loss, as presented in our paper, will change according to the temporal granularity of the samples. If the data have high temporal granularity, the positive pairs (which the loss will learn to represent more closely in space) will obey an ordered sequence of events. For instance, 2 magnetic resonance imaging tests will be proximate if they belong to the same patient and happen close to each other in time and if they are visually and semantically similar. Conversely, if the data have low temporal granularity, the embeddings should be learned to align patient samples to their outcome embeddings. Then, for the analysis of such embeddings, we would have to analyze the raw data samples closer to the outcome embeddings. If one splits the time, say, in 2 years and is working with the "death" outcome, one would be expected to have 1 such outcome for each year. Then, analyzing the samples closer to each of the outcome embeddings should help build an understanding of the relevant changes in a more generalized setting, and this might require some domain expertise. We intend to explore these ideas in future work.

Finally, we cannot claim that our 3 steps (encompassing the "if," "what," and "why" of a data drift) are a comprehensive list of all possible steps to analyze a temporal shift. Instead, we believe our steps to be a minimum required subset. While it is possible that these steps might not cover all possible situations, they allowed us to obtain interesting insights from the 2 data sets presented in our work, as discussed earlier. We and other researchers plan to continue to study, extend, and adapt this methodology in future work to test the limits of our approach and whether new steps or a refinement of the ones proposed at the fiber granularity level is necessary.

We intend to explore methods for enhancing models' resilience to data drifts, as well as examine different health care–relevant data types, such as images, wavelets, and multimodal data.

Conclusions

We have proposed DIS, a temporal data drift methodology for analyzing the changes in health outcomes and variables over time while discovering contextual changes for outcomes in large volumes of data. We applied DIS to 2 very different case studies and demonstrated how it can provide valuable insights into changing patterns in the data and the underlying reasons driving such changes.

The DIS methodology goes beyond simple detection; it comprehensively characterizes temporal data drifts. By analyzing the underlying causes, patterns, and magnitudes of drifts, health care stakeholders can gain a deeper understanding of the factors influencing data changes over time. This deeper understanding has practical implications for health care organizations, allowing them to improve patient care, optimize resource allocation, and enhance operational efficiency by leveraging the insights gained from monitoring and characterizing temporal data drifts.

The practical implications of our methodology are far-reaching. Early detection of data drifts can trigger timely interventions, enabling proactive adjustments to treatment plans, health care policies, and quality improvement initiatives. Our methodology empowers health care practitioners and data analysts to effectively monitor and manage temporal data drifts, ultimately leading to better health care outcomes and informed decision-making processes.

Acknowledgments

The authors would like to thank the hospitals and staff for their support in this project. This study was supported by the Minas Gerais State Agency for Research and Development (Fundação de Amparo à Pesquisa do Estado de Minas Gerais [FAPEMIG]; grants APQ-01154-21 and APQ-00262-22), National Institute of Science and Technology for Health Technology Assessment (Instituto de Avaliação de Tecnologias em Saúde [IATS])/National Council for Scientific and Technological Development

Abstract

Background: The completeness of adverse event (AE) reports, crucial for assessing putative causal relationships, is measured using the vigiGrade completeness score in VigiBase, the World Health Organization global database of reported potential AEs. Malaysian reports have surpassed the global average score (approximately 0.44), achieving a 5-year average of 0.79 (SD 0.23) as of 2019 and approaching the benchmark for well-documented reports (0.80). However, the contributing factors to this relatively high report completeness score remain unexplored.

Objective: This study aims to explore the main drivers influencing the completeness of Malaysian AE reports in VigiBase over a 15-year period using vigiGrade. A secondary objective was to understand the strategic measures taken by the Malaysian authorities leading to enhanced report completeness across different time frames.

Methods: We analyzed 132,738 Malaysian reports (2005-2019) recorded in VigiBase up to February 2021 split into historical International Drug Information System (INTDIS; n=63,943, 48.17% in 2005-2016) and newer E2B (n=68,795, 51.83% in 2015-2019) format subsets. For machine learning analyses, we performed a 2-stage feature selection followed by a random forest classifier to identify the top features predicting well-documented reports. We subsequently applied tree Shapley additive explanations to examine the magnitude, prevalence, and direction of feature effects. In addition, we conducted time-series analyses to evaluate chronological trends and potential influences of key interventions on reporting quality.

Results: Among the analyzed reports, 42.84% (56,877/132,738) were well documented, with an increase of 65.37% (53,929/82,497) since 2015. Over two-thirds (46,186/68,795, 67.14%) of the Malaysian E2B reports were well documented compared to INTDIS reports at 16.72% (10,691/63,943). For INTDIS reports, higher pharmacovigilance center staffing was the primary feature positively associated with being well documented. In recent E2B reports, the top positive features included reaction abated upon drug dechallenge, reaction onset or drug use duration of <1 week, dosing interval of <1 day, reports from public specialist hospitals, reports by pharmacists, and reaction duration between 1 and 6 days. In contrast, reports from product registration holders and other health care professionals and reactions involving product substitution issues negatively affected the quality of E2B reports. Multifaceted strategies and interventions comprising policy changes, continuity of education, and

human resource development laid the groundwork for AE reporting in Malaysia, whereas advancements in technological infrastructure, pharmacovigilance databases, and reporting tools concurred with increases in both the quantity and quality of AE reports.

Conclusions: Through interpretable machine learning and time-series analyses, this study identified key features that positively or negatively influence the completeness of Malaysian AE reports and unveiled how Malaysia has developed its pharmacovigilance capacity via multifaceted strategies and interventions. These findings will guide future work in enhancing pharmacovigilance and public health.

KEYWORDS

pharmacovigilance; medication safety; big data analysis; feature selection; interpretable machine learning

Introduction

Background

Pharmacovigilance (PV) is the science and activities related to the detection, assessment, understanding, and prevention of adverse effects or any other possible drug-related problems [1]. Individual case safety reports (ICSRs) of suspected adverse drug reactions and adverse events following immunization (hereafter collectively referred to as adverse events [AEs]) collected in spontaneous reporting systems (SRSs) remain the cornerstone of postmarketing drug safety surveillance [2,3] (see Multimedia Appendix 1 for a list of definitions [4-10]).

Over 170 participating countries in the World Health Organization (WHO) Programme for International Drug Monitoring (PIDM) share reports of suspected AEs and collaborate worldwide in monitoring and identifying signals of AEs [4]. The WHO PIDM signal detection process is anchored on data recorded in the WHO global ICSR database, VigiBase, developed and maintained by the WHO Collaborating Centre for International Drug Monitoring, Uppsala Monitoring Centre (UMC), Sweden. Common technical specifications for report transmission and standard terminologies for drugs and reactions have evolved over the years to facilitate global information sharing and efficient analysis [4,5]. Currently, VigiBase accepts 3 standard formats: the original International Drug Information System (INTDIS) and 2 revisions of the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) Guidelines for the Electronic Transmission of ICSRs, namely E2B(R2), and the latest E2B(R3), with all data being transformed to a format most closely resembling E2B(R2) in VigiBase [4].

The participating members are characterized by diverse contexts—sociocultural, political, and clinical—that affect the measures in which reports are collected and processed, as well as their quality [4]. Ideally, a robust PV system should consider all data quality parameters, including accuracy, completeness, conformity, consistency, currency, duplication, integrity, precision, relevance, and understandability. Among all these parameters, problems associated with completeness (ie, missing data) have long been regarded as critical factors hampering the usefulness of existing reports [5,6]. Influxes of poorly documented reports could increase operational burdens, upsurge a system's resources, and even mask or delay the detection of drug safety signals [11].

While only 4 elements (identifiable patient, identifiable reporter, medicinal product, and AE) are required for a valid report, they are often insufficient for productive analyses of potential causal relationships between medicinal products and AEs [6]. In 2014, the UMC developed the vigiGrade completeness score, an automated multidimensional tool that measures the amount of clinically relevant information in reports essential for causality assessment, replacing the 4-grade WHO documentation grading scheme since the 1990s [6,12]. The vigiGrade score quantifies report completeness based on a selection of ICH-E2B fields: time to onset, indication, event outcome, patient age and sex, dose information, country of origin, reporter, type of report, and free-text fields. The vigiGrade score can be used to pinpoint trends in report quality over time and reflect systematic data quality issues in collections of reports from member countries. For instance, vigiGrade uncovered miscoded age units in US reports and missing AE outcomes in Italian reports [6]. The score may also guide reviewers in judging whether the information in a report suffices for a problem to be investigated [4]. Notably, vigiGrade has proven to be an indicator of a true signal and is part of the data-driven predictive model used by the UMC, vigiRank, for signal detection [13].

The PV System in Malaysia

PV activities in Malaysia began in the 1980s with the establishment of the Malaysian Adverse Drug Reactions Advisory Committee (MADRAC) under the Drug Control Authority (DCA) [7]. The Malaysian national PV center is based within the National Pharmaceutical Regulatory Agency (NPRA) under the Pharmaceutical Services Programme of the Ministry of Health (MOH). Malaysia became a member of the WHO PIDM in 1990 and is regarded as an established PV center, receiving >30,000 reports annually, which is well above the WHO criteria of 200 reports per million inhabitants per year since 2009. Every AE report recorded in the national PV database (QUEST; see Multimedia Appendix 1 [7] for a detailed description) is carefully processed and assessed by trained pharmacists at the national center and subsequently reviewed by the MADRAC before submission to the UMC for inclusion in VigiBase (Figure S1 in Multimedia Appendix 2).

Problem Statement and Research Benefits

Previous studies have not evaluated the quality of Malaysian AE reports, and little is known about the underlying factors affecting their vigiGrade completeness scores. However, identifying and validating factors associated with report quality

was made difficult by the large number and variety of potentially correlated characteristics of a spontaneous report—at the reaction, drug, patient, reporter, sender, or regulator level (see the literature review on AE report quality in Multimedia Appendix 3 [6,14-38]). As of 2019, Malaysian reports demonstrated a 5-year average completeness score of 0.79, surpassing the global average of approximately 0.44 in VigiBase and approaching the benchmark for well-documented reports (0.80). Therefore, this study primarily aimed to use a hypothesis-free, data-driven approach to explore the main drivers influencing the completeness of Malaysian reports in VigiBase over a 15-year period using vigiGrade. A secondary objective was to understand the strategic measures taken by the Malaysian authorities that preceded the relatively high completeness score across different time frames. A better understanding of the drivers of AE report completeness may be helpful for the NPRA and regulators worldwide.

Methods

Data-Driven Framework for Identifying Factors Associated With AE Report Quality

Overview

Our study used big data analysis approaches incorporating machine learning (ML) methods, which are becoming increasingly prevalent in clinical and epidemiological research [8,39]. These approaches aimed to overcome limitations inherent in traditional approaches in handling complex interactions among variables (eg, multicollinearity and nonlinearity). Importantly, ML methods focus on identifying patterns and associations within complex data rather than on establishing causal inference [39]. For clarity, we have outlined the similarities in concepts and nomenclatures between ML and traditional medical statistics in Multimedia Appendix 1.

Hybrid Feature Selection

Our study leveraged ML methods for feature selection, mitigating human bias in analyzing extensive report characteristics, which might be overlooked by traditional hypothesis-driven approaches that are prone to high selection biases [9]. We combined statistical filtering and ML algorithms to preselect features, reducing overfitting risks (often arising from redundancy and multicollinearity) and computational costs [40,41]. Notably, Stevens et al [9] used random forest (RF)–based feature selection to identify potential risk factors associated with cardiovascular diseases. In almost all domains, incorporating domain expertise remains vital for developing meaningful and effective models [8]. Multimedia Appendix 4 [8,9,39-48] provides detailed explanations.

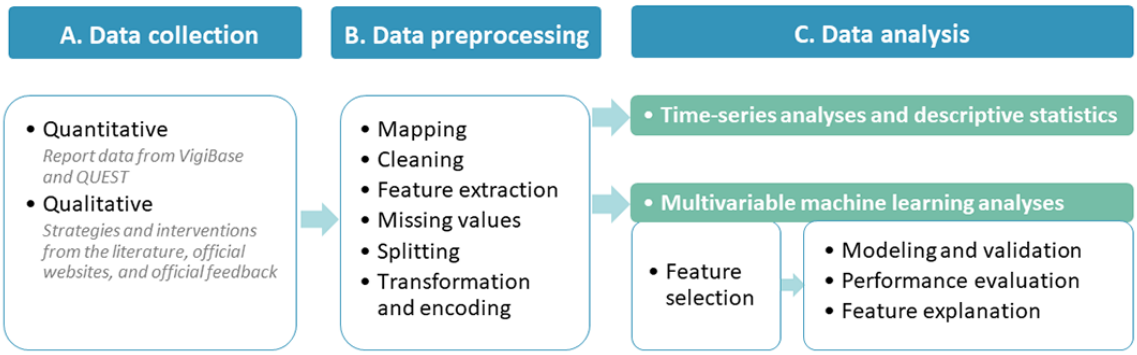
Interpretable ML

Post hoc explanation methods such as Shapley additive explanations (SHAP) have been increasingly used to provide interpretability for complex black-box models such as RF [49]. Van den Bosch et al [50] used regression coefficients and SHAP value analyses to identify risk factors associated with 30-day mortality among patients undergoing colorectal cancer surgery. Gong et al [51] also developed an ML framework for acute kidney injury prediction and interpretation using SHAP values to assess feature contributions and identify specific patient impacts. Multimedia Appendix 5 [49-57] provides detailed explanations.

Study Design

This observational study used interpretable ML and descriptive time-series analyses of PV database data. Fundamentally, it was an exploratory data analysis assessing a large number of report characteristics without prespecified hypotheses [42] aiming to identify factors influencing report quality. The main steps of our methodological workflow are illustrated in Figure 1.

Figure 1. Overview of study workflow.



Data Collection

AE report data were obtained from VigiBase in CSV format. Supplementary information, such as means of reporting, sender type, and sender region, was retrieved from the NPRA QUEST3+ (latest version) database in CSV format. For the secondary objective of understanding the key drivers of AE report completeness, strategies and interventions implemented in Malaysia were collected from the literature, official websites, and feedback from the NPRA. We included all reports recorded in VigiBase as of February 2021; reported in Malaysia; and received by the NPRA from January 1, 2005, to December 31, 2019. This 15-year range was chosen for its relevance to current PV needs and to enable the timely identification of necessary improvements. We excluded reports that (1) were suspected duplicates identified by the UMC's vigiMatch [4] (see Multimedia Appendix 1 for operational definitions), (2) were not sourced from Malaysia, (3) had null average completeness scores, and (4) lacked drugs marked as suspected or interacting.

Study Variables

Dependent Variables or Outcomes

The vigiGrade completeness score (*C*; ranges from 0.07 to 1) was classified as well documented ($C>0.8$) or not well documented ($C\leq0.8$; see Multimedia Appendix 1 for operational definitions).

Independent Variables or Explanatory Features

The variables related to administrative, sender, reporter, patient, drug, and reaction characteristics are presented in Table S1 in Multimedia Appendix 2.

Data Preprocessing

Data Mapping

Supplementary data from QUEST3+ were mapped to the primary data set from VigiBase using the primary identifier. Given the distinct differences in reporting elements of INTDIS and E2B formats (input values vary in certain data fields), we divided the data set for separate analysis.

Data Cleaning and Feature Extraction

We cleaned and engineered the features from the available data based on the literature, domain knowledge, and previous experience. Information about the WHO Anatomical Therapeutic Chemical (ATC) classification system codes was provided by the UMC in the data set. If an active ingredient was linked to more than one code, an ATC level-2 code was manually assigned based on indication, route of administration, dosage, product information, and clinical narratives. Reporting qualifications in INTDIS format were harmonized with the E2B format with reference to supplementary data from the NPRA. We calculated the number of suspected or interacting drugs, concomitant drugs, and reactions for each report. We also included the annual staffing level of the national PV center in Malaysia and the means of reporting (based on report identifier).

Missing Values

Continuous variables consisting of null values were converted to categorical variables based on data distribution and domain knowledge. Missing values for categorical variables were grouped as a *null* category.

Data Splitting

To ensure a consistent distribution of target classes, we applied stratified random sampling. We allocated 90% of the data for training, which underwent 10-fold cross-validation, and reserved 10% for testing to gauge model performance on unseen samples. Our approach prioritized the extraction of insights from the current data set rather than overgeneralizations on future data.

Transformation and Encoding

To overcome data complexity and maximize interpretability, data at the drug event level were transformed to the case (report) level. Observations related to concomitant drugs were excluded as the vigiGrade scoring method is restricted to drugs listed as suspected or interacting [6]. We took the average value of a case for continuous variables whereby, for categorical variables, we examined the presence (or absence) of a particular drug- or event-related characteristic. Continuous variables were standardized. Binary categorical variables such as patient sex were integer encoded. One-hot encoding was performed on the remaining categorical variables, including ordinal variables and categories labelled as *null* or *unknown*. In the following sections, we distinguish variables from features, where the latter correspond to the processed variables in a binary fashion for the ML model input [43,56].

Multivariable ML Analysis

Feature Selection

We performed hybrid feature selection to eliminate redundant or less informative features before data mining using the ML algorithm. To avoid data leakage and the corresponding model overfitting, we conducted a 2-stage feature selection solely based on training data [8,44]. We first applied the univariable filter method to independently assess and preselect the features and subsequently selected the top-ranked features using RF-based recursive feature elimination coupled with multicollinearity assessment. The detailed processes are provided in Multimedia Appendix 4.

Modeling and Validation

We applied a supervised ML method to identify key features relevant to the reports classified as well documented. Specifically, the RF classifier was selected for its robustness to nonparametric distributions, nonlinearity, and outliers [58] and its out-of-the-box performance. Its built-in feature importance metrics allowed us to assess the relative attribution of a feature to the classification task. The more a feature is used to make key decisions with the forest of decision trees, the higher its relative importance. To mitigate class imbalance in the INTDIS data set, we used RandomUnderSampler with a 0.25 ratio that achieved optimal balanced performance of prediction and recall. We chose undersampling over synthetic sampling methods to preserve the real-world data characteristics. For the imbalanced INTDIS data set, we adjusted the class_weight parameter in the RF classifier to *balanced*. We evaluated the RF classification models using 10-fold cross-validation.

Performance Evaluations

Classification performance was measured using the area under the receiver operating characteristic curve, accuracy, recall (sensitivity), and precision (positive predictive values). For the imbalanced INTDIS data set, F_1-scores (harmonic average of precision and recall) were reported.

Feature Explanations

To mitigate the issue of black-box predictions**,** we used TreeExplainer [52] to generate SHAP summary plots that succinctly display the magnitude, prevalence, and direction of a feature's effect by measuring each feature's attributions to the classification. In SHAP, the feature effect is a measure of how much the value of a specific feature influences the prediction made by the model.

Software and Packages

All ML analyses were developed in Jupyter Notebook (Project Jupyter) using Python (version 3.7.9; Python Software

Foundation). Statistical tests were performed using *pandas* (version 1.2.4) and *statsmodels* (version 0.12.2) [59]. ML analysis was completed using the *scikit-learn* package (version 0.24.2) [60]. SHAP values were calculated using TreeExplainer [52].

Time-Series and Descriptive Statistical Analysis

We used time-series analysis and descriptive statistics to evaluate the trends in report quality and the characteristics associated with well-documented reports over different time frames. One-way ANOVA or 2-tailed Student *t* tests were conducted on continuous variables, whereas the chi-square or Fisher exact test was used to compare categorical variables, as appropriate. A *P* value of <.05 was considered statistically significant. All analyses were conducted using the SAS software (version 9.4; SAS Institute).

Ethical Considerations

This study was registered with the Malaysian National Medical Research Register (NMRR-20-983-53984 [Investigator Initiated Research]) and received ethics approval from the Medical Review and Ethics Committee, MOH, Malaysia (reference: KKM/NIHSEC/P20–1144(4)).

Results

Overview

We analyzed the completeness of Malaysian AE reports in VigiBase received by the NPRA over 15 years. A total of 132,738 reports were included in the analysis following the predefined inclusion and exclusion criteria (Figure S2 in Multimedia Appendix 2). Table S1 in Multimedia Appendix 2 summarizes the characteristics of the INTDIS and E2B reports included in this study concerning administration, reporter, patient, drug, and reaction by status of being well documented. Among the included reports, 48.17% (63,943/132,738) were in the INTDIS format, and 51.83% (68,795/132,738) were in the E2B format. Over two-thirds (46,186/68,795, 67.14%) of E2B reports were well documented compared to 16.72% (10,691/63,943) of INTDIS reports.

Multivariable ML Analysis

Selected Features

For the INTDIS subsets, 90 features were preselected using univariate filter methods and further narrowed down to 33 features following RF-based recursive feature elimination ranking and multicollinearity assessment. For the E2B subsets, 90 features were preselected and subsequently reduced to 40.

Classification Performance

The performance of the RF models in classifying reports as well or not well documented is presented in Table 1.

Table 1. Classification performance of random forest model for the training (10-fold cross-validation) and test set.

	Recall (%)	Precision (%)	Accuracy (%)	AUROC[a] (%)	F_1-score (%)
INTDIS[b]					
Training, mean (SD)	99.6 (0.03)	95.4 (0.13)	99.0 (0.03)	99.8 (0.01)	97.4 (0.06)
Validation, mean (SD)	73.7 (1.90)	77.0 (1.02)	90.3 (0.39)	95.0 (0.33)	75.3 (1.16)
Test	74.9	74.3	91.5	95.1	74.6
E2B					
Training, mean (SD)	99.7 (0.02)	99.7 (0.02)	99.6 (0.01)	99.9 (0.001)	99.7 (0.01)
Validation, mean (SD)	96.9 (0.27)	91.6 (0.34)	92.0 (0.24)	94.9 (0.29)	94.2 (0.20)
Test	96.9	90.9	91.4	95.1	93.8

Top Factors Predicting Status of Malaysian Reports Being Well Documented

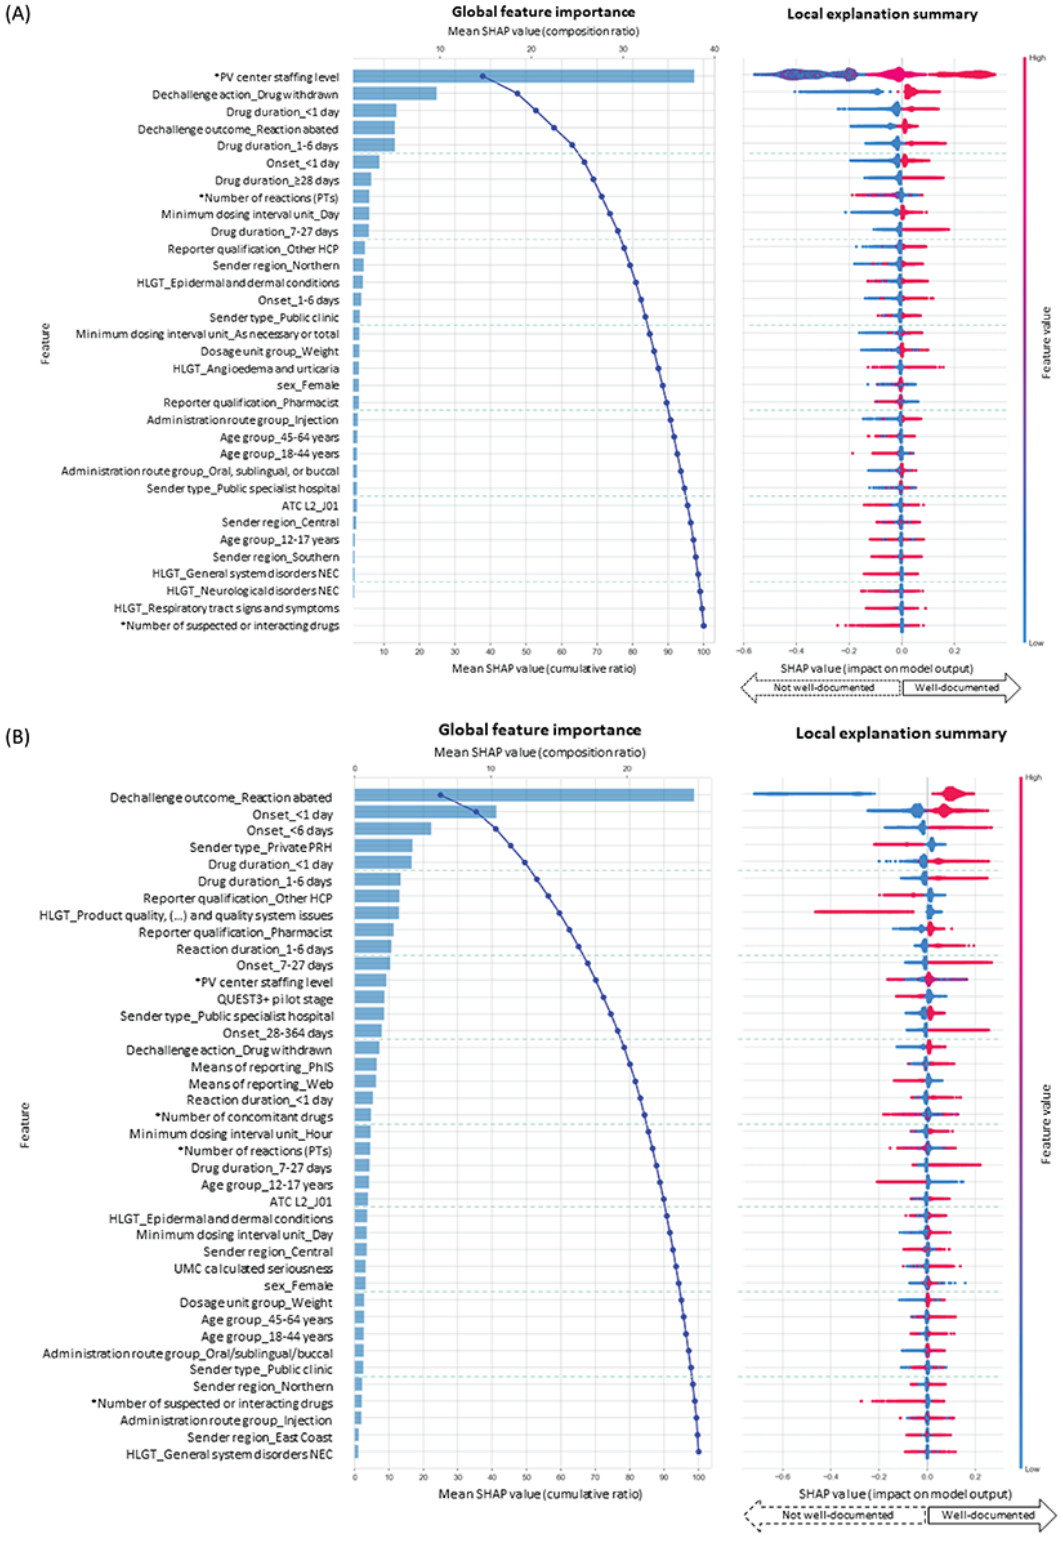
RF ML Model

Figure S3 in Multimedia Appendix 2 reveals the top-ranked features that contributed to the status of INTDIS and E2B reports being well documented derived from the RF ML model's built-in feature importance metrics. However, the directions of their contribution were not known due to the black-box nature of the RF model. For INTDIS reports received between 2005 and 2016, PV center staffing was identified as the most important factor in predicting their status of being well documented. Other important factors included suspected drug withdrawal, the number of reactions reported, reaction abated upon drug dechallenge, and patient sex. Reaction abated upon drug dechallenge, on the other hand, appeared to be the most important factor predicting whether an E2B report received between 2015 and 2019 was well documented. Reports from other health care professionals (HCPs), reactions occurring <1 day, reports submitted by product registration holders (PRHs), and the number of concomitant drugs were also among the top 5 important factors.

SHAP Interpretation Method

The SHAP post hoc interpretations provided us with an understanding of the magnitude, prevalence, and direction of feature effects. Figure 2 depicts rich summaries of individual attributions for all features, allowing us to discover key factors that influence well-documented reports. Features with higher global importance have a greater influence on the model's predictions. A feature with predominantly red dots to the right (eg, reaction abated upon drug dechallenge in Figure 2B) implies a positive contribution to well-documented reports, whereas a negative contribution is indicated if the direction is to the left (eg, reports submitted by PRHs in Figure 2B). Features with lower global importance but a long tail stretching in one direction indicate a rare but high-magnitude effect [52,56]. As mean SHAP values are calculated across all cases, a feature with a lower impact but higher prevalence may have a higher SHAP value [50]. For the least globally important features, we observed that their feature effects were not constant across cases, with blue and red dots dispersed in both directions. This variation may arise from interactions with other features that modulate their importance in different cases [52].

Figure 2. (A) Top 33 features for the International Drug Information System (INTDIS) subset from 2005 to 2016; (B) top 40 features for the E2B subset during the years 2015 to 2019. The Shapley additive explanation (SHAP) bar plot illustrates global feature importances based on mean absolute SHAP values, highlighting the impact of each feature on the model's predictions. Higher values represent greater influence. The waterfall plot indicates the cumulative contribution of features to the model. The SHAP summary plot of local explanations displays each observation as a dot, with its position on the x-axis (SHAP value) indicating the impact of a feature on the model's classification for that observation. Continuous features (marked with an asterisk) range from low (blue) to high (red) values, whereas categorical features of a binary nature are either absent (blue) or present (red). The distribution of dots indicates the magnitude and prevalence of a feature effect. Features are ordered by global importance. ATC: Anatomical Therapeutic Chemical; HCP: health care professional; HLGT: Medical Dictionary for Regulatory Activities High-Level Group Term; NEC: not elsewhere classified; PhIS: pharmacy hospital information system; PRH: product registration holder; PT: Medical Dictionary for Regulatory Activities Preferred Term; PV: pharmacovigilance; UMC: Uppsala Monitoring Centre; UMC calculated seriousness: serious cases classified automatically by a UMC-developed algorithm.



Regarding INTDIS reports, in earlier years, PV center staffing was the primary factor driving the Malaysian rate of reports being well documented, with this factor alone accounting for >35% of the model's explainability. The next most important factor favoring well-documented reports was drug withdrawal, followed by a duration of drug use of <1 week, reaction abated upon drug dechallenge, and reaction occurring <1 day. In contrast, an increased number of reported reactions and reports from pharmacists predicted not well-documented INTDIS reports.

In more recent years, the most important factor favoring well-documented E2B reports from Malaysia was reaction abated upon drug dechallenge, which alone was responsible for >25% of the model's explainability. Among the top 25 features, which provided 90% of the model's interpretation on classifying status of being well documented, 6 (24%) were found to be negatively associated with well-documented reports: reports submitted by PRHs; reports made by other HCPs; reactions under the Medical Dictionary for Regulatory Activities (MedDRA) High-Level Group Terms (HLGTs) *product quality, supply, distribution, manufacturing,* and *quality system issues*; reports received during the QUEST3+ pilot stage, reports received via web reporting, and adolescent patients (aged 12-17 years). E2B reports that involved reactions with a shorter time to onset and duration of drug use were more likely to be well documented. Other identified key drivers of Malaysian well-documented E2B reports were reports made by pharmacists, reports submitted from public specialist hospitals, pharmacy hospital information system (PhIS)–integrated reporting, and the involvement of systemic antimicrobials (ATC code J01).

Time-Series and Descriptive Statistical Analysis

Trend Analysis of Malaysian AE Report Quality (2005-2019)

Figure 3 depicts the time trends in AE reporting in Malaysia, illustrating how both the quantity and completeness scores of AE reports received by the NPRA grew over a 15-year period from 2005 to 2019. In Tables 2 and 3, we summarize the trends divided into 5-year subperiods, further stratified by sender type and reporter qualification. Of the total 132,738 reports received, 56,877 (42.84%) were well documented. Before 2014, the average completeness score consistently fell short of 0.5 but was slightly above the global average of 0.44. The volume of reports surged by 121% from 2013 to 2014, whereas the proportion of well-documented reports rose from practically 0% to 18.93% (2843/15,013). Since 2015, more than half (53,929/82,497, 65.37%) of the Malaysian reports were well documented, averaging 0.79 (SD 0.23) over the last 5 years, with a new high of 0.82 in 2019.

Figure 3. Distribution of average completeness scores and counts of Malaysian reports by status of being well documented in VigiBase over the study period.

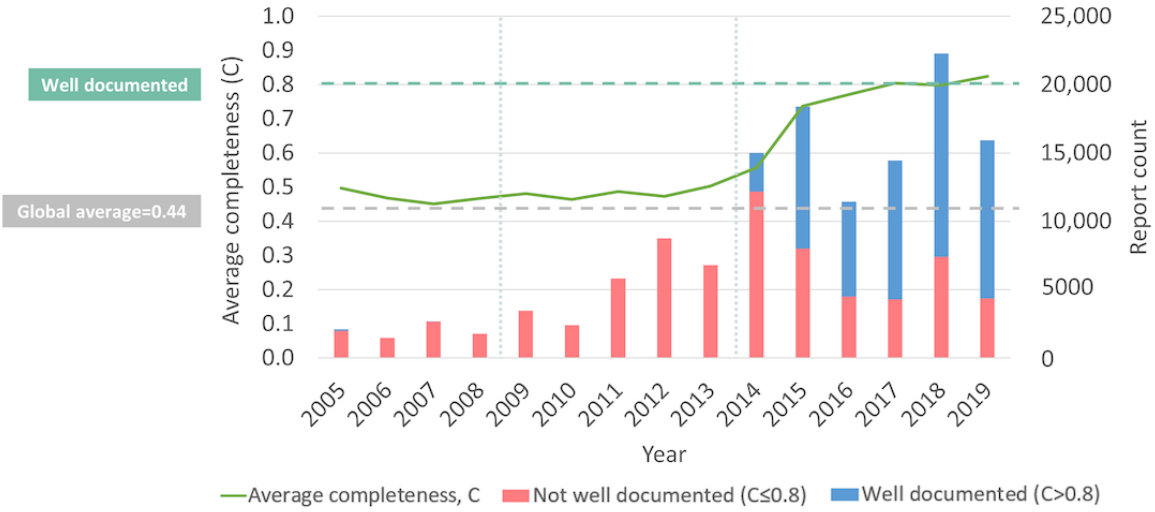


Table 2. The 5-year stratified summary statistics of overall Malaysian report quality.

	Total	2005-2009	2010-2014	2015-2019	*P* value[a]

[b]PRH: product registration holder.

[c]HCP: health care professional.

Over the 15 years, most well-documented reports in Malaysia came from public health facilities, with public specialist hospitals contributing more than half (31,503/56,877, 55.38%). Public clinics emerged as key contributors in later stages, with well-documented reports increasing considerably from 3.8% (4/105) in the period from 2005 to 2009 to 30.46% (866/2843) in the following 5 years. Compared to public services, the private sector consistently demonstrated a marginal contribution to quality AE reporting in Malaysia. In the earlier years, physicians contributed approximately half (53/105, 50.5%) of the well-documented reports. In the subsequent periods, reports from pharmacists showed a rise in quantity and average completeness, yielding the highest overall rate of being well documented (1850/2843, 65.07% to 38,429/53,929, 71.26%) among all reporter types from 2010 to 2019.

Key Strategies and Interventions Implemented in Malaysia (2005-2019)

In Malaysia, various strategies and interventions were implemented over the 15 years with the intent of improving AE reporting, as summarized by 5-year period in Figure 4 [7,61-65]. While the impacts of most interventions are usually multifaceted at the national level and challenging to measure with limited quantitative information, there is a particular interest in understanding the influence of staffing levels at the PV center, the introduction of a new PV database, and enhancements to reporting tools on reporting quality at different time points.

Figure 4. Key strategies and interventions implemented to improve adverse event (AE) reporting in Malaysia between 2005 and 2019. CPD: continuing professional development; DIS: drug information service; HCP: health care professional; PhIS: pharmacy hospital information system; PRH: product registration holder; PRP: provisionally registered pharmacist; PV: pharmacovigilance; RiMUP: *risalah maklumat ubat untuk pengguna*.

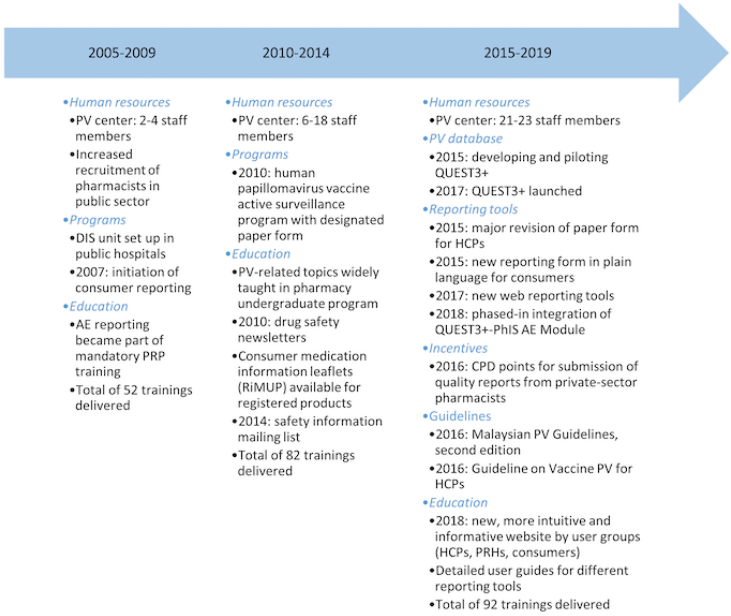

Figure 5 shows the annual trends in PV center staffing in relation to rates of reports being well documented. Figure 6 depicts how the transition in report submission format (from INTDIS to E2B) and reporting means correlated with report quantity and average completeness. In Figure 7, we focus on the rates of reports being well documented before and after the implementation of the new PV database (QUEST3+) and key enhancements to reporting tools since 2015. Information about reporting means was not available for INTDIS reports collected from the historical QUEST2 database. We further examined the influence and popularity of different reporting means among various reporters following the official launch of QUEST3+ and new web reporting tools in the first quarter of 2017 (Figure S4 in Multimedia Appendix 2).

Figure 5. Annual trends in pharmacovigilance (PV) center staffing levels and rate of reports being well documented (2005-2019).

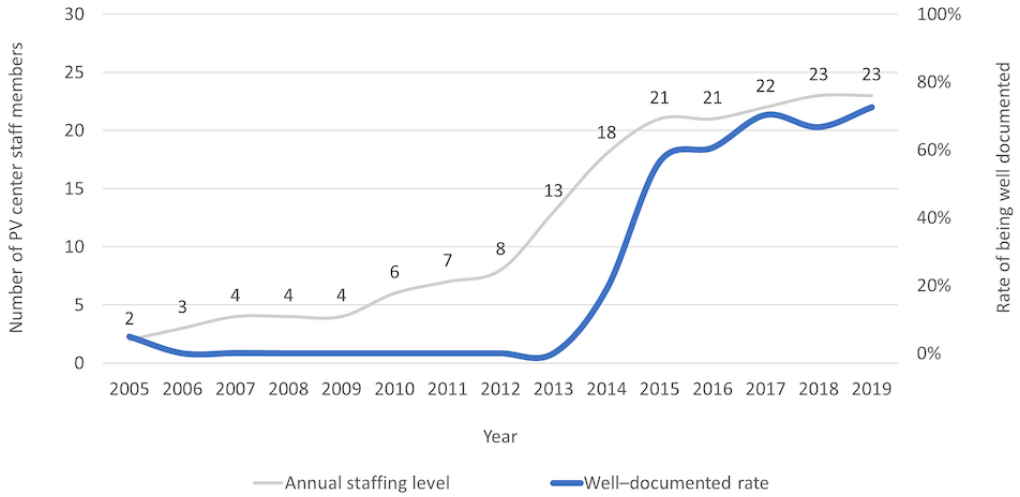

Figure 6. Mean completeness score and report count by submission format, pharmacovigilance database, and means of reporting yearly from 2013 to 2019. The size of the bubble corresponds to the report count. INTDIS: International Drug Information System; PhIS: pharmacy hospital information system.

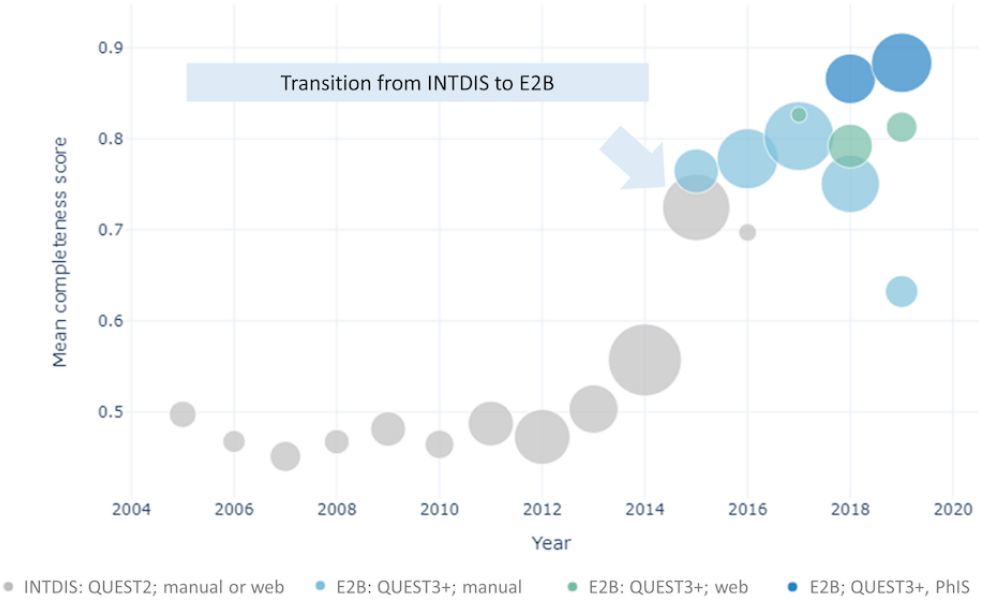

Figure 7. Rate of reports being well documented by submission format, pharmacovigilance database, and means of reporting quarterly from 2013 to 2019. 95% CI error bars (equivalent to 1.96×SE) were constructed. INTDIS: International Drug Information System; PhIS: pharmacy hospital information system; Q: quarter.

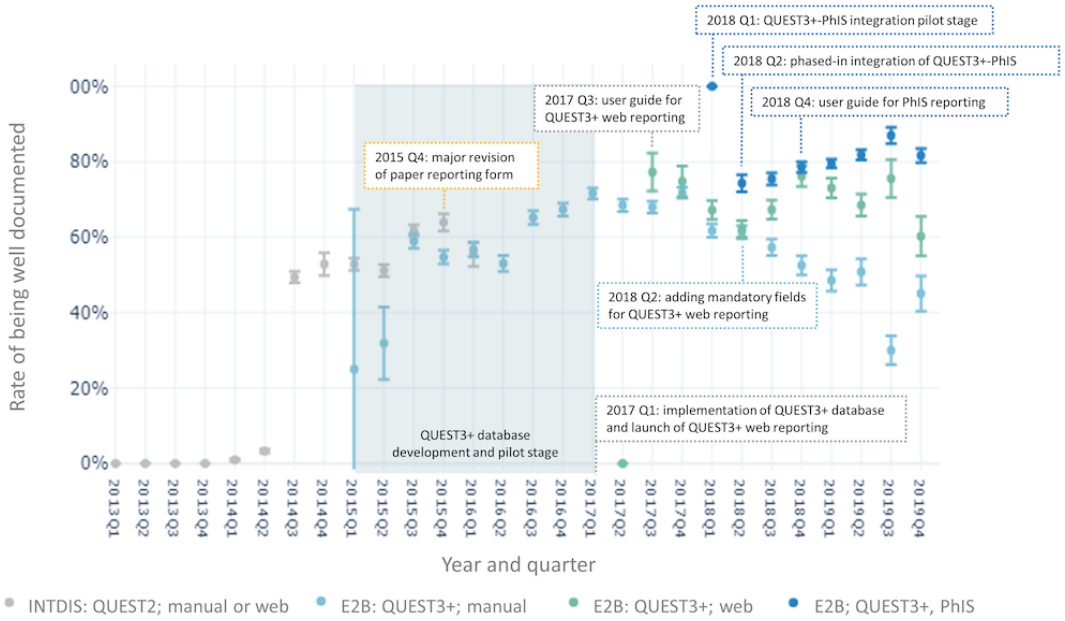
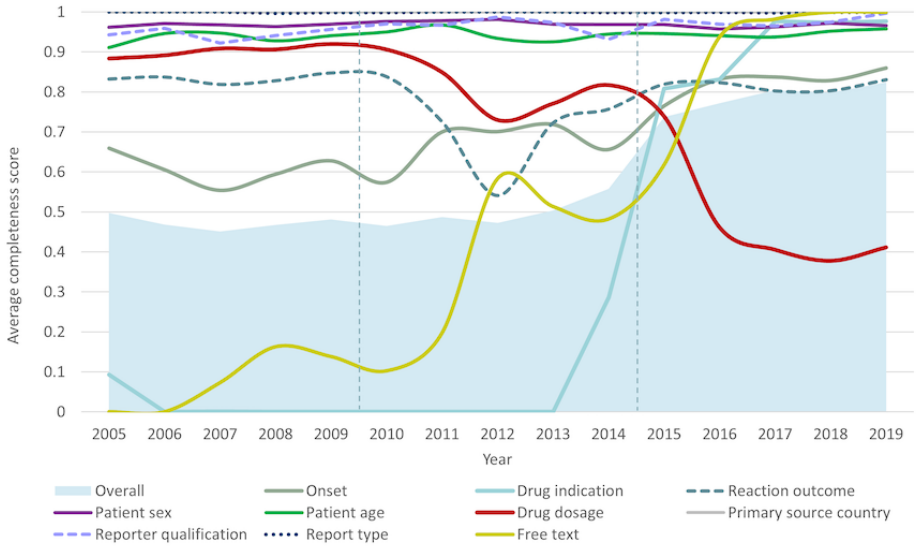


Average Completeness of Individual Dimensions for Malaysian AE Reports

Figure 8 illustrates the trends in the average completeness of the individual dimensions for Malaysian reports in VigiBase. The dimensions for report type, primary source country, reporter qualification, and patient age and sex were consistently the most completed. Completeness of free text and drug indication improved from zero in the earlier period of 2005 to 2009 to >0.9 in recent years. An uptrend in improvements was also observed for reaction onset. Completeness for reaction outcome dipped in 2011 to 2012 but subsequently rebounded to >0.8. Unexpectedly, we observed a noteworthy drop in drug dosage completeness since 2010. The average completeness of each individual dimension for vigiGrade was evaluated for E2B subsets (Figure S5 in Multimedia Appendix 2).

Figure 8. Trends in the distribution of average completeness scores for Malaysian reports in VigiBase over the study period. The shaded area indicates overall completeness; the line represents the individual dimension.



Discussion

Overview of Principal Findings

In our study, we used a comprehensive approach to examine the factors influencing the quality of Malaysian AE reports and decipher the temporal trends and interventions that shaped the Malaysian PV landscape from 2005 to 2019. In the first part of our study, by harnessing a data-driven approach that encompassed ML-based feature selection and analysis, we identified the key features that predict the status of Malaysian reports in VigiBase being well documented. Our hybrid feature selection helped in mitigating the risks of overfitting and unstable interpretability that are commonly associated with high variance [8,9,40] and resulted in a robust and valid RF model, as evidenced by the excellent classification performance (>90%) across all training, validation, and test sets for the E2B subset that reflects recent patterns of Malaysian reports (Table 1). While the model for the highly imbalanced INTDIS subset (containing only 10,691/63,943, 16.72% of well-documented reports) demonstrated satisfactory performance, with recall, precision, and F_1-scores of >70%, the model faced overfitting. This issue, evident from the decreased validation and test performance, has been acknowledged as a limitation in our study. The black-box RF model was made interpretable using SHAP values that, in agreement with human intuition, did not contradict the findings from the time-series analyses. To the best of our knowledge, this is the first study to use state-of-the-art interpretable ML methods to obtain insights concerning the key factors contributing to AE report quality in the PV field. Supplemented with insights drawn from our time-series and descriptive analyses, we summarized the identified features associated with well-documented Malaysian reports under 3 main themes: administrative; sender and reporter; and reaction, drug, and patient.

In the second part of our study, our extensive time-series and descriptive analyses illuminated the notable progress Malaysia has made in both the quantity and quality of AE reports over the years. We delved further into the chronological trends and characteristics of Malaysian AE reports, outlined the key strategies and interventions implemented at 5-year intervals, and tracked the influence of interventions of interest. These findings offer valuable insights into the multifaceted strategies and interventions that have driven enhancements in Malaysian AE reporting quality. Finally, by focusing on individual dimensions for vigiGrade completeness scoring, we not only gained additional insights into the specific characteristics and aspects of report completeness within the Malaysian context but also pinpointed systematic data quality issues that warrant further attention and improvement work.

Factors and Characteristics Associated With Well-Documented Malaysian Reports

Administrative

Our ML analysis distinguished PV center staffing level as the most important factor positively associated with well-documented INTDIS reports over 12 years between 2005 and 2016 (Figure S3 in Multimedia Appendix 2 and Figure 2A). Previous studies [66-68] have also highlighted manpower at national PV centers as a barrier to functional and sustainable PV systems. During the initial stage (2005-2009), only 2 to 4 staff members handled all PV operations in Malaysia (Figure 5). As the number of reports grew rapidly, the center struggled with a backlog of reports. The center swiftly grew from 8 to 21 staff members within 3 years (2012-2015) alongside the expansion of PV functions and task specializations, which coincided with a notable improvement in the completeness of reports received (Figures 3 and 5). Compared to the period from 2005 to 2009, more training workshops were delivered from 2010 to 2019 (Figure 4) to enhance staff and reporter competencies. As the staffing level and rate of reports being well documented became relatively stable afterward (Figure 5), the influence of PV staffing levels appeared less distinctive for E2B reports (Figure 2B). This could be due to some staff members focusing on other PV duties such as signal detection and assessment, risk management, and risk communication

rather than AE processing. It is worth noting that the transition to E2B may have also obfuscated the influence of increased staffing on report completeness. While less distinctive in our model, we cannot exclude that other centers with E2B reports and low staffing may still face overall low report completeness.

The capabilities and scalability of PV databases are essential for effective data collection and management [5]. Integrating electronic reporting into hospital information systems has been reported to reduce duplicate work and effectively improve AE reporting [69]. In Malaysia, the new QUEST3+ database was later integrated with the AE reporting module of a centralized PhIS implemented at Malaysian public hospitals and clinics, enabling the automatic input of reporter and sender information and improved reporter accessibility to patient, drug use, and regulatory information (eg, product registration number and batch number). Our ML analysis of E2B subsets (Figure 2B) revealed that PhIS-integrated reporting positively contributed to well-documented Malaysian reports, whereas web reporting had an unexpected negative association. The volume of PhIS reports surpassed other means in 2019 (Figure 7 and Figure S4 in Multimedia Appendix 2) and maintained the highest reporting quality. Web reporting was initially introduced in 2000, but due to unstable systems and slowly developing IT infrastructures at some public health facilities in the last decade, most reports before 2015 were submitted manually via postage, fax, or email. After mandatory fields were added, web reporting recorded a rate of >70% of reports being well documented, but it later declined to 60%. A similar but larger declining trend was also observed with manual reporting (Figure 5). These declines corresponded to the shift to PhIS reporting by public-sector pharmacists and were likely associated with other HCPs and consumers (Figure S4 in Multimedia Appendix 2). Our findings highlight that electronic reporting tools serve as ad hoc support for well-trained reporters but IT infrastructure maturity and widespread user acceptance are required for success. This is in line with a recent realist review [70] asserting that technological interventions alone, without capacity building, have little or no impact on health data quality.

Sender and Reporter

Our study revealed that the greatest proportion of well-documented Malaysian reports, amounting to 91.54% (52,066/56,877), originated from public health facilities overseen by the MOH (Table 3). Among the well-documented reports, 98.15% (55,825/56,877) were submitted by HCPs. This finding aligns with those of previous studies [71-73] conducted across different regions of Malaysia, which consistently highlight that most HCPs recognize AE reporting as part of their professional obligations. In Malaysia, consumer-generated reports constituted only 0.14% (78/56,877) of the well-documented reports, which stands in contrast to countries such as Denmark and Norway where three-fifths of well-documented reports came from consumers or non-HCPs [6].

Our observations revealed that Malaysian pharmacists generated 70.85% (40,295/56,877) of well-documented reports (Table 3), with most serving the public health sector [63]. Specifically, we identified public specialist hospitals and pharmacists as key features that positively contributed to the well-documented Malaysian E2B reports (Figure 2B). It is noteworthy that, during the earlier stage (2005-2009), pharmacists' reports exhibited the poorest quality and were recognized as a key factor predicting not well-documented INTDIS reports from 2005 to 2016 (Figure 2A). Nonetheless, over the years, following increased recruitment in public health services [74,75] and multifaceted initiatives aimed at strengthening pharmacists' roles and skills (Figure 4), pharmacists have become an integral part of AE monitoring in Malaysia. Almost 9 in 10 public hospital pharmacists in Malaysia have reported at least one AE in the past [76].

Malaysia presents a unique scenario in which pharmacists play a leading role in PV activities, distinguishing it from global trends, in which physicians contribute nearly two-thirds of well-documented reports [6]. The Malaysian context aligns with findings from a Spanish study in which pharmacists reported a great majority of the AEs due to the integration of PV into routine hospital pharmacy practices [77]. Similar observations were made in a pharmacist-led AE monitoring and management model in China, where pharmacists provided higher-quality reports among all HCPs [14]. Within Malaysian public hospitals, the pharmacist-led Drug Information Service (DIS) unit is responsible for facility-level PV activities, including responding to queries related to AEs; disseminating safety information; and compiling, verifying, and submitting AE reports to the NPRA [65,78]. In addition to direct detection and reporting by pharmacists, a collaborative mechanism exists within public health facilities where physicians and other HCPs are aware of the role of pharmacists in monitoring and reporting the AEs detected during clinical rounds or discussions. Moreover, we observed that over half (19,188/33,559, 57.18%) of the well-documented E2B reports made by pharmacists came from public specialist hospitals. These reports were believed to have benefited from the input of specialist physicians, suggesting a positive contribution of collaborative efforts among HCPs in enhancing the quality of AE reports.

In contrast, reports from PRHs and other HCPs (including regulatory affairs officers, clinical trial associates, nurses, and medical assistants) were flagged as the key features negatively associated with Malaysian report completeness (Figure 2B). These findings are consistent with the features observed in the United States [15], Brazil [16], Spain [17], South Korea [18], and Japan [19,20]. Of note, the NPRA classified the reports from PRHs as reported by other HCPs when the primary reporter was unknown. Among 7833 E2B reports from PRHs, only 778 (9.93%) reports were well documented (Table S1 in Multimedia Appendix 2), with an overall completeness score of 0.39 (Figure S5 in Multimedia Appendix 2). Information regarding drug dosage, reaction onset, reaction outcome, and patient age was most incomplete in Malaysian reports from PRHs. This could be attributed to the lack of a robust PV culture among PRHs. Existing literature [6,79] suggests that PRHs might prioritize submitting a report to fulfill pharmaceutical legislation [80] that mandates that PRHs report any suspected AEs within strict timelines even when minimal information is available. There could also be instances in which the primary reporter did not provide consent for follow-up. Conversely, it is conceivable that pharmacists and physicians serving at health facilities were

more motivated to make a clinically meaningful report even on a voluntary basis [17,79,81].

Reaction, Drug, and Patient

As AE reporting is highly dependent on individual motivation [5], we were interested in understanding whether the nature of drugs and reactions affects the quality of reports. While a report may involve more than one drug or reaction, most studies on AE report quality have not assessed all drugs and reactions reported in a case. Toki and Ono [21] examined only the primary suspected drug in a multivariable logistic regression model, whereas Araujo et al [22] and Masuka and Khoza [23] evaluated a specific drug group using simple univariable analysis. Other studies have evaluated only case-level information, such as case seriousness [14,18,24-26], fatal outcome [15], and causality [18]. As we converted drug-reaction pairs to case-level data, we evaluated the influence of drug- and reaction-related factors on overall report completeness for all reported suspected and interacting drugs.

Our ML analysis of the E2B subset (Figure 2B) revealed that a case where the reaction abated following a drug dechallenge (ie, positive dechallenge) was the primary key feature associated with a well-documented report. While information on drug dechallenge was unknown in most cases (Table S1 in Multimedia Appendix 2), it is possible that a positive dechallenge may have strengthened the reporter's confidence in the drug-reaction causal relationship and, thus, the motivation to construct a clinically meaningful report. While our findings suggest that positive dechallenge may have motivated more complete reports, there is no supporting study on this. It is important to note that reports that are well documented by vigiGrade standards might also tend to have a positive dechallenge. In other words, it may be that vigiGrade tends to flag those reports that have a positive dechallenge as well documented.

As expected, cases containing information on time to onset were more likely to be well documented as the onset dimension incurs the highest penalty of 50% for missing data and 30% if the uncertainty exceeds 1 month [6]. Our findings suggest that cases with a shorter (ie, <1 day) time to onset, dosing interval, and duration of drug use were most likely to be well documented. This observation might be attributable to better recall and description of events occurring within a shorter time frame following drug use or to greater reporter confidence in the drug-reaction relationship due to stronger temporal association and a lower likelihood of confounding factors. On the other hand, reports that involved reactions lasting 1 to 6 days tended to carry more information compared to those that involved reactions lasting <1 day or >6 days. A competing hypothesis is that reactions occurring within this time frame allow for sufficient time for more observation or data gathering while still being easily observed and described by patients and HCPs. Nevertheless, further research is needed to determine the specific factors contributing to the observed differences in report quality for cases with varying time to onset, dosing intervals, and durations of drug use.

Antibiotics for systemic use (ATC code J01) emerged as a key feature favorably contributing to well-documented E2B reports. First, it could be attributed to the baseline reporting patterns, where systemic antibiotics were the most commonly reported drug group in Malaysia, with over one-fifth of AE reports involving at least one systemic antibiotic (Table S1 in Multimedia Appendix 2). Second, this observation might suggest that Malaysian HCPs exercise heightened caution when using anti-infectives, leading to a higher likelihood of detecting AEs related to anti-infectives with higher report completeness. According to a study from a Malaysian infectious disease hospital [65], most inquiries (37.8%) received by the DIS unit concerned anti-infective drugs (ATC code J), which included other β-lactam antibacterials (ATC code J01D), direct-acting antivirals (ATC code J05A), and penicillins (ATC code J01C), with the largest proportion of the inquiries pertaining to their AEs and pediatric dosage adjustments. Although this observation could be expected in an infectious disease hospital, it also highlights the role of pharmacist-led DIS in AE monitoring and reinforces our previous discussion regarding pharmacists working in public health facilities tending to submit more complete reports. Trainings by the NPRA often prioritized pharmacists working in DIS units, who then conducted echo training for HCPs in their respective health facilities.

In addition, our analysis revealed a positive association between reports marked as serious and well-documented Malaysian reports (Figure 2B), consistent with previous studies from France [25,26], China [14,24], and South Korea [18] that highlighted higher completeness for serious reports. Previous research has also indicated that Malaysian HCPs prioritize reporting serious AEs [71]. The heightened gravity and potential consequences of these cases might prompt reporters to exercise greater diligence in ensuring reporting quality, including PRHs who are subjected to stricter reporting timelines for serious cases. Fatal outcomes were not flagged as the key feature contributing to Malaysian reports being well documented, likely due to their low prevalence (1048/68,795, 1.52%; Table S1 in Multimedia Appendix 2). Nonetheless, Malaysian fatal reports had a low overall completeness of 0.55 compared to 0.80 for nonfatal reports (Figure S5 in Multimedia Appendix 2). Another observational study evaluating reports submitted to the US Food and Drug Administration [15] also found that cases of patient deaths had the lowest completeness scores across reporting sources. This could be attributed to the absence of medical terminology describing the cause of death or indicate an investigation into a potential drug involvement.

Reactions under the HLGTs *product quality, supply, distribution, manufacturing,* and *quality system issues*, of which 97.78% (2242/2293) were related to product substitution issues and 91.41% (2096/2293) were sourced from public health facilities primarily by pharmacists, were captured as the key feature that negatively contributed to E2B reports being well documented. Subsequent investigations revealed that product substitution issues were most prevalent in 2018 (1355/2242, 60.44%) and primarily involved brand switching between 2 generic products: amlodipine (1012/2242, 45.14%) and perindopril (291/2242, 12.98%). Among these, only 24.8% (251/1012) and 32.6% (95/291) of the reports involving amlodipine and perindopril, respectively, were well documented. In the Malaysian public health care sector, drugs are procured

through 3 distinct mechanisms: a national concessionaire, national tenders, and direct purchases by health facilities for items not covered by the former 2 mechanisms [82]. However, in situations in which a product substitution issue is suspected and public health facilities need to directly procure alternative products for items already listed in the former 2 mechanisms, AEs or product complaints must be submitted as justification. It is believed that the reporters might submit reports containing only minimal information solely to comply with the drug procurement procedure.

Another key negative feature identified in the E2B subset was the presence of adolescent patients (aged 12-17 years). In comparison, reports involving adult patients (aged 18-44 years) and midlife adult patients (aged 45-64 years), which comprised the largest proportion of Malaysian reports, tended to be well documented. In South Korea, overall reports involving children and adolescents (aged 0-19 years) were negatively associated with being well documented in comparison to the older adult group (aged ≥65 years), whereas reports involving adults (aged 19-65 years) had a positive association [18].

Trends in Malaysian AE Reporting Quality Between 2005 and 2019

Building on the preceding discussion on the factors and characteristics associated with well-documented Malaysian AE reports, we expanded our scope to the chronological progression of AE reporting in Malaysia from 2005 to 2019. Our analyses underline that policy changes, continuity of education, and human resource development laid the foundation for a functional and sustainable SRS in Malaysia. Meanwhile, advancements in technological infrastructure, PV databases, and reporting tools contributed to the observed increase in both the quantity and quality of AE reports. These findings echo the expert-recommended 4-tier hierarchy of needs to achieve systemic capacity building for PV [83]—progressing from structures, systems, and roles to staff and infrastructure to skills to tools.

Malaysia, with its SRS governed within an established legal and regulatory framework, has historically struggled with challenges of underreporting and poorly reported AEs, as evidenced in Figure 3. In an effort to establish a functional and sustainable PV system, Malaysia placed early priorities on cultivating a reporting culture among HCPs and strengthening national PV capacities through collaborative efforts involving multiple stakeholders (Figure 4). Among them were policy changes to strengthen pharmacists' role in AE monitoring, increased recruitment of public-sector pharmacists and PV staff, active surveillance programs for targeted medicinal products, public awareness campaigns, and continuity of PV education to HCPs from undergraduate and preservice to at-service levels [7,61-63,65,74,75]. These initiatives were consistent with the existing literature, which emphasizes that multifaceted strategies and interventions work more synergistically to improve AE reporting than a single intervention [79,84,85]. Notably, our findings from the ML analysis suggest a positive association between higher staffing levels at the PV center and well-documented INTDIS reports, which could underscore the potential need for capacity building in the early phase of PV implementation.

As PV activities in Malaysia attained a higher level of maturation, the NPRA began to put greater emphasis on improving report quality. Comparative studies examining reporting forms from various countries have consistently highlighted that the Malaysian paper reporting form captures the most comprehensive information [86,87]. In response to the influx of reports observed in 2014 (Figure 3), the NPRA set their efforts on enhancing AE reporting tools and processing capabilities (Figure 4). Enhancements were made to the paper reporting form in 2015, including the addition of structured checkboxes and a reporting guide to ensure that more complete and harmonized clinical information could be obtained for subsequent causality assessment [27,88]. Concurrently, the NPRA began developing and piloting QUEST3+, an upgraded regulatory database system that marked a new submission format to the UMC—transitioning from INTDIS to E2B (Figure 6). The official launch of the QUEST3+ database took place in January 2017, replacing the historical QUEST2 database. Alongside these paradigm shifts, the NPRA also revamped and relaunched its web reporting tool for HCPs and introduced a new plain-language web reporting tool specifically for consumers (ConSERF). With the maturation of IT infrastructures, in 2018, the QUEST3+ database was integrated in phases with the centralized PhIS across Malaysian public health facilities. Reporting guides, drop-down lists, and validation alerts were also added to web and PhIS-integrated reporting tools to enhance the completeness and consistency of the collected data. Interestingly, as previously discussed, our comparative findings regarding PhIS-integrated tools used by well-trained pharmacists and new web reporting tools likely used by other HCPs and consumers highlight the complementary role of electronic reporting tools as ad hoc aids for well-trained reporters, whereas the effectiveness of these tools in improving AE reporting also relies on the maturity of IT infrastructures and their acceptance by users.

As a consequence of continuous efforts to strengthen PV capacities and technological advancements, Malaysia has seen considerable improvements not only in the quantity but also in the quality of reports. From 2015 to 2019, approximately two-thirds of Malaysian reports were well documented compared to approximately 1 in 5 reports from the rest of the world [28]. It is worth noting that, while overall completeness improved after the transition to the E2B submission format in 2015, our investigations revealed that low completeness in drug dosage (Figure 8) was systematically confounded by miscoding errors during report conversion to E2B-XML files before report transmission to VigiBase and, thus, was comparatively lowest in all subsets (Figure S5 in Multimedia Appendix 2). As a consequence of missing "number of unit in the interval" and miscoded "number of separate dosages," the drug dosage dimension for a Malaysian report in E2B format was penalized when the total daily dose for a case could not be calculated from the specified fields [29,89]. Similar to global reports [6], Malaysian E2B reports carried more administrative information, such as report type followed by reporter qualification and patient characteristics (ie, sex and age), but less drug- and

reaction-related information, such as drug dosage (despite the aforementioned confounding), reaction onset, and reaction outcome. In contrast to global reports [6], the inclusion of mandatory fields in electronic reporting tools led to a higher completeness of drug indication and free-text narratives in Malaysian reports. Reports from the literature and other sources, made by other HCPs, and submitted by PRHs had the lowest overall completeness scores (<0.5). Fatal reports and those from community pharmacies or other public services also tended to contain less information (<0.6).

Limitations

Our study is constrained by the limitations inherent to cross-sectional observational data and ML analysis, where causal reasoning and statistical inference cannot be determined [54]. The features identified in our study should be understood as predictors associated with well-documented reports but not as causal factors. Owing to the assumptions that multifaceted interventions often work synergistically and that control groups are frequently absent in nationwide implementation [79], the exact impact of individual interventions on reporting quality cannot be determined. As such, our study serves as an exploratory analysis, and the highlighted features offer a starting point for further in-depth review.

Our study faced challenges with the class imbalance inherent to the INTDIS data set, which heightened the risk of model overfitting. While undersampling improved the balanced performance of precision and recall, it could introduce new biases. Given that the INTDIS format is now obsolete in Malaysia, our focus is shifting toward the more recent E2B features.

Our models did not include causality information for several reasons. AE reports received by the NPRA and VigiBase come from a variety of sources, and the probability that the suspected AE is drug related is not the same in all cases [90]. Reporters and senders might use different methods for assessing causality, such as Naranjo probability scores and WHO-UMC causality categories, which were not available. In addition, it is important to note that causality may change as knowledge expands, and the UMC does not validate the causality assessments of the received reports.

Our data set is also constrained by the timeliness of report submission from QUEST to VigiBase and did not include all the reports received by the NPRA by December 31, 2019. As the systematic data quality issues uncovered in our study have already been communicated to the NPRA, follow-up work is underway to address these issues. Therefore, the findings of this study will not be representative of the future completeness scores of Malaysian reports in VigiBase. This also implies that the key features identified in our study were subject to multiple systematic biases, which are typically encountered when using real-world data [90,91].

Conclusions and Future Work

By using a data-driven approach and the vigiGrade method, we pinpointed the trends and milestones of the Malaysian AE reporting system and demonstrated how the country has striven to contribute large numbers of high-quality reports to global PV. Our work also highlights the vigiGrade method by the UMC as an effective tool for monitoring the quality of AE reports and aiding countries in evaluating to enhance reporting. Our multidimensional perspective on AE reporting trends and strategies in Malaysia, informed by data-driven insights, underlines the complexity and evolving nature of the SRS and the importance of continual improvement for global PV.

Using interpretable ML methods, we identified specific features that were positively associated with Malaysian AE reports being well documented. Notable factors include higher PV center staffing for INTDIS reports, reaction abated upon drug dechallenge, reaction onset or drug use duration of <1 week, dosing interval of <1 day, reports from public specialist hospitals, reports by pharmacists, and reaction duration between 1 and 6 days for recent E2B reports. Conversely, reports from PRHs and other HCPs indicated areas for potential improvement in the quality of Malaysian reports. These identified features could potentially serve as a basis for future research and strategies aimed at improving PV practices, thus improving drug safety surveillance and, ultimately, public health outcomes.

Furthermore, our time-series analysis showcased how Malaysia has built up and strengthened its PV capacity via multifaceted strategies and interventions to enhance both the quantity and quality of AE reports. Policy changes, continuity of education, and human resource development have all contributed to the foundation for a functional and sustainable SRS in Malaysia, whereas advancements in technological infrastructure, PV databases, and reporting tools concurred with the rise in both the quantity and quality of AE reports. These findings resonate with the expert-recommended 4-tier hierarchy of needs for systemic PV capacity building—from structures, systems, and roles to staff and infrastructure to skills to tools [83,92].

Building on our findings on Malaysia's progress in AE reporting and factors identified for report quality, we propose several areas for future work. To understand how and in what measure the findings from the time-series analysis contributed to the completeness of Malaysian reports, viewing the interventions set up by the NPRA as complex [93]—targeting multiple individuals or a wide range of behaviors and involving multiple interacting components—could be instrumental. Future evaluations may use this newly updated framework for complex intervention research [94].

Our findings revealed that the private health sector, including PRHs, private hospitals, private clinics, and community pharmacies, exhibited suboptimal contributions. This highlights persistent challenges pertaining to underreporting and unsatisfactory report quality in these sectors, necessitating further research into understanding behavioral or organizational barriers for developing targeted interventions [95,96]. Considering that preservice and in-service trainings often do not adequately prepare HCPs for data-related tasks [96], stronger stakeholder coordination and collaboration are imperative for continuous competency-based training and fostering an effective data use culture across health systems [95]. Regular feedback on reporting performance could be considered to facilitate self-monitoring among all senders.

Sustainable improvement in surveillance data quality and use requires a whole-systems approach encompassing governance, people, tools, and processes [95]. Given that data quality is highly reliant on their collection at health facilities, future work can prioritize people and environments essential for functional information systems as well as validation upon data entry to ensure completeness, accuracy, and consistency [88]. Our identification of systematic data quality issues highlighted a gap in data-driven continuous quality improvement [95], underscoring the need for internal quality assurance procedures for AE data management and transmission, including routine systematic checks and periodic in-depth reviews [88,97].

Looking ahead, as Malaysian reports currently use the E2B(R2) format, future efforts can navigate toward transitioning to the E2B(R3)-compliant database and reporting tools as the inclusion of null flavors in the E2B(R3) format helps address missing information by explaining data absence. Future work on data governance could explore leveraging automation, ML, and natural language processing to improve the overall efficiency and quality of AE data collection, processing, and management [98,99].

Acknowledgments

This paper is based on the master's thesis completed by SMC at the Graduate Institute of Biomedical Informatics, Taipei Medical University, under the supervision of SS-A and the joint supervision of DS and Jim Barrett from the Uppsala Monitoring Centre (UMC), as well as SCL from the National Pharmaceutical Regulatory Agency (NPRA). No generative artificial intelligence tools were used to create the original content for publication. The views expressed in this paper do not represent the opinions of the NPRA, the UMC, or the World Health Organization. The authors thank the Director-General of Health Malaysia for his permission to publish this study and are indebted to all stakeholders who contributed reports to QUEST and VigiBase. Special thanks to Usman Iqbal, Ekansh Gayakwad, Suo-Chen Chien, and Yu-Chin Chu from Taipei Medical University and Wai Lam Hoo from the University of Malaya for their valuable assistance and advice. The authors are also grateful for the unwavering support provided by Azuana Ramli, Norleen Mohamed Ali, Kobu Thiruvanackan, Nora Ashikin Mohd Ali, Mohd Ghazli Ismail, and Wee Kee Wo from the NPRA. The publication fund for this research was sponsored in part by the National Science and Technology Council (NSTC) Taiwan under grant NSTC 110-2320-B-038-029-MY3.

Data Availability

The data sets generated during and analyzed during this study are not publicly available due to the data protection policies of the Uppsala Monitoring Centre and the National Pharmaceutical Regulatory Agency. Data requests should be made directly to the institutions.

Authors' Contributions

SMC contributed to conceptualization, methodology, data curation, software, formal analysis, and original draft writing. DS and SCL contributed equally to conceptualization, methodology, formal analysis, and supervision. SS-A contributed to conceptualization, methodology, supervision, and funding acquisition. HCY contributed to methodology, formal analysis, and funding acquisition. All authors have reviewed, edited, and approved the final manuscript. SS-A and HCY are co-corresponding authors on this article.

Abstract

Background: Medication safety in residential care facilities is a critical concern, particularly when nonmedical staff provide medication assistance. The complex nature of medication-related incidents in these settings, coupled with the psychological impact on health care providers, underscores the need for effective incident analysis and preventive strategies. A thorough understanding of the root causes, typically through incident-report analysis, is essential for mitigating medication-related incidents.

Objective: We aimed to develop and evaluate a multilabel classifier using natural language processing to identify factors contributing to medication-related incidents using incident report descriptions from residential care facilities, with a focus on incidents involving nonmedical staff.

Methods: We analyzed 2143 incident reports, comprising 7121 sentences, from residential care facilities in Japan between April 1, 2015, and March 31, 2016. The incident factors were annotated using sentences based on an established organizational factor model and previous research findings. The following 9 factors were defined: procedure adherence, medicine, resident, resident family, nonmedical staff, medical staff, team, environment, and organizational management. To assess the label criteria, 2 researchers with relevant medical knowledge annotated a subset of 50 reports; the interannotator agreement was measured using Cohen κ. The entire data set was subsequently annotated by 1 researcher. Multiple labels were assigned to each sentence. A multilabel classifier was developed using deep learning models, including 2 Bidirectional Encoder Representations From Transformers (BERT)–type models (Tohoku-BERT and a University of Tokyo Hospital BERT pretrained with Japanese clinical text: UTH-BERT) and an Efficiently Learning Encoder That Classifies Token Replacements Accurately (ELECTRA), pretrained on Japanese text. Both sentence- and report-level training were performed; the performance was evaluated by the F_1-score and exact match accuracy through 5-fold cross-validation.

Results: Among all 7121 sentences, 1167, 694, 2455, 23, 1905, 46, 195, 1104, and 195 included “procedure adherence,” “medicine,” “resident,” “resident family,” “nonmedical staff,” “medical staff,” “team,” “environment,” and “organizational management,” respectively. Owing to limited labels, “resident family” and “medical staff” were omitted from the model development process. The interannotator agreement values were higher than 0.6 for each label. A total of 10, 278, and 1855 reports contained no, 1, and multiple labels, respectively. The models trained using the report data outperformed those trained using sentences, with macro F_1-scores of 0.744, 0.675, and 0.735 for Tohoku-BERT, UTH-BERT, and ELECTRA, respectively. The report-trained models also demonstrated better exact match accuracy, with 0.411, 0.389, and 0.399 for Tohoku-BERT, UTH-BERT, and

ELECTRA, respectively. Notably, the accuracy was consistent even when the analysis was confined to reports containing multiple labels.

Conclusions: The multilabel classifier developed in our study demonstrated potential for identifying various factors associated with medication-related incidents using incident reports from residential care facilities. Thus, this classifier can facilitate prompt analysis of incident factors, thereby contributing to risk management and the development of preventive strategies.

KEYWORDS

residential facilities; incidents; non-medical staff; natural language processing; risk management

Introduction

The prevention of medication-related incidents and the development of preventive measures are crucial for ensuring medication safety. Heinrich law suggests that for every serious accident, 29 minor accidents and 300 incidents exist [1]. Analysis of these incidents and formulation of countermeasures can help prevent serious medical accidents and enhance patient safety. Moreover, these incidents result in a significant psychological impact on the health care providers [2-5], known as “second victim syndrome” [6-8]. Thus, incident prevention measures are considered vital.

The core of incident prevention is focused on the details of the incident; thus, the creation of incident reports plays a key role. Hospitals have traditionally been the primary sources of such data, resulting in extensive research [9-19] and the development of sophisticated incident prevention strategies. However, residential care facility settings, in which residents live for extended periods, present unique challenges. Unlike hospitals, these facilities serve as communal living spaces for older people and often rely on nonmedical staff (not doctors or nurses) to perform health care–related tasks, including medication assistance. This practice raises significant concerns regarding the potential for medication incidents, underlining the importance of extending incident prevention strategies beyond hospital settings. Moreover, previous studies have highlighted a range of medication incidents in Japanese residential care facilities, including dropped drugs and misdelivery or misuse of medicines [20].

Natural language processing (NLP) technology demonstrates considerable potential for enhancing the analysis of incident reports. NLP is an analytical technique involving deep learning processing of human language for extracting meaningful information. Recently, this technology has been applied to classify various types of text data, including blogs [21,22] and electronic medical records [23], and has been extended to incident report classification in health care settings [24,25]. Specifically, classifiers using NLP were constructed to determine the classification and severity of incidents, with hospital incident reports serving as the training data [24,26,27]. Although the incident reports obtained and their corresponding text data, primarily comprising open-ended descriptions, from residential care facilities are considered suitable for NLP analysis, limited efforts have been made toward using NLP for extracting information from incident reports at these facilities.

Our previous research, which focused on identifying the causes of medication incidents in residential care facilities, demonstrated the complex and multifactorial nature of various elements contributing to these incidents [28]. Therefore, this study aimed to create a multilabel classifier that can extract various factors related to medication-related incidents based on incident reports in residential care facilities.

Methods

Data Set

This study included incidents that occurred in residential care facilities in Japan from April 1, 2015, to March 31, 2016, in 106 long-term residential care facilities operated by a single company. The residential care facilities included in our study are privately run, where residents usually pay monthly fees for housing and various care or support services, including meal provision, assistance with activities of daily living, and recreational opportunities. Notably, the majority of the residents avail medication assistance, which is a crucial component of these services.

We exclusively focused on incidents involving care staff who were not medical professionals. An incident report was completed after each incident, documenting the type of incident (forgetting to take medicines, misdelivery or misuse of medicines, loss of medicines, discovery of dropped drugs, and spitting up or falling while taking medicines), conditions at the time, and factors contributing to the incident. All the reports were written in Japanese. The care staff at the participating facilities were encouraged to record even minor incidents in their reports.

The data set comprised 2143 reports. The free-text descriptions of the factors contributing to the incident in each report were segmented into 7121 sentences for further analysis.

Annotation and Data Analysis

Incident factor labels were established based on the organizational factor model by Reason [29] and findings from our previous study [28], which explored the factors of medication assistance-related incidents in residential care facilities. In our previous study, we interviewed individuals involved in incidents, such as misdelivery or misuse of medications. Our findings indicated that “not following procedures” often resulted in these incidents, and identified 4 key contributing factors, namely individual residents, individual staff, team, and work environment. Considering the diverse nature of incidents in residential care facilities that extend

beyond medication omissions or dropped drugs, a broader range of factor labels is warranted. We developed the following 9 causal labels: procedure adherence, medicine, resident, resident family, nonmedical staff, medical staff, team, environment, and organizational management. To establish the labels, we also consulted James Reason [29] organizational accident model. Reason model posits that incidents, which are often precipitated by unsafe acts attributed to multiple factors, are fundamentally rooted in the culture of the organization. This model provides a framework for understanding the complex interplay of the factors resulting in incidents in our study.

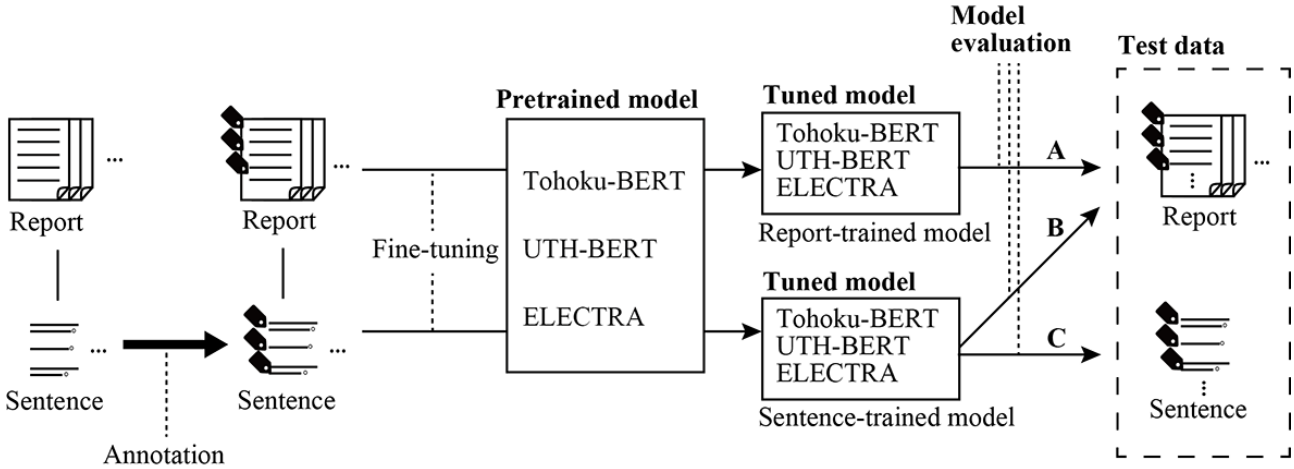
The criteria for annotating the reports were based on our previous study [28] and an analysis of actual medication incident conditions in Japan [20]. To evaluate the reliability of these criteria, we selected a random sample of 50 reports comprising 183 sentences from the data set. These reports were annotated by 2 researchers with relevant medical knowledge (HK and SE). The interannotator agreement (IAA) was assessed using Cohen κ, a statistical measure of agreement. Cohen K values are interpreted as follows: values close to 1 indicate perfect agreement, <0.00, "poor"; 0.00-0.20, "slight"; 0.21-0.40, "fair"; 0.41-0.60, "moderate"; 0.61-0.80, "substantial"; and 0.81-1.00, "almost perfect" [30]. Following this initial assessment, one of the researchers (HK) annotated all the sentences.

The distribution of reports according to the number of labels assigned was analyzed. The average number of labels per incident type was calculated and compared. Incident types were categorized as "forgetting to take medicines," "misdelivery or misuse of medicines," "loss of medicines," "discovery of dropped drugs," and "spitting up or falling while taking medicines," as defined in our previous study [20]. For factor analysis, we used the Student *t* test (2-tailed), applying the Bonferroni correction to account for multiple comparisons. We established the significance criterion at $P<.05$. Furthermore, the percentage of reports that contained each label for every type of incident was calculated, thus providing a detailed view of the label distribution across different incident categories.

Deep Learning Models

Figure 1 shows an overview of the model development. In this study, a multilabel classifier was built from an annotated multilabel data set to manage multiple descriptions of incident factors. Due to the insufficient number of labels, which made the accurate evaluation of the model's performance challenging, the limited labels associated with "resident family" and "medical staff" were excluded from the model development process. Consequently, the refined model development approach enabled the classifier to simultaneously identify 7 distinct labels. The development of this classifier involves fine-tuning existing pretrained models. These models included 2 Bidirectional Encoder Representations From Transformers (BERT) models, each using different pretraining data sources, and an Efficiently Learning Encoder That Classifies Token Replacements Accurately (ELECTRA) model. ELECTRA, while maintaining a foundational structure similar to that of BERT, achieves enhanced performance in NLP tasks through improved pretraining methods. The input of these models was limited to 512 tokens due to the capability of the pretrained model.

Figure 1. Overview of model development and evaluation. (A) Report-trained model evaluated using reports. (B) Sentence-trained model evaluated using reports. (C) Sentence-trained model evaluated using sentences. BERT: Bidirectional Encoder Representations From Transformers; ELECTRA: Encoder That Classifies Token Replacements Accurately; UTH: University of Tokyo Hospital.



Specifically, one of the BERT models we used was developed by the Natural Language Processing Research Group at Tohoku University (Tohoku-BERT), which was pretrained on the Japanese Wikipedia data as of September 1, 2019 [31] (BERT-based model; 12 layers, 768 dimensions of hidden states, and 12 attention heads, tokenizer: MeCab [32]). The other, University of Tokyo Hospital (UTH)-BERT, was developed by the Department of Artificial Intelligence and Digital Twin in Healthcare at the University of Tokyo and pretrained using extensive Japanese clinical text [33] (BERT-based model: 12 layers, 768 dimensions of hidden states, and 12 attention heads, tokenizer: MeCab [32]). The ELECTRA model was developed by the Izumi Laboratory at the University of Tokyo and pretrained with Japanese Wikipedia data as of June 1, 2021 [34] (ELECTRA-based model; 12 layers, 768 dimensions of hidden states, and 12 attention heads, tokenizer: MeCab [32]). No additional preprocessing was conducted beyond what is described.

Our study used 2 distinct models: one based on reports and the other on sentences. In the report-trained model, each report

served as a single training unit, whereas in the sentence-trained model, each sentence served as a training unit.

The hyperparameters that can be adjusted before training are defined in Table S1 in Multimedia Appendix 1.

Task and Metrics

Performance was evaluated in terms of precision, recall, F_1-score, and exact match accuracy. The exact match accuracy specifically measures the percentage of predictions that are correct across all labels. The data set was divided into training and test data at a ratio of 4:1, and the model was evaluated using the average of the 5-fold cross-validation results.

The report-trained model was evaluated using the reports as test data (Figure 1A). The sentence-trained model was evaluated using reports (Figure 1B) and sentences (Figure 1C) as test data.

Generalizability Analysis

We extracted 136 incident reports involving nonmedical staff and 31 reports involving care staff from hospital incident data collected by the Japan Council for Quality Health Care between January 2010 and June 2023 to examine the generalizability of the constructed model. We assessed the ability for extrapolation of the report-trained model derived from the extractor pretrained on Tohoku-BERT using the F_1-score.

Ethical Considerations

All the procedures were performed per the principles of the Declaration of Helsinki. In this study, all data were analyzed anonymously, and informed consent was waived owing to the retrospective observational design of this study. Residents and staff in residential facilities were informed of this study through postings at each facility and were allowed to refuse permission concerning the use of their data. This study was approved by the Research Ethics Review Committee of the Faculty of Pharmaceutical Sciences, University of Tokyo (approved on August 3, 2023) and the Research Ethics Review Committee of the Faculty of Pharmacy, Keio University (approved on July 14, 2023; 230714-1).

Results

Data Set Analysis

The average report length was 62.6 (SD 34.3; median 56, IQR 38-81) tokens, and the average sentence length was 18.2 (SD 9.8; median 16, IQR 11-23) tokens. None of the sentences or reports exceeded 512 tokens. The incidents were categorized as follows: forgetting to take medicines (648 incidents), misdelivery or misuse of medicines (293 incidents), loss of medication (18 incidents), discovery of dropped drugs (1024 incidents), and spitting up or falling while taking medicines (160 incidents).

Annotation and Features of the Incident Factors

An example of this label is presented in Textbox 1. The IAA for each label was calculated, and all the labels achieved an IAA score exceeding 0.6 (Table 1), thereby validating the effectiveness of the developed annotation guidelines. Notably, the κ coefficients for the factors related to “resident family” and “team” were exceptionally high, exceeding 0.9 in all instances. Using these guidelines, the remaining reports were sequentially annotated. The “resident” related factor label was most frequently assigned as shown in Table 1. Conversely, the “resident family” and “medical staff” factors were rarely assigned.

Table 2 presents the distribution of the number of labels assigned per sentence and per report. The most frequent occurrences were 1 label per sentence and 2 labels per report, accounting for 77.5% (5518) sentences and 34.2% (733) reports of the total occurrences, respectively. Table 3 categorizes the number of labels per report according to the incident type. Reports involving forgetting to take medicines and misdelivery or misuse of medicines tended to have a higher number of labels than other incidents (P<.001).

Table 4 shows the percentage of incident reports, with each label categorized by the incident type. Reports describing incidents, such as “spitting up or falling while taking medicines” and “discovery of dropped drugs,” often included “resident” factors and less frequently mentioned “team” factors. In contrast, reports of “forgetting to take medicines” and “misdelivery or misuse of medicines” commonly included “environmental” factors.

Textbox 1. Example of the label.

Procedure adherence

- Care staff did not follow the instructions for double-checking medication assistance.
- Care staff failed to confirm that medications were swallowed until the end.

Medicine

- Due to the concurrent use of herbal medicine with pills, there was a higher risk of dropping them.
- The number of medications to be taken after breakfast was large.

Resident

- The resident was unable to manage their medications.
- Their life rhythm was irregular, with mealtimes being inconsistent.

Resident family

- Family members were assisting with meals, which prevented intervention in medication administration.
- Medication management was being handled by the family.

Nonmedical staff

- Preparation for breakfast was not sufficient, leading to delays in service time and causing staff to rush.
- There was a low awareness that numbness made it difficult for residents to hold medication packets.

Medical staff

- Inexperienced nurses relied on each other, resulting in a lack of necessary checks.
- The nursing notes failed to include the required documentation.

Team

- There was a lack of coordination between meal assistance and medication assistance staff.
- Important information from doctor visits was not properly communicated.

Environment

- The resident was taking medicines during the busiest time for medication assistance.
- The proximity of tables in the restaurant made it impossible to check medication intake.

Organizational management

- Measures against the previous incidents had not been implemented.
- The procedure manual had not been updated.

Table 1. The IAA[a] values and number of sentences for the 9 labels (N=7121).

Label	IAA	Sentences, n
Procedure adherence	0.634	1167
Medicine	0.741	694
Resident	0.898	2455
Resident family	0.954	23
Nonmedical staff	0.638	1905
Medical staff	0.869	46
Team	0.930	195
Environment	0.755	1104
Organizational management	0.692	195

[a]IAA: interannotator agreement.

Table 2. The number of labels per incident report (N=2143) and per sentence (N=7121).

Number of labels	Reports, n (%)	Sentences, n (%)
0	10 (0.5)	508 (7.1)
1	278 (13.0)	5518 (77.5)
2	733 (34.2)	1021 (14.3)
3	689 (32.2)	70 (1.0)
4	348 (16.2)	3 (0.04)
5	78 (3.6)	0 (0)
6	7 (0.3)	0 (0)
≥7	0 (0)	0 (0)

Table 3. The average number of labels per incident contents.

	Labels, mean (SD)
Forgetting to take medicines (n=648)	2.92 (1.10)
Misdelivery or misuse of medicines (n=293)	2.85 (1.12)
Loss of medicines (n=18)	2.61 (1.38)
Discovery of dropped drugs (n=1024)	2.45 (0.94)
Spitting up or falling while taking medicines (n=160)	2.19 (0.93)

Table 4. The percentages of reports that contain each label for every type of incident.

	Procedure adherence	Medicine	Resident	Resident family	Nonmedical staff	Medical staff	Team	Environ-ment	Organizational management
Forgetting to take medicines (n=648)	41.0	33.0	59.0	2.3	72.8	2.8	17.0	53.4	11.0

Model

Table S2 in Multimedia Appendix 1 shows the average label distributions for both the training and test data as part of the 5-fold cross-validation process. Since the labels for "resident family" and "medical staff" are notably fewer than those of other categories, they were excluded from the development of the multilabel classifier.

The performances of the fine-tuned Tohoku-BERT, UTH-BERT, and ELECTRA models were assessed using 3 different approaches: a report-trained model evaluated using reports (Table 5), sentence-trained model evaluated using reports (Table 6), and sentence-trained model evaluated using sentences (Table 7), as summarized in Tables 5-7. The analysis revealed that the report-trained model (Table 5) generally achieved higher F_1-scores than the sentence-trained model evaluated using the report data (Table 6). The performance of the sentence-trained model was better when evaluated using sentences (Table 7) than when evaluated using reports (Table 6).

Table 8 lists the exact match accuracies of these models across the board, specifically for instances involving multiple labels. The sentence-trained model evaluated using sentences exhibited the highest exact match accuracy for the overall test data. When limited to the test data with multiple labels, the report-trained model evaluated using reports demonstrated the highest exact match accuracy.

The extrapolation of the report-trained model, fine-tuned using Tohoku-BERT, revealed that the mean F_1-score (micro F_1-score) was 0.72 for reports involving care staff alone and 0.65 for those involving nonmedical staff (Table S1 in Multimedia Appendix 2).

Discussion

Principal Results

Our study constructed a multilabel classifier that used NLP models, including BERT and ELECTRA, to identify the factors contributing to medication-related incidents by nonmedical staff using incident reports of residential care facilities. Unlike previous studies that mainly focused on classifying incident types and harm severity in hospital settings [24-27], our approach focused on the complex factors involved in medication-related incidents involving nonmedical staff. This complexity often renders accurate classification challenging. To our knowledge, our study is the first to demonstrate the potential contribution of NLP technology in extracting incident factors and formulating measures from incident reports obtained from residential care facilities.

In our study, we identified and annotated 9-factor labels, leading to over 99% (2133) of the reports and more than 92% (6613) of the sentences being assigned these labels. Reports without factor labels merely described the conditions of the incident occurrences, lacking in-depth factor analysis. Hence, the 9-factor labels identified appear to be suitable for representing the contributory factors in medication-related incidents involving nonmedical staff in residential care facilities. In contrast, 2 specific labels, “resident family” and “medical staff,” were relatively limited. In residential care facilities in Japan, where

nonmedical staff primarily provide medication assistance, the involvement of medical staff is limited, and family member participation is irregular. Consequently, these factors are less frequently represented, resulting in a small number of labels.

This study developed 2 types of models: 1 trained on individual sentences and the other on the entire reports. The report-trained model consistently outperformed the sentence-trained model, particularly achieving over 0.1 improvement in the F_1-score for factors involving nonmedical staff. Thus, report-level training, which retains more contextual information than sentence-level training, significantly enhanced the model performance. The exact match accuracy was the highest using the sentence-trained model, exceeding 0.6. However, this accuracy dramatically decreased to approximately 0.3 when the test data were limited to those with multiple labels. This significant reduction underscores the prevalence of sentences with a single label, deeming it unsuitable for evaluation as a multilabel classifier. Therefore, we also evaluated the performance of the sentence-trained model using report units as test data; however, the performance was significantly inferior to that of the report-trained model. Conversely, training on the report data yielded an exact match accuracy of approximately 0.4, which remained stable across tests with multiple labels. These findings demonstrate the successful development of a multilabel classifier that can rather accurately classify multiple labels; nevertheless, the potential for further improvement exists. Further, 1 approach for model improvement involves analyzing label co-occurrences that are prone to errors and creating a data set of these label combinations from an existing data set for upsampling. Additionally, modifications to the model, such as incorporating other pretrained models or applying domain adaptation techniques, could also be effective methods for improving performance.

Within our report-trained multilabel classifier, the macro F_1-scores of Tohoku-BERT and ELECTRA were notably similar, outperforming those of UTH-BERT, which had a lower score. This variation in performance was likely attributed to the characteristics of the pretraining data. Tohoku-BERT and ELECTRA were pretrained using the Japanese Wikipedia data, offering a broad range of general knowledge, whereas UTH-BERT was specifically pretrained on clinical texts. The lower classification performance for UTH-BERT may be attributed to the less specialized terminology included in the incident reports predominantly completed by nonmedical staff in residential care facilities compared to that in clinical texts.

Our analysis of the report-trained model's performance across various labels revealed that, with the notable exceptions of organizational management and team factors, as assessed by UTH-BERT, the F_1-scores consistently exceeded 0.6. Thus, the model accurately classified a broad spectrum of labels, thus demonstrating its effectiveness in automatically identifying incident factors from medication-related reports in residential care settings. However, classifying organizational management has proven to be more challenging. This difficulty can be attributed to the variability in the label assignment and the relatively limited number of labels in this category. Notably, the κ coefficient for the organizational management label was lower than that for the other labels, and the number of labels assigned to this category was also smaller. We assume that the low κ coefficient is partly attributed to the broader range of factors covered by this label, contributing to greater ambiguity compared to other labels. This highlights potential areas for the enhancement of the design and training process of our classifier.

Evaluation of the extrapolation of the constructed report-trained model confirmed that the F_1-score was slightly inferior to that of its initial construction. This reduction was primarily due to the notably few reports used for extrapolation evaluation. Furthermore, the characteristics of the individual who completed the report could have influenced their performance, particularly since the report was from a hospital setting. Moreover, the extrapolation results showed that the model's performance on reports involving care staff alone (F_1-score=0.72) was higher than that on those involving nonmedical staff (F_1-score=0.65). These findings indicate that the model is particularly effective in identifying factors in medication-related incidents involving care staff, suggesting specialization in extracting relevant information from such reports.

Limitations

In total, 1 limitation of this study is the inclusion of data with a limited number of labels. Although 9 labels were assigned at the annotation stage, 2 specific labels, "resident family" and "medical staff," were excluded from the multilabel classifier due to insufficient quantity. When a multilabel classifier that included these 2 labels was constructed, the F_1-score for both labels was nearly zero. The F_1-scores for the other labels remained almost unchanged compared to the case where the multilabel classifier was developed without including these 2 labels. Therefore, the impact of excluding these 2 labels is considered to be minimal. Furthermore, the performance of the model for each label tended to show higher F_1-scores with a higher IAA and a greater number of labels. This problem can be resolved by increasing the number of incident reports and labels.

Future Directions

Our model has the potential to streamline the identification of factors underlying medication-related incidents in residential care settings. This could result in a more effective planning of measures to prevent medication-related incidents. Moreover, it can offer nonmedical staff opportunities for learning and growth through prompt feedback following the occurrence of medication-related incidents.

Conclusions

The multilabel classifier developed in this study can identify various factors associated with medication-related incidents based on incident reports from residential care facilities. This classifier can facilitate prompt analysis of incident factors, thereby contributing to risk management and the development of preventive strategies.

Acknowledgments

We would like to thank all residents and care staff in the residential facilities operated by SOMPO Care and Mr Daisuke Yamamoto, BSc, of the SOMPO Care Corporation for his efforts in providing the data. This study was supported by the Japan Society for the Promotion of Science (JSPS) KAKENHI (JP22K19657).

Data Availability

Permission to provide data to individuals other than this study's investigators was not included under ethical approval and would require a new application for approval. The anonymized analyzed data may be obtained from the corresponding author upon reasonable request.

Authors' Contributions

HK, HS, and SH designed this study. HK, HS, and SE conducted the annotation and created the annotation guidelines. HK performed the data analysis, created the NLP model, and conducted all the experiments. SW supported the development of the NLP model from an NLP technical perspective. SI and YS advised on this study's concepts and processes. HS and SH supervised this study. All the authors have reviewed and approved the final paper. Authors HK (hayatokizaki625@keio.jp) and HS (satoh@mol.f.u-tokyo.ac.jp) are co-corresponding authors for this article.

Conflicts of Interest

HK, SE, SW, SI, and SH declare no conflicts of interest. YS and HS are researchers in a laboratory that received grants from SOMPO Care, Inc.

Abstract

Background: Assessing disease progression among patients with uncontrolled hypertension is important for identifying opportunities for intervention.

Objective: We aim to develop and validate 2 models, one to predict sustained, uncontrolled hypertension (≥2 blood pressure [BP] readings ≥140/90 mm Hg or ≥1 BP reading ≥180/120 mm Hg) and one to predict hypertensive crisis (≥1 BP reading ≥180/120 mm Hg) within 1 year of an index visit (outpatient or ambulatory encounter in which an uncontrolled BP reading was recorded).

Methods: Data from 142,897 patients with uncontrolled hypertension within Atrium Health Greater Charlotte in 2018 were used. Electronic health record–based predictors were based on the 1-year period before a patient's index visit. The dataset was randomly split (80:20) into a training set and a validation set. In total, 4 machine learning frameworks were considered: L2-regularized logistic regression, multilayer perceptron, gradient boosting machines, and random forest. Model selection was performed with 10-fold cross-validation. The final models were assessed on discrimination (C-statistic), calibration (eg, integrated calibration index), and net benefit (with decision curve analysis). Additionally, internal-external cross-validation was performed at the county level to assess performance with new populations and summarized using random-effect meta-analyses.

Results: In internal validation, the C-statistic and integrated calibration index were 0.72 (95% CI 0.71 - 0.72) and 0.015 (95% CI 0.012 - 0.020) for the sustained, uncontrolled hypertension model, and 0.81 (95% CI 0.79 - 0.82) and 0.009 (95% CI 0.007 - 0.011) for the hypertensive crisis model. The models had higher net benefit than the default policies (ie, treat-all and treat-none) across different decision thresholds. In internal-external cross-validation, the pooled performance was consistent with internal validation results; in particular, the pooled C-statistics were 0.70 (95% CI 0.69 - 0.71) and 0.79 (95% CI 0.78 - 0.81) for the sustained, uncontrolled hypertension model and hypertensive crisis model, respectively.

Conclusions: An electronic health record–based model predicted hypertensive crisis reasonably well in internal and internal-external validations. The model can potentially be used to support population health surveillance and hypertension management. Further studies are needed to improve the ability to predict sustained, uncontrolled hypertension.

Introduction

Hypertension is a major chronic disease affecting nearly half of the adults in the United States, of whom less than half have their blood pressure (BP) under control [1]. Uncontrolled hypertension, defined as BP ≥140/90 mm Hg may lead to major cardiovascular diseases, organ damage, stroke, or even death, if not properly managed over time [2,3]. Effective treatment for uncontrolled hypertension requires proper monitoring so that further disease progression can be detected and prevented.

Numerous studies have examined the risk factors related to hypertension. Surveillance data show that hypertension is more prevalent in men than in women and in older adults than in younger persons [4]. Racial or ethnic disparities in BP control have been described, owing to risk factors that include racism-related stress, and social barriers such as low health literacy, poverty, and limited access to care [5-7]. Prior studies have also revealed other clinical predictors of hypertension such as comorbidities (eg, coronary heart disease and diabetes), laboratory biomarkers (eg, cholesterol levels), and BMI [8-10]. Leveraging the extensive knowledge base about hypertension risk factors, various prediction models, based on statistical and machine learning methods, have been developed to assess the risk of hypertension onset in the general population [11,12]. However, literature searches revealed a lack of research involving risk prediction for clinically important hypertension states, such as future BP measurements that are consistently elevated, also called sustained uncontrolled hypertension, or hypertensive crisis (ie, BP ≥180/120 mm Hg) in patients with uncontrolled hypertension [13,14].

Predictive models of sustained, uncontrolled hypertension and hypertensive crisis within 1-year following an index visit could inform clinical decision support prompting discussions between patients and clinicians about medication intensification. This index visit can be designated as an outpatient or ambulatory clinic appointment in which the patient had an uncontrolled BP reading and did not have a new antihypertensive medication class added. These specifications can identify a targeted population who may benefit from additional consideration to intensity hypertension medications. From a design perspective, the intended use case for the proposed risk models is to either serve as a real-time nudge that informs a shared decision-making conversation between provider and patient at the index visit or to be deployed as a tool for population health surveillance to help guide timely, proactive outreach. For instance, a care manager may reach out to a patient who is at high risk and did not have medication intensification to schedule a follow-up visit sooner, address barriers to medication adherence, or inquire with the care team about enrolling the patient in a hypertension management program. Furthermore, a valid risk score may aid patients in understanding the importance of treatment decisions; thereby helping to address nonadherence to medications, which is a major risk factor for suboptimal BP control [15]. This study presents the development and validation of 2 risk models, one to predict sustained, uncontrolled hypertension, and one to predict hypertensive crisis within 1 year following an index visit.

Methods

Study Population

This study's cohort consisted of patients aged 18 years or older who had an uncontrolled BP reading (systolic BP ≥140 mm Hg or diastolic BP ≥90 mm Hg) during an ambulatory or outpatient encounter in 2018 at a Greater Charlotte facility of Atrium Health, a large hospital network in the southeastern United States. This study's cohort only included active patients in the health system, that is, those having at least one encounter during the following year, 2019. The first ambulatory or outpatient encounter during 2018 showing an uncontrolled BP reading was considered the patient's index visit. Patients were excluded if, on the index visit, they were prescribed a new antihypertensive drug class that was not present in the 1-year historical medication records. Patients on more than 4 drug classes of antihypertensive medication were excluded. Patients were also excluded if they were in hospice care, were pregnant during 2018 or 2019, were diagnosed with end-stage renal disease, received dialysis, had a renal transplant, or died before December 31, 2019.

Study Variables

Sustained, uncontrolled hypertension in a patient was a binary outcome indicating the presence of ≥2 uncontrolled BP readings (≥140/90 mm Hg) or ≥1 particularly high BP reading (≥180/120 mm Hg) within 1 year following an index visit. The hypertensive crisis outcome was a binary indicator showing whether a patient had any BP reading ≥180/120 mm Hg within 1 year following the index visit.

We determined that using a 1-year look-back window prior to index visit would be appropriate to capture recent, clinically relevant predictor data from the health system's electronic health records (EHRs). This decision also relied on previous observations of models predicting 1-year hypertension status demonstrating successes when they were also using 1-year-old data prior to prediction [16,17]. We collected basic data at the index visit including the patient's age, gender, race and ethnicity, medical insurance, and the last systolic and diastolic BP measurements. Based on a patient's primary address, we determined census tract-level neighborhood socioeconomic disadvantage indicators: the Area Deprivation Index (ADI, national-level percentile), based on the 2016 - 2020 American Community Survey, and the Centers for Disease Control and Prevention's Social Vulnerability Index (version 2020; overall score, national-level percentile) [18,19]. Health care–related predictors included the presence of individual Elixhauser Comorbidities, antihypertensive drug classes prescribed, and number of visits within different clinical settings [20]. We considered several biological measurements including total cholesterol, high-density lipoprotein cholesterol, and low-density lipoprotein cholesterol, triglycerides, and creatinine, as well as weight and BMI. BP measurements in the past 1 year of index visit were aggregated into prediction features (eg, count of BP readings ≥140/90 mm Hg). A detailed description of all prediction features can be found in Table S3 in Multimedia Appendix 1.

Statistical Analyses

We calculated the required sample size of a validation dataset so that the 95% CI for validation C-statistics had a width of 0.05 or less [21]. A sample size of 11,520 patients is adequate for an outcome prevalence between 5% - 50% and a C-statistics between 0.6 - 0.8.

We randomly split the dataset into a training set and an internal validation set according to an 80:20 ratio. We performed median imputation for numerical variables and used imputed median values from the training set for subsequent imputation with the

validation set. To handle considerable missingness with laboratory tests, we categorized the variables using standard cutoff values for their normal ranges and applied the "missing" category to the variable when the value was not available. Once categorical variables were 1-hot encoded, we performed data standardization, subtracting the variables by the sample mean then dividing by the sample SD. No variable selection procedure was conducted. Further, 4 machine learning frameworks were considered: (L2) regularized logistic regression, multilayer perceptron (with 1 hidden layer), gradient boosting machines, and random forest. For hyperparameter tuning, we used grid search strategy with discrimination power (C-statistic) as the selection criteria and performed 10-fold cross-validation on the training set. Hyperparameter-tuned models were identified, one for each modeling framework, and further compared on their cross-validation performance for the final model.

For internal validation, in addition to discrimination, we assessed calibration performance of the 2 final models, one for each outcome, using smoothed calibration curves, estimated with generalized additive models. Based on the calibration curves, we computed the average (ie, integrated calibration index [ICI]), median (E50), 90th percentile (E90) of the absolute difference between expected event rate and predicted risk to summarize calibration errors [22]. We computed 95% CIs using standard methods for C-statistics (DeLong method) and calibration metrics (simulation-based inference) [23]. Additionally, we reported sensitivity, specificity, and positive or negative predictive values and 95% CIs (using exact binomial method) with respect to different decision thresholds. We performed decision curve analysis with the validation set to assess the models' net benefit in comparison with the default policies, that is, treating all and treating no patients [24]. We evaluated net benefit within a range of probability decision threshold, which was 50% - 70% for the outcome sustained, uncontrolled hypertension and ≤20% for the outcome hypertensive crisis.

Finally, we carried out internal-external cross-validation (IECV) at the county level to examine the final models' predictive ability in new patient cohorts, using the existing data [25]. With this approach, we used data from patients receiving care within a given county to validate models developed with the data of all other patients. For reliable validation, we only validated the counties yielding sufficient sample size of at least 200 events [26]. Using random-effect meta-analyses, we estimated the pooled performance measures, that is, the C-statistic, and ICI, across validations. We assessed heterogeneity across validations using the SD of the random effect, denoted as τ, and a chi-square test with a significance level of .05.

Model building was performed using Python (Python Software Foundation, eg, "scikit-learn" package). Other analyses were conducted using R (R Foundation, eg, "pROC," "pmcalibration," and "meta" packages).

Ethical Considerations

The Atrium Health institutional review board approved our research protocol. Informed consent was waived as there were no more than minimal risks to study participants. The study data will not be made available publicly to ensure patient confidentiality and privacy.

Results

Patient Characteristics

This study's cohort consisted of 142,897 patients, almost all of whom received care in 13 North Carolina counties and 1 South Carolina county in the year 2018. The patients were 72.33% (n=103,361) White and 22.52% (n=32,174) Black, had a median age of 61 (IQR 49-71) years and a median national-level ADI ranking of 55 (IQR 35-73). All patients were observed with known sustained, uncontrolled hypertension and hypertensive crisis status during follow-up period. The observed prevalence of sustained, uncontrolled hypertension and hypertensive crisis were 41.67% (n=59,547) and 4.53% (n=6,470), respectively. Across the counties, there were notable racial and socioeconomic differences (Table 1). Except for 1 county, the percentage of White patients ranged between 62.64% and 93.13% and the median of ADI ranking ranged between 39 and 88. The observed prevalence of outcomes among the counties ranged between 37.35% and 47.26% for sustained, uncontrolled hypertension, and, except for 1 county, between 3.89% and 6.06% for hypertensive crisis.

Table . Patient characteristics.

[b]SUHTN: sustained, uncontrolled hypertension.

[c]HC: hypertensive crisis.

Final Models

For each prediction problem, the hyperparameter-tuned models from different modeling frameworks achieved practically equivalent 10-fold cross-validated C-statistics of around 0.71 - 0.72 for the outcome sustained, controlled hypertension and 0.79 - 0.80 for hypertensive crisis, respectively (Table 2). Given that the L2-regularized logistic regression (LR) was a simpler and more computationally efficient framework, we selected the hyperparameter-tuned LR models for training and final validations. Additionally, we examined the relative variable importance in a trained LR model via the magnitude of predictor coefficients and investigated each model's top 10 variables (Table S1 in Multimedia Appendix 1). Notably, increases in systolic BP at index visit, the number of encounters with systolic BP≥140 mm Hg and the number of encounters with BP≥140/90 mm Hg in the past 1 year, age, as well as a prior diagnosis of hypertension and higher ADI ranking, predicted both higher risk of sustained, uncontrolled hypertension and hypertensive crisis.

Table . Optimized hyperparameters and 10-fold cross-validated C-statistics of the hyperparameter-tuned models.

Framework and hyperparameter options[a]		Sustained, uncontrolled hypertension		Hypertensive crisis	
		Optimal value	Cross-validated C-stat (SE)	Optimal value	Cross-validated C-stat (SE)

Internal and Internal-External Validations

In the internal validation dataset, the LR models achieved acceptable discrimination power for predicting sustained, uncontrolled hypertension with a C-statistic of 0.72 (95% CI 0.71 - 0.72), and reasonably good discrimination power for predicting hypertensive crisis with a C-statistic of 0.81 (95% CI 0.79 - 0.82). Both sustained, uncontrolled hypertension and hypertensive crisis models had accurate risk estimates with an ICI of 0.015 (95% CI 0.012 - 0.020) and 0.009 (95% CI 0.007 - 0.011), respectively. Other metrics (E50 and E90) and calibration curves can be examined in Table 3 and Figure 1. Sensitivity, specificity, and predictive values of the final models across potential decision thresholds were also reported in Table S2 in Multimedia Appendix 1. Further, in decision curve analyses, the models demonstrated higher net benefit than treat-all and treat-none policies within the ranges of plausible decision thresholds (Figure 2).

From IECV of the sustained, uncontrolled hypertension model, the pooled estimates were 0.70 (95% CI 0.69 - 0.71) for C-statistic and 0.021 (95% CI 0.016 - 0.026) for ICI; additionally, there was a small or moderate heterogeneity in C-statistic (τ=0.02, 95% CI 0.01 - 0.03, P<.001) and a small heterogeneity in ICI (τ=0.01, 95% CI 0.01 - 0.01, P<.001). From IECV of the hypertensive crisis model, the pooled estimates were 0.79 (95% CI 0.78 - 0.81) for C-statistic and 0.007 (95% CI 0.005 - 0.009) for ICI; across validations, variation in C-statistic was small or moderate (τ=0.01, 95% CI 0.00 - 0.04, P=.004) and variation in ICI was small (τ=0.00, 95% CI 0.00 - 0.01, P=.009).

Table . Discrimination and calibration performance (with 95% CIs) of the final models on training and internal validation datasets.

Model and dataset		Sample size (missing[a]) n	C-stat	ICI[b]	E50	E90
Sustained, uncontrolled hypertension						
	Training	114,317 (7730)	0.71	0.015	0.015	0.030
	Internal validation	28,580 (1959)	0.72 (0.71-0.72)[c]	0.015 (0.011 - 0.020)[c]	0.009 (0.005 - 0.017)[c]	0.040 (0.030 - 0.047)[c]

Discussion

Principal Results

Using a large, diverse (in terms of geography, race, and socioeconomic status) patient cohort in the Greater Charlotte area of the United States, we developed and validated risk models to predict sustained, uncontrolled hypertension and hypertensive crisis occurring within 1 year following an index ambulatory or outpatient encounter in which an uncontrolled BP reading was documented. Internal validation showed discrimination performance that was reasonably good for the hypertensive crisis model and lower but acceptable for the sustained, uncontrolled hypertension model. Overall, both models predicted the risks accurately (calibration performance) in the internal validation dataset and further demonstrated clinical utility through decision curve analyses. Using the existing data, IECV assessed the models' predictive ability with new patient cohorts and showed that the models' overall discrimination and calibration performance across validations were consistent with internal validation results. In addition, across validations, we observed small to moderate variation in discrimination performance and a small variation in calibration performance.

Our findings show that the risk of hypertensive crisis in patients with uncontrolled hypertension can be predicted well. The hypertensive crisis model, in particular, showed satisfactory

performance to serve patients within Atrium Health's North and South Carolina markets, and potentially patients from other nearby areas. Based on the model's internal and internal-external validation performance, it also has the potential to be applicable to other health systems. For our final models to be further validated and used elsewhere, the complete specifications of the models can be found in Table S3 in Multimedia Appendix 1.

Therapeutic inertia (TI), that is, the failure of providers to initiate or intensify medication therapy when patients fail to achieve their treatment goals, is a well-known barrier to better clinical outcomes [27]. Among patients with hypertension, TI contributes to worse short- and long-term BP control [28,29]. While the causes of TI are multifactorial, interventions that include provider and patient education and leverage health care data to guide clinical decision-making at the point of care are promising approaches for reducing TI. Within this context, our prediction models can provide useful data to facilitate clinician-patient discussions on the potential need to intensify medications. Our expectation is that the use of these models will ultimately improve medication adherence and BP control in patients with uncontrolled hypertension. Future studies will be needed to assess the models' clinical impacts to support implementation into routine clinical care.

While models such as ours are becoming increasingly more common as clinical decision support tools, several challenges to implementation can be expected. First, there is a need to continuously monitor for potential drifts from the models' expected behaviors, at regular intervals [30]. This may include monitoring for changes in predictive performance, model usefulness, patient population, and predictor data being applied to the models. Substantial efforts may be required for monitoring, investigation of model issues, and model updating. Additionally, based on the 5 rights of clinical decision support framework (ie, right information, right person, right format, right channel, and right time) other challenges can be foreseen [31]. For example, alert fatigue is an issue where a high volume of alerts can overwhelm users and result in total disregard of the information provided. There is also a need to build clinical trust through proper presentation of the models' facts to end users, such as the approved use case, potential risks and benefits of the model, and validation data on performance and clinical utility. All of these factors require careful attention in implementation studies to guide the proper use of the models in practice.

Our study also found that even with a comprehensive set of EHR-based predictors, predicting sustained, uncontrolled hypertension remains a challenging problem. The marginally acceptable discrimination performance results indicate a need to improve further our ability to predict this outcome. As we already attempted complex machine learning methods and a large sample size, more powerful predictors are needed to improve predictive performance. One future direction is to increase our ability to monitor and collect BP data, as BP-related predictors had relatively large impacts on risk scores. Wearable devices, such as fitness trackers, for example, are increasingly popular and can be used to collect BP data and support BP monitoring and management [32].

Limitations

Our study has several limitations. First, our models, while adequate, have room for improvement by adding important predictor variables that were either unavailable or not considered. For example, modifiable risk factors, such as lifestyle behaviors, medication adherence, and medication dosing, are known to be associated with BP control, but these data were either not accessible from the EHR or came from unstructured data sources (eg, clinical notes), which can be challenging to process for prediction. Second, because patients without a BP reading in the prediction window were excluded, and models can only be developed and validated for patients who had some follow-up BP measurements, there is a risk for bias. Fortunately, a relatively small number of patients had no BP reading during the follow-up period, thus, the extent of bias, if any, can be deemed minor. Third, the models were developed for patients on 4 or less antihypertensive drug classes and may not generalize beyond this patient group. Fourth, additional prospective studies are needed to understand how our models would perform when implemented in real-world clinical settings.

Comparison With Prior Work

Our study presented novel applications of predictive modeling to the area of hypertension management. From a design perspective, the prediction outcomes, targeted patient cohort, and intended use case were carefully chosen to optimize models' usefulness for managing hypertension. We noted that while little research was performed about predicting clinically important hypertension states in patients with hypertensiveness, a much larger amount of literature was devoted toward predicting hypertension onset in the general population [11-13]. Comparing with other hypertension prediction studies, ours made use of a relatively diverse set of predictors, including EHR-based data that were not often considered, such as usage of different health services, drug classes prescribed, and social determinants of health [11]. In terms of performance, the C-statistics in our models were similar to those from existing prediction models of hypertension onset, which were between 0.63 - 0.84 according to a meta-analysis [11]. A more recent, published prediction model of uncontrolled hypertension demonstrated a C-statistics of 0.76 [16]. Finally, a large and geographically diverse patient sample allowed us to assess (weak) generalizability through IECV, as well as to assess internal validity with confidence. In contrast, the vast majority of hypertension prediction studies were only internally validated and had smaller sample sizes [11].

Conclusions

We developed and validated risk models for sustained, uncontrolled hypertension, and hypertensive crisis, within 1 year of an index visit showing an uncontrolled BP reading. The hypertensive crisis risk model showed good predictive performance with internal validation and new patient cohorts during IECV. This model could be prospectively validated as a next step. If validity and clinical utility are confirmed, it could then be used within our health system, and potentially elsewhere, as a public health surveillance tool for early detection of hypertensive crises and for supporting physicians with treatment decisions. Further efforts are required to improve the ability to

predict sustained, uncontrolled hypertension, particularly by adding and improving predictor variables.

Authors' Contributions

YT supervised this study. YT, AM, HMN, WA, SHC, JZ, and NP conceptualized this study. HMN, WA, SHC, and JZ developed the statistical analysis plan and performed formal analysis. HMN prepared the first draft of this paper. HMN, WA, SHC, AM, YT, JZ, and NP reviewed and edited this paper.

Abstract

Background: Increasing and substantial reliance on electronic health records (EHRs) and data types (ie, diagnosis, medication, and laboratory data) demands assessment of their data quality as a fundamental approach, especially since there is a need to identify appropriate denominator populations with chronic conditions, such as type 2 diabetes (T2D), using commonly available computable phenotype definitions (ie, phenotypes).

Objective: To bridge this gap, our study aims to assess how issues of EHR data quality and variations and robustness (or lack thereof) in phenotypes may have potential impacts in identifying denominator populations.

Methods: Approximately 208,000 patients with T2D were included in our study, which used retrospective EHR data from the Johns Hopkins Medical Institution (JHMI) during 2017 - 2019. Our assessment included 4 published phenotypes and 1 definition from a panel of experts at Hopkins. We conducted descriptive analyses of demographics (ie, age, sex, race, and ethnicity), use of health care (inpatient and emergency room visits), and the average Charlson Comorbidity Index score of each phenotype. We then used different methods to induce or simulate data quality issues of completeness, accuracy, and timeliness separately across each phenotype. For induced data incompleteness, our model randomly *dropped* diagnosis, medication, and laboratory codes independently at increments of 10%; for induced data inaccuracy, our model randomly *replaced* a diagnosis or medication code with another code of the same data type and induced 2% incremental change from −100% to +10% in laboratory result values; and lastly, for timeliness, data were modeled for induced *incremental shift* of date records by 30 days to 365 days.

Results: Less than a quarter (n=47,326, 23%) of the population overlapped across all phenotypes using EHRs. The population identified by each phenotype varied across all combinations of data types. Induced incompleteness identified fewer patients with each increment; for example, at 100% diagnostic incompleteness, the Chronic Conditions Data Warehouse phenotype identified zero patients, as its phenotypic characteristics included only diagnosis codes. Induced inaccuracy and timeliness similarly demonstrated variations in performance of each phenotype, therefore resulting in fewer patients being identified with each incremental change.

Conclusions: We used EHR data with diagnosis, medication, and laboratory data types from a large tertiary hospital system to understand T2D phenotypic differences and performance. We used induced data quality methods to learn how data quality issues may impact identification of the denominator populations upon which clinical (eg, clinical research and trials, population health evaluations) and financial or operational decisions are made. The novel results from our study may inform future approaches to shaping a common T2D computable phenotype definition that can be applied to clinical informatics, managing chronic conditions, and additional industry-wide efforts in health care.

Introduction

Type 2 diabetes (T2D) is a common chronic disease affecting more than 11% of the US population [1]. Given the rapidly increasing burden of T2D on health care services and resources, health systems have devised strategies to address such demands by identifying and managing T2D patients across their populations [1]. However, despite clinical guidelines to identify T2D at the point of care, identifying T2D patients in large clinical repositories is still a challenge [2]. Ambiguity of algorithms to identify T2D patients in complex data sets and

data quality issues in routine clinical data sources such as electronic health records (EHRs) are still hindering the development of generalizable approaches to identify T2D patients across different health systems.

Over the last two decades, several approaches have been developed for health care professionals to identify patients with T2D in large clinical data repositories. Multiple T2D phenotype definitions (also known as computational algorithms) are available that define characteristics to identify T2D populations. Some examples of T2D definitions include the Surveillance, Prevention, and Management of Diabetes Mellitus (SUPREME-DM) [3], the Centers for Medicare and Medicaid Services (CMS) Chronic Conditions Data Warehouse (CCW) [4], the Electronic Medical Records and Genomics (eMERGE) Northwestern Group [5], and the Durham Diabetes Coalition (DDC) [6] phenotypes. Each phenotype definition has its own set of inclusion and exclusion criteria using different data types. Data types may include *International Statistical Classification of Diseases, Tenth Edition* (*ICD-10*) diagnosis codes, RxNorm medication codes, and Logical Observation Identifiers Names and Codes (LOINC) laboratory codes, with sequences and frequencies of occurrences of diagnosis, medication and laboratory codes; defined time periods; and care pathways. However, despite these detailed definitions, it is unclear which of the existing T2D phenotypes are prone to inherit data quality issues from clinical data sources such as EHRs. The uncertainty of T2D phenotypes' performance for identifying populations with T2D using real-world data has led to the lack of a universally agreed-upon T2D phenotype.

The concept of data quality in health care varies based on the problems and functional needs of end users. Health care providers, data scientists, or policy makers may differ in their approach to data quality and its significance in practice [7]. Typically, health care data such as captured in EHRs are collected for continuity of clinical care, coding, and billing purposes, and not necessarily to answer specific research questions. Thus, the quality of data collected in EHRs may be sufficient for clinical purposes but may not meet the needs of a researcher or population health intervention. For example, a clinician may identify a patient with T2D at the point of care despite having incomplete data; however, a T2D phenotyping algorithm may miss the same patient in a large EHR data warehouse due to the underlying data quality issues; hence, the patient may inadvertently be excluded from a research study or population health intervention.

Various data quality frameworks have been proposed to measure the quality of health care data. Completeness, accuracy, and timeliness are a few key data quality characteristics that are used across several frameworks [7-9]. The assessment for completeness defines how complete the data are, what the missing elements are, and how usable the data are in their "as is" format. Accuracy is the correctness and consistency of the data elements [8], and timeliness is how recent or current the data are for research and analysis. The assessment of data quality in health care is crucial with the continuous and prominent use of EHRs; however, despite the increasing use of EHR data to identify patients with T2D, the effect of varying levels of key data quality characteristics (ie, completeness, accuracy, and timeliness) on T2D phenotypes is still unknown.

The ongoing challenge of understanding the effect of key data quality issues on T2D phenotypes is further exacerbated by the fact that T2D phenotypes use multiple data types, such as diagnosis codes, medications, and laboratory results. Additionally, given the variability of key data quality issues of these data types across EHRs [10,11], measuring the effect of key existing data quality issues on T2D phenotypes in one EHR may not translate into generalizable findings. For example, one provider's EHR may suffer from incompleteness of diagnosis codes, while another provider's EHR may be affected by inaccurate medication data. Thus, to measure the effect of an EHR's data quality on T2D phenotypes, varying (simulated) levels of key data quality characteristics across all data types (ie, diagnosis, medication, and laboratory) used by T2D phenotypes should be studied. These simulated levels of key data quality issues will in turn help providers to compare their EHR data quality issues with the simulated levels, contrast the potential impact of such data quality issues on identifying T2D patients using various phenotypes, and eventually select the most suitable T2D phenotype for their EHR data.

Currently, evidence is lacking on the effect of data quality issues (eg, completeness, accuracy, and timeliness) and the identification of T2D populations in large clinical data sources such as EHRs. This gap in evidence is further amplified given the variations in characteristics of published T2D phenotypes and potential discrepancies in underlying data types (ie, diagnosis, medication, and laboratory) in EHRs. To address these gaps, our study aimed to assess the impact of varying (simulated) levels of data quality issues across the different data types used by T2D phenotypes. Our study findings can inform health care providers and other stakeholders to select T2D phenotype algorithms that best match their underlying EHR data quality issues.

Methods

Data Source

Our cross-sectional study used retrospective EHR data from the Johns Hopkins Medical Institute (JHMI) data warehouse over a 3-year period from 2017 to 2019. Clinical data included T2D primary diagnostic data (*ICD-10*), laboratory data (LOINC), and medication data (RxNorm). The demographic data included age, sex, race, ethnicity, and the patients' residential state.

Study Population

Our overall study population included approximately 208,000 patients in age groups of 18 to 90 years. This population denominator was identified and extracted in a prior study focusing on T2D patients and funded by the US Food and Drug Administration (5U01FD005942-05). This population denominator, also known as the raw data cut, was identified by the most inclusive query of the JHMI's EHR data warehouse, which also included patients with mentions of diabetes in their clinical notes. Each of the identified T2D phenotypes was applied to the overall study population. At total of approximately

164,000 patients were included in at least one of the T2D phenotypes assessed.

Considering the size of the EHR data set, and given the impracticality of reviewing the individual records of almost a quarter of a million patients, no gold standard population was identified for this research. Indeed, the aim of this research study was not to assess the accuracy of the common T2D phenotypes; instead, we aimed to measure the performance of T2D phenotypes given the underlying data quality issues in EHR data repositories.

T2D Phenotype Definitions

Our assessment included 4 published T2D phenotype definitions, from the CCW, DDC, SUPREME-DM, and eMERGE, as well as 1 unpublished definition (Johns Hopkins University; JHU). Since not all T2D phenotype definitions were defined with the most current *ICD* codes, we converted the DDC, SUPREME-DM, and eMERGE diagnostic phenotypes from *ICD-9* to *ICD-10* [12]. Additionally, not all phenotype definitions using medications had the list of specific RxNorm codes (eg, the DDC and SUPREME-DM phenotypes included only the names of the T2D medication and not the codes). We identified the RxNorm codes for each medication using the National Library of Medicine's RxNav tool [13]. For the purposes of this study, we selected only those RxNorm codes that were associated with the primary ingredient or ingredients of the medication name in the T2D phenotype definition.

Of the 4 published T2D phenotypes, CCW only included diagnosis codes with a reference period of 2 years in the definition. The DDC, SUPREME-DM, and eMERGE phenotypes included a series of detailed care pathways with diagnosis, medication, and laboratory codes and results within specified time periods. However, the unpublished definition from JHU did not have pathways and was the most inclusive definition, as it included all data types (diagnosis, medication, and laboratory) with wide eligibility criteria to identify patients with T2D.

Factors Affecting T2D Phenotyping

The data included demographics, T2D-related data types (ie, diagnosis, medication, and laboratory), and the Charlson Comorbidity Index [14]. The demographic data included age, sex (male, female, and other), race (White, Black, Asian, and other), ethnicity (Hispanic/Latino or non-Hispanic/Latino) and patient location (state of Maryland or other locations). The "other" category for sex, race, and ethnicity was primarily composed of missing data entries. Since the JHMI is in Baltimore, Maryland, the majority (169,215/207,813, 81.4%) of our study population was from Maryland and the remainder (38,598/207,813, 18.6%) was from the surrounding states. The outcome measures included the extent of overlap in identifying patients with T2D and the degree of robustness against data quality issues across phenotypes.

Statistical Analysis

We performed descriptive data analyses across the 5 different phenotypes to identify EHR populations with T2D. We used the χ^2 test for categorical variables and ANOVA for continuous variables. Our analysis included distribution and overlap of the population of interest by diagnosis, medication, and laboratory data types across each of the 5 T2D phenotypes. We introduced methods that simulated or induced data incompleteness, inaccuracy, and lack of timeliness (eg, date shifting) to assess the robustness of each phenotype in capturing the populations of interest. We created unique analytical functions for each data quality issue considering the data types that were applicable across all T2D phenotypes.

To simulate or induce data incompleteness, our procedure randomly dropped codes at 10% increments, from 0% to 100%, for diagnosis, medication, and laboratory codes within each of the T2D phenotypes. Incompleteness was simulated up to 100% as no thresholds of data missingness were known to affect the performance of T2D phenotypes beforehand. Incompleteness was induced for diagnosis, medication, or laboratory codes independently of the other 2 data types. For each increment of incompleteness, T2D phenotypes were reapplied to identify a new (and logically smaller) cohort of patients.

To gauge the impact of inconsistency and inaccuracy in our denominator population for each T2D phenotype, the diagnosis and medication codes were replaced at random at increments of 10% (the same as for incompleteness) from 0% to 100% with another code of the same data type, including T2D and non-T2D codes. We included T2D codes to illustrate expected data quality issues that may impact the phenotypes' performance. For example, 10% of instances of the *ICD-10* diagnosis code E08 (ie, diabetes mellitus due to underlying condition) were replaced at random with the *ICD-10* code E09 (ie, drug- or chemical-induced diabetes mellitus—endocrine, nutritional, or metabolic disease). For laboratory codes, the laboratory values were induced with a 2% incremental change from −100% to 10% in laboratory results. For example, our procedure for simulated or induced laboratory values yielded results of 5.6% to 5.8% for hemoglobin A_{1c} (LOINC code 55454‐3). Additionally, we simulated or induced inaccuracy in units of laboratory data results. We did this by intentionally converting reported laboratory units from US standards to UK standards; in particular, blood glucose level units in mg/dl were converted to mmol/L, and hemoglobin A_{1c} level from percentage to mmol/mol [15].

For timeliness, we simulated or induced date shifts at increments of 30 to 365 days for all phenotypes. For example, our procedure induced a forward shift on December 1, 2019, by 30 days, shifting the date to December 31, 2019, and so on. Lastly, we also induced compounded data quality issues (incompleteness, inaccuracy, and lack of timeliness) to understand each phenotype's resistance to changes that occurred across diagnosis, medication, and laboratory codes simultaneously. Induced compounded incompleteness would mean dropping diagnosis, medication, and laboratory codes randomly at increments of 10% up to 100%. Induced compounded inaccuracy would mean replacing diagnosis and medication codes randomly at increments of 10% up to 100% (laboratory codes were not replaced; their values were manipulated instead). Induced compounded lack of timeliness would mean inducing date shifts

across diagnosis, medication, and laboratory codes at increments of 30 to 365 days.

SQL queries were written for data extraction. All visualizations and statistical analyses were conducted using R (version 4.2.0; R Foundation for Statistical Computing) [16]. The overall findings are showcased as descriptive data tables, Venn diagrams, and line charts depicting the effect of simulated or induced data quality issues on identifying T2D populations using the common T2D phenotype definitions.

Ethical Considerations

This study was reviewed and approved by the IRB committee of the Johns Hopkins School of Public Health (00014440). The deidentified population denominator used in this study is from a prior study funded by the US Food and Drug Administration (5U01FD005942-05).

Results

Characteristics of the Overall and Phenotype-Identified T2D Populations

Our overall study population included 207,813 patients with T2D from between 2017 and 2019 in the JHMI EHR data. For the purposes of this analysis, we refer to this population as the raw data cut or the overall study population/denominator. The mean age of the overall study population was 62.4 (SD 15.4) years, with 81.4% (n=169,215) of the population residing in the state of Maryland. Women accounted for 51.3% (n=106,704) of the study population, with 31.8% (n=66,073) Black patients and 89.9% (n=186,785) non-Hispanic/Latino patients. The overall population had a mean number of 0.657 (SD 1.61) inpatient visits and 1.01 (SD 3.61) emergency department visits across the study duration. The mean Charlson Comorbidity Index score was 2.17 (SD 2.25). Table 1 shows the overall characteristics of the study population.

Table . Characteristics of the overall study population (N=207,813).

Characteristics		Values
Age (years)

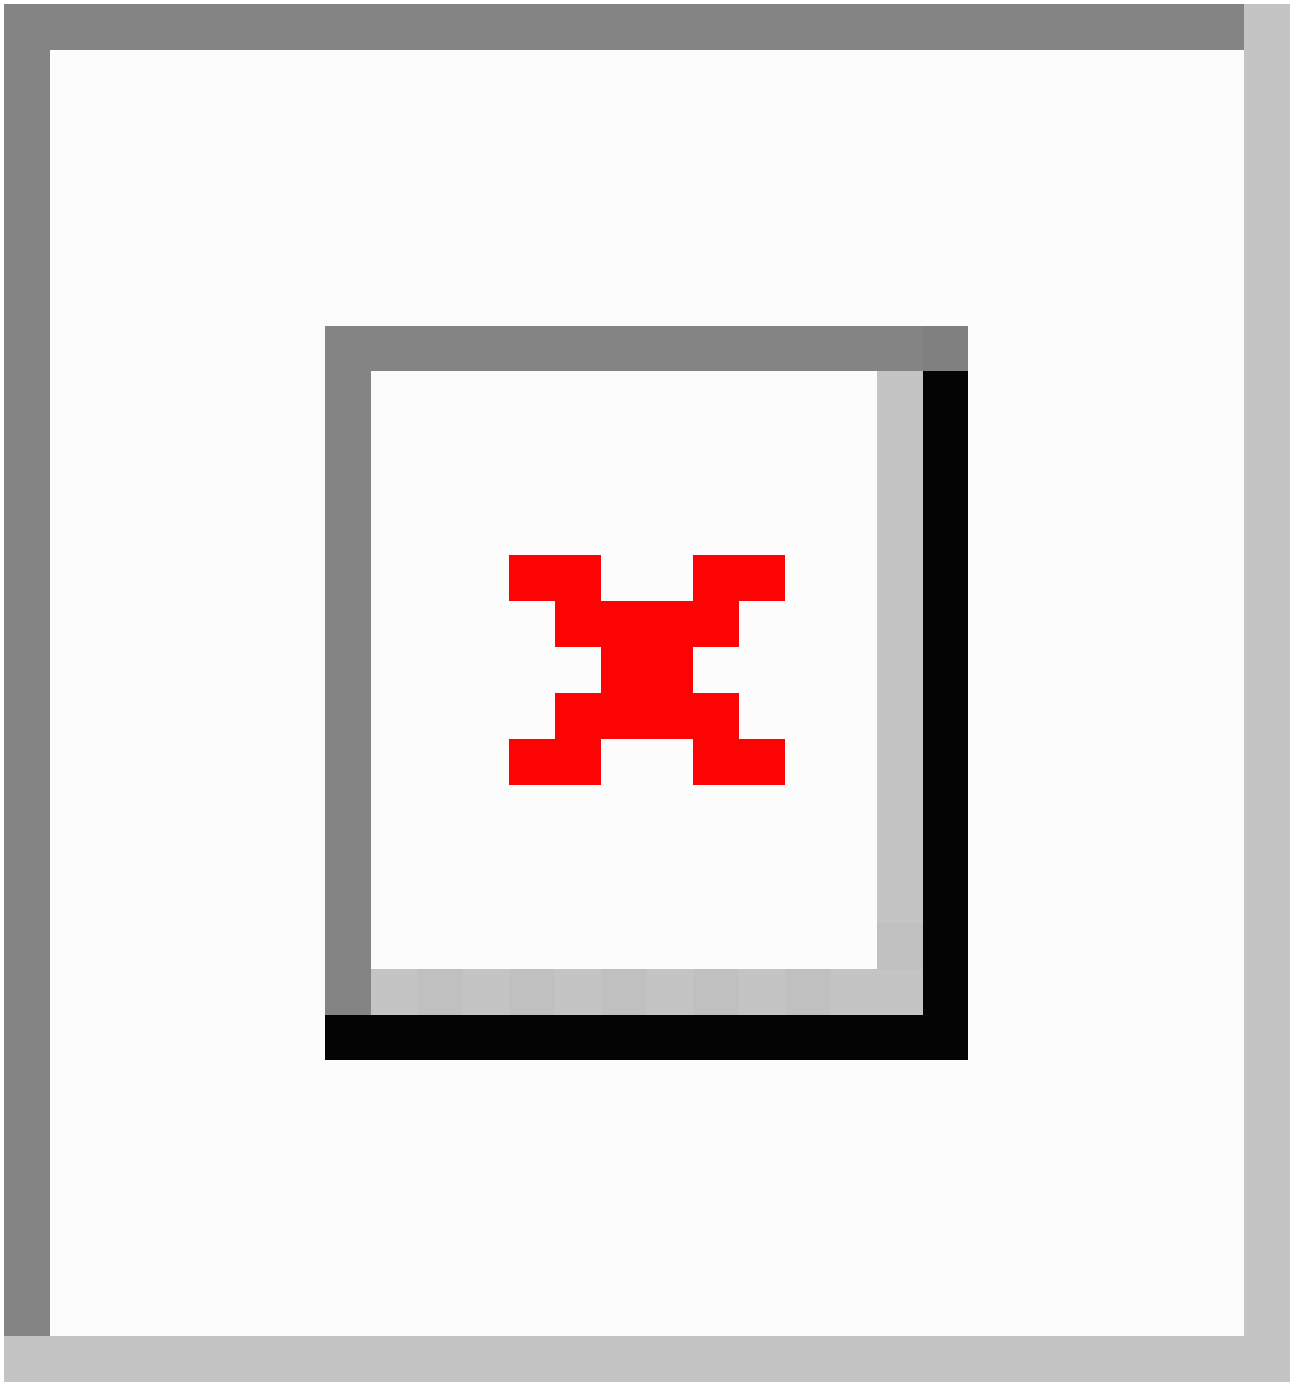
T2D phenotypes were applied to the overall study population. The characteristics of the population identified by each phenotype were notably different due to the phenotypes' varying constraints on medical events and diagnosis, medication, and laboratory codes. The Venn diagram displayed in Figure 1 shows the overlap of the population with T2D across the phenotypes in comparison to the overall study population (ie, the largest, gray circle denotes the raw data cut). These T2D populations were identified using all EHR data types (diagnosis, medication, and laboratory) as needed by the T2D phenotypes. A total of 78% (n=160,030 patients) of the overall study population was identified by at least 1 phenotype, but only 23% (n=47,326) of the overall study population was identified by all T2D phenotypes. DDC identified 139,832 patients with T2D, of which 11,154 (7.98%) were not identified by the other 4 phenotype definitions. Of the 89,772 patients with T2D identified by SUPREME-DM, there were 5911 (3%) patients with T2D that were also identified by the DDC and JHU phenotypes. Additionally, 23,659 (12%) patients were identified by all phenotypes except eMERGE. Additional details of population overlap counts are available in Multimedia Appendix 1, Table S1.

Figure 1. Venn diagram showing overlap of type 2 diabetes populations identified across all phenotype definitions using electronic health record data. CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus; eMERGE: Electronic Medical Records and Genomics.



The distributions of T2D populations identified across phenotype definitions by diagnosis, medication, and laboratory data types were separately calculated (Table 2). The SUPREME-DM phenotype identified the most patients (n=33,268) across all 3 data types, followed by eMERGE with 30,573 patients. Zero patients were observed for some phenotypes when using specific data types. The zero observations were due to the representation of the data types as defined by the criteria of each phenotype definition. For example, the eMERGE phenotype does not have a pathway to identify a patient with T2D based on diagnosis code only, medication code only, or medication and laboratory codes only. Hence, we observed zero patients with diagnosis only, medication only, or medication and laboratory only for eMERGE (Table 2). In the case of CCW, since the phenotype does not include medication or laboratory codes in its definition, zero patients were observed when medication or laboratory codes were required for the identification of T2D patients (Table 2).

We measured the effect of simulated or induced data quality issues of completeness, accuracy, and timeliness for diagnosis, medication, and laboratory data across all T2D phenotypes. The following results include the percentage of patients identified by each phenotype while simulating data quality issues using diagnosis codes. Figures S1 to S3 in Multimedia Appendix 1 show the same diagnosis results but depict the frequency of patients identified by each phenotype. Figures S4 to S17 in Multimedia Appendix 1 show results as the percentages and frequencies of patients identified by each phenotype while simulating data quality issues using medication and laboratory data types.

Table . Distribution of type 2 diabetes (T2D) populations identified by T2D phenotype definitions using different combinations of data types.

Data type	DDC[a] (n=139,832), n	SUPREME-DM[b] (n=89,772), n	eMERGE[c] (n=77,977), n	JHU[d] (n=139,231), n	CCW[e] (n=79,967), n
Diagnosis	40,133	15,983	0	75,027	79,967

Data Quality Issues

Completeness

To depict the impact of the simulated or induced incompleteness of diagnosis codes on the identified population using the T2D phenotypes, Figure 1 was recreated at increasing levels of data incompleteness (Figure 2). As the percentage of induced missing diagnosis codes increased, the size of the T2D population identified by each phenotype decreased. The CCW phenotype saw the largest decline in the identified population with increasing incompleteness. At 100% induced incompleteness, there were no T2D patients identified by CCW, as the CCW phenotype relies entirely on diagnosis codes for the identification of T2D patients. Lastly, the eMERGE, SUPREME-DM, DDC, and JHU phenotypes continued to identify patients with T2D despite 100% incompleteness of diagnosis codes (Figure 2).

Figure 3 shows the decrease in the percentage of T2D population identified by each phenotype when diagnostic incompleteness was induced from 0% to 100%, that is, diagnosis codes from the *ICD-10* were dropped in increments of 10%. All phenotype definitions showed a similar decrease in the percentage of patients from 0% to approximately 80% of diagnostic incompleteness. The eMERGE and CCW phenotypes saw significant declines in T2D population sizes when the induced incompleteness increased from 80% to 100%. At 100% incompleteness, CCW identified no patients and eMERGE identified only 21% (16,348/77,977) of the patients with T2D, consistent with Table 2 and Figure 2.

Figure 2. Overall population identified by each of the type 2 diabetes phenotype definitions when diagnosis codes were dropped from 20% to 100% to simulate increasing incompleteness of diagnosis codes. CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; eMERGE: Electronic Medical Records and Genomics; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus.

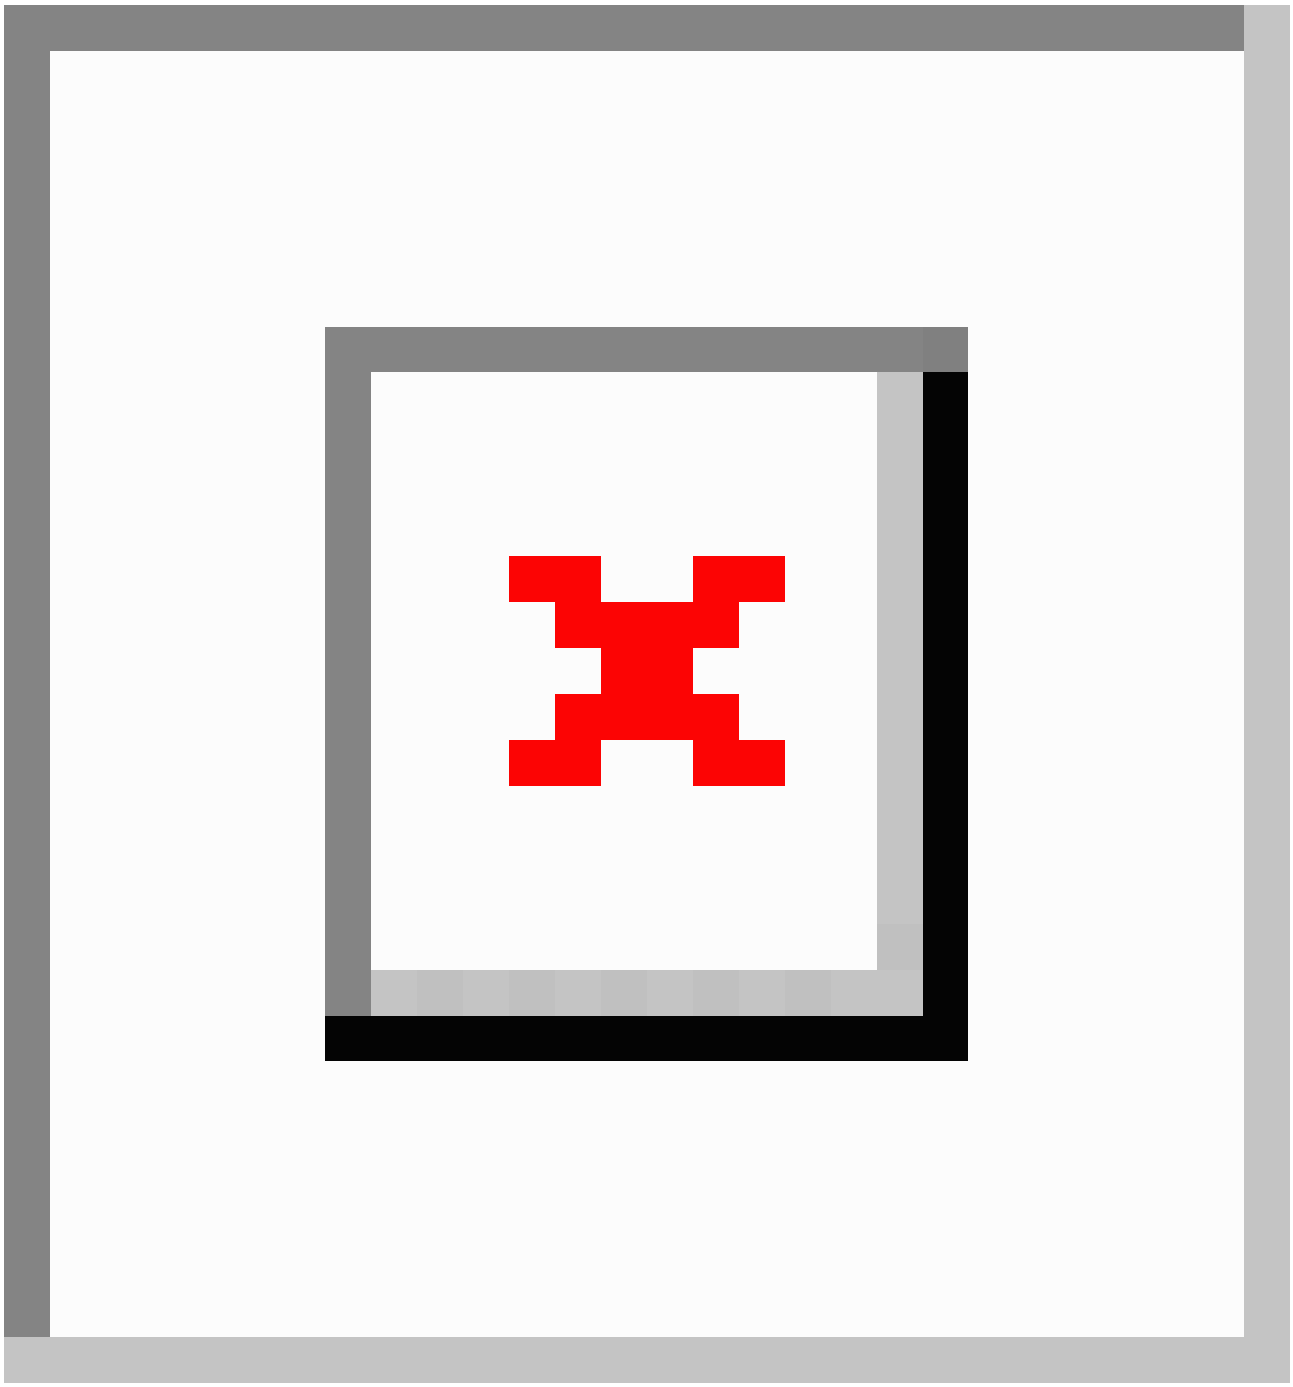

Figure 3. Percent of type 2 diabetes population identified by each type 2 diabetes phenotype definition with increasing incompleteness of diagnosis codes. CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; eMERGE:lectronic Medical Records and Genomics; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus.

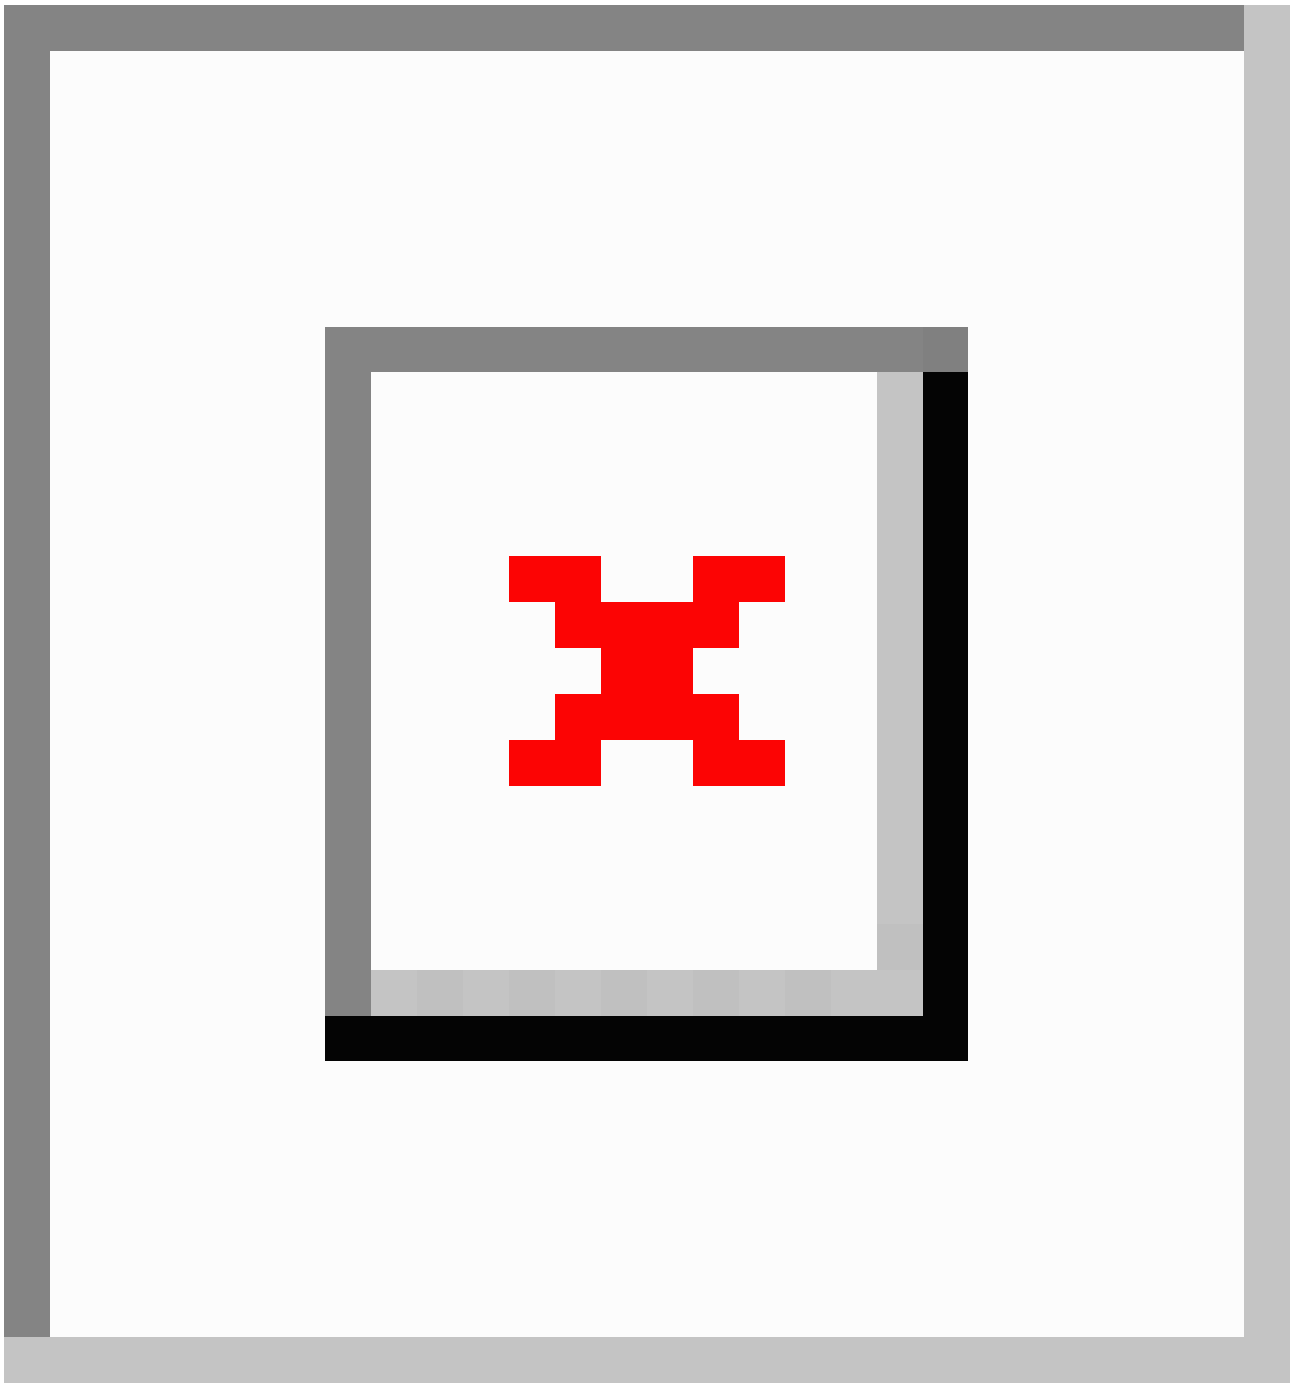

Accuracy

Figures 4 and 5 show the overlap and percentages, respectively, of T2D populations identified by each phenotype definition with an increasing percentage of induced replacement of diagnosis codes at random. All phenotype definitions were impacted and continued to identify populations with T2D even with 100% induced inaccuracy despite reductions overall. The CCW, SUPREME-DM, and eMERGE phenotypes showed the greatest decrease when 75% - 100% of the diagnosis codes were replaced, resulting in identification of only 27% - 45% of the patients with T2D.

Figure 4. Overall population identified by each of the type 2 diabetes phenotype definitions when diagnosis codes are replaced at random to simulate increasing diagnostic inaccuracy. CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; eMERGE: Electronic Medical Records and Genomics; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus.

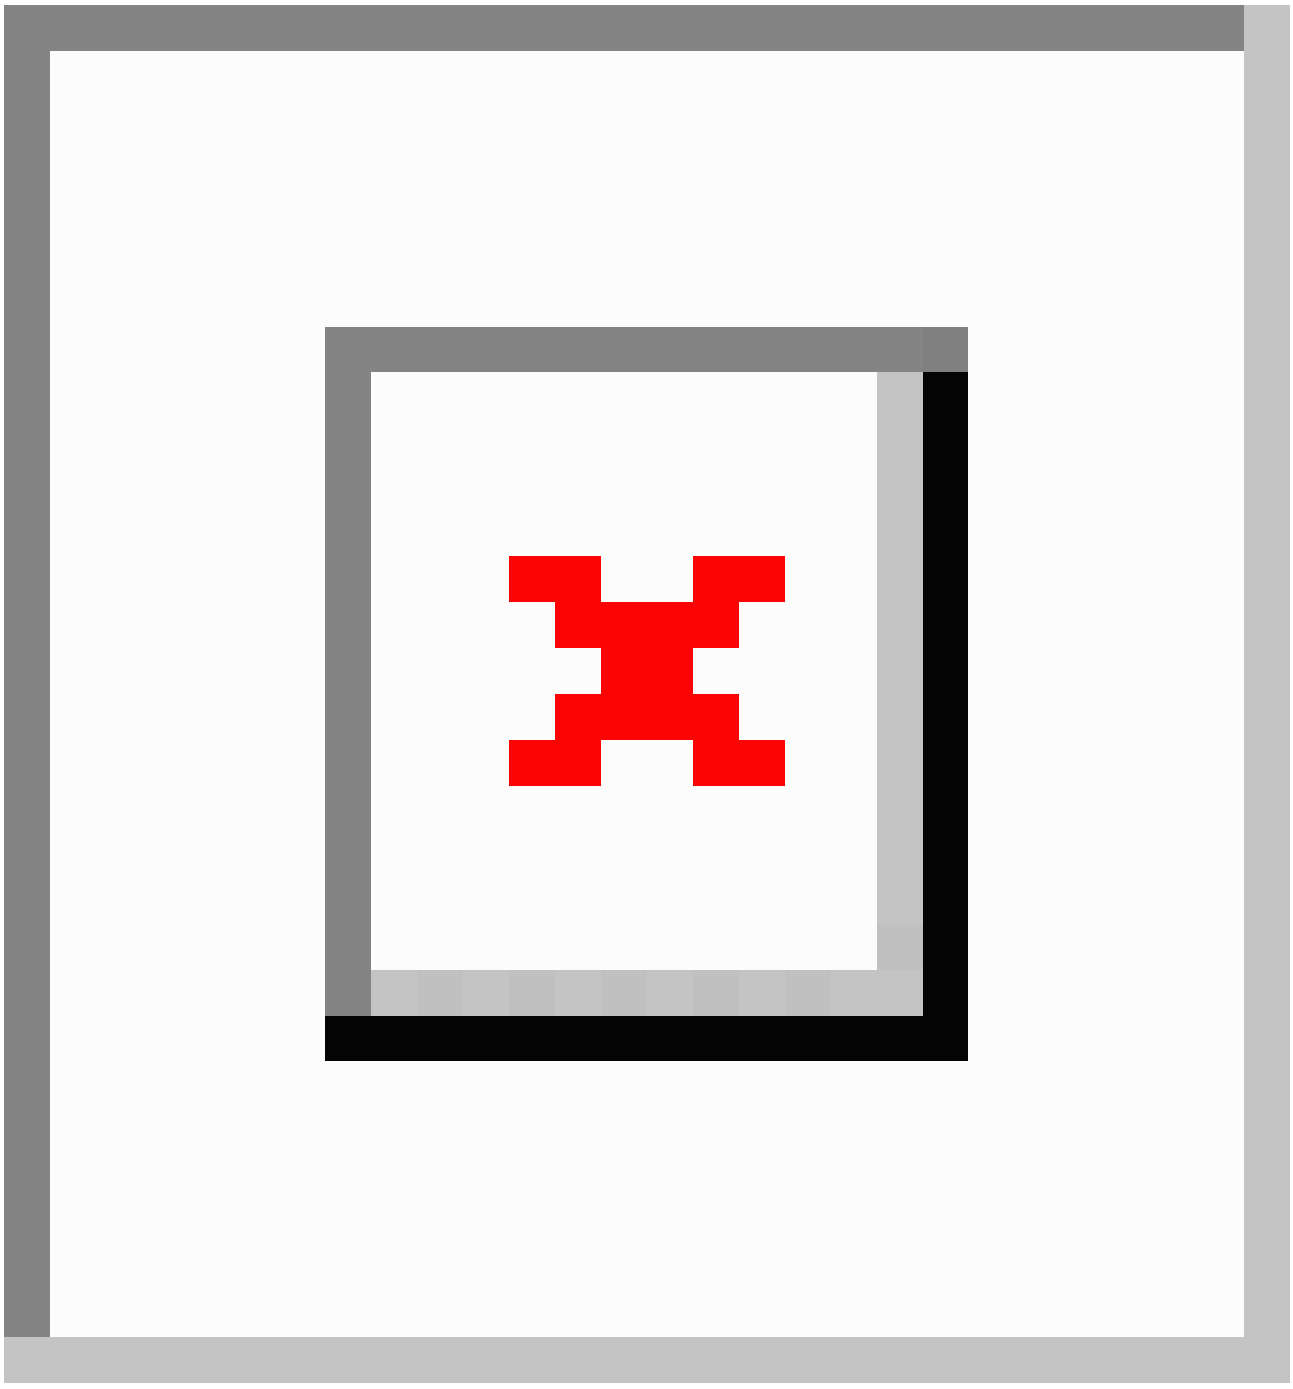

Figure 5. Percentage of type 2 diabetes population identified by each type 2 diabetes phenotype definition with increasing inaccuracy of diagnosis codes. CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; eMERGE: Electronic Medical Records and Genomics; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus.

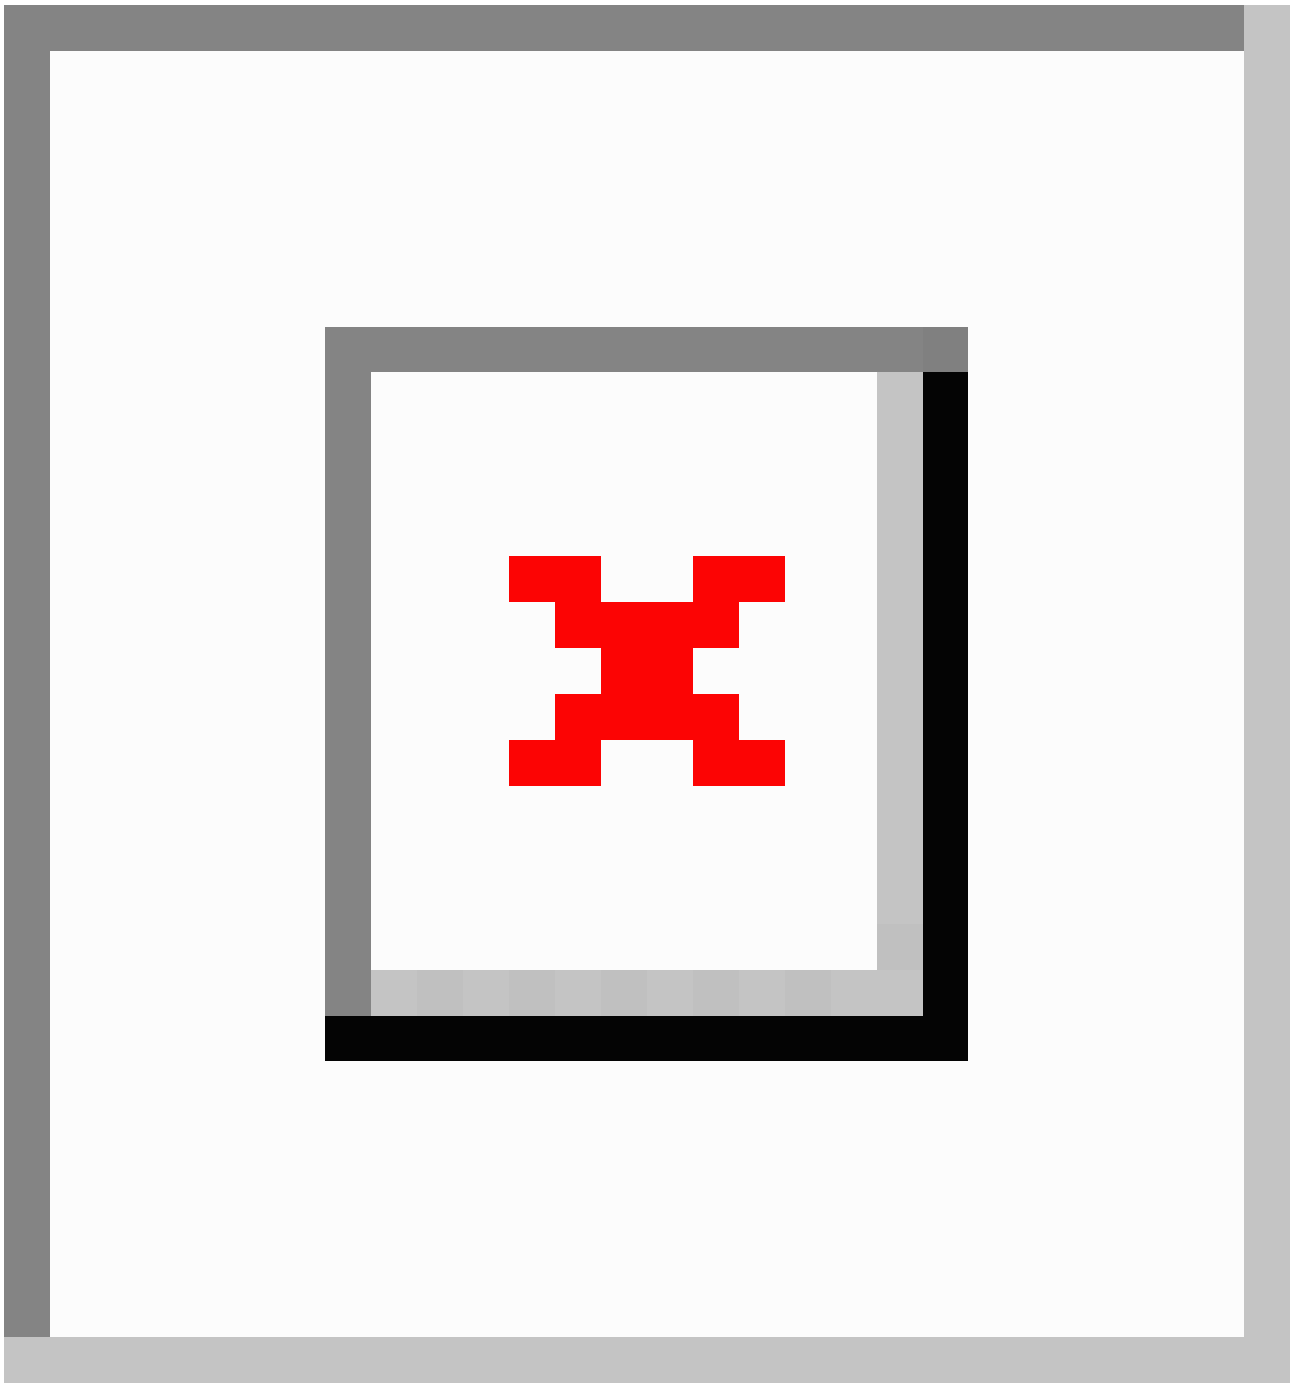

Timeliness

All T2D phenotypes were similarly impacted by simulated or induced shifts in the date of recorded diagnosis from 30 days to 365 days. The patterns of overlap in population were similar across all phenotypes with each incremental date shift (Figure 6). The percentage of patients identified with T2D showed a decrease over time, however, with at least 85% (176,641/207,813) of the patients with T2D identified during the progression of a year across all phenotypes. The data quality issue of timeliness showed the least impact in the DDC phenotype (Figure 7).

Figure 6. Overall population identified by each of the type 2 diabetes phenotype definitions with shifts in timeliness of diagnostic data ranging from 30 to 365 days. CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; eMERGE: Electronic Medical Records and Genomics; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus.

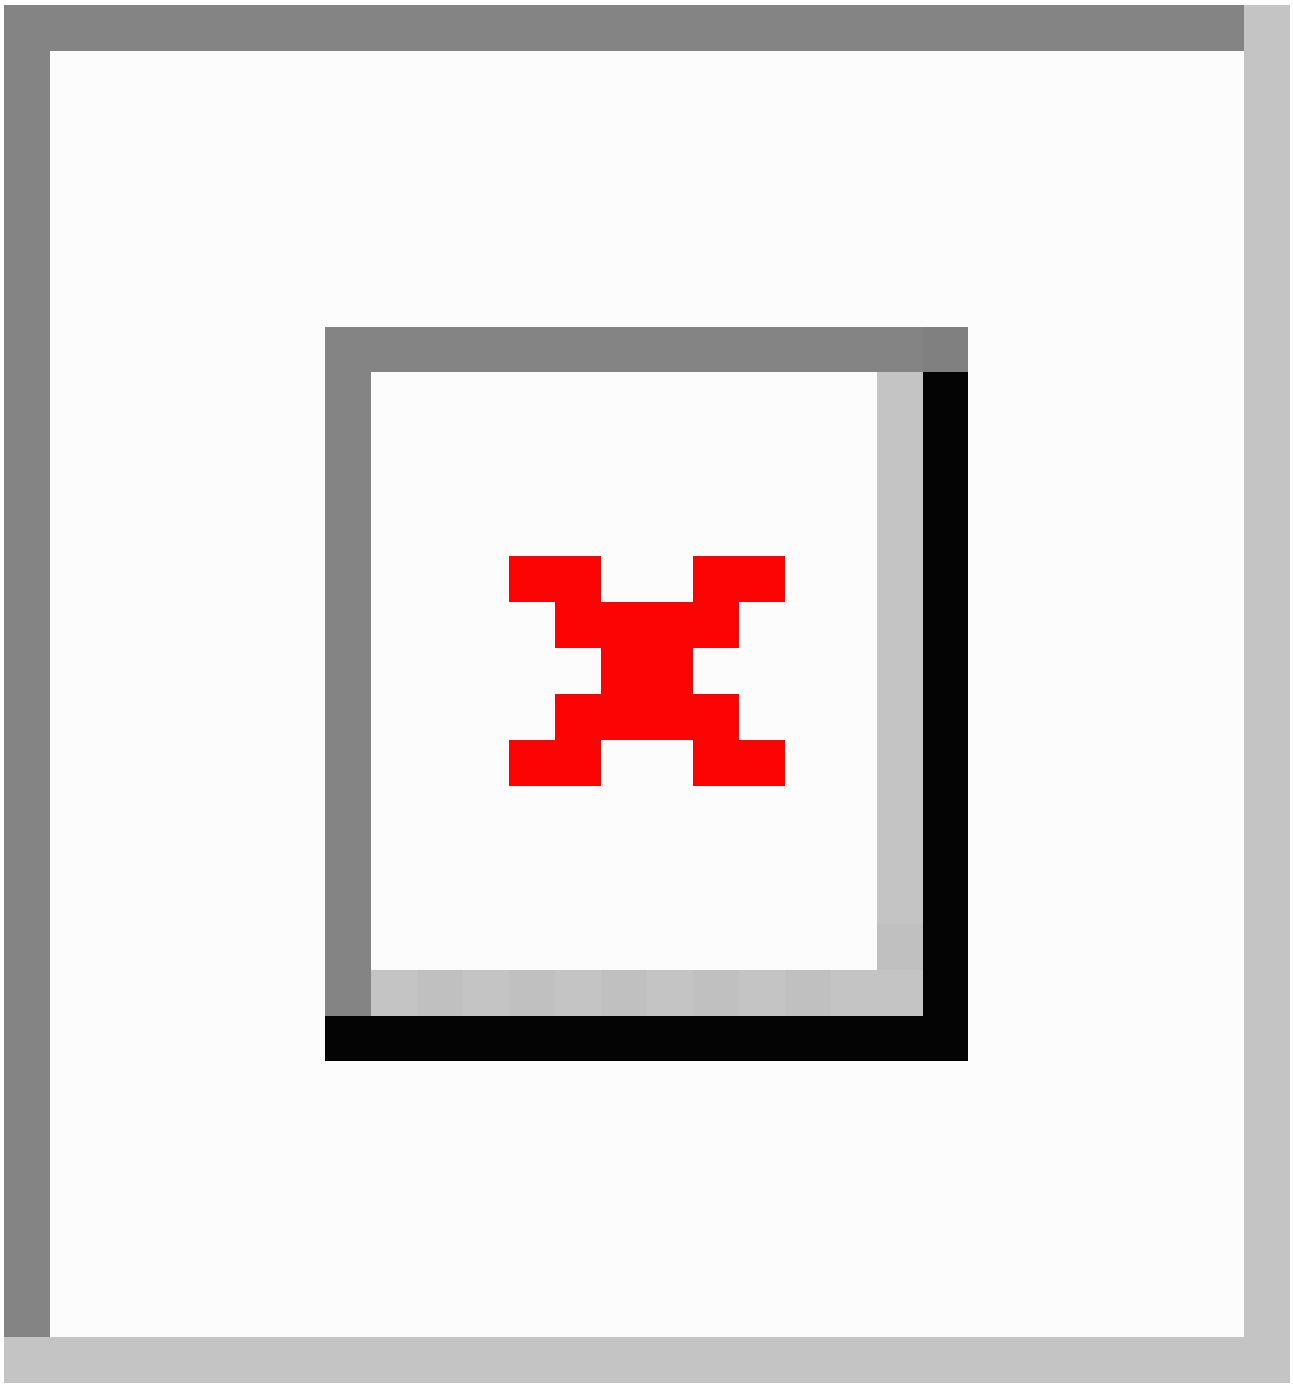

Figure 7. Percentage of type 2 diabetes population identified by each type 2 diabetes phenotype definition with an increasing shift in diagnostic timeliness (ie, number of days shifted). CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; eMERGE: Electronic Medical Records and Genomics; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus.

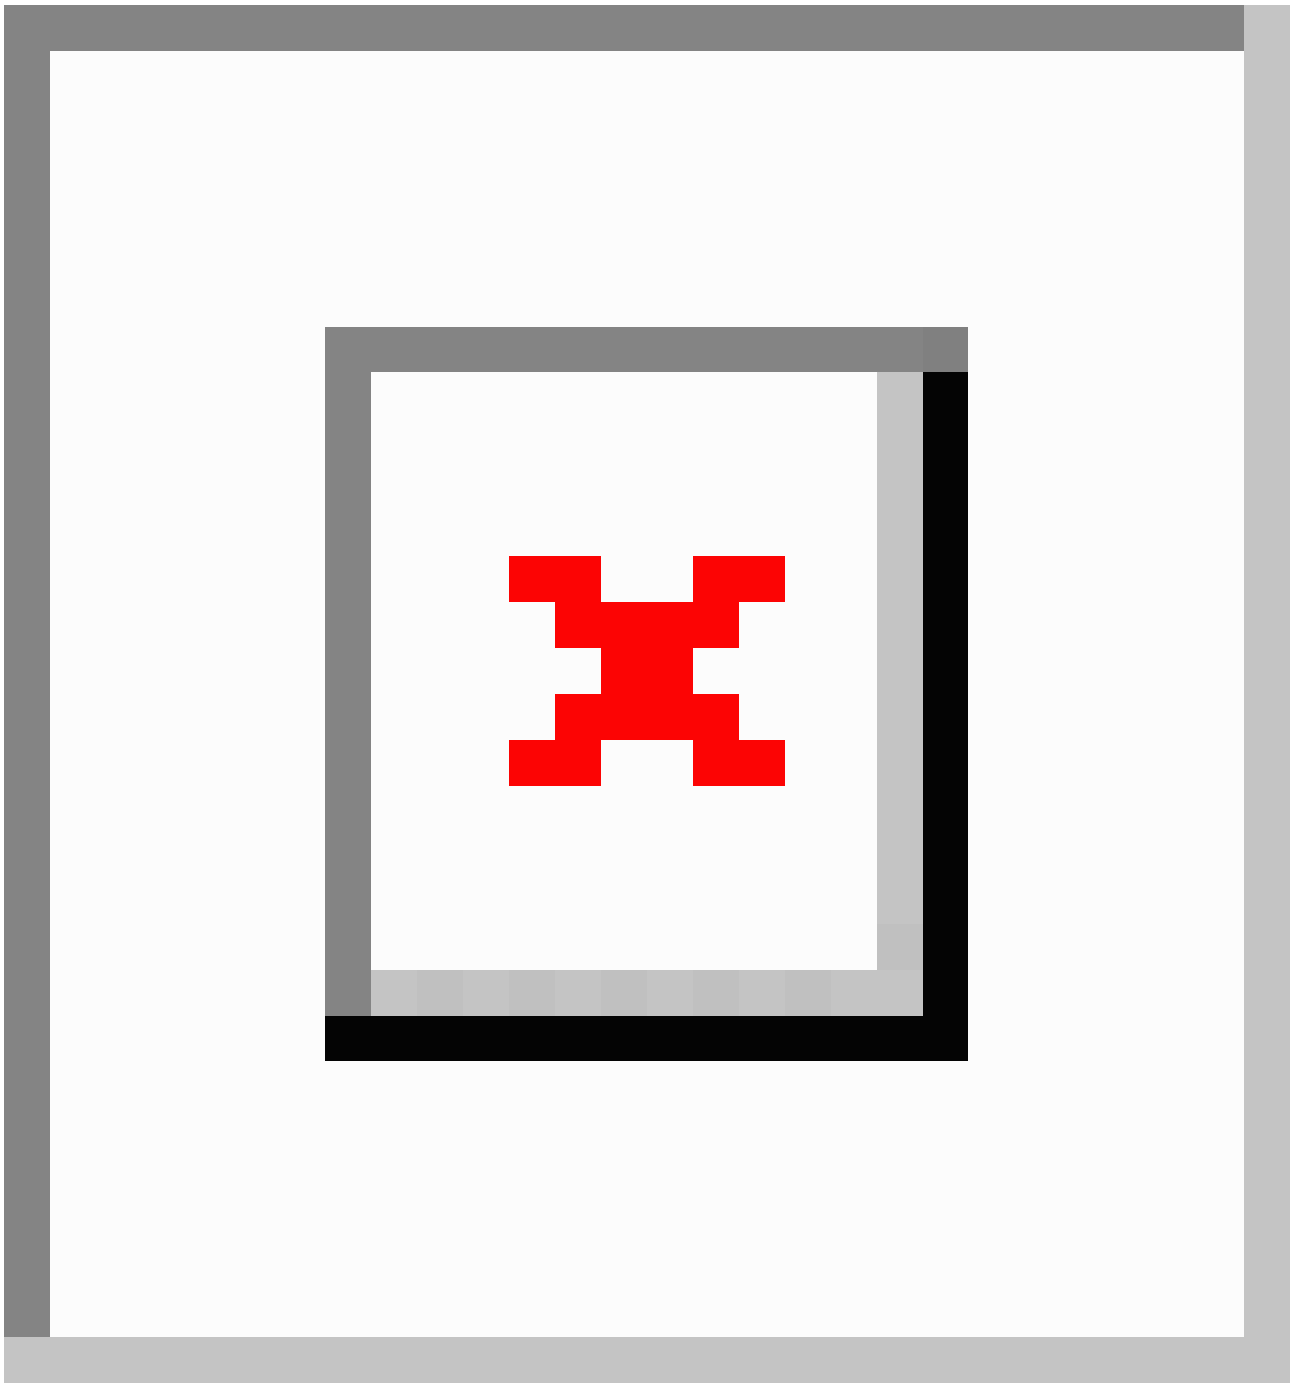

Compounded Data Quality Issue: Completeness

Figures 8 and 9 show the overlap and percentages, respectively, of T2D populations identified by each phenotype definition with an increasing percentage of induced compounded incompleteness across diagnosis, medication, and laboratory codes. All phenotype definitions were impacted and continued to identify populations with T2D until 100% induced incompleteness, as expected. While all phenotypes exhibited similar rates of decrease with increased compounded incompleteness, CCW was the most robust to incompleteness. SUPREME-DM was the least resistant to induced compounded incompleteness. Figures S18 and S21 in Multimedia Appendix 1 provide results for the percentages and frequencies of patients identified by each phenotype while simulating the compounded data quality issues of inaccuracy and lack of timeliness.

Figure 8. Overall population identified by each of the type 2 diabetes phenotype definitions with compounded increasing incompleteness (diagnostic, medication, and laboratory codes). CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; eMERGE: Electronic Medical Records and Genomics; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus.

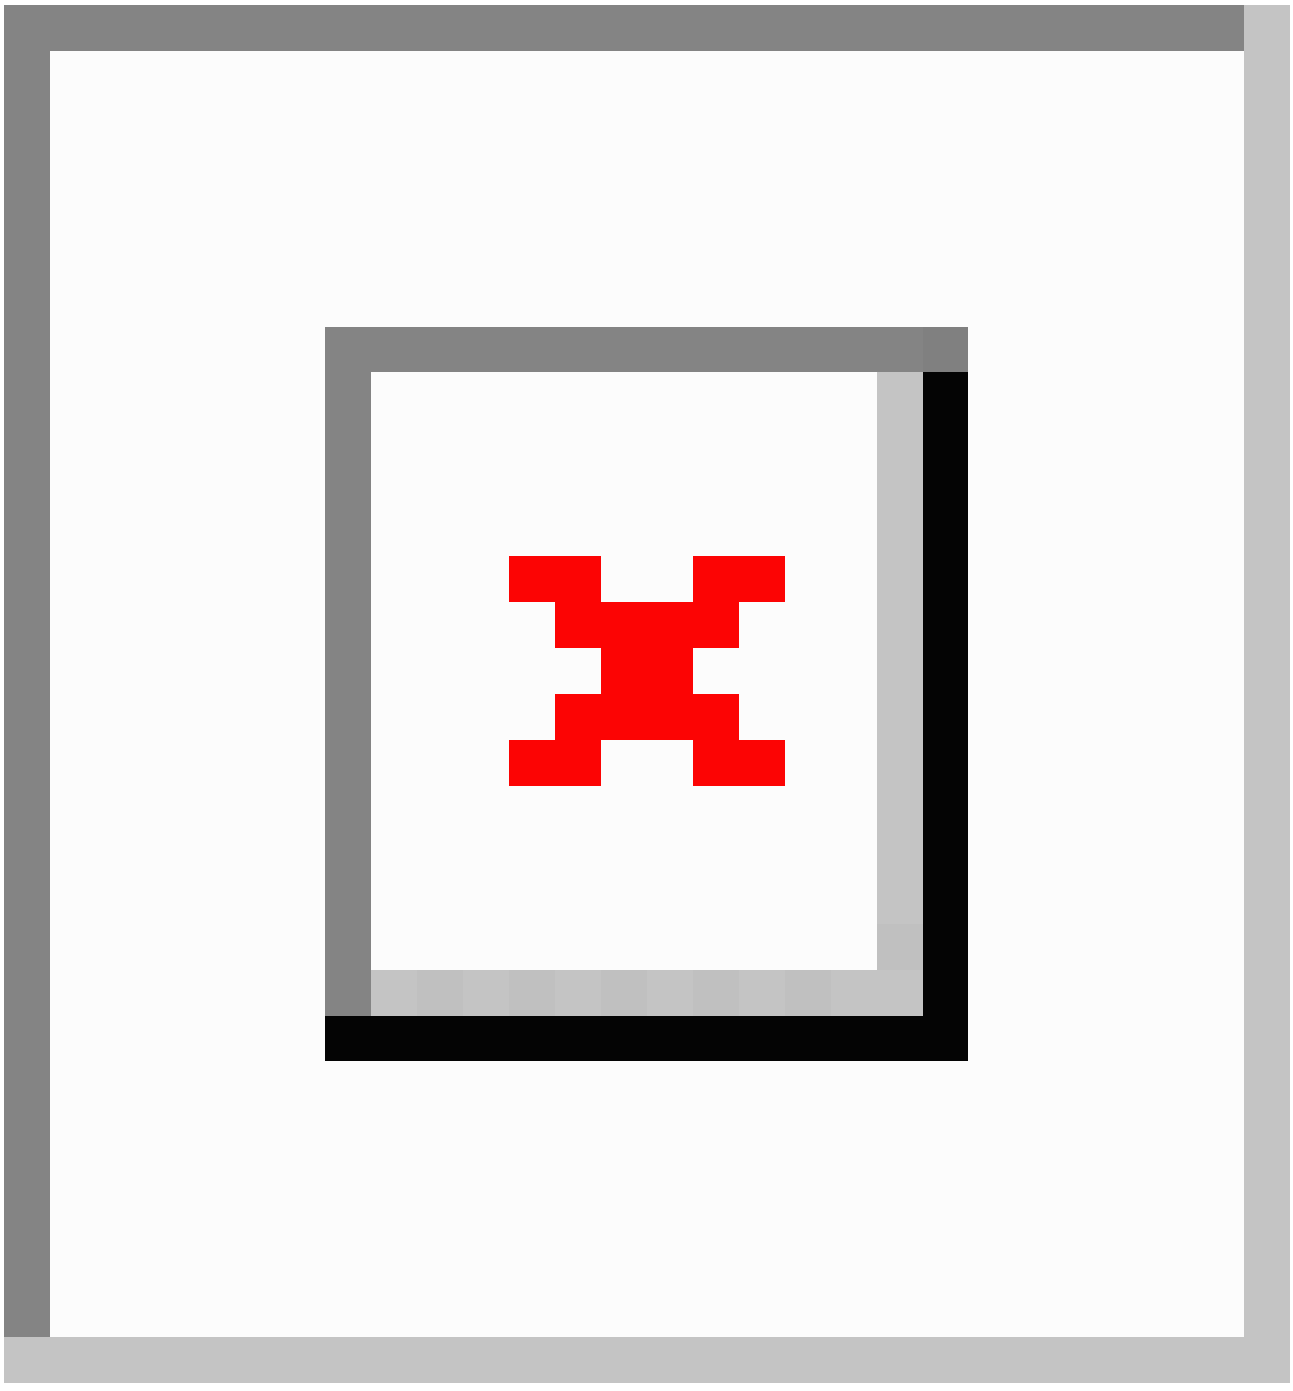

Figure 9. Percentage of type 2 diabetes population identified by each type 2 diabetes phenotype definition with compounded increasing incompleteness (diagnostic, medication, and laboratory codes). CCW: Chronic Conditions Data Warehouse; DDC: Durham Diabetes Coalition; eMERGE: Electronic Medical Records and Genomics; JHU: Johns Hopkins University; SUPREME-DM: Surveillance, Prevention, and Management of Diabetes Mellitus.

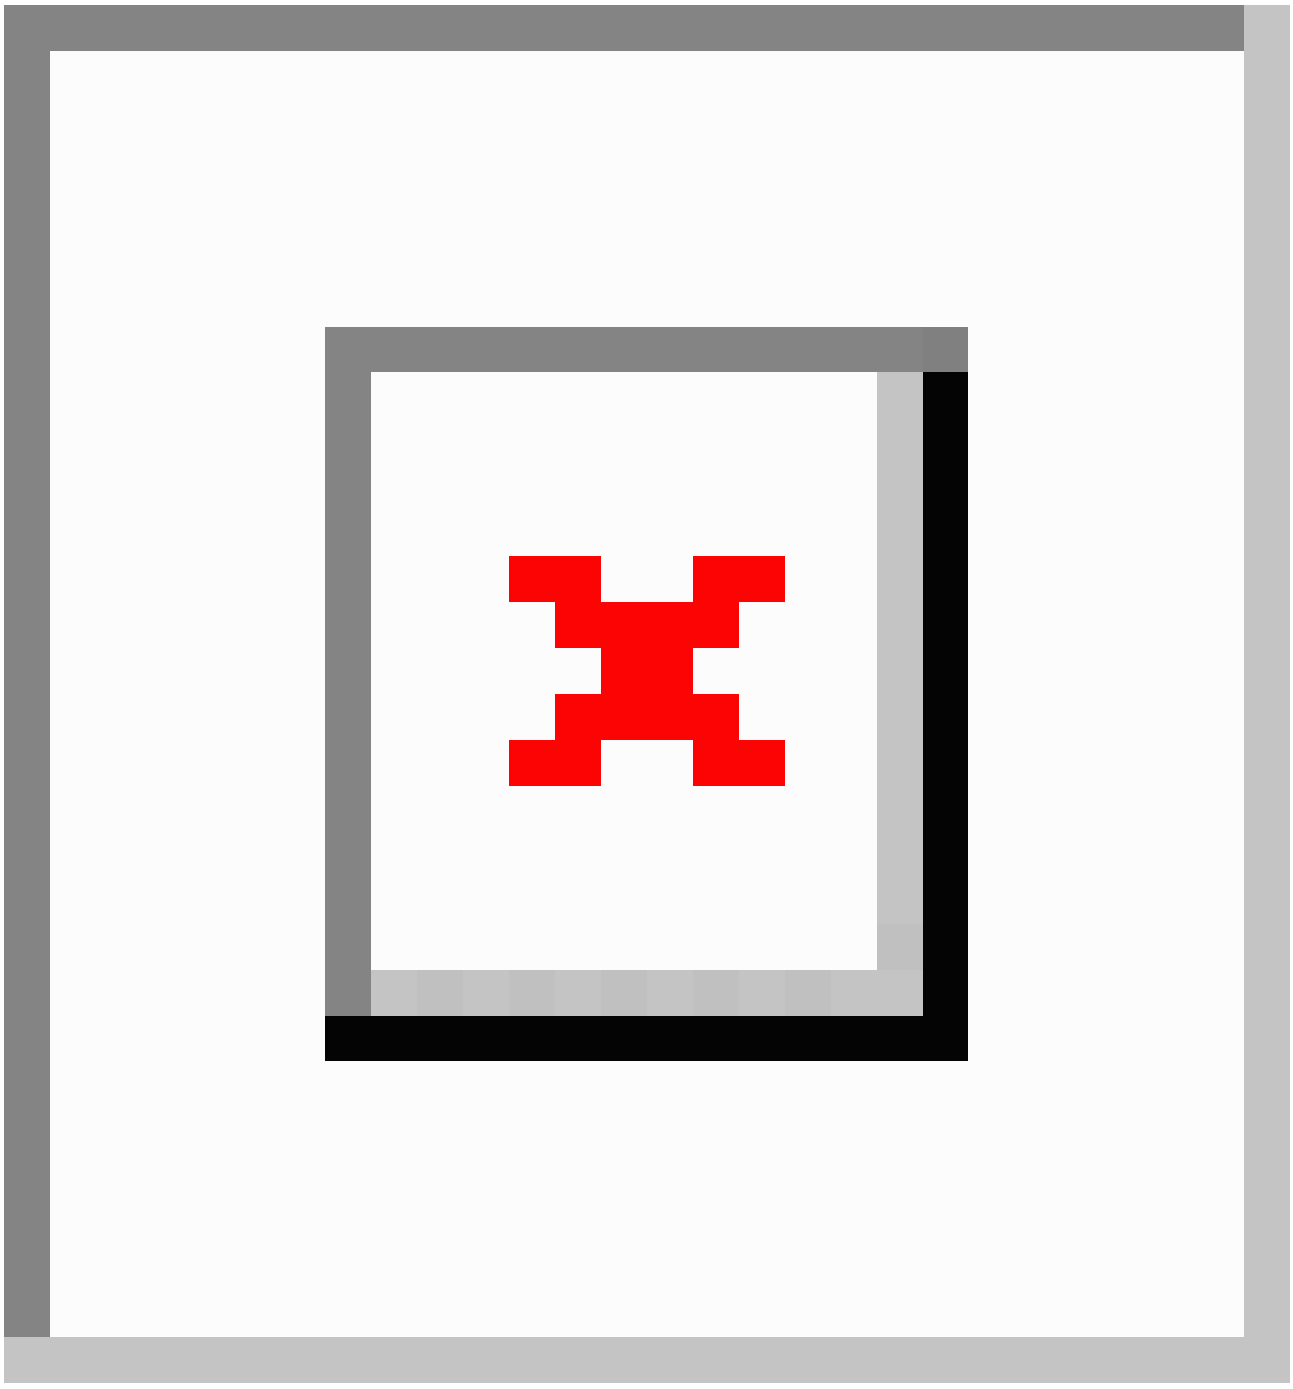

Discussion

T2D is a common chronic disease with no known universally defined phenotype definition. This is further complicated by lack of assessments that are necessary to understand the quality of data in real-world health care settings against common phenotypes. In our study, we investigated how data quality issues of completeness, accuracy, and timeliness may impact the implementation of existing T2D phenotypes using different data types of diagnosis, medication, and laboratory codes extracted from common clinical data sources such as EHRs. Each data quality issue and phenotype definition may present unique implications at an unpredictable scale in any given health care setting. Collectively, these variables can pose challenges in identifying an eligible denominator population and implementing study population enrollment strategies for epidemiological studies, population health and management, disease surveillance, financial operations, and policies for populations with T2D.

Although each phenotype has distinct characteristics, our results showed considerable overlap in the population identified with T2D across the phenotype definitions (Figure 1 and Table 2). Given the uniqueness of the CCW phenotype, which only includes diagnosis codes, the CCW phenotype identified

approximately 38.4% (79,967/207,813) of the overall study population with T2D, whereas the DDC phenotype, which was inclusive of all data types, identified approximately 67.2% (139,832/207,813) of the total population with T2D. This was similar to the 66.9% (139,231/207,813) of the total population identified by the Hopkins phenotype. Additionally, we observed that the T2D phenotype definitions of SUPREME-DM and eMERGE had similar characteristics and therefore resulted in the identification of approximately 43.2% (89,772/207,813) and 37.5% (77,977/207,813) of the overall study population, respectively. Moreover, when analyzing the distribution of population by data types, the identified populations were significantly different, with no noticeable patterns.

This study revealed significant findings resulting from simulated or induced data quality issues on the overall study population using EHR data across different T2D phenotype definitions. Induced incompleteness of diagnostic data showed the least impact on the DDC phenotype, however, identifying only approximately 60% of the population with T2D at 100% diagnostic incompleteness. The CCW phenotype was the most impacted, as 100% of the diagnosis codes were missing with 100% induced incompleteness given the characteristics of its phenotype definition. With more incomplete data, the uniqueness of the population identified by each phenotype may also shift, thereby showing a decrease in overlap of the population with T2D across all phenotypes. Although trends displayed by phenotype definitions of Hopkins and SUPREME-DM may seem similar, the quantification of the slightest differences in trends can have significant population health implications, resulting in compromised financial and logistical (eg, staffing needs) outcomes. Thus, it is important to understand the resistance of data quality issues across phenotypes given different data types.

The results for induced inaccuracy were similar to those for completeness, but data quality issues for timeliness showed a different trend. The phenotypes of eMERGE, CCW, and SUPREME-DM showed significant decreases in the number of identified patients when the majority of the diagnosis codes were replaced. However, induced timeliness continued to capture significant numbers of patients for all phenotypes, at well above 85%. While the impact of induced inaccuracies of laboratory values (in the negative direction) was mitigated by other pathways of the phenotypes, overall, completeness and accuracy showed a much larger impact on the identification of the population with T2D. The trends for the data quality issues of completeness and accuracy paint a similar picture, which may translate into considerations for population health interventions. The effect of data quality on identifying T2D populations using commonly available T2D phenotypes can affect a variety of interventions and outcomes, such as clinical research, financial analysis, staffing needs, and logistical issues, to name a few.

Lastly, induced compounded (diagnosis, medication, and laboratory) data quality issues showed different trends compared to induced single component (diagnosis, medication, or laboratory) data quality issues. Overall, all phenotypes captured fewer patients when there were compounded data quality issues compared to single-component data quality issues. The CCW phenotype was the most resistant phenotype across compounded incompleteness, inaccuracy, and lack of timeliness. The CCW phenotype's robustness to compounded incompleteness owes to its reliance solely on diagnosis codes; other phenotypes with medication and laboratory components faced steeper drops in patients captured when medication and laboratory codes were both incomplete. When it came to induced compounded inaccuracy, the CCW phenotype demonstrated the greatest resistance until 80% of both diagnosis and medication codes were replaced, at which point the Hopkins phenotype became the most robust (Figure S19 in Multimedia Appendix 1). Similarly, compounded lack of timeliness became a bigger problem for phenotypes that rely on time interval for not only diagnosis, but also medication and laboratory codes. Simulating compounded data quality issues has implications for evaluating the fit of phenotype definitions for various data sources and availabilities of multiple data elements. For instance, if a particular data source only has reliable diagnosis codes, then the CCW phenotype would be the most robust. However, it may come with more false positives due to its sole reliance on diagnosis codes.

Our study highlights the importance of understanding the effects of data quality issues on phenotypes, particularly for common diseases such as T2D. The results from our study are novel and can inform how to better identify denominators for a given purpose, which may be beneficial for both research and operational decisions. Although there is no gold standard data set to compare and analyze baseline thresholds of impact on phenotypes, the results of this study can be used by any researcher using real-world data. Additionally, our study describes methods for assessment of multiple data quality issues that can be applied simultaneously in any clinical and health care research setting.

Our study has some limitations. First, the results discussed are based on the EHR data of JHMI over a period of 3 years; hence, generalizability of the findings may be limited to populations like that of this study population. That said, it may also be not applicable to populations of much smaller sample sizes. Second, our study results should be tested against the epidemiological trends and spread of T2D over time. Third, our study did not measure the embedded issues of data quality problems (ie, only simulated or induced data quality issues); understanding and resolving these issues at the beginning of any study can be vital. Fourth, we did not study other data quality dimensions such as concordance and provenance, the assessment of which can be important. Fifth, all T2D phenotypes used in this study relied on diagnosis, medication, and laboratory codes to identify T2D patients; however, some patients may only have clinically diagnosed information in physician notes (ie, unstructured data or free text) that will be missed using structured diagnosis, medication, or laboratory codes. As a result, there may be some false negatives that may have been excluded from our overall study population despite incorporating the most inclusive criteria for the raw data cut. Sixth, we explored compounded data incompleteness, inaccuracy, and timeliness by dropping multiple data types together at the same increments for each data quality domain. However, there could be alternative versions of compounded simulation where diagnosis, medication, and laboratory data qualities are induced at different levels

simultaneously; this may be of interest for future research. Seventh, we assessed the robustness of the phenotypes as they were designated. However, future research could stratify the analysis by the severity of the condition of interest, as severity could impact diagnosis, medication, and laboratory coding behavior and quality. And lastly, our study did not consider any existing data quality thresholds to assess epidemiological impacts on T2D patients using EHRs (eg, comparing national rates of T2D in a neighborhood vs T2D rates identified using EHR data of patients residing in the same neighborhood).

As a result of these observations, we believe that there is a growing need in the United States for a standardized phenotype definition to identify T2D populations while considering the challenges of data quality issues in real-world data, such as from EHRs. The universal phenotype definition should have the ability to integrate features of EHR data while being resistant to common data quality issues. Such a phenotype definition ought to also consider factors that may introduce racial bias and disparities, which eventually may result in health inequities. And lastly, this fundamental definition must also consider integration and interoperability with other data sources, such as claims data, and alignment with existing data interoperability standards. Our research hopes to inspire T2D subject matter experts, at least, to begin conversations toward creating a universal definition for a disease that is extremely common. That said, there is opportunity for additional research that ties issues of data quality with those of phenotypes, data types, and data sources.

Our research provides novel results to understand the effect of data quality issues in data sources like EHRs to identify T2D population-level groups of interest using commonly available T2D phenotype definitions. The study results can inform research or operational efforts using large clinical data repositories to identify T2D populations. Lastly, the study findings can inform efforts to consolidate T2D phenotypes in the near future.

Abstract

Background: Synthetic patient data (SPD) generation for survival analysis in oncology trials holds significant potential for accelerating clinical development. Various machine learning methods, including classification and regression trees (CART), random forest (RF), Bayesian network (BN), and conditional tabular generative adversarial network (CTGAN), have been used for this purpose, but their performance in reflecting actual patient survival data remains under investigation.

Objective: The aim of this study was to determine the most suitable SPD generation method for oncology trials, specifically focusing on both progression-free survival (PFS) and overall survival (OS), which are the primary evaluation end points in oncology trials. To achieve this goal, we conducted a comparative simulation of 4 generation methods, including CART, RF, BN, and the CTGAN, and the performance of each method was evaluated.

Methods: Using multiple clinical trial data sets, 1000 data sets were generated by using each method for each clinical trial data set and evaluated as follows: (1) median survival time (MST) of PFS and OS; (2) hazard ratio distance (HRD), which indicates the similarity between the actual survival function and a synthetic survival function; and (3) visual analysis of Kaplan-Meier (KM) plots. Each method's ability to mimic the statistical properties of real patient data was evaluated from these multiple angles.

Results: In most simulation cases, CART demonstrated the high percentages of MSTs for synthetic data falling within the 95% CI range of the MST of the actual data. These percentages ranged from 88.8% to 98.0% for PFS and from 60.8% to 96.1% for OS. In the evaluation of HRD, CART revealed that HRD values were concentrated at approximately 0.9. Conversely, for the other methods, no consistent trend was observed for either PFS or OS. CART demonstrated better similarity than RF, in that CART caused overfitting and RF (a kind of ensemble learning approach) prevented it. In SPD generation, the statistical properties close to the actual data should be the focus, not a well-generalized prediction model. Both the BN and CTGAN methods cannot accurately reflect the statistical properties of the actual data because small data sets are not suitable.

Conclusions: As a method for generating SPD for survival data from small data sets, such as clinical trial data, CART demonstrated to be the most effective method compared to RF, BN, and CTGAN. Additionally, it is possible to improve CART-based generation methods by incorporating feature engineering and other methods in future work.

Introduction

When submitting an application for the approval of a new pharmaceutical product to health authorities, it is imperative to demonstrate its efficacy and safety through multiple clinical trials. However, 86% of these trials encounter difficulties meeting the targeted number of subjects within the designated recruitment period, often leading to extensions of the trial duration or completion of the trial without reaching the target number of subjects [1-3]. The challenge of patient recruitment not only delays the submission of regulatory applications but also hinders the timely provision of effective treatment to patients, which consequently contributes to increased development costs and the escalation of drug prices and potentially exacerbates the strain on health care financing.

In recent years, the use of real-world data (RWD) has emerged as a potential solution for addressing these issues. The Food and Drug Administration has also released draft guidelines [4], garnering attention on the application of RWD as an external control arm in clinical trials [5,6]. Furthermore, it has been reported that it is possible to optimize eligibility using RWD and machine learning, thereby increasing the number of eligible subjects that can be included [7].

In addition to these approaches, we hypothesize that it is possible to generate synthetic patient data (SPD) from control arm data in past clinical trials and use it to establish a control arm for a new clinical trial. The use of SPD, an emerging research approach in the health care research field [8-17], involves the generation of fictitious individual patient-level data from real data, which possess statistical properties similar to those of actual data. This approach is anticipated to facilitate health care research while addressing data privacy concerns [14,18-21].

Regarding its application in clinical trials, concerns have been raised about the feasibility of generating SPDs with statistical properties similar to those of actual data due to the relatively smaller volume of clinical trial data compared to RWD, such as electronic health records or registry data. However, previous studies [22-25] have reported the successful generation of SPDs with statistical properties generally comparable to the actual data, although there are certain limitations. Additionally, with the expansion of clinical trial data-sharing platforms such as ClinicalStudyDataRequest.com, Project Data Sphere, and Vivli, acquiring subject-level clinical trial data has become more accessible. Consequently, advancements in research on the utility of SPD and the expansion of clinical trial data-sharing platforms are expected to have potential applications in clinical trials.

Our focus lies in the application of this technology in oncology clinical trials that evaluate popular efficacy end points such as overall survival (OS) and progression-free survival (PFS)–related survival functions and median survival time (MST) [26]. In previous studies on SPD, there has been a notable emphasis on reporting patient background data and single–time point data [22-25]. However, research focusing specifically on the relationship between SPD and survival data remains relatively insufficient [27].

As the first step in examining our hypothesis that the use of SPD can be beneficial in accelerating health care research, the aim of this study was to determine the most suitable SPD generation method for oncology trials, specifically focusing on both OS and PFS, which are set as the primary evaluation end points in oncology trials. To achieve this goal, we conducted a comparative simulation of 4 generation methods: classification and regression trees (CART) [28], random forest (RF) [29], Bayesian network (BN) [30], and the conditional tabular generative adversarial network (CTGAN) approach [31], and the performance of each method was evaluated.

Methods

Overview

To generate the SPD, subject-level clinical trial data were obtained from Project Data Sphere for the following 4 clinical trials (Table 1): (1) each had a different cancer type, (2) included control arm data, (3) contained both OS and PFS data, and (4) had a ready data format for analysis.

Table . List of selected oncology clinical trials in this study.

ClinicalTrials.gov ID	Titles	Phase	Cancer type	Intervention for the control arm	Subjects in the control arm, n
NCT00119613	A Randomized, Double-Blind, Placebo-Controlled Study of Subjects With Previously Untreated Extensive-Stage Small-Cell Lung Cancer (SCLC) Treated With Platinum Plus Etoposide Chemotherapy With or Without Darbepoetin Alfa.	III	Small cell lung cancer	Placebo	232
NCT00339183	A Randomized, Multicenter Phase 3 Study to Compare the Efficacy of Panitumumab in Combination With Chemotherapy to the Efficacy of Chemotherapy Alone in Patients With Previously Treated Metastatic Colorectal Cancer.	III	Metastatic colorectal cancer	FOLFIRI[a] Alone	476
NCT00339183	A Phase 3 Randomized Trial of Chemotherapy With or Without Panitumumab in Patients With Metastatic and/or Recurrent Squamous Cell Carcinoma of the Head and Neck (SCCHN).	III	Recurrent or metastatic (or both) head and neck cancer	Cisplatin and 5-fluorouracil	260
NCT00703326	A Multicenter, Multinational, Randomized, Double-Blind, Phase III Study of IMC-1121B Plus Docetaxel versus Placebo Plus Docetaxel in Previously Untreated Patients With HER2-Negative, Unresectable, Locally-Recurrent or Metastatic Breast Cancer.	III	Breast cancer	Placebo and docetaxel	382

[a]FOLFIRI: panitumumab plus fluorouracil, leucovorin, and irinotecan.

Preparation of the Training Data Set

The patient data for the control arm contained within each trial data set were extracted and used as the actual data for the training data set. The selection of variables in the training data set aimed to include as many variables related to the subjects' background as possible, excluding variables concerning tests and evaluations conducted during the trials. Furthermore, variables that had the same value were excluded, even if they were related to the subjects' background (Multimedia Appendices 1-4).

Generation of Synthetic Data

The SPDs in this study were generated using the following 4 methods:

1. CART: the synthpop package (version 1.8) in R (The R Foundation) was used, specifying the cart method for the syn function's method argument.
2. RF: the synthpop package (version 1.8) in R was used, specifying the Ranger method for the syn function's method argument.
3. BN: the bnlearn package (version 4.9) in R was used to conduct structural learning through the score-based algorithm hill-climbing, followed by parameter estimation using the bn.fit function. The default maximum likelihood estimator was used for parameter estimation.
4. CTGAN: the CTGANSynthesizer module included in the Python package sdv (version 1.3) was used.

In all these generation methods, to ensure the absence of conflicting data regarding the relationship between PFS and OS, constraints were set to ensure that the values of PFS and OS were greater than zero and that PFS was less than or equal to OS. Specific individual patient data in the generated SPD, which did not meet these constraints, were excluded, and new individual patient data were regenerated. The SPDs were generated in a manner that equaled the number of subject-level data to the record count in the actual data.

To ensure the reproducibility of SPD generation, 1000 random numbers were generated as seed values using the Mersenne Twister algorithm. The same seed value set was used for all generation methods.

Statistical Analysis

Histogram

Histograms were created to visually inspect the distributions of the MST of the synthetic data (MSTS) for PFS and OS for the 1000 SPD data sets generated by each method. The histograms also included the MST of the actual data (MSTA) as a vertical line and the range of its 95% CI as a rectangular background. For PFS and OS, a higher percentage of MSTS covered by the 95% CI of the MSTA was determined to indicate a greater level of reliability for the generation method.

Evaluation of Similarity

A hazard ratio (HR) of 1 signifies that the 2 survival functions are entirely identical. Thus, the closer the HR is to 1, the more similar the 2 survival functions are. Accordingly, based on the following calculation formula, the HR distance (HRD) for PFS and OS from the SPD and the actual data were computed and evaluated:

$$HRD=1-abs(HR-1)$$

Kaplan-Meier Plot

In the evaluation of similarity, the SPD that showed the highest HRD value was considered the best case, and the SPD with the lowest HRD value was considered the worst case. Three groups of Kaplan-Meier (KM) plots were created, including the actual data, the best case, and the worst case for each SPD generation method. The best case and worst case for each SPD generation method in both PFS and OS were compared to actual survival by using the log rank test. Multiple comparisons were not performed, nor were *P* values adjusted because controlling for the type I error rate does not affect the conclusions of this study.

Since the purpose of this study was to evaluate the method of generating SPD that closely resemble actual survival data, it might be unnecessary to calculate a *P* value that indicates a significant difference from actual survival, but the *P* value was calculated in this study from the viewpoint that if a significant difference is also observed in the best-case, that method should not be adopted.

All analyses and data generation were performed using R (version 4.3.1; The R Foundation) and Python (version 3.10; Python Software Foundation).

Ethical Considerations

Ethical review was not needed for this simulation study for methodology comparison. All actual clinical trial data sets obtained from Project Data Sphere were used in accordance with relevant guidelines and regulations when the clinical trials were conducted.

Results

Figure 1 shows a histogram of the MSTS for PFS in the NCT00703326 trial. Using CART, RF, and BN, most of the generated MSTS values were within the 95% CI of the MSTA. In contrast, when CTGAN was used, SPD generation resulted in a widened variance in the distribution of MSTS. For the MSTS of PFS in the other 3 trials, RF exhibited a shift in the distribution of the MSTS, shortening the survival period, while BN displayed a shift in the distribution and prolonged the survival period. Similar trends to Figure 1 were observed for CART and CTGAN (Multimedia Appendices 5-7).

Figure 2 displays a histogram of the MSTS for OS in the NCT00460265 trial. The divergence from the PFS findings is that the MSTS of RF was more frequently included within the 95% CI of the MSTA, with similar results observed in other trials (Multimedia Appendices 8-10). In other aspects, similar findings were obtained as with the PFS.

Table 2 presents the number and proportion of the generated MSTS values included within the 95% CI of the MSTA for each trial and each method. In the case of CART for PFS, a high percentage ranging from 88.8% to 98.1% was exhibited for all trials. However, the OS ranged from 60.8% to 96.1%, with some trials displaying a lower percentage than the PFS.

Figure 1. Histogram of the median survival time of the synthetic data for progression-free survival in the NCT00703326 trial. The dashed vertical line represents the median survival time of the actual data, and the light blue background indicates its 95% CI. BN: Bayesian network; CART: classification and regression tree; CTGAN: conditional tabular generative adversarial network; MST: median survival time; RF: random forest.

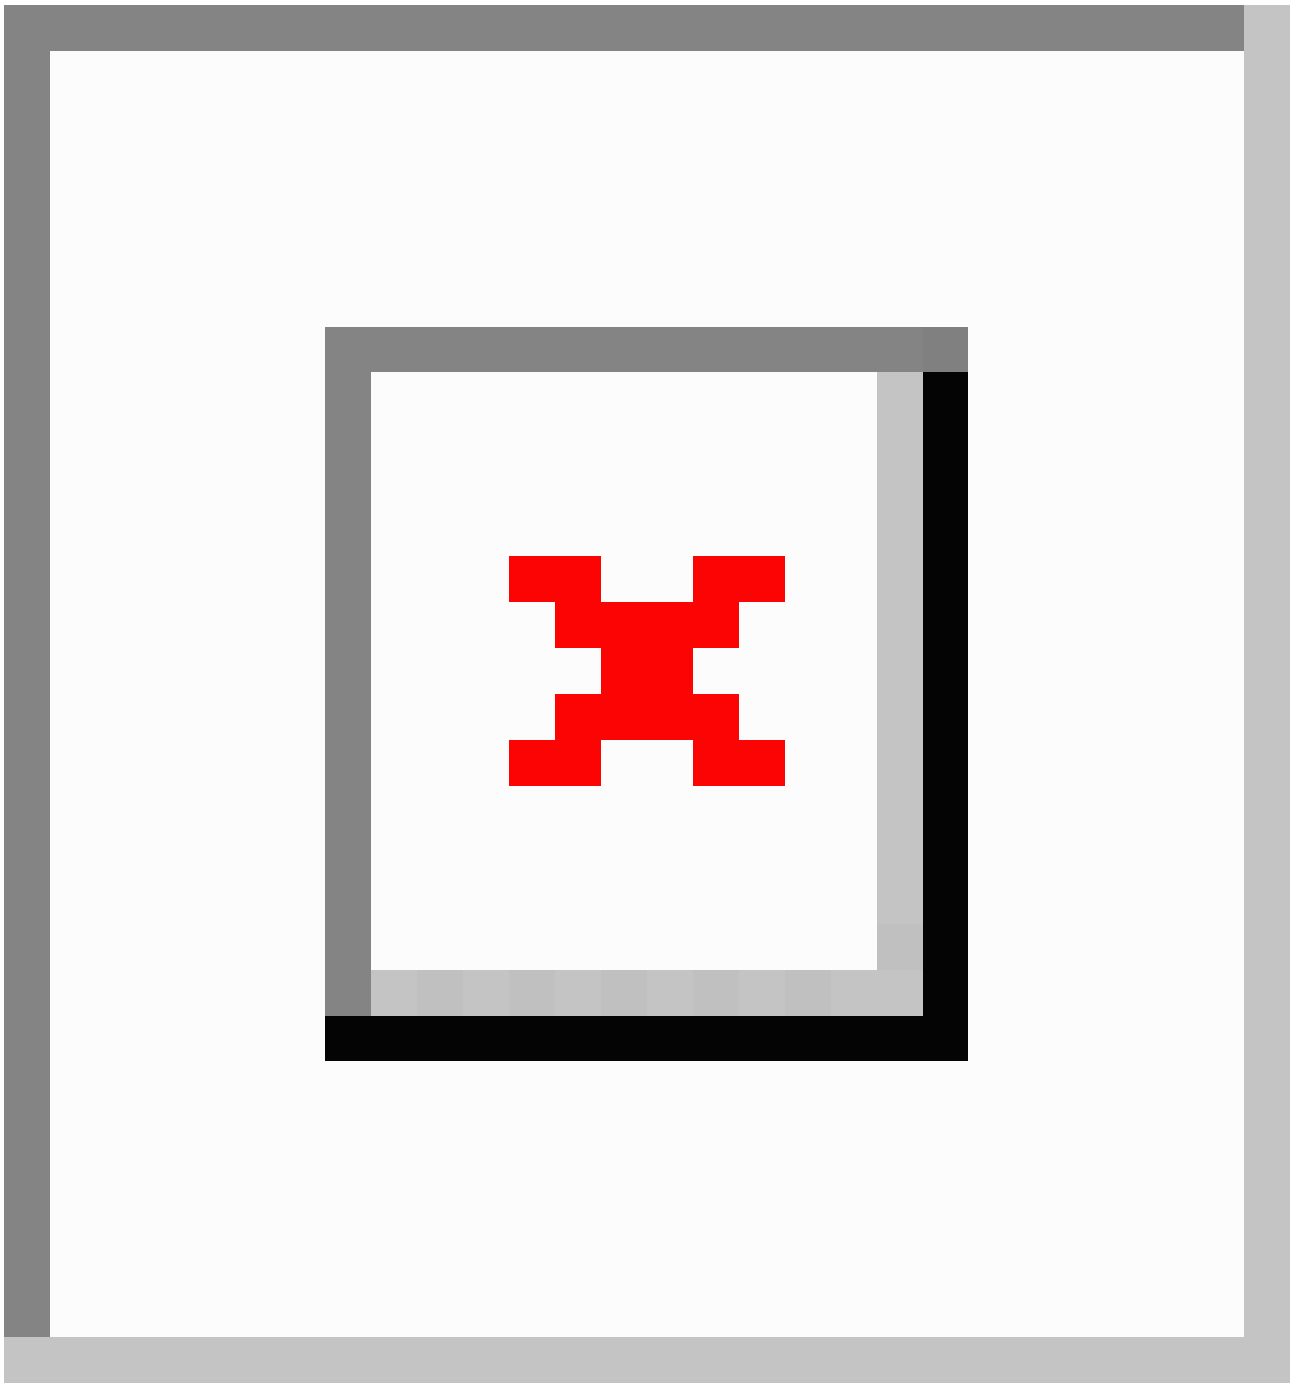

Figure 2. Histogram of the median survival time of the synthetic data of overall survival in the NCT00460265 trial. The dashed vertical line represents the median survival time of the actual data, and the light blue background indicates its 95% CI. BN: Bayesian network; CART: classification and regression tree; CTGAN: conditional tabular generative adversarial network; MST: median survival time; RF: random forest.

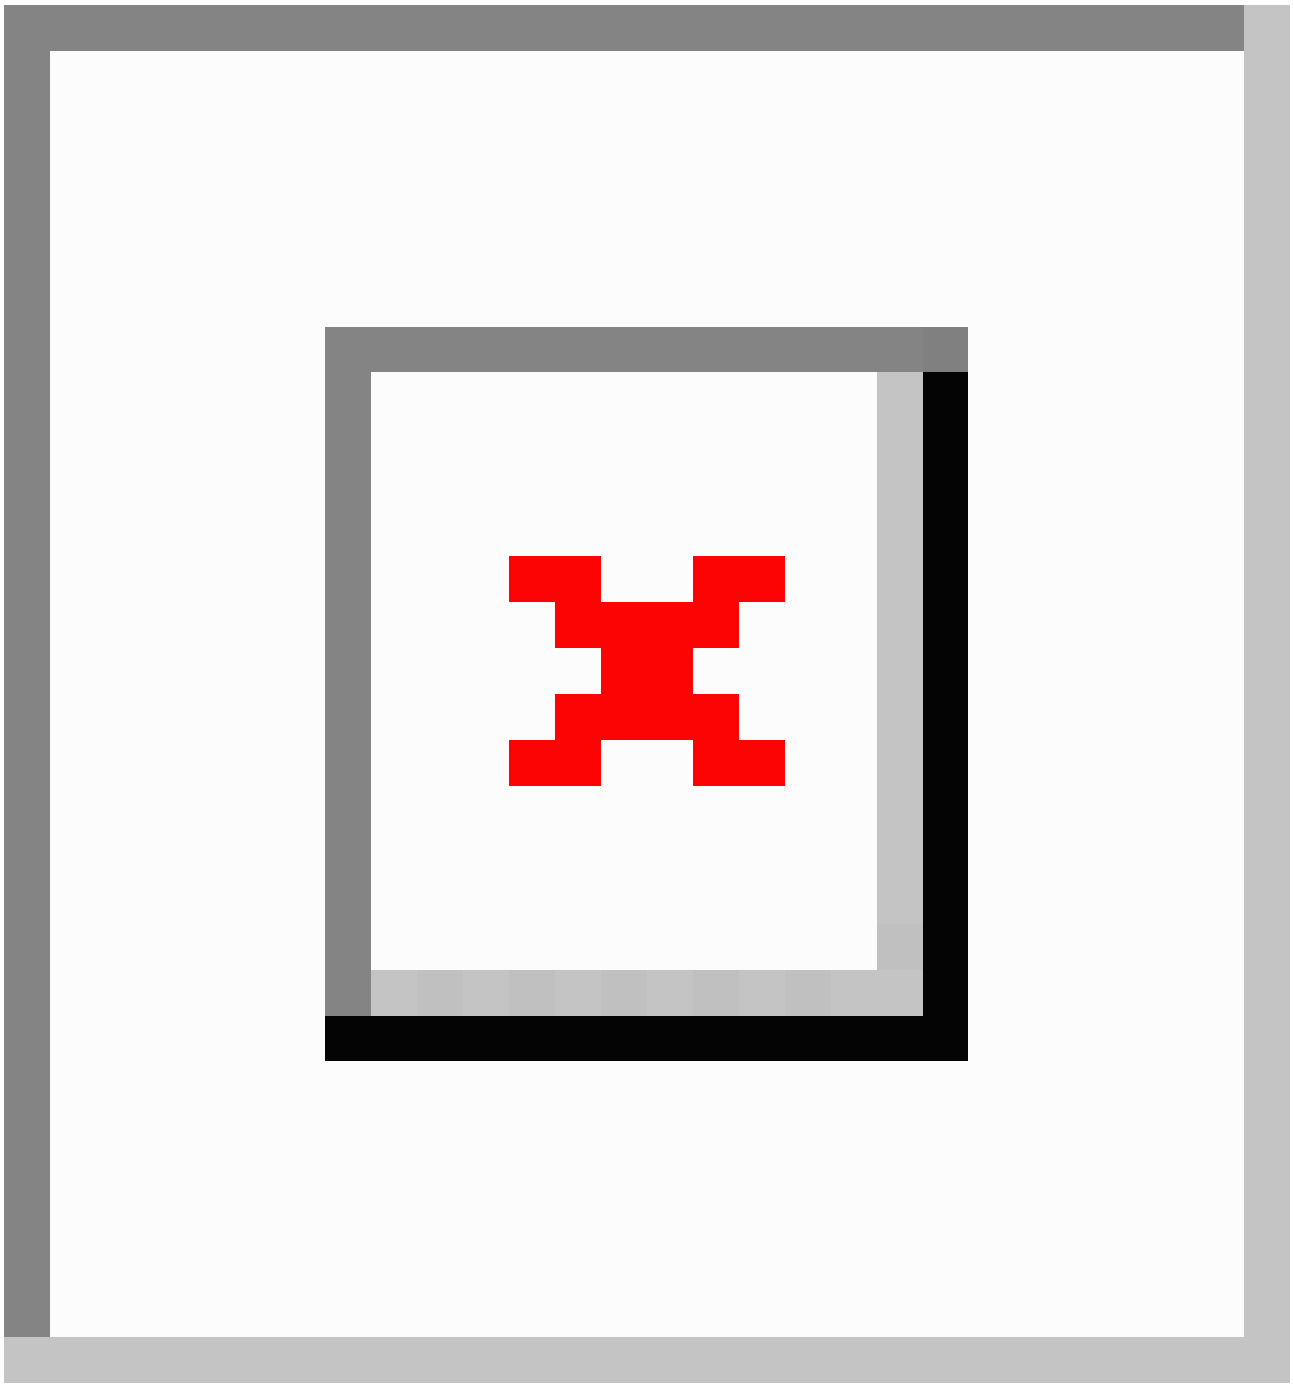

Table . The number and proportion of median survival times of the synthetic data (MSTSs) falling within the 95% CI of the median survival time of the actual data (MSTA).

		ClinicalTrials.gov ID			
		NCT00119613	NCT00339183	NCT00460265	NCT00703326
Progression-free survival					
	MSTA (95% CI)	169 (163-183)	155 (121-168)	133 (121-167)	424 (380-504)
MSTSs, n (%)					
	CART[a] (n=1000)	981 (98.1)	888 (88.8)	955 (95.5)	918 (91.8)
	RF[b] (n=1000)	693 (69.3)	248 (24.8)	426 (42.6)	919 (91.9)
	BN[c] (n=1000)	10 (1.0)	0 (0.0)	37 (3.7)	976 (97.6)
	CTGAN[d] (n=1000)	65 (6.5)	378 (37.8)	322 (32.2)	254 (25.5)
Overall survival					
	MSTA (95% CI)	276 (259-303)	361 (319-393)	286 (255-357)	1452 (1417-1507)
MSTSs, n (%)					
	CART (n=1000)	831 (83.1)	608 (60.8)	719 (71.9)	961 (96.1)
	RF (n=1000)	757 (75.7)	697 (69.7)	980 (98.0)	599 (59.9)
	BN (n=1000)	0 (0.0)	0 (0.0)	0 (0.0)	622 (62.2)
	CTGAN (n=1000)	72 (7.2)	155 (15.5)	197 (19.7)	81 (8.5)

[a]CART: classification and regression tree.

[b]RF: random forest.

[c]BN: Bayesian network.

[d]CTGAN: conditional tabular generative adversarial network.

For RF, a high proportion of 91.9% was observed for PFS in the NCT00703326 trial and 98.0% for OS in the NCT00460265 trial, whereas in other cases, the proportion for RF was not as high as that for CART.

In the case of BN, proportions of 97.6% and 62.2% were observed for PFS and OS, respectively, in the NCT00703326 trial, but in the other 3 trials, BN showed an extremely low percentage ranging from proportion ranging from 0.0% to 3.7%.

CTGAN showed a low proportion ranging from 6.5% to 37.8% for both PFS and OS in all trials.

Figure 3 shows the KM plot for PFS in the NCT00703326 trial. The best-case curves of CART and RF were similar to the actual data curve. In contrast, for BN and CTGAN, even the best-case curves deviated from the actual data curve. In other trials, some SPD did not show a similar trend. However, at least for the best-case scenarios of CART and RF, the generated synthetic survival curves closely resembled the actual survival curve (Multimedia Appendices 11-13).

Figure 4 displays the KM plot for OS in the NCT00460265 trial. Similar to the KM plots for PFS, the best-case curves of CART and RF resembled the actual data curve, whereas those of BN and CTGAN deviated from the actual data curve. These trends were also observed in other trials (Multimedia Appendices 14-16).

Figures 5 and 6 present box plots of the HRD. When using CART, the HRD values for both PFS and OS in all trials were concentrated at approximately 0.9. Conversely, for the other methods, no consistent trend was observed for either PFS or OS.

Figure 3. Kaplan-Meier plots for progression-free survival in the NCT00703326 trial. BN: Bayesian network; CART: classification and regression tree; CTGAN: conditional tabular generative adversarial network; RF: random forest.

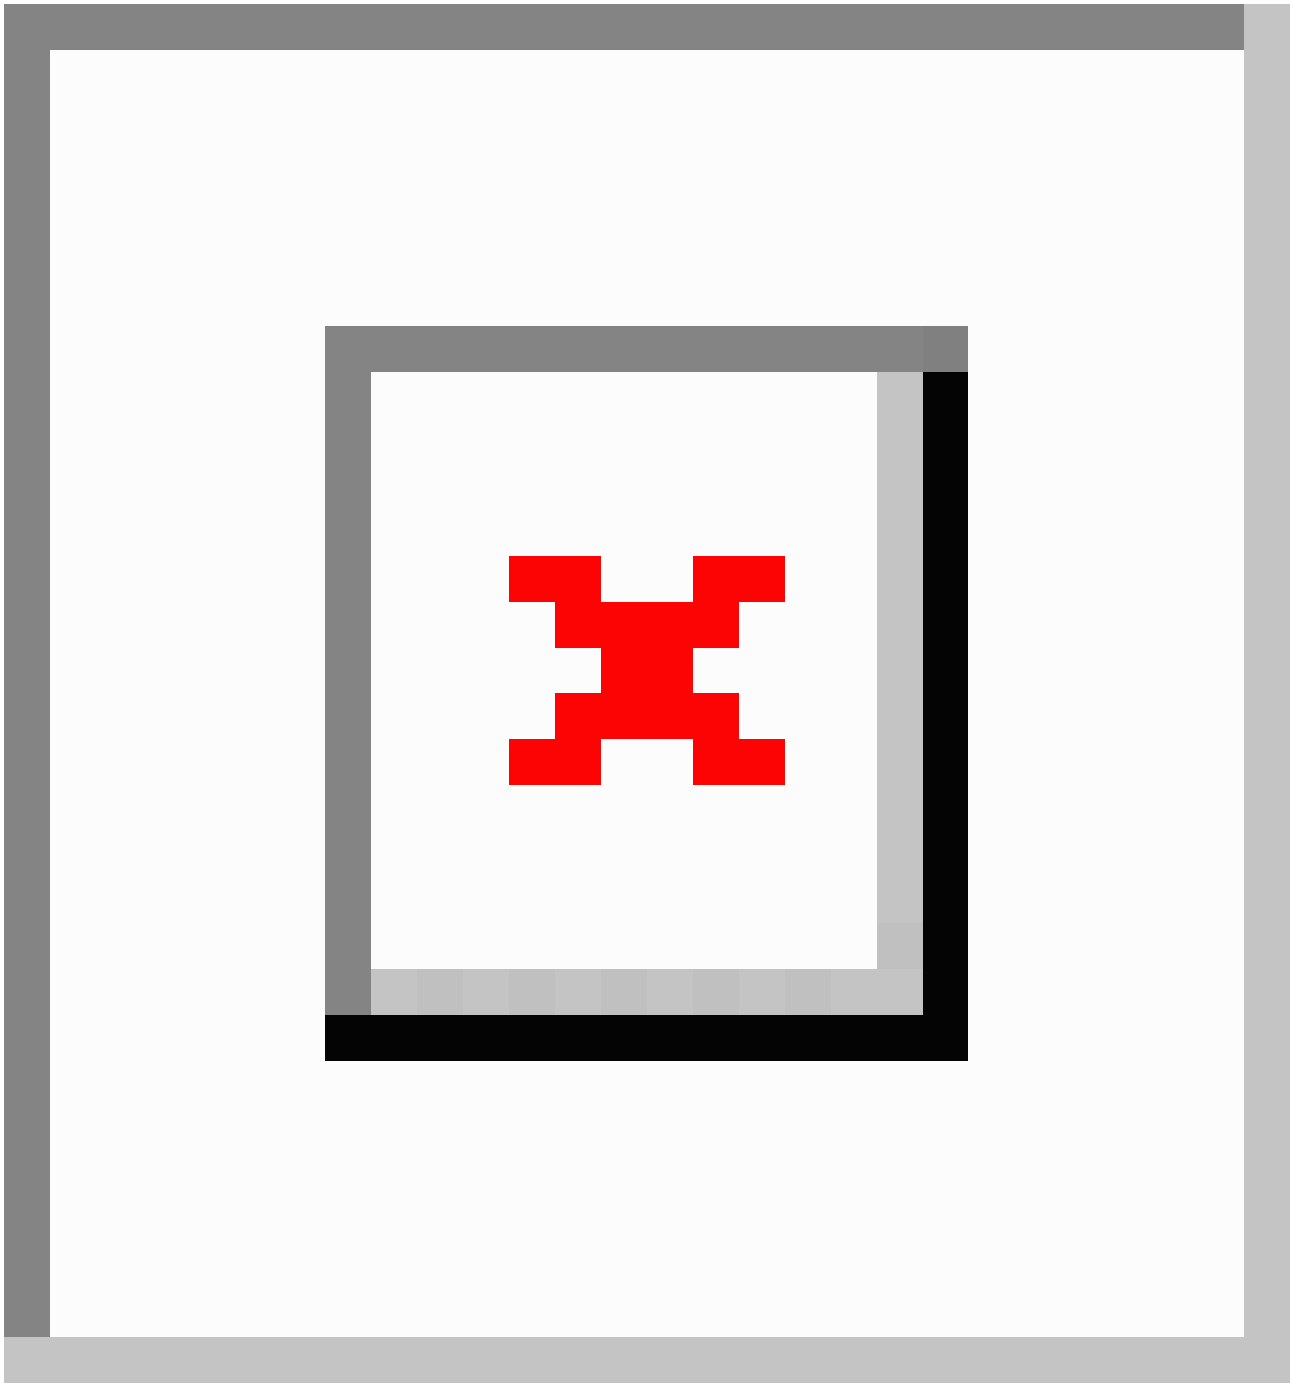

Figure 4. Kaplan-Meier plots for overall survival in the NCT00460265 trial. BN: Bayesian network; CART: classification and regression tree; CTGAN: conditional tabular generative adversarial network; RF: random forest.

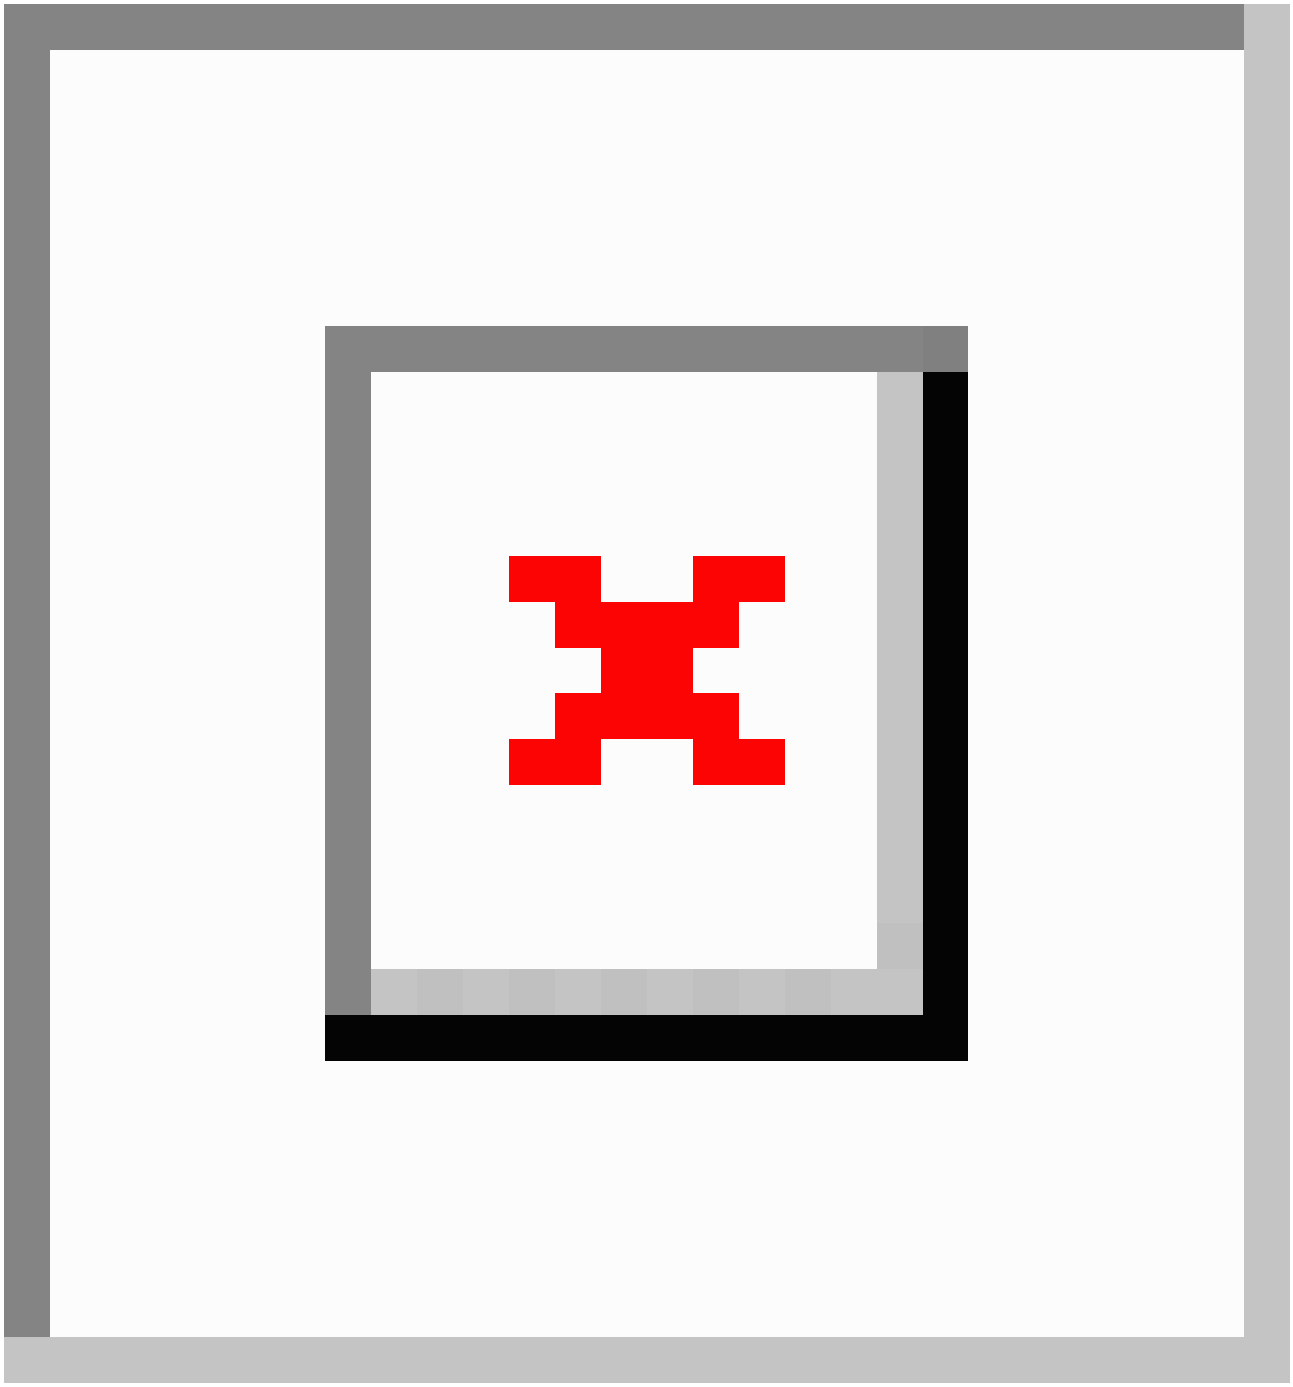

Figure 5. Box plot of progression-free survival hazard ratio distance (HRD) for each method and clinical trial. BN: Bayesian network; CART: classification and regression tree; CTGAN: conditional tabular generative adversarial network; RF: random forest.

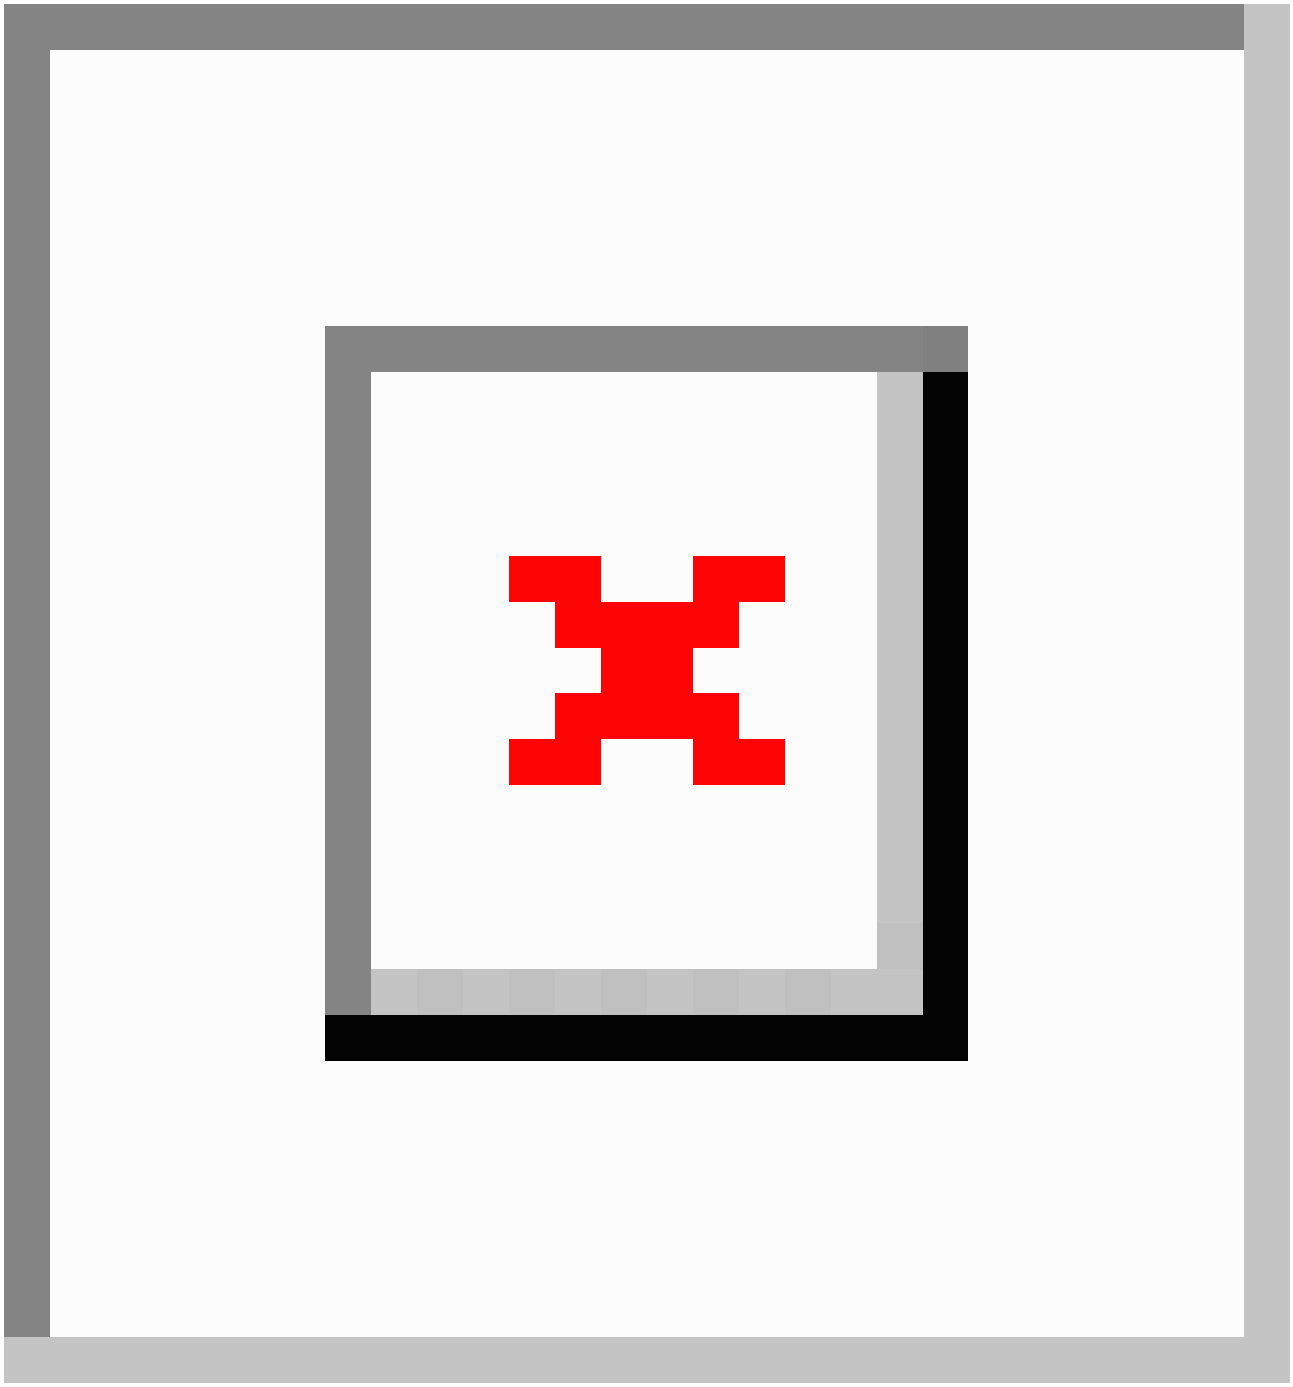

Figure 6. Box plot of overall survival hazard ratio distance (HRD) for each method and clinical trial. BN: Bayesian network; CART: classification and regression tree; CTGAN: conditional tabular generative adversarial network; RF: random forest.

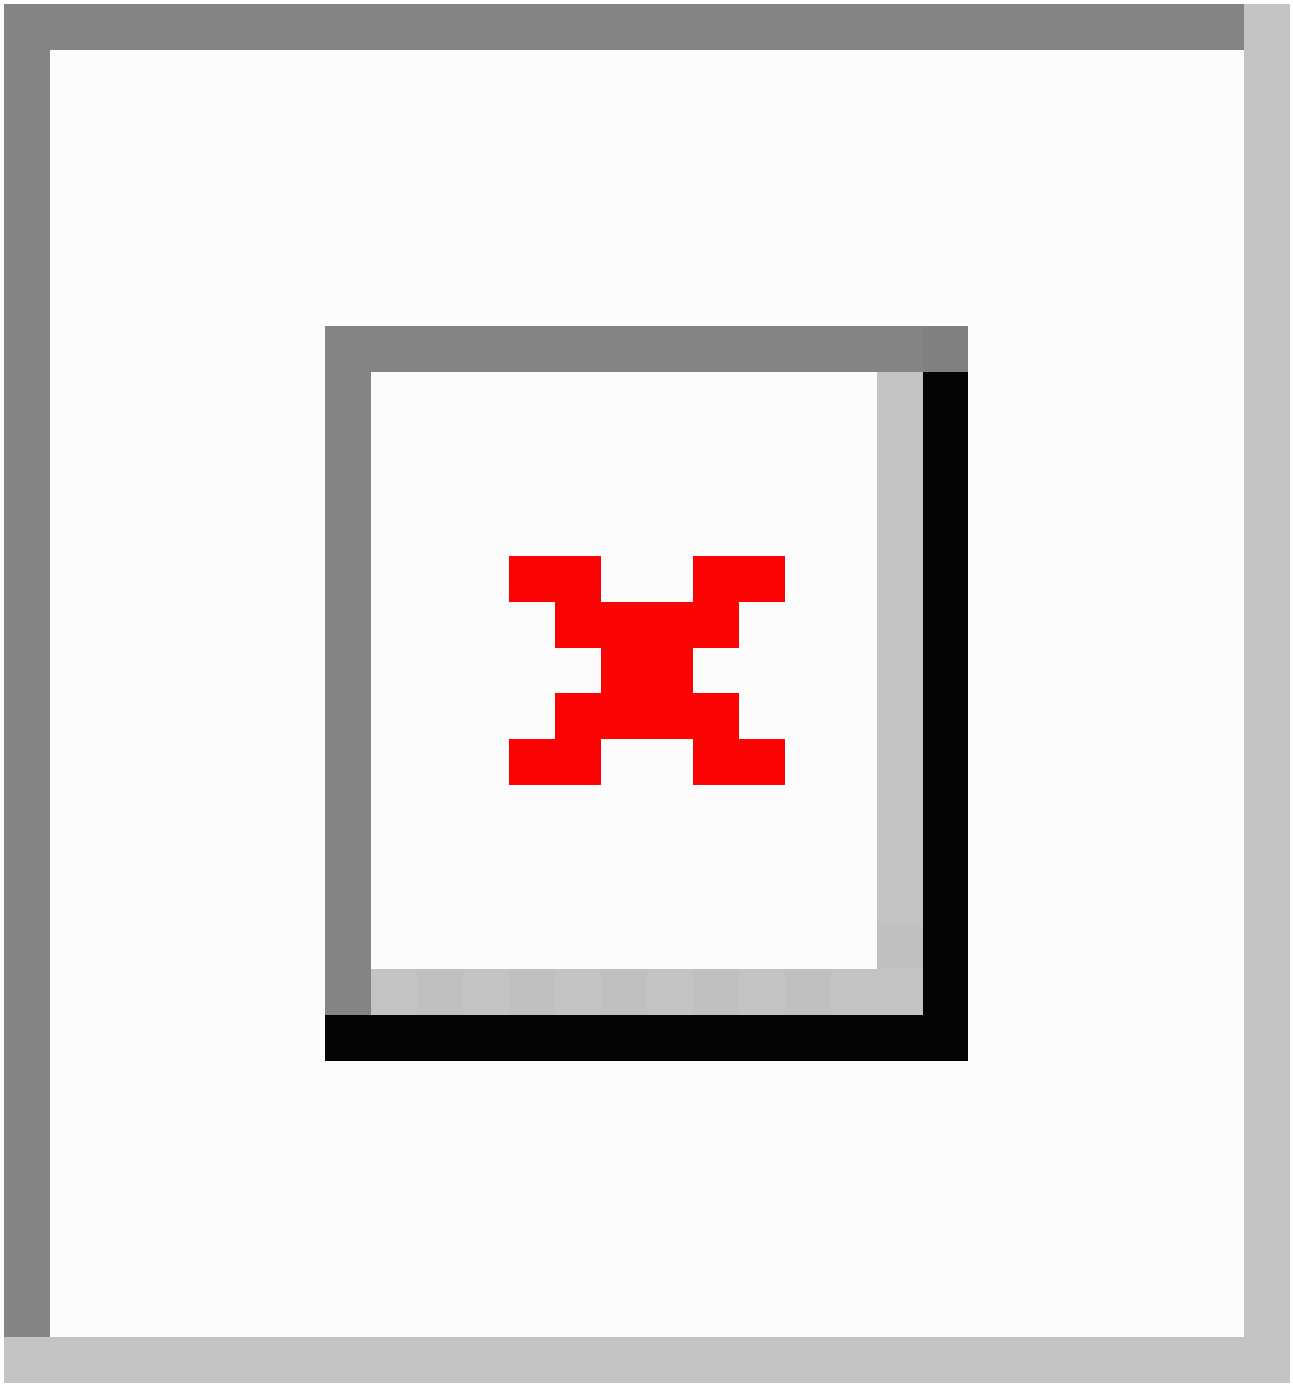

Discussion

Regarding the survival SPD, CART often yielded better results than the other methods in evaluations using MST, HRD, and visual analysis via KM plots. Given the crucial importance of the hazard ratio and MST as end points in oncology trials [26], demonstrating the utility of both of these evaluation metrics is essential. Therefore, using CART for generating survival SPD was suggested as a beneficial approach.

While both CART and RF generally yielded preferable results across all trials, they share the common characteristic of using tree models. RF, with its use of the bootstrap method for resampling and constructing tree models for ensemble learning, is known to prevent overfitting. In general, in terms of constructing machine learning models with high generalization performance, RF performs better than CART. However, CART is prone to overfitting as the layers of the tree become deeper [32]. Although RF is considered a superior method for constructing high–generalization-performance machine learning models, the results from Table 2 and the KM plots in this study suggest that CART is a better approach than RF. This discrepancy might be due to differing views on what is a higher performance between the machine learning prediction model and SPD. In the machine learning prediction model, it is important to prevent overfitting and reduce bias; however, SPD is expected to match its statistical properties with actual data.

Thus, in the case of SPD, the overfitting suppression mechanism possessed by RF might have resulted in inferiority to that of CART from the perspective of improving similarity.

In the case of using BN, the percentage of MSTSs falling within the 95% CI of MSTAs was 0% for the PFS of the NCT00339183 trial, and for OS, this phenomenon also occurred in the NCT00119613, NCT00339183, and NCT0046265 trials. This implies that the SPD failed to accurately reflect the statistical properties of the actual data. Conversely, a high value of 97.6% was observed for the PFS in the NCT00703326 trial. The reason for this discrepancy could not be determined on the basis of the results of this study. Tucker et al [24] reported that they could generate data highly similar to actual data when using BN for the generation of SPD, which differs from our findings. One notable difference is that while Tucker et al [24] used a large-scale actual data set of 27.5 million patients for their study, this study used only a few hundred patients for training data. This difference likely had a significant impact on the accuracy of the SPD generation model, resulting in conflicting results. However, the SPD generated by BN were not distributed in the direction of shortening PFS or OS. Thus, this would not be harmful when the SPD generated by BN is used as a more conservative control arm in clinical trials.

Using CTGAN, the percentage of the MSTSs falling within the 95% CI of the actual data was low, indicating low performance associated with the generation of SPD that reflect the statistical properties of the actual data. However, Krenmayr et al [23] reported favorable performance results when using the same generative adversarial network (GAN)–based methods and RWD. The differences between their study and our study were as follows: their study did not include SPD on survival time or generate multiple SPD data sets from the same actual data, and there was a large amount of individual patient data in their study. In particular, focusing on the amount of individual patient data, the number of patients in each trial included in this study was relatively small, with the NCT00119613 trial having 232 patients, the NCT00339183 trial having 476 patients, the NCT0046265 trial having 260 patients, and the NCT00703326 trial having 382 patients, while the trial conducted by Krenmayr et al [23] had 500 or more patients. GAN-based methods using deep neural networks are known to perform poorly with small amounts of data [25,33]. In this study, although the NCT00339183 trial had the largest number of individual patient data, the best case of CTGAN for NCT00339183 produced a KM plot similar to the actual data, suggesting that a larger data set yields better results. Thus, there is no contradiction. Another characteristic of using CTGAN in this study was the larger variance in the estimated MSTSs, as indicated in Figures 1 and 2. Goncalves et al [34] showed that using MC-MedGAN, a GAN-based method, to generate an SPD from small data resulted in a large SD of the data utility metrics, leading to results with larger variance, similar to those of this study. Therefore, it is extremely challenging to generate useful SPD by applying GAN-based methods to small data sets, such as clinical trial data.

When generating SPDs for survival data and using them as a certain arm in a clinical trial, it is important to verify that the statistical properties closely match those of the actual data with the MST and the hazard ratio with the actual data being close to 1. Based on our results, we conclude that CART, which can concentrate the MSTSs within the range of 95% CI of MSTAs and approximately 0.9 for HRD, is an efficient method for generating SPD that meets the abovementioned conditions. However, even when using CART, slight variations were observed in the MSTSs, and some cases fell outside the 95% CI of the MSTAs, as revealed by our results. Therefore, for practical use, it is necessary to verify that the MSTSs are included in the 95% CI of the MSTAs and that both are close in value. It is also necessary to verify whether the HRD of the actual data and the SPD are close to 1 and then decide whether to adopt the generated SPD. Hence, the generation process must be repeated until an acceptable SPD is obtained. There may also be a need to use statistical methods to match characteristics between the SPD and the actual treatment arm in clinical trials.

In this study, even the most useful CART method produced SPDs that did not meet the requirements of MST and HRD. We expect that this issue will be addressed by incorporating feature engineering, such as dimension reduction, imputing missing values, derived variable creation, and other processing. Additionally, in clinical research, as subgroup analyses are frequently conducted, it is necessary to improve the generation method to reflect the statistical properties of the actual data even when the data are divided into subgroups under certain conditions. Moreover, from the perspective of data privacy, it is essential to incorporate approaches to prevent data reidentification into the generation method [35].

In conclusion, as a method for generating SPD for survival data from small data sets, such as clinical trial data, CART is the most effective method for generating SPD that meet the 2 conditions of having an MSTSs close to the MSTAs and an HRD close to 1. However, as SPD might be generated, which do not meet these 2 conditions, it is necessary to incorporate mechanisms to improve a CART-based generation method in future studies. Overcoming these challenges would make it possible to reduce the recruitment period and costs of clinical trial participants to ≥50% in comparative trials of new drug development against existing therapeutic drugs. This approach could accelerate clinical development, similar to the use of RWD.

Acknowledgments

We would like to express our gratitude to Project Data Sphere, the platform that provided the necessary data for this study, and to the clinical trial data providers Amgen and Eli Lilly.

Abstract

Background: Clinical decision support systems (CDSSs) embedded in electronic medical records (EMRs), also called electronic health records, have the potential to improve the adoption of clinical guidelines. The University of Alberta Inflammatory Bowel Disease (IBD) Group developed a CDSS for patients with IBD who might be experiencing disease flare and deployed it within a clinical information system in 2 continuous time periods.

Objective: This study aims to evaluate the impact of the IBD CDSS on the adherence of health care providers (ie, physicians and nurses) to institutionally agreed clinical management protocols.

Methods: A 2-period interrupted time series (ITS) design, comparing adherence to a clinical flare management protocol during outpatient visits before and after the CDSS implementation, was used. Each interruption was initiated with user training and a memo with instructions for use. A group of 7 physicians, 1 nurse practitioner, and 4 nurses were invited to use the CDSS. In total, 31,726 flare encounters were extracted from the clinical information system database, and 9217 of them were manually screened for inclusion. Each data point in the ITS analysis corresponded to 1 month of individual patient encounters, with a total of 18 months of data (9 before and 9 after interruption) for each period. The study was designed in accordance with the Statement on Reporting of Evaluation Studies in Health Informatics (STARE-HI) guidelines for health informatics evaluations.

Results: Following manual screening, 623 flare encounters were confirmed and designated for ITS analysis. The CDSS was activated in 198 of 623 encounters, most commonly in cases where the primary visit reason was a suspected IBD flare. In Implementation Period 1, before-and-after analysis demonstrates an increase in documentation of clinical scores from 3.5% to 24.1% (P<.001), with a statistically significant level change in ITS analysis (P=.03). In Implementation Period 2, the before-and-after analysis showed further increases in the ordering of acute disease flare lab tests (47.6% to 65.8%; P<.001), including the biomarker fecal calprotectin (27.9% to 37.3%; P=.03) and stool culture testing (54.6% to 66.9%; P=.005); the latter is a test used to distinguish a flare from an infectious disease. There were no significant slope or level changes in ITS analyses in Implementation Period 2. The overall provider adoption rate was moderate at approximately 25%, with greater adoption by nurse providers (used in 30.5% of flare encounters) compared to physicians (used in 6.7% of flare encounters).

Conclusions: This is one of the first studies to investigate the implementation of a CDSS for IBD, designed with a leading EMR software (Epic Systems), providing initial evidence of an improvement over routine care. Several areas for future research were identified, notably the effect of CDSSs on outcomes and how to design a CDSS with greater utility for physicians. CDSSs for IBD should also be evaluated on a larger scale; this can be facilitated by regional and national centralized EMR systems.

Introduction

Limited or delayed adoption of professional society–developed clinical care guidelines into practice is a common problem in medicine [1,2]. In 2007, researchers estimated that it took 17 years on average for only 14% of published evidence in guidelines to be translated into clinical practice [3,4]. One purported reason is that clinical guidelines by themselves are not actionable, as they largely describe what to do but not how to do it [5,6].

Clinical decision support systems (CDSSs) are tools that can be used to support provider decision-making. A CDSS uses clinical, patient, and other health information to supply providers with recommendations to assist in a variety of aspects of care, including diagnosis, treatment, and management [7,8]. Recent systematic reviews suggest that the use of CDSSs in clinical settings can improve practitioner performance in relation to adherence to best practice guidelines [7,9].

There are several demonstrated gaps in the adoption of professional society clinical care guidelines and best practices for inflammatory bowel disease (IBD). These include practices in medication management, preventative care, and bone health [10,11]. The University of Alberta IBD outpatient clinic (Edmonton, Alberta, Canada) has previously developed and implemented several clinical care pathways to consolidate best practices for IBD [10,12]. To further increase adoption, a clinical decision support (CDS) project was undertaken to integrate the pathways into the local electronic medical record (EMR). There are thousands of CDS projects built and deployed within commercial EMRs [13,14], yet there are few published evaluations of EMR-based CDSSsfor IBD [15,16]. Consequently, the objective of this pilot study was to evaluate the effectiveness and provider acceptance of an EMR-integrated CDSS in the context of IBD.

Methods

Ethical Considerations

This study received approval from the University of Alberta Health Research Ethics Board (Pro00083538). A waiver of informed consent was also approved as part of our study by the Health Research Ethics Board.

Organizational Setting

The study was conducted in the Comprehensive Academic Outpatient Center at the University of Alberta Hospital, which provides care for patients with IBD in the Greater Edmonton region as well as rural and remote communities across Alberta, Canada. It also serves a small number of patients with IBD from Saskatchewan, Northwest Territories, and British Columbia.

System Details and System in Use

The clinic's preexisting system was an enterprise EMR based on the 2014 version of Epic EMR (Epic Systems), which was being used for outpatient medical care in Edmonton, Alberta. This system was customized and branded locally as eCLINICIAN. Medication lists, allergies, and health problems are recorded and shared between users as part of clinical documentation, order entry, and planning. The system was implemented for gastroenterology outpatient care in March 2014.

As Epic is a general-purpose EMR, it includes built-in CDS functionality. For example,this includes generic functionality, such as alerting users when duplicate orders exist. More specialty-specific CDS features are often customized at the request and guidance of end users.

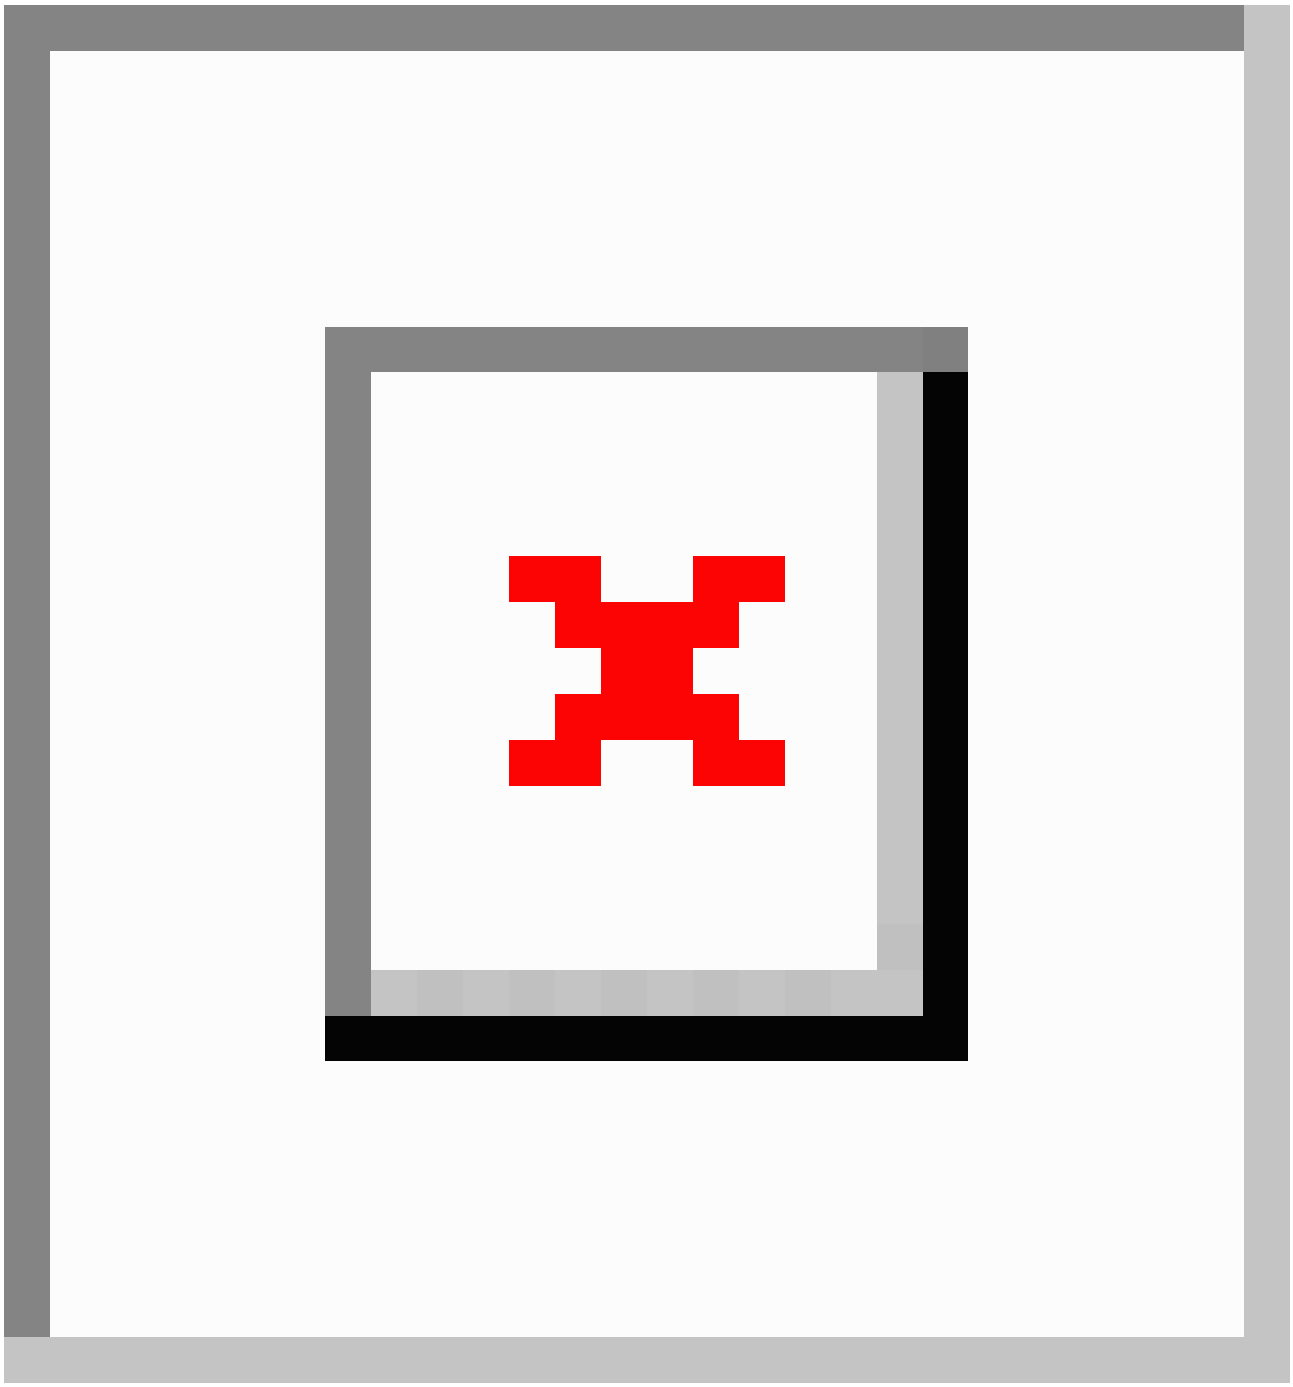
Functionality can be administered through a number of tools, including those referred to by Epic as "Flowsheets" (documentation tables), "Best Practice Advisories (BPAs)" (alerts) [17], and "SmartSets" (ie, grouping of orders and clinical content) [18].

These tools, particularly BPAs and SmartSets, are clinical data and test result driven; they can be triggered by unique combinations of provider characteristics, patient demographics, test results, clinical problems, as well as current and requested medications.

System Interruption and Intervention

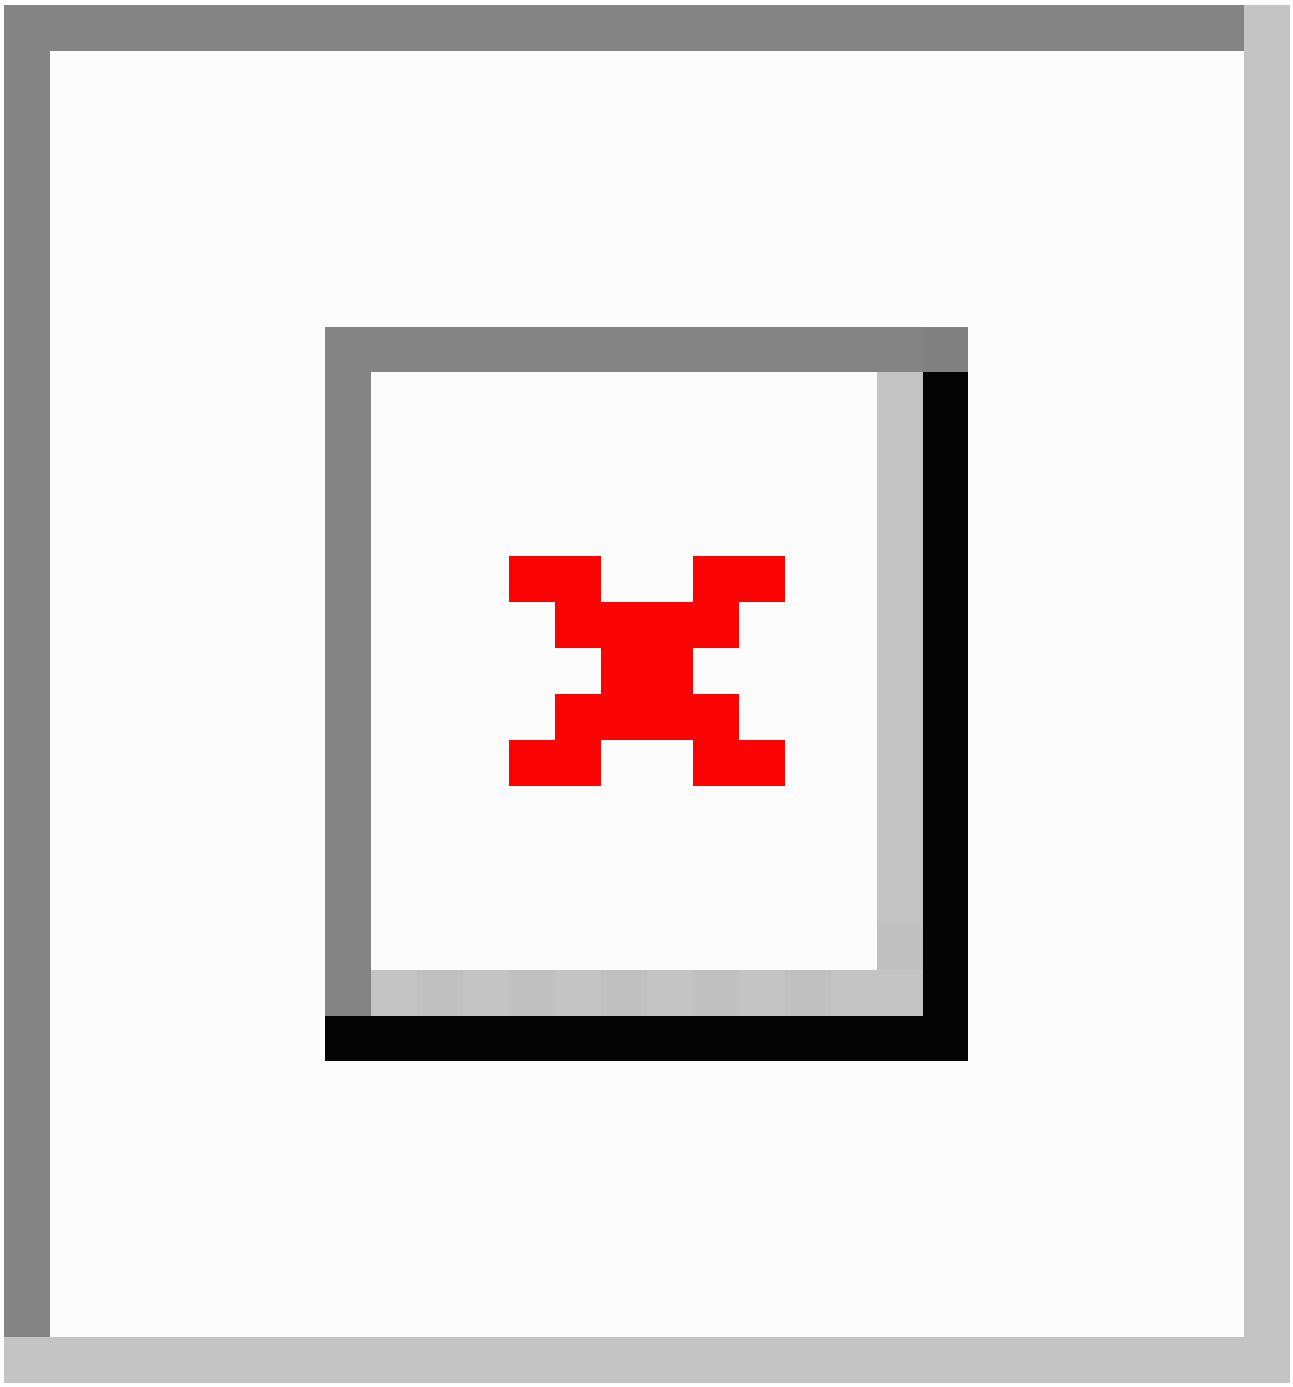
The system interruption and intervention uses BPA appearing in the clinician's navigator workflow. The BPA is triggered by the existence of IBD in the patient problem list or visit diagnosis fields. The BPA (Figure 1) prompts the clinician to complete clinical symptom indices—modified Harvey Bradshaw Index (mHBI) [19] for Crohn disease or partial Mayo (pMayo) score [20] for ulcerative colitis—for the encounter. If the score is indicative of a disease flare, the BPA instructs the user to activate a corresponding SmartSet.

Figure 1. Snapshot of the inflammatory bowel disease (IBD) flare clinical decision support system, showing the initial Best Practice Advisory. Best Practice Advisories act as alerts that present targeted patient-specific guidance to users. They can be active (disruptive pop-ups) or passive (navigation workflow) and can link to actions such as placing orders, order sets, initiating a care plan, or sending a message. This alert appeared passively in the providers' workflow navigation whenever IBD was in the patient problem list.



The SmartSet offers ordering and printing of appropriate lab panels, stool cultures, and other investigations, including imaging, procedures, and medication prescriptions. All recommendations were designed to be consistent with established IBD care guidelines and the flare protocol for the clinic. For example, during a flare encounter, the IBD flare lab panel and fecal calprotectin (FCP) tests are automatically selected for ordering (they can still be deselected by the provider). A snapshot of the SmartSet portion of the CDSS is shown in Figure 2.

Figure 2. Snapshot of the inflammatory bowel disease (IBD) flare clinical decision support system, showing the SmartSet, after activation by Best Practice Advisory. Not all sections of the SmartSet are shown, including sections for medications, imaging investigations, billing, and follow-up appointment booking. ALT: alanine transaminase; AST: aspartate aminotransferase; Cl: chloride; CO2: carbon dioxide; ESR: erythrocyte sedimentation rate; K: potassium; Na: sodium; NO DIFF: no differential.



Study Design

The study used a pre- and postimplementation interrupted time series (ITS) design, the interruption being the enhanced CDSS used within the EMR. Each data point represented 1 month of clinical encounters. For each intervention period, there was a total of 18 data points, 9 before and 9 after the intervention. Multimedia Appendix 1 presents an elaboration on the rationale for using an ITS design.

Physicians at the participating clinic were not guaranteed to have outpatient clinics on a weekly basis due to their service rotation; therefore, it was decided to aggregate the data points by month instead of by week. This avoided the potential week-to-week variation and ensured an adequate number of individual patient encounters (IBD flares) for each data point.

The Quality Criteria for ITS Designs checklist was used in the study design and assessment of appropriateness [21], and the Statement on Reporting of Evaluation Studies in Health Informatics (STARE-HI) guidelines were used for health informatics evaluations [22,23].

Participants

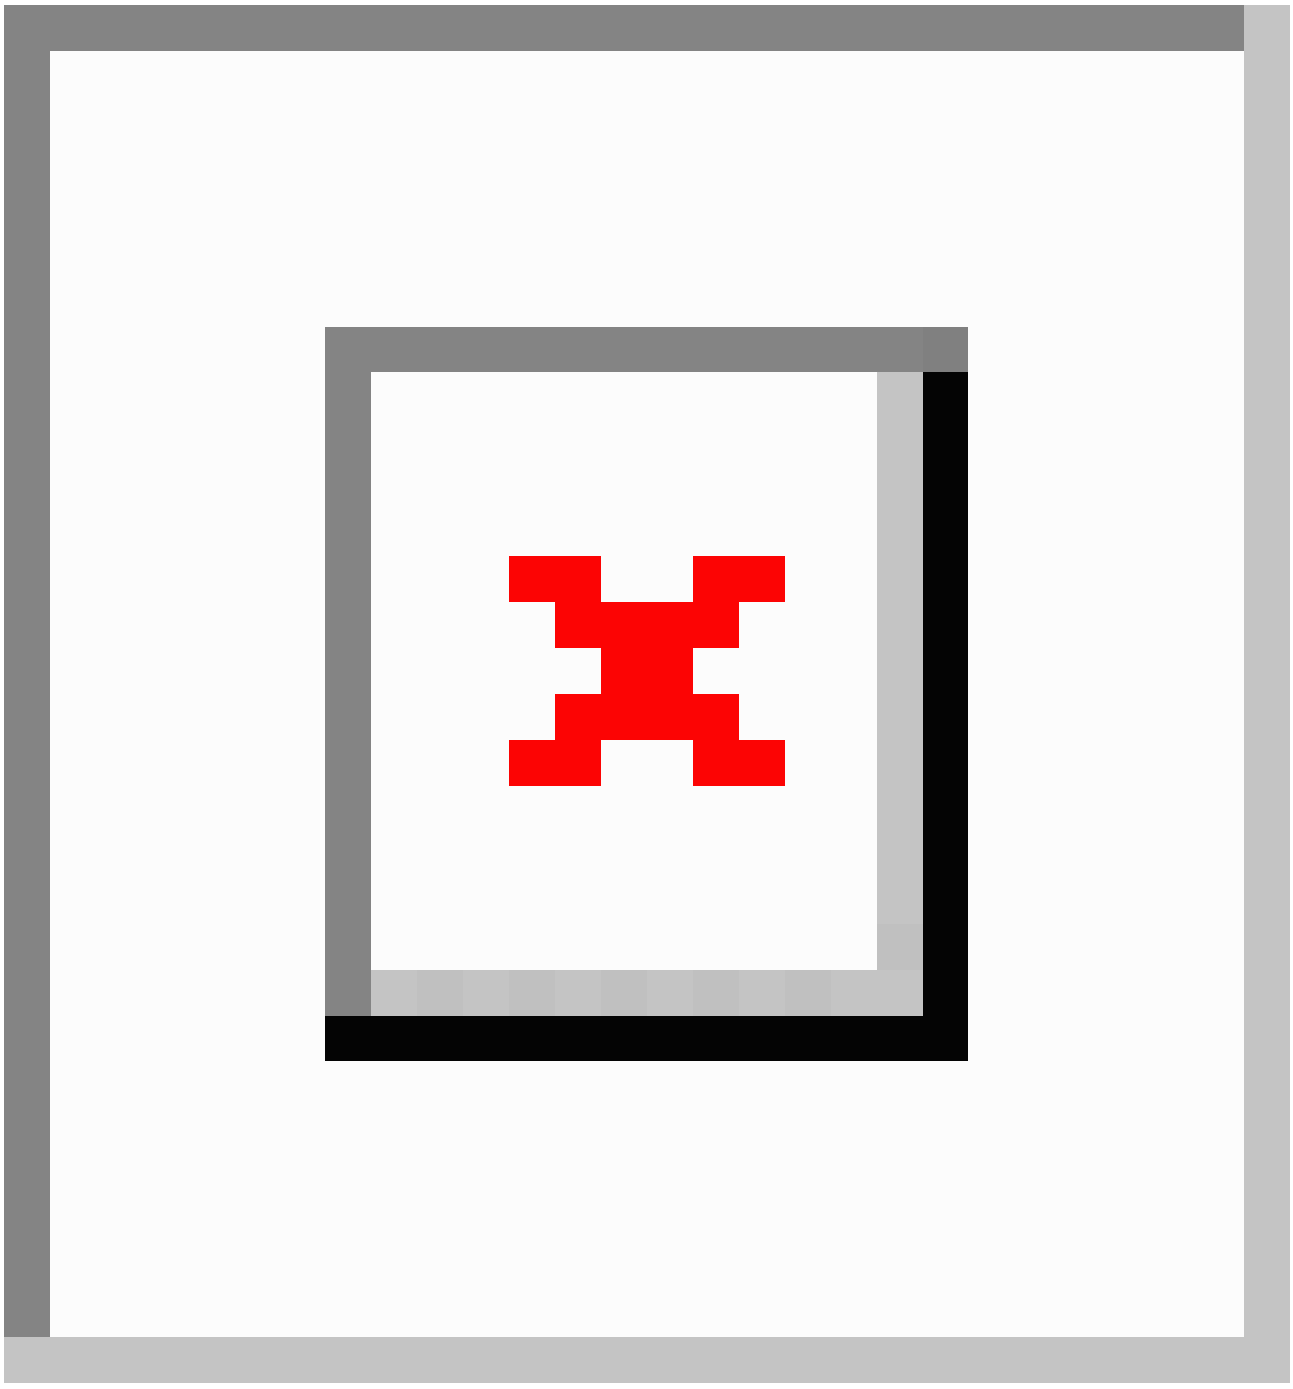
All IBD care providers at the university-based outpatient clinic were included in the study and invited to use the CDSS, including 7 IBD specialist clinicians, 1 IBD nurse practitioner, and 4 IBD specialist nurses. The term "IBD practitioner" will be used to collectively refer to IBD specialists and IBD nurse practitioners.

To be included in the data set, patients had to be under the care of the IBD providers; aged ≥18 years; and diagnosed with either Crohn disease or ulcerative colitis confirmed by imaging, pathology, or endoscopy report. They also had to be experiencing a flare of the disease during the included encounter, as defined by clinical scores (mHBI >5; pMayo >2) or noted symptoms in combination with physician judgment. Only initial encounters in a flare episode spanning multiple encounters were included.

Study Flow

The intervention was implemented and evaluated in 2 continuous periods (Figure 3). First, a pilot version was trialed by IBD nurses (Implementation Period 1), and then, the polished version was implemented across all providers in the division (ie, clinicians, nurse practitioners, and IBD nurses) as Implementation Period 2. The pilot version was trialed beginning in September 2017 and included the following 3 SmartSets available within the BPA, corresponding to different positions along the care path of a patient with flaring IBD: suspected flare, 2 to 4 weeks into the flare, and 16 weeks' postflare assessments. Feedback was gathered informally from providers (Multimedia Appendix 2) to inform further improvement to the CDSS.

Figure 3. Study design diagram of the 2-period interrupted time series design. First, the clinical decision support system (CDSS) was implemented as a limited pilot with inflammatory bowel disease (IBD) nurses (intervention 1), and then, it was fully implemented across all providers (intervention 2). Each data point (abbreviated as D) corresponds to 1 month of clinical encounters by study providers. NP: nurse practitioner.



After collecting feedback from the pilot, further changes were made to the CDSS. Aside from minor modifications to update included lab tests, the most significant change was the consolidation of the 3 separate SmartSets into 1, targeting the "suspected flare," the first step in the care pathway. The activation of the BPA in the initial CDSS was entirely manual and relied on the provider entering a specific visit diagnosis. However, in the full version, the BPA was set to automatically trigger based on the presence of an IBD diagnosis in the patient's problem list. This change was expected to improve the adoption and ease of use of the SmartSet for flare encounters.

The full implementation of the CDSS began on October 10, 2018. An instructional memo with paper-based workflow and educational material was sent to each provider (Multimedia Appendix 3). Over the course of 1 month, each participant was given the opportunity to ask questions about using the system and access to use the system in the sandbox environment. A demonstration of the system was also presented at weekly clinical rounds, with an opportunity to ask questions.

Outcome Measures

Process indicators were used to measure the proportion of adherent IBD practitioner flare encounters. These indicators include completion of clinical scores (mHBI or pMayo);

laboratory testing, such as standard lab panel, FCP, stool cultures, and *Clostridium difficile* toxin (only if diarrhea is present); and of vitamin D or calcium in conjunction with corticosteroid prescription, patient information given and documented, and modification of maintenance therapy. A secondary outcome was the adoption or acceptance of the CDSS measured by application rate (ratio of CDSS uses to CDSS available for activation).

Methods for Data Acquisition and Measurement

Potential encounters in the pre- and postintervention periods were initially identified by querying the eCLINICIAN EMR database for encounters with the included IBD providers, where patients had documentation of IBD in their problem list or diagnosis field (*International Classification of Diseases* coding). A sampling method was used to exclude encounters with specific reasons for visit deemed unlikely to constitute a flare based on exploratory analysis of the data set. Examples of excluded reasons for the visit included "medication refill," "medical insurance coverage," and "review results" (a more detailed description of the sampling method is available in a previous publication [10]). Encounters were then screened manually for inclusion and exclusion eligibility by one of the authors (RTS) and a research assistant.

Data for primary outcome measures were also queried and extracted from the EMR database, in collaboration with the eCLINICIAN reporting team in Alberta Health Services (AHS). The various database codes and IDs as well as the final SQL queries used to extract data are included in the Multimedia Appendix 4.

Methods for Data Analysis

Descriptive statistics were calculated to determine patient characteristics, with data presented as counts and proportions for categorical variables, mean (SD) values for normally distributed continuous variables, and median (IQR) values for nonnormally distributed continuous variables. Proportions were compared by using the Pearson χ^2 test [24].

A segmented regression analysis was performed for each primary outcome variable to determine the level and slope in the preintervention period as well as the change in level and slope in the postintervention period regarding the mean percentage of adherent encounters [25]. Autocorrelation in the residuals was tested using the Durbin-Watson test.

Data analysis was performed using IBM SPSS Statistics (version 23; IBM Corp) and R 3.5.1 (RStudio Inc) [26]. A 95% CI was used in all analyses unless otherwise specified.

Sample Size Determination

The sample size was first calculated for pre- and postimplementation cohorts based on logistic regression (Multimedia Appendix 5). With a power of 0.80 and a type I error set to 5%, the sample size required was approximately 634 for small effects and 145 for medium effects [27]. This assumes equal sample sizes (N) in the comparison groups and an initial proportion of adherence to each guideline component of approximately 70%, chosen based on a recent study by Jackson et al [11]. The sample size was calculated using G*Power 3.2.9.2 [28].

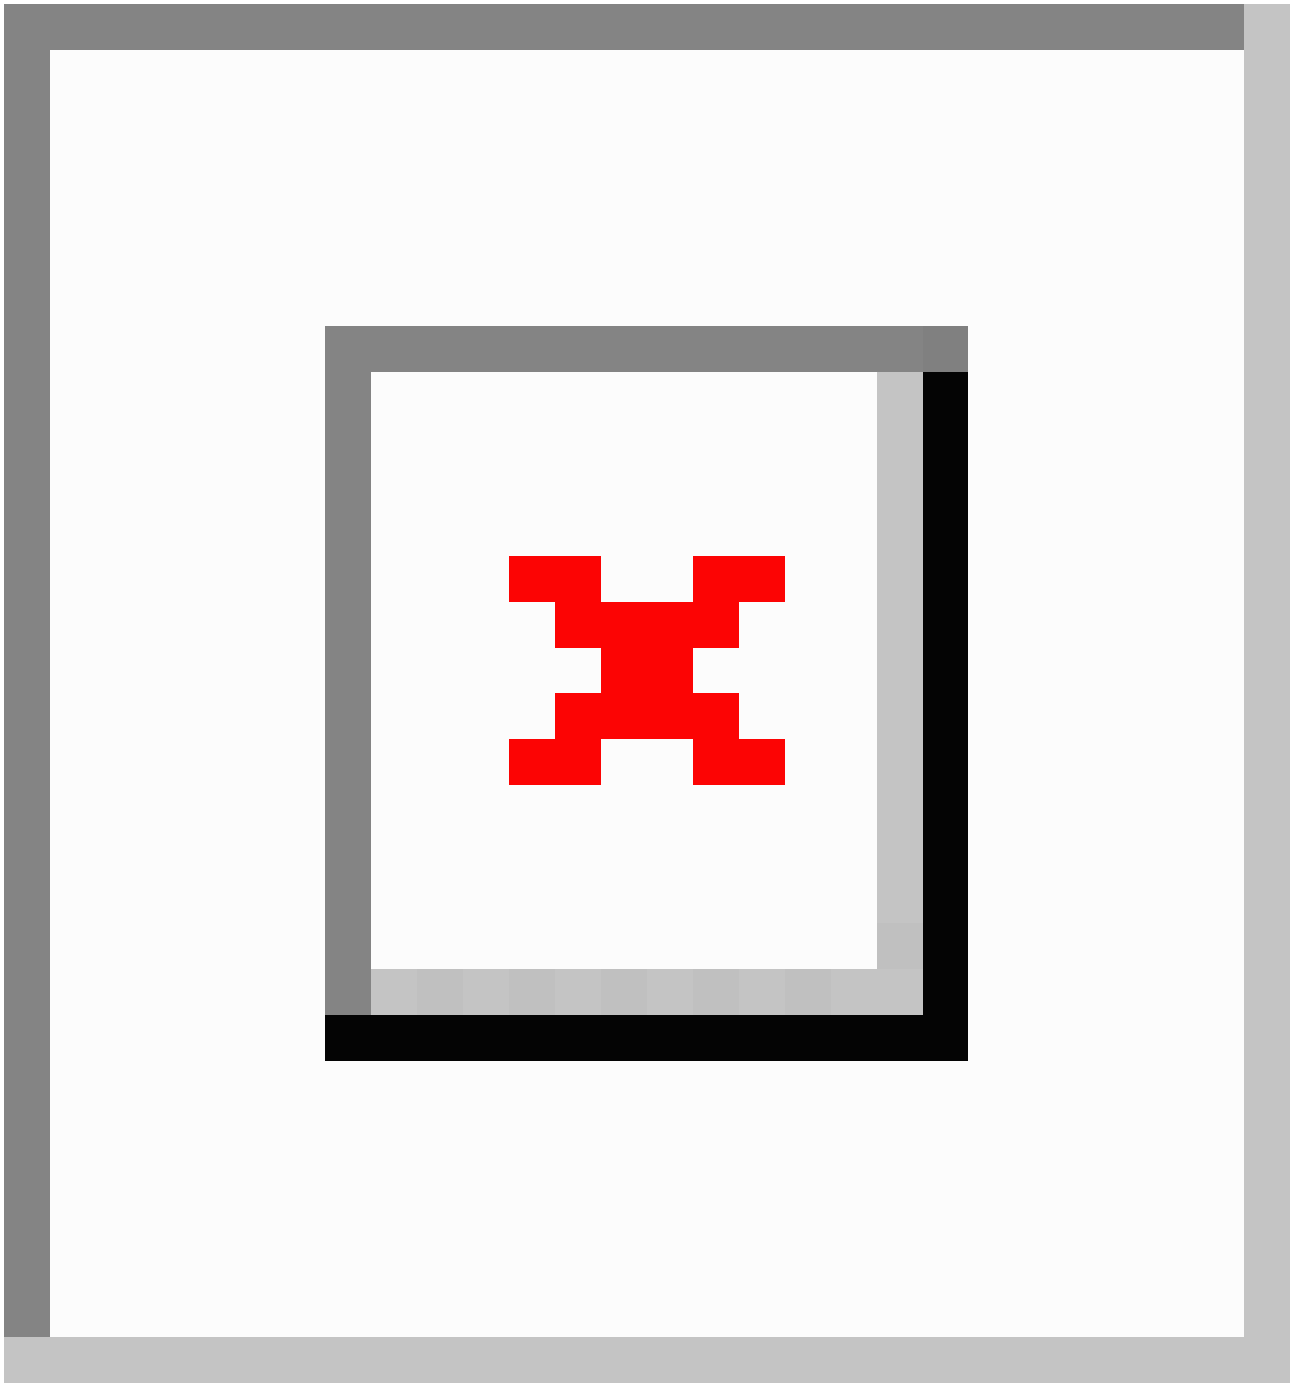
There is no standard method for determining power in time series analyses. However, a simulation-based power calculation displayed that with N=16 (8 data points in the preintervention period and 8 data points in the postintervention period), there is a 70% chance to detect an effect size of 0.5 or more, and over 90% chance to detect an effect size of 1 or more, at an alpha level of .05 [29]. It is also generally recommended in the literature to have over 100 observations per data point [25,30].

Results

Initial Data Set and Preprocessing

Figure 4 shows the study's flow diagram. The complete, extracted data set includes 31,726 encounters from January 1, 2017, to June 30, 2019. When considering only clinic visits (7655), orders (16,485), and telephone (5220) encounter types, the data set totals 29,360 (92.5%) encounters. There was an average of 998 encounters per month, with a minimum of 735 (December 2018) and a maximum of 1202 (May 2017) encounters. Of note, there is an overlap between both implementation periods (Figure 3), and thereby, a number of flare encounters appear in both analyses.

Figure 4. Flow data diagram for data extraction, screening, and analyses. CDSS: clinical decision support system.



Demographics of CDSS-Enabled Encounters

From September 2017 to June 2019, the CDSS was activated a total of 214 times across 214 encounters with 207 patients. Of these, 16 encounters were excluded from analysis due to, upon review, not being used appropriately for a flare or suspected flare encounter with a patient with IBD. This left 198 encounters, which are detailed in Table 1. More detailed demographics of providers using the system are included in Multimedia Appendix 6.

Table . Demographics of users and encounters invoking the inflammatory bowel disease (IBD) flare clinical decision support system.

Demographic variables	Study population (n=198)
Provider characteristics	
Provider type, n (%)	
IBD nurse	172 (86.9)
IBD practitioner	26 (13.1)
Patient characteristics

Study Findings and Outcome Data

Exploratory Analysis of Adherence to Clinical Protocols

Symptom Documentation

Of 192 patients with clinical scores (mHBI or pMayo) that were applicable (excluding those without pouch or short bowel or those newly diagnosed), 133 (69.3%) had a clinical score completed and documented in their chart at the index dispensation. Of all 198 encounters, 196 (99.0%) had symptoms (ie, pain, number and characteristics of stool, and the presence of blood) documented in the chart by the provider.

Laboratory Investigations

Full flare lab panels, including complete blood count, ferritin, electrolytes, creatinine, albumin, alkaline phosphatase, alanine transaminase, aspartate transaminase, and C-reactive protein (CRP), were ordered for 109/198 (55.1%) patients exactly at the encounter. Including orders up to 1 month prior, full panels were ordered for 183/198 (92.4%) patients. However, 113/198 (57.1%) had at least a partial lab panel, including complete blood count and CRP, ordered at the encounter, and 193/198 (97.5%) had partial lab panels, including complete blood count and CRP ordered up to 1 month prior to the encounter.

FCP was ordered at the encounter for 147/198 (74.2%) patients and within 1 month of the encounter for a further 36/198 (18.2%). This leaves only 15 (7.6%) who had no evaluation of FCP at all. Furthermore, testing for *Clostridium difficile* infection was done in 164/198 (82.8%) patients and for stool cultures in 160/198 (80.8) patients. In 138 patients with liquid stool or diarrhea mentioned in the progress note, 127 (92%) had *Clostridium difficile* testing ordered and 123 (89.1%) had stool cultures ordered.

Provision of Steroid-Sparing Therapy and Osteoprotective Therapy

In this data set, only 12 (6.1%) patients were prescribed steroids at their encounter. Of these, 6 (50%) had maintenance IBD therapy adjusted or added. In contrast, 37 (20%) of the 185 patients who were not prescribed steroids had maintenance therapy adjusted (P=.02 for χ^2).

Vitamin D or calcium supplementation was recommended for 8/12 (67%) patients prescribed steroids and 8/10 (80%) when excluding patients with vitamin D or calcium supplementation already documented in their medication list.

Implementation Period 1: Pilot CDSS Version With IBD Nurses

Implementation Period 1 included data from January 2017 to June 2018 (18 months), where September 2017 and beyond were labelled as the active intervention months (postintervention). Of the total 623 confirmed flare encounters, 502 occurred during Implementation Period 1 (Figure 3). Table 2 compares outcome measures before and after the intervention using chi-square tests. Notably, there was a substantial increase in the proportion of flare encounters with completed clinical scores from 3.5% (8/228) to 24.1% (66/274) post intervention. There was also an increase in the proportion of flare encounters with FCP ordered, from 16.7% (38/228) to 27% (74/274).

Table . Before-and-after analysis of process measures from Implementation Period 1.

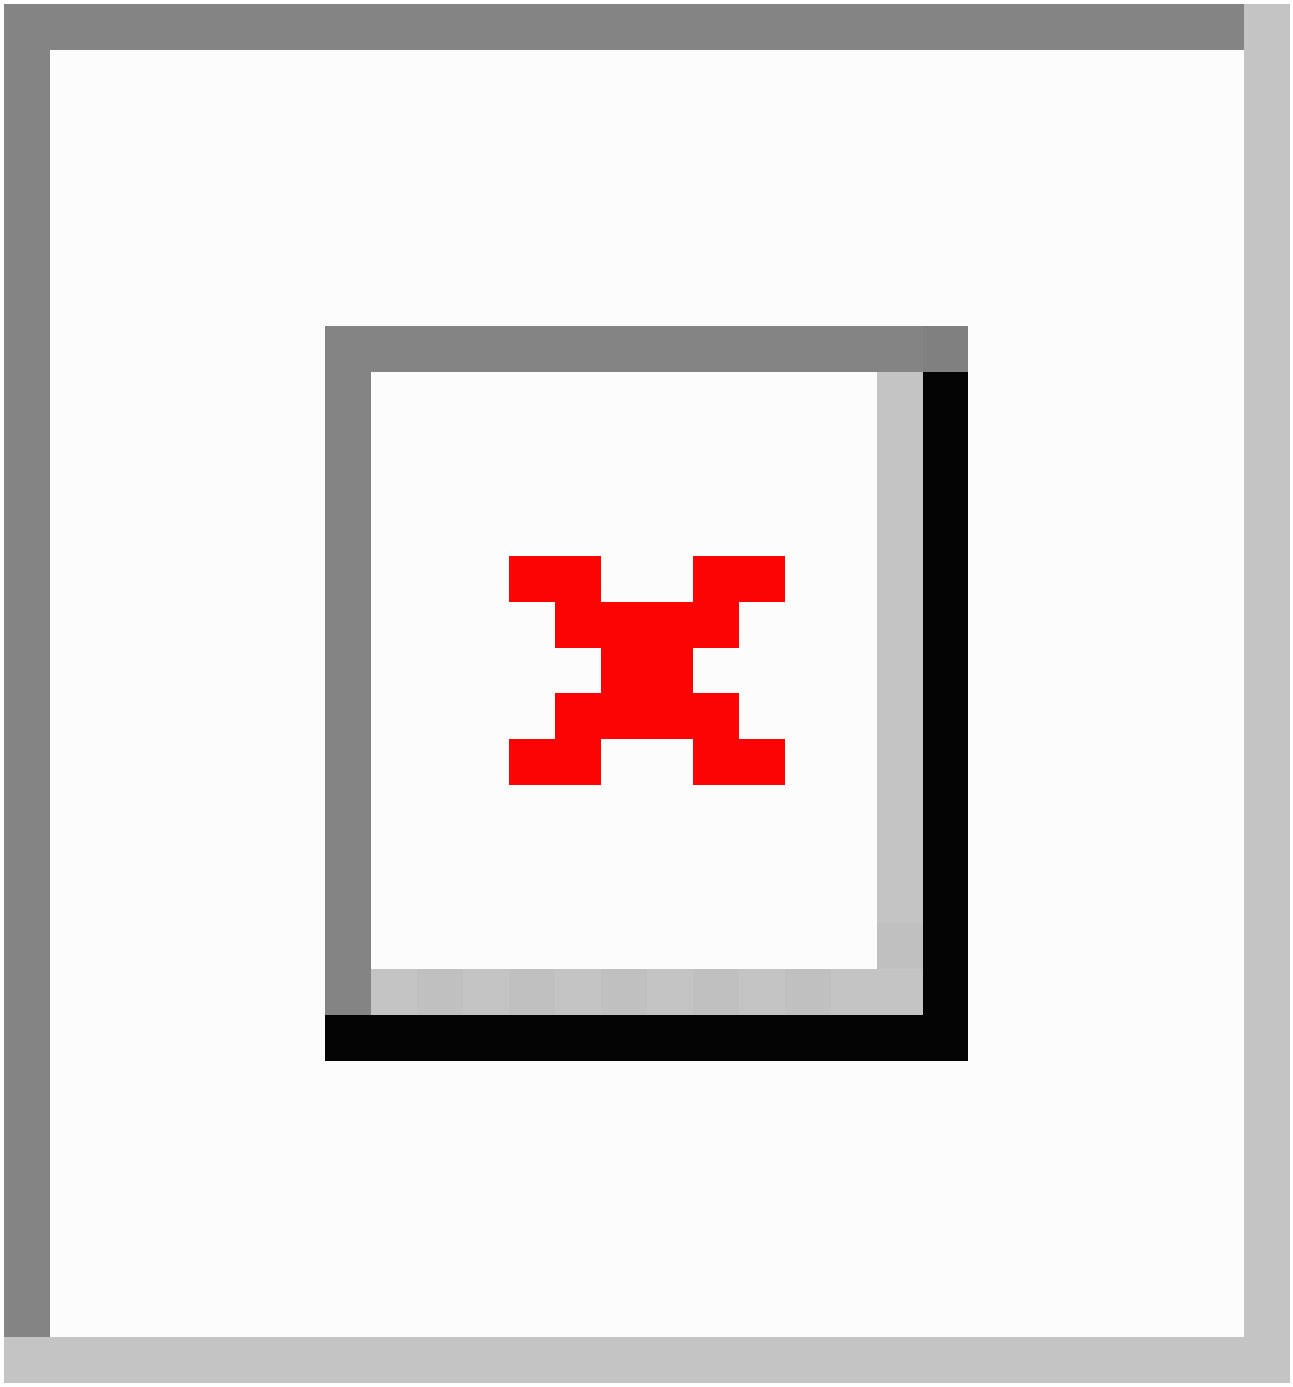
Parameter	Preintervention (n=228), n (%)	Postintervention (n=274), n (%)	*P* value[a]
CDSS[b] activated	0 (0)	66 (24.1)	<.001
Clinical score completed	8 (3.5)	66 (24.1)	<.001
Flare labs ordered	124 (54.4)	132 (48.2)	.33
C-reactive protein ordered	156 (68.4)	178 (65.0)	.56
Fecal calprotectin ordered	38 (16.7)	74 (27.0)	.048
Stool cultures ordered	128 (56.1)	162 (59.1)	.63
Clostridium difficile test ordered	128 (56.1)	172 (62.8)	.29

[a]*P* value of the Pearson chi-square test comparing proportions.

[b]CDSS: clinical decision support system.

ITS analysis was done for outcomes that were significant in the before-and-after analyses (Figure 5). For clinical score completion rates, there was no slope change (estimated β −1.22, 95% CI −4.44 to 2.01; P=.43), but there was a level increase (estimated β 19.0, 95% CI 2.39-35.60; P=.03). For calprotectin testing, there was no slope change (estimated β −2.45, 95% CI −6.21 to 1.32; P=.19) or level change (estimated β 14.77, 95% CI −4.63 to 34.17; P=.13).

Figure 5. Segmented regression for Implementation Period 1 (pilot) of the inflammatory bowel disease flare clinical decision support system on rates of (A) clinical score completion and (B) calprotectin testing.



Implementation Period 2: Full CDSS Implementation With All Providers

Implementation Period 2 included data from January 2018 to June 2019 (18 months), where October 2018 and beyond were postintervention months. Of the total 623 confirmed flare encounters, 492 occurred during Implementation Period 2 (Figure 3). Table 3 compares outcome measures before and after the intervention using chi-square tests. There were increases in the proportion of flare encounters with completed flare labs (109/229, 47.6% to 173/263, 65.8%), CRP ordered (147/229, 64.2% to 207/263, 78.7%), calprotectin ordered (64/229, 27.9% to 98/263, 37.3%), and stool cultures ordered (125/229, 54.6% to 176/263, 66.9%).

Table . Before-and-after analysis of process measures from Implementation Period 2.

Parameter	Preintervention (n=229), n (%)	Postintervention (n=263), n (%)	*P* value[a]
Application of SmartSets	52 (22.7)	72 (27.4)	.23
Clinical score completed	58 (25.3)	75 (28.5)	.43
Flare labs ordered	109 (47.6)	173 (65.8)	<.001
C-reactive protein ordered	147 (64.2)	207 (78.7)	<.001
Fecal calprotectin ordered	64 (27.9)	98 (37.3)	.03
Stool cultures ordered	125 (54.6)	176 (66.9)	.005
Clostridium testing ordered	136 (59.4)	177 (67.3)	.70

[a]*P* value of the Pearson chi-square test comparing proportions.

The ITS analysis for significant outcomes is shown in Figure 6, and accompanying β values for slope change and level change with 95% CIs are shown in Table 4. For Period 2, there were no slope or level increases that reached significance at *P*=.05, although CRP testing and stool culture testing would be significant for a level increase at *P*=.10.

Figure 6. Segmented regression for Implementation Period 2 of the inflammatory bowel disease (IBD) flare clinical decision support system on rates of (A) clinical score completion, (B) flare lab testing, (C) C-reactive protein testing, (D) calprotectin testing, (E) stool culture testing, and (F) *Clostridium difficile* testing.

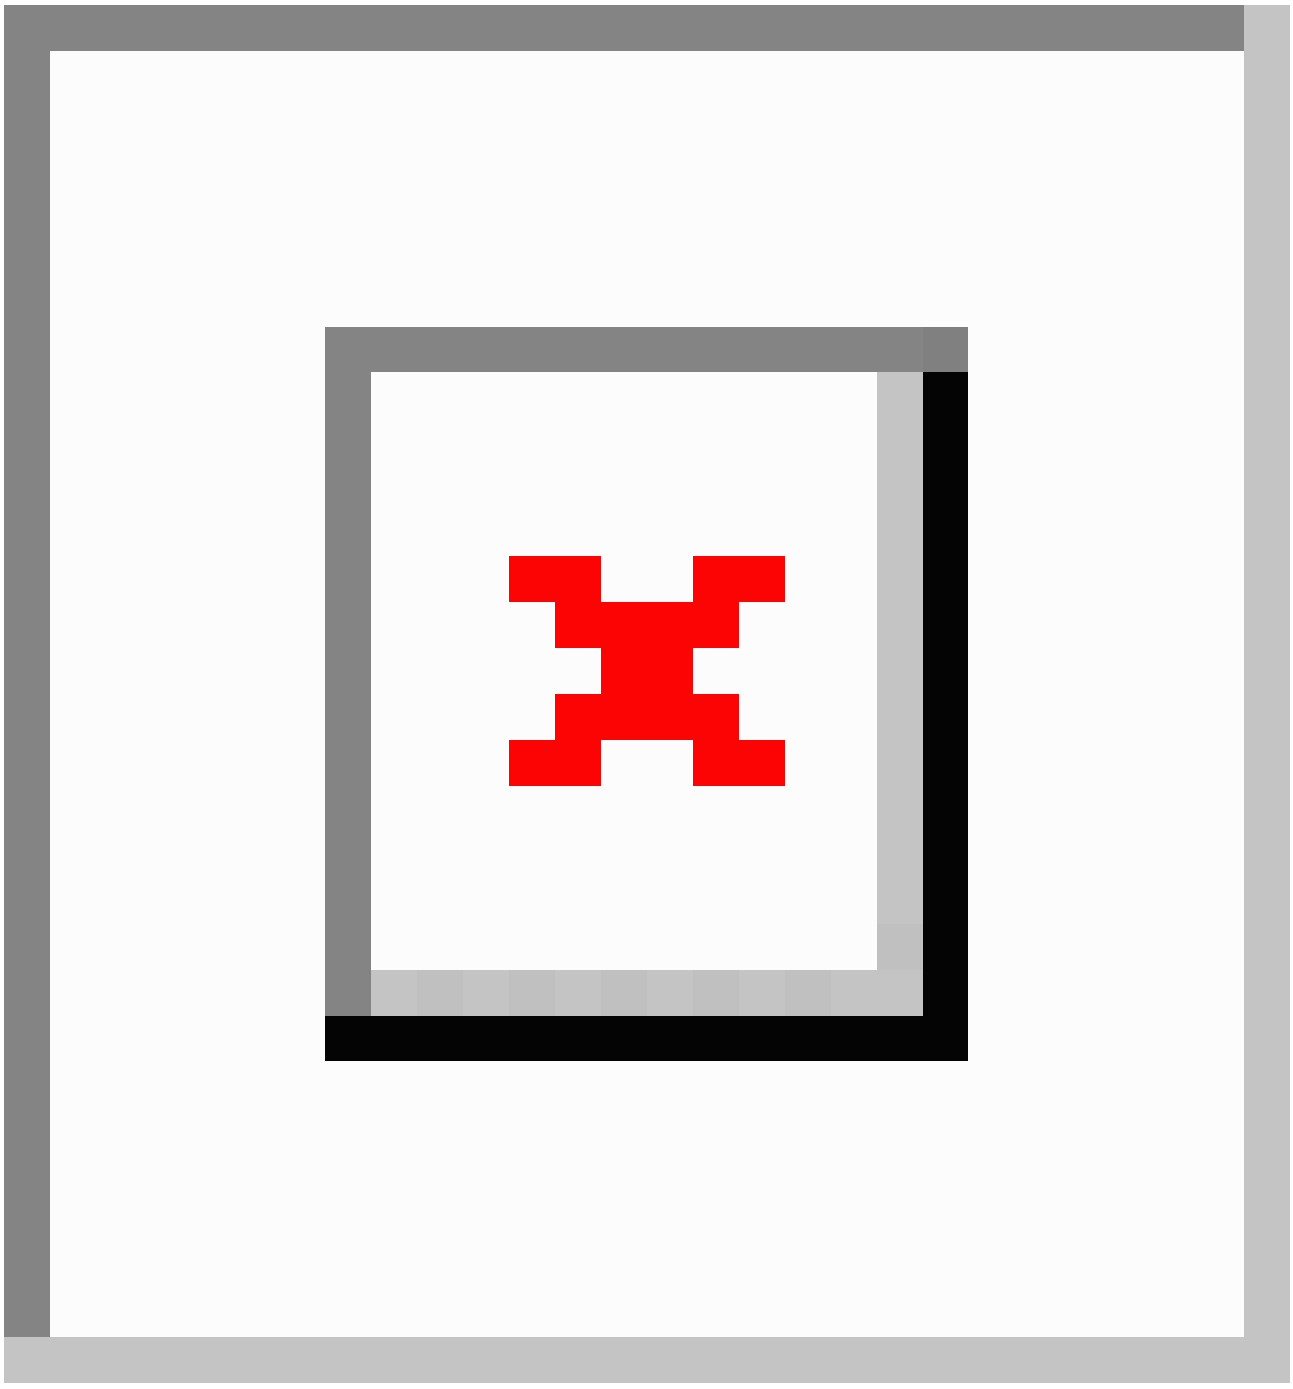


Table . Parameters for segmented logistic regression analysis of the inflammatory bowel disease (IBD) clinical decision support system (CDSS) in Implementation Period 2.

Parameter		ß	95% CI	*P* value
Application rate				
	Preintervention slope (secular trend, per month)	0.151	−3.757 to 4.059	.94
	Change in slope (gradual effect, per month)	2.019	−3.508 to 7.546	.45
	Change in intercept (immediate effect)	−5.048	−33.86 to 23.76	.71
Clinical scores completed and documented				
	Preintervention slope (secular trend, per month)	1.648	−1.596 to 4.893	.29
	Change in slope (gradual effect, per month)	−2.463	−7.051 to 2.125	.27
	Change in intercept (immediate effect)	−0.992	−24.91 to 22.92	.93
IBD flare lab tests ordered				
	Preintervention slope (secular trend, per month)	−0.016	−2.693 to 2.662	.99
	Change in slope (gradual effect, per month)	1.929	−1.858 to 5.715	.29
	Change in intercept (immediate effect)	12.60	−7.137 to 32.34	.19
C-reactive protein ordered				
	Preintervention slope (secular trend, per month)	−0.742	−3.121 to 1.637	.52
	Change in slope (gradual effect, per month)	1.253	−2.111 to 4.618	.44
	Change in intercept (immediate effect)	14.89	−2.645 to 32.43	.09
Fecal calprotectin ordered				
	Preintervention slope (secular trend, per month)	1.298	−2.209 to 4.806	.44
	Change in slope (gradual effect, per month)	0.183	−4.778 to 5.143	.94
	Change in intercept (immediate effect)	−1.034	−26.89 to 24.82	.93
Stool cultures ordered				
	Preintervention slope (secular trend, per month)	−1.060	−3.650 to 1.529	.40
	Change in slope (gradual effect, per month)	1.714	−1.948 to 5.376	.33
	Change in intercept (immediate effect)	15.37	−3.715 to 34.46	.11
	Clostridium difficile ordered			
	Preintervention slope (secular trend, per month)	−0.228	−2.613 to 2.158	.84
	Change in slope (gradual effect, per month)	1.825	−1.549 to 5.198	.27
	Change in intercept (immediate effect)	3.258	−14.33 to 20.84	.70

Discussion

Answering the Study Question

In this study, we evaluated the effectiveness of a CDSS that aimed to standardize protocols for patients with IBD experiencing an acute disease flare. An increase in several practices was demonstrated following the CDSS implementation, including increased FCP use. Completion of clinical scores also increased during Implementation Period 1 (before-and-after analysis and ITS analysis) and remained increased throughout Implementation Period 2.

We did not reach significance in slope changes or level changes in any ITS analysis in Period 2. This could be due to the sample size, which may also account for the large variance seen in some data points. There were, however, some encouraging upward trends in flare lab testing, particularly CRP (P<.10 in the ITS analysis) and stool cultures.

In characterizing the adoption of this CDSS by the application rate, an interesting finding was that the CDSS was used more by IBD nurses compared to nurse practitioners. This could represent the nurses' increased experience with the CDSS from the pilot phase and our CDSS focus on decisions related to patients experiencing a disease flare. In the University of Alberta clinic, patients are instructed to call the IBD nurse flare line if they experience changes in symptoms, and so nurses are often the first point of contact in the flare clinical pathway. This is supported by our data showing flare encounters are primarily telephone encounters. Other research has shown that flares are unlikely to coincide with scheduled clinic appointments, which aligns with the current uptake in remote monitoring and rapid access clinics [31-33].

Our observed CDSS use by specialized IBD nurses is in contrast to several other studies that have demonstrated that nurses are less likely to use CDSSs when making decisions about care they are experienced and confident in delivering, especially in the case of telephone triage decisions [34-36]. Our results could be a product of the integration of the nurses' feedback after the pilot phase, a strategy that may have increased the utility of the CDSS for nurses. This highlights recommendations from other research that emphasize the importance of engaging all stakeholders but especially end users in the CDSS design [37,38].

Limitations of the Study

There are several limitations to this research. Although the ITS design allows for better characterization of temporal changes compared to before-and-after analyses, it is still possible that other changes, such as clinic structure and release or dissemination of guidelines, could have led to the changes observed. However, apart from the intervention activation and the released memo and instructions for use that were disseminated, to our knowledge, there were no other educational campaigns, institutional changes, or major publications promoting the specific care guidelines investigated by the study. There were subtle changes in staff, for example, the joining of a new IBD physician and the leaving of another. However, there were no changes in IBD nurse staff, who were the primary users of the CDSS.

In contrast to the advantage of our 2-phased design regarding the opportunity for feedback from nurses, the design may have hindered our ability to demonstrate change. As we used the same group of IBD nurses in the pilot (Phase 1) and implementation (Phase 2) periods, our baseline use prior to the beginning of Phase 2 had already started. This may have accelerated the observed uptake speed of the CDSS by practitioners and could have also led to an underestimation of the changes before and after Implementation Phase 2.

Sample size is another limitation. In an ITS analysis, it is recommended to have a minimum of 16 data points and 100 observations per data point [25,29,30]. Although we met the data point requirement, the number of flares per month was consistently under 50. Future studies should aim to include more data points, which may require multisite participation. Unfortunately, at the time of this study, the EMR software was only deployed at a single site.

We only captured data from orders that were tied to the encounter. If a decision was made to not order labs for any reason (eg, they were recently completed), they would not be captured by our extraction. As a consequence, estimates of protocol adherence could be deflated.

Finally, it is important to note that for process measures that depend on manual data entry, such as clinical score completion, this research method can only determine whether a process was documented as completed but not necessarily whether it was actually completed. This may have resulted in underestimates of protocol adherence.

Future Directions

The currently available CDSS in this study was limited in its ability to support complex multiprovider pathways and tie together multiple visits along a pathway. More advanced CDSS workflows should be investigated in future versions of the CDSS software and evaluated for effectiveness.

Triggering logic for CDSSs should also be precisely targeted. For example, a CDSS should determine whether a patient has had a test done within a certain time span, and if not, prompt the user to order it. The reverse should also be possible; if a test has been recently ordered (eg, *Clostridium difficile*, which can only be tested once every 2 weeks), the CDSS could automatically deselect or prompt the user to remove this order to save downstream resources. This was not possible with the resources available in our CDSS environment.

In extracting data for analysis, a significant challenge was identifying flare encounters based on EMR data. The problem stems from a lack of discrete data identifying patients with active diseases (clinical scores were not regularly documented as discrete data). Future research should seek to develop a case definition for disease flare through administrative provincial data sets. This could include quantitative metrics, such as CRP and FCP, that predict the likelihood of flare, but it could also include the integration of a case-finding algorithm that uses natural language processing to parse clinical notes. This strategy

has been explored in several other diseases and has been shown to significantly improve case detection [39]. Some work has been done in IBD to identify phenotypic information from clinic notes using natural language processing [40].

The methodology used in this research should be expanded to investigate the effects of improved versions of CDSS for IBD on other community clinics and nonacademic practices throughout Alberta. Cluster-randomized designs or stepped-wedge designs could be explored since multiple clinics could be available for randomization.

This study did not investigate the impact on patient outcomes, which would require a longer follow-up period (ideally 2 or more years). Nonetheless, long-term patient outcomes for the CDSS are of great importance [9] and should be explored in the future.

Conclusions

Through our study, we designed and implemented, in 2 phases, a CDSS for IBD disease flare embedded in existing EMR software and evaluated the impact of the CDSS on provider adoption of clinical guidelines and local best practices. We have shown moderate adoption and acceptance of this system by providers, particularly by IBD nurses, as measured by the system application rate. Findings from the first phase support the hypothesis that the CDSS improved the use of FCP and the documentation of clinical scores. Findings from the second phase support further improvement in ordering flare lab panels, CRP, and stool cultures, as shown in before-and-after analysis and multivariate analysis. In addition, potential improvements in workflow integration were identified through qualitative questionnaires and feedback forms; areas for future research have also been established.

Acknowledgments

The authors acknowledge the faculty and staff of the inflammatory bowel disease (IBD) Unit and Division of Gastroenterology at the University of Alberta Hospital, who helped with the design and implementation of the IBD clinical care pathway (CCP). We also acknowledge the staff of Alberta Health Services (AHS) for their assistance with supplying the data. We thank Mr Darryl Wilson, the reporting systems analyst for the AHS Information Systems, for his assistance with the natural language queries (SQL) data acquisition from eCLINICIAN, and Mr Nathan Stern for helping with the chart review. Finally, we would like to thank the late Dr Richard Fedorak for his contribution to this work.

All results and inferences reported in this manuscript are independent of the funding and support sources.

Authors' Contributions

RTS contributed to study design, data collection, data analysis, and manuscript drafting. KDC contributed to drafting and revision of the manuscript. DP, DCS, and DCB contributed to the critical revision of the manuscript. KIK contributed to the study design as well as the analysis and critical revision of the manuscript. All authors approved the final version. KIK is the guarantor of the paper.

Conflicts of Interest

This study was supported by the Crohn’s and Colitis Canada via the Promoting Access and Care through Centres of Excellence (PACE) initiative. RTS was also supported by studentships from Alberta Innovates, the Faculty of Medicine and Dentistry, University of Alberta, and the Canadian Institutes of Health Research (CIHR). All other authors have no conflicts of interest to declare.

Abstract

Background: Numerous pressure injury prediction models have been developed using electronic health record data, yet hospital-acquired pressure injuries (HAPIs) are increasing, which demonstrates the critical challenge of implementing these models in routine care.

Objective: To help bridge the gap between development and implementation, we sought to create a model that was feasible, broadly applicable, dynamic, actionable, and rigorously validated and then compare its performance to usual care (ie, the Braden scale).

Methods: We extracted electronic health record data from 197,991 adult hospital admissions with 51 candidate features. For risk prediction and feature selection, we used logistic regression with a least absolute shrinkage and selection operator (LASSO) approach. To compare the model with usual care, we used the area under the receiver operating curve (AUC), Brier score, slope, intercept, and integrated calibration index. The model was validated using a temporally staggered cohort.

Results: A total of 5458 HAPIs were identified between January 2018 and July 2022. We determined 22 features were necessary to achieve a parsimonious and highly accurate model. The top 5 features included tracheostomy, edema, central line, first albumin measure, and age. Our model achieved higher discrimination than the Braden scale (AUC 0.897, 95% CI 0.893-0.901 vs AUC 0.798, 95% CI 0.791-0.803).

Conclusions: We developed and validated an accurate prediction model for HAPIs that surpassed the standard-of-care risk assessment and fulfilled necessary elements for implementation. Future work includes a pragmatic randomized trial to assess whether our model improves patient outcomes.

Introduction

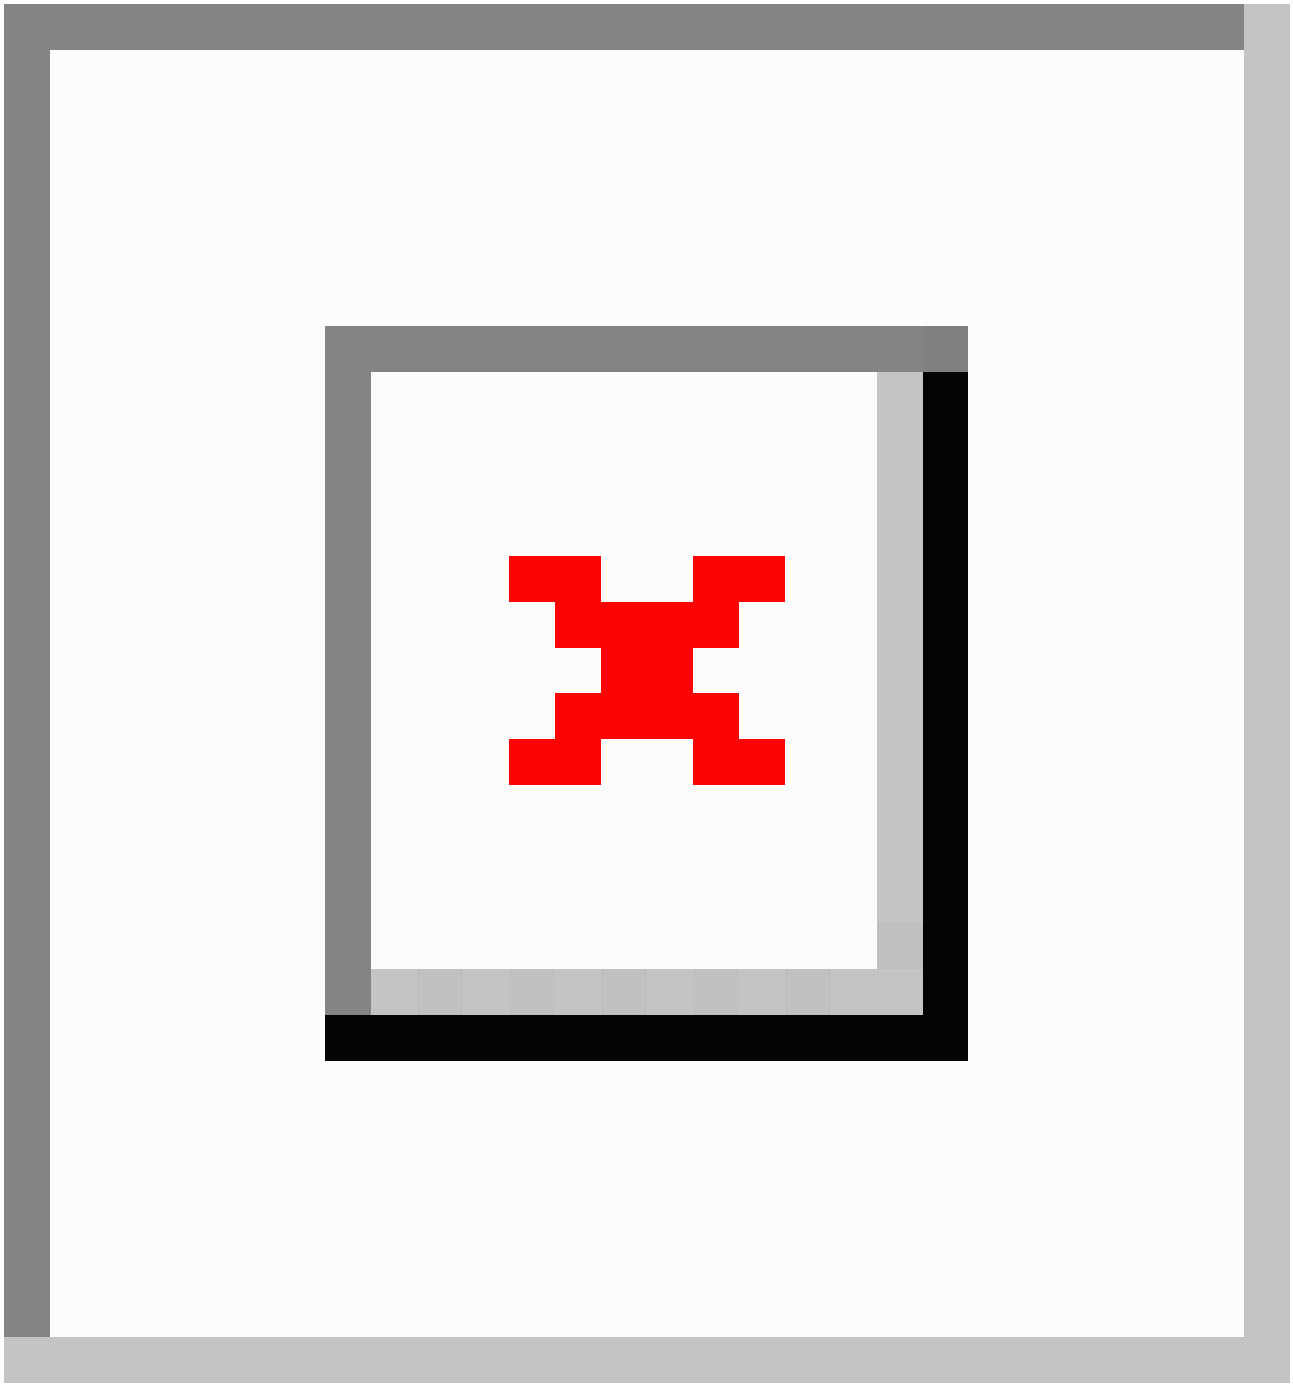
Pressure injuries comprise damage to skin and underlying tissue that usually occurs over a bony prominence but can be related to placement of medical devices [1]. The injury occurs because of intense or prolonged pressure that is combined with shear forces. Pressure injuries are a widespread and costly problem. A recent study found the prevalence of pressure injuries may be close to 30% for patients in intensive care units, which is 10% higher than previous estimates [2,3]. Patients with pressure injuries experience pain and the potential for infection and debilitation, which prolongs hospital stays and impacts recovery. Furthermore, increasing evidence supports the association between severity of pressure injuries and patient mortality [2]. In the United States, health care systems absorb on average US $10,000 per hospital-acquired pressure injury (HAPI), which contributes to a cost burden that will soon exceed US $30 billion [4,5].

Prevention of pressure injuries requires an accurate risk assessment and an interdisciplinary approach with routine repositioning, maintaining dry skin, and padding pressure points to reduce injury [6-8]. Currently, health care systems are striving to accurately measure and prevent HAPIs, since they can be common and negatively impact patient care [9]. Patient factors such as age, vasopressor support, mechanical ventilation, low

albumin, and renal failure can increase the risk for pressure injuries [10,11]. Multiple standardized risk assessment tools have been developed to systematically assess patient factors and assist clinicians in identifying at-risk patients [12,13]. Of these tools, the Braden scale has remained the standard of care across health systems for decades. The Braden scale incorporates components of sensory perception, activity, mobility, and nutrition, as well as skin moisture, friction, and shear force, to produce a score that indicates the risk of developing a pressure injury [14]. Although use of the Braden scale is widespread, its accuracy and reliability in diverse settings and patients is in question; thus, researchers have turned to more advanced risk prediction models that incorporate additional patient factors [12,13,15,16].

Recent literature reviews of advanced risk prediction models have highlighted excellent performance in predicting pressure injuries [17-21]. Zhou and colleagues [20] found that 74% of studies achieved an area under the receiver operating curve (AUC) between 0.68 and 0.99. Although these models were exceptionally accurate at predicting pressure injuries, no studies to our knowledge have implemented such models to reduce the number of pressure injuries. Numerous prediction models have been developed across clinical domains, but few have improved patient outcomes, leading researchers to identify a variety of required elements that may be necessary to implement prediction models in practice [22-24]. For instance, Randall Moorman [23] proposed properties, such as change of risk over time (eg, dynamic risk), for predictive analytics in neonatal intensive care units. Keim-Malpass and colleagues [24] found that potential users want prediction tools to be integrated with the electronic health record (EHR; eg, feasibility). We reviewed and agreed upon 5 elements that applied to HAPI prediction (ie, it should be feasible, broadly applicable, include dynamic risk and actionable criteria, and be rigorously validated) and then applied these elements to 22 recent models from 2020 to 2022 (Figure 1) [17,20,21]. We found no models fulfilled all the necessary elements to impact patient care. To help bridge the gap from model development to implementation, the objective of this study was, therefore, to develop and validate a model that fulfilled these elements and then compare its performance to usual care (ie, the Braden scale).

Figure 1. Comparison of current pressure injury prediction models according to elements of implementable models [25-45].



Methods

Study Population

We used retrospective data from the EHR at Vanderbilt University Medical Center between January 1, 2018, and July 1, 2022. All hospital admissions were included if the length of stay was longer than 24 hours and patient age was greater than 18 years on admission. HAPIs were identified using nurse flowsheet documentation. Nurses use flowsheets to document a variety of assessments, with our institution using a dedicated section for pressure injuries. The presence or absence of a pressure injury is assessed on admission and daily for each patient in the hospital. If a pressure injury is identified, the nurse documents whether it was present on admission and additional characteristics of the pressure injury, including the stage and location. We considered pressure injuries documented with a "no" in the column "present on admission" as HAPIs. For patients who had more than one HAPI, we used the first documented. The cohort included 197,911 hospitalizations, 129,100 patients, and 5458 HAPIs.

Feature Selection and Cohort Development

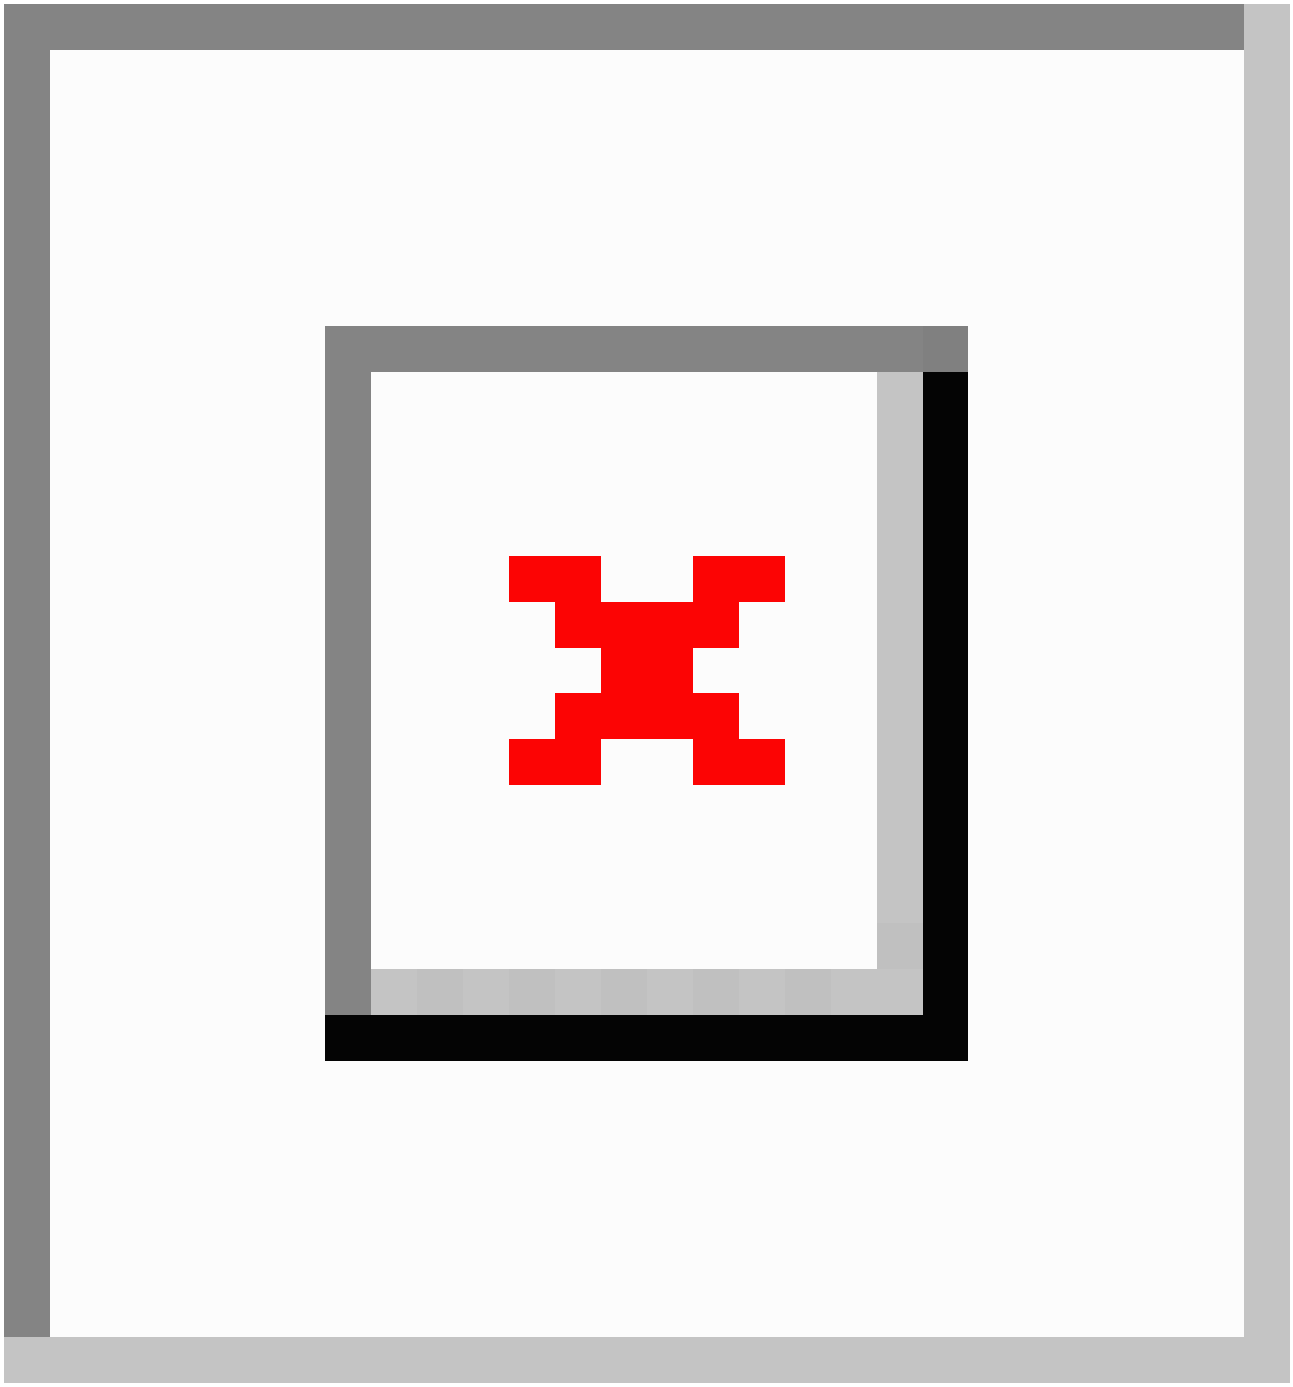
We first identified relevant features associated with pressure injuries from the literature. The list of relevant features was supplemented and pruned by clinical domain experts and informaticians at Vanderbilt University Medical Center. In total, 51 features were extracted as candidate features for predicting HAPIs. Importantly, features were only extracted if they were

available at the time of hospitalization and could be used to update the risk prediction during the encounter (ie, no claims data were used). Table 1 provides a summary of the extracted features. Missing values were imputed with the cohort median [46,47]. Multimedia Appendix 1 provides the full cohort characteristics, including missing values and a full list of measures. We split the full cohort temporally into model development and validation cohorts based on the number of events, with the development and validation cohorts including 80% and 20% of HAPIs, respectively. The development cohort included 161,816 hospitalizations and 4362 HAPIs from January 1, 2018, to August 26, 2021, and the validation cohort included 36,095 hospitalizations and 1096 HAPIs from August 27, 2021, to June 29, 2022 (Figure 2). Outcomes and features were identified and extracted in the same manner for the development and validation cohorts.

Table . Overview of extracted features.

Source	Feature
Patient demographics and social history	Age; gender; race; ethnicity; smoking status
Administration	Hospital admission through emergency department; intensive care unit admission; length of stay
Flowsheets	Hospital-acquired pressure injury (primary outcome); temperature; respiratory rate; heart rate; BMI; oxygen saturation; blood pressure; Braden scale (items and composite score); consciousness; gait transfer; Glasgow Coma Scale; malnutrition score; spinal cord injury; dialysis during hospitalization; tracheostomy; gastric tube; central line; chest tube; ostomy; drain; extracorporeal membrane oxygenation
Laboratory results	Hemoglobin; hemoglobin A_{1C}; hematocrit; mean corpuscular hemoglobin concentration; red cell distribution width; platelet count; chloride; blood urea nitrogen; creatinine; lactate; albumin; glucose

Figure 2. Model development and validation cohorts.



Model Development

We developed 3 models for comparison using logistic regression. The present model (Vanderbilt) used a broad set of candidate features (Table 1). The second model used the sum of the individual item measures from the Braden scale (ie, continuous Braden) [14]. Finally, since the Braden scale is typically operationalized using a single composite score (ie, less than 18=high risk; greater than or equal to 18=low risk), we included the dichotomous Braden for comparison as well. Logistic regression is the most frequently used model in clinical care [20,48]. The primary advantages of using logistic regression are that feature importance is easily interpretable and that the mathematical equation used to extract features and calculate a risk prediction is readily available in most commercial EHRs. Currently, the output from many machine learning models is not operationalizable for patient care in the EHR. To account for nonlinearity of the numeric features, we tested 3 knot-restricted cubic splines but found the discrimination failed to improve by using the nonlinear model [49]. Since the purpose was to develop a model that could be easily implemented in the EHR and compare it to standard care, we focused on use of logistic regression for the Vanderbilt and continuous Braden models.

We first included all 51 candidate features in the present (Vanderbilt) model to examine complexity versus accuracy as measured by cross-validation AUC. Again, included features were derived from the literature and refined by clinical domain

experts and informaticians. We tested for multicollinearity by examining the proportion of variance in each candidate feature that could be explained by other candidate features and removed hemoglobin. Included features had to be structured and readily available for automated processing in the EHR without additional input by the user. Using the conservative 15:1 rule, we were able to include 290.8 degrees of freedom in the model. To ensure the model was broadly applicable across settings and patients, we used a least absolute shrinkage and selection operator (LASSO) approach to identify important candidate features. Candidate features were standardized (scaled and centered) prior to running the LASSO regression. LASSO introduces a penalty term to the standard regression model, which forces some of the regression coefficients to shrink toward zero, effectively performing feature selection [50]. Variables with nonzero coefficients were included in the final model. The model was designed to calculate a risk prediction on admission and daily while the patient was in the hospital. Missing numeric measures were to be imputed with the cohort median until measures became available.

Model Evaluation

The final model was assessed in an external cohort that was temporally separated from the model development cohort. We evaluated the model using traditional and novel performance measures, which included the AUC, Brier score, slope, intercept, integrated calibration index, and calibration curve. AUC is a performance measure for the discrimination of HAPI versus no HAPI. It combines the true and false positive rates, with an AUC of 0.5 indicating no meaningful discrimination. The Brier score accounts for the predicted HAPI outcome as well as the estimate and is calculated by the squared difference between the prediction (0 to 1) and outcome (0=no HAPI and 1=HAPI) [51]. For example, if a patient had a 90% probability of developing a HAPI and did develop a HAPI during that encounter, the Brier score would be 0.01. A Brier score of 0 indicates perfect accuracy and a score of 1 indicates perfect inaccuracy. The integrated calibration index is a numeric summary of model calibration across the predicted probabilities [52]. It is the weighted average of the absolute difference between the observed and predicted probabilities; therefore, a lower integrated calibration index indicates better calibration. A slope equal to 1 indicates agreement between the observed response and the predicted probability, while a slope greater than 1 indicates potential underfitting, and a slope lower than 1 indicates potential overfitting [52]. Similarly, an intercept of zero is ideal. As with prior models, no adjustments were made for multiple comparisons [47,53,54]. We used the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) reporting guidelines (Checklist 1) and performed all analyses in R (version 4.2.3; R Foundation for Statistical Computing) with relevant extension packages [55].

Ethical Considerations

This study was approved by the Vanderbilt University Medical Center Institutional Review Board (220644), and data were deidentified.

Results

Cohort Characteristics

The full cohort of patient encounters was split temporally, based on the number of HAPIs, into model development and validation cohorts. The characteristics for each cohort are provided in Table 2. Among the model development cohort, those who developed HAPIs were older and male. Table 3 provides the model development cohort characteristics divided by whether a HAPI occurred.

Table . Characteristics for model development and validation cohorts. Measures were first taken during the hospital stay unless specified otherwise. Race and ethnicity were not included as candidate features.

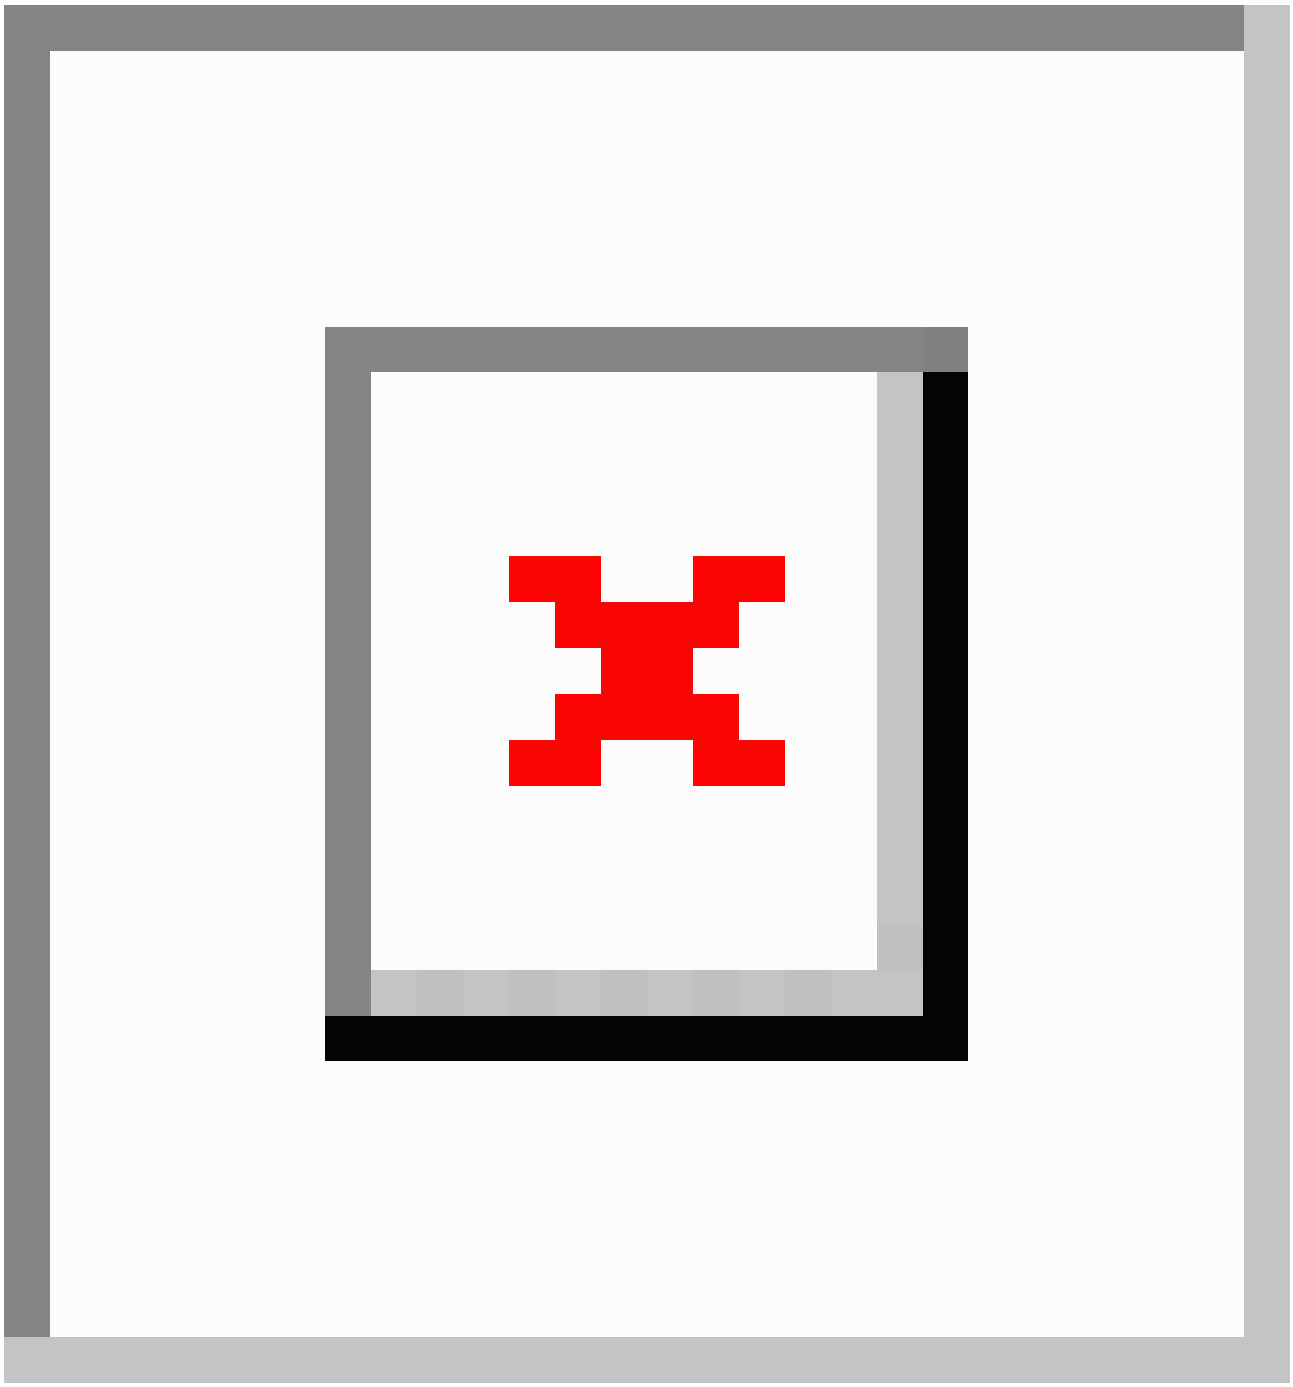
Model Description

We determined 22 features were necessary to achieve a parsimonious yet highly accurate model. Again, features were selected using a LASSO approach. We fit the final model with 4362 HAPI encounters and 291 degrees of freedom, which indicated the model was unlikely to overfit the data. Of the 40 features that exhibited association with developing a HAPI, the top 5 features included tracheostomy (odds ratio [OR] 4.5, 95% CI 4.0-5.1), peripheral edema (OR 2.9, 95% CI 2.6-3.2), central line (OR 2.1, 95% CI 1.9-2.3), first albumin measure (OR 0.6, 95% CI 0.6-0.6), and age (OR 1.2, 95% CI 1.2-1.2) (Figure 3). Although the directionality for each feature may vary, the relative importance in Figure 3 was ranked on a single scale. Additional significant features included whether the patient was on sympathomimetic medications, had a spinal cord injury or chest tube, and individual Braden score component measures. The final Vanderbilt model with 22 features provided excellent discriminatory ability with an AUC of 0.897 (95% CI 0.893-0.901). Multimedia Appendix 2 depicts the probability density plot for the development and validation cohorts.

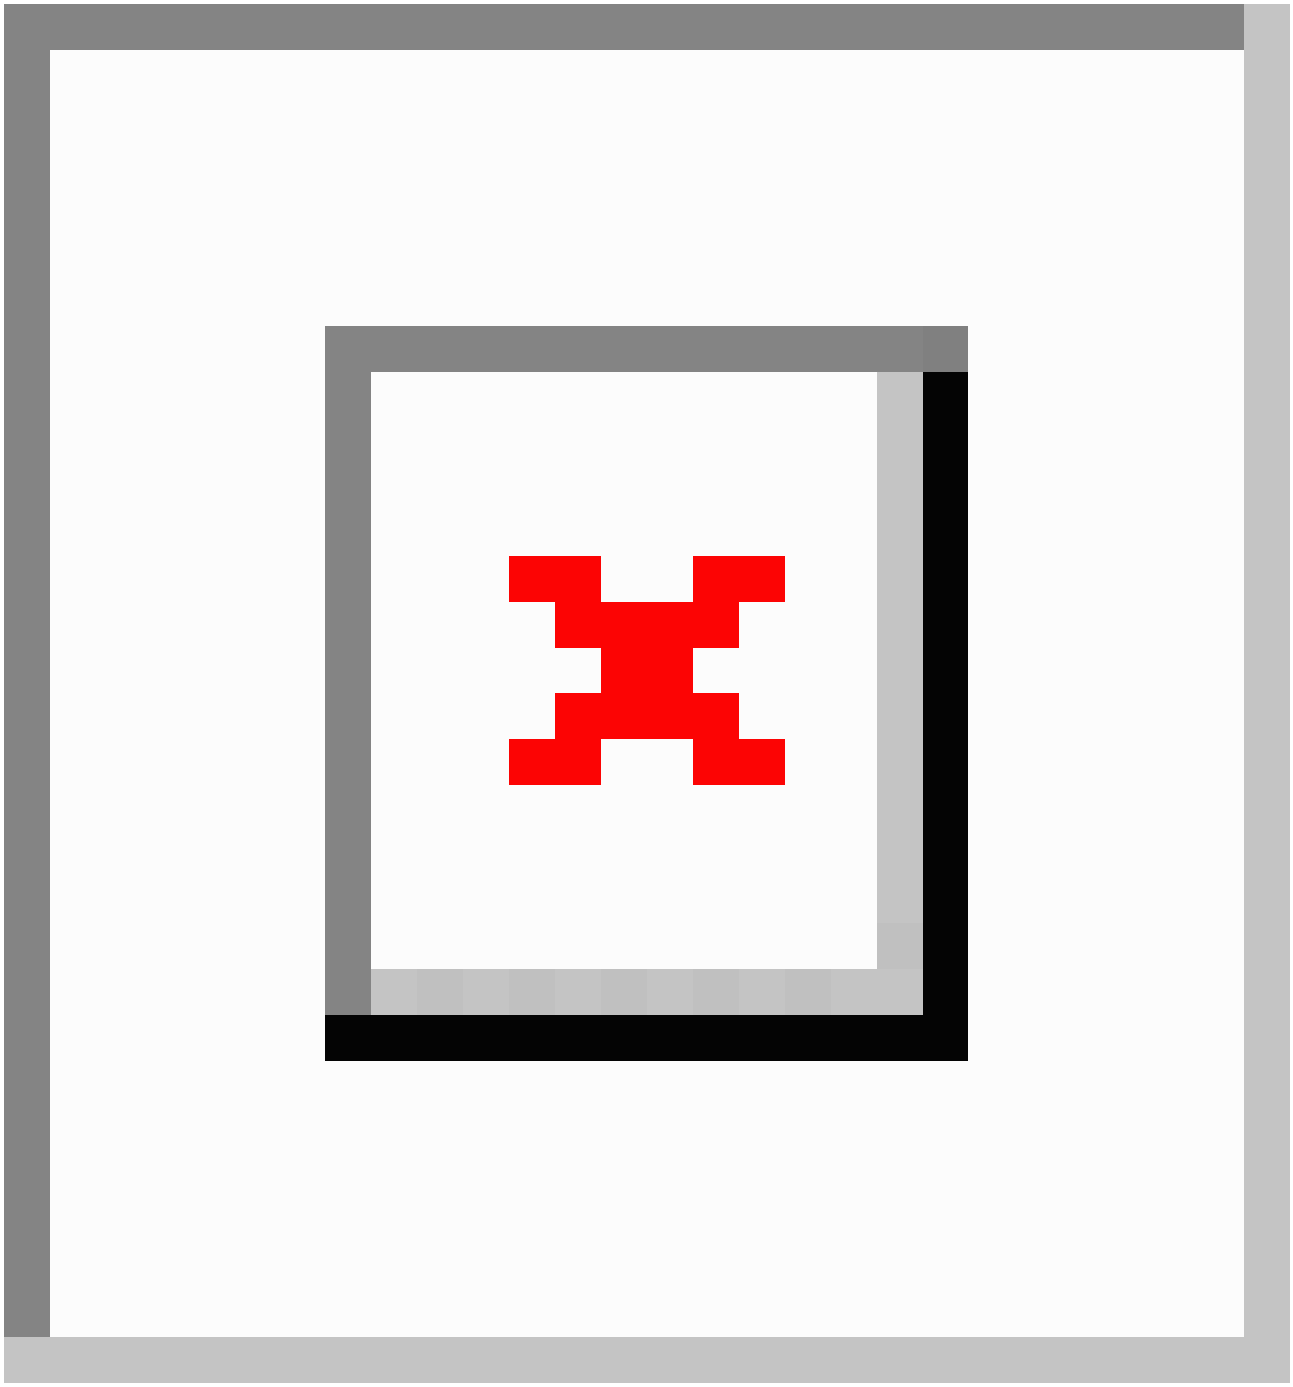
Figure 3. Relative importance of features used in the final Vanderbilt model. Gray subfeatures represent item comparisons used to generate features. *P* values for variable significance were derived using the Wald χ^2 test. BUN: blood urea nitrogen; ECMO: extracorporeal membrane oxygenation; ICU: intensive care unit; RDW: red cell distribution width.



Comparison With the Braden Scale

Using the model development cohort, the Vanderbilt model achieved an AUC of 0.897 (95% CI 0.893-0.901), compared to 0.798 (95% CI 0.791-0.803) and 0.733 (95% CI 0.725-0.740) for the continuous and dichotomous Braden, respectively (Figure 4).

Figure 4. Area under the receiver operating characteristic curve comparing the Vanderbilt (gold), continuous Braden (blue), and dichotomous Braden (gray) models.



Model Validation

The validation cohort consisted of 34,999 hospitalizations without a HAPI and 1096 hospitalizations with at least one HAPI. Model development and validation cohorts were compared to confirm that each had similar characteristics. Overall, characteristics were similar between the 2 cohorts (Table 3). We applied the same model from the development cohort to the validation cohort without adjusting coefficients, which provided a concordance statistic of 0.893 (95% CI 0.885-0.899; Table 4). Model calibration was consistent between the development and validation cohorts. The calibration curve indicated the model most accurately predicted risk for patients in the range of 0%-25% predicted risk (Figure 5); above this, the model could overpredict a HAPI. Since the model was intended to bring nurse attention and interventions to patients who would otherwise be overlooked, we believe the miscalibration at higher percentages was less clinically relevant. There was no evidence of collinearity. We are confident that this model performs well for most patients across the intensive care and general hospital settings, as 98.2% of the cohort had a predicted risk of less than 25%.

Since the model was designed to be used broadly in the general adult hospital, we performed a post hoc analysis among subpopulations for age (older than 65 years), gender, race, ethnicity, intensive care unit admission, and Braden score (greater than 18). The subpopulation analysis revealed only

slight changes in discrimination performance (Multimedia Appendix 3).

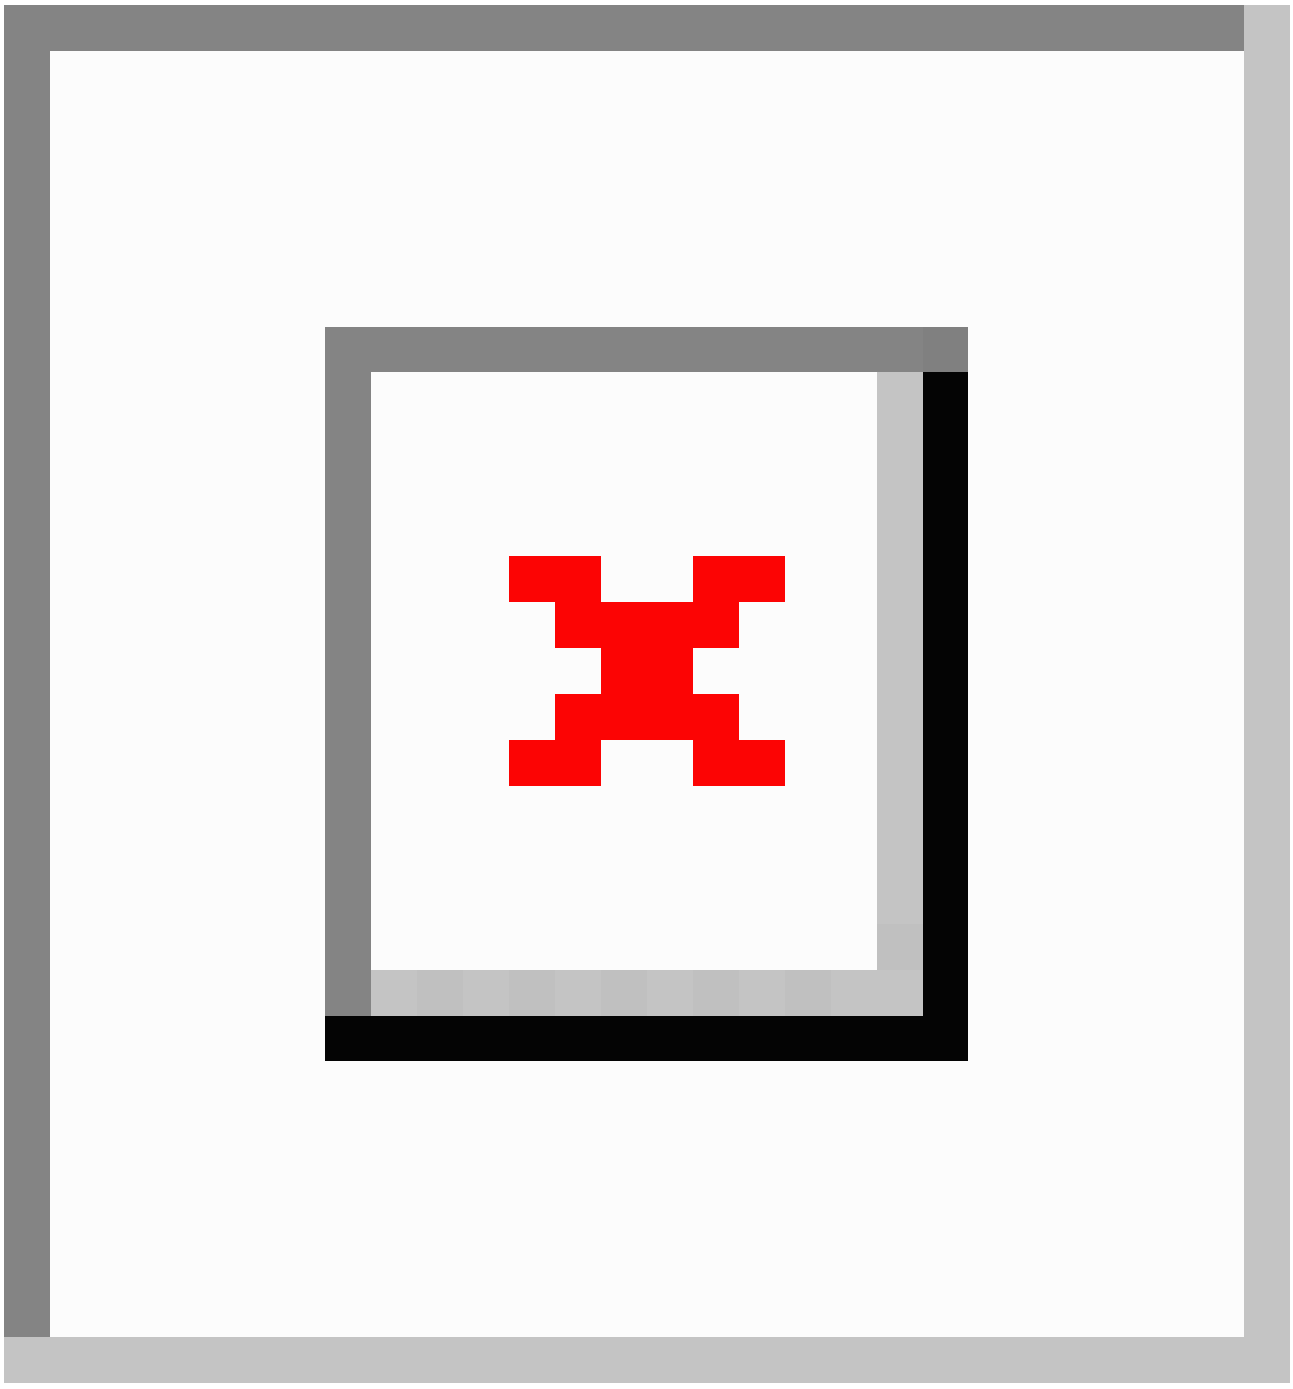
To operationalize the Vanderbilt model in the EHR (Epic), we generated the equation below. The output from the equation is a numeric probability from 0 to 1. Z is the sum of –4.1812002 and the product of the coefficient and measured value (eg, first albumin) for each feature. In Multimedia Appendix 4, we provide the coefficients for the equation. The model has been deployed as a population management tool to generate risk prediction data at Vanderbilt University Medical Center, but the output is only available for the research team until a trial period has been completed and governance has approved it for patient care. Within a report for multiple patients, output from the model is available as a column among other relevant factors to prioritize pressure injury interventions. As part of the implementation plan, we have created an application for potential users to test the model [56].

$$\text{Probability of hospital-acquired pressure injury} = 1/(1+\exp(-Z))$$

Table . Prediction model performance for hospital-acquired pressure injury.

Model	Area under the curve (95% CI)	Brier score	Integrated calibration index	Intercept	Slope
Vanderbilt (logistic regression)	0.893 (0.885-0.899)	0.026	0.006	−0.041	0.977
Continuous Braden (logistic regression)	0.799 (0.789-0.811)	0.028	0.006	0.178	1.034
Dichotomous Braden (score<18)	0.733 (0.725-0.740)	0.025	Too few levels to compute	0.0	1.0

Figure 5. Calibration curves for model development (left) and validation (right). Logistic calibration (solid line) represents parameter-based calibration (logistic regression model fit between predicted and observed values). Nonparametric calibration (dotted line) represents locally estimated scatterplot smoothing trend between predicted and observed values.



Discussion

Principal Findings

We developed and validated a risk prediction model for HAPIs that can be used in the general adult population. The model achieved excellent discrimination and adequate calibration (Table 4). Although several recent models have achieved similar performance, our model may have the greatest likelihood of reducing HAPIs because it was built with the foresight of overcoming known barriers to implementation of risk-prediction clinical decision support (Figure 1). According to the scoring criteria in Figure 1, the present model would have achieved 8 of a possible 10, compared to the current highest score of 6. It lost points for being limited to adults from a single institution (broadly applicable) and partially specified intervention (actionable criteria). Limiting development of the model to a single institution could limit the generalizability due to documentation patterns and data availability. Although we specified how to deploy the model in the EHR, the intervention components and implementation strategies were underspecified for implementation and evaluation. The next step is to test the effectiveness of the model in a pragmatic randomized clinical trial in which the intervention will be fully specified [57].

Although our model achieved similar performance and used the same regression approach as the top 3 models in Figure 1 (Ladios-Martin et al [25], Levy et al [27], and Song et al [26]), many of the most important features among the models varied. Among the most important features in the Ladios-Martin et al [25] model (eg, medical service, days of antidiabetic therapy, ability to eat, number of red blood cell units transfused, and hemoglobin range), only medical service was similar to our model. Relatedly, 2 important features in the Levy et al [27] model overlapped (friction and mobility). However, several important features from the Song et al [26] model (albumin, gait/transferring, activity, blood urea nitrogen, chloride, and spinal cord injury) overlapped with our model. We anticipate the similarity in features between our model and the Song et al [26] model was due to use of the same EHR and the models being developed at academic medical centers in the United States.

Limited implementation of risk prediction models in the EHR presents a critical challenge in health care today; the barrier is now less about the performance of risk prediction models and more the sociotechnical obstacles to uptake in patient care [58-60]. Despite the growing availability and sophistication of these models, their integration into routine clinical practice remains inadequate. Of the 22 models identified, we were unable to find one that decreased HAPIs. Even when prespecified elements for an implementable model are fulfilled, concerted efforts are needed from various stakeholders. Collaboration between health care organizations, technology developers, and regulatory bodies is essential to establish standards and guidelines for incorporating risk prediction models into EHR systems [61]. Enhancing data infrastructure, promoting data standardization, and developing robust privacy and security frameworks are crucial steps toward facilitating the implementation of these models [62]. Additionally, targeted education and training initiatives can help build trust and confidence among health care providers, encouraging their acceptance and use of risk prediction models in clinical practice, along with actionable steps to take for patients at highest risk [63,64]. Furthermore, there are significant socio-organizational barriers that impede the implementation of risk prediction models in EHRs. Resistance to change, lack of awareness or understanding among health care providers, and concerns regarding liability and accountability are common challenges faced by health care institutions. Clinicians may be skeptical of relying on risk prediction models, fearing that their judgment and decision-making autonomy may be compromised. The integration of risk prediction models also requires extensive training and education for health care providers, which may be resource-intensive and time-consuming [65,66]. Only when these barriers are addressed in a pragmatic manner can risk-prediction clinical decision support models improve patient outcomes.

Pragmatic trials are crucial in testing the real-world effectiveness and utility of interventions in health care settings [57,67,68]. These trials provide valuable insights into how interventions perform when integrated into routine clinical practice, considering factors such as patient outcomes, workflow integration, and usability. Institutions are beginning to develop the infrastructure and stakeholder engagement to support pragmatic trials. At our institution, Semler and colleagues [69] tested the effectiveness of balanced crystalloids and saline for fluids in critically ill adults. This pragmatic trial was cluster-randomized with 5 intensive care units. The authors found that use of balanced crystalloids resulted in a lower rate of death. A key aspect that makes pragmatic trials feasible is the use of existing infrastructure and real-world practice, which typically includes an inclusive patient population, minimal staff training, flexible protocols, minimally disruptive interventions, and outcomes captured as part of care. For pressure injuries specifically, the intervention infrastructure and guidance already exist as part of routine care; however, risk prediction will help identify and prioritize the most at-risk patients for targeted intervention. Preliminarily, we envision a clinician will use a list of patients ranked highest to lowest risk for HAPI.

Strengths and Limitations

Pressure injury prediction models have shown promise in identifying individuals at risk of developing pressure injuries. However, there are several limitations with these models, including ours, that should be considered. First, documentation of pressure injuries varies by institution and can lead to misclassification. We found that documentation of some pressure injuries carried over from previous encounters. On further testing, we found that missing measures (eg, albumin) can lead to inaccurate prediction. Thus, we chose to use a replicable imputation method with the median. Although our prediction model was developed and validated using incident HAPIs, documentation errors should be carefully considered. To increase the generalizability of our model, we chose not to include text from notes, despite evidence that use of clinical notes may have predictive power. Although we had a relatively large sample size that was sufficient to include all important features, the patient cohort was from a single institution and may not generalize to institutions in different geographical areas or using different EHRs. Finally, we chose to use an interpretable model that could be operationalized in current EHRs; however, other models may provide slightly higher performance. We anticipate certain EHR vendors will continue to develop capabilities for implementing complex machine learning models for more complicated prediction tasks. In anticipation of this, we performed a preliminary analysis of random forest, generalized additive model, and XGBoost. Of these models, we found that XGBoost had higher discrimination than ours in the model development cohort (AUC 0.960, 95% CI 0.957-0.962 vs AUC 0.893, 95% CI 0.885-0.899). In the model validation cohort, however, performance was not superior to logistic regression (AUC 0.869, 95% CI 0.861-0.877 vs AUC 0.893, 95% CI 0.885-0.899). Future work is needed to fully optimize the machine learning models and explore the tradeoff between interpretability and performance.

Conclusion

Despite numerous models developed to predict pressure injuries, studies demonstrating improved patient outcomes are missing. This is because implementing risk prediction models for routine patient care is complex and requires model developers, clinicians, and researchers to address challenges early in the

process. Therefore, we developed and validated an accurate prediction model for HAPIs that fulfilled necessary elements for implementation. The next step is to overcome socio-organizational barriers to rigorously evaluate the model through a pragmatic randomized clinical trial that includes targeted intervention for patients at highest risk. Our approach to developing an implementable risk prediction model, with feasible plans to evaluate its effectiveness, is generalizable to risk prediction and may be necessary to unlock the potential of this technology and improve decision-making.

Acknowledgments

We would like to thank Donald Sengstack for helping with the data extraction and Lance Mailloux for guidance on pressure injury quality improvement. This study was funded by the National Institutes of Health (R01 AG062499) and the Advanced Vanderbilt Artificial Intelligence Laboratory.

Abstract

Background: Despite restrictive opioid management guidelines, opioid use disorder (OUD) remains a major public health concern. Machine learning (ML) offers a promising avenue for identifying and alerting clinicians about OUD, thus supporting better clinical decision-making regarding treatment.

Objective: This study aimed to assess the clinical validity of an ML application designed to identify and alert clinicians of different levels of OUD risk by comparing it to a structured review of medical records by clinicians.

Methods: The ML application generated OUD risk alerts on outpatient data for 649,504 patients from 2 medical centers between 2010 and 2013. A random sample of 60 patients was selected from 3 OUD risk level categories (n=180). An OUD risk classification scheme and standardized data extraction tool were developed to evaluate the validity of the alerts. Clinicians independently conducted a systematic and structured review of medical records and reached a consensus on a patient's OUD risk level, which was then compared to the ML application's risk assignments.

Results: A total of 78,587 patients without cancer with at least 1 opioid prescription were identified as follows: not high risk (n=50,405, 64.1%), high risk (n=16,636, 21.2%), and suspected OUD or OUD (n=11,546, 14.7%). The sample of 180 patients was representative of the total population in terms of age, sex, and race. The interrater reliability between the ML application and clinicians had a weighted kappa coefficient of 0.62 (95% CI 0.53-0.71), indicating good agreement. Combining the high risk and suspected OUD or OUD categories and using the review of medical records as a gold standard, the ML application had a corrected sensitivity of 56.6% (95% CI 48.7%-64.5%) and a corrected specificity of 94.2% (95% CI 90.3%-98.1%). The positive and negative predictive values were 93.3% (95% CI 88.2%-96.3%) and 60.0% (95% CI 50.4%-68.9%), respectively. Key themes for disagreements between the ML application and clinician reviews were identified.

Conclusions: A systematic comparison was conducted between an ML application and clinicians for identifying OUD risk. The ML application generated clinically valid and useful alerts about patients' different OUD risk levels. ML applications hold promise for identifying patients at differing levels of OUD risk and will likely complement traditional rule-based approaches to generating alerts about opioid safety issues.

Introduction

In the past few decades, the "opioid epidemic" has become a public health crisis. According to a 2020 US survey, 2.7 million people aged 12 years or older had an opioid use disorder (OUD), and only 1 in 9 (11.2%) received medication-assisted therapy [1]. OUD is a frequently underdiagnosed condition, and it is estimated that for every patient with an OUD diagnosis, there are at least 2 who remain undiagnosed [2]. In 2021, nearly 92,000 drug overdose deaths were reported in the United States [3]. Furthermore, 54% and 46% of the US $1.02 trillion aggregate annual societal costs in 2020 in the United States were attributed to overdose deaths and OUD, respectively [4].

There is an immediate urgency to identify patients at high risk of OUD and those with OUD. Clinicians have reported major barriers to adequately assessing patients' risk, including time pressure, incomplete or restricted medical records, and a lack of robust clinical decision support systems (CDSSs) [5,6]. The current rule-based approaches, such as Medicare Part D's Overutilization Monitoring System or statewide Prescription Drug Monitoring Programs, fail to incorporate clinical data and are often underused [7]. Moreover, unless CDSSs use individual patient-specific clinical data in generating alerts, many false positive alerts may be presented to clinicians contributing to alert fatigue [8].

Artificial intelligence and machine learning (ML) algorithms have recently demonstrated their usefulness in CDSSs; however, compared with conventional statistical methods, their black-box nature and a lack of studies assessing the clinical validity of these interventions have created uneasiness in the medical community [9-12]. MedAware is a commercial software application that uses various statistical and ML methods to identify and prevent medication safety issues, including the risk of OUD [13]. It uses an iterative development process and has conducted pilot testing to optimize its OUD risk prediction algorithm to increase its accuracy in patient risk identification.

The goals of this study were to assess the clinical validity of the ML application by (1) determining the agreement between the ML algorithm's output and the outcomes of structured clinicians' review of medical records in classifying patients into distinct categories of OUD risk, including not high risk, high risk, or suspected OUD or OUD; (2) determining the potential utility of using the ML application as an alerting tool by evaluating its test characteristics against the gold standard; and (3) identifying major factors contributing to discrepancies between the ML application and clinician risk assignments to provide a knowledge base for future system improvement.

Methods

Ethical Considerations

This study was approved by the Mass General Brigham Institutional Review Boards (#2014P002167) that granted a patient waiver of consent for this study. Patients did not receive any compensation.

Evaluation of the ML Application

MedAware (Ra'anana, Israel) has developed an ML software application to identify prescription errors and adverse drug events [13]. This application identifies medication issues based on ML methods including random forest algorithms—a widely used ML method in medical applications [14]. Multiple studies using ML models for disease prediction have achieved robust performance [15,16].

Based on clinical data in the electronic health record (EHR), the ML application's algorithms generate patient-specific alerts on medication orders that deviate from predominant prescribing patterns in similar patient situations. Previously, it was found that the ML application generates medication error alerts that might otherwise be missed with existing applications with a high degree of alert usefulness, and it has the potential to reduce costs [17,18].

The ML application has been enhanced to generate alerts in real time to identify patients at risk of OUD and overdose based on clinical, psychosocial, and medication data. The input features used in the model were age, gender, opioid and nonopioid medication history (for each prescription: drug name, route of administration, duration, and dosage), and diagnosis history found in *ICD-9* (*International Classification of Diseases*) diagnoses codes and problem lists. The application can also produce aggregate alert data about the risk of OUD or overdose, which may be used for population health management.

The model outcome was defined by MedAware by combining OUD diagnosis codes, medication use, and experts' annotation. The test cohort was independent from the training set to avoid overfitting. Random data splitting was conducted to separate training (50%) and test (50%) sets. MedAware used a scikit-learn (1.2.0) implementation of the random forest algorithm. It was used in a cross-fold manner and some of its hyperparameters (mainly: n_estimators, max_depth, class_weight) were tuned for optimization while leaving others at their default values. Additional details of the ML algorithm were not available to the research team because of intellectual property protections and were not the focus of this study; our study aimed to clinically validate OUD alerts generated by the algorithm against clinician judgement.

Study Setting and Patient Population

The patient population of this study comprised patients who had at least 1 outpatient encounter between January 1, 2012,

and December 31, 2013, and were prescribed at least 1 opioid medication between January 1, 2010, and December 31, 2013, in an outpatient setting at 2 large academic medical centers in the United States. Patients diagnosed with cancer and those with incomplete data were excluded. Once a patient had a documented OUD diagnosis or started receiving opioid rehabilitation drugs (eg, suboxone, naltrexone, methadone, and bezitramide), any subsequent patient data were excluded from the analysis as the patient's status was known.

The evaluated application classified patients into 3 levels of OUD risk: not high risk, high risk, and suspected OUD or OUD. Alerts to clinicians are generated for only the high risk and suspected OUD or OUD categories. The risk alerts are generated when a clinician initiates an opioid medication prescription. A short textual description is created by the application for each alert generated to explain why the alert fired, for example, *the patient has a long opioid sequence, concurrent benzodiazepines use*. This explanation enables clinicians to understand the general reasoning underlying the alert. To improve study efficiency, the validation study comprised a random sample of 60 patients from each risk category for a total of 180 cases for which a retrospective review was performed by clinicians [19].

Data Collection and Transfer

Clinical and encounter data on the patient population from 2010 to 2013 were extracted and sent to MedAware, including demographics, diagnoses, problem lists, outpatient and inpatient encounters, encounter clinicians, clinician specialties, procedures, medications, allergies, vital signs, and selected blood test outcomes. Patient and clinician names and medical record numbers were removed from the data set, and a random study ID was assigned to each patient and clinician before the limited data set was sent through a secure transfer application (password-protected and encrypted) for analysis.

Development of a Risk Classification Scheme and Pilot Testing

Evaluation criteria for risk assignment by clinicians using the clinical data were developed with an extensive review of established guidelines, such as those of the Centers for Disease Control and Prevention and *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*), and risk factors for OUD through an iterative process in consultation with experts in the field of pain and opioid management [20-24]. The research clinicians and team reviewed the Centers for Disease Control and Prevention's and *DSM-5* guidelines and created draft criteria based on these guidelines to reflect 3 levels of risk, and then these criteria were reviewed by 2 pain management experts (a physician and a pharmacist). After modifications, this risk classification scheme was piloted to evaluate its effectiveness and compatibility with the ML application. We conducted the pilot review of medical records with 25 randomly selected medical records. One research assistant (CD) extracted data from the medical records using a standardized data collection tool as described below and 2 physician reviewers (FB and TE) individually reviewed the data. The reviewers reached a consensus on their risk determinations, and revisions were made to criteria, as needed, to standardize assessments and support a more transparent, generalizable validation process. MedAware sent a list of those patients for whom a risk assessment was conducted to be used for selecting the random sample for review of medical records.

Structured Clinicians' Review of Medical Records Using a Standardized Data Collection Tool

In total, 180 patients with a history of opioid use were randomly selected from those patients classified by the ML application into 3 risk categories (60 in each group), and structured reviews of medical records were conducted to evaluate patients' OUD risk. Clinicians were blinded to the patients' risk assignment by the application. A data abstraction tool was developed to organize relevant patients' clinical data from an EHR and facilitate the process for the review of medical records (Figure 1). This tool contains important demographic, patient, and family medical history including psychiatric and psychosocial information, patient complaints as documented in relevant clinical notes, relevant laboratory findings and drug history with graphical representation of opioid drug start and stop dates (ie, medication timeline; Figure 2), clinical events relevant to pain management such as surgeries or dates of major accidents, admission and emergency room visits, and curated clinical notes related to relevant clinical events. Collected data included both structured and free-text data that were extracted by research staff and organized into the abstraction tool. Data collection was focused on relevant information during the 2010-2013 time period; however, as the complete medical record was available for review, relevant information available prior to 2010 may have been considered. After training, 5 research assistants (CD, AA, SG, AR, and MM) individually extracted clinical data. Information from medical records was reviewed by extractors and clinicians up to the ML application's first alert date (index date). For patients determined to be not high risk by the ML application, a random date was assigned up to which medical record data were extracted and reviewed.

Figure 1. Tool used to extract data from patients' medical records. Template used to organize patient information extracted during the review of electronic health records (EHRs). A patient's demographics and relevant past medical, psychosocial, family, and medication histories were captured. Provider notes and encounters relevant to opioid use and pain management were described and recorded by date. Any patient's laboratory findings relevant to opioid use or other medications of interest were also recorded. Clinician reviewers recorded their risk categorization and rationalization after reviewing the information captured on the data extraction tool and reviewing the EHR, as needed. OUD: opioid use disorder; PRN: pro re nata; SUD: substance use disorder.

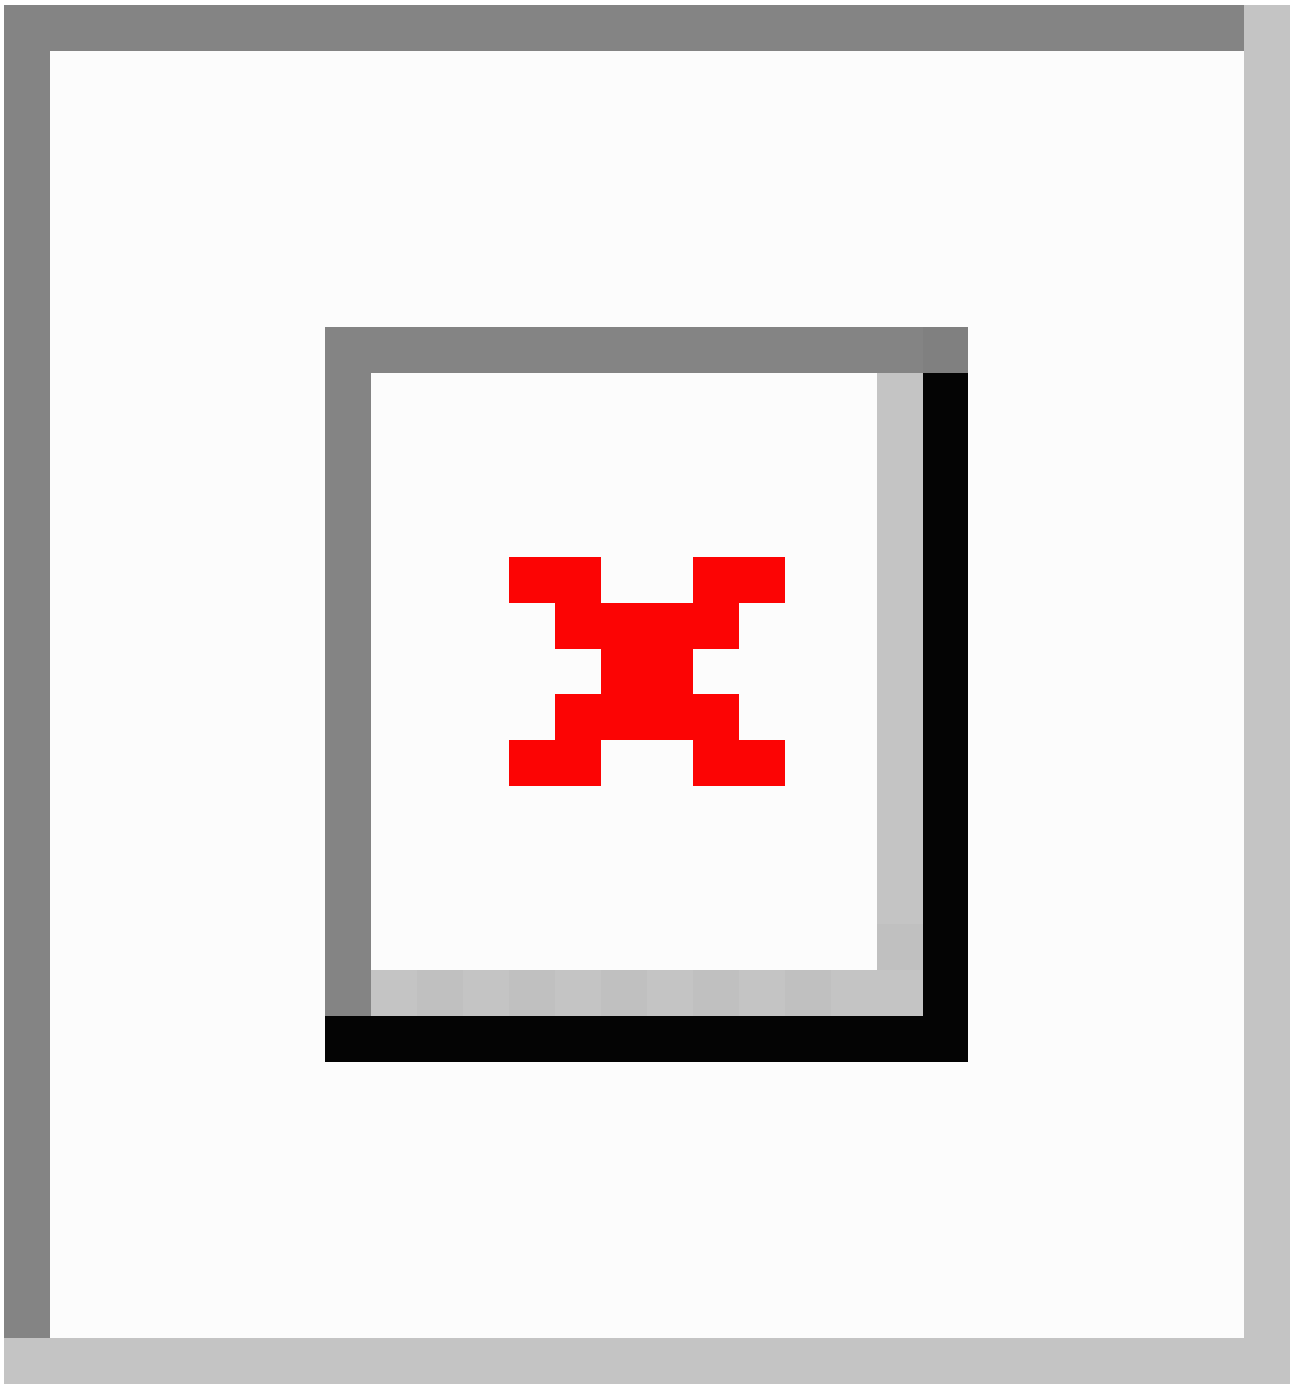

Figure 2. Example medication timeline from the tool used to extract data from the review of medical records. This timeline was created after medication history was recorded and morphine milligram equivalent (MME) conversion for opioid medications was included. Relevant encounters were recorded by date to provide context for the medication timeline (eg, surgery). Medications of interest included opioids, benzodiazepines, antidepressants, anticonvulsants, and other nonopioid medications contributing to risk. BID: twice a day; Q6H: every 6 hours; Q8H: every 8 hours; QD: every day, daily; SR: sustained release.

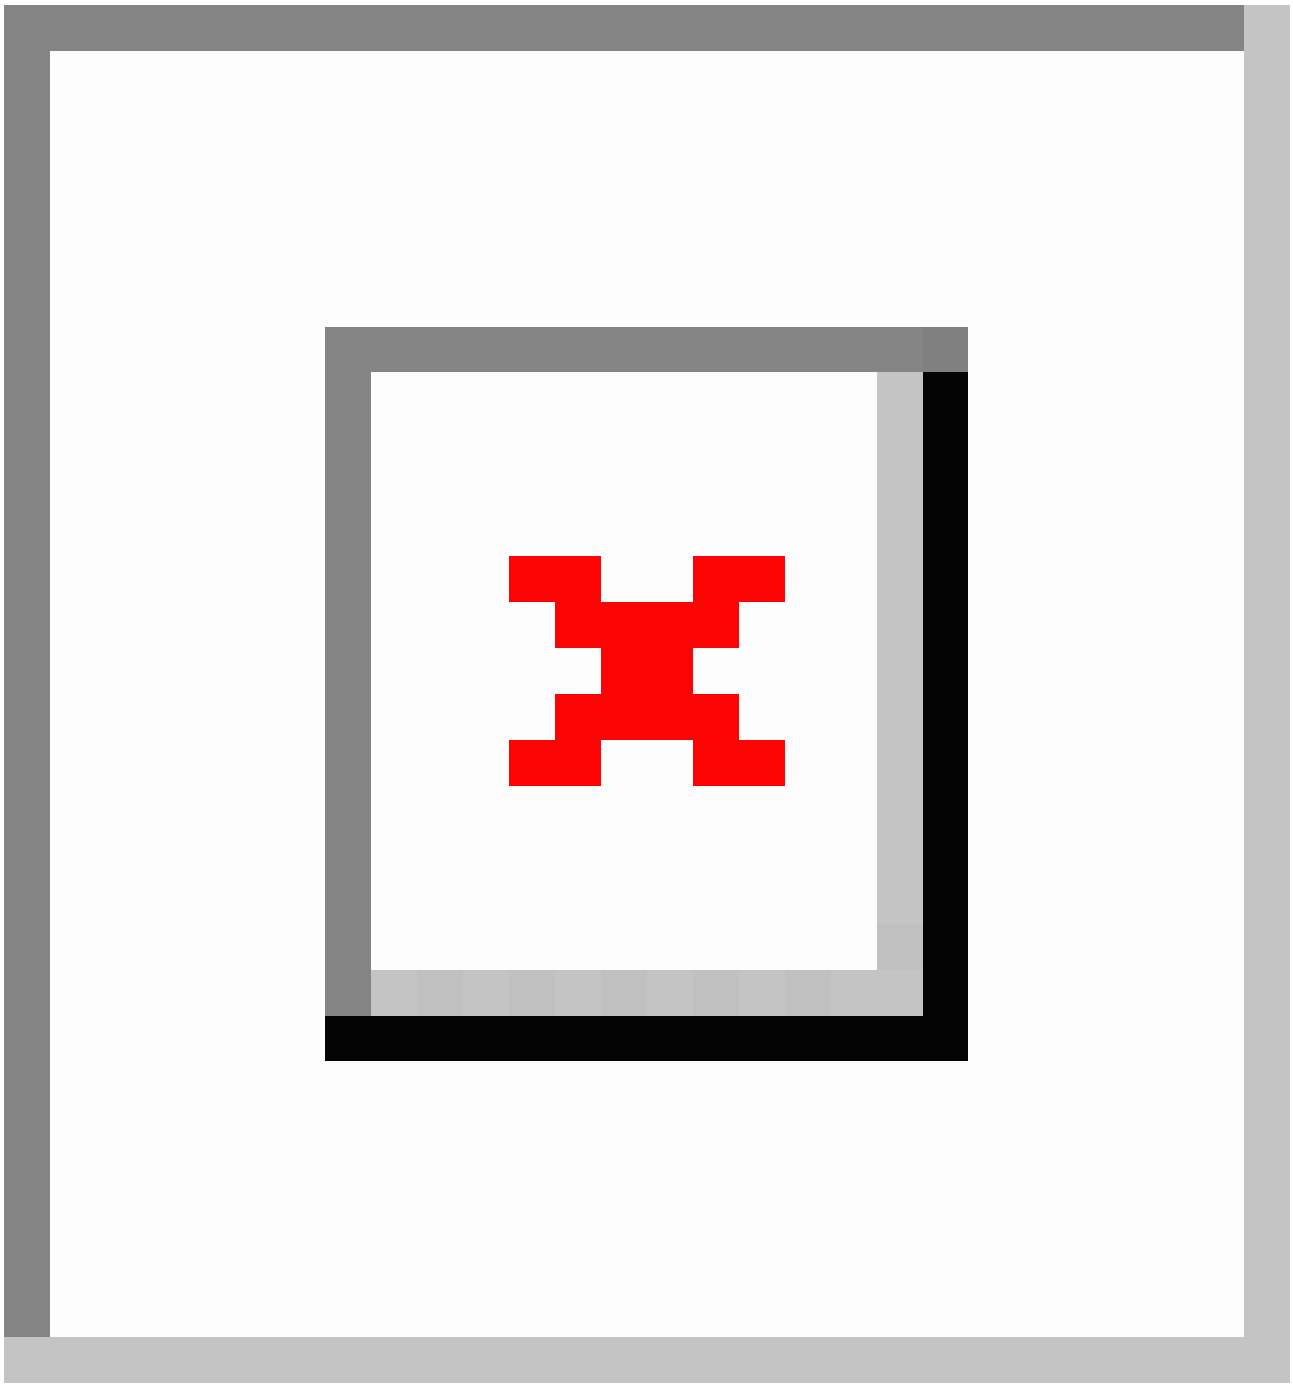

Four clinician reviewers (FB, TE, DM, and YE) individually examined data extracted by the research assistants and reviewed the EHRs directly, as needed, to holistically understand the clinical context of opiate prescription for the patients. The reviewers comprised 2 general internal medicine physicians, a hospitalist with extensive daily opioid prescribing experience, one with a PhD focusing on pharmacoepidemiology and drug safety, a recent medical student, and a pharmacist. All medical records were reviewed by 2 independent clinicians. After the primary review of medical records, a second reviewer blinded to the risk assignment of the first reviewer determined the risk level for OUD. The 2 clinicians discussed the case to reach consensus when their risk assignments differed. This consensus determination was then compared to the ML application's alert. Statistical analyses were conducted to evaluate the level of agreement between the clinician reviewers and the ML application's risk classifications.

Evaluation of Reasons for Disagreement Between Risk Assignments

To evaluate and identify the main reasons for disagreement between the clinician reviewers and the ML application's risk

classifications, a qualitative analysis was also conducted. For cases where there was disagreement, additional information contributing to the system risk assessment was requested from MedAware. Using a thematic analysis approach, 3 members of the research team (AR, LAV, and MM) independently conducted a qualitative analysis of the alert information. They reviewed the ML application's reasoning for assigning a particular risk category, information from the data extraction sheet, and information from the clinician reviewer's final risk assignment consensus. Then, this information was systematically coded to identify, categorize, and sort key concepts for the disagreements. Codes were then grouped into emergent themes and relationships after iterative review and discussion. In cases where there was disagreement, all 3 researchers reviewed and discussed the case together to reach consensus.

Statistical Analysis

We used descriptive statistics to summarize demographic characteristics of the study population, patients in each of the 3 risk categories identified by the ML application, and the 180 patients sampled for the validation study. We assessed the validity of the application by comparing them to the structured clinicians' review of medical records. The agreements between the 2 methods were evaluated with the following parameters:

1. Overall percent agreements were calculated, including percent agreements for the 3 risk categories. Disagreements were reported for the overall validated sample and the 3 opioid risk categories.
2. Weighted kappa and 95% CIs were reported because of the ordered nature of the risk categories to measure the agreement between the 2 methods.
3. Naïve sensitivity and naïve specificity were calculated along with positive and negative predictive values for the ML application using the structured clinicians' review of medical records as a gold standard and combining the 2 opioid risk categories, namely high risk and suspected OUD or OUD.
4. Corrected sensitivity and corrected specificity were calculated to account for verification bias, that is, overestimation of sensitivity and underestimation of specificity [19,25,26]. Verification bias occurs when disease status (eg, the presence or absence of OUD) is not ascertained in all participants by the gold-standard method (review of medical records) and proportionately more high risk and suspected OUD or OUD patients identified by the test methodology (eg, the ML algorithm) were selected for verification. This verification-biased sampling increases sensitivity and decreases specificity, and these parameters are mathematically corrected to adjust for the biased sampling method.
5. Descriptive statistics were calculated for evaluating risk assignments to determine the most frequently occurring themes for disagreement between the 2 methods.

Results

Patient Risk Categories and Demographics

Of the 649,504 eligible patients with at least 1 prescription in the source data, 78,587 (12.1%) were classified by the ML application into the 3 risk categories after excluding patients with no opioid prescription, patients without sufficient data to evaluate opioid risk, or patients with a diagnosis of cancer (Figure 3). Patients were excluded due to insufficient data if they did not have 1 day before and 1 year of data after their first opioid prescription, or if they were identified as having OUD (based on a diagnosis or rehabilitation drug) and did not have a first opioid prescription before identification of OUD. Patients with opioids prescribed within 2 years of a cancer diagnosis based on *ICD-9* (*International Classification of Diseases, Ninth Revision*) codes were excluded. Accordingly, 50,405 (64.1%) patients were classified by the ML application as being in the not high risk category, 16,636 (21.2%) as being in the high risk category, and 11,546 (14.7%) as being in the suspected OUD or OUD category. We excluded patients who do not have 1 day before and 1 year of data after the first opioid Rx or, if identified as having OUD (based on diagnosis or rehabilitation drug) and do not have a first opioid Rx before identification.

Table 1 details the distribution of eligible patients by demographic characteristics across the different ML application risk assignment categories and sampled patients. Female sex and age 30-64 years were overrepresented in the groups with opioid prescriptions and validation samples for medical records review compared to the eligible patient pool. The sample randomly selected for validation with the structured review of medical records was representative of the patients on opioid treatment with regard to age, sex, and race.

Figure 3. Patient flow diagram with the final verification sample. Patients were excluded from the overall population if they did not have any opioid prescriptions since 2010, were diagnosed with cancer, or had insufficient data to predict opioid risk. The remaining patients were evaluated for opioid risk and stratified by risk classification category. A total of 60 patients were randomly sampled from each risk classification category to be used for the review of medical records and clinician evaluation.

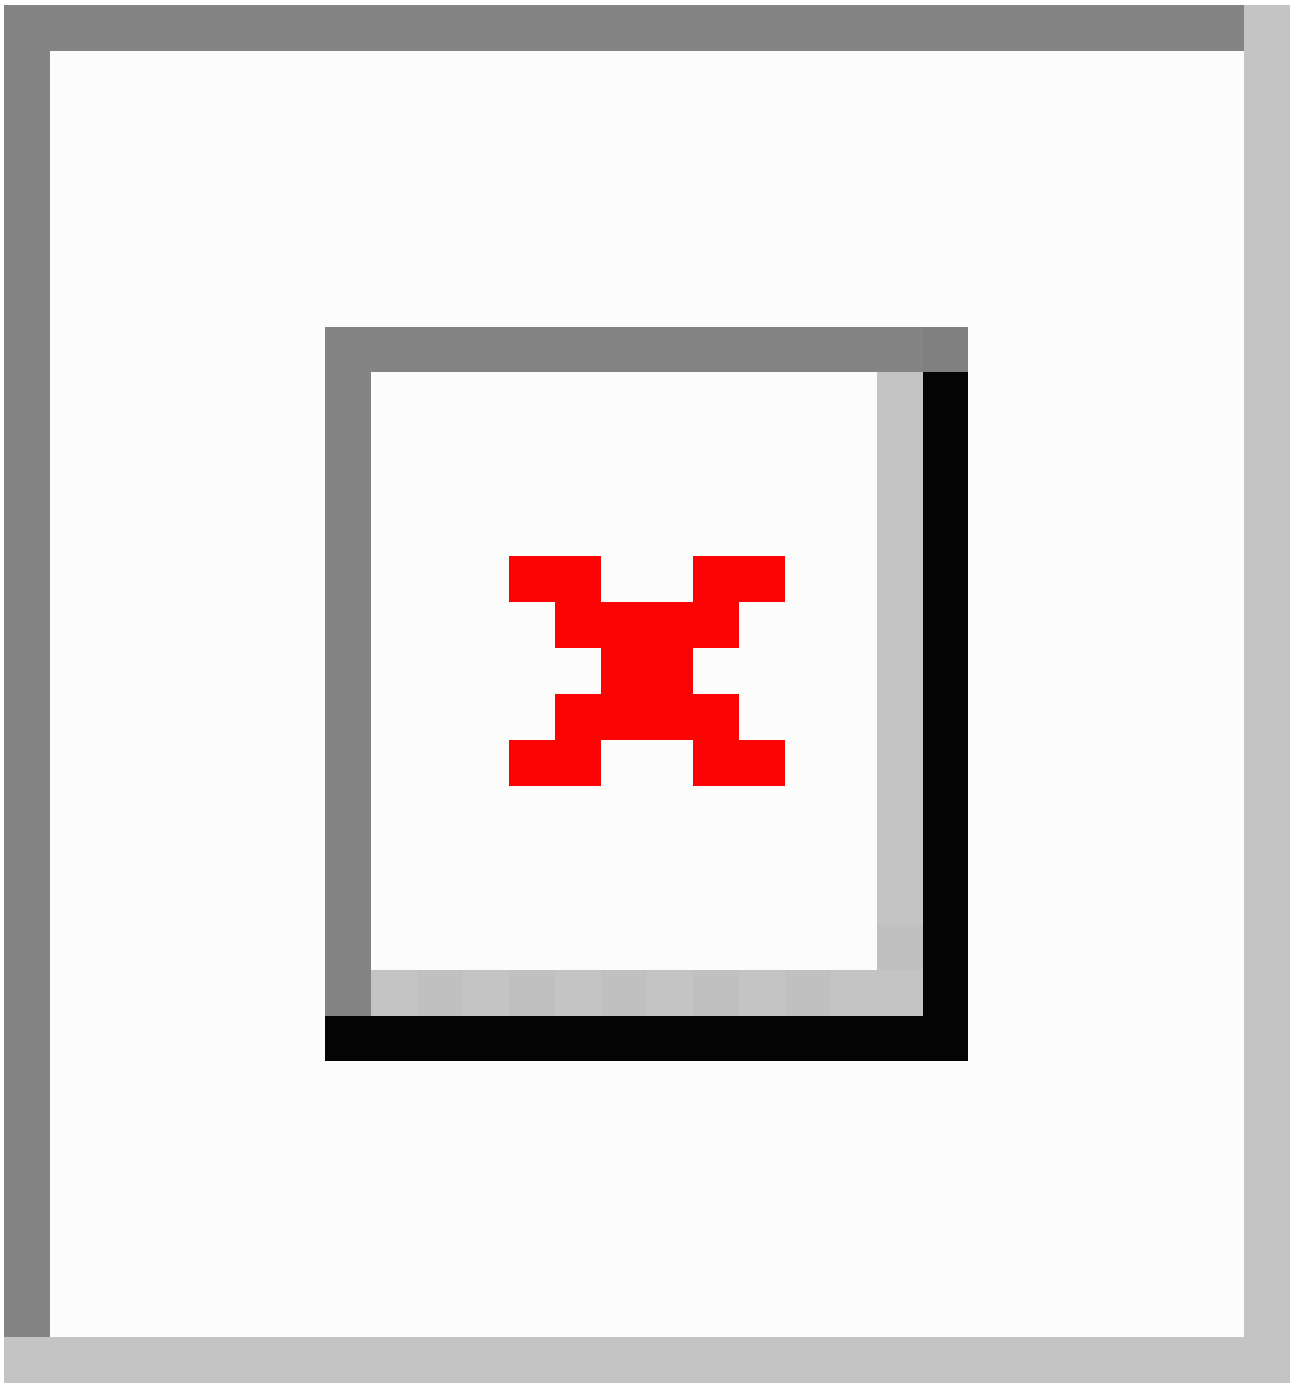

Table . Demographic characteristics of the study populations, including the overall patient population, patients who met the criteria for opioid risk evaluation, patients stratified by the machine learning (ML) application's risk categories "not high risk," "high risk," or "suspected OUD or OUD," and for the validation sample for total review of medical records.

Patient characteristics		Patients with at least 1 prescription (n=649,504), n (%)	Patients meeting criteria for opioid risk evaluation (n=78,587), n (%)	Not high risk (n=50,405), n (%)	High risk (n=16,636), n (%)	Suspected OUD or OUD (n=11,546), n (%)	Sampled patients (n=180), n (%)

[a]Race and ethnicity data are based on coded fields in the electronic health record.

[b]Other refers to non-Hispanic or non-Latino, declined to respond, and unknown.

Percent Agreement and Kappa Statistics

Prior to conducting final consensus assessments, the independent clinician reviewers' assessment of the levels of risk matched exactly for 70% (126/180) of the patients. When comparing assessments of the not high risk group and those of the high risk and suspected OUD or OUD groups, the clinician reviewer assessments matched 88% of the time.

The overall percent agreement between the ML application and clinician reviewers in stratifying patients into 3 risk categories was 70% (126/180 patients; Table 2). Of the 30% disagreements, 22.8% (n=41) and 7.2% (n=13) indicated underestimation and overestimation of risk by the ML application, respectively, compared to the clinicians' structured review of medical records. Among different risk categories, percent agreement was the highest (90%) for the suspected OUD or OUD category than for the not high risk and high risk categories (60% each). Of the patients classified to the suspected OUD or OUD category by the ML application, 8.3% and 1.7% of them were classified to the high risk and not high risk categories, respectively, by the clinicians' review of medical records. Of the patients classified to the not high risk category by the ML application, clinician reviews classified 40% of patients to the 2 higher risk categories: 30% of patients to the high risk category and 10% of patients to the suspected OUD or OUD category.

Table . Distribution in opioid risk assignment between the machine learning (ML) application and clinicians' structured review of medical records of 180 randomly sampled patients (percent agreement 70%, 95% CI 63.3%-76.7%; weighted kappa coefficient 0.62, 95% CI 0.52-0.71).

ML system risk assignment	Clinician reviewer risk assignment, n			
	Not high risk	High risk	Suspected OUD/OUD	Total
Not high risk	36	18	6	60
High risk	7	36	17	60
Suspected OUD[a] or OUD	1	5	54	60

[a]OUD: opioid use disorder.

The interrater reliability, as expressed using the weighted kappa coefficient for the 2 methods, was 0.62 (95% CI 0.53-0.71), indicating good or substantial agreement [27].

Corrected Sensitivity, Corrected Specificity, and Positive and Negative Predictive Values

Table 3 presents a revised version of Table 2, where the 2 higher-level opioid risk categories (high risk and suspected OUD or OUD) were combined to investigate the potential utility of the ML application in generating signals or alerts to prescribing clinicians, that is, how complete and accurate the ML application is in identifying patients who are at the risk of developing or who may already have OUD. The naïve sensitivity of the ML application was 82.4% (95% CI 75.9%-88.9%), and its naïve specificity was 81.8% (95% CI 70.2%-93.4%). After accounting for verification-biased sampling, the corrected sensitivity of the ML application was 56.6% (95% CI 48.7%-64.5%) and its corrected specificity was 94.2% (95% CI 90.3%-98.1%). The positive and negative predictive values of the ML application were 93.3% (95% CI 88.2%-96.3%) and 60.0% (95% CI 50.4%-68.9%), respectively.

Table . Distribution in opioid use disorder (OUD) risk assignment between the machine learning (ML) application and clinicians' structured review of medical records when the 2 higher-risk categories were combined to investigate the utility of an OUD risk alert at the time of prescribing.

ML system risk assignment	Clinician reviewer risk assignment, n		
	High risk and suspected OUD or OUD	Not high risk	Total
High risk and suspected OUD or OUD	112	8	120
Not high risk	24	36	60
Total	136	44	180

Key Reasons for Disagreements in OUD Risk Categories Between the ML Application and Clinician Reviewers

Table 4 contains the 6 themes that emerged as reasons for disagreements between the ML application and the clinicians' structured review of medical records after conducting a qualitative analysis. Disagreement between the 2 methods was noted for 54 patients, among whom the ML application underestimated the OUD risk in 41 patients and overestimated it in 13 patients. Two or more themes were identified as reasons for most of the disagreements (74.9%). Of the 6 themes, the theme "differences in risk assessment of medication information," accounted for most of the disagreements (72%), followed by the theme "information in clinical notes not available to the ML application" (55.6%).

Table . Key reasons for disagreements in opioid use disorder (OUD) risk assignments between the machine learning (ML) application and clinician reviewers. The reasons for discrepancies were categorized into 6 major themes. More than 1 reason might be identified for a given patient. Results are displayed by whether the assigned risk category was underestimated or overestimated by the ML application in comparison with the clinician reviewers.

Themes of reasons for disagreements in OUD risk assignment	Description of the themes	Patients with at least 1 reason coded in a given theme category, n (%)		
		Cases underestimated by MedAware[a] (n=41)	Cases overestimated by MedAware[b] (n=13)	Total discrepant cases (n=54)
I. Differences in risk assessment of medication information	Medication information available to both the clinician reviewers and the MedAware system contributed to differing risk assessments (eg, medication duration, dose, indication, and gaps in medication timelines).	30 (73.2)	9 (69.2)	39 (72.2)
II. Information in clinical notes not available to MedAware system	Information in patients' clinical notes was available to the clinician reviewers but not to the MedAware system (eg, psychosocial information, experience with opioids and other medications, patient participation in pain management and substance abuse services, and medication information not on the medication list).	27 (65.9)	3 (23.1)	30 (55.6)
III. Differences in risk assessment of psychosocial issues	Psychosocial or psychiatric information available to both the clinician reviewers and the MedAware system contributed to differing risk assessments (eg, patient history of substance abuse, family members with a history of psychosocial or psychiatric issues, and the presence of patients' individual psychiatric conditions contributed to differing risk assessments).	17 (41.5)	2 (15.4)	19 (35.2)
IV. Differences in risk assessment of nonopioid medications	Information on nonopioid medications available to both research reviewers and the MedAware system, which reflects an increased complexity of the patient's medical situation (eg, pain level) or a higher risk when combined with opioids, contributed to differences in risk assessments (eg, zolpidem and gabapentinoids).	10 (24.4)	2 (15.4)	12 (22.2)
V. Bugs identified in the MedAware system	Bugs in the MedAware system included inaccurate mapping of data elements (eg, dosage units and incorrect medication), missing medication in drug class, and incorrectly constructed alert messages.	5 (12.2)	5 (38.5)	10 (18.5)

Themes of reasons for disagreements in OUD risk assignment	Description of the themes	Patients with at least 1 reason coded in a given theme category, n (%)		
		Cases underestimated by MedAware[a] (n=41)	Cases overestimated by MedAware[b] (n=13)	Total discrepant cases (n=54)
VI. Presence of other clinical information not considered by the MedAware system or the clinician reviewers	Clinical information that may indicate the risk of OUD not considered by the clinician reviewers or the MedAware system, but not both, such as hepatitis C diagnosis, urine toxicity tests, and MedAware system access to *ICD-9*[c] diagnostic information that clinician reviewers did not see.	6 (14.6)	0 (0.0)	6 (11.1)

[a]The ML application's risk assignment was lower in severity compared to the clinician reviewers' risk assignment.

[b]The ML application's risk assignment was higher in severity compared to the clinician reviewers' risk assignment.

[c]*ICD-9*: *International Classification of Diseases, Ninth Revision*.

Discussion

Principal Results

ML algorithms can leverage large-scale EHR and medical claims data and potentially identify patients at risk of OUD [28-32]. However, very few studies have assessed the clinical validity and potential utility of ML algorithms designed to differentiate among levels of patients' OUD risk. In this study, we examined the agreement between an ML application and clinicians' structured review of medical records in classifying patients on opioid drug treatment into 3 distinct categories of OUD risk (ie, not high risk, high risk, or suspected OUD or OUD). We also assessed the application's utility in identifying clinically valid alerts and identified and quantified reasons that could lead to disagreements between clinicians' judgment and outputs of ML applications. The ML application was validated in an outpatient database, and it appeared to have value.

There was substantial agreement between the application and the clinician reviewers' structured review of medical records. The agreement between the 2 methods was the highest for the suspected OUD or OUD category. The ML application correctly identified this most vulnerable group of patients to increase clinician awareness and responsiveness to improve patient management, including modifications to their medication regimen or referral to a specialized treatment service to mitigate the complications of opioid use. Moreover, if the ML application is used to generate alerts on patients at high risk of OUD or those who already have OUD, it will identify approximately 60% of these patients with a 93.3% precision (positive predictive value). Thus, the results of this study show that this ML application was able to generate clinically valid and useful alerts to screen for patients at risk of OUD. It is important to recognize that alerting clinicians regarding patients at risk of OUD should be coupled with clinician education on appropriate treatment guidelines and practices to avoid undertreatment of pain and patient stigma [33,34].

Comparison With Prior Work

Previous studies have shown that artificial intelligence tools using ML algorithms can improve treatment, enhance quality of care and patient safety, reduce burden on providers, and generally increase the efficiency with which resources are used, resulting in potential cost savings or health gains [7,32,35-38]. In addition, our findings align with those of previous studies that highlight the potential of ML applications to predict individual patients' risk of specific medical conditions and associated complications to offer specialized care programs to high-risk patients [39,40]. Our study also confirms and extends the findings of a few studies that examined other ML applications and highlighted the potential to identify patients at risk for substance misuse and abuse, including OUD and opioid overdose [31,38,41]. Nevertheless, these comparable ML applications were plagued with very low positive predictive values due, in part, to low OUD prevalence as a result of suboptimal definitions of OUD by relying solely on *ICD* (*International Classification of Diseases*) codes [42]. A few previous studies identified additional limitations and challenges related to comparable ML applications. For example, Afshar et al [43] described the use of an algorithm to identify patients at risk for any substance misuse at the time of admission, based on clinical notes from the first 24 hours after hospital admission. In this study, we found that the positive predictive value of this tool was 61%-72%, which was lower than that of the ML application. The tool that Afshar et al [43] studied does not identify patients outside of the hospital setting and depends on physicians' notes. As a result, this tool is not suited for more general screening using structured clinical EHR data and medical claims data. Another recent study by Lo-Ciganic et al [41] described an algorithm to predict the occurrence of overdose episodes, but does not identify patients who are most at risk of OUD in the future.

We believe that the substantial agreement, high specificity, and high positive predictive value of the ML application was achieved because we pilot-tested the ML models in comparison with clinician assessments and then used an iterative process

with continuous calibration of model parameters to optimize the accurate identification of OUD risk categories. In addition, we used a composite definition of OUD not restricted to *ICD* codes resulting in a higher prevalence of OUD identified in the patient population. The ML application classified 1 in 7 and about one-fifth of the eligible population with prescribed opioids in the suspected OUD or OUD and high risk categories, respectively, compared to other studies that reported a prevalence of OUD in the range of 1%-5% [44,45]. Furthermore, the full accessibility of the EHR at the time of case evaluation, coupled with standardized data extraction and a medication timeline visualization tool, allowed seamless analysis of cases contributing to the high accuracy rates.

Our study also identified the main reasons for disagreements between the clinician reviewers and the ML application's risk assignments. These reasons included information available in the clinical notes not being accessible to the ML application (eg, psychosocial issues and patients' participation in substance abuse services), and different interpretation of available information such as differences in the impact of antidepressant treatments. Clinicians considered stable and sufficiently treated depression as not being a risk factor for OUD [46]. In analyzing the reasons for discrepancies, we observed factors related to model training processes, data quality, and outcome definitions. The knowledge gained through our analytic process could be useful to further optimize their ML algorithm development pipeline. As of today, it is critical to standardize the ML development process and make it more understandable to clinical end users. However, to our knowledge, few efforts have been made to systematically analyze each component of the model development process from the clinician's point of view and further evaluate its impact on the model's clinical implementation. We believe that our work can facilitate a better bridging of the gap between ML model builders and clinicians.

Limitations

Our study has some limitations. We used retrospective data to evaluate an algorithm primarily designed to be used in real time. Although many of the findings from our retrospective analysis should be applicable to real-time alerting, it is difficult to predict whether some alerts would perform differently or how clinicians would respond to real-time alerts. Second, although our clinician reviewers were carefully trained and a coding manual was developed with clear operational definitions, each risk assessment required a degree of judgment on the part of the reviewers; human factors could impact the final risk assignment. Finally, our study was limited to outpatients at 2 large academic medical centers in the United States, which limits the generalizability of our results. Additional biases may have been introduced into the ML application in ways that the research team were not able to assess [7,47]. Although the total population of patients receiving outpatient care within an academic medical center was included, there may have been biases in patients who were able to access care, those receiving opioid prescriptions, and in the clinical documentation of concerns regarding opioid use and substance abuse. Validation across different sites and populations (eg, veterans' facilities) may reveal site-specific differences and may require unique models or warrant the identification and capture of new descriptive features.

Conclusions

We tested an ML application that assessed OUD risk in an extensive outpatient EHR database and found that it appeared to classify patients into differing levels of OUD risk, and that there was substantial agreement with clinicians' review of medical records. We identified key themes for disagreements between the commercial application and clinician review, which can be used to further enhance ML applications. ML algorithms applied to available EHR clinical data hold promise for identifying patients at differing levels of OUD risk and supporting better clinical decision-making regarding treatment. Such tools will likely complement traditional, rule-based approaches to provide alerts about potential opioid prescribing safety issues.

Acknowledgments

This work was supported in part by MedAware, Ltd. DWB reports grants and personal fees from EarlySense, personal fees from Center for Digital Innovation Negev, equity from ValeraHealth, equity from Clew, equity from MDClone, personal fees and equity from AI-Enhanced Safety of Prescription, and grants from Merative, outside the submitted work. RR reports having equity from Hospitech Respiration, equity from Tri.O Medical Device, equity from AEYE Health, equity from RxE2, equity from OtheReality; equity from Co-Patient Support, and equity from Medyx.ai, all of which are unrelated to this work. He is also receiving research funding from Telem, Calosense Health, Breath of Health, and BriefCam.

MedAware's contributions to this study were limited to running the patient data through their ML application, providing risk assessment results from their system, and additional information on selected patients to clarify their risk assessment results. They were not involved in any data analysis or interpretation. They had no influence on the results, and they were not part of the manuscript writing process.

Data Availability

The data sets generated in this study are not publicly available due to hospital institutional review board (IRB) regulations and patient privacy policies, but deidentified data sets are available from the corresponding author upon reasonable request. These deidentified data sets would include the model training set to facilitate independent model replications, patient demographics, and risk level assessments generated by the MedAware system and clinician review for the study cohort of 180 patients. Detailed

electronic medical record data extracted on this cohort of patients in support of clinician risk assessments will not be available due to IRB and institutional policy restricting the use of clinical notes and sharing of patient-sensitive data. The MedAware system algorithm will not be available for sharing as this is a proprietary commercial product.

Abstract

Background: Timely and comprehensive collection of a patient's medication history in the emergency department (ED) is crucial for optimizing health care delivery. The implementation of a medication history sharing program, titled "Patient's In-home Medications at a Glance," in a tertiary teaching hospital aimed to efficiently collect and display nationwide medication histories for patients' initial hospital visits.

Objective: As an evaluation was necessary to provide a balanced picture of the program, we aimed to evaluate both care process outcomes and humanistic outcomes encompassing end-user experience of physicians and pharmacists.

Methods: We conducted a cohort study and a cross-sectional study to evaluate both outcomes. To evaluate the care process, we measured the time from the first ED assessment to urgent percutaneous coronary intervention (PCI) initiation from electronic health records. To assess end-user experience, we developed a 22-item questionnaire using a 5-point Likert scale, including 5 domains: information quality, system quality, service quality, user satisfaction, and intention to reuse. This questionnaire was validated and distributed to physicians and pharmacists. The Mann-Whiteny *U* test was used to analyze the PCI initiation time, and structural equation modeling was used to assess factors affecting end-user experience.

Results: The time from the first ED assessment to urgent PCI initiation at the ED was significantly decreased using the patient medication history program (mean rank 42.14 min vs 28.72 min; Mann-Whitney U=346; P=.03). A total of 112 physicians and pharmacists participated in the survey. Among the 5 domains, "intention to reuse" received the highest score (mean 4.77, SD 0.37), followed by "user satisfaction" (mean 4.56, SD 0.49), while "service quality" received the lowest score (mean 3.87, SD 0.79). "User satisfaction" was significantly associated with "information quality" and "intention to reuse."

Conclusions: Timely and complete retrieval using a medication history-sharing program led to an improved care process by expediting critical decision-making in the ED, thereby contributing to value-based health care delivery in a real-world setting. The experiences of end users, including physicians and pharmacists, indicated satisfaction with the program regarding information quality and their intention to reuse.

Introduction

Health information systems (HISs) play a vital role in the delivery of health care services, as they provide access to the patient's medical records, help track treatment progress, and support health care providers in making care decisions [1-3]. Although the development of HISs has revolutionized the provision of patient care and handling of patients' health information, in the transitional period toward the era of the fourth industrial revolution, studies that evaluate humanistic outcomes as well as clinical or economic outcomes caused by

HIS, are needed [4]. As leaders in health care settings have made various investments, such as time, money, and manpower, in managing HIS [5], the multifaceted evaluation of whether end users can use the HIS skillfully and achieve satisfaction in functionality and usability would be increasingly important in the future [4,6].

Health care organizations can ensure effective HIS use and improve the quality of patient care by conducting evaluations of HISs. These evaluations could allow health care organizations to proactively address issues related to system performance, integration, and data accuracy. However, evaluating the diversity and complexity of HISs in real-world clinical settings is a significant challenge [5,7]. Hospitals use different HISs depending on their work process, and the program related to direct patient care, including documentation and retrieval of medical records, or clinical decision support systems varies [8-10]. In addition, health care environments are constantly evolving with the emergence of innovative technologies [11]. Newly developed information systems or programs tend to be integrated into homegrown HISs after establishing a fully electronic medical record system. Thus, although HIS evaluations reporting economic, clinical, and humanistic outcomes could provide a balanced picture of the comprehensive impact of the health care interventions implemented, comprehensive evaluations of HISs are rarely conducted [12].

Acquisition of patients' complete medication use history could greatly enhance medication management and support physicians in making informed decisions. Accurate and efficient compilation of information can be more important when time-sensitive clinical decisions and subsequent interventions are made [13], especially in the emergency department (ED). However, previous studies have demonstrated that accurate and timely collection of patients' medication histories is challenging especially in the ED for various reasons, including patients with altered mental status due to confusion or intoxication, patients taking multiple outpatient prescriptions, and first-time patients to the hospital [14-16]. Since the treatment plan would change depending on the medication history, the prompt and complete evaluation of the medication history is vital. The process of collecting medication history was also described as a labor-intensive process, often requiring manual retrieval of information from outside the hospital [17,18]. Thus, a medication history sharing program called "Patient's In-home Medications at a Glance" was developed and successfully launched within a homegrown HIS known as BESTCare in Seoul National University Bundang Hospital (SNUBH) on January 11, 2021. The program enabled health professionals to access the patients' nationwide medication history swiftly and accurately from the Healthcare Insurance Review and Assessment Service database in South Korea with added features about the patient instructions and the identification guide for each medication. The rate of identification of patients' medication history within 24 hours was significantly improved at the ED after the implementation of the program [19]. However, comprehensive evaluations of querying patient medication history were necessary to provide a balanced picture of the medication history program, as an HIS intervention could have had an impact not only on the care process but also on humanistic outcomes, such as end-user experience about its functionality and usability, which may evolve over time.

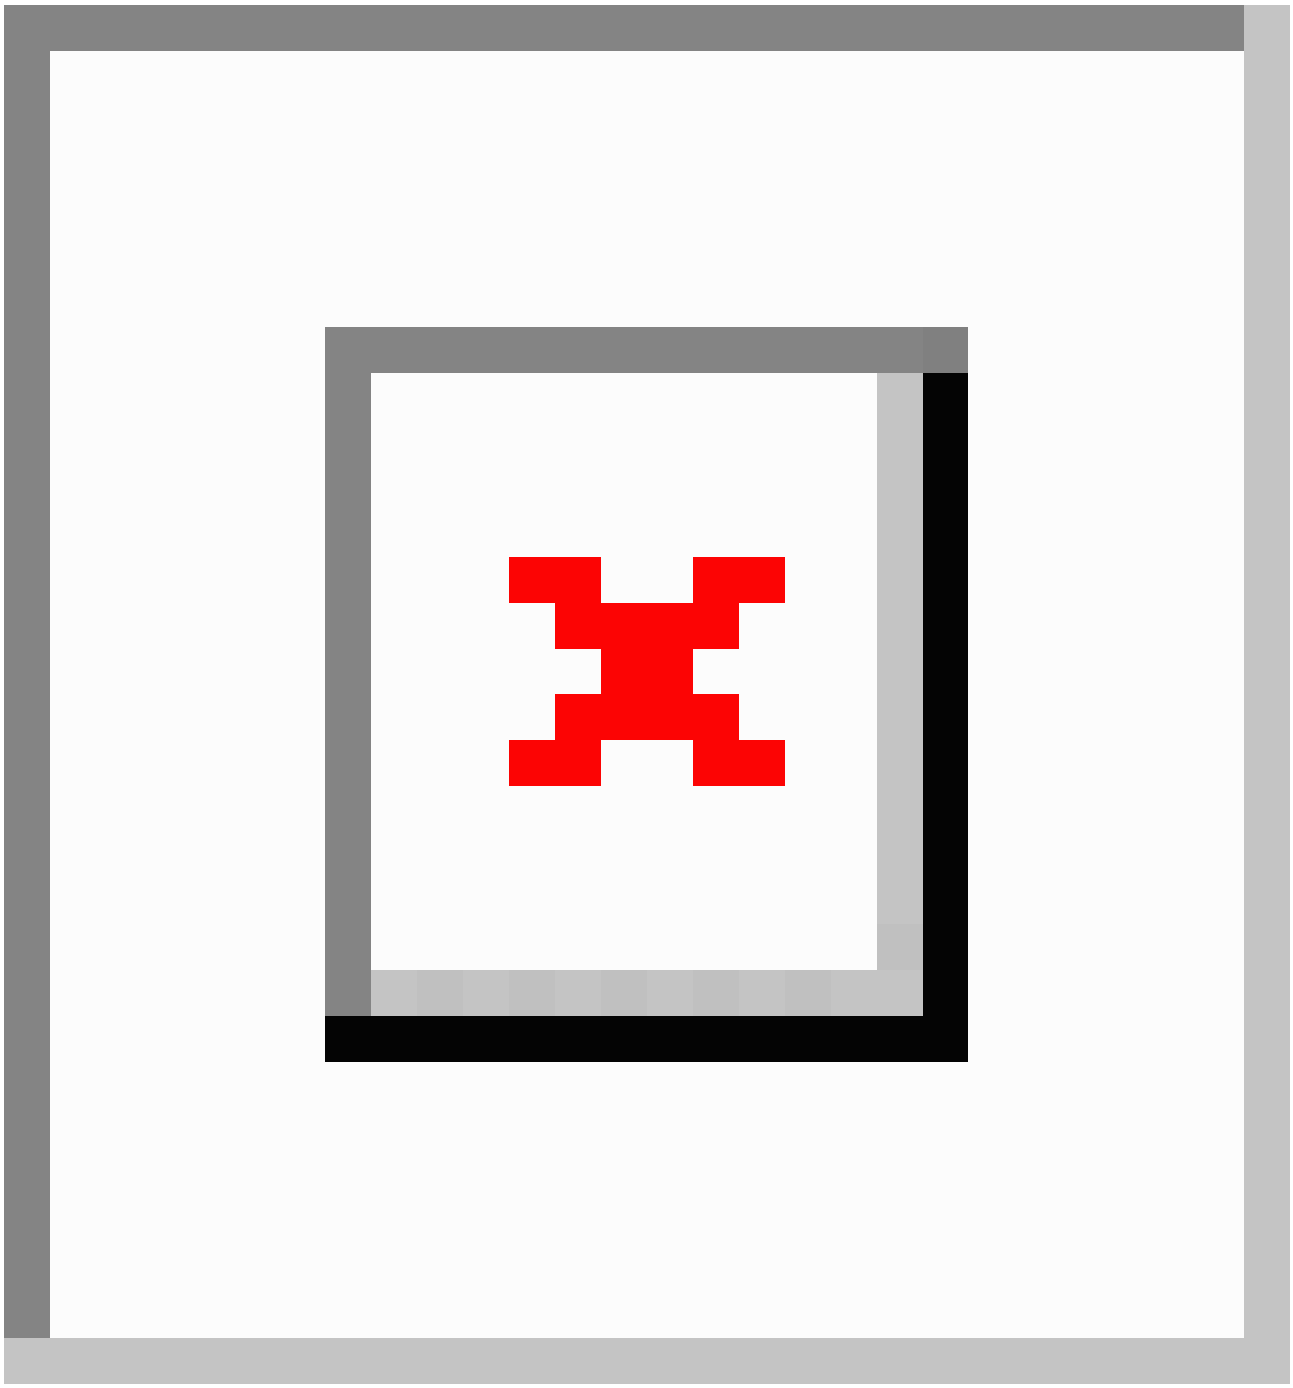
Therefore, this study aimed to evaluate the impact of an HIS intervention on health care delivery, namely medication history retrieval, using the "Patient's In-home Medications at a Glance" program. Specifically, we evaluated the care process outcome, that is, the time from the first ED assessment to urgent percutaneous coronary intervention (PCI) initiation, and the humanistic outcome, that is, the end-user experience among physicians and pharmacists.

Methods

Study Design

We conducted a cohort study and a cross-sectional study to evaluate both outcomes. We evaluated the impact of medication history retrieval using the "Patient's In-home Medications at a Glance" program on two aspects: (1) the care process outcome and (2) the end-user experience among physicians and pharmacists. Figure 1 shows the ED process and medication history check to describe the 2 outcomes of this study.

Figure 1. Emergency department (ED) process and medication history check depicting two outcomes: (1) time from the first ED assessment to urgent percutaneous coronary intervention (PCI) initiation as the care process outcome and (2) the end-user experience among physicians and pharmacists using the program as a humanistic outcome. Delayed medication history checks could increase the time of PCI initiation at the ED, especially in urgent clinical situations. The "Patient's In-home Medications at a Glance" program linking to the nationwide personal medication records provides more rapid and complete collections of medication history compared to manual retrievals that often require interviews with patients or caregivers at the ED (icons are made by Freepik).



First, we analyzed the care process to determine whether physicians' use of the program could expedite the time from the first ED assessment to urgent PCI initiation. Second, to assess end-user experience, we developed a questionnaire consisting of 22 survey items that were validated. We then conducted a website-based survey among physicians and pharmacists who served as end users of the program.

Care Process Outcome

Data Collection

For the care process, patients who were admitted to the ED for the first time from January 1, 2021, to December 31, 2022, were included to estimate the impact of the program on the collection of patients' drug therapy. The outcome was defined as the time of initiating urgent PCI after the first assessment by ED physicians from January 1, 2021, to December 31, 2022. Urgent PCI was defined as PCI performed within an hour of admission

to the ED. As the identification of the patient's medication use history was required to further improve the care plan, the time from the first ED assessment to urgent PCI initiation was analyzed.

Data Analysis

To analyze the impact of the program on the care process, data were extracted from the SNUBH electronic database. We performed a Mann-Whitney *U* test to evaluate the difference in the time from the first ED assessment to urgent PCI initiation between patients who were queried about their medication use history by physicians via the program and those who were not.

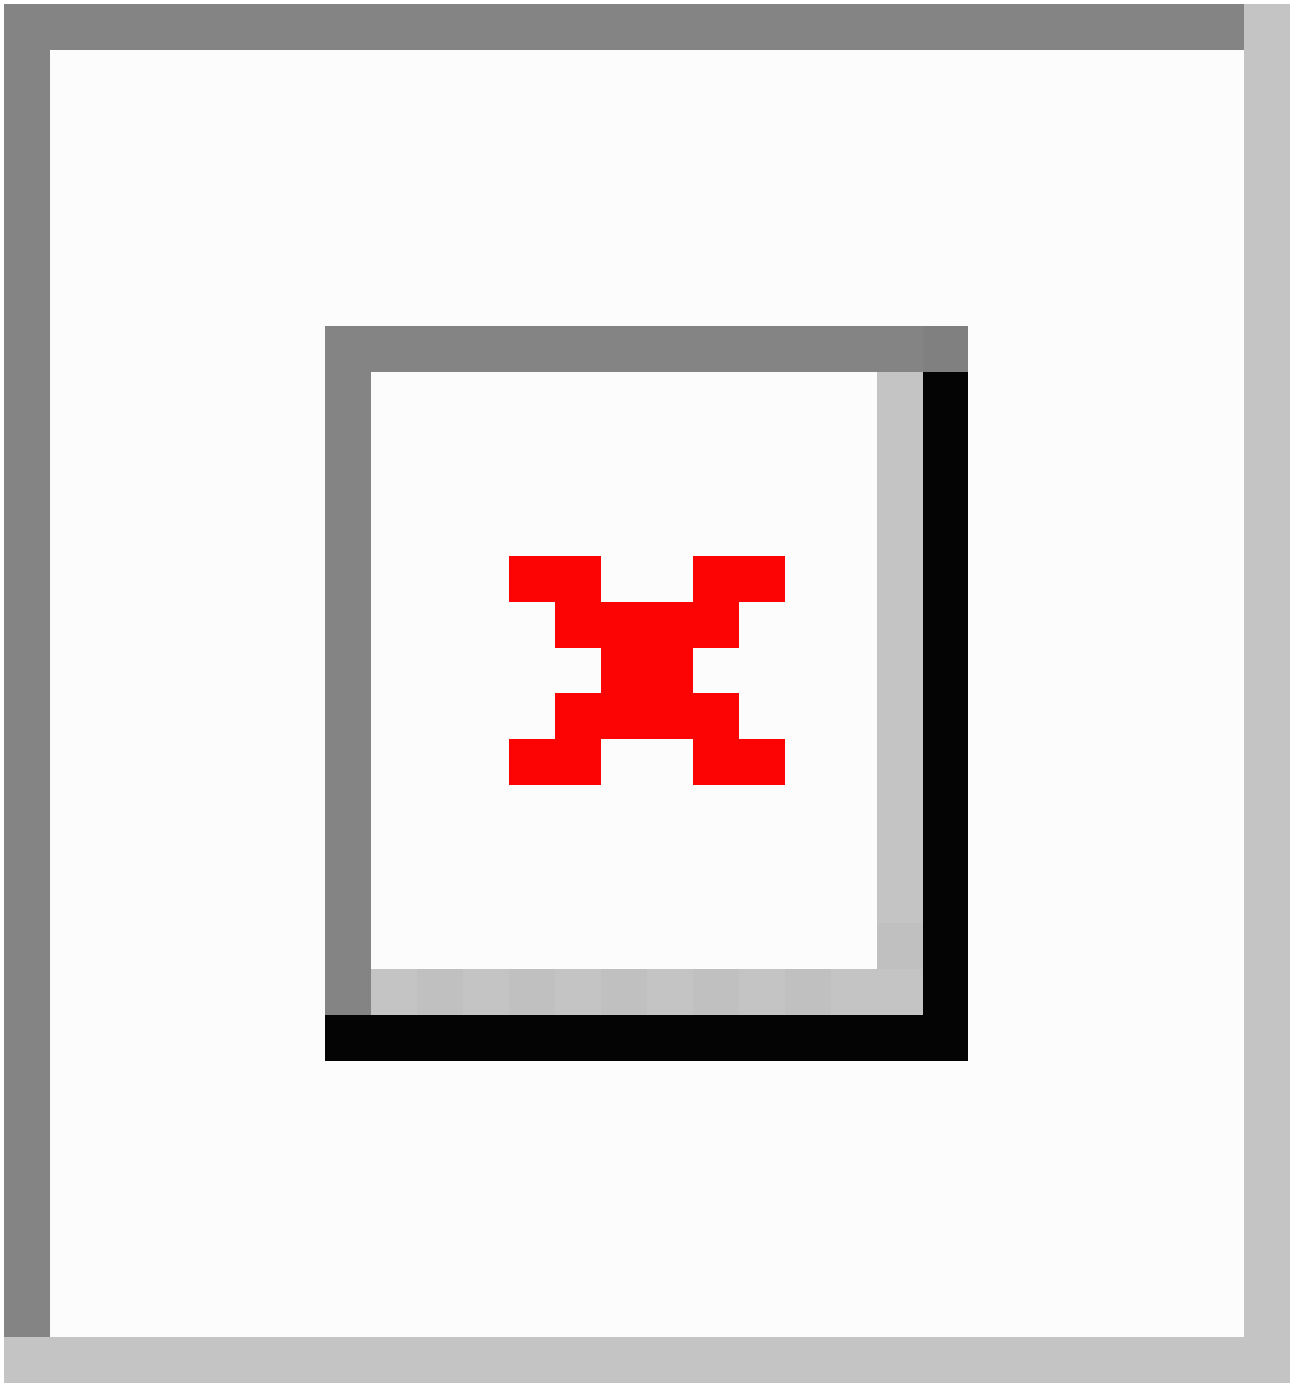
All analyses were performed using IBM SPSS Statistics (version 22.0; IBM Corp) and R (version 4.0.2; R Foundation for Statistical Computing).

Survey and Assessing Factors Affecting End-User Experience on the Program

Survey Development With a Conceptual Framework

To assess end-user experience and whether end users are satisfied with HIS and their intention to reuse it, we adopted the updated DeLone and McLean Model of Information Systems Success (DMISM) [20] for survey development. The updated DMISM provides a conceptual framework to suggest the factors necessary for the provision of use and benefits from the HIS. Based on the updated DMISM, we proposed that the quality of the information system consists of 3 quality domains: information quality, system quality, and service quality. These domains are necessary for user satisfaction and are instrumental in driving users' intentions to reuse the system. In this study, we narrowed the scope to physicians and pharmacists who were already using the program. Therefore, we adjusted the factor of "intention to use" and "use" in the updated DMISM to "intention to reuse." Due to the nature of the HIS, "intention to reuse" of the program by end users is considered the ultimate and crucial goal. By setting it as the final outcome variable, "intention to reuse" is influenced by preceding user satisfaction. Therefore, we established the research model with the relationship that "user satisfaction" affects "intention to reuse." These domains were used to develop the survey (Figure 2).

Figure 2. A research model for the survey development. The updated DeLone and McLean Model of Information Systems Success [20] provides domain variables consisting of 3 quality domains (ie, information, system, and service quality) as well as outcome domains.



We collected 32 survey questionnaires that assessed each quality domain regarding previous studies [3,21-24]. Through face validation with 6 pharmacists, a physician, and a medical informatics professor every 2 weeks for 3 months, the survey questionnaires were classified according to each domain. The questionnaires were eliminated or revised to reflect the contextual significance of the program. The draft survey finally consisted of 22 questionnaires, and a pilot study was conducted with 10 pharmacists and 2 physicians at SNUBH.

The survey was conducted from December 15, 2022, to December 28, 2022, at SNUBH. We used a web-based survey to collect data on the end-user experience efficiently and rapidly. The survey link was distributed to all physicians and pharmacists at the hospital via email. Survey completion was expected to take approximately 5 minutes. The items in the survey were rated on a 5-point Likert scale (1=not at all; 5=very much). Only those who provided consent after receiving an explanation of the background and purpose of the survey were included.

Data Analysis

An exploratory factor analysis of the results was then performed to determine how the items were classified into components. We used the Kaiser-Meyer-Olkin measure to assess sampling adequacy and obtained a specific value of 0.858, surpassing the recommended threshold of 0.5. The suitability of the data for factor analysis was further confirmed through the Bartlett test

of sphericity, yielding a statistically significant result (χ^2_{105}=723.6; P<.001). The analysis of communality, indicating the explanatory power between measurement variables and extracted factors, was performed. Considering the general criterion that variables with communality below 0.4 are deemed low and should be excluded from factor analysis, 8 questions were excluded. Consequently, 14 questionnaires were retained (Table S1 in Multimedia Appendix 1).

Subsequently, we conducted a reliability analysis of the survey items and calculated Cronbach α. We analyzed the convergent and discriminant validity of the constructs. We used SPSS to conduct statistical analyses, including factor and reliability analyses. Finally, structural equation modeling (SEM) was used to evaluate the structural correlations among the domains using the AMOS 25 software (version 25.0; IBM Corp). SEM was chosen to provide a comprehensive understanding of the relationships among survey variables and to help validate the theoretical models with a visual representation.

Ethical Considerations

This study was approved by the Institutional Review Board of SNUBH (B-2203-746-001; April 21, 2022), and the requirement of obtaining written consent was waived, as this study did not contain sensitive personally identifiable information.

Results

Care Process Outcome

Of the 162 patients who were admitted to the ED and visited the hospital for the first time over a 2-year period, 77 who underwent urgent PCIs within an hour from the first ED assessment to urgent PCI initiation were included. Patients who were regularly visiting hospitals with chronic diseases were excluded. Table 1 describes the demographic characteristics of patients, including gender, age, department, tests, and diagnosis, between the patient group (n=59), for which the doctor did not use the program, and the patient group (n=18), whose medications were accessed through the program.

Table . Demographics of patients receiving urgent percutaneous coronary intervention by use of the medication history program during the study period at an emergency department (n=77[a]).

Characteristics		No (without the program; n=59)	Yes (with the program; n=18)
Sex (male), n (%)		50 (84.7)	11 (61.1)
Age (years), mean (SD)		64.3 (12.1)	68.9 (12.4)
Department at discharge, n (%)			
	Cardiology	54 (91.5)	16 (88.9)
	Others	5 (8.5)	2 (11.1)
Had CT[b] scan, n (%)		12 (20.3)	3 (16.7)
Diagnosis, n (%)			
	ST elevation myocardial infarction	53 (89.8)	16 (88.9)
	Others	10 (16.9)	4 (22.2)

[a]Patients receiving percutaneous coronary intervention within an hour at an emergency department from January 12, 2021, to December 31, 2022.

[b]CT: computed tomography.

Changes in time from the first ED assessment to urgent PCI initiation significantly decreased in patients who used the program (n=18; mean rank 28.72 min) versus patients who did not use the program (n=59; mean rank 42.14 min; Mann-Whitney U=346; P=.03).

Survey and Assessing Factors Affecting End-User Experience on the Program

Survey Participants' Characteristics

During the 2-week survey period, we received survey responses from 112 participants in the hospital. Among them, we removed the responses of 10 participants who never used the "Patient's In-home Medication at a Glance" based on their answers to the first question. In addition, the responses of 5 participants who gave the same rating to the negative and positive questions were removed, as they were considered either not meaningful or not sincere to the survey, leaving 97 responses for analysis. Table 2 presents the characteristics. Participants included 62 (63.9%) physicians and 35 (36.1%) pharmacists, and the mean use count during the week was approximately 10.8 (SD 13.9).

Table . Participants' characteristics (N=97).

Characteristics				Values, n (%)
Occupation				
	Physician (n=62, 63.9%)			
		Position		
			Professor	35 (56.5)
			Resident	27 (43.5)
		Department		
			Internal medicine	50 (80.6)
			Surgery	12 (19.3)
		Workplace

Weekly frequency of using the program				
	Mean (SD)			10.7 (13.9)
	Median (IQR)			6 (4-10)

[a]EHR: electronic health record.

Evaluation of the Survey Results

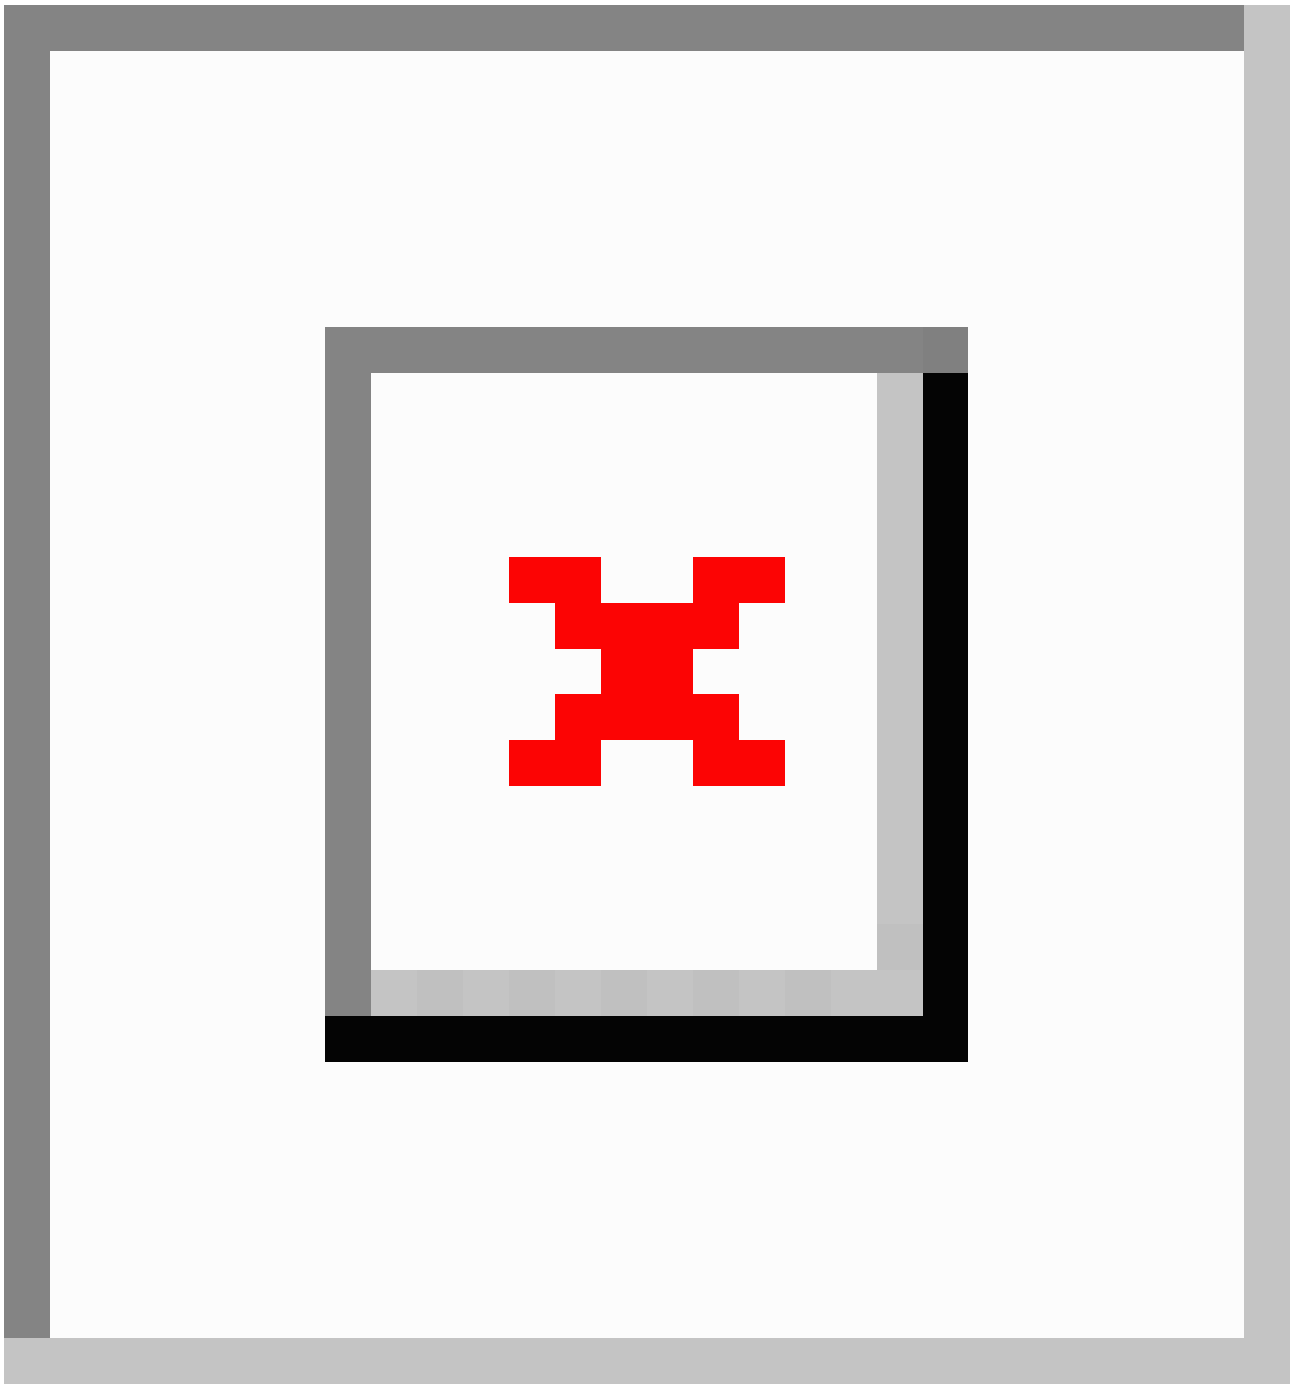
Of the 22 survey questions, the updated DMISM comprised 14 questions in 5 domains. After performing exploratory factor analysis, we calculated the mean score of each domain and Cronbach α to confirm the consistency of the items. This reliability analysis revealed that Cronbach α for all variables exceeded 0.80 (information quality: 0.808; system quality: 0.834; and service quality: 0.800), except for user satisfaction (Cronbach α=0.788) and intention to use (Cronbach α=0.795).

On a 5-point scale, the mean scores values for the information, system, and service quality of the program were 4.11 (SD 0.76), 4.24 (SD 0.75), and 3.87 (SD 0.79), respectively. User satisfaction (4.56, SD 0.49) and intention to reuse (4.77, SD 0.37) were measured. Among the 5 domains of the survey questionnaire, intention to reuse obtained the highest score. The estimates and weights of all 5 domains were analyzed, and no issues were observed in the convergent validity of the constructs (Table S2 in Multimedia Appendix 1). In addition, the subsequent analysis revealed the absence of discriminant validity (Table S3 in Multimedia Appendix 1).

Structural Correlations Between Domains

The SEM images are shown in Figure 3. The model fit indices were calculated as follows: χ^2_{70}=103.413 (P<.001); goodness-of-fit index=0.868 (recommended: 0-1.0); root mean square residual=0.039 (recommended: 0-0.05); and root mean square error of approximation=0.071 (recommended: 0.05-0.08). The comparative fit index and the Tucker-Lewis index for the model exceeded 0.9. The normed fit index and adjusted goodness-of-fit index values were lower than the recommended values of 0.859 and 0.802, respectively. Thus, this model was confirmed to be appropriate for assessing the factors affecting the “intention to reuse” program as an end-user experience.

Figure 3. Results of the research model using the structural equation modeling analysis. Significant paths are indicated with solid lines, while nonsignificant paths are shown with dotted lines. Two significant paths are shown: information quality toward user satisfaction and user satisfaction toward intention to reuse. The standardized beta values are presented. *P=.01; ***P<.001. CFI: Comparative Fit Index; RMSEA: root mean square error of approximation; TLI: Tucker-Lewis Index.



The associations between the latent variables were positive, supporting our hypotheses. Among the 3 quality domains, “information quality” had a significantly positive influence on “user satisfaction.” Consequently, the influence of “information quality” in “user satisfaction” and the influence of “user satisfaction” in “intent to reuse” were significantly associated.

Discussion

Principal Results

This study aimed to evaluate the impact of medication history retrieval using the "Patient's In-home Medications at a Glance" program in homegrown HISs during the 2-year maintenance phase after program implementation. The significance of our findings was twofold. First, we conducted a comprehensive evaluation of the impact of the nationwide medication history-sharing program, consisting of care process outcomes and end-user experiences as humanistic outcomes. We elaborately planned both the care process and humanistic outcomes of 2-year use, which allowed the program to stabilize, after its implementation in the HIS [23]. The care process, focusing on the time required for urgent PCI initiation, was improved in the patient group, whose physicians used the program and experienced expedited urgent PCI initiation. Thus, the use of the program could help identify whether patients are taking an antiplatelet or anticoagulant agent when they are unconscious or are unable to identify their medications. Regarding humanistic outcomes, the survey showed high scores overall, especially for "user satisfaction" and "intention to reuse." The increasing trend in the use of the "Patient's In-home Medications at a Glance" program by physicians and pharmacists indicates the successful integration of the newly developed program into the HIS, as evidenced by a positive end-user experience.

Second, we assessed factors affecting end-user experience using SEM; "information quality" significantly influenced "user satisfaction," and "user satisfaction," in turn, positively enhanced "intention to reuse." Since the survey was developed with the updated DMISM, which is a conceptual framework to suggest factors necessary for the "intention to reuse" the program, we could examine whether and how the 3 quality domains, including information, system, and service, affect "user satisfaction" and how "user satisfaction" affects "intention to reuse." These findings highlight the potential of the HIS in supporting clinical decision-making and contributing to value-based health care through the provision of a comprehensive medication use history.

Implications

Value-based health care is an approach to health care delivery in which providers are paid based on the patient's health outcomes [25], while reducing costs [26]. The benefits of a value-based health care system include reduced treatment costs, increased care efficiency, and reduced risks [27]. Measuring a patient's clinical outcomes is a major aim of value-based health care. In our study, we measured both care process outcomes and end-user experiences, which help present humanistic outcomes. Hence, a comprehensive evaluation was conducted by selecting both outcomes to determine the impact of the interventions using the HIS. Health service providers should provide patient-centered team care, share patients' medical information, and measure the care process using the HIS. The physicians were able to collect the patients' complete medication use histories in a friendly manner, even if the patients were unable to identify the exact medications they were taking. As access to a complete medication use history could help physicians make clinical decisions and collaborate care within the hospital [28], the HIS could help improve the patient's outcomes. Thus, HISs can play a vital role in value-based health care by delivering comprehensive and up-to-date information, including medication use history, laboratory results, and other medical records.

In terms of the association between the survey domains, the updated DMISM was applied to identify the quality factors that contribute to "user satisfaction," which affects end users' "intention to reuse." According to Alzahrani et al [29], 3 quality domains are significantly related to "user satisfaction" and "intention to reuse" and consequently affect actual usage. By conducting an SEM analysis of the survey results, our model revealed a significant effect of "information quality" on "user satisfaction," as well as "user satisfaction" on "intention to reuse." These results indicate that providing complete, accurate, and regent information is important for "user satisfaction," ultimately driving the "intention to reuse." A previous study stated that studies assessing the acceptance of HISs have been conducted from the physicians' perspective, not the clinical pharmacists' [30]. Since the program has been used by physicians and pharmacists, we could assess the factors affecting end-user experience in both professional groups. If the quality of information in an HIS is not guaranteed, health care professionals will not use specific programs in the HIS.

Limitations

This study had some limitations. First, we developed and implemented the "Patient's In-home Medications at a Glance" program in a single hospital. Thus, outcomes, such as care processes or factors affecting end-user experience, cannot be generalized to other hospitals in South Korea. However, as the Healthcare Insurance Review and Assessment Service has established guidelines for program development, further studies that use similar HISs could be conducted in other hospitals. Second, the pretest and posttest studies had the inherent limitations of nonrandomized, uncontrolled study designs. Although we showed the impact of the program on the time to PCI as the care process, we could not capture the long-term effects on clinical outcomes, such as survival rates or extended hospital stays. Nevertheless, our findings regarding the care process, specifically the reduction in time from the first ED assessment to urgent PCI initiation, could be meaningful not only in expediting clinical decisions but also in the evaluation of HISs in a real-world health care setting. Third, a notable limitation of our study is the imbalanced distribution of participants between the patient groups with or without the program (18 vs 59 participants) and the small number of patients in the group using the program. This uneven and small sample size raises concerns about the statistical robustness of our findings. Future research endeavors should prioritize achieving a more equitable number and distribution of patients to enhance the reliability and generalizability of our conclusions. Although our study offers valuable insights, the limitation of uneven and small sample sizes underscores the importance of cautious interpretation and highlights a potential area for improvement in subsequent research. Fourth, in the results of the SEM analysis, "information quality" was a standalone significant

factor among 3 quality domains influencing "user satisfaction." It is possible that the developed survey item may not adequately address the measurement of the quality domain. Lastly, our focus in this study was on system acceptability rather than the direct improvement in the health of the patients. We plan to focus more on the clinical outcome of the program, which includes not only medication information but also ensuring comprehensive disease management. This approach should be followed up for future measurements in subsequent studies.

Conclusions

Our findings highlight the impact of the rapid and complete medication history retrieval using the "Patient's In-home Medications at a Glance" program on the care process and end-user experience. A significantly positive effect was found on the care process by expediting urgent PCI initiation time at the ED, thereby contributing to value-based healthcare delivery in a real-world setting. Moreover, the HIS intervention provided high-quality information to physicians and pharmacists, resulting in high satisfaction. Long-term assessments can provide valuable insights into the sustained impact of the program, further optimizing patient outcomes.

Acknowledgments

We would like to thank the project team and program developer of the Medical Informatics Team for developing and implementing the program and assisting with data retrieval. We are grateful to all the pharmacists and physicians who participated in patient care. We would like to acknowledge the contributions of EEL as a cocorresponding author. We would also like to thank the Brain Korea (BK) 21 Plus Project of the National Research Foundation of Korea.

Authors' Contributions

JC, SY, HYL, and EEL contributed to the conception and design of the research, the acquisition and analysis of the data, as well as the interpretation of the data. They also drafted the manuscript. All authors critically revised the manuscript, agreed to be fully accountable for ensuring the integrity and accuracy of the work, and read and approved the final manuscript.

Conflicts of Interest

Abstract

Background: Although evidence-based medicine proposes personalized care that considers the best evidence, it still fails to address personal treatment in many real clinical scenarios where the complexity of the situation makes none of the available evidence applicable. “Medicine-based evidence” (MBE), in which big data and machine learning techniques are embraced to derive treatment responses from appropriately matched patients in real-world clinical practice, was proposed. However, many challenges remain in translating this conceptual framework into practice.

Objective: This study aimed to technically translate the MBE conceptual framework into practice and evaluate its performance in providing general decision support services for outcomes after congenital heart disease (CHD) surgery.

Methods: Data from 4774 CHD surgeries were collected. A total of 66 indicators and all diagnoses were extracted from each echocardiographic report using natural language processing technology. Combined with some basic clinical and surgical information, the distances between each patient were measured by a series of calculation formulas. Inspired by structure-mapping theory, the fusion of distances between different dimensions can be modulated by clinical experts. In addition to supporting direct analogical reasoning, a machine learning model can be constructed based on similar patients to provide personalized prediction. A user-operable patient similarity network (PSN) of CHD called CHDmap was proposed and developed to provide general decision support services based on the MBE approach.

Results: Using 256 CHD cases, CHDmap was evaluated on 2 different types of postoperative prognostic prediction tasks: a binary classification task to predict postoperative complications and a multiple classification task to predict mechanical ventilation duration. A simple poll of the *k*-most similar patients provided by the PSN can achieve better prediction results than the average performance of 3 clinicians. Constructing logistic regression models for prediction using similar patients obtained from the PSN can further improve the performance of the 2 tasks (best area under the receiver operating characteristic curve=0.810 and 0.926, respectively). With the support of CHDmap, clinicians substantially improved their predictive capabilities.

Conclusions: Without individual optimization, CHDmap demonstrates competitive performance compared to clinical experts. In addition, CHDmap has the advantage of enabling clinicians to use their superior cognitive abilities in conjunction with it to make decisions that are sometimes even superior to those made using artificial intelligence models. The MBE approach can be embraced in clinical practice, and its full potential can be realized.

Introduction

Congenital heart disease (CHD) is the most common type of birth defect, with birth prevalence reported to be 1% of live births worldwide [1]. Despite remarkable success in the surgical and medical management that has increased the survival of children with CHD [2], the quality of treatment and prognosis after congenital heart surgery remains unsatisfactory and varies across centers [3,4]. The reason for this is that the complexity of the disease, clinical heterogeneity within lesions, and small number of patients with specific forms of CHD severely degrade the precision and value of estimates of average treatment effects provided by randomized controlled trials on the average patient. Some visionary researchers have proposed a new paradigm called "medicine-based evidence" (MBE), in which big data and machine learning techniques are embraced to interrogate treatment responses among appropriately matched patients in real-world clinical practice [5,6].

Postoperative complications in congenital heart surgery have been inconsistently reported but have important contributions to mortality, hospital stay, cost, and quality of life [7-9]. Heart centers with the best outcomes might not report fewer complications but rather have systems in place to recognize and correct complications before deleterious outcomes ensue [8]. The early detection of deterioration after congenital heart surgery enables prompt initiation of therapy, which may result in reduced impairment and earlier rehabilitation. Several risk scoring systems, such as the Risk Adjustment for Congenital Heart Surgery 1 (RACHS-1) method, Aristotle score, and Society of Thoracic Surgeons–European Association for Cardiothoracic Surgery (STS-EACTS) score, have been developed and used to adjust the risk of in-hospital morbidity and mortality [10-13]. However, most of these consensus-based risk models only focus on the procedures themselves and ignore the differences between centers and patients. Specific patient characteristics, such as lower weight [14] and longer cardiopulmonary bypass time [15], especially the quantitative echocardiographic indicators used by clinicians to understand CHD conditions, were not incorporated into these models nor can they be adjusted for. Based on the increasing number of CHD databases being built, some machine learning–based predictive models have recently been used to identify independent risk factors and predict complications after congenital heart surgery [16-18]. These predictive models achieved outstanding performance compared to traditional risk scores, but these models are usually only capable of performing a single task. In addition, such models often contain hundreds of features, so for clinicians, understanding how to interpret the prediction from a complicated machine learning model is still a challenge [19]. Based on our previous studies [16-18], as the model becomes more complex and more variables are included, the results are better, but it is more difficult to understand and accept clinically. Although some explainable artificial intelligence (AI) techniques continue to evolve [20,21], machine learning prediction models are still a black box for clinicians. Due to the lack of understanding and manipulation of the model, clinicians often lack confidence in the predicted outcomes, which severely hampers the entry of these machine learning models into routine care.

Patient similarity networks (PSNs) are an emerging paradigm for precision medicine, in which patients are clustered or classified based on their similarities in various features [22,23]. PSNs address many challenges in data analytics and is naturally interpretable. In a PSN, each node is an individual patient, and the distance (or edge) between 2 nodes corresponds to pairwise patient similarity for given features. PSNs naturally handle heterogeneous data, as any data type can be converted into a similarity network by defining similarity measures [24,25]. A PSN generated based on a large cohort of patients will show several subgroups of patients who are tightly connected. If a new patient is located on the PSN, neighbors that have similar features with known risk or prognosis will inform clinicians of the potential risk and prognosis of the patient. This mimics the clinical reasoning of many experienced clinical experts, who often relate a patient to similar patients they have seen. Moreover, representing patients by similarity is conceptually intuitive and explainable because it can convert the data into network views, where the decision boundary can be visually evident [26]. PSNs can also provide a feasible engineering solution for the MBE framework, which, based on a library of "approximate matches" consisting of a group of patients who share the greatest similarity with the index case, can be examined to estimate the effects of various treatments within the context of the individual patient's specific characteristics [6].

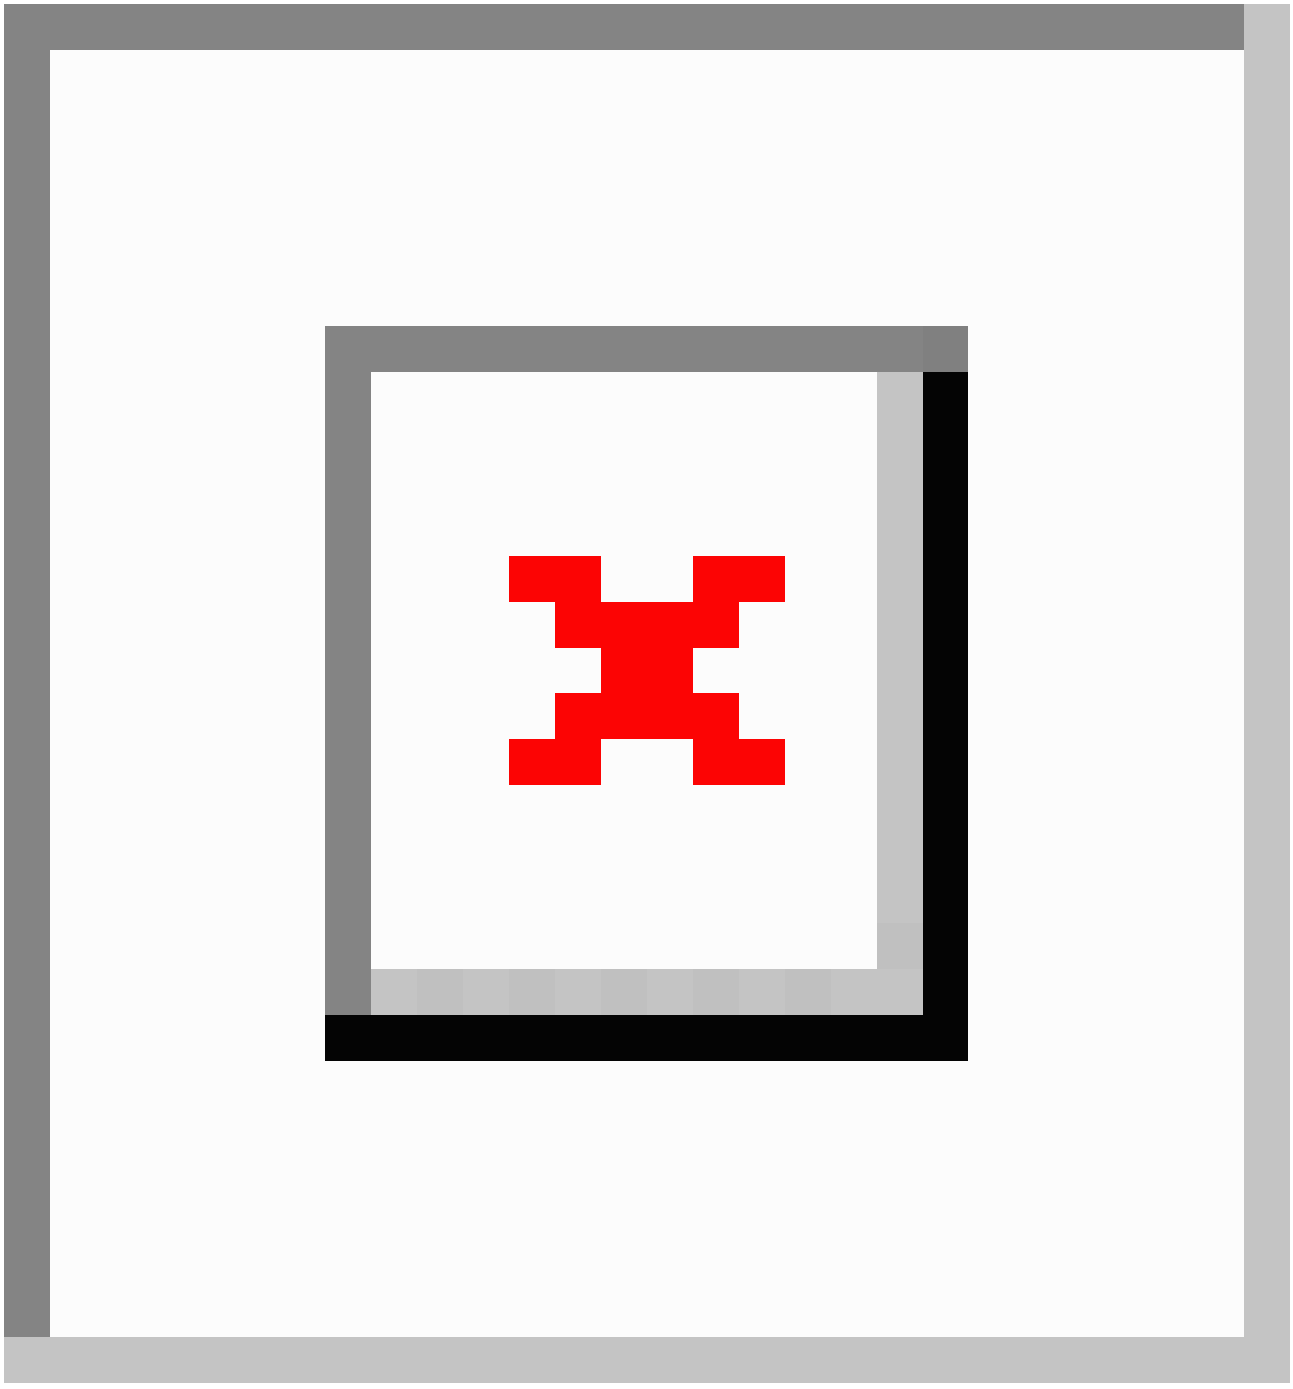
PSNs have been reported in many studies. Although early PSN studies have focused on using omics data in precision medicine [27-29], with the development of electronic health record (EHR) systems, abundant, complex, high-dimensional, and heterogeneous data are being captured during daily care, and some EHR-based patient similarity frameworks have been proposed for diagnosis [30], subgroup patients [31,32], outcome prediction [33], drug recommendation [34,35], and disease screening [36]. However, studies of PSNs that predict the outcome after CHD surgery have not been reported. A perspective article proposed an MBE conceptual framework for CHD [6], in which similarity analysis is used to generate a library of "approximate matches." However, they did not provide any technical solution for this framework. The challenge in applying PSNs in a real clinical setting is, first of all, to assess the distance between patients with complex conditions such as CHD in a computable way. However, mimicking clinical analogy reasoning is not a simple math formula based on various patients' attributes. The structure-mapping theory in cognitive science argues that advanced cognitive functions are involved in the analysis of relationship similarity above attribute similarity [37]. Analogy inference requires advanced cognitive activity, which current AI technology lacks but clinical experts are good at. However, all established models ignore this important feature of patient similarity analysis, in that it should not only measure patients' distance but also put clinicians back behind the wheel to generate MBE for clinical decision-making. In this study, we aimed to develop and evaluate a clinician-operable PSN of CHD to try to mitigate the above problems.

Methods

Study Design and Population

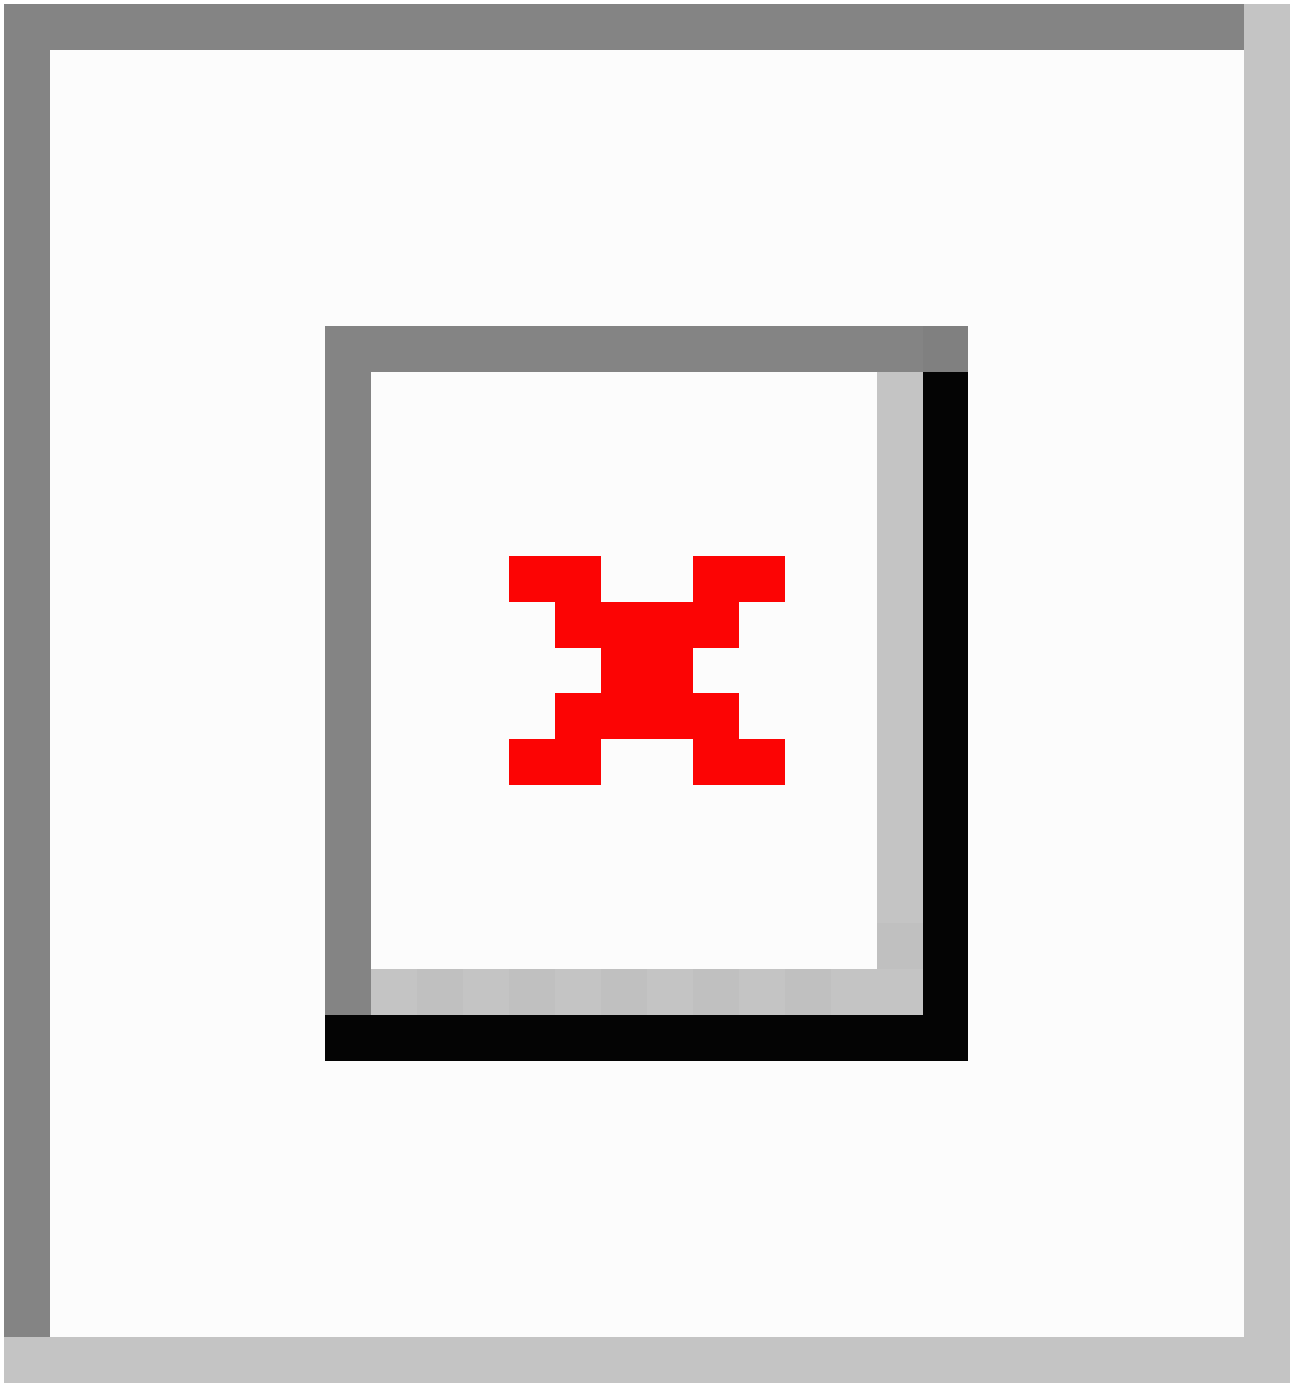
As shown in Figure 1, using data available at different stages, 4 PSNs were generated and named as screening map, echo map, patient map, and surgery map. These data were obtained from the ultrasound reporting system and EHR system of the Children's Hospital, Zhejiang University School of Medicine, Hangzhou, China.

Figure 1. CHDmap contains 4 patient similarity networks generated from 4 different clinical phases, with different data obtained at each phase. CHD: congenital heart disease; ICU: intensive care unit; LOS: length of stay.



A schematic of the data processing and workflow for the construction of the PSN is shown in Figure 2 and described below.

Figure 2. Schematic of data processing and workflow of the construction of the congenital heart disease (CHD) patient similarity network. NLP: natural language processing; t-SNE: t-distributed stochastic neighbor embedding.



Ethical Considerations

This retrospective study was performed according to relevant guidelines and approved by the institutional review board of the Children's Hospital of Zhejiang University School of Medicine with a waiver of informed consent (2018_IRB_078). All cases included in this study were anonymized. Intensive care unit (ICU) clinicians who participated in the trial received cash compensation (RMB ¥100 [US $14.06] per day), which complied with local regulatory requirements for scientific labor.

Data Collection and Preprocessing

In addition to preoperative echocardiography reports that described the CHD conditions, the following patient and surgical characteristics were also collected: age, sex, height, weight, preoperative oxygen saturation of the right-upper limb, surgery time, cardiopulmonary bypass time, aortic cross-clamping time, mechanical ventilation time, duration of postoperative hospital stay, duration of ICU stay, and postoperative complications (the detailed definitions of postoperative complications are shown in Table S1 in Multimedia Appendix 1 [38-40]).

The most challenging part of patient similarity analysis was defining all the semantic concepts in the domain. An ontology of CHD was developed based on reviewing a large number of clinical guidelines for CHD to cover 436 CHD conditions and 87 related echocardiographic indicators. The OWL format ontology file is available on the CHDmap website [41]. The

ontology was used to normalize all concepts and measure semantic similarity among them. It was also used to identify quantitative indicators from the unstructured text of echocardiography reports. In addition to recording some routine cardiac structure indicators, the echocardiography report also provided quantitative indicators regarding various malformations, such as the size of various defects, shunt flow velocity, and pressure difference at the defect, depending on the specific CHD structural malformation. Natural language processing (NLP) technology [38] was used to extract 66 commonly used quantitative indicators. A range of processing and computational methods were used to assess similarity between patients (details information are shown in the supplemental methods and Tables S2 Table S3 in Multimedia Appendix 1). The various automatically extracted measurement values were subject to quality control, and any abnormal data (outside the reasonable range of the corresponding values) were modified or removed after manual verification. The diagnosis in the report was also extracted and mapped to the normalized terms defined in the CHD ontology.

Measuring Patient Similarity

In this study, the similarity of patients with CHD was measured using 4 groups of features: the quantitative echocardiographic indicators, the specific CHD diagnosis, preoperative clinical features, and surgical features. Different distance measurement methods were adopted for different groups of features, as described in the supplemental methods in Multimedia Appendix 1. We provided 3 types of methods to handle the echocardiographic indicators: the origin value, the *z* score, and the indicator combination ratio. The similarity between 2 diagnoses was calculated using the depth of the corresponding nodes in the CHD ontology, which organizes hundreds of CHD diagnoses in a hierarchical structure. Two approaches were used to measure the distance between diagnosis lists: one treats all diagnoses equally, referred to in the result section as “ungrade,” whereas the other distinguishes between basic and other diagnoses, referred to as “grade.” Finally, the patient distance was measured as the weighted sum of the 4 distances as shown in equation (1), and the final distances were also normalized to [0,1].

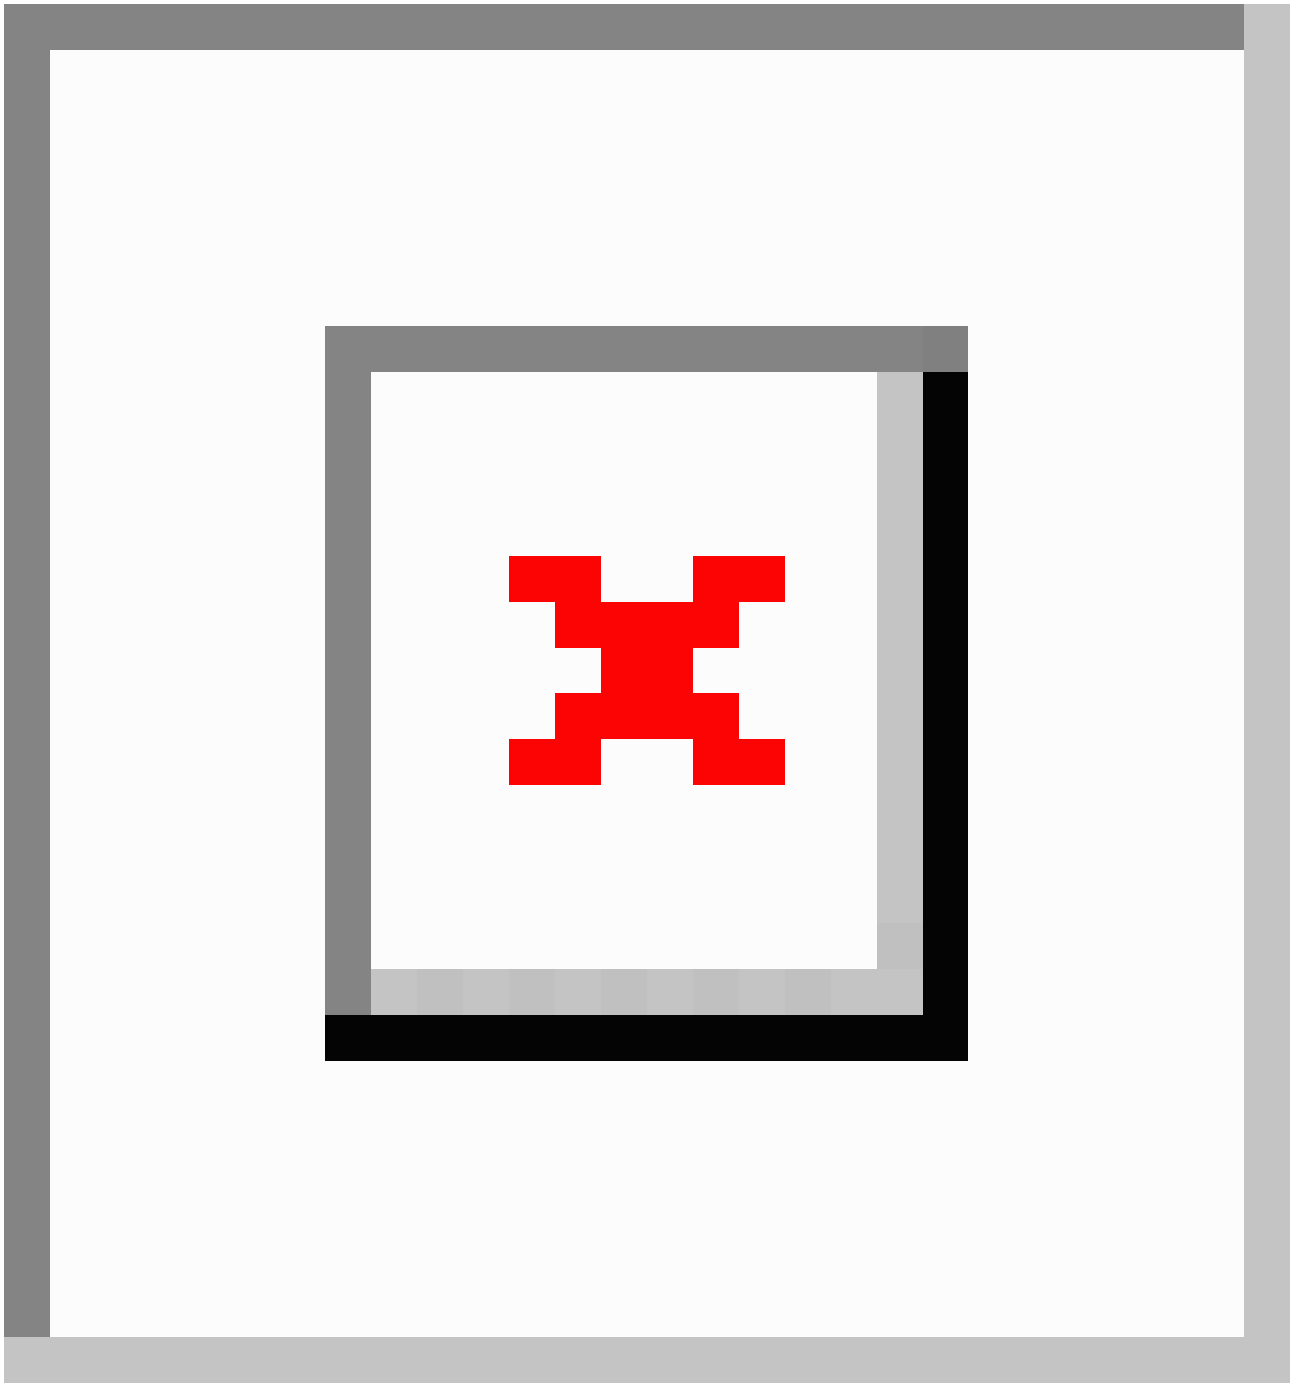
(1)

The weights in equation (1) and the different methods used to measure distance can also be modified by users depending on their experience in different tasks to fully exploit the advanced cognitive ability of clinical professionals. The distance matrix among historical patients can be calculated based on the aforementioned methods. We used t-distributed stochastic neighbor embedding [42] to convert the distance matrix into 2D points, which can be visualized as a map. The user-operable CHDmap was developed based on ECharts [43] using React (Meta) and Node.js (OpenJS Foundation). The patient similarity analysis engine, which measures the distances between a new patient and patients in CHDmap, was developed using Python (Python Software Foundation).

CHDmap

A user-operable CHD PSN called CHDmap was developed and published on the web [44]. The introduction video of this tool is also available in Multimedia Appendix 2. Based on the different available data for each clinical phase, as shown in Figure 1, CHDmap provides 4 different PSNs: the screening map, echo map, patient map, and surgery map. The workspace of CHDmap comprises 3 major modules: (1) map view, (2) cockpit view, and (3) outcome view (as shown in Figure 3).

Figure 3. Screenshot of CHDmap. The map view, cockpit view, and outcome view of the workspace are marked separately. CHDmap was published on the web [44]. CHD: congenital heart disease.



The map view presents the PSN as a zoomable electronic map, in which a node presents a patient and the distance between nodes shows their similarity. The map can be enhanced by using different colors to show the diagnostic labels as well as relevant prognostic indicators (eg, length of stay and complications). Different methods to handle the echocardiographic indicators, such as normal, z score, or combination ratio value, can be selected on the web. The similar patient group is also highlighted on the map view during similarity analysis.

The cockpit view provides a navigation function that helps clinicians locate cases based on specified query conditions, such as age, gender, and CHD subtypes. In practice, clinicians were allowed to create a new case, in which an NLP-based information extraction tool will assist users in filling in most of the echocardiographic indicators based on Chinese echocardiography reports. The top *k* value, or threshold of patient similarity, is used to customize the similar group. For advanced users, a customized map can be generated by adjusting the weights for the patient similarity measurement defined in the *Methods* section.

The outcome view provides an overview of outcomes, including the length of hospital stay, mechanical ventilation time, length of ICU stay, complications, and hospital survival of the selected similar patient group. Multiple charts are used to show the difference between the selected patient group and others. The Mann-Whitney *U* test and the χ^2 test are used to determine the

significance of differences between groups. When there are significant differences between the selected patient group and other patients, the color of the check box at the top of the outcome view will turn red; otherwise, it will stay gray. Checking the box will show detailed charts and tables of the outcome. This real-time feedback will help clinicians adjust the parameters in the cockpit view based on the requirements of the scenario for clinical decision-making. Based on a selected group of similar patients, CHDmap provides machine learning models to personalize the prediction of relevant outcome metrics for the current patient. Therefore, for each case, different parameters can be applied and compared to ultimately assess the credibility of the relevant decision support information.

Evaluation Method

The closer 2 patients are located on the CHDmap, the more similar their conditions and postoperative outcomes are considered to be. When a new patient is admitted to the hospital, historical patients can be divided into similar and nonsimilar groups based on some criteria. There are 2 criteria to define patient similarity groups: one is to use the most similar k patients, also known as k-nearest neighbor (KNN), to form a patient similarity group, and the other is to define a threshold above which patients form a similarity group. The statistical characteristics or regression value of postoperative outcomes in the similarity group are used to predict the outcomes of the current patient.

In this paper, we evaluated the performance of the surgery map of CHDmap on 2 tasks: predicting postoperative complications as a binary classification task, in which more than 50% of patients in the similarity group with complications were assigned ‘True” for the target patient, and predicting mechanical ventilation duration as a multiple-label classification task (I: 0-12 h, II: 12-24 h, III: 24-48 h, and IV: >48 h), in which the category with the highest proportion in the similarity group was assigned to the target patient.

As the optimum k of KNN to form a similarity group for a specific case is always different, the unified population-level optimized k on the training data set was used to evaluate CHDmap on the test data set without individual customization. Different data preprocessing methods (original, z score, and combination ratio) and whether to distinguish primary diagnoses (grade and ungrade) were tested and compared.

Making decisions may not be straightforward if the outcome of a similar patient group is extremely heterogeneous, whereby a machine learning model based on a similar patient population can provide a more personalized prediction of the relevant prognostic indicators. Although there are numerous machine learning models to choose from, the focus of this study was to demonstrate the advantages of basing the model on similar patient populations, so we chose to use the most conventional and easily understood logistic regression (LR) model. Clinical users obtained a population of similar patients after various parameter adjustments and threshold settings on CHDmap, and the data from this population were used to train an LR model (KNN+LR), which can be accomplished on the web in real time because this population of similar patients is usually not very large. To demonstrate the effect of similar patient populations, we trained another LR model (k-Random+LR) based on randomly collected cases of the same size in parallel in the evaluation. We evaluated such approaches and compared the LR models based on k similar patients and k random patients.

The accuracy, recall, F_1-score, and area under the receiver operating characteristic curve (AUC), which are defined below, were adopted to evaluate the performance of the classification. Accuracy is defined as the total correctly classified example including true positive (TP) and true negative (TN) divided by the total number of classified examples. Recall quantifies the number of correct positive predictions made out of all positive predictions that could have been made. F_1-score is a weighted average of precision and recall. As we know, in precision and recall, there are false positive (FP) and false negative (FN), so F_1-score also considers both of them. AUC provides an aggregate measure of the performance across all possible classification thresholds. The higher the accuracy, recall, F_1-score, and AUC, the better the model’s performance is at distinguishing between the positive and negative classes.

(2)

(3)

(4)

(5)

The performance was evaluated on an independent test set, which included 256 patients with CHD. These test cases were also available on CHDmap when users created a new case. Three clinicians working in the cardiac ICU with extensive experience were also asked to make relevant judgments for these test cases based on their clinical experience. After half a year following the initial trial, we conducted an experiment where the 3 clinicians were asked to make further predictions based on the output of CHDmap, and this prediction was compared with the previous results based on clinical experience alone to validate the benefits of CHDmap in supporting clinical decision-making.

Results

Population Characteristics

A total of 4774 patients who underwent congenital heart surgery between June 2016 and June 2021 at the Children’s Hospital of Zhejiang University School of Medicine were used to generate the CHD PSN. The performance of the PSN in predicting complications and mechanical ventilation duration was evaluated on an independent test data set, which included 256 pediatric patients who underwent congenital heart surgery between July 2021 and November 2021 at the Children’s Hospital of Zhejiang University School of Medicine. The characteristics of patients used to generate the PSN and for evaluation are described in Table 1. Since the test data and the

data used by the PSN were generated and collected in different time periods, as shown in Table 1, they are somewhat statistically different. The test data were older; therefore, the patients were significantly larger in terms of height and weight (P<.001), and there were also relatively large differences in the distribution of outcomes, lower complication rates, and shorter duration of mechanical ventilation. It should be noted that the diagnostic label is not the complete diagnostic information; we just use a few of the most common CHD subtypes to facilitate statistics and visualization, and this cohort contains a complete range of epidemiological characteristics as well as a variety of complex CHD subtypes such as transposition of the great arteries, tetralogy of Fallot, etc, which may appear in various diagnostic labels that they are combined with. When the case has 2 common CHD subtypes, such as ventricular septal defect and patent ductus arteriosus, only the more common subtype, ventricular septal defect, is labeled.

Table . Characteristics of patients with CHD[a] used to generate CHDmap and in the test data set.

Characteristic		Patients of CHDmap (n=4774)	Patients of the test data set (n=256)	*P* value
Gender (male), n (%)		2336 (48.9)	111 (43.4)	.09
Age (mo), median (IQR)		12.0 (4.0-32.0)	22.1 (7.8-50.9)	<.001
Height (cm), median (IQR)		75.0 (63.0-94.0)	85.5 (67.0-106.3)	<.001
Weight (kg), median (IQR)		9.2 (6.0-13.4)	10.8 (6.8-16.5)	<.001
Preoperative oxygen saturation (%), median (IQR)		98.0 (97.0-99.0)	98.0 (97.0-99.0)	.007
Surgery time (min), median (IQR)		119.0 (96.0-147.0)	120.0 (100.0-147.0)	.25
Cardiopulmonary bypass time (min), median (IQR)		60.0 (48.0-82.0)	61.5 (49.3-80.0)	.55
Aortic cross-clamping time (min), median (IQR)		40.0 (28.0-54.0)	38.5 (27.0-52.0)	.55
Duration of hospital stay (d), median (IQR)		9.0 (7.0-13.0)	7.0 (6.0-11.0)	.003
Duration of ICU[b] stay (d), median (IQR)		3.0 (1.0-4.0)	3.0 (1.0-4.0)	.49

[d]VSD: ventricular septal defect.

[e]PFO: patent foramen ovale.

[f]PDA: patent ductus arteriosus.

Performance of CHDmap

Three methods for preprocessing the echocardiographic indicators (origin, *z* score, combination) and 2 distinguishing primary diagnoses (grade and ungrade) were used to compare their effect on CHDmap performance. The performance of the CHDmap and 3 clinicians is shown in Table 2 and Figure 4.

Table . Evaluation results in the 2 tasks.

Methods		Prediction of postoperative complications				Prediction of mechanical ventilation duration			
		Accuracy	Recall	F_1-score	AUC[a]	Accuracy	Recall	F_1-score	AUC

[a]AUC: area under the receiver operating characteristic curve.

[b]KNN: *k*-nearest neighbor.

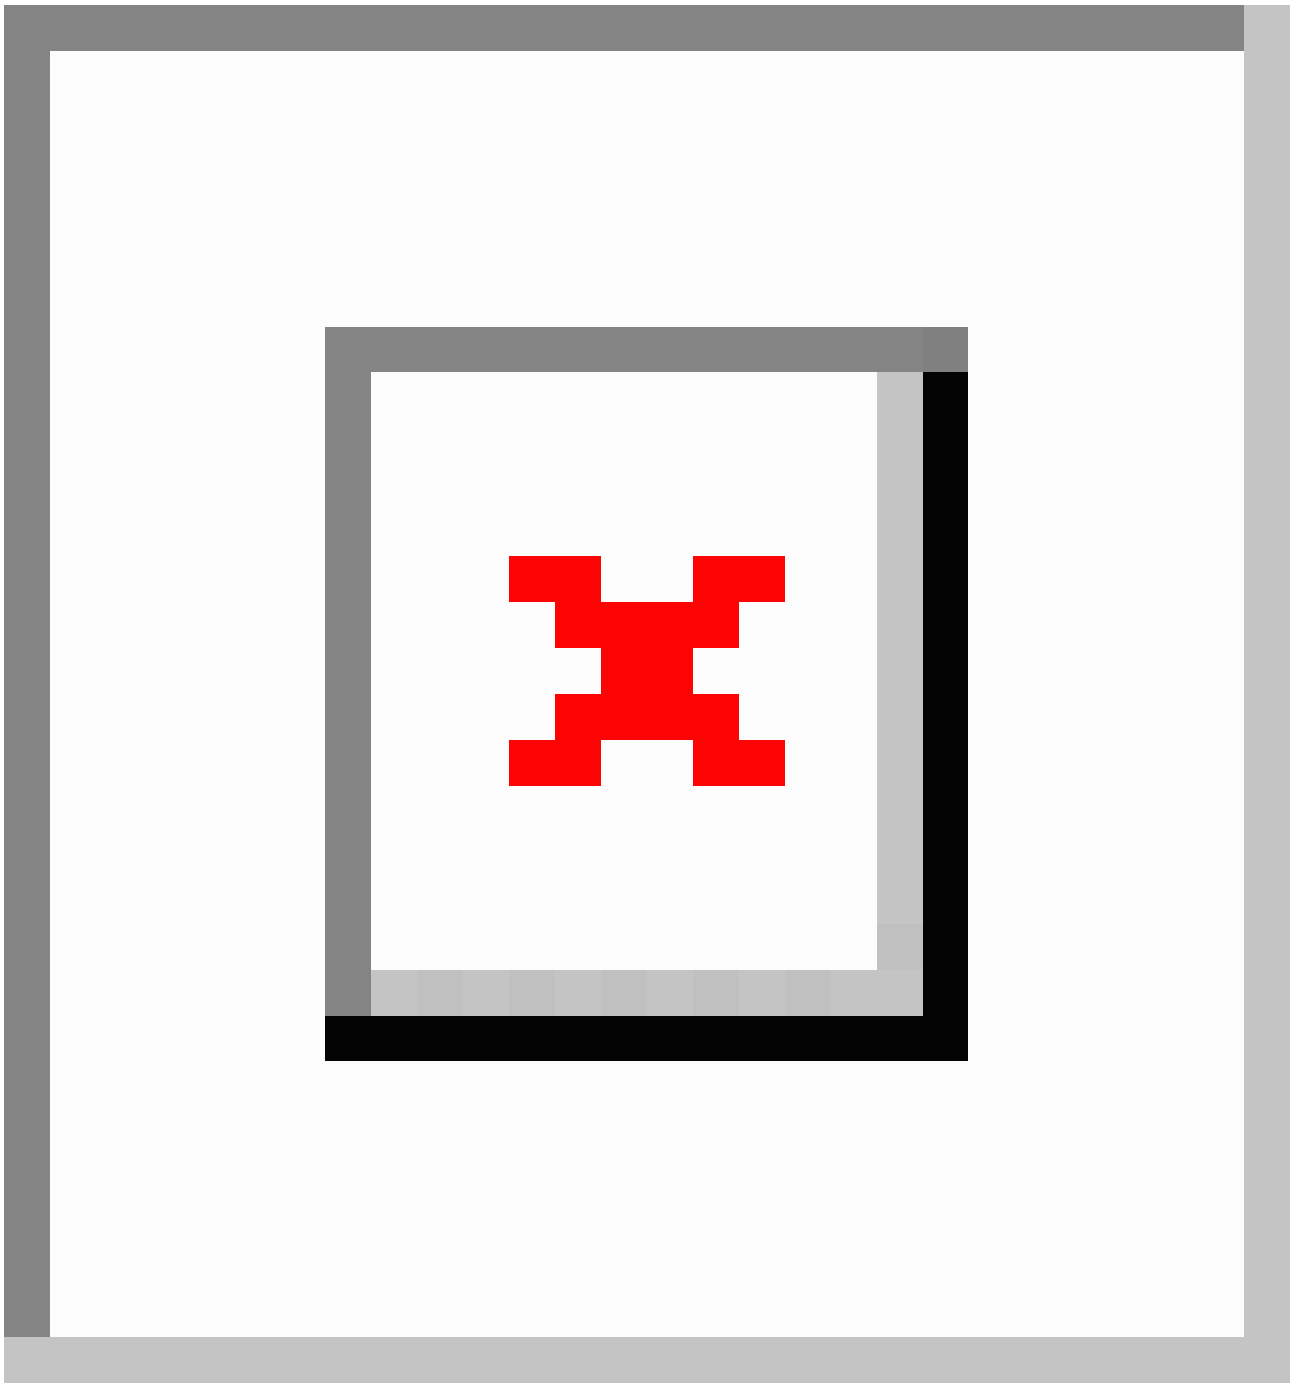
[c]LR: logistic regression.

[d]In each column, the maximum value is italicized.

[e]The performance of the 3 clinicians are labeled as C1, C2, and C3.

[f]N/A: not applicable.

Figure 4. Evaluation result based on receiver operating characteristic curves. (A) Binary postoperative complication prediction using KNN; (B) to (E) multilabel mechanical ventilation duration prediction (I: 0-12 h, II: 12-24 h, III: 24-48 h, and IV: >48 h) using KNN, respectively; (F) binary postoperative complication prediction using KNN+LR; (G) to (J) multilabel mechanical ventilation duration prediction (I: 0-12 h, II: 12-24 h, III: 24-48 h, and IV: >48 h) using KNN+LR, respectively. The performance of 3 clinicians are labeled as black stars in different tasks as C1, C2, and C3. The performance of 3 clinicians enhanced by CHDmap are labeled as red stars. CHD: congenital heart disease; KNN: *k*-nearest neighbor; LR: logistic regression.



In the postoperative complication prediction task, the F_1-score of methods using KNN exceeded the average of the 3 clinicians, although 1 clinician achieved the best accuracy when dropping a high recall value. In all 6 KNN methods, introducing the indicator combination ratio and distinguishing the primary diagnosis in the similarity measurement can truly improve the overall performance of the F_1-score. LR models constructed using the KNN-obtained patient groups were able to generally achieve better predictions compared to simple voting of similar patients and the LR model based on k random patients. Interestingly, both the model with the best F_1-score performance and the model with the best AUC used the original values. This may be because original values are more reflective of individualized patient differences in a similar patient population. The main improvement of CHDmap on this task is reflected in the general improvement in recall values, with the best recall method being 0.250 higher than the clinician average.

In another multiclassification task that predicts mechanical ventilation duration, the differences among these different KNN methods in overall performance were not consistent. The

KNN+LR approaches also achieved better composite performance (F_1-score and AUC), although 1 of the human experts got the best recall value.

From the test result, clinicians do not have the same performance for such predictive judgments. Some raise the standard and thus miss some events; on the other hand, some lower the judgment threshold, and thus the accuracy of the judgment decreases. At the same time, the performance of clinical experts on different tasks is inconsistent. A simple poll of the *k*-most similar patients provided by the CHDmap can achieve better results than the clinician average. When 3 clinicians were allowed to use the results of CHDmap (KNN+LR) as a reference to give predictions again, all 3 clinicians achieved a substantial improvement in their prediction ability. The averages of accuracy, recall, and F_1-score in the first task improved by 0.026, 0.017, and 0.061, respectively. The averages of accuracy, recall, and F_1-score in the second task improved by 0.119, 0.021, and 0.028, respectively. One of the enhanced clinicians also surpassed the KNN+LR CHDmap.

It is important to note that the evaluation is performed with population-optimized parameters, whereas in practice, clinicians can adjust the relevant parameters such as *k* or similarity threshold for each case in a personalized manner, which theoretically leads to better results. The use of the obtained similar patient population to construct modern deep learning models for prediction can further improve the performance of each prediction task. Especially important is that the experience and cognitive ability of the clinical expert combined with CHDmap can further enhance the accuracy of the prediction.

Discussion

Principal Findings

Medicine remains both an art and a science, which are congruent to the extent that the individual patient resembles the average subject in randomized controlled trials. Although the evidence-based medicine approach proposes personalized care, it still fails to address the physician's most important question—"How to treat the unique patient in front of me?"—in many real clinical scenarios where the complexity of the situation makes none of the available evidence applicable [45]. The proposal of MBE represents a fundamental change in clinical decision-making [5,6]. Although how to construct an MBE clinical decision support tool still faces many challenges, the CHDmap seems to be a very promising first step in realizing what has been coined MBE.

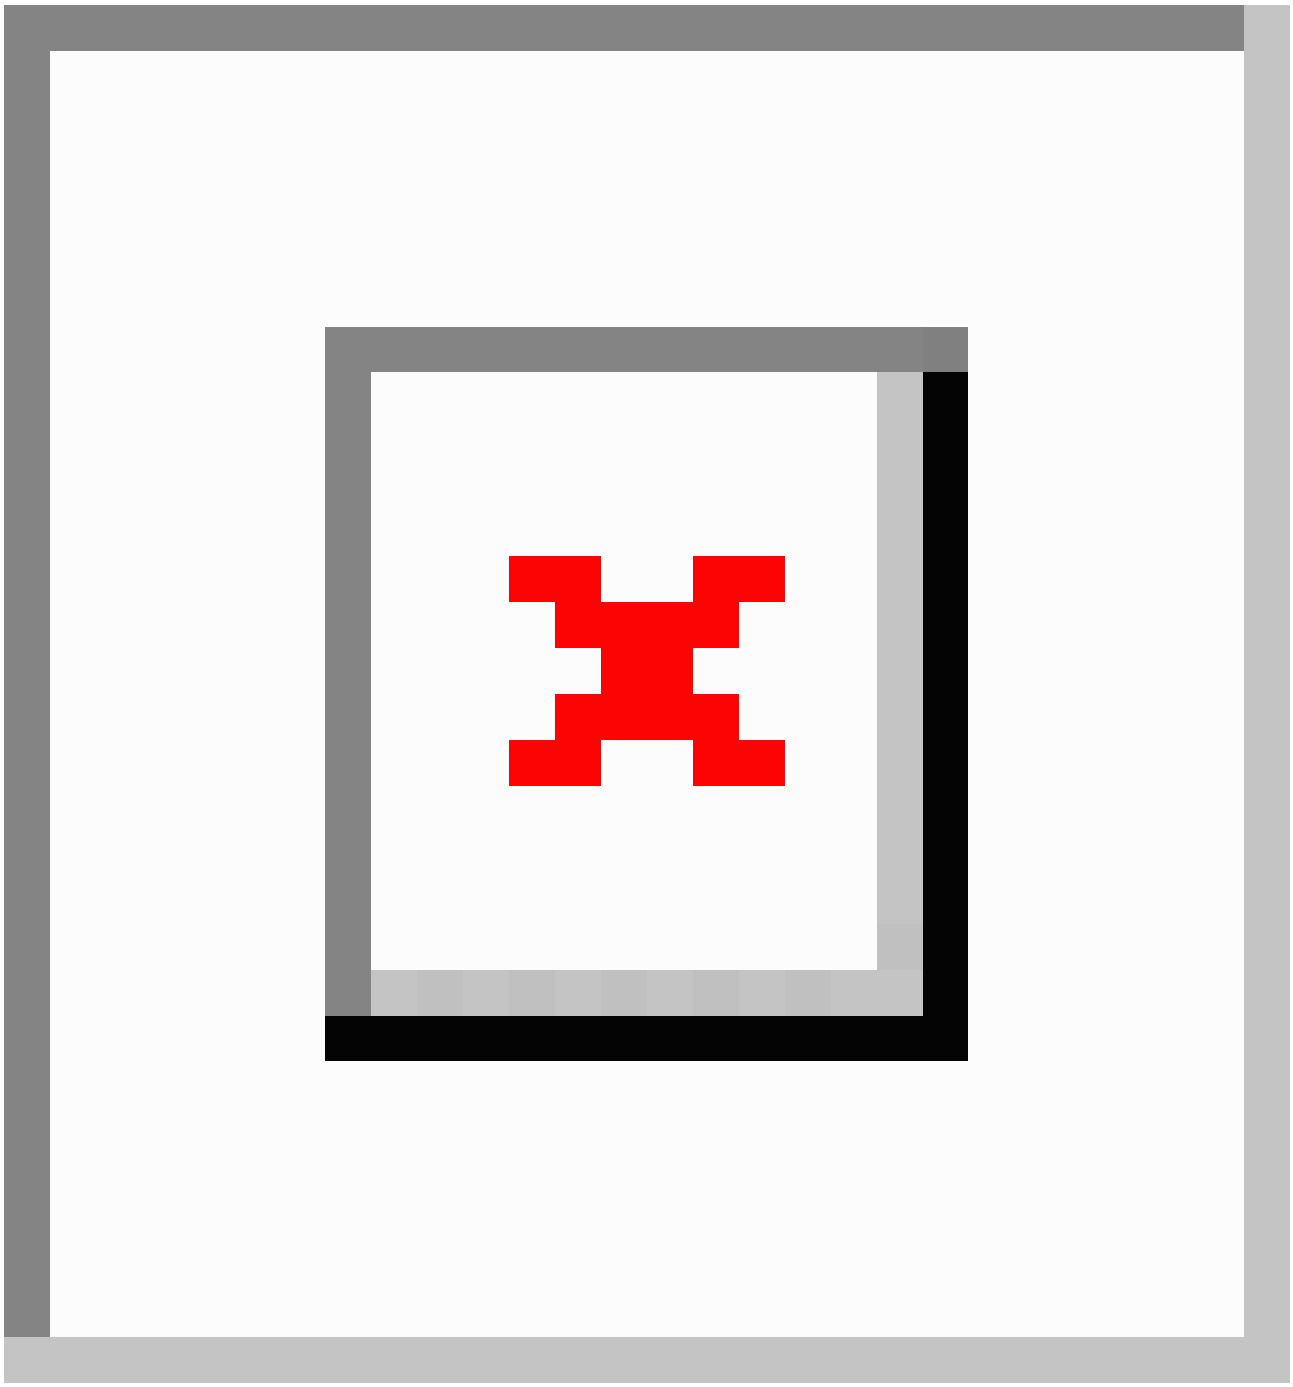
AI is poised to reshape health care. Many AI applications, especially modern deep learning models, have been developed in recent years to improve clinical prediction abilities. In addition to supervised and unsupervised machine learning, PSNs, another form of data-driven AI, have shown many unique properties in the clinical field, especially in complex clinical settings such as surgery for CHD. Moreover, their potential to construct a "library of clinical experience" will gradually be recognized, discovered, and used in the context of the continuous accumulation of medical big data.

In many other popular AI paradigms, such as supervised or unsupervised machine learning, models are usually trained toward a specific task, and thus, the models are only capable of performing that single task. This, coupled with the black-box nature of many machine learning models, especially deep learning models, makes it difficult to widely apply these techniques in practice. In contrast, patient similarity analysis exhibits many natural advantages. First, PSNs usually do not serve a single task; all characteristics exhibited by the patient similarity group, such as disease risk, various prognostic outcomes, and cost of care, can be used as MBE for decision support. Second, instead of a model that simply gives black-box predictions, CHDmap allows users to see how the patient similarity group is segmented and bounded across the patient population and then adjust the size of the patient similarity group or set custom quantitative thresholds based on their knowledge and experience. On CHDmap, the results after parameter adjustments during user manipulation are reflected in the visualized map in real time, and the statistical characteristics of multiple predictors that distinguish the current patient's similar group from other patients are also highlighted by the color of the title of the outcome view. The process of continuously adjusting and optimizing parameters through visualized feedback combines the computational advantages of computers and the advanced cognitive abilities of the human brain and truly puts the clinician, who is responsible for the decision, in control of the decision-making. Third, many machine learning models tend to require that the test and training data have consistent statistical distribution characteristics, but as shown in this evaluation, similarity analyses are still very compatible with test data with different characteristics. Finally, this PSN framework does not exclude any type of machine learning models, and all models constructed based on similar patient populations are expected to be more adaptable to individualized decision-making needs than models trained on heterogeneous populations.

Because the goal of patient similarity analysis is to be able to mimic clinical analogy reasoning, the major challenge is constructing computational patient similarity measurements that are consistent with sophisticated clinical reasoning. This is especially true when faced with complex scenarios containing a large number of dynamic features with different dimensions. Some deep learning models have been introduced to address this challenge [46-49], but they do not exhibit the interpretability and tractability of PSNs. Another way to address this challenge is to open up the computational process to clinicians, allowing them to determine and adjust the weights of different dimensions and thresholds for the similarity group themselves, thus better simulating their clinical reasoning process, as shown in Figure 5. We believe that clinical users will be able to learn how to better optimize these parameters as they continue to gain experience and understanding of this "large history data set" in the process of using CHDmap. Using a data-driven approach on how to customize the parameters of PSNs to be able to self-optimize and adapt to different tasks is also a good research direction for the future. In this study, CHDmap serves as a personalized decision aid for clinicians, using the computer's power in data storage and processing while giving clinicians more control over the decision-making process. We believe

CHDmap can perform better with the full involvement of clinicians.

Figure 5. Collaborative decision-making based on the congenital heart disease patient similarity network (PSN). The right half shows the storage and computational capacity of the PSN for a large number of cases; the left half shows the role of the clinical user who, by receiving a variety of feedback and his or her own experience, can autonomously adjust the parameters of the similarity group and reconstruct the similarity network so that the strengths of both can be used to make collaborative decisions. ASD: atrial septal defect; PDA: patent ductus arteriosus; PFO: patent foramen ovale; VSD: ventricular septal defect.



CHDmap can be used in several scenarios: for the intensivists in cardiac ICUs, CHDmap can be used to predict postoperative complications after cardiac surgery, as evaluated in this paper; for surgeons, CHDmap can also be used to assess the prognosis of surgical procedures; and for departmental managers, CHDmap can be used to assess the lengths of stay and costs. By far, CHDmap is still in the early stages of a research project. Transforming this tool into routine care is dependent on the availability of funding and the willingness of users to change their existing working patterns. The publication of this paper will also facilitate the advancement of our subsequent translational work.

It is important to note that associations between treatments and outcomes obtained by observation in similar patient populations may not be causal. The real causal effects often rely on a matching process to control for the bias introduced by the treatment itself in the selection of patients [50]. An initial demo feature is available on CHDmap to estimate treatment outcome

effects based on matched patient groups. CHDmap can match 1 or *k* patients for each patient receiving the treatment using a PSN and then allow for a more visual and unbiased assessment of treatment outcomes by showing the difference in prognosis between these 2 groups of patients. It is important to note that this causal assessment assumes that there are no other factors outside the variables covered by the patient's similarity analysis that may influence treatment choice or prognosis. Thus, the reliability of this real world–generated evidence usually relies on clinical experts to judge it as well. In future versions, we hope to incorporate more modern frameworks for causal inference (such as DoWhy [51]) to automatically quantitatively assess causal effects as well as their reliability.

There are several limitations to this study. First, limited clinical features were used to measure the similarity of patients with CHD. In addition to the information presented by the echocardiography, there is a wealth of other clinical information that can be used to assess the patient's status. Second, the use of NLP to automatically extract measurement information can also be subject to errors or mismatches, and although manual quality control is carried out, it is still not possible to ensure that all of the measurements are 100% accurate. Third, just as clinicians gain clinical experience by continuously treating different patients, PSNs need to expand their ability to dynamically accumulate cases. A PSN with a web-based automatic update mechanism will be the next key research step. Fourth, data from only a single center were used to evaluate this tool, and the introduction of data from multiple centers during PSN construction may pose unknown risks that require attention in future studies. Finally, different clinicians may have different decision-making philosophies, and different weights can be assigned to different indicators for different tasks. CHDmap offers only a limited number of customizations that may be difficult to adapt to all scenarios. A way to attribute weights to each of the indicators and dimensions by AI for specific tasks may potentially improve the performance of CHDmap in the future.

Conclusions

A clinician-operable PSN for CHD was proposed and developed to help clinicians make decisions based on thousands of previous surgery cases. Without individual optimization, CHDmap can obtain competitive performance compared to clinical experts. Statistical analysis of data based on patient similarity groups is intuitive and clear to clinicians, whereas the operable, visual user interface puts clinicians in real control of decision-making. Clinicians supported by CHDmap can make better decisions than both pure experience-based decisions and AI model output results. Such a PSN-based framework can become a routine method of CHD case management and use. The MBE can be embraced in clinical practice, and its full potential can be realized.

Abstract

Background: The early prediction of antibiotic resistance in patients with a urinary tract infection (UTI) is important to guide appropriate antibiotic therapy selection.

Objective: In this study, we aimed to predict antibiotic resistance in patients with a UTI. Additionally, we aimed to interpret the machine learning models we developed.

Methods: The electronic medical records of patients who were admitted to Yongin Severance Hospital, South Korea were used. A total of 71 features extracted from patients' admission, diagnosis, prescription, and microbiology records were used for classification. UTI pathogens were classified as either sensitive or resistant to cephalosporin, piperacillin-tazobactam (TZP), carbapenem, trimethoprim-sulfamethoxazole (TMP-SMX), and fluoroquinolone. To analyze how each variable contributed to the machine learning model's predictions of antibiotic resistance, we used the Shapley Additive Explanations method. Finally, a prototype machine learning–based clinical decision support system was proposed to provide clinicians the resistance probabilities for each antibiotic.

Results: The data set included 3535, 737, 708, 1582, and 1365 samples for cephalosporin, TZP, TMP-SMX, fluoroquinolone, and carbapenem resistance prediction models, respectively. The area under the receiver operating characteristic curve values of the random forest models were 0.777 (95% CI 0.775-0.779), 0.864 (95% CI 0.862-0.867), 0.877 (95% CI 0.874-0.880), 0.881 (95% CI 0.879-0.882), and 0.884 (95% CI 0.884-0.885) in the training set and 0.638 (95% CI 0.635-0.642), 0.630 (95% CI 0.626-0.634), 0.665 (95% CI 0.659-0.671), 0.670 (95% CI 0.666-0.673), and 0.721 (95% CI 0.718-0.724) in the test set for predicting resistance to cephalosporin, TZP, carbapenem, TMP-SMX, and fluoroquinolone, respectively. The number of previous visits, first culture after admission, chronic lower respiratory diseases, administration of drugs before infection, and exposure time to these drugs were found to be important variables for predicting antibiotic resistance.

Conclusions: The study results demonstrated the potential of machine learning to predict antibiotic resistance in patients with a UTI. Machine learning can assist clinicians in making decisions regarding the selection of appropriate antibiotic therapy in patients with a UTI.

KEYWORDS

antibiotic resistance; machine learning; urinary tract infections; UTI; decision support

Introduction

Urinary tract infection (UTI) refers to an infection that occurs in any part of the urinary system, including the kidneys, ureters, urinary bladder, urethra, and other auxiliary structures [1,2]. Globally, UTIs are the most prevalent type of infectious disease, with around 150-250 million cases occurring each year [3]. Considerable morbidity and mortality result from these infections [4]. Typically, the most effective treatment for UTIs is the administration of antibiotics [3]. However, inappropriate use of antibiotics can permanently affect the normal microbiota of the urinary tract system and lead to antibiotic resistance [5].

The antibiotic susceptibility test is commonly used to identify antibiotic resistance, but it takes 24-48 hours to obtain test results [6,7]. However, in the clinical workflow, clinicians need to identify antibiotic resistance quickly to provide effective treatment for patients with UTIs. For this reason, early prediction of antibiotic resistance in patients with UTIs is important to guide the selection of appropriate antibiotic therapy. Machine learning can be used to develop prediction models and clinical decision support systems (CDSSs) to identify antibiotic resistance and support the selection of appropriate antibiotic therapy for patients with a UTI.

Several efforts have been made to predict antibiotic resistance in patients with UTIs using data from patients' electronic medical records (EMRs), including demographics, prescriptions, comorbidities, procedures, and laboratory tests. These investigations have yielded promising results. Some of these studies were limited to specific patient groups, including patients with uncomplicated UTIs [8] and patients treated in the emergency department [9]. In other studies, researchers worked with heterogeneous data that were not limited to a specific patient group [10-12]. However, prior studies that analyzed heterogeneous data did not address the interpretation of machine learning models. The black-box nature of machine learning is a limiting factor not only in its use for antibiotic resistance prediction but also in its wider clinical use [13,14]. Thus, interpreting the results obtained by the machine learning model is crucial in increasing users' trust in the machine learning model [15,16]. Furthermore, these studies did not address the development of the CDSS with the prediction models they built.

In this study, we aimed to predict antibiotic resistance in patients with a UTI. Heterogeneous data that were not limited to a specific patient group were used. UTI pathogens were classified as either sensitive or resistant to 5 commonly used antibiotics in UTI treatment: cephalosporin, piperacillin-tazobactam (TZP), carbapenem, trimethoprim-sulfamethoxazole (TMP-SMX), and fluoroquinolone. In addition, our objective was to understand and explain the inner workings of the machine learning models we developed. Eventually, a prototype CDSS was developed to provide clinicians the resistance probabilities for each antibiotic.

Methods

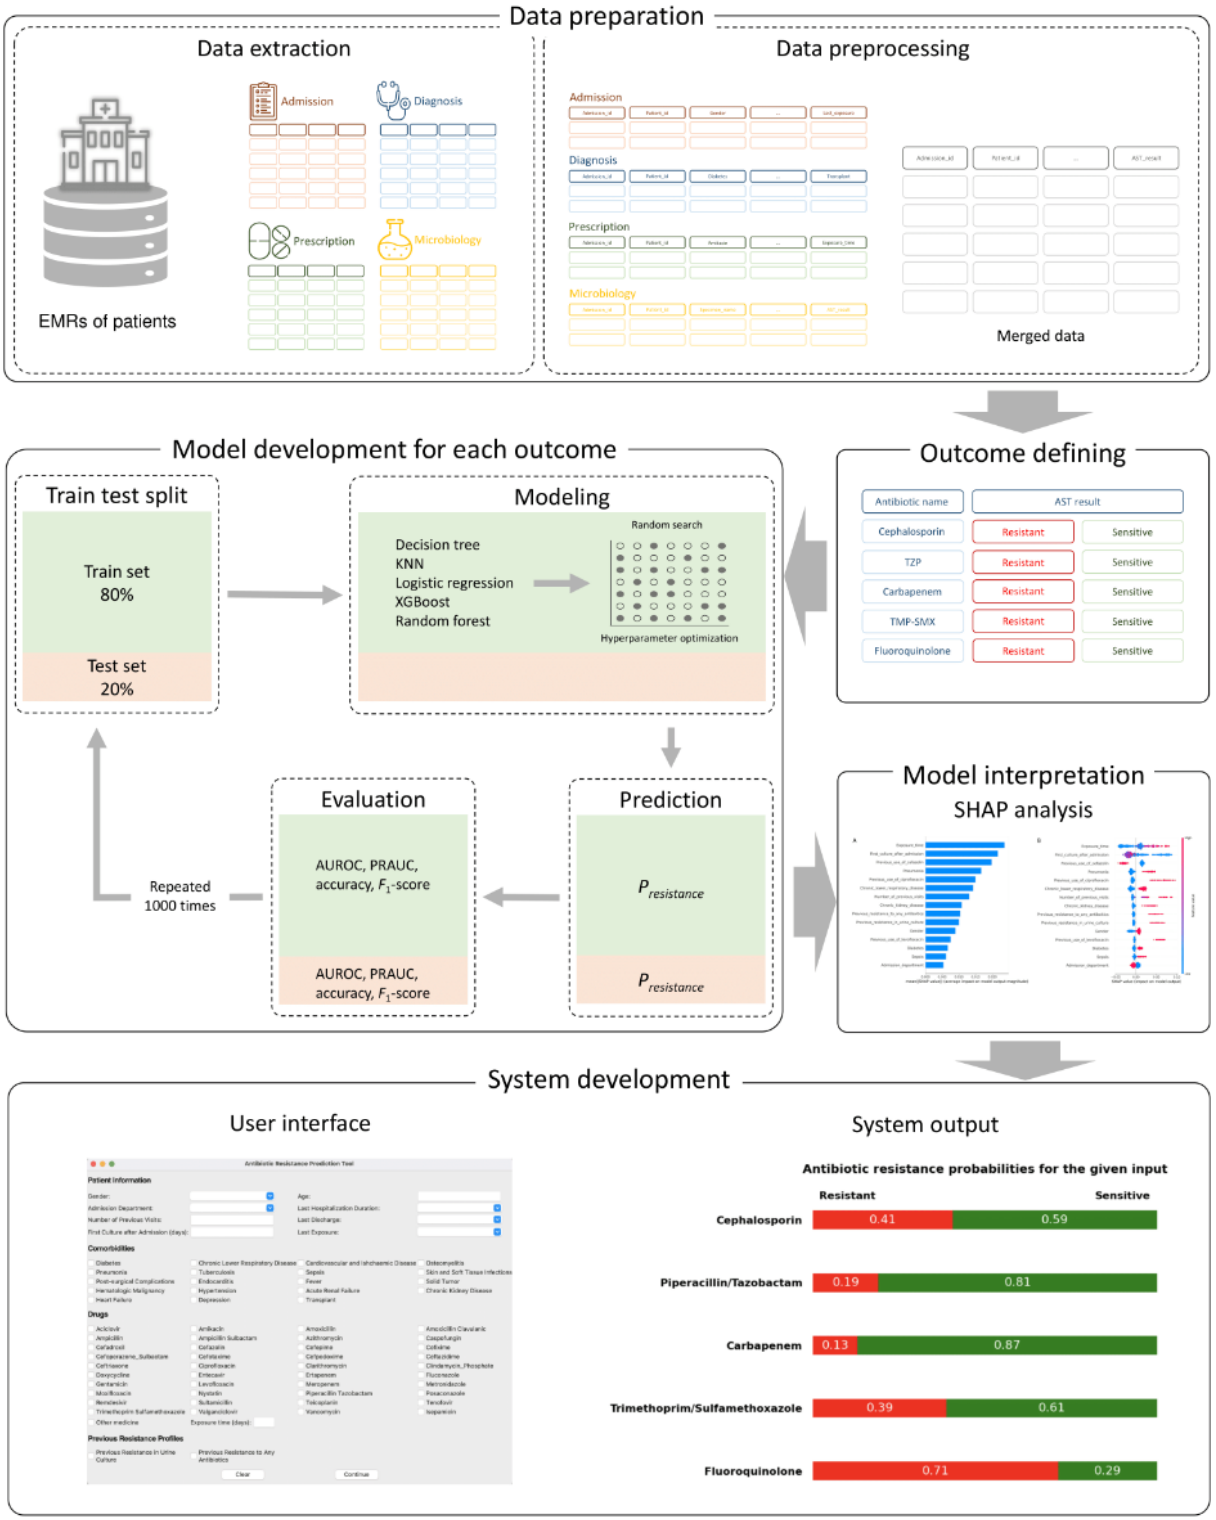
Ethical Considerations

Ethics approval for the study was obtained from the institutional review board of Yonsei University Severance Hospital on June 6, 2022 (approval 9-2023-0095). The informed consent was not required due to the retrospective nature of the study.

Data Set Description and Study Design

In this study, we used the EMRs of patients who were admitted to Yongin Severance Hospital, South Korea, between October 2012 and October 2022. To build the prediction models, admission, diagnosis, prescription, and microbiology records were extracted. The summary of the research process is presented in Figure 1.

Figure 1. Summary of the research process. AST: antibiotic susceptibility test; AUROC: area under the receiver operating characteristic curve; EMR: electronic medical record; KNN: k-nearest neighbor; PRAUC: precision-recall area under the curve; SHAP: Shapley Additive Explanations; TMP-SMX: trimethoprim-sulfamethoxazole; TZP: piperacillin-tazobactam; XGBoost: Extreme Gradient Boosting.



Data Preprocessing

The microbiology table contained 143,114 urine cultures collected from 6011 patients during 7719 admissions. Since positive samples typically indicate the presence of bacteriuria, and urine culture samples were typically collected from patients with UTI symptoms, we considered these to be indicative of a UTI [10]. The resistance profiles were evaluated based on the Clinical and Laboratory Standards Institute guidelines, where intermediate-level resistance was considered sensitive. To assess the resistance of UTI pathogens to antibiotic classes, antibiotics were grouped as cephalosporin, TZP, carbapenem, TMP-SMX, and fluoroquinolone. The antibiotics included in each antibiotic class are presented in Multimedia Appendix 1. The patients' demographic information was extracted from the admission

table, their comorbidities were extracted from the diagnosis table, and their drug use information was extracted from the prescription table. For all input variables, the time of the first culture test was considered as the end point, and only data collected before the first culture test were used. After preprocessing and variable extraction from the raw data, the tables were combined using the admission number as the primary key. Missing data were excluded from the study. Patients aged 19 years and older and 100 years and younger at admission were included in the study, and numerical variables were standardized. A total of 71 features were used to classify UTI pathogens as either sensitive or resistant to each antibiotic. The predictors for the prediction models were selected by considering related works and using clinical judgment. Additionally, the threshold values for binarization were selected according to the literature [17] and the expert assessment of a specialist in infectious diseases. Detailed information about the predictors can be found in Multimedia Appendix 2.

Machine Learning Model Development

We used a repeated train test split approach for modeling. The data sets were split into training and test sets using an 80:20 ratio, and the training sets were used for the development of the machine learning models. When splitting the data into training and test sets, data points from the same patient and admission were exclusively included in either the training or test data set to prevent potential data leakage and ensure the models were evaluated on previously unseen data. At each iteration, we created different training and test data sets by changing the random seed. Decision tree, k-nearest neighbor, logistic regression, Extreme Gradient Boosting, and random forest were used for modeling. The hyperparameters of the machine learning models were optimized by using the random search hyperparameter optimization method with 10-fold cross-validation on the training data set. We stored the performance of the prediction models at each iteration, and the mean of performance metrics was calculated. The procedure of splitting the data, optimizing hyperparameters, modeling, and evaluation was iteratively repeated 1000 times to classify UTI pathogens as either sensitive or resistant to cephalosporin, TZP, carbapenem, TMP-SMX, and fluoroquinolone. The machine learning models were built using Python (version 3.10.4; Python Software Foundation).

Machine Learning Model Interpretation

To analyze the contribution of the variables to the machine learning models in predicting antibiotic resistance, we used the Shapley Additive Explanations (SHAP) method. The SHAP values of the random forest models that showed superior performance compared to other machine learning methods were evaluated. The random forest model with the highest area under the receiver operating characteristic curve (AUROC) on the test set across all iterations for each antibiotic was used for SHAP analysis. Python (version 3.10.4; Python Software Foundation) was used for SHAP analysis.

CDSS Development

To develop the CDSS prototype, the random forest model with the highest AUROC on the test set across all iterations for each antibiotic was used. The CDSS prototype was developed using the *tkinter* package in Python (version 3.10.4; Python Software Foundation).

Evaluation

The performance of the machine learning model for predicting antibiotic resistance was evaluated on the training and test sets using the AUROC with 95% CIs, precision-recall area under the curve (PRAUC), accuracy, and F_1-score performance metrics. Herein, the AUROC value was considered the main evaluation metric. The definitions of the performance metrics we used are provided below.

- AUROC: The AUROC is a widely used metric that represents a classifier's ability to discriminate between positive instances and negative instances [18].
- PRAUC: PRAUC refers to the area under the precision-recall curve that plots precision as a function of recall for all the possible decision thresholds [19].
- Accuracy: Accuracy is the ratio of correctly classified samples to all samples.

- F_1-score: F_1-score is the harmonic mean of precision and recall metrics.

Python (version 3.10.4; Python Software Foundation) was used to evaluate the prediction models.

Results

Data Set Characteristics

The general characteristics of the data set used in this study are presented in Table 1. The data set included 3535, 737, 708, 1582, and 1365 samples for cephalosporin, TZP, TMP-SMX, fluoroquinolone, and carbapenem resistance prediction models, respectively. *Escherichia coli* was the most frequently isolated bacterial specimen across all antibiotics.

Table 1. General characteristics of the data set.

	Cephalosporin	TZP[a]	TMP-SMX[b]	Fluoroquinolone	Carbapenem
Samples, n	3535	737	708	1582	1365
Admissions, n	396	366	374	571	392

[a]AUROC: area under the receiver operating characteristic curve.

[b]PRAUC: precision-recall area under the curve.

[c]TZP: piperacillin-tazobactam.

[d]TMP-SMX: trimethoprim-sulfamethoxazole.

Important Features

The SHAP values of the 15 most important features in the random forest models are presented in Figure 2.

The SHAP feature importance bar plot (Figure 3A) and SHAP summary plot (Figure 3B) of the fluoroquinolone resistance prediction model are presented in Figure 3. The SHAP feature importance plot and SHAP summary plot of the other antibiotic prediction models are presented in Multimedia Appendices 7-10.

Figure 2. SHAP values of the 15 most important features in the prediction models. SHAP: Shapley Additive Explanations; TMP-SMX: trimethoprim-sulfamethoxazole; TZP: piperacillin-tazobactam.

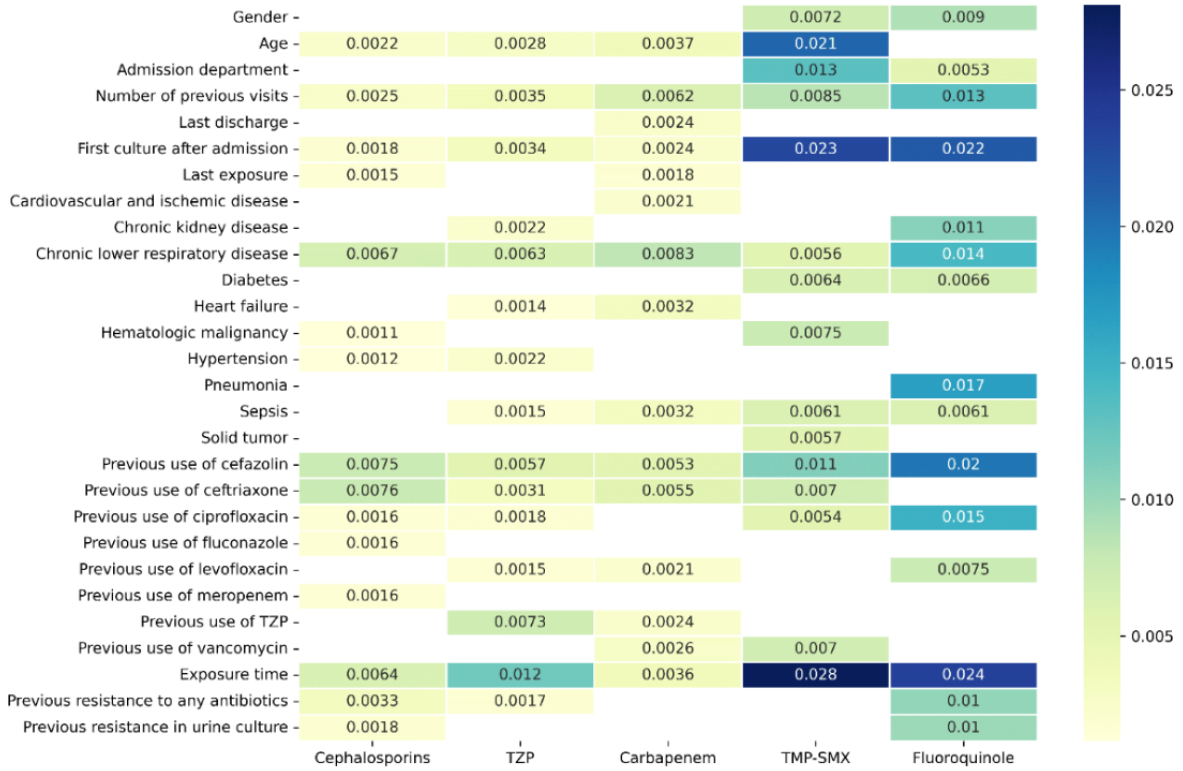

Figure 3. SHAP analysis results of fluoroquinolone resistance prediction model. (A) The feature importance bar plot. (B) The SHAP summary dot plot. SHAP: Shapley Additive Explanations.

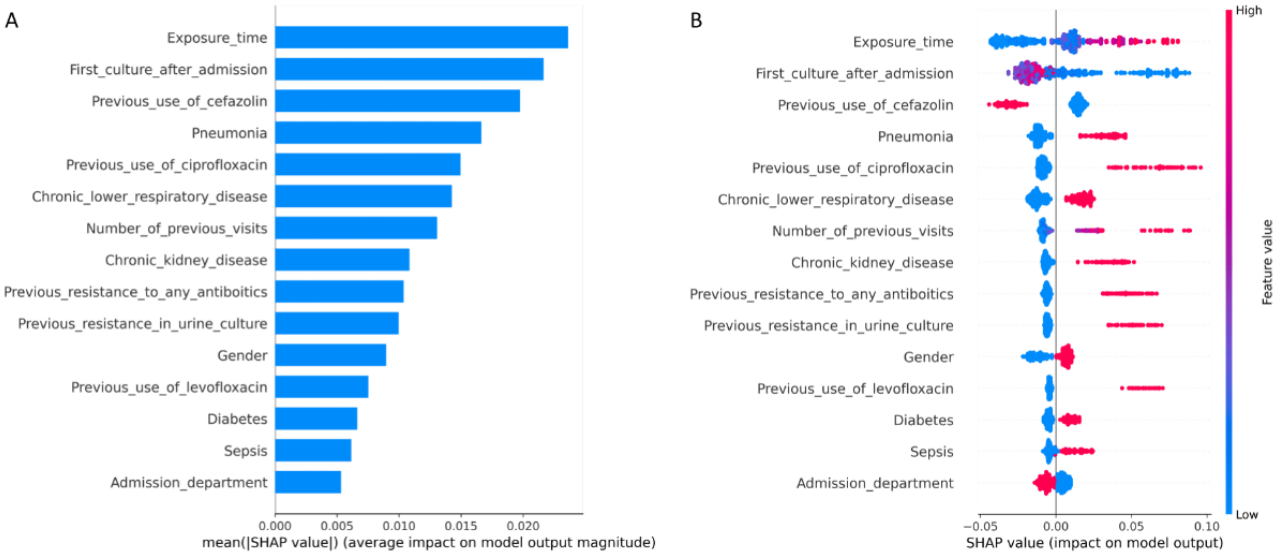

Clinical Decision Support System

The user interface of the CDSS is shown in Figure 4. The CDSS prototype obtains data from the user and produces antibiotic resistance probabilities for each antibiotic.

We presented the CDSS prototype on a scenario. In this case, a female aged 55 years was admitted to the hospital's outpatient department. The patient previously visited the hospital 3 times and was readmitted to the hospital within 30 days of her last 3-day stay. The duration between the patient's admission to the hospital and the first culture was 1 day. The patient was previously diagnosed with diabetes and chronic lower respiratory disease. Additionally, the patient had a history of cefazolin use in the last 30 days and resistance in urine culture.

The system output for the given scenario is shown in Figure 5. The system produced resistance probabilities for each antibiotic. For the given scenario, the system produced a 71% probability of fluoroquinolone resistance, a 41% probability of cephalosporin resistance, a 39% probability of TMP-SMX resistance, a 19% probability of TZP resistance, and a 13% probability of carbapenem resistance.

Figure 4. The user interface of the clinical decision support system.

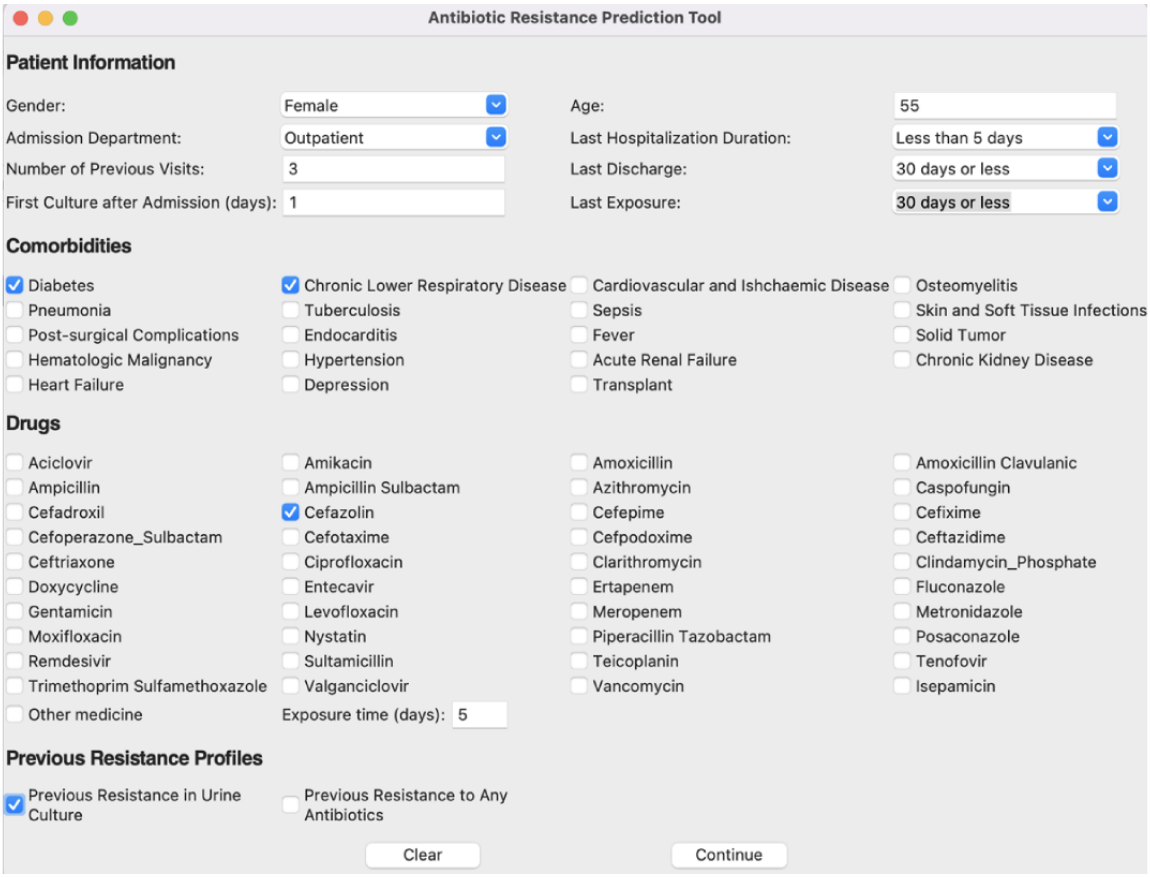

Figure 5. The screenshot of system output for the given data.

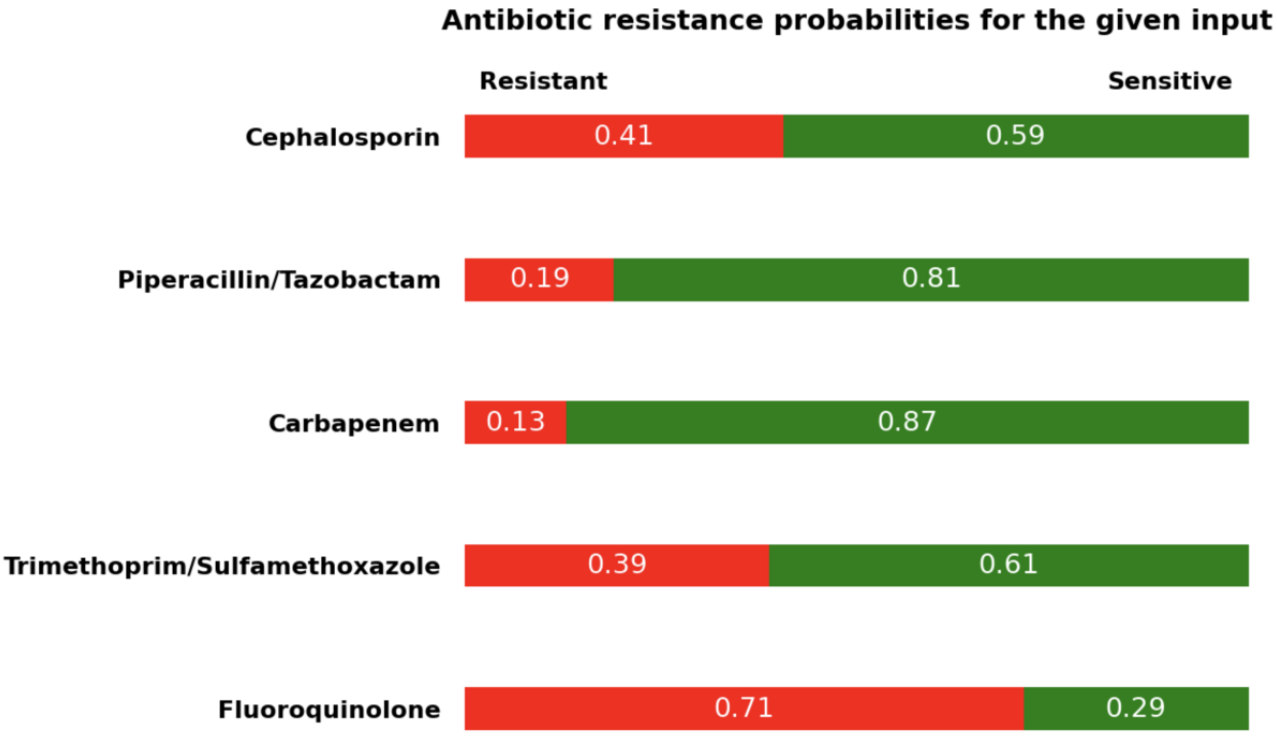

Discussion

Principal Findings

In this study, our main objective was to predict cephalosporin, TZP, carbapenem, TMP-SMX, and fluoroquinolone resistance in patients with UTI and develop a CDSS with the machine learning models we built. Moreover, we identified the most important features for predicting antibiotic resistance in patients with UTI using SHAP analysis.

Our prediction models achieved AUROCs of 0.777 (95% CI 0.775-0.779), 0.864 (95% CI 0.862-0.867), 0.877 (95% CI 0.874-0.880), 0.881 (95% CI 0.879-0.882), and 0.884 (95% CI 0.884-0.885) in the training set and 0.638 (95% CI 0.635-0.642), 0.630 (95% CI 0.626-0.634), 0.665 (95% CI 0.659-0.671), 0.670 (95% CI 0.666-0.673), and 0.721 (95% CI 0.718-0.724) in the test set for predicting resistance to cephalosporin, TZP, carbapenem, TMP-SMX, and fluoroquinolone, respectively. The fluoroquinolone resistance prediction model showed superior performance, as confirmed by its high AUROC values in both the training and test sets. On the other hand, the cephalosporin resistance prediction model showed poor performance, as confirmed by the low AUROC values in both training and test sets.

According to SHAP analysis, the contribution of the variables varied for each antibiotic; however, we found that the number of previous visits, first culture after admission, chronic lower respiratory diseases, administration of drugs before infection, and exposure time to these drugs were important predictors across all antibiotics. Factors such as the first culture after admission, exposure time, and the number of previous visits were found to affect resistance, which can be explained by the impact of health care–associated infections. Chronic lower respiratory and kidney diseases are also likely to be associated with frequent visits to health care facilities, although it is difficult to confirm the actual number of visits. However, this suggests that the characteristics of health care–seeking behavior in patients with specific underlying diseases may influence resistance [20]. Interestingly, the use of cefazolin had a negative impact on the development of resistance for all antibiotics. This is because cefazolin is one of the narrow-spectrum antibiotics used in less severe patients. Further research is needed to examine these results.

Comparison to Prior Work

Past efforts to predict antibiotic resistance in patients with UTIs have had promising results, with the lowest AUROC being 0.58 for predicting TMP-SMX resistance [12] and the highest AUROC being 0.83 for predicting ciprofloxacin resistance [9]. In comparison, our prediction models demonstrated comparable performance to these prior works. Some previous studies on predicting antibiotic resistance in patients with UTIs were limited to specific patient groups, including patients with uncomplicated UTIs [8] and patients treated in the emergency department [9]. We analyzed heterogeneous data that were not limited to a specific patient group or bacteria. This approach provides a more comprehensive insight into the prediction of antibiotic resistance in patients with UTIs. Similarly, Lewin-Epstein et al [21] analyzed heterogeneous data and were able to achieve AUROC values ranging from 0.73 to 0.79 for the prediction of ceftazidime, gentamicin, imipenem, ofloxacin, and TMP-SMX resistance. Their data contained multiple culture tests, which provided a more comprehensive approach to predicting antibiotic resistance. Although urine cultures can be used to infer colonized resistance in patients, further research is needed to extend culture results beyond urine.

Limitations

While this study provides insights into predicting antibiotic resistance in patients with UTIs, it has some limitations. First, this study is the lack of multidrug resistance classification. The data set we used in this study did not contain a sufficient amount of multidrug resistance outcomes to build a classification model for the prediction of multidrug resistance. Furthermore, our prediction models were developed using prescription records within the hospital setting. However, patients may have used antibiotics outside of the hospital setting during visits to other hospitals. The lack of information about past drug use could have negatively impacted the performance of our prediction models. To overcome this limitation, we intend to conduct further studies using data from the National Health Insurance Service of South Korea, which contain all past drug use information of the patients. Thus, we will have a more comprehensive data set. By using this approach, we may be able to develop more accurate machine learning models to predict antibiotic resistance and improve our ability to guide appropriate antibiotic therapy selection. Additionally, further development is required to address the limitations of prototype CDSS, including the integration of real-time patient data and validation in larger patient cohorts. Moreover, the prototype CDSS only gives the resistance risk probability to the user. However, a more comprehensive system that can provide decision support on the selection of appropriate therapy, dosage, and duration of treatment can be developed in further studies. Such a system has the potential to reduce the duration of treatment, number of antibiotics used, cost, mortality, and morbidity [22,23].

Conclusions

In conclusion, our study results demonstrated that prediction models to predict antibiotic resistance in patients with UTIs can be constructed using routinely collected EMR data alone, without requiring additional laboratory tests or specialized tests. Machine learning techniques can be used to develop systems that can guide clinicians in selecting appropriate antibiotic therapy. This has the potential to prevent the risk of inappropriate antibiotic administration, thereby reducing patients' risk of developing antibiotic resistance.

Acknowledgments

This study was supported by the National Institute for International Education of the Government of the Republic of Korea, The Scientific and Technological Research Council of Turkey (grant 2214-A), and a faculty research grant of Yonsei University College of Medicine (6-2022-0118).

Authors' Contributions

Nİ, AY, SYP, and DY contributed to the conceptualization of the study and to the funding acquisition. JK, JAR, and SYP were responsible for data curation. Nİ performed the formal analysis of the collected data and wrote the paper. Nİ, SYP, and DY contributed to the development of the study methodology. SYP and DY reviewed and edited the paper.

Abstract

Background: Predicting the bed occupancy rate (BOR) is essential for efficient hospital resource management, long-term budget planning, and patient care planning. Although macro-level BOR prediction for the entire hospital is crucial, predicting occupancy at a detailed level, such as specific wards and rooms, is more practical and useful for hospital scheduling.

Objective: The aim of this study was to develop a web-based support tool that allows hospital administrators to grasp the BOR for each ward and room according to different time periods.

Methods: We trained time-series models based on long short-term memory (LSTM) using individual bed data aggregated hourly each day to predict the BOR for each ward and room in the hospital. Ward training involved 2 models with 7- and 30-day time windows, and room training involved models with 3- and 7-day time windows for shorter-term planning. To further improve prediction performance, we added 2 models trained by concatenating dynamic data with static data representing room-specific details.

Results: We confirmed the results of a total of 12 models using bidirectional long short-term memory (Bi-LSTM) and LSTM, and the model based on Bi-LSTM showed better performance. The ward-level prediction model had a mean absolute error (MAE) of 0.067, mean square error (MSE) of 0.009, root mean square error (RMSE) of 0.094, and R^2 score of 0.544. Among the room-level prediction models, the model that combined static data exhibited superior performance, with a MAE of 0.129, MSE of 0.050, RMSE of 0.227, and R^2 score of 0.600. Model results can be displayed on an electronic dashboard for easy access via the web.

Conclusions: We have proposed predictive BOR models for individual wards and rooms that demonstrate high performance. The results can be visualized through a web-based dashboard, aiding hospital administrators in bed operation planning. This contributes to resource optimization and the reduction of hospital resource use.

Introduction

Background

The global health care market continues to grow, but the burden of health care costs on governments and individuals is reaching its limits. Consequently, there is increasing interest in the efficient use of limited resources in health care systems, and hospitals must develop approaches to maximize medical effectiveness within budgetary constraints [1,2]. One approach to this is optimizing the use of medical resources. Medical resources can be broadly categorized into 3 categories: human resources, physical capital, and consumables. The appropriate and optimized use of these resources is critical for improving health care quality and providing care to a larger number of patients [3,4].

Among the 3 medical resources, hospital beds are considered one of the physical capitals provided by hospitals to patients. These beds are allocated for various purposes, such as rest, hospitalization, postsurgical recovery, etc. They constitute one of the factors that can directly influence the patient's internal satisfaction within the hospital. However, owing to limited space, hospitals often have a restricted number of beds. Moreover, the number and functionality of beds are often fixed owing to budgetary or environmental constraints, making it difficult to make changes. Nonetheless, if hospital administrators can evaluate bed occupancy rates (BORs) according to different time periods, they can predict the need for health care professionals and resources. On the basis of this information, hospitals can plan resources efficiently, reduce operational costs, and achieve economic objectives [5]. In addition, excessive BORs can exert a negative effect on the health of staff members and increase the possibility of exposure to infection risks. Hence, emphasizing only maintaining a high BOR may not necessarily lead to favorable outcomes for the hospital [6,7]. Considering these reasons, BOR prediction plays a vital role in hospitals and is recognized as a broadly understood necessity for resource optimization in the competitive medical field.

In the medical field, optimizing resources is crucial in the face of limited bed capacity and intense competition. Therefore, bed planning is a vital consideration aimed at minimizing hospital costs [8]. To achieve this, hospitals need to plan staffing and vacations weeks or months in advance [9]. The use of machine learning (ML) technology for BOR prediction is necessary to address fluctuations in patient numbers due to seasonal variations or infectious diseases, ensuring continuous hospital operations. In the Netherlands, hospitals have already implemented ML-based BOR prediction [10], and Johns Hopkins Hospital uses various metrics to effectively manage bed capacity for optimization. Predicting BORs based on quantitative data contributes to validating the clinical quality and cost-effectiveness of treatments. This, in turn, enhances overall accountability throughout the wards and contributes to improving hospital efficiency [11].

Prior Work

Hospital BOR prediction has been investigated using various approaches recently. From studies predicting bed demand using mathematical statistics or regression equation models based on given data [12-15], the focus has shifted toward modeling approaches using time-series analysis. This approach observes recorded data over time to predict future values.

A previous study has taken an innovative approach using time-series analysis alongside the commonly used regression analysis for bed demand prediction, and the study demonstrated that using time-series prediction for bed occupancy yielded higher performance results than using a simple trend fitting approach [16]. Another study used the autoregressive integrated moving average (ARIMA) model for univariate data and a time-series model for multivariate data to predict BORs [17]. With the advancement of deep learning (DL) models that possess strong long-term memory capabilities, such as recurrent neural network (RNN) and long short-term memory (LSTM), there has been an increase in studies applying these models to time-series data for prediction purposes. For instance, in the study by Kutafina et al [9], hospital BORs were predicted based on dates and public holiday data from government agencies and schools, without involving the personal information of patients. The study used a nonlinear autoregressive exogenous model to predict a short-term period of 60 days, with an aim to contribute to the planning of hospital staff. The model demonstrated good performance, with an average mean absolute percentage error of 6.24%. In emergency situations, such as the recent global COVID-19 pandemic, the sudden influx of infected patients can disrupt the hospitalization plans for patients with pre-existing conditions [18]. Studies have been conducted using DL architectures to design models for predicting the BOR of patients with COVID-19 on a country-by-country basis. Some studies incorporated additional inputs, such as vaccination rate and median age, to train the models [19]. Studies have also been conducted to focus on the short-term prediction of BORs during the COVID-19 period [20,21]. Prior studies are summarized in Table 1.

Although previous research has contributed to BOR prediction and operational planning at the hospital level, more detailed and systematic predictions are necessary for practical application in real-world operations. To address this issue, studies have developed their own computer simulation hospital systems to not only predict bed occupancy but also execute scheduling for admissions and surgeries to enhance resource utilization [22-24]. Nevertheless, existing studies have the limitation of focusing solely on the overall BOR of the hospital. As an advancement to these studies, we aim to propose a strategy for predicting the BOR at the level of each ward and room using various variables

in a time-series manner. Interestingly, to our knowledge, this is the first study to apply DL to predict ward- and room-specific occupancy rates using time-series analysis.

Table 1. Summary of prior studies.

Study	Year	Data set	Method	Prediction target
Mackay and Lee [12]	2007	Deidentified data, the date and time of patient admission and discharge between 1998 and 2000	Comparison of 2 compartment models through cross-validation	Entire hospital bed occupancy (annual average)
Littig and Isken [13]	2007	Historical and real-time data warehouse and hospital information systems (emergency department, financial, surgical scheduling, and inpatient tracking systems)	Computerized model of MLR[a] and LR[b]	Entire hospital short-term occupancy (24 h or 72 h) based on LOS[c]
Kumar and Mo [14]	2010	Bed management between June 1, 2006, and June 1, 2007; Information: (1) In each class based on length of stay and admission data; (2) Historical previous year's same week admission data; (3) Relationship between identified variables to aid bed managers	The 3 methods are: (1) Poisson bed occupancy model; (2) Simulation model; and (3) Regression model	The 3 prediction targets are: (1) Estimation of bed occupancy and optimal bed requirements in each class; (2) Bed occupancy levels for every class for the following week; and (3) Weekly average number of occupied beds
Seematter-Bagnoud et al [15]	2015	Inpatient stay data in 2010 (acute somatic care inpatients and outpatients)	Three models of hypothesis-based statistical forecasting of future trends	The 3 targets are: (1) Number of hospital stays; (2) Hospital inpatient days; and (3) Beds for medical stay
Farmer and Emami [16]	1990	Inpatient stay data for general surgery in the age group of 15-44 years between 1969 and 1982	The 2 methods are: (1) Forecasting from a structural model and (2) The time-series or Box-Jenkins method	Entire hospital short-term daily bed requirements
Kim et al [17]	2014	Data warehouse between January 2009 and June 2012	The 2 methods are: (1) The ARIMA[d] model for univariate data and (2) The time-series model for multivariate data	Entire hospital bed occupancy (1 day and 1 week)
Kutafina et al [9]	2019	Inpatient stay data between October 14, 2002, and December 31, 2015 (patient identifier, time of admission, discharge, and name of the clinic the patient was admitted to; no personal information on the patients or staff was provided)	NARX[e] model, a type of RNN[f]	Entire hospital mid-term bed occupancy (60 days, bed pool in units of 30 beds)
Bouhamed et al [19]	2022	COVID-19 hospital occupancy data in 15 countries between December 2021 and early January 2022	The 3 models are: LSTM[g], GRU[h], and SRNN[i]. Incorporate vaccination percentage and median age of the population to improve performance	Entire hospital bed occupancy
Bekker et al [20]	2021	Historical data publicly available until mid-October 2020	The 2 methods are: (1) Using linear programming to predict admissions and (2) Fitting the remaining LOS and using results from the queuing theory to predict occupancy	The 2 targets are: (1) Patient admission and (2) Entire hospital short-term bed occupancy
Farcomeni et al [21]	2021	Patients admitted to the intensive care unit between January and June 2020	The 2 methods are: (1) Generalized linear mixed regression model and (2) Area-specific nonstationary integer autoregressive methodology	Entire hospital short-term intensive care bed occupancy

Goal of This Study

The aim of this study was to predict the BORs of hospital wards and rooms using time-series data from individual beds. Although overall bed occupancy prediction is useful for macro-level resource management in hospitals, resource allocation based on the prediction of occupancy rates for each ward and room is required for specific hospital scheduling and practicality. Through this approach, we aim to contribute to the efficient operational cost optimization of the hospital and ensure the availability of resources required for patient care.

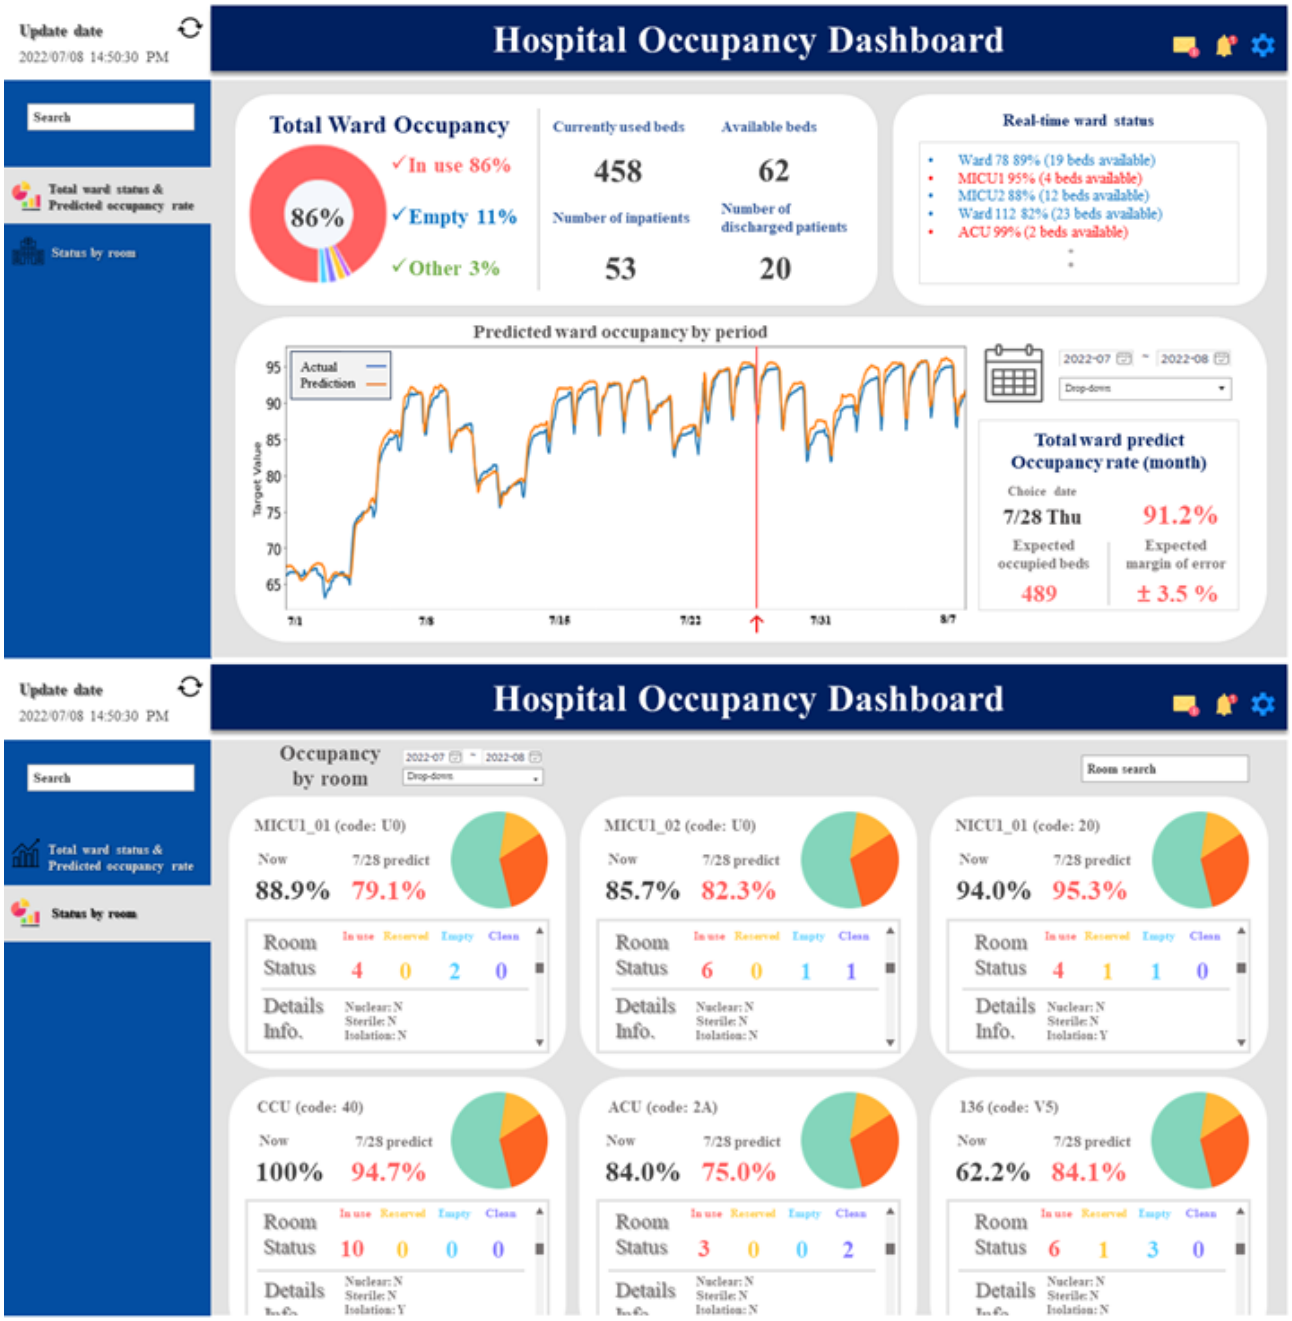
We have developed time-series prediction models based on deep neural network (DNN), among which 1 model combines data representing room-specific features (static data) with dynamic data to enhance the prediction performance for room bed occupancy rates (RBORs). Based on bidirectional long short-term memory (Bi-LSTM), the RBOR prediction model demonstrates a lower mean absolute error (MAE) of 0.049, a mean square error (MSE) of 0.042, a root mean square error (RMSE) of 0.007, and a higher R^2 score of 0.291, indicating the highest performance among all RBOR models.

We developed 6 types of BOR prediction models, of which 2 types were used for predicting ward bed occupancy rates (WBORs), and the other 4 types focused on predicting RBORs. These models use LSTM and Bi-LSTM architectures with strong long-term memory capabilities as their basic structure. We created 6 models for each architecture, resulting in a total of 12 models. The WBOR models were used for predicting weekly and monthly occupancy rates, serving long-term hospital administrative planning purposes. Conversely, the RBOR models were designed for immediate and rapid occupancy planning and were trained with 3- and 7-day intervals. Each RBOR model was enhanced by combining static data, which represent room-specific features, to generate more sophisticated prediction models.

Figure 1 shows the potential application of our model as a form of web software in a hospital setting. Through an online dashboard, it can provide timely information regarding bed availability, enabling intelligent management of patient movements related to admission and discharge. It facilitates shared responsibilities within the hospital and simplifies future resource planning [25].

In the Introduction section, we explored the importance of this research and investigated relevant previous studies, providing a general overview of the direction of our research. In the Methods section, we provide descriptions of the data set used and the structure of the DNN algorithm used, and explain the model architecture and performance. In the Results section, we present the performance and outcomes of this study. Finally, in the Discussion section, we discuss the contributions, limitations, and potential avenues for improvement of the research.

Figure 1. Virtual dashboard of the status and forecast of the ward bed occupancy rate (WBOR) and room bed occupancy rate (RBOR). The first screen presents the overall bed occupancy rate of the hospital, along with the number of beds in use and available. Moreover, a predictive graph displays the anticipated WBOR for selected dates. The second screen presents the WBOR for individual beds, indicating their statuses, such as "in use," "reserved," "empty," and "cleaning." Detailed information about each room is also displayed.



Methods

Overview

We intended to predict the BORs of individual hospital wards and rooms based on the information accumulated in individual bed–level data on an hourly basis, aggregated on a daily basis. For this purpose, we developed 12 time-series models. As the base models, we applied LSTM and Bi-LSTM, which are suitable for sequence data. These models address the limitation of long-term memory loss in traditional RNNs and were chosen because of their suitability for training bed data represented as sequence data.

Based on the model architecture, there were 2 WBOR prediction model types, which were trained at 7- and 30-day intervals to predict the occupancy rate for the next day. Moreover, there were 2 RBOR prediction model types, similar to the ward models, which were trained at 3- and 7-day intervals. Furthermore, as another approach, each RBOR prediction model was augmented with static data, and 2 DL algorithms were proposed for the final comparison of their performances in predicting RBORs.

Ethical Considerations

The study was approved by the Asan Medical Center (AMC) Institutional Review Board (IRB 2021-0321) and was conducted in accordance with the 2008 Declaration of Helsinki.

Materials

Study Setting

This was a retrospective single-center cohort study. Data were collected from AMC, with information on the occupancy status of each bed recorded at hourly intervals between May 27, 2020, and November 21, 2022. The data set comprised a total of 54,632,684 records. This study used ethically preapproved data. Deidentified data used in the study were extracted from ABLE, the AMC clinical research data warehouse.

A total of 57 wards, encompassing specialized wards; 1411 rooms, including private and shared rooms; and 4990 beds were included in this study. Wards and rooms with specific characteristics, such as intensive care unit, newborn room, and nuclear medicine treatment room, were excluded from the analysis as their occupancy prediction using simple and general variables did not align with the direction of this study.

Supporting Data

Supporting data for public holidays were added in our data set. We considered that holidays have both a recurring pattern with specific dates each year and a distinctive characteristic of being nonworking days, which could affect occupancy rates. Based on Korean public holidays, which include Chuseok, Hangeul Proclamation Day, Children's Day, National Liberation Day, Memorial Day, Buddha's Birthday, Independence Movement Day, and Constitution Day, there were 27 days that corresponded to public holidays during the period covered by the data set. We denoted these dates with a value of "1" if they were public holidays and "0" if they were not, based on the reference date.

Preprocessing and Description of Variables

Among the variables representing individual beds, the reference date, ward and room information, patient occupancy status, bed cleanliness status, and detailed room information were available. Based on the recorded date of bed status, we derived additional variables, such as the reference year, reference month, reference week (week of the year), reference day, and reference day of the week.

Room data were derived from the input information representing the cleanliness status of beds. This variable had 2 possible states, namely, "admittable" and "discharge." If neither of these states was indicated, it implied that a patient was currently hospitalized in the bed. As the status of hospitalized patients was indicated by missing values, we replaced them with the number "1" to indicate the presence of a patient in the bed and "0" otherwise. The sum of all "1" values represented the current number of hospitalized patients. The count of beds in each room indicated the capacity of each room. The target variable BOR was calculated by dividing the number of patients in the room by the room capacity, resulting in a room-specific patient occupancy rate variable. The ward data were subjected to a similar process as that of the room data, with the difference being that we generated ward-specific variables, such as ward capacity and WBOR, using the same approach. The static room data consisted of 14 variables, including the title of the room and the detailed information specific to each room.

For the variables in the ward and room data, we disregarded the units of the features and converted them into numerical values for easy comparison, after which we performed normalization. Regarding the variables representing detailed room information, we converted them to numerical values where "yes" was represented as "1" and "no" was represented as "0."

The final set of variables used in this study was categorized into date, ward, room, and detailed room information. Table 2 provides the detailed descriptions of the variables used in our training, including all the administrative data related to beds that are readily available in the hospital.

The explanation of the classification for generating the data sets for training each model is provided in Table 3. The static features of the detailed room information were combined with the room data set, which has sequence characteristics, to generate a separate data set termed Room+Static.

Table 2. Description of variables by category.

Variable	Type	Description
Date		
Year	3 categories	Reference year for bed status
Month	12 categories	Reference month for bed status
Week	53 categories	Reference week for bed status
Day	31 categories	Reference day for bed status
Weekday	7 categories	Reference day of the week for bed status
Holiday	2 categories	Holiday status
Ward		
Ward abbreviation	57 categories	Abbreviations for entire ward names
Ward capacity	Numeric	Number of available ward beds
Ward bed capacity	Numeric	Number of patients currently admitted to the ward
Ward occupancy rate	Numeric	Ward bed capacity divided by ward capacity
Room		
Room abbreviation	1411 categories	Abbreviations for entire room names
Room capacity	Numeric	Number of available room beds
Room bed capacity	Numeric	Number of patients currently admitted to the room
Room occupancy rate	Numeric	Room bed capacity divided by room capacity
Room static feature		
Room code	34 categories	Room grade code
Nuclear	2 categories (N[a]/Y[b])	Nuclear medicine room availability
Sterile	2 categories (N/Y)	Sterile room availability
Isolation	2 categories (N/Y)	Isolation room availability
EEG[c] testing	2 categories (N/Y)	EEG testing room availability
Observation	2 categories (N/Y)	Observation room availability
Kidney	2 categories (N/Y)	Kidney transplant room availability
Liver	2 categories (N/Y)	Liver transplant room availability
Sub-ICU[d]	2 categories (N/Y)	Sub-ICU room availability
Special	2 categories (N/Y)	Special room availability
Small single	2 categories (N/Y)	Small single room availability
Short-term	2 categories (N/Y)	Short-term room availability
Psy-double	2 categories (N/Y)	Psychiatry department double room availability
Psy-open	2 categories (N/Y)	Psychiatry department open room availability

[a]N: No.

[b]Y: Yes.

[c]EEG: electroencephalogram.

[d]ICU: intensive care unit.

Table 3. Data set classification and included variables.

Data set	Variables
Ward data set	Ward abbreviation, year, month, week, day, weekday, holiday, ward capacity, ward bed capacity, and ward occupancy rate
Room data set	Room abbreviation, year, month, week, day, weekday, holiday, room capacity, room bed capacity, and room occupancy rate
Static data set	14 static variables related to detailed room information
Room+Static data set	Room abbreviation, year, month, week, day, weekday, holiday, room capacity, room bed capacity, 14 static variables related to detailed room information, and room occupancy rate

Separation

Each data set was split into training, validation, and test sets for training and evaluation of the model. The training set consisted of 32,153 rows (67.8%), with data from May 27, 2020, to December 2021. The validation set, used for parameter tuning, included 7085 rows (15.0%), with data from January to June 2022. Finally, the test set comprised 8208 rows (17.2%), with data from July 2022 to November 21, 2022.

DL Algorithms

We used various DL algorithms for in-depth learning. In the following subsections, we will provide explanations for each model algorithm used in our research.

LSTM Network

RNN [26] is a simple algorithm that passes information from previous steps to the current step, allowing it to iterate and process sequential data. However, it encounters difficulties in handling long-term dependencies, such as those found in time-series data, owing to the vanishing gradient problem. To address this issue, LSTM [27] was developed. LSTM excels in handling sequence data and is commonly used in natural language processing, machine translation, and time-series data analysis. LSTM consists of an input gate, output gate, and forget gate. The “cell state,” is carefully controlled by each gate to determine whether the memory should be retained or forgotten for the next time step.

Bi-LSTM Network

Although RNN and LSTM possess the ability to remember previous data, they have a limitation in that their results are primarily based on immediate past patterns because the input is processed in a sequential order. This limitation can be overcome through a network architecture known as Bi-LSTM [28]. Bi-LSTM allows end-to-end learning, minimizing the loss on the output and simultaneously training all parameters. It also has the advantage of performing well even with long data sequences. Because of its suitability for models that require knowledge of dependencies from both the past and future, such as LSTM-based time-series prediction, we additionally selected Bi-LSTM as the base model.

Attention Mechanism

Attention mechanism [29,30] refers to the process of incorporating the encoder’s outputs into the decoder at each time step of predicting the output sequence. Rather than considering the entire input sequence, it focuses more on the relevant components that are related to the predicted output, allowing the model to focus on important areas. This mechanism helps minimize information loss in data sets with long sequences, enabling better learning and improving the model’s performance. It has been widely used in areas such as text translation and speech recognition. Nevertheless, as it is still based on RNN models, it has the drawbacks of slower speed and not being completely free from information loss issues.

Combining Static and Dynamic Features

Data can exhibit different characteristics even at the same time. For instance, in data collected at 1-hour intervals for each hospital bed, we can distinguish between “dynamic data,” which include features that change over time, such as the bed condition, date, and patient occupancy, and “static data,” which consist of information that remains constant, such as the ward and room number.

DL allows us to use all the available information for prediction. Therefore, for predicting the RBOR, we investigated an approach that combines dynamic and static data using an LSTM-based method [31]. This approach demonstrated better performance than LSTM alone [32]. Our approach involves adding a layer that incorporates static data as an input to the existing room occupancy prediction model.

Model Architecture

Base Model

Our objective was to predict the intermediate-term occupancy rates of wards and rooms within the hospital to contribute to hospital operation planning. Bi-LSTM was chosen as the base model owing to its improved predictive performance compared with the traditional LSTM model. However, to quantitatively compare these models, we conducted a comparison of the results for each model (6 for each, with a total of 12 models).

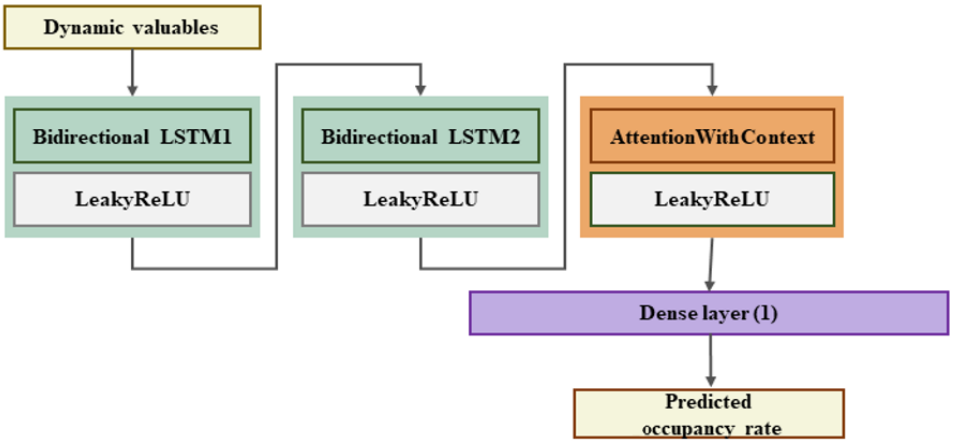
A typical LSTM model processes data sequentially, considering only the information from the past up to the current time step. However, Bi-LSTM, by simultaneously processing data in both forward and backward directions, has a unique feature that allows it to leverage both current and future information for predictions. This bidirectionality helps the model effectively learn temporal dependencies and intricate patterns. However, despite these advantages, Bi-LSTM comes with the trade-off of doubling the number of model parameters, resulting in increased computational costs for training and prediction. While a more complex model can better adapt to the training data, there is an increased risk of overfitting, especially with small

data sets. Nevertheless, the reason for choosing Bi-LSTM for tasks like predicting BORs in hospitals, involving time-series data, lies in its ability to harness the power of bidirectional information. Bi-LSTM processes input data from both past and future directions simultaneously, enabling it to effectively incorporate future information into current predictions. This proves beneficial for handling complex patterns in long time-series data [28].

Moreover, we have enhanced the performance of our models by adding an attention layer to Bi-LSTM. The attention layer assigns higher weights to features that exert a significant impact on the prediction, allowing the model to focus on relevant information and gather necessary input features. This helps improve the accuracy of the prediction. Furthermore, the attention layer reduces the amount of information processed, resulting in improved computational efficiency. Ultimately, this contributes toward enhancing the overall performance of the model.

The window length of the input sequence was divided into 3 different intervals, namely, 3, 7, and 30 days. The WBOR model was trained on sequences with a window length of 7 and 30 days, whereas the RBOR model was trained on sequences with a window length of 3 and 7 days. The first layer of our model consisted of Bi-LSTM, which was followed by the leaky rectified linear unit (LeakyReLU) activation function. LeakyReLU is a linear function that has a small gradient for negative input values, similar to ReLU. It helps the model converge faster. After applying this process once again, the AttentionWithContext layer was applied, which focuses on important components of input sequence data and transforms outputs obtained from the previous layer. After applying the activation function again, a dense layer with 1 neuron was added for generating the final output. The sigmoid function was used to limit the output values between 0 and 1. Finally, our model was compiled using the MSE loss function, Adam optimizer, and MAE metric. The parameters for each layer were selected based on accumulated experience through research. Figure 2 visually represents the above-described structure.

Figure 2. Base bidirectional long short-term memory (Bi-LSTM) model architecture. LeakyReLU: leaky rectified linear unit; LSTM: long short-term memory.



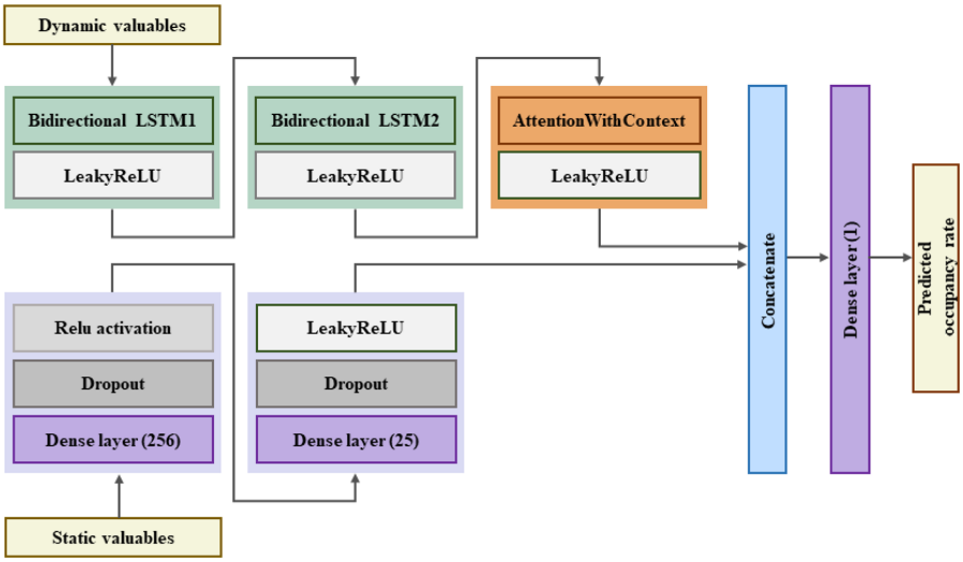
Combining Dynamic and Static Data Using the DL Model

The accumulated bed data, which were collected on a time basis, were divided into dynamic and static data of the rooms, which were then inputted separately. To improve the performance of the BOR prediction model, we designed different DL architectures for the characteristics of these 2 types of data.

We first used a base model based on LSTM and Bi-LSTM to learn the time-series data and then focused the model's attention using the dense layer to process fixed-size inputs. To prevent overfitting, we applied the dropout function to randomly deactivate neurons in 2 dense layers. The hidden states of the 2 networks were combined, and the resulting output was passed to a single layer, combining the time dynamic and static data.

Finally, the hidden states of the 2 networks were combined, and the combined result was passed to a single layer to effectively integrate the dynamic and static data. This allowed us to use the information from both the dynamic and static data for BOR prediction. This architecture is illustrated in Figure 3.

Figure 3. Bidirectional long short-term memory (Bi-LSTM) model architecture combining static and dynamic variables. LeakyReLU: leaky rectified linear unit; LSTM: long short-term memory.



Hyperparameter Tuning

One of the fundamental methods to enhance the performance of artificial intelligence (AI) learning models is the use of hyperparameter tuning. Hyperparameters are parameters passed to the model to modify or adjust the learning process. While hyperparameter tuning may rely on the experience of researchers, there are also functionalities that automatically search for hyperparameters, taking into account the diversity of model structures.

Various methods for search optimization have been proposed [33,34], but we implemented our models using the Keras library. By leveraging Keras Tuner, we automatically searched for the optimal combinations of units and learning rates for each model, contributing to the improvement of their performance.

Time Series Cross-Validation

Time-series data exhibit temporal dependencies between data points, making it crucial to consider these characteristics when validating a model. Commonly used K-fold cross-validation is effective for evaluating models on general data sets [35], providing effectiveness in preventing overfitting and enhancing generalizability by dividing the data into multiple subsets [36,37]. However, for time-series data, shuffling the data randomly is not appropriate owing to the inherent sequential dependency of the observations.

Time series cross-validation is a method that preserves this temporal dependence while dividing the data [38]. It involves splitting the entire hospital bed data set into 5 periods, conducting training and validation for each period, and repeating this process as the periods shift. This approach is particularly effective when observations in the dynamic data set, such as hospital bed data recorded at 1-hour intervals, play a crucial role in predicting future values based on past observations.

Shuffling data randomly using K-fold may disrupt the temporal continuity, leading to inadequate reflection of past and future observations. Therefore, time series cross-validation sequentially partitions the data, ensuring the temporal flow is maintained, and proves to be more effective in evaluating the model's performance. This method enables the model to make more accurate predictions of future occupancy based on past trends.

Evaluation

We selected various metrics to evaluate the performance of time-series data predictions. Among them, MAE represents the absolute difference between the model's predicted values and the actual BOR. We also considered MSE, which is sensitive to outliers. Moreover, to address the limitations of MSE and provide a penalty for large errors, we opted for RMSE. We also used the R^2 score to measure the correlation between the predicted and actual values.

MAE is a commonly used metric to evaluate the performance of time-series prediction models. MAE is intuitive and easy to calculate, making it widely used in practice. Because MAE uses absolute values, it is less sensitive to outliers in the occupancy rate values for specific dates. MAE is calculated using the following formula:

MSE is a metric that evaluates the magnitude of errors by squaring the differences between the predicted and actual values and then taking the average. It is calculated using the following formula:

RMSE is used to address the limitations of MSE where the error scales as a square, providing a more intuitive understanding of the error magnitude between the predicted and actual values. It penalizes large errors, making it less sensitive to outliers. RMSE is calculated using the following formula:

The R^2 score is used to measure the explanatory potential of the prediction model, and it is calculated using the following formula:

Here, SSR represents the sum of squared differences between the predicted and actual values, and SST represents the sum of squared differences between the actual values and the mean value of actual values. Figure 4 shows the prediction method and overall flow in this study.

Results

We used 2 DL models, LSTM and Bi-LSTM, and compared the performance of 12 different prediction models. These models have been denoted as ward 7 days (W7D), ward 30 days (W30D), room 3 days (R3D), room 7 days (R7D), room static 3 days (RS3D), and room static 7 days (RS7D). Using Keras Tuner, we adjusted the hyperparameters of the models and subsequently validated the models through a 5-fold time series cross-validation.

The prediction performances of the models for WBOR and RBOR were compared, which showed that they were more accurate at predicting WBOR, with MAE values of 0.06 to 0.07. The W7D model based on Bi-LSTM, which used 7 days of ward data to predict the next day's ward occupancy, had a MAE value of 0.067, MSE value of 0.009, and RMSE value of 0.094, showing high accuracy. The R^2 score was also 0.544, which was approximately 0.240 higher than that of the W30D model (0.304), indicating that the variables in that model explained occupancy reasonably well.

We next compared the performances of the 8 models for RBOR prediction, and among them, the RS7D model based on Bi-LSTM, which was trained on a 7-day time step by integrating static and dynamic data, showed the best performance. It achieved a MAE value of 0.129, MSE value of 0.050, RMSE value of 0.227, and R^2 score of 0.260. In particular, the R^2 score outperformed that of the R3D model by 0.014. These data are summarized in Table 4. Regarding the WBOR prediction model, the model with a shorter training unit, W7D, demonstrated better performance. However, regarding the RBOR prediction model, the model with a longer training unit of 7 days, which incorporated detailed room-specific information, exhibited slightly higher performance than the model with a shorter

training unit of 3 days. The model with the added room-specific information still demonstrated superior performance overall.

We visualized the predicted and actual occupancy for Bi-LSTM models and investigated the occupancy trends since July 2022 on our test data set. First, we selected a specific ward in W7D to demonstrate the change in the WBOR over 2 months. The right panel of Figure 5 shows the WBOR change over 5 months from July 2022 in W30D. The blue line represents the actual occupancy value, and the red line represents the predicted occupancy value by the model. This provides an at-a-glance view of the overall predicted occupancy level for each month and allows hospital staff to observe trends to obtain a rough understanding of the WBOR.

Figure 6 shows graphs of occupancy rate values for a randomized specific room, displaying the predicted and actual values for the 4 RBOR prediction models, with 2 graphs for each model. The left graph shows the occupancy rate change over 5 months from July to November 2022, and the right graph shows the occupancy rate for the months of July and August, providing a detailed view of the RBOR. By examining the trends of the predicted and actual values for the 4 models in this period for a specific room, we can observe that the models maintain a similar trend to the actual occupancy rate.

Discussion

Principal Findings

The entire data set of this study consisted of administrative data collected at AMC at an hourly interval for each ward from May 27, 2020, to November 21, 2022. To improve the hospital's challenges, we developed a model to predict the occupancy rate of wards and rooms. Our aim was to contribute toward administrative and financial planning for bed management within the hospital.

During the specified period, we compared the results of using DL models to predict the overall BOR for each ward and individual rooms. In the case of WBOR prediction, the MAE of the 7-day window model based on Bi-LSTM was approximately 0.067, demonstrating a remarkably close prediction to the occupancy compared with that of the 30-day

window model based on LSTM, with a difference of approximately 0.035. Furthermore, the MSE and RMSE were 0.009 and 0.094, respectively, indicating high accuracy in the predictions. Moreover, the R^2 score of 0.544 indicated that the model had better explanatory potential than the average. For the individual RBOR prediction, among the 8 models, the RS7D model based on Bi-LSTM performed the best, exhibiting a MAE of approximately 0.129, which was remarkably lower than that of the other models. Moreover, the MSE and RMSE were significantly lower than those of the RBOR models, with differences of 0.042 and 0.07, respectively. The R^2 score of 0.260 indicated that it had higher explanatory potential than the RS3D models based on LSTM, with the value being higher by 0.291.

Finally, we visualized the predicted and actual values on a graph for a specific period and observed that each model captured the trend of the actual BOR quite well. Although the models were less accurate in predicting low occupancy periods, they followed the general trend closely. Overall, these findings demonstrate that our DL models effectively predicted BORs for both wards and individual rooms, with certain models demonstrating superior performance in different scenarios.

Strengths and Limitations

Although the models in this study demonstrated good performance in following the trends of BORs and achieved good results, there were several limitations in this research. First, there were limitations in the data. Although we used administrative data and detailed room information available from the hospital to enable the models to capture occupancy trends, the relationship between the variables and the model's explanatory potential showed room for improvement, as indicated by the R^2 score. To achieve higher prediction accuracy, it would be beneficial to incorporate diverse data sources and real-time updated information.

Second, there was variability in external factors. Hospital BORs are heavily influenced by external environmental factors. Sudden events, such as environmental factors and outbreaks of infectious diseases like COVID-19, can render accurate prediction of bed occupancy challenging [18,32]. Furthermore, seasonal effects and accidents can increase the number of patients. Sufficient collection of long-term data on these external factors would be necessary, but such uncertainties can reduce the accuracy of predictions.

Despite these limitations, our study demonstrated a significant level of adherence to trends in the prediction of individual ward and room occupancy. More detailed variables and a longer period of data accumulation would be required to predict the specific number of beds.

Conclusion

We presented models that can predict the occupancy rates of wards and individual hospital rooms using artificial neural networks based on time-series data. The predicted results of these models demonstrated a high level of accuracy in capturing the future trends of the BOR. In particular, we presented 8 RBOR models with structure and window changes to compare their performance and found that the RS7D model showed the best performance. Our results can be implemented as a web application on hospital online dashboards, as depicted in Figure 1 [25]. In fact, Johns Hopkins University has been applying these methods in their command center to monitor hospital capacity and achieve effectiveness in patient management planning [39].

Furthermore, predicting BORs supports patient admission and discharge planning, helping to alleviate overcrowding in emergency departments and reduce patient waiting times. Staff members can effectively schedule patient admission and discharge, and minimize waiting times by understanding the BOR, providing urgent treatment to emergency patients. Moreover, providing appropriate information to patients waiting in the emergency department can increase patient satisfaction and facilitate efficient transition to hospital admission [40,41]. By applying AI models that combine BOR prediction, which contributes toward reducing emergency department waiting times with individual patient admission and discharge prediction, hospitals can achieve resource optimization and cost savings, resulting in improved patient satisfaction.

Acknowledgments

This work was supported by a Korea Medical Device Development Fund grant funded by the Korean government (the Ministry of Science and ICT; the Ministry of Trade, Industry and Energy; the Ministry of Health & Welfare, Republic of Korea; the Ministry of Food and Drug Safety) (project number: 1711195603, RS-2020-KD000097, 50%) and by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant number: HR20C0026).

Abstract

Background: Tinnitus diagnosis poses a challenge in otolaryngology owing to an extremely complex pathogenesis, lack of effective objectification methods, and factor-affected diagnosis. There is currently a lack of explainable auxiliary diagnostic tools for tinnitus in clinical practice.

Objective: This study aims to develop a diagnostic model using an explainable artificial intelligence (AI) method to address the issue of low accuracy in tinnitus diagnosis.

Methods: In this study, a knowledge graph–based tinnitus diagnostic method was developed by combining clinical medical knowledge with electronic medical records. Electronic medical record data from 1267 patients were integrated with traditional Chinese clinical medical knowledge to construct a tinnitus knowledge graph. Subsequently, weights were introduced, which measured patient similarity in the knowledge graph based on mutual information values. Finally, a collaborative neighbor algorithm was proposed, which scored patient similarity to obtain the recommended diagnosis. We conducted 2 group experiments and 1 case derivation to explore the effectiveness of our models and compared the models with state-of-the-art graph algorithms and other explainable machine learning models.

Results: The experimental results indicate that the method achieved 99.4% accuracy, 98.5% sensitivity, 99.6% specificity, 98.7% precision, 98.6% F_1-score, and 99% area under the receiver operating characteristic curve for the inference of 5 tinnitus subtypes among 253 test patients. Additionally, it demonstrated good interpretability. The topological structure of knowledge graphs provides transparency that can explain the reasons for the similarity between patients.

Conclusions: This method provides doctors with a reliable and explainable diagnostic tool that is expected to improve tinnitus diagnosis accuracy.

Introduction

Tinnitus is a common refractory disease in the field of otolaryngology, and its diagnosis has always been a cutting-edge research topic in audiology. With changes in the social environment and an accelerated pace of life, an increasing number of patients, particularly among the younger generation, have sought medical assistance for tinnitus as their primary complaint in the last decade. Globally, approximately 14% (95% CI 0.8%-1.6%) of adults are affected by tinnitus [1,2], which can cause stress, anxiety, and depression [3]. Distress and hearing impairment brought on by the disease can affect cognitive abilities and lead to suicidal tendencies in severe cases, greatly affecting the work and daily lives of patients [4].

The pathogenesis of tinnitus is extremely complex and not fully understood. Currently, no effective objectification methods are available. Traditional Chinese medicine (TCM) classifies tinnitus into 5 different syndrome patterns: wind fire attacking internally (WFAI), liver fire bearing upward (LFBU), phlegm fire stagnation internally (PFSI), Qi deficiency of the spleen and stomach (QDSS), and kidney essence deficiency (KED). The diagnosis of tinnitus remains a challenge in medical science because it is influenced by several complex factors [5,6], including individual differences among patients and atypical symptom presentations. Clinical diagnosis relies heavily on the personal knowledge and clinical experience of doctors, thereby introducing subjectivity, uncertainty, and ambiguity. Consequently, achieving a high tinnitus diagnostic accuracy becomes difficult. Therefore, tinnitus diagnosis remains an urgent issue requiring further exploration and resolution by medical researchers.

Previous studies have focused on the use of artificial intelligence (AI) to assist doctors in diagnosing tinnitus and improving diagnostic accuracy. Liu et al [7] proposed a meta-learning method based on lateral perception for cross–data set tinnitus diagnosis. Sun et al [8] used a support vector machine classifier to distinguish between patients with tinnitus and healthy individuals. Shoushtarian et al [9] used a naive Bayes algorithm to classify patients with tinnitus and control groups. Sanders et al [10] used a spiking neural network model to classify patients with tinnitus into 2 groups based on different classification criteria. Manta et al [11] used clinical data and patient features to build a machine learning (ML) model for classifying the degree of tinnitus-related distress in individuals and their ears. Allgaier et al [12] used a gradient-boosting engine to classify transient tinnitus. Rodrigo et al [13] used a decision tree model to identify variables related to the success of internet-based cognitive behavioral therapy for tinnitus. Liu et al [14] used a support vector machine model to explore cortical or subcortical morphological neuroimaging biomarkers that effectively distinguished patients with tinnitus from healthy individuals. Niemann et al [15] proposed a LASSO model to predict the severity of depression in patients with tinnitus. Although previous studies have achieved success using their respective data sets, the developed ML- or deep learning–based methods are entirely data-driven modeling approaches that do not make full use of existing medical knowledge. Models built using such methods are equivalent to “black boxes” for doctors, lack interpretability, and are not conducive to clinical promotion and application.

In this study, the aim is to incorporate clinical medical knowledge into a diagnostic model, enabling the integration of knowledge and data for interpretable results. Knowledge graph–based modeling methods offer solutions to such issues by using a novel knowledge representation format that connects entities and concepts in an objective world using semantic relationships. Such methods offer reasoning and interpretability that are highly sought after by both medical practitioners and academia. Li et al [16] used a knowledge graph to predict diabetic macular edema, overcoming the limitations of traditional ML and data-mining techniques that deal with missing feature values. Zhou et al [17] used 124 medical records to construct a knowledge graph for recommending hypertension medication. Lyu et al [18] created a knowledge graph for diabetic nephropathy diagnosis using patient data. Lin et al [19] extracted knowledge from medical texts and historical prescription data to construct a medical knowledge graph and accurately detect clinical prescription risks. Recently, knowledge graph applications have expanded to TCM; for instance, Yang et al [20] built a knowledge graph to extract medical information from TCM case records. Xie et al [21] constructed a knowledge graph using ancient Chinese medical books to infer symptoms and syndromes. Yang et al [22] used electronic medical records (EMRs) to build a knowledge graph, transforming TCM diagnostic issues into multilabel classification problems. Lan et al [23] integrated knowledge graphs with graph neural networks to introduce graph-based supervised contrastive learning, effectively enabling the classification of TCM texts. However, no previous studies have used knowledge graphs in the complex medical field of tinnitus diagnosis. Therefore, this study focuses on knowledge graph technology to assist doctors in tinnitus diagnosis and improve diagnostic accuracy.

This paper aims to establish a comprehensive knowledge graph in TCM specifically tailored for tinnitus. Leveraging this knowledge graph, we propose a novel method for calculating patient similarity. This method takes into account the weighting of symptom-syndrome type relationships, thereby facilitating the inference of syndrome types in patients with tinnitus according to TCM principles. By implementing this approach, clinicians can increase the accuracy of tinnitus diagnosis within the realm of TCM.

In general, we make several noteworthy contributions as follows:

- We propose a method for tinnitus knowledge graph construction based on heterogeneous patient EMRs and TCM clinical knowledge.
- We introduce weights to measure patient similarity into the tinnitus knowledge graph using a method based on prior probabilities and mutual information values.
- A collaborative neighbor algorithm that uses patient similarity scores to obtain recommended diagnostic results is proposed to assist doctors in understanding the model-generated conclusions, thereby improving the accuracy of tinnitus diagnosis.

Methods

Patients

For this study, we collected the EMRs of 1267 patients with tinnitus who visited the ear, nose, and throat departments of 11 medical institutions in Shanghai, China, from November 2019 to July 2023. The inclusion criteria included (1) tinnitus as the primary complaint and (2) the ability to communicate normally. The exclusion criteria included (1) objective tinnitus, (2) nonotogenic tinnitus caused by factors such as endocrine and blood disorders, (3) tinnitus caused by head or ear trauma, and (4) difficulties in communication or severe psychiatric history that could hinder follow-up compliance. After screening the data for quality, 1265 cases were included for further analysis.

The clinical EMR data set recorded medical data of real patients including the relationship between patient symptoms and disease, which was crucial for disease diagnosis. The data set contained patient information such as age, sex, inducement, medical history, tinnitus sound, accompanying symptoms, tongue coating, pulse condition, TCM syndrome differentiation, and sleep status. Each patient had a clear diagnosis that could be classified into 1 of 5 categories: WFAI, LFBU, PFSI, QDSS, and KED. Statistical data are presented in Figures 1-4 .

Figure 1. Age distribution of different syndromes by sex. KED: kidney essence deficiency; LFBU: liver fire bearing upward; PFSI: phlegm fire stagnation internally; QDSS: Qi deficiency of the spleen and stomach; WFAI: wind fire attacking internally.

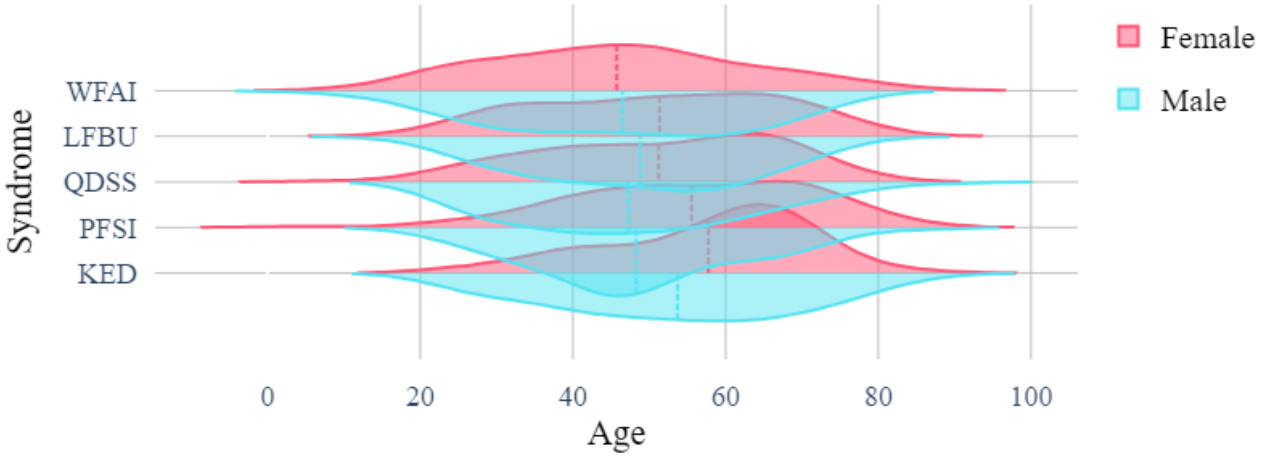

Figure 2. The tongue body distribution of different syndrome types. KED: kidney essence deficiency; LFBU: liver fire bearing upward; PFSI: phlegm fire stagnation internally; QDSS: Qi deficiency of the spleen and stomach; WFAI: wind fire attacking internally.

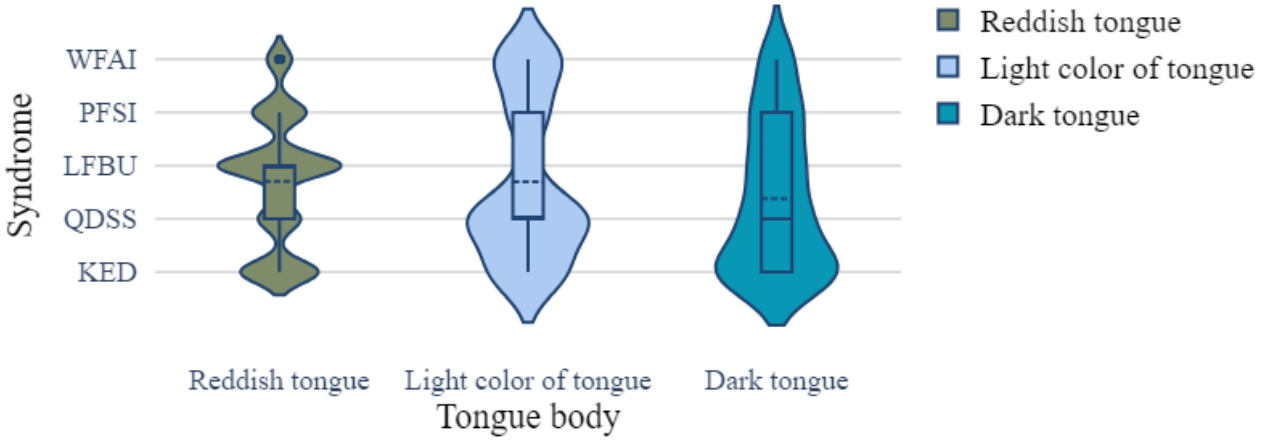

Figure 3. The tongue fur distribution of different syndrome types. KED: kidney essence deficiency; LFBU: liver fire bearing upward; PFSI: phlegm fire stagnation internally; QDSS: Qi deficiency of the spleen and stomach; WFAI: wind fire attacking internally.

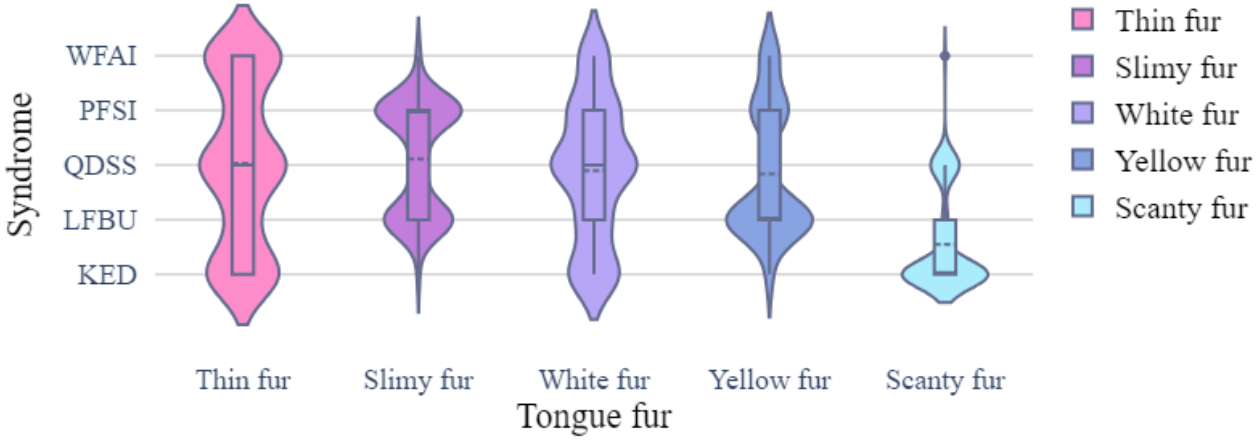

Figure 4. The pulse condition distribution of different syndrome types. KED: kidney essence deficiency; LFBU: liver fire bearing upward; PFSI: phlegm fire stagnation internally; QDSS: Qi deficiency of the spleen and stomach; WFAI: wind fire attacking internally.

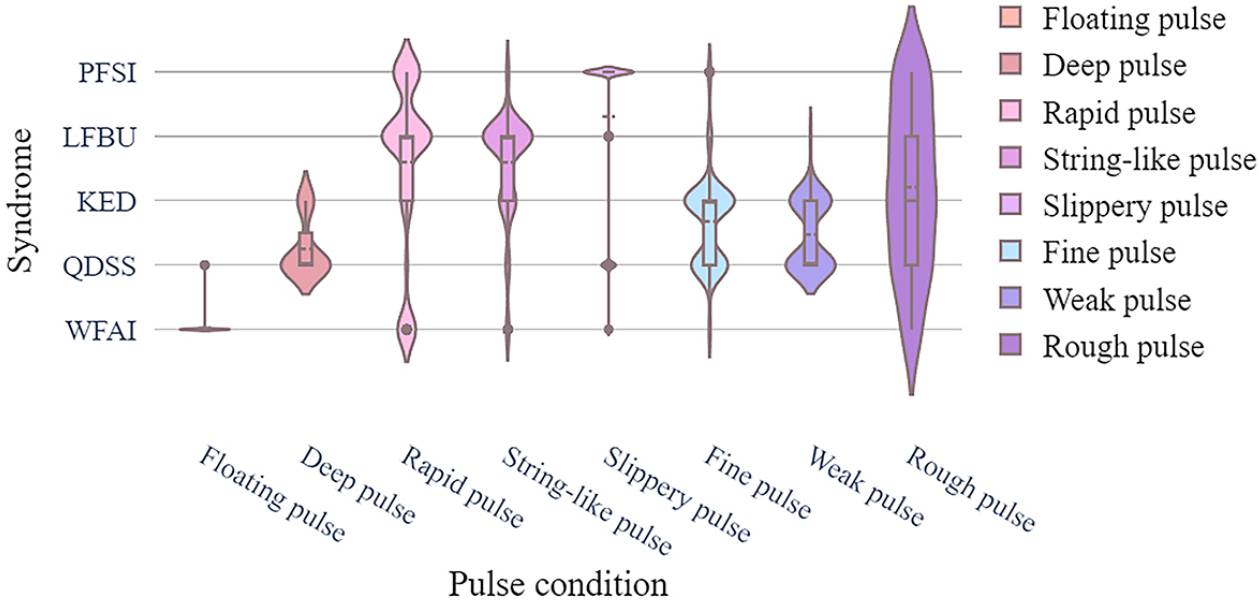


Ethical Considerations

This study's protocol was approved by the ethics committee of the Shanghai Municipal Hospital of Traditional Chinese Medicine, Shanghai, China (2021SHL-KY-70).

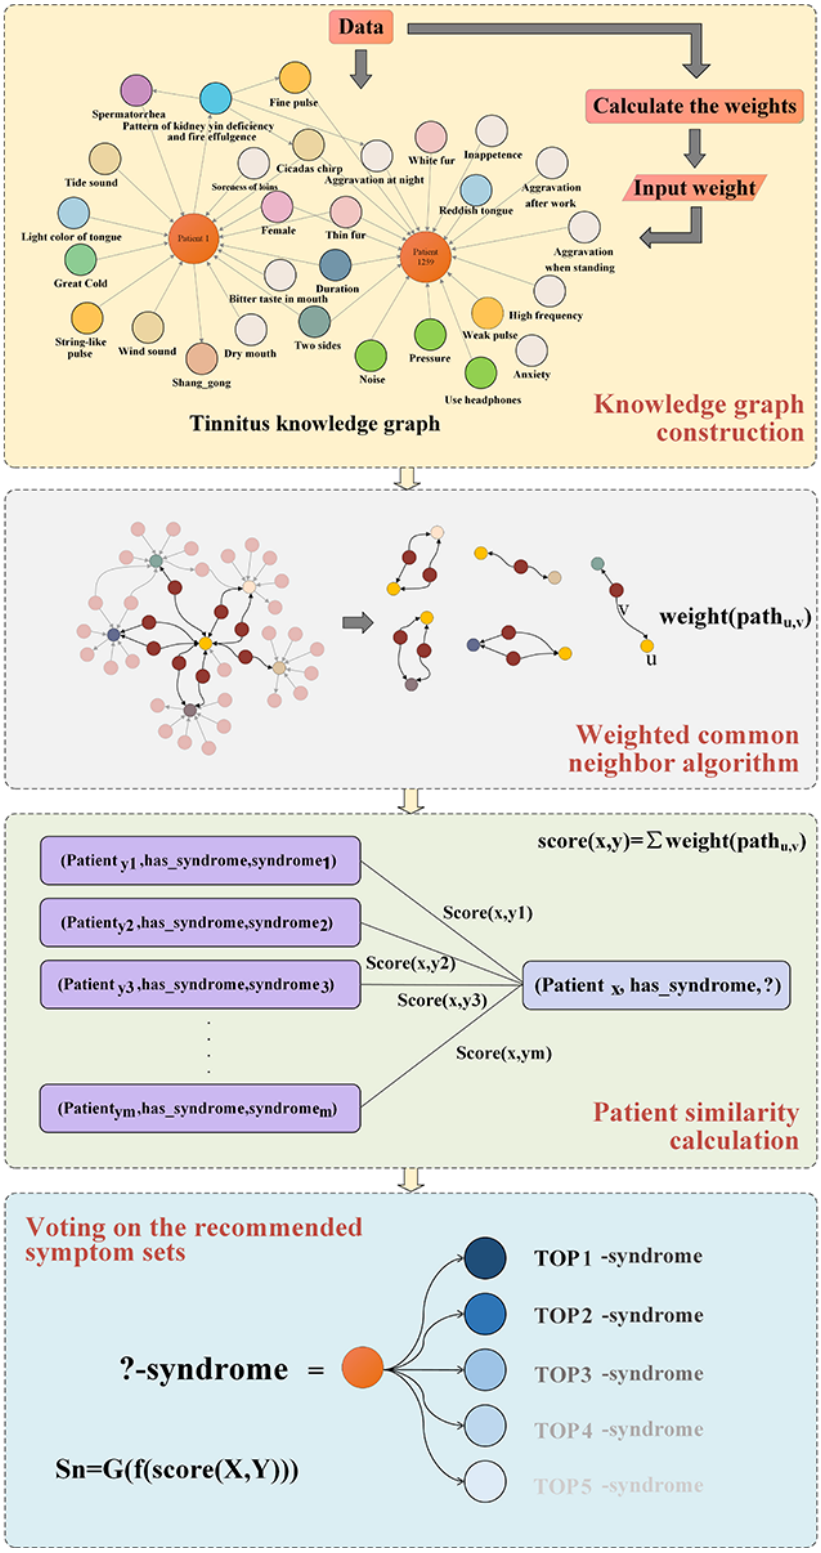
The data was anonymized in order to protect patient privacy. Patients could receive free examinations and treatments throughout the entire process, so no compensation was provided.

Clinical Decision Support for Tinnitus

Overview

To integrate patient EMRs with diagnostic knowledge from TCM textbooks, we constructed a knowledge graph using a combined "top-down" and "bottom-up" approach [24]. First, a patient-centered knowledge graph was developed using EMRs. Then, the knowledge graph was enriched with tinnitus diagnostic knowledge from TCM textbooks. Finally, we used a mutual information–based weight calculation method to enhance the knowledge graph by fusing patient case data with diagnostic knowledge. The resulting knowledge graph simulated the diagnostic reasoning processes of experienced physicians. The entire method consisted of three steps: (1) building a weighted tinnitus knowledge graph, (2) finding and scoring common neighbors, and (3) predicting syndrome patterns based on patient similarity. The overall framework is illustrated in Figure 5.

Figure 5. Overall framework of the proposed method.



Knowledge Graph of Tinnitus Based on Heterogeneous Sources

In response to the diagnostic needs of tinnitus in TCM, the ontology structure of a tinnitus medical knowledge graph should revolve around symptoms, syndrome patterns, diseases, drugs, and treatment methods. For this study, we extracted such common concepts from expert-reviewed EMRs and classic medical textbooks, constructed a conceptual knowledge system, and built a top-level ontology structure. Natural language processing techniques [25] were used to extract entities and relationships from the patient EMRs based on a defined conceptual knowledge system for tinnitus. By applying certain rules and conducting string matching within the text, we extracted 15 and 10 categories of entities and relationships from the 1265 EMR records, respectively. Once the entity types and hierarchy were determined, we embedded the data into the conceptual knowledge system and established a patient-centric

tinnitus knowledge graph in the form of a triple, which maximized the retention of both explicit and implicit diagnostic information.

Furthermore, we enhanced the constructed tinnitus knowledge graph using knowledge extracted from authoritative medical textbooks to supplement tinnitus knowledge information that was not fully expressed in EMRs. Together with the EMR knowledge graph, a complete tinnitus knowledge graph was developed. The knowledge we selected came from 2 classic Chinese medicine textbooks [26,27], from which we extracted basic concepts related to tinnitus including TCM syndromes, prescriptions, Chinese medicinal herbs, and treatment methods to construct the TCM knowledge graph.

Heterogeneous Knowledge Fusion

Redundancy in the entities and relationships extracted from heterogeneous sources was observed owing to the different sources of data and knowledge. Therefore, knowledge fusion was required. First, data normalization and entity alignment were performed to standardize the named entities extracted from multiple data sources. The entities were associated using string-matching and similarity-calculation methods. As entity and attribute texts were relatively short, a lower similarity threshold was more appropriate; therefore, the similarity judgment threshold was set as 0.6 to prevent errors and omissions. The entity similarity calculation results are listed in Table 1. As the knowledge graph was established in Chinese, we calculated the similarity of the Chinese strings.

Then, a matching path was built from the tinnitus ontology–based knowledge graph entity to the EMR-based knowledge graph entity. Patient data were linked to diagnostic knowledge through an ontology. The 2 knowledge graphs were linked by unifying entities with duplicate meanings in the 2 graphs. Manual verification was performed to ensure the accuracy of the knowledge graph. The specific method is illustrated in Figure 6. Finally, the tinnitus knowledge graph consisted of 1247 entities and 9234 relationships.

Table 1. Entity similarity calculation results.

Standardized and ambiguous entities (Chinese)	Similarity
WFAI[a]	
风热外侵证 (wind-heat invasion syndrome)	0.8
风热外犯证 (wind-heat exterior syndrome)	0.6
风热外侵证 (wind-heat exterior assault syndrome)	0.8
LFBU[b]	
肝火上炎证 (liver fire flaming upward syndrome)	0.8
肝热上扰证 (liver heat disturbing upward syndrome)	0.8
肝火上扰清窍证 (liver fire disturbing upward and disturbing clearing orifices syndrome)	0.83
QDSS[c]	
脾胃虚证 (spleen and stomach deficiency syndrome)	0.89
脾胃虚弱证 (spleen and stomach weakness syndrome)	0.8
PFSI[d]	
痰火壅结证 (phlegm-fire concretions syndrome)	0.8
KED[e]	
肾精不足证 (kidney essence insufficiency syndrome)	0.6
肾精亏虚证 (kidney essence deficiency syndrome)	0.8

Calculation of Knowledge Graph Relationship Weights Based on Mutual Information

Considering the varying importance of different entities for different syndrome patterns, the imbalance in data categories, and the varying amount of information carried by symptoms, the calculation of weights required consideration of entities' importance for diagnostic pattern identification and information content carried by the entities themselves. The data used for weight calculation were derived from real clinical case data used for constructing the knowledge graph. First, the mutual information value (w_{if}) possessed by each entity was obtained using the mutual information method. The obtained value represented the extent to which a variable could acquire diagnostic pattern information.

For a given set of entities $X = \{x_1, x_2, ..., x_n\}$ with corresponding probabilities $P = \{p_1, p_2, ..., p_n\}$, the target variable to be measured was the diagnostic pattern Y. By calculating the overall entropy $H()$, conditional entropy $H(Y|X)$, and mutual information value $Gain(S,x)$, the degree to which the diagnostic pattern was determined based on the entity values or the weight value w_{if} of the entity was calculated. The calculations were performed using equations 1-3.

(1)

(2)

$$w_{if} = Gain(Y,X) = H(Y) - H(Y|X) \quad (3)$$

Further, the feature weights were calculated based on the syndrome patterns under the prior conditions. The probability of each symptom appearing under different syndrome patterns was obtained using statistical methods such as:

$$w_{sd} = p(sym_i|sd_j) \quad (4)$$

where $sym = \{sym_1, sym_2, ..., sym_n\}$ represents the symptom set and $sd = \{sd_1, sd_2, ..., sd_m\}$ represents the diagnostic pattern set. Finally, the edge weight from node u to node v was defined using equation 5.

$$Weight(u,v) = w_{if} + w_{sd} \quad (5)$$

The weights of various symptoms under different syndrome patterns are presented in Table 2.

Patient Similarity Scoring Based on Weighted Common Neighbor Algorithm

By transforming the TCM syndrome diagnostic problem into a prediction problem of linked patient nodes to TCM syndrome nodes, the similarity between 2 patients was calculated to obtain TCM syndrome similarity. For 2 patients, the higher the similarity, the greater the likelihood of having the same diagnostic result. This study measured the similarity using common features. In the knowledge graph, the higher the number of common neighbors to 2 patient nodes, the greater the likelihood of them belonging to the same community (linked to the same TCM syndrome node). The common neighbor graph of patients with different TCM syndromes is shown in Figure 7, where fewer common neighbors were observed. The common neighbor graph of patient 1 and patient 2 with the same TCM syndrome is shown in Figure 8, where more common neighbors were observed; however, different nodes had different importance. In TCM, the importance of pulse condition is greater than that of tinnitus duration while diagnosing tinnitus. The edge weight values of continuous tinnitus and thin pulse-to-kidney deficiency syndrome were 0.6991 and 1.1448, respectively, as shown in Figure 7; however, even for the same pulse condition, the importance varied for different TCM syndromes. In Figure 8, the edge weight values of thin pulse to QDSS and KED syndromes were 1.078 and 1.1447, respectively. Therefore, considering the edge weights of common neighbors to the patient nodes and calculating the score of common neighbors based on the edge weight values were essential when counting the number of common neighbors between patient nodes.

The similarity scoring function between patients x and y was defined by equation 6.

(6)

where $X = \{u_1, u_2, ..., u_m\}$ and $Y = \{v_1, v_2, ..., v_n\}$ represent the sets of neighboring nodes for patients x and y, respectively; $Path_{u,h,v} = (u, h, v)$ denotes the 2-hop path from node u to node v, where h represents the common neighbor of nodes u and v; $Path_{u,h} = (u, h)$ represents the path from node u to the common neighbor h; and $weight(path_{u,h})$ indicates the weight of the path.

When 2 paths with a hop count of 2 between the patient nodes existed, the weights of the paths were calculated to obtain a similarity score list for the patients. The list was then sorted in descending order, and the top 20 patient node syndromes with the highest scores were counted, which represented the most frequently occurring syndrome. Finally, the recommended syndrome was obtained.

$$S_n = G(f_{20}(\text{score}(X,Y))) \quad (7)$$

where G denotes a frequency-counting method in which X and Y represent sets of patient nodes. $f_{20}()$ was used to obtain the top 20 patient syndromes based on the scores.

Figure 7. Sketch map of common neighbors between different syndromes.

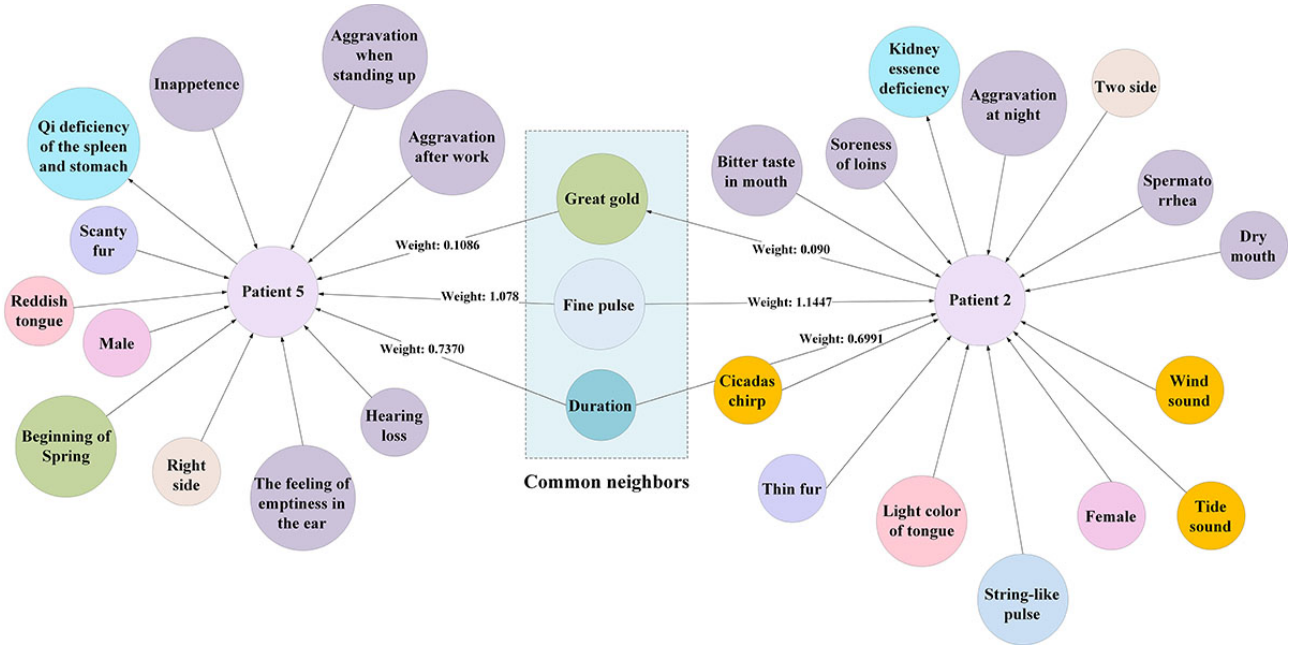

Figure 8. Sketch map of common neighbors between same syndromes.

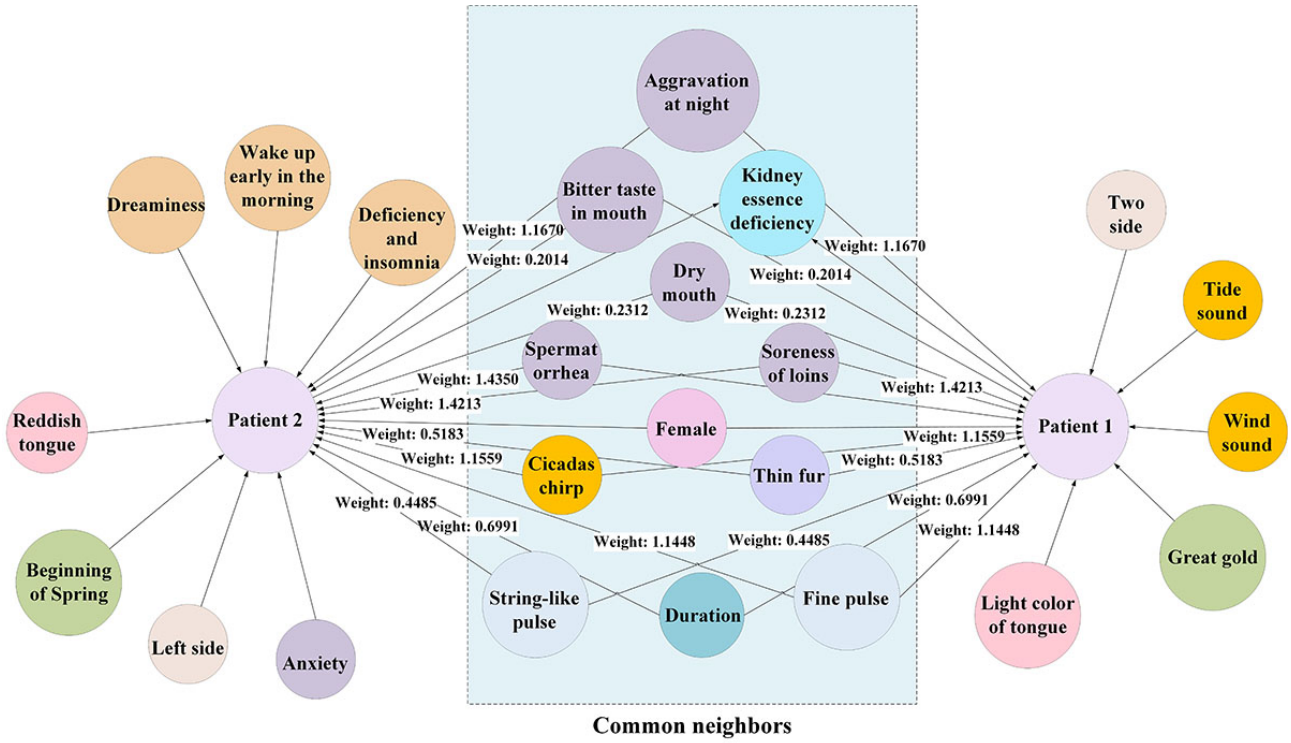

Experimental Design

In total, 2 experiments were conducted to verify the effectiveness of the proposed method. The first experiment was performed to compare the proposed method with similar graph algorithms, while the second experiment was performed to compare the proposed method with other common explainable ML methods. The evaluation metrics of the algorithm are accuracy, precision, sensitivity, specificity, F_1-score, area under receiver operating characteristic curve (AUC), etc. To demonstrate the interpretability of our method, we selected a tinnitus case for result interpretation to showcase the inference process and interpretability of our method.

Results

Performance Verification

For a given knowledge graph, we extracted the patient nodes and their neighboring nodes to form a knowledge network. The node and edge sets in the knowledge network were divided into training and testing sets. The testing set did not contain syndrome entities. To reasonably divide the training and testing sets, we used a stratified sampling cross-validation method of

randomly dividing the network node and edge sets into 5 subsets: 1 subset as the testing set, and the other 4 subsets as the training set. The training set served as a known network, whereas the testing set was used to verify the syndrome prediction results and evaluate the accuracy of the syndrome prediction algorithm.

Evaluation Outcomes

Comparison With Similar Graph Algorithms

The proposed method was compared with similar graph algorithms such as CommonNeighbors and Adamic-Adar. CommonNeighbors is a common graph algorithm used to infer the potential relationships and proximity between 2 nodes [28]; however, the differences between common neighbors are not considered. Adamic-Adar is a typical algorithm for determining the closeness of 2 points by measuring the outdegree of common neighbors [29]. ResourceAllocation calculates the closeness between 2 nodes using a set of neighboring nodes near the target node [30]. We added common neighbor edge weights based on CommonNeighbors. Unlike Adamic-Adar and ResourceAllocation, our weight calculation method considered each syndrome, which had a higher adaptability to TCM diagnosis by the doctors. The experimental results are listed in Table 3; our method outperformed similar graph algorithms in diagnosing each syndrome.

Comparison With Other Interpretable ML Methods

The proposed method was compared with common ML classification algorithms including decision tree, random forest, naive Bayes, logistic regression, and k-nearest neighbors algorithms. The results are presented in Table 4. The graph algorithm based on WightedCommonNeighbor outperformed other models in the comprehensive diagnosis of each syndrome on the same data set but was lower than the random forest model in terms of the AUC metric. Although the random forest model had a certain degree of interpretability, the overall complexity of model interpretation increased when a large number of decision trees were included. The higher the number of decision trees in the random forest model, the greater the difficulty of interpreting the relationships and decision processes within the model. Compared to the random forest model, our proposed method had higher interpretability and was more readily accepted by doctors.

Discussion

Principal Findings

The experimental results show that the accuracy, sensitivity, specificity, precision, F_1-score, and AUC of our proposed method all exceed 98% for 5 tinnitus subtypes. Compared to the traditional graph algorithm, our method comprehensively considers the number of neighboring nodes and the weight of edges for patient nodes. This method of calculating the strength of node connections and feature importance can more comprehensively measure the similarity between patient nodes. Further, by calculating the common neighbor score, the similarity between patient nodes can be quantitatively measured, providing a reliable quantitative indicator for the prediction problem of patient-to-syndrome node links. In addition, in the field of TCM, the impact of different features on diagnostic results may vary. This method considers the importance of features through edge weight values, making similarity calculations more realistic. By considering the edge weight values, the reasons for the formation of similarity between patient nodes and the importance of features can be explained, enhancing the interpretability of the model results. This method is not only applicable to the diagnosis of syndrome types in the field of TCM but can also be applied in other fields, especially in the similarity calculation problem that needs to consider feature importance and node correlation strength, which has universality.

In terms of interpretability, the proposed method integrated the knowledge of TCM differential diagnosis and clinical experience into a knowledge graph, which made the method more interpretable. To illustrate the explainability of our method, we randomly selected a patient from the patient records and used their medical information as input to the syndrome diagnosis algorithm, as shown in Figure 9. The patient information was input to the knowledge graph, where we searched for other patients who shared common neighbors with the selected patient. We calculated the common neighbor scores and returned the top k (k=20) patients with the highest scores. The results are summarized in Table 5. Based on the syndromes of the top k patients that were most similar to the target patient, we deduced that the predicted syndrome of the target patient was KED, which was consistent with the actual syndrome of the patient.

383	16	13.78

Limitations

The proposed method considered the weight of common neighbors and the importance of different symptoms for different syndrome types, but this makes similarity calculation more complex, requiring more computing resources and time. Meanwhile, the calculation of edge weight values requires relatively rich and accurate feature data. If the data quality is not high or features are missing, it will affect the accuracy of similarity calculation. However, compared to large-scale knowledge graphs, our research has a smaller sample size and requires continuous data collection to enrich the knowledge base.

From the experimental results, our method achieved good results in the diagnosis of WFAI, LFBU, PFSI, and QDSS. However, some deficiencies existed in the differential diagnosis of QDSS and KED syndrome types, which could create confusion between the two. The analysis of 3 patients who were misclassified with KED instead of QDSS revealed common entities between them and the top 5 most similar patients among their neighbors (Textbox 1). The common entities between patient 1 (ID 415) and the top 5 most similar patients among their neighbors, who were all patients with QDSS but were misclassified with KED, are listed in Textbox 1. The common entities included worsening conditions when standing up, empty feeling in the ears, left side, worsening condition after physical exertion, hypertension, red tongue, anxiety, thin pulse, hearing loss, continuous symptoms, female sex, and dizziness. Similarly, patient 2 (ID 601) and the top 5 most similar patients among their neighbors shared common entities including worsening condition when standing up, empty feeling in the ears, left side, worsening condition after physical exertion, thin and white coating on the tongue, red tongue, anxiety, thin pulse, and continuous symptoms. Patient 3 (ID 423) and the top 5 most similar patients among their neighbors shared common entities including worsening condition after physical exertion, worsening condition at night, left side, use of headphones, exercise, pale tongue, thin coating on the tongue, tinnitus, middle to low frequency, and intermittent symptoms. By comparing the common entities between the patients and their top 5 most similar neighbors, we found that entities such as worsening condition after physical exertion and left side had higher scores in the differential diagnosis of the 2 syndrome types. However, ML algorithms were prone to confusion in the differential diagnosis because both QDSS and KED could be present in patients with these symptoms.

Textbox 1. Misclassified patient entity.

Patient 1 (ID 415)

- Aggravation when standing up, ear emptiness, left side, aggravation after work, hypertension, tongue redness, anxiety, fine vein, hearing loss, duration, male, and dizziness.

Patient 2 (ID 601)

- Aggravation when standing up, ear emptiness, left side, aggravation after work, thin fur, white fur, tongue redness, anxiety, fine vein, and duration.

Patient 3 (ID 423)

- Aggravation after work, nighttime aggravation, left side, use headphones, exercise, tongue dullness, thin fur, cicada chirping, and interval.

Conclusions

Tinnitus is a complex ear disease that poses challenging issues in clinical diagnosis due to the lack of specific indicators and the reliance on patient complaints. In this study, we constructed a medical knowledge graph based on EMRs and authoritative knowledge of patients with tinnitus and proposed an explainable tinnitus-assisted diagnosis model. The experimental results showed that our proposed method not only performed better in diagnostic performance with a diagnostic accuracy of over 98% for all syndromes but also offered better interpretability compared to general ML algorithms owing to the natural interpretability of the knowledge graph. Thus, the effectiveness of the proposed method was demonstrated to assist Chinese medicine doctors in diagnosing tinnitus during clinical practice.

Abstract

Background: Diagnostic errors pose significant health risks and contribute to patient mortality. With the growing accessibility of electronic health records, machine learning models offer a promising avenue for enhancing diagnosis quality. Current research has primarily focused on a limited set of diseases with ample training data, neglecting diagnostic scenarios with limited data availability.

Objective: This study aims to develop an information retrieval (IR)–based framework that accommodates data sparsity to facilitate broader diagnostic decision support.

Methods: We introduced an IR-based diagnostic decision support framework called CliniqIR. It uses clinical text records, the Unified Medical Language System Metathesaurus, and 33 million PubMed abstracts to classify a broad spectrum of diagnoses independent of training data availability. CliniqIR is designed to be compatible with any IR framework. Therefore, we implemented it using both dense and sparse retrieval approaches. We compared CliniqIR's performance to that of pretrained clinical transformer models such as Clinical Bidirectional Encoder Representations from Transformers (ClinicalBERT) in supervised and zero-shot settings. Subsequently, we combined the strength of supervised fine-tuned ClinicalBERT and CliniqIR to build an ensemble framework that delivers state-of-the-art diagnostic predictions.

Results: On a complex diagnosis data set (DC3) without any training data, CliniqIR models returned the correct diagnosis within their top 3 predictions. On the Medical Information Mart for Intensive Care III data set, CliniqIR models surpassed ClinicalBERT in predicting diagnoses with <5 training samples by an average difference in mean reciprocal rank of 0.10. In a zero-shot setting where models received no disease-specific training, CliniqIR still outperformed the pretrained transformer models with a greater mean reciprocal rank of at least 0.10. Furthermore, in most conditions, our ensemble framework surpassed the performance of its individual components, demonstrating its enhanced ability to make precise diagnostic predictions.

Conclusions: Our experiments highlight the importance of IR in leveraging unstructured knowledge resources to identify infrequently encountered diagnoses. In addition, our ensemble framework benefits from combining the complementary strengths of the supervised and retrieval-based models to diagnose a broad spectrum of diseases.

Introduction

Background

Identifying an accurate and timely cause for a patient's health problem represents a challenging and complex cognitive task. A clinician must consider a complex range of composite information sources, including the patient's medical history, current state, imaging, laboratory test results, and other clinical observations, to formulate an accurate diagnosis. Diagnostic errors are a leading cause of delayed treatment, potentially affecting millions of patients each year. Research suggests that these errors contribute to 6% to 17% of adverse events [1].

Studies [2,3] have shown that, rather than relying on a single physician for a final diagnosis, obtaining recommendations from multiple physicians increases diagnostic accuracy. To improve the diagnostic process while maintaining economic feasibility, different variants of automated assistants, also known as diagnostic decision support systems (DDSSs) and symptom checkers, have been introduced [4]. Early DDSSs [1,5] were driven by structured databases that maintain information about diseases and other medical information in a structured form. Although promising, these systems have yet to be highly successful for several reasons, including limited accessibility, poor flexibility, and scalability issues [6,7]. Hence, the traditional DDSS is gradually being replaced by machine learning and deep learning models.

Recent studies [8-13] highlight the importance of electronic health records for supervised machine learning algorithms in health care. These algorithms use the electronic health record of a patient as input to predict their diagnosis. However, supervised model development has been limited to a select number of diseases with higher prevalence and extensive documentation due to the availability of large amounts of labeled data. As a result, infrequently occurring diagnoses remain poorly studied. In real-world diagnostic scenarios, physicians are faced with the challenge of identifying the correct diagnosis from a plethora of possibilities. Therefore, a system that considers a broad range of diagnoses, including rare conditions, is desirable for improved diagnostic accuracy. However, recent studies [14,15] demonstrate that traditional supervised learning models are challenging to use in such scenarios due to their reliance on large, labeled data sets with many examples per diagnosis. However, most clinical cohorts exhibit imbalanced class distributions, characterized by a long-tailed pattern [15,16] in which certain diagnostic classes represent most training samples whereas others exhibit few or even 0 data points. In such scenarios, most traditional supervised models overfit the majority class, resulting in poor performance for the minority classes. As such, large labeled data sets may not be a straightforward solution for achieving an efficient supervised classifier that supports diverse diagnoses.

In response, researchers have leveraged a technique called transfer learning, which is a widely used method for building classifiers that enables generalization to classes with limited labeled data. A common transfer learning technique involves fine-tuning pretrained models—models trained on large and diverse data sets—on a smaller, domain-specific corpus to enhance model performance. However, the effectiveness of this approach still relies on the size of the data set available for fine-tuning. Zero-shot learning and few-shot learning [17,18] represent promising alternatives for fine-tuning large models with limited labeled data. In zero-shot learning, the model can classify samples from classes without labeled training data. Few-shot learning requires at least one labeled example per class to enable the model to make accurate predictions. Although some studies [19,20] have shown that pretrained language models have zero-shot and few-shot learning capabilities, their performance remains inferior to that of models trained on extensive labeled data. While zero-shot and few-shot approaches have demonstrated success in the vision domain [21,22], their application to language models remains an ongoing area of research.

Leveraging external knowledge resources can improve predictive performance, especially with a limited training sample size, as shown in previous work by Prakash et al [7] and Müller et al [6]. Classical information retrieval (IR) systems can use a vast collection of resources for various applications with low computational complexity and no need for labeled data. In the medical setting, studies [23-25] and competitions such as the text retrieval conference (TREC) clinical decision support track [26] have focused on developing and evaluating IR systems to support clinician decision-making. Typically, these IR systems have been applied to biomedical literature retrieval to aid in clinical decision support. However, these systems can also be adapted for other downstream clinical tasks. For example, Naik et al [27] trained a model to predict patient admission outcomes (ventilation need, mortality, and length of stay) by integrating relevant medical literature with patient notes, leaving an open question of how IR systems would fare in directly predicting the underlying diagnosis. Therefore, our study applied IR techniques to perform literature-guided diagnostic prediction.

Objectives

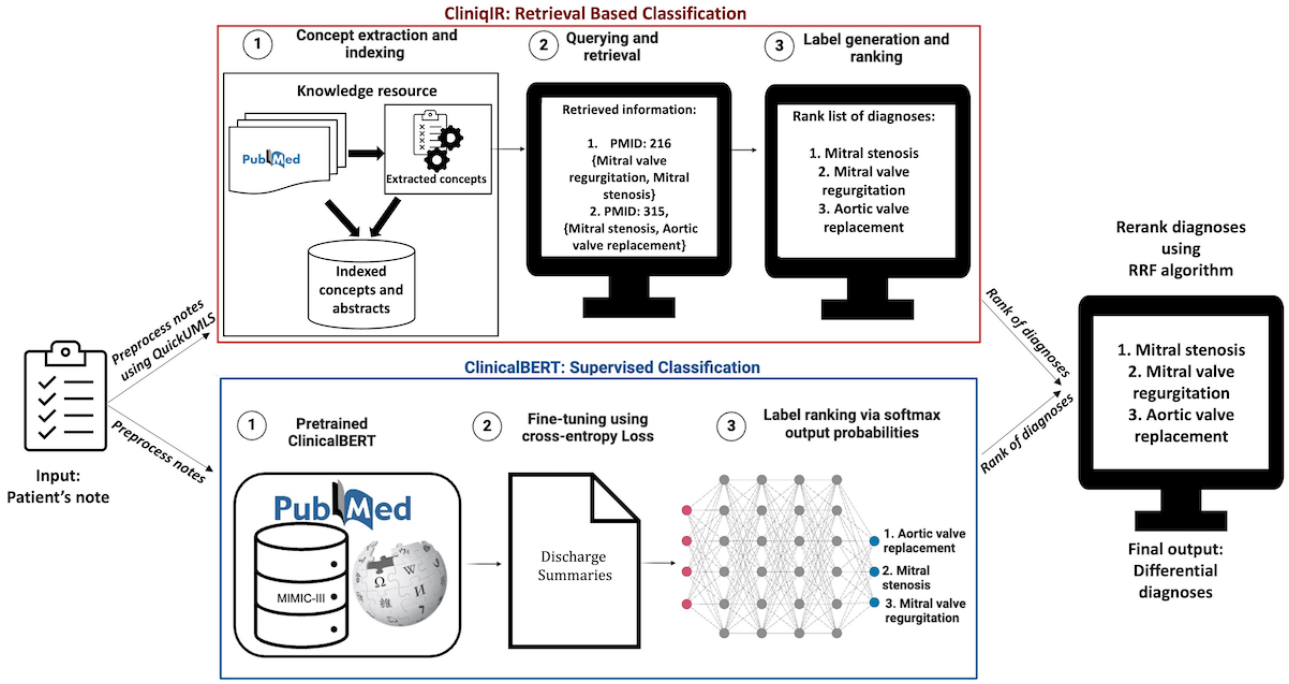
We introduce "CliniqIR," a novel clinical decision support algorithm that uses an IR system to match a patient's medical record to a specific diagnosis from a large pool of possible diagnoses. Our study aimed to improve the current state of predictive modeling and diagnostic decision support for a broad range of diagnoses regardless of their training data availability. By using clinical text records and external knowledge sources, including the Unified Medical Language System (UMLS) Metathesaurus [28] and PubMed abstracts [29], we demonstrated that "CliniqIR" successfully generalizes to less common diagnostic categories with heavily skewed data distributions. Our work also shows CliniqIR to be highly adaptable, allowing for easy integration with any IR system. This flexibility ensures the model's ability to adapt to available resources and work across various retrieval methods.

To assess CliniqIR's ability to predict diagnoses with no available training samples, we evaluated its performance on the DC3 data set [30]. We compared its performance to that of pretrained clinical models in a zero-shot setting, and our results showed that CliniqIR has the capability to recognize a broad spectrum of rare and complex diseases without relying on labeled training data. We also compared the performance of

CliniqIR with that of supervised fine-tuned pretrained biomedical large language models and found that supervised models have limitations when used on highly imbalanced data, especially for diagnoses with limited training samples. Then, we leveraged an ensemble strategy combining CliniqIR and a fine-tuned Clinical Bidirectional Encoder Representations from Transformers (ClinicalBERT) to make predictions for a wide range of diagnoses that include frequent and infrequent conditions, summarized in Figure 1.

Our study highlights the valuable synergy between retrieval-based systems and supervised learning models, showcasing how their combination can achieve state-of-the-art performance, particularly in data sets characterized by a long-tailed distribution. This finding holds significant promise and offers new avenues to address the challenges of imbalanced data in various domains.

Figure 1. CliniqIR and Clinical Bidirectional Encoder Representations from Transformers (ClinicalBERT), classify patient notes and generate ranked lists of potential diagnoses. The reciprocal rank fusion (RRF) ensemble reranks the lists from both models to provide clinicians with a more accurate final ranking of differential diagnoses to aid the diagnostic process. MIMIC-III: Medical Information Mart for Intensive Care III; PMID: PubMed ID.



Methods

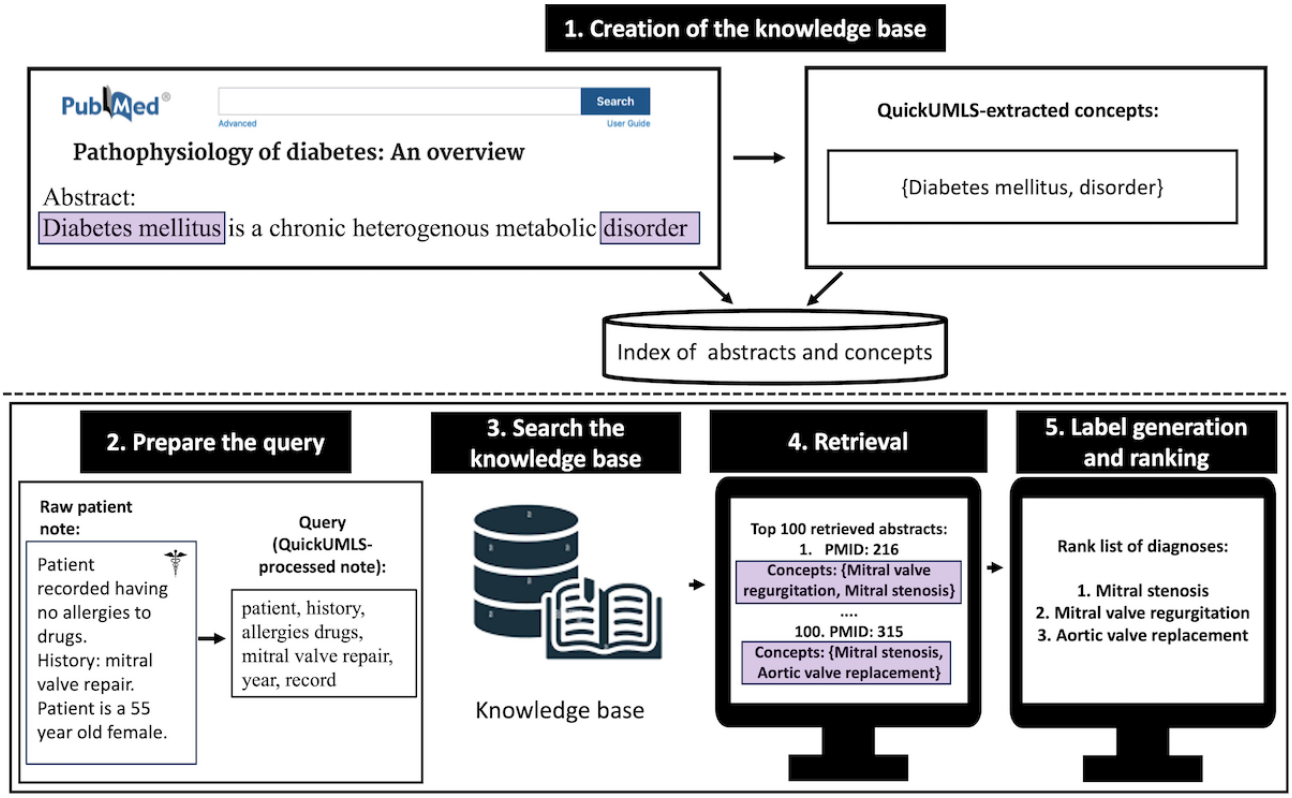
CliniqIR: The Retrieval-Based Model

Overview

We present CliniqIR, a novel literature-guided system that maps a patient's note to a specific diagnosis. By leveraging unlabeled external knowledge sources, CliniqIR uses an IR system to classify a wide range of diagnoses without relying on the availability of notes for each individual diagnosis (labeled training data). As a result, CliniqIR represents a valuable disease classification tool when labeled training data are limited or unavailable.

An overview of our method is shown in Figure 2. The backbone of CliniqIR is its knowledge base. Once the knowledge base is built, we can query the system to provide a list of probable diagnoses. In this study, a clinical narrative with a patient's medical history or summary was preprocessed and treated as a query. To make inferences given a patient's clinical note, as a preprocessing step, we first used QuickUMLS (Soldani and Goharian [31]) explained in the *Knowledge Extraction Using QuickUMLS* section, to extract medical keywords from the note to obtain a query. Next, we fed the query (preprocessed note) to the retrieval system, which returned a list of matching relevant PubMed abstracts alongside the medical conditions mentioned in each abstract. Afterward, we selected the top 100 items from the list and then computed the frequency of each concept across the list of abstracts. Finally, the model returned a list of concepts ranked according to their term frequency–inverse document frequency (TF-IDF) defined in equation 1. The list returned was similar to a medical differential diagnosis (a ranked list of possible diagnoses that could cause a patient's illness). The medical condition with the highest TF-IDF score was predicted as the most likely diagnosis. We provide a detailed description of the individual processing steps in the following sections.

Figure 2. Overview of CliniqIR, the retrieval-based clinical decision support system. PMID: PubMed ID.



Concept Extraction and Indexing

We extracted unique medical concepts (conditions) from each PubMed abstract using QuickUMLS, described in the *Knowledge Extraction Using QuickUMLS* section. Medical concepts included diseases, symptoms, or any information about a medical procedure. Subsequently, we built the knowledge base of the retrieval system by indexing each abstract and its corresponding article title, article ID, and a concept dictionary that contained all the unique concepts mentioned in that abstract. Indexing involves storing and organizing data to enable efficient IR at search time. Using the index of PubMed abstracts, the model inputs a patient's notes as a query and returns relevant information from the indexed abstracts as an output. Figure 2 provides visual details.

Querying and Retrieval

Once the index was built, we submitted queries to the retrieval system. The *Retrieval System Implementation* section provides more details. After we submitted a query, the system returned a list of abstracts and their corresponding attributes (dictionary of concepts, article title, and article ID number) ranked according to query relevance. For each query, we selected the top 100 abstracts because the top few documents are most likely to contain relevant query information.

Label Generation

After the querying operation, we focused on the extracted concepts of the top 100 abstracts. The previous retrieval phase can potentially return multiple abstracts that contain similar information in response to a given query, resulting in concept dictionaries of ≥2 abstracts containing similar concepts. Multiple occurrences could indicate the relevance of a concept across abstracts. To account for such duplication, we calculated each unique concept's recurrence, or term frequency (TF), across the list. The TF of a concept across a list of abstracts would be 1 if it appeared in only 1 abstract. If it appeared in 2 abstracts, its TF would become 2, and so on. Calculating the recurrence of concepts across the top-100 list resulted in a new list that contained medical concepts and their TFs. These medical concepts were regarded as labels and used for classification purposes. Thus, each unique concept became a potential diagnosis, and the TF of each concept is subsequently used for ranking purposes in equation 1. Textbox 1 describes the concepts the model returned (in no order of importance) after the retrieval stage given a set of queries processed using QuickUMLS. The list was filtered for a simple illustration. As mentioned previously, concepts are biomedical terms that include symptoms, signs, and diseases, among other things. On the other hand, a diagnosis could represent a disease, an injury, a neoplastic process, or a medical term describing a condition a patient is experiencing. Therefore, to account for a wide range of possible diagnoses, we kept all concepts in the label generation phase, and we considered a concept as a diagnosis when it matched the ground truth. Therefore, in this paper, we use *concepts* and *diagnoses* interchangeably.

Textbox 1. The output returned by the retrieval-based model (CliniqIR) given a query.

Query and concepts retrieved (labels)

- Abdominal pain, bloating, rectal bleeding, weight loss, anxiety, disruptive thoughts, and suicidality: "generalized anxiety disorder," "panniculitis," "chronic abdominal pain," "Burkitt's lymphoma," and "Whipple's disease"
- Chest pain, radiation to neck, dyslipidemia, lung crackles, bradycardia, and ST elevation: "acute myocardial infarction," "acute coronary syndrome," "coronary artery disease," "myocardial ischemia," "myopericarditis," and "myocardial infarctions"
- Night sweats, abdominal pain (pleuritic), nausea, loose stools, lymphadenopathy (inguinal), plaques, leucopenia, neutrophilia, and elevated (Angiotensin converting enzyme) ACE: "sarcoidosis," "lymphomas," "lymph node," "tuberculosis," "lupus erythematosus," "Rosai-Dorfman disease," and "Kikuchi-Fujimoto disease"

Ranking and Predictions

It is important to note that our model differs from traditional classification schemes. In our case, the observed mappings between patients' notes and ground-truth diagnoses are not provided for learning purposes. Therefore, a list of relevant diagnoses (a subset of the retrieved concepts) must be generated independently for each query. However, as the diagnosis list is not generated based on ground truth, it may contain information that is not relevant to the data set to be evaluated. For example, given a data set with 3 possible ground-truth diagnoses—*lymphoma*, *coronary artery disease*, and *gastroenteritis*—the model might return concepts such as *coronary artery disease*, *myocardial infarction*, and *chest pain* in the label retrieval phase for a query whose ground truth is *coronary artery disease*. To address this and ensure a fair comparison with other classification models, we filtered the retrieved concepts during the evaluation and only kept diagnoses that were part of the ground truth. Therefore, in the aforementioned example, we filtered out *myocardial infarction* and *chest pain*. Then, we assigned ranks to the remainder of the diagnoses in the list using the TF-IDF function shown in equation 1:

$$\text{TFIDF}(c,a,d) = \text{TF}(c,a).\text{IDF}(c,d) \quad \textbf{(1)}$$

Knowledge Resources: PubMed Abstracts

Over the years, research in predictive modeling for diagnostic decision support has witnessed enormous success in transfer learning, particularly where a model leverages an auxiliary data source (often a knowledge base) to perform several predictive tasks. Some studies [7,22,32] have used resources such as Wikipedia and PubMed [29] to create systems that perform classification tasks or retrieve useful articles with specific information. In contrast, most early DDSSs [1,33] were built on structured knowledge bases; however, most computable knowledge bases are not freely accessible.

Inspired by previous research, we used abstracts from PubMed articles as an unstructured collection of knowledge resources to guide the prediction of diagnoses for all our experiments. An abstract may contain information about a specific condition, its signs, or its symptoms. Some abstracts include medical case reports, whereas others may contain information about a medical device. To build a retrieval system grounded in reliable information, we leveraged the vast collection of abstracts in the PubMed database. PubMed, maintained by the National Library of Medicine, houses >33 million citations for biomedical literature, encompassing life science journals and books dating back to 1946. However, the number of abstracts available per condition varies considerably. Therefore, for our core experiments, we implemented a 100-abstract inclusion threshold for diagnoses (Multimedia Appendix 1).

Knowledge Extraction Using QuickUMLS

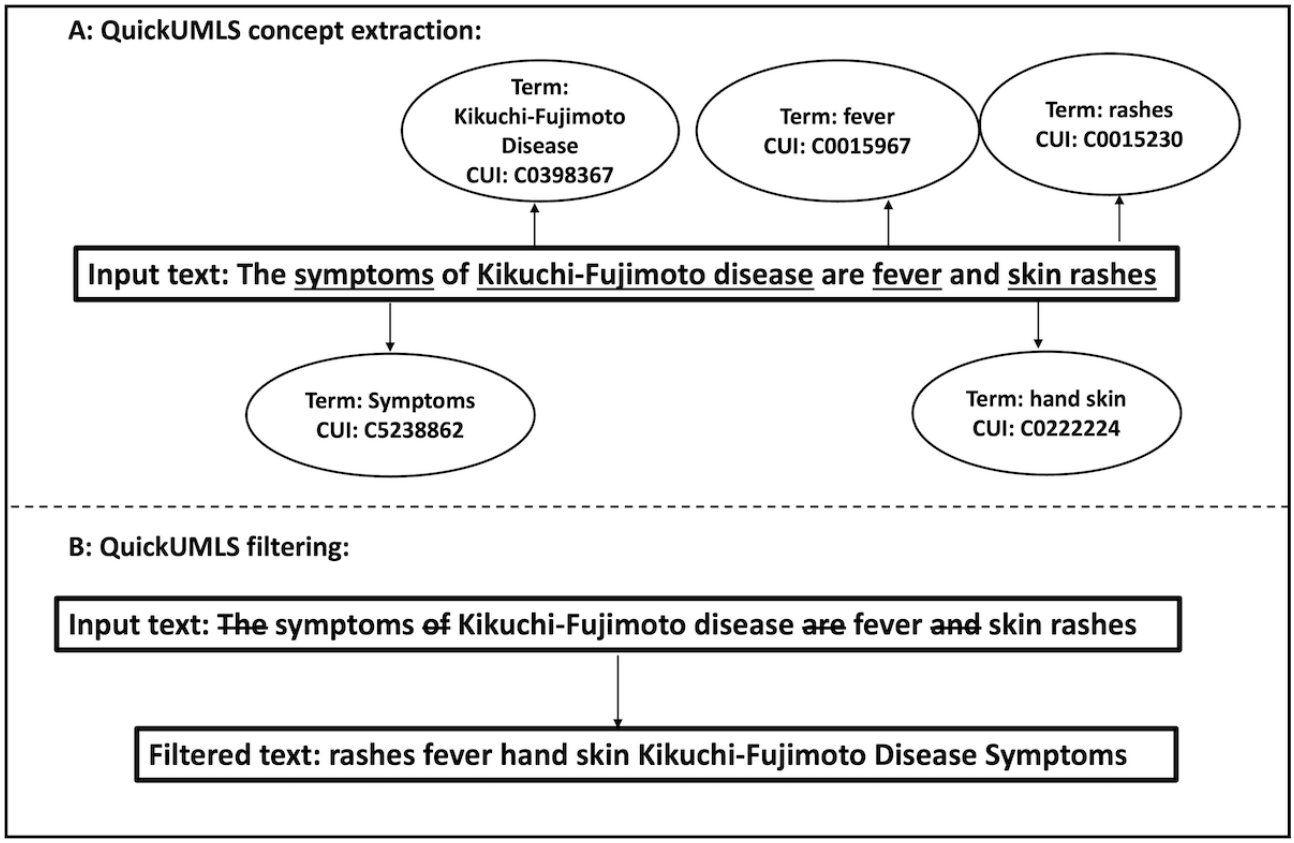
Overview

QuickUMLS [31] is an unsupervised medical concept extraction tool that detects mentions of medical entities such as diseases, symptoms, and other medical concepts from unstructured text. Given a document, QuickUMLS matches each possible token in the document against concepts in the UMLS [28]. In this study, we used QuickUMLS for 2 different purposes.

Extraction

We used QuickUMLS to extract unique biomedical concepts from each PubMed abstract. A concept can be any medical term, including a diagnosis or symptom. As shown in Figure 3, each biomedical term in a text is a concept with a corresponding unique alphanumeric identifier (concept ID) in the UMLS vocabulary. We kept all the concepts associated with each abstract in a dictionary.

Figure 3. Outputs from the QuickUMLS tool developed by Soldani and Goharian [33] showing: (A) a graph of extracted concepts and their concept unique identifier (CUI) for a specific input text; the underlined texts are considered important words, and their corresponding Unified Medical Language System terms and CUIs are returned, (B) a query processing pipeline. Each text marked with a strike-through is filtered out to obtain a query.



Filtering

We also used QuickUMLS as a data preprocessor to filter out noisy, uninformative, and nonclinical terms, such as stop words, from a patient's clinical note, resulting in a query that contained only medical terms. Citing the input text example in Figure 3, the outcome of the filtering operation was "rashes fever hand skin Kikuchi-Fujimoto disease symptoms." This filtering step is equivalent to keeping only the QuickUMLS-recognized medical terms and concepts.

Retrieval System Implementation

Overview

CliniqIR is designed to be highly adaptable to arbitrary IR systems. This flexibility ensures the model's ability to work across various retrieval methods, adapting to the resources available. In this study, we performed experiments on a sparse and a dense retriever.

Sparse Retriever

We built our knowledge base by indexing PubMed abstracts and their concepts using Apache Lucene (Apache Software Foundation [34]), which enables users to search this index with queries ranging from single words to sentences. The relevance of an abstract to a query is determined by a similarity score, with Lucene's default "BM25" [35] function estimating the best-matching abstract.

Dense Retriever

Unlike sparse retrievers, which represent queries as word frequencies, dense retrievers capture the semantic meaning and relationships within the text using dense embedding vectors. This allows for retrieval based on similarity, usually calculated through maximum inner-product search. To implement this approach, we leveraged the Medical Contrastive Pre-trained Transformers (MedCPT) [36], a state-of-the-art biomedical retrieval system in a zero-shot setting using its default parameters. Section S1 and Figure S1 in the Multimedia Appendix 1 provides details on the parameter settings for both retrieval systems.

Pretrained Transformer Models

In this study, we used 2 well-known methods, namely, supervised fine-tuning and zero-shot learning, to harness the benefits of transfer learning from 6 pretrained clinical and biomedical language models. The models we used are ClinicalBERT, PubMed Bidirectional Encoder Representations from Transformers (PubMedBERT), Scientific Bidirectional Encoder Representations from Transformers (SciBERT), Self-alignment Pretrained Bidirectional Encoder Representations from Transformers (SapBERT), cross-lingual knowledge-infused medical term embedding (CODER) and MedCPT. We describe them briefly in the follows:

ClinicalBERT Model

The ClinicalBERT [37] is an extension of Biomedical Bidirectional Encoder Representations from Transformers [38]

trained further on discharge summary notes from the Medical Information Mart for Intensive Care III (MIMIC-III) database [39]. It was designed to handle the complexity and nuances of clinical text.

PubMedBERT Model

PubMedBERT [40] was specifically designed to capture domain-specific knowledge present in biomedical literature. It was initialized from Bidirectional Encoder Representations From Transformers (BERT) and trained further on the collection of PubMed abstracts.

SciBERT Model

SciBERT [41] is a BERT-based language model pretrained on 1.14 million full-text papers from Semantic Scholar. The corpus domain cuts across the field of computer science and the biomedical space.

SapBERT Model

SapBERT [42] is also a BERT-based model initialized from PubMedBERT. SapBERT was further pretrained on UMLS [28], which consists of a wide range of biomedical ontologies for >4 million concepts.

CODER Model

CODER [43] is another BERT-based model formulated to generate biomedical embeddings. It was also initialized from PubMedBERT. CODER was further pretrained using the concepts from the UMLS [28] and optimized to increase the embedding similarities between terms with the same concept unique identifier.

MedCPT Model

MedCPT [36] is a contrastive pretrained PubMedBERT-based model also formulated to generate biomedical text embeddings for multiple tasks.

Supervised Fine-Tuning

Given a set of patients' notes (hereinafter also referred to as *notes*) as inputs and their corresponding diagnoses as outputs, we fine-tuned the pretrained models in a supervised fashion to classify diagnoses by feeding in a series of notes and their corresponding ground-truth diagnoses. Each note was a textual document describing a patient's health condition and medical history. The ground-truth diagnosis of a note was the corresponding health condition of the patient. Multimedia Appendix 1 provides details of the models' parameter settings. After fine-tuning, given a test set of notes, a model assigned probabilities to each ground-truth diagnosis for each note. The diagnosis with the highest probability corresponded to the model's most confident prediction. We assigned ranks to each diagnosis in the order of their decreasing probability score for all our predictions. These ranks were further used to compute the mean reciprocal rank (MRR) for model evaluation (refer to the *Evaluation Metrics* section for details). We justify the use of ranking output probabilities across classes to compute the MRR because the probabilities generated by the classifier represent the classifier's confidence in predicting each incidence. Supervised fine-tuning requires diagnosis-specific training data (availability of historic patient notes for each diagnosis) to deliver state-of-the-art performance. Unfortunately, labeled data are expensive to generate. This requirement makes it impractical to use a supervised fine-tuned model to diagnose those diseases without (many) notes for training. Hence, we used this method to make predictions only when training data were available.

Zero-Shot Learning

Given our focus on predicting diagnoses with few or 0 training samples, we included zero-shot learning methods as baselines. Leveraging the high quality of the aforementioned pretrained transformer embeddings, we adopted a zero-shot strategy by classifying patients' notes based on their semantic similarity to potential diagnoses. This can be achieved by using pretrained models as biencoders [18,44]. Using this approach, we accounted for the diagnosis classes (classes without training samples) that the supervised fine-tuned models could not handle.

Given a patient's note (our query) and the list of candidate diagnoses as labels, we used different variants of BERT as biencoders to encode queries and the full names of all ground-truth diagnoses to produce their respective representation vectors separately. Next, we computed their cosine similarity score and ranked each diagnosis for each query according to this score. The diagnosis with the highest cosine similarity became the model's most confident diagnostic prediction (refer to Multimedia Appendix 1 for more details).

Model Ensemble: Reciprocal Rank Fusion

The label retrieval process allowed the CliniqIR (retrieval-based model) to diagnose unseen conditions regardless of training data availability. This property is beneficial for diagnoses with little or no training data. On the other hand, a supervised fine-tuned model can draw much deeper insights from available historical case data. We adopted an ensemble strategy to combine the advantages of both paradigms.

In IR and general machine learning, ensemble strategies combine results from multiple models to produce a single joint output. Ideally, the ensemble model should produce a new output whose performance is superior to that of the individual constituent models. Several studies [32,45,46] have shown that high-performance gains can be achieved through model ensembling. One of the simplest ways to build such a model is to focus on applying a reranking heuristic to the ranks of each item in a model's output list. Hence, we collected the ranked list of diagnoses from a CliniqIR model and that of the best-performing supervised fine-tuned model, ClinicalBERT, and combined the 2 lists. We then applied a modified version of the reciprocal rank fusion (RRF) [45] algorithm using equation 2 to merge their results and produce a single, final output list. Given a set *C*of concepts(diagnoses) to be ranked and a set of rankings *R*for all concepts obtained from each ensemble member (CliniqIR and ClinicalBERT), we computed the RRF score for each concept ($c \in C$) as follows:

(2)

In the aforementioned equation, "$r \in R$" is the rank of concept *c*according to an ensemble member. We summed up the individual ranks of a concept from each ensemble member "$r(c)$"

with *k* and computed the inverse. Previous work by Cormack et al [45] reported that setting *k*to 60 was the near-optimal choice for most of their experiments. Hence, we set *k* to 60 for all experiments. When concepts (diagnoses) had more than one training sample, we selected their individual ranks *r*from each ensemble member to compute the RRF score; otherwise, we selected ranks from the CliniqIR model. We used the RRF algorithm due to some key advantages: (1) it is a simple unsupervised method that eliminates the need for training samples, and (2) it effectively combines the results from various models without reliance on a weighting or voting mechanism.

Experimental Setup

Data Sources

DC3 Data Set

The DC3 data set [30] was designed specifically for the evaluation of diagnostic support systems. The data set comprises 30 rare and difficult-to-diagnose cases compiled and solved by clinical experts in the *New England Journal of Medicine* Case Challenges. This data set lacks large, labeled training data, but it covers a wide range of diagnostic cases for various specialties. Therefore, we used this data set to determine the applicability of CliniqIR for diagnostic inference when the underlying patient condition is rare. Each case is a patient's note and its corresponding true diagnosis written as free text. We mapped the true diagnoses to their UMLS concept IDs to produce test labels for evaluation consistency. When we did not find an exact matching term for a diagnosis, we considered the closest match returned by the UMLS browser. During the preprocessing step, we found that some cases in the DC3 data set had multiple terms representing a ground-truth diagnosis, making it difficult to find a single UMLS concept ID for such cases. To ensure an accurate mapping with the UMLS concept IDs, we split such cases into separate terms. For example, the case "Acute and chronic cholecystitis and extensive cholelithiasis with transmural gallbladder inflammation" was split into 2 separate terms: "Acute and chronic cholecystitis" and "Extensive cholelithiasis with transmural gallbladder inflammation." Then, we mapped each case to its corresponding UMLS concept ID. Next, we computed the document frequency of all the true diagnoses (now represented as concepts) across all PubMed abstracts. In these cases, either of the concepts could be considered as the ground truth. As the data did not contain sufficient notes to train a model, we formulated this task as a zero-shot multiclassification problem. Specifically, we expected a model to predict the underlying condition given a patient's note without labeled training data.

MIMIC-III Data Set

The MIMIC-III [39] is a freely accessible medical database that contains information on >50,000 intensive care unit patients. The data include laboratory events, vital sign measurements, clinical observations, notes, and diagnoses structured as *ICD-9-CM* (*International Classification of Diseases, Ninth Revision, Clinical Modification*), codes. We worked with the discharge notes for all experiments because they document a free-text synopsis of a patient's hospital stay from admission to discharge. In MIMIC-III, each discharge note is mapped to multiple diagnoses ranked according to priority. We considered the highest-priority diagnosis to be the admission's ground-truth diagnosis (and prediction target). We excluded admissions primarily for birth and pregnancy as they did not represent a primary pathological diagnosis. After preprocessing, the discharge notes contained 2634 unique *ICD-9-CM* diagnoses. We mapped these *ICD-9-CM* diagnoses to their corresponding UMLS concept IDs to calculate their TF across the knowledge resource (PubMed abstracts). The resulting unique diagnoses were associated with notes ranging from thousands of occurrences of frequent conditions, such as coronary atherosclerosis and aortic valve disorders, to rare ones, such as Evans syndrome and ehrlichiosis, with just a single instance forming a long-tailed distribution. A total of 902 diagnoses fell into the singleton category. One discharge note representing a specific diagnosis is insufficient to train and test a model. Thus, we reserved all diagnoses with only 1 available note for model testing. For diagnoses with <5 note samples, we reserved 1 sample for testing, and the rest were included in model training. We split the remainder of the data set (instances of diagnoses with ≥5 associated notes) into training, validation, and testing sets in the ratio 70:15:15; this split resulted in the training set containing notes representing 1732 unique diagnoses and the test set containing notes representing a total of 2634 unique diagnoses (refer to Multimedia Appendix 1 for more details). For models that did not require training (eg, the retrieval model), we used the validation and training sets for hyperparameter tuning purposes and the test set for final model evaluations.

Baselines

Previous studies and competitions, such as the TREC clinical decision support track, have emphasized the development and evaluation of IR systems to aid clinical decision-making. While these systems are commonly used for evidence-based literature searches, our study explored their adaptation for direct literature-guided diagnosis prediction. Although a direct comparison to the systems in the TREC clinical decision support track was not possible, insights gained from these competitions informed the engineering of our retrieval system. To evaluate our model, we used 2 transfer learning techniques—supervised fine-tuning and zero-shot classification methods (refer to the *Pretrained Transformer Models* section)—because of their performance in scenarios where labeled data are limited or unavailable. In addition, some studies [47-49] have shown pretrained language models to attain superior performance to that of count vector–based models and traditional supervised methods in various medical tasks. We used "Z" to identify when models were used in a zero-shot classification setting, an "S" for supervised fine-tuning, and "CliniqIR" when models were used in a retrieval setting. Table 1 provides details.

Table 1. Overview of the experiments conducted using the different models and their task description.

Experiment	Models used	Task description
Retrieval-based experiments (CliniqIR)	BM25[a] and MedCPT[b]	Models retrieved relevant abstracts to inform diagnostic predictions.
Zero-shot experiments (Z)	ClinicalBERT[c], PubMedBERT[d], CODER[e], SapBERT[f], and MedCPT	Models classified diseases in a zero-shot setting without previous task-specific training.
Supervised experiments (S)	ClinicalBERT	Models were fine-tuned using labeled data for enhanced disease prediction accuracy.

[b]MedCPT: Medical Contrastive Pretrained Transformers.

[c]ClinicalBERT: Clinical Bidirectional Encoder Representations from Transformers.

[d]PubMedBERT: PubMed Bidirectional Encoder Representations from Transformers.

[e]CODER: cross-lingual knowledge-infused medical term embedding.

[f]SapBERT: Self-alignment Pretrained Bidirectional Encoder Representations from Transformers.

Evaluation Metrics

In our experiments, each model returned a ranked list of diagnoses analogous to a ranked list of differential diagnoses formulated by a medical expert. Given a query and a list of ranked items produced by a model, a simple classification accuracy metric tracks whether the model made the correct prediction at the top of the list. Instead, we used the MRR [50] because it told us *where* the true diagnosis was placed in the list in equation 3. If a model returned the reference diagnosis at rank 1 (ie, at the top of the list), the reciprocal rank (RR) was 1; if the most appropriate item was at rank 2, then the RR was 0.5. The RR decreases as the relevant item moves farther down the list. We calculated the MRR by computing the average RR across admissions. An MRR of 1 meant that the model returned the correct diagnosis at the top of its list for every patient, and an MRR of 0 implied that the model never produced a correct diagnosis. Mathematically, the MRR can be represented as follows:

(3)

where $|Q|$ denotes the total number of queries and denotes the rank of the correct diagnosis. We also calculated the mean average precision (MAP) to evaluate the balance between precision and recall of the retrieval systems (for details, refer to Multimedia Appendix 1).

Ethical Considerations

No ethics approval was pursued for this research, given that the data were publicly accessible and deidentified.This aligns with the guidelines outlined by the US Department of Health and Human Services, Office for Human Research Protections, §46.101 (b)(4) [51].

Results

CliniqIR Models Retrieved Useful Literature and Meaningful Concepts

Table 2 showcases qualitative results for 3 selected queries, displaying the top 3 documents retrieved by the CliniqIR model. Notably, the retrieved articles and their corresponding concepts demonstrated clear relevance to the ground-truth diagnoses of the respective queries.

Table 2. Qualitative overview of the top documents and concepts retrieved for 3 selected queries along with their respective correct concepts. This table illustrates the types of results our system generates for each query, showing the alignment with the ground-truth concepts.

CliniqIR Models Yielded State-of-the-Art Performance for Rare and Complex Diagnoses

We examined the retrieval-based models’ (CliniqIR) performance on the DC3 data set to show their applicability for rare and complex diagnostic cases. The absence of training data for this data set implied that supervised learning would not be applicable and the models could only make predictions in an unsupervised or zero-shot setting. Hence, on this data set, we compared the CliniqIR models’ performance to that of pretrained transformers in a zero-shot setting. In contrast to the CliniqIR model, which creates its own set of labels, we supplied the pretrained transformers with a range of potential diagnoses for each query to enable zero-shot predictions. This gave the models a significant advantage over their use in a real-world setting, where such information would not be readily available. Table 3 shows the MRR of the chosen models on the DC3 data set. Even with the supporting assumption that the range of possible diagnoses was known to the pretrained models, the CliniqIR models outperformed them with an MRR of 0.35 and 0.32 for CliniqIR_BM25 and CliniqIR_MedCPT, respectively. This means that, on average, CliniqIR_BM25 and CliniqIR_MedCPT were more likely to return the correct diagnosis within the top 3 predictions for a case.

The MRR scores of the pretrained zero-shot methods were similar to one another but markedly lower; the scores were 0.15, 0.22, 0.25, 0.25, 0.24, and 0.18 for ClinicalBERT, PubMedBERT, SciBERT, CODER, SapBERT, and MedCPT, respectively. Our results show that the CliniqIR models are capable of making useful predictions in the case of rare and complex diagnoses with limited or no training data availability.

Table 3. Performance evaluation of the models on the DC3 data sets across all case. The retrieval-based models, denoted using "CliniqIR" gave the best overall performance compared to the zero-shot models, denoted using "Z."

Model used	Mean reciprocal rank
ClinicalBERT[a] (Z)	0.15
PubMedMERT[b] (Z)	0.22

Performance on MIMIC-III

Supervised Prediction Models Failed at Making Rare Diagnoses

When training data are available, supervised models are preferred. Thus, we investigated the effectiveness of a supervised learning approach for a highly imbalanced data set such as MIMIC-III. We fine-tuned the pretrained models to predict diagnoses using available clinical notes. Diagnoses were categorized based on the frequency of associated notes to show how training data availability affects a supervised model's predictive capacity. A total of 902 diagnoses had no training data (only 1 note representative in MIMIC-III), whereas 1732 had at least one training sample (≥2 note representatives in MIMIC-III). Predictions were made only for the 1732 diagnoses, excluding those without training data. We introduced sample weights in the loss function to handle the enormous data imbalance. This approach weighs the loss computed for samples differently depending on their class training size. Our results in Figure S2 in Multimedia Appendix 1 show that ClinicalBERT performed best among all pretrained models. Hence, we used ClinicalBERT as our supervised baseline for the remainder of our experiments.

After training ClincalBERT, we tested it on different clinical note frequency–based categories (Table 4). In Table 4, we observed that the MRR score of the ClinicalBERT model was higher for diagnosis categories with many training examples (>10 notes). In addition, in the data set category with 1 to 10 notes available per diagnosis (1<notes≤10), ClinicalBERT obtained a low MRR score of 0.07. An MRR of 0.08 indicates that, on average, ClinicalBERT returned the correct diagnosis for a case among its top 13 predictions for these diagnoses. While the model could not perform predictions for 902 diagnoses due to the lack of training data, the drastic decline in ClinicalBERT's performance also indicates that the model is not suitable for making predictions for diagnoses with <10 clinical notes available for training. We also noticed a decline in performance for diagnoses with training samples between 500 and 750. This was likely due to many diagnoses having similar symptoms and manifestations. Therefore, the supervised learning approaches struggle to find a fine delineation of boundaries between similar classes without sufficient training data.

Table 4. Performance of the best-performing fine-tuned supervised model, Clinical Bidirectional Encoder Representations from Transformers on the Medical Information Mart for Intensive Care III data set. We categorized the results by the frequency of training note representation per diagnosis.

Data set category	Mean reciprocal rank
0 note	—[a]
1≤Notes≤10	0.08
10<Notes≤50	0.33
50<Notes≤100	0.49
100<Notes≤250	0.52
250<Notes≤500	0.57
500<Notes≤750	0.44
750<Notes	0.41
0<Notes	0.37

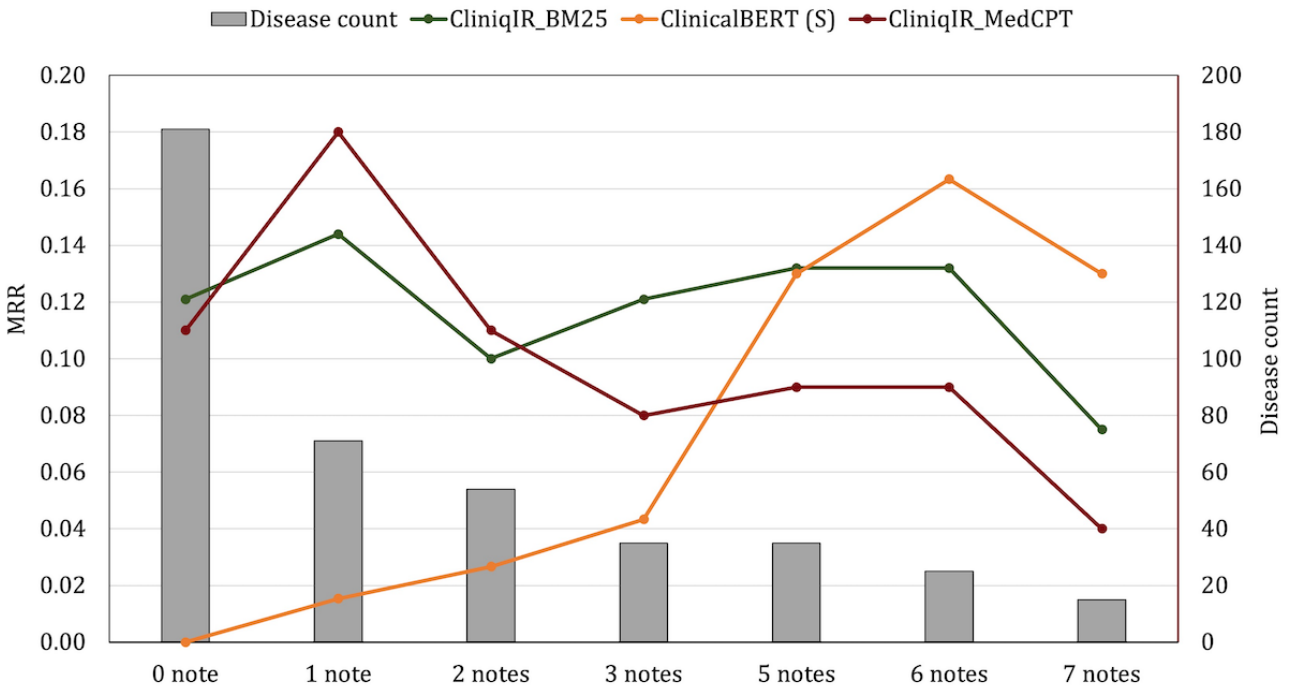
CliniqIR Models Outperformed ClinicalBERT for Rare Diagnoses

The objective of this experiment was to determine to what extent the CliniqIR models can be used in place of a supervised model when the training sample size is small. Results in Figure 4 show that CliniqIR-based models performed better than ClinicalBERT for diagnoses with up to 3 training samples. In addition, CliniqIR_BM25 and ClinicalBERT had similar MRR scores for diagnoses with 5 training samples. The average MRR score for the CliniqIR-based models was approximately 0.1 across most categories except for diagnoses with at least 7 training samples. This result indicates that, on average, their correct prediction for a query was ranked 10th on the list. The disease count bars in Figure 4 (in gray) also show that the number of diseases with <5 training samples was more than twice the number of diseases with >5 training samples. Thus, CliniqIR allows for more disease coverage and also generalizes well for cases with low note availability. This result confirms that, while supervised models may perform well with sufficient labeled training data, CliniqIR-based models' performance stands out as remarkable for diagnoses in the low-data regime.

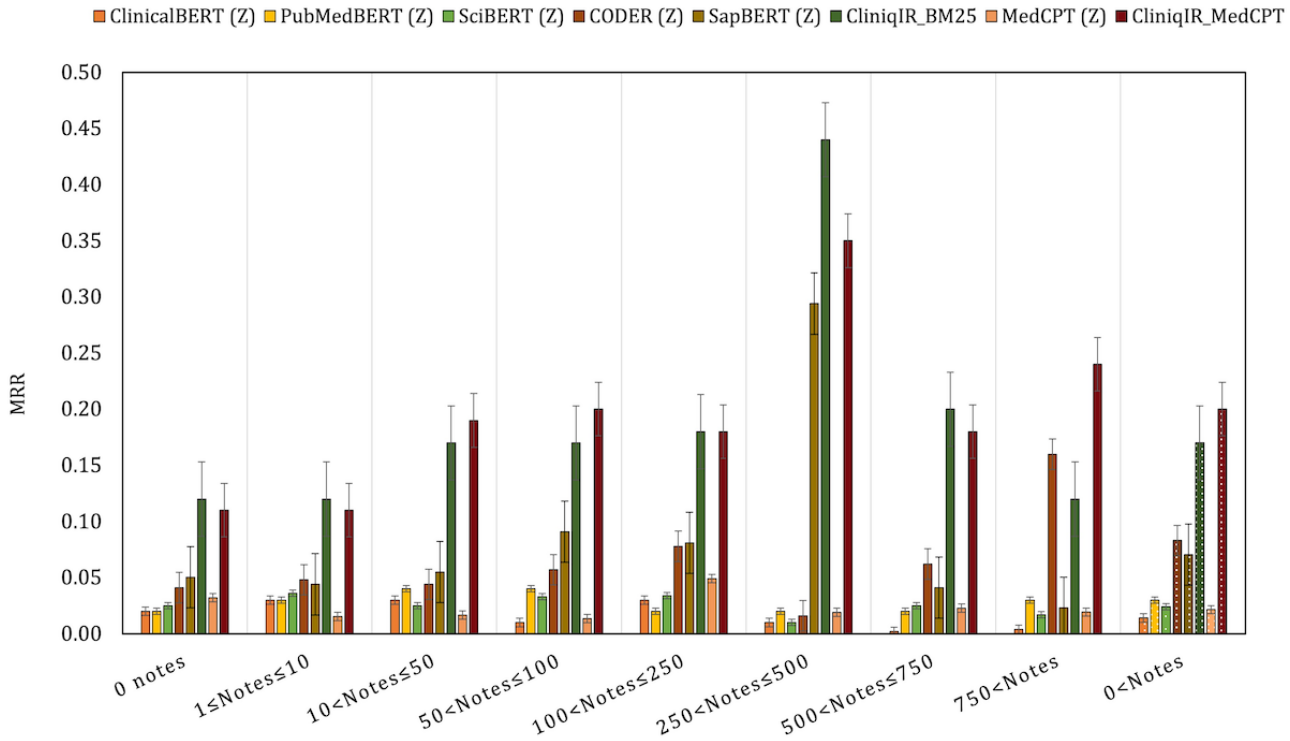
Figure 4. Mean reciprocal rank (MRR) results for CliniqIR-based models and Clinical Bidirectional Encoder Representations from Transformers (ClinicalBERT) when predicting diagnoses with training sample sizes of 0, 1, 2, 3, 5, 6, and 7. Results indicate that the CliniqIR-based models perform best when the training sample size is between 0 and 5. However, ClinicalBERT performs best as training data size increases. "S" denotes that the ClinicalBERT model was used in a supervised setting.



CliniqIR Models Outperformed Zero-Shot Baselines for Rare Diagnoses

To further demonstrate the utility of CliniqIR models for diagnoses with little or no training samples, we compared its performance to that of the pretrained models in a zero-shot setting. As mentioned previously, the MIMIC-III data set comprises >2634 diagnoses, but the supervised fine-tuned models were effective only for a subset of diagnoses with training data; 902 diagnoses had no training samples at all. In zero-shot settings, pretrained models can make predictions without reliance on training data. In Figure 5, we observe that CliniqIR models outperformed the zero-shot pretrained models across most data set categories, especially when diagnoses had a low number of associated training notes. The highest and lowest MRR scores obtained by CliniqIR_BM25 were 0.44 and 0.12, respectively, whereas CliniqIR_MedCPT's highest and lowest scores were 0.35 and 0.11.

Figure 5. Performance evaluation of CliniqIR models and each pretrained zero-shot baseline on the Medical Information Mart for Intensive Care III data set. We categorized the results by the frequency of note representative per diagnosis. "Z" represents models used in a zero-shot setting. The CliniqIR models performed best across data set categories in the low-resource regime. ClinicalBERT: Clinical Bidirectional Encoder Representations from Transformers; CODER: cross-lingual knowledge-infused medical term embeddin; MedCPT: Medical Contrastive Pre-trained Transformers; MRR: mean reciprocal rank; PubMedBERT: PubMed Bidirectional Encoder Representations from Transformers; SapBERT: Self-alignment Pretrained Bidirectional Encoder Representations from Transformers; SciBERT: Scientific Bidirectional Encoder Representations from Transformers.



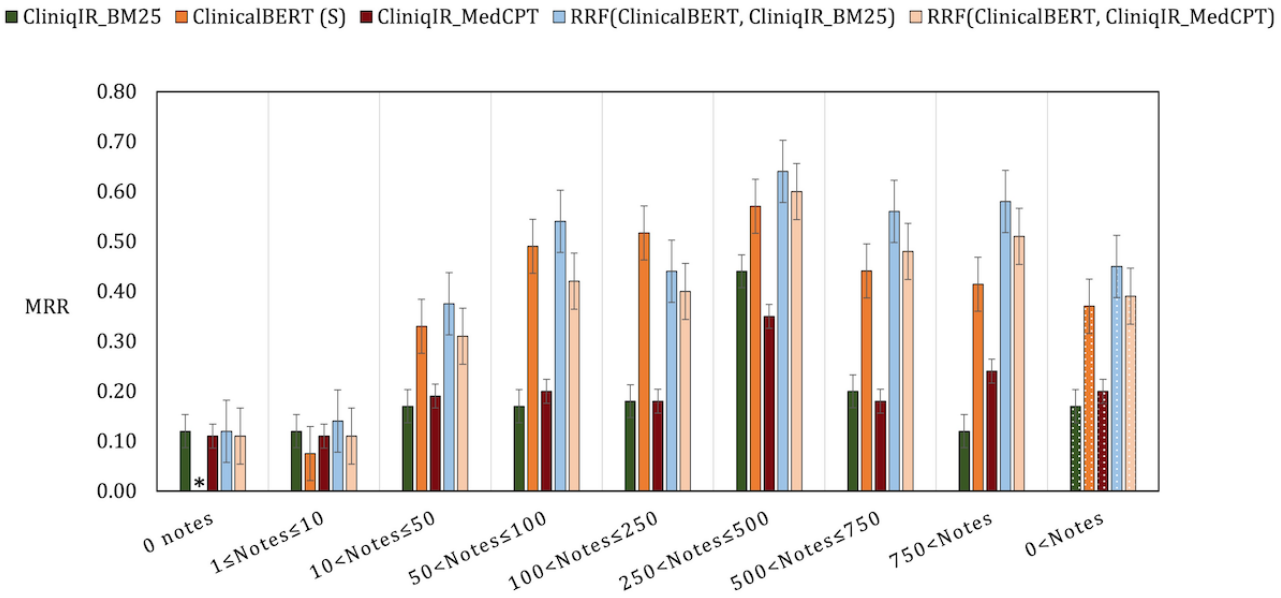
Among the zero-shot baseline, CODER and SapBERT's performances were better across most data set categories. However, in the category in which all diagnoses were considered (diagnoses with >0 notes), CODER outperformed SapBERT, obtaining a maximum and minimum MRR score of 0.16 and 0.02, respectively. These MRR scores indicate that, on average, both CliniqIR models returned the correct diagnosis for a case among their top 5 predictions. In contrast, the best-performing pretrained zero-shot baselines, CODER and SapBERT, returned an accurate diagnosis for a query among their top 15 and 12 predictions, respectively.

Ensemble Models Yielded State-of-the-Art Performance

We have shown that CliniqIR models deliver valuable diagnostic decision support in the setting of limited or unavailable training data. On the other hand, a supervised pretrained model such as ClinicalBERT is an efficient alternative when training data are abundant. To combine the strengths of both models, we used the RRF algorithm as an ensemble strategy. The RRF algorithm combines the ranks of all the ensemble members (a CliniqIR model and a supervised model) to produce a new ranked list of diagnoses for a given patient's clinical note. We hypothesized that creating an ensemble with both models would boost predictive performance across various diagnoses regardless of the availability of associated clinical notes.

To implement the RRF algorithm introduced in the *Model Ensemble: Reciprocal Rank Fusion* section, we used ClinicalBERT and a CliniqIR model to obtain separate ranked lists for each diagnosis and concept across queries. We compared the predictive performance of each individual model to that of the ensemble in terms of MRR for each note availability category. Figure 6 shows the output of the experiments before and after fusing the predicted ranks from both models.

Figure 6. Performance evaluation of the models on the Medical Information Mart for Intensive Care III data set before and after the ensemble. Adopting the reciprocal rank fusion (RRF) algorithm as an ensemble strategy boosted predictive performance across the data set. The Clinical Bidirectional Encoder Representations from Transformer (ClinicalBERT) model cannot directly make predictions for diagnoses with no training samples. Hence, we used "*" to mark such data set categories. The letter "S" denotes that ClinicalBERT was used as a supervised model. MedCPT: Medical Contrastive Pre-trained Transformers; MRR: mean reciprocal rank.



Interestingly, for either of the CliniqIR models used, the ensemble model improved the overall average performance for predicting a wide range of diagnoses (>0 notes) in the MIMIC-III data set. We also found that the RRF ensemble successfully boosted performance across diagnosis categories with both high and low note availability. On average, the RRF ensemble model performed better than either of its constituent models. Notable exceptions include the categories in which the individual mean average precision of both CliniqIR_BM25 and CliniqIR_MedCPT was <0.50 (refer to Multimedia Appendix 1 for details) and in the 100 to 250 training example range, in which the ensemble was slightly worse than the supervised model. In all other conditions, the interaction between both models (the ensemble) led to better performance.

Discussion

Principal Findings

With thousands of known diseases potentially causing a patient's condition, it is often difficult—even for experienced clinicians—to accurately diagnose every disease. Unlike the pretrained models that require user input of possible diagnoses before predictions can be made, CliniqIR represents a potential decision support tool that takes advantage of the wealth of medical literature in PubMed to generate a differential diagnosis. Our study evaluated CliniqIR's ability to formulate differentials and predict uncommon diagnoses with few or no training examples, reflecting conditions easily missed in real-life practice. Results comparing CliniqIR's performance to those of pretrained biomedical transformers in supervised and zero-shot settings highlight CliniqIR's ability to operate successfully as an unsupervised model. Therefore, our model's strength is not limited to rare and infrequent diagnosis prediction, and our model is also a useful tool for generating a first-stage differential diagnosis list. As such, a diagnostic decision support tool such as CliniqIR can enhance physician differential diagnoses and facilitate more efficient diagnoses by providing literature-guided suggestions. Beyond disease prediction, CliniqIR also demonstrates relevance in medical education as a patient-centric literature search tool. Our study demonstrated its ability to accurately cultivate a list of PubMed literature relevant to a patient's clinical narrative. This functionality could greatly improve physician researcher efficiency in performing dedicated literature reviews on behalf of their patients.

In the era of large complex neural models, it is critically important that diagnostic support tools remain simple and interpretable. In health care, where decision-making is critical and patient outcomes are at stake, clinicians' ability to understand and trust the inner workings of a diagnostic tool is paramount. In response, CliniqIR is built on retrieval systems that use simple and transparent weighting schemes to retrieve and rank important terms in a collection of documents. This transparency fosters trust in the tool's accuracy and facilitates collaboration between the tool and the health care professionals, leading to ongoing model refinement as well as enhanced clinical decision-making.

Limitations

The medical field is witnessing a growing trend in applications built on generative large language models [52]. While our work used a simpler approach, it remains valuable in scenarios with limited access to significant computing resources. In addition, it serves as a proof of concept for a retrieval-augmented medical model, potentially leading to enhanced explainability and accuracy for large language models in the health care domain.

Our study has 3 potential limitations. First, CliniqIR's knowledge source is limited to abstracts in PubMed, which has well-known publication biases toward certain diagnoses [53,54].

Therefore, the use of a single knowledge resource limits CliniqIR's generalizability to diseases and conditions not represented in the PubMed corpus. For instance, conditions such as COVID-19 and Alzheimer disease or rare diseases such as sarcoidosis and cholangitis are covered in thousands of published literature entries, whereas other conditions such as "cellulitis and abscess of the leg" or "closed fracture of the sternum" may receive less attention. Future studies will involve a review of seemingly unrepresented diagnostic codes by linking them back to their parent diagnostic codes to ensure appropriate mapping between diagnosis codes and PubMed.

Second, our main experimental results were restricted to diagnoses with at least 100 PubMed abstract representatives. We identified a significant number of *ICD-9-CM* codes in MIMIC-III with no associated medical literature among the 33 million PubMed abstracts (an overview of MIMIC-III diagnosis distribution classes can be found in Multimedia Appendix 1). We also found that CliniqIR's predictive performance improved with increasing PubMed coverage of the diagnosis, guiding our decision to establish the 100-abstract inclusion criterion for diagnoses (Multimedia Appendix 1). Future work will combine information from biomedical journals, medical textbooks, and Wikipedia for wider disease coverage.

Third, our MIMIC-III experiments limited the input to patient discharge summaries containing a succinct synopsis of a patient's hospital stay, including symptoms, diagnostic evaluation, clinical progression, and treatment information. In real-world clinical situations, such complete retrospective information would not be available during the initial diagnostic process. Therefore, the results presented in this paper represent a first feasibility study of CliniqIR and highlight some of the difficulties involved in developing diagnostic support tools.

Conclusions

In this study, we presented CliniqIR, an unsupervised retrieval-based model that leverages unstructured knowledge resources to aid in the diagnostic process. We showed that the CliniqIR models outperformed a supervised fine-tuned pretrained clinical transformer model in predicting diagnoses with <5 training samples. We also demonstrated that CliniqIR outperformed pretrained clinical transformers in making predictions for rare and complex conditions in a zero-shot setting. While many existing research studies on diagnostic prediction have focused on one disease at a time or only on highly prevalent conditions, we combined the strengths of CliniqIR and supervised learning to build a single ensemble model that aids in diagnosing a broad spectrum of conditions regardless of training data availability. Overall, our study reveals the potential of IR-based models in aiding diagnostic decision-making in an efficient, transparent, and educational manner. This work will direct future studies to facilitate successful application of machine learning and IR to building robust and accurate clinical diagnostic decision support tools.

Acknowledgments

LM's research is supported in part by a grant (T32DA013911) from the National Institutes of Health. We acknowledge support from the Open Access Publication Fund of the University of Tübingen.

Data Availability

The datasets analyzed during this study are available. The Medical Information Mart for Intensive Care III data set can be accessed with permission via the work by Johnson et al [39]. The DC3 data set can be accessed via the work by Eickhoff et al [30]. The code to implement this work is also available [55].

Conflicts of Interest

None declared.

Abstract

Background: Childhood tumors in the central nervous system (CNS) have longer diagnostic delays than other pediatric tumors. Vague presenting symptoms pose a challenge in the diagnostic process; it has been indicated that patients and parents may be hesitant to seek help, and health care professionals (HCPs) may lack awareness and knowledge about clinical presentation. To raise awareness among HCPs, the Danish CNS tumor awareness initiative hjernetegn.dk was launched.

Objective: This study aims to present the learnings from designing and implementing a decision support tool for HCPs to reduce diagnostic delay in childhood CNS tumors. The aims also include decisions regarding strategies for dissemination and use of social media, and an evaluation of the digital impact 6 months after launch.

Methods: The phases of developing and implementing the tool include participatory co-creation workshops, designing the website and digital platforms, and implementing a press and media strategy. The digital impact of hjernetegn.dk was evaluated through website analytics and social media engagement.

Implementation (Results): hjernetegn.dk was launched in August 2023. The results after 6 months exceeded key performance indicators. The analysis showed a high number of website visitors and engagement, with a plateau reached 3 months after the initial launch. The LinkedIn campaign and Google Search strategy also generated a high number of impressions and clicks.

Conclusions: The findings suggest that the initiative has been successfully integrated, raising awareness and providing a valuable tool for HCPs in diagnosing childhood CNS tumors. The study highlights the importance of interdisciplinary collaboration, co-creation, and ongoing community management, as well as broad dissemination strategies when introducing a digital support tool.

Introduction

Aim and Context

Primary tumors of the central nervous system (CNS) are the second most prevalent childhood cancer, constituting approximately 20% of all cases [1,2]. The 5-year survival has risen to 75% [3], but survivors face severe late effects [4]. In Denmark, approximately 50 patients younger than 18 years are diagnosed every year [3]. Early diagnosis is crucial for the quality of life of survivors, and early detection and diagnostic delay have been in focus for decades [5-7]. The presenting symptoms at the time of onset can be vague, adding difficulty to diagnostics [8]. Time from first symptom to diagnosis can be divided into intervals, with the potential to identify inequities in the diagnostic process [9]. The total diagnostic interval (TDI) is the sum of the patient interval (PI) and the diagnostic interval [DI] PI: the time from symptom onset to first contact to a health care professional (HCP). DI: time from first contact to an HCP to diagnosis. Intervals are shown in Figure 1).

Over the past decade, research has reported TDI ranging from 28 to 123 days [10-26]. Recent studies indicate a knowledge gap in HCPs, causing a delay in the DI, and advocate for interventions specifically aimed toward HCPs to reduce the DI [27-29]. To map the trajectory for Danish patients, a questionnaire study was undertaken in 2022. The results showed an elongated median TDI of 106 days, with DI providing the larger part of the delay, thus displaying that challenging diagnostic processes are present in Denmark too. The results in detail have been reported separately [30].

In 2017, The Danish Collaborative Comprehensive Childhood CNS Tumor Consortium (5C) was established, providing a long-term strategic research platform, to accelerate diagnostics and reduce late effects specifically in patients with CNS tumors [31]. The decision was made to create a Danish childhood CNS tumor awareness initiative, with the aim of reducing diagnostic delay. hjernetegn.dk was launched after 4 years of preparation. Figure 2 shows the phases of progression from 2020 onward.

Figure 1. The diagnostic route: visualization of diagnostic intervals. HCP: health care professional.

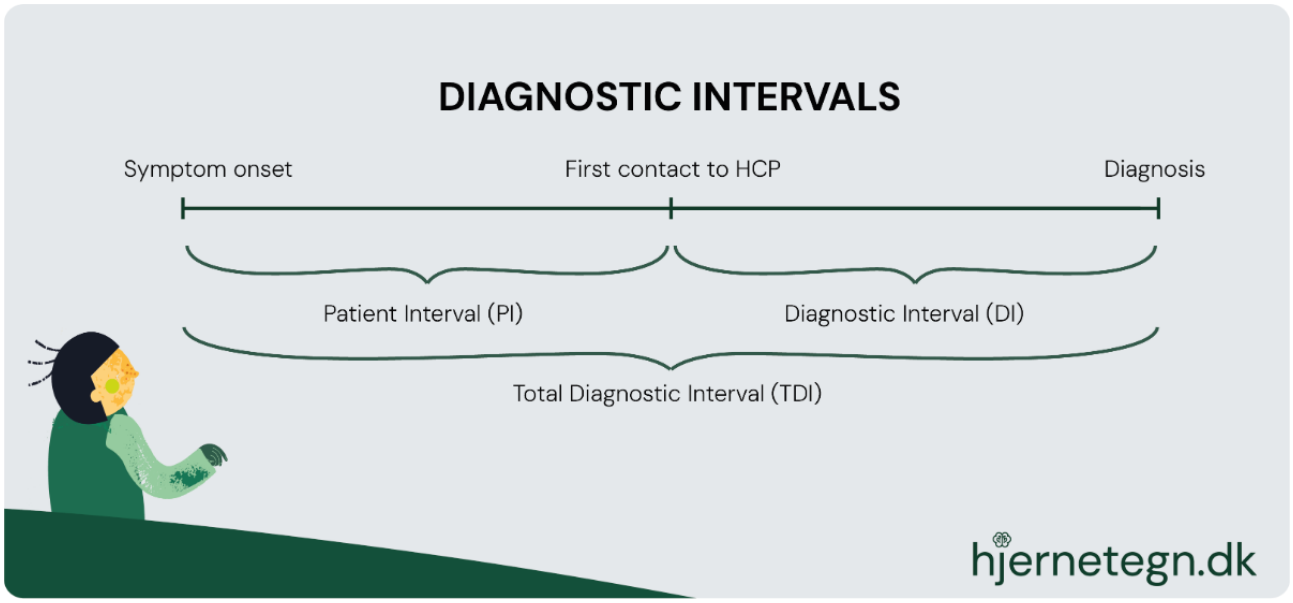

Figure 2. Workflow creating hjernetegn.dk. The initiative was launched on August 21, 2023. The evaluation of the digital impact was initiated in February 2024, 6 months after launch. SoMe: social media.

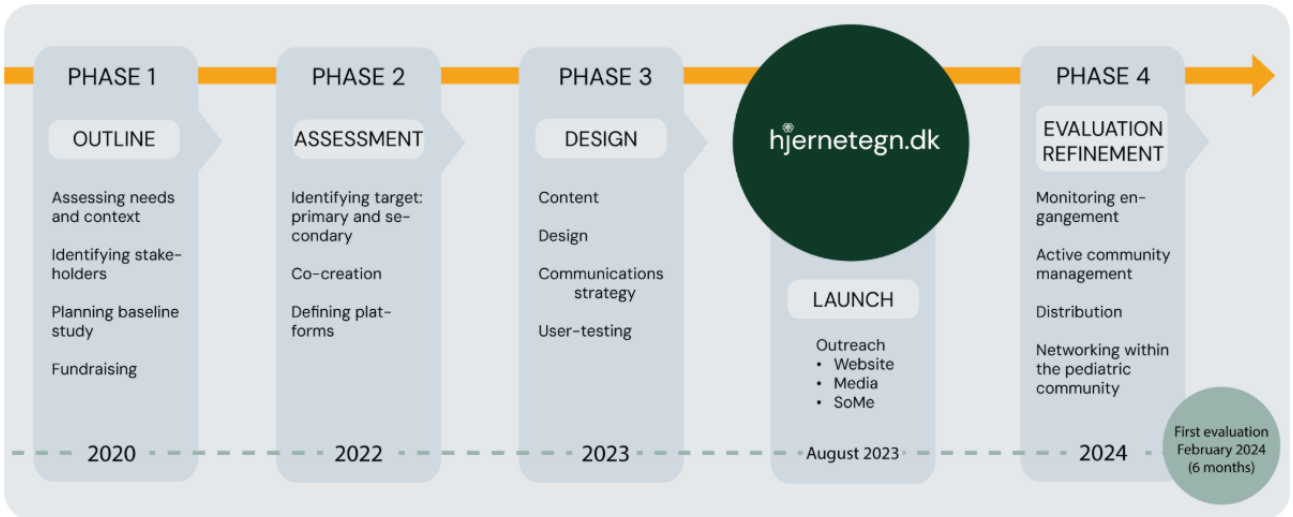

Similar Interventions

Efforts to accelerate timely diagnosis to enhance survival and the quality of life after cancer are advocated for worldwide. Childhood cancer has been a World Health Organization priority since 2018 [32]. In the United Kingdom, the HeadSmart campaign was initiated in 2011; actively reducing the time from symptom onset to diagnosis by several weeks, with a reduction in the time from onset until families approached a HCP, as well as an accelerated referral within the primary and secondary sector [18,33,34]. The HeadSmart initiative was set up as a nationwide public campaign, creating awareness in the public and among HCPs on alarm symptoms of CNS tumors in children.

Different organization of, and access to, the health care system may influence the differences in delay between countries. For hjernetegn.dk, we found inspiration in the methods of the HeadSmart campaign, but the Danish medical culture and health care organization, as well as being in an era of digitization, required designing a novel approach for the Danish initiative including constricting our target audience to HCPs.

The implementation is reported in accordance with iCHECK-DH (Guidelines for the Reporting on Digital Health Implementation) [35].

Methods

We report the approach and implementation of the Danish CNS tumor initiative hjernetegn.dk, a tool to support the diagnostic process of childhood CNS tumors in the interface between primary and secondary care.

Target

HCPs targeted for the initiative and tool were determined based on their involvement in clinical diagnostics, thus covering all HCPs who would first assess a child presenting with complaints that might be caused by a CNS tumor. Primary targets were general practitioners (GPs), ophthalmologists, and pediatricians. Secondary targets were nurse practitioners; neurologists; psychiatrists; ear, nose, and throat doctors; optometrists; child physiotherapists; and chiropractors.

We approached all specialists with a vested interest in contributing to the content and guidelines provided. We also included associations from specialties identified as recipients, involving them in the early process. National health authorities were informed prior to launch, timely enough for them to be able to respond but not with the intent to consult. Patient associations and advocacy groups were informed as well.

Participating Entities

Setting up hjernetegn.dk required interdisciplinary experts, covering academic and clinical knowledge, communication strategy skills, and digital know-how. A qualified team of pediatric oncologists formulated the idea, nested within the 5C, and then included the Danish Cancer Society and the Danish Childhood Cancer Foundation in the collaboration to support the commercial and communications strategical part of the initiative.

Hjernetegn.dk: Web Use, Website, and Social Media

We invited specialists from the primary target groups to participate in a co-creation workshop, encouraging "a collaborative approach of creative problem solving between stakeholders" [36]. The approach was set up to create a user journey map to identify the workflow in general practice and pediatric clinics, and to define what would be required in content and design to make the decision support tool feasible and successful.

The established key points were carried into the process of defining which platforms to make our tool accessible. In a postpandemic online era, printed material is obsolete in a Danish setting. To enable timely updated content, online platforms were used: a website as a nest for the tool and social media (SoMe) platforms to nest the outreach and network. We chose LinkedIn as the platform for SoME outreach based on its profile as a professional community for audience augmentation, with an algorithm that enables outreach by profession, favoring peer-to-peer communication [37]. Furthermore, funds were allocated to develop a LinkedIn campaign and ads on Google Search.

Blueprint Summary: Hjernetegn.dk

The hjernetegn.dk website offers a list of alarm symptoms that require assessment to rule out a CNS tumor; a checklist for examination, listing what to include in the primary assessment; and finally, a decision support tool, offering a hands-on algorithm to decide whether to approach with watchful waiting, reevaluate within a certain timeframe, or refer directly for further evaluation including neuroimaging.

Content was provided by pediatric oncologists in collaboration with stakeholders from relevant specialties. Using national Danish guidelines and the National Institute of Health and Care Excellence–accredited Brain Pathways guideline [38] from the HeadSmart initiative as a backbone, website material applicable to a Danish setting was developed for the digital era, framing dissemination in a primarily digital strategy.

An example of the assessment tool is shown in Figures 3-5. Figure 3 displays alarm symptoms, Figure 4 displays points for examination and assessment, and Figure 5 displays the decision support tool.

A communications bureau provided design and graphical solutions.

The design accommodated the reported timeframe from the co-creation, allowing only 1 minute to unravel the algorithm. The aim was to facilitate an overview and to promote awareness of other symptoms to consider while using the tool for a specific assessment.

Press/Media and Digital Strategy

The press/media strategy aimed to create awareness as well as drive users to the website when launched. Interviews were set up with major Danish health news outlets to be released on the day of launch. Within the first 3 months after release, 8 written articles were published in trade journals.

A written press release carrying information on the initiative and a graphical package was provided to all stakeholders, thereby inviting them to share the launch on their platforms and with their networks.

In the digital strategy, sponsored LinkedIn ads were planned for 3 iterations of advertising, each 3 weeks long (August 21, 2023, and 12 weeks after), and a Google Search strategy and ads first ran for 2 months, with plans to restrategize later. Furthermore, a plan for the organic content for the LinkedIn profile was designed. To embrace the algorithm, weekly posts were planned.

Goals for Digital Performance the First 6 Months After Launch

We expected high activity at launch and in the following months, aligning with press releases and published articles. We presumed we would reach a more indicative plateau after 2 months.

Key performance indicators (KPIs), measurable variables for the evaluation of an initiative, were defined covering the number of visitors to the website, number of impressions on LinkedIn (impressions are defined as the number of exposures to posts or ads of individual feeds on the platform; organic impressions are defined as tailored content managed by hand), and number of searches on Google Search.

Defining the KPIs for using the website, we set a standard estimate of the possible number of assessments of children who visit their general practice, suggesting the number of cases where using the guideline and tool provided in hjernetegn.dk would be relevant. In consensus with experts from general practice, it was estimated that less than 20% of children's visits with their GP require active use of guidelines, and by the same consensus, most likely <1 patient per week would require the GP to use hjernetegn.dk. With 3500 practicing doctors in Denmark, the KPI for visitors to the website was set to 500 visits per month. On LinkedIn, the KPI was set to 180,000 impressions, estimated from the number of possible recipients by the stated occupation on the platform. In Google Search, the KPI was set to 500 clicks per month, estimated from GP usage and searches. For the web page bounce rate KPI, the percentage of users departing from the entry page without further interaction was targeted as <55%.

Data

Data analysis to monitor digital use and traffic was conducted utilizing Piwik PRO Analytics (version 16.26; Piwik Pro) [39]. Details on LinkedIn activity were extracted directly from the platform.

Budget and Resources

The initiative was managed as part of a PhD study at Aarhus University Hospital, endorsed by the pediatric neuro-oncology network.

In the 4-year period, the allocation of work hours varied, with workload increasing and peaking at the time of launch. The project manager and a communications officer from the Danish Cancer Society had 20% of a full-time equivalent (FTE) workload from 2020 to 2022. Starting in 2023, the workload increased to 100% FTE for the project manager and 70% FTE for the communications officer.

Brand and graphic design, technical support, and digital solutions were provided by an external communications bureau. Collaboration and joint strategy were initiated 18 months before launch. The budget for the external bureau was approximately €100,000 (US $108,000), covering all external costs for building

and implementing the initiative, as well as running the project 6 months after launch. Funding of approximately €65,000 (US $70,000) was allocated to refine, recommunicate, and manage the web page and SoMe platforms the second year after launch.

Sustainability

The initiative is intended to become a part of a clinician's toolbox, implying sustained use.

Implementation to stay is highly dependent on ongoing advocacy and a well-planned strategy for communication and up-to-date management of the community and web pages. Dissemination, through advertising, participating in relevant events, and reaching out on digital and real-life platforms are continuously required. Consequently, continuous funding is crucial.

Managing the community day to day requires active surveillance on SoMe channels to enable fast and sufficient responses, totaling 5 hours of work per week, inevitably spread out and not only as office hours.

Ethical Considerations and Potential Barriers

It was important to balance the need to identify patients presenting strong indications for neuroimaging without instigating high numbers of unnecessary referrals and contacts to specialty units in both the primary and secondary sectors.

We acknowledged the risk and barrier that GPs might be reluctant to support the initiative due to worries of added workload in the primary sector.

Introducing an initiative as the one described, does not require ethical approval in the state of Denmark, when initiated by specialist networks as the 5C. Furthermore, when conducting the mentioned baseline studies [31], ethical approval was obtained from the Danish Data Protection Agency (file number: 1-16-02-300-19).

Implementation (Results)

Digital Results and Engagement

hjernetegn.dk had 13,705 visitors from August 21, 2023, to February 25, 2024. Each visit had a mean of 6 engaging actions (click, scrolling, or other interactions). Figure 6 shows the number of visitors and returning visitors to the website in the first 6 months after launch. Access from smartphones and desktops covered 78% and 19%, respectively. The remaining 3% was accessed from other smart devices.

From August 21 to February 25 the overall bounce rate was 63%. On the page level, the bounce rate was <10%, indicating the use of the tool within the site. For desktop users, the bounce rate was 46%. The average time spent on the page was 1 minute and 45 seconds, and the average number of page views was 2.3.

By November, a plateau was met, showing an average of 300 visits per week, with a return rate of 10%. The bounce rate was reduced to 54% accordingly. The average time spent on a web page was 2 minutes, and the average number of web page views was 2.5 web pages.

On the website, 33,075 pages were viewed, with 60% (n=19,713 views, bounce rate 60%) of visits being the home page.

Half of all visitors accessed the web pages through Google Search, and 24% accessed them by URL. SoMe outlets constituted 21% of the visitors, particularly LinkedIn and Facebook. Less than 5% of visitors were directed by referral from other platforms, such as guidelines, health authority outlets, health care–related media, and collaborators' websites.

The sponsored LinkedIn ad campaign constituted the most impressions, covering 201,888 impressions and reaching the set KPI. Organic impressions formed 14,133 impressions in the same period. Figure 7 shows sponsored and organic impressions in the first 6 months.

Figure 6. Website engagement 6 months after launch. Visitors on hjernetegn.dk from launch August 2023 to February 2024. The lower graph shows the number of visitors after the plateau was reached from November 2023 to February 2024.

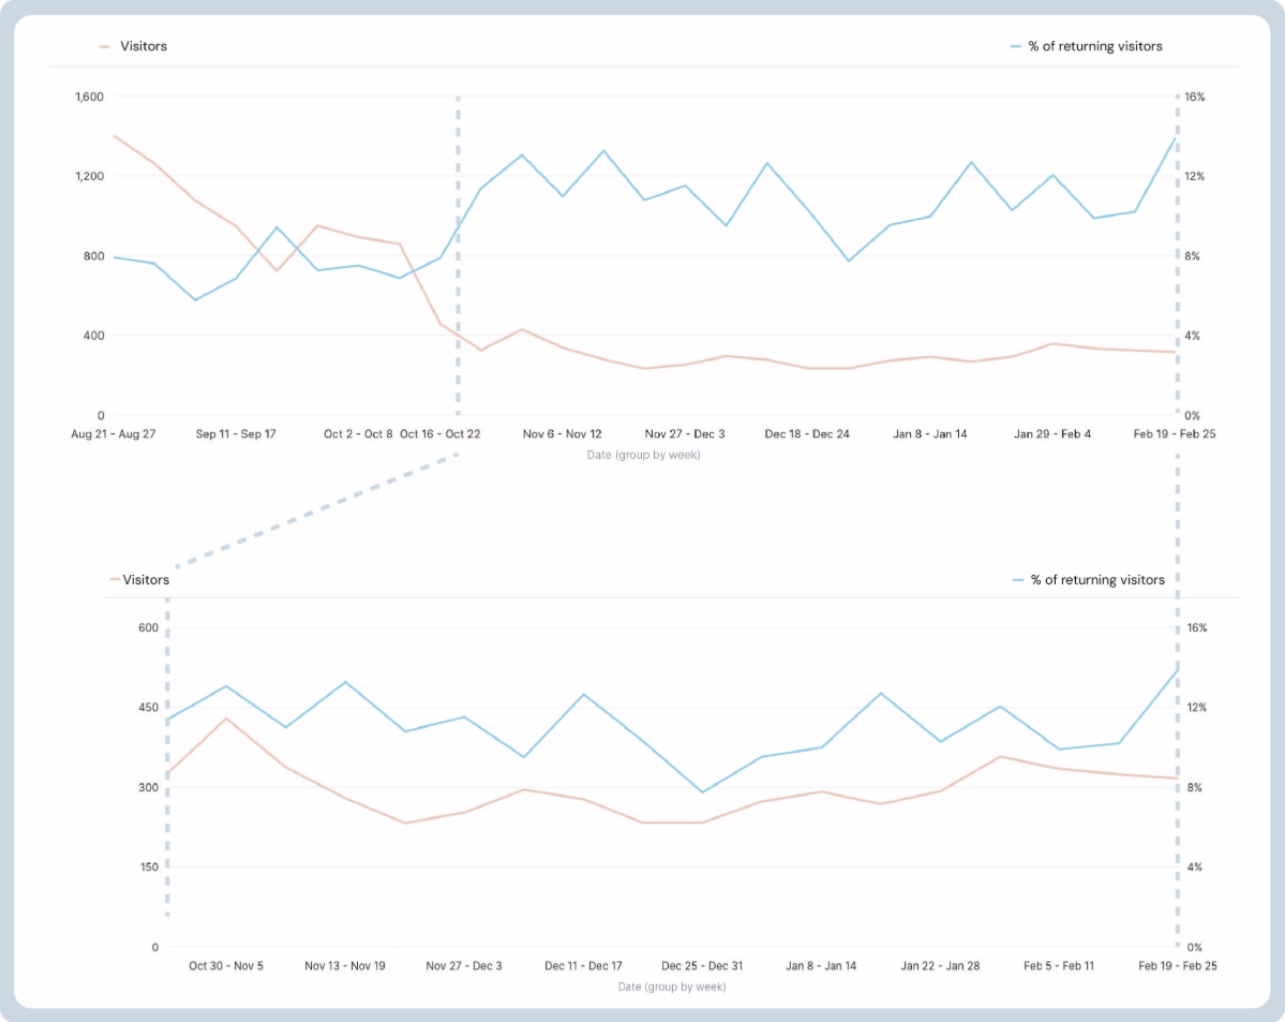

Figure 7. Impressions of active content on LinkedIn 6 months after launch. Impressions indicate number of exposures to individual user feeds. Sponsored impressions: impressions by ads. Organic impressions: tailored content managed directly from the hjernetegn.dk LinkedIn-page.

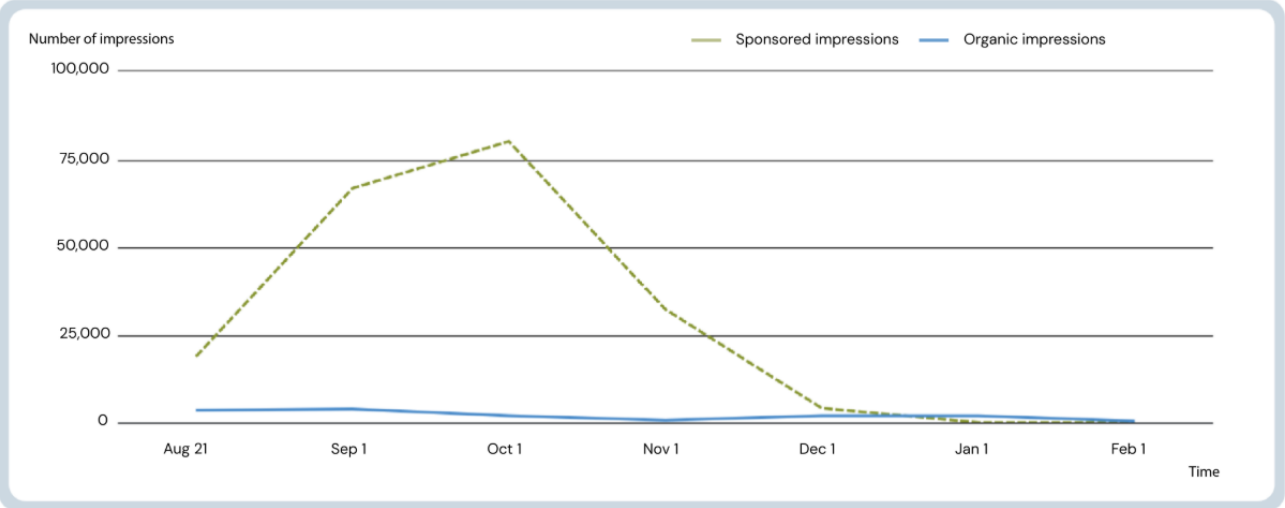

Implementation to Sustain

hjernetegn.dk is nested within the 5C and the four pediatric oncology centers nationwide. Efforts to maintain and update the website as well as strategizing to reach even more HCPs are ongoing. We are planning to solicit feedback from site users to better target HCPs and enhance the site and tool.

The hjernetegn.dk approach and guidelines are now taught in medical programs and among pediatric fellows as part of the

curriculum, and the tool is continuously being introduced to GPs.

Discussion

This study reports the development and implementation of hjernetegn.dk and the digital impact in the first 6 months after launch. The initiative covered the development of the digital diagnostic decision support tool and dissemination.

Impact of the Digital Dissemination Strategy

Contemplating results from the digital strategy, as anticipated, we saw a very high interest following the main events around the launch, and from August 21 to October 22, the number of visitors peaked in alignment with publications in health media. From November, a plateau was reached, showing a stable number of visitors and returning visitors. When introducing new eHealth innovations, it is proposed in other works that the Gartner Hype Cycle can be applied [40,41]. It shows that reaching a plateau of productivity is natural but will be preceded by a so-called peak of inflated expectations and a trough of inflated expectations; although there was no true trough, the suggested phases in implementation matched our digital results, and the plateau was met with approximately 50 users daily, of whom 10% were returning visitors.

The results met our set KPIs. In fact, the number of visitors to the website far exceeded our expectations. At the plateau, the monthly number of visitors reached 1500, while the KPI was originally set to 500 within the first 6 months. This might have been a low target, but it was estimated based on expert notions of the number of contacts and that new guidelines take time to implement. Our results indicate that the communications strategy in our initiative has some effect. Using a so-called push-pull strategy, SoMe and ads endorsed and directed users to the website, introducing potential users to the tool, and the website as the actual tool had the effect of pulling in viewers. The bounce rate dropping over time indicates the tool is in actual use for supporting diagnostics and not only for visitors viewing the website.

For the LinkedIn campaign, the main focus was to create awareness and curiosity. A recent review on SoMe in public health campaigning presents the modified hierarchy of effect model, suggesting that health outcomes can be improved simply by SoMe exposure changing individuals' behaviors [42]. Engagement leads to further impressions in secondary networks, raising awareness, directing traffic to the website, and supporting the push-pull strategy setup. Access from users via Facebook may be the result of user engagement on LinkedIn.

Moving forward, we will adjust set KPIs to encompass the results from the first 6 months of the initiative. Furthermore, it is being discussed whether to include more SoMe platforms.

Lessons Learned

Inviting key stakeholders and primary targets to identify drivers and solutions and to point out barriers in the process is essential to design for sustainability. Finding a common understanding of the problem of diagnostic delay, especially when approaching GPs, was a time-consuming and delicate process. GPs were hesitant and implied that the motivation for the initiative was a criticism of their efforts in clinical practice, whereas the actual motivation was to provide support in a challenging process. The same issue was raised with the external communications consultants. A clear objective and common vocabulary is imperative for effective communication and collaboration between clinicians in different fields and the design producers. Barnes et al [43] advocate for interdisciplinary team approaches, bringing together specialists across the fields of health sciences, IT, and communications when producing initiatives in a computational health science era. We support this structural mindset as well as stress the importance of co-creation for content, setting the scene for successful health care interventions.

Through our efforts, we have strived to but not succeeded in reaching all GPs. In the interface between the analog and digital eras, substantial funds and resources are required to reach all areas. We realize some individuals will not be reached unless contacted directly.

The multiphase setup allowed stakeholders to participate continuously, which strengthened the implementation and is strongly advised. The design and platforms ensure flexible editing, allowing add ons easily. This enables future changes or revisions, or even more tools, to be embedded when needed.

When initiating a similar initiative, we would recommend the following:

- Establish a multidisciplinary team by involving communication experts, graphic designers, and technical designers from an early stage. Common ground and understanding of the aim during production is of utmost importance.
- Invite and engage stakeholders to define drivers for success and possible positive or negative attitudes toward the effort.
- Willingness to "kill your darlings." As senders and clinical experts, be receptive to feedback from stakeholders if they do not see eye to eye.
- Have sufficient time and funding. Time is money, and fundraising takes time. In our case, it took 4 years from the formation of the project group to the launch of hjernetegn.dk. We had initially planned for 5 to 8 months.
- Develop realistic plans for follow-up and monitoring. Initiatives should be dynamic and easy to edit; create ongoing revision plans. If possible, conduct a baseline study so that both digital impact and impact in the clinic, as well as on the primary goal, namely the patients, can be measured and evaluated, and the initiative improved accordingly.

Perspectives

We believe our study design is applicable to many rare diseases. Initiatives such as the website presented in this study create a hub for all applications necessary to recognize and interpret cardinal symptoms, followed by guidelines to support relevant and timely referrals. In this first edition, the initiative was targeted toward HCPs. In time, we will revisit the strategy and may plan to broaden the format to raise public awareness, thus covering the entire trajectory for patients with a CNS tumor.

Acknowledgments

We owe gratitude to all participants in workshops and tests throughout the process of developing hjernetegn.dk. Our gratitude also goes to colleagues and collaborators across specialties, sectors, and regions for offering time and expertise providing insight to their domain and knowledge to ours. Furthermore, we thank the Department of Prevention and Information at The Danish Cancer Society and The Danish Childhood Cancer Foundation for their support. Finally, we wish to acknowledge Professor David Walker and his team at the Children's Brain Tumour Research Centre, Nottingham, United Kingdom, for their initiative HeadSmart, which laid the ground stones for this and many projects to be built.

hjernetegn.dk was made possible by donations from The Danish Cancer Society and The Danish Childhood Cancer Foundation.

Conflicts of Interest

Abstract

Background: In response to the high patient admission rates during the COVID-19 pandemic, provisional intensive care units (ICUs) were set up, equipped with temporary monitoring and alarm systems. We sought to find out whether the provisional ICU setting led to a higher alarm burden and more staff with alarm fatigue.

Objective: We aimed to compare alarm situations between provisional COVID-19 ICUs and non–COVID-19 ICUs during the second COVID-19 wave in Berlin, Germany. The study focused on measuring alarms per bed per day, identifying medical devices with higher alarm frequencies in COVID-19 settings, evaluating the median duration of alarms in both types of ICUs, and assessing the level of alarm fatigue experienced by health care staff.

Methods: Our approach involved a comparative analysis of alarm data from 2 provisional COVID-19 ICUs and 2 standard non–COVID-19 ICUs. Through interviews with medical experts, we formulated hypotheses about potential differences in alarm load, alarm duration, alarm types, and staff alarm fatigue between the 2 ICU types. We analyzed alarm log data from the patient monitoring systems of all 4 ICUs to inferentially assess the differences. In addition, we assessed staff alarm fatigue with a questionnaire, aiming to comprehensively understand the impact of the alarm situation on health care personnel.

Results: COVID-19 ICUs had significantly more alarms per bed per day than non–COVID-19 ICUs (P<.001), and the majority of the staff lacked experience with the alarm system. The overall median alarm duration was similar in both ICU types. We found no COVID-19–specific alarm patterns. The alarm fatigue questionnaire results suggest that staff in both types of ICUs experienced alarm fatigue. However, physicians and nurses who were working in COVID-19 ICUs reported a significantly higher level of alarm fatigue (P=.04).

Conclusions: Staff in COVID-19 ICUs were exposed to a higher alarm load, and the majority lacked experience with alarm management and the alarm system. We recommend training and educating ICU staff in alarm management, emphasizing the importance of alarm management training as part of the preparations for future pandemics. However, the limitations of our study design and the specific pandemic conditions warrant further studies to confirm these findings and to explore effective alarm management strategies in different ICU settings.

Introduction

Background

Patients critically ill with COVID-19 frequently experience multiple organ failure and need life-sustaining measures such as continuous renal replacement therapy, mechanical ventilation, or even extracorporeal membrane oxygenation [1]. Therefore, during major COVID-19 outbreaks (eg, in 2019 and 2020), intensive care units (ICUs) worldwide saw an increase in admission rates of up to 300% [2]. Intensive care capacities became stretched; in some regions, treatment facilities were fully occupied [3]. Hospitals thus had to increase their intensive care capacities to cope with the proliferating number of patients with COVID-19 [4]. As a consequence, in many countries, provisional ICUs were set up [5-9].

In provisional COVID-19 ICUs, as in standard ICU settings, patients require continuous monitoring of their vital signs, which include heart rate, cardiac rhythm, and peripheral oxygen saturation (SpO_2) via pulse oximetry. If an abnormal situation occurs (eg, a vital sign exceeds a predetermined threshold), an alarm is issued to alert clinicians [10]. However, ICU staff today often experience alarm fatigue [11] because of high rates of false positive or nonactionable alarms [12]. Alarm fatigue can be hazardous for patient safety, especially when critical alarms are missed [13,14]. The constant noise can cause high levels of stress among staff and disrupt patients' sleep-wake cycles, increasing the risk of delirium and potentially poorer recovery outcomes [15,16].

In COVID-19 ICUs, the alarm situation might have been even worse: ICU staff, likely overworked due to an overwhelming patient load and a massive workload, had to cope with the psychological burden of the fear of infection and the distressing reality of witnessing numerous patient deaths. ICU staff experienced poor mental health during the COVID-19 pandemic [17-19], and more errors in clinical settings occurred [20].

Moreover, the makeshift nature of the ICUs, which were set up in haste to handle the surge in patients, likely exacerbated these problems. The often improvised and provisional nature of these ICUs likely introduced additional operational complexities and stressors, such as limited space and insufficient technical equipment, further taxing the already strained staff. All these issues may have been compounded by a loud and potentially unreliable alarm system.

Objectives

This study systematically assesses the alarm situations in 2 provisional COVID-19 ICUs and 2 non–COVID-19 ICUs, focusing on both the actual alarm rates and the extent of alarm fatigue experienced by ICU staff. By incorporating expert interviews with medical professionals who have worked in COVID-19 ICUs, alongside quantitative analyses of alarm log data from the bedside monitors [21-23] and results from the alarm fatigue questionnaire [24], this investigation follows a multimodal approach.

Methods

Study Design

In this study, the alarm situations in 2 provisional COVID-19 ICUs were compared with those in 2 non–COVID-19 ICUs; all 4 ICUs were situated on the same campus at a tertiary care university hospital in Berlin, Germany. A retrospective observational analytical study design was used, with the comparison being approached from three perspectives: (1) hypotheses were derived and tested based on interviews with medical experts, exploring potential differences in alarm situations between COVID-19 and non–COVID-19 ICUs; (2) alarm log data from both types of ICUs were analyzed; and (3) the results from an alarm fatigue questionnaire, which was administered as part of another study [24] during the same period, were collected and analyzed.

The non–COVID-19 ICUs consist of an interdisciplinary ICU with patients who have recently undergone surgery or are in the perioperative stage (hereinafter *surgical ICU*); and an ICU with a focus on internal medicine (hereinafter *medical ICU*) where patients with severe infection, cardiac diseases, kidney failure, or other single- or multiple-organ failures are treated.

The medical and surgical ICUs have single and multiple bedrooms and contain 20 and 21 beds, respectively. The COVID-19 ICU was divided into 2 separate units: COVID-19 ICU-A had single bedrooms with 16 beds, and COVID-19 ICU-B had single and multiple bedrooms with 24 beds.

Expert Interviews for Hypothesis Design

To derive hypotheses regarding how alarm situations might differ between COVID-19 and non–COVID-19 ICUs, 5 medical experts (physicians: n=2, 40%; nurses: n=3, 60%) were interviewed from July to December 2021. The interviews were semistructured [25,26]. The foundational questions were grounded in our overarching research question: "What distinguishes the alarm situations in COVID-19 ICUs from those in non–COVID-19 ICUs?" A detailed list of these questions can be found in Table S1 in Multimedia Appendix 1.

In addition, 2 job shadowing sessions were conducted (one on October 1, 2021, in the medical ICU; and another on November 12, 2021, in COVID-19 ICU-B). During the second session, an interview was conducted in COVID-19 ICU-B. The remaining 4 interviews were held online via Microsoft Teams [27]. An integral aspect of the interviews was that beyond the structured questions, the medical experts were proactively asked about potential hypotheses regarding the differences in alarm situations between the ICU types.

Subsequent to the interviews, the collected data, including transcripts and notes, were meticulously examined. The

hypotheses were derived through an in-depth examination and collective discussion within an interdisciplinary team.

Statistical Analysis

Data Analysis

The alarm logs were processed and analyzed as previously described [22], using R (R Foundation for Statistical Computing) [28] with RStudio (Posit Software, PBC) [29] in combination with the following packages: *lubridate* [30], *ggplot2* [31], and *dplyr* [32]. The logs were extracted from the Philips IntelliVue patient monitoring systems (in the surgical and medical ICUs: MX800, software version *m*; in the COVID-19 ICUs: MX750, software version *p*) as CSV files from the non–COVID-19 ICUs and as XML files from the COVID-19 ICUs (structure of the cleaned alarm log data frames is listed in Table S2 Multimedia Appendix 1). Alarm signals from mechanical ventilation devices were not correctly stored in the alarm log data due to transmission errors and were therefore excluded from the analysis. The included alarm signals and the assignment to their medical device are listed in Table S3 in Multimedia Appendix 1. The logs range across 113 days (from November 19, 2020, to March 11, 2021).

Hypothesis Testing

To test for statistical differences between COVID-19 and non–COVID-19 ICUs, the units were grouped accordingly. All tests were 1-tailed, with a significance level of α=.05. *P* values were adjusted using the Bonferroni correction. The first hypothesis (H1) proposed that the alarm load is higher in COVID-19 ICUs than in non–COVID-19 ICUs. This hypothesis was further subdivided into total alarm load, clinical red alarms, clinical yellow alarms, and technical alarms.

The second hypothesis (H2) posited that more alarms are issued from specific medical devices, namely electrocardiogram (ECG) and invasive blood pressure (IBP) devices, in COVID-19 ICUs than in non–COVID-19 ICUs. The alarms from these devices were further categorized based on the alarm color (red: potentially life-threatening events; yellow: vital signs exceed predetermined thresholds).

The third hypothesis (H3) proposed that the alarm duration is longer in COVID-19 ICUs than in non–COVID-19 ICUs. For this hypothesis, the alarm durations from clinical alarms were subdivided into medical devices (non-IBP [NIBP], temperature, SpO_2, ECG, and IBP devices) and alarm colors (red and yellow).

For H1 and H2, the alarm load was quantified in alarms per bed per day. Given that the distributions were skewed to the right and approximately gamma distributed, a dummy-coded no-intercept generalized linear model with a log link function was used. Cohen *d* was used as the effect size measure and was calculated using the package *effsize* developed by Torchiano [33].

For H3, testing was conducted with median alarm durations. The distributions of alarm durations were highly skewed to the right and approximately exponentially distributed; therefore, nonparametric bootstrapping with the *boot* package developed by Canty et al [34] was used with an a priori estimation of the difference in alarm duration with equation 1.

$$H_0: \mu_1 - \mu_2 \leq 3 \quad \textbf{(1)}$$

$$H_A: \mu_1 - \mu_2 > 3$$

Differences of 3 seconds were considered significant, while smaller effects that could already be significant due to the large sample were considered not significant. A median-based estimator for Cohen *d*–type effect size (equation 2) with an estimation of variance (equation 3) was used, where *k* is the number of units and *l* is the number of alarms.

To test the differences in alarm fatigue experienced by ICU staff between COVID-19 and non–COVID-19 ICUs (H4), an unpaired 1-tailed *t* test using Cohen *d* as the effect size measure was conducted.

Exploratory Data Analysis

Metrics defined in our previous study [22] were used for the evaluation of alarm situations in the ICUs: alarms per bed per day, critical alarms, alarms per device, alarm flood conditions (≥10 alarms within 10 minutes), use of the alarm pause function per bed per day, proper pause-to-pause ratio, and concurrent alarm duration per bed per day. The last metric was first introduced by Varisco et al [12] and is calculated by summing the number of active parallel alarms. Specifically, if 2 alarms sound simultaneously within a second, this is counted as 1 second of concurrent alarm duration, and if 3 alarms sound simultaneously within a second, 2 seconds are counted.

The metrics were related to bed occupancy and time period to compare the results between the different ICUs. Due to the absence of information regarding the cause of termination in the data, it was not possible to determine the alarm response time. Therefore, alarm duration was used instead.

In the calculations of alarm flood conditions and concurrent alarm duration, only alarms with an auditory modality, specifically yellow and red alarms, were included. For the alarm duration used in calculating concurrent alarm duration, a cutoff was set at 1800 seconds. Alarm durations exceeding this limit were considered outliers and were therefore excluded from the analysis.

Alarm Fatigue Questionnaire

The questionnaire data were taken from a separate study [24] that coincided with our data collection phase. The questionnaire, distributed as a web-based survey via REDCap (Research Electronic Data Capture; Vanderbilt University) [35] to ICU staff at the same German hospital between April and June 2021, provided responses from COVID-19 ICU-A, COVID-19 ICU-B, a third COVID-19 ICU (COVID-19 ICU-C), and the 2 non–COVID-19 ICUs (medical and surgical ICUs). The original questionnaire consisted of 27 items; however, only those aligning with the 9-item questionnaire developed by Wunderlich et al [36] were included in this analysis. Each item was measured on a 5-point Likert scale, ranging from *I strongly agree* to *I strongly disagree*.

Demographic questions about work experience, place of work, and position (nurses and physicians, as well as support staff, ie, students or nurses from general wards) were also part of the questionnaire. Only responses from participants who consented to data analysis were included in the study. Submissions with 1 or 2 missing items were imputed at random based on the predictive mean matching algorithm using 1 imputation with the *mice* package [37]. To calculate an alarm fatigue score, the items were scored from –2 (*I strongly disagree*) to 2 (*I strongly agree*). *I partly agree* was scored with 0. Four items were scored reversely. The sum of all Likert items results in the alarm fatigue score, which ranges from –18 to 18. A score of –18 would indicate that the staff members are not experiencing alarm fatigue at all, while a score of 18 would mean that the staff members are experiencing extreme alarm fatigue; the midpoint is 0. We report the alarm fatigue in percentage as recommended by Wunderlich et al [24] with equation 4.

Ethical Considerations

Ethics approval for this study was granted by the ethics commission of Charité–Universitätsmedizin Berlin (EA4/218/20). All participants provided consent before the study. Data confidentiality was ensured through anonymization in compliance with General Data Protection Regulation. No compensation was provided to participants.

Results

Beginning with insights from expert interviews to formulate our hypotheses, we proceeded to test them empirically using alarm log data and an alarm fatigue questionnaire, concluding with insights from our exploratory data analysis.

Expert Interviews for Hypothesis Design

Of the 5 expert interviewees, 2 (40%) reported that only approximately one-third of the staff in COVID-19 ICUs had experience in intensive care, while the remaining two-thirds consisted of nurses, who until then had only worked on general wards; or individuals without specific experience, such as medical students; and even untrained personnel. The staff were assigned different tasks depending on their qualifications. Of the 2 physicians, 1 (50%) suggested that staff were not trained on how to properly apply sensors, such as ECG electrodes, potentially leading to additional (medically irrelevant) alarms. Of the 3 nurses, 1 (33%) suggested that alongside the alarm burden, the high fatality rate among patients imposes psychological strains on the staff. According to the interviewees, the patient cohort in the COVID-19 ICUs presented a more or less homogeneous clinical picture with varying COVID-19 severity. Many patients needed mechanical ventilation and underwent continuous renal replacement therapy with dialysis devices that produce very loud and unpleasant alarms. However, these alarms were not recorded in the alarm logs.

Of the 2 physicians, 1 (50%) reported that patients with COVID-19 infection often have multiple organ failure and a high length of stay; therefore, they are often equipped with ≥7 perfusors for medications (eg, antibiotics, catecholamines, sedatives, and parenteral nutrition), all of which trigger additional alarms that are also not recorded in the alarm logs. All 3 nurses reported a higher alarm burden compared with those working in non–COVID-19 ICUs. All interviewees described the removal and reattachment of all patient sensors during transition from prone to supine position or vice versa as a possible cause of false alarms if the alarm pause function was not used. On the basis of this information, we hypothesized as follows: (H1) The alarm load is higher in COVID-19 ICUs than in non–COVID-19 ICUs.

Of the 3 nurses, 2 (67%) reported that they perceived many patients to be multimorbid, overweight, and of older age, with many having a cardiac or pulmonary history and tachycardia. All interviewees reported that the blood circulation of patients with COVID-19 was extremely unstable, which led us to hypothesize that medical devices related to blood circulation (ie, the ECG, NIBP, or IBP devices) issue more alarms in COVID-19 ICUs: (H2) More alarms are issued from ECG, NIBP, and IBP devices in COVID-19 ICUs than in non–COVID-19 ICUs.

Both COVID-19 ICUs featured long corridors with inward-opening doors, which were usually closed to isolate patients who were infectious. The interviewees reported that the corridors, the dispensary room, and the physician's room were not equipped with central monitoring; thus, the health care providers had no overview of the patients, which made it difficult to locate the origin of the auditory alarms. Only the nurses' room was equipped with central monitoring, but alarms could not be turned off remotely. According to the interviewees, temporary arrangements were made by the staff to address this problem, such as leaving the doors to patients' rooms slightly open or placing speakers linked to the monitors in the hallway. However, to respond to or turn off an alarm, staff had to enter the patient's room. This required them to don personal protective equipment (ie, gloves, a protective hood, a polypropylene protective gown, and a face shield or goggles), which took approximately 30 seconds and hindered quick movement between rooms. All 3 nurses reported that the protective equipment did not interfere with turning off the alarms, the usability of the monitor displays, or the adjustment of monitor settings. However, they all described it as strenuous and time consuming. Accordingly, we derived the third hypothesis: (H3) The alarm duration is higher in COVID-19 ICUs than in non–COVID-19 ICUs.

Patients in COVID-19 ICUs often present with severe, complex medical conditions that require close monitoring and interventions. Of the 3 nurses, 1 (33%) suggested that next to the alarm burden and heavy workload, the high fatality rate among patients could strain and distress staff psychologically. This mental and emotional strain could potentially affect staff performance and cognitive abilities, potentially hindering their response to alarms. Combining this information with our reasoning for the previous 3 hypotheses, we formulated the fourth hypothesis as follows: (H4) Staff alarm fatigue is higher in COVID-19 ICUs than in non–COVID-19 ICUs.

Having delineated the hypotheses informed by the expert interviews, we proceeded to empirically test each of them, starting with the alarm load in different ICU settings.

Hypothesis 1: The Alarm Load Is Higher in COVID-19 ICUs Than in Non–COVID-19 ICUs

Significant differences were observed in all 4 tests, which confirmed our hypothesis that the alarm load was higher in provisional COVID-19 ICUs than in non–COVID-19 ICUs (P<.001; Tables 1 and 2). COVID-19 ICUs experienced an average of 23% more alarms in total, 41% more red critical alarms, and 24% more yellow alarms compared with non–COVID-19 ICUs. The alarm load caused by technical alarms was 109% higher in COVID-19 ICUs. The alarm load results, subdivided by medical device and alarm color, are reported in Figure S1 in Multimedia Appendix 1. The technical alarm signal that resulted in the most alarms per bed per day was *ECG lead off*, with mean values recorded as follows: surgical 3.42 (SD 2.10), medical 3.84 (SD 2.87), COVID-19 ICU-A 7.22 (SD 1.93), and COVID-19 ICU-B 7.77 (SD 2.41).

Table 1. Alarm load from all intensive care units (ICUs; n=113).

	Alarm load (alarms per bed per day)			
	Surgical ICU, mean (SD)	Medical ICU, mean (SD)	COVID-19 ICU-A, mean (SD)	COVID-19 ICU-B, mean (SD)
Total alarms	122.84 (38.95)	122.54 (27.85)	142.47 (41.49)	157.40 (42.58)
Red alarms	10.94 (2.43)	10.99 (2.82)	14.99 (5.89)	15.81 (4.01)
Yellow alarms	108.48 (37.86)	107.71 (26.68)	126.23 (37.93)	140.56 (41.08)
Technical alarms	5.10 (2.17)	5.03 (2.97)	10.30 (2.30)	10.84 (2.51)

Table 2. The results from the hypothesis testing for H1 (n=113).

	Alarm load (alarms per bed per day)		P value	Cohen d
	Non–COVID-19 ICUs[a], mean (SD)	COVID-19 ICUs, mean (SD)		
Total alarms	122.21 (22.37)	151.26 (31.02)	<.001	1.04
Red alarms	10.98 (1.90)	15.51 (3.33)	<.001	1.67
Yellow alarms	108.33 (21.73)	134.59 (29.24)	<.001	1.02
Technical alarms	5.06 (1.87)	10.62 (1.86)	<.001	2.98

[a]ICU: intensive care unit.

Hypothesis 2: More Alarms From ECG, NIBP, and IBP Devices Are Issued in COVID-19 ICUs Than in Non–COVID-19 ICUs

Table 3 shows the results of hypothesis testing for alarms issued by the IBP and ECG devices, subdivided by alarm color and ICU type. In both ICU types, the IBP device was responsible for the majority of the alarms, followed by the ECG and NIBP devices. Yellow alarms issued by the IBP and NIBP devices and red alarms issued by the ECG device occurred significantly more often in COVID-19 ICUs (P<.001). However, we did not find significant differences in the occurrence of yellow ECG alarms and red IBP alarms. The results of the alarm load, subdivided by medical device and alarm color, from all ICUs are presented in Table S4 in Multimedia Appendix 1. While certain alarm types exhibited significant differences, the overall impact was not profound enough to affirm the second hypothesis, with the exception of the notable difference in the frequency of red ECG alarms (as indicated by the Cohen d value of 1.13).

Table 3. Results of the hypothesis testing for H2 (n=113).

Devices	Alarm load (alarms per bed per day)		*P* value	Cohen *d*[a]
	Non–COVID-19 ICUs[b], mean (SD)	COVID-19 ICUs, mean (SD)		
ECG[c] (yellow)	39.01 (17.65)	38.79 (18.70)	.99	0.00
ECG (red)	2.51 (1.18)	4.60 (2.34)	<.001	1.13
IBP[d] (yellow)	53.87 (11.38)	66.16 (18.22)	<.001	0.81
IBP (red)	5.16 (1.14)	5.22 (1.34)	.99	0.05
NIBP[e]	0.34 (0.40)	0.56 (0.51)	<.001	0.49

[a]Cohen *d* has been reported in absolute values.

[b]ICU: intensive care unit.

[c]ECG: electrocardiogram.

[d]IBP: invasive blood pressure.

[e]NIBP: noninvasive blood pressure.

Hypothesis 3: The Alarm Duration Is Higher in COVID-19 ICUs Than in Non–COVID-19 ICUs

All ICUs had a median clinical alarm duration of 10 seconds. Yellow alarms issued by the NIBP device had the longest alarm durations (Table 4; all group sizes are reported in Table S5 in Multimedia Appendix 1). The durations of yellow alarms triggered by IBP and ECG devices were shorter than those of alarms from all other medical devices, a pattern consistent across all types of ICUs. The median duration of technical alarms in COVID-19 ICUs was significantly longer. Yellow alarms issued by the NIBP, temperature, and SpO_2 devices had significantly longer durations in COVID-19 ICUs (*P*<.001; Table 5; all group sizes are reported in Table S5 in Multimedia Appendix 1). The results of the median alarm duration, subdivided by medical device and alarm color, are presented in Figure S2 in Multimedia Appendix 1. The results show a mixed picture: <50% of the total alarms had a significant difference in alarm duration between the ICU types, implying that most alarm durations did not differ significantly between the 2 ICU types. As such, our data do not provide sufficient empirical evidence to support H3.

Table 4. Results of the hypothesis testing for H3 across each type of intensive care unit (ICU).

	Alarm duration (s)			
	Surgical ICU, median (IQR)	Medical ICU, median (IQR)	COVID-19 ICU-A, median (IQR)	COVID-19 ICU-B, median (IQR)
Clinical alarms	10 (4-27)	10 (4-25)	10 (3-28)	10 (3-29)
Technical alarms	7 (4-66)	4 (4-62)	13 (4-65)	14 (4-68)

Table 5. Results of the hypothesis testing for H3 across the 2 types of intensive care units (ICUs).

Alarms	Alarm duration (s)		*P* value	Cohen *d*[a] type
	Non–COVID-19 ICUs, median (IQR)	COVID-19 ICUs, median (IQR)		
Technical	5 (3-27)	14 (4-67)	<.001	0.016
NIBP[b]	62 (25.00-179.75)	99 (29-337)	<.001	0.094
Temperature	24 (8-86)	32 (9-192)	<.001	0.009
SpO_2[c] (yellow)	14 (7-32)	23 (11-57)	<.001	0.069
SpO_2 (red)	28 (11-89)	33 (14-75)	.11	0.004
IBP[d] (yellow)	13 (6-32)	11 (4-30)	.99	0.014
IBP (red)	24 (9-84)	20 (9-48)	.99	0.005

ECG (red)	23 (9-119)	16 (8-35)	.99	0.005

[a]Cohen *d* has been reported in absolute values.

[b]NIBP: noninvasive blood pressure.

[c]SpO_2: peripheral oxygen saturation.

[d]IBP: invasive blood pressure.

[e]ECG: electrocardiogram.

Hypothesis 4: Staff Alarm Fatigue Is Higher in COVID-19 ICUs Than in Non–COVID-19 ICUs

The questionnaire was completed by 707 participants (n=78, 11% returned blank questionnaires; n=44, 6.2% returned incomplete questionnaires). Of the 585 participants who returned complete questionnaires, we included 144 (24.6%) in the analysis. Of these 144 participants, 88 (61.1%) were from non–COVID-19 ICUs (n=32, 36% from the medical ICU; n=56, 64% from the surgical ICU), and 56 (38.9%) were from COVID-19 ICUs (n=48, 86% from COVID-19 ICU-A; n=8, 14% from COVID-19 ICU-B). The majority of the respondents (92/144, 63.9%) were intensive care nurses (COVID-19 ICUs: 25/56, 45%; non–COVID-19 ICUs: 67/88, 76%). The COVID-19 ICUs had a notable proportion of additional support staff among the respondents, including nursing students and nurses from regular wards (24/56, 43%) compared with non–COVID-19 ICUs (9/88, 10%). The least represented group among the respondents were physicians (COVID-19 ICUs: 7/56, 12%; non–COVID-19 ICUs: 9/88, 10%). The overall alarm fatigue score was higher in COVID-19 ICUs (mean 56.00, SD 15.80) than in non–COVID-19 ICUs (mean 55.27, SD 13.76). Statistical testing of the alarm fatigue score revealed no significant differences between COVID-19 and non–COVID-19 ICUs ($t_{105.41}$=0.2841; *P*=.39; Cohen *d*=0.05). Importantly, when considering only experienced ICU staff—nurses and physicians—the alarm fatigue scores were significantly higher in COVID-19 ICUs than in non–COVID-19 ICUs (t_{109}=1.7332; *P*=.04; Cohen *d*=0.363). Figure S3 in Multimedia Appendix 1 depicts the results of the questionnaire, subdivided by profession. Nurses and physicians reported a higher alarm fatigue score than support staff, who generally reported an overall low alarm fatigue score in both ICU types. Given the results of the hypothesis testing (Table 6), we cannot conclusively validate H4, especially when considering all staff types; however, among ICU staff, there is evidence suggesting higher alarm fatigue in COVID-19 ICUs than in non–COVID-19 ICUs.

Table 6. Results of the hypothesis testing for H4.

	Alarm fatigue questionnaire scores		*P* value	Cohen *d*
	Non–COVID-19 ICUs, mean (SD)	COVID-19 ICUs, mean (SD)		
All participants	55.27 (13.76)	56.00 (15.80)	.39	0.050
Clinicians (nurses and physicians)	59.00 (13.05)	64.28 (14.20)	.04	0.363

Insights From the Exploratory Data Analysis

While the surgical and medical ICUs were approximately fully occupied over the entire period, the COVID-19 ICUs were often only partly occupied depending on the patient load. Average bed occupancy was 97.26% and 92.27% in the surgical and medical ICUs, respectively; and 88.79% and 82.75% in COVID-19 ICU-A and COVID-19 ICU-B, respectively. Figure S4 in Multimedia Appendix 1 displays the unit occupation over the entire period.

The use of the alarm pause function per bed per day was substantially less frequent in COVID-19 ICUs (mean 5.08, SD

1.69) compared with alarm pauses per bed per day in non–COVID-19 ICUs (mean 12.21, SD 2.21). The medical ICU recorded the highest proper pause-to-pause ratio of 0.08, followed by the surgical ICU and COVID-19 ICU-A, both at 0.04. COVID-19 ICU-B had the lowest pause-to-pause ratio: 0.03. Figure S5 in Multimedia Appendix 1 displays the number of threshold changes per bed per day and profile changes per bed per day from all ICUs.

In COVID-19 ICUs, alarm flood conditions per bed per day occurred on average 35% more frequently (COVID-19 ICU-A: mean 2.60, SD 1.29; COVID-19 ICU-B: mean 2.73, SD 1.47) compared with their non–COVID-19 counterparts (surgical ICU: mean 1.71, SD 1.33; medical ICU: mean 1.95, SD 0.92). In addition, COVID-19 ICUs experienced on average 27% more instances of concurrent alarm duration per bed per day (mean 5201.76, SD 1156.00) than non–COVID-19 ICUs (mean 4101.42, SD 965.00).

Discussion

Overview

We compared alarm situations in 2 provisional COVID-19 ICUs with those in 2 non–COVID-19 ICUs. Interviews with nurses and physicians who worked in the COVID-19 ICUs led us to hypothesize that COVID-19 ICUs have a higher alarm load, a higher number of specific alarm signals, and longer-sounding alarms than non–COVID-19 ICUs. We also hypothesized that staff working in COVID-19 ICUs experience more alarm fatigue than staff working in non–COVID-19 ICUs.

There Was a Higher Alarm Load in the Provisional COVID-19 ICUs

COVID-19 ICUs had a significantly higher alarm load from red, yellow, and technical alarms. This higher alarm load led to an increased number of alarm flood conditions and concurrent alarm duration, escalating the nurses' workload and potentially causing sensory overload [38]. While some differences can be attributed to the COVID-19 condition itself—such as the higher number of red critical alarms, possibly due to the high mortality rate and bad conditions of the patients—we suspect that most differences in alarm load were due to the interaction of staff with the alarm system (eg, not using the pause function when turning a patient from prone to supine position or vice versa, not adjusting thresholds specifically to patients' conditions, not installing or not using monitoring profiles specific to patients with COVID-19 infection, or improperly applying sensors).

Patients With COVID-19 Infection Had Similar Alarm Signals as Those Without COVID-19 Infection

We anticipated that some devices—such as ECG, NIBP, and IBP devices—would generate more alarms in COVID-19 ICUs due to the unique physiological manifestations of COVID-19, but this was not the case. Only red ECG alarms were notably more frequent in COVID-19 ICUs than in non–COVID-19 ICUs; other numbers of different clinical alarm signals were similar across all ICUs and seem to be a recurring theme because similar results were reported in previous studies [12,22].

In both ICU types, *ECG lead off* was the most frequent technical alarm signal. Interestingly, it occurred more than twice as often in COVID-19 ICUs. This also might be attributed to practices such as moving patients between prone and supine positioning, which necessitates the removal and subsequent reattachment of all sensors and electrodes each time.

The Alarm Duration Was Equally Long in Both ICU Types

While our initial theory posited that alarm durations would be longer in COVID-19 ICUs—owing to the time required for staff to don protective equipment before entering a patient's room—our findings did not confirm this hypothesis. We found no significant differences in the overall median alarm durations between COVID-19 and non–COVID-19 ICUs, except in the case of a few medical devices.

Devices displaying visual information such as ECG waveforms allow staff to rapidly assess alarm urgency. By contrast, the numerical values displayed by devices such as those measuring temperature or NIBP require more time for staff to interpret, potentially causing longer alarm durations.

We must also acknowledge the impact of other factors, for example, the floor layout of the unit, different unit policies [23], nurse-patient ratio [39], and the individual traits of the staff members [40].

Interestingly, red alarm durations were consistently longer than yellow alarm durations across all medical devices and in both ICU types. This may be due to health care providers promptly turning off yellow alarms first (without checking the patient's condition) [39], placing more emphasis on critical alarms, and only then checking the patient's condition.

In our exploratory analyses, we found that the alarm pause function was used more frequently in non–COVID-19 ICUs than in COVID-19 ICUs. This might be explained by the fact that many nurses in COVID-19 ICUs had limited critical care experience and therefore did not know that this function exists or how to use it; COVID-19 ICU staff also might have entered the patients' rooms less often because they were required to don protective gear, which is a time-consuming process.

ICU Staff Experienced More Alarm Fatigue in COVID-19 ICUs

While overall alarm fatigue questionnaire scores were similar between both types of ICUs, the situation varied among different health care professionals. Nurses and physicians in COVID-19 ICUs had significantly higher alarm fatigue scores, whereas support staff in both types of ICUs reported low alarm fatigue scores. Notably, a substantial portion of questionnaire participants in COVID-19 ICUs consisted of support staff, that is, students or nurses from normal wards (COVID-19 ICUs: 25/56, 45%; non–COVID-19 ICUs: 9/88, 10%), reflecting the recruitment of nurses from other services and students with varying levels of critical care experience due to the exceptional circumstances. Unlike the experienced and well-rehearsed teams typically found in non–COVID-19 ICUs, COVID-19 ICU teams often incorporated diverse teams that lacked experience in critical care medicine, training, and familiarity with the

monitoring system and alarm management. This inexperience extended to their training and understanding of monitoring systems and alarm management, mirroring findings from existing literature [41]. In some hospitals, the patient-nurse ratio was increased, which occasionally resulted in poorer quality of care [42]. However, it is important to note that greater fatigue was identified among those working with patients with COVID-19 infection, rather than directly associating alarm fatigue with the COVID-19 condition itself.

There seemed to have been challenges with the alarm system in the COVID-19 ICUs that might have impeded appropriate monitoring. Due to the absence of central monitors in the corridors, dispensary room, and physicians' room, it was difficult for health care providers to locate or swiftly identify and respond to alarms. Interviewees mentioned the protective gear worn in the COVID-19 ICUs as an additional burden when responding to alarms. Protective equipment can impede swift movement, thus slowing response times to alarms, which might intensify the stress and sensory overload associated with alarm fatigue. This finding aligns with the conclusions drawn by Akturan et al [43] that suggested that personal protective equipment could contribute to increased alarm fatigue.

Recommendations for ICU Alarm Systems in Future Pandemics

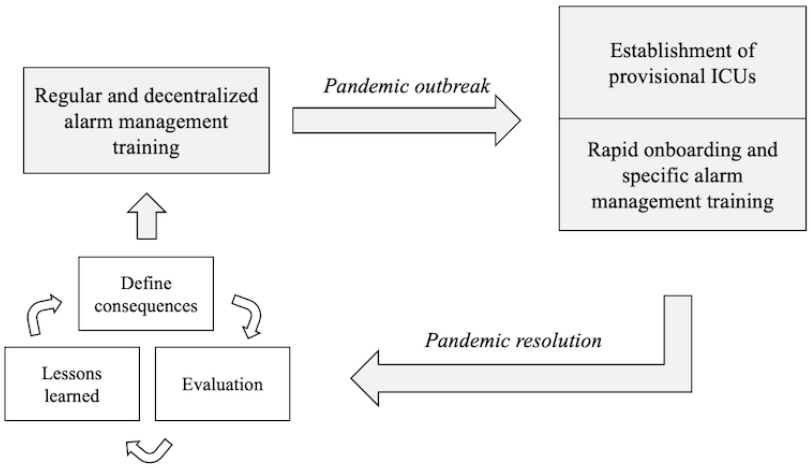
Due to extensive international traffic, the risk of future pandemics remains high in a globalized world [44], and the COVID-19 pandemic will be followed by a new pandemic at some point. Such pandemics will again likely require the setting up of provisional ICUs to cope with rapid patient admissions. When preparing for such events, we recommend also preparing the alarm systems and their human operators. Even outside of pandemics, the shortage of specialist staff is increasing the willingness of authorities to deploy untrained personnel in certain functions in the medical field.

Alarm management aims to reduce the number of unnecessary alarms on the premise that a lower alarm rate decreases alarm fatigue among staff [22]. Provisional ICUs can benefit from effective alarm management, as do regular ICUs, where it helps to significantly decrease the number of false alarms and the overall alarm burden [45-49].

Unnecessary alarms stem from insufficient alarm management knowledge, including using default instead of customized alarm limits, rarely using the pause function during patient manipulation or being unaware of its existence, using insufficient consumables, or attaching electrodes improperly [50]. Previous studies [51] highlight a lack of knowledge about these functions among nurses, pointing to a pressing need for education on physiological monitors [52].

Given the urgency with which new staff members have to be onboarded, the training should be decentralized and easily accessible. To cater to these requirements, we recommend developing educational microcredentials, such as video tutorials that provide guidance on adjusting alarm limits on specific monitoring devices, implementing remote alarm turn-off, and transitioning from individual to smart alarm systems. To visualize and operationalize our approach to pandemic preparedness in ICU alarm systems, we propose a bicyclical strategy, as illustrated in Figure 1. This strategy underscores the significance of continuous learning and adaptability in alarm management. Operating modern bedside monitors requires a blend of cognitive knowledge, psychomotor skills, critical thinking, and an understanding of alarm systems [53]. Hence, this educational program should use the skillmap from the study by Sowan et al [51] as a foundation, expanding it to address the broader technical and practical aspects of monitor use. Modular content that teaches specific skills can be easily adapted to meet unique situational needs; for example, tutorials can be designed to explain how to respond to alarms while wearing protective gear or how to mobilize patients in prone position without causing alarm artifacts. These resources could be beneficial for ICU staff training not only during pandemics but also in routine situations.

Figure 1. Two-phase approach to intensive care unit (ICU) alarm system preparedness and refinement. This figure details continuous training during nonpandemic periods, rapid onboarding, and specialized training at the onset of a pandemic, followed by an evaluation cycle after the pandemic to improve future alarm management strategies.



Limitations

ICUs function as complex sociotechnical systems, making it inherently challenging to compare them. All ICUs were equipped with similar technical equipment (eg, mechanical ventilators and dialysis devices), but our comparison between ICUs was complicated by the variations in the specific devices used across units, leading to differences in alarm signals. Therefore, we only included alarms that occurred in all units. In addition, numerous devices in all ICUs are not connected to the central monitoring system, meaning that the alarms could not be recorded and evaluated. Alarms from mechanical ventilation had to be excluded from the ICU data due to a technical error, preventing us from testing our hypothesis about an increase in such alarms in COVID-19 ICUs.

The monitoring systems in the 2 ICU types varied in their version numbers and settings, further affecting the comparability. In COVID-19 ICUs, the *ECG lead off* alarm was set as a yellow alarm, while in non–COVID-19 ICUs, it was set as a blue alarm. This discrepancy likely stemmed from a lack of awareness or understanding about the settings. We had to exclude this alarm from the yellow alarm load comparison due to this discrepancy.

Our metrics, calculated relative to the number of occupied beds per day, could potentially skew the results. When metrics are calculated this way, it might not accurately reflect the real-life impact of alarm flood conditions on health care workers. In a larger ICU (such as the one with 24 beds), the same rate of alarms per bed would create a larger absolute number of alarms because there are more beds. Consequently, the staff in this ICU would be exposed to a higher number of total alarms than the staff in a smaller ICU (one with, say, 10 beds), although the rate of alarms per bed is the same. While the surgical and medical ICUs were approximately fully occupied over the entire period under study, the occupancy of the COVID-19 ICUs often varied, depending on the patient load. The average bed occupancy was 97.26% and 92.27% in the surgical and medical ICUs, respectively; and 88.79% and 82.75% in COVID-19 ICU-A and COVID-19 ICU-B, respectively. The occupancy of all examined ICUs is reported in Figure S2 in Multimedia Appendix 1. The staff members interviewed from the COVID-19 ICUs were not the same as those from the non–COVID-19 ICUs, which introduces a limitation related to team differences and experience levels.

Regarding the alarm durations, we could not investigate the impact of the isolation process by analyzing alarm response times between COVID-19 ICUs and isolation rooms in non–COVID-19 ICUs. Due to the provisional and time-limited nature of the COVID-19 ICUs, the alarm fatigue in health care providers might reflect not only the conditions in the COVID-19 ICUs but also the individual exposure to alarm load during their former career. We cannot definitively determine whether the increased alarm load was caused by the COVID-19 condition itself or by the differences in ICU settings. Unfortunately, more detailed clinical data for every patient associated with the alarm data were not available at the time of the study. From a clinical perspective, the patient cohorts in the COVID-19 ICUs and general ICUs were comparable in terms of the severity of their conditions. In addition, fatigue among health care professionals working with patients with COVID-19 infection was inherently greater due to the overall stress and workload of managing COVID-19 cases, which cannot be attributed solely to alarm load. We suggest propensity score matching or similar statistical techniques as areas for future research. Similarly, determining isolation rooms from non–COVID-19 ICUs is recommended for further studies to gain a deeper understanding of the impact of the isolation process on alarm response times.

Conclusions

In this study, the COVID-19 ICUs registered significantly more alarms than the non–COVID-19 ICUs. The higher number of alarms led to a higher level of alarm fatigue among the clinicians working in COVID-19 ICUs. We believe that this was caused by the high proportion of untrained staff who were deployed to the temporary ICUs during the pandemic and the provisional setting. The absence of central monitors in individual rooms and corridors further compounded these challenges, making it difficult for health care providers to swiftly identify and respond to alarms. However, it is important to note that our findings are limited by the study design and specific circumstances during the pandemic, which might affect the strength of our conclusions. Further studies are warranted to better understand the broader implications of alarm management in different ICU settings.

To mitigate alarm overload in provisional ICUs during future pandemics, we recommend creating skill-oriented video tutorials on alarm management and monitor use. These tutorials should provide easily accessible training for new staff, who may be rapidly recruited and could have limited or no prior ICU experience. This educational material could equip them with the necessary knowledge to effectively navigate the ICU alarm system.

Acknowledgments

The authors express their gratitude to the intensive care unit staff for their participation in this study. ASP is a participant in the Digital Clinician Scientist Program funded by Charité–Universitätsmedizin Berlin and the Berlin Institute of Health. The cost of publishing open access was covered by Projekt DEAL.

Data Availability

The data sets generated and analyzed during this study are available in the Zenodo open data repository [54]. The code is available from the corresponding author on reasonable request.

Authors' Contributions

ASP and MMW had the idea for the study. The study was conceived by NF, MMW, ASP, and FB. NF and MMW analyzed the data and conducted the interviews, supported by ASP. NF wrote the manuscript, supported by ASP, CH, SA-W, and MMW. FB supervised all parts of the study. All authors critically reviewed and approved the manuscript. The paper was extracted from NF's MSc thesis.

Conflicts of Interest

FB reports grants from the German Federal Ministry of Education and Research, the German Federal Ministry of Health, the Berlin Institute of Health, the Hans Böckler Foundation, the Einstein Foundation, the Berlin University Alliance, and from the Robert Koch Institute, as well as personal fees from Elsevier Publishing, outside the submitted work. All other authors declare no conflicts of interest.

Multimedia Appendix 1
Alarm load and management differences between COVID-19 and non–COVID-19 intensive care units (ICUs). Figures include alarm frequencies by device and color, unit occupancy, alarm durations, and adjustments in settings across ICUs. Table data cover interview questions, alarm log structure, included alarm signals, hypothesis testing group sizes, and statistical analysis of alarm load per bed per day.

Abstract

Background: Integrating decision support systems into telemedicine may optimize consultation efficiency and adherence to clinical guidelines; however, the extent of such effects remains underexplored.

Objective: This study aims to evaluate the use of *ICD* (*International Classification of Disease*)-coded prescription decision support systems (PDSSs) and the effects of these systems on consultation duration and guideline adherence during telemedicine encounters.

Methods: In this retrospective, single-center, observational study conducted from October 2021 to March 2022, adult patients who sought urgent digital care via direct-to-consumer video consultations were included. Physicians had access to current guidelines and could use an *ICD*-triggered PDSS (which was introduced in January 2022 after a preliminary test in the preceding month) for 26 guideline-based conditions. This study analyzed the impact of implementing automated prescription systems and compared these systems to manual prescription processes in terms of consultation duration and guideline adherence.

Results: This study included 10,485 telemedicine encounters involving 9644 patients, with 12,346 prescriptions issued by 290 physicians. Automated prescriptions were used in 5022 (40.67%) of the consultations following system integration. Before introducing decision support, 4497 (36.42%) prescriptions were issued, which increased to 7849 (63.57%) postimplementation. The physician's average consultation time decreased significantly to 9.5 (SD 5.5) minutes from 11.2 (SD 5.9) minutes after PDSS implementation (P<.001). Of the 12,346 prescriptions, 8683 (70.34%) were aligned with disease-specific international guidelines tailored for telemedicine encounters. Primary medication adherence in accordance with existing guidelines was significantly greater in the decision support group than in the manual group (n=4697, 93.53% vs n=1389, 49.14%; P<.001).

Conclusions: Most of the physicians adopted the PDSS, and the results demonstrated the use of the *ICD*-code system in reducing consultation times and increasing guideline adherence. These systems appear to be valuable for enhancing the efficiency and quality of telemedicine consultations by supporting evidence-based clinical decision-making.

KEYWORDS

telemedicine; clinical decision support systems; electronic prescriptions; guideline adherence; consultation efficiency; International Classification of Disease–coded prescriptions; teleheath; eHealth

Introduction

Telemedicine increasingly serves as a primary point of entry into the health care system for patients, particularly in urgent care scenarios [1]. Physicians providing digital consultations are tasked with maximizing efficiency in terms of encounter duration while ensuring that prescriptions issued adhere to established guidelines, which is a crucial component of the cost-effectiveness and quality of telemedicine services [2].

The role of prescription decision support systems (PDSSs) is critical in the digital health care environment [3]. Within electronic health records (EHRs), PDSSs can streamline the amount of time that clinicians spend navigating complex medical terminology [4]. Research indicates that standardizing data input can enhance routine documentation in medical records [5]. Apart from time efficiency, EHRs have been linked to improved care quality and increased compliance with clinical guidelines [6]. Although EHR adoption is associated with significant challenges, the development of strategies to facilitate their use is gradually progressing [7]. To date, however, research exploring voluntary PDSS use and its impact on the outcomes of direct-to-consumer telemedicine consultations for acute conditions has been lacking.

We propose that physicians' adoption of a PDSS will demonstrate both a reduction in the time needed to deliver care and increased adherence to clinical guidelines. This study explored the relationships between telemedicine use and *ICD* (*International Classification of Diseases*)-triggered PDSS scores, consultation duration, and guideline adherence.

Methods

Study Design and Participants

A single-center retrospective study is conducted at the Telemedicine Center of Hospital Israelita Albert Einstein in São Paulo, Brazil. The data were collected by physicians at the Telemedicine Center, which ensured secure data storage. All authors contributed to the initial draft of the study and conducted a thorough examination of the complete data set, to which they had full access. The paper was exclusively written by the named authors, without contributions from nonauthors. All data analyses were conducted internally by the supervisory team of the Telemedicine Center. All authors collectively decided to submit this paper for publication and also supported the authenticity and integrity of the reported data.

The study included patients aged 16 years and older who voluntarily accessed digital direct-to-consumer care from October 2021 to March 2022. We considered all patients who were presented with any medical condition for inclusion in this study. The only exclusion criterion was the occurrence of connection issues that precluded the creation of medical records; these patients were excluded because they did not undergo a complete medical evaluation and were consequently not documented in the institution's database.

Ethical Considerations

The protocol for the study, which is known as the "Tele AUTOMATION" trial, and a consent waiver (based on an analysis of anonymized retrospective data from routine care) were approved by the Hospital Israelita Albert Einstein Review Board (registration: CAAE 69981423.6.0000.0071). Institutional digital archives, which were not linked to any external financial support, served as repositories for all of the data related to this study. The collected data were treated confidentially and protected by strict security measures, in accordance with the internal data protection policies of the Hospital Israelita Albert Einstein. All stages of the study involving privacy and personal data protection were conducted in accordance with Brazil's General Data Protection Law (LGPD). No compensation was provided to participants.

Telemedicine Consultations

Telemedicine consultations were conducted over the internet using proprietary videoconferencing software and EHRs. All participating physicians were board-certified and had additional training in both telemedicine and emergency medicine. The Telemedicine Center provided streamlined access to up-to-date clinical guidelines. Medical information was recorded in EHRs, which featured a specific field for the primary *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) diagnosis.

Decision Support and Guideline-Directed Prescribing

A suite of 26 international guidelines adapted for telemedicine was available for immediate reference during the consultations. These guidelines were structured to suggest appropriate prescriptions, as outlined in Multimedia Appendix 1. Physicians received training on how to effectively consult these guidelines, with the aim of aligning prescriptions with scientific evidence, resource efficiency, side effect mitigation, and overall service safety. In 2021, a voluntary feature allowing prescription autopopulation was introduced, providing shortcuts to medications listed in guidelines corresponding to the *ICD-10*, which is central to patient care. With a single keystroke, the autopopulation feature filled prescription fields with medications, dosages, administration routes, and durations as indicated by the relevant guidelines. This new functionality was introduced during the testing period, and no further adaptations were made to the system. By January 2022, this functionality was fully integrated into the medical record system, and physicians were instructed on its use according to clinical findings. Prescription adaptations for comorbidities were tailored based on clinical judgment and evaluated on an individual basis.

Patient and physician acceptance was not directly assessed. The functionality was made available for voluntary use. Although system adoption was not directly measured, a substantial portion of prescriptions were issued using the decision support system, allowing us to infer that a significant number of physicians accepted this strategy.

Data Extraction and Adherence to Institutional Protocols

The data from each TM encounter were extracted from the institution's medical record database. The *ICD-10* code

associated with each telemedicine consultation was used to cross-reference the institutional protocol. Prescriptions issued by the telemedicine physicians were compared to the protocol's medication list using data from the medication prescription field in the telemedicine consultation record.

First, the *ICD-10* code from each telemedicine consultation was used to identify the proper institutional protocol. Then, the set of medications provided in the protocol was compared with the medications prescribed by the telemedicine physicians as documented in the dedicated fields for prescriptions on the telemedicine consultation record. We added a binary feature (1=matching and 0=not matching) to the data set to denote matches between prescribed medication and institutional directives. After applying this procedure to all records in our data set, we were able to compute summary statistics to compare protocol adherence before and after autocomplete system implementation. Table 1 provides the main summary statistics for our data set.

Table 1. Summary statistics for the data set before and after implementation of the clinical decision support autocomplete system.

Data set feature (year)	2021	2022	Total
Consultations, n (%)	3873 (36.94)	6612 (63.06)	10,485
Patients, n (%)	3628 (37.62)	6174 (68.38)	9644
Physicians, n (%)	211 (72.76)	231 (79.65)	290
Medication prescriptions, n (%)	4497 (36.42)	7849 (63.58)	12,346
Mean encounter duration (in minutes), mean (SD)	11.23 (5.92)	9.49 (5.57)	10.13 (5.77)
ICD-10[a] codes documented, n (%)	286 (65.15)	312 (71.07)	439

[a]*ICD-10*: *International Statistical Classification of Disease, Tenth Revision*.

Statistical Analysis

The study analyzed a convenience sample of all patients who were consecutively registered during the defined period. Continuous variables are reported as the mean (SD) or as the median (IQR) ranges for descriptive purposes, whereas categorical variables are summarized as counts and percentages. To test for normality in the distribution of our sample, we used the Kolmogorov-Smirnov test. The Mann-Whitney *U* test was used for continuous variables that were not normally distributed. A *P* value less than .001 indicated statistical significance and 95 % CIs were calculated. All statistical analyses were conducted using IBM SPSS Statistics (version 22.0) for Windows.

Results

Throughout the 6-month study period, we analyzed a total of 10,485 encounters with 9644 patients. Patient demographic data and the most common diagnoses are described in Table 2. These encounters resulted in 12,346 prescriptions being issued by 290 different attending physicians. Notably, some patients had multiple consultations within the study timeframe, and multiple prescriptions were occasionally dispensed during a single consultation; these prescriptions were not individualized. Before the implementation of the self-report prescription system, 4497 (36.42%) prescriptions were issued, which increased to 7849 (63.58%) after its implementation. A preliminary test of the system commenced in 2021; however, the system was not fully operational and made available for voluntary use by all physicians until January 2022. Following its implementation, the automated prescription feature was used in 5022 (40.67%) of the encounters.

During the brief trial period of the PDSS tool in 2021, a total of 261 (5.80%) prescriptions were made with electronic assistance, while 4236 (94.19%) prescriptions were issued without such assistance. Following the full deployment of the PDSS tool in 2022, the figures shifted significantly, with 5022 (63.98%) prescriptions being made with electronic assistance compared to 2827 (36.02%) without assistance.

The data demonstrated a significant reduction in consultation time after self-reporting: 9.5 (SD 5.5) minutes versus 11.2 (SD 5.9) minutes (P<.001; Mann-Whitney U test=12,118,181.5; Figure 1). Figure 2 shows that the decrease in the average consultation duration was correlated with service density, which was defined as the volume of services delivered by the center within a specified timeframe.

Regarding guideline adherence among the 12,346 medications prescribed, a substantial number of these medications (n=8683, 70.34%) were prescribed in accordance with guidelines. Notably, compared with manual prescription entry, the use of the automated filling system significantly increased guideline adherence (n=4697, 93.5% vs n=1389, 49.1%; P<.001; z score=45.24).

Regarding adherence to the institutional protocol for medical prescriptions, when the PDSS tool was not used, 1438 (50.87%) prescriptions deviated from the standard recommendations, while 1389 (49.13%) complied. Our analysis demonstrated that the application of the PDSS tool significantly improved adherence, with only 325 (6.47%) prescriptions failing to comply with the protocol, compared to 4697 (93.53%) that were aligned.

Table 2. Patient demographic data and the most common diagnoses.

Variable	2021-2022
Encounters	10,485
Patients	9644
Sex, n (%)	
Male	6669 (69.15)
Female	2875 (29.81)
Not declared	100 (1.04)
Age (years), mean (SD)	0.0-92.0 (32.2)
Most common diagnoses, n (%)	
J01, acute sinusitis	2627 (25.05)
N30, cystitis	1839 (17.54)
J03, acute tonsillitis	1271 (12.12)
J02, acute pharyngitis	478 (4.56)
J06.9, acute upper respiratory infection, unspecified	324 (3.09)

Figure 1. Comparison of consultation times with and without the use of autocomplete functionality for medical prescriptions revealed a statistically significant decrease in consultation time (*P<.001; 9.5, SD 5.5 minutes vs 11.2, SD 5.9 minutes; Mann Whitney U test=12,118,181.5).

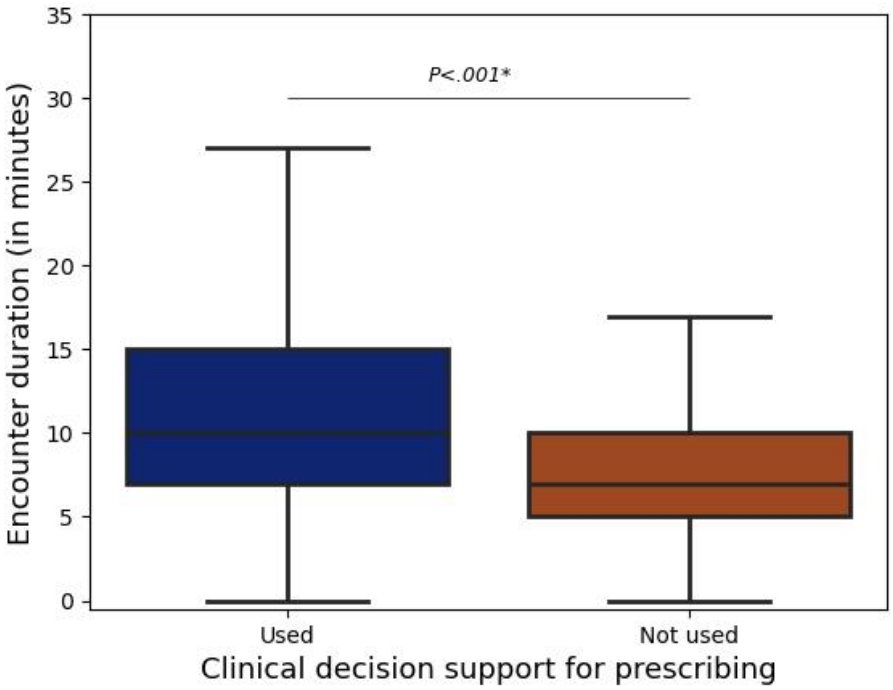

Figure 2. Distributions of consultation times and encounter frequency. The dotted vertical lines indicate the median values for each distribution (8 and 10 minutes, respectively).

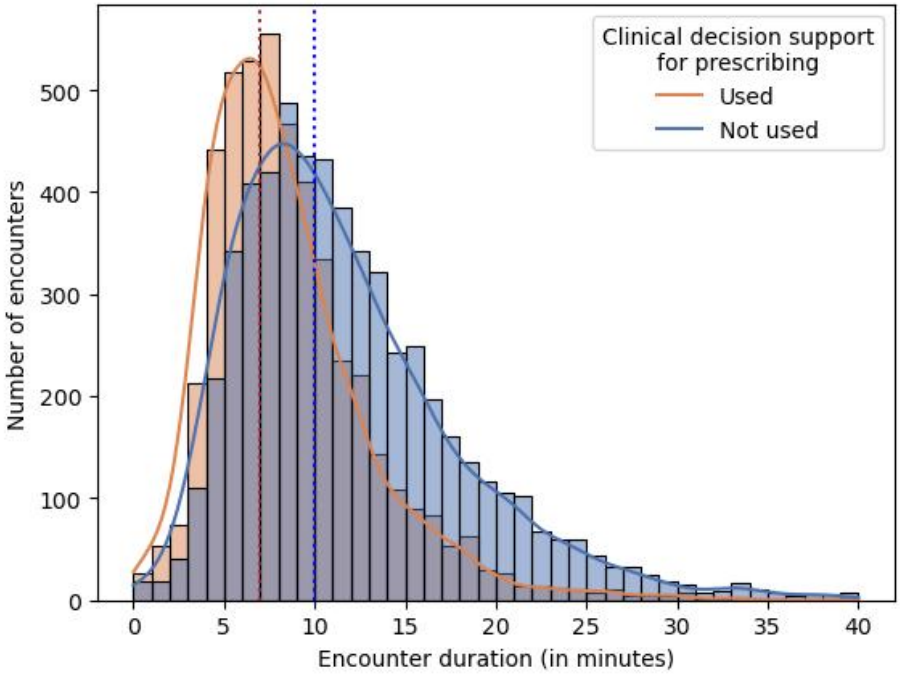

Discussion

This study demonstrated that shortly after becoming available, most physicians opted to voluntarily use the decision support autocomplete functionality for medical prescriptions. Innovative approaches that facilitate the use of EHRs tend to be well received by medical practitioners [8]. The integration of new information technologies has transformed numerous aspects of health care and thus revolutionized care delivery within health systems [9], representing a significant advancement in digital health care, although certain challenges still need to be overcome. These challenges include poor interface designs, suboptimal performance, maintenance issues, overreliance, and dependency, all of which could jeopardize patient safety [10].

This study revealed an impressive rate of 94.7% adherence to recommendations, suggesting a potential improvement in the safety of telemedicine consultations with the use of autocomplete prescriptions. Guideline adherence is a measure of how well health care providers follow established clinical guidelines and protocols and is crucial for minimizing risks and ensuring optimal care quality and safety [11]. Notably, given that evidence suggests frequently deficient adherence with respect to in-person consultations, telemedicine shows promise as a method of care associated with better compliance [12-14].

The safety of prescribing practices and reductions in medication errors have been supported by evidence from electronic prescriptions selected through the use of standardized medication lists, codified instructions, and multimodal decision support [15]. Nonetheless, the prevalence of electronic prescribing errors can be high, with rates nearing 60%, particularly when considering incorrect field entries [16]. Previous studies have identified numerous potential error types in electronic prescriptions [17], and the electronic prescription strategy chosen has been noted to be a source of medication errors [18], which underscores the importance of continuing to improve electronic prescription systems.

The option for voluntary prescription autopopulation has several potential benefits for health care delivery. This approach may alleviate bureaucratic burdens associated with current medical practices, thereby enhancing communication with patients [19]. In high-demand settings, an autocomplete option can optimize consultation times as part of a broader management strategy [20]. Additionally, access to checklists for possible medication recommendations may reduce bias [21].

Our analysis revealed a 15.18% decrease in physicians' average consultation time, from 1123 to 949 minutes, when the autocomplete feature was used, although reliance entirely on manual prescription entry was noted in 31% of consultations. Intriguingly, even with voluntary use, most prescriptions issued using the autocomplete function strictly adhered to medication recommendations, indicating high adherence to these recommendations. Prior to our study, no research had specifically investigated telemedicine quality based on guideline-directed prescribing facilitated by an autocomplete function. Accordingly, the establishment of high-quality telemedicine centers that continuously update management guidelines and develop strategies to meet policy requirements and deliver excellent remote medical consultations is imperative to enhance EHR systems. In addition to prescribing practices alone, administrators need to ensure the usability and appropriate implementation of coding for the autocomplete method to prevent misuse and maintain safety.

No specific security assessment was conducted. However, protocol adherence is recognized as a primary indicator of safety in care delivery, including referrals for in-person care when warning signs are identified. This study revealed enhanced

adherence to guideline recommendations through the use of the self-report system, indirectly suggesting that increased safety was observed within this group.

Among the limitations of this study, the observed outcomes from the use of the clinical decision support system may not be solely attributable to changes in care practices. Instead, these outcomes might also reflect changes in the *ICD* codes selected by physicians, possibly for the convenience of prescribing. Moreover, the clinical support decision system may have encouraged excessive prescribing despite many of these conditions being manageable with nonpharmacological interventions, especially for those with mild symptoms. Notably, care quality assessed based solely on whether *ICD* codes matched medication recommendations may not effectively represent the true quality of care and may reflect decreased care quality, as previously mentioned. Another possible limitation was that the group that used decision support may have included patients with simpler diagnoses.

In this study, a PDSS was voluntarily used by physicians for most encounters. Decision support incorporation for prescription selection within EHRs, particularly in scenarios where policies are clearly established, may contribute to reducing consultation times and promoting high rates of adherence to guideline-directed prescriptions. This finding highlights the potential role of these systems in improving both the efficiency and quality of health care delivery, especially within telemedicine environments where prompt and precise decision-making is essential.

Abstract

Background: Tolvaptan is the only US Food and Drug Administration–approved drug to slow the progression of autosomal dominant polycystic kidney disease (ADPKD), but it requires strict clinical monitoring due to potential serious adverse events.

Objective: We aimed to share our experience in developing and implementing an electronic health record (EHR)–based application to monitor patients with ADPKD who were initiated on tolvaptan.

Methods: The application was developed in collaboration with clinical informatics professionals based on our clinical protocol with frequent laboratory test monitoring to detect early drug-related toxicity. The application streamlined the clinical workflow and enabled our nursing team to take appropriate actions in real time to prevent drug-related serious adverse events. We retrospectively analyzed the characteristics of the enrolled patients.

Results: As of September 2022, a total of 214 patients were enrolled in the tolvaptan program across all Mayo Clinic sites. Of these, 126 were enrolled in the Tolvaptan Monitoring Registry application and 88 in the Past Tolvaptan Patients application. The mean age at enrollment was 43.1 (SD 9.9) years. A total of 20 (9.3%) patients developed liver toxicity, but only 5 (2.3%) had to discontinue the drug. The 2 EHR-based applications allowed consolidation of all necessary patient information and real-time data management at the individual or population level. This approach facilitated efficient staff workflow, monitoring of drug-related adverse events, and timely prescription renewal.

Conclusions: Our study highlights the feasibility of integrating digital applications into the EHR workflow to facilitate efficient and safe care delivery for patients enrolled in a tolvaptan program. This workflow needs further validation but could be extended to other health care systems managing chronic diseases requiring drug monitoring.

Introduction

Autosomal dominant polycystic kidney disease (ADPKD) is the leading genetic cause and the fourth overall cause of end-stage kidney failure (ESKF) [1]. Patients with polycystic kidney disease 1 (PKD1) mutations develop ESKF 20 years earlier than those with PKD2 mutations [2,3]. The Mayo imaging classification (MIC) is a validated tool that identifies patients at risk for rapid progression to kidney failure, and disease-modifying therapy is recommended for patients with class 1C, 1D, or 1E, who have higher total kidney volume (TKV) growth rates [4]. In 2018, tolvaptan (brand name Jynarque; Otsuka America Pharmaceutical) was approved by the US Food and Drug Administration (FDA) as the first drug to slow kidney function decline in patients with rapidly progressive ADPKD. Tolvaptan reduces kidney volume growth and estimated glomerular filtration rate (eGFR) decline, delaying the need for kidney replacement therapy [5,6]. Tolvaptan acts by blocking the vasopressin V2 receptors in the distal nephron and collecting duct, inhibiting urinary concentration and sodium reabsorption and reversing the tubuloglomerular feedback inhibition induced by vasopressin, thus acutely and reversibly decreasing eGFR and possibly glomerular hyperfiltration [5]. However, tolvaptan is associated with several side effects, including polyuria, urinary frequency, thirst, and nocturia, which require patient education on adequate hydration. Tolvaptan can also cause significant hepatotoxicity in 5% of patients; thus, periodic liver function tests are mandated by the FDA through the risk evaluation and mitigation strategy (REMS) safety program. Due to the side effects profile and the necessary frequent laboratory test monitoring, the cost associated with staff time to manage the program beyond face-to-face care can limit the ability of health care teams to safely provide this disease-modifying therapy [7,8].

Tools that are directly integrated in the electronic health record (EHR) workflow can increase efficiency, reduce cost, and improve drug monitoring and quality of care [9-12]. For example, a cluster randomized clinical trial in primary care provided access, within the EHR, to a prescription drug monitoring program (PDMP) before the prescription of opioids. The integration increased PDMP-querying rates, suggesting that direct access reduced hassle costs and could improve adherence to guideline-concordant care practices [13]. Another study reported that the design and implementation of an electronic registry with a complementary workflow established an active tracking system that improved monitoring of patients on anticoagulation therapy [14]. However, no prior EHR-integrated workflow has been developed and validated to safely and successfully monitor patients with ADPKD treated with tolvaptan.

This paper describes the design, development, and implementation of an intelligent automated application within the EHR to efficiently manage and monitor ADPKD patients enrolled in the Mayo Clinic tolvaptan program. The goal of this paper is to illustrate how digital applications integrated into the EHR workflow can facilitate efficient and safe care for patients enrolled in a drug monitoring program and how this workflow can be extended to similar programs in chronic disease management and lay the groundwork for quality improvement efforts.

Methods

Ethical Considerations

This work was reviewed by the Mayo Clinic Institutional Review Board (21-005428). The study was exempt from clinical research overight because it was considered to be a quality improvement project. Informed consent was waived and data were deidentified.

Practice Setting

The Mayo Clinic is an integrated, multispecialty, multistate, large academic health system with locations in Minnesota, Florida, and Arizona; there are also other Mayo Clinic health system hospitals across Minnesota and Wisconsin. Since 2018, the Mayo Clinic uses a single, integrated EHR (Epic Systems) across all campuses. The Minnesota practice where the tolvaptan EHR application was initially launched includes 5 experienced nephrologists and 4 nurses directly involved in the ADPKD practice and various other specialists (ie, geneticists, hepatologists, liver surgeons, neurologists, neurosurgeons, pain specialists, interventional radiologists, transplant experts, and research coordinators) who care for these patients as needed. The tolvaptan EHR application was eventually adopted enterprise-wide in 2022, although the workflow may differ slightly by site based on the specificity and resources available in each practice. The 3 main Mayo Clinic campuses in Minnesota, Florida, and Arizona are designated as centers of excellence for ADPKD care by the Polycystic Kidney Disease Foundation.

Clinical Protocol—Indications and Monitoring of Tolvaptan Treatment

Tolvaptan is prescribed in patients aged 18 to 55 years with eGFR ≥25 mL/min/1.73 m^2 and at risk of rapid progression, defined by having an age-indexed height-adjusted TKV within MIC class 1C, 1D, and 1E [5,6,15]. Contraindications to initiate tolvaptan include history of liver injury, uncorrected hypernatremia, hypovolemia, inability to sense thirst, urinary tract obstruction, and concomitant use of strong CYP3A (cytochrome P450, family 3, subfamily A) enzyme inhibitors [16]. Tolvaptan initiation requires a multidisciplinary approach led by the treating nephrologist and a well-trained nursing team. In our program, following a shared decision discussion, eligible patients who agree to start tolvaptan are referred to a specialized nephrology nurse for a detailed educational session. The nurse visit includes a blood pressure check, assessment of alcohol consumption, dietary review, and in-depth education about the side effects of tolvaptan and the need for routine laboratory test monitoring. Patients are instructed to have a drug holiday in certain situations, such when they are unable to maintain adequate fluid intake, are hospitalized, are about to undergo an elective procedure, or are traveling. After confirming their willingness to take the medication, the nurse enrolls the patient in the mandatory REMS program, a drug safety program developed by the FDA for certain medications with serious safety concerns. As part of the tolvaptan REMS program, the

following laboratory tests are performed before the morning dose of tolvaptan: aspartate transaminase (AST), alanine transaminase (ALT), total bilirubin, serum sodium (advised but optional), and creatinine (advised but optional). Results are collected 2 and 4 weeks after tolvaptan initiation, then monthly for 18 months, and every 3 months thereafter [16]. Staff must log in to complete a REMS attestation every 3 months for each patient. Liver enzyme elevation and changes in serum sodium or creatinine are reviewed after each test in a timely fashion by the nursing team and the prescribing nephrologist. This process is designed to detect any laboratory test abnormality or the development of drug complications that could otherwise go unnoticed. For example, one threshold for suspending the medication is elevation in AST or ALT twice above their baseline level, which might not be flagged in the test report. However, this process can be very cumbersome and time consuming for the clinical team. An intelligent, automated, and streamlined real-time EHR-based process of tracking and monitoring is essential for efficient and safe care delivery, especially in specialized centers with a large patient population.

Architecture and Application Development by the Cohort Knowledge Intelligence Solutions Team

At the Mayo Clinic, the Cohort Knowledge Intelligence Solutions (CKIS) team is behind the development of many innovative patient cohort management solutions using the Epic Healthy Planet module. The CKIS team uses a collaborative, agile approach that incorporates feedback from clinical stakeholders and informatics to create care management solutions based on agreed-upon protocols of care that improve and automate processes for clinical staff, all managed within the EHR. All projects are reviewed through a standard intake process that factors in the scope of the project, enterprise impact, patient safety, quality of care, and revenue impact, among other criteria. Once approved and assigned, a business analyst and a builder will work with a group of stakeholders anywhere between several weeks to several months, depending on the scope of the project, to complete a solution build.

After the scope of a project is defined, a registry is used to gather a patient cohort along with a subset of metrics required to support the practice needs. The registry is an internal tool housed within Epic's software and uses a rule-based framework consisting of 2 main components: an inclusion rule and metrics. The inclusion rule is used to define the population and uses a combination of charted data, such as the patient's diagnosis, medication, and surgeries, or general demographics (eg, age and gender). The metrics (ie, rules) define what data will be captured for the population. Once a patient meets the defined inclusion criteria, the underlying metrics are processed, and data is captured. Metrics are designed to support the monitoring workflow in addition to future quality analysis and outcomes. They typically capture dates, laboratory test values, appointment information, patient demographics, and more. Finally, a report is built allowing users to visualize and interact with the registry data. Within the reports, specific patient metrics are displayed pertinent to the practice and may include laboratory test results, appointment information, or customized algorithms to create alerts for care team members to help them prioritize their work. The last phase of the build process includes testing and ensuring that the initial agreed-upon requirements have been met. Several months after the build is complete, the CKIS team meets with the customers to complete a value assessment that measures the impact of the solution provided.

Process of Tolvaptan Application Development

The nephrology ADPKD practice assembled a team of stakeholders to streamline the enrollment and monitoring of patients in the tolvaptan program. After an initial discussion in early 2020, the clinical team determined the content of the application. The stakeholders met on average every 2 weeks over a 3-month period to develop, in an iterative fashion, the initial application and test the efficiency of the system over the subsequent 3 to 4 months. The team determined that 2 applications were required to serve the clinical need. The first and main application, titled Tolvaptan Monitoring Registry, manages all patients actively treated with tolvaptan by consolidating all relevant information in one screen. Patients who discontinue tolvaptan are removed from the first application and automatically added to the second application, titled Past Tolvaptan Patients. The second application allows the care team to maintain a log of all past participants and record the reason for drug discontinuation, such as adverse effects or requiring renal replacement therapy.

Results

In September 2020, 2 EHR-based applications for monitoring patients taking tolvaptan were activated for clinical use. The tolvaptan clinic was established 2 years earlier when the FDA approved tolvaptan for the treatment of ADPKD. All patients enrolled in the program prior to September 2020 (n=32) were retrospectively added to the tolvaptan monitoring application.

Clinical Workflow Using the Tolvaptan Application

The tolvaptan application workflow involves the submission of an electronic prescription order by a nephrology nurse (Figure 1) and completion of an electronic activation form to enroll patients in the EHR-based tolvaptan monitoring application (Figure 2). This form includes the patient's Mayo Clinic site, primary nephrology clinician, and date of treatment initiation. The automated addition of patients into the registry reduces the risk of missing any patient prescribed tolvaptan, ensuring that all treated patients are closely monitored for any adverse events that might occur while on therapy. Quarterly meetings take place between the nursing team and the nephrologists to review workflow issues and assess any new complications that may arise.

Figure 1. Tolvaptan order report. REMS: risk evaluation and mitigation strategy.

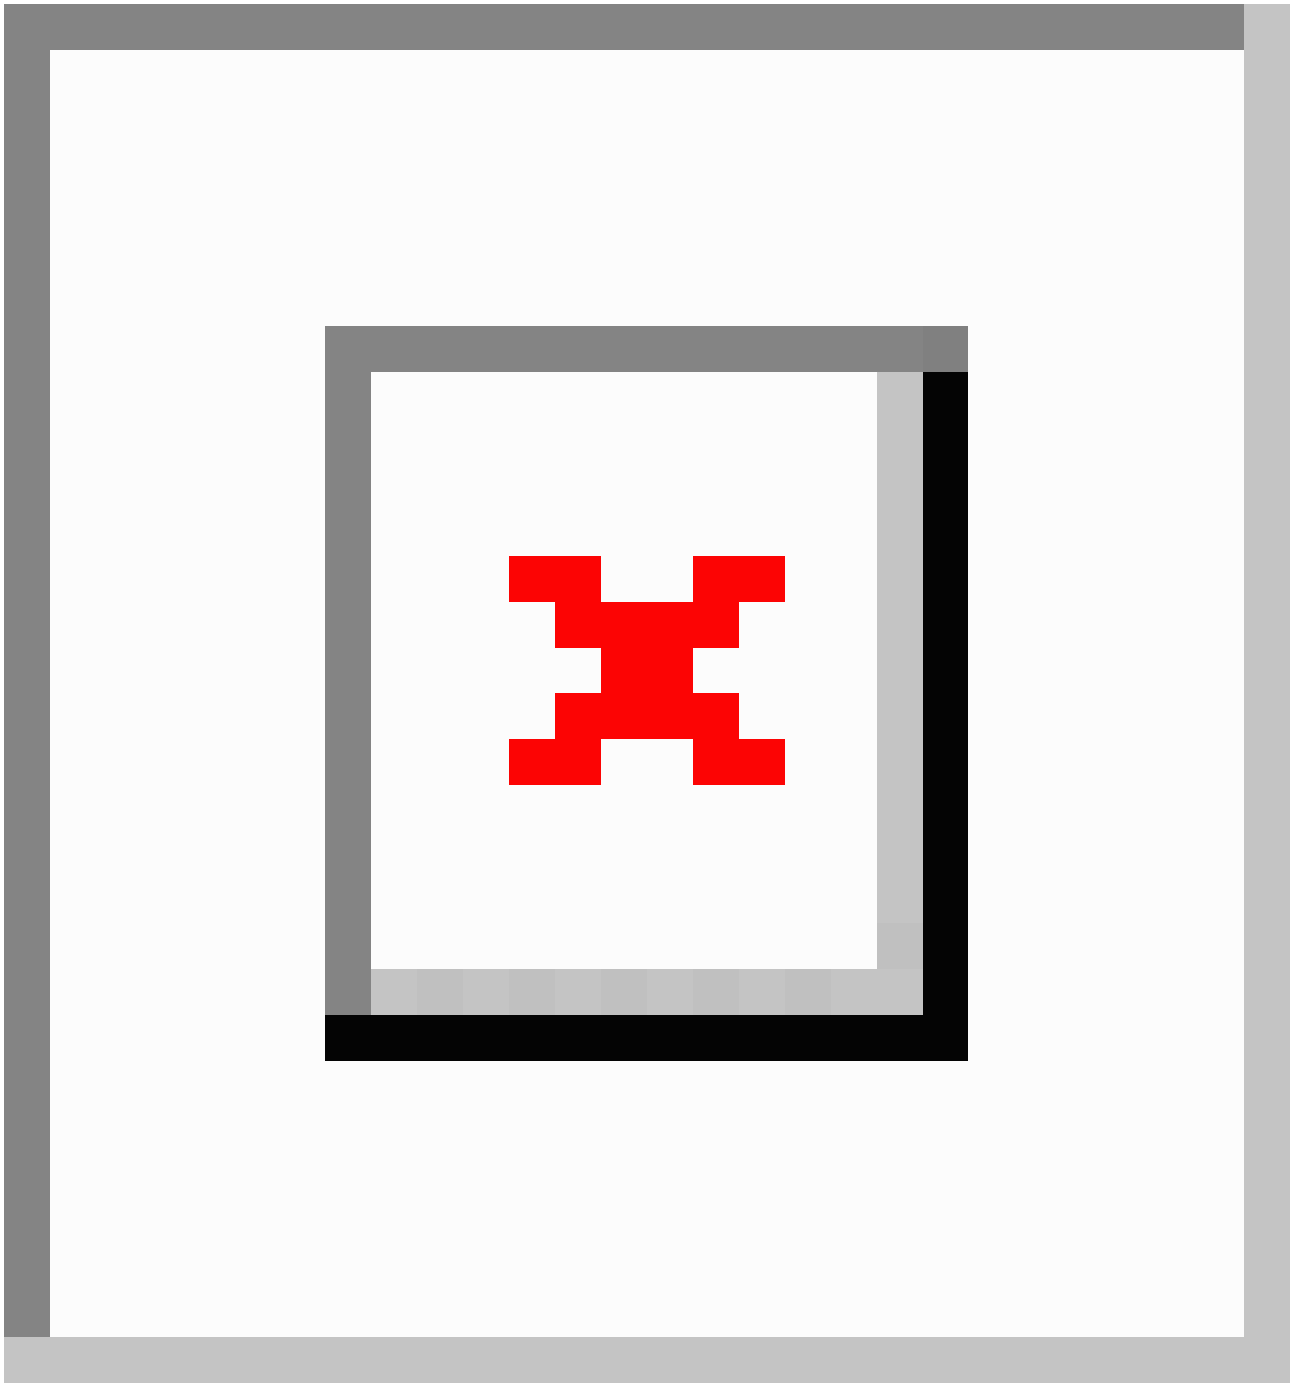

Figure 2. Smart form. MCHS: Mayo Clinic Health System; MN: Minnesota; NE: northeast; NW: northwest; REMS: risk evaluation and mitigation strategy; SW: southwest; WI: Wisconsin.

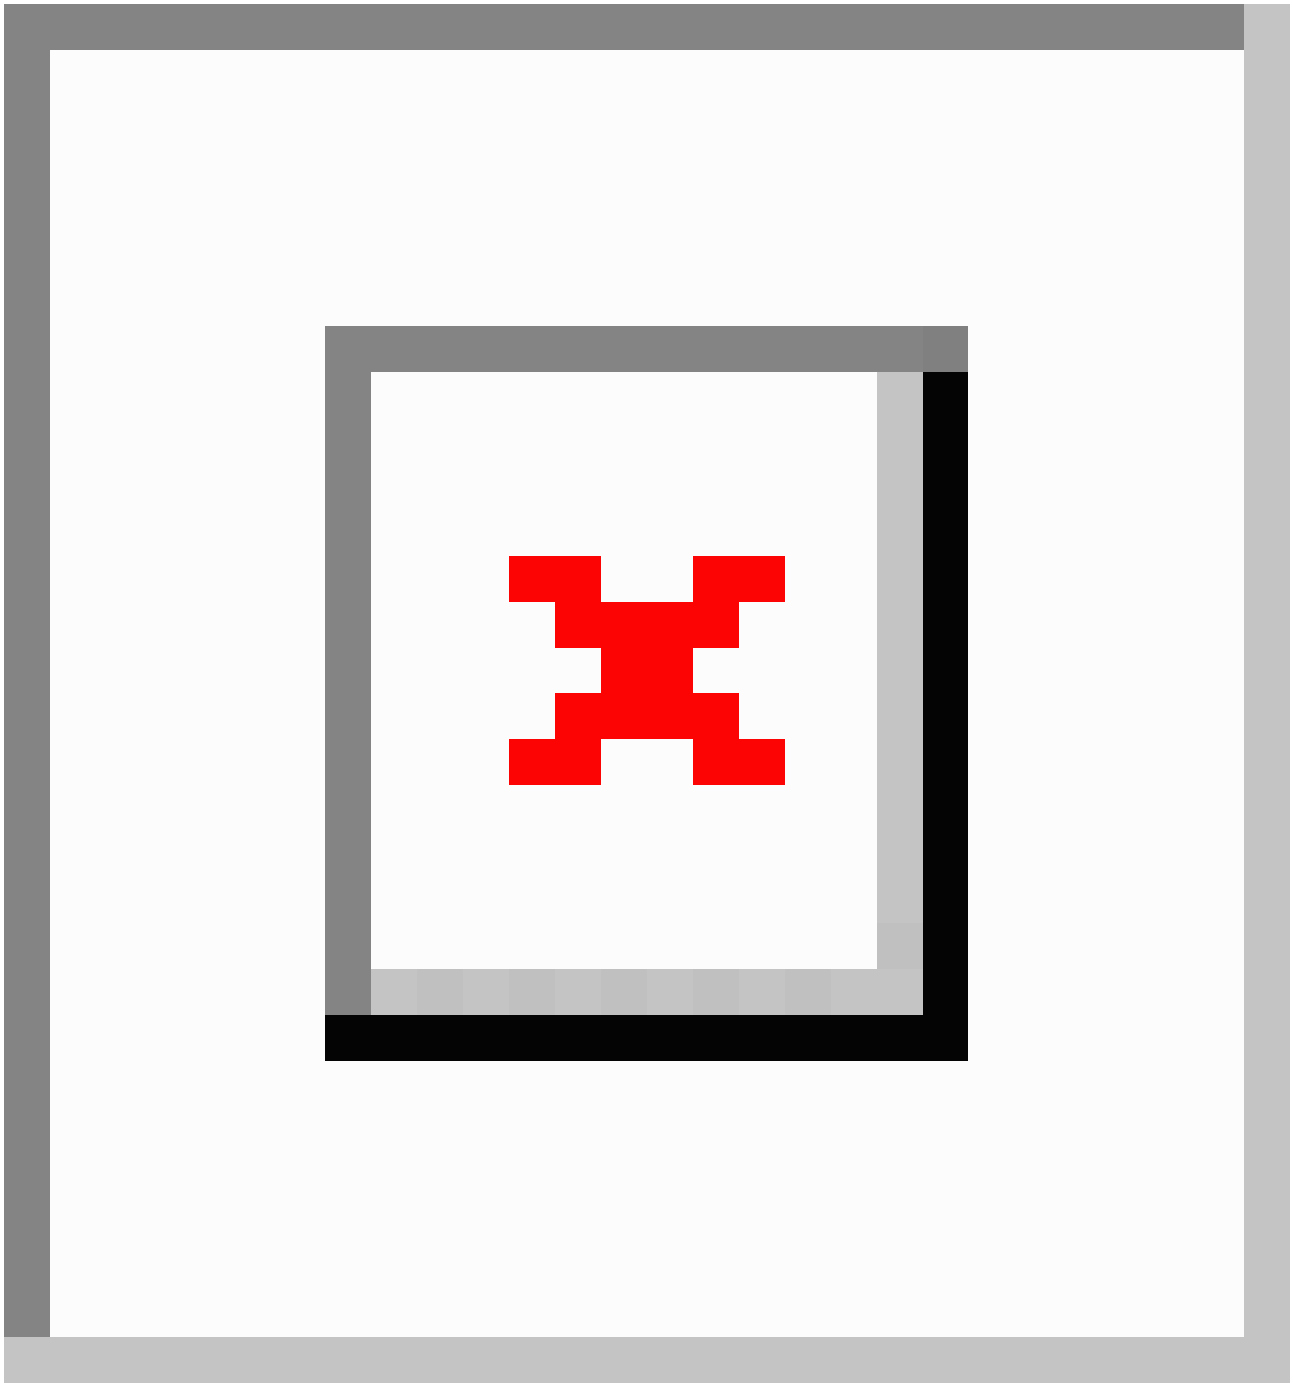

The main application lists all patients actively taking tolvaptan and includes several columns with relevant information, such as the patient's name, medical record number, date of initiation of tolvaptan, date of last liver function test, abnormal or urgent laboratory test flags, a "needs review" flag (Multimedia Appendix 1 provides details and flag criteria), the recommended laboratory test frequency based on the first dose date (ie, monthly or quarterly), the laboratory test's due date and the date of the next scheduled laboratory test, the last and next (when applicable) nursing outreach dates to the patient, the name of the treating nephrologist, and the last clinic visit date (Figure 3). The application allows filtering based on these variables, such as visualizing only patients who have abnormal laboratory tests or need review based on new laboratory tests since the last outreach date. The application also provides more detailed information for a specific patient based on several reports embedded at the bottom of the screen. These include Tolvaptan Monitoring Summary, Patient Visits, Nephrology Notes/Orders, and Patient Message Review. In our clinical workflow, every week, 1 of 4 dedicated nurses (on a rotation basis) reviews all flagged patients and takes appropriate action based on our clinical protocol. The EHR-based tolvaptan monitoring application provides several reports that allow for a more detailed review of a specific patient without having to open their chart. The Tolvaptan Monitoring Summary displays all monitored laboratory test results, such as AST, ALT,

bilirubin, serum creatinine, eGFR, serum sodium, and urine osmolarity (Figure 4). The Tolvaptan Monitoring Metrics window in the same section allows for quick access to recorded baseline laboratory test measurements and any abnormalities recorded. For example, the report displays a question and response: "Any Abnormal Liver Labs?" (answers are yes or no) (Figure 5). Additionally, all attempted or completed outreach interactions are listed with the name of the nurse conducting the activity and most recent nephrology note (Figure 6).

The Patient Visits report shows future scheduled appointments and surgeries, as well as a record of the patient's last 10 outpatient visits. This report also includes the patient's care team, demographics, and emergency contacts. The Nephrology Notes/Orders report displays pertinent medical history, current medication, immunizations, renal replacement therapy status, allergies, procedures, and the latest nephrology notes and specific ADPKD management–related comments by the nephrologist. Lastly, the Patient Message Review report includes all the patient's communications with personnel, nurses, and clinicians, as well as patient online services.

Characteristics of Enrolled Patients

As of September 1, 2022, a total of 214 patients have been enrolled in the tolvaptan program across the Mayo Clinic Health System in Minnesota, Arizona, Florida, and Wisconsin (Table 1).

Of the 214 patients, 126 (59%) were enrolled in the Tolvaptan Monitoring Registry, and the remaining 88 patients were included in Past Tolvaptan Patients. A total of 10 nephrologists were caring for these patients across the 4 locations. Table 2 displays characteristics of the patients in the Tolvaptan Monitoring Registry, including their demographics and MIC status.

The registry included 57.9% (n=124) female, 96.2% (n=206) White, 2.8% (n=6) Hispanic, and 0.9% (n=2) African American individuals. The mean age at enrollment was 43.1 (SD 9.9) years, and 86 patients had a documented MIC. Most patients had an MIC of 1C (n=38, 44.2%), followed by 1D (n=25, 29.1%) and 1E (n=19, 22.1%). Additionally, 3 patients (5.1%) had an MIC of 1B but were prescribed tolvaptan based on a non-MIC criterion. Of note, 33 (15.4%) patients were taking tolvaptan as part of a clinical trial and remained on the drug after trial completion (following FDA approval of the drug). These patients were added retrospectively to the application because they were taking tolvaptan prior to the creation of the EHR-based application.

Outcomes of Using the Tolvaptan Application

The implementation of the tolvaptan EHR-based application streamlined the monitoring process of patients treated with tolvaptan in several ways. First, the automated addition of patients into the registry reduced the risk of missing any patients started on tolvaptan, thus assuring that all treated patients were closely monitored for any adverse events that might occur while on therapy. Second, the application allowed for efficient and timely identification of patients who had abnormal laboratory test results and enabled nursing outreach to patients who might need further intervention or education on medication management. Overall, 20 (9.3%) patients had liver function test abnormalities, but only 5 (2.3%) had to discontinue the drug because of hepatotoxicity. The most common reason for drug discontinuation was related to the aquaretic effect, in 10 patients (4.7%), while only 4 (1.8%) could not continue in the program because of medical insurance–related issue. Third, the application provides a comprehensive and up-to-date summary of all pertinent clinical information related to the management of ADPKD, including medications, appointments, laboratory tests, and notes from the care team. Fourth, the application facilitated communication and collaboration among the multidisciplinary team involved in the care of patients with ADPKD. The standardization process and easy data access to all enrolled patients in the registry provided an opportunity for the care team to meet quarterly to review and discuss specific scenarios. These discussions sometimes led team members to share their experiences regarding challenging situations or drug-related adverse events or drug intolerance and at other times to propose enhancements to the EHR application. Finally, the application enhanced the efficiency of the tolvaptan program by reducing the time and effort (informally reported by the care team) required for enrollment, tracking, and monitoring of patients. More specifically, for the physicians, the only required task to enroll a patient in the program was identifying the candidate and making an electronic referral to the nursing team. The nursing team then initiated the education, treatment, and monitoring without any further escalation to the physician, unless there were concerns. For the nurses, all relevant information was consolidated, reducing the need to navigate to various EHR screens and modules.

Discussion

Principal Findings

In this report, we share our experience in developing and implementing an EHR application to manage and monitor patients with ADPKD who were enrolled in the tolvaptan program across several sites at our institution. This application streamlined the clinical workflow and enabled the nephrology nursing team to proactively take appropriate action to mitigate drug-related serious adverse events. Tolvaptan is the first and only FDA-approved drug to slow the progression of ADPKD, but it has multiple adverse effects, most seriously liver toxicity, which can be potentially severe, albeit rare. Therefore, frequent laboratory test monitoring is required to detect early drug-related toxicity. This application is crucial in facilitating the monitoring of patients taking tolvaptan, especially in large centers with high case load or smaller clinics with limited staff and resources. Overall, 20 (9.3%) patients had liver function test abnormalities, but only 5 (2.3%) had to discontinue the drug because of hepatotoxicity. The frequency of these events is very similar to those reported in the REPRISE clinical trial (10.9% hepatotoxicity and 1.6% discontinuation for a liver event) [6]. The most common reason for drug discontinuation was related to the aquaretic effect, which occurred in 4.7% (n=10) of patients. This is higher than the frequency reported in the REPRISE trial (2.1%) but not surprising since participants enrolled in clinical trials may be more motivated to adhere to the treatment protocol. Nonetheless, these clinical outcomes are reassuring.

The logistical requirements of any tolvaptan program may limit the ability of nephrology practices to provide this effective therapy. With the shortage of physicians and their high level of burnout [17-19], well-designed EHR integration that helps review, in a consolidated manner, relevant data for clinical care is important, although it comes with a higher up-front cost [20-23]. This is now more relevant because about 90% of office-based physicians in the United States use an EHR [24], and higher perceived EHR usability is associated with higher levels of perceived positive outcomes (improved patient care) and lower levels of perceived negative outcomes (worse patient interactions and work-life integration) [25]. Whether developing such digital systems is worth the investment is a relevant question for health care systems [26], but they can certainly be scaled in real-world settings. The cost of creating similar EHR-based applications will vary depending on each organization structure and is mostly an up-front cost. This includes the time required by both the clinical care team (nurses, physicians, and other clinical staff) and informatics team (program manager and technical build team) to identify the clinical need and develop and test the product. For our practice, it required at least 1 physician and 1 nurse champion to be present at each meeting (4 staff members were engaged) with the informatics team for 1 hour every 2 weeks on average over a 6-month period (12 hours per staff member involved). Since all our staff are salary based, this work was primarily supported by discretionary efforts and during nonclinical activities (lunch hour or administrative time). Regarding the informatics team (CKIS), our institution has allocated an operational budget to support various EHR-related projects across the enterprise; thus, we did not have to request extra funds to support this effort.

The advantages of these applications and data analytics capabilities within the EHR have been well described for various diseases and conditions, recently including more COVID-19–related activities, to manage the clinical practice safely [27-37]. Besides keeping track of a defined patient population, aggregating data, and identifying care gaps, communication with patients through the patient portal is readily accessible. In addition, bulk messaging (sending the same message to a group of patients in one click) is a convenient feature of the application. For example, staff can easily remind patients to do their monthly or quarterly laboratory tests when these have lapsed and do a synchronous or asynchronous quick health check if needed.

Limitations

The design, development, and deployment in clinical practice of this integrated digital application has limitations. The process is iterative and requires buy-in from various stakeholders, an up-front investment in time, resources, and change management capabilities. Our clinical team was receptive, open to change, and willing to embrace new workflows because of the perceived value of adopting the application (more efficient and safer care delivery). One limitation of our study is that it was conducted in a single health care system. However, the successful implementation of this application in our Minnesota practice, followed by its expansion to all Mayo Clinic practices, highlights the potential for scaling to other health care systems. Another limitation of our study is the lack of objective efficiency outcome measures. The workflow improvement and satisfaction were not evalutated in a formal manner by the physicians and nurses. Ideally, our study would assess the impact of the application using (1) direct observation (time-motion studies), (2) EHR log-based analysis (EHR log data), (3) care team pre- and postimplementation surveys, or a combination of these. However, prior to the implementation of the application, the management of the tolvaptan program was ad hoc, carried out by a care team that performed multiple unrelated clinical activities. This made it impractical to use time-motion studies and impossible to meaningfully use EHR log data. A care team survey was considered, but because the transition to the application was done during the COVID-19 pandemic when our personnel resources were very strained, noncritical activities were paused. Prospective studies are necessary to validate the effectiveness of this application and its potential for improving care processes and ultimately patient outcomes.

Conclusion

In conclusion, our multidisciplinary team developed an EHR-integrated digital monitoring protocol that could facilitate safe, efficient, and high-quality care for patients with ADPKD who were prescribed tolvaptan. The implementation of this application in our health care system can be scaled to other health care systems or smaller clinics after further validation. This can reduce some barriers and help safely provide the best available treatment for eligible patients.

Conflicts of Interest

ZZ serves as a member of the Epic nephrology steering board committee. MH has received consulting fees from Otsuka in the past for work unrelated to this study. All other authors report no conflicts of interest.

Abstract

Background: Accurate history taking is essential for diagnosis, treatment, and patient care, yet miscommunications and time constraints often lead to incomplete information. Consequently, there has been a pressing need to establish a system whereby the questionnaire is duly completed before the medical appointment, entered into the electronic health record (EHR), and stored in a structured format within a database.

Objective: This study aimed to develop and evaluate a streamlined electronic questionnaire system, BEST-Survey (Bundang Hospital Electronic System for Total Care-Survey), integrated with the EHR, to enhance history taking and data management for patients with pediatric headaches.

Methods: An electronic questionnaire system was developed at Seoul National University Bundang Hospital, allowing patients to complete previsit questionnaires on a tablet PC. The information is automatically integrated into the EHR and stored in a structured database for further analysis. A retrospective analysis compared clinical information acquired from patients aged <18 years visiting the pediatric neurology outpatient clinic for headaches, before and after implementing the BEST-Survey system. The study included 365 patients before and 452 patients after system implementation. Answer rates and positive rates of key headache characteristics were compared between the 2 groups to evaluate the system's clinical utility.

Results: Implementation of the BEST-Survey system significantly increased the mean data acquisition rate from 54.6% to 99.3% (P<.001). Essential clinical features such as onset, location, duration, severity, nature, and frequency were obtained in over 98.7% (>446/452) of patients after implementation, compared to from 53.7% (196/365) to 85.2% (311/365) before. The electronic system facilitated comprehensive data collection, enabling detailed analysis of headache characteristics in the patient population. Most patients (280/452, 61.9%) reported headache onset less than 1 year prior, with the temporal region being the most common pain location (261/703, 37.1%). Over half (232/452, 51.3%) experienced headaches lasting less than 2 hours, with nausea and vomiting as the most commonly associated symptoms (231/1036, 22.3%).

Conclusions: The BEST-Survey system markedly improved the completeness and accuracy of essential history items for patients with pediatric headaches. The system also streamlined data extraction and analysis for clinical and research purposes. While the electronic questionnaire cannot replace physician-led history taking, it serves as a valuable adjunctive tool to enhance patient care.

Introduction

Headache is one of the most common neurological symptoms in children, with a reported prevalence of 54.4% to 58.4% in previous population-based studies [1-4]. Using an appropriate approach in the differential diagnosis of pediatric headache is critical because it can potentially impact children's quality of life in a significant manner [5,6]. A thorough history taking is required to differentiate the symptoms of different primary headaches and to rule out a small but critical number of life-threatening secondary headaches, such as brain tumors or intracranial hypertensions [7].

Despite its importance, many studies have shown that history taking can be the major contributing factor in the misdiagnosis of pediatric headache due to miscommunications and limited time available, leading to missing key information in a real-world setting [8,9]. To overcome such obstacles, various questionnaires for efficient history taking and early detection of specific types of primary headaches have been developed in the past, such as the Diagnostic Headache Diary [10], ID Migraine [11], Migraine Screen Questionnaire [12], and Brief Headache Screen [13]. Even with the development of different history-taking tools, a paper-based, self-administered questionnaire itself poses a significant limitation in data collection and organization since it requires laborious, time-intensive, manual input [14]. Consequently, there has been a pressing need to establish a system whereby the questionnaire is duly completed before the medical appointment, entered into the electronic health record (EHR), and stored in a structured format within a database.

Numerous studies across multiple clinical fields comparing the effectiveness of paper-based and computer-based questionnaires have consistently shown that electronic health history questionnaires have higher usability scores and are more cost-effective than paper-based ones [14-20]. In this study, we developed an electronic questionnaire system named BEST-Survey (Bundang Hospital Electronic System for Total Care-Survey) that enables a streamlined previsit electronic questionnaire, with automatic integration into the EHR to aid clinicians' history taking and the construction of a structured database for further data analysis. This study aimed to develop and evaluate the BEST-Survey system among patients with pediatric headaches.

Methods

Electronic Questionnaire System (BEST-Survey) Development

At Seoul National University Bundang Hospital, we constructed an electronic questionnaire system named BEST-Survey to enhance the clinical utility of patient-provided medical information. Using the BEST-Survey system, patients complete the questionnaire on a tablet PC before their visit, and the information is automatically integrated into our EHR to aid clinicians during their history taking. The patient-provided information is stored in a structured database for further data analysis.

The BEST-Survey system is composed of 2 parts: questionnaire archives and electronic questionnaire system structure. A task force comprising 30 members, including doctors, nurses, and medical information technologists, evaluated the questionnaires based on 5 criteria: predicted demand, target age group, questionnaire availability, clinical utilization within the EHR, and copyright issues. A total of 59 questionnaires were created based on the needs of 12 departments, one of which was the pediatric headache questionnaire. The electronic questionnaire system structure within BEST-Survey consists of the following components: (1) an electronic questionnaire input system, delivered using technology such as a tablet PC or computer, for patients to complete during the preclinic visit; (2) automatic integration of patient response to the EHR to aid clinicians' history taking; and (3) construction of a structured database based on patient input for further data analysis.

Pediatric Headache Questionnaire Development

At our pediatric neurology outpatient clinic, located in Gyeonggi Province, the largest province in South Korea by population, we see 200‐250 new patients with pediatric headaches annually. As a tertiary referral center, we primarily see patients with red-flag symptoms or refractory headaches referred from primary and secondary clinics. To improve the history-taking process and enhance clinical assessments for these patients, we developed a previsit questionnaire specifically for patients with headache attending their initial consultation. The questionnaire was developed with reference to Swaiman's *Pediatric Neurology 5th edition* [21]. To ensure patient comprehension without guidance from medical staff, we used simple language that is easily comprehensible and provided detailed explanations for complex concepts.

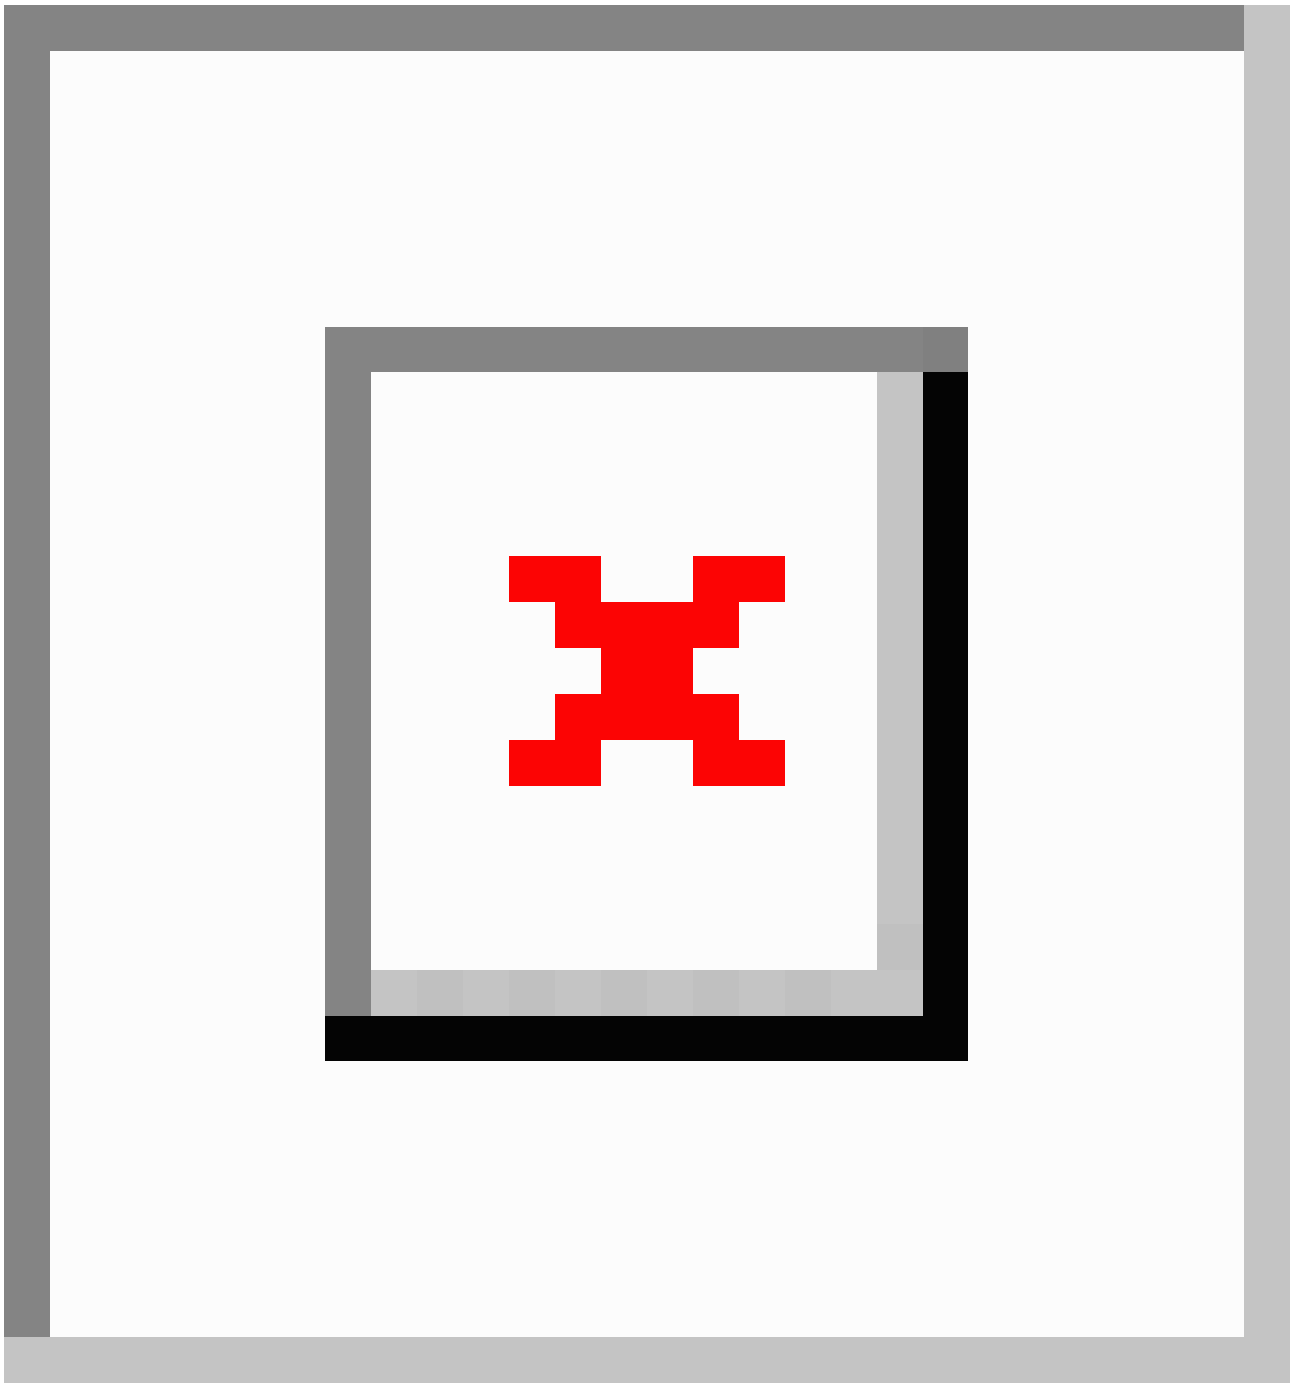
The initial visit questionnaire asks about detailed characteristics of the patient's headaches, utilizing multiple-choice questions with an option for free-text entry. To evaluate detailed headache patterns, patients were asked to provide information about their headache patterns, including location, nature, duration, frequency, recent exacerbation and its nature, frequent headache timing, and aggravating or alleviating factors. The accompanying aura and its types were also inquired to provide detailed information for migraine classification. Red-flag symptoms; family history of headache; limitation in daily activity; and previous headache diagnosis, evaluations, and treatments were also included in the questionnaire to aid clinicians in the detailed evaluation of patient's headache history and characteristics. The questionnaire ends with an open-ended question for patients to freely write down any additional concerns or questions for the initial visit. Headache severity is rated on the Numeric Pain Rating (NRS) scale or as mild, moderate, or severe for infants, as observed by their parents. A total of 35 previsit questions were developed for integration into the BEST-Survey system. The complete questionnaire created in Korean was translated into English. Both versions are shown in Multimedia Appendix 1.

Clinical Utilization of BEST-Survey in the Pediatric Headache Clinic

When the patient visited the pediatric headache clinic, trained medical staff introduced the BEST-Survey system in the waiting

room and provided education on completing the headache questionnaire using a tablet PC. Patients were asked to fill out the survey with the help of their parents when necessary. The completed questionnaire was automatically integrated into the EHR, in both a free format and a structured format for the clinicians to review. The completed questionnaire was further stored into a structured database for further data analysis and tracking of the patient's headache history. Neither the time it took for the patient to complete the survey nor the number of patients who refused to participate in the survey was recorded. Upon request for data collection, data retrieval was conducted automatically in a common data warehouse format, ensuring the exclusion of personal identifiers. Clinical information, including headache characteristics, age, sex, and other patient details, was retrieved in accordance with the preauthorized institutional review board (IRB) approval. An overview of the BEST-Survey system utilized in the pediatric headache clinic is summarized in Figure 1.

Figure 1. Overview of the BEST-Survey system. BEST-Survey: Bundang Hospital Electronic System for Total Care-Survey; EHR: electronic health record; HIS: hospital information system.



Comparison of Acquired Clinical Information Before and After the Implementation of BEST-Survey

We conducted a retrospective analysis on the health records of patients with headaches who visited the pediatric neurology outpatient clinic at Seoul National University Bundang Hospital. The analysis included patients who visited from March 2013 to March 2015—before the implementation of the BEST-Survey system ("Before e-system group")—and patients who visited from September 2015 to September 2017—after the implementation of the system ("After e-system group"). All new patients with pediatric headaches aged <18 years were recruited in the study, and patients were given the option to not to use the electronic questionnaire system. There was no lower age limit to the study. Patients and families who refused to use electronic questionnaire system were not included in the study. We collected information on 18 headache characteristics and associated symptoms, such as severity, onset, frequency, duration, location, characteristics, nausea, vomiting, dizziness, photophobia, phonophobia, visual aura, timing, sleep breakage, relieving factor, aggravating factor, aggravation by increased intracranial pressure, and family history in both groups. We then compared the answer rates and positive rates of 10 specific findings (onset, frequency, location, nature, duration, severity, frequent timing of the headache, factors of aggravation, associated symptoms, and visual aura) between the 2 groups to evaluate the clinical utility of BEST-Survey. The overall headache characteristics, including 10 previously mentioned, were further described to provide clinical overview our pediatric headache population group. Patients and parents were asked to complete the entire survey but were permitted to skip questions if necessary. Data analysis was processed using SPSS Statistics for Windows (version 27.0; IBM Corp). Descriptive statistics were used to express data as means, ranges, and percentages. The Mann-Whitney *U* test was used for nonparametric comparisons between the 2 groups. Statistical significance was set at $P<.05$.

Ethical Considerations

This study was approved by the IRB of Seoul National University Bundang Hospital (B-1805-468-106). All participants were deidentified by assigning them random codes instead of hospital numbers and personal identifiers. No compensation was provided to the participants. The waiver of informed consent was approved by the IRB, as the study utilized deidentified medical records.

Results

Comparison of Information Achieved Before and After the Implementation of BEST-Survey

This study included 365 patients in the before e-system group and 452 patients in the after e-system group. There were no differences in onset age and sex between the 2 groups: the mean age at the visit was 9.7 (95% CI 9.4-10.2) years in the before e-system group and 10.0 (95% CI 9.7-10.4) years in the after e-system group, and 52.9% (193/365) and 49.3% (223/452) of the patients in the before and after e-system groups were female, respectively. The clinical characteristics of headaches obtained from the 2 groups were further analyzed. The mean rate of data acquisition increased significantly ($P<.001$) from 54.6% (range 27/365, 7.4% to 311/365, 85.2%) to 99.3% (range 410/452, 90.7% to 452/452, 100%) after the implementation of the e-system. The data acquisition rate for the 6 cardinal clinical features of headaches (onset, location, duration, severity, nature, and frequency) increased from a range of 53.7% (196/365) to 85.2% (311/365) in the before e-system group to a range of 98.7% (446/452) to 100% (452/452) in the after e-system group. The 3 least obtained clinical features in the before e-system group were aggravating factor (27/365, 7.4%), aggravation by increased intracranial pressure (70/365, 19.2%), and relieving factors (110/365, 30.1%), while onset (311/365, 85.2%), vomiting (298/365, 81.6%), and duration (287/365, 78.6%) were the features with the highest level of data acquisition. All clinical features were obtained in over 90% (range 410/452, 90.7% to 452/452, 100%) of patients in the after e-system group. Timing (410/452, 90.7%), location (446/452, 98.7%), and severity (450/452, 99.6%) were the 3 least obtained clinical features after the implementation of the e-system (Table 1).

Table . Comparison of data acquisition rate between before and after introduction of the electronic questionnaire system (BEST-Survey[a]).

Clinical features	Before e-system (n=365), n (%)	After e-system (n=452), n (%)
Severity (NRS[b] score)	196 (53.7)	450 (99.6)
Onset	311 (85.2)	452 (100)
Frequency	285 (78.1)	452 (100)
Duration	287 (78.6)	451 (99.8)
Location	248 (67.9)	446 (98.7)
Characteristics	221 (60.5)	452 (100)
Nausea	276 (75.6)	452 (100)
Vomiting	298 (81.6)	452 (100)
Dizziness	263 (72.1)	452 (100)
Photophobia	174 (47.7)	452 (100)

[a]BEST-Survey: Bundang Hospital Electronic System for Total Care-Survey.

[b]NRS: Numeral Rating Scale.

[c]IICP: increased intracranial pressure.

Clinical Characteristics of Headaches From Patients Who Visited Our Hospital After the Implementation of BEST-Survey

Detailed clinical headache characteristics of our pediatric patient group was acquired from the BEST-Survey system. In our patient group, most patients (280/452, 61.9%) had their onset of headache less than or equal to 1 year ago, and they most frequently complained of daily headaches (116/452, 25.6%). The temporal region was the most common location of headaches (261/703, 37.1%; unilateral: 111/703, 15.8% and bilateral 150/703, 21.3%), followed by the frontal head region (111/703, 15.8%). Pain characteristics were often pulsatile (188/861, 21.8%), pressing (140/861, 16.3%), or dull (159/861, 18.5%). More than half of patients (232/452, 51.3%) had headaches lasting less than 2 hours, with nausea and vomiting (231/1036, 22.3%) as the most commonly associated symptoms. Red-flag symptoms were reported by 316 (69.9%) out of 452 patients. Of the patients reporting red-flag symptoms, sleep breakage and improvement by vomiting accounted for 137 (26.5%) and 71 (13.7%) out of 517 red-flag symptoms, respectively. The clinical characteristics of the patients with headaches obtained from BEST-Survey are shown in Table 2.

Table . Clinical characteristics of headaches obtained from BEST-Survey[a]. Multiple answers were allowed in some questions.

Clinical characteristics	Value, n (%)
Headache onset (n=452 patients)	
Within 1 month	70 (15.5)
Within 3 months	77 (17)
Within 6 months	50 (11.1)
Within 1 year	83 (18.4)
Within 2 years	70 (15.5)
Within 3 years	44 (9.7)
Within 4 years	21 (4.6)
Within 4 years	13 (2.9)
>5 years	24 (5.3)
Headache frequency (n=452 patients)	
Daily	116 (25.6)
3 - 4 times/week	74 (16.3)
1 - 2 times/week	89 (19.6)
1 - 3 times/month	76 (16.8)
<1 time/month	29 (6.4)
Not definite	68 (15)
Headache nature (n=452 patients; multiple answers allowed: n=861 answers)	
Stabbing	26 (3)
Pressing	140 (16.3)
Tightening	151 (17.5)
Pulsatile	188 (21.8)
Aching	99 (11.5)
Dull	159 (18.5)
Not definite	98 (11.4)
Headache duration (n=452 patients)	
<30 minutes	76 (16.8)
30 minutes to 1 hour	89 (19.7)
1-2 hours	67 (14.8)
2–3 hours	52 (11.5)
3–4 hours	39 (8.6)
4–5 hours	11 (2.4)
5–6 hours	14 (3.1)
6–12 hours	24 (5.3)
12–24 hours	23 (5.1)
>24 hours	12 (2.7)
Unspecified	45 (10)
Headache location (n=452 patients; multiple answers allowed: n=703 answers)	
Whole	80 (11.4)
Bilateral temporal	150 (21.3)
Unilateral temporal	111 (15.8)
Vertex	74 (10.5)

Occipital	90 (12.8)

Distraction	177 (17.1)
Transient amnesia	6 (0.6)
Sensitivity to lights or sounds	213 (20.6)
Cramping	25 (2.4)
Tearing or ptosis	56 (5.4)
Yawning	72 (6.9)
Increased urination	12 (1.2)
Diarrhea	14 (1.4)
Depression	47 (4.5)
Aura (n=452 patients; multiple answers allowed: n=405 answers)	
Vertigo	14 (3.5)
Dizziness	84 (20.7)
Ataxia	15 (3.7)
Altered consciousness	5 (1.2)
Motor aura	38 (9.4)
Language aura	9 (2.2)
Sensory aura	4 (1)
Auditory aura	105 (25.9)
Visual aura	113 (27.9)
Not definite	18 (4.4)
Red-flag symptoms (n=316 patients; multiple answers allowed: n=517 answers)	
Headache after hyperventilation	154 (29.8)
Sleep breakage	137 (26.5)
Improved by vomiting	71 (13.7)
Morning headache	155 (30)

[a]BEST-Survey: Bundang Hospital Electronic System for Total Care-Survey.

Discussion

Principal Findings in Comparison to Prior Works

In this study, we developed an electronic questionnaire system named BEST-Survey and utilized it to collect medical history from patients with pediatric headaches. This system, which includes a streamlined previsit electronic headache questionnaire, automatic integration into the EHR, and construction of a structured database for further analysis, was significantly effective in ensuring the completeness of collecting the key clinical features of pediatric headaches. Furthermore, the system allowed easy data extraction and analysis for the comprehensive clinical characterization of pediatric headaches. To the best of our knowledge, this is the first study describing an integrated electronic questionnaire system linked to an EHR for pediatric headache.

Traditional history taking involves interactive conversations with patients to establish rapport, assess communication skills, observe their condition, and collect relevant clinical information [22]. However, comprehensive history taking could be hindered by miscommunication between a patient or parent and their physician, as well as the limited time available. Inquiring all necessary questions and retrieving accurate answers is crucial for accurate diagnosis and appropriate management [23].

Omitting important questions can significantly impact diagnosis and treatment outcomes [24]. Moreover, the time-consuming EHR documentation process further hinders accurate history taking and medical care delivery.

Studies on ambulatory practices have shown that physicians spend 18% to 20% of their time on documentation or writing [25]. Another study revealed that 52.9% of their time is dedicated to direct clinical face time, while 37% is spent on EHR and desk work [26]. Taking medical histories from children poses unique challenges compared to adults. Limited expression of symptoms and reliance on parents or guardians for information [27], as well as the potential for distraction and poor cooperation from the children [28], require detailed explanations and additional time for history taking. To address the limitations to accurate history taking, our system offers several advantages. First, a predetermined questionnaire form ensures that essential data are gathered without omitting important questions. Second, utilizing the waiting time before a consultation gives the patients more time to report their symptoms. Third, automatic integration with the EHR saves efforts required for documentation. Additionally, the computerized and stored data facilitate further processing and analysis.

Strengths of the Streamlined Electronic Questionnaire System

Our system's advantage in capturing essential history items without omission was demonstrated through a comparison of data acquisition rates before and after its implementation. The findings revealed a significant increase in obtaining answers to each item after introducing our system. Prior to using the system, interviews alone resulted in less than 90% of patients providing essential headache diagnosis information such as onset time, frequency, duration, location, and characteristics. Furthermore, inquiries regarding factors worsening the condition, increased intracranial pressure, and relief had the lowest response rates. These results align with previous studies demonstrating the efficacy of digital questionnaires in enhancing data collection. In a systematic review examining the benefits of electronic patient-reported outcome measures, 10 (31%) out of 32 studies reported having missing or incomplete data. Among those 10 studies, 7 (70%) reported lower rates of missing data and more complete information with electronic methods compared to paper-based approaches [19]. Another study comparing histories acquired by physicians and a computer program directly interacting with patients found that the computer-acquired histories revealed 160 problems not documented by physicians. Conversely, there were 13 problems reported by physicians but not by the computer program, indicating the usefulness of computer programs in acquiring more comprehensive and detailed medical histories [29].

We also examined differences in the rate of positive findings for each history item. We observed variations in the rate of positive responses, with interview-based inquiries generally yielding higher positive rates, except for sleep breakage. The high positive rates of various clinical characteristics obtained through physician interviews may be due to discrepancies and inaccuracies in reflecting the actual phenomenon. For instance, in our study, the proportion of patients with photophobia was 41.4% in the before e-system group and 12.2% in the after e-system group. In previous studies of patients with pediatric headaches in South Korea, 43% were diagnosed with migraines, 35% had tension headaches, and 22% had other primary headaches [30]. Considering that approximately half of patients with migraines experience photophobia [31], the finding of 41.4% of patients with photophobia in our study is likely an overestimation even when considering the higher likelihood of patients with debilitating headaches seeking care at tertiary hospitals. Discrepancies between physician interview–based information and patient-reported data have been reported in previous studies. In an analysis of clinical interviews and computer-acquired history data among patients with chest pain, inconsistencies were observed in the collected data [32]. Both our study and previous studies on chest pain have consistently found higher levels of missing data when obtaining medical history through interviews compared to using e-questionnaires or computerized history taking. The primary reason for these discrepancies can be attributed to data incompleteness during the interview-based, history-taking process.

Another advantage of the proposed system in this study is that the computerization of data enables easy data processing, analysis, and storage for future use. This facilitates efficient data analysis and saves processing time. For instance, we conducted an analysis on the clinical characteristics of patients with headaches visiting our hospital, providing an overview of their features. In our study population, predominant headache characteristics included daily occurrence (25.7%), severity rating around an NRS score of 7 - 8 (40.9%), pulsatile nature (21.6%), onset between 6 months to 1 year (18.4%), duration less than 4 hours (71.5%), and involvement of the entire or bilateral temporal area of the head (37.1%). Several studies have evaluated headache characteristics in children attending headache outpatient clinics. In one study with a questionnaire collected from 437 pediatric patients referred to headache outpatient clinics, 5.9% had underlying organic diseases, while 94% had primary headaches [33]. The characteristics of patients with primary headaches analyzed in this study showed similarities to our study, including a significant proportion of patients with headache duration between 2 - 12 hours (68.8%), a high incidence of bilateral pain (63.9%), and a high frequency of severe intensity ratings (63.9%) and pulsatile features (27.1%). The incidence of accompanying symptoms such as nausea (49.1%), vomiting (37%), photophobia (27.8%), phonophobia (24.4%), and aura (13.5%) was similar or slightly higher compared to our study population. Another study of 194 pediatric patients with primary headaches presenting to an outpatient clinic in Jordan also showed similarities to the headache characteristics in our study. The main patient population experienced moderate to severe headaches (80.4%), daily occurrence (34.5%), duration of 0.5 - 4 hours (25.5%), and a higher proportion of bilateral pain (78.9%). The prevalence of accompanying symptoms, including nausea or vomiting (43.1%), dizziness (31%), and photophobia (38.8%), was similar or slightly higher than those in our study [34]. In this study, we included both primary and secondary headaches, whereas previous studies solely focused on primary headaches. However, due to the relatively small proportion of patients with secondary

headaches within the overall group of patients with headache patients, similar results were obtained.

We were also able to identify key considerations for implementing the EHR-integrated, e-questionnaire system in clinical practice. First, using plain language in the questions is crucial as they are asked without additional explanations. However, care must be taken to avoid excessive simplification, which can result in a higher false positive rate. Therefore, continuous updating of the questions is necessary to minimize discrepancies between physician-led history taking and patient-reported questionnaires. For example, the question "Is there weakness in the arms or legs?" is intended to assess symptoms of transient ischemic attacks, a key symptom of Moyamoya disease. However, patients often misinterpret this question as fatigue or general weakness. Thus, more detailed questions differentiating between fatigue and paralysis are necessary. Second, the system should serve as a supplement to, rather than a replacement for, physician-led history taking. Double-checking items marked positively by the patient through the questionnaire is necessary. Third, appropriate question styles should be considered for different age groups to compensate for different levels of understanding. Tailored questionnaires for different age groups are essential for the success of electronic questionnaire system in the clinical field.

Limitations and Future Directions

Our study has several limitations. First, we did not directly compare the history-taking methods used by physicians with the electronic system for the same patient simultaneously. Second, we did not assess the validity of the questionnaire. Third, we did not evaluate whether the introduction of the system resulted in clinically significant changes in diagnosis and management. Based on our limitations, we suggest the following future studies utilizing the system developed in this study. First, a study should be conducted to assess the system's validity by comparing data obtained from physician-led history taking and patient-completed questionnaires for the same individuals. Second, investigations are needed to examine the impact of the system on patient care and outcomes in real-world clinical settings. Third, the development of a clinical decision support system based on the electronic system should be explored. Fourth, the development of our survey was conducted internally and did not undergo validation by external reviewers. Due to this lack of validation, our survey maybe limited in detailed characterization for certain subtypes of headaches, such as tension-type headaches. Fifth, the lack of investigation into the time spent to complete the questionnaire limits us in comparing the total saved clinic time. Sixth, the lack of quantitative feedback from patients, families, and clinicians about the acceptability of the electronic questionnaire limits us in understanding the acceptability of the system. Finally, future studies could investigate the improved diagnostic rate of headache subtypes following system implementation and explore changes in headache burden after administering various medications. A streamlined questionnaire could enhance the completeness of phenotypic data, facilitating the diagnosis of complex, rare diseases and potentially shortening their diagnostic odyssey. Our proposed system could also be adapted for use in other disease contexts [35]. Such studies would help demonstrate the qualitative improvement of the information collected by our electronic questionnaire system.

Conclusion

In this study, we developed an electronic questionnaire system named BEST-Survey and utilized it to implement a patient-reported electronic questionnaire for patients with pediatric headaches. A streamlined, previsit electronic questionnaire that is automatically integrated to the EHR showed several strengths over traditional interview-based history taking. First, it ensures the completeness of essential history items. Second, it enables more accurate history taking, particularly in key clinical features that may be overestimated in traditional methods. Finally, the system facilitates easy data extraction, processing, and analysis, enabling detailed clinical characterization of the specific patient population of interest. While the electronic questionnaire system cannot replace the complex role of physician-led history taking, it can serves as a helpful adjunctive tool to improve patient care.

Data Availability

The datasets used and/or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Electronic medical records (EMR) are considered a key component of the health care system's digital transformation. The implementation of an EMR promises various improvements, for example, in the availability of information, coordination of care, or patient safety, and is required for big data analytics. To ensure those possibilities, the included documentation must be of high quality. In this matter, the most frequently described dimension of data quality is the completeness of documentation. In this regard, little is known about how and why the completeness of documentation might change after the implementation of an EMR.

Objective: This study aims to compare the completeness of documentation in paper-based medical records and EMRs and to discuss the possible impact of an EMR on the completeness of documentation.

Methods: A retrospective document analysis was conducted, comparing the completeness of paper-based medical records and EMRs. Data were collected before and after the implementation of an EMR on an orthopaedical ward in a German academic teaching hospital. The anonymized records represent all treated patients for a 3-week period each. Unpaired, 2-tailed *t* tests, chi-square tests, and relative risks were calculated to analyze and compare the mean completeness of the 2 record types in general and of 10 specific items in detail (blood pressure, body temperature, diagnosis, diet, excretions, height, pain, pulse, reanimation status, and weight). For this purpose, each of the 10 items received a dichotomous score of 1 if it was documented on the first day of patient care on the ward; otherwise, it was scored as 0.

Results: The analysis consisted of 180 medical records. The average completeness was 6.25 (SD 2.15) out of 10 in the paper-based medical record, significantly rising to an average of 7.13 (SD 2.01) in the EMR (t_{178}=–2.469; *P*=.01; *d*=–0.428). When looking at the significant changes of the 10 items in detail, the documentation of diet (*P*<.001), height (*P*<.001), and weight (*P*<.001) was more complete in the EMR, while the documentation of diagnosis (*P*<.001), excretions (*P*=.02), and pain (*P*=.008) was less complete in the EMR. The completeness remained unchanged for the documentation of pulse (*P*=.28), blood pressure (*P*=.47), body temperature (*P*=.497), and reanimation status (*P*=.73).

Conclusions: Implementing EMRs can influence the completeness of documentation, with a possible change in both increased and decreased completeness. However, the mechanisms that determine those changes are often neglected. There are mechanisms that might facilitate an improved completeness of documentation and could decrease or increase the staff's burden caused by

documentation tasks. Research is needed to take advantage of these mechanisms and use them for mutual profit in the interests of all stakeholders.

Introduction

The digital transformation of the health care system is considered an essential subject to meet current and future societal challenges such as an aging population or rising health care expenditures while at the same time maintaining a high quality of care [1]. An important early step in hospitals' digitalization and a fundamental requirement for expanding digital maturity is the implementation of an electronic medical record (EMR) [2]. This EMR is considered to be an **"**electronic record of health care information of an individual that is created, gathered, managed, and consulted by authorized clinicians and staff within 1 health care organization" [3] and replaces the internal clinical documentation on preprinted paper-based charts. Studies show that the implementation of an EMR can lead to various improvements in the clinical context (eg, in the availability of information [4], coordination of care [5], or patient safety [6]). Moreover, the EMR facilitates the secondary usage of the documented data for research purposes through its digital accessibility [7]. To reach those benefits, it is indispensable that the EMR contain documentation that is of high quality. However, there are varying definitions regarding the quality of documentation. In that matter, the Institute of Medicine defined completeness, legibility, accuracy, and meaning as the main aspects of a medical record's data quality [8]. For those, the completeness of documentation was shown to be the most common dimension of data quality when empirically analyzing the documentation in EMRs [9], and it was highlighted to be especially important for secondary uses such as big data analyses [10].

Our recent systematic review also stated the completeness of documentation as the state of the art for the comparison of paper-based and EMRs [11]. This comparison is important since the implementation of an EMR and the associated transition from handwritten documentation to digital documentation can heavily affect the documentation subject since the transition offers the possibility to adjust which information has to be documented in which way [12]. For example, digitization enables the adoption of certain functionalities that can alter the completeness of documentation, like automatically transferring information from other digital devices to the EMR [13]. Moreover, when working with the EMR, information can be documented remotely, while the paper-based medical record had to be located and physically accessed first. In this matter, several studies conducted in the inpatient setting showed increased completeness in the EMR compared to the paper-based medical record, for example, for the documentation of signs and symptoms [13,14], weight and height, or malnutrition screening [15]. This suggests that the implementation of an EMR might lead to improvements in the completeness of documentation in general. It is therefore the main purpose of this study to evaluate the change in completeness due to the implementation of an EMR in an inpatient setting. Literature already provides proof of a change of completeness in regard to some specific documented information that is analyzed in this work (eg, the documentation of vital signs) [13,14]. Those empirical results might thus be validated for the presented work's specific setting and discipline. In addition, some of the information that is analyzed in this work is not described in literature yet (eg, the documentation of pain). It is examined for the first time with regard to changes in completeness after the implementation of an EMR.

The knowledge gained can not only support the implementation of new EMRs but could also help understand and optimize arising changes in documentation when existing EMRs need to be adapted [16,17]. This is an important aspect, as the implementation of new EMRs is described as one of the most important interventions to improve the quality of documentation [18]. In this process, mechanisms affecting the completeness of documentation in medical records are not completely understood [10]. On the other hand, this knowledge is needed to fulfill reported educational needs regarding how to reach the optimum quality of documentation [19]. In this context, this study contributes to a more comprehensive understanding of the impact of an EMR on the quality of documentation.

Methods

Overview

This study follows the "Strengthening the Reporting of Observational Studies in Epidemiology" (STROBE) statement [20] whenever it is applicable. It offers reporting standards to ensure the reporting of any important information in empirical research studies. A checklist with details, where the STROBE information is mentioned in the manuscript, can be found in Multimedia Appendix 1.

Ethical Considerations

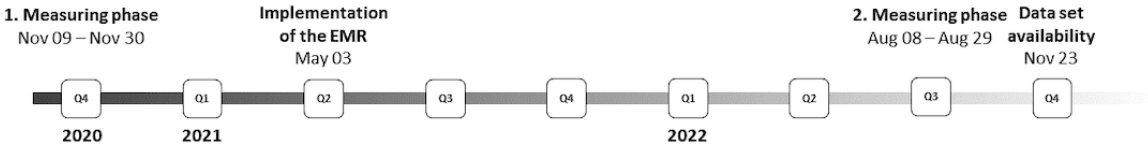
The study has been approved by the ethics committee of the Medical Faculty of the University of Cologne, Germany (20-1349). All data was anonymized at all times during the scientific analysis. No compensation was paid.

Setting and Participants

The study took place as part of the research project eCoCo, which Beckmann et al [21] described in detail. Within the eCoCo project, the researchers collected various types of data

(observations, surveys, interviews, documents, and administrative data) to investigate a possible change in interprofessional collaboration and clinical workflows following the implementation of an inpatient EMR. This study is part of the related work package on documentation content and quality, which took place in a large academic teaching hospital in Germany. The hospital replaces its internal documentation on preprinted paper-based charts with a commercial EMR system (Meona; Mesalvo Freiburg GmbH). The EMR runs on multiple computers that can be moved flexibly over the ward on trolleys. The study follows a pre-post design, retrospectively analyzing the content of the medical records before and after the implementation of the EMR on the hospitals' orthopaedical ward. Within the first measuring phase, the paper-based medical records were provided as a digital copy of the paper sheets. Those paper-based records represent all patients who were treated on the ward during the last 3 weeks in November 2020 (t0). After 6 months, employees received training on how to use the EMR before the implementation of the EMR took place in May 2021. The EMRs were again provided as a digital copy within a second measuring phase, representing all patients who were treated on the same ward during the first 3 weeks of August 2022 (t1). This resulted in a gap of 15 months between the first and second measuring phases. The complete data set was available to the research team in November 2022 (Figure 1). The hospital provided anonymized medical records to the research team after the records were archived and cleared of sensitive personal data (eg, the patient's name or date of birth) in the hospital's internal processes. Any assignment of the patient data or linking of the records' contents to any individual patient was therefore impossible for the research team, which is, thus, in compliance with the European Union General Data Protection Regulation. This also implies the absence of sociodemographic information for describing the compared samples. The hospital's mandatory annual quality report, which is available to the public through a designated database [22], is therefore used to describe the ward's patient sample and the performed treatments in general. This allows an approximation to a description and comparison of the compared samples in terms of their *International Classification of Diseases* (*ICD*)–diagnoses distribution.

Figure 1. Data collection. EMR: electronic medical record.

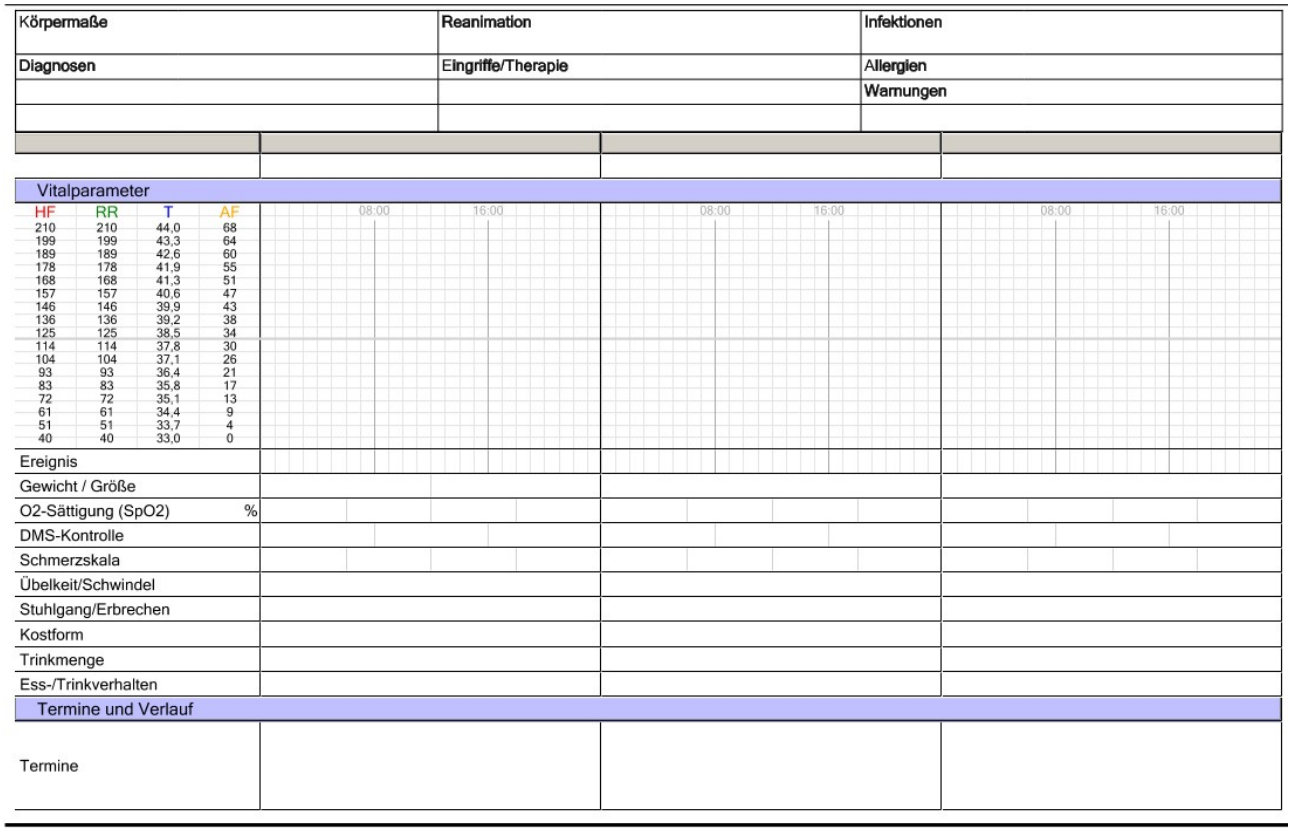


Study Objective

To answer the question of a possible change in completeness, the records were analyzed by content [23]. The change from paper-based documentation to EMRs always offers the opportunity to fundamentally change the structure of the records. This was shown exemplarily by Montagna et al [12] when the documentation as a continuously written text in the paper-based record was changed to a list of events in the EMR. It is therefore important to ensure the comparability between the 2 record types for the purpose of analyzing a possible change in their completeness. To achieve comparability, the medical records progress note was selected as a specific object of interest for this study's analyses since it retained the same structure and format in both record types. Part of this progress note is the fever chart (Figures 2 and 3), which includes basic details about vital signs, personal health data, etc [24].

Figure 2. Paper-based fever chart.

Figure 3. Electronic fever chart.



All information that was commonly documented in both of the 2 record types (paper-based and electronic) became part of this work. Weiskopf and Weng [9] described this selection mechanism for assessing data quality based on the parallels between the EMR and the paper-based record. This procedure resulted in a total of 10 key items that were analyzed for completeness in this work: blood pressure, body temperature, diagnosis, diet, excretions, height, pain, pulse, reanimation

status, and weight. The documentation of this information is equally possible and performed by nurses and physicians. However, there is no information available about who specifically entered the information.

All of those items should be documented immediately when patient care begins on the ward [25]. However, while the documentation of vital signs can take place up to several times a day, the documentation of the patient's diet usually occurs once a day, and the documentation of the reanimation status (patient's preference regarding a possible resuscitation) is probably documented only once per hospital stay. Because of these varying documentation practices and to ensure comparability, the analysis focuses on certain documentation in the progress notes that was entered on the first day of patient care on the ward. With regard to the documentation of a diagnosis, it is therefore the diagnosis with which a patient is admitted to the hospital. This diagnosis is mainly responsible for the allocation to specific medical specialties as well as a certain ward and does not necessarily have to match the final diagnosis at the time of discharge, which is important for reimbursement purposes.

Statistical Analysis of Completeness

For every record, each of the 10 items received a dichotomous score of 1 if it was documented on the first day of patient care on the ward; otherwise, it was scored as 0. This resulted in a percentage of completeness for each item per record type. Chi-square tests for independence were used to assess statistically significant differences in the percentage of completeness per item between the 2 record types. Relative risks were calculated for the association between the electronic record type and a possible increase in completeness. To improve the reliability of the associated confidence intervals, they were calculated with 5000 bootstrap replications since the original sample sizes are unbalanced. Moreover, the overall completeness was assessed as sum of the 10 items, resulting in a mean score of completeness per record type ranging from 0 (no item documented) to 10 (all 10 items documented). Those mean scores of completeness per record type were analyzed for equality of variance and statistical difference using unpaired, 2-tailed *t* tests. Assumptions were checked using several methods (normal distribution: QQ plots and Shapiro-Wilk test; homogeneity of variances: Levene test; and linearity: scatter plot). The level of significance was set to be $P<.05$ for all calculations. The data were stored in Microsoft Excel (Microsoft Corp) and analyzed in December 2022 using SPSS software (version 29; IBM Corp).

Results

Participants

During the first measuring phase (November 2020), a total of 44 patients (paper-based) were treated on the orthopaedical ward. They were encountering a total of 136 treated patients (electronic) during the second measuring phase (August 2022). This resulted in a total of 180 medical records that became part of this analysis. Due to the data protection regulation and the accompanied anonymization of the records data, there is no information regarding the demographics of the specific study population. Therefore, the ward's ICD-diagnosis distribution is given as an approximation of a sample description. In 2020, the 3 most frequently coded diagnoses for the orthopaedical ward were complications of internal orthopedic prosthetic devices, implants and grafts (ICD-T84), dorsalgia (ICD-M54), and fracture of shoulder and upper arm (ICD-S42). This report is not yet published for 2022, but the top 3 treated diagnoses in 2019 or 2021 were similar to those in 2020 (Table 1). It can therefore be expected that the treated diagnoses will be similar in 2022, too. Another supporting fact is that the most frequently performed procedure (surgical access to the lumbar spine, the sacrum, or the coccyx [coded as OPS-5-032 in the German adaptation of the International Classification of Procedures in Medicine which is part of the coding system for hospitals reimbursement]) was the same in all 3 years (2019-2021).

Table 1. Most frequently coded diagnoses.

ICD[a] Code	Values, n[b]/N[c] (%)
2019	
Dorsalgia (ICD-M54)	213/3147 (6.77)
Other spondylopathies (ICD-M48)	133/3147 (4.23)
Fracture of forearm (ICD-S52)	131/3147 (4.16)
2020	
Complications of internal orthopedic prosthetic devices, implants and grafts (ICD-T84)	166/2912 (5.7)
Dorsalgia (ICD-M54)	148/2912 (5.08)
Fracture of shoulder and upper arm (ICD-S42)	121/2912 (4.16)
2021	
Complications of internal orthopedic prosthetic devices, implants and grafts (ICD-T84)	164/3091 (5.3)
Dorsalgia (ICD-M54)	163/3091 (5.27)
Fracture of forearm (ICD-S52)	159/3091 (5.14)

[a]ICD: International Classification of Diseases.

[b]Frequency of coded diagnosis.

[c]Total inpatient cases.

Change of Completeness

The mean number of documented items was 6.25 (SD 2.15) out of 10 in paper-based medical records and 7.13 (SD 2.01) out of 10 in EMRs. The Levene test confirmed the homogeneity of variances. The Shapiro-Wilk test did not confirm normal distributions, but the QQ plots show an approximation to a normal distribution and a comparable degree of normality (Multimedia Appendix 2). The unpaired *t* test confirmed the EMRs were statistically significantly more complete than the paper-based medical records under equal variances in the 2 record types (t_{178}=–2.469; *P*=.01; *d*=–0.428). When looking at the 10 items separately, data from chi-square tests showed that the documentation of diet increased from being present in 30% (13/44) of the paper-based medical record to 75% (102/136; *P*<.001) in the EMR, height from 27% (12/44) to 85.3% (116/136; *P*<.001), and weight from 27% (12/44) to 86% (117/136; *P*<.001). At the same time, documentation of diagnosis decreased from being present in 100% (44/44) of the paper-based medical records to 49% (66/136; *P*<.001) in the EMR, excretions from 86% (38/44) to 68% (92/136; *P*=.02), and pain from 95% (42/44) to 78% (106/136; *P*=.008). The documentation of vital signs such as blood pressure (*P*=.47), body temperature (*P*=.497), and pulse (*P*=.28) remained unchanged on a high level of completeness, while the documentation of reanimation status (*P*=.73) remained unchanged on a low level of completeness (Table 2). Positive relative risks (Figure 4) illustrate the association of the electronic record type (exposure) with complete documentation (outcome). The confidence intervals represent 5000 bootstrap replications.

Table 2. Change of completeness.

Variable	Type of record		Chi-square (*df*)	*P* value	RR[a] (95% CI)
	Paper (n=44), n (%)	Electronic (n=136), n (%)			
Blood pressure	37 (84)	120 (88.2)	0.5 (1)	.47	1.05 (0.92-1.23)
Body temperature	36 (81.8)	117 (86)	0.5 (1)	.497	1.05 (0.91-1.25)
Diagnosis	44 (100)	66 (48.5)	37.1 (1)	<.001	0.48 (0.40-0.57)
Diet	13 (29.6)	102 (75)	29.8 (1)	<.001	2.54 (1.70-4.69)
Excretions	38 (86.4)	92 (67.7)	5.8 (1)	.02	0.78 (0.66-0.93)
Height	12 (27.3)	116 (85.3)	54.5 (1)	<.001	3.13 (2.06-5.91)
Pain	42 (95.4)	106 (77.9)	7.0 (1)	.008	0.82 (0.73-0.91)
Pulse	36 (81.8)	120 (88.2)	1.2 (1)	.28	1.08 (0.94-1.29)
Reanimation status	5 (11.4)	13 (9.6)	0.1 (1)	.73	0.84 (0.33-3.33)
Weight	12 (27.3)	117 (86)	56.5 (1)	<.001	3.15 (2.07-6.00)

Discussion

Principal Findings and Comparison to Previous Work

The main findings of this study confirm an improved completeness of the analyzed information in the EMR on average. This provides further evidence for the suggestion that the general completeness of documentation can improve after the implementation of an EMR. The findings align with the results of similar studies, showing improvements in other data quality dimensions like the accuracy [26] or legibility [27] of documentation. However, when looking at the completeness of the analyzed 10 items in detail, the improvements can only be seen in 3 out of 10 items (diet, height, and weight), while 3 different items exhibited a deterioration in completeness (diagnosis, excretions, and pain). This links to the results of Coffey et al [28], who found 5 of their 11 analyzed items to be more complete while also proving 1 of their elements to be less complete. The reason for the variation in the change in completeness may lie in the mechanism of how information reaches the record. In the paper-based medical records, all information was documented by hand by the various professional groups. EMRs, on the other hand, offer technical features, for example, automatically obtaining information from other digital sources, like patients' health insurance data [29]. This was manifested as a possible mechanism by Jang et al [30], who showed improved completeness in the EMR for the automatically filled information but not for the manually documented ones.

The analysis shows that roughly every second EMR was missing the documentation of a diagnosis. This is a remarkable change, as it was present in every paper-based record (44/44, 100% vs 66/136, 48.5%). In the first place, it must be clarified that the diagnosis is determined by a physician who enters it into an independently run hospital information system (HIS). This documented diagnosis can also be a preliminary diagnosis, which is used for distribution to the clinical disciplines and is present for every admitted patient. The HIS was already in operation when medical staff was still using the paper-based preprints for documentation purposes. After the EMR's implementation, the HIS was still in operation along with the EMR. That being said, it is undisputed that during the paper-based period as well as the electronic period, a diagnosis was indeed present for the patients. In the paper-based period, the diagnosis was transferred manually from the HIS into the paper-based preprints, when a record for a recently admitted patient was prepared by a nurse. Since the HIS and the EMR are produced by different software developers, the diagnosis cannot be transferred automatically from the HIS into the EMR. Due to this noninteroperability of the 2 independent digital systems, the manual transfer is still necessary in the electronic period. With the drop of completeness in mind, this double documentation was accepted and carried out in the period of the paper-based record. In the electronic period, the described double documentation has decreased. One possible explanation is that the HIS was not automatically accessible, when an employee had the paper-based record at hand. With the introduction of the EMR, the availability of the EMR became synonymous with the availability of the HIS, since both are accessible from a computer. Therefore, the transfer of the diagnosis from the HIS to the EMR may no longer have been considered necessary. Nevertheless, the reason for this difference remaining unclear illustrates that the sole analyzation of completeness of the documentation alone does not provide sufficient information about the actual quality of the provided treatment. In that matter, it must also be highlighted that the record can contain additional qualitative data entries, like free texts, which might complement the analyzed quantitative information. This underlines that an insufficient quality of documentation does not necessarily allow conclusions to be drawn about the quality of care, and vice versa.

Brown [31] emphasizes this by cautioning people to always consider the circumstances under which people put information into the record before drawing conclusions. This is a major issue because the completeness of documentation might be biased due to aspects that do not directly derive from clinical care. On the one hand, the hospital's reimbursement for the delivered care depends on what is documented and might cause a possible strengthened thorough filling of certain fields [32]. On the other hand, the burden caused by documentation tasks is critically

heavy. It is responsible for a high prevalence of burnout among physicians and nurses [33]. Therefore, clinically or legally unnecessary documentation might be evaded [34]. However, even though complete documentation might neither necessarily arise from nor be essential for the delivery of excellent clinical care, it is likewise of concern under the aspect of big data analytics. In this regard, it would be desirable for the discussed diagnosis to indeed be present in the EMR, even if it already exists in the HIS. An automatic transfer of this information could help to prevent the burden on staff resulting from manual transmission and ensure a complete data set. This is an important point, as the insights gained from analyzing big data offer numerous opportunities, like data-based personalized care in diagnostics and therapy or the support of scientific activities, both with the chance of saving lives and reducing health care costs at the same time [7,35]. It is therefore indispensable to recognize the possibility of changes in documentation due to the implementation or adaptation of EMRs. Only with this attention will it become possible to optimize the documentation process with a focus on the various benefits for all stakeholders, like patients [6], practitioners [36], organizations [5], and society [7].

Strengths and Limitations

The German health care system, in which the study was conducted, was heavily strained by the high number of COVID-19 cases and the associated use of intensive care units during the study period. Especially the first measuring phase (November 2020) fell into the first pandemic year when many planned procedures were suspended to increase hospital capacities. For the first lockdown period in Germany (March 2020), a decrease in orthopedic surgeries is described by approximately 80% [37]. A lockdown-like situation was again declared during the first measuring phase [38], which probably explains the difference in treated patients over the 2 measuring phases (n_{Paper}=44 vs $n_{Electronic}$=136). However, the similarity between the coded ICD diagnoses over different years (Table 1) suggests that the proven changes in completeness of documentation are not due to significant changes in the studied patient sample, but a detailed sample description based on socioeconomical data is missing due to data protection regulations. On the other hand, there is a study assuming a positive influence of the pandemic on the completeness of documentation since an incomplete documentation might have led to repetitive contacts with the patient, which could have been avoided if the documentation would have been complete in the first place [39]. However, this cannot be verified in this paper due to the lack of further measuring phases. Within this given context, the generalizability of the presented results remains limited.

Further, limitations regarding the analyzed data set have to be stated. The chosen unpaired *t* test is theoretically based on the assumption of normal distributions. This could not be confirmed statistically for the mean completeness scores by the Shapiro-Wilk test. Although *t* test has been shown to be robust to a missing normal distribution [40] and the QQ plots (Multimedia Appendix 2) indicate an approximation to a normal distribution, the results could still be biased by the broken assumption.

Moreover, the analyzed data set is missing any information on which person was entering the documentation regarding which patient. On the one hand, it might be arguable that the same physicians or nurses were documenting during the first and also the second measuring phases. This circumstance would make the 2 compared measuring phases dependent samples, having an impact on the chosen statistical model. Since the analyzed data set is missing this information, the results might be biased regarding a possible dependent or independent sample. However, the time passed between the 2 measuring phases might have led to a change of the employees since the teaching status of the hospital results in many young physicians or nurses who do not necessarily stay on the same ward for a long time. Moreover, the hospital in which the study was conducted has a rotation system in which clinicians rotate hospital-wide across different wards of the same discipline. Those 2 facts let us assume that the 2 compared samples are indeed independent. However, the lack of information regarding the documenting individual is preventing the use of advanced tests like mixed effect models. These could equally consider the record type on the one hand and the possible documenting individuals on the other hand, potentially advancing the results' reliability. However, the 15-month interval from the implementation date of the EMR to the second data collection signifies that there is only little risk of any possible changes in documentation due to a bias from the described effects of preimplementational documentation training [41] since the employees indeed underwent software training before they were allowed to use the EMR. Therefore, the shown changes in completeness are, in fact, most likely due to the implementation of the EMR.

Conclusions

The results show that implementing EMRs can influence the completeness of documentation. A demonstrated improved completeness might also facilitate an improvement of the described outcomes that depend on documentation that is of high quality, like the availability [4] and analyzability of information [7,35], the coordination of care [5], or patient safety [6]. However, at the same time, the results show that a deterioration of completeness is also conceivable with the accompanied risks. This highlights the importance of understanding the underlying mechanisms that determine these changes. The knowledge may help stakeholders manage the implementation of new EMRs or the optimization of existing EMRs. Future research should address mechanisms that can improve documentation while simultaneously reducing the burden on practitioners caused by documentation tasks.

Abstract

Background: The completeness and accuracy of the front pages of electronic medical records (EMRs) are crucial for evaluating hospital performance and for health insurance payments to inpatients. However, the quality of the first page of EMRs in China's medical system is not satisfactory, which can be partly attributed to deficiencies in the EMR system. Failure mode and effects analysis (FMEA) is a proactive risk management tool that can be used to investigate the potential failure modes in an EMR system and analyze the possible consequences.

Objective: The purpose of this study was to preemptively identify the potential failures of the EMR system in China and their causes and effects in order to prevent such failures from recurring. Further, we aimed to implement corresponding improvements to minimize system failure modes.

Methods: From January 1, 2020, to May 31, 2022, 10 experts, including clinicians, engineers, administrators, and medical record coders, in Zhejiang People's Hospital conducted FMEA to improve the quality of the front page of the EMR. The completeness and accuracy of the front page and the risk priority numbers were compared before and after the implementation of specific improvement measures.

Results: We identified 2 main processes and 6 subprocesses for improving the EMR system. We found that there were 13 potential failure modes, including data messaging errors, data completion errors, incomplete quality control, and coding errors. A questionnaire survey administered to random physicians and coders showed 7 major causes for these failure modes. Therefore, we established quality control rules for medical records and embedded them in the system. We also integrated the medical insurance system and the front page of the EMR on the same interface and established a set of intelligent front pages in the EMR management system. Further, we revamped the quality management systems such as communicating with physicians regularly and conducting special training seminars. The overall accuracy and integrity rate of the front page (P<.001) of the EMR increased significantly after implementation of the improvement measures, while the risk priority number decreased.

Conclusions: In this study, we were able to identify the potential failure modes in the front page of the EMR system by using the FMEA method and implement corresponding improvement measures in order to minimize recurring errors in the health care services in China.

KEYWORDS

front page; EMR system; electronic medical record; failure mode and effects analysis; FMEA; measures

Introduction

The electronic medical record (EMR) system is the main carrier of medical information that has details about the whole process of a physician's treatment for a patient [1]. The information on the front page of the EMR is condensed, which includes a patient's basic information, disease diagnosis, information on surgical or invasive operations, and medical expenses [2]. Since January 1, 2013, almost all tertiary hospitals in China have submitted the front pages of the EMRs of inpatients to the Hospital Quality Monitoring System led by the Bureau of Medical Administration and Medical Service Supervision and National Health and Family Planning Commission of the People's Republic of China [3]. The quality and management of the front pages of EMRs are critical for their application in medical services [4], research [2,5], education [6], and hospital management [7]. For example, some indicators for assessing the capacity of hospital medical services, such as the services for surgery and disease diagnosis, often utilize the information through the front page of the EMR for statistical purposes. However, there are many difficulties in the management of the front page of EMR. A survey conducted by the National Medical Record Management Quality Control Center of China [8] showed that more than 230 million front pages of EMRs in 2020 are established in China. Each of them contain over 100 fields. However, there are only 2.5 full-time coders on average in each hospital among 5439 medical institutions, and only 67.9% of them perform special quality control, while 24.2% of them use information technology to control the quality of the front page of the EMR system.

For reforming the medical insurance payment methods in China, the Chinese State Council's version of health insurance issued a notice in 2019 on the issuance of technical specifications and grouping schemes for the national pilot of diagnosis-related grouping payments for diseases [9]. Therefore, the front page of an EMR needs to be uploaded on the websites of the Health and Wellness Committee and the Health Insurance Authority, which means coders need to edit a front page twice to meet the different needs of both the sectors. The former is for hospital performance evaluation and the latter is for patient health insurance payment. The introduction of this policy in 2019 increased the difficulty of medical record management.

Failure mode and effects analysis (FMEA) is a proactive risk management tool that originated in the US military in the 1940s. It is widely applicable to human, equipment, and system failure modes, as well as hardware and software programs. FMEA finds out all the potential failure modes in a system and analyzes their possible consequences by mapping the subsystems and each subprocess that makes up the process one by one in the product design stage and process design stage [10]. Thus, the advantage of FMEA is that problems can be identified and improved during the system development phase to avoid possible problems. Moreover, the costs incurred to address software defects and failures at an early stage are lower compared to those incurred to address defects at a later stage. Initially, FMEA was widely used in engineering [11], food safety management [12], financial management [13], and so on. Thereafter, with the rising demands in health care services, FMEA was used for proactive health care risk analysis. Doctors often use the EMR system to record patients' visits. Any issue in the EMR system can affect the patient's visit process and visit records. According to a systematic review [14], 158 studies published from 1998 to 2018 and classified under 4 categories, namely, health care process, hospital management, hospital informatization, and medical equipment and production, reported the use of FMEA in health care systems for proactive health care risk evaluation. In FMEA, the risk priority number (RPN) is calculated by giving a numerical value (scoring) for the severity, frequency, and detectability of the risks or failures, which enable risk assessment of the system [10]. An EMR system named Heren (Zhejiang Heren Technology Corporation), which is installed in many hospitals in China, is used by physicians and medical record management coders and quality controllers for filling out the front page. The purpose of this study was to identify the possible failures in the front page data of the EMR and their causes and effects and to propose specific improvement measures to minimize errors. Moreover, we aimed to compare the EMRs before and after introducing the measures to verify the efficacy of the improvement measures. For this, we reviewed previous relevant literature through PubMed, Embase, Web of Science, and Cochrane Library. During this review, we found that although FMEA has been used in some studies for improvement of some facets of EMRs, no study has used FMEA for improving the efficiency the front page of the EMR [15,16]. Thus, to the best of our knowledge, ours is the first study to apply FMEA to identify the potential failures on the front page of the EMR in China and the causes and effects of these failures and to perform a before-and-after comparison of the revised front page of the EMR.

Methods

Study Design

We conducted a cross-sectional study from January 1, 2020, to May 31, 2022, in Zhejiang People's Hospital, which is one of the largest public hospitals in Zhejiang province with more than 100,000 hospital discharges per year. During the period of our research, the number of hospital discharges reached 250,774, which means the same number of front pages of EMRs needed to be filled and coded.

Steps of FMEA

Assembling a Panel for FMEA

Ten experts, including clinicians, medical record coders, and hospital administrators, were invited to assess the potential risks of the EMR system in China. Since coders and quality controllers were necessary to ensure the accuracy of the front page of the EMR, only those who had been working full-time on this task for more than 5 years and who had achieved a coding accuracy rate of more than 95% and who had checked more than thousands of medical records for quality were included. Before we began our study, the organizer introduced the theme of our study to ensure that every expert knew the process of FMEA and the importance of a front page of an EMR. Then, the time and place for each discussion was planned to ensure that the process ran smoothly.

Mapping the Process and Subprocesses

Each expert mapped the process and subprocess of completing a front page of an EMR alone initially to avoid interference from others. For example, there are 2 data sources for the content on the front page of the EMR: information automatically imported from the hospital information system that is mainly used by physicians and information that is filled in manually by the physician. Thus, different experts could map their own process according to their work experience. Thereafter, all experts were gathered to draw the final process and subprocess to achieve the completeness of the whole system.

Brainstorming to Identify Potential Failure Modes in Each Subprocess and Their Causes and Effects

The implementation process of this step is consistent with the mapping process. At first, each expert could think about every potential failure mode individually. Then, all the experts summarized all the modes and discussed many more potential failure modes by brainstorming once again. In addition, the views on effects and reasons for failure modes were exchanged by experts. Since there were so many issues that could result in potential failure modes, our team summarized the main causes and created a questionnaire for randomly selected physicians and coders to answer.

Calculating the RPN

A scoring criterion was used to evaluate the severity, frequency, and detectability of the failures, and each dimension was divided into 10 points. Then, the RPN was calculated by using the score of the 3 dimensions (RPN = Severity × Frequency × Detectability) to evaluate the final score of each failure mode, which ranges from 0 to 1000. To improve the consistency and accuracy of scoring, the rating weight of each expert was based on their professional title grade, work experience, and familiarity with FMEA. In addition, a risk assessment criterion was established to avoid any dispute about the scores given by the experts.

Proposing Improvement Measures for Each Failure Mode

Since a low RPN could result from severity, frequency, or detectability and a low score for each dimension could be caused by many different reasons, it is necessary to find out the main issues. According to the Pareto principle, 80% of the consequences are due to only 20% of the potential causes [17]. Our team used the Pareto principle to identify the pressing causes that need to be addressed. Then, the experts proposed one or more corresponding improvement measures for each failure mode. Further, the feasibility and effectiveness of improvement measures were also discussed.

Comparing the Quality Before and After the Improvements

The experts evaluated the quality of the front page of the EMR before and after the application of the improvement measures. The RPN score was bound to improve if these improvement measures were effective.

Ethical Considerations

This study did not involve any patient data or ethical data, and the ethics approval committee of Zhejiang Provincial People's Hospital specified that no ethics approval was required.

Statistical Analysis

We performed statistical analyses using SPSS (version 20.0; IBM Corp). Two-sided *t* tests were performed to compare the RPNs of the front page of the EMR before and after applying the improvement measures. *P* values <.05 were considered statistically significant.

Results

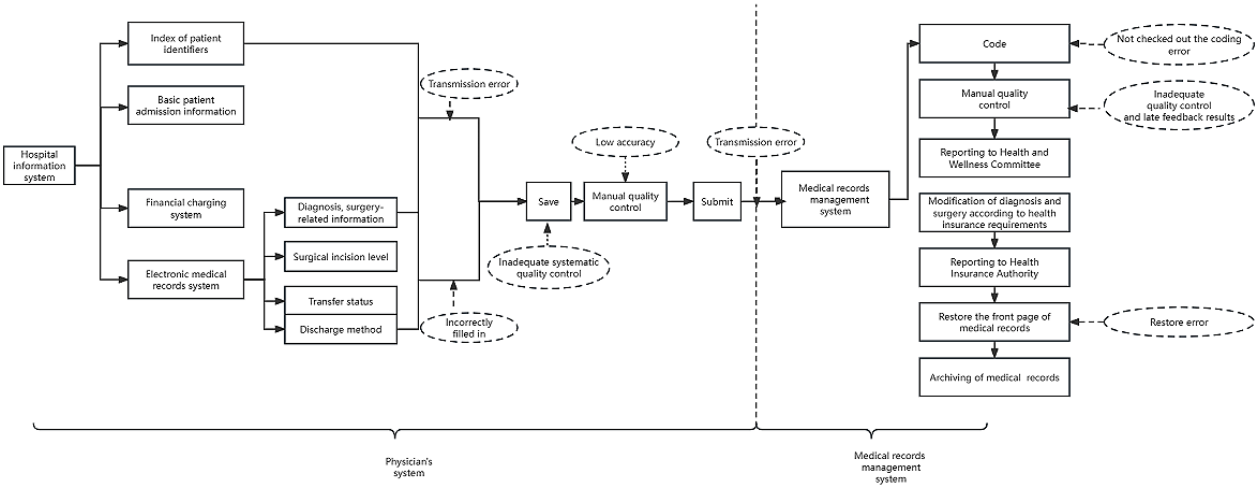
Assembling a Panel for FMEA

Our expert panel consisted of 10 experts in 5 different fields. There were 4 physicians, 2 coders, 2 hospital administrators, 1 quality control staff, and 1 information engineer who expressed different views and opinions on the front page of the EMR.

Mapping the Process and Subprocesses of the Front Page of EMR

The expert panel identified 2 main process steps and 6 subprocesses after discussion (Figure 1). The 2 main process steps were management of the physician’s system and management of the medical record system. The 6 subprocesses were information import from physicians’ hospital information system, front page filled by physicians, front page quality control by physicians, transmission of information in the EMR system, coders’ proofreading and coding, and front page quality control by EMR management.

Figure 1. Process map of the front page of the electronic medical record system.



Brainstorming to Identify Potential Failure Modes in Each Subprocess and Their Causes and Effects

The front page of the EMR that was evaluated in this study is shown in Figure 2. According to the process map of the front page of the EMR, the expert panel found that there were 13 potential failure modes, which can be mainly divided into 2 categories. One category is the low accuracy in a variety of information, including basic patient information, treatment information, and cost information. The other category is the low detection in a variety of information, including incorrect case header coding, incomplete quality control, and transmission errors. Regarding the causes for the failures, 115 physicians and coders filled out a questionnaire and summarized 15 main causes. The main causes were incompleteness of the front page, error in information, or incorrect diagnosis-related group, which is risky for hospital medical quality management, academic research, and medical insurance payment (Table 1).

Calculating the RPN

Before calculating the RPN, a risk assessment criterion was established to evaluate the quality of the front page of the EMR (Table 2).

The rating weight of each expert was calculated to reduce the influence caused by the individual subjective factors of the experts (Table 3).

Table 2. Risk assessment criteria for the quality management of the front page of the electronic medical record system.

Grade	Severity	Criteria for risk severity	Frequency	Criteria for risk frequency	Detectability	Criteria for risk detectability
10	Very high	Make the score of the front page of the EMR[a] below 20	Extremely high	Every time	Very low	Cannot be detected
9	Very high	Make the score of the front page of the EMR between 20 and 30	Very high	Almost every time	Very low	Hard to detect
8	High	Make the score of the front page of the EMR between 30 and 40	Very high	One time every half day	Low	Seldom detected
7	High	Make the score of the front page of the EMR between 40 and 50	High	More than one time every day	Low	Seldom detected
6	Middle	Make the score of the front page of the EMR between 50 and 60	High	More than one time every week	Middle	Easy to be detected
5	Middle	Make the score of the front page of the EMR between 60 and 70	Middle	More than one time every month	Middle	Easy to be detected
4	Middle	Make the score of the front page of the EMR between 70 and 80	Middle	More than one time every year	High	Very easy to be detected
3	Low	Make the score of the front page of the EMR between 80 and 90	Low	One time every year	High	Very easy to be detected
2	Low	Make the score of the front page of the EMR between 90 and 100	Very low	Less than one time every year	High	Very easy to be detected
1	Very low	Does not affect the score of the front page of the EMR	Extremely low	Never	Very high	No failure modes

[a]FMEA: failure mode and effects analysis.

Proposing Improvement Measures for Each Failure Mode

According to the principle of Pareto, there were 7 causes in our study that contributed to 80% of the consequences (Figure 3), which can be addressed by revamping the information and quality management. For example, we integrated the medical insurance system with the front page of the EMR on the same interface and established a set of intelligent front pages for the EMR management system. In addition, we revamped the management of quality, such as communicating with physicians regularly and conducting special training seminars (Table 4).

Figure 3. The 7 causes that contributed to 80% of the failure modes in the electronic medical record system, according to the principle of Pareto. QC: quality control.

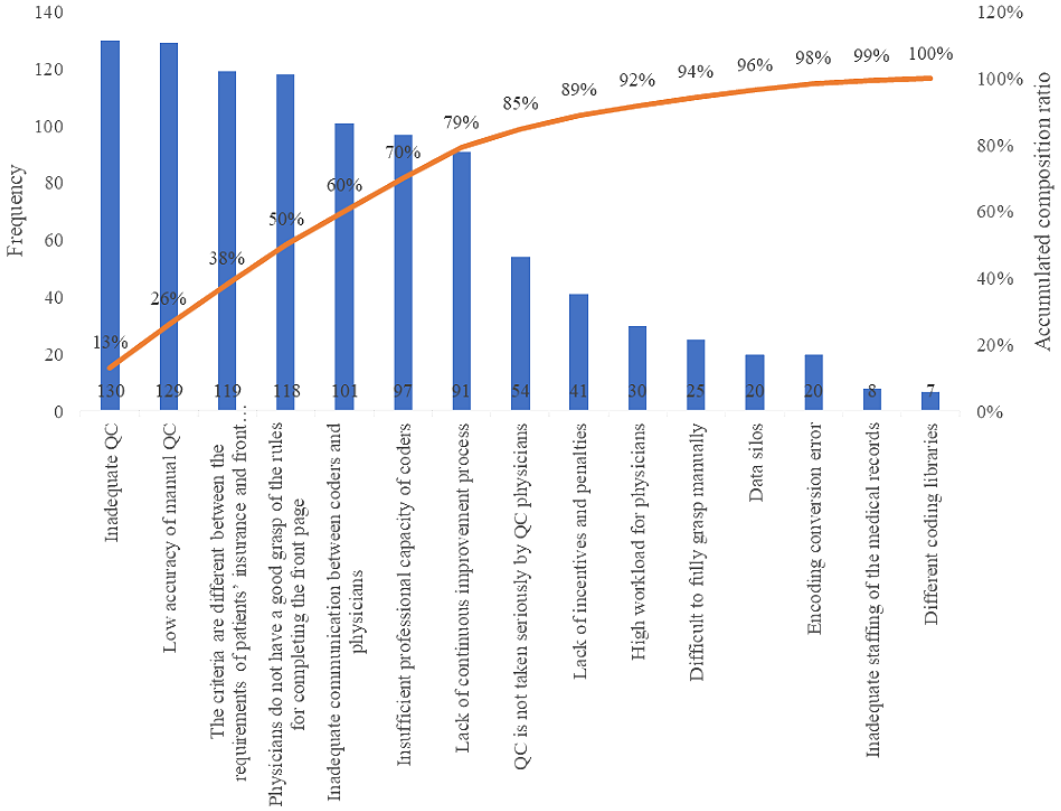

Table 4. Improvement measures for the causes of potential failure modes.

	Why	What	How and When	Where	Who
Revamp the information	• The rules for quality control are inadequate • Low accuracy in manual quality control • The criteria are different between the requirements of patients' insurance and front page details	• Establish a set of intelligent front pages in the EMR[a] management system	• Added quality control rules from May to September 2021 • Embedded quality control systems into the physician's system and front page system from July to October 2021 • Integrated medical insurance system and the front page of the EMR from July to December 2021	• EMR center and information center	• Staffs of EMR center and information engineers
Revamp quality management	• Formal quality control rules are simple • Insufficient professional capacity of coders • Inadequate communication between coders and physician • Lack of a continuous improvement process	• Improve the correctness of the front page by physician • Improve the professional capacity of coders • Establish effective communication channels • Form a continuous improvement process	From January to May 2021 • Conducted special training seminars • Prepared a quality and information management manual • Implemented professional training regularly • Invited experts for guidance • Communicated with physicians regularly • Provided timely feedback to physicians on quality control results	• EMR center and clinical departments	• Staffs of EMR center, information engineers, and physicians

[a]EMR: electronic medical record.

Comparing the Front Page of EMR Before and After Improvement

Before carrying out improvement measures, the highest RPN given by the experts was 296.3 for the failure mode "wrong code for diagnosis, surgery, or operation," which was due to the quality rules being too simple, while the lowest was 50.6 for "basic information transmission error," which was caused by wrong data interface or conversion error. On average, the final RPN was 181.2. The highest score for severity was for "wrong code for diagnosis, surgery, or operation" and the lowest was for "expense information transmission error." The highest score for frequency was for "incorrectly filled-in medical information" and the lowest was for "expense information transmission error." As for detectability, the highest score was for "wrong diagnosis-related group code of diagnosis, surgery, or operation," "restoration error," and "late feedback for quality control results." The lowest score for detectability was for "basic information transmission error." Our team calculated the RPN of the revised front page of the EMR after implementing the improvement measures mentioned in Table 5, and the final RPN was 95.0, which was lower than that of the original front page of the EMR (RPN=181.2).

The RPN of every failure mode decreased after implementing the improvements, and the mode for the late feedback for quality control decreased the most remarkably (Table 5). In addition, the accuracy rate of the basic information (χ^2_1=269.6; P<.001); inpatient information (χ^2_1=175.9; P<.001); diagnosis, surgery, and operation code (χ^2_1=32.9; P<.001); and the overall accuracy rate of the front page (χ^2_1=239.3; P<.001) and the integrity rate of the front page (χ^2_1=110.4; P<.001) increased significantly (Table 6).

Table 5. Comparison of the risk analysis before and after failure mode and effects analysis model improvement.

Process, failure modes	Before FMEA[a]				After FMEA			
	Severity	Frequency	Detectability	Risk priority number	Severity	Frequency	Detectability	Risk priority number

Discussion

The quality of the front page of an EMR is quite important not only for hospital performance management [2] but also for insurance payments to patients [15]. Thus, it is necessary to improve the effectiveness of the front page of the EMR. There are many risk management tools for investigating the potential problems in an EMR system, such as Expert Delphi [18], scenario analysis method [19], and SWOT (strengths, weaknesses, opportunities, and threats) analysis method [20]. The advantage of Expert Delphi is that everyone's opinions are collected and that of scenario analysis is that it identifies risks by designing multiple possible future scenarios. The advantage of SWOT is that it identifies the strengths, weaknesses, opportunities, and costs of the project, thus qualitatively identifying the project risks from multiple perspectives. FMEA is a risk management tool that has most of the advantages of the above tools. FMEA can not only change the occurrence of risk from postprocessing to preemptive prevention but is also a simple and a practical risk quantification method [10]. In recent years, FMEA has been widely used in various fields, including the medical field. Studies on medical services [21], medicine distribution [22], infection control [23], and medical equipment operation and maintenance [24] have used FMEA to date.

In this study, we found potential failures existing in the EMR system of China and proposed improvement measures to solve the problems by using FMEA. Our results showed that there were 2 main processes and 6 subprocesses in the EMR system that showed 13 potential failure modes. The 2 main process steps were management of the physician's system and management of the medical record system. The 6 subprocesses were information transmission in the hospital information system, front page filled by physicians, front page quality control by physicians, information transmission in the EMR system, coders' proofreading and coding, and front page quality control by EMR management. This finding is similar to that reported in a study performed in Indonesia [25], wherein potential failure modes included incomplete or missing medical record files, mistakes caused by coders, and excessive code writing or upcoding [25].

According to the principle of Pareto and from questionnaire responses, we found that there were 7 causes in our study that contributed to 80% of the consequences, which can be divided into 2 aspects for the resolution of errors. One aspect was to revamp the information by establishing a set of intelligent front pages in the EMR management system to solve the problems of inadequate information and inaccurate quality control and to implement different codes of management or payment. In this study, we established quality control rules for medical records and embedded them in the system first. Accurate quality control rules are important for maintaining data quality. For example, Carlson et al [26] used quality control rules to identify common logical problems, including incomplete data, invalid values, and inconsistent data, in a clinical data set of an intensive care unit. Hart et al [27] reported >50% decrease in rejected records across patient information, service information, and financial information in 6 months by using quality rules. In addition, we integrated the medical insurance system with the front page of the EMR on the same interface. The other aspect was to revamp the management of quality by conducting multichannel trainings for doctors and coders, creating a quality and information management manual, and communicating with physicians and coders regularly. Previous studies [28-30] have shown a high rate of errors in physician coding for professional services, which can be risky in medical care services. One study [31] showed that clinicians and coders differ in their understanding of disease coding and need to communicate in a timely manner. Some of our measures are also consistent with those previously reported [25] that a hospital needs to update coding training for coders and provide guidance and validation of coding for physicians as well.

After implementing improvement measures, we found that the RPN of every failure mode decreased. The most significant decline in RPN was for the mode on the late feedback for quality control results. Many studies have proved the benefits of artificial intelligence. For example, machine learning could improve the content of medical records by identifying patients' medical information [32] or by predicting the onset of disease [33]. Therefore, we applied artificial intelligence to establish an intelligent front page for the EMR management system and then embedded it in the doctor's medical record writing interface and medical record quality control interface, which made it possible for real-time quality control of the front page. The second indicator of decline was inaccurate quality control of the front page by physicians. The original data on the front page, such as basic patient information, expenses, and surgery, are filled by physicians who decide the quality of the front page mostly [34]. After the amendments, the accuracy and integrity

of the front page were both improved for those measures, which helped the diagnosis-related group to be more specific and the evaluation of the hospital performance more precise. In addition, the quality of the front page of EMR is quite important for patients. A complete front page of the medical record enables doctors to grasp important information about the patient in a short period, such as family history, allergy history, and important test results and facilitates doctors to quickly and accurately judge the patient's condition and formulate diagnosis and treatment plans, thereby reducing overmedication and even erroneous medical treatment.

Human factors engineering and user-centered designs are indispensable components of mobile health technology design and implementation [35]. Human factors emphasize human needs and capabilities as the core of the design technology system, making people the most important consideration in the design process and aiming to achieve the goal of "making machines fit people." Regarding EMR system update, physicians, medical record coders, and quality controllers are the target users, and they will resist the technology when they believe it does not meet their expectations and needs [36]. For this reason, this study was conducted through brainstorming and questionnaires to inform the needs of physicians, coders, and others regarding the front page of the EMR system. For example, incorrectly filled-in medical information and quality control proposed by physicians, coders, and other users prompted engineers to establish a set of intelligent front pages in the EMR management system. The usability of the EMR system is evaluated by its effectiveness, efficiency, and suitability for target users. Although we did not use questionnaires to analyze the satisfaction of doctors, coders, and others with the improved EMR system, the results of FMEA showed that RPN was greatly reduced after the system was improved; thus, it can be hypothesized that the user's satisfaction with the system has been enhanced. Moreover, the overall accuracy rate of the front page (P<.001) and the integrity rate of the front page (P<.001) were significantly enhanced after implementing the improvement measures, thereby demonstrating the increase in the effectiveness of the system. The number of front pages of EMR increased from 48,509 to 78,890 with the same amount of time and labor, which proves that the efficiency of the system was also improved.

Our study has several strengths. First, medical research FMEA has mostly been performed for health care processes, hospital management, etc. For example, a study performed in Sri Lanka used FMEA to improve medication safety in the dispensing process [22], while another study aimed to increase the efficiency and success rate of patients with acute ischemic stroke [25]. No study has used FMEA for improving the front page of EMR in China before. Therefore, this is the first study performed in China, which can provide the base for future studies. Second, most studies only used FMEA to find potential failure modes and propose improvement measures, but the system was not evaluated after the application of those measures. However, our study used FMEA to compare the RPN of the front page of the EMR before and after applying the improvement measures to verify the efficiency of the system. Our study also has some limitations. The first limitation was that the method we used is not advanced since there are many better methods such as data envelopment analysis [37] and fuzzy RPN method [38]. The second limitation was that the process of scoring the system by the experts was subjective although we had set weights for the experts' scores. The third limitation was that we did not use additional methods to validate the results, which we aim to improve in the future. Lastly, although the EMR system called Heren has been used in many hospitals, different hospitals may use different types of Heren. Consequently, the generalizability of this study and the findings should be considered cautiously. In conclusion, we improved the front pages of the EMRs in China based on the potential failure modes found by the FMEA method.

Abstract

The cognitive load theory suggests that completing a task relies on the interplay between sensory input, working memory, and long-term memory. Cognitive overload occurs when the working memory's limited capacity is exceeded due to excessive information processing. In health care, clinicians face increasing cognitive load as the complexity of patient care has risen, leading to potential burnout. Electronic health records (EHRs) have become a common feature in modern health care, offering improved access to data and the ability to provide better patient care. They have been added to the electronic ecosystem alongside emails and other resources, such as guidelines and literature searches. Concerns have arisen in recent years that despite many benefits, the use of EHRs may lead to cognitive overload, which can impact the performance and well-being of clinicians. We aimed to review the impact of EHR use on cognitive load and how it correlates with physician burnout. Additionally, we wanted to identify potential strategies recommended in the literature that could be implemented to decrease the cognitive burden associated with the use of EHRs, with the goal of reducing clinician burnout. Using a comprehensive literature review on the topic, we have explored the link between EHR use, cognitive load, and burnout among health care professionals. We have also noted key factors that can help reduce EHR-related cognitive load, which may help reduce clinician burnout. The research findings suggest that inadequate efforts to present large amounts of clinical data to users in a manner that allows the user to control the cognitive burden in the EHR and the complexity of the user interfaces, thus adding more "work" to tasks, can lead to cognitive overload and burnout; this calls for strategies to mitigate these effects. Several factors, such as the presentation of information in the EHR, the specialty, the health care setting, and the time spent completing documentation and navigating systems, can contribute to this excess cognitive load and result in burnout. Potential strategies to mitigate this might include improving user interfaces, streamlining information, and reducing documentation burden requirements for clinicians. New technologies may facilitate these strategies. The review highlights the importance of addressing cognitive overload as one of the unintended consequences of EHR adoption and potential strategies for mitigation, identifying gaps in the current literature that require further exploration.

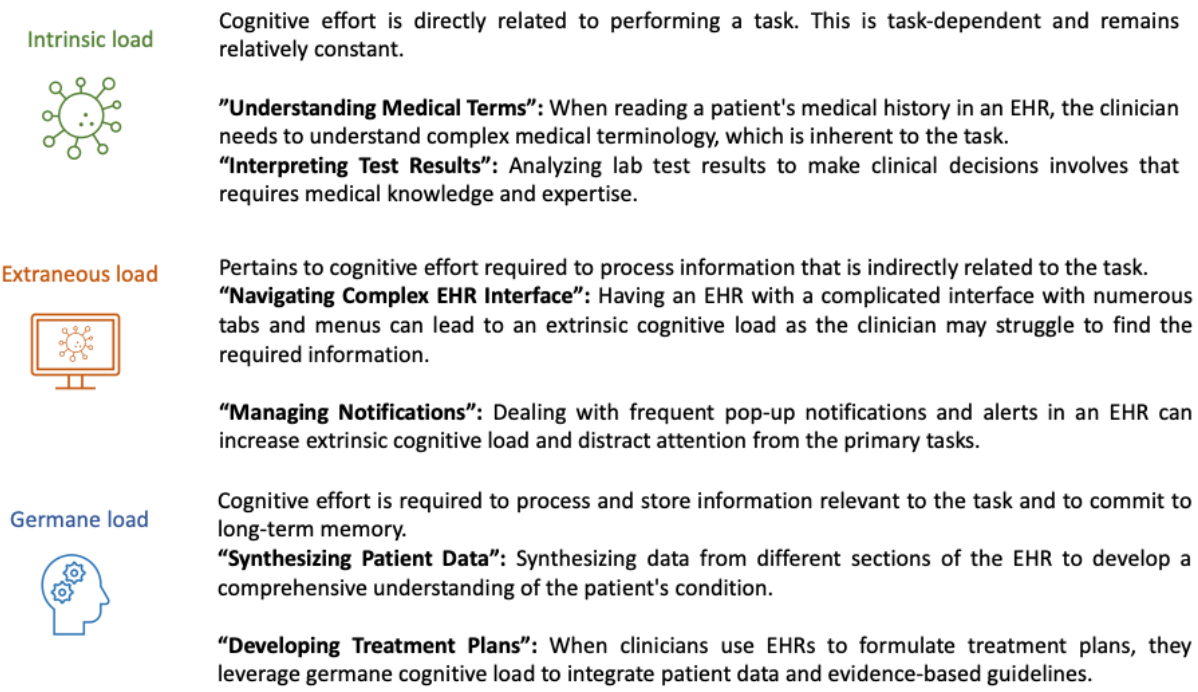
KEYWORDS

electronic health record; cognitive load; burnout; technology; clinician

Introduction

Sweller [1] defined cognitive load as "the amount of mental effort required to process and store information in working memory." The cognitive load theory argues that completing a task requires a complex interplay between sensory inputs, working memory, and long-term memory [1]. The working memory helps interpret the sensory input and then commits processed information into long-term memory. This psychological theory stipulates that while both sensory and long-term memories can handle large volumes of input data, working memory has a comparatively limited capacity and can keep 3 to 5 items in mind at a time [2]. When the amount of information exceeds this given capacity, it leads to cognitive overload. For any given task, there are 3 main factors that contribute to its perceived cognitive load: intrinsic, extraneous, and germane [1]. Figure 1 provides a description of each cognitive load with examples of how they are affected when clinicians use electronic health records (EHRs).

Figure 1. Factors contributing to cognitive load and examples of how they are affected when clinicians use EHRs. EHR: electronic health record.



Physician burnout refers to a state of chronic physical and emotional exhaustion experienced by clinicians, often due to prolonged stress and heavy workloads. It is a growing concern in the medical sector, both in the United Kingdom and globally, and it affects individual health care professionals as well as the health care system as a whole. Key aspects include emotional exhaustion, demoralization, and a reduced sense of accomplishment [3].

Contributing factors to burnout include unremitting workloads, administrative burdens, emotional stress, work-life imbalance, the lack of autonomy, and insufficient support systems. Physicians who work long hours and have high patient loads can experience physical and mental fatigue. Additionally, administrative tasks, paperwork, and EHR requirements add to the workload, causing frustration [4].

According to a report from the World Health Organization, the average life expectancy globally has risen by 6 years, from 66.8 years in 2000 to 73.4 years in 2019 [5]. It is estimated that 1 in 3 adults have multiple long-term conditions [6]. With advancements in science and technology, there are now more diagnostic and treatment options available, which require additional monitoring and follow-up. Consequently, physicians face an increased cognitive load due to the larger volume of information they need to process from complex patients to deliver high-quality care.

Simultaneously, the extraneous load experienced by clinicians is influenced by the presentation of this information. When information is disorganized, unnecessary, or incomplete, clinicians are exposed to a higher extraneous load, placing a greater demand on their working memory [7], which in turn has a knock-on effect on the germane load. This effect is most pronounced among early-career clinicians with a significant amount of new material to learn [7].

Working memory is also attenuated in the presence of physiological or emotional stress [8], which in recent times has become increasingly more common among clinicians following the COVID-19 pandemic, leading to widespread burnout.

Although EHR systems are widely used in health care settings worldwide, there are not enough comprehensive studies evaluating their advantages and disadvantages or examining how they can be improved. In a systematic review, Moy and colleagues [9] aimed to identify the studies on physician and nursing burnout related to using EHR systems. They found that 40% of the 35 studies meeting their inclusion criteria had mentioned clinical burnout. However, they noted a lack of standardized and validated measures to assess the documentation

burden related to EHR use. There is also a lack of objective measures to assess the cognitive load associated with using EHRs.

In summary, the increasing cognitive load experienced by physicians is a sum of the increasing complexity of the information presented, the quality and clarity of that presentation, as well as the emotional and psychological context in which the information is received [1]. The usability of EHRs, including their design, interoperability, and various regulatory requirements, impacts this cognitive burden. By working constantly above the cognitive load threshold, clinicians may exhibit symptoms of cognitive overload, which is considered an immediate precursor to burnout [10]. This narrative review examines the existing literature on cognitive overload experienced by health care professionals, specifically in relation to their use of EHRs and the associated burnout. The review also explores potential solutions that could help reduce the EHR-related cognitive load and improve the well-being of clinicians.

Use of EHRs in Health Care

The digitization of health care has been a growing trend over the past decades, which has seen most patient data transferred from paper records to EHRs. The use of EHR dates back to the 1960s but was only limited to government use [11]. Since the 1970s, EHR systems have been developed with hierarchical or relational databases for various indications, such as to help with hospital billing and scheduling systems, to help improve medical care, and for use in medical research. As computers have become more accessible, larger health care organizations have begun using them to gather patient information [12]. This shift has gradually expanded to encompass nonclinical tasks such as administration, medicolegal work, research, and education [13], which have also increased in demand and complexity over time.

Poor physician acceptance and the lack of incentives, in addition to high costs and errors associated with data entry, hindered EHR implementation uptake in the 1990s, and thus, digital records were not widespread [14]. By the 2000s, countries such as the United States and the United Kingdom began implementing national projects to digitize paper records [12]. The UK government attempted to create the National Programme for Information Technology [15] in 2002 to create a universal EHR system for the entire United Kingdom. The nationwide initiative was centered around 3 main objectives: lifelong EHRs, 24/7 web-based access by public health care professionals, and seamless information sharing throughout all sectors of the National Health Service [16]. The project failed to meet its objectives, and digitization became fragmented and slow once again [17]. However, by 2022, a total of 86% of the UK hospital trusts had successfully transitioned from paper notes to a digital system (although only a minority have enterprise-wide EHR capability), with the figure expected to reach 90% by December 2023 [18]. In the United States, the *Health Information Technology for Economic and Clinical Health Act* was signed into law in February 2009 to promote the adoption of and meaningful use of health information technology (HIT) as part of the American Recovery and Reinvestment Act. Financial incentives that were allocated as part of the *Health Information Technology for Economic and Clinical Health Act* led to a significant increase in the adoption of EHRs in the United States [14].

Factors Impacting the Usability of EHR Systems

The usability of EHR systems continues to be a major concern, whereby clinicians are subjected to too much or too little information, preprogrammed workflows, and multiple alerts [19]. There have been problems with chaotic, nonintuitive visual displays and numerous default settings that might not be relevant for a given task or patient [20]. Navigating through the same information includes unnecessary steps, for example, multiple clicks and duplicated information [21]. Users experience higher fatigue, leading to potential room for errors and decreased efficiency [22,23]. In addition to documentation and chart review, managing inbox tasks has been noted as one of the significant burdens for clinicians [24]. Receiving excessive notification has been shown to cause alert fatigue, leading to missing important information and poor patient outcomes [25]. Although clinical decision support systems have been introduced to enhance patient care, excessive use of interruptive clinical decision support systems in the EHRs can lead to alert fatigue and reduced effectiveness. Chaparro and colleagues [26] have described how interruptive alerts can increase cognitive burden and lead to reduced acceptance of the alert and an increase in the number of errors.

Several factors have been highlighted as contributing to the use of EHR and physician well-being. Nguyen and colleagues [27] studied this in a systematic review, where they found that EHR-related physician well-being is determined by multiple factors, including EHR usability, EHR system features, and physician-level characteristics and beliefs.

The sheer volume of data that a physician can access during a specific clinical encounter proves challenging [28]. As an example, Hill and colleagues [29] found that emergency health care physicians see an average of 2.4 patients per hour and use 4000 mouse clicks in a 10-hour shift. This can result from a combination of poor EHR design and information overload and adds to physician stress [30,31]. Information overload is a part of the 5 main hazards of “information chaos” alongside information underload, information scatter, information conflict, and erroneous information [32]. Clinicians are then required to spend more effort to filter through the information, clarify conflicting documentation, or reassess potentially erroneous information, leading to excess workload and adverse outcomes on not only patient care and health systems but, more importantly, clinician well-being [33].

Gal and colleagues [34] studied this in a pediatric intensive care unit where they calculated that each patient generated an average of 1460 new data points in a 24-hour period. Pediatric intensive care unit attending physicians cared for an average of 11 patients during the day and 22 patients overnight, resulting in exposure to 16,060 (range 11,680-18,980) and 32,120 (range

23,360-37,960) individual data points during the day and night, respectively.

Wanderer and colleagues [35] have described how optimal data visualization in various specialties can lead to improved decision-making for clinicians and more efficient use of their time. Many EHR vendors use visual analytic systems to improve physician workflow and reduce medical errors [36].

Blink rate, measured using eye-tracking technology, has been associated with cognitive workload. Visual tasks that require more focused attention and working memory load have been shown to reduce blink rate [37]. A decreased blink rate has been found to occur in EHR-based tasks that require more cognitive workload [38].

The NASA Task-Load Index (NASA-TLX) is a widely used questionnaire to assess perceived workload (available in Multimedia Appendix 1) [39]. It consists of 6 questions, which can be rated from 1 to 10. Nurses rated their perceived workload from 0 (very low) to 10 (very high).

Using blink rate in addition to the NASA-TLX, Mazur and colleagues [40] tested the implications of the EHR usability interface in a study where they assigned tasks, including the review of medical test results for 20 and 18 individuals using baseline and enhanced EHR versions, respectively, that provided policy-based decision support instructions for next steps. Interestingly, they found that the baseline group had poorer performance and higher cognitive load compared with those who used the enhanced version, suggesting the importance of improving the usability of EHRs to address issues such as clinician burnout and patient safety events.

Harry and colleagues [7] studied the direct relationship between cognitive load with physician burnout in a national sample of US physicians. Using the NASA-TLX, they had responses from 4517 (85.6%) of the 5276 physicians included in the survey. The median age of the physicians was 53 years; 61.8% were male, 37.9% were female, and 0.3% were other gender; and 24 specialties were identified. They identified a dose-response relationship between physician task load and the risk of burnout independent of age, gender, practice setting, and hours worked per week.

To demonstrate a more accurate association between EHR use and stress, Yen and colleagues [41] used blood pulse wave monitoring (previously used as a surrogate for chronic stress) in addition to NASA-TLX on 7 nurses during 132 hours of work. They found that the nursing staff spent 45.54 minutes using EHR during a 4-hour shift, which was much more than the time spent on any other communication or hands-on activities. In addition, the nurses' stress when using EHR was associated with higher perceived physical demand and frustration.

The level of EHR-related burnout has also been shown to be in part influenced by physician specialty. In a large study that used assessing questionnaires among physicians in various specialties with over 25,000 respondents, the investigators found the level of burnout ranged from 22% to 34% by specialty [42]. The specialties with the highest levels of burnout were family medicine (34%) and hematology or oncology (33%). The specialties with the lowest levels of burnout were psychiatry (22%) and anesthesiology (24%). After adjusting for confounding variables, physicians with 5 or fewer hours of weekly out-of-hours charting were twice as likely to report lower levels of burnout than those with 6 or more hours. Those who agree that their organization has performed well with EHR implementation, training, and support were also twice as likely to report lower levels of burnout than those who disagreed. This highlights the importance of training and support following the implementation of EHR for their optimal use.

In a scoping review, Muhiyaddin and colleagues [43] studied the causes and consequences of physician burnout related to the use of EHRs. Reviewing 30 eligible studies out of 500, they identified 6 main causes that are related to physician burnout, including EHR documentation and related tasks, poor design of EHR systems, workload leading to overtime work, inbox alerts, and alert fatigue. Not surprisingly, physician burnout was associated with a low quality of care, behavioral issues, and mental health complications, as well as career dissatisfaction and a reduction in patient safety and satisfaction.

In a survey of 640 clinicians from 3 institutions, with 282 (44.1%) responses to 105 questions, Kroth and colleagues [30] identified 7 EHR design and use factors associated with high stress and burnout. These were information overload, slow system response times, excessive data entry, inability to navigate the system quickly, note bloat, interference with the patient-clinician relationship, fear of missing something, and notes geared toward billing.

Another study [44] aiming to quantify burnout due to the use of HIT used a survey sent to 4197 physicians, where 1792 responded (response rate: 42.7%). They found that HIT-related stress was measurable, prevalent, and specialty related. About 70% of physicians with EHRs experienced HIT-related stress in their sample, and the presence of any of the 3 HIT-related stress measures independently predicted burnout symptoms among respondents. In particular, those with time pressures for documentation or those doing excessive "work after work" on their EHR at home had approximately twice the odds of burnout compared to physicians without these challenges. Time spent after hours on the EHR and the volume of inbox messages have been found to relate to physician exhaustion [45].

Using live observational design and NASA-TLX surveys, Khairat and colleagues [46] assessed the effect of EHRs on emergency department attending and resident physicians' perceived workload, satisfaction, and productivity through completing 6 EHR patient scenarios. They found that EHR frustration levels are significantly higher among more senior attending physicians compared with more junior resident physicians. Among the factors causing high EHR frustrations are (1) remembering menu and button names and commands use; (2) performing tasks that are not straightforward; (3) system speed; and (4) system reliability.

Advantages and Disadvantages of Using EHRs

Overview

As highlighted in the previous section, despite their potential benefits, there have been growing concerns that EHRs also have detrimental effects. Here, we summarize some of the advantages and disadvantages of using EHRs.

Information overload is a significant concern when using EHRs [47-49]. Various studies also suggest a correlation between the usability of the EHR and cognitive load and burnout among clinicians [34,50-52]. Clinicians feel that work-life balance, satisfaction rates, attrition, and burnout are all affected due to the continuous daily interaction with EHR systems [22,53-55].

Advantages

The transition from paper-based medical records to EHRs has been perceived as a positive development in several areas [9,56]. In addition to being easily accessible, EHR systems have been shown to improve communication between clinicians and enhance the continuity of care [57,58]. They can lead to better-informed decisions due to the availability of data and avoid the duplication of diagnostic testing [59]. However, a review of the impact of EHR use on enhancing medication safety, one of the biggest risks to patient care, has shown only modest improvements [60].

EHRs also contain a high volume of clinical data, providing us with multiple opportunities to conduct research and audit [13,59]. A good example of this in the United Kingdom is OpenSAFELY, a secure, transparent, and open-source software platform for the analysis of EHR data [61]. During the COVID-19 pandemic, scientists and statisticians could use the data available on this platform to provide insights into population demographics most at risk of death following COVID-19 infection, which aided with the national policy strategy for prioritizing care [62-65].

Disadvantages

Over the past decade, there has been a reported increase in burnout levels among clinicians, with one potential factor being the introduction of EHR systems [23,34]. The introduction of EHRs has resulted in changes in workflow, with frontline clinicians taking on administrative tasks such as ordering tests, correcting notes, and placing referrals. This has led to increased cognitive load, which is often overlooked [66,67].

On a day-to-day basis, clinicians face time constraints; administrative load; and consequently, elongated workdays. The current documentation methods used in EHRs are under scrutiny by clinicians due to the perceived poor quality of user interfaces, ultimately leading to burnout [52]. Factors such as increased structured documentation requirements, physician order entry, inbox management, and patient portals contribute to more work that is not direct face time with patients [19,68].

Inflated documentation also extends to the excessive use of templates and copy-and-paste workflows in EHR systems that introduce data that are neither required nor accurate [48,49,69]. EHRs allow information to be copied from almost anywhere in the record to another section. This can save time and allow clinicians to focus on clinical tasks rather than documentation; however, it comes with its own challenges. Erroneous information can be copied and pasted without editing, leading to data integrity issues and diagnostic errors [70]. This also creates room for false assumptions and inferred incorrect information between different health care professions, perpetuating previous inaccuracies. It might also sanction junior clinicians to rely solely on readily available information rather than conducting a thorough history and examination for themselves and constructing their own differential thought processes [71].

Although thorough documentation is key for clinical care, there has been a rise in complex and lengthy documentation of content that is required for billing purposes, quality improvement measures, avoiding malpractice, and signs of compliance [72]. In countries such as the United States, the regulatory requirements for data entry beyond what is required for direct patient care can contribute to an increasing workload [73]. Examples of these include collecting data for claim submission, prior authorization, billing, and quality reporting. In addition, a lack of interoperability between EHR systems can result in clinicians not having access to adequate patient information and fragmented care [74]. Often the clinical needs to spend a significant amount of time to obtain this information from various medical records between different health care organizations and sometimes even within one facility. Textbox 1 summarizes some of the advantages and disadvantages of using EHRs.

Textbox 1. Advantages and disadvantages of using electronic health records (EHRs).

Advantages of using EHRs

- Improved communication between clinicians
- Remote access to clinical records enhances care delivery
- Convenient access to patient information for clinicians
- Facilitates research and audit through a high volume of clinical data storage

Disadvantages of using EHRs

- Information overload leading to cognitive overload
- Increased cognitive load due to EHRs can contribute to feelings of exhaustion and burnout
- Continuous interaction with EHRs affects work-life balance and may lead to burnout
- Complex and lengthy documentation required for billing and quality reporting can be cumbersome
- Poor quality of user interfaces in EHRs leads to clinician burnout
- Excessive use of templates and copy-and-paste workflows can lead to data integrity issues
- The lack of interoperability between EHR systems can lead to missed information and duplication of investigations

Overcoming EHR-Related Burnout

Health care organizations and policy makers worldwide are increasingly recognizing the importance of addressing clinician burnout [75]. Here, we have summarized some of the interventions recommended in the literature that can reduce various types of cognitive load and potentially clinician burnout related to EHR use.

Dymek and colleagues [24] have made a case for producing an evidence base to reduce EHR-related clinician burden. Describing documentation, chart review, and inbox tasks as some of the key contributing factors causing burnout, they have made suggestions to help overcome these challenges. Some of these approaches include using speech recognition software and natural language processing to help with documentation and the generation of progress notes; the use of natural language processing and machine learning to process, filter, and rank patient information so that the attention can be paid to where it is most needed; and the use of better inbox design by involving clinicians in their development. Understanding the workflow of the clinicians and involving them in the design of the EHR have been shown to positively impact its usability and user satisfaction [76].

Several studies have reviewed alert burden in EHRs and described potential solutions on how to manage them effectively. One of the very interesting and useful recommended suggestions is developing an Interruptive Alert Stewardship by implementing metrics to assess the alert burden and their effectiveness in improving outcomes [26]. McGreevey and colleagues [77] have comprehensively described reasons for alert fatigue and suggest that organizations develop an alert governance specific to their needs. They propose that key stakeholders including clinicians, informatics, information technology, and administration groups need to participate in developing the alert governance and oversee the design and purpose of alerts. They also recommend using a checklist to assess the purpose and justification of alerts and suggest using metrics to assess their effectiveness and efficiency. Organizations such as Geisinger Health System and Penn Medicine have successfully improved their EHR alert to help with clinician well-being [77].

Clinicians have specific and feasible suggestions for reducing EHR-related burdens, such as providing high-quality EHR training; having an on-site EHR support team; involving support staff or scribes in the documentation process; and, importantly, obtaining physician input and feedback in improving EHRs [27]. Future efforts should focus on implementing the strategies and upgrades requested by these frontline users.

In a recent systematic review, Kang and Sarkar [78] looked at interventions that have been used to reduce EHR-related burnout. The study identified 3 primary interventions, including the use of scribes, EHR training, EHR modifications, and a combination of training and modifications. The use of scribes has been overall well received by clinicians and patients and, in some cases, led to increased productivity, but there were downsides, in particular, the cost, which would be difficult to overcome in smaller centers. EHR training had varying outcomes, with some studies showing a reduction in documentation time, whereas others did not demonstrate this benefit. Nevertheless, subjective EHR proficiency increased, which could help improve clinicians' perception of EHR.

The study [78] has also examined several EHR modification techniques, such as data entry automation technology, improving EHR workflows, reducing unnecessary inbox alerts, and providing support teams to resolve EHR issues promptly. These interventions resulted in positive outcomes, such as a reduction in documentation time ranging from 18.5 to 60%, improved documentation quality and completion rate, decrease in data errors, and subjective EHR usability and satisfaction. However, these positive effects did not lead to a significant reduction in physician burnout. The authors suggest that this could be due to the fact that although EHR enhancements can improve some aspects of the clinician's workflow, they probably do not address the defects in the EHR usability, which contribute to burnout. In addition, there are other factors contributing to burnout, such

as overall workload, organizational culture, and work-life balance that extend beyond EHR systems.

Improving interoperability and health information exchange through understanding the barriers, appropriate incentives, and legislation can facilitate the clinicians' workflow, reduce workload, and enhance patient safety [79].

In 2020, The Office of the National Coordinator for Health Information Technology published a report outlining strategies to reduce regulatory and administrative burden related to the use of HIT and EHR systems [80]. The report focuses on the challenges of EHR and HIT-related burden, which hinder the achievement of interoperability. They recognize that these burdens increase the time and expense clinicians must invest in interacting with EHRs, reducing the value of information, and diverting resources from patient care. They propose a framework for trusted exchange among health information networks to reduce clinician burden while benefiting patients and the health care system.

The National Academy of Medicine published a potential roadmap for EHR optimization and clinician well-being [81]. They have described several strategies currently available that can improve the usability of EHRs, such as EHR optimization, in-basket management techniques, documentation strategies, team-based workflow, and EHR training, as well as the use of artificial intelligence and add-on applications that can help with interoperability, automation, and decision support tools in the future. Gandhi and colleagues [82] have described how the use of artificial intelligence can reduce the cognitive workload by helping with data gathering, documentation, and decision support. They also suggest useful methods to assess the impact of these technologies.

Gaps in the Current Literature

Given the increasingly interconnected digital ecosystem and the complexity of health care systems, which are influenced by physical, emotional, and human factors, it can be challenging to attribute specific outcomes to any particular technology.

Therefore, to maximize the benefits of new tools, it is essential to create frameworks for scientifically assessing the impact of any technology used.

By using user-friendly interfaces, customization options, and context-sensitive information presentation, EHRs can streamline data management [83]. Incorporating decision support tools, data visualization techniques, and smart documentation practices further enhances health care staff's ability to focus on patient care, reducing the risk of errors and burnout [36]. EHR optimization to support clinical workflow and real-life working is a key to uplifting the well-being of health care professionals.

Addressing physician burnout requires systemic changes, including improving work environments with a renewed focus on teamwork, reducing administrative burdens, providing support, and promoting work-life balance within health care organizations.

Individual strategies, such as self-care, stress management, and professional pastoral help, are crucial for clinicians to mitigate and recover from burnout [84]. This will support the well-being of the health care workforce and ensure ongoing high-quality care delivery for all.

As our patients and work environments become more complex and more health technology products become available, it is crucial that we assess their impact through studies and engaging with our health care staff and patients throughout all stages of their development and use [85].

Conclusion

The use of EHR systems may provide benefit for centralizing patient data and simplifying the process of reviewing records, requesting laboratory and imaging tests, and reviewing results, as well as conducting clinical audits, research, and quality improvement projects.

However, there is a noticeable difference in the quality of various EHR systems health care organizations use. Many of these EHR systems do not communicate with each other, keeping data isolated in silos. Our review highlights the cognitive load that their use places on clinical staff, which is not always considered. Improving the design, user interface, and data visualization or retrieval of EHR systems can help to reduce cognitive load, support working memory, and potentially reduce physician workload while enhancing patient care.

Abstract

Background: Over 200 health information exchanges (HIEs) are currently operational in Japan. The most common feature of HIEs is remote on-demand viewing or searching of aggregated patient health data from multiple institutions. However, the usage of this feature by individual users and institutions remains unknown.

Objective: This study aims to understand usage of the on-demand patient data viewing feature of large-scale HIEs by individual health care workers and institutions in Japan.

Methods: We conducted audit log analyses of large-scale HIEs. The research subjects were HIEs connected to over 100 institutions and with over 10,000 patients. Each health care worker's profile and audit log data for HIEs were collected. We conducted four types of analyses on the extracted audit log. First, we calculated the ratio of the number of days of active HIE use for each hospital-affiliated doctor account. Second, we calculated cumulative monthly usage days of HIEs by each institution in financial year (FY) 2021/22. Third, we calculated each facility type's monthly active institution ratio in FY2021/22. Fourth, we compared the monthly active institution ratio by medical institution for each HIE and the proportion of cumulative usage days by user type for each HIE.

Results: We identified 24 HIEs as candidates for data collection and we analyzed data from 7 HIEs. Among hospital doctors, 93.5% (7326/7833) had never used HIEs during the available period in FY2021/22, while 19 doctors used them at least 30% of days. The median (IQR) monthly active institution ratios were 0.482 (0.470 - 0.487) for hospitals, 0.243 (0.230 - 0.247) for medical clinics, and 0.030 (0.024 - 0.048) for dental clinics. In 51.9% (1781/3434) of hospitals, the cumulative monthly usage days of HIEs was 0, while in 26.8% (921/3434) of hospitals, it was between 1 and 10, and in 3% (103/3434) of hospitals, it was 100 or more. The median (IQR) monthly active institution ratio in medical institutions was 0.511 (0.487 - 0.529) for the most used HIE and 0.109 (0.0927 - 0.117) for the least used. The proportion of cumulative usage days of HIE by user type was complex for each HIE, and no consistent trends could be discerned.

Conclusions: In the large-scale HIEs surveyed in this study, the overall usage of the on-demand patient data viewing feature was low, consistent with past official reports. User-level analyses of audit logs revealed large disparities in the number of days of HIE use among health care workers and institutions. There were also large disparities in HIE use by facility type or HIE; the percentage of cumulative HIE usage days by user type also differed by HIE. This study indicates the need for further research into why there are large disparities in demand for HIEs in Japan as well as the need to design comprehensive audit logs that can be matched with other official datasets.

health information exchange; audit log; Japan; HIE; audit; logs; usage; medical informatics; rate; hospitals; electronic health record

Introduction

A health information exchange (HIE) is an electronic mobilization system of clinical data across entities such as institutions or organizations, or an organization that controls such systems [1-3]. The appropriate sharing of medical information using HIEs enables fewer duplicated procedures, less duplicated imaging, and fewer total orders. HIE usage is also associated with improved medication reconciliation and immunization [1,4,5]. HIEs have several major features. The first feature enables sharing (ie, sending and receiving) of secure information electronically between care providers to support

coordinated care, known as directed exchange [1,6]. The second enables remote, on-demand viewing or searching of aggregated patient health data from multiple health care institutions. This feature is known as query-based exchange or query-based HIE [1,6,7]. In addition to these two features, consumer-mediated exchange allows patients to aggregate and control the use of their health data among providers [1].

In Japan, HIEs are not widely used. Instead, systems called "Chiiki iryo joho renkei nettowa-ku" have provided features equivalent to HIEs [8-11]. In some literature, these are called "regional health care networks" (RHNs) in English [10]. Past surveys show that over 200 RHNs of various sizes operate in Japan [9]. Most of these RHNs are sponsored by governments or local authorities. According to a Ministry of Health, Labour and Welfare (MHLW) report, 27 RHNs cover entire prefectures, 104 RHNs are within the secondary medical area, 32 are the size of a municipality, and 15 are smaller than a municipality [9]. Item 2.10.2 of the Japan Medical Association Research Institute's 2021 survey [8] investigates the services provided by 229 RHNs, revealing that "sharing of medical data" was the most common service, provided by 190 (83%) RHNs, followed by "sharing of medical images," provided by 187 (81.6%). These features are equivalent to a query-based exchange. In addition, 66 (28.8%) RHNs provide email services and 45 (19.7%) provide electronic patient referral documents, which is equivalent to a directed exchange. Only 9 (3.9%) RHNs provide self-management systems for patients, which is equivalent to a consumer-mediated exchange. In other words, query-based exchange is the most common feature of Japanese HIEs. Since HIEs and RHNs essentially refer to systems with the same features, we will refer to RHNs as HIEs in the subsequent paragraphs. To avoid confusion between computer systems and organizations, we refer to the organization that promotes HIEs as a regional health information organization (RHIO), a term adopted in most literature [7,12].

It is crucial to evaluate the benefits of HIEs for individual health care workers and institutions. Review papers on HIEs have highlighted the importance of understanding whether the system is used [13]. To study the actual use of HIEs, audit logs have often been analyzed [14-25]. The Japanese Association of Healthcare Information Systems Industry published a technical document called "JAHIS's Guide Ver.1.0 on Evaluation Indicators for Regional Medical Collaboration" [26], which emphasizes the importance of evaluating HIE systems using audit log analysis. However, most previous reports [8,9,27] or peer-reviewed journal articles [28-30] about HIE in Japan either did not include audit log analysis or were limited to simple analyses. The MHLW conducted a survey [9] on access to HIEs in 2019. The average monthly active institution ratio based on the MHLW report was 0.381 (SD 0.199) for HIEs connected to 100 or more institutions (Table S1 in Multimedia Appendix 1), meaning that more than half of the connected institutions did not access HIEs. Although the MHLW report suggested low utilization of large-scale HIEs, it did not include a user-level analysis. As there are no studies analyzing the audit logs of multiple HIEs in Japan at the user level, the usage of HIE by individual users or medical institutions remains unknown.

The primary objective of this study was to clarify the extent to which query-based exchange is used by individual health care workers and institutions in large-scale HIEs in Japan by analyzing audit logs at the user level. One reason for investigating only query-based exchange is that, as already mentioned, it is the most common feature of such systems in Japan. The other reason is that, while directed exchange has alternatives such as patient referral letters on paper and consumer-mediated exchange has alternatives such as prescription records on paper, query-based exchange can only be achieved through HIEs. Therefore, analyzing the usage of this feature indicates the significance of HIEs. There are two reasons for investigating only large-scale HIEs. First, it is not realistic to investigate the audit logs of all 200 or more HIEs. Second, large-scale HIEs appear to have spread, as they are accepted by many medical institutions and many patients in the region. When conceptualizing this study, we thought that by investigating large-scale HIEs, we would be able to make suggestions for the increased use of small-scale HIEs.

Methods

Study Design and Data Collection

In this study, we collected data on HIEs that met the following inclusion criteria: (1) they must be included in the list of the survey report, "About the current situation of regional healthcare network" [9] published by the MHLW, and (2) each HIE must be connected to more than 100 institutions and have more than 10,000 patients according to the report above. We asked all RHIOs operating HIEs that met the inclusion criteria to cooperate in this study. When requesting data from each RHIO, we promised to conceal the identity of the RHIO that provided the data in this study. We also agreed to present our published analysis and results in such a way that the RHIO that provided the data would be concealed. This was done to avoid any potential effects that public disclosure of the usage status of each HIE would have on its operation. We obtained data from RHIOs that provided informed consent.

The profile and audit log data of health care workers enrolled in the HIE were collected. In this study, we did not collect patient data from the HIE. Textbox 1 displays the data requested for each HIE; we only received the available data each RHIO could provide. Consequently, datasets and data representation formats differ among HIEs. We also obtained data on the number of connected institutions per month or year for each RHIO. The maximum period of the audit log data was 5 years. We aimed to acquire audit log data from April 1, 2017, to March 31, 2022, but if there were no accumulated data for that period, we asked the RHIO to provide data for the period that could be extracted.

Textbox 1. User data analyzed in this study.

1. Occupation
2. Institution
3. Anonymous identifier
4. Date of account registration and account deletion in health information exchange
5. Date and time of access to query-based exchange
6. Type of data accessed by the user
7. Type of device used for access

Ethical Considerations

This study was approved by the ethics committee of Kyoto University Graduate School and the Faculty of Medicine. The accession number was R3266-7. The disclosure document regarding the research plan and the data to be extracted were published on the Kyoto University Hospital website [31], ensuring that research subjects had the opportunity to opt out. Personal data obtained in the study were pseudonymized by the HIEs that provided the data. Research subjects did not receive compensation.

Measures and Data Analyses

Overview

We refer to "viewing patient medical data using query-based exchange" as "HIE use" in this study. Patient medical data viewed by health care workers can be obtained from multiple storage locations such as hospital electronic medical records (EMRs). If a patient agrees to the disclosure of their medical data stored by the institution, the institution or the RHIO office will take steps to release the stored medical data to HIEs. The types of medical data disclosed by institutions and RHIOs to HIEs vary by institution. Patients can also choose the types of facilities to which their medical data can be disclosed. Several models have been proposed by the MHLW for viewing the medical data disclosed in this way [11]. For example, doctors at a clinic can see which medical tests a patient has previously had when they visit a clinic for the first time. Patients referred from a clinic to a hospital can later check at the clinic the kind of treatment they will receive at the hospital to which they were referred. We investigated how often these types of use cases presented by the MHLW occur by analyzing audit logs. Audit logs for logging into the HIE system are not subject to analysis. Furthermore, the sending and receiving of documents between medical workers using the directed exchange was not included in the analysis.

As a unit for measuring access, 1 man-day was defined as HIE use on 1 day with 1 user account. The cumulative man-days for an institution are the cumulative number of days of HIE use by each user belonging to the institution. For example, consider use by a virtual clinic within a given month. At that clinic, one doctor used HIE on 3 days, and one nurse used HIE on 2 days, which was the clinic's total use of HIE for that month. In this case, the clinic's usage for that month was 5 man-days. If multiple users share a common account, this aggregation methodology may underestimate HIE usage. However, sharing accounts is generally not recommended when using HIEs.

We classified the institutions enrolled in HIEs as hospitals, medical clinics, dental clinics, pharmacies, visiting nursing stations, or nursing facilities. The institutions that could not be classified into these categories were excluded from the analysis; for example, this study did not analyze public institutions such as fire departments, public health centers, local medical associations, or vendors that developed HIEs.

In this study, the financial year (FY) is from April 1 of one year to March 31 of the next year. For example, FY2021/22 started on April 1, 2021, and ended on March 31, 2022. We used R (version 4.3.1; R Foundation for Statistical Computing) to perform the analysis.

Percentage of Days of HIE Use by Each Hospital Doctor in FY2021/22

For each user account of doctors affiliated with hospitals, we calculated the ratio of the number of days of active HIE use. We analyzed the data of HIEs that met the following two criteria: (1) audit log data for all periods in FY2021/22 were available, and (2) each user's date of account registration and date of account deletion in the HIE were available (Textbox 1). For all HIEs that met the criteria, the annual number of days of HIE use by each hospital doctor's account in FY2021/22 was counted. Next, we calculated the number of days that the doctor could use HIEs in FY2021/22. For each doctor's account that was registered with the HIE during FY2021/22, we subtracted from 365 the number of days from April 1, 2021, to the day before the account registration date. For accounts that were removed from the HIE during FY2021/22, we subtracted the number of days from the day after the account deletion date to March 31, 2022, from the remaining number of days. The number of days remaining after these subtractions is the number of days that the doctor could use the HIE in FY2021/22. For accounts that were able to use the HIE on all days in FY2021/22, we used 365 as the number of days that the account could use the HIE. We then calculated the ratio of days of HIE use by each hospital doctor. The ratio of days of HIE use was defined as follows:

(1) Data number of days of HIE use in FY2021/22 / Number of days doctor could use HIE in FY2021/22

Man-Days for Monthly HIE Use by Each Institution in FY2021/22

We calculated the man-days for monthly HIE use by each institution for each month and aggregated them by facility type. We analyzed the data of HIEs that met the following two criteria: (1) the audit log data for all periods in FY2021/22 were available, and (2) data were available on the number of participating institutions by facility type, matching our facility classification. For each institution belonging to any HIEs that meet the criteria, man-days for monthly HIE use in FY2021/22 were aggregated. Next, by each facility type, we tallied the number of months for each man-day group divided into 5 or 10 increments. Finally, for each facility type, the percentage of each man-day group was calculated.

Monthly Active Institution Ratio in FY2021/22

We calculated the monthly active institution ratio for each facility type, defining it as follows:

$$\frac{\text{Number of institutions that used HIE on the last day of each month}}{\text{Number of institutions participating in HIE on the last day of each month}}$$

We analyzed the data of HIEs that met the following two criteria: (1) audit log data for all periods in FY2021/22 were available, and (2) data on the number of participating institutions by facility type, which matched our facility classification, were available. For each facility type, the total number of participating institutions for the last day of each month in FY2021/22 was aggregated in all HIEs that met the criteria. This corresponds to the denominator of Equation 2. Next, all months in FY2021/22 and all institutions were flagged as to whether they used HIE. If at least one account within an institution used HIE for at least one day in a month, the institution was deemed to have used the HIE that month. Subsequently, for each facility type, we calculated the sum of the institutions that used HIE for each month. This corresponds to the numerator in Equation 2. Finally, for each facility type, we calculated the active institution ratio for each month using Equation 2.

Within facility types, hospitals were further classified based on the number of beds. Hospitals were divided into three categories: those with ≥200 beds, those with 100-199 beds, and those with ≤99 beds, and Equation 2 was calculated for each classification.

Monthly Active Institution Ratio of Medical Institutions and Man-Days of HIE Use for Each User Type

We compared the monthly active institution ratios at medical institutions for each HIE and the proportion of man-days of HIE use by user type. Equation 2 defines the monthly active institution ratio. “Medical institutions” include the facility types “hospital,” “medical clinic,” and “dental clinic.” We analyzed all HIEs during all periods for which data could be obtained.

The total number of medical institutions participating in each HIE on the last day of each month was calculated. Next, for each HIE in each month, each medical institution of each HIE was flagged as to whether it used the HIE. If at least one account from within the institution used the HIE for at least one day in a month, the institution was deemed to have used HIE that month. Subsequently, for each HIE in each month, we calculated the sum of the institutions that used it. We then calculated the active institution ratio of medical institutions for each HIE for each month, according to Equation 2.

Next, we classified all user occupation data into 8 user types: “doctor,” “nurse,” “rehabilitation staff,” “pharmacist,” “dental profession,” “nursing care staff,” “other medical professions,” and “type unknown.” We aggregated the total number of man-days of HIE use by user type and calculated the proportion of man-days by user type.

Results

Data Collection

The MHLW report listed 218 HIEs. However, numbers 57-60 in the report are federated, and the aggregated statistics are shown as number 61. After removing these duplicates, there were 214 HIEs listed [9]. Of the 214 HIEs, 36 HIEs were connected to more than 100 institutions and 45 were connected with more than 10,000 patients. Overall, 21 HIEs met both inclusion criteria. Considering number 61 to be 4 HIEs, 24 HIEs were considered candidates for data collection.

Initially, we requested research cooperation from each RHIO administrator via email. The data request document is shown in Multimedia Appendix 2. Thereafter, we requested each RHIO to provide data through a web conference once we were able to have detailed discussions. We obtained research data from 8 HIEs. Although these tasks were sometimes performed free of charge, the extraction of access logs from 2 HIEs was performed for a fee. One of the 8 HIEs was unable to extract comprehensive audit log data of query-based exchange and was removed from the final analysis. The flow diagram is depicted in Figure 1. Among the 24 HIEs that met the inclusion criteria for this study, we calculated the average and standard deviation of the monthly active institution ratio based on the MHLW report separately for the HIEs that were included in the final analysis and those that were not. The results are shown in Table 1.

To avoid identification, all RHIOs and HIEs were assigned a pseudonym using letters from A to G. We obtained the audit log data from RHIO A, RHIO C, and RHIO E from April 2017 to March 2022. We obtained audit log data from April 2018 to March 2022 from RHIO B. From RHIO F and RHIO G, we obtained audit log data from April 2021 to March 2022. We obtained audit log data from October 2021 to March 2022 from RHIO D. HumanBridge [32] (developed by Fujitsu Limited) has an audit log extraction feature added by default. Therefore, audit log extraction in RHIOs that used HumanBridge was performed using this feature. The extraction of audit logs from HIEs other than HumanBridge was conducted by requesting the system vendor to extract audit logs from the RHIO secretariat.

Figure 1. Flow diagram of HIE selection. HIE: health information exchange. *HIE number 61 was considered to be 4 HIEs.

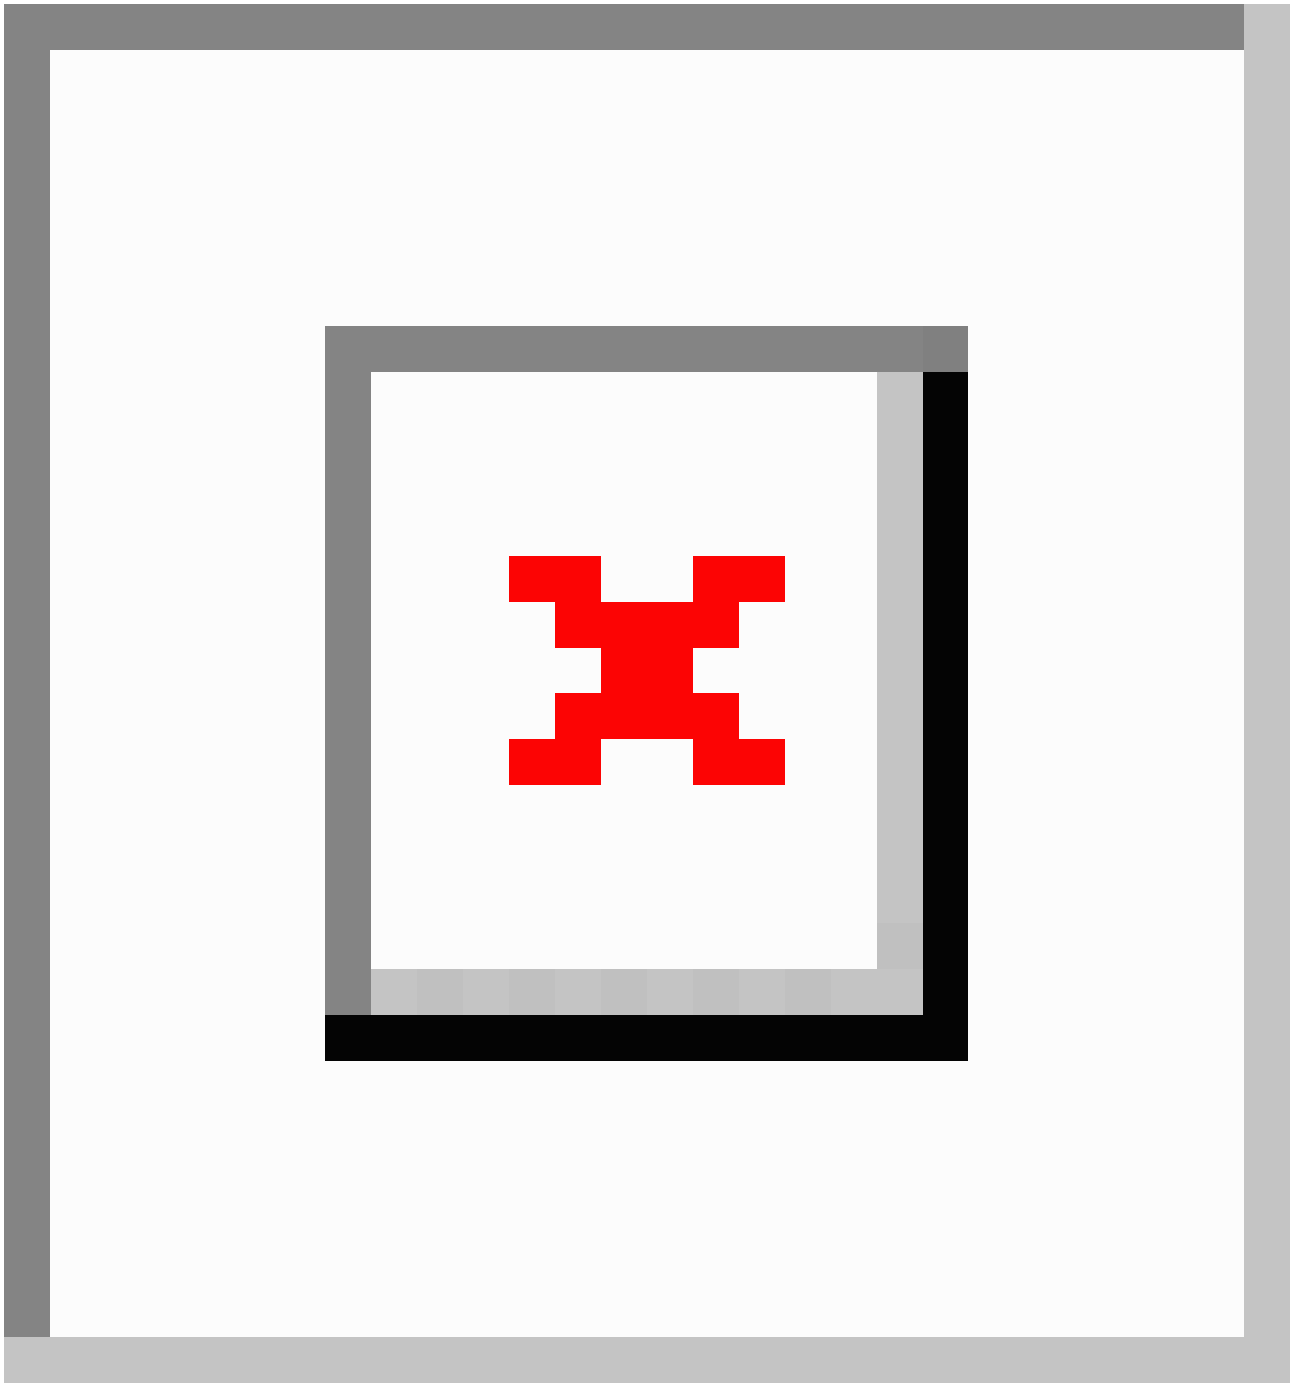

Table . Average monthly active institution ratio based on the MHLW[a] report.

	Health information exchange[b], n	Monthly active institution ratio based on the MHLW report (%)[c], mean (SD)
Included in the final analysis	7	46.1 (24.4)
Not included in the final analysis	17	46.4 (19.1)

[a]MHLW: Ministry of Health, Labour and Welfare.

[b]Among the health information exchanges listed in the MHLW report, those connected to more than 100 institutions and with more than 10,000 patients were included in this analysis.

[c]For each health information exchange, the MHLW report lists the number of participating medical institutions and the number of medical institutions that accessed health information exchange (ie, the number of institutions that used health information exchange during the month covered by the survey). We divided the number of medical institutions that accessed health information exchange by the number of participating medical institutions for each health information exchange and called this number “monthly active institution ratio based on the MHLW reports.”

Of the data items we attempted to obtain in advance (Textbox 1), the type of device used for access was not collected by any HIEs. Consequently, we could not analyze the type of device with which the HIE was accessed. We obtained users' date of account registration and account deletion in the HIE from only 3 RHIOs. For the remaining 4 HIEs, we could not determine the exact number of registrants in each period.

Characteristics of HIEs Included in the Final Analysis

All 7 HIEs began operations between 2010 and 2015. Of the 24 HIEs that met the inclusion criteria, 9 did not have membership fees, and of the 7 HIEs included in the final analysis, 3 did not have participation fees for connected institutions. Overall, 5 RHIOs adopted ID-Link for the HIEs they operate, 3 RHIOs adopted HumanBridge, and 2 RHIOs employ products other than these. The reason that the sum of these products is more than 7 is that some RHIOs operate multiple products in parallel.

For HIE A to G, the patient consent rates for HIE in 2022 were 21.2%, 5.6%, 69.5%, 1.9%, 2%, 4%, and 6.5%. Patient consent rate was obtained by dividing the number of patients connected with the HIE by the population of the area. All 6 HIEs except HIE C required patients to complete a paper consent form for their medical data to be viewed by health care workers using the HIE. HIE C uses paper consent forms as well as the "patient demographic data synchronization feature" provided by ID-Link. For institutions that disclose patient data to HIE C, basic patient profiles such as name, date of visit, and public insurance data are automatically accumulated in the HIE. This feature allows health care workers to use query-based exchange to obtain patient data in the event of emergency treatment, even if the patient cannot explicitly consent to the use of the HIE in advance. Patient enrollment in an HIE using this feature is opt-out, that is, individuals are considered to implicitly consent to participate in the HIE unless participation is explicitly declined. Therefore, the apparent consent rate of HIE C is extremely high.

Percentage of Days of HIE Use by Each Hospital Doctor in FY2021/22

A total of 3 HIEs met the criteria: HIE A, HIE B, and HIE C. The number of hospital doctor accounts registered in HIEs operated by these 3 HIEs in FY2021/22 was 7833. For each of these doctor accounts, we calculated the percentage of days of HIE use according to Equation 1. The overall results are shown in Table 2.

Table . Percentage of days of HIE[a] use by doctors affiliated with the hospital.

Days of HIE use, %	Hospital doctors, n
0	7326
>0 and ≤5	412
>5 and ≤10	39
>10 and ≤15	11
>15 and ≤20	17
>20 and ≤25	5
>25 and ≤30	4
>30 and ≤35	5
>35 and ≤40	5
>40 and ≤45	1
>45 and ≤50	1
>50	7

[a]HIE: health information exchange.

Man-Days for Monthly HIE Use by Each Institution in FY2021/22

Different HIEs met the criteria for each facility type as shown in Table S2 in Multimedia Appendix 1. The cumulative number of months of hospital participation in HIEs in FY2021/22 was 3434. The distribution of man-days for monthly HIE use by hospitals is shown in Table 3. Table 4 shows the analysis results for facility types other than hospitals. The number of institutions connected to the HIEs included in the analysis for each month in FY2021/22 is shown in Table S3 in Multimedia Appendix 1.

Table . Distribution of man-days for monthly HIE[a] use for hospitals.

Man-days for monthly HIE use	Cumulative number of months, n
0	1781
1-10	921
11-20	287
21 - 30	129
31 - 40	67
41 - 50	59
51 - 60	28
61 - 70	14
71 - 80	11
81 - 90	21
91 - 100	13
≥101	103

[a]HIE: health information exchange.

Table . Distribution of man-days for monthly HIE[a] use by medical care institutions other than hospitals.

Man-days for monthly HIE use per institution	Months per institution, n (%)				
	Medical clinic (7791 months)	Dental clinic (1006 months)	Pharmacy (5140 months)	Visiting nursing station (983 months)	Nursing facility (3629 months)

[a]HIE: health information exchange.

Monthly Active Institution Ratio in FY2021/22

Table S2 in Multimedia Appendix 1 lists the HIEs that met the criteria in this section. The median (IQR) monthly active institution ratios were 0.482 (0.470 - 0.487) in hospitals, 0.244 (0.231 - 0.247) in medical clinics, 0.030 (0.024 - 0.048) in dental clinics, 0.202 (0.188 - 0.216) in pharmacies, 0.307 (0.301 - 0.325) at visiting nursing stations, and 0.197 (0.185 - 0.204) in nursing facilities. We illustrated the monthly active institution ratios using box plots in Figure 2.

Table 5 shows the monthly active hospital rate for each category subdivided by the number of hospital beds. HIE F data could not be combined with hospital bed data and was therefore excluded from the analysis.

Figure 2. Monthly active institution ratio of health information exchange categorized by facility type.

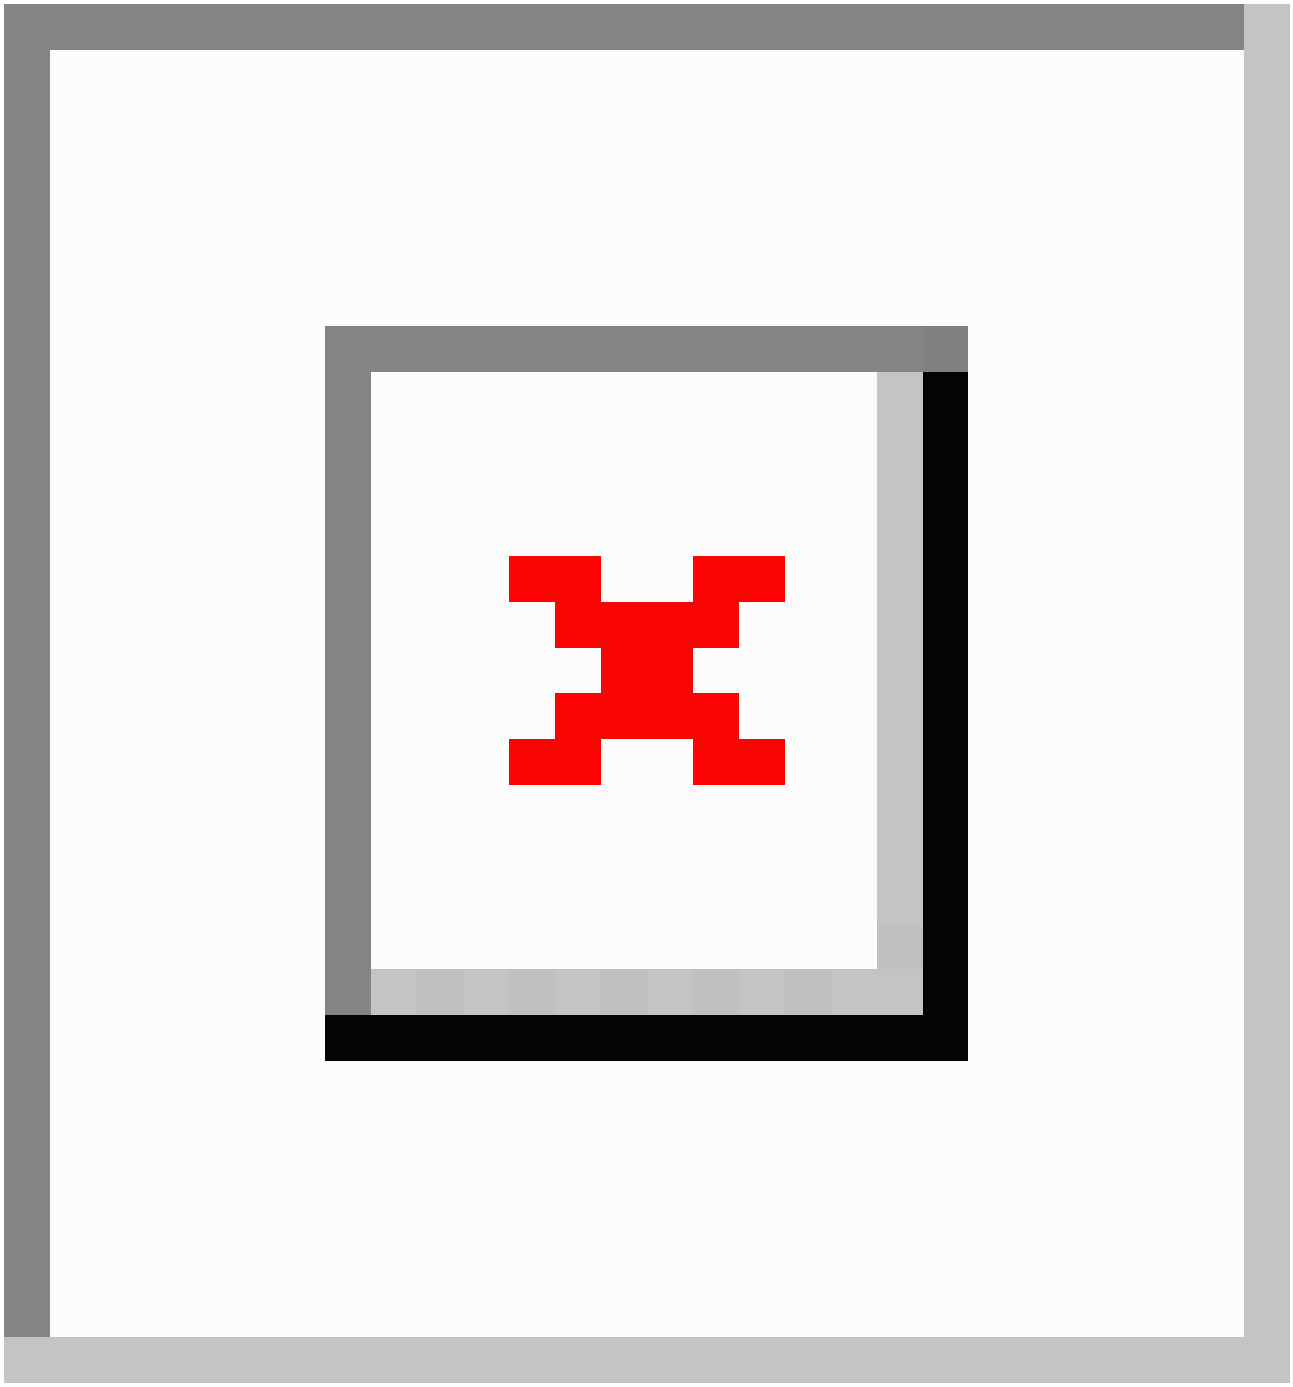

Table . Monthly active hospital ratio subcategorized by the number of hospital beds per institution.

Hospital beds, n	Monthly active institution ratio (%), median (IQR)
≤99	34.2 (30.9 - 39.5)
100 - 199	65.2 (65.2 - 69.6)
≥200	75.0 (72.9 - 77.1)

Monthly Active Institution Ratio of Medical Institutions and Man-Days of HIE Use for Each User Type

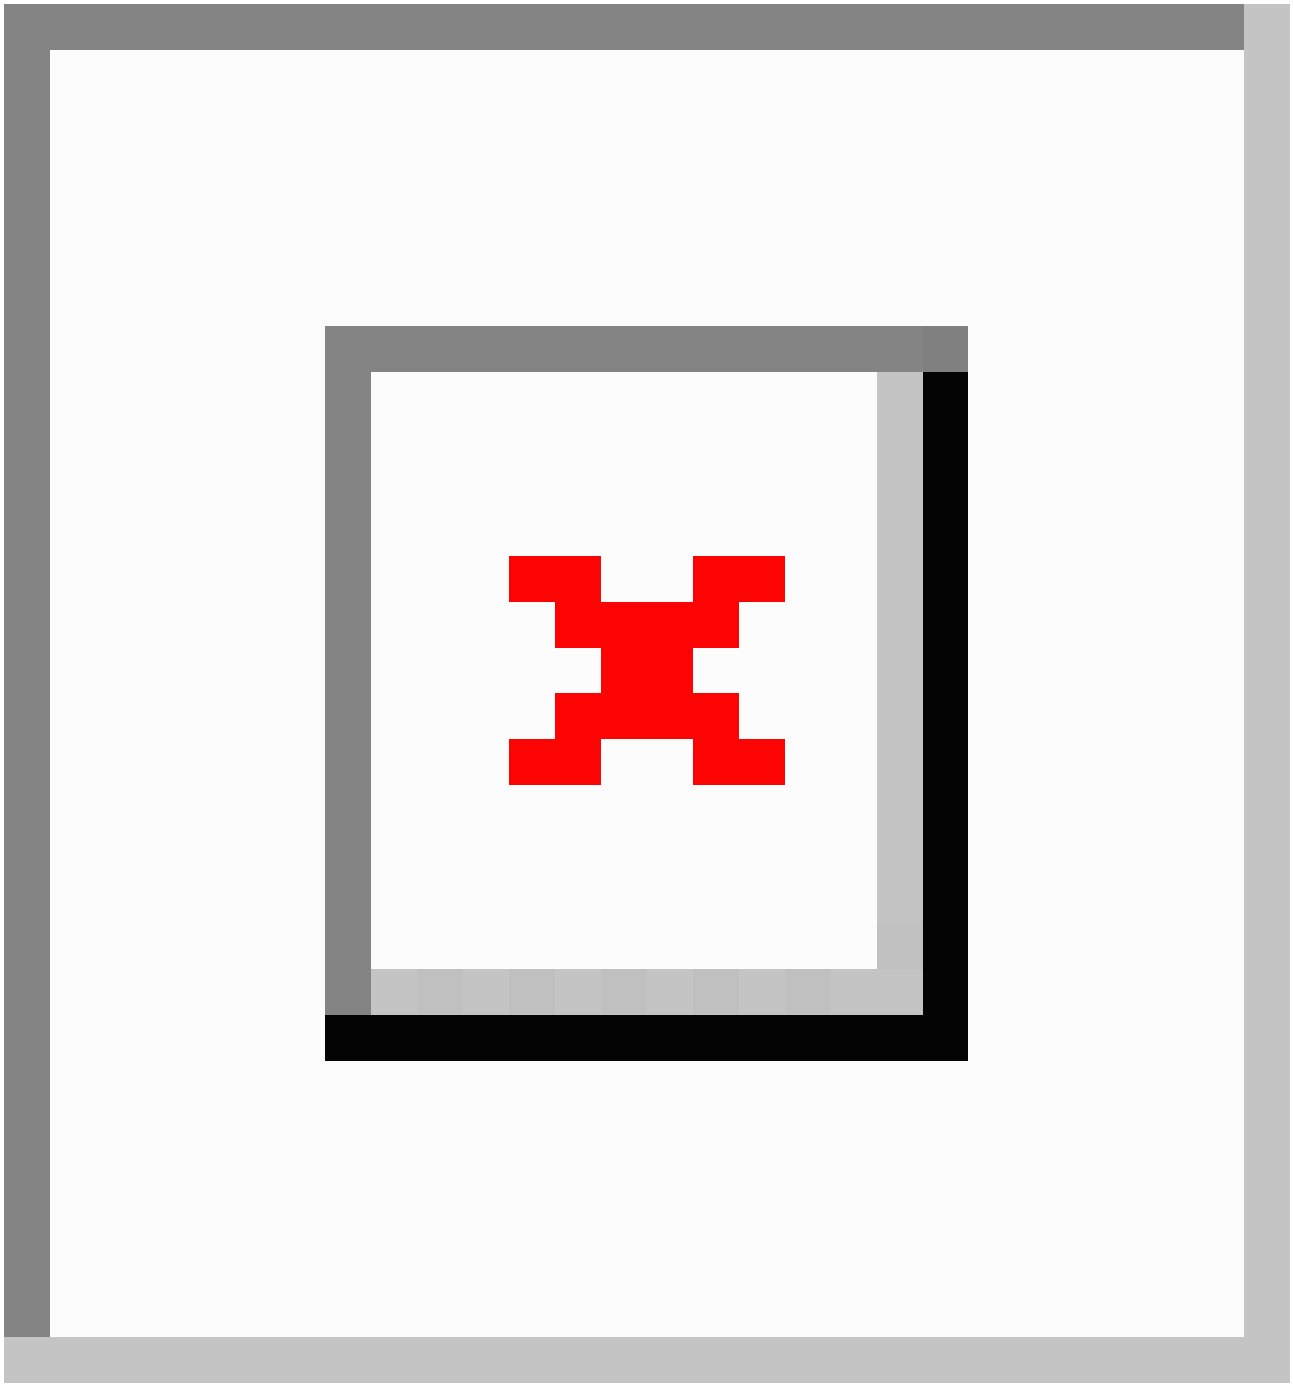
We analyzed all 7 HIEs. As the period of audit log data obtained differs for each HIE, the analysis period also differs. A total of 5 HIEs included all types of medical institutions; however, no dental clinics participated in HIE D and HIE E. Regarding user type data, precise data were not available for HIE D. Occupational data for HIE F could only be obtained for "doctors" and "other medical professions."

Some HIEs have restrictions on the types of users that can use the HIE. In 2 HIEs, users affiliated with medical clinics could only use the HIEs if they were doctors. In one HIE, users who were affiliated with hospitals that did not disclose patient data to the HIE could only use the HIE if they were doctors. In addition, 6 HIEs had no restrictions on the type of data that authorized health care workers could view. One HIE was set up so that people other than doctors affiliated with the hospital could not view outpatient treatment data.

We illustrated the monthly active institution ratio of HIE and the proportion of man-days of HIE use by user type in medical institutions using box plots and bar graphs (Figure 3).

Monthly active institution ratios of HIE in medical institutions are also shown in Table S4 in Multimedia Appendix 1. The proportions of man-days of HIE use by user type in medical institutions are also shown in Table S5 in Multimedia Appendix 1.

Figure 3. (A) Monthly active institution ratio and (B) proportion of man-days of HIE use by user type for each HIE. HIE: health information exchange.



Discussion

Overview of HIE Use

As already mentioned, the low utilization of large-scale HIEs has previously been suggested by MHLW reports (Table S1 in Multimedia Appendix 1). Our analysis included data from only 18% (7/32) of such HIEs. However, among HIEs that met the inclusion criteria, monthly active institution ratios based on the MHLW report were similar for HIEs included in the final analysis and those not included (Table 1). This suggests that the results of this study apply to some extent to large-scale HIEs in general. However, HIEs with fewer participating institutions have a higher monthly active institution ratio based on the MHLW report than large-scale HIEs (Table S1 in Multimedia Appendix 1). Therefore, it is possible that small-scale HIEs are used more actively than the results of this study suggest. However, the MHLW report includes 13 HIEs where the number of participating medical institutions is 1 or 2, and the number of participating institutions is equal to the number of institutions that have accessed HIEs. The active institution ratio based on the MHLW report should be interpreted with caution because extremely small-scale HIEs are driving up the ratio.

Across the large-scale HIEs analyzed in this study, many health care workers and institutions did not use query-based exchange. These results are consistent with MHLW reports (Table S1 in Multimedia Appendix 1). We found that 93.5% (7326/7833) of the doctors at hospitals registered with HIEs do not use them even once per year (Table 2). In addition, 51.9% (1781/3434) of hospitals did not use query-based exchange even once per month (Table 3). This is lower than the values reported by previous studies conducted in other countries [20,33]. The monthly active institution ratio is higher for hospitals with more beds. The median (IQR) monthly active institution ratio for hospitals with ≤99 beds is 34.2% (30.9%-39.5%), but it is 75% (72.9%-77.1%) for hospitals with ≥200 beds (Table 5). Among facilities other than hospitals, the monthly active institution ratio is even lower than for hospitals with ≤99 beds. The median (IQR) monthly active institution ratio for visiting nursing stations reached 30.7% (30.1% - 32.5%), but it was only approximately 20% for medical clinics, pharmacies, and nursing care facilities (Figure 2). As for dental clinics, the median (IQR) monthly active institution ratio was only 3% (2.4%-4.8%). Previous studies outside Japan have also revealed that HIEs are not often used by dental practices [34]. This is the first study to reveal the active institution ratio of HIE by facility type in Japan.

Where query-based exchange was used, most people and institutions only used it for a limited number of days. Previous reports have not provided user-level analysis; therefore, this study is the first to reveal the total number of days of HIE use by health care workers and institutions. Of the 507 hospital-affiliated doctor accounts that actively used query-based exchange in FY2021/22, we found that 81.3% (412/507) used it for 5% or fewer days (Table 2). In other words, assuming the average doctor works 20 days per month, most of these doctors use query-based exchange less than once per month. As the percentage of days of HIE use increases, the number of corresponding hospital doctor accounts tends to decrease. This trend is reflected in man-days for monthly HIE use of hospitals. We found that 90.8% (3118/3434) of all hospitals use HIE for 30 or fewer man-days per month (Table 3). In these hospitals, query-based exchange is used by less than one user daily. The number of man-days of HIE use in hospitals also shows a tendency for the number of applicable months to decrease as the number of man-days increases. This trend remains true for man-days for monthly HIE use at facilities other than hospitals (Table 4). However, some institutions and users use query-based exchange for many days. Of the hospital-affiliated physician accounts, 19 users used query-based exchange for 30% or more days. Of the cumulative months of hospital participation in HIEs in FY2021/22, we found that 3% (103/3434) had over 101 man-days for HIE use (Table 3). This exceeds the number of months when man-days of monthly HIE use are in the range of 91-100. For visiting nursing stations and nursing care facilities, the number of months in which the number of man-days for HIE use exceeds 26 is greater than the number of months in which the number of man-days is 21-25 (Table 4), showing there are significant disparities in HIE use across institutions and users.

Monthly active institution ratios for medical institutions vary widely by HIE. HIE A, which has the highest monthly active institution ratio, has a median rate of 50.9% (IQR 48.7%-52.9%), but some HIEs have a rate of over 10% (Figure 3, Table S4 in Multimedia Appendix 1). The proportion of man-days of HIE use by each user type is not constant for each HIE. However, regarding the HIEs that could be confirmed, the number of man-days of HIE use was low for dental professionals, pharmacists, and rehabilitation workers.

Possible Factors Influencing HIE Use

Many other factors could have influenced monthly active institution ratios and man-days of monthly HIE use, for example, the system used and whether there are membership fees and usage restrictions based on use type. The data viewed by health care professionals when using HIEs is also extremely important. None of these can be shown as individual HIE data due to privacy considerations; therefore, they cannot be discussed in relation to the results shown in Figure 3. This is a significant limitation of this study and indicates the need for further research into why there are such large disparities in demand for HIE in Japan.

Although a detailed elucidation must be reserved for future research, two factors may have influenced the monthly active institution ratio of facilities in the HIEs in our analysis. One is the consent rate of patients to participate in HIEs. HIE A, which had the highest monthly active institution ratio among medical institutions in this analysis, had a relatively high patient consent rate of over 21%. HIE C, which had the second highest monthly active institution ratio, has a partial opt-out policy and a very high consent rate. However, HIEs G, D, and B, where the monthly active institution ratio was 20% or less, had patient consent rates of 7% or less. The patient consent rate in HIEs E and F, where the monthly active institution ratio was in the 20% range, was less than 5%, and therefore lower than in G and B. High consent rates may have contributed to the high active

institution ratios for HIEs A and C, but this study cannot determine whether these factors are causally related.

Another factor that may have influenced the monthly active institution ratio is the number of staff at each participating institution. As already shown, the active institution ratio was higher in hospitals with ≤99 beds than in medical clinics, and it was higher in hospitals with ≥200 beds than in hospitals with ≤99 beds. It is natural to assume that this difference is caused by the absolute number of staff working at each institution. Therefore, when considering the active institution ratio for a given HIE, the value is likely to be high if a large proportion of the institutions participating in the HIE are large hospitals.

Audit Log for Further Research Analysis

To analyze HIE use in detail, proper design of the audit log is extremely important. When analyzing the audit logs in this study, two characteristics of some audit logs posed obstacles. One was that the extracted audit logs are not comprehensive. In HIEs that were configured using products from multiple vendors [35], each product generally had its own unique audit log design and storage. To perform detailed analysis of the usage of such HIEs, it was necessary to extract the logs from each product. This was difficult when each product was controlled by a different institution; specifically, the HIE platform system is managed by the RHIO, but the EMR data viewing system may be managed by each hospital. In this case, we need to obtain consent for research collaboration from each institution to perform overall log extraction. If user access to individual systems via the platform system is recorded in the audit log, analyzing the general usage status may be possible by extracting only the platform system's audit log. However, in practice, access to individual systems is not necessarily recorded in the platform system's audit log. In HIEs configured using products from multiple vendors, careful attention must be paid to facilitating comprehensive log extraction.

The second obstacle was the incompatibility of the institution IDs and user IDs used in HIEs. To clarify the factors that create the disparities in HIE usage across users and across institutions, more detailed data on users and medical institutions were required, such as medical specialty and whether institutions provide acute or chronic care. However, such data are not generally included in the audit log itself; therefore, log data needs to be cross-referenced with institution IDs compiled in the master dataset by the government or the detailed user data of each institution. As the institution IDs used in the audit log data extracted in this study did not necessarily correspond to the institution IDs assigned by the MHLW, it was difficult to cross-reference log data with other datasets. To investigate HIE usage in greater depth than this study, it is recommended to use master data that can be matched with EMR and official datasets when designing audit logs.

Limitations

This study had several limitations. The most significant limitation was the need to maintain the anonymity of the HIEs included in the analysis. Therefore, important data, such as the systems employed by individual HIEs and the types of medical data disclosed, were either kept private or disclosed anonymously. Consequently, it was almost impossible to analyze the causes of differences in active institution ratios for individual HIEs from the data. We also attempted to evaluate the viewing situation for all data types, such as images and prescriptions. However, it was difficult to perform a comprehensive analysis because the data storage format was not standardized for each HIE. The list of HIEs included in the analysis differed for each analysis because the data items that could be obtained differed for each HIE. Data regarding the type of device used to access the HIE could not be obtained from any HIE.

Some HIEs have features other than viewing patient medical data, such as sending and receiving documents or messages [8]. Previous reports indicated that some HIEs actively used these additional features when treating COVID-19 patients [27]. As this study focused on query-based exchange, we did not perform a quantitative analysis of the usage of other features. Another study is required on the actual usage of features other than query-based exchange.

This study revealed that most users do not use query-based exchange or use it infrequently, but it is impossible to prove whether this is due to a lack of patients' medical data in the HIE repository or a lack of need to view data. As mentioned above, HIEs vary widely in both patient consent rates and the types of data that health care professionals can view. Therefore, it is difficult to provide a single answer to this remaining question. To answer this question, a deeper investigation of each HIE is required, using more detailed audit log analysis, system descriptions, and qualitative research.

Conclusions

In the large-scale HIEs surveyed in this study, the overall usage of the on-demand patient data viewing feature was low, consistent with past MHLW reports. User-level analysis of audit logs revealed large disparities in the number of days of HIE use among health care workers and institutions. There were also large disparities in HIE use by facility type or HIE, and the percentage of cumulative HIE usage days by user type also differed by HIE. This study indicates the need for further research into why there are large disparities in demand for HIEs in Japan, as well as the need to design comprehensive audit logs that can be matched with other official datasets.

Abstract

Background: Reaching meaningful interoperability between proprietary health care systems is a ubiquitous task in medical informatics, where communication servers are traditionally used for referring and transforming data from the source to target systems. The Mirth Connect Server, an open-source communication server, offers, in addition to the exchange functionality, functions for simultaneous manipulation of data. The standard Fast Healthcare Interoperability Resources (FHIR) has recently become increasingly prevalent in national health care systems. FHIR specifies its own standardized mechanisms for transforming data structures using StructureMaps and the FHIR mapping language (FML).

Objective: In this study, a generic approach is developed, which allows for the application of declarative mapping rules defined using FML in an exchangeable manner. A transformation engine is required to execute the mapping rules.

Methods: FHIR natively defines resources to support the conversion of instance data, such as an FHIR StructureMap. This resource encodes all information required to transform data from a source system to a target system. In our approach, this information is defined in an implementation-independent manner using FML. Once the mapping has been defined, executable Mirth channels are automatically generated from the resources containing the mapping in JavaScript format. These channels can then be deployed to the Mirth Connect Server.

Results: The resulting tool is called FML2Mirth, a Java-based transformer that derives Mirth channels from detailed declarative mapping rules based on the underlying StructureMaps. Implementation of the *translate* functionality is provided by the integration of a terminology server, and to achieve conformity with existing profiles, validation via the FHIR validator is built in. The system was evaluated for its practical use by transforming Labordatenträger version 2 (LDTv.2) laboratory results into Medical Information Object (*Medizinisches Informationsobjekt*) laboratory reports in accordance with the National Association of Statutory Health Insurance Physicians' specifications and into the HL7 (Health Level Seven) Europe Laboratory Report. The system could generate complex structures, but LDTv.2 lacks some information to fully comply with the specification.

Conclusions: The tool for the auto-generation of Mirth channels was successfully presented. Our tests reveal the feasibility of using the complex structures of the mapping language in combination with a terminology server to transform instance data. Although the Mirth Server and the FHIR are well established in medical informatics, the combination offers space for more research, especially with regard to FML. Simultaneously, it can be stated that the mapping language still has implementation-related shortcomings that can be compensated by Mirth Connect as a base technology.

Introduction

Digitalization is progressively transforming health care systems, and its rapid pace is creating new clinical data sources that need to be integrated. This is of enormous importance for patient care, as data integration and the fusion of all sources allow a comprehensive, holistic overview and ensure the best treatment possible. However, the lack of interoperability of health care systems is a significant, long-lasting problem [1]. Nonetheless, interoperability is required to ensure seamless and effortless access to essential health care information. Existing medical data are presented in a multitude of proprietary formats and in line with different standards [2]. Therefore, it is inevitable to transform data into a harmonized structure to enable collective use. Current national and international initiatives are integrating large volumes of data in clinical environments to enable their use [3-5]. The established data integration is close to the origin of the data, which is highly desirable since late mapping harbors disadvantages and issues can be addressed accordingly [6].

Aligning the multitude of standards and thus making data usable is a major task. The mapping from source to target data structures is mainly defined by data stewards and is followed by a qualitive evaluation involving medical professionals. The involvement of these key professional groups is much easier if concise, declarative mapping rules are used instead of less comprehensible program instructions in various scripting languages. Basically, the creation of mapping rules is time-consuming and demands a significant number of resources. It occurs at every site involved, which commits a substantial additional number of stewards and medical professionals across the entire health care system [6,7]. Furthermore, sharing and reusing of declarative mapping rules in a standardized and adaptable manner is highly desirable and can release the needed resources and accelerate data enabling. Hence, this study aims to provide a software solution called "FML2Mirth," which is based on the separation of declarative mapping rules from a transformation pipeline leveraging the functionalities of Mirth.

Methods

The transformation of health care–related information needs two major components to enable generalization: a highly adaptable exchange format and a modular transformation engine. Our approach is based on the HL7 (Health Level Seven) Fast Healthcare Interoperability Resources (FHIR) standard and the Mirth communication server.

Ethical Considerations

No ethics committee approval was required for this study, as the data used comprised 20 anonymized laboratory data carriers (LDT) that were provided by the laboratory company LADR Laboratory Group as part of its quality control and represent a complete blood count. According to institutional and local policies, ethics approval is not necessary for studies using anonymized laboratory testing data, and this poses no risk to individual participants.

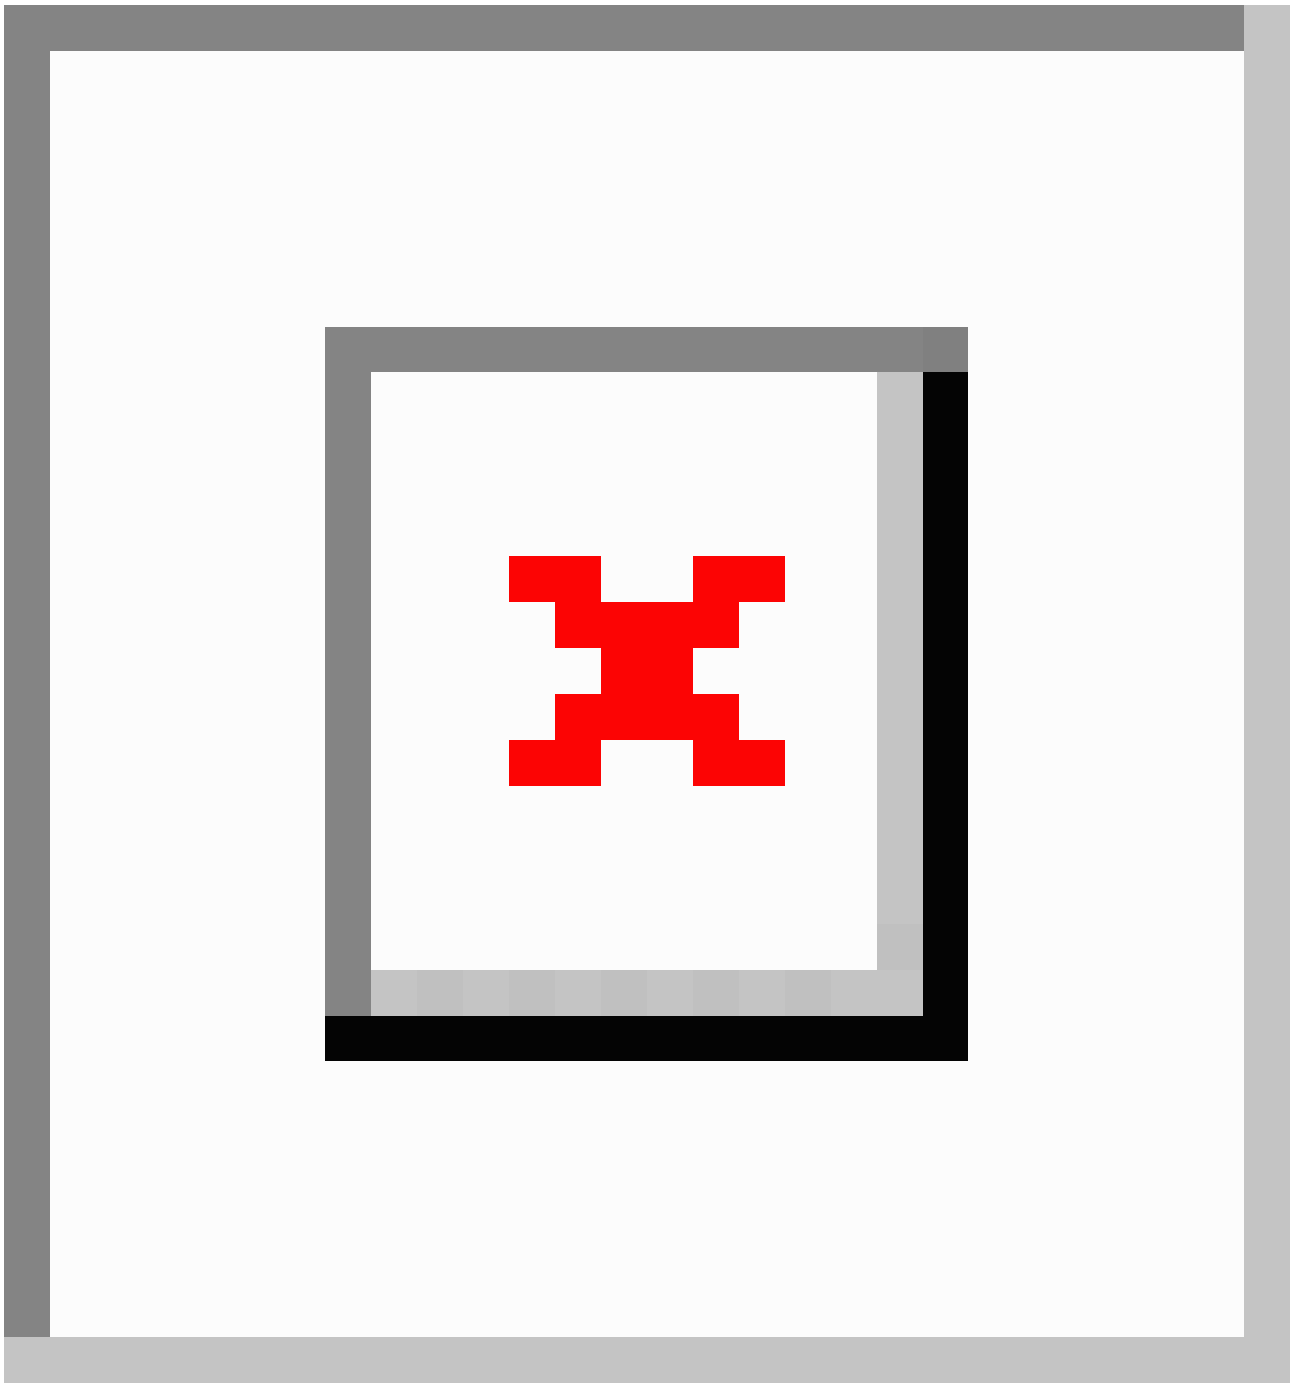
HL7 FHIR and the FHIR Mapping Language

HL7 FHIR is the emerging standard for health care–specific data exchange and has been broadly adapted worldwide [8]. FHIR provides state-of-the-art technologies to modernize the current health care landscape using extensible resources as harmonized and semantically annotatable information units [9]. However, FHIR also provides mechanisms to natively define transformations on its structures. The essential FHIR resource for automated conversion of instance data is the StructureMap, which defines a mapping from a source structure to a target structure [10] and provides all necessary information for an automatic transformation. To aid the definition of StructureMap resources, FHIR has specified a domain-specific, declarative language, the FHIR mapping language (FML) [11], which was introduced as part of FHIR release 3. By specifying the mappings in an implementation-independent manner, the mapping between structures can be easily shared within the medical informatics community.

One major benefit is the use of generic data structures as input formats, since FML can define mappings on non-FHIR structures. Consequently, FML can also be used to map older health care–related formats such as HL7 (version 2) or LDT to FHIR.

The declarative syntax of FML enables users to define mappings concisely. The mapping itself is structured in so-called *groups* within the mapping, being formalized by mapping rules. These rules consist of two parts separated by an arrow. On the left side of the arrow is the source part. Here, fields of source structures can be accessed, and the values can be written in variables. On the right side, the fields of a target structure can be accessed and built-in transformation functions can be invoked (see Figure 1). Those provided functions cover a broad functionality, ranging from a simple *copy* to a *translate* function to resolve given concept codes using an external FHIR ConceptMap.

Figure 1. The code illustrates a snippet of the FHIR (Fast Healthcare Interoperability Resources) mapping language, showing how a conventional laboratory test in Labordatenträger format can be mapped to an FHIR observation resource. The mapping is structured in groups, containing specific rules.



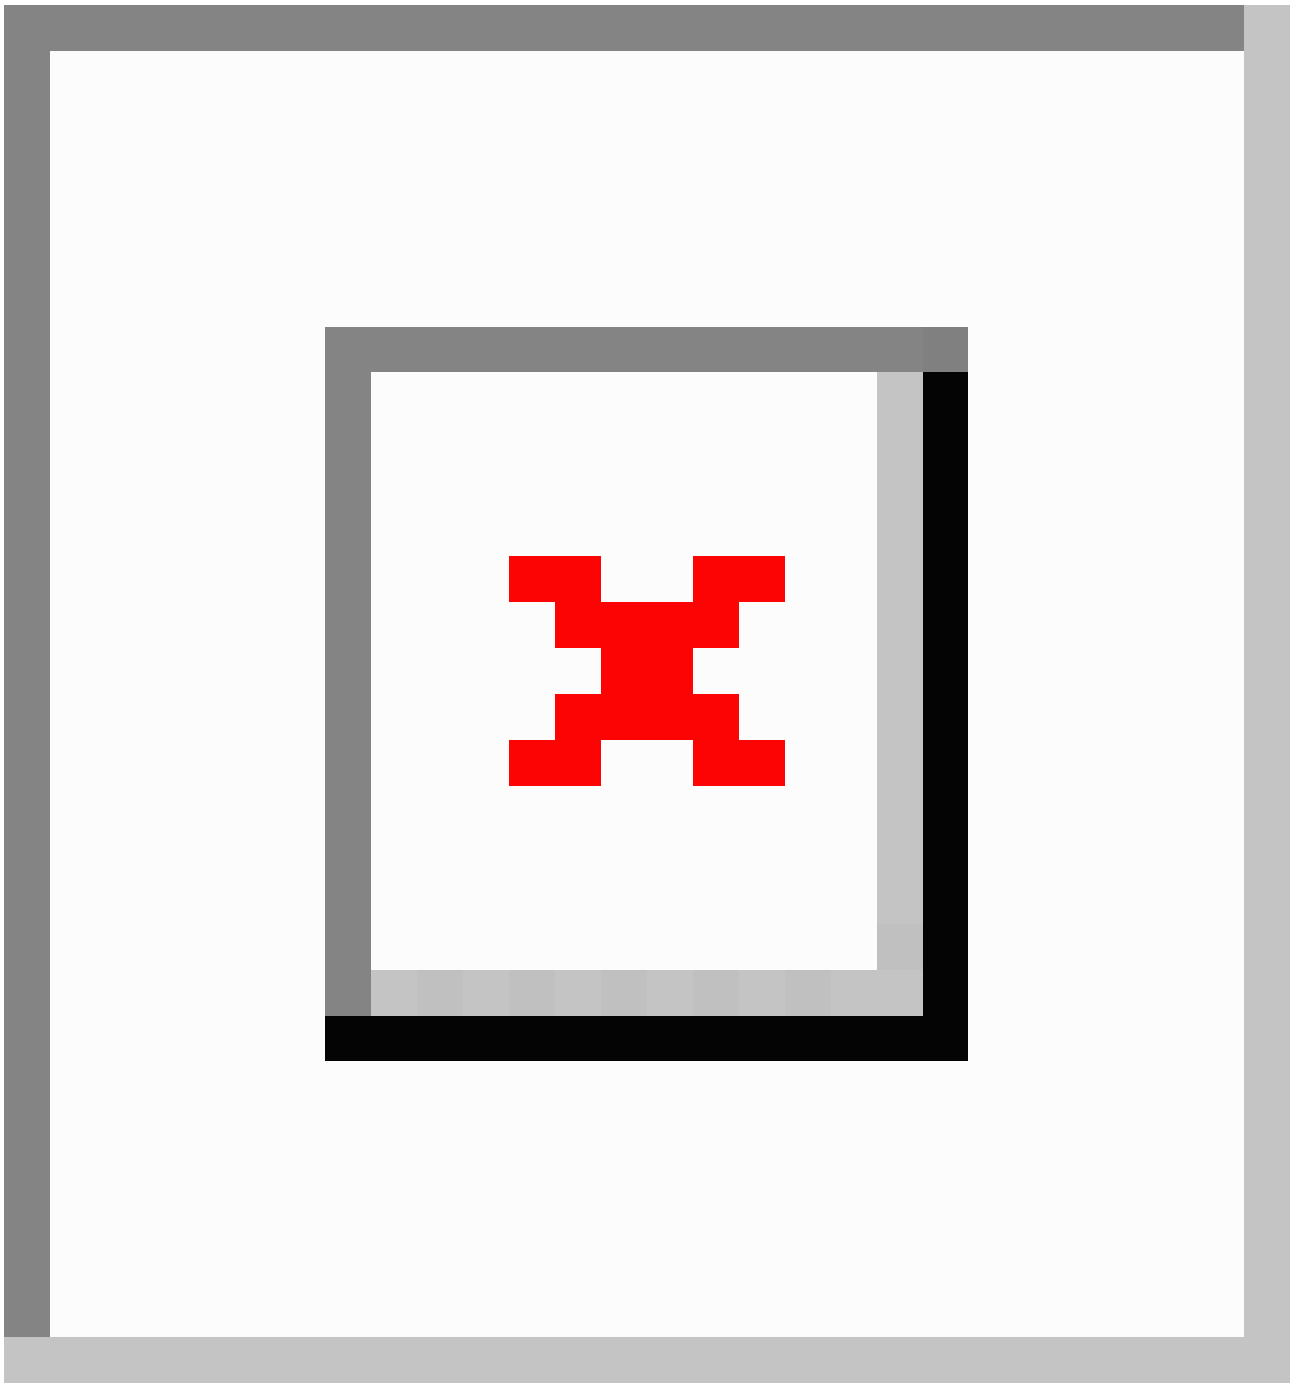
Mirth Connect Communication Server

Mirth Connect is an open-source communication server designed specifically for the health care sector. It features support for domain-specific formats, such as HL7 (version 2), as well as more general formats such as XML and JSON. Mirth is widely used as a communication server and is applied in various areas for data integration [12,13]. As a communication server, Mirth receives messages from one system and forwards them to downstream systems. Mirth introduces the concept of *channels* to establish a connection from a source system to various target systems. Within the channels, rule-based transformers can be defined to enable message manipulation. The received message can be automatically modified in terms of content or structure. The transformer rules are implemented as JavaScript code snippets, which Mirth applies to the messages. The channels including its transformers are serialized as XML files and can easily be shared and redeployed at other sites.

Architecture for Generic Data Transformation

The two-fold process shown in Figure 2 enables light and adaptable data transformation: the first step is transformation design and the second one is staging.

Figure 2. Conceptual overview of the 2-step process. In the first phase, the mapping is formalized as an FHIR (Fast Healthcare Interoperability Resources) mapping language script and corresponding semantic CodeSystems are aligned with each other in a ConceptMap. In the second phase, prior defined rules are used to deploy the mapping to Mirth. If semantic translation is needed, the ConceptMaps can be queried during run time.



During the transformation design phase, the source and target systems are selected, and the mapping is declared in FML. The mapping needs to be created manually by a data steward. This process can be supported by previously proposed algorithms and tools [14]. In addition, semantic concepts and codes can be mapped from source to target based on prepared mapping relationships provided by the FHIR ConceptMap resource, if necessary. It is recommended that this process is carried out by a health care professional to ensure data validity and integrity.

In the staging phase, the Mirth channel, which was built on the basis of prior mapping efforts, is injected in the productive communication server at run time. Mapping within the transformer uses the rules derived from FML for format manipulation, and dynamically translates the semantic codes using the ConceptMap.

Results

Overview

The proposed system implements the transition between the two process phases: transformation design and staging. This transition is achieved by the in Java-implemented generator FML2Mirth [15], which derives Mirth channels from a given mapping. There are two types of files used in the process, which

need to be created upfront. The first type is ConceptMaps used by a terminology server to provide a translation service for concepts that need to be translated during data transformation in the production phase. These ConceptMaps are referenced by the *translate* operations in the FML to specify how a given concept in the source structure should be mapped to a concept used in the target structure.

In the second file, the FML script, the mapping between source and target structure is defined. This script is then used as an input for FML2Mirth. As a first step, the FML script must be parsed, for which we use the official FHIR validator, since it provides functionality to generate a StructureMap from a given FML-Script. An additional advantage of this approach is, that by using a standard tool, it is guaranteed that the produced artifact is a standard-compliant StructureMap. Using these files as the input, FML2Mirth should also be compatible with every other StructureMap that adheres to the standard.

Besides the FML script, FHIR2Mirth needs the API (application programming interface) address of the Mirth server to which the generated channel should be deployed, as well as the address of the terminology server that is queried for the translation service during a transformation in the production phase. The tool then parses the StructureMap and generates the JavaScript code needed for every transformation specified. Once the generation is finished, the resulting code is embedded within a Mirth channel definition and deployed on the specified server via the Mirth REST-API. Subsequently, the incoming messages are automatically transformed into the desired structure. On encountering the FML *translate* function, Mirth queries the given terminology server to carry out translation between the different CodeSystems of the source and the target structure based on the previously created ConceptMaps. In our setting shown in Figure 3, an HAPI FHIR JPA server instance is used as an external terminology server, but any other FHIR terminology server implementation could be used instead. The transformed message is then forwarded to the defined target system, for example, an FHIR repository.

Evaluation of the transformation within Mirth is implemented using the JUnit testing framework. While JUnit is most commonly used for unit testing, it can also be used for end-to-end integration testing. The JUnit runner loads LDT laboratory messages from files and sends them to the Mirth server via the REST API. The destination connector of the test channel is a JavaScript connector that returns the transformed message as a response to the requesting system. The JUnit runner then receives the transformed message and uses HAPI FHIR to parse the incoming bundles as FHIR instances. Thus, the incoming resources are automatically tested for their conformity to the specification and validated against the corresponding profiles using the HAPI instance validator (Figure 4).

Figure 3. Conceptual overview of the proposed architecture for a generic data transformation process.

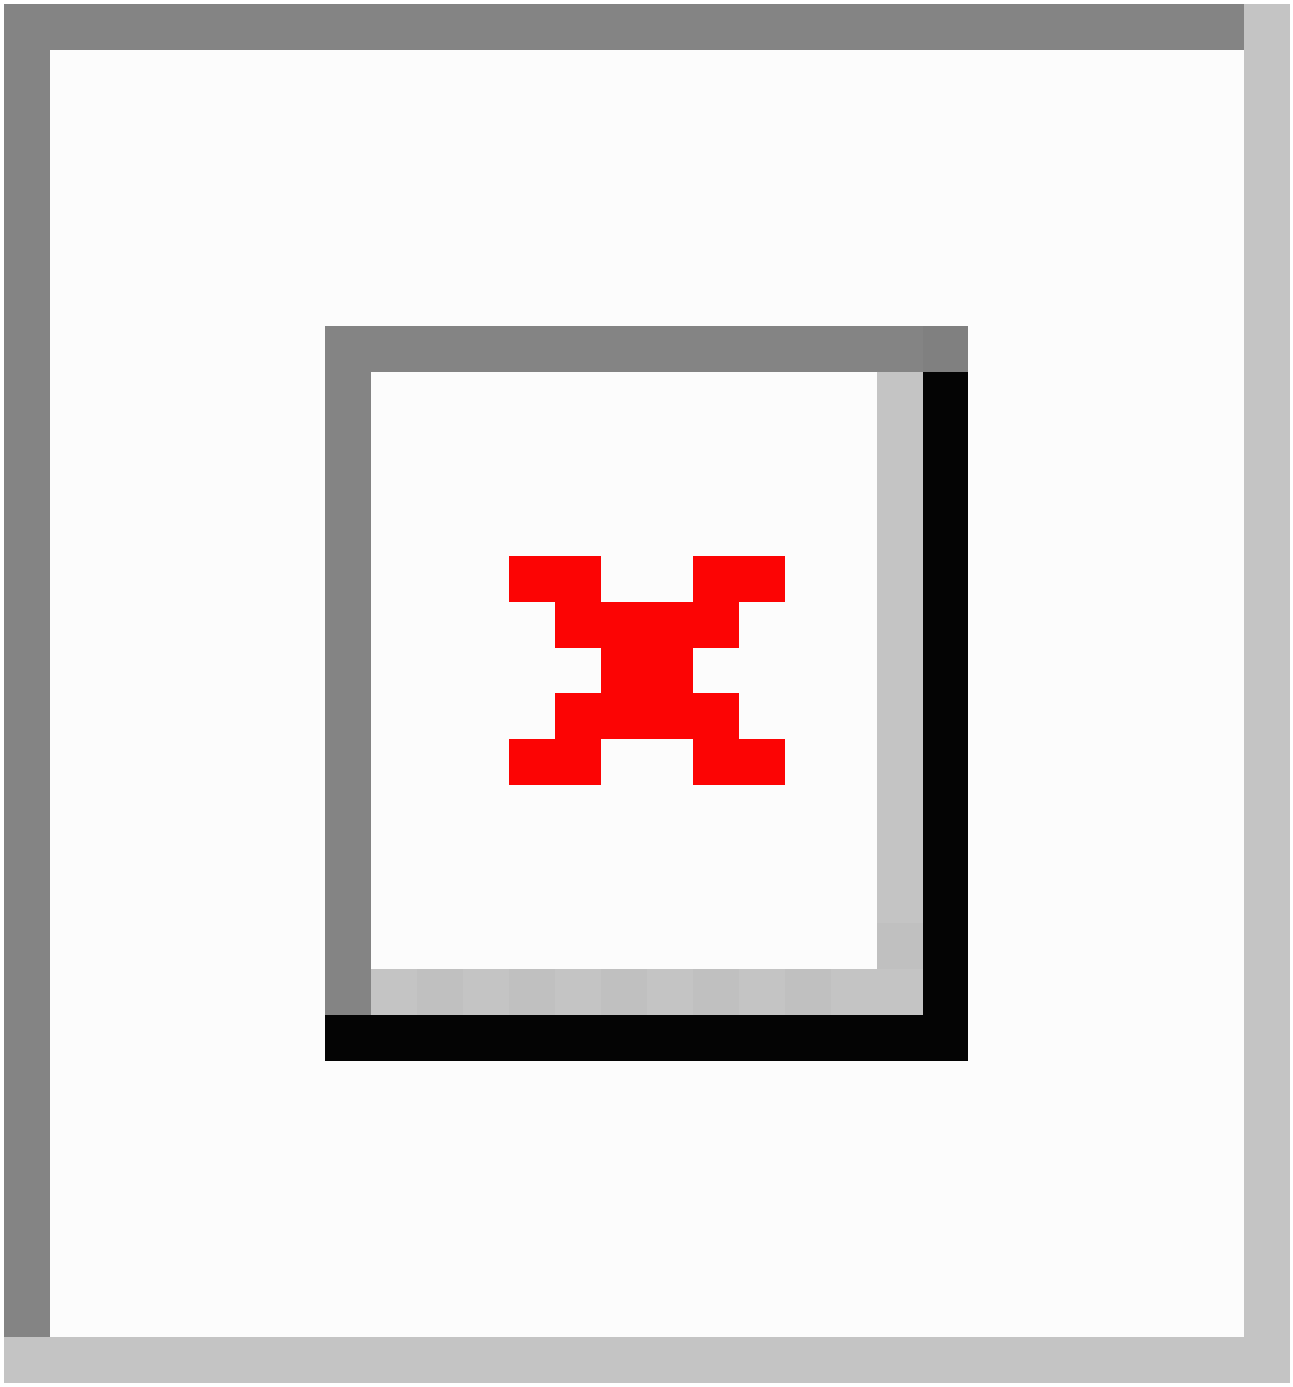


Figure 4. This example shows the different transformation steps, including the FHIR (Fast Healthcare Interoperability Resources) StructureMap and JavaScript result.

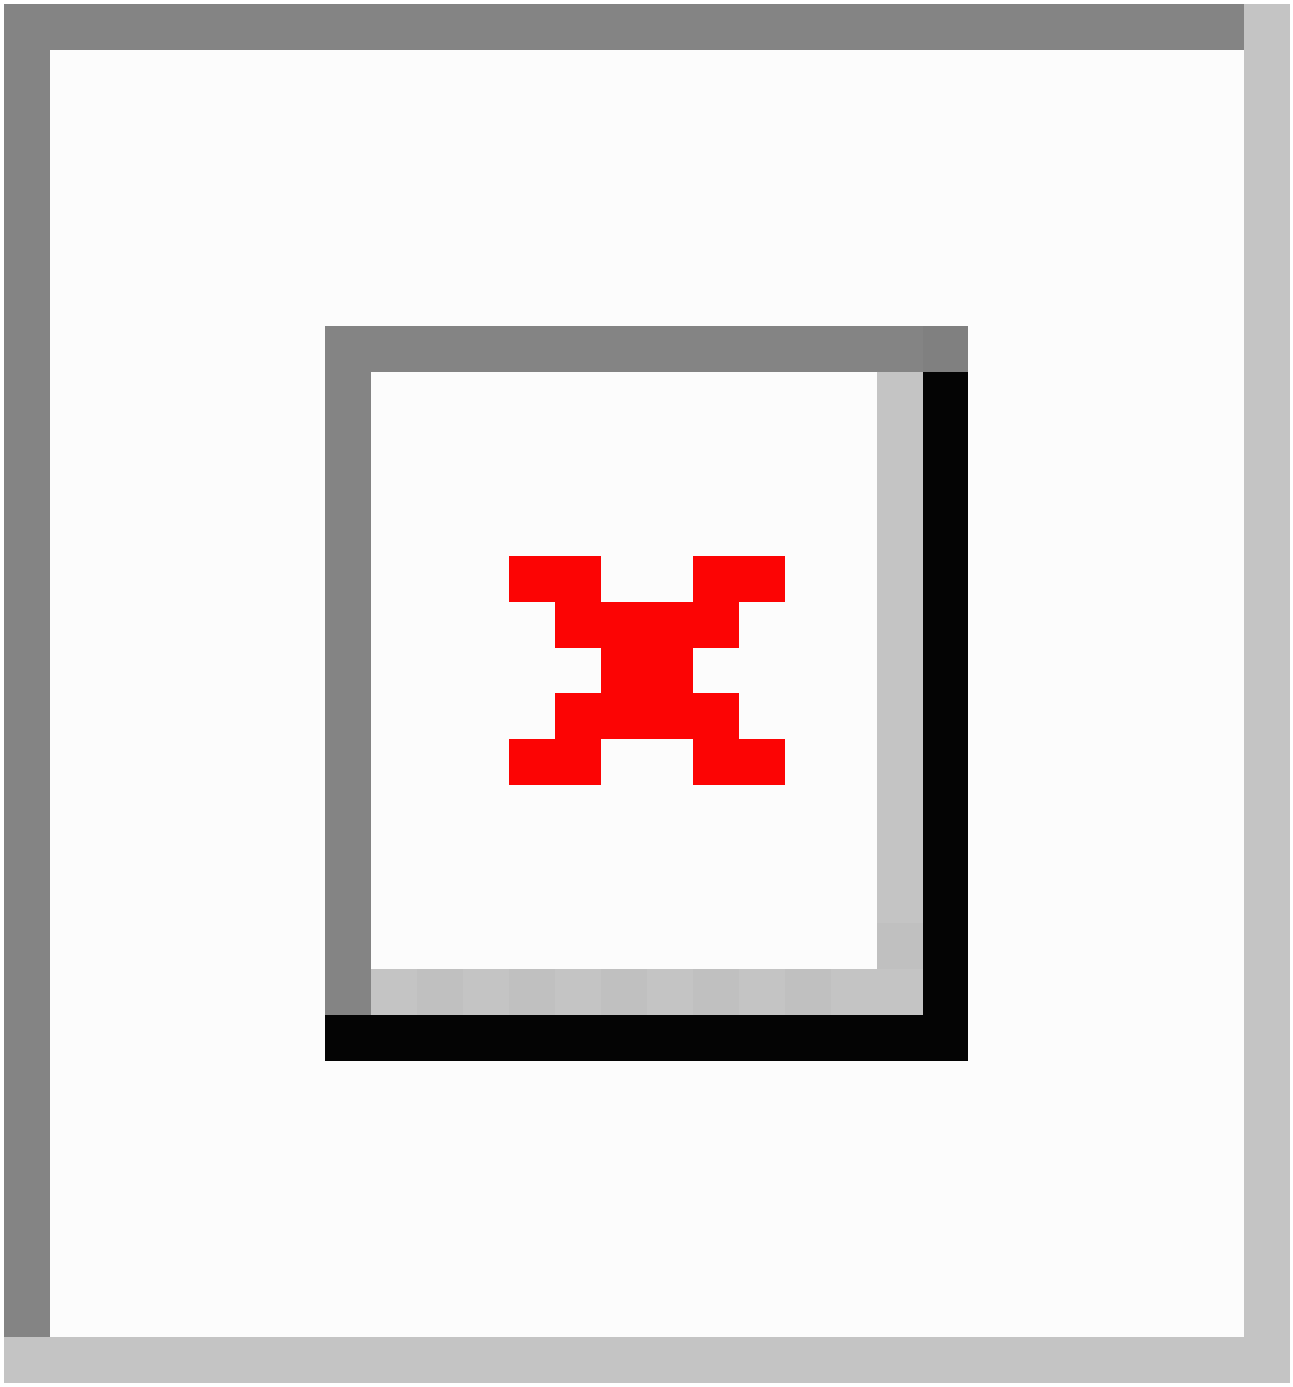

Evaluation

Assessment of our proposed transformation process is carried out in cooperation with the LADR laboratory network [16], an association of 19 specialist laboratories throughout Germany serving more than 400 clinics. As an evaluation scenario, laboratory findings standardized in the German LDT [17] format are transformed into FHIR. The LDT format is a perennial standard developed and published by the National Association of Statutory Health Insurance Physicians (NASHIP; German: Kassenärztliche Bundesvereinigung [KBV]) and is used daily for communicating up to 1 million messages in Germany. In our evaluation scenario, LADR provided 20 anonymized LDT laboratory messages representing complete blood counts in LDT (version 2) according to the data format description in FHIR (version 5.12) for the evaluation. Two different FHIR implementation guides were used as target formats: the *German Laboratory finding of the NASHIP* and the *HL7 Europe Laboratory Report* [18].

The LDT format is mapped to both target formats using FML. Using the FML2Mirth generator, the FML scripts are translated into StructureMaps, and two separate channels are generated and deployed on a Mirth instance. Each format has a distinct set of semantic codes, which are permissible values for certain elements (binding). The sending system in our evaluation scenario uses proprietary codes that must be mapped to the specified CodeSystem in the target profiles. A terminology

server is used to provide a translate service based on ConceptMaps, which is accessed by the Mirth channel via a REST API. The initial FML script for the transformation to the target format *MIO Laborbefund* with its 9 profiles [19] of the NASHIP consists of over 400 lines of formalized mapping rules, resulting in StructureMaps with over 3500 lines and more than 2300 elements. The 20 transformed LDT laboratory findings resulted in an average of 62 unique FHIR each. Only one report failed the closing instance validation due to a missing first name within the corresponding patient resource.

The second Mirth channel transforming LDT to the 8 profiles of the Europe Laboratory Report is based on the initial FML script. The same 20 LDT laboratory results sum up a total of over 694 FHIR resources, resulting in an average of 35 resources each. The subsequent validation process revealed for all test cases a structural issue that occurred due to a required extension of the DiagnosticReport profile. The extension should be a Composition reference to the report, but the extension itself is missing in the provided FHIR package by EU (European Union) laboratory report, and the referral link is nonfunctional. Yet, a manual check and a comparison with the NASHIP MIO resources proved their validity.

Discussion

This study presents a concept and the implementation of an adaptable transformation process for various data structures into a standardized format. Our approach is based on FHIR as a standardized data exchange format, FML as declarative transformation rules, and Mirth Connect as the transformation executor.

Principal Results

The approach focusses on separating the transformation rules from the actual transformation to extract the rules out of the process. Due to the detachment, the rules, which are created in a labor-intensive process, can be shared in a declarative and standardized manner. The use of FML for defining the mappings can cover technical operations such as network calls to the terminology server and are triggered by FML2Mirth dynamically during JavaScript generation. In addition, the separation allows a degree of modularization and, thus, the reuse of the created rules. For example, it was possible to modify the mapping for the MIO reports to generate laboratory reports, which conform to the profiles of the EU laboratory report within a few hours. This emphasizes the flexibility of the proposed method. A significant advantage of this approach is that it allows mappings of concepts to be exchanged at run time of the Mirth channel and be developed and updated independently of the structural mapping. Compared to common ETL jobs, this approach needs much less manual intervention.

The mapping is defined using FML to render the StructureMap using the official FHIR Validator. The declarative mapping is enclosed in the generated StructureMap instances as a parse tree. Referring and combining various FML scripts is possible per the specification but has not been implemented yet. Therefore, the mapping shall be edited incrementally during the transformation design phase in the FML scripts rather than in the StructureMaps directly. Nevertheless, initial creation of the FML scripts is less time-consuming but still a labor-intensive task, and currently there is a lack of suitable tool support. An FML script is always a 1-way mapping, and reverse transformation is not automatically assumed.

The functionality provided by Mirth highly constrains the design of our approach, as external dependencies should be minimized to ensure ease of use. With this in mind, the implemented single command line tool in Java injects the transformations into a specified Mirth channel. In addition, only the Mirth server and an FHIR server, which provides terminology services, are required. Simultaneously, the system should be as flexible as possible and support arbitrary StructureMaps. To fulfill these requirements, it was necessary to work with the circumstances provided by Mirth. Since Mirth itself works on XML objects, it is prudent to use this approach as well. Hence, the transformations defined in the StructureMap are translated into transformations on XML objects. Mirth itself first translates incoming data such as HL7v2 to XML as a first processing step, so all formats supported by Mirth can automatically also be transformed using the generated transformer from FML2Mirth. If a format is not supported by Mirth, such as LDT, another transformation step can simply be added to transform the incoming data into an XML structure.

Limitations

During the evaluation, an issue was discovered with the FHIR implementation within the different FHIR servers. In particular, the issue concerned FHIRPath implementation, which is used by the FHIR Validator to evaluate the validation rules. In our test setting, one rule is interpreted differently depending on the implementation used. On the tested laboratory reports, the .NET and JavaScript implementations returned true, which is correct per our understanding. In contrast, both Java implementations tested (HAPI and IBM) returned false.

Alongside the complex structural mapping, semantic integrity must also be ensured. In our approach, the semantic mappings are created and validated by health care professionals and stored in an FHIR server as an external service, which is standard procedure. While existing terminology systems generally provide transition rules to newer versions, the maintenance of FHIR resources is not standardized and is an ongoing topic of investigation in medical informatics [20].

Furthermore, a mechanism was missing to process further StructureMaps, which are referenced from a given StructureMap. FML uses FHIRPath as an embedded language in several instances. The associated specification is extensive and was implemented in this study only in parts.

Comparison With Prior Work

The use of formalized mapping rules in data integration is a well-studied topic, and Mirth as a transformation engine for clinical data integration is also a renowned tool. However, the combination of both topics with the goal of a generic and easily adaptive mapper is missing in the literature, to our knowledge. Alongside declarative rules, the work of Ong et al [21] must be mentioned; they present a dynamic ETL approach that uses a custom mapping language to transform health care–related data

into the OMOP (Observational Medical Outcomes Partnership) common data model. The formalized rules are rich in details but are proprietary and rather database-oriented due to their use case. An innovative feasibility study for FML has been presented by Dimitrov et al [22]; they used FML for transforming the HL7 CDA (Clinical Document Architecture)–based national Austrian electronic patient record. Using FML, a transformation from CDA documents to the International Patient Summary based on FHIR could be accomplished. The usage of Mirth as a transformation engine is an intuitive choice due to its functionality and product scope. Hence, various studies are focusing on the transformation from HL7 (version 2) messages into further target formats, including structural reformation into JSON [23] or standardization into HL7 FHIR [24].

Our approach is based on that of a prior study that evaluated the transformation of StructureMaps into Mirth channels [25]. The results were promising, but it also emerged that the manual definition of StructureMaps became cumbersome and rapidly very complex. The presented approach overcomes this shortage using FML and its intuitive nature.

Conclusions

We successfully implemented a functional system based on Mirth, which automatically generates transformations from StructureMaps and integrates them into a Mirth channel. This system supports large parts of the FML specification. Initial tests revealed that complex structures based on FML maps, generated in a channel in conjunction with a terminology server and ConceptMaps are feasible. If a new format is to be supported, it may only be necessary to insert another Mirth transformation step before the transformation from the StructureMap, to transform the input structure into XML. One advantage of the current solution is its flexibility and robustness in that only one resource is used for translation. The topic of FML is still an ongoing discussion and has not been extensively investigated in the FHIR community so far. Accordingly, the tooling in this area is currently rather rudimentary.

Acknowledgments

This study was funded by the German Federal Ministry of Education and Research (grants 01ZZ2312A and 01ZZ2011). We acknowledge financial support provided by Land Schleswig-Holstein within the funding program Open Access Publikationsfonds.

Abstract

Background: Indonesia has rapidly embraced digital health, particularly during the COVID-19 pandemic, with over 15 million daily health application users. To advance its digital health vision, the government is prioritizing the development of health data and application systems into an integrated health care technology ecosystem. This initiative involves all levels of health care, from primary to tertiary, across all provinces. In particular, it aims to enhance primary health care services (as the main interface with the general population) and contribute to Indonesia's digital health transformation.

Objective: This study assesses the information and communication technology (ICT) maturity in Indonesian health care services to advance digital health initiatives. ICT maturity assessment tools, specifically designed for middle-income countries, were used to evaluate digital health capabilities in 9 provinces across 5 Indonesian islands.

Methods: A cross-sectional survey was conducted from February to March 2022, in 9 provinces across Indonesia, representing the country's diverse conditions on its major islands. Respondents included staff from public health centers (*Puskesmas*), primary care clinics (*Klinik Pratama*), and district health offices (*Dinas Kesehatan Kabupaten*/*Kota*). The survey used adapted ICT maturity assessment questionnaires, covering human resources, software and system, hardware, and infrastructure. It was administered electronically and involved 121 public health centers, 49 primary care clinics, and 67 IT staff from district health offices. Focus group discussions were held to delve deeper into the assessment results and gain more descriptive insights.

Results: In this study, 237 participants represented 3 distinct categories: 121 public health centers, 67 district health offices, and 49 primary clinics. These instances were selected from a sample of 9 of the 34 provinces in Indonesia. Collected data from interviews and focus group discussions were transformed into scores on a scale of 1 to 5, with 1 indicating low ICT readiness and 5 indicating high ICT readiness. On average, the breakdown of ICT maturity scores was as follows: 2.71 for human resources' capability in ICT use and system management, 2.83 for software and information systems, 2.59 for hardware, and 2.84 for infrastructure, resulting in an overall average score of 2.74. According to the ICT maturity level pyramid, the ICT maturity of health care providers in Indonesia fell between the basic and good levels. The need to pursue best practices also emerged strongly. Further analysis of the ICT maturity scores, when examined by province, revealed regional variations.

Conclusions: The maturity of ICT use is influenced by several critical components. Enhancing human resources, ensuring infrastructure, the availability of supportive hardware, and optimizing information systems are imperative to attain ICT maturity in health care services. In the context of ICT maturity assessment, significant score variations were observed across health care levels in the 9 provinces, underscoring the diversity in ICT readiness and the need for regionally customized follow-up actions.

Introduction

Digital health plays a significant role in enhancing health care services for people and has developed beyond providing electronic health records to supporting health care services provision, health surveillance, health literature, health research, and data-driven health policies [1-4]. The massive growth of technology use in health propelled to the top of the global agenda, as summarized in the World Health Organization's (WHO) Global Strategy on Digital Health 2020 - 2025 [1]. According to this report, each country is expected to adopt the strategies best suited to its conditions, culture, and values to reach its digital health sustainability.

In 2022, the Ministry of Health (MoH) of the Republic of Indonesia launched its health system transformation strategy. The transformation strategy had 6 pillars; one of them was primary health care transformation, which focused on strengthening promotive and preventive activities in its implementation to create more healthy people, improve health screening, and increase primary service capacity. Health care services in Indonesia are primarily provided at a public health care facility called *Puskesmas* (short for *Pusat Kesehatan Masyarakat* or public health centers) and community-based public health services (called *Posyandu*) since the 1980s.

Puskesmas in Indonesia are spread across all types of characteristic regions, such as urban, rural, remote, and very remote regions in Indonesia within all 38 provinces and 514 districts or cities. The number of *Puskesmas* has increased since 2017, from 9825 units to 10,374 in 2022. The ratio of *Puskesmas* in Indonesia to subdistricts was 1.4 in 2022. This illustrates that the ideal ratio of *Puskesmas* to subdistricts, namely a minimum of 1 *Puskesmas* in 1 subdistrict, has been fulfilled nationally. In terms of an average ratio, each *Puskesmas* serve 27,000 - 30,000 residents in 2023.

Puskesmas serve two main functions: providing integrated individual health care services and essential public health services. Other tasks of *Puskesmas* are to provide continuous and comprehensive care, refer patients to specialists and hospital services, coordinate health services, and guide patients within the network of public health services. *Puskesmas* play roles in promotive, preventive, and curative services for the population, while primary clinics and other primary health services, such as private general practitioner (DPM) and private midwife (BPM), are more focused on curative and specific health services approaches. Other than that, *Puskesmas* also have a responsibility to provide technical guidance to primary clinics, DPMs, and BPMs as the networking partner institutions in the area. Besides *Puskesmas* and *Posyandu*, essential health services are provided by other primary care centers, such as clinics, DPMs, and BPMs. In 2023, the primary care clinics also increasingly grew and reached more than 11,000 units, while DPM and BPMs reached 5800 units across all 38 provinces in Indonesia.

In terms of organizational governance, *Puskesmas* are considered the technical implementation unit of district health offices. In this case, the district health office is responsible for providing guidance, monitoring, and evaluation for *Puskesmas* in its region. However, *Puskesmas* have autonomy to synchronize and harmonize the health development goals in their working area. All health service activities in the area are conducted by *Puskesmas* and their networking partners (ie, primary clinics, DPMs, and BPMs). *Puskesmas* coordinate and report these activities to the district health office on an annual, monthly, and weekly basis using either electronic or nonelectronic systems. The reports include (1) activity report, (2) financial report, (3) field survey report, (4) related cross-sector reports, and (5) the health services network (clinics, DPM, BPM) reports in the area. This reporting scheme continues by the district health office to the province health office and then to the MoH as the national authority.

The health services and public health programs that were routinely reported using an electronic information system included maternal and child health, nutrition, surveillance, as well as disease prevention and control. These programs use multiple, separate applications that currently lack interoperability data standards. Besides that, there are multiple electronic medical record systems widely developed by hundreds of private vendors, designed to provide patient medical records for health care providers. These systems include *Sistem Informasi Puskesmas* (SIMPUS) for *Puskesmas* and *Sistem Informasi Klinik* (SIMKLINIK; clinic information systems) for primary clinics, as well as telemedicine and tele consultation platforms. These syetms are still not integrated and interoperable with other public health information systems developed by the MoH.

Indonesia has pursued continuous improvements in the national digital health implementation. To this end, the COVID-19 pandemic accelerated the introduction of national digital health capacity and raised the number of daily health applications users, currently exceeding 15 million people [5,6]. Through the launch of the Blueprint of Digital Health Transformation Strategy 2024, the government committed to using digital technology and data for public health to support the realization of a healthy Indonesia. The priority of Indonesia's digital health transformation activities include the integration and development of health data, the integration and development of application systems, and the developmet of a health technology ecosystem. These transformations aimed to collect standardized health data into a centralized platform named *Satu Sehat* (One Health Data). This process began with designing the health data architecture and interoperability as well as assessing the current infrastructure and security levels [7].

Implementing such a large-scale digital transformation requires technical maturity in the health sectors' information and communication technology (ICT). The critical factors of ICT maturity include infrastructure, policies, human capital development, change management, strategy, leadership, partnership, and collaboration [8]. In 2017, the MoH used the Health Metrics Network of the World Health Organization as the basis for a national digital health strategic framework, incorporating a holistic approach in planning, developing, implementing, and evaluating the use of ICT in health services. The strategic framework contained seven components: (1) governance and leadership; (2) strategy and investment; (3) services and application; (4) standards and interoperability; (5)

infrastructure; (6) legislation, policy, and compliance; as well as (7) workforce [2,9].

Chanyagorn and Kungwannarongkun [10] developed an ICT maturity assessment tool to explore ICT readiness in small- and medium-sized organizations in middle-income countries, covering both public and private sectors. This assessment tool was used to evaluate the ability of consumers, businesses, and governments to use ICT to their advantage; however, this study assessed ICT maturity in sample governmental public health services' facilities and institutions. The most significant aspect of this tool was the assessment of maturity for various aspects, as it could be adjusted to reflect best the different mixes of conditions in middle-income countries like Indonesia. The tool assessed four main ICT factors: (1) infrastructure, (2) hardware, (3) software and system information, as well as (4) people and human resources [10].

Therefore, as part of the digital health development in Indonesia, it is important to understand the ICT maturity level in services immediately after the pandemic, as a benchmark for future ICT initiatives. This study focused its assessment on ICT maturity across primary health care services and district health offices in Indonesia, applying the ICT maturity assessment tool for middle-income countries. To maintain a high level of inclusivity of services across different geographical regions, the evaluation of digital health capability was investigated in 9 provinces, spread over the 5 biggest islands in Indonesia. This study is the first study to assess the ICT maturity through middle-income country approaches for public health centers, primary clinics, and district health offices.

Methods

Data Collection

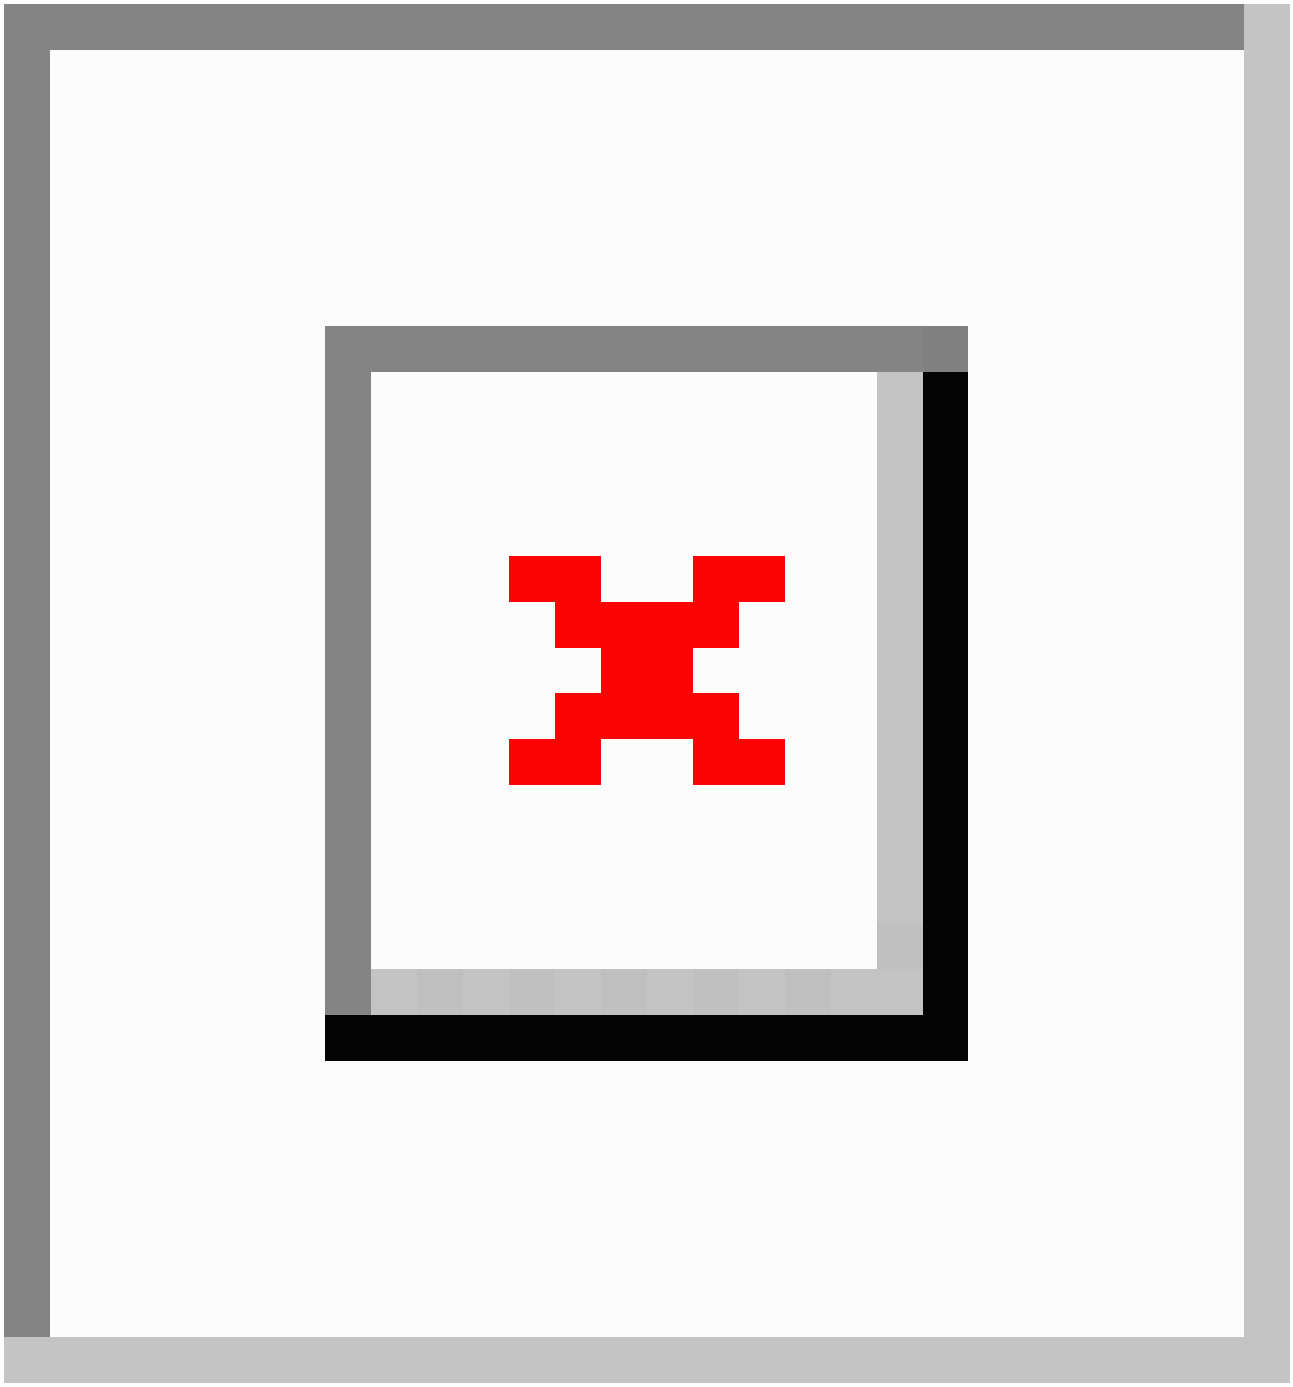
A cross-sectional survey design involving the ICT maturity assessment tool for middle-income countries was used in 9 provinces in Indonesia. Targeted stratified sampling was applied to choose the participants from provinces on the 5 largest islands in the country. DKI Jakarta, West Java, Banten, and East Java provinces on Java Island; Aceh province on Sumatra Island; East Kalimantan province on Kalimantan Island; Central Sulawesi province on Sulawesi Island; West Nusa Tenggara on the Nusa Tenggara Islands; and Maluku province on Maluku and Papua Islands. Provinces chosen on the 5 largest islands were based on region representativeness and health facility characteristics, which included urban, rural, and remote areas.

The targeted respondents were representatives of 3 main health sites in the province, including public health centers (*Puskesmas*), primary care clinics (*Klinik Pratama*), and district health offices (*Dinas Kesehatan Kabupaten*/*Kota*). A letter of invitation was sent to the targeted province district health office as the official invitation for an electronic survey and a forum group discussion (FGD) session. Each participant involved in the survey and FGD session was selected based on top management's assignment to attend the electronic survey and FGD meeting. To address participant selection and response biases, all assigned participants from all regions needed to fulfill the following inclusion criteria: (1) personnel who handled and oversaw the health information system implementation in each site, (2) with knowledge of the health information system used at the health site, and (3) with the ability to communicate with local staff to complete the survey accurately.

An ICT maturity assessment questionnaire was adopted and modified, adjusting to the local country's situation (Multimedia Appendix 1). The modification was made to the questions of each ICT subcomponent, especially the organization knowledge component, software security and document component, and network security component (Figure 1). A pilot survey test was conducted with 20 participants to gather feedback from participants, ensuring the questions were easy to understand, determining the time required to complete the questionnaire, and capturing suggestions to improve the assessment form. The questionnaire (Multimedia Appendix 2) consisted of four sections: (1)human resources, covering the availability and capacity of the personnel in using ICT; (2) software and systems, covering the number of health information systems used, data reporting in the health information system, troubleshooting, and maintenance performance; (3) hardware, including the availability of PCs/laptops, servers, storage, and manual entry data; and (4) infrastructure, including access to the internet access, electricity, and physical facility/building (Figure 1).

The survey was conducted by gathering the respondents through web-based meetings. The process was completed between February and March 2022. There were 237 respondents divided into 7 FGDs, with each FGD facilitated by 5 facilitators. The data were collected through 2 sessions in the meetings, which took 2.5 hours to complete. The 2 sessions were as follows: (1) filling out the questionnaires for the quantitative score and (2) an FGD session to discuss the survey findings and further explore the assessment results obtained. Each individual component of the ICT maturity questionnaire was discussed in more detail to obtain more comprehensive qualitative information. Discussions were continued until thematic saturation was reached.

Figure 1. The modified components evaluated in the information and communication technology (ICT) maturity assessment.

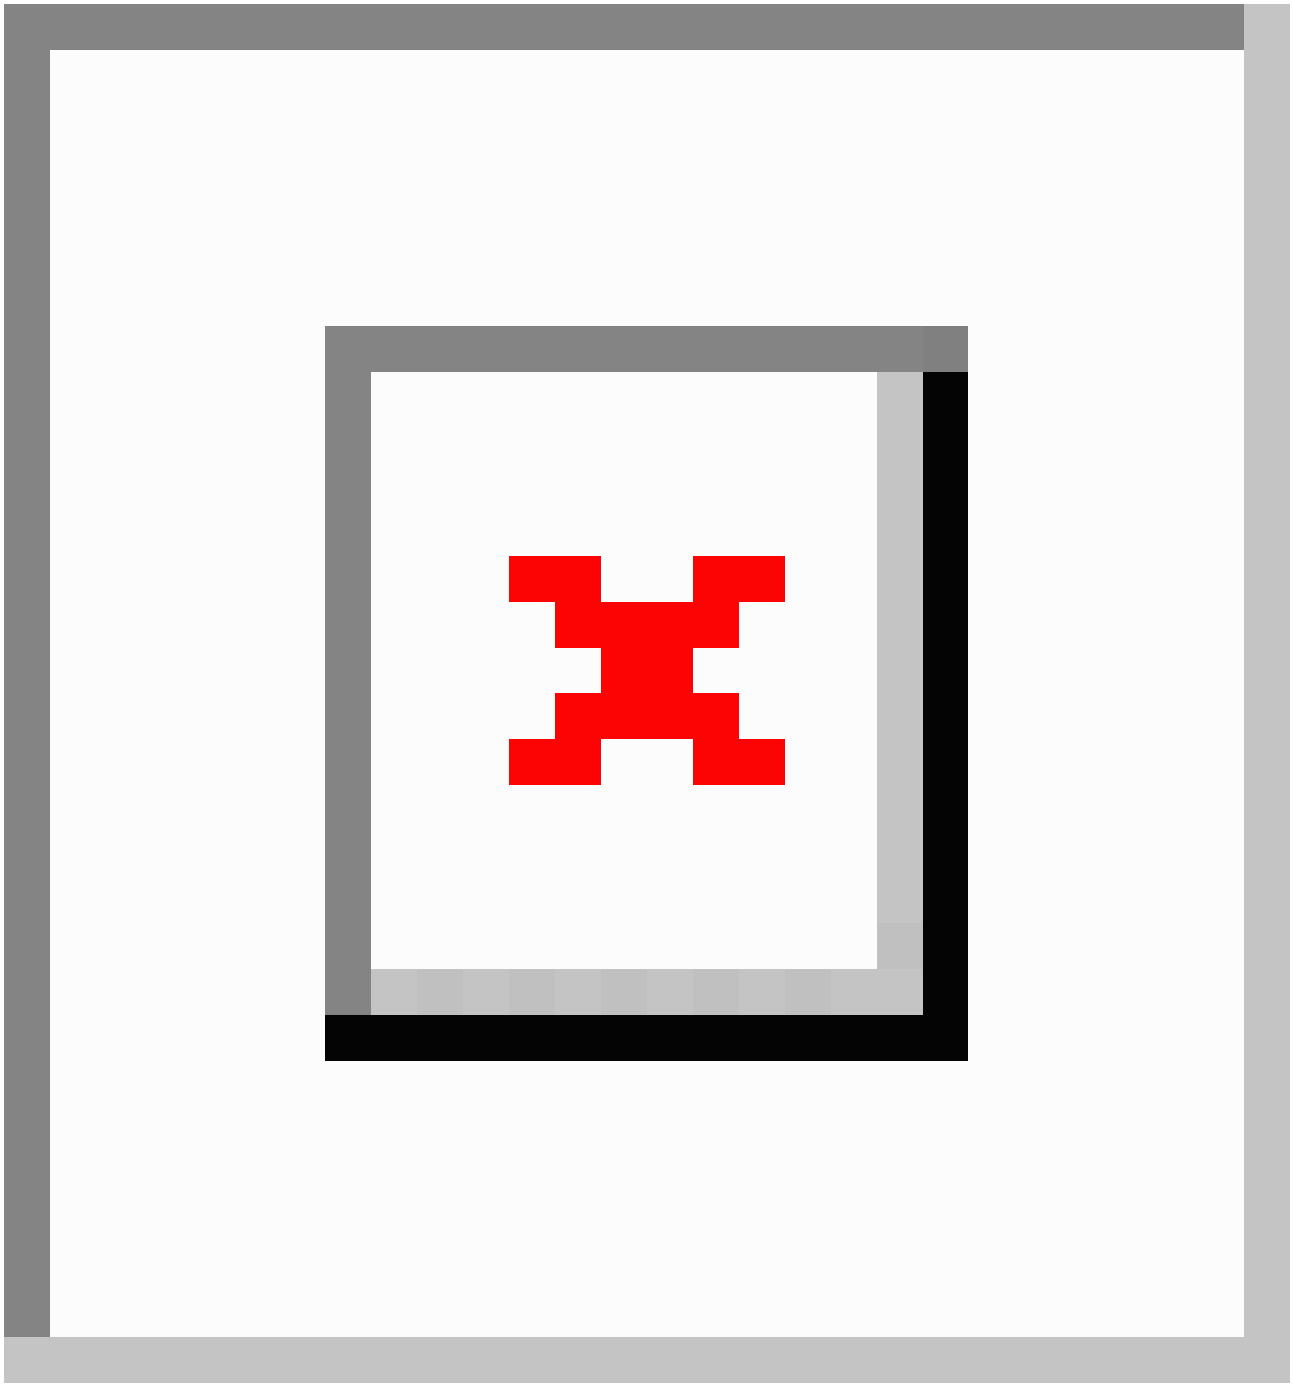


Data Analysis

The ICT maturity assessment tool consisted of 14 subsections containing 30 questions (Multimedia Appendix 2). The participants' responses to these questions were categorized into 5 levels of digital maturity: (1) initial, (2) basic, (3) good, (4) best practice, and (5) excellent (Figure 2), with a score of 1 indicating the lowest level of digital maturity (initial) and 5 representing the highest (excellent). The electronic survey responses were recorded by our team using the Mentimeter forms database tools, and the FGD results were input into a table using Microsoft Excel. The scores of each participating organization, including public health centers, primary care clinics, and district health offices, were used to determine their ICT maturity levels. The organization's score was calculated and averaged for each province.

The analysis was performed in Microsoft Excel. The scores from the 4 components were used to produce the mean score. A comparison analysis at the district and province levels was also generated. The FGD, held via Zoom, was recorded, and qualitative information obtained from participants was categorized based on the ICT component to be summarized as the FGD results for all provinces.

Figure 2. Information and communication technology maturity level.



Ethical Considerations

According to the "Exemption" section of the Indonesian MoH's National Guidelines and Standards for Ethical Research and Development in Health (2017), studies are exempted from review process if there is no/little potential risk/harm arising from the conduct of the research or when the information collected is available from the public domain; if they involve the use of educational tests (cognitive, diagnostic, attitude, and achievement); and if they involve survey or interview procedures, or public behavior observations. Research and demonstrations conducted by or subject to the approval of a department or agency and designed to study, evaluate, or assess the benefits of public programs or services, as well as other goods and services identified in the regulations, are also exempted from obtaining ethics approval. The original guidelines are available in Indonesian language of the MoH's guidelines (Chapter IIIB, point 2) [11]. The participants' data were also anonymized, following the Indonesian MoH's National Guidelines and Standards for Ethical Research and Development in Health (2017), Chapter IIIB, point 2.

Results

The study respondents were 237 in total and included 121 representatives of public health centers, 67 IT staff from district health offices, and 49 primary care clinic staff (Table 1). The provinces of East Java, Aceh, East Kalimantan, and West Nusa

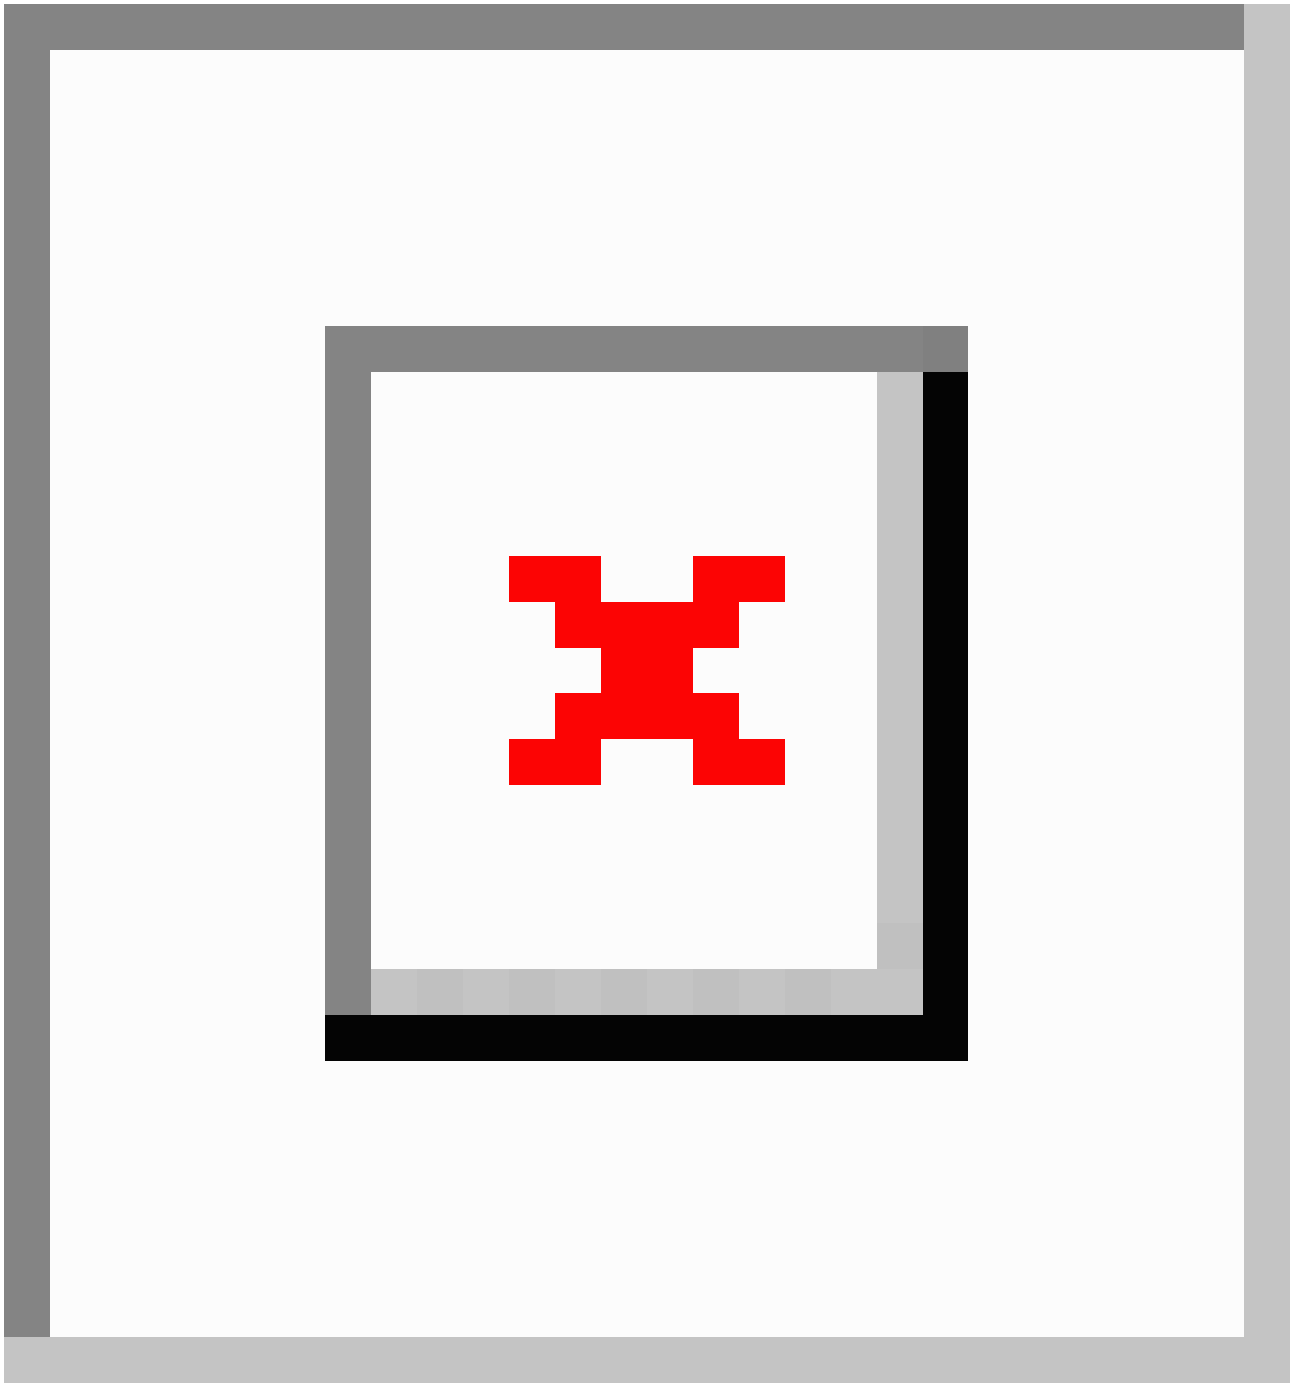
Tenggara had the largest representation among the participating public health centers, with 27, 17, 15, and 15 public health centers from each province, respectively. As for the district health offices, Aceh, West Nusa Tenggara, and East Kalimantan each had 11, 9, and 9 district health offices, respectively, while East Java had the highest representation with 13 district health offices. Notably, representatives from West Nusa Tenggara led the primary care clinic segment, accounting for 12 primary care clinics, followed by East Java with 9 primary care clinics and Aceh with 8 primary care clinics.

On average, the ICT maturity scores were broken down as follows: 2.71 for human resource, 2.83 for software and systems, 2.59 for hardware, and 2.84 for infrastructure, resulting in an overall average score of 2.74 (Figure 3). Based on the analysis, health care providers in Indonesia had an ICT maturity between basic and good according to the ICT maturity level pyramid.

Table . The study participants.

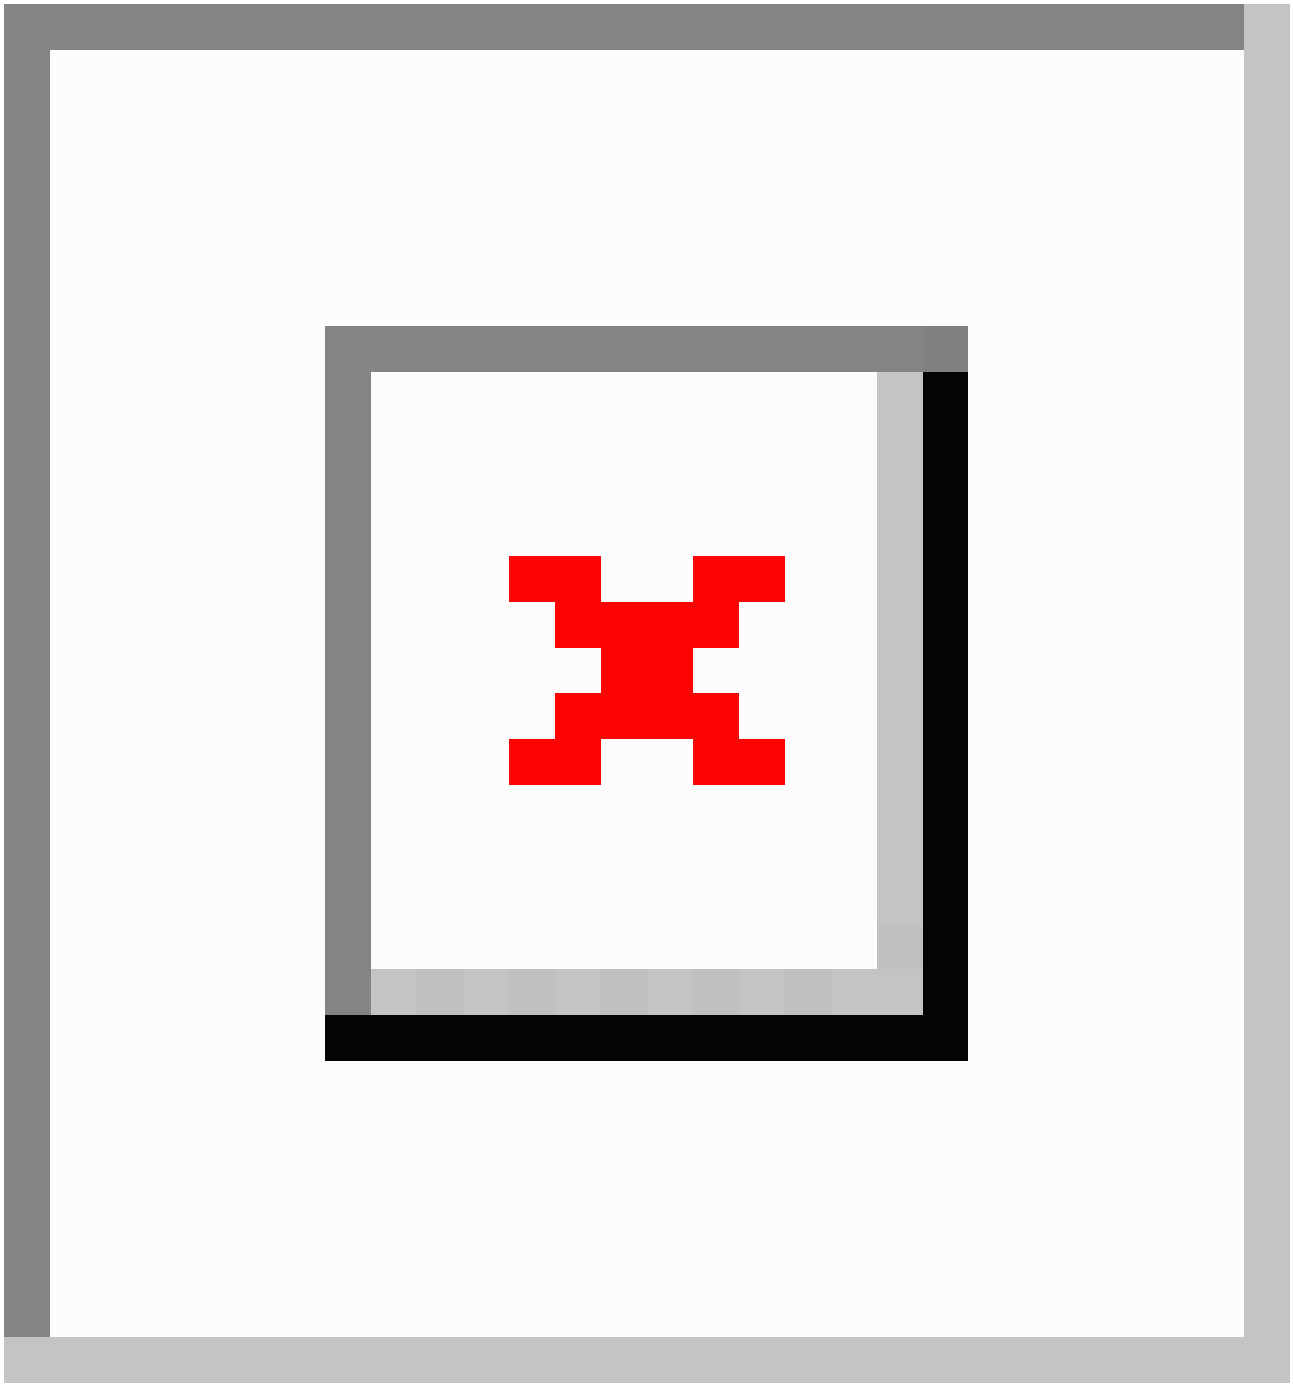
Island and province	Public health center, n	District health office, n	Primary care clinic, n	Subtotal, n
Java, DKI Jakarta	6	5	1	12
Java, West Java	13	6	5	24
Java, Banten	5	2	1	8
Sumatra, Aceh	17	11	8	36
Java, East Java	27	13	9	49
Nusa Tenggara, West Nusa Tenggara	15	9	12	36
Kalimantan, East Kalimantan	15	9	6	30
Sulawesi, Central Sulawesi	11	8	2	21
Maluku, Maluku	12	4	5	21
Total	121	67	49	237

Figure 3. Information and communication technology maturity scores across four main components at each site.



There were variations in the ICT maturity scores by province (Figure 4). On average, the ICT maturity score at the district health offices level was 2.60. Banten Province had the best overall score (3.00), followed by East Java (2.85), DKI Jakarta (2.75), and West Nusa Tenggara (2.75). At the public health center level, the average score was 2.69, with the highest average score belonging to Jakarta (3.18), followed by West Nusa Tenggara (2.93) and East Java (2.83). The average ICT maturity scores at the primary care clinics level were 2.87 for human resource capability and system management, 2.87 for software and information systems, 2.90 for hardware, and 3.11 for infrastructure. The DKI Jakarta province had the highest average ICT maturity score at the primary care clinic level (3.30), followed by Banten (3.10) and Aceh (3.05).

Figure 4. Average scores for the information and communication technology maturity level at (A) district health offices (DHOs); (B) public health centers (PHCs); and (C) primary care clinics.



Our analysis revealed that the public health centers, primary care clinics, and district health offices exhibited varying degrees of maturity across provinces (Figure 5). Important findings included the human resource scores, where Aceh, Banten, and Sulawesi had better developed human resource capacities, with ratings exceeding 3. A total of 9 provinces had scores ranging from 2 to 3 when it came to software and system maturity; the only exceptions were the public health centers and primary care clinics in DKI Jakarta, with scores of 3.54 and 3.38, respectively. In terms of hardware maturity, the majority of regions scored between 2 and 3, although some had significantly lower scores than others, such as Maluku's district health office (1.67) and the *Puskesmas* in Central Sulawesi (1.83). Primary care clinics typically showed greater maturity in terms of infrastructure, with an average score of 3 or higher. However, Maluku's public health center received a score of 2.06, whereas the district health offices in Maluku and Central Sulawesi received a lower score, ranging around 2.

When examining the differences in ICT maturity based on the location of public health centers, the distribution is evident. Figure 6 shows a detailed scatter plot graph created with the ICT maturity assessment scores, indicating differential maturity levels across urban and remote locations. In terms of human resources, it is apparent that isolated locations have lower maturity scores compared to their equivalent urban sites, although urban and rural areas have different variances. In

addition, there are significant differences in the software maturity scores between rural and urban areas. The software maturity varies in rural areas compared to urban areas, where the scores are constantly higher. On the other hand, software maturity varies in remote places.

Figure 5. Information and communication technology maturity assessment score ranges across various provinces and health care levels.

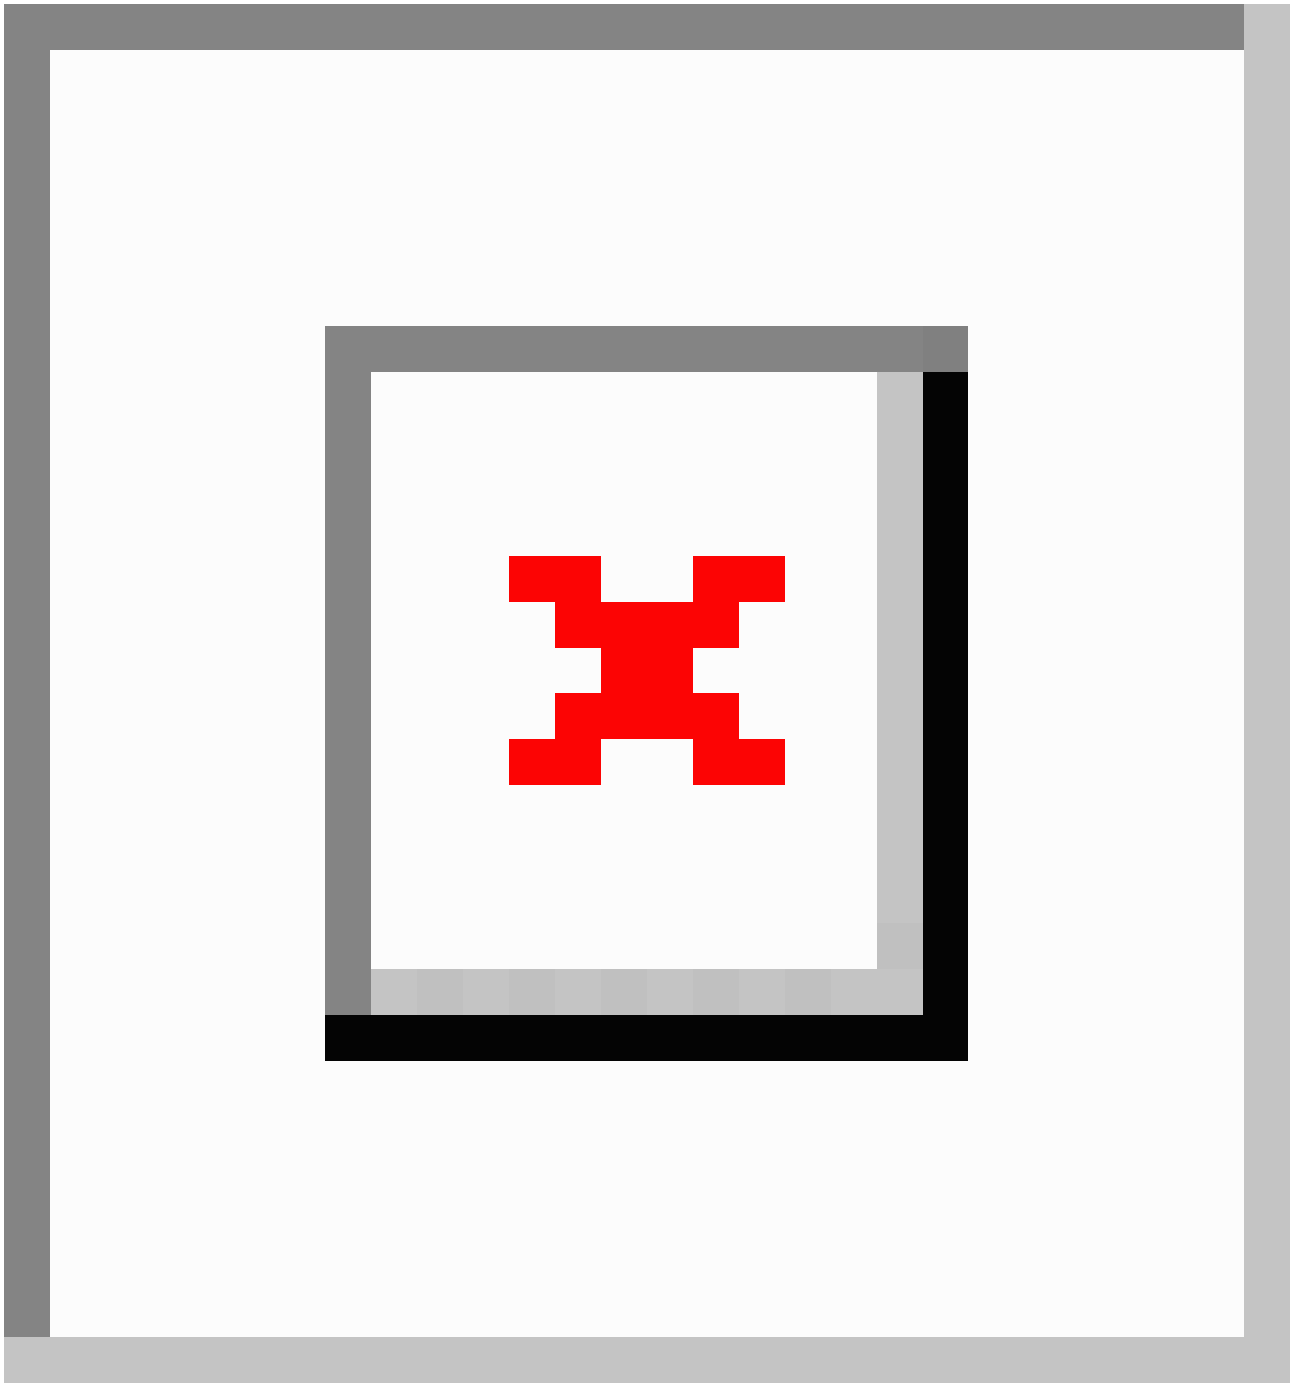


Figure 6. Information and communication technology maturity scores scatter plot by main components and site locations in the 9 targeted provinces.

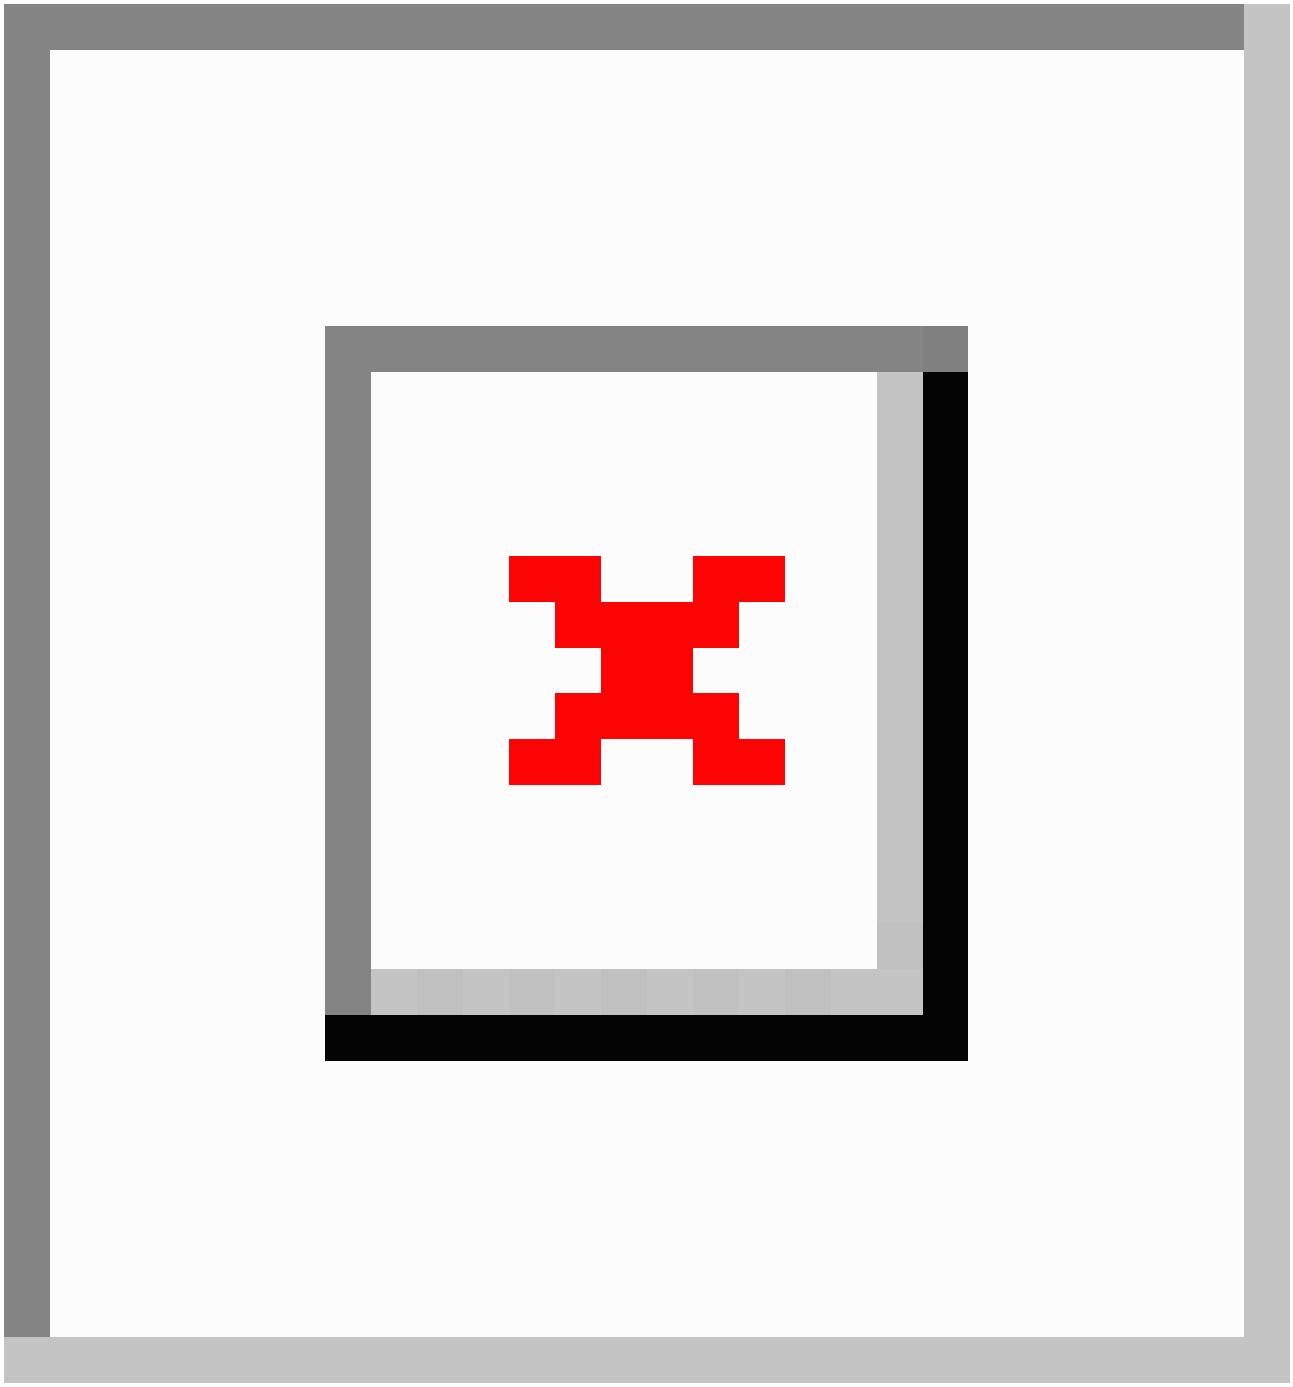

The lower scores for the software system maturity indicated that the facility's questionnaire responses reflected qualities that hindered digital transformation or digital maturity. Key issues identified included the absence of trained or specialized personnel for data input and IT. Additionally, there was an excessive number of applications or information systems mandated by central or local governments. Despite the abundance of applications, not all were used effectively, and many lacked interoperability, resulting in data duplication and increased workloads for health workers. Hardware components were scored based on several factors, including the reliance on manual, paper-based methods or computer-based Excel tables for data input; the insufficient number of personal computers available for health care services and data input; the type of data storage used, such as computer-based or cloud-based to minimize data loss; and the quality and stability of the data server. For infrastructure, the scores for some regions were lower due to the poor internet quality in health facilities and the inconsistent power availability, which was not guaranteed 24 hours a day. In some cases, power outages occured even during operational hours.

Regional differences in hardware quality were also evident, with varying degrees of quality found in rural, urban, and remote locations. While remote areas had challenges due to lower quality or limits, rural and urban areas generally had higher standards for hardware quality. The trends seen in hardware and infrastructure were strikingly comparable, highlighting a shared tendency between these elements. These findings offer

important insights into the particular opportunities and problems in various situations and they portrait an intricate picture of ICT maturity across various geographies. Additionally, these findings highlight specific area characteristics, which may aid the government in deciding appropriate approaches for ensuring the effective implementation of digital health services in these areas.

In addition to assessing digital maturity through scoring, we conducted FGDs, the findings of which highlighted a number of staffing- and human resources–related issues. First, there were people in the health care facilities and district health offices with a variety of backgrounds, but not all of them were IT literate. Second, data input was typically done by health officials or health workers; these staff members lacked professional IT certification or training. Third, data analysis was usually performed by nurses and staff at health centers due to a shortage of professionals with necessary capabilities. Fourth, a large number of different unintegrated health information systems added to the burden of data reporting. Lastly, the lack of hiring civil servants to fill the paucity of IT professionals with computer knowledge was a further obstacle.

In terms of software and information systems, issues included frequent system disruptions, poor system performance, and operational difficulties. The largest issue with software was the sheer number of health information systems that required data input but were not interoperable. For instance, a question about immunization status appeared in two existing systems: the system for tracking toddlers' nutritional status and the immunization system. As there were no data integration in place, health care personnel were forced to continually enter the same data into multiple systems as a result of this redundancy.

The complexity was further increased by the ongoing addition of new applications from numerous sources, such as the MoH, other governmental organizations, or municipal governments. These applications frequently demanded a lot of data entry, which made data management quite difficult. Furthermore, the prevalence of paper-based reporting techniques persisted even in the face of digital alternatives. These difficulties highlight the need for more efficient and integrated solutions in the health care industry by impeding the overall simplification of data entry and system operations.

Numerous hardware-related issues emerged during the FGDs. Program managers frequently had to use their own laptops because their public health centers did not have enough resources. Despite the fact that the office had multiple computers, they were for shared use and in some subdistricts, the computers were limited and used only for the registration and administrative sections. In others, there were only 2-5 computers available to fulfill the management requirements of the entire public health center. Staff members occasionally used their personal laptops for data reporting. Furthermore, there were service recording delays due to PC storage limits. In addition, operational difficulties were exacerbated when individuals' PCs experienced slowness or malfunctions and when data storage was not centralized but rather restricted to individual PCs without cloud backup.

Regarding infrastructure, the intermittently weak signal on Wi-Fi and internet-connected devices in several places was mentioned. The employees routinely used Wi-Fi, but they frequently ran into network issues. Consequently, all reporting needed to be completed manually in certain locations or by using personal mobile data or paper-based data collection. Moreover, server outages occasionally caused delays or even entirely stopped the data recording process. Additionally, there was no dedicated data storage, thus data were at risk during sporadic power outages, which were particularly problematic in situations such as wildfires.

Discussion

Principal Findings

The analysis of ICT maturity in Indonesia's care providers reveals an overall average score of 2.74, indicating maturity between basic and good levels, aligned with the ICT maturity level pyramid. Variations exist across provinces and health care levels, with Banten Province exhibiting the highest overall score. The DKI Jakarta Province stands out with superior scores at the public health center and primary care clinic levels. Disparities in human resource, software, hardware, and infrastructure maturity exist between provinces and health care levels, with rural areas generally lagging behind urban areas. These findings underscore the importance of tailored strategies to address regional disparities and enhance digital health service implementation effectively.

The ICT maturity level has the potential to affect the quality of national health services, with the highest impact felt in middle-income countries. Excellent ICT maturity can lead to a good digital health implementation and potentially contribute to the improvement of health care, such as quality of care, supplies and logistics, training and communication, community engagement and participation in health services, as well as the availability and use of routine data by decision-makers [12-14]. The current research provides a snapshot of the ICT maturity in several health care services across Indonesia and explores factors that would require further attention.

The results of the questionnaires show the variety of ICT maturity among provinces, districts, and health facilities, with variations in critical components, such as human resource capabilities, software and information systems, hardware, and infrastructure. These disparities not only indicate the different provinces' ICT readiness but also highlight potential areas for improvement and development to enhance health care service delivery and information management in each respective region. Understanding these variations is crucial for devising targeted strategies to address specific ICT-related challenges and opportunities within the health care system across diverse geographical locations.

The development of ICT in Indonesia is facing tough challenges due to the country's geography, consisting of thousands of islands and many cultures, affecting educational, social, and economical aspects in the country. Moreover, Indonesia as an archipelago has many remote areas where telecommunication and internet service providers cannot develop the sufficient

infrastructure; as such, these areas are unavoidably underrepresented [14-16]. Indonesia ranked 111 on the 2017 ICT Development Index, falling behind other countries in Southeast Asia like Singapore (ranking 18), Brunei Darussalam (ranking 53), Malaysia (ranking 63), Thailand (ranking 78), and Philippines (ranking 101) [17].

Regarding human resources, often staff members do not have adequate digital literacy, and yet are required to report using IT processes, as it was also indicated in our work [18,19]. Moreover, there is a shortage of staff with computer expertise and insufficient data management training opportunities to mitigate this issue. The same is described in Malaysia, where challenges related to human resources include workload, readiness, skills, and user dependency. Additionally, tasks often require health workers to focus on mining data, instead of improving service provision [20-23].

Indonesia also faces a mind shift challenge for staff, as the plurality of overlapping systems comes against a context of well-established manual data collection, using paper or status books. In contrast, frequent input of overlapping variables across multiple software, adds to the work burden of individual health care staff and makes the digital health process inefficient. Countries in sub-Saharan Africa have also faced a similar challenge: they documented 738 distinct digital health interventions at different levels of functioning in the sub-Saharan African region over the past 10 years. One in 5 of those did not have a link to any health service outcomes, and only half could be classified as “established” at the end of the study period. Two of every 3 were focused solely on solutions for a single health care activity, limiting integration [20]. This aspect has not been researched as yet for the countries neighboring Indonesia.

The existence of infrastructure remains the main challenge in developing and implementing e-governments in middle-income countries [24,25]. In the health care industry, the continuity of using ICT in daily and routine operations depends on the availability of a robust IT infrastructure. Unfortunately, many middle-income countries lack the necessary infrastructure to support digital health, specifically telecommunication and electricity networks coverage [25-27]. This is also supported by other studies that found that IT systems used in the health care industry would only be optimal, effective, and efficient when adequate facilities and infrastructure supported them [28-31].

The discrepancies in infrastructure availability across the provinces in Indonesia directly affect a stable internet connection. Frequent internet signal downtime, network problems, poor connection, and insufficient computer availability, including the lack of electricity supplies in some remote areas, were found in this study, showing the need for further improvements in technology infrastructure and facilities. This lack and instability of IT infrastructure, such as the limitation of internet access, electricity supply, and availability of computers, is common across low- and middle-income countries, as similar findings were described for Brazil, sub-Saharan Africa as a whole, Sierra Leone, and Tanzania [32-36].

These findings are crucial for gaining a better understanding to support the Indonesian health technology transformation mentioned in the Blueprint of Health Transformation Strategy 2024. The foundation to transform the health systems lies in having a solid platform architecture design and infrastructure to implement integrated and interoperable health systems. The blueprint highlighted the plan to integrate all electronic medical record systems from public health centers, hospitals, primary care clinics, and laboratories into the *Satu Sehat* platform and to adopt the *Satu Sehat* standard. This study showed that to support the implementation of digital health transformation, the government should identify the gap; map the area based on capacity; and provide assistance to improve the software, hardware, infrastructure, and human resource capacity, especially in areas with lower ICT maturity scores.

Strengths and Limitations

The strengths of the study involve exploring ICT maturity in Indonesia, engaging several health care service sites (ie, *Puskesmas*, clinics, and health departments). Furthermore, the results of the FGDs provided a more detailed overview of the challenges related to the four assessed components, thus highlighting areas for future improvements to support the ongoing digital transformation of health care.

The limitations of the study are as follows: (1) the involvement of public health centers and primary clinics in the study was limited in each province and perhaps not entirely representative, although health departments involved in the study represented 80% - 90% of the 9 targeted provinces and districts; (2) other health care facilities, such as hospitals, laboratories, and pharmacies, were not involved in this study, and as such, additional aspects of needs or challenges may exist that have not been highlighted as yet; this may have implications for the representativeness of health care data users by volume; (3) the representativeness based on infrastructure distribution and regional characteristics (eg, urban, rural, remote, and very remote regions) should be viewed only as indicative, as health care services from more remote rural regions are less likely to have access to stable internet connection, and thus, unable to complete such questionnaires distributed by digital channels; (4) the respondents’ capacity can influence data completeness, and thus, it will be useful for future iterations if staff representing more functions of the health care centers are able to complete the questionnaire.

Conclusions

This study investigated for the first time the variations of ICT maturity across the health care systems (eg, public health centers, primary clinics, and district health offices) in 9 provinces in Indonesia, underscoring the diversity in ICT implementation and readiness. The maturity of ICT use was influenced by several critical components, specifically enhancing human resources, ensuring infrastructure, the availability of supportive hardware, and optimizing information systems. The findings of this study are in line with similar studies in other middle-income countries in the world. Our results demonstrate that to attain ICT maturity in health care services in Indonesia, it is imperative to address all of the above aspects, as each

represents ongoing needs and has been shown to be equally important and necessary in the field.

Conflicts of Interest

Abstract

Background: To ensure interoperability, both structural and semantic standards must be followed. For exchanging medical data between information systems, the structural standard FHIR (Fast Healthcare Interoperability Resources) has recently gained popularity. Regarding semantic interoperability, the reference terminology SNOMED Clinical Terms (SNOMED CT), as a semantic standard, allows for postcoordination, offering advantages over many other vocabularies. These postcoordinated expressions (PCEs) make SNOMED CT an expressive and flexible interlingua, allowing for precise coding of medical facts. However, this comes at the cost of increased complexity, as well as challenges in storage and processing. Additionally, the boundary between semantic (terminology) and structural (information model) standards becomes blurred, leading to what is known as the TermInfo problem. Although often viewed critically, the TermInfo overlap can also be explored for its potential benefits, such as enabling flexible transformation of parts of PCEs.

Objective: In this paper, an alternative solution for storing PCEs is presented, which involves combining them with the FHIR data model. Ultimately, all components of a PCE should be expressible solely through precoordinated concepts that are linked to the appropriate elements of the information model.

Methods: The approach involves storing PCEs decomposed into their components in alignment with FHIR resources. By utilizing the Web Ontology Language (OWL) to generate an OWL ClassExpression, and combining it with an external reasoner and semantic similarity measures, a precoordinated SNOMED CT concept that most accurately describes the PCE is identified as a Superconcept. In addition, the nonmatching attribute relationships between the Superconcept and the PCE are identified as the "Delta." Once SNOMED CT attributes are manually mapped to FHIR elements, FHIRPath expressions can be defined for both the Superconcept and the Delta, allowing the identified precoordinated codes to be stored within FHIR resources.

Results: A web application called PCEtoFHIR was developed to implement this approach. In a validation process with 600 randomly selected precoordinated concepts, the formal correctness of the generated OWL ClassExpressions was verified. Additionally, 33 PCEs were used for two separate validation tests. Based on these validations, it was demonstrated that a previously proposed semantic similarity calculation is suitable for determining the Superconcept. Additionally, the 33 PCEs were used to confirm the correct functioning of the entire approach. Furthermore, the FHIR StructureMaps were reviewed and deemed meaningful by FHIR experts.

Conclusions: PCEtoFHIR offers services to decompose PCEs for storage within FHIR resources. When creating structure mappings for specific subdomains of SNOMED CT concepts (eg, allergies) to desired FHIR profiles, the use of SNOMED CT Expression Templates has proven highly effective. Domain experts can create templates with appropriate mappings, which can then be easily reused in a constrained manner by end users.

Introduction

Background

The growing digitization of medical records has led to an increase in patient data available for health care analysis. These data must be utilized to improve medical care and offer more personalized treatments. However, to accomplish this, the ability to automatically exchange and process data between different systems is essential. This requires not only technical compatibility but also semantic interoperability, ensuring that the data's meaning is preserved when transferred to another system. The ability to exchange and utilize data across different systems is crucial for fully leveraging digital medical records and improving patient care [1].

To ensure semantic interoperability, it is essential to follow both structural and semantic standards. Structural standards specify the syntax for accessing data fields within information models. In recent years, the newly developed HL7 (Health Level 7) standard, FHIR (Fast Healthcare Interoperability Resources), has gained international recognition due to its emphasis on simplified implementation and the use of modern technologies [2]. Semantic standards, by contrast, involve terminologies that use language-independent codes to represent the meaning of data in an interoperable manner. SNOMED CT is widely recognized as the most comprehensive medical terminology for enhancing semantic interoperability [3]. In 2021, Germany acquired a national license for SNOMED CT, leading to increased interest and usage of the terminology. SNOMED CT concepts are now being integrated into data modeling efforts, such as the Medical Information Objects by the German National Association of Statutory Health Insurance Physicians (NASHIP) [4] and the core data set of the Medical Informatics Initiative (MII) [5]. The use of SNOMED CT, which contains over 350,000 concepts, aims to provide a machine-readable interlingua that minimizes coding issues specific to different countries and medical fields. However, due to the complexity of natural language, not all medical situations can be accurately coded using SNOMED CT's extensive set of precoordinated concepts. To address this and avoid a rapid increase in the number of new concepts, SNOMED CT, unlike many other vocabularies, supports postcoordination. This feature allows the combination of precoordinated concepts into new expressions using a formal grammar.

Therefore, postcoordination is a unique feature that significantly enhances the precision of medical documentation and greatly increases SNOMED CT's expressive power. However, the adoption of postcoordination has been slow due to various challenges. While some of these obstacles have already been addressed [6-9], integrating postcoordinated expressions (PCEs) into the electronic health records of legacy hospital information systems remains difficult for several reasons (Textbox 1).

Textbox 1. Obstacles to integrating postcoordinated SNOMED Clinical Terms expressions into electronic health records.

- **Adherence to familiar data structures**

Medical circumstances are usually documented using individual codes, and there are established methods for storing and processing these codes. While restrictions such as length-limited data types can be managed with simple codes, they pose challenges when dealing with arbitrarily large formal expressions, such as postcoordinated expressions (PCEs). This has led to concerns about the practicality of using PCEs [10].

- **Lack of technical support**

The technical handling of PCEs is inherently complex, requiring at a minimum a description logic reasoner and the implementation of several formal specifications, such as the Concept Model, Compositional Grammar, and Expression Constraint Language, as defined by SNOMED International [3]. While specialized terminology servers can help alleviate the implementation burden, currently only the CSIRO (Commonwealth Scientific and Industrial Research Organization) Ontoserver [11] supports postcoordination [12].

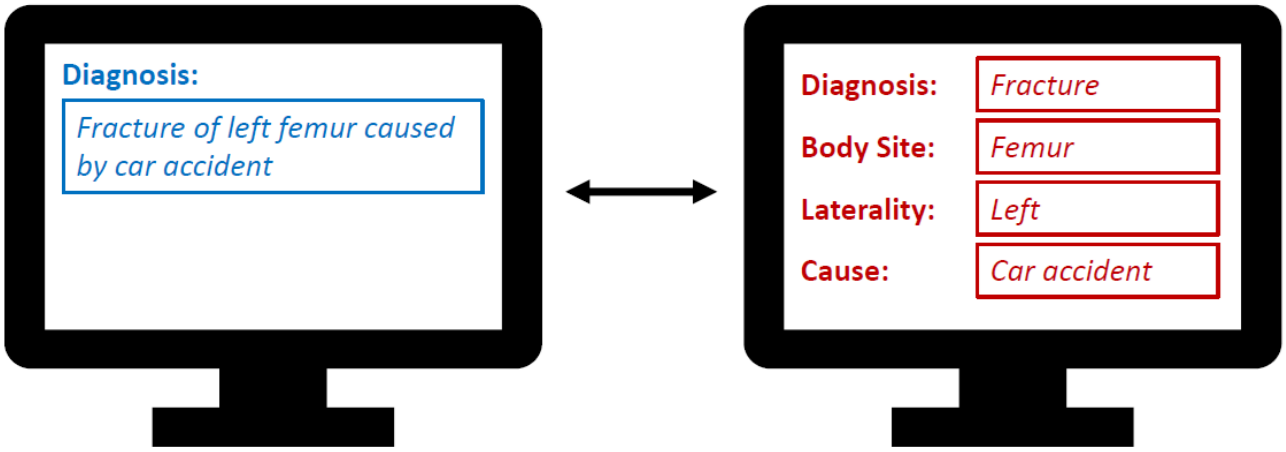
- **Difficulties with FHIR (Fast Healthcare Interoperability Resources) search**

When searching for information in FHIR resources, postcoordination is supported only if the exact same PCE has been explicitly and previously defined in a FHIR CodeSystem supplement. These supplements enable the extension of the standard FHIR CodeSystem for SNOMED CT with a collection of PCEs (eg, for value set definitions), but they do not support the recording of PCEs in a patient's electronic health record.

Given that these challenges are unlikely to be resolved in the short term, a different approach is needed to ensure interoperability between systems that support postcoordination and those that do not. Consequently, this paper will present an alternative representation of PCEs.

It has long been recognized that there is significant overlap between the scopes of structural and semantic standards, leading to unclear responsibilities and potentially ambiguous representations of medical facts, as well as inconsistent redundancies. This issue, known as the TermInfo problem [3,13-15], largely arose from the independent development of these standards, which resulted in mutual coverage of the same data elements (Figure 1). SNOMED CT's postcoordination capability further blurs the distinction between structure and semantics, potentially exacerbating the existing problem. However, PCEs are fully interpretable, allowing the information components they contain to be identified and flexibly disassembled. Building on extensive knowledge from previous projects [6,16-18] and the current integration of SNOMED CT with FHIR, the authors propose PCEtoFHIR—an application designed to decompose PCEs for storage as FHIR resources in a manner that preserves their meaning.

Figure 1. TermInfo: The same medical fact can be represented using either the terminology (left side) or the information model (right side) more heavily.



Related Work

Although there is a growing body of literature on the postcoordination of SNOMED CT concepts [6,16,19-21], a literature search revealed no existing publications specifically addressing the storage of PCEs in FHIR resources. However, a Health Level Seven International (HL7) working group is addressing this topic and provides several resources. For selected FHIR resources, such as Condition and Observation, mappings of some SNOMED CT attributes to FHIR are currently available (see [22] and [23]). Additionally, the Confluence pages "SNOMED on FHIR" ("Bindings to FHIR Clinical Resources") [24] outline various options for mapping SNOMED CT attributes to FHIR while avoiding semantic overlaps. The information from these documents is considered in our work.

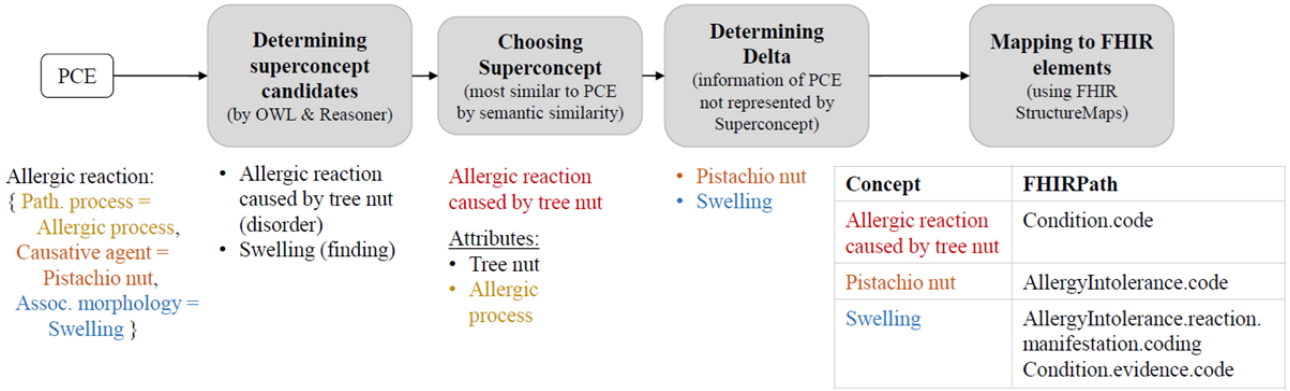
Additionally, some papers discuss the use of SNOMED CT in combination with standardized information models based on the HL7 Reference Information Model (RIM), HL7 Clinical Document Architecture, and HL7 FHIR resources. For instance, a project by Perez-Rey et al [25] focused on linking the normal form of precoordinated SNOMED CT concept definitions, normalizing SNOMED CT concepts, and binding them to HL7 RIM classes. This approach could potentially be extended to PCEs. However, the HL7 version 3 standard has not been widely adopted due to its complexity [1]. A project by Arguello-Casteleiro et al [26] addressed mapping precoordinated SNOMED CT concepts or PCEs from Consolidated Clinical Document Architecture to FHIR resources. While the objectives of this approach are similar to those of our work, Arguello-Casteleiro et al focused heavily on ontology. By contrast, our work primarily utilizes the widely adopted FHIR and SNOMED CT native specifications. Additionally, the specific ocular diseases examined by Arguello-Casteleiro et al pertain to a very narrow subset of SNOMED CT expressions. Further, the publication by Arguello-Casteleiro et al does not provide information on the extent to which all the data included in the PCEs can be transferred into the FHIR representation.

Methods

Overview

This work aims to develop and implement an approach that enables the storage of a SNOMED CT PCE within FHIR resources using only precoordinated codes. In this alternative representation, the PCE will be decomposed into precoordinated concepts, which can then be stored in appropriate elements of corresponding FHIR resources. An overview of the proposed approach is shown in Figure 2.

Figure 2. The decomposition of a PCE into elements of (profiled) FHIR resources consists of 4 steps. FHIR: Fast Healthcare Interoperability Resources; OWL: Web Ontology Language; PCE: postcoordinated expression.



A PCE, once verified for syntactic and semantic correctness, serves as the input. This PCE can be classified within SNOMED CT using the Web Ontology Language (OWL) and a reasoner, allowing for the identification of its direct supertype ancestors. Among these concepts, the most similar one to the PCE is selected as the Superconcept. The Delta is then calculated

between the Superconcept and the PCE, encompassing all the information in the PCE that is not represented by the Superconcept. In the final step, suitable elements of corresponding FHIR resources must be identified to store the information of the Superconcept and the Delta. To facilitate this, FHIR StructureMaps that define these associations on a general level need to be created in advance.

Validation of PCE

To ensure that flexible PCEs can be accurately interpreted and evaluated, they must adhere to the syntactic requirements of the Compositional Grammar and the semantic rules of the Concept Model defined by SNOMED International. In the initial step, the input PCE is checked for syntactic and semantic correctness using the HL7 FHIR service *$validate-code* and Ontoserver. Ontoserver, a FHIR-based terminology server provided by the Australian Commonwealth Scientific and Industrial Research Organization (CSIRO), supports and facilitates working with key coding systems such as SNOMED CT and LOINC (Logical Observation Identifiers Names and Codes) [11]. Additionally, Ontoserver provides an integrated description logic reasoner and full support for SNOMED CT postcoordination, enabling PCE validation directly on the Ontoserver [11]. Only if a PCE is both syntactically and semantically correct will the process automatically proceed to the next steps.

Determining Superconcept Candidates

OWL serves as an exchange format for ontologies and is used here to determine the ancestors of a PCE. OWL allows for the representation of complex knowledge about concepts and their interrelationships [27,28]. SNOMED CT can also be represented as an OWL ontology, with the definitions of individual SNOMED CT concepts provided as OWL expressions in the monthly release packages of SNOMED CT, alongside other formats [29].

To obtain SNOMED CT as an OWL ontology, the SNOMED OWL Toolkit [30] was used in the Release Format 2 of the International Edition, dated 2023-04-30 [31]. The generated ontology includes, among other components, precoordinated SNOMED CT concepts and their definitions in functional syntax.

PCEs, by contrast, are based on the syntax of the Compositional Grammar. Therefore, a PCE must be transformed into an OWL ClassExpression for further processing. For each component of the PCE, the corresponding OWL counterpart is determined based on the existing concept definitions, as shown in Table 1. An algorithm utilizing the Java (Oracle Corporation) library OWL API [32] is developed to automate this transformation. The result of the algorithm is an OWL ClassExpression structured similarly to the OWL ClassExpressions created by SNOMED International for SNOMED CT concept definitions. An exemplary OWL expression for a PCE is shown in Figure 3, with Fully Specified Names added for improved readability. The symbol ":" serves as a placeholder for the defined namespace, which in this case is "http://snomed.info/id/" [29].

Table 1. Various OWL[a] constructs are used for the representation of the components of a PCE[b]. While the components in the first 2 rows are exclusively used in the native OWL ontology of SNOMED CT[c], the OWL constructs below are also used for the transformation of PCEs.

PCE component	OWL construct
SNOMED CT concept	OWL Class
SNOMED CT attribute, attribute value: SNOMED CT concept	OWL ObjectProperty
Linking of ungrouped attribute relationships	OWL ObjectIntersectionOf
Linking between individual attribute relationships in a Role Group	OWL ObjectIntersectionOf
Linking between focus concept and all attribute relationships of ungrouped attributes and Role Groups	OWL ObjectIntersectionOf
Attribute relationship of attribute and SNOMED CT Identifier as attribute value	OWL ObjectSomeValuesFrom
All grouped attribute relationships and Role Group Identifier	OWL ObjectSomeValuesFrom

)
```

Output (direct superconcepts):

- 65124004 |Swelling (finding)|
- 15920521000119105 |Allergic reaction caused by tree nut (disorder)|

In the next step, the previously formed OWL ontology of SNOMED CT, the created PCE-specific OWL ClassExpression, and a description logic reasoner are used to classify the PCE within the existing SNOMED CT hierarchy. A reasoner generates new knowledge through logical inferences from the existing content of an ontology, such as determining superrelationships between concepts [27]. In this work, the ELK reasoner is used because it is one of the few reasoners capable of handling the extensive SNOMED CT ontology [33].

The direct ancestors of PCEs are determined using the ELK reasoner with the Java library elk-reasoner [33]. This process identifies at least one OWL Class corresponding to a precoordinated SNOMED CT concept. All identified precoordinated SNOMED CT concepts are considered potential Superconcept candidates.

Choosing Superconcept

Overview

One of the previously identified Superconcept candidates must be selected as the Superconcept. The Superconcept is the precoordinated SNOMED CT concept that most closely resembles the PCE, covering the largest portion of the information contained within the PCE compared with any other precoordinated SNOMED CT concept.

Semantic Similarity Measure

To identify the most similar concept, the semantic similarity between concepts is assessed. This measure calculates the taxonomic proximity between two elements within a knowledge base, such as SNOMED CT. Higher semantic similarity indicates that the two elements are more closely related [34].

While several semantic similarity measures have been proposed in the literature, this work uses a path-based approach developed by Sánchez and Batet [34]. This method is specifically designed for large knowledge bases with a subtype-relationship–based polyhierarchy, such as SNOMED CT [34]. The equation for the calculation is as follows:

where $T(c_i)$ is the set of all ancestors of a concept c_i and the concept c_i itself. To calculate the semantic similarity between two concepts c_1 and c_2, the ratio between the set of nonshared ancestors (nominator) and the union of all ancestors of both concepts (denominator) is considered [34].

In our work, the semantic similarity between the classified PCE and each of its Superconcept candidates needs to be calculated. Therefore, the equation is modified as follows:

with c_i being one of the Superconcepts. The calculated similarities for the exemplary PCE are shown in Table 2.

Table 2. To choose the most fitting Superconcept, the semantic similarity between the PCE[a] and each of its Superconcept candidates is calculated using the measure proposed by Sánchez and Batet [34]. The previously introduced exemplary PCE shares a larger ratio of ancestors with *Allergic reaction caused by tree nut* than with *Swelling*. Thus, the former leads to a higher semantic similarity and is determined as Superconcept.

Superconcept candidates	Nonshared ancestors	Union of all ancestors	Semantic similarity
Allergic reaction caused by tree nut	8	30	2.10
Swelling	29	30	0.10

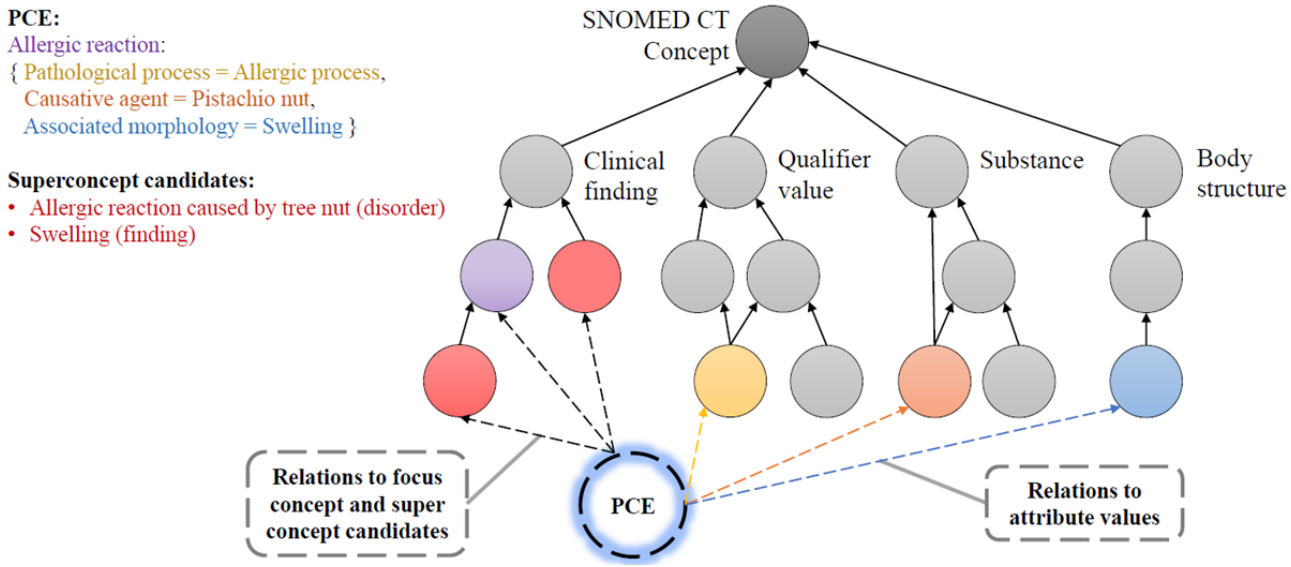
[a]PCE: postcoordinated expression.

Implementation

An algorithm was developed to select the most suitable (ie, the most semantically similar) SNOMED CT concept from the Superconcept candidates. The calculation of semantic similarity is based on the graph-based approach by Sánchez and Batet [34], as described above. To achieve this, SNOMED CT must first be transformed into a directed acyclic graph (DAG). The DAG was constructed by algorithmically processing the Release Format 2, version 2023-04-30 [31], of SNOMED CT using the Python (Python Foundation) library NetworkX [35]. In the resulting graph, SNOMED CT concepts are represented as nodes, while their relations, including relation types, form the connecting edges.

To enable semantic similarity calculation, the PCE must be temporarily inserted into the DAG. For this purpose, a node called “pce” is introduced into the graph as a subnode of its focus concept and the previously determined Superconcept candidates (Figure 4). The algorithm iterates over the individual attribute values of the PCE and inserts edges between these attributes and the “pce” node.

Figure 4. The PCE is represented as a subconcept of its focus concept and the Superconcept candidates. It also has edges to its attribute values. PCE: postcoordinated expression; SNOMED CT: SNOMED Clinical Terms.

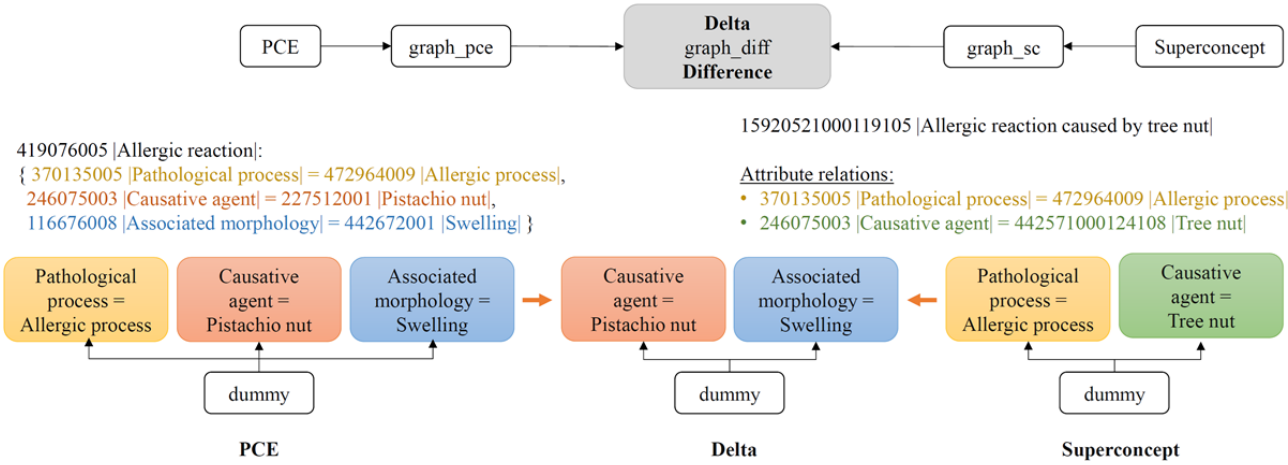


Next, the semantic similarity between the PCE and all potential Superconcept candidates is calculated based on the DAG. The Superconcept candidate with the highest semantic similarity describes the PCE most accurately among all precoordinated SNOMED CT concepts. This concept is then defined as the Superconcept.

Determining Delta

Although the Superconcept is the most similar precoordinated concept available in SNOMED CT, it does not cover all the information contained within the PCE. Therefore, the missing parts of information, referred to as the “Delta” between the PCE and the Superconcept, need to be determined. This is achieved using a graph-based approach, where both the attribute relations of the PCE and those of the Superconcept are represented in separate graphs. To facilitate merging later, a dummy root node with the same name is introduced into both graphs. Next, the attribute relations of the PCE and the Superconcept are added as nodes and connected via edges, as shown on either side of Figure 5. The Delta is then calculated by subtracting the edges of the Superconcept graph from the PCE graph. This process eliminates all equivalent components present in both graphs, leaving only the attribute relationships that are not or not precisely represented in the Superconcept graph (see the Delta graph in the middle of Figure 5).

Figure 5. When calculating the delta, the graph of the Superconcept is subtracted from that of the PCE. The determined edges contain attribute relations that were not covered by the Superconcept but are necessary for the precise representation of the PCE. PCE: postcoordinated expression.



Mapping to FHIR Elements

In the final step, the Superconcept and the Delta must be stored as precoordinated concepts in suitable FHIR elements. This can be accomplished using either the base FHIR resources from HL7 or more specific FHIR profiles. FHIR profiles are customized versions of FHIR resources tailored to national characteristics, legislation, or specific use cases [35].

In our work, 2 sets of FHIR profiles were considered as target representations for the mapping:

- profiles of the NASHIP (version 1.4.0, based on FHIR R4) [4] and
- profiles of the core data set of the German MII (version 1.0, based on FHIR R4) [5].

To accurately map a decomposed PCE to these profiled FHIR resources, mapping rules are required to align its Superconcept and Delta with the appropriate FHIR elements. As PCEs are often highly individualized, they can be categorized according to their focus concept, attribute relationships, and SNOMED CT Expression Templates. Consequently, it is not necessary to define a mapping rule for each PCE; instead, PCEs with similar content can be mapped using a uniform set of rules.

To demonstrate the applicability of our approach, we consider 5 content categories of PCEs from the top-level hierarchies *Procedure* and *Clinical finding*. These categories include *General procedures* for *Procedure* and *Allergies, Diseases due to allergy, Allergic reactions*, and *General clinical findings* for *Clinical finding*. To ensure the unambiguous assignment of PCEs, SNOMED CT's Expression Constraint Language (ECL) is used to formally define the scope of each category, creating pairwise disjoint partitions of the two hierarchies.

For each combination of 1 of the 5 content categories and either of the 2 sets of target representations, mapping rules are manually defined based on the respective Expression Templates [36], concept definitions of related precoordinated concepts, existing documents (as described in the "Related Work" section), and the author's expertise. These rules are formally transcribed into FHIR StructureMaps (R4) [37] using the Java library HAPI FHIR [38]. The resulting 10 FHIR StructureMaps are stored on a local HAPI FHIR server [39].

An excerpt of the FHIR StructureMap for the category "Allergic reaction" and the NASHIP profiles is shown in Figure 6. Each StructureMap contains exactly a single "rule" entry for the Superconcept and each relevant attribute relationship for the category. The mapping rule's "source" is either the string "Superconcept" or the SNOMED CT identifier of the respective attribute. For the "target" element, FHIRPath is used to traverse the FHIR resources and explicitly identify the correct subelement [2]. Illustrated in orange in Figure 6, the mapping of the attribute "Causative agent" ("246075003") to the FHIRPath *AllergyIntolerance.code* is exemplified. This specifies that the attribute value associated with the PCE should be stored in the code element of the *AllergyIntolerance* resource.

Figure 6. Extract of the FHIR StructureMap for allergic reactions in JSON format. It contains an entry for each SNOMED CT attribute and the Superconcept as well as references and names of the profiles. FHIR: Fast Healthcare Interoperability Resources; SNOMED CT: SNOMED Clinical Terms.

Mapping rule for each attribute or superconcept

References between FHIR resources

Names of FHIR profiles for respective resources

Apart from the central mapping rules, some further information is included in the FHIR StructureMaps.

If necessary, references between FHIR elements and resources are indicated (Figure 6, in pink). Additionally, the FHIR resources associated with the FHIRPath entries are mapped to the names of the respective profiles (Figure 6, in green).

With these general preparations completed, individual decomposed PCEs can now be mapped to appropriate FHIR resources. First, the PCE is assigned to 1 of the 5 content categories by identifying the subsuming subset using the ECL definitions and Ontoserver. Based on the category and desired target representation, the correct FHIR StructureMap is selected. The mapping rules in the StructureMap are then automatically

applied to the PCE's Superconcept and Delta, determining the combinations of FHIR elements and precoordinated SNOMED CT concepts needed for the alternative representation.

Ethics Approval

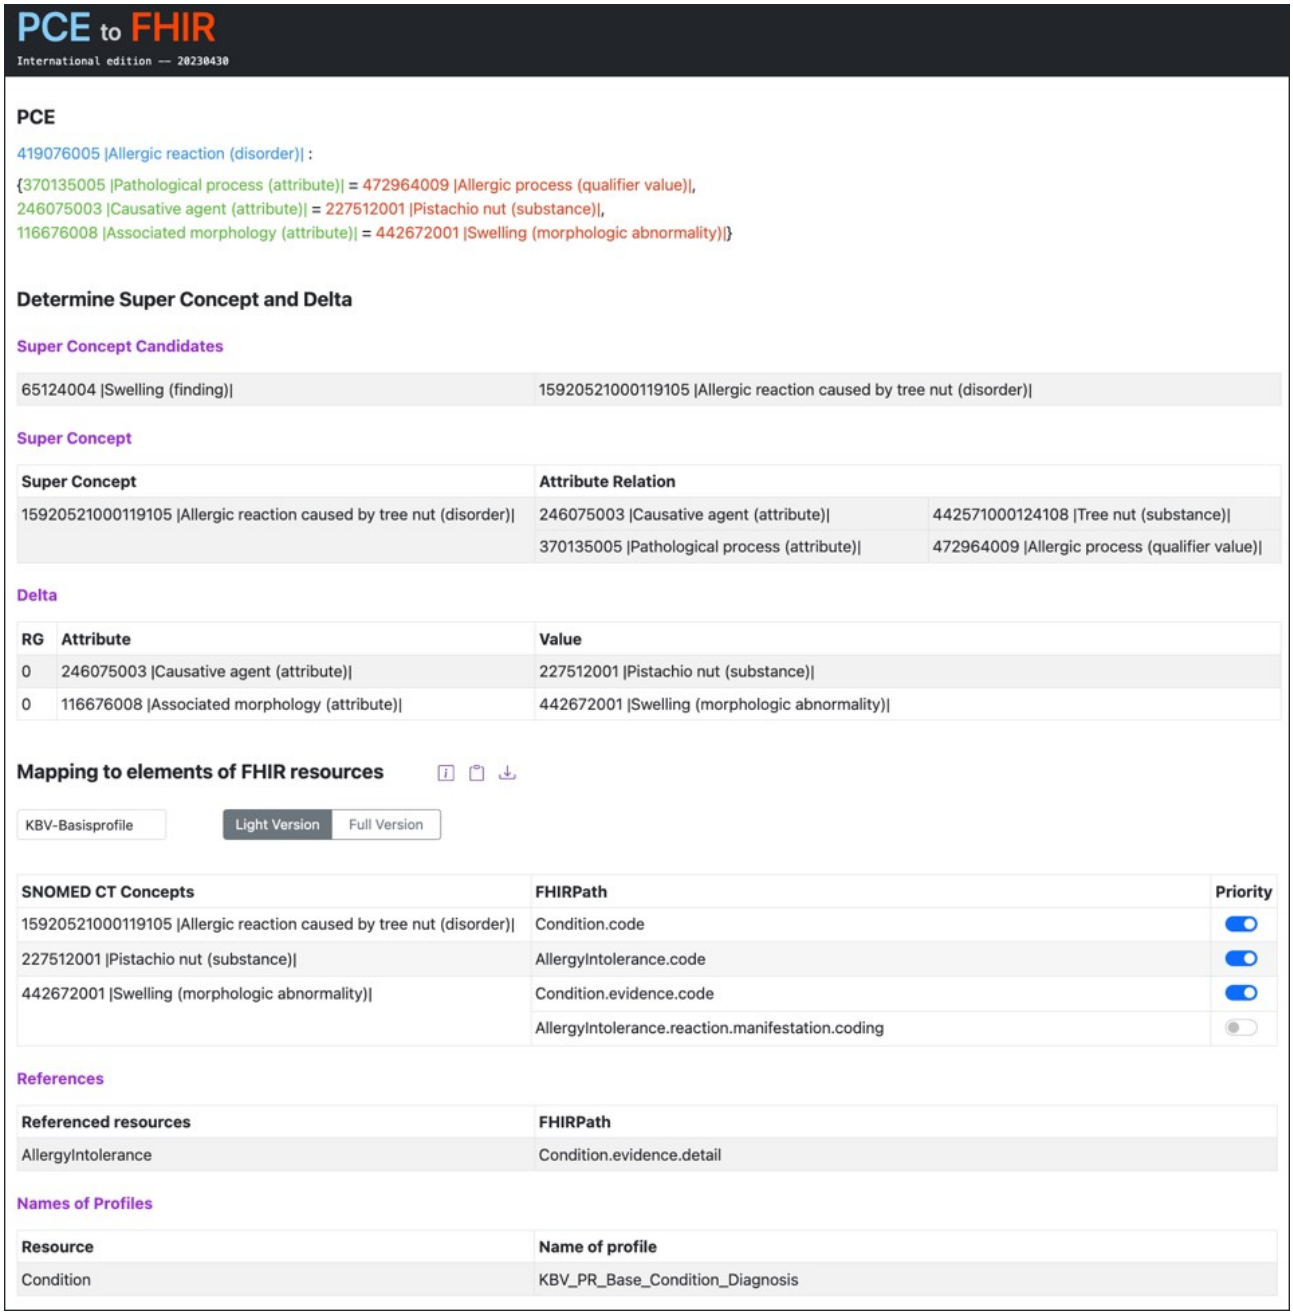
This research neither involves human nor animal subjects so ethics approval was not required.

Results

Web Application

Bringing all the previously explained preliminary considerations and processing steps together, a web application called "PCEtoFHIR" was developed (Figure 7). This single-page web application was built using Angular (version 15.2.2; Google LLC/Alphabet Inc.) and the Java framework Spring Boot (version 2.7.2; Java version 17).

Figure 7. Excerpt of the web application PCEtoFHIR. FHIR: Fast Healthcare Interoperability Resources; PCE: postcoordinated expression.



An excerpt of the web application is shown in Figure 7. After the entered PCE has been checked for syntactic and semantic correctness, the Superconcept candidates, the Superconcept, and the Delta are determined automatically. This information is displayed to the user in the "Determine Super Concept and Delta" section. The Superconcept and Delta are then mapped to FHIR elements according to the category-specific FHIR StructureMaps. The appropriate StructureMap is automatically determined for the PCE based on its content category and the desired mapping target is selected in a combo box. Figure 6 illustrates the target mapping category "KBV-Basisprofile" (KBV Base Profiles; Kassenärztliche Bundesvereinigung [KBV]

is the German abbreviation for the NASHIP). Using the StructureMap's mapping rules, the FHIRPaths, corresponding SNOMED CT concepts, required references, and profile names are displayed and can be copied to the clipboard or downloaded as a text file. This information is shown in Figure 7 in the section "Mapping to elements of FHIR resources."

The source code of PCEtoFHIR, the created FHIR StructureMaps, and all validation results as described in the following paragraphs are available on GitHub [40].

Determining Superconcept Candidates

To ensure the correct functionality of the algorithm for generating OWL ClassExpressions, validation was performed with 600 randomly selected precoordinated SNOMED CT concept definitions. These definitions, from the monthly release 2023-04-30 [31], were initially examined for diverse structures and then transformed into OWL ClassExpressions using PCEtoFHIR's regular algorithm. The generated OWL ClassExpressions was compared with the official OWL ClassExpressions of the concepts, available as part of the same SNOMED CT release, as reference data.

The comparison involved checking whether the OWL ClassExpressions matched syntactically and semantically. Focus concepts were excluded from the semantic validation because the reference data's OWL ClassExpressions are based on Stated Concept Definitions, while our approach uses Inferred Concept Definitions. Thus, the validation focused solely on whether the focus concepts were syntactically in the correct position within the OWL ClassExpression.

In summary, the comparison revealed no discrepancies between the OWL ClassExpressions generated by PCEtoFHIR and those from the reference data.

Choosing Superconcept

As described previously, a path-based measure by Sánchez and Batet [34] is applied to calculate semantic similarity in our work. A preliminary analysis was conducted to ensure both the theoretical and practical applicability of this measure.

SNOMED CT's most striking characteristics include its reliance on subtype relationships and the resulting, heavily interwoven polyhierarchy. Using a path-based approach that incorporates each concept's ancestors, these central features are prioritized. While several path-based semantic similarity measures are available [34], they mostly rely on the shortest path between concepts [41-44]. Sánchez and Batet [34] argue that in large knowledge bases such as SNOMED CT, a concept inherits information from several hierarchies and is connected to many concepts simultaneously. Therefore, considering only the shortest path is insufficient.

In their proposed measure, Sánchez and Batet [34] consider the ratio between the set of nonshared ancestors and the set of all ancestors of both concepts. Adapted to our approach, this means that for the PCE and each of its Superconcept candidates, all ancestors in the SNOMED CT hierarchy are determined, and the ratio is calculated. Thus, this measure is applicable in principle.

To evaluate if the calculated values are reasonable beyond that, a practical validation by means of an exemplary sample was done in succession. For 33 PCEs taken from a publication by Kate [45] (see detailed explanation in the "Overall Evaluation With Existing PCEs" section), the most similar Superconcept candidate was determined manually and compared with the Superconcept calculated by PCEtoFHIR via Sánchez and Batet's semantic similarity measure. In 76% (25/33) of the cases, the same Superconcept was chosen [34]. An analysis of the remaining 24% (8/33) revealed that different information components within the PCE were prioritized during Superconcept selection (eg, favoring localization over procedure type), but the divergent choices made by the algorithm were considered plausible. Consequently, the measure by Sánchez and Batet [34] was found to be feasible for Superconcept determination and is therefore used to calculate semantic similarity in this work.

Mapping to FHIR Elements

As previously described, the Basisprofile of the NASHIP (version 1.4.0) [4] and the profiles of the Core Data Set of the MII (version 1.0) [5] were used for mapping to the FHIR profiles. To illustrate the mapping, 5 categories were considered. For each category and profile type, a FHIR StructureMap was created, resulting in a total of 10 FHIR StructureMaps. Table 3 shows the FHIR resources used for the mapping.

Table 3. Utilization of different FHIR[a] resources per profile type, organized by content category.

Category and profile type	FHIR resources

For the category of general *Clinical finding*, the FHIR StructureMaps include mappings for the Superconcept and the following 5 SNOMED CT attributes: *Causative agent*, *Finding site*, *Associated morphology*, *Pathological process*, and *Clinical course*. In addition to the 5 SNOMED CT attributes, the following attributes were considered for the remaining *Clinical finding* categories focusing on allergies: *Has realization*, *Occurrence*, and *Due to*. Furthermore, for the hierarchy *Procedure*, mapping rules for the Superconcept and the following 12 additional SNOMED CT attributes are established: *Method*, *Procedure site—Direct*, *Procedure site—Indirect*, *Direct substance*, *Direct morphology*, *Using substance*, *Using device*, *Using access device*, *Has intent*, *Access*, *Surgical approach*, and *Has focus*.

Table 4 shows an example of the mapping of SNOMED CT elements to FHIRPath for Allergic reactions. The complete set of mapping rules and the associated StructureMaps are available online [46].

Table 4. The SNOMED CT elements and the associated FHIRPath for the category "Allergic reaction" based on the profiles of the NASHIP[a].

SNOMED CT element	FHIRPath in NASHIP profiles
Super concept	• Condition.code
Causative agent	• AllergyIntolerance.code

[a]NASHIP: National Association of Statutory Health Insurance Physicians.

To ensure their correctness, the created FHIR StructureMaps were validated by author AE, who had not been involved in the PCEtoFHIR project up to that point. AE possesses in-depth knowledge of FHIR and SNOMED CT and is profoundly familiar with the MII and NASHIP profiles due to her former and current work. She validated the FHIR StructureMaps based on the definitions of the profiles used, ensuring the correct choice of profiles, the accurate mapping of SNOMED CT elements to FHIRPaths, and appropriate references. The validation yielded the following results: the choice of profiles and references was found to be entirely correct. The mapping rules between SNOMED CT elements and FHIR paths were largely correct as well; however, 8 suggestions for improvement were provided. These suggestions were reviewed by the other authors, and the FHIR StructureMaps were updated accordingly based on their agreement.

Lastly, the finalized FHIR StructureMaps were analyzed for their coverage of the SNOMED CT attributes listed above. Table 5 illustrates the number of attributes per category that could be successfully mapped in the respective profile (mappable). Depending on the category, up to 4 attributes could not be mapped to the native profiles (unmappable). For some of these attributes, existing FHIR extensions, such as those from HL7, can be introduced into the profiles to achieve a more complete mapping (with extension). Overall, between 56% (5/9) and 92% (12/13) of attributes (76.1% on average) can be mapped without modifications, depending on the category and profile. By introducing these extensions, coverage could be increased to an average of 93.5% (ranging from 67% [6/9] to 100% [eg, 9/9, 6/6, 13/13, for individual combinations]).

Table 5. The number of SNOMED CT elements that can be mapped directly to the profiles are represented by “mappable,” whereas elements that cannot be mapped are shown as "ummappable". FHIR[a] offers extensions to map items that are not mappable by default, which could reduce the number of unmappable elements. The number of unmappable elements to represent by extension is shown in the last column.

Category: number of elements (total)	Profile type	Number of mappable elements (total)	Number of unmappable elements	
			Total	Could be mapped using extensions
Allergies: 9 elements				
	NASHIP[b]	5	4	1
	MII[c]	5	3	2
Disease due to allergies: 9 elements				
	NASHIP	7	2	2
	MII	7	2	2
Allergic reaction: 9 elements				
	NASHIP	7	2	2
	MII	7	2	1
Clinical finding (general): 6 elements				
	NASHIP	4	2	2
	MII	4	2	2
Procedure: 13 elements				
	NASHIP	12	1	1
	MII	12	1	1

Overall Evaluation With Existing PCEs

After validating several steps individually, the entire process of PCEtoFHIR was evaluated. To achieve a realistic scenario, 35 existing PCEs from the publication “Automatic Full Conversion of Clinical Terms into SNOMED CT Concepts” by Kate et al [45] were used, which are available online [50]. This publication presents a method for converting clinical texts into SNOMED CT PCEs, with the 35 PCEs manually created from clinical terms for a small-scale evaluation (see the “4.3. Evaluation Methodology” section in [45]).

To use this data set as input for PCEtoFHIR, the 35 provided PCEs were manually reviewed and automatically checked for syntactic and semantic correctness, as described previously. As a result, 2 PCEs were excluded from further processing: 1 for violating cardinality restrictions of the Concept Model and 1 for being equivalent to another. The remaining 33 PCEs include 23 from the top-level hierarchy *Clinical finding* and 10 from the top-level hierarchy *Procedure.* The following SNOMED CT attributes are used:

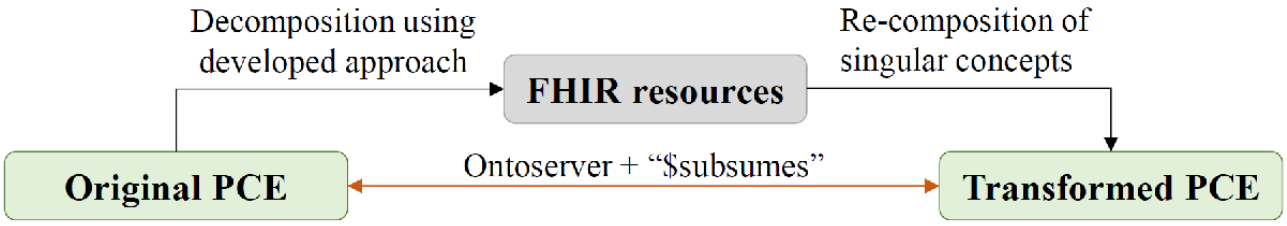
- *Clinical finding: Associated morphology, Finding site, Causative agent, Clinical course, Finding method,* and *Pathological process*
- *Procedure: Method, Procedure site—Direct, Using device,* and *Using substance*

These 33 PCEs were imported into PCEtoFHIR in bulk, bypassing the web front end but using the developed algorithm as usual. Each PCE was decomposed into a Superconcept and Delta, with FHIRPaths determined using the appropriate FHIR StructureMap. Based on these FHIRPaths, the corresponding attribute values were populated into FHIR resources, which had been prefilled with additional required data elements (such as references to a FHIR resource “Patient”). The resulting FHIR resources for each PCE were then stored on the local HAPI FHIR server [39].

To determine whether all information contained within the original PCE has been successfully translated into the FHIR resources, the process shall now be reversed as shown in Figure 8. Based on the separate precoordinated SNOMED CT concepts spread across multiple FHIR elements, a PCE will be recomposed and compared with the original. For this, the values of the stored FHIR resources were extracted, and the respective StructureMap was applied in the reverse direction. The recomposed PCE uses the Superconcept as the focus concept, while its refinement consists of attribute relationships with the extracted SNOMED CT concepts as attribute values. For each of the extracted concepts, the corresponding SNOMED CT attribute must be determined according to the StructureMap’s mapping rules. As most mappings are inherently unidirectional [3], using them in the reverse direction can lead to several possible SNOMED CT attributes for some FHIRPaths. In these

cases, the 3 rules listed in Textbox 2 are applied successively until a clear distinction is achieved.

Figure 8. Validation process: The original PCE is decomposed by PCEtoFHIR as usual, and accordingly stored in FHIR resources. Based on this representation, the singular concepts are recomposed into a second PCE. The original and the recomposed PCE are compared. FHIR: Fast Healthcare Interoperability Resources; PCE: postcoordinated expression.



Textbox 2. Rules applied for case distinction.

- **By attribute value range**

For each of the attributes in question, a value range is defined by the SNOMED Clinical Terms Concept Model. This allows checking if the extracted concept falls within the respective value range and is thus a valid value for the corresponding attribute. If only a single value range matches, the correct attribute is identified.

- **By attribute hierarchy**

Some SNOMED CT attributes are organized hierarchically (eg, *Procedure device—Using device—Using access devices*). If multiple attributes from the same hierarchy are available, the most general attribute within this hierarchy is selected (in this case: *Procedure device*).

- **By occurrence heuristic**

The concept definitions of precoordinated concepts are analyzed to identify which SNOMED CT attribute is most frequently used for the given concept. The attribute with the highest statistical occurrence is selected.

Finally, each recomposed PCE was compared with the corresponding original PCE as a reference by testing their subsumption relationship via Ontoserver and the FHIR service $subsumes. For 32 of the 33 comparisons, the PCEs were evaluated as equivalent, indicating that no information was lost during the process. In the remaining comparison, the recomposed PCE was found to be a subclass of the original. Further analysis revealed that while some semantic precision was lost due to the required case distinctions, the FHIR representation achieved through PCEtoFHIR remained semantically equivalent to the original PCE. The approach thus proved successful, demonstrating the preservation of a PCE's content.

Discussion

Principal Findings

This work aimed to develop an algorithm for generating alternative representations of SNOMED CT PCEs. The "Introduction" section discussed various reasons for the reluctance to use PCEs, including the preference for editing and saving individual codes. Precoordinated concepts offer the advantage of a single code representing a medical circumstance, along with a human-readable description. These aspects are seen as advantages when using precoordinated concepts but are not present in postcoordination. However, by identifying a Superconcept using OWL and semantic similarity, a precoordinated SNOMED CT concept that most accurately describes the PCE can be determined. The PCE, as a subconcept of this Superconcept, can then be effectively displayed and analyzed. In addition, the decomposition of the PCE results in individual codes that users are familiar with from practical experience. FHIR, recognized as a central interoperable data standard in health care, is gaining increasing importance both in Germany [51] and globally [51-53].

The calculation of semantic similarity is crucial for identifying the concept most similar to a PCE. In this work, the measure by Sánchez and Batet [34] was selected due to its suitability for SNOMED CT's polyhierarchies and multiple inheritances. While this measure has been validated as effective, other approaches to semantic similarity calculation could also be considered. Although choosing an appropriate Superconcept is important, any remaining information is represented through the Delta, so alternative semantic similarity measures would have minimal impact on the overall functionality of PCEtoFHIR. However, PCEtoFHIR could be enhanced by allowing users to manually select or adjust the Superconcept.

As described above, the Superconcept and the Delta are stored in the relevant FHIR profiles, within their corresponding elements. For this purpose, the profiles of the NASHIP [4] and the profiles of the core data set of the MII [5] were utilized. However, the approach can also be adapted to other profiles. As shown in Table 5, depending on the content category and profile type, between 56% (5/9) and 92% (12/13) of attributes could be mapped directly to the respective profile without modifications, demonstrating a high coverage of content but also highlighting some gaps.

An analysis of the unmappable attributes revealed that these relations mostly concern very specific details that occur infrequently in precoordinated concept definitions. As PCEs are generally constructed based on existing concept definitions,

they are unlikely to regularly utilize these highly specific attributes. SNOMED CT, however, provides the capability to include medical facts at such a granular level. By contrast, HL7 FHIR was designed with a pragmatic approach, focusing on the most prevalent information. This fundamental design discrepancy accounts for the majority of mapping challenges.

Nevertheless, as intended by the FHIR standard, suitable extensions from HL7 are available to appropriately represent some of these attribute relations (see Tables 4 and 5) and could be integrated into the profiles to extend their coverage of PCE content. Currently, the core data set lacks a profile for the FHIR resource AllergyIntolerance, which limits the representability of this content category. However, because the core data set is an ongoing modeling initiative, such a profile may be added in the future.

Apart from the unmappable attributes, the proposed mapping rules cannot always ensure an exact translation. In some cases, there is no precisely matching FHIR element for a specific attribute, or multiple attributes must be mapped to the same element (eg, *Using access device* and *Using device* can both only be recorded via the FHIR element *Device.type*, which is then referenced via *Procedure.usedReference*). As a result, some semantic precision may be lost. Therefore, it is advisable to store the original PCE in the metadata of the FHIR representation to ensure the preservation of the original meaning.

Nevertheless, the outlined difficulties in achieving a semantically equivalent representation through FHIR elements highlight the precision attainable through SNOMED CT's postcoordination, underscoring its importance for detailed medical data description.

Several validations were conducted to ensure the correctness of both the individual processing steps and the overall functionality of PCEtoFHIR. Although a large data set from SNOMED International's releases could be used to firmly validate the OWL expression generation, other evaluations required preexisting real-world PCEs of specific content categories, which are not readily available. The employed set of 35 PCEs meets these criteria and effectively facilitates our validation approaches. However, the limited number and semantic variance of these exemplary PCEs suggest that incorporating additional reference data could enhance the significance of the results.

Another validation included the manual review of the FHIR StructureMaps by a FHIR expert. This review revealed only minor inaccuracies, which were corrected in the current version of StructureMaps. Using these StructureMaps, the mapping for the considered categories was successfully completed and can be extended to other subhierarchies of SNOMED CT without difficulty. Hence, further possibilities of application may be considered, such as addressing the TermInfo problem. As mentioned, the choice between representing medical facts in a terminology or an information model often varies and depends on the intended use. For example, "Fracture of the left femur" can either be represented using a single PCE as the FHIR element *Condition.code* like

- *Condition.code: 71620000:{363698007=722738000}*
  (Fracture of femur : {Finding site = Structure of bone of left femur})

or by splitting the semantic meaning up into two precoordinated SNOMED CT concepts using further element-code-combinations of the FHIR resource *Condition*:

- *Condition.code: 71620000 |Fracture of femur (disorder)|*
- *Condition.bodySite: 722738000 |Bone structure of left femur (body structure)|*.

This variability in expressing medical facts was leveraged in the presented approach, enabling flexible transformation between terminology-focused and information model–focused representations. This allows for an alternative when replacing PCEs and may help address some challenges related to the TermInfo problem. By enabling flexible switching between different expression methods, semantic interoperability is maintained regardless of the representation paradigm used in an electronic health record. Additionally, this approach facilitates the plausibility check of recorded medical information by allowing the integration of disjointed elements (eg, scattered across various FHIR elements) into a single *interpretable* expression.

Despite the general ambiguity regarding the scope of semantic versus structural standards, some specific recommendations do exist, such as the suggestion that "contextual meaning should rather be represented via the information model" [54]. Contrarily, concepts within the SNOMED CT hierarchy *Situation with explicit context* encompass contextual information that extends beyond the typical scope of a terminology, such as suspected diagnoses, procedures not done, or family history facts. This additional contextual information can affect logical conclusions. An explanation of the reasons behind this, involving epistemological versus ontological components of meaning, is beyond the scope of this paper (see [3,13]). Based on the logical definitions of concepts directly related to PCEs, the approach presented in this paper enables the extraction of problematic pieces of information and their storage within separate elements of the information model. As a result, a concept like *165008002 |Allergy testing not done (situation)|* could be represented by separating the epistemological aspect "not done" into the suitable FHIR element *Procedure.status*:

- *Procedure.code: 252512005 |Allergy test (procedure)|*
- *Procedure.status: not-done* (according to the required HL7 FHIR ValueSet).

In this way, the integrity of SNOMED CT's hierarchies may be preserved.

Conclusions

The use of PCEs greatly enhances SNOMED CT's capacity to capture medical details comprehensively. However, despite its advantages, postcoordination has not yet been widely adopted in routine data collection. To address this, PCEtoFHIR offers a solution to ensure semantic interoperability between systems that are adept at postcoordination and those that are not, by leveraging the globally accepted HL7 FHIR standard to provide an alternative representation. State-of-the-art techniques in description logic and terminology services are integrated into

a largely automated web application that decomposes PCEs into their core components. Validation of both individual steps and the overall process confirms the approach's functionality. PCEtoFHIR is designed and implemented modularly, positioning it for future adaptations in the evolving landscape of health informatics. In addition to straightforward extensions to other SNOMED CT hierarchies or FHIR profiles by adding more StructureMaps, the algorithm can be adapted to work with other information models, such as openEHR or relational databases. The approach also holds the potential for addressing further challenges in semantic and structural standards, such as the TermInfo problem. By reversing the processing direction—from FHIR elements back to PCE—meaningful SNOMED CT-based analyses could be facilitated.

Abstract

Background: Event analysis is a promising approach to estimate the acceptance of medication alerts issued by computerized physician order entry (CPOE) systems with an integrated clinical decision support system (CDSS), particularly when alerts cannot be interactively confirmed in the CPOE-CDSS due to its system architecture. Medication documentation is then reviewed for documented evidence of alert acceptance, which can be a time-consuming process, especially when performed manually.

Objective: We present a new automated event analysis approach, which was applied to a large data set generated in a CPOE-CDSS with passive, noninterruptive alerts.

Methods: Medication and alert data generated over 3.5 months within the CPOE-CDSS at Heidelberg University Hospital were divided into 24-hour time intervals in which the alert display was correlated with associated prescription changes. Alerts were considered “persistent” if they were displayed in every consecutive 24-hour time interval due to a respective active prescription until patient discharge and were considered “absent” if they were no longer displayed during continuous prescriptions in the subsequent interval.

Results: Overall, 1670 patient cases with 11,428 alerts were analyzed. Alerts were displayed for a median of 3 (IQR 1-7) consecutive 24-hour time intervals, with the shortest alerts displayed for drug-allergy interactions and the longest alerts displayed for potentially inappropriate medication for the elderly (PIM). Among the total 11,428 alerts, 56.1% (n=6413) became absent, most commonly among alerts for drug-drug interactions (1915/2366, 80.9%) and least commonly among PIM alerts (199/499, 39.9%).

Conclusions: This new approach to estimate alert acceptance based on event analysis can be flexibly adapted to the automated evaluation of passive, noninterruptive alerts. This enables large data sets of longitudinal patient cases to be processed, allows for the derivation of the ratios of persistent and absent alerts, and facilitates the comparison and prospective monitoring of these alerts.

KEYWORDS

clinical decision support system; CDSS; medication alert system; alerting; alert acceptance; event analysis

Introduction

Computerized physician order entry (CPOE) systems with integrated clinical decision support systems (CDSS) can reduce medication errors by highlighting critical medication constellations [1]. To realize their full potential, medication alerts must be recognized and followed by users. Hence, measuring “alert acceptance” is a key prerequisite for evaluating the effectiveness of a CDSS.

In principle, two methods can estimate alert acceptance: (1) in-dialog analysis where users interactively click to accept or override displayed alerts; and (2) event analysis where the medication chart and associated documentation are reviewed for evidence of alert acceptance through further actions (“events”) responsive to the alert (eg, discontinued medication orders), which often requires extensive manual screening [2]. Most studies addressing alert acceptance used in-dialog analyses because the display of alerts, especially in English-speaking countries, is part of the technical architecture of the CPOE-CDSS [3]. There is limited evidence on how to perform event analyses because it is uncertain whether the prescribing behavior is influenced by alerts or other clinical therapeutic circumstances (eg, scheduled end of treatment) [2]. Moreover, the manual screening of the medication documentation is a time-consuming process [4], especially when administrative

processes such as changing wards and the simultaneous transfer of physicians' responsibility for the medication are considered in the alert presentation.

As CDSS installations presenting passive, noninterruptive alerts become increasingly popular in European countries [5,6], the need for developing and validating techniques for automatic event analyses is increasing. This is particularly important when considering all alerts throughout the inpatient stay.

We present a new approach to perform an automated event analysis, which was applied to a large data set of medication alerts.

Methods

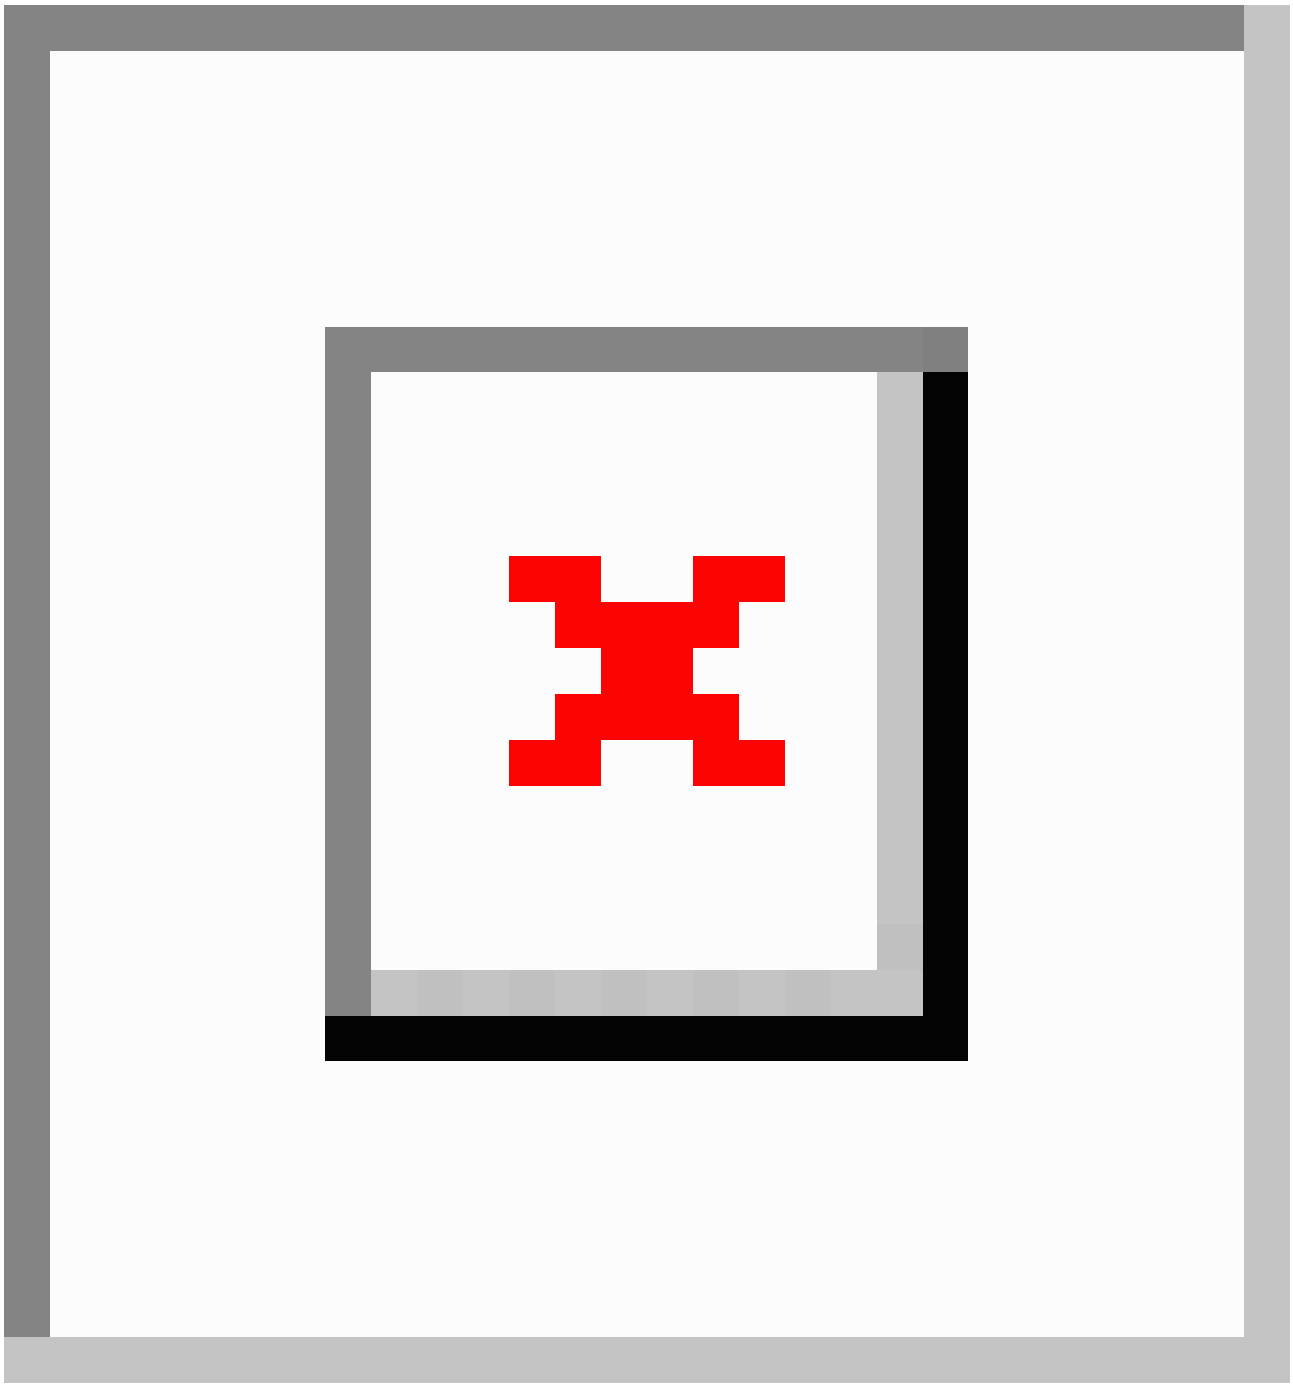
Ethical Considerations

Study approval was granted by the responsible Ethics Committee of the Medical Faculty of Heidelberg University (S-467/2020) and by the local data protection officer for the data protection concept. Human subjects were not directly involved; all data were pseudonymized and could neither be linked to individual patients nor to prescribers.

Setting

We analyzed the prescription and alert data issued over 3.5 months during routine care at Heidelberg University Hospital (a 2500-bed tertiary care hospital) within the local CPOE (*i.s.h.med Smart Medication*, Oracle Cerner, North Kansas City, USA) with an integrated CDSS (AiD*Klinik*, Dosing GmbH, Heidelberg, Germany). To view the presented passive and noninterruptive alerts, users actively navigate from their prescription screen to a separate window that opens upon request. In this window, all alerts are displayed in a single table sorted by severity and presented with a brief summary (Figure 1). Users are required to click on each alert to access more detailed information. The system does not recognize whether an alert has been viewed. Additionally, users are not obliged to directly flag alerts as accepted or overwritten. Therefore, these data are not available in our CPOE-CDSS. Implemented alert types comprised checking for drug-drug interactions (DDIs), drug-allergy interactions (DAIs), duplicate prescriptions (DPs), advanced dosing recommendations for potentially inappropriate medication for the elderly (aged ≥65 years, PIM), or prescriptions exceeding the maximum recommended daily dose (PE-MDDs).

Figure 1. Schematic display of an exemplary alert window listing all alerts for a patient in a table. Each alert is presented in a separate line, sorted by severity, with the most severe alerts listed first. The first column displays the alert type in a color-coded scheme (black=contraindicated, red=severe, orange=moderate), followed by an explanation for the severity, a brief description of the problem, and the name of the causative drug.



Data Collection

The relevant parameters extracted from the CPOE-CDSS were information on prescriptions, issued alerts, administrative patient data, and setting data. Prescription schedules with regimen changes were documented as separate entries so that prescriptions potentially resulting from previous prescriptions (eg, because of dose reduction or conversion of fixed to as-needed prescriptions) could be linked retroactively. Follow-up prescriptions were defined as prescriptions of the same drug and administration route when the previous prescription ended and the subsequent one started within 10 minutes.

Alert Management

In this CDSS, prescriber review of alerts may result in alerts disappearing due to prescription changes and adaptations or in alerts being continuously displayed for unchanged prescriptions.

In this methodology, alerts are defined as “absent” when they disappear during continuous prescriptions for which underlying risk constellations no longer exist (eg, dose reduction of an overdosed prescription but the prescription itself remains continuous). In contrast, alerts consistently displayed until patient transfer, discharge, or end of the prescription are categorized as “persistent” (eg, the prescription remains valid

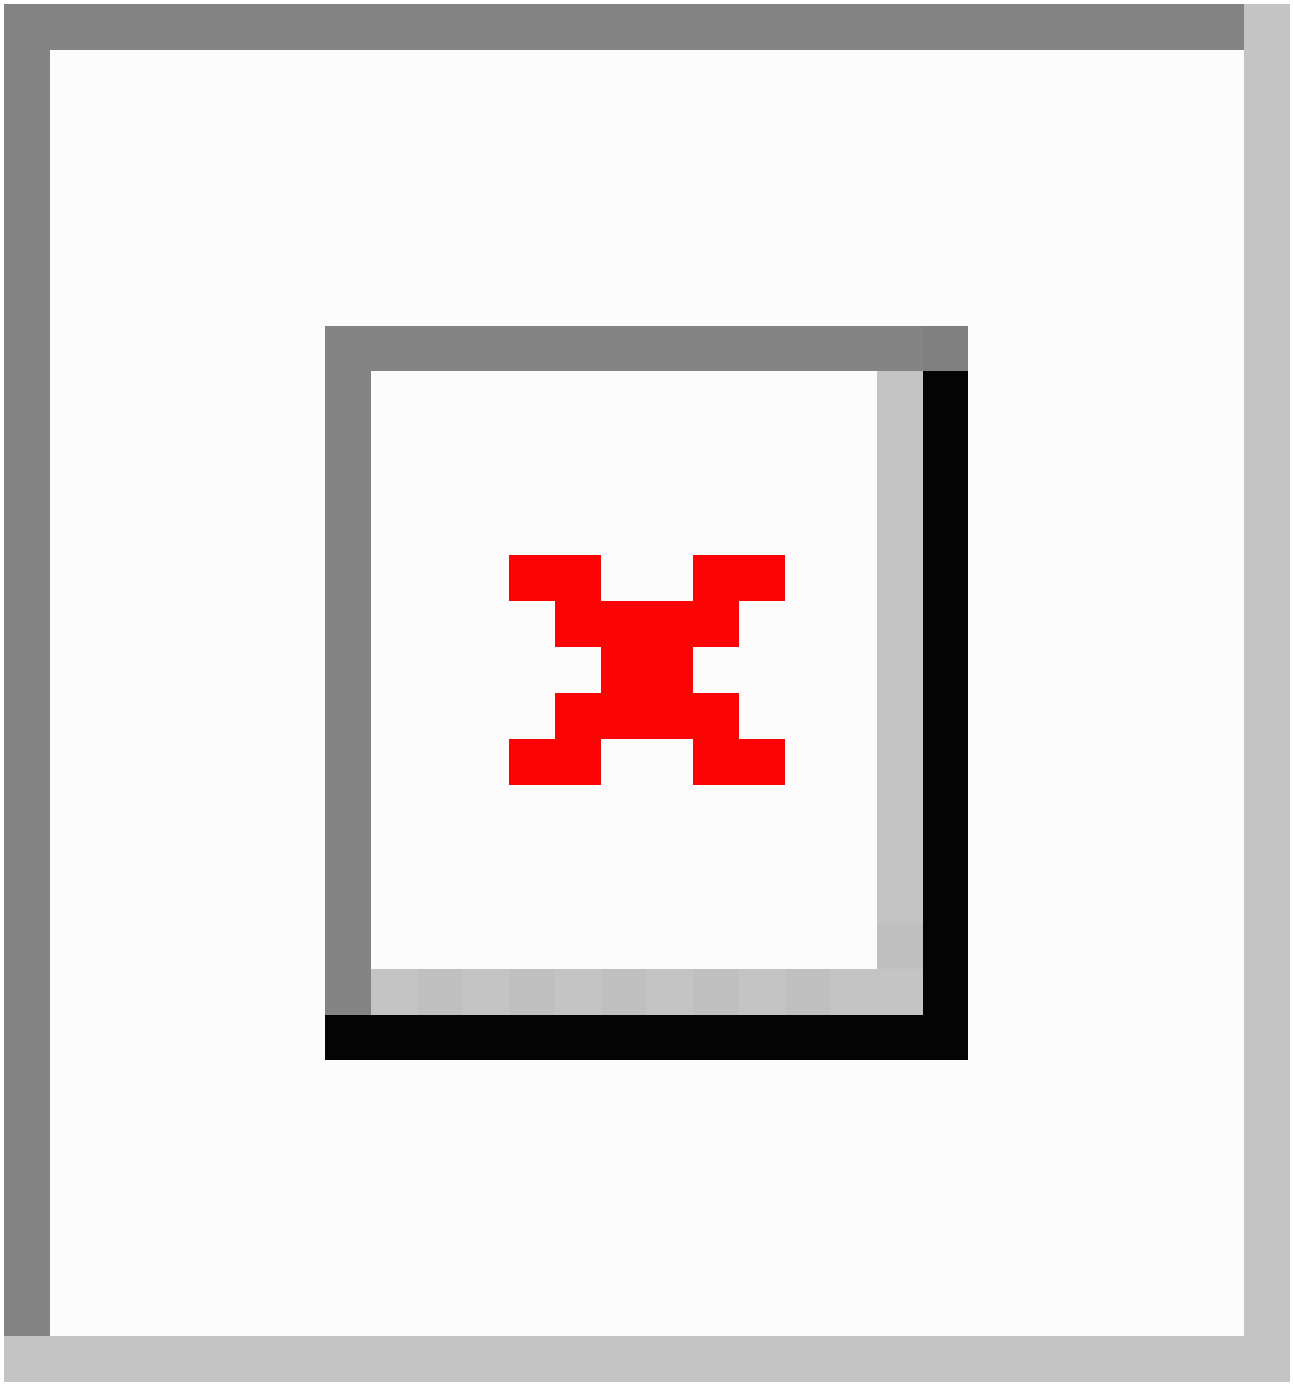
even though the prescribed active ingredient is alerted by a DAI).

Data Analysis

To automatically identify absent alerts, the medication and corresponding alert data were divided into 24-hour time intervals. Since reproducible time stamps were lacking in the database, selection of this conservative interval allowed the retroactive linkage of alert display and associated changes in the corresponding prescription. Therefore, two consecutive time intervals were compared according to whether or not the alerts were continuously displayed. Alerts were excluded if (1) they were first displayed on the discharge day (Figure 2, Alert 4); (2) required user interaction (eg, answering questions to decide whether conditions for alerts are present); or (3) were triggered by one-time prescriptions, in which case the alert response cannot be assessed the next day (Supplementary Methods section A and Figure S1 in Multimedia Appendix 1). The display duration of alerts (DDoA) was calculated from the time interval between the first and last alert display (Figure 2). Further details on the development of the 24-hour time intervals can be found in Supplementary Methods section B in Multimedia Appendix 1; examples of data analysis of different alert types are provided in Tables S1-S3 and Figure S2 of Multimedia Appendix 1.

Based on the exploratory rates of absent alerts, basic descriptive statistics were applied. The χ^2 test was performed to evaluate whether absent alerts differed stratified by alert types considering a two-tailed P value <.05 as significant (IBM SPSS Statistics version 25, Ehningen, Germany). The R packages *gpmodels* [7], *survival*, and *ggplot2* (version 4.1.2, R Foundation for Statistical Computing, Vienna, Austria) were used for data analysis and visualization.

Figure 2. Proposed methodology for identification of absent alerts, exemplified for a 5-day inpatient stay. Each midnight (dotted lines), all alerts displayed within the last 24-hour time interval were identified. Alert 1 is displayed between day 1 (admission) and day 4; the display duration of alerts (DDoA) is 4 days. Alert 2 is displayed from day 2 until discharge; the DDoA is 4 days. Alert 3 is displayed only on day 3; the DDoA is 1 day. Alert 4 is displayed for the first time on the day of discharge and remained until discharge; the DDoA is 1 day. Alert 4 was excluded from the analysis because, due to the discharge, there is no subsequent (sixth) 24-hour time interval with which the fifth interval could have been compared to evaluate the alert display. Each alert could be identified because of a unique alert ID code. Using this identification concept, alert IDs detected within a 24-hour time interval could be compared to alerts detected in the previous 24-hour time interval. Therefore, it was possible to automatically classify which alerts were (1) newly displayed (no matching ID in the previous interval: Alert 1, Day 1), (2) displayed for more than 24 hours (matching ID in consecutive intervals; Alert 1, Days 2-4), or (3) absent (no matching ID in the current 24-hour time interval: Alert 1, Day 4).



Results

Alert Display and Composition

We considered the data of 1670 patient cases (Figure S3 in Multimedia Appendix 1) with a median hospital stay of 7 days (IQR 4-13). During this time, 13,979 alerts were displayed. Because 2284 alerts (16.3%) were triggered by one-time prescriptions and 267 alerts (1.9%) were first displayed on the discharge day, the remaining 11,428 alerts (81.8%) formed the basis for analysis. The alert types triggering the alerts are shown in Table 1.

The median DDoA was 3 days (IQR 1-7) and varied by alert type, with alerts for DAIs showing the shortest DDoA (Table 1).

Table . Alert types triggering the alerts, corresponding rates of absence, and display duration of the alerts.

Alert type	Triggered alerts, n (%)[a]	Absent alerts, n (%)[b]	Display duration of alerts (days), median (IQR; range)
Alerts for duplicate prescriptions	7643 (66.9)	3674 (48.1)	3 (1-8; 1-31)
Alerts for drug-drug interactions	2366 (20.7)	1915 (80.9)	2 (1-5; 1-31)
Alerts for drug-allergy interactions	517 (4.5)	416 (80.5)	1 (1-2; 1-24)
Alerts for potentially inappropriate medication for the elderly	499 (4.4)	199 (39.9)	4 (2-8; 1-31)
Alerts for prescriptions exceeding the maximum recommended daily dose	403 (3.5)	209 (51.9)	3 (1-6; 1-30)
Total number of alerts	11,428	6413	3 (1-7; 1-31)

[a]Percentages are based on the total number of analyzed alerts (N=11,428).

[b]Percentages are based on the number of analyzed alerts for each alert type.

Absent and Persistent Alerts

From all 11,428 analyzed alerts, 43.9% (n=5015) persisted and 56.1% (n=6413) were absent, with alerts for DDIs showing the highest rate of absence (80.9%) and PIMs the lowest (39.9%) (Table 1).

The proportions of absent alerts differed significantly between the individual alert types (P_{χ^2}<.001), except for DDI alerts compared to DAI alerts (P_{χ^2}=.80) and for DP alerts compared to alerts for PE-MDDs (P_{χ^2}=.14). The proportion of absent alerts in relation to the DDoA was the highest for DAI alerts and the lowest for alerts for PIMs in the first 24 hours after admission (Figures S4-S5 in Multimedia Appendix 1).

Discussion

Principal Findings

A new methodological approach for routine care data was applied performing an automated event analysis that is transferable to other CPOE-CDSS with passive, noninterruptive alerts. In previous studies using event analyses, alert acceptance rates were identified at the drug administration level [8], prescription level [9], or at both levels [10]. There is general consensus that alert acceptance rates vary widely depending on the measuring method and study setting, resulting in different and incomparable rates [11]. Since in-dialog analysis is often not possible in a European CPOE-CDSS, this new methodology adapted to the technical structures of such a CPOE-CDSS is needed.

A key strength of the proposed method is that it variably adjusts the time intervals and consequently the lookback windows underlying the method's programming. Thus, temporary changes in prescriptions within the determined time interval (here 24 hours) are considered persistent alerts; however, this CPOE-CDSS interrupts the alert display in certain cases, such as when patients change wards and responsibility for medication is handed over to another physician. This transfer results in automatic prescription pauses that are actively suspended by physicians, technically leading to the redisplay of alerts. Without the definition of this time interval, these pauses would incorrectly increase the overall number of alerts when reappearing and the rate of absent alerts as they disappear for a few hours during valid prescriptions. Hence, this method considers administrative processes of the daily clinical routine and guarantees that only alerts of real prescription changes are evaluated. For retrospectively matching the time-dependent correlations of the alerts over time and in the clinical routine, it is essential to consider alerts throughout the inpatient stay and our proposed method meets this need.

However, according to the technical architecture of this CPOE-CDSS, there is no obvious link between reviewing alerts and possible resulting changes in prescription data. Therefore, various assumptions had to be made for this data evaluation. Alerts were categorized as either persistent or absent based on the assumptions that alerts were regularly checked and that alerts disappeared because underlying risk constellations no longer existed due to previously displayed alerts. This general assumption may overestimate the rate of actual alert acceptance, as a prescribed medication could be switched based on patient conditions (eg, adverse events, intolerance) or treatment schedules. As it remains unclear whether the change in drug prescriptions was caused by the alert display or due to other variables and because no control group was available due to the retrospective design, caution is required when interpreting absolute numbers and comparing the proportion of absent alerts to previously published acceptance rates. In the future, this retrospective method will need to be prospectively evaluated including validity measurements by comparing the results of this automated approach with those derived from manual screening. Another limitation is that this study was conducted in a single center with a CPOE-CDSS that is highly specific and strongly adapted to workflows and care processes at our institution. This analysis only considered alerts at the prescribing level and did not measure whether the respective drugs were indeed administered. For instance, many of the alerts for DPs were triggered by drugs that were prescribed as as-needed prescriptions. Hence, these DPs tended to indicate a variety of treatment options rather than actually being administered together. This might have contributed to the reduced occurrence of the absence of alerts for DPs on a prescribing level compared to other alerts. However, in our CPOE-CDSS, it is unalterably

stipulated that medication alerts are implemented in a passive and noninterruptive way. While it may be challenging to transfer this complex method to systems with differing data infrastructures, to our knowledge, this is the first automated method for processing persistent and absent medication alerts in a system with passive, noninterruptive alerts. Additionally, since this method was programmed in a modular way, it seems feasible to transfer and adapt it to other settings.

Conclusions

A methodology was applied to an automatic event analysis in a CPOE-CDSS with passive, noninterruptive alerting. This enables the processing of large data sets of longitudinal periods of inpatient stays and can be used to automatically derive the percentage of absent alerts. Once implemented, this analysis can be repeated at any time and one could even imagine that real-time monitoring of persistent alerts in daily clinical routines could be set up using these data for future optimization of the CPOE-CDSS.

Abstract

Background: Systematic literature review (SLR), a robust method to identify and summarize evidence from published sources, is considered to be a complex, time-consuming, labor-intensive, and expensive task.

Objective: This study aimed to present a solution based on natural language processing (NLP) that accelerates and streamlines the SLR process for observational studies using real-world data.

Methods: We followed an agile software development and iterative software engineering methodology to build a customized intelligent end-to-end living NLP-assisted solution for observational SLR tasks. Multiple machine learning–based NLP algorithms were adopted to automate article screening and data element extraction processes. The NLP prediction results can be further reviewed and verified by domain experts, following the human-in-the-loop design. The system integrates explainable articificial intelligence to provide evidence for NLP algorithms and add transparency to extracted literature data elements. The system was developed based on 3 existing SLR projects of observational studies, including the epidemiology studies of human papillomavirus–associated diseases, the disease burden of pneumococcal diseases, and cost-effectiveness studies on pneumococcal vaccines.

Results: Our Intelligent SLR Platform covers major SLR steps, including study protocol setting, literature retrieval, abstract screening, full-text screening, data element extraction from full-text articles, results summary, and data visualization. The NLP algorithms achieved accuracy scores of 0.86-0.90 on article screening tasks (framed as text classification tasks) and macroaverage F1 scores of 0.57-0.89 on data element extraction tasks (framed as named entity recognition tasks).

Conclusions: Cutting-edge NLP algorithms expedite SLR for observational studies, thus allowing scientists to have more time to focus on the quality of data and the synthesis of evidence in observational studies. Aligning the living SLR concept, the system has the potential to update literature data and enable scientists to easily stay current with the literature related to observational studies prospectively and continuously.

Introduction

Systematic literature reviews (SLRs) are widely recognized as a robust method to identify and summarize evidence from published sources [1]. However, conducting an SLR can be a complex, time-consuming, labor-intensive, and expensive task, depending on the breadth of the topic, level of granularity, or resolution of the review needed [2,3]. One recent study estimated the time and cost required to conduct an SLR can be as high as 1.72 person-years of scientist effort and approximately $140,000 per review [4]. Because SLRs are so resource intensive, it is difficult to stay up to date, and once an SLR is complete and new literature is published, the SLR may become incomplete and obsolete as time goes by.

Natural language processing (NLP) refers to artificial intelligence (AI) technologies that can extract structured information from textual documents such as medical charts, lab results, and many other types of unstructured text. NLP has significantly advanced a variety of biomedical applications in recent years. There is considerable community interest in using AI such as machine learning (ML) and NLP to improve automation in aspects of literature reviews [2,5-7]. For example,

Thomas et al used NLP to identify randomized controlled trials for Cochrane reviews, and Wallace et al developed methods to extract sentences from literature related to clinical trial reports. There are also some SLR management software, such as Raynan.ai [8], which leverages NLP to expedite certain SLR steps, including article screening.

Despite these existing efforts, there is a lack of systematic and integrated NLP solutions for SLR to cover its full aspects, preventing the wide adoption of such tools in SLR projects.

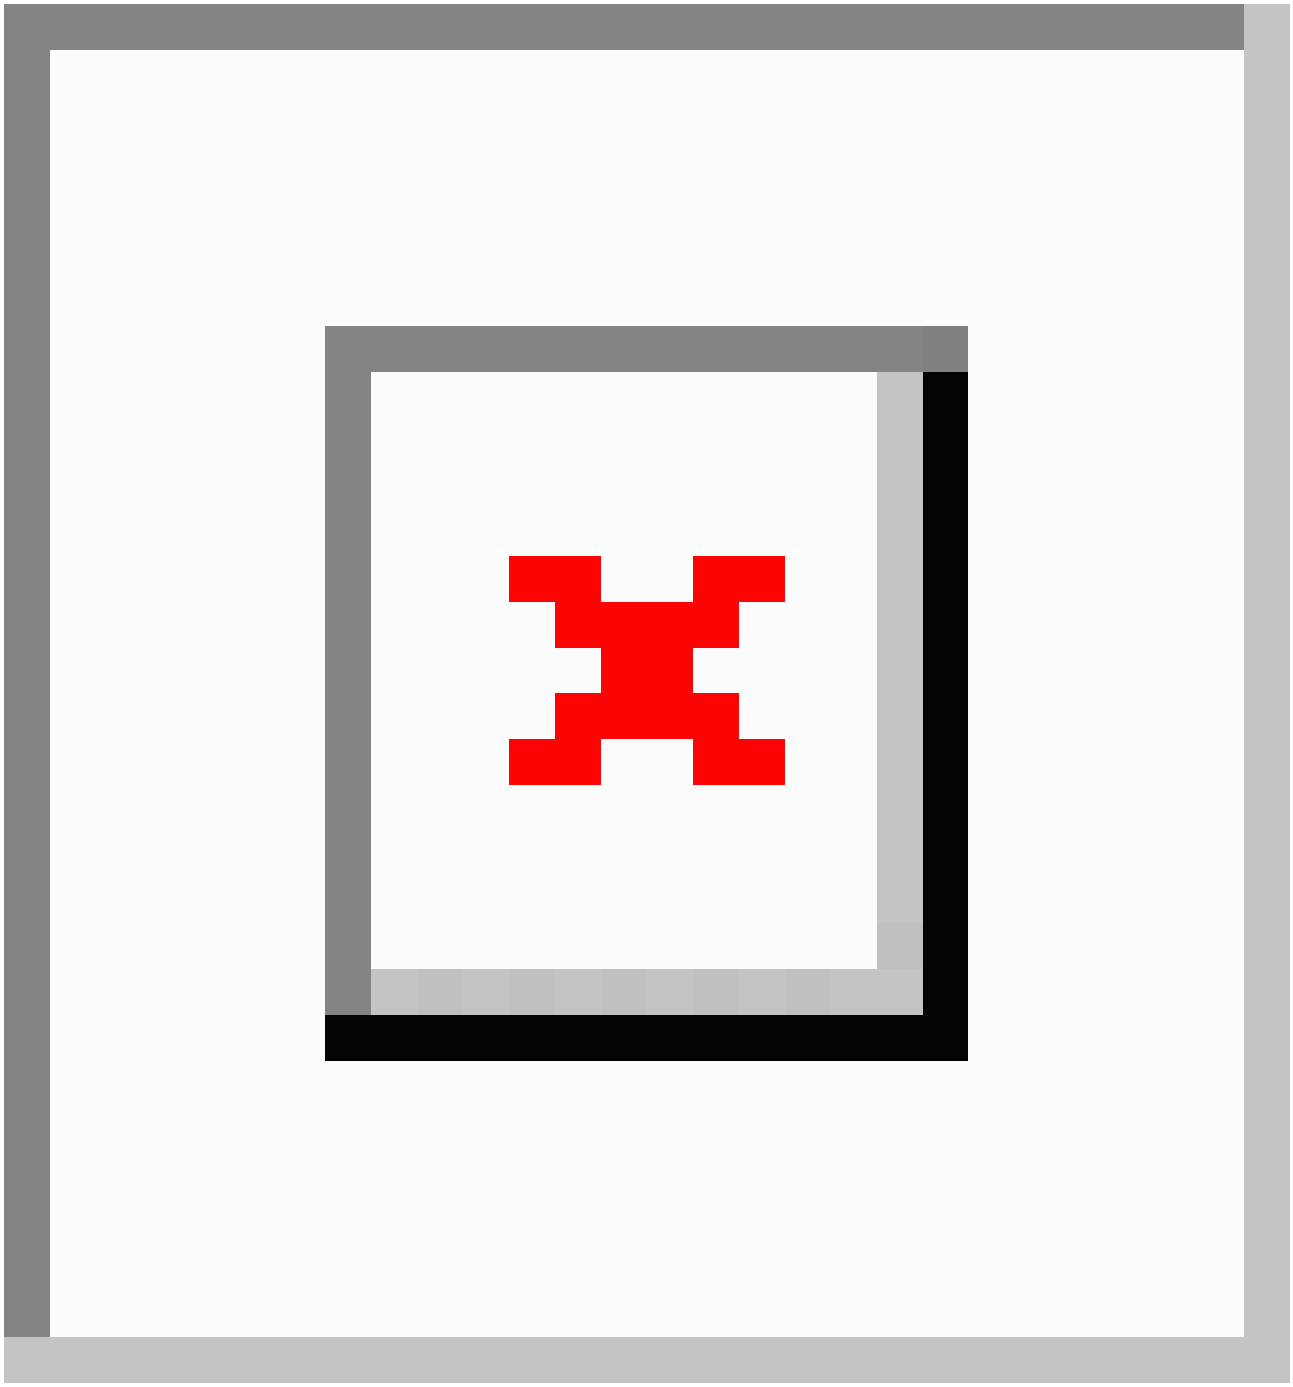
Thus, in this study, we evaluated an intelligent SLR system (hereinafter referred to as ISLR) for observational SLR tasks. The use of NLP improves efficiency, while the human-in-the-loop approach improves accuracy and reduces errors. The system uses cutting-edge NLP tools that employ ML and deep learning (DL) approaches to expedite the time-consuming processes involved in an SLR by making a series of learned recommendations to the end user. The purpose of this study is to evaluate an AI tool that accelerates and streamlines the SLR process and to demonstrate the validity of this tool in 3 use cases.

Methods

Workflow and System Architecture

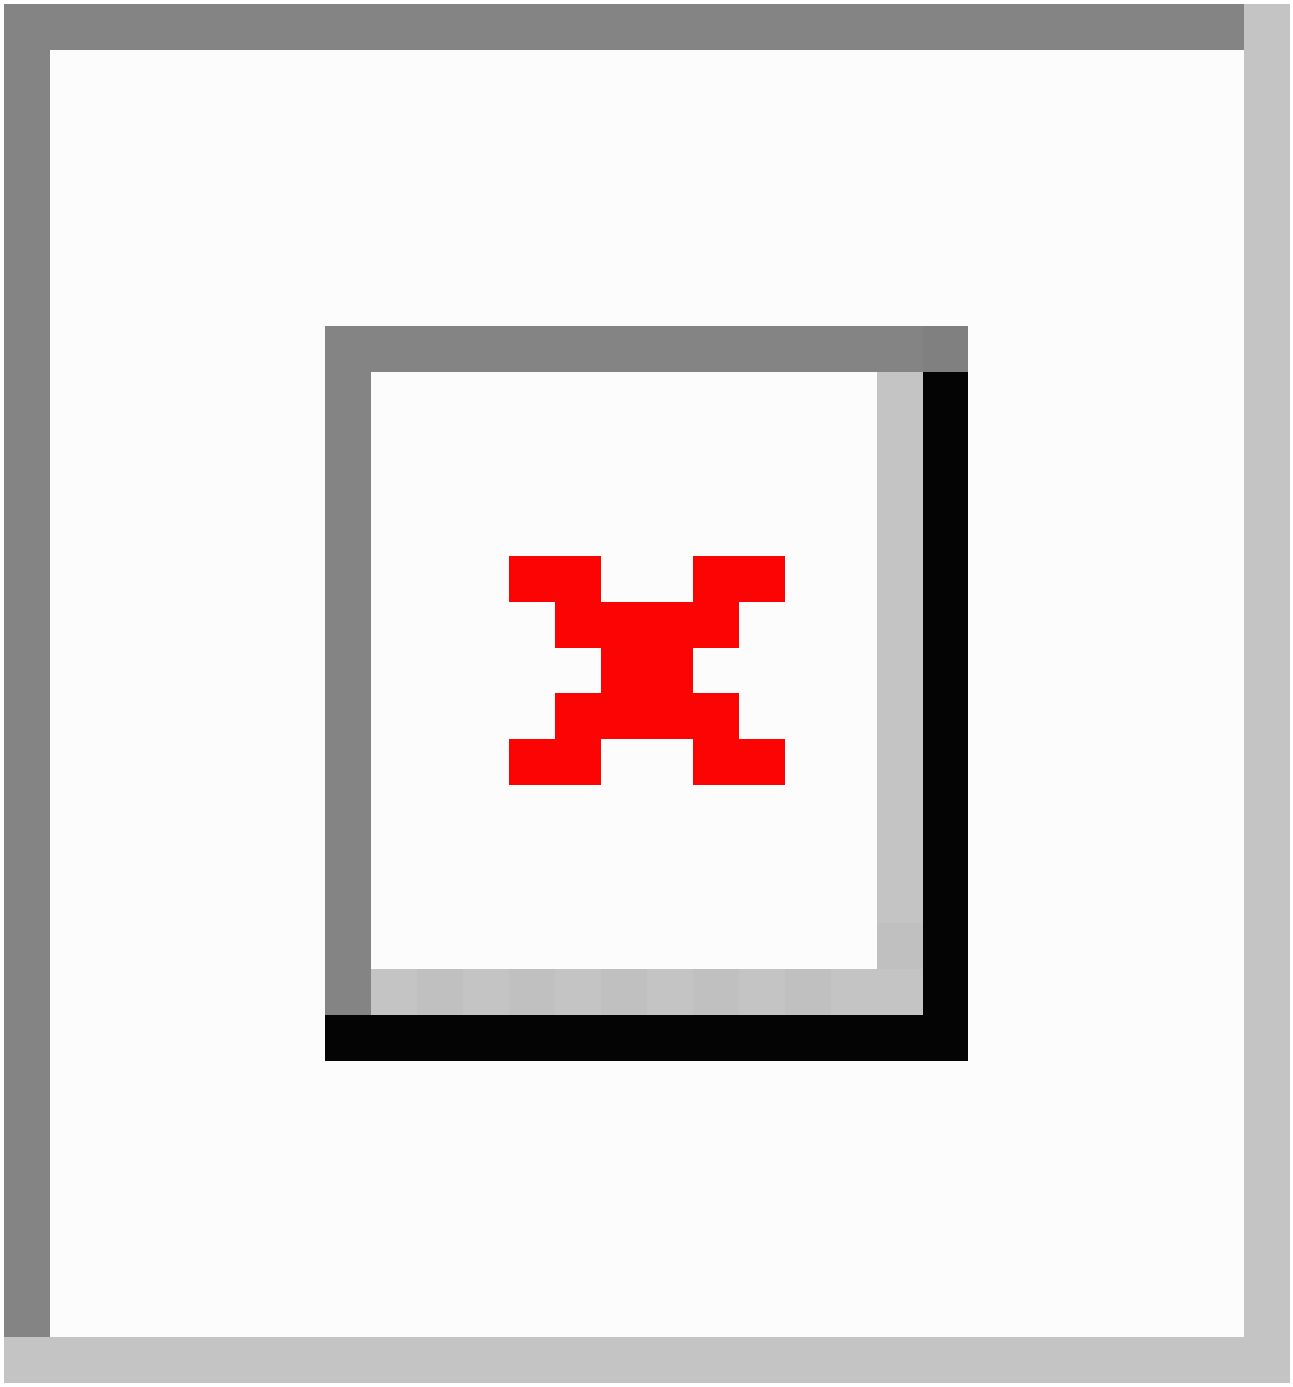
ISLR has 2 major views that target 2 types of users in the observational studies in an SLR lifecycle: (1) an intelligent SLR workbench for literature reviewers who conduct routine literature reviews, and (2) a living literature data dashboard for researchers and analysts who focus on analyzing SLR data and keep up to date on new evidence. Figure 1 shows the overview architecture, including the 2 major views and data flow of the SLR system. ISLR integrates AI technologies and an SLR workflow management system to support literature collection, screening, and data extraction. The living literature dashboard continuously searches and updates the SLR, allowing users to interactively navigate the updated literature and develop new insights.

Figure 1. Overall data flow architecture of ISLR demonstrating the 2 major views. AI: artificial intelligence; ISLR: intelligent systematic literature review; SLR: systematic literature review.



Reliable NLP systems depend heavily on the development of a reasonable workflow, user interfaces, and high-performance NLP algorithms. To develop the system and define the system workflow and user interfaces, we collaborated with end users who are experts in SLR using an iterative approach that employed industry-standard agile methodology. The team identified 6 major functional areas that were essential for the application: (1) protocol specification assistance, (2) literature search and indexing, (3) abstract screening with NLP assistance, (4) support for full-text searching, uploading, and screening, (5) full-text data element extraction using NLP assistance to identify and extract relevant data elements from full-text and embedded tables, and (6) literature data visualization to enable users to assess the SLR results and perform data discovery. Figure 2 shows the system workflow and the embedded NLP services to expedite two of the most time-consuming steps, which are article screening and data element extraction.

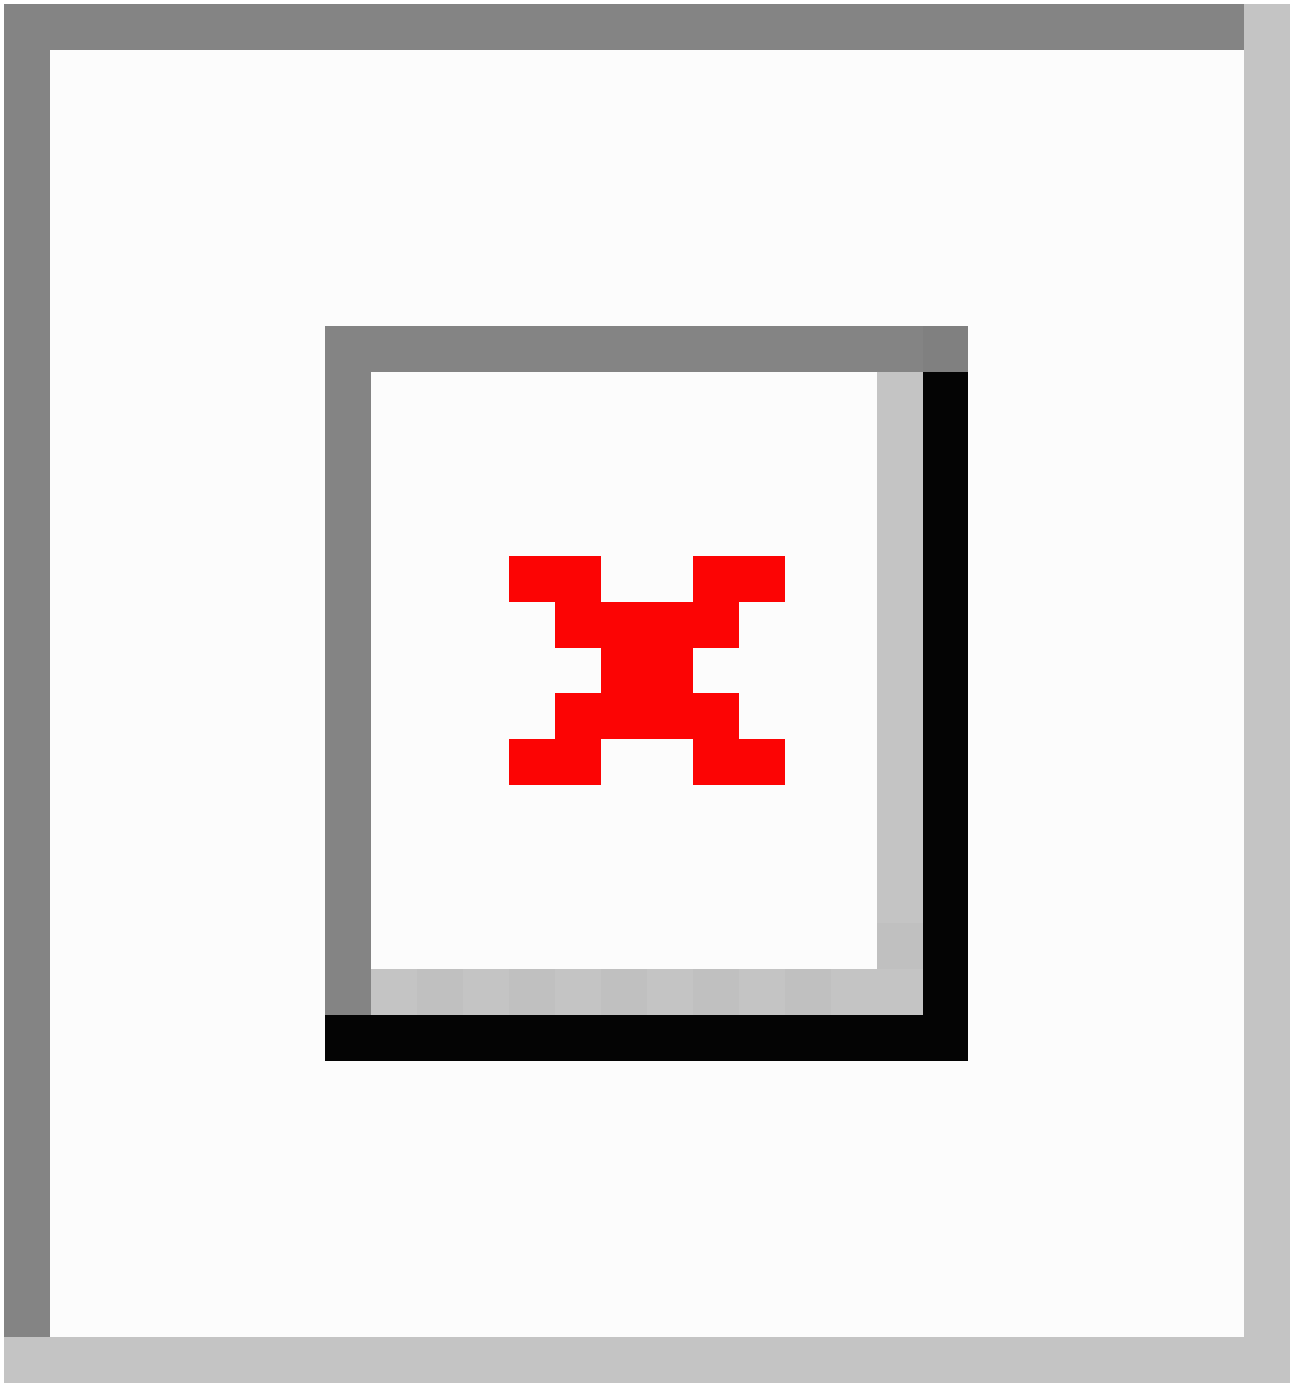
Figure 2. ISLR workflow and embedded NLP engines. ISLR: intelligent systematic literature review; NLP: natural language processing.



Development and Validation of NLP Algorithms

As mentioned earlier, 2 sets of NLP algorithms are required for a specific SLR project, including abstract screening and full-text data element extraction. Figure 3 outlines the NLP algorithm development process for these 2 steps separately. For abstract screening, the first step is to annotate and build a corpus that includes the abstract text, citation metadata, and inclusion/exclusion status. Once the corpus is prepared, NLP algorithm training, evaluation, and selection can be performed, and the best-performing algorithms will be chosen for deployment.

Figure 3. SLR NLP algorithm development steps. NLP: natural language processing; SLR: systematic literature review.



Similar to abstract screening, the NLP algorithm for the full-text data element extraction also requires a complete NLP development lifecycle. Unlike abstract screening, where labeled corpora may be available from previous SLR projects, data annotation is required to curate a labeled data set for training and evaluating NLP algorithms. The best-performing algorithms will be selected for deployment after evaluation. The following figure describes details on NLP algorithm development and validation process for SLR projects.

Three previously completed SLRs were used to guide and validate NLP development. These 3 projects included: (1) the prevalence of human papillomavirus (HPV) detected in head and neck squamous cell carcinomas (referred to as *HPV Prevalence*); (2) the epidemiology of the pneumococcal disease (referred to as *Pneumococcal Epidemiology*), and (3) the economic burden of pneumococcal disease (referred to as *Pneumococcal Economic Burden*). The inclusion and exclusion criteria for these 3 SLRs can be found in Table S1 in Multimedia Appendix 1.

Developing the Abstract Screening Corpora

Abstract screening was treated as a binary document classification task, ie, inclusion or exclusion of the article based on the abstract. Consequently, it was necessary to select and train NLP models for the task that demonstrated adequate performance and that had a reasonable computational time. The annotated screening literature sets from the 3 previous SLRs were used as the gold standard to train and validate models,

including 1697, 207, and 421 articles for *HPV Epidemiology*, *Pneumococcal Epidemiology*, and *Pneumococcal Economic Burden*, respectively. The corpora contained citation metadata, including title, authors, Medical Subject Heading terms [9], and the text of the corresponding abstracts.

Developing the Full-Text Data Element Extraction Corpora

We selected 190, 25, and 24 full-text articles for *HPV Prevalence*, *Pneumococcal Epidemiology*, and *Pneumococcal Economic Burden* for annotation, respectively. Based on the key outcome variables defined in the 3 SLRs, we annotated 12 types of data elements, covering information related to general observational studies, such as *Study Population*, to disease-specific information such as *HPV Lab Technique* and *Pneumococcal Disease Type*.

Abstract Screening NLP Algorithms

For abstract screening, the NLP model classifies each article for its relevance based on its title, abstract, and other citation meta data. To build the abstract screening module, we evaluated 4 traditional ML-based document classification algorithms, XGBoost [10], support vector machines [11], logistic regression [12], and random forest [13] on the binary inclusion/exclusion classification task for abstract screening. The abstract screening corpora were used to evaluate NLP models by calculating standard metric of *precision (fraction of relevant instances among the retrieved instances, also called positive predictive value*), *recall (fraction of relevant instances that were retrieved, also called sensitivity*), *accuracy*, and *F1 scores* (the harmonic mean of precision and recall). The full features include title, abstract, authors, keywords, journal, Medical Subject Heading term, and publication types. We concatenated all features and extracted the term frequency-inverse document frequency vector as feature representation.

Data Element Extraction NLP Algorithms

To construct the module for data element extraction, we treated the problem of data element recognition and extraction as a named entity recognition (NER) problem, which aims to recognize the mentions of entities from the text [14]. We evaluated a series of NLP algorithms consisting of ML and DL algorithms to recognize and extract data elements from full text, including (1) conditional random fields (CRFs), a classic statistical sequence modeling algorithm that has been widely applied to NER tasks [15,16]; (2) long short-term memory (LSTM), a variation of recurrent neural networks that has achieved remarkable success in NER tasks [17,18]; and (3) "Clinical BERT (Bidirectional Encoder Representations from Transformers)" [19], a novel transformer-based DL model. Standard metrics, including *precision*, *recall*, *accuracy*, and *F1 scores*, were calculated.

Ethical Considerations

This is not applicable as this study is not human subjects research.

Results

Here, we report the results of the construction of the annotation corpora and the results of the NLP algorithm for abstract screening and data element extraction, respectively.

Abstract Screening Corpora Description

The *HPV Prevalence* corpus we constructed from the existing SLR project contained 1697 total citations, of which 538 were included, and 1159 were excluded due to study criteria. The constructed *Pneumococcal Epidemiology* contained 207 citations, of which 85 were included and 122 were excluded. The constructed *Pneumococcal Economic Burden* corpus contained 421 citations, of which 79 were included, and 342 were excluded.

Abstract Screening NLP Evaluation Results

Extensive studies have shown the superiority of transformer-based DL models for many NLP tasks [20-23]. Based on our experiments, however, adding features to the pretrained language models did not significantly boost their performance. The performance comparison results for each task are shown in Table 1. XGBoost achieved the highest accuracy on *HPV Prevalence* and *Pneumococcal Economic Burden* tasks, while a support vector machine achieved the highest accuracy on *Pneumococcal Epidemiology* task. XGBoost was ultimately chosen for deployment due to its better generalizability.

Table . Comparison of article screening natural language processing model performance.

Task and algorithm	F1 score	Precision	Recall	Accuracy
HPV Prevalence **(n=1697)**				
XGBoost	0.808	0.769	0.851	0.888
Support vector machine	0.727	0.781	0.681	0.859
Logistics regression	0.684	0.897	0.553	0.859
Random forest	0.523	0.944	0.362	0.818
Pneumococcal Economic Burden **(n=421)**				
XGBoost	0.750	0.857	0.667	0.907
Support vector machine	0.533	0.667	0.444	0.667
Logistics regression	0.333	0.667	0.222	0.831
Random forest	0.429	0.600	0.333	0.814
Pneumococcal Epidemiology **(n=207)**				
XGBoost	0.667	0.533	0.889	0.619
Support vector machine	0.667	0.667	0.667	0.861
Logistics regression	0.429	0.600	0.333	0.619
Random forest	0.615	1.000	0.444	0.762

Full-Text Data Element Extraction Corpora Description

The human annotators annotated 190, 25, and 24 full-text articles for the *HPV Prevalence*, *Pneumococcal Epidemiology*, and *Pneumococcal Economic Burden* tasks, respectively. Among these full-text articles, 4498, 579, and 252 entity mentions were annotated for 3 projects, respectively. However, the distribution of annotated entities is highly imbalanced. For example, data elements like *HPV Lab Technique* and *HPV Sample Type* were very prevalent, but data elements like *Maximum/Minimum Age in Study Cohort* were rarely annotated in the corpora.

Results of the Full-Text Screening and Data Element Extraction NLP Methods

Tables 2 and 3 show the comparison of NLP performance among CRFs, LSTM, and BERT on the 3 corpora. For each of the 3 corpora used to train the NLP models, LSTM demonstrated superiority over the conventional ML algorithm (ie, CRF) on entity recognition. Among DL models, we did not observe significant improvement in F1 scores by use of the BERT model. The BERT model achieved similar or worse performance on most data elements. The performance across different tasks varies, primarily due to the availability of annotated data. For example, on average, models' performance on *HPV Prevalence* is higher than *Pneumococcal Epidemiology* and *Pneumococcal Economic Burden*, as *HPV Prevalence* has the largest annotated data. Due to the highly imbalanced distribution of annotated entities, we observe a variation in performance across different data elements for the same model. For example, in the *Pneumococcal Epidemiology* task, the LSTM model has achieved 0.412 in the identification of the *Study Cohort* and 0.768 in the identification of the *Pneumococcal Disease Type*.

Table . Overall performance comparison for the named entity recognition task in the 3 natural language processing training corpora. Scores averaged across all 12 extracted data elements. Measured in lenient F1 score.

Measure	*HPV Prevalence*			*Pneumococcal Epidemiology*			*Pneumococcal Economic Burden*		
	CRF[a]	LSTM[b]	Clinical BERT[c]	CRF	LSTM	Clinical BERT	CRF	LSTM	Clinical BERT
Microaverage (global average that uses the total number of true positives, false positives, and false negatives)	0.856	0.890	0.782	0.571	0.646	0.444	0.609	0.615	0.478
Macroaverage score (arithmetic mean of all the per-entity type scores)	0.522	0.674	0.685	0.270	0.295	0.227	0.216	0.238	0.231

Final NLP Algorithm Selection

NLP algorithms were needed for the 2 tasks, abstract screening, and data element extraction, in the ISLR system. The abstract screening was treated as a classification task. Based on our experimental results, XGBoost was selected for this task due to good performance on our document classification experiments and less computational complexity than DL-based models. For the data element extraction task, LSTM was selected over CRF and BERT for the same reasons.

ISLR System Components

Study Protocol Specification

Study protocol specification is one of the first steps in an SLR project. Users can upload a PDF document to the system that describes the SLR study protocol for reference. The SLR system has a default list of data elements with their descriptions and answer types (eg, free text, multiple choice, and checkbox), which will be extracted from full-text PDFs of articles. The system also allows users to create and modify the list. At the

end of the project, all the extracted data elements can be exported in a structured format.

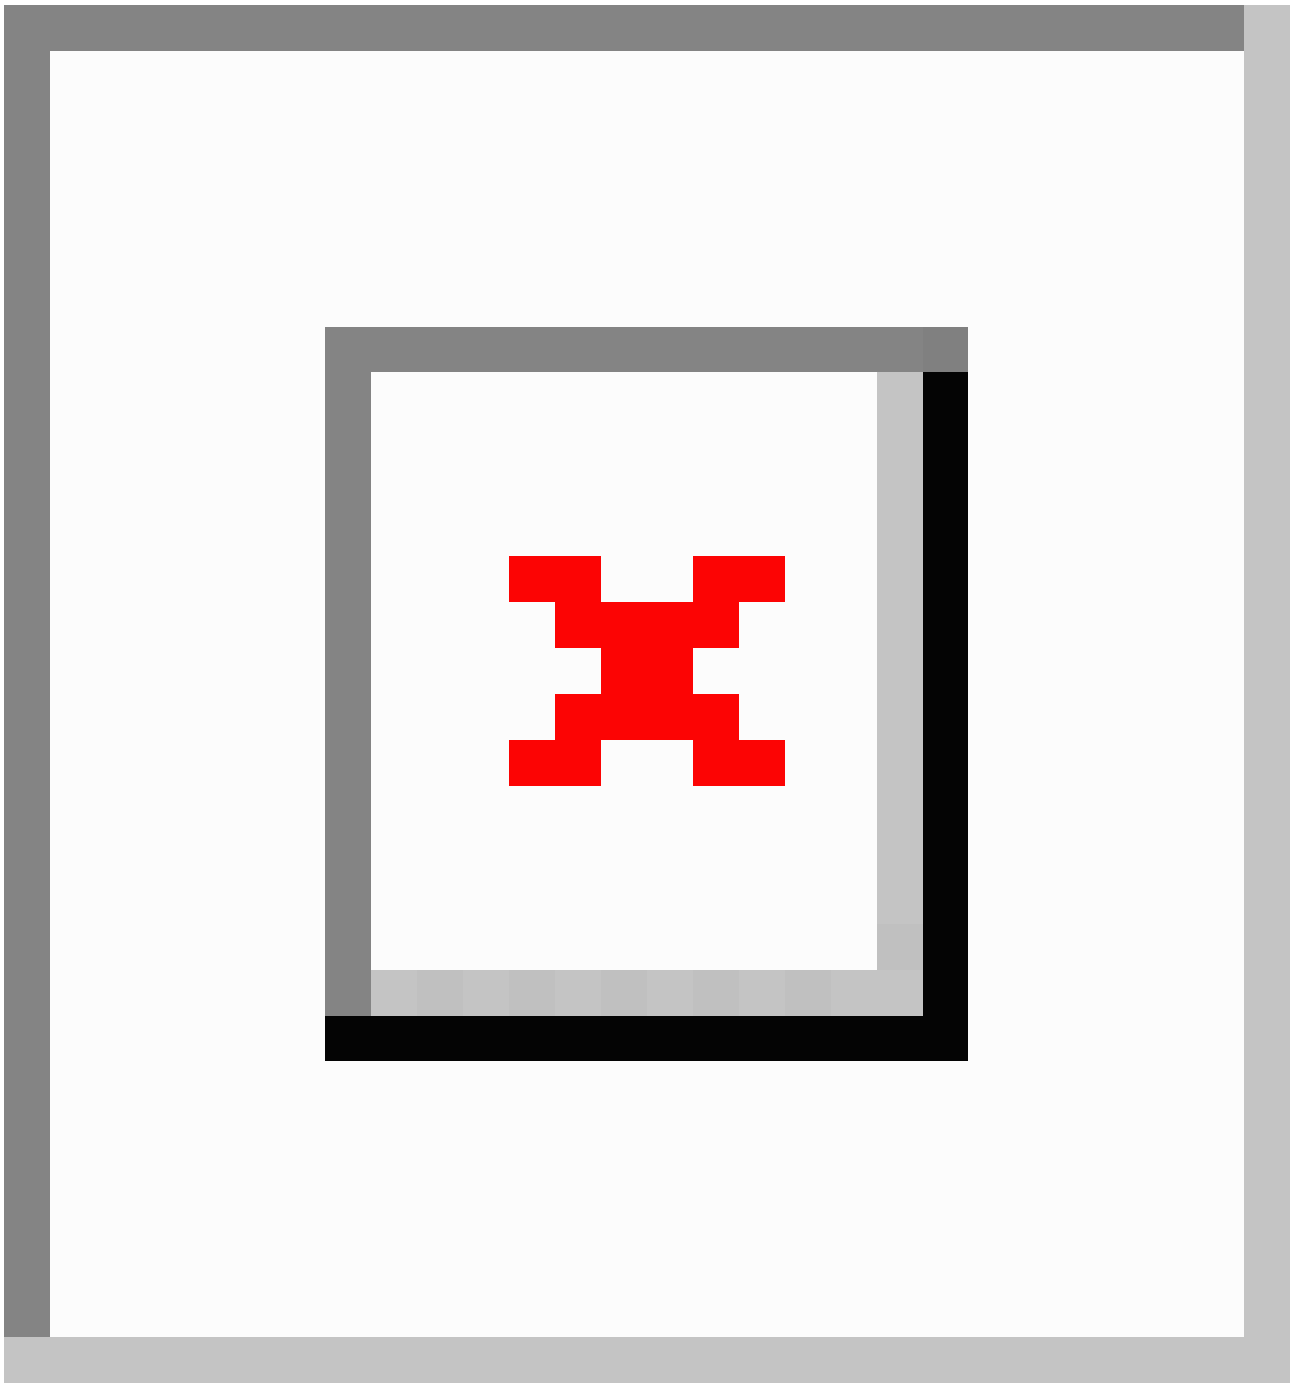
Literature Search

The ISLR system is integrated with the PubMed E-utilities application programming interface, which enables users to perform direct searches on PubMed. Citation metadata such as abstracts, titles, journals, and authors can be retrieved from PubMed and indexed in the system for further screening and data element extraction. Additionally, the system provides an option for users to retrieve this citation metadata by uploading a list of individual PubMed IDs.

Abstract Screening

The purpose of abstract screening is to review collected articles' relevance based on their title, abstract, and other relevant metadata, such as journal names, article types, and keywords. The relevant articles will be included for the following full-text screening and data element extraction steps. NLP services are provided at this step to make recommendations on whether a particular article should be included for full-text review. The supporting information (eg, salient words that are impactful to inclusion and exclusion) for the NLP recommendation will also be shown to provide explainable evidence. Human experts can further review the predictions for each article and decide on abstract screening status (keep or exclude). Figure 4 shows the abstract screening interface demonstrating prediction results and relevant terms discovered by the NLP algorithms.

Figure 4. Abstract screening interface. Terms that support inclusion in the finalized cohort of relevant articles are shown in green, while terms that detract from inclusion are shown in red. The scale of the colors shows how significantly one term can impact prediction decisions (eg, darker color indicates higher impact).



Full-Text Searching, Uploading, and Screening

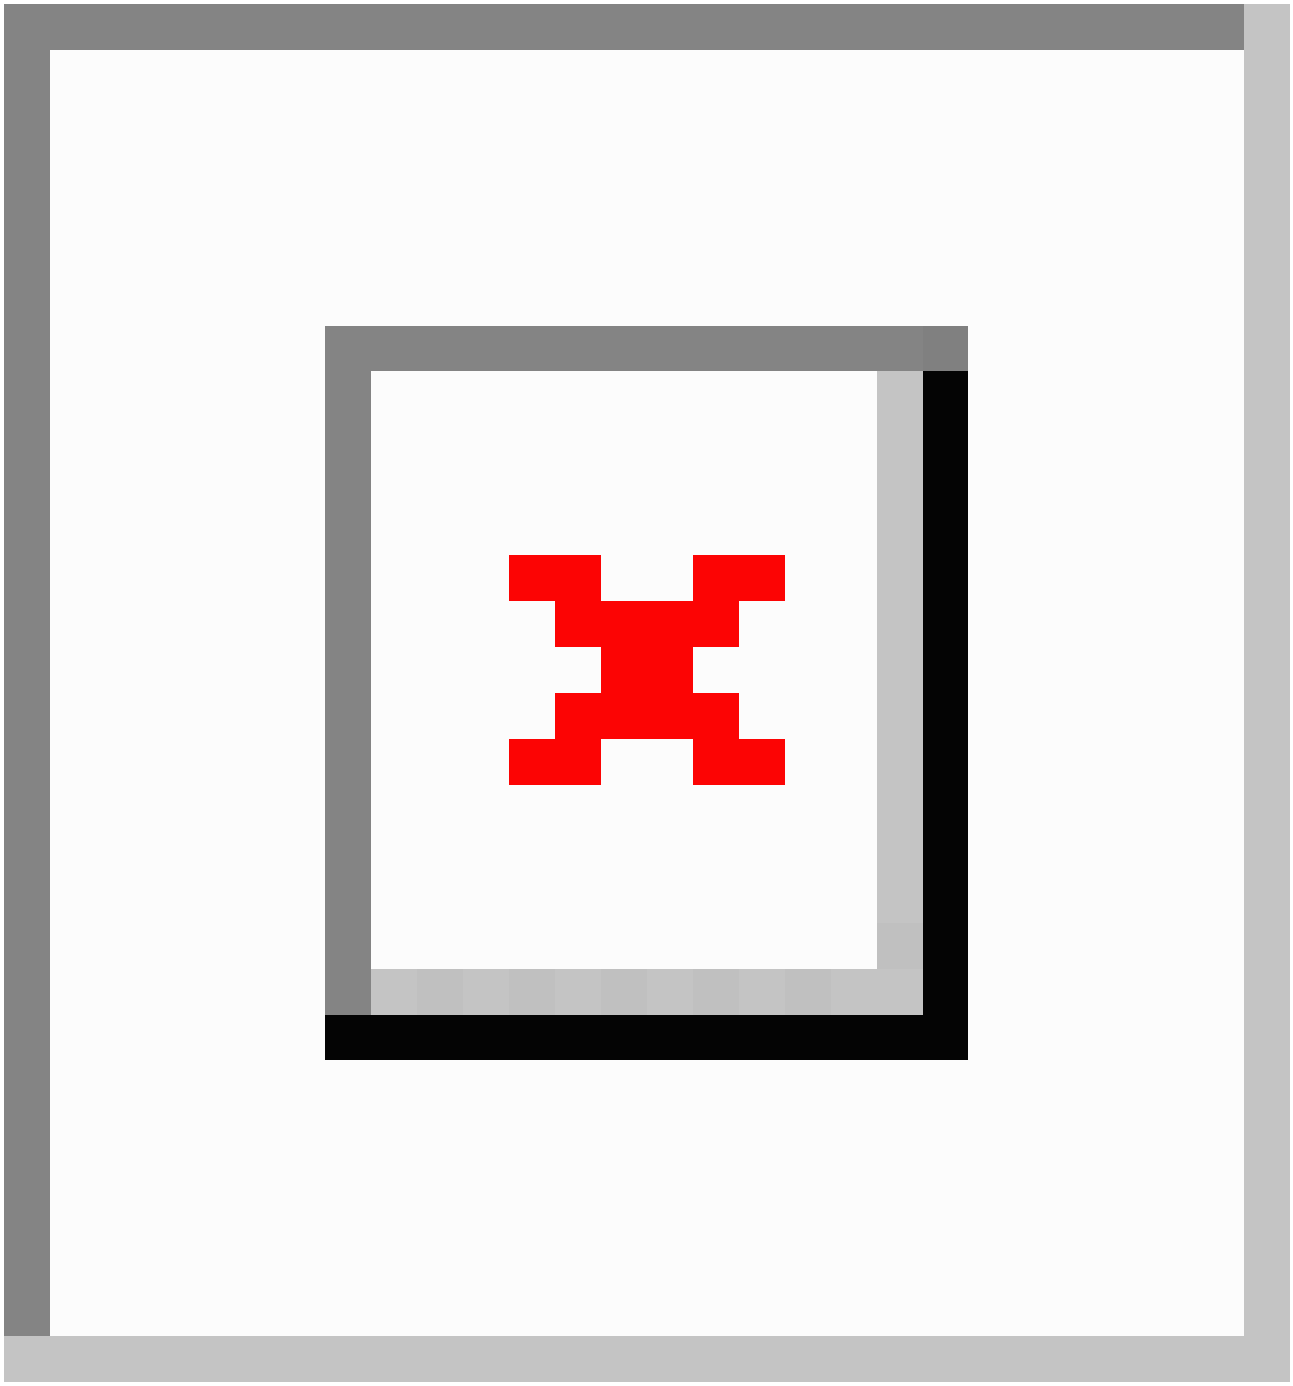
This step aims to identify full-text PDF documents for each included article and further screen their relevance based on the SLR study protocol. Only the articles that are deemed relevant after this stage will be included in the final full-text data element extraction step. The process of locating full-text PDF documents for each article can be time-consuming. The ISLR system integrates with PubMed Central to automatically find and collect full-text PDFs if they are publicly available. However, for articles whose full-text PDFs are not publicly available, users need to manually locate the articles through publishers and upload the corresponding PDFs to the system through the provided user interface.

Full-Text Data Element Extraction

Extracting full-text data elements is a time-consuming process in SLR projects. It requires reviewing the full-text article and extracting multiple relevant pieces of information defined in the study protocol. These data elements are often found in various sections of an article, including tables. The ISLR system uses Amazon Textract [24] for optical character recognition to extract text and tables from PDF files, followed by NLP services to further extract information from both text and tables. The NLP services can recommend potential answers for each data

element, and human experts can review, select, and modify the extracted information. Figure 5 shows a screenshot of the user interface for this step.

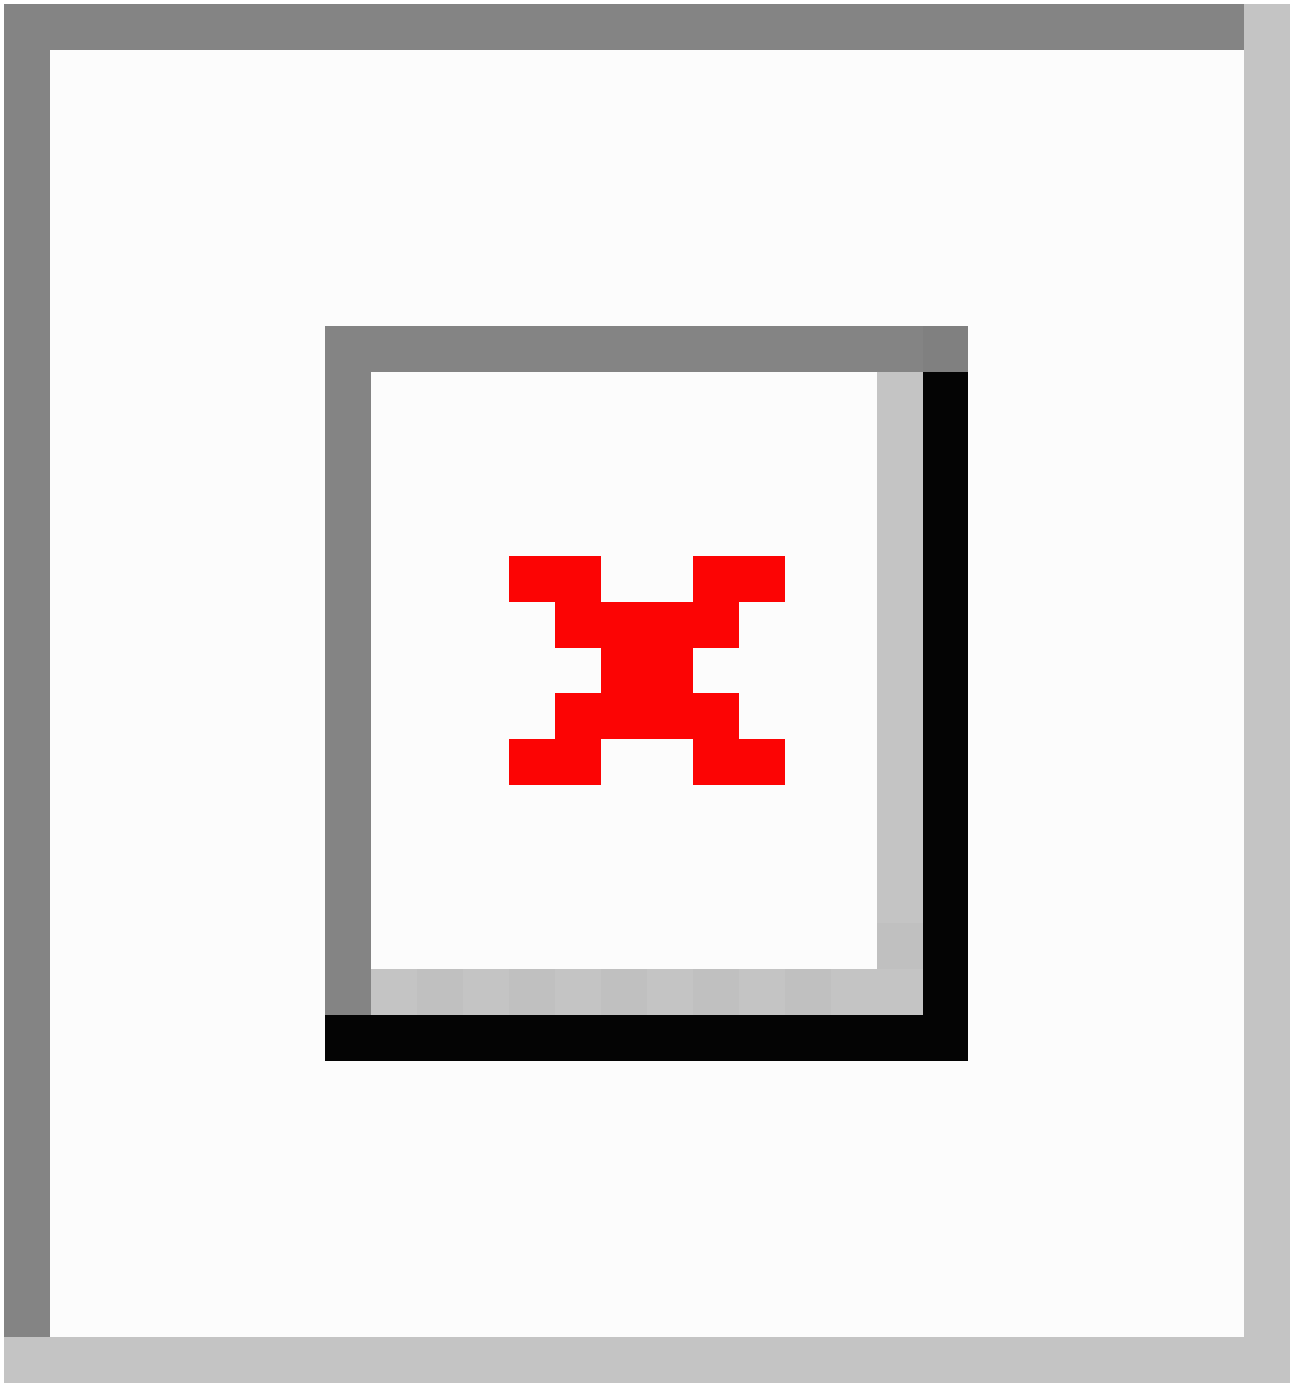
Figure 5. Full-text data element extraction user interface. Data elements from the article extracted by the NLP algorithms are color-coded and highlighted in the PDF. Highlight colors in the PDF text are linked to the data elements as shown in the right-hand frame. For the data element list on the right side, all the extracted data elements can pop up as candidates for the users to choose from. NLP: natural language processing.



Data Summary and Visualization

The ISLR system offers interactive dashboards to end users, such as researchers, for exploring the SLR results and data. These dashboards allow users to apply data filters, such as study location and cohort size, to refine their search results. For each data element extracted from full-text articles, users can click on the element to navigate to the corresponding article, ensuring traceability and appropriate references to source documents in the SLR project. Additionally, the dashboards recommend recent relevant articles and suggest articles that may require full-text screening. Figure 6 displays the major functions and screenshots of the dashboard.

Figure 6. Interactive visualization of existing SLR data, lists of relevant publications, and data exportation control. SLR: systematic literature review.



Discussion

Principal Findings

As described in the introduction, conducting an SLR is complex and expensive. There is also a rapid growth of the available number of publications and other data, such as clinical trial reports used in the article search and screening processes, with an average annual growth rate for the life sciences of around 5% [25]. Consequently, there is considerable community interest in applying various types of automation, including AI, DL, and NLP, to the multiple tasks required for producing an accurate SLR [2,5-7].

An important consideration for using the results of an SLR is how often the SLR is updated and hence how timely and complete these data are with respect to the real-world evidence. “Living” ISLR system addresses the difficulty of updating an SLR by providing an automated workflow including review tools to detect when new data are available and to trigger at least a semi-automated update process for the expedited review. The system is also expandable to cover additional data elements of interest by updating existing NLP pipelines.

The major accomplishments of this ISLR system include improving the time, efficiency, cost, completeness of evidence, and error avoidance through techniques to assist researchers with decision-making (so-called human-in-the-loop). The ISLR system is aligned with the living SLR concept, as it supports a

rapid update of existing literature data. Additionally, since the classification and data element extraction tasks are maintained by the system, results can be used for retraining the classification and NLP algorithms on a routine basis. Consequently, the performance of the system should improve over time.

The focus of this work was to evaluate an intelligent system that includes all major steps of an SLR with humans in the loop. The corpora evaluated in this study mostly focus on health economics and outcomes research in specific therapeutical areas. The generalizability of the learning algorithms to another domain will benefit from further formal examination. Since we have not yet conducted a time analysis of an SLR study conducted both manually and with this tool, we are unable to precisely quantify the time savings from the ISLR system. In addition, our NLP technologies limit to the extraction of relevant information directly from the text but are not able to conduct reasoning with long context to support complex data element extraction, such as GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) or RoB2 (Risk of Bias 2). The recent advances in large language models, such as generative pretrained transformer 4, bring NLP technologies expert-level performance on various professional and academic benchmarks. Given its high performance, generalizability, and reasoning capacity, it would be interesting to further assess the efficacy and accuracy of large language models in various SLR tasks and complex data element extraction.

As an early and innovative attempt to automate SLR lifestyle through NLP technologies, ISLR does not fully support PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) reporting yet. We plan to continuously iterate ISLR to cover the PRISMA checklist and report generation in the future. In addition, we have not yet conducted formal usability studies of the user interface, although agile methods involving iterative refinement of the interface through input from domain experts in SLR were employed throughout the software development process.

Conclusions

Our ISLR system is a user-centered, end-to-end intelligent solution to automate and accelerate the SLR process and supports “living” SLRs with humans in the loop. The system integrates cutting-edge ML- and DL-based NLP algorithms to make recommendations on article screening and data element extraction, which allow the system to prospectively and continuously update relevant literature in a timely fashion. This allows scientists to have more time to focus on the quality of data and the synthesis of evidence and to stay current with literature related to observational studies.

Abstract

Background: Social determinants of health (SDOH) are critical drivers of health disparities and patient outcomes. However, accessing and collecting patient-level SDOH data can be operationally challenging in the emergency department (ED) clinical setting, requiring innovative approaches.

Objective: This scoping review examines the potential of AI and data science for modeling, extraction, and incorporation of SDOH data specifically within EDs, further identifying areas for advancement and investigation.

Methods: We conducted a standardized search for studies published between 2015 and 2022, across Medline (Ovid), Embase (Ovid), CINAHL, Web of Science, and ERIC databases. We focused on identifying studies using AI or data science related to SDOH within emergency care contexts or conditions. Two specialized reviewers in emergency medicine (EM) and clinical informatics independently assessed each article, resolving discrepancies through iterative reviews and discussion. We then extracted data covering study details, methodologies, patient demographics, care settings, and principal outcomes.

Results: Of the 1047 studies screened, 26 met the inclusion criteria. Notably, 9 out of 26 (35%) studies were solely concentrated on ED patients. Conditions studied spanned broad EM complaints and included sepsis, acute myocardial infarction, and asthma. The majority of studies (n=16) explored multiple SDOH domains, with homelessness/housing insecurity and neighborhood/built environment predominating. Machine learning (ML) techniques were used in 23 of 26 studies, with natural language processing (NLP) being the most commonly used approach (n=11). Rule-based NLP (n=5), deep learning (n=2), and pattern matching (n=4) were the most commonly used NLP techniques. NLP models in the reviewed studies displayed significant predictive performance with outcomes, with F1-scores ranging between 0.40 and 0.75 and specificities nearing 95.9%.

Conclusions: Although in its infancy, the convergence of AI and data science techniques, especially ML and NLP, with SDOH in EM offers transformative possibilities for better usage and integration of social data into clinical care and research. With a significant focus on the ED and notable NLP model performance, there is an imperative to standardize SDOH data collection, refine algorithms for diverse patient groups, and champion interdisciplinary synergies. These efforts aim to harness SDOH data optimally, enhancing patient care and mitigating health disparities. Our research underscores the vital need for continued investigation in this domain.

(JMIR Med Inform 2024;12:e57124) doi:10.2196/57124

KEYWORDS

data science; social determinants of health; natural language processing; artificial intelligence; NLP; machine learning; review methods; review methodology; scoping review; emergency medicine; PRISMA

Introduction

Medical care, while crucial, contributes to only about 20% of the modifiable factors influencing a population's health outcomes, while 80% are influenced by genetics, individual behaviors, and socioeconomic factors. The latter two form the social determinants of health (SDOH) [1] that operate at various levels. From macroeconomic policies of nations to public education and housing policies, these structural factors shape resource distribution and societal positions. Consequently, they influence living conditions, access to essential resources, and daily life circumstances, ultimately molding health and health disparities [2]. Every patient's health trajectory is influenced by SDOH, which can manifest positively (eg, high income, food security) or adversely [3]. The negative aspects can be categorized into social risks, conditions linked to poor health, and social needs, which are individual preferences for assistance [4]. These determinants, especially when adverse, can hinder optimal care and impact clinical outcomes [5]. While not the focus of this review, health-related social needs reflect individual level social needs, and are inextricably related to the impacts and conditions of SDOH.

Emergency medicine (EM) is a unique medical specialty: it can both identify and address adverse SDOH, making it a pivotal setting for intervention. The high prevalence of social needs among emergency department (ED) patients, especially those with low socioeconomic status, housing insecurity, or limited access to care, underscores the potential of ED-based SDOH interventions [6,7]. However, there are significant challenges; comprehensive social risk screenings in the ED are often impractical due to patient volume, acuity, and health system financial constraints. Relying solely on electronic health records (EHRs) is time-consuming and inconsistent. Furthermore, the scattered and unstructured nature of SDOH data in EHRs makes it difficult for ED physicians to identify patients with adverse SDOH [8-10]. However, advancements in techniques in the data sciences provide novel methods to address these issues.

Social informatics, a subfield of medical informatics, refers to the usage of information technology to better harmonize social and health data through improved capture and usage. It bridges the gap between the technical and social worlds, offering insights into how technology and societal factors interplay. The vast possibilities of social informatics lie in its potential to reshape how we understand, interpret, and act on social data in health care settings. By integrating social data with health data, it aims to enhance clinical care and overall health outcomes [11]. Techniques like natural language processing (NLP), artificial intelligence (AI), and machine learning (ML) are being harnessed to extract, use, and model SDOH data effectively [12-14]. AI represents an umbrella term that broadly encompasses computer systems that can achieve human-level performance on cognitive tasks [15], while NLP, a subfield of AI, is a field of computational linguistics that involves analyzing and understanding human language. This entails using a combination of statistical approaches, including ML, to extract structure and meaning from language [16]. Pertinent to this review, ML can also be used as an analytic technique for predictive modeling and better understanding patterns in data sets.

While existing literature has touched upon SDOH in the ED, a comprehensive review focusing on the application of data sciences in this context is lacking. This scoping review aims to map the current literature, pinpoint areas for future research, and highlight the transformative potential of integrating data sciences into EM SDOH research.

Methods

Data Sources and Literature Search Strategy

To capture the evolving role of AI and advancing data science techniques for patients seen in the ED, particularly pertaining to SDOH, we searched the literature from 2015 to 2022, a period marked by rapid advancements in AI applications in health care. We included articles from databases such as Medline (Ovid), Embase (Ovid), CINAHL, Web of Science, and ERIC, prioritizing research that melded data science with emergency care settings.

Our search encompassed terms related to SDOH, data science techniques such as ML algorithms, NLP, AI, and EM (see Multimedia Appendix 1 for search terms used). We chose to include EM patient populations to best understand this clinical context. While there is no uniform definition for data science, for this review we have used the definition proposed by Mike and Hazzan [17] that considers data science as a research method by "integration of research tools and methods taken from statistics and computer science that can be used to conduct research in various application domains, such as social science and digital humanities".

Article Selection

We focused our review on studies leveraging data science techniques to extract or model SDOH data in EM. Recognizing the paucity of EM-specific research using AI/ML algorithms, we also considered studies on emergency-related conditions that might be seen in other clinical non-ED settings. This included conditions such as opioid use disorder (OUD), HIV, and epilepsy. We intentionally excluded COVID-19 studies, given their unique characteristics and sheer volume of literature. This exclusion ensured a more focused review with current relevance. Two independent reviewers (DA and EA) assessed titles and abstracts for final inclusion. Any disagreements were resolved through joint discussions. We used Covidence (Covidence systematic review software; Veritas Health Innovation), a standardized systematic review software.

Data Extraction

We extracted data from the selected studies using a standardized form, ensuring uniformity. We captured study objectives, methods, clinical care setting, ML algorithms, modeling approaches, and specified outcomes (see Multimedia Appendix 2). We focused on broad data science techniques, including subfields of AI such as ML algorithms, NLP key SDOH domains, and overall clinical outcomes. While our focus remains descriptive, we abstained from a quality assessment, aligning with standard scoping review guidelines.

Results

Overall Study Characteristics

After screening 1047 studies, 26 met our final inclusion criteria (Figure 1 and Multimedia Appendix 1). We excluded a significant number of studies because they did not focus on EM conditions or complaints and did not use AI/ML techniques in the overall approach to the study question. Most studies were published after 2020 (Figure 2) and included patient populations focusing exclusively on the ED (n=9), pediatric patients (n=2), patients treated by emergency medical services (n=2), and US veterans (n=2), among other examples.

Figure 1. Preferred reporting for systematic reviews and meta-analysis flow chart (PRISMA) diagram: 2015 - 2022 search of Medline (Ovid), Embase (Ovid), Cumulative Index to Nursing and Allied Health Literature (CINAHL), Web of Science, and Education Resource Information Center (ERIC).

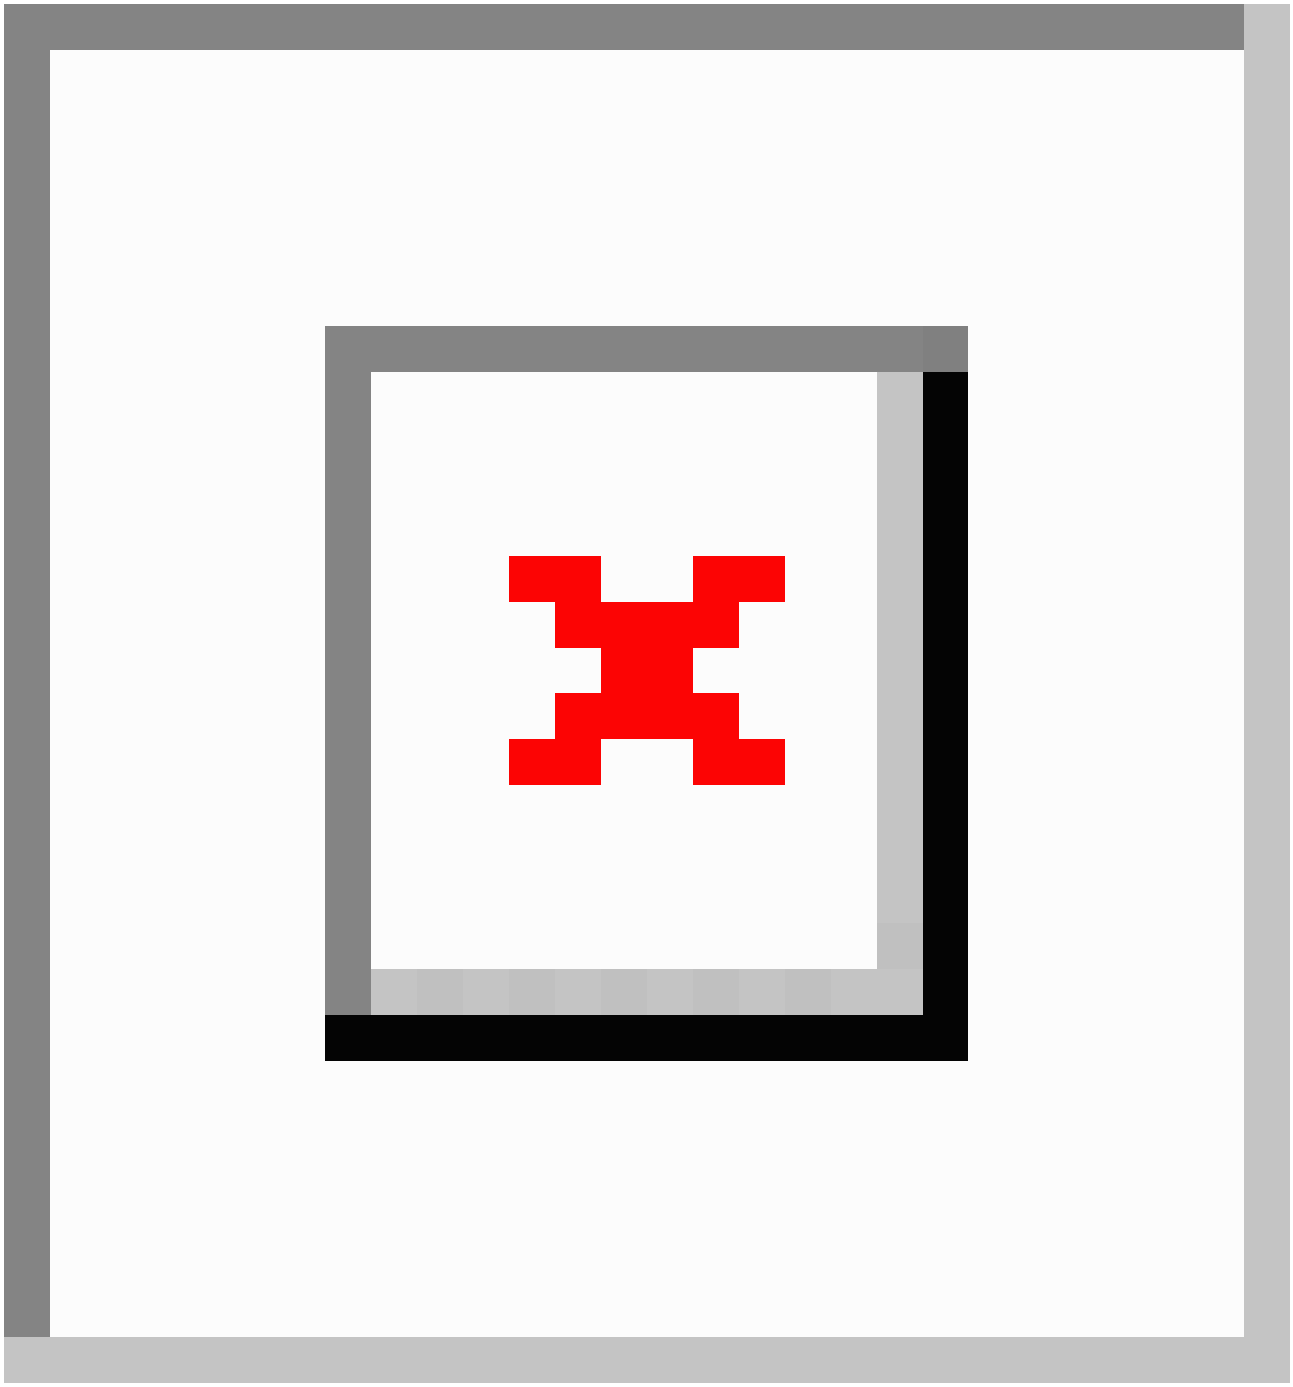

Figure 2. Number of publications by year (2015 - 2022) identified in this review. Word clouds show main themes of papers for the corresponding year.

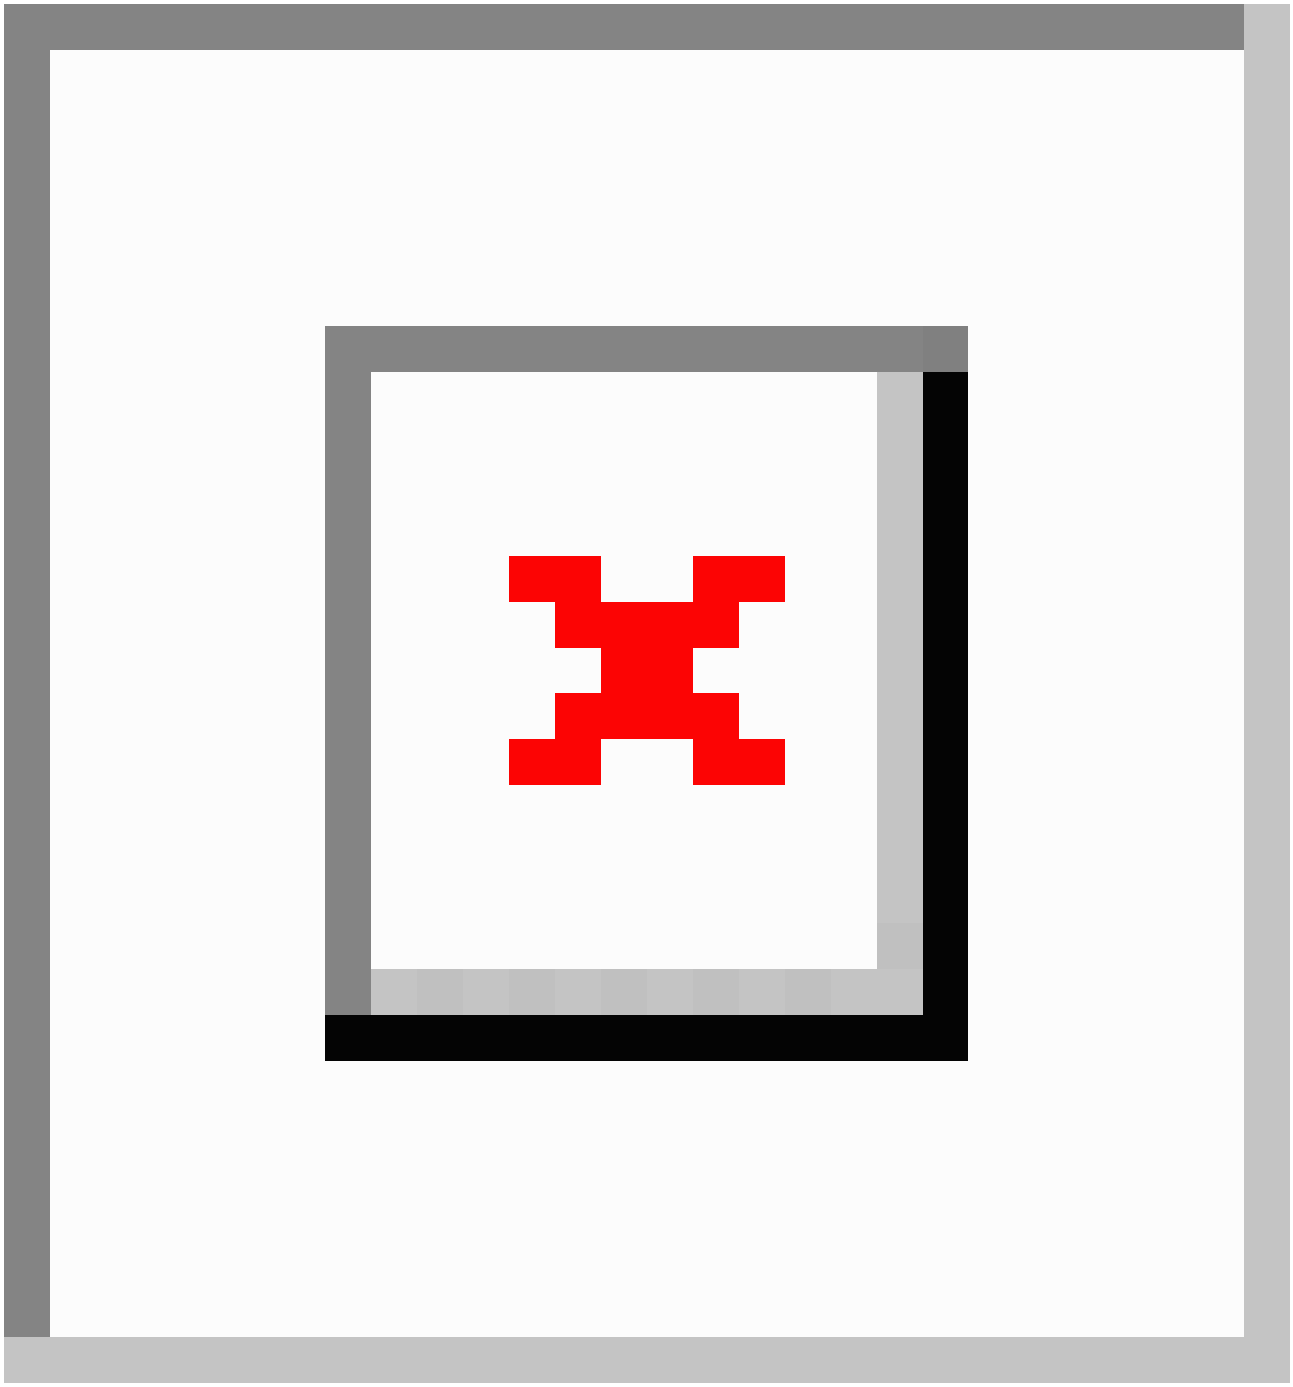

SDOH Domains

Over 60% of studies we identified (n=16) used a broad array of data science techniques such as ML or NLP to use, model, or extract features across more than one of the major SDOH domains, resulting in significant overlap across publications included in this review (Figure 2). These domains included housing insecurity and homelessness, neighborhood and built environment, income and socioeconomic status, employment, family and social support, food insecurity, insurance status and stability, and history of incarceration. While individual level SDOH data was the prevalent unit of analysis, 5 studies used area level data or aggregated measures such as the Social Deprivation Index, Area Deprivation Index, or the Gini coefficient. Housing insecurity and homelessness emerged as the most predominant SDOH domains assessed among 23% of the studies identified (n=6). The domain of neighborhood and built environment was also present across multiple studies and the focus of several publications (n=4). Exposure to or history of incarceration (n=2) as well as OUD (n=2) were also notable.

Exploration of Emergency Medicine Conditions

The scope of EM clinical conditions and complaints that were studied were broad, including sepsis, acute myocardial infarction, heart failure, asthma, diabetes, chest pain, and epilepsy (Multimedia Appendix 3). Sepsis was the only specific EM condition we identified in more than one study (n=2). Several studies focused on all-cause ED revisits (n=2),

"preventable visits" and admissions (n=2), and ED utilization (n=2).

AI and ML Algorithms

AI techniques were used in 23 studies, encompassing methods like random forest, classification and regression trees, support vector machines, neural networks, and NLP (Figure 3 and Table 1). Of these, random forest emerged as the most common (n=13), closely followed by NLP (n=11). Key algorithms are discussed in further detail.

Figure 3. Overall counts of AI/ML algorithms used. AI: artificial intelligence; ML: machine learning; NLP: natural language processing; CART: classification and regression trees; LSTM: long short-term memory.

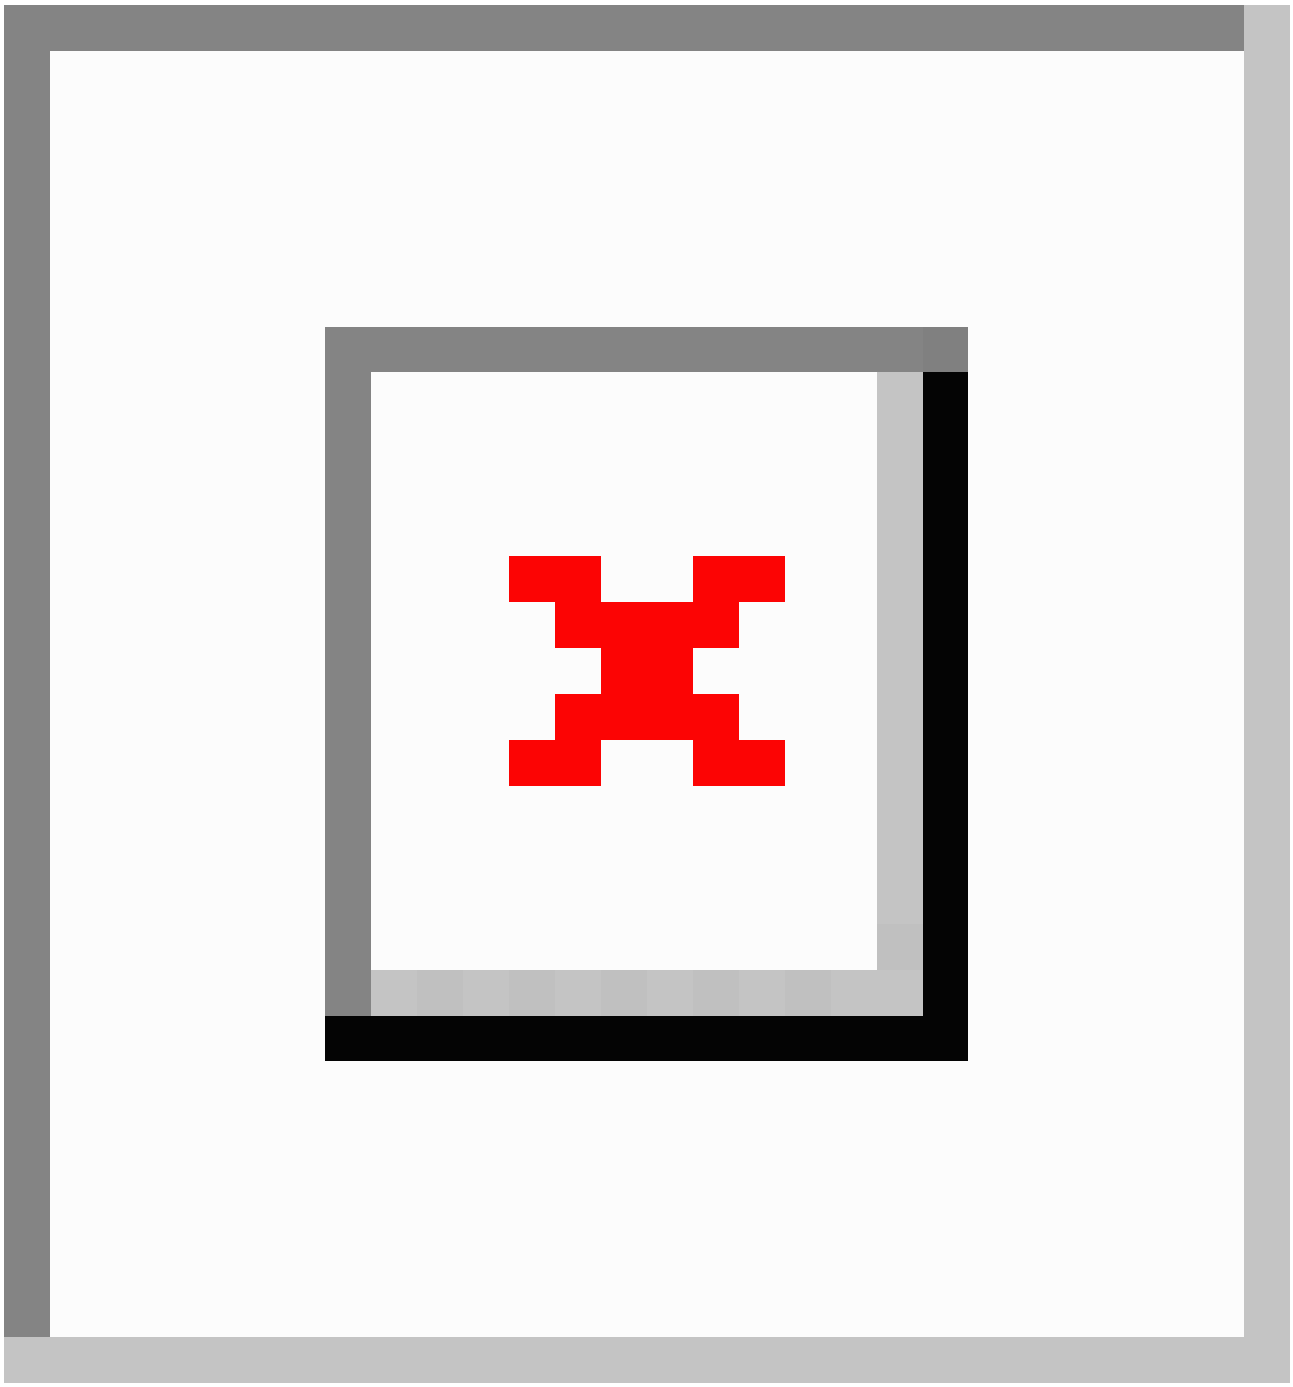

Table . Emergency medicine applications of random forest techniques used for extraction of social determinants of health data.

Category	Instances (n, %)
Identifying and highlighting pivotal SDOH[a] variables	2 (15.4)
Predictive modeling for potential health trajectories	1 (7.7)
Imputation using random forest techniques	3 (23.1)
Data integrity and robustness evaluation	5 (38.5)
Tree representations	2 (15.4)

[a]SDOH: Social Determinants Of Health

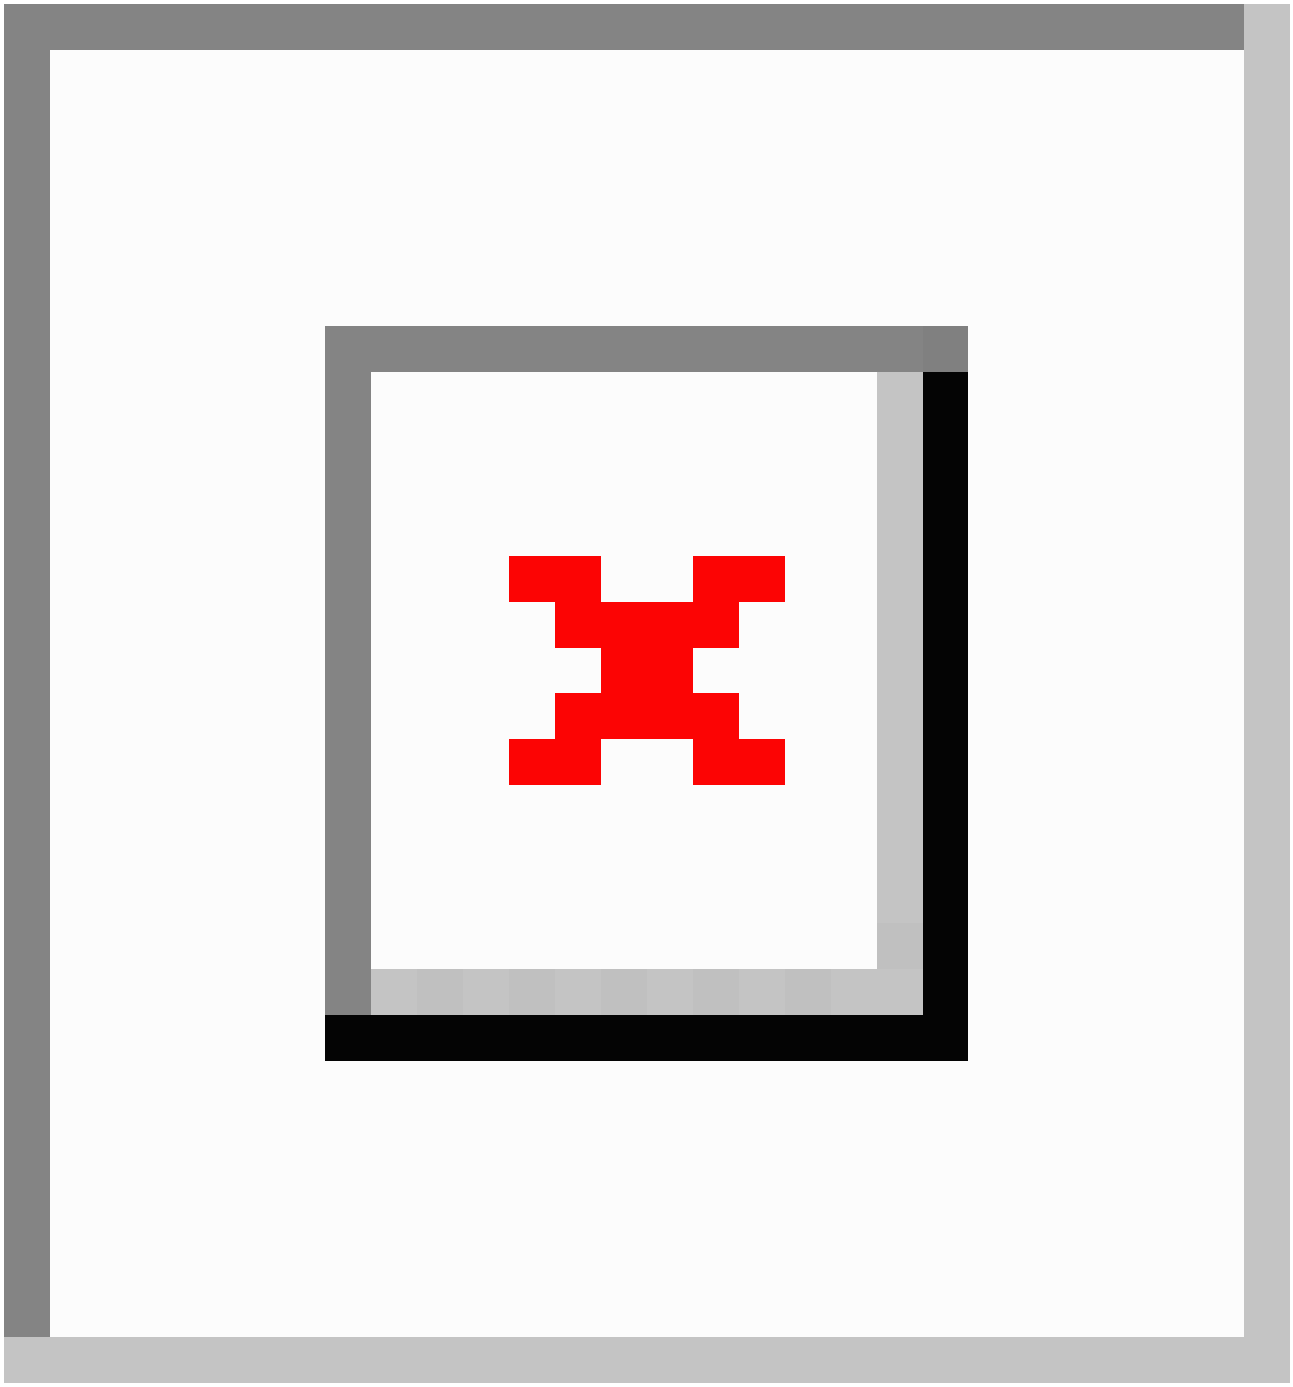
Random Forest in SDOH Variable Classification and Data Management

Random forest, an advanced ensemble ML method, was notably present across multiple studies identified in this review. This technique was used to discern and highlight pivotal SDOH variables. Its ability to create predictive models, offering foresight into potential health trajectories based on the subtleties of SDOH indicators was also evident. For example, in "Improving Fairness in the Prediction of Heart Failure Length of Stay and Mortality by Integrating Social Determinants of Health," the authors used random forest classifiers on sex, ethnoracial, and insurance for study subpopulations, finding differences in underdiagnosis and overdiagnosis of heart failure [18]. The most common use of random forest, however, was to address missing EHR data through imputation, ensuring the integrity and robustness of analyses. Beyond its analytical capabilities, it was also used to create insightful visual representations, offering a comprehensive view into the intricate web of variables, their interactions, and their overarching impact on disease states like acute coronary syndrome, epilepsy, asthma, and OUD.

NLP for SDOH Data Extraction

The integration of NLP in the realm of EM offers a promising avenue for the precise extraction of SDOH from EHRs. Traditional methodologies, such as manual reviews and rudimentary keyword searches, are increasingly recognized for their inherent limitations, particularly in the context of vast and intricate EHR data sets. Our scoping review elucidated the prevalence of several NLP techniques in the field. Text representation methods like term frequency-inverse document frequency (n=4), Bag of Words (n=3), and Word2Vec (n=1) were prominently used, underscoring their fundamental role in converting textual data into computationally amenable formats (Figure 4). In the realm of topic modeling and semantic analysis, latent Dirichlet allocation was noted in 2 studies, highlighting its potential in discerning latent topics within medical records. Approaches favored rule-based methodologies, found in 5 studies, followed by deep learning (n=2) particularly structures like bidirectional long short-term memory and pattern matching (n=4). From a software perspective, both proprietary (n=5) and open source (n=6) tools were harnessed, reflecting the diverse ecosystem of NLP tools available for research. These NLP methodologies, especially the dominant ones like Bag of Words, term frequency-inverse document frequency, and deep learning structures, have demonstrated notable efficacy. However, to achieve the pinnacle of precision in SDOH data extraction, it is imperative to continually refine these NLP techniques. Collaborative endeavors involving domain experts, iterative model training, and the assimilation of multifaceted data sources are paramount to enhancing the accuracy and relevance of extracted insights.

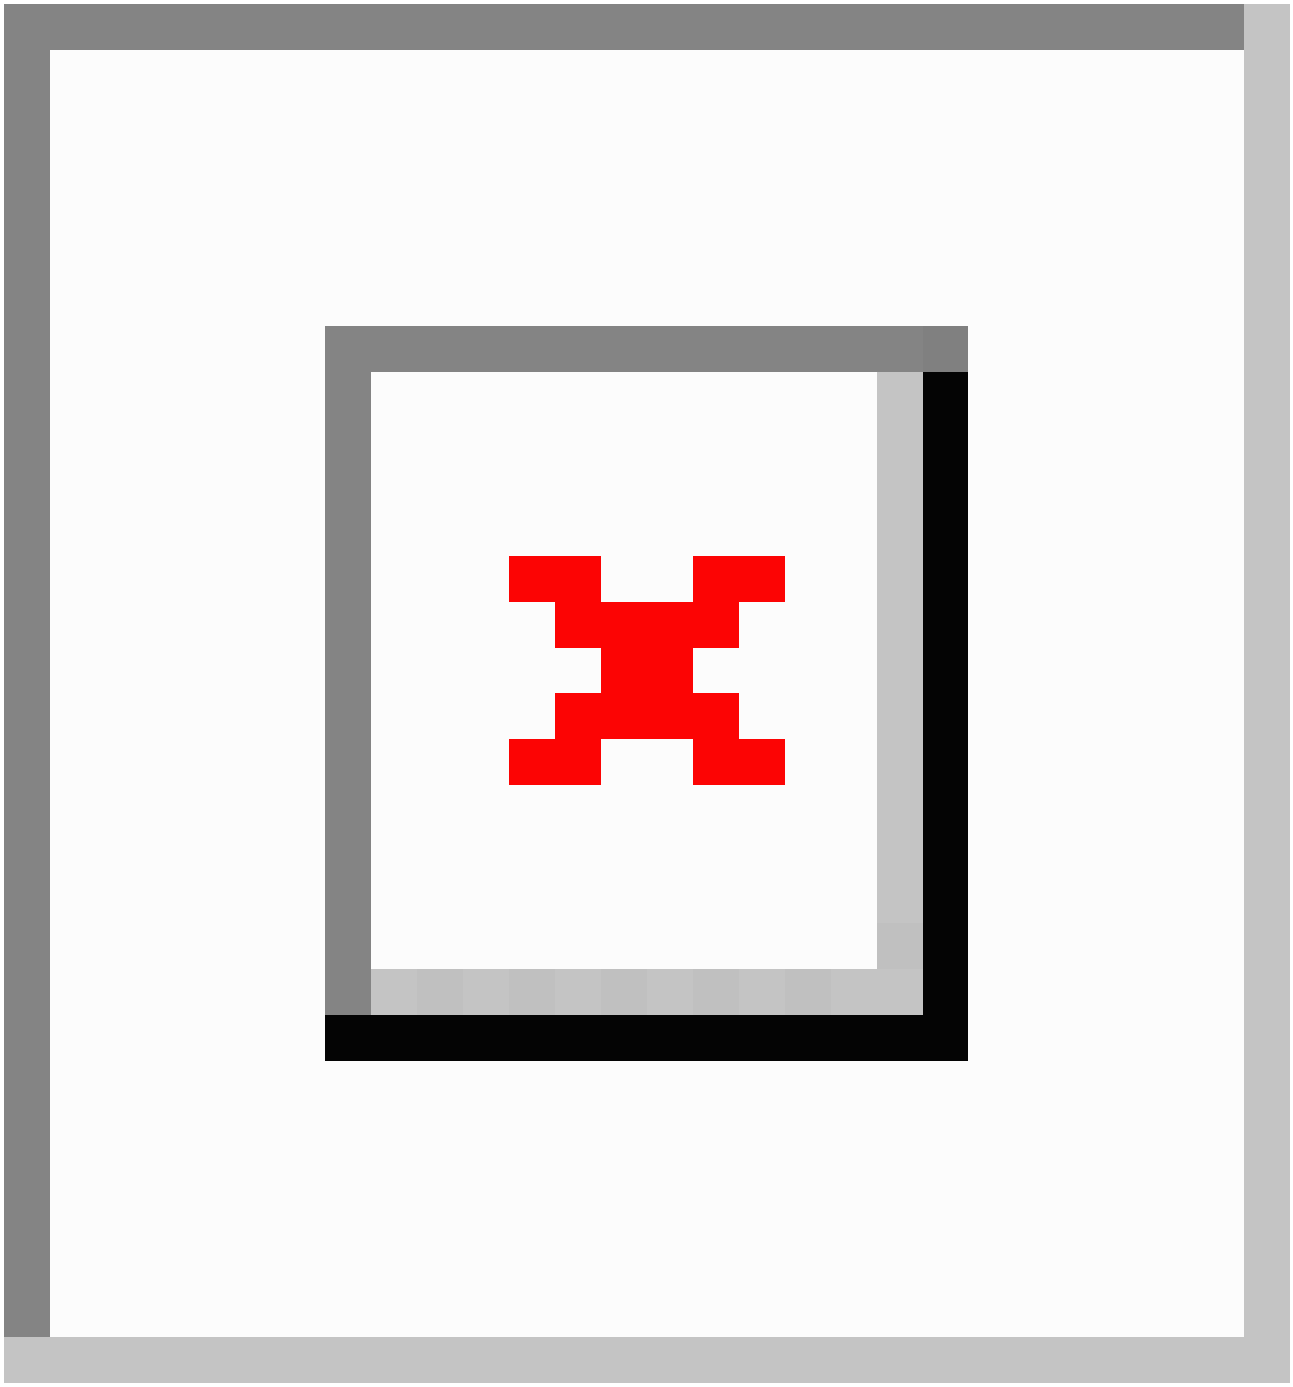
Figure 4. Overall counts of NLP techniques used for extraction of SDOH data including natural language processing (NLP), social determinants of health (SDOH), term frequency-inverse document frequency (TF-IDF) .



Health Information Exchange (HIE) for SDOH Data Aggregation

Health information exchange (HIE), featured in 4 out of 26 studies (Figure 5), aggregates patient data across health care entities, providing a comprehensive view of a patient's clinical journey. With 40% of patients in one study having encounters at multiple organizations, the importance of HIE in reflecting the distributed nature of ED care becomes evident. HIE can aid in analyzing care transitions and augmenting the sample size and diversity for SDOH research. However, challenges like data sharing, data quality, and privacy regulations need to be addressed. In essence, HIE holds immense potential for EM research, offering both multi-organizational and community-level insights.

Figure 5. Overall counts for identified articles by domain and/or task.



Predictive Applications

ML techniques can be important tools to leverage for clinical outcome predictions, and we identified a significant number of studies in our review. A total of 19 studies, representing a diverse array of ML strategies were identified, each tailored for distinct predictive outcomes. The efficacy of predictive models was a pivotal outcome in 10 studies. Performance metrics for these models, when used as a primary outcome, showcased a range of F1-scores from 0.4 to 0.75, indicating varied precision and recall across studies. These ranged from supervised models like random forest classifiers for acute coronary syndrome predictions to neural networks targeting sepsis-related readmission risks. Notably, ensemble methods were adeptly used to discern primary risk factors for OUDs. Within this realm, NLP proved instrumental, particularly in classification tasks, risk stratification, and fortifying clinical decision-making processes. Beyond this, key outcomes highlighted patterns in ED revisits (n=6), in-hospital mortality (n=2), algorithmic bias (n=1), and mismatches between physician annotations and claims data (n=1).

Data Quality, Privacy, and Algorithmic Bias

In the comprehensive spectrum of studies analyzed, an intriguing observation surfaced: a noticeable gap in the examination of data quality and privacy concerns within the realm of SDOH and EM. Despite sifting through a multitude of research articles, we did not encounter any study that directly tackled these pivotal

issues. This omission underlines the potential vulnerabilities in the application of AI and ML techniques, especially when handling sensitive patient data. Furthermore, a singular study broached the topic of algorithmic bias, a topic of paramount importance given the potential repercussions on health care outcomes and equity. The underrepresentation of these themes hints at uncharted territories that warrant meticulous exploration in future research endeavors, ensuring that the integration of AI and ML in EM is both robust and ethically sound.

Discussion

Principal Findings

The leveraging of SDOH data within EM research and clinical care is pivotal for gaining new insights, improving patient outcomes, and optimizing health care delivery. Our scoping review highlights the transformative role of data science, chiefly AI/ML, and the subdiscipline of NLP, in improving SDOH data integration and modeling within EM. Emerging from our review is an increase toward using data science to harness, operationalize, and model SDOH in emergency care settings. This progression signifies a shift: a pivot toward a comprehensive, data-infused approach that addresses not just emergent conditions but also the intricate web of social and economic determinants impacting health. NLP excels at extracting SDOH information from the unstructured text of EHRs, while ML's predictive strength can transform these insights into actionable predictions. Such models, equipped with SDOH data, can catalyze precision interventions, potentially identifying mechanisms for ED revisits, in-hospital mortality, and readmissions.

Delving deeper into the SDOH domains, housing insecurity and the neighborhood environment emerged as primary determinants, witnessing significant attention across the studies. Their frequent appearance in the research landscape underscores their profound impact on health outcomes within emergency settings. While these domains were at the forefront, other determinants like education, employment, and social networks were also featured, albeit to a lesser extent. The emphasis on these SDOH domains, especially housing insecurity, suggests a pressing need for targeted interventions and policies within emergency care settings. As the health care sector continues to evolve, understanding these predominant SDOH domains and harnessing the power of data science will be pivotal in offering a more holistic, patient-centric approach to emergency care.

Our comprehensive review, while offering insights, bears certain limitations warranting acknowledgment. The time frame for our study, confined to 2015-2022, captures most contemporary advancements but might inadvertently omit foundational studies predating this period, potentially offering evolutionary insights. While we highlighted NLP and other ML techniques, the vast expanse of data science boasts other emerging tools such as the recent and rapid development of large language modeling (LLM) such as ChatGPT (OpenAI), which were absent in our review. The potential applications of LLM in harnessing and modeling SDOH within the EM setting are rapidly emerging and will likely expand the possibilities for improving health outcomes and disparities.

Second, the encompassing scope of our review, spanning diverse SDOH domains and emergency conditions, enriches the study's comprehensiveness. Yet, the scope also poses challenges in distilling specific conclusions regarding the utility of data science techniques across distinct SDOH or EM conditions. Comparative analysis across studies was hampered by the varied outcome measures adopted. Although a significant number focused on the performance of predictive models, this only scratches the surface of data science's potential impact on SDOH within EM. Lastly, our review refrained from assessing the methodological quality of the incorporated studies. This approach aligns with scoping review guidelines but omits considerations of each study's methodological soundness during our synthesis.

Amidst these intricacies and challenges, there are still other pressing concerns. Data quality, privacy concerns, and algorithmic biases are potential hurdles that merit attention. In particular, the limited exploration and assessment of algorithmic bias in our reviewed studies, given its potential to perpetuate health care disparities, suggests an urgent avenue for further investigation. Without careful assessment of algorithmic biases, there exists the potential for reinforcing racial and ethnic discrimination and institutional racism. Only one study we identified in our review specifically assessed ML model bias and fairness in the context of heart failure outcomes [18]. ML algorithmic biases are critical to address in the context of SDOH research, as prior studies have demonstrated the potential for reinforcement of pre-existing racial, ethnic, and socioeconomic disparities [19].

Future Works and Recommendations

Potential Areas of Exploration

Our review has illuminated the significance of certain domains like housing insecurity, within the context of SDOH in EM. However, the vast landscape of SDOH offers numerous other domains that remain relatively unexplored:

1. **Education:** Investigating the role of educational attainment and access to quality education can provide insights into its impact on health outcomes. For instance, understanding how literacy levels influence patient adherence to medical advice in emergency settings could be pivotal. AI techniques could be used to better understand the complexity of both current educational attainment and future or desired educational needs through careful extraction or modeling of data.
2. **Employment:** Employment status, job security, economic mobility, and workplace conditions can have profound effects on mental and physical health. Exploring these factors can shed light on stress-related conditions or injuries that present in EDs.
3. **Social networks:** The influence of social support systems, community engagement, and familial ties can play a crucial role in patient recovery and mental well-being. Delving into these aspects can offer a holistic view of a patient's environment and its implications for health.

With these potential areas in mind, it becomes evident that a multi-faceted approach to SDOH within EM is the way forward.

Building on these areas of exploration, we propose several recommendations to harness the full potential of SDOH in EM.

Recommendations

1. **Establishing gold standard metrics:** For the evolution and standardization of emergency SDOH research, it is essential to define and adopt gold standard metrics. These metrics should be robust, universally accepted, and tailored to capture the nuances of SDOH in emergency settings. Collaborative efforts among researchers, clinicians, and policy makers should be made to create these benchmarks.
2. **Innovative data capture and implementation:** The high-paced nature of emergency settings necessitates innovative solutions for capturing SDOH data. Leveraging AI-assisted tools or predictive algorithms based on existing patient data could offer one approach. Creating automated workflows to allow for capture and implementation of SDOH data at the patient encounter level will be important for addressing social risks and needs.
3. **Algorithmic innovation:** The prominence of ML and NLP in our findings suggests a horizon brimming with algorithmic advancements and adaptation for EM. As these tools evolve and new tools emerge, crafting and evaluating interventions tailored to specific SDOH is crucial.
4. **Connecting SDOH with clinical outcomes:** Beyond identifying SDOH, understanding their tangible impact on patient outcomes is vital. A concerted effort in this direction can revolutionize our care approach. The intersection of SDOH and clinical outcomes is recognized by the Centers for Medicare and Medicaid Services, which requires health care systems to screen for key SDOH domains.
5. **Interdisciplinary collaboration:** The confluence of expertise, from clinicians to data scientists, will be instrumental in harnessing the full potential of SDOH data.
6. **Addressing algorithmic bias:** As we increasingly rely on algorithms, it is imperative to ensure they are free from biases that could perpetuate or exacerbate health disparities. Rigorous testing, validation, and refinement of algorithms, with a focus on fairness and equity, should be prioritized.

Conclusions

This scoping review underscores the transformative potential of data science in elevating the understanding and application of SDOH within EM. Through the adept integration of data science methodologies, particularly ML and NLP, we are poised to redefine the way SDOH data is adopted within EM. This offers a broader and more data-informed approach to influencing critical patient outcomes. The literature landscape indicates a promising embrace of this cross-disciplinary synergy, manifesting in an increasing number of studies that deploy data science methodologies to unearth, interpret, or model SDOH within emergency care contexts. Such a trajectory not only affirms the growing acknowledgment of these methodologies' efficacy but also underlines the health care sector's commitment to delivering more holistic care.

Nevertheless, our review also pinpoints avenues that warrant deeper exploration. Despite the expansive focus on various SDOH domains, certain determinants like housing insecurity and the neighborhood environment have garnered disproportionate attention. A more balanced exploration across SDOH domains would provide a richer, more comprehensive insight into their collective and individual impacts on patient trajectories. Moreover, while the current trend leans heavily on ML and NLP, there exists a vast expanse of data science techniques yet to be fully leveraged like LLM. Diving into these untapped methodologies might further refine our capabilities in SDOH identification and intervention.

In conclusion, the fusion of data science with EM marks the dawn of a new health care epoch. It envisions a future where EDs transcend their traditional roles, evolving into hubs that address the foundational SDOH challenges within communities. As we navigate this promising trajectory, the potential to revolutionize EM and fortify patient-centric care is immense.

Abstract

Background: The importance of real-world evidence is widely recognized in observational oncology studies. However, the lack of interoperable data quality standards in the fragmented health information technology landscape represents an important challenge. Therefore, adopting validated systematic methods for evaluating data quality is important for oncology outcomes research leveraging real-world data (RWD).

Objective: This study aims to implement real-world time to treatment discontinuation (rwTTD) for a systemic anticancer therapy (SACT) as a new use case for the Use Case Specific Relevance and Quality Assessment, a framework linking data quality and relevance in fit-for-purpose RWD assessment.

Methods: To define the rwTTD use case, we mapped the operational definition of rwTTD to RWD elements commonly available from oncology electronic health record–derived data sets. We identified 20 tasks to check the completeness and plausibility of data elements concerning SACT use, line of therapy (LOT), death date, and length of follow-up. Using descriptive statistics, we illustrated how to implement the Use Case Specific Relevance and Quality Assessment on 2 oncology databases (*Data sets A and B*) to estimate the rwTTD of an SACT drug (*target SACT*) for patients with advanced head and neck cancer diagnosed on or after January 1, 2015.

Results: A total of 1200 (24.96%) of 4808 patients in Data set A and 237 (5.92%) of 4003 patients in Data set B received the target SACT, suggesting better relevance of the former in estimating the rwTTD of the target SACT. The 2 data sets differed with regard to the terminology used for SACT drugs, LOT format, and target SACT LOT distribution over time. Data set B appeared to have less complete SACT records, longer lags in incorporating the latest data, and incomplete mortality data, suggesting a lack of fitness for estimating rwTTD.

Conclusions: The fit-for-purpose data quality assessment demonstrated substantial variability in the quality of the 2 real-world data sets. The data quality specifications applied for rwTTD estimation can be expanded to support a broad spectrum of oncology use cases.

Introduction

Background

The importance of real-world evidence drawn from real-world data (RWD) is widely recognized in oncology research [1-5]. Over the past decade, federal legislation and incentives promoting the secondary use of RWD in the United States [6-8], coupled with advances in health information technology, have resulted in an explosion of RWD sources and a complex RWD ecosystem [1]. However, this rich data landscape can also pose challenges in identifying fit-for-purpose RWD to meet biopharma research needs.

Two key obstacles to identifying high-quality data are the fragmentation of RWD sources and the lack of interoperable data quality standards. These obstacles are particularly pertinent in the United States, where progress is slow in reaching full interoperability of data sourced from thousands of providers who customized their electronic health record (EHR) systems from solutions provided by >40 different EHR software vendors [9]. Therefore, adopting validated systematic methods for evaluating data quality is important for research leveraging RWD [10-12].

In 2016, an expert panel proposed the concepts of *conformance*, *completeness*, and *plausibility* as 3 categories (with subcategories) to describe the intrinsic data quality of EHR databases and to serve as a framework for assessing data quality that could then be verified (with organizational data) or validated using an accepted gold standard [13]. Several working groups and authors have applied these terms or proposed others for defining research data quality [14-16], and multiple initiatives in the United States, both public and private, have developed frameworks and tools to evaluate and improve the quality of EHR data sets [17-21] and to implement model-driven, quantitative approaches to address RWD completeness and plausibility issues [22-25]. However, there is no single RWD source that can fit the needs of all studies, and the selection of RWD to support an individual use case must also consider data relevance and measurement thresholds in addition to data quality.

Objective

In a previous study, we introduced the Use Case Specific Relevance and Quality Assessment (UReQA) framework, an RWD quality framework that combines both the data quality and the relevance aspects of assessing RWD, with the goal of developing data quality assessment specifications tailored to use cases [3]. In this study, we aimed to implement this framework in the use case for estimating real-world time to treatment discontinuation (rwTTD) in oncology. Our work had two main components: (1) to design comprehensive data quality assessment checks for estimating rwTTD for a systemic anticancer therapy (SACT) and (2) to illustrate how these quality checks can be used to evaluate EHR-derived RWD products.

We selected rwTTD as the first use case to implement the UReQA framework because of its high utility as a pragmatic real-world effectiveness end point for continuously administered SACTs (such as immunotherapies) and its known correlation with overall survival [26-28]. Moreover, the estimation of rwTTD requires information on medication use patterns, mortality, and follow-up. These data elements are foundational to outcomes research. Therefore, implementation of the rwTTD use case can be expanded to other use cases in or beyond oncology, as well as different data sources, such as claims databases.

Methods

Ethical Considerations

This study used 2 commercially licensed deidentified structured secondary data sources accessible to the study team. It was exempted from institutional review board review because of the following: (1) each data source contains a significant level of protection against the release of personal information to outside entities and (2) the use of such databases presents the lowest risk to potential subjects because the analysis involves only anonymous data; hence, conducting the study will not place the subjects at risk.

Study Overview

This study comprised four main steps: (1) conceptual definition of the rwTTD use case; (2) mapping of the rwTTD use case definition to RWD elements (operational definition); (3) identifying data quality checks for the required data elements to determine rwTTD for an SACT, designated the “target SACT”; and (4) implementing the UReQA framework [3] in assessing the RWD fitness for estimating rwTTD. The data quality assessment was undertaken on 2 US EHR-based oncology databases for estimating rwTTD for a target SACT, an immunotherapy drug that is administered intravenously in advanced-stage head and neck cancer (HNC). The targeted SACT received approval in 2016 for the treatment of previously treated advanced HNC and in 2019 for its use as a first-line therapy in advanced HNC. The focus of this study is on designing data quality assessment methods that are tailored for specific use cases, rather than calculating rwTTD for a particular medication. Therefore, we mask the name of the actual drug product.

Step 1: Conceptual Definition of the rwTTD Use Case

The end point, rwTTD, is defined as the length of time from initiation to discontinuation of a medication (*[date of last recorded dose – date of first recorded dose] + 1 d*), with discontinuation defined as the date of the last dose if a patient died during therapy or initiated a new treatment or if there is a gap of ≥120 days between the last recorded dose and last recorded activity in a data set. Patients who do not meet the discontinuation criteria are censored at the last medication use [26-28].

Step 2: Mapping of the rwTTD Use Case Definition to RWD Elements

Owing to the variations in data element definition and data structures between real-world EHR databases, we need to operationalize the concept of rwTTD by deconstructing its definition and mapping it to four sets of required data elements that are commonly available from oncology EHR–derived data

sets: (1) SACT, (2) line of therapy (LOT) specifying the regimen names and sequence of current treatment in the treatment plan [29,30], (3) mortality status, and (4) follow-up time, as summarized in Table 1. Although SACT, mortality status, and follow-up time are often recorded directly as procedure, prescription, and administrative events in raw EHR databases, the LOT was often derived from raw EHR by the algorithm.

Table 1. Required data elements for determining real-world time to treatment discontinuation (rwTTD) for a systemic anticancer therapy (SACT) drug in a specific line of therapy (LOT).

Operational steps to ascertain rwTTD and type of data category	Commonly used data elements
Identify records of the drug of interest	
SACT drug	Drug_name, NDC[a], HCPCS[b] code, RxNorm code
SACT administration	Drug administration date[c]
SACT order	Drug order date[d]
Identify discontinuation date from subsequent LOT start date	
LOT	LOT name[e]
LOT	LOT number
LOT	LOT start date
LOT	LOT end date
If no subsequent LOT, identify discontinuation date from patient death record during treatment	
Mortality status	Vital status or date of death
If no date of death, identify discontinuation date by last follow-up date subheading	
Last follow-up	Date of last follow-up[f]

[a]NDC: National Drug Code.

[b]HCPCS: Healthcare Common Procedure Coding System.

[c]The drug administration date is defined as the date of receiving medication at a health care facility as a medical service, often applicable to an intravenous drug.

[d]The drug order date is defined as the order date for drugs used at home, often applicable to an oral drug.

[e]The LOT name is determined by the combination of SACT drugs administered or ordered from the LOT start to end dates.

[f]The date of last follow-up is defined as the last documented clinic visit or procedure in the electronic health record.

We defined SACT as any systemic anticancer medication received by the patient, documented as given either by a health care provider at the site of care (eg, by infusion), with the date defined as the "administration" date, or as a prescription to take or apply at home, with the date defined as the "drug order" date. The number of refills (or alternative data elements such as days of supply or expected medication end date) was used to determine the last use of oral drugs (Table 1).

LOT was defined as the sequence of the SACT regimens prescribed for an individual patient, as previously described in detail [29,30]. In brief, the first LOT (line 1 [1L]) begins with the first SACT initiated after a study index date (often the advanced or metastatic cancer diagnosis date), and any other drug introduced within the next 28 days is considered part of that LOT [29]. We defined the start of a new LOT when a new SACT not belonging to the prior LOT was introduced or if a new SACT was initiated after a ≥120-day gap in therapy.

Because the target SACT was administered intravenously, we omitted 2 tasks applicable only to oral target SACTs: the check of patient numbers with target drug order date after the index date (Multimedia Appendix 1, task 6 [13]) and the check for distribution of gaps between drug order dates (Multimedia Appendix 1, task 9).

The patient mortality status was determined based on the recorded dates of death. For patients who were still alive at data cutoff, the date of the last follow-up was defined as the last documented clinical activity date in the EHR (Table 1).

Step 3: Identifying Data Quality Checks for Required Data Elements

For each of the required data elements, we identified corresponding verification checks to assess data quality at both the variable level and the cohort level. A total of 20 data quality checks (tasks) were identified and categorized into the quality dimensions of conformance, completeness, and plausibility, as per the harmonized data quality assessment terms and framework developed by Kahn et al [13] (Multimedia Appendix 1). Our goal in creating these tasks was to develop a comprehensive toolbox for assessing data quality for the rwTTD use case. However, when adapting them to a specific RWD database and a SACT drug of interest, not every task and check would be necessary. For example, the checks for LOT, mortality, and follow-up are not needed if a data set already provides the reason for discontinuation and censored status for each drug exposure. In addition, tasks 3-5 were applicable to cancer therapies received in hospitals or clinics as intravenous or infusion procedures, whereas tasks 4-9 were dedicated to oral

cancer therapies that were mostly self-administrated at home. As tracking the actual time patients took oral therapies was infeasible, researchers examined days supply and refill records to estimate the drug exposure period. Therefore, when investigating the rwTTD of an oral SACT drug, it is necessary to check the completeness of these oral therapy–specific data elements (task 7).

Step 4: Implementing the rwTTD Use Case for Assessing 2 RWD Sets

Data Set Preassessment

We followed the preassessment step in UReQA [3] to identify 2 anonymized, commercially available US real-world oncology databases, designated as *Data set A* and *Data setB* in this report, which included patients with advanced (metastatic or unresectable, recurrent) HNC. Both databases contained data elements sourced from structured and unstructured information captured within health care providers' EHR systems as part of routine cancer care.

Cohort Selection and Patient Characteristics

Data set A was commercialized and included patients with advanced HNC, whereas Data set B included patients with all stages of HNC. To align the 2 patient populations as having advanced HNC, we restricted Data set B to the subset of patients with HNC and a record of the American Joint Committee on Cancer stage IV and *International Classification of Diseases* (ICD), *revision 9 or 10* (ICD-9 or ICD-10) code for metastatic tumor (ICD-9 codes 196.x, 197.x, and 198.x and ICD-10 codes C76.x, C77.x, and C78.x). The distributions of the patient characteristics were then tabulated for the 2 data sets.

Data Elements Harmonization

In Data set A, the names of SACT medications were harmonized from clinic formulary information and medical service records to standard generic drug names in a commercial drug database along with drug category information. In Data set B, all medication records in the raw EHR data were harmonized into the RxNorm code [31]; however, drug category information was not available. To harmonize all SACT medication in Data set B, we retrieved the RxNorm codes for generic names of all SACT medications using the RxNav software developed by and available from the US National Library of Medicine [32].

The LOT information was previously derived by both data providers but was presented differently in the 2 data sets. In Data set A, the LOT table provided the LOT number, LOT regimen name, LOT start date, and LOT end date, with a flag indicative of maintenance therapy, as appropriate. Instead, Data set B included only the LOT number and LOT start date. Therefore, to evaluate the LOT information in Data set B, we indirectly deduced the end date of each LOT as the date before the start of the next LOT or as the data cutoff date for the last LOT in the data set. Then, all individual SACT medications administered or ordered between the LOT start and end dates were combined to serve as the LOT regimen name. This approach was a necessary but imperfect solution because the LOT end date and the LOT regimen name should ideally be generated using a more rigorous algorithm [29,30].

The date of death was provided at the month and day levels in Data set A, whereas in Data set B, the death date was aggregated by year. Given the relatively short length of survival of many patients with advanced HNC [33-36], the allocation of death dates by year was not sufficiently granular for accurate rwTTD calculation; better precision (ie, month of death) would be needed for accurate rwTTD calculation. Consequently, quality assessment tasks related to mortality variables were omitted (task 17) for Data set B.

Reporting the Verification Results

Descriptive statistics were used to summarize the results of implementing rwTTD data quality checks on Data sets A and B. We used frequencies to summarize categorical variables and mean (SD) and median (IQR or range) to summarize continuous variables. The study index date was the date of first advanced HNC diagnosis, and the cutoff date was November 25, 2019.

All analyses were conducted using SAS Studio release 3.8 (Basic Edition; SAS Institute, Inc).

Results

Patient Characteristics

Data set A included 7366 patients with advanced HNC, and we identified 11,386 patients in Data set B with advanced HNC. The median patient age at the first advanced HNC diagnosis was 65 (IQR 58-72) years in Data set A and 61 (IQR 54-68) years in Data set B, and the percentages of male individuals were 74.16% (5643/7366) and 69.97% (7967/11386), respectively (Table 2), similar to the HNC population data from the United States [33,37].

Table 2. Baseline characteristics of patients with advanced head and neck cancer (HNC) included in 2 data sets under evaluation[a].

Characteristic	Data set A (n=7366)	Data set B (n=11,386)

SACT Data Checks

Overall, 75.91% (5592/7366) and 38.74% (4411/11386) of the patients in Data sets A and B, respectively, had a recorded drug administration or drug order for any SACT (Table 3, task 1). A complete start date (y, mo, and d) was recorded for all SACT administrations and orders in both data sets (Table 3, tasks 4 and 8).

Table 3. Data quality assessment of SACT[a] administration and order records after the advanced HNC[b] diagnosis[c].

SACT data quality checks	Data set A	Data set B
Task 1: patients with any SACT drug administration or order record after the advanced HNC diagnosis date, n (%)[d]	5592 (75.9)	4411 (38.7)
Task 2: SACT drug records with missing drug identity (name and code) information		
Value, n (%)	0 (0)	0 (0)
Normalization of medication name	Normalized generic name	RxNorm ingredient level
Task 3: patients with target SACT administration date after the advanced HNC diagnosis date, 2015 onward, % (n/N)[e]	24.96 (1200/4808)	5.92 (237/4003)
Task 4: SACT drug administration records with complete administration date, n (%)	425,505 (100)	37,662 (100)
Task 5: gap (in d) between the target SACT drug administration dates, median (IQR; range)	21 (21-21; 1-113)	21 (11-21; 1-824)
Task 6: patients with target SACT order date after the advanced HNC diagnosis date	N/A[f,g]	N/A[g]
Task 7 SACT drug order records with complete days supply and refill information, n (%)	1732 (53.4)	N/A[h]
Task 8: SACT drug order records with complete order date, n (%)[i]	3241 (100)	8380 (100)
Task 9: distribution of gaps (in d) between target SACT drug order dates, normalized by days supply, refill, and cancelation record	N/A[g]	N/A[g]

[a]SACT: systemic anticancer therapy.

[b]HNC: head and neck cancer.

[c]Drug *administration* refers to drugs administered by health care providers at the site of care, whereas drug *order* refers to prescriptions for drugs used at home.

[d]Task 1 was applied to the full data sets, including 7366 and 11,386 patients in Data sets A and B, respectively.

[e]Task 3 was applied for patients with the first advanced HNC diagnosis on or after January 1, 2015, including 4808 and 4003 patients in Data sets A and B, respectively.

[f]N/A: not applicable.

[g]Tasks 6 and 9 were not conducted because they apply to an oral target SACT.

[h]Information about the number of refills, days supply, or alternative data elements was not available in Data set B.

[i]The total number of drug order records in Data set A (3241) and Data set B (8380) was used as the denominator in task 8.

We determined that 4808 (65.27%) of the 7366 patients in Data set A and 4003 (35.16%) of the 11,386 patients in Data set B had a first advanced HNC diagnosis on or after January 1, 2015, the timeline we applied for the study index date as it covered the key diagnostic and therapeutic timeline of the target SACT (first approved in 2016). A total of 1200 (24.96%) of the 4808 patients meeting this timeline in Data set A and 237 (5.92%) of the 4003 patients meeting this timeline in Data set B had a record of receiving the target SACT (Table 3, task 3).

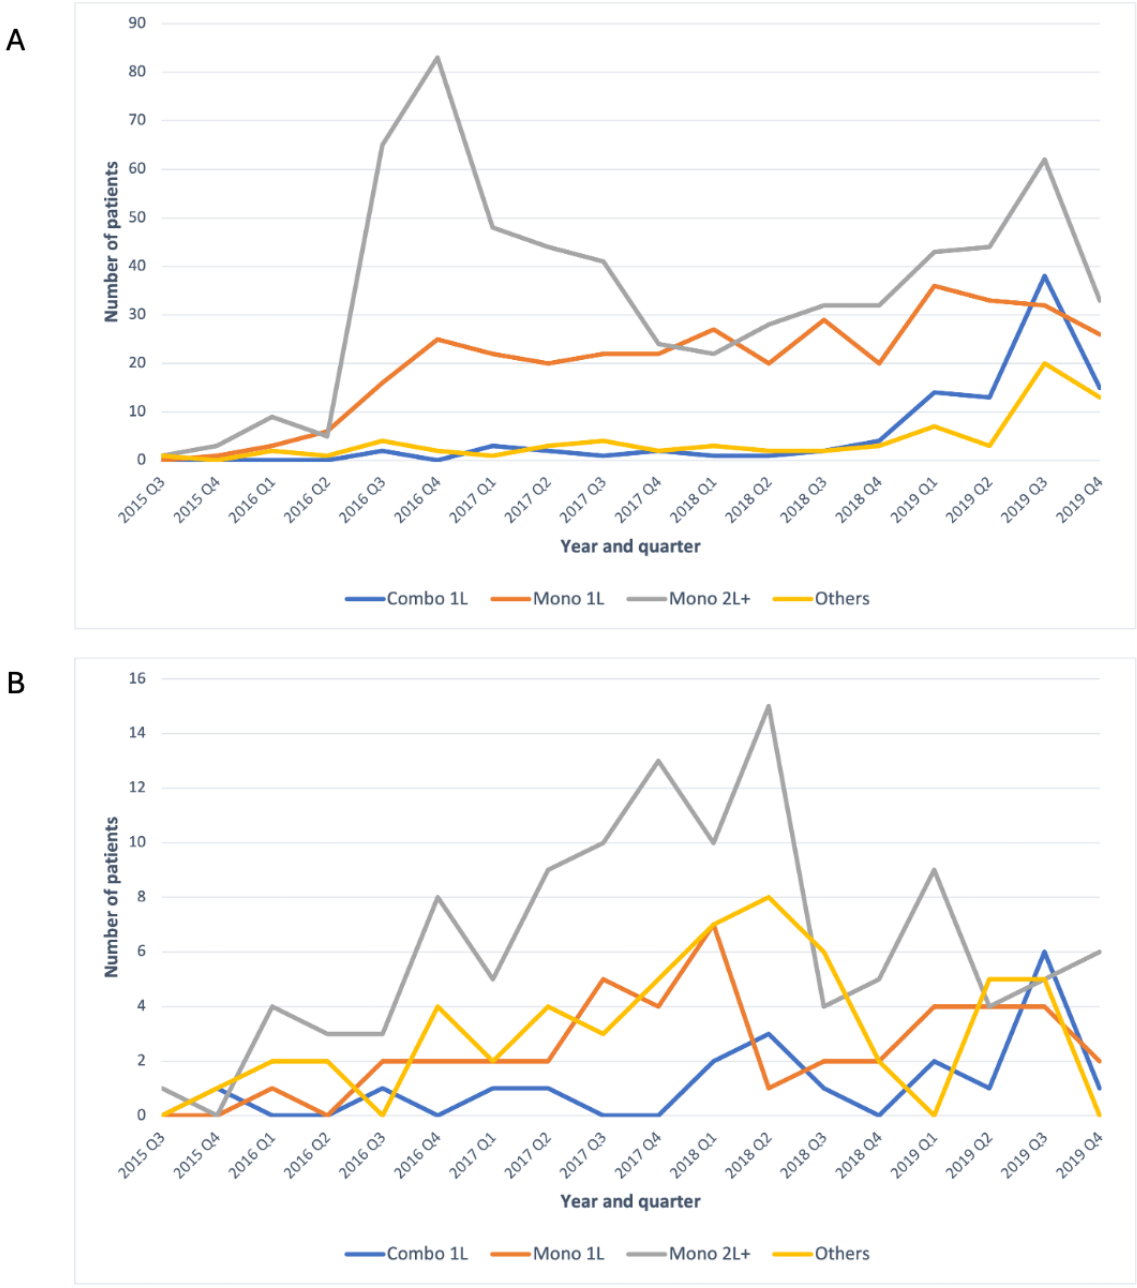
The median length of the gap between target SACT administrations was 21 days in both the data sets, which aligned with the expected dose schedule for the target SACT (Table 3, task 5). However, the range of the gap was considerably shorter in Data set A (1-113 d) than in Data set B (1-824 d), suggesting incomplete target SACT administration records in Data set B.

For the oral SACT records, Data set A included the number of refills and a flag for canceled medication orders, whereas Data set B did not provide refill information (Table 3, task 7). This could impact the accuracy of calculating rwTTD for an orally dispensed SACT because the drug orders for patients remaining on treatment through refills would not be recorded in the database.

LOT Data Checks

The 2 data sets differed in terms of the target SACT LOT distribution over time. The cumulative frequency of target SACT initiation, including as monotherapy or combination therapy and in any LOT, tended to be greater in later years in Data set A, peaking in the third quarter (Q3) of 2019, than in Data set B, peaking in the first and second quarters of 2018 (Figure 1, task 10). In Data set A, a greater frequency of target SACT initiation as second-line or later monotherapy was consistent with approval timing in this setting (2016), which preceded the first-line approvals (2019). The later time points for second-line or later monotherapy initiation in Data set B suggest the possibility of longer data lags than for Data set A.

Figure 1. Task 10: number of patients initiating the target systemic anticancer therapy (SACT) by year and quarter in (A) Data set A and (B) Data set B. Note: Y-axis heights in panels A and B differ but were selected to best depict the patient numbers in Data sets A and B. 1L: first-line therapy; 2L+: second-line or later therapy; combo: target SACT in any combination therapy (approved or not approved); mono: target SACT monotherapy; Q1: first quarter; Q2: second quarter; Q3: third quarter; Q4: fourth quarter.



In both data sets, we observed the inclusion of patients who initiated the target SACT therapy before the applicable first-line or second-line or later US Food and Drug Administration approval dates. We believe that these are true real-world findings, which do not always correspond to recommended or approved indications, rather than data quality issues.

In Data set B, only 40.3% (4589/11386) of patients had SACT LOT records (Table 4, task 11), which coincides with the finding of lower-than-expected SACT drug administration and order rates (Table 3, task 1).

Table 4. LOT[a] rules for SACT[b] and mortality information.

Task	Data set A	Data set B
Task 10: number of patients initiating the target SACT by year and quarter	Figure 1A	Figure 1B
Task 11: completeness of LOT information, n (%)[c]		
Patients with complete line number	5594 (75.94)	4589 (40.3)
Patients with complete line name	5594 (75.94)	N/A[d,e]
Patients with complete line start date	5594 (75.94)	4589 (40.3)
Patients with complete line end date	5594 (75.94)	N/A[e]
Task 12: patients for whom the first LOT number after the advanced HNC[f] diagnosis date was not 1, n (%)[c]	0 (0)	434 (3.81)
Task 13: distribution of LOT number at target SACT initiation		
Patients who received the target SACT, n	1200	237
Line 1, n (%)	481 (40.08)	65 (27.43)
Line 2, n (%)	486 (40.5)	92 (38.82)
Line 3, n (%)	161 (13.42)	54 (22.78)
Line 4, n (%)	46 (3.83)	16 (6.75)
Line 5, n (%)	13 (1.83)	10 (4.22)
Lines 6-10, n (%)	13 (1.83)	0 (0)
Task 14: use of target SACT in 1L[g] before approval date		
1L monotherapy		
Patients who received target SACT, % (n/N)	78.37 (377/481)	67.69 (44/65)
First administration date[h] in database	July 15, 2015	November 10, 2014
Cutoff date for the earliest 5% receipt	August 29, 2016	February 4, 2016
Cutoff date for the earliest 10% receipt	November 3, 2016	September 23, 2016
Cutoff date for the earliest 25% receipt	June 28, 2017	April 27, 2017
Approved 1L combination		
Patients who received the target SACT in approved 1L combination, % (n/N)	7.69 (37/481)	6.15 (4/65)
First administration date in database	December 18, 2018	July 1, 2019
Cutoff date for the earliest 5% receipt	February 18, 2019	N/A[i]
Cutoff date for the earliest 10% receipt	April 2, 2019	N/A[i]
Cutoff date for the earliest 25% receipt	July 9, 2019	N/A[i]
Task 15: patients with death record, n (%)[c]	4695 (63.74)	3531 (31)
Task 16: patients with multiple death records on different dates, n (%)	0 (0)	N/A[j]
Task 17: patients with clinical records showing health care activity after death date (n=4695), n (%)	1497 (31.88)	N/A[j]
≥1 d after date of death	1436 (30.59)	N/A[j]
≥3 d after date of death	1290 (27.48)	N/A[j]
≥7 d after date of death	1002 (21.34)	N/A[j]
≥30 d after date of death	79 (1.68)	N/A[j]

[a] LOT: line of therapy.

[b]SACT: systemic anticancer therapy.

[c]Tasks 11, 12, and 15 were applied to the full data sets, including 7366 and 11,386 patients in Data sets A and B, respectively.

[d]N/A: not applicable.

[e]Line name and line end date were not available in Data set B.

[f]HNC: head and neck cancer.

[g]1L: first line of therapy after the advanced HNC diagnosis date.

[h]Dates are written as month/day/year.

[i]Not calculated as only 4 patients received the target SACT in a 1L combination LOT.

[j]Only the year of death was available in Data set B.

The LOT start date in both data sets included year, month, and day, and the minimum LOT number started from 1 (first line) after the earliest advanced HNC diagnosis date for all but 3.81% (434/11386) of the patients in Data set B (Table 4, task 12). A line number other than 1 after the advanced HNC diagnosis date suggests that either a definition different from the commonly used definition [29,30] was used or that there was an earlier advanced HNC diagnosis date that was not documented.

In Data set A, 40.08% (481/1200) of patients received the target SACT in first-line therapy and 59.91% (719/1200) in second-line or later therapy, including 13.42% (161/1200) in third-line therapy (Table 4, task 13). In Data set B, 27.4% (65/237) of patients received the target SACT in first-line therapy, and 72.6% (172/237) received it in the second-line or later therapy, with frequent third-line receipt (54/237, 22.8%). Therefore, LOT rules may have been applied differently in Data set A and Data set B.

Complete information about the start date of first-line target SACT drug administration (as both monotherapy and combination therapy) was available for 377+37=414 (86.1%) of 481 patients in Data set A and 44+4=48 (74%) of 65 patients in Data set B (Table 4, task 14). In Data set A, first-line target SACT monotherapy was initiated for the first time in 2015, and approximately 5% of first-line monotherapy initiation dates fell on or before 2016, when the target SACT was approved for second-line or later therapy. Target SACT in combination therapy was first initiated in late 2018, with approximately 25% of the initiation dates falling before the start of Q3 in 2019, shortly after the approval of first-line combination therapy. In Data set B, first-line target SACT monotherapy initiation was first recorded in the fourth quarter in 2014, earlier than in Data set A, and close to 10% of initiation dates occurred before the end of Q3 in 2016. Instead, the approved target SACT combination therapy was first initiated at the start of Q3 in 2019, in line with the approval date for this indication.

Mortality Data

Among 7366 and 11,386 patients in Data sets A and B, 4695 (63.74%) and 3531 (31%), respectively, had a recorded date of death (Table 4, task 15); and 4427 (60%) and 3093 (27%) patients, respectively, had death records within 3 years after the date of advanced HNC diagnosis. These percentage differences indicate that Data set B may have incomplete mortality records (or a high loss to follow-up).

In Data set A, one-third of patients (1497/4695, 31.88%) with a recorded date of death had clinical records recorded after the death date (Table 4, task 17), with a median of 11 days from the death date to the last activity date. Thus, clinical records could be entered into the health information system after the reported death date, but extreme values (eg, >30 d after the death date) might indicate integrity issues in collecting mortality data. This information was not available for Data set B, in which the dates of death were recorded only by year.

Follow-Up Data

In Data set A, most patients (5840/7366, 79.28% to 7269/7366, 99.86%) had recorded data for diagnosis, drug records, laboratory results, facility visits, and vital sign measurements (Table 5, task 18). Similarly, in the subset of 7754 patients in Data set B whose advanced HNC diagnosis date was on or after January 1, 2011, the earliest date in Data set A, these data categories were also recorded for most patients (6123/7754, 78.97% to 6893/7754, 88.7%). Records of medical procedures not related to drug administration and genomic testing were not available in Data set A, which could result in inaccurate estimates of follow-up times.

Table 5. Unique number of patients and patient-date pairs after the advanced HNC[a] diagnosis date (task 18): follow-up data for patients with advanced HNC diagnosis on or after January 1, 2011.

Variable	Data set A (n=7366)			Data set B (n=7754)		
	Value, n (%)	Unique patient-date pairs, n	Pairs per patient, n	Value, n (%)	Unique patient-date pairs, n	Pairs per patient, n
Diagnosis	6567 (89.15)	60,178	9.2	6893 (88.9)	370,671	53.8
Drug records[b]	5840 (79.28)	113,948	19.5	6802 (87.72)	269,225	39.6
Laboratory records	6860 (93.13)	179,177	26.1	6403 (82.58)	147,314	23
Facility visit	7269 (98.68)	274,714	37.8	6838 (88.19)	392,175	57.4
Vital sign measurements	7254 (98.48)	233,623	32.2	6123 (78.97)	217,797	35.6
Nondrug medical procedure	N/A[c]	N/A	N/A	6740 (86.92)	390,556	57.9
Genomic test	N/A	N/A	N/A	118 (1.52)	208	1
Biomarker test	440 (5.97)	469	1.1	N/A	N/A	N/A
ECOG PS[d]	5416 (73.53)	100,607	17.7	N/A	N/A	N/A

[a]HNC: head and neck cancer.

[b]Any drug, not just systemic anticancer therapies.

[c]N/A: not applicable.

[d]ECOG PS: Eastern Cooperative Oncology group performance status.

The median frequency of visits (normalized by length between first and last target SACT administration) for patients who received the target SACT was somewhat less in Data set A, varying from 0.05 to 0.12, depending on treatment line, than in Data set B, in which it varied from 0.14 to 0.18 (Table 6, task 19). This might indicate that more clinical activities were recorded in Data set B during treatment.

Table 6. Follow-up data for patients with advanced HNC[a] diagnosis on or after January 1, 2011.

Task	Data set A (n=7366)			Data set B (n=7754)		
	Value, n	Value, median (IQR; range)	Value, mean (SD)	Value, n	Value, median (IQR; range)	Value, mean (SD)
Task 19: frequency of visits during target SACT[b,c]						
1L[d] combination therapy	101	0.11 (0.07-0.16; 0.02-0.33)	0.13 (0.07)	19	0.17 (0.11-0.24; 0-0.36)	0.17 (0.09)
1L monotherapy	358	0.05 (0.05-0.08; 0.01-0.50)	0.07 (0.05)	44	0.18 (0.09-0.22; 0-0.48)	0.16 (0.11)
2L+[e] monotherapy	634	0.06 (0.05-0.10; 0.01-0.95)	0.08 (0.06)	106	0.13 (0.07-0.25; 0-0.75)	0.17 (0.14)
All other	104	0.12 (0.09-0.17; 0.02-0.48)	0.14 (0.08)	76	0.14 (0.09-0.21; 0-1.3)	0.17 (0.17)
Task 20: for patients still alive, gap (in d) from the last target SACT administration and last visit[f]	708	28 (6-187; 0-1118)	128 (199)	167	70 (29-223; 0-1755)	159 (215)

[a]HNC: head and neck cancer.

[b]SACT: systemic anticancer therapy.

[c]Frequency defined as number of visits between the first and last target SACT administration dates within the same LOT number and name, divided by number of days between the last and first target SACT administration.

[d]1L: first line of therapy after the advanced HNC diagnosis date.

[e]2L+: second-line or later therapy.

[f]Limited to patients who (1) were still alive ≥180 days after last receipt of target SACT and (2) received last dose of target SACT ≥180 days before data cutoff on November 25, 2019 (thus on or before May 29, 2019).

Discussion

Principal Findings

This study identified 20 data quality assessment tasks for the use case of estimating the rwTTD of an SACT. By executing the 18 tasks pertinent to the intravenously administered target SACT, we demonstrated that the UReQA framework for the rwTTD use case can be implemented to generate descriptive summary statistics and charts. These visualizations provide additional insights into the relevance and quality of 2 US EHR-based oncology RWD. The approach is generalizable to implement for other SACT and databases.

Both data sets in the evaluation provided all the required data elements; however, verification checks revealed that Data set B might not be suitable for analyzing rwTTD for the target SACT because (1) the large decrease in patient receiving the target SACT in recent years suggests longer lags in incorporating the most recent data and (2) the completeness and plausibility issues in the SACT, LOT, and mortality data could cause faulty determination of treatment discontinuation date and status of censoring.

The fact that Data set B included a lower percentage of patients receiving the target SACT (237/4003, 5.9% vs 1200/4808, 24.96% in Data set A) limited the utility of the data for determining the rwTTD. This finding highlights the need and importance of conducting a rigorous and use case–specific data quality assessment in the planning stage of RWD studies. In addition, for Data set B, findings of extremely low and high gaps between target SACT administration dates would warrant further investigation of each patient's trajectory to verify the specific data quality issue before taking proper data quality improvement actions such as removing the patient or the SACT record as outliers.

Limitations

This study has several limitations that require further discussion. First, adequately assessing the reasons for missingness across different RWD sources is challenging. In particular, the data feeds and capture of elements across different data sources are variable. A lack of transparency and consistency means that different RWD sources are often not fully interoperable [38]. In this study, we applied cohort attrition steps to align populations represented in the 2 data sets and imputed the LOT end date and LOT name that were missing in Data set B. However, a major remaining roadblock was the vendor's privacy-preserving aggregation, which does not allow data sources to be adequately reviewed on more granular level to understand the reason behind missing data, data quality issues, or data discrepancies.

Second, the implementation of data quality checks for new RWD sources, especially for those with data table structures that differ from those of prior data sets, requires customization and reconfiguration that are often time consuming. We are developing a data dashboard tool that can accelerate this process for both raw data and a common data model such as that of the Observational Health Data Sciences and Informatics [17,18].

Third, use case–specific data quality assessment checks often provide only a limited view of the comparative validity of the RWD under consideration, particularly when a well-recognized gold standard is absent. The paucity of data often limits an effective comparison with the distribution of key data elements in the general population (external validity). In this study, we set a priori metrics for these checks by using domain knowledge such as HNC prevalence [33] and regulatory approval timelines. It would be interesting for future studies to validate and update these metrics.

Comparison With Prior Work

Prior studies have evaluated rwTTD, also known as the duration of therapy and real-world time on treatment, for immuno-oncology agents used in treating recurrent or metastatic HNC [39], advanced non-small cell lung cancer [28,40-42], and other solid cancers [42]. In contrast to this study, these studies drew on research-ready databases (as would be identified in the preassessment step of UReQA [3]), and the actions taken to ensure RWD fitness and quality were limited to aligning patient eligibility criteria (the cohort definition step of UReQA [3]).

New use cases can be created for other medication-related outcomes or therapeutic areas by following the first 3 steps of implementing the rwTTD use case in this study. In addition, the data quality checks that we identified and created for the rwTTD use case can be used for other types of use cases. For example, checks on medication identification and dates can also be used to evaluate the fitness of RWD sources for studying medication adherence. The checks on mortality and follow-up visits could validate the applicability of an RWD source for survival analyses.

Future Work

We selected 2 US EHR-based oncology databases to implement the UReQA use case of rwTTD. These were the only 2 databases the research team had access to that provided both oncology treatment and LOT information during the time of study execution. Each database may have its own bias in representing the overall advanced HNC population in the United States. Future work could implement (1) evaluation of more US EHR-based oncology databases to bring more impactful findings and (2) investigating the associations between rwTTD calculation and quantitative data quality assessment for various medications of interest and cancer types.

Conclusions

The fit-for-purpose quality assessment demonstrated the high level of variability in quality of the 2 real-world data sets for estimating the rwTTD of an SACT for advanced HNC. This study illustrates the application and value of use case–specific data assessment tasks in identifying high-quality RWD for research studies. The data quality specifications supporting this comprehensive use case can be expanded to other use cases in oncology outcomes research. Incorporating such comprehensive data quality assessment could help the study team select the most suitable database in the planning stage of a real-world evidence study. In addition, understanding data quality concerns particularly relevant to research questions can provide additional insights for properly preparing data in full study execution.

Abstract

Background: Data from multiple organizations are crucial for advancing learning health systems. However, ethical, legal, and social concerns may restrict the use of standard statistical methods that rely on pooling data. Although distributed algorithms offer alternatives, they may not always be suitable for health frameworks.

Objective: This study aims to support researchers and data custodians in three ways: (1) providing a concise overview of the literature on statistical inference methods for horizontally partitioned data, (2) describing the methods applicable to generalized linear models (GLMs) and assessing their underlying distributional assumptions, and (3) adapting existing methods to make them fully usable in health settings.

Methods: A scoping review methodology was used for the literature mapping, from which methods presenting a methodological framework for GLM analyses with horizontally partitioned data were identified and assessed from the perspective of applicability in health settings. Statistical theory was used to adapt methods and derive the properties of the resulting estimators.

Results: From the review, 41 articles were selected and 6 approaches were extracted to conduct standard GLM-based statistical analysis. However, these approaches assumed evenly and identically distributed data across nodes. Consequently, statistical procedures were derived to accommodate uneven node sample sizes and heterogeneous data distributions across nodes. Workflows and detailed algorithms were developed to highlight information sharing requirements and operational complexity.

Conclusions: This study contributes to the field of health analytics by providing an overview of the methods that can be used with horizontally partitioned data by adapting these methods to the context of heterogeneous health data and clarifying the workflows and quantities exchanged by the methods discussed. Further analysis of the confidentiality preserved by these methods is needed to fully understand the risk associated with the sharing of summary statistics.

Introduction

Health Analytics at Scale

Learning health systems (LHSs) are coming of age and are being deployed to address important health challenges at different scales. The framework starts by leveraging health data created across various activities. It obviously includes data points from clinics and hospitals, but the perimeter of data required to meaningfully and optimally address important problems is much wider and includes research cohorts, biobanks, quantified self-data, environmental exposures, and social service delivery.

While some questions might be addressed at the scale of an individual organization, LHSs focus on system interactions and often require the analysis of processes and outcomes from various organizations. For example, to fully understand a cancer care trajectory, multiple data sources from multiple organizations will need to be examined to cover all relevant aspects (both within the traditional health system and in the community). This often implies organizations that are at least regional or of a wider scope (provinces, states, and countries),

such as in the context of the Health Data Research Network Canada or Health Data Research United Kingdom. Similarly, comparing various approaches is often a fruitful way to identify the best approaches and understand what works, why, and how to scale the promising projects. It can also be a way to amass a critical number of observations in the context of rarer diseases. Nevertheless, working with data from multiple sources, from multiple organizations, and located in multiple jurisdictions poses significant challenges.

Traditionally, the analytical methods used by researchers in health-related and other domains have relied on data pooling (sometimes referred to as data centralization)—all required data are physically copied to a single location where analysis can take place. However, when working with data from multiple jurisdictions (even when part of the same country, such as the Canadian provinces and territories), data pooling is often very difficult, if not impossible, for ethical, legal, and social acceptability reasons.

Therefore, there is a pressing need to offer analytical methods allowing for the analysis of such data without the need to physically copy the data in a central location.

The primary intent of this study was to lay the foundations for future practical assessments of the feasibility of conducting distributed statistical analyses in health-related contexts. We achieved this by reviewing the literature on existing methods, evaluating which ones could be applied to a class of widely used regression models, and precisely identifying their operational and information sharing requirements in a notational framework that allows for straight comparisons. This unified framework enables the description of methods' operational workflows, quantities exchanged, and algorithmic implementation and operates under assumptions commonly satisfied in health analytics.

This paper is structured as follows. We begin with a formal description of the distributed analytical framework considered in this study, followed by a discussion on the challenges associated with its implementation in health analytics. Next, we state our specific objectives and outline the methodology used to achieve them, including a scoping review and our approach to establishing the common notational framework for method description and comparison. After presenting the results pertaining to each objective, we discuss our findings and remaining challenges regarding distributed statistical analyses for health analytics.

Distributed Analysis

Overview

This study was concerned with frameworks in which the data needed for a statistical analysis consisted of the data about n individuals (referred to as the *analytical data set*), which are not all stored in a single source but are partitioned among K locations that will be called *nodes* hereafter. Therefore, the mereological sum of all the data held at each node forms the analytical data set. Data can be partitioned horizontally or vertically (or in a mixed way).

A horizontal partition implies that all data pertaining to a given individual can be found in a single node. If we assume that patients receive care only in 1 province, Canadian provincial health administrative data sets hosted by organizations such as Population Data BC, the Institute for Clinical Evaluative Sciences in Ontario, or the Manitoba Centre for Health Policy in Manitoba can be part of a horizontal partition. A clinical trial in which each recruiting site captures all data for a given participant is another example.

A vertical partition occurs when all data of a certain type are available in a single node for a group of individuals. A classic example is a hospital with its various information systems. All pathology results can be found in the pathology system, all billing information can be extracted from the finance system, and all x-rays are accessible in the picture archiving and communication system. However, to obtain the full picture of the care received by a patient, multiple systems need to be interrogated. Similarly, in the research setting, health administrative data may be in a provincial data center, and genomics data could be held in a research institute.

A mixed partition occurs when both principles partly apply—some individuals may have their data spread out across nodes, and different individuals may be present in different nodes.

Assumptions

The difficulties in conducting analyses on a large scale mentioned previously are often associated with horizontally partitioned data, and this work focused on this type of partition. Therefore, the methods presented in this paper might not be directly applicable to vertically partitioned data.

One group of approaches often labeled as *distributed analysis* involves calculations at each participating node and exchanges of the resulting aggregated statistics with a *coordinating center* (CC), which can itself also perform additional calculations based on the received aggregated statistics. The CC can be an organization not responsible for a data node or a data node taking on the additional role of CC for a given analysis.

It is important to note that, whether in the more traditional way of data pooling or using distributed approaches (in which the data are not copied centrally), data sources will be different on multiple levels. They will represent information using data models with significant variability in terms of structure and technology but also in terms of semantics. This situation also leads to heterogeneous data in which the presence of predictors and outcomes is likely to be different in different nodes. Different approaches (eg, data mediation or extract, transform, and load) have been developed to address these issues, and this work assumed that one of them was applied so that the data nodes mentioned hereafter are assumed to share the same structure, the same technological syntax, and the same semantics, as well as no missing data.

Horizontally Partitioned Statistical Analytics

In what follows, the field that pertains to the statistical analysis of horizontally partitioned and semantically homogeneous data

that cannot be consolidated into a central location will be called *horizontally partitioned statistical analytics* (HPSA).

Methodological contributions to this field have arisen from several streams of literature. Meta-analysis and meta-regression methods [1] can be viewed as part of HPSA (eg, by considering that each node-specific data set belongs to a different pseudostudy). However, their scope is narrower compared to that of HPSA because they typically assume that only established study-level estimates are available as data. Conversely, HPSA allows for the sharing of additional summary statistics between the nodes and the CC, such as gradients and Hessians, to ensure the best possible performance at the global level. As meta-analysis does not leverage any supplementary information that could be obtained from studies with access to patient-level data, it can be susceptible to biased estimation, especially in settings with rare outcomes or in the presence of data nodes with limited sample sizes [2]. As meta-analysis and meta-regression methods have been extensively covered in the literature, approaches specifically designed for the analysis of already established study-level estimates will not be discussed hereafter.

An important research community that has generated a significant amount of analytical contributions is concerned with the massive data setting. There, a data set often cannot be processed by a single server and, therefore, is split across multiple machines, which are then considered as nodes able to perform computations and send aggregated results to a CC tasked with fitting a global model from them. The methodological avenues proposed in this setting share similarities with the ones designed for the multi–research facility setting involved in LHSs but also have important differences. For example, in a massive data setting, the experimenter has control over the distribution of individuals across nodes, which is typically not the case in multi–research facility studies. Thus, while these approaches share mechanistic similarities and have been suggested as options to consider in the health domain, some hypotheses may not hold. In regression settings, it is often reasonable to assume that the regression link between the response and covariate predictors is the same across nodes. However, assuming that the sampling distribution of covariates involved is equal across nodes is unrealistic in the health domain, particularly due to the presence of data centers that may systematically involve different types of patients. For example, certain clinics may predominantly serve older individuals. While this may not affect the estimation of parameter values, it can have implications for computing CIs to ensure the validity of inferences.

So far, 2 reviews discussing methods applicable to horizontally partitioned data have been published [3,4]. However, their focus is on the massive data setting, which works almost invariably under the assumption of even sampling distribution of covariates and equal sample sizes across nodes, and statistical inference tasks beyond parameter estimation are barely covered. This makes them less helpful for health analytics purposes as most studies involving data analyses rely on CIs or hypothesis testing in settings in which predictors' distribution and sample sizes vary across nodes.

Contemporary Challenges in HPSA

Overview

The problem is 3-fold. First, there is a need to raise awareness regarding the existence of HPSA approaches among researchers aiming at undertaking statistical analyses from horizontally partitioned data, especially in health analytics. The reflex is often to request data pooling because it is perceived as the sole option. This has been the tendency of requests made by researchers to the Health Data Research Network Canada. Practitioners are usually concerned with finding the most appropriate statistical model that will take into account as many of the features of their specific context of application as possible. Consequently, a clear and unifying mapping of the state of the HPSA field is needed for them to be informed of the scope of existing methods available for their analyses to see whether alternatives to pooling exist.

Second, as underlined previously, methodological contributions came from research fields whose working assumptions can be fundamentally different from the ones researchers would be willing to make in health analytics. To ensure proper use of statistical inference techniques, it is necessary that the underlying assumptions of existing methods be adequately identified and understood. If necessary, these methods should be adapted to suit the specific requirements of health applications, thereby ensuring accurate and reliable results.

Third, data custodians have to be properly informed on data sharing requirements entailed by the use of a specific HPSA method applicable to a given research setting. While HPSA avoids the complexities of pooling data, there are still flows of information that have to be acceptable to data stewards. However, even in basic statistical scenarios, available methods are often presented in a way that makes them challenging to compare in terms of information sharing requirements and operational complexity. Therefore, there is a need for clearer and more accessible presentations of these methods to facilitate decision-making regarding data sharing and operational implementation.

Although it would be ideal to offer managers a comprehensive operational workflow for each identified method to evaluate the information shared and execution complexity, with their accompanying underlying modeling assumptions, the abundance and diversity of available approaches make it unfeasible to accomplish this in a single paper. In fact, methods often differ in terms of their targeted application beyond their distributed aspect. For example, differences may exist in the studied model (eg, linear, logistic or Cox regression, and additive models), the dimensionality and sparsity of the predictor variable space, the use of regularization or shrinkage, the presence of missingness, confounders, imbalances, and heterogeneity.

Objectives

The objectives of this study were as follows:

1. To identify and map, from the literature, methodological approaches that make it possible to perform CI estimation and hypothesis testing from a horizontally partitioned data set

2. Among the approaches identified, to describe the ones that allow for the conduct of generalized linear model (GLM) analyses and identify their distributional assumptions
3. On the basis of the approaches identified for GLM-based inferences, to present methods adapted to the setting of uneven sampling distributions across nodes and compare them in terms of information sharing requirements and operational complexity

A scoping review methodology was chosen to achieve objective 1 of mapping the state of the field of HPSA that pertains to inference procedures. For our second objective (objective 2), we identified from the articles selected from the literature search the ones that presented a methodological framework for conducting statistical inference procedures from a GLM with horizontally partitioned data. We then used these frameworks to derive and describe GLM estimators that are applicable to horizontally partitioned data sets. For each identified method, we analyzed and reported its communication workflow and the distributional assumptions. For our third objective (objective 3), we first used statistical theory to adapt the identified procedures to the unequal sample size and uneven covariate distribution setting. Algorithms and mathematical expressions for the quantities involved are reported. For conciseness, we present mathematical formulas for estimation procedures of CIs only. Expressions involved for hypothesis testing are similar and can be deduced following the close connection between CIs and hypothesis tests in GLMs (eg, see Agresti [5]).

The mathematical description of the GLM setting considered for this analysis is described in the following section along with the mathematical notations to be used.

Mathematical Foundations and Notation

Notation

In the following, lowercase letters in bold will represent vector-valued quantities, whereas uppercase letters in bold will denote matrices. The jth element of any vector $\boldsymbol{a} \in {}^{p}$ will be denoted as $[\boldsymbol{a}]_j$. Similarly, the entry at position (j, l) of any matrix $\boldsymbol{A} \in {}^{p \times p}$ will be denoted as $[\boldsymbol{A}]_{jl}$. If g is a real-valued and invertible function, we will use $g^{(-1)}$ to represent its inverse. In addition, if f_θ is a real-valued function that depends on a parameter vector θ and is twice continuously differentiable, $\nabla_\theta f_\theta$ and $\nabla^2_\theta f_\theta$ will, respectively, indicate the gradient and Hessian matrix of f_θ with respect to θ.

Model Mathematical Assumptions

A mathematical depiction of the horizontally partitioned data framework studied in this paper is as follows. There are n individuals horizontally partitioned across K data storage nodes. Each node's data set is denoted by $D_k=\{z_{ik}=x_{1ik},\ldots,x_{pik},y_{ik}\}_{i=1}^{n_k}$, where $1 \le k \le K$. Here, z_{ik} represents the measurements on the ith individual at node k, where $y_{i(k)} \in \mathbb{R}$ denotes their response variable and $[x_{1i(k)},\ldots,x_{pi(k)}] \in \mathbb{R}^p$ denotes their covariate vector. The total sample size at node k is denoted by $n^{(k)}$. The combined data set $D_{(1)},\ldots,D_{(K)}$ make up the whole data set without any duplicated individuals, indicating that $\sum_{k=1}^{K} n_k = n$.

Throughout the analysis, it is assumed that each z_{ik} is independent across $1 \le i \le n^{(k)}$ and $1 \le k \le K$ and there are no missing data. In addition, the size of the covariate space (ie, the dimension of $x_{1ik},\ldots,x_{pik}$, which is equal to p representing the number of features to include as predictors in the GLM) is assumed to be low, eliminating the need for regularization or variable selection. Finally, it is assumed that each node possesses a nonnegligible proportion of the whole data set. Specifically, for each $k \in \{1, \ldots, K\}$, the quantity $n^{(k)}/n$ is bounded away from 0 and 1 as the sample size n tends to infinity, denoted as $n^{(k)}/n \to p^{(k)} \in (0,1)$.

Mathematical Description of the GLM Framework

The formulation of the GLM considered in this paper encompasses various commonly used regression models, such as linear regression, logistic regression, Poisson regression, and probit models. It assumes that the density or probability mass function of each response variable (known as the random components) belongs to the exponential family of distributions. Within this formulation, the mean of the response variable is expressed as a function of a linear combination of the corresponding covariate vector. Formally, it assumes that there exist unknown parameters $\beta \in \mathbb{R}^{p+1}$ and $\varphi > 0$ and known model-specific functions b, c, g, and h such that, with $x_{ik}=x_{0ik},x_{1ik},\ldots,x_{pik}$ and $x_{0ik}=1$, $y_{i(k)} \mid x_{i(k)} \sim f(\cdot\,; x_{i(k)}, \beta, \varphi)$, where, for any $\beta=[\beta_0,\beta_1,\ldots,\beta_p] \in \mathbb{R}^{p+1}$ and φ,

$$f(y; x_{i(k)}, \beta, \varphi) = \exp[y h(\beta^{\top} x_{i(k)}) - b\{h(\beta^{\top} x_{i(k)})\}\varphi + c(y,\varphi)] \quad (1)$$

In formula 1, b is such that $b'\{h(\beta^{\top} x_{i(k)})\} = E(y_{i(k)} \mid x_{i(k)}) = g^{-1}(\beta^{\top} x_{i(k)})$, with $b'(x)=\partial b(x)/\partial x$. In this framework, g is called *link function*, the term $h(\beta^{\top} x_{i(k)})$ is usually referred to as the *natural parameter*, and b is referred to as the *cumulant* function. φ is often called the *dispersion parameter* and is either known (eg, with $\varphi=1$) or unknown. When $h(x)=x$ (ie, h is the identity function), the link g is called *canonical*.

The logistic regression model is obtained upon taking $\varphi=1$, $h(x)=x$, $b(x)=\log(1+e^x)$, $c_{y,\varphi}=0$, and $g(x)=\log\{x/(1-x)\}$. The linear regression model with homoscedastic residual error variance φ is derived upon setting $h(x)=x$, $b(x)=x^2/2$, $c_{y,\varphi}=-y^2/2\varphi-\log 2\pi\varphi/2$, and $g(x)=x$. Hence, both the logistic and the linear regression models rely on a canonical link function in the exponential family distribution.

Methods

Methodology Related to Objective 1

Overview

Scoping reviews are well suited to efficiently map key concepts within a research area [6]. They are widely acknowledged for their ability to clarify working definitions and conceptual boundaries in a specific topic or field [7], facilitating a shared understanding among researchers regarding the status of the research area. These considerations make the scoping review methodology well designed to achieve objective 1.

Scoping studies use systematic searches of relevant databases, using specific keywords to define the boundaries of the research

field. However, identifying these keywords can be challenging, particularly when relevant papers are scattered across different research streams or in independent clusters that do not reference each other. To address the risk of overlooking significant methodological contributions due to a limited number of keywords, a snowballing literature search was initially conducted to generate a comprehensive list of keywords related to HPSA. The scoping review then proceeded with a systematic literature search using the identified keywords. It is worth noting that, as the planning of the scoping review is independent of the search approach, the guidelines presented in the work by Arksey and O'Malley [6] are still appropriate.

Methodology Pertaining to the Snowballing Keyword Search

Snowballing is generally used as a literature search method aimed at identifying papers belonging to a given field [8]. It typically consists of three steps: (1) initiate searches in prominent journals or conference proceedings to gather an initial set of papers, (2) conduct a backward review by examining the reference lists of the relevant articles discovered in step 1 (continue iterating until no new papers are found), and (3) perform a forward search by identifying articles that cite the papers identified in the previous steps.

To avoid selection bias, the initial set of papers for the snowballing approach in step 1 is sometimes generated through a search in Google Scholar [9]. The latter strategy was used in this study, too.

As mentioned previously, in this review, the snowballing search strategy was used in preparation for the application of the scoping review protocol with the goal of identifying relevant keywords. Specifically, the starting set of papers was assembled by screening titles and abstracts from the first 50 papers generated through a Google Scholar search using the strings *distributed inference* and *federated inference*. The main inclusion criterion was "presents, applies or discusses a statistical inference method to analyse horizontally partitioned data." The backward and forward snowballing step approaches were then applied.

From the set of keywords found in the selected papers, a list of those relevant to HPSA but not directly associated with any specific method was retained for the scoping review step. It is worth noting that, as the objective of this scoping review was to identify statistical inference methods for horizontally partitioned data, keywords linked to method identifiers had to be excluded from the retained list to avoid preselection bias in the scoping review phase of this project.

The selected keywords that were identified from the snowballing literature search were *distributed algorithms*, *distributed estimation*, *distributed inference*, *distributed learning*, *distributed regression*, *federated inference*, *federated estimation*, *federated learning*, *privacy-protecting algorithm*, *privacy-preserving algorithm*, and *aggregated inference*.

Methodology Pertaining to the Scoping Review

The scoping review methodological framework by Levac et al [10] (see also the work by Arksey and O'Malley [6]) was followed. The steps are briefly described in this section. A detailed protocol is available in Multimedia Appendix 1 [2,4,6,10-19].

We conducted a comprehensive search across 4 bibliographic databases—MEDLINE, Scopus, MathSciNet, and zbMATH—to encompass the interdisciplinary nature of the topic and identify relevant research articles. Our search strategies were based on 2 key concepts: distributed data and statistical inference. In addition to the keywords obtained from the snowballing step, we incorporated terms such as *confidence interval* to target articles focusing specifically on statistical inference. To ensure the inclusion of recent advancements, our search was limited to papers published from 2000 onward. This cutoff date was chosen to account for the emergence of distributed data, the prevalence of massive data sets, and advancements in technology. It was set conservatively to capture any early developed methods and ensure comprehensive coverage of the topic.

After completing the primary search, a 2-stage selection process was used. Initially, 2 authors (MPD and FCL) collaborated to screen all articles identified through the search strategy based on their titles and abstracts. Subsequently, the full texts of the selected articles were independently reviewed by both authors to finalize the selection. This rigorous approach ensured a thorough evaluation of each article's relevance and eligibility for inclusion.

The primary inclusion criterion for the selection process was as follows: *presents a solution for conducting inferential statistics on horizontally partitioned data*. This criterion was used to ensure that the chosen articles specifically addressed methods associated with performing statistical inference on horizontally partitioned data.

The following exclusion criteria were derived directly from objective 1: (1) does not address inferential statistics, including CIs, hypothesis testing, or asymptotic normality; (2) does not provide a methodological contribution; and (3) presents a solution for encryption or secret sharing.

To ensure the inclusion of validated approaches, the selection process only considered published papers that had full-text availability in English or French. Discussion papers were excluded as they do not present novel methods or approaches.

Exclusion was considered if any of the exclusion criteria were met or if any of the inclusion criteria were not met.

Finally, the references of each included article from the databases were assessed to identify any relevant articles that may not have been captured during the initial screening due to specific keywords. This additional step in the selection process was necessary given the broad range of vocabulary used to describe applicable approaches in our context.

Data extraction for the included articles was conducted by one author (MPD) and followed a collectively developed data-charting form. Model type (*parametric regression*, *semiparametric regression*, *nonparametric regression*, or *not specific to regression*) and number of communications from the CC to the nodes (0 or ≥1) were among the data extracted. All

methods from the included articles were subsequently classified according to their specified characteristics, as outlined in the protocol. In addition, as part of the analysis, we conducted a screening of the general distributed approaches commonly used across all specific methods.

Methodology Related to Objective 2

Overview

To achieve objective 2, a total of 3 steps were taken. First, we identified methodological approaches from articles included in this scoping review that enable parameter and CI estimations from horizontally partitioned data within a standard GLM framework. Methods designed specifically for the particular cases of linear or logistic regression were also reported but were not analyzed in detail. Second, we extracted workflows for each approach to determine the information exchanged between data storage nodes and the CC. Third, we analyzed the mathematical assumptions necessary for parameter estimation and the consistency of CI procedures. We specifically reported the assumptions related to the distribution of node-specific covariates.

Identification of the Approaches

To identify approaches that enabled the fitting of any GLM using horizontally partitioned data, 2 authors (FCL and MPD) independently assessed all articles included in this scoping review. The reviewers specifically looked for articles that discussed approaches applicable to the GLM class described in the *Mathematical Foundations and Notation* section, including likelihood-based methods, M-estimation, and estimating equations. In addition, we identified and reported articles that specifically focused on regression settings for linear or logistic regression. However, unless the method described was considered easily adaptable to the GLM framework, these articles were not retained for detailed analysis.

A method was selected if it provided an algorithm for fitting GLMs using horizontally partitioned data, aligning with the characteristics outlined in the *Mathematical Foundations and Notation* section. In cases in which an article presented asymptotic normality results for the estimators but did not provide an estimator for the asymptotic variance-covariance matrix, the article was still retained, and an estimator for the asymptotic variance was derived using the available calculated quantities.

As our GLM framework assumes no missing values, low dimensionality, and a small number of nodes relative to the total sample size, any terms related to these specific conditions mentioned in an article's methodology were disregarded. Consequently, the calculations for CIs were adjusted accordingly. If an article solely focused on one of these aspects without contributing to the overall methodology, it was not included in the final selection.

Methodological components regarding parameter estimation and CI procedures were extracted from the screened articles. Specifically, the focus was on understanding how parameters should be estimated within a horizontally partitioned framework and how CIs should be computed for these parameters. For each article, the formulas related to quantities shared among the nodes and quantities calculated by the CC were derived and analyzed. These formulas were examined within a workflow that indicated the necessary circulation of information for the procedure to be executed. The derived workflows constituted the first part of our defined unified framework for HPSA approach comparisons in GLM settings.

For the reported results, the rationale behind each method that was deemed suitable for fitting GLMs was documented, along with the corresponding reference to the paper included in this scoping review in which the method was introduced or discussed.

Articles that discussed approaches specifically applicable to the cases of linear or logistic regression were also mentioned but not elaborated on in detail.

Methodology Related to Objective 3

In most statistical settings with horizontally partitioned data, it is commonly assumed that the sample sizes of the data nodes are equal and that the distribution of covariates is the same across all nodes. However, when the number of nodes is fixed and relatively small compared to the sample sizes, it is possible to adapt a particular approach to handle situations in which the sample sizes and covariate distributions vary across nodes. This can be achieved by combining the theoretical arguments presented in the original article on the method in question with the principles of asymptotic statistics theory concerning maximum likelihood estimation.

To adapt a given approach for situations in which sample sizes and covariate distributions differ across nodes, the following steps were taken:

1. The formulas for the relevant quantities were modified to emphasize the changes caused by this scenario. It was ensured that the adapted quantities were equivalent to their counterparts presented in the original article for an equal sample size setting.
2. Using asymptotic theory, an asymptotic normality result was derived for the estimators of interest considering a set of assumptions that accommodated potential variations in sample sizes and covariate sampling distribution across nodes while still enabling meaningful theoretical arguments.
3. Formulas for the asymptotic variances were derived. Statistical theory on maximum likelihood estimation was used to obtain consistent estimators for asymptotic variances. The latter estimators were derived under the constraint that they had to be calculated without requiring any additional communication round between the CC and the nodes. Thus, throughout the adaptation process, the communication workflow remained unchanged compared to the original method.

These steps ensured the mathematical correctness of adapting the approaches to handle different sample sizes and covariate distributions across nodes. Importantly, these adaptations maintained consistency with the original method's communication workflows. To adapt and compare the methods based on their information sharing requirements, common assumptions and a unified mathematical and algorithmic notation

were necessary. Ultimately, these assumptions and the notation, along with the workflow types derived for objective 2, enabled us to establish a unified notational framework for approach comparisons when performing HPSA based on GLMs in the context of health analytics.

We describe the statistical estimates of interest. A standard GLM typically includes 1 or 2 unknown parametric components. The first are the β parameters, which are commonly assumed to be unknown. The second component is the nuisance parameter φ, which can be either known (eg, in logistic models) or unknown (eg, in linear models). In practical applications, when φ is unknown, its estimated value is often not the main focus, although the latter is necessary to estimate the asymptotic variance of the β parameter estimates.

In the upcoming analysis, we will assume that the parameter φ is unknown and estimated using the recommended approach in the selected methods. However, in cases in which φ is known, the process becomes simpler. This involves substituting the known value of φ and disregarding the estimation step. It is important to highlight that estimating φ requires additional information to be shared between the nodes and the CC but it does not necessitate any extra communication round between them.

The estimation processes for both the β and φ parameters are discussed. In addition, we explain how to compute an estimator for the asymptotic variance specifically for the estimator of β. It is important to note that the results presented in the following section can be modified and extended to develop a similar procedure for estimating φ.

Using these results, based on an estimator of β (eg, $\hat{\beta}$) and a formula for the estimator of the asymptotic variance-covariance matrix involved in its associated asymptotic normality result (eg, $\hat{\Sigma}$), Wald-type $(1-\alpha)$ CIs can be computed for each component of β using the following formula:

$$[\hat{\beta}]_j \pm z_{1-\alpha/2}\sqrt{[\hat{\Sigma}]_{jj}/n} \text{ for } j \in \{1,\ldots,p+1\}$$

Regarding the reported results, for each approach considered, we present the formulas necessary to compute the final estimates of the β parameters and their corresponding CIs. The presentation of these formulas was designed to emphasize the communication workflow. Furthermore, a comprehensive algorithm is provided outlining the step-by-step process.

In addition, the asymptotic normality of the β parameter estimators is stated accompanied by the formula for the asymptotic variance and its consistent estimator. Detailed proofs for these results can be found in Multimedia Appendix 2 [20-22].

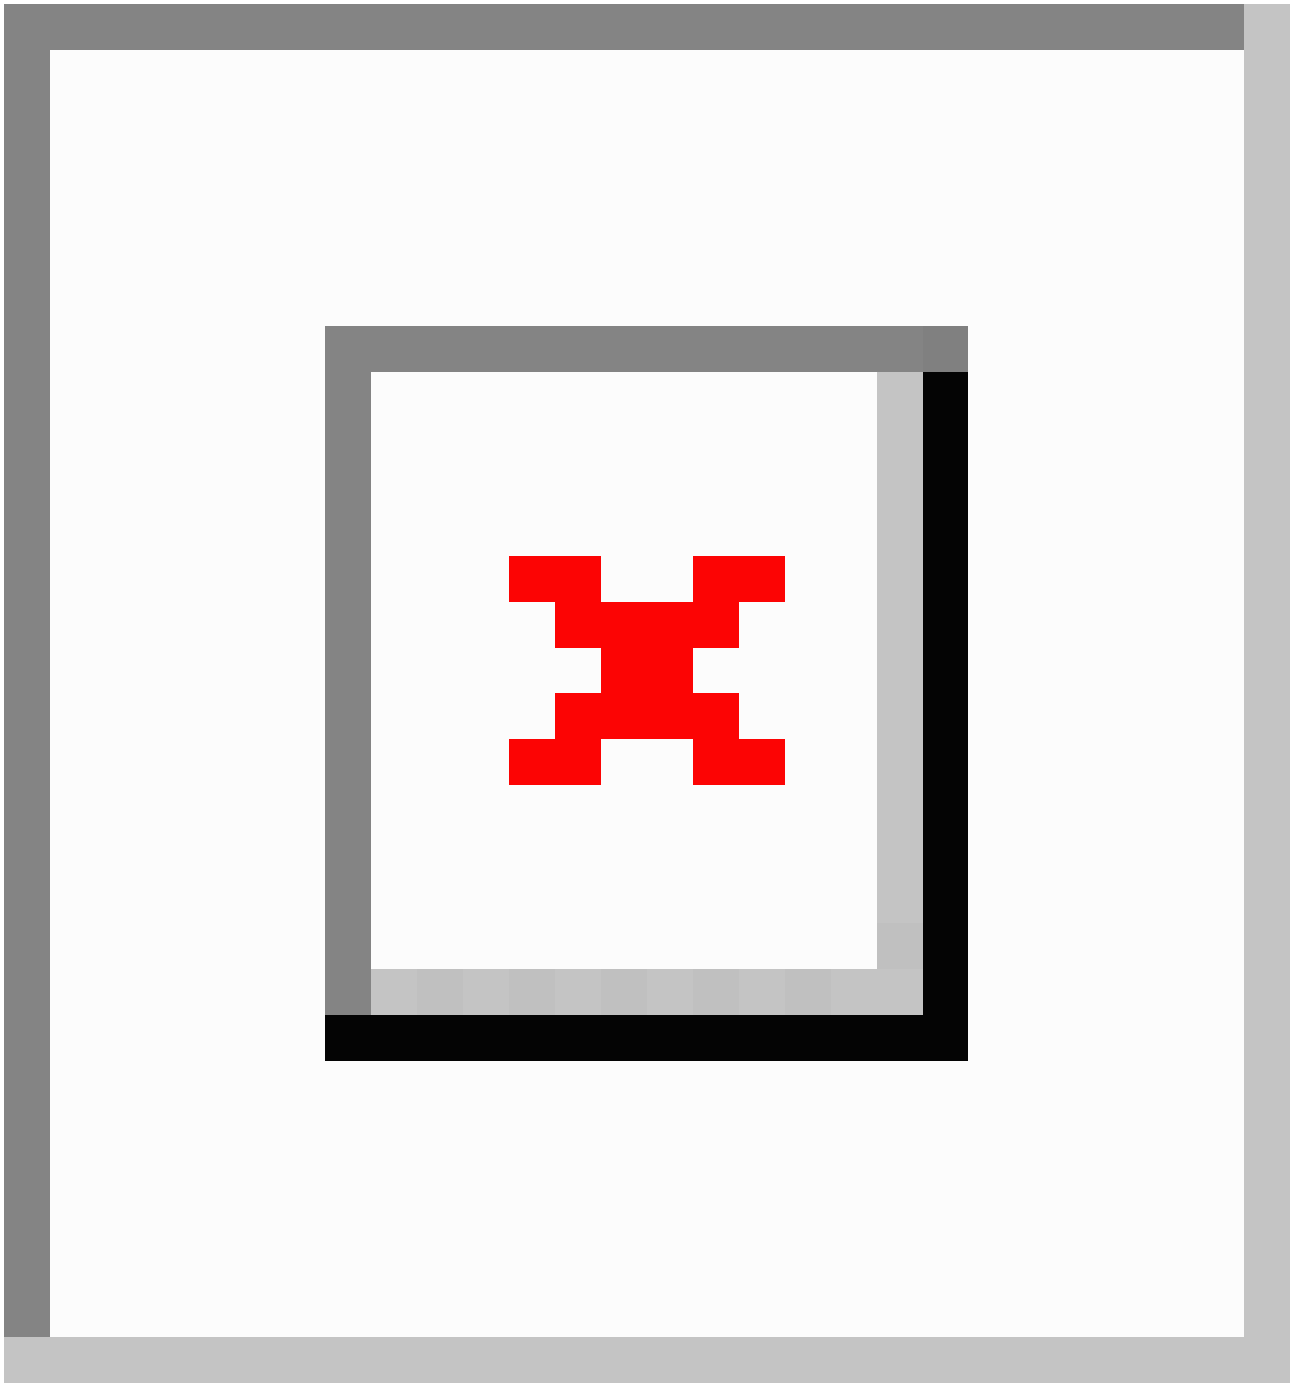
Results Related to Objective 1

Search Outcomes From the Scoping Review

As presented in Figure 1, a total of 1407 articles were initially identified across all 4 databases after removing duplicates. Subsequently, most of these articles (1274/1407, 90.55%) were excluded based on the evaluation of titles and abstracts, leaving 9.45% (133/1407) of the articles for eligibility assessment through full-text review. Following this assessment, 29 articles were included from the databases. In addition, by reviewing the references of the included articles, 12 more articles were identified and added to the study.

Figure 1. Article selection process for the scoping review. Detailed inclusion and exclusion criteria are described in the text and in the protocol.



Regarding the additional 12 articles obtained through the assessment of references of the included articles, it was observed that most of them did not mention statistical inference or related terms in their abstracts [2,11,23]. Consequently, these articles were not captured in the initial database search results. Furthermore, some articles directly referred to the specific method used without including any keywords related to horizontally partitioned data in their abstracts or titles [24,25], which greatly reduced the chance of initially identifying them. However, during the process of reviewing the references of the included articles, all the relevant papers that were initially identified through the snowballing strategy were eventually retrieved either through the search strategy or the selection process based on the references of the included articles.

Results of the Scoping Review

Each article included in this scoping review put forth one or multiple methodological approaches pertaining to objective 1. The similarities and differences regarding the communication schemes involved and their background of origin are summarized in this section.

First, all the selected articles discussed one or more statistical procedures that operate on horizontally partitioned data using one of the communication schemes depicted in Figures 2-5.

Figure 2. Workflow I: each node calculates summary statistics from its own samples. Results are sent to the coordinating center, which combines the information provided by each node to produce the final estimates.

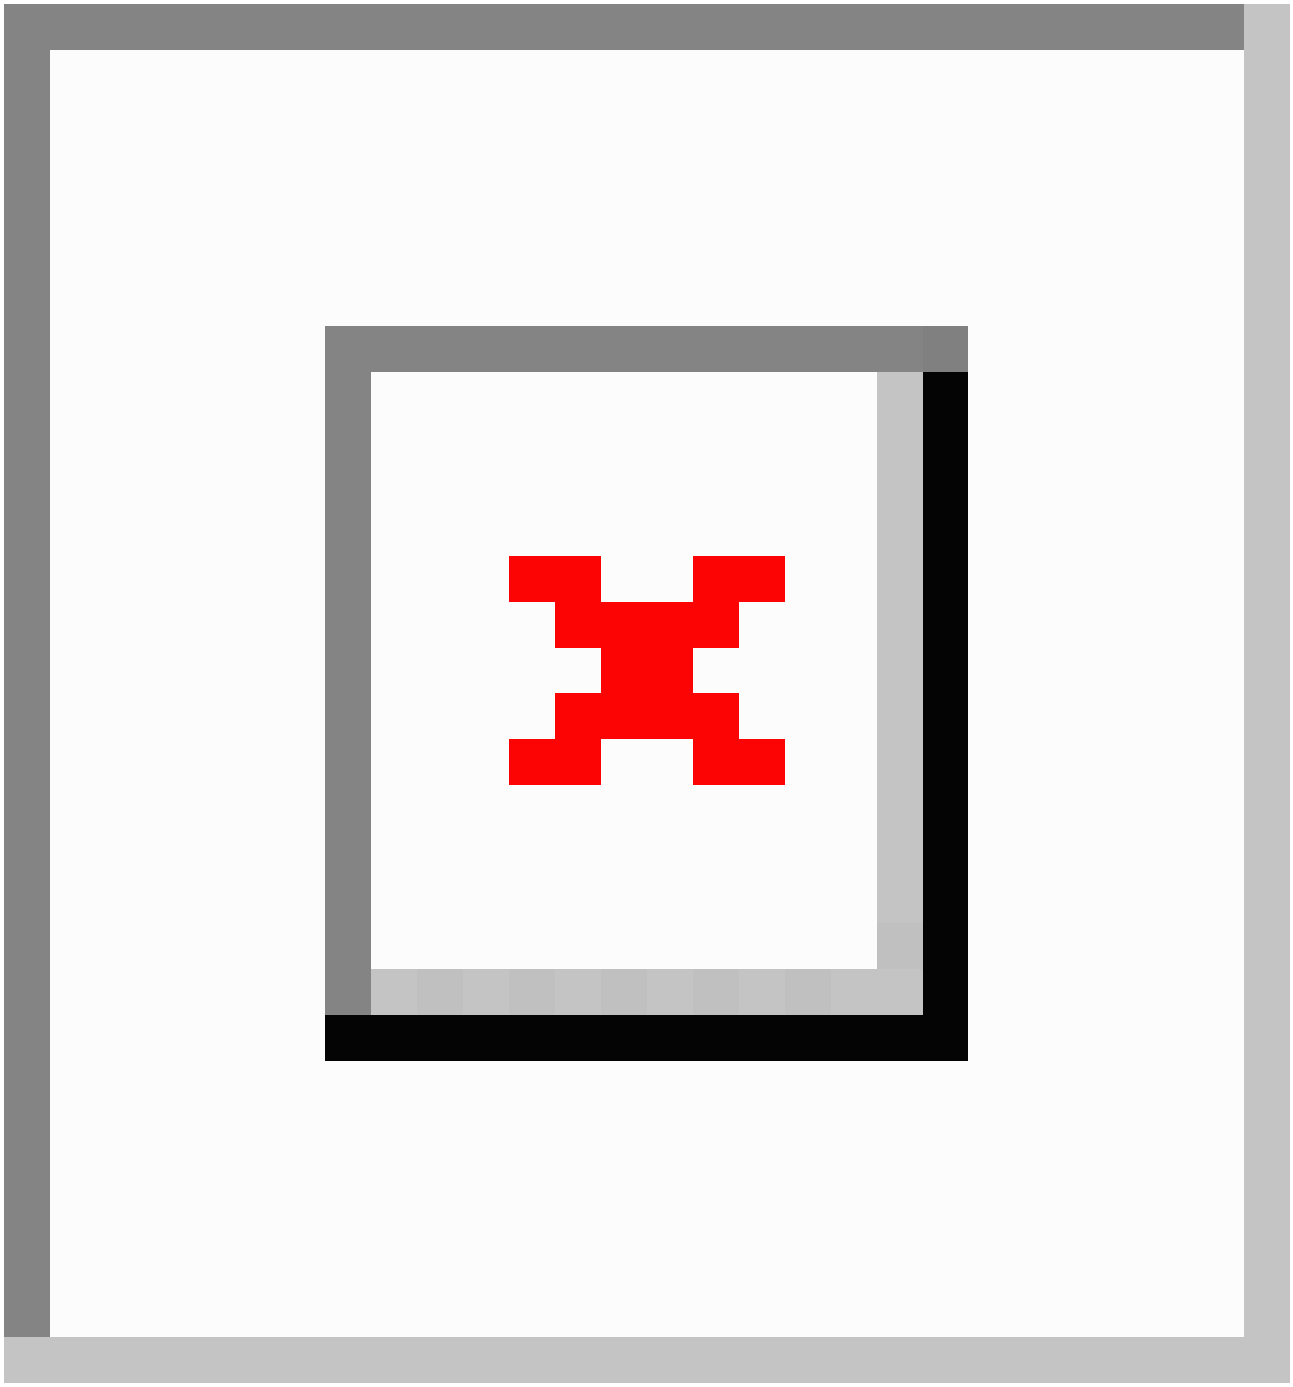


Figure 3. Workflow II: multiple communication rounds are allowed between the coordinating center and the data storage nodes.

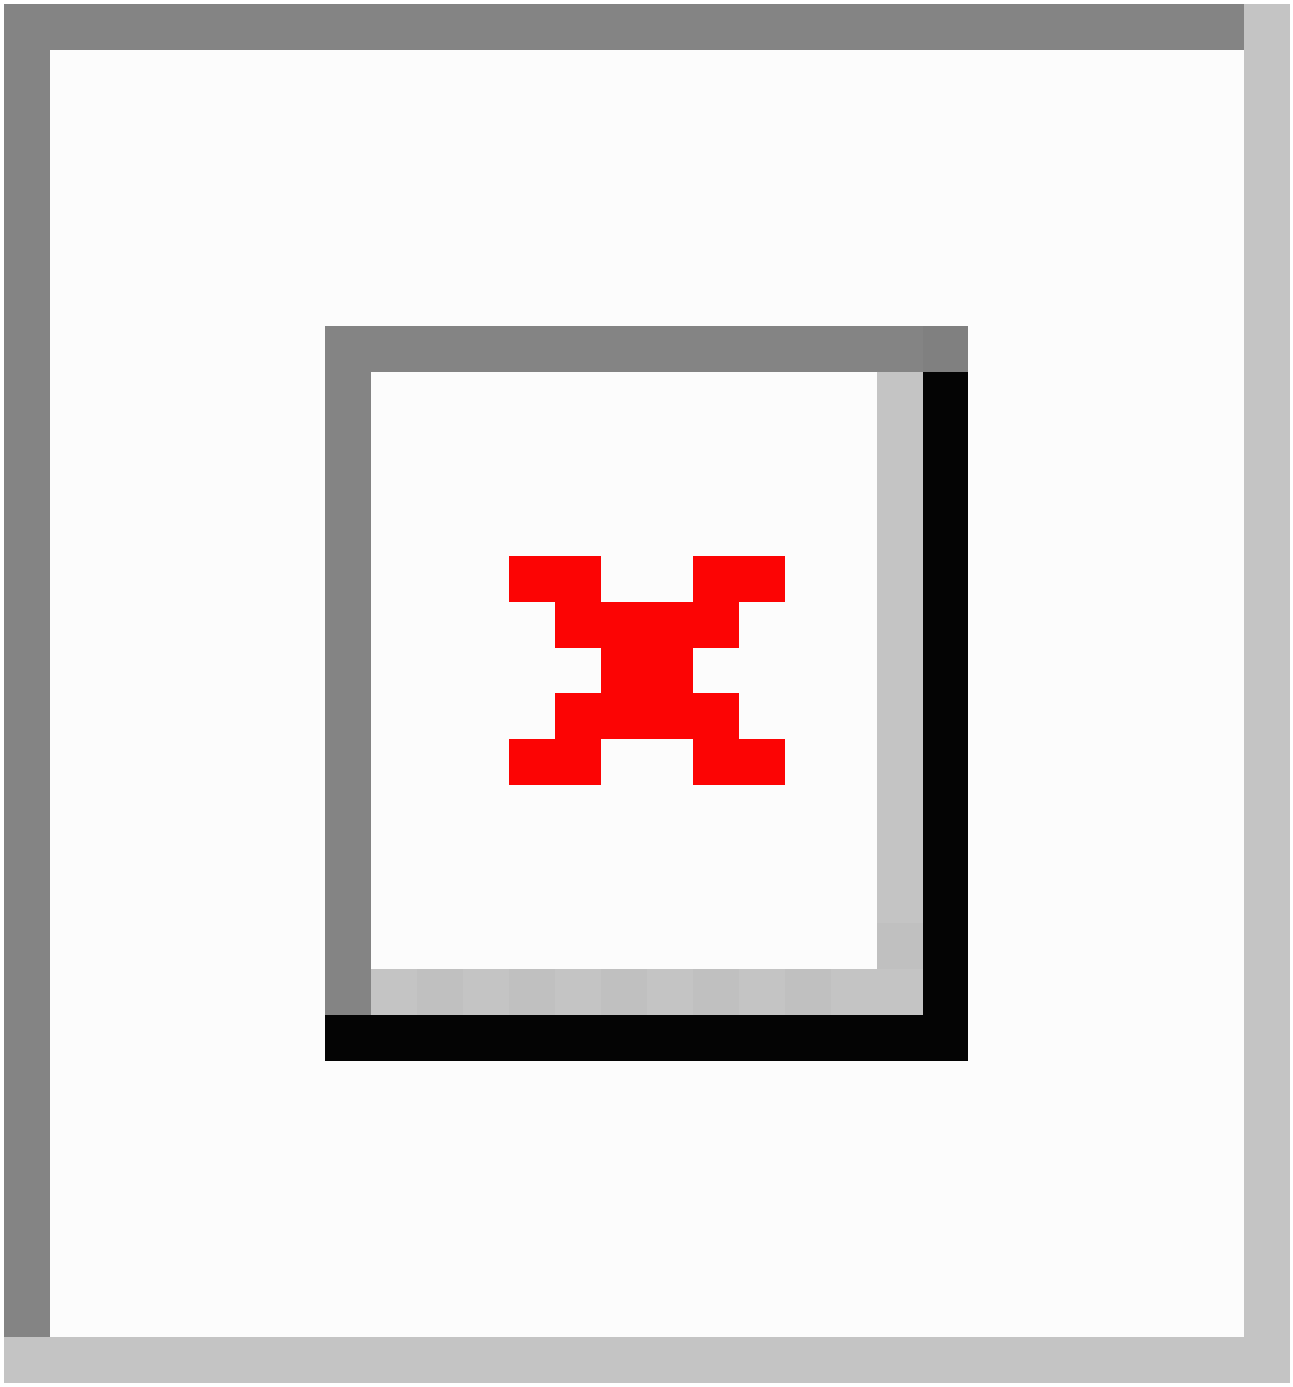

Figure 4. Workflow III: multiple communication rounds are allowed between the coordinating center and the data storage nodes, with node 1 following a distinct communication pattern compared to the other nodes.

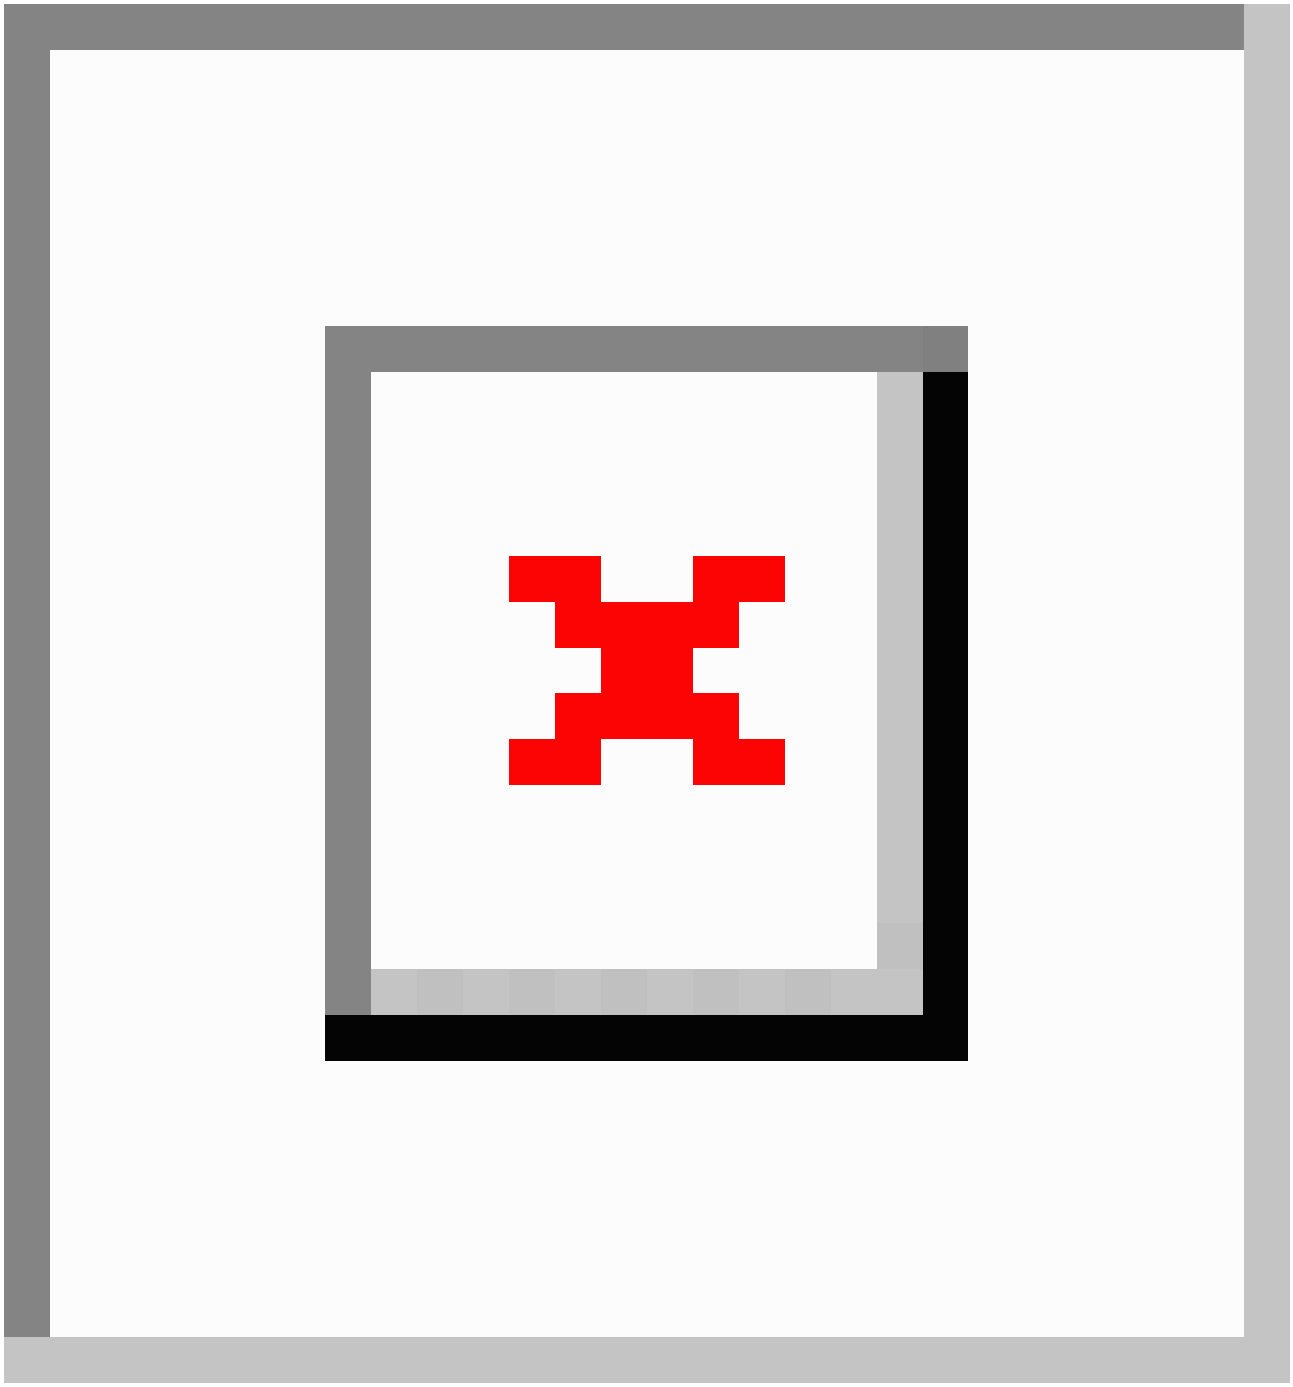

Figure 5. Workflow IV: multiple communication rounds are allowed between the coordinating center (CC) and the data storage nodes, with 2 back-and-forth distinct communication exchanges between each node and the CC at each iteration.

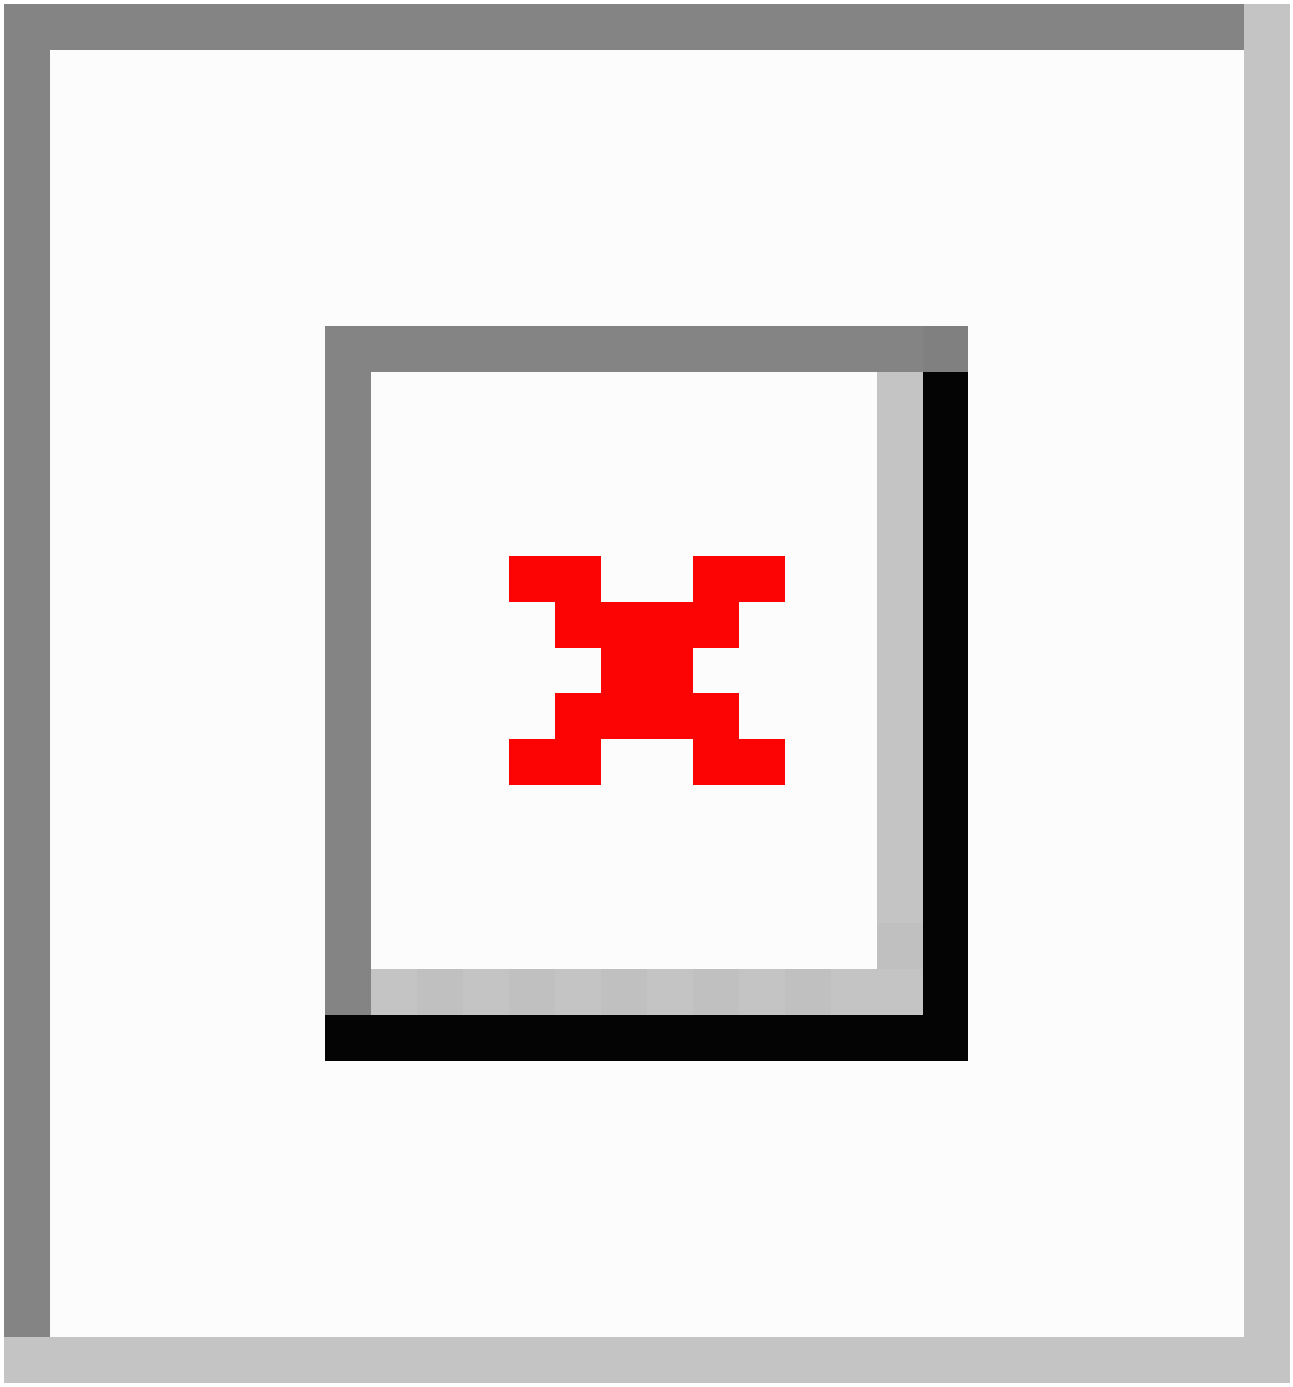

In workflow I, as shown in Figure 2, each node calculates summary statistics from its own samples, and the results are sent to the CC. The CC combines the information provided by each node to produce the final estimates. This communication approach is commonly referred to as "one-shot" or "noniterative" in the literature, although not always consistently.

In workflow II, as shown in Figure 3, multiple communication rounds are allowed between the CC and the data storage nodes. This allows for iterative interactions between the nodes and the CC to refine the estimates.

Some approaches fundamentally differ from the 2 previous workflows by assigning a different role to one of the nodes (eg, node 1) compared to the others. These approaches operate using workflow III, as illustrated in Figure 4, where node 1 follows a distinct communication pattern compared to the other nodes. In the papers included in this scoping review that discussed these approaches, node 1 was invariably designated as the CC. However, in the context of this paper, their roles were differentiated. The additional step performed by the CC, which involves data aggregation, can be particularly well suited for privacy protection purposes in practice.

The particular setting shown in workflow IV in Figure 5 requires 2 back-and-forth communication exchanges between each node and the CC at each iteration. This communication pattern distinguishes this workflow from the others.

In light of the preceding discussion, from an operational standpoint, 2 categories of workflows emerge. On the one hand, there are workflows that do not necessitate any communication from the CC to the nodes, which are captured in workflow I. On the other hand, there are workflows that involve one or more communication exchanges from the CC to the nodes, which are captured in workflows II, III, and IV.

To emphasize similarities among the methods presented in the articles in this review and facilitate the identification of methods suitable for specific purposes, a systematic classification is presented in Table 1. The articles are categorized based on the type of models used and the number of communications from the CC to the individual nodes.

Table . Classification of the articles included in this scoping review.

Type of model	0 communication from CC[a] to nodes	≥1 communication exchange from CC to nodes
Parametric regression	• Basiri et al [26] • Battey et al [27] • Fan et al [28] • Guo et al [29] • Chen and Xie [25] • Lin and Xi [30] • Rosenblatt and Nadler [23] • Zhang et al [31] • Chang et al [32] • Wu et al [33] • Hector and Song [34]	• Huang and Huo [12] • Jordan et al [13] • Mozafari-Majd and Koivunen [35,36] • Yue et al [37] • Duan et al [38] • Duan et al [2] • Tong et al [39] • Di et al [40] • Edmondson et al [41] • Luo and Li [42] • Shu et al [43]
Semiparametric regression	• Zhao et al [44] • Park et al [14]	• Luo et al [45] • Duan et al [11]
Nonparametric regression	• Liu et al [46] • Zhang et al [47] • Volgushev et al [48]	• Wang et al [49]
Not specific to regression	• Atta-Asiamah and Yuan [50] • Minsker [51] • Lin and Xi [52] • Bruce et al [53] • Chen and Peng [54] • Nezakati and Pircalabelu [55] • Banerjee et al [24] • Shi et al [56] • Wu et al [57]	• Lai et al [58]

[a]CC: coordinating center.

Most of the methods were published the big or massive data and multi-machine methodological setting, whereas some were reported within the context of health analytics. Within the big or massive data and multi-machine methodological setting, many methods involved an initial step of random data partitioning among multiple machines. However, certain methods assumed a scenario in which data were already stored on separate machines, as observed in the studies by Fan et al [28] and Jordan et al [13]. Furthermore, it is worth noting that no articles published before 2010 were included, aligning with our initial hypothesis regarding the identification of contemporary methodological settings. Most of the included articles (30/41, 73%) were published after the year 2018.

Most articles (33/41, 81%) addressed a setting in which a CC existed external to the nodes, as exemplified by articles such as those by Lin and Xi [52], Volgushev et al [48], and Yue et al [37]. In contrast, as mentioned previously, some studies (8/41, 19%) designate one of the nodes to assume this central role, as demonstrated in the study by Chang et al [32].

The methods identified through our search strategy shared a common characteristic of using a global model that incorporated population-level parameters. In some cases, these parameters may also include node-specific components to accommodate node-specific statistical heterogeneity in the outcome-predictors relationship, which captures deviations from the population-level conditional probability distribution of the outcome given the predictors.

A few of the reported methods had the capability to yield results identical to those obtained if the individual line data were pooled from all nodes [33,43].

While most articles (31/41, 76%) featured methods related to regression models, including semiparametric and nonparametric designs, a few (10/41, 24%) reported results for other modeling frameworks. These included methods for M-estimation, U-statistics, symmetrical statistics, and natural parameter estimation, some of which encompassed regression models as a specific instance.

Results Related to Objective 2

In total, 6 approaches were selected as applicable to the standard GLM framework. They all assumed that nodes had equal sample sizes and identical distributions for the covariates.

Simple Averaging

One of the simplest methods for horizontally partitioned data analysis, often referred to as the "simple averaging method" or the "divide-and-conquer" approach, has been extensively studied in the literature, for example, the studies by Zhang et al [31] and Shamir et al [59], which were included in our scoping review. This method operates through workflow I in Figure 2. In this approach, node-level model estimates are gathered and averaged at the CC to generate the final estimates.

In the context of GLM, each node is initially tasked with calculating the maximum likelihood estimator (MLE) of the β and φ parameters using their respective data. In addition, the Hessian matrix of the log-likelihood function with respect to the β parameters must be computed for constructing Wald-type CIs. The estimated parameters and the computed Hessian matrix are then transmitted to the CC.

The final parameter estimates of are obtained by averaging the node-specific estimates while the local Hessians and estimates of φ are used to compute an estimator for the asymptotic variance.

Single Distributed Newton-Raphson Updating

The single distributed Newton-Raphson updating method is an iterative procedure that includes an additional communication round between the CC and the nodes compared to the simple averaging method. It was originally proposed as the "distributed one-step" method in the study by Beyan et al [60], but in this study, it is referred to by a different term to avoid any confusion regarding communication complexity. This method operates using workflow II, as depicted in Figure 3, with t=1 (where T represents the number of cycles in the iteration scheme). It enhances the simple averaging estimators by incorporating a single distributed Newton-Raphson updating step.

In the context of GLM, each node first calculates the MLE of β and φ and transmits them to the CC. The CC aggregates these estimates using averaging and sends the result back to the nodes. The nodes then compute the gradient and the Hessian matrix of the log-likelihood function, evaluated at the received β and φ estimates. Subsequently, the gradient and the Hessian matrix are sent back to the CC, which averages them and computes a Newton-Raphson updating step based on the simple averaging estimates. An estimator for the asymptotic variance can be calculated by using the received Hessian matrices and the updated estimate of φ .

Multiple Distributed Newton-Raphson Updatings

The multiple distributed Newton-Raphson updating method leverages the fact that, for standard GLMs, the algorithm typically used to calculate the MLE of β and φ in a centralized pooled setting can be executed in a distributed manner without any loss of information. This is possible because the algorithm relies on Newton-Raphson updatings (or, sometimes, Fisher scoring updatings) that are expressed using 2 sums of node-specific summary statistics, namely, local gradients and local Hessian matrices of the log-likelihood function, evaluated at the β and φ estimates from the previous iteration. A version of this method is proposed in the study by Wu et al [33] under the logistic regression framework. It operates through workflow II in Figure 3 for a general $T \geq 1$.

Distributed Estimating Equation

The class of estimating equation estimators is vast and encompasses a broad range of statistical estimation techniques, including likelihood-based approaches that rely on searching for critical points. The fundamental idea behind estimating equation methods is to establish a system of equations that involve both the sample data and the unknown model parameters. These equations are then solved to determine the parameter estimates. MLEs, which are obtained by setting the gradient of the log-likelihood function with respect to the unknown parameters equal to 0, belong to the class of estimating equation estimators.

The distributed estimating equation approach involves gathering summary statistics from nodes at the CC level, enabling the reconstruction of the estimating equations, or, more commonly, an approximation of them that would have been obtained in a pooled centralized setting. This method is discussed in the study by Lin and Xi [30] and operates using workflow I, as depicted in Figure 2.

In the context of GLMs, the distributed estimating equation approach involves initially assigning each node the task of computing and sending their local MLEs and the Hessian matrix of their local log-likelihood, evaluated at those MLEs, to the CC. The CC uses these received quantities to reconstruct the global estimating equations or an approximation thereof. This reconstruction ultimately leads to an analytical solution for obtaining the resulting estimates. CIs are computed using a combination of the Hessian matrices and the final estimator of φ .

It is important to note that, when this approach is applied in the context of linear regression, it enables the acquisition of β parameter estimates that are identical to those obtained in a pooled centralized setting.

Distributed Estimation Using a Single Gradient-Enhanced Log-Likelihood

This method differs fundamentally from the ones discussed thus far as it involves a distinct role for one particular node in obtaining model parameter estimates. It operates using workflow III, as depicted in Figure 4, and was proposed in the study by Jordan et al [13] under the name "Surrogate likelihood." This approach relies on an approximation of the global likelihood by viewing it as an analytic function. It expands the global likelihood into an infinite series around an initial guess β^SGE,0 and replaces the higher-order derivatives (order of ≥ 2) of the global likelihood with those of a Taylor expansion of a node's (eg, node k=1) local likelihood around the same value. By following this procedure, the so-called surrogate likelihood can be solved using data from node k=1and aggregated gradients from nodes $k \in \{2, ..., K\}$.

In the context of GLM, the CC first collects the necessary information to compute initial estimates for the parameters β and φ . These initial estimates can be obtained through various approaches, such as a simple averaging estimator or the MLEs

computed using data from node 1. These initial estimates are then transmitted to nodes $k \in \{2, ..., K\}$. Each of these nodes calculates the gradient of the log-likelihood function, evaluated at the received estimates, and sends it back to the CC. The CC averages these gradients and sends the result to node 1. Node 1 solves a gradient-enhanced log-likelihood using its own data and the received average gradient. The resulting estimate is sent back to the CC as the final estimate. To compute CIs, each node must send the Hessian matrix of its local log-likelihood function, evaluated at the initial received estimate.

The steps related to estimation can be repeated multiple times.

Distributed Estimation Using Multiple Gradient-Enhanced Log-Likelihoods

This method is in the spirit of the *distributed estimation using a single gradient-enhanced log-likelihood* approach described previously except that all nodes have to solve a gradient-enhanced log-likelihood instead of only one of them. Results pertaining to statistical inference are discussed in the study by Fan et al [28] under a penalized setting. A nonpenalized version of this method was introduced in the study by Shamir et al [59], although the latter did not discuss CIs or hypothesis testing and, hence, was not included in our scoping review. It operates through workflow IV depicted in Figure 5.

The following subsection presents the 6 approaches described in objective 2 within a unified notational framework that accounts for the peculiarities commonly encountered in health analytics. Algorithms were derived using this common notation to rigorously describe the methods and enable their comparison. Theoretical results regarding the estimators involved are detailed and proven in Multimedia Appendix 2. While this section is necessary to increase trust in HPSA methods by transparently showing precisely what information is shared with the CC through comprehensive mathematical formulas, the summary provided in Table 2 suffices for a high-level understanding of the overall picture.

Table . Quantities shared in each adapted method's communication workflow.

Method number	Method	Exchanged quantities from nodes to CC[a]		Exchanged quantities from CC to nodes
		S0(k)	St(k), $t \geq 1$	C_t
1	Simple averaging	β^MLE(k); φ^MLE(k); VMLE(k)	—[b]	—
2	Single distributed Newton-Raphson updating	β^MLE(k); φ^MLE(k)	DNR,1(k); VNR,1(k); ENR,1(k); FNR,1(k)	β^NR,0; φ^NR,0
3	Multiple distributed Newton-Raphson updatings (with *T* Newton-Raphson updatings)	β^MLE(k); φ^MLE(k)	DNR,t(k); VNR,t(k); ENR,t(k); FNR,t(k)	β^NR,t-1; φ^NR,t-1
4	Distributed estimating equations	β^MLE(k); φ^MLE(k); VMLE(k); FMLE(k)	—	—
5	Distributed single gradient-enhanced log-likelihood	β^MLE(k); φ^MLE(k)	Nodes 2 to *K*: DSGE,1(k), VSGE,1(k), and ESGE,1(k); node 1: β^SGE,1, φ^SGE,1, and VSGE,1(1)	β^SGE,0; φ^SGE,0; to node 1 only: DSGE,1 and ESGE,1
6	Distributed multiple gradient-enhanced log-likelihood	β^MLE(k); φ^MLE(k)	DMGE,1(k); VMGE,1(k); EMGE,1(k); β^MGE,1(k); φ^MGE,1(k)	β^MGE,0; φ^MGE,0; D¯MGE,1; E¯MGE,1

Results Related to Objective 3

Notation for Shared Quantities

In what follows, let the log-likelihood of the data stored in node k (using $D^{(k)}$) be denoted by

$$l(k)(\beta,\varphi)=1n(k)\sum i=1n(k)\{yi(k)h(\beta xi(k))-b\{h(\beta xi(k))\}\varphi+c(yi(k),\varphi)\}.$$

In addition, let $\mathbf{D}^{(k)}(\beta) \in R^{p+1}$ be such that

$$(2)D(k)(\beta)=1n(k)\sum i=1n(k)xi(k)h'(\beta xi(k))[yi(k)-b'\{h(\beta xi(k))\}]$$

and define the $(p+1)\times(p+1)$ matrix $\mathbf{V}^{(k)}(\beta)$ as

$$(3)V(k)(\beta)=1n(k)\sum i=1n(k)xi(k)xi(k)h(\beta xi(k))2b'\{h(\beta xi(k))\}-h(\beta xi(k))yi(k)-b'\{h(\beta xi(k))\}$$

As $D(k)(\beta)=\varphi\nabla\beta l(k)(\beta,\varphi)$, solving the equation $D(k)(\beta)=0$ yields the node-specific MLE of β, denoted hereafter using β^MLE(k). The matrix $V(k)(\beta)$ is equal to $-\nabla\beta D(k)(\beta)$ and relates to the Fisher information matrix through the equation $V(k)(\beta)=-\varphi\nabla\beta 2l(k)(\beta,\varphi)$.

Finally, set

$$(4)E(k)(\varphi,\beta)=1n(k)\sum i=1n(k)yi(k)h(\beta xi(k))-b\{h(\beta xi(k))\}-\varphi 2n(k)\sum i=1n(k)\partial\partial\varphi c(yi(k),\varphi)$$

and

$$(5)F(k)(\varphi)=2\varphi n(k)\sum i=1n(k)\partial\partial\varphi c(yi(k),\varphi)+\varphi 2n(k)\sum i=1n(k)\partial 2\partial\varphi 2c(yi(k),\varphi).$$

Because $E(k)(\varphi,\beta)=-\varphi 2(\partial/\partial\varphi)l(k)(\beta,\varphi)$, when φ is unknown, solving the equation $E(k)(\varphi,\beta\text{^}MLE(k))=0$ for φ yields its node-specific MLE of φ . We have $F(k)(\varphi)=-(\partial/\partial\varphi)E(k)(\varphi,\beta)$.

Simple Averaging

The simple averaging method follows upon execution of algorithm 1 (Textbox 1). First, each data node computes their local maximum by solving successively D(k)(β)=0 and E(k)(φ,β^MLE(k))=0. To compute the CIs at the CC level, the entries of the (p+1)×(p+1) matrix VMLE(k)=V(k)(β^MLE(k)) have to be computed from formula 3 with β=β^MLE(k). Then, the set

(6)S0(k)={β^MLE(k),φ^MLE(k),VMLE(k)}

is sent to the CC. The parameter estimates are then aggregated by the CC through averaging. Specifically, the CC computes

(7)β^SA=∑k=1Kw(k)β^MLE(k)andφ^SA=∑k=1Kw(k)φ^MLE(k),

where $w^{(1)}$, ..., $w^{(K)}$ are weights (ie, $w^{(k)}\geq 0$ and ∑k=1Kw(k)=1) used to combine each node's contribution. Often, weights can be taken proportional to local sample sizes, leading to the choice $w^{(k)}=n^{(k)}/n$.

Textbox 1. Algorithm 1—simple averaging inference procedure.

Input at the coordinating center (CC) level: Weight $w^{(1)}$, ..., $w^{(K)}$ attributed to each node's contribution

Step required from each node $k \in \{1, \ldots, K\}$:

Using data in D(k), compute the following quantities:

- MLE β^MLE(k) of β by solving D(k)(β)=0;
- MLE φMLE(k) of φ by solving E(k)(φ,β^MLE(k))=0;
- VMLE(k)=V(k)(β^MLE(k)) using formula (3) with β=β^MLE(k)

Send to the CC: S0(k)={β^MLE(k),φ^MLE(k),VMLE(k)}.

Step required from the CC:

Using the received sets of quantities S0(1),…,S0(K), calculate

- The simple averaging estimators β^SA=∑k=1Kw(k)β^MLE(k) and φ^SA=∑k=1Kw(k)φ^MLE(k);
- The estimator of the variance-covariance matrix Σ^SA=φ^SA∑k=1Knw(k)2n(k)VMLE(k)

Output from the CC:

Final estimates: R={β^SA,Σ^SA}

Wald-type CIs for β can be constructed based on the fact that the sequence n(β^SA−β) converges in distribution to a centered normal random variable with covariance matrix

ΣSA=φ∑k=1Kw(k)2p(k)Tβ(k),whereTβ(k)=E{Vk(β)}.

As Tβ(k) is consistently estimated using VMLE(k) and φ by φ^SA, and as $p^{(k)}$ can be estimated using $n^{(k)}/n$, it follows that a consistent estimator for Σ_{SA} is given by

Σ^SA=φ^SA∑k=1Knw(k)2n(k)VMLE(k).

The simple averaging final estimates are then given by

R={β^SA,Σ^SA}.

Single Distributed Newton-Raphson Updating

The single distributed Newton-Raphson updating method follows upon execution of algorithm 2 (Textbox 2) with T=1. First, the CC gathers summary statistics to compute the simple averaging estimators of β and φ without their accompanying CI. Hence, for $k\in\{1, ..., K\}$, and with β^MLE(k) as mentioned previously (equation 6), node k sends to the CC the quantities

(8)S0(k)={β^MLE(k),φ^MLE(k)},

and the CC uses them to compute β^SA and φ^SA using the formulas in equation 7.

Textbox 2. Algorithm 2—distributed Newton-Raphson updatings procedure.

Input at the coordinating center (CC) level: Weight $w^{(1)}$, …, $w^{(K)}$ attributed to each node's contribution

Step required from each node $k \in \{1, \ldots, K\}$:

Using data in D(k), compute

- β^MLE(k) by solving $\boldsymbol{D}^{(k)}(\beta)=0$;
- φ^MLE(k) by solving E(k)(φ,β^MLE(k))=0

Send to the CC: S0(k)={β^MLE(k),φ^MLE(k)}.

Step required from the CC:

Using the received quantities S0(1),…,S0(K):

- Calculate β^SA=∑k=1Kw(k)β^MLE(k) and φ^SA=∑k=1Kw(k)φ^MLE(k);
- Initialize β^NR,t=0=β^SA and φ^NR,t=0=φ^SA.

Execute for *t*=1, ..., *T*:

Step required from the CC:

Broadcast to nodes: Ct={β^NR,t-1,φ^NR,t-1}

Step required from each node $k \in \{1,\ldots,K\}$:

Using data in $D^{(k)}$ and quantities in C_t, compute:

- DNR,t(k) using formula (2) with β=β^NR,t-1;
- VNR,t(k) using formula (3) with β=β^NR,t-1;
- ENR,t(k) using formula (4) with φ=φ^NR,t-1 and β=β^NR,t-1;
- FNR,t(k) using formula (5) with φ=φ^NR,t-1 and β=β^NR,t-1.

Send to the CC: St(k)={DNR,t(k),VNR,t(k),ENR,t(k),FNR,t(k)}.

Step required from the CC:

Using the quantities in St(k), compute

- D¯NR,t=∑k=1Kw(k)DNR,t(k)
- V¯NR,t=∑k=1Kw(k)VNR,t(k)
- E¯NR,t=∑k=1Kw(k)ENR,t(k)
- F¯NR,t=∑k=1Kw(k)FNR,t(k)

Using, β^NR,t-1, φ^NR,t-1 and the aggregated quantities, update previous parameter estimates

- β^NR,t=β^NR,t-1+V¯NR,t−1D¯NR,t
- φ^NR,t=φ^NR,t+E¯NR,tF¯NR,t

Step required from the CC:

Compute Σ^NR=(V¯NR,T)−1{φ^NR,T∑k=1Knw(k)2n(k)VNR,T(k)}(V¯NR,T)−1

Output from the CC:

Estimates R={β^NR,T,Σ^NR}

For reasons of convenience that will become clear later, the notation β^NR,0 and φ^NR,0 will be used instead of β^SA and φ^SA, respectively. In this notation, the set of values

C1={β^NR,0,φ^NR,0}

is broadcasted to data nodes, which are then tasked with computing and sending back the quantities

S1(k)={DNR,1(k),VNR,1(k),ENR,1(k),FNR,1(k)} ,

where, for any integer $t \geq 1$, one defines

[illegible]

Upon receiving the S1(k)s from each node, the CC calculates the following weighted averages:

[illegible]

This enables the CC to execute Newton-Raphson updates from β^NR,0 and φ^NR,0, respectively:

(10)β^NR,1=β^NR,0+V¯NR,1−1D¯NR,1φ^NR,1=φ^NR,0+F¯NR,1−1E¯NR,1.

It is shown in the Multimedia Appendix 2 that

n(β^NR,1−β)→N(0,ΣNR),whereΣNR=(∑k=1Kw(k)Tβ(k))−1{φ∑k=1Kw(k)2n(k)Tβ(k)}(∑k=1Kw(k)Tβ(k))−1

As Tβ (k) is consistently estimated using VNR,1(k) and φ by φ^NR,1, and as p(k) can be estimated using n(k)/n, it follows that a consistent estimator for ΣNR is given by

Σ^NR=(∑k=1KnV^NR,1(k))−1{φ^NR,1∑k=1KnW^(k)2n(k)V^NR,1(k)}(∑k=1KnV^NR,1(k))−1

The method's final estimates are then given by

R={β^NR,1,Σ^NR}.

Multiple Distributed Newton-Raphson Updatings

The multiple distributed Newton-Raphson updatings method follows upon execution of algorithm 2 with *T*>1.

The first communication cycle follows the same procedure described previously for the single distributed Newton-Raphson updating method. It involves distributively computing a simple averaging estimator and then performing a Newton-Raphson iteration starting from this estimator. The Newton descent is calculated as described in equation 10.

Formally, the algorithm begins with each data node *k* sending the set of quantities S0(k), as described in equation 8, to the CC. Next, the CC calculates the simple averaging estimators using formula 7 and uses them to initialize β^NR,Step=0=β^SA and φ^NR,Step=0=φ^SA.

The following steps are then repeated for a certain number of iterations. At iteration t, starting from t=1, the CC broadcasts the values Ct=(β^NR,t-1,φ^NR,t-1) to the data nodes. The data nodes compute the quantities DNR,t(k), VNR,t(k), ENR,t(k), and FNR,t(k) as defined in equation 9 and send them back to the CC.

The CC then uses these quantities to perform a Newton update. Specifically, it calculates β^NR,t=β^NR,t-1+VNR,t−1DNR,t and φ^NR,t=φ^NR,t-1+ENR,t/FNR,t.

If the iterative cycle is repeated until convergence, the resulting estimates of β are equivalent to the MLEs derived from pooled data. This is because, in GLMs, for MLEs, if both the pooled and distributed algorithms are initialized using the same values for β^NR,Step=0 and φ^NR,Step=0, then, at each subsequent iteration, the distributed Newton update computed by the CC will be identical to the update obtained in a pooled setting.

For the method to yield consistent estimates, it is not necessary to initialize it using simple averaging estimators. However, using simple averaging estimators as initialization may speed up convergence, particularly in large sample sizes, as these estimators are n-consistent.

Let β^NR,T denote the estimator obtained at convergence. As it is (nearly) equal to the pooled MLE of β , we can deduce from the Multimedia Appendix 2 that

(11)n(β^NR,T−β)→N(0,ΣNR),whereΣNR=(∑k=1Kw(k)Tβ(k))−1{φ∑k=1Kw(k)2n(k)Tβ(k)}(∑k=1Kw(k)Tβ(k))−1

Following the same reasoning used previously for the single distributed Newton-Raphson updating method, we can consistently estimate the variance-covariance matrix as

Σ^NR=(V¯NR,T)−1{φ^NR,T∑k=1Knw(k)2n(k)V^NR,T(k)}(V¯NR,T)−1.

Distributed Estimating Equation

The distributed estimating equation method follows upon execution of algorithm 3 (Textbox 3). First, each node is responsible for computing the MLEs β^MLE(k) and φ^MLE(k) of β and φ , respectively, using its own data. These estimators, along with the Hessian matrix VMLE(k)=V(k)(β^MLE(k)) and FMLE(k)=F(k)(φ^MLE(k)), are then sent to the CC. The set

(12)S0(k)={β^MLE(k),φ^MLE(k),VMLE(k),FMLE(k)}

is transmitted to the CC. The CC calculates the weighted average of the Hessians and the FMLE(k) values as follows:

(13)V¯EE=∑k=1Kw(k)VMLE(k)andF¯EE=∑k=1Kw(k)FMLE(k).

The parameter estimates can then be calculated as

(14)β^EE=V¯EE−1∑k=1Kw(k)VMLE(k)β^MLE(k)φ^EE=F¯EE−1∑k=1Kw(k)FMLE(k)φ^MLE(k)

It is shown in the Multimedia Appendix 2 that n(β^EE−β) converges in distribution to a centered normal random variable with the variance-covariance matrix given by

ΣEE=(∑k=1Kw(k)Tβ(k))−1{φ∑k=1Kw(k)2n(k)Tβ(k)}(∑k=1Kw(k)Tβ(k))−1

It can be consistently estimated by

Σ^EE=(V¯EE)−1{φ^EE∑k=1knw(k)2n(k)VMLE(k)}(V¯EE)−1

Textbox 3. Algorithm 3—distributed estimating equation inference procedure.

Input at the coordinating center (CC) level: Weights $w^{(1)}$, …, $w^{(K)}$ attributed to each node's contribution

Step required from each node $k \in \{1, \ldots, K\}$:

Using data in Dk, compute the following quantities:

- MLE β^MLE(k) of β by solving D(k)(β)=0;
- MLE φ^MLE(k) of φ by solving E(k)(φ,β^MLE(k))=0;
- VMLE(k)=V(k)(β^MLE(k)) using formula (3) with β=β^MLE(k);
- FMLE(k)=F(k)(φ^MLE(k)) using formula (5) with φ=φ^MLE(k).

Send to the CC: S0(k)={β^MLE(k),φ^MLE(k),VMLE(k),FMLE(k)}.

Step required from the CC:

Using the received sets of quantities S01,…,S0K, calculate

- Aggregated quantities $\bar{V}EE=\sum_{k=1}^{K} w(k)VMLE(k)$ and $\bar{F}EE=\sum_{k=1}^{K} w(k)FMLE(k)$
- EE estimators $\hat{\beta}EE=\bar{V}EE^{-1}\sum_{k=1}^{K} w(k)VMLE(k)\hat{\beta}MLE(k)$ and $\hat{\varphi}EE=\bar{F}EE^{-1}\sum_{k=1}^{K} w(k)FMLE(k)\hat{\varphi}MLE(k)$; the variance-covariance matrix $\hat{\Sigma}EE=(\bar{V}EE)^{-1}\{\hat{\varphi}EE\sum_{k=1}^{K} nw(k)2n(k)VMLE(k)\}(\bar{V}EE)^{-1}$.

Output from the CC:

Parameter estimates and CIs R={β^SA,Σ^EE}

Distributed Estimation Using a Single Gradient-Enhanced Log-Likelihood

Overview

This method operates through algorithm 4 (Textbox 4). First, the necessary information is collected by the CC to compute the initial estimates of β and φ, denoted as β^SGE,0 and φ^SGE,0. In what follows, we assume that these estimates are obtained using the simple averaging estimators calculated through algorithm 1.

Textbox 4. Algorithm 4—inference procedure based on the distributed estimation using a single gradient-enhanced log-likelihood method.

Input at the coordinating center (CC) level: Weights $w^{(1)}$, …, $w^{(K)}$ attributed to each node's contribution

Step required from each node $k \in \{1, \ldots, K\}$:

Using data in Dk, compute

- β^MLE(k) by solving D(k)(β)=0;
- φ^MLE(k) by solving E(k)(φ,β^MLE(k))=0

Send to the CC: S0(k)={β^MLE(k),φ^MLE(k)}.

Step required from the CC:

Using the received sets of quantities S01,…,S0K, calculate

- simple averaging estimators β^SA=∑k=1Kw(k)β^MLE(k) and φ^SA=∑k=1Kw(k)φ^MLE(k)
- initialize β^SGE,0=β^SA and φ^SGE,0=φ^SA.

Broadcast to nodes: C1,1={β^SGE,0,φ^SGE,0}.

Step required from each node $k \in \{2, \ldots, K\}$:

Using data in Dk, compute the following quantities:

- DSGE,1(k)=D(k)(β^SGE,0) using formula (2) with β=β^SGE,0;
- VSGE,1(k)=V(k)(β^SGE,0) using formula (3) with β=β^SGE,0;
- ESGE,1(k)=E(k)(φ^SGE,0,β^SGE,0) using formula (4) with (φ,β)=(φ^SGE,0,β^SGE,0)

Send to the CC: S1,1(k)={DSGE,1(k),VSGE,1(k),ESGE,1(k)}

Step required from the CC:

Using the received sets of quantities S1,12,…,S1,1K, calculate

- DSGE,1=∑k=2Kw(k)DSGE,1(k)
- ESGE,1=∑k=2Kw(k)ESGE,1(k)

Broadcast to node k=1: $C_{2,1} = \{\mathbf{D}_{\mathrm{SGE},1}, \boldsymbol{E}_{\mathrm{SGE},1}\}$

Step required from node k=1:

Using data in D1, calculate

- DSGE,1(1)=D(1)(β^SGE,0) using formula (2) with β=β^SGE,0;
- VSGE,1(1)=V(1)(β^SGE,0) using formula (3) with β=β^SGE,0;
- ESGE,1(1)=E(1)(φ^SGE,0,β^SGE,0) using formula (4) with (φ,β)=(φ^SGE,0,β^SGE,0)
- D¯SGE,1=DSGE,1+w(1)DSGE,1(1)
- E¯SGE,1=ESGE,1+w(1)ESGE,1(1)

Send to the CC: S2,1(1)={β^SGE,1,φ^SGE,1,VSGE,1(1)}

Step required from the CC:

Compute

- A^SGE,1(k)=w(k)Ip+1+{VSGE,1(1)−(∑k′=1Kw(k′)VSGE,1(k′))}(VSGE,1(k))−1 for $k \in \{1, \ldots, K\}$
- Σ^SGE,1=φ^SGE,1(VSGE,1(1))−1{∑k=1Knn(k)(A^SGE,1(k)) VSGE,1(k)A^SGE,1(k)}(VSGE,1(1))−1

Output from the CC:

Parameter estimates R={β^SGE,1,Σ^SGE,1}

Subsequently, the CC broadcasts C1,1={β^SGE,0,φ^SGE,0} to node $k \in \{1, \ldots, K\}$. Each node is then requested to compute and transmit back the following quantities:

S1,1(k)={DSGE,1(k),VSGE,1(k),ESGE,1(k)},

with DSGE,1(k)=D(k)(β^SGE,0), VSGE,1(k)=V(k)(β^SGE,0), and ESGE,1(k)=E(k)(φ^SGE,0,β^SGE,0).

The CC aggregates the D(k)s and the E(k)s using averaging by calculating

$$D_{SGE,1}=\sum_{k=2}^{K} w(k) D_{SGE,1}(k) \text{ and } E_{SGE,1}=\sum_{k=2}^{K} w(k) E_{SGE,1}(k)$$

.

The Vks are momentarily stored and will be used later to compute the estimator for the asymptotic variance-covariance matrix of the final estimator of β . The quantities

$$C_{2,1}=\{D_{SGE,1}, E_{SGE,1}\}$$

are then sent to node k=1. Node k=1 computes the global average of the Dks by adding its own counterpart; that is, it first computes

$$\bar{D}_{SGE,1}=D_{SGE,1}+w(1)D_{SGE,1}(1), \text{ and } \bar{E}_{SGE,1}=E_{SGE,1}+w(1)E_{SGE,1}(1),$$

and then solves the surrogate likelihood function. Formally, it finds successively the values $\hat{\beta}_{SGE,1}(1)$ and $\hat{\varphi}_{SGE,1}(1)$ that solve

$$D_{(1)}(\beta)+\bar{D}_{SGE,1}-D_{SGE,1}(1)=0 \quad E_{(1)}(\varphi,\hat{\beta}_{SGE,1})+\bar{E}_{SGE,1}-E_{SGE,1}(1)=0.$$

The results are sent back to the CC, along with $V_{SGE,1}(1)$, yielding

$$S_{2,1}(1)=\{\hat{\beta}_{SGE,1}, \hat{\varphi}_{SGE,1}, V_{SGE,1}(1)\}.$$

If simple averaging estimators for $\hat{\beta}_{SGE,0}$ and $\hat{\varphi}_{SGE,0}$ are chosen, then $n(\hat{\beta}_{SGE,1}-\beta)$ converges in distribution to a mean-zero multivariate normal random variable with a variance-covariance matrix given by

$$\Sigma_{SGE,1}=\varphi(T_\beta)^{-1}\sum_{k=1}^{K} w(k)\left(A_{(k)}(\beta)A_{(k)}(\beta)^{-1}\right)\left(A_{(k)}(\beta)A_{(k)}(\beta)^{-1}\right)^{T}\varphi(T_\beta)^{-1}+w(k)\left(A_{(k)}(\beta)-I_{p+1}\right)\left(T_\beta\right)^{-1}\left(A_{(k)}(\beta)-I_{p+1}\right)^{T}\left(T_\beta\right)^{-1},$$

with Ip+1, the *p*+1 square identity matrix, and $T_\beta=\sum_{k=1}^{K} w(k)T_\beta(k)$. The Multimedia Appendix 2 contains the proofs. The latter can be consistently estimated by

$$\hat{\Sigma}_{SGE,1}=\hat{\varphi}_{SGE,1}(V_{SGE,1}(1))^{-1}\sum_{k=1}^{K} w(k)\left(A_{SGE,1}(k)V_{SGE,1}(k)A_{SGE,1}(k)^{T}\right)(V_{SGE,1}(1))^{-1}$$

where

$$A_{SGE,1}(k)=n(k)nI_{p+1}+\{V_{SGE,1}(1)-T_{\hat{\beta}}\}(V_{SGE,1}(k))^{-1}$$

With $T_{\hat{\beta}}=\sum_{k=1}^{K} w(k)V_{SGE,1}(k)$.

Remark

In the study by Jordan et al [13], where the method described previously was originally proposed, the authors discuss a version in which the latter process is repeated multiple times. Their version assumes that the data are uniformly and randomly split across nodes. Under this assumption, the resulting estimator of β is asymptotically equivalent to the pooled estimator regardless of the number of iterations executed. This equivalence occurs because, when the predictors' distribution is the same across nodes and the node sample sizes are equal, then $T_\beta(k)\equiv T_\beta$ and $p(k)\equiv 1/K$. By choosing $w(k)=1/K$, it follows that $A_\beta(k)=I_{p+1}$, resulting in the following expression for $\Sigma_{SGE,1}$: $\Sigma_{SGE,1}=\varphi(T_\beta)^{-1}$. The aforementioned variance-covariance matrix is also the same as that of the simple averaging estimator in the setting of equal sample sizes and even predictor distributions. Consequently, at each iteration, the probability distribution of the resulting estimator remains unchanged. However, in a more general setting in which predictor distributions and sample sizes vary across nodes, these cancellations no longer occur. Therefore, in this case, the probability distribution of the obtained estimator changes after each iteration, and tracking these changes falls beyond the scope of objective 3 (see the Multimedia Appendix 2). Hence, this presentation focused on the case in which only 1 iteration is executed.

Distributed Estimation Using Multiple Gradient-Enhanced Log-Likelihood

This method operates through algorithm 5 (Textbox 5). First, the CC collects the necessary information to compute the initial estimates, denoted as $\hat{\beta}_{MGE,0}$ and $\hat{\varphi}_{MGE,0}$. In this case, we assume that these estimates are obtained using the simple averaging estimators calculated through algorithm 1.

Textbox 5. Algorithm 5—inference procedure based on the distributed estimation using a multiple gradient-enhanced log-likelihood method.

Input at the coordinating center (CC) level: Weight $w^{(1)}$, …, $w^{(K)}$ attributed to each node's contribution

Step required from each node $k \in \{1, \ldots, K\}$:

Using data in D(k), compute

- β^MLE(k) by solving D(k)(β)=0;
- φ^MLE(k) by solving E(k)(φ,β^MLE(k))=0

Send to the CC: S0(k)={β^MLE(k),φ^MLE(k)}.

Step required from the CC:

Using the received sets of quantities S0(1),…,S0(K), calculate

- simple averaging estimators β^SA=∑k=1Kw(k)β^MLE(k) and φ^SA=∑k=1Kw(k)φ^MLE(k)
- initialize β^MGE,0=β^SA and φ^MGE,0=φ^SA.

Broadcast to nodes: C1,1={β^MGE,0,φ^MGE,0}.

Step required from each node $k \in \{1, \ldots, K\}$:

Using data in Dk, calculate

- DMGE,1(k)=D(k)(β^MGE,0) using formula (2) with β=β^MGE,0;
- VMGE,1(k)=V(k)(β^MGE,0) using formula (3) with β=β^MGE,0;
- EMGE,1(k)=E(k)(φ^MGE,0,β^MGE,0) using formula (4) with (φ,β)=(φ^MGE,0,β^MGE,0).

Send to the CC: S1,1(k)={DMGE,1(k),VMGE,1(k),EMGE,1(k)}

Step required from the CC:

Using the received sets of quantities S1,11,…,S1,1K, calculate

- D¯MGE,1=∑k=1Kw(k)DMGE,1(k)
- E¯MGE,1=∑k=1Kw(k)EMGE,1(k)

Broadcast to nodes: C2,1={D¯MGE,1,E¯MGE,1}.

Step required from each node $k \in \{1, \ldots, K\}$:

Using data in Dk, calculate

- β^MGE,1(k) that solves D(k)(β)+D¯MGE,1−DMGE,1(k)=0
- φ^MGE,1(k) that solves E(k)(φ,β^MGE,1)+E¯MGE,1−EMGE,1(k)=0

Send to the CC: S2,1(k)={β^MGE,1(k),φ^MGE,1(k)}

Step required from the CC:

Compute

- β^MGE,1=∑k=1Kw(k)β^MGE,1(k)
- φ^MGE,1=∑k=1Kw(k)φ^MGE,1(k)
- T^β =∑k=1Kw(k)VMGE,1(k)
- U^β =∑k=1Kw(k)(VMGE,1(k))−1
- Σ^MGE,1=φ^MGE,1∑k=1Knw(k)2n(k)[U^β VMGE,1(k)+(Ip+1−U^β T^β)]×[U^β +(Ip+1−U^β T^β)(VMGE,1(k))−1]

Output from the CC:

Parameter estimates R={β^MGE,1,Σ^MGE,1}

Subsequently, the CC broadcasts C1,1={β^MGE,0,φ^MGE,0} to each node, which is then requested to compute and transmit back the following quantities:

Here DMGE,1(k)=D(k)(β^MGE,0), VMGE,1(k)=V(k)(β^MGE,0), and EMGE,1(k)=E(k)(φ^MGE,0,β^MGE,0).

S1,1(k)={DMGE,1(k),VMGE,1(k),EMGE,1(k)}.

The CC aggregates the Dks and the Eks using averaging by calculating $\bar{D}_{MGE,1}=\sum_{k=1}^{K} w(k) D_{MGE,1}(k)$ and $\bar{E}_{MGE,1}=\sum_{k=1}^{K} w(k) E_{MGE,1}(k)$.

The CC then broadcasts $C_{2,1}=\{\bar{D}_{MGE,1}, \bar{E}_{MGE,1}\}$ to each node, which is then tasked with solving the surrogate likelihood function. Formally, they find successively the value $\hat{\beta}_{MGE,1}(k)$ and $\hat{\varphi}_{MGE,1}(k)$ that solves

$$D_1(k)(\beta)+\bar{D}_{MGE,1}-D_{MGE,1}(k)-E_1(k)(\varphi,\hat{\beta}_{MGE,1}(k))+\bar{E}_{MGE,1}-E_{MGE,1}(k)=0$$

Each node then transmits their set of local surrogate likelihood estimators to the CC:

$$S_{2,1}(k)=\{\hat{\beta}_{MGE,1}(k), \hat{\varphi}_{MGE,1}(k)\}.$$

Using the received sets of quantities $S_{2,11},\ldots,S_{2,1K}$, the CC aggregates them through averaging using the following formulas:

$$\hat{\beta}_{MGE,1}=\sum_{k=1}^{K} w(k)\hat{\beta}_{MGE,1}(k) \text{ and } \hat{\varphi}_{MGE,1}=\sum_{k=1}^{K} w(k)\hat{\varphi}_{MGE,1}(k).$$

It is shown in the Multimedia Appendix 2 that $n(\hat{\beta}_{MGE,1}-\beta)$ converges in distribution to a multivariate normal random variable with mean 0 and a variance-covariance matrix given by

$$\Sigma_{MGE,1}=\varphi\sum_{k=1}^{K} w(k)[\ddot{\varphi}_1(k)U_\beta^{-1}T_\beta(k)+(\dot{\varphi}+1-U_\beta^{-1}T_\beta)\dot{\varphi}_1(k)][\ddot{\varphi}_1(k)U_\beta^{-1}+(\dot{\varphi}+1-U_\beta^{-1}T_\beta)\dot{\varphi}_1(k)]^{-1}$$

where $U_\beta=\sum_{k=1}^{K} w(k)(T_\beta(k))^{-1}$. The latter can be consistently estimated using

$$\hat{\Sigma}_{MGE,1}=\hat{\varphi}_{MGE,1}\sum_{k=1}^{K} w(k)[\ddot{\varphi}_1(k)\hat{U}_\beta^{-1}V_{MGE,1}(k)+(\dot{\varphi}+1-\hat{U}_\beta^{-1}\hat{T}_\beta)\dot{\varphi}_1(k)][\ddot{\varphi}_1(k)\hat{U}_\beta^{-1}+(\dot{\varphi}+1-\hat{U}_\beta^{-1}\hat{T}_\beta)\dot{\varphi}_1(k)]^{-1}$$

where $\hat{T}_\beta=\sum_{k=1}^{K} w(k)V_{MGE,1}(k)$ and $\hat{U}_\beta=\sum_{k=1}^{K} w(k)(V_{MGE,1}(k))^{-1}$

Summary of Quantities Exchanged in the Adapted Methods

Table 2 presents a summary of the quantities exchanged between the nodes and the CC in both directions. Table 2 demonstrates that the quantities involved in exchanges from the nodes to the CC consist of parameter estimates, gradients (Dk vectors), Hessians (Vk matrices), and real numbers (Ek and Fk). On the other hand, the quantities shared from the CC to the nodes primarily consist of parameter estimates. Notably, methods 5 and 6 differentiate themselves by requiring the sharing of aggregated gradient vectors and Hessian matrices as well.

Comparison of Adapted Methods

Table 3 compares the main adapted HPSA methods regarding the quantities shared between the CC and the nodes and the operational complexity of the procedures. Methods 1 and 4 require only 1 communication from the data nodes to the CC and no communication back from the CC to the nodes. These so-called one-shot methods have the lowest operational complexity. Method 4 requires the additional quantity FMLEk to be transmitted from each node to the CC.

Table . Comparison of adapted methods.

[a]CC: coordinating center.

Methods 2 and 3 perform Newton-Raphson updating using some initial estimator as a basis, usually the simple averaging estimator. While method 2 requires this initial estimator to be n-consistent, if *T* is large enough, any initial value will work for method 3 (although convergence may be slower). Both methods require D(k),V(k),E(k), and Fk to be evaluated and sent to the CC *T* times, with *T*=1 for method 2. Compared to method 1, method 2 requires the additional quantities Dk, Ek, and Fk, and method 3 further requires these quantities to be evaluated and communicated multiple times.

Method 5 relies on an approximation of the log-likelihood function. It requires an initial estimator, usually the simple averaging estimator. This approach treats node 1 differently, making it solve the surrogate log-likelihood using aggregates from the other nodes and its own data. The CC sends the initial estimator to each node and then requires them to evaluate Dk,Vk, and Ek and send the result back to the CC once. It averages the results and then communicates them to node 1, which solves the surrogate log-likelihood and sends its results back to the CC.

Method 6 applies method 5 to every node, making each node solve the surrogate log-likelihood function using its own data before averaging the resulting local estimators.

Discussion

Summary of Findings

The first objective of this study (objective 1) aimed to identify and map the methodological approaches used and developed in the literature regarding HPSA. To achieve this, we conducted a scoping review, which included 41 articles following our protocol. These articles were categorized based on the types of models and communication schemes involved, as presented in Table 1. The analysis revealed that most methods included in this scoping review focused on methodological settings associated with massive data. The communication schemes of

these methods were demonstrated through workflows I, II, III, and IV.

The second objective of this study (objective 2) aimed to describe the approaches that can be used for basic GLM regression analyses and identify the distributional assumptions they require. To accomplish this, we identified 6 approaches and classified them within workflows I to IV, enabling their comparison in terms of operational communication protocols within a unified framework. However, a limitation of these methods is that they assume identical node sample sizes and node covariate distributions. This assumption reduces their suitability in settings commonly encountered in health analytics, where data-collecting nodes are prone to generating different covariate distributions.

The third objective of this study (objective 3) was to present methods that relaxed these assumptions by adapting the approaches identified in objective 2 to the unequal sample sizes and nonidentical covariate sample distribution setting. In addition, we compared these methods in terms of the information shared and operational complexity. This involved adapting the quantities and estimators described in the original articles and deriving new asymptotic results with relaxed assumptions. We defined a unified framework to describe inference procedures using these methods. This unified framework encompasses common hypotheses and notation and allows for both estimation and the construction of CIs, providing detailed steps for both the data nodes and the CC.

Challenges and Opportunities

Work pertaining to objective 1 illustrated why it is so challenging for researchers and data custodians alike to find information regarding HPSA. While the HPSA literature is very recent (all the included articles were published in 2010 or later), the literature is nonhomogeneous, and it has not come to a consensus on nomenclature. No universal terminology exists, and different terms are used in the different fields developing and applying HPSA methods. Many specific methods introduced in applied contexts are special cases of more general methods that may or may not be cited. These characteristics make finding useful and efficient keywords arduous. This required adapting our search strategy.

This difficulty is compounded by the fact that statistical inference is not the main focus of most of the HPSA literature. Most published work falls within the prediction, learning, and optimization contexts. As a result, method assumptions are rarely discussed. This can be a problem when adapting these methods for inference. Furthermore, the methodological setting is often assumed to be in the massive data context, in which data are randomly distributed between nodes. This allows the authors to make strong assumptions on node sample sizes and covariate distributions that may be unrealistic in the confidential data context using multiple data sources. These methods cannot be used directly for inference using confidential health data. While some work remains to be done when the structure of association between the covariate and the outcome is heterogeneous between nodes, we adapted widely used methods for when the distribution of covariates and sample sizes between nodes is not identical.

Table 1 illustrates how most HPSA methods are focused on parametric models. Some work has also been done for semiparametric and nonparametric regression, and some methods are introduced outside of the regression framework (although they can also be applied to regression). Many methods do not require communication of quantities from the CC to the data nodes—they only require 1 transmission from the nodes to the CC. Given the lack of awareness regarding HPSA, starting by implementing lower–operational complexity methods while providing useful results offers a promising path.

LHSs seek to improve health by generating knowledge during practice and making use of that knowledge to improve practice. This requires analyzing data from a variety of sources. HPSA methods offer a way to tackle the challenges that come with multi-jurisdictional data.

The methods can be implemented “manually” (eg, via email exchanges), but platforms enabling semiautomated distributed fittings of statistical models have been proposed in the literature [60]. As LHSs work by continuously monitoring and analyzing data rather than through cross-sectional studies only, automated platforms are necessary. Ideally, these platforms should be able to link and standardize data sources from multiple jurisdictions as well as perform HPSA. On the other hand, explicit descriptions of these methods’ algorithms and the quantities exchanged are not always easily accessible, and this complicates the evaluation of the tools by data custodians and researchers.

This is especially important as it is essential to clarify here that operating an HPSA algorithm does *not* ensure confidentiality in and of itself.

For example, it is known that sharing sample moments can compromise confidentiality. It can be shown that a set of n observations is uniquely determined by its first n sample moments [61]. This could prove problematic for methods that rely on sharing the first few moments of each node’s sample, especially if the number of observations is low, as the sample could be partially reconstructed by the CC.

The results presented in this paper contribute to this objective by clarifying the workflows and quantities exchanged in each method. Nevertheless, further analysis of the confidentiality preserved by HPSA methods is needed to fully understand the risk associated with the sharing of summary statistics, especially as more rounds of communication between the CC and data nodes are completed. The framework of differential privacy has been used to guarantee the preservation of confidentiality in a few HPSA methods, but a wider application of differential privacy to existing and popular methods has yet to be explored.

Acknowledgments

Abstract

Background: The incidence of breast cancer has remained high and continues to rise since the 21st century. Consequently, there has been a significant increase in research efforts focused on breast cancer prevention and treatment. Despite the extensive body of literature available on this subject, systematic integration is lacking. To address this issue, knowledge graphs have emerged as a valuable tool. By harnessing their powerful knowledge integration capabilities, knowledge graphs offer a comprehensive and structured approach to understanding breast cancer prevention and treatment.

Objective: We aim to integrate literature data on breast cancer treatment and prevention, build a knowledge graph, and provide support for clinical decision-making.

Methods: We used Medical Subject Headings terms to search for clinical trial literature on breast cancer prevention and treatment published on PubMed between 2018 and 2022. We downloaded triplet data from the Semantic MEDLINE Database (SemMedDB) and matched them with the retrieved literature to obtain triplet data for the target articles. We visualized the triplet information using NetworkX for knowledge discovery.

Results: Within the scope of literature research in the past 5 years, malignant neoplasms appeared most frequently (587/1387, 42.3%). Pharmacotherapy (267/1387, 19.3%) was the primary treatment method, with trastuzumab (209/1805, 11.6%) being the most commonly used therapeutic drug. Through the analysis of the knowledge graph, we have discovered a complex network of relationships between treatment methods, therapeutic drugs, and preventive measures for different types of breast cancer.

Conclusions: This study constructed a knowledge graph for breast cancer prevention and treatment, which enabled the integration and knowledge discovery of relevant literature in the past 5 years. Researchers can gain insights into treatment methods, drugs, preventive knowledge regarding adverse reactions to treatment, and the associations between different knowledge domains from the graph.

Introduction

Breast cancer is the most common malignant tumor in women worldwide, with a reported death toll exceeding 600,000 in 2018 alone [1]. Breast cancer has emerged as the most prevalent cancer and a primary cause of mortality among women. The global incidence of new cases of female breast cancer witnessed a sharp increase from 1.05 million in 2000 to 2.09 million in 2018 [2]. In 2020, global cancer burden data revealed that new breast cancer cases reached 2.26 million, constituting 11.7% of all newly diagnosed cancer cases worldwide. The newly reported mortality cases numbered 0.68 million, representing 6.9% of global newly reported deaths [3]. Factors such as old age, young age at menarche, family history of breast cancer, smoking, and drinking alcohol increase the risk of breast cancer [4-6]. On the contrary, regular physical exercise; breastfeeding; regular work and rest; and intake of fruits, vegetables, whole grains, and dietary fiber can appropriately reduce the risk of breast cancer [7]. Various treatment methods are used for patients with breast cancer, including surgery, radiation therapy, endocrine therapy, chemotherapy, and targeted therapy. So far, most countries have primarily focused on population education for breast cancer prevention, including encouraging increased physical activity, controlling BMI, and limiting alcohol intake [8]. Despite the increasing number of research literature, a large amount of literature on breast cancer prevention and treatment has not been systematically integrated. Knowledge graph technology allows for the independent connection and integration of disparate literature, resulting in a more comprehensive and cohesive knowledge framework.

Knowledge Graph is a knowledge repository proposed by Google in 2012 to enhance the functionality of search engines.

It describes concepts and their relationships in the real world using triplets in the form of entity-relation-entity [9]. Knowledge graphs can integrate information from diverse sources and domains, including text, databases, and web pages, and intricately interlink them. These integrations serve to mitigate information silos, fostering the establishment of a more comprehensive knowledge framework. Knowledge graphs have been widely used in various fields, such as medicine, network security, journalism, finance, and education [10]. Knowledge graphs in the biomedical domain have applications in studies related to disease associations [11], genomics [12], drug interactions [13], and support for physicians in formulating individualized treatment regimens [14]. At present, there are well-established knowledge graphs, including DisGeNET [15], which integrate information on the associations between genes and diseases; DrugBank [16], a comprehensive bioinformatics and cheminformatics knowledge base; and ClinVar [17], a compilation of genetic variation information from diverse laboratories worldwide. One study extracted breast cancer–related features from Chinese breast cancer mammography reports and built a knowledge graph for diagnosing breast cancer by combining diagnosis and treatment guidelines and insights from clinical experts [18]. Another study integrated triples from clinical guidelines, medical encyclopedias, and electronic medical records to build a breast cancer knowledge graph [19]. Despite a small number of scholars having constructed knowledge graphs for breast cancer, the varied emphases and diverse data sources employed render their applicability limited. A knowledge graph specifically focused on the prevention and treatment of breast cancer has not been constructed at present. Therefore, this study primarily collects information related to the prevention and treatment of breast cancer to construct a knowledge graph.

In the biomedical field, there are already mature tools (eg, SemRep) for extracting knowledge from medical texts. SemRep is a natural language processing program based on the Unified Medical Language System (UMLS), which performs operations such as text tokenization, syntactic analysis, part-of-speech disambiguation, phrase mapping, semantic predicate normalization, and syntactic constraints [20]. It extracts entities and relationships from biomedical texts and outputs triplets stored in the Semantic MEDLINE Database (SemMedDB) [21]. SemMedDB currently encompasses details on approximately 96.3 million predications derived from all PubMed citations (around 29.1 million citations) and serves as the foundation for the Semantic MEDLINE application [22]. We downloaded the entity and relationship data provided by SemMedDB. NetworkX is an open-source library for Python, primarily designed for creating, analyzing, and visualizing complex network structures. NetworkX plays a significant role in knowledge visualization, facilitating users in intuitively presenting and comprehending intricate knowledge graphs or network data.

Methods

Ethics Approval

This study was approved by the Board of Medical Ethics Committee of Shenzhen Maternal and Child Health Hospital (SFYLS[2022]003).

Data Source

We conducted a search on PubMed using Medical Subject Headings terms “breast cancer,” “prevention,” and “treatment,” covering the period from January 1, 2018, to December 31, 2022, and the study type was clinical trials. A total of 3589 articles were retrieved. We obtained the entity and relationship data from SemMedDB.

Data Processing and Construction of Knowledge Graph

We matched the PMIDs of the retrieved articles with the database and extracted the corresponding triplet information. We initially obtained 33,060 Subject-Predicate-Object (SPO) triplets of data.

Next, we made improvements according to the SPO cleaning principles proposed by Fiszman et al [9] (ie, relevance, connectivity, novelty, and significance). We combined them with expert manual screening to ensure that the selected SPO triplets have a higher relevance. In the improved process, we did not predefine semantic patterns. Instead, we used a series of cleaning operations to select core SPO triplets and connected SPO triplets, eliminating SPO triplets lacking specific information and those that appeared only once in the frequency. The specific process is as follows:

1. In the same article, there may be repeated occurrences of identical SPO triplets. To maintain equal contribution from each article, we counted the repeated SPO triplets once within the same article.
2. To ensure statistical reliability, we calculated the occurrence frequency of each SPO triplet across different articles. SPO triplets with low occurrence frequencies may lack statistical significance. Therefore, we filtered SPO triplets with frequencies greater than or equal to 2.
3. Based on expert domain knowledge, we manually screened the selected SPO triplets with frequencies greater than or equal to 2 to identify those of research value.

Finally, we obtained 25,449 SPO triplets data. We imported the filtered SPO triplets information into the NetworkX for visual analysis to explore knowledge and information related to breast cancer prevention and treatment.

All analyses were conducted in a Python program (version 3.11.3; Python Software Foundation), primarily using Pandas, Matplotlib, WordCloud, and NetworkX packages [23-26].

Results

Summary of Included Literatures

A total of 3589 articles were published in 618 different journals. Among them, 191 articles were published in the same journal, while 293 journals had only 1 article published. The journals

were ranked based on the number of publications, and the top 100 journals accounted for 2631 articles, which is 73.30% of the total.

Semantic Relationships and Semantic Patterns

We mainly summarize semantic associations into 3 types: treatment and prevention, influencing or associated factors, and related diseases (Table S1 in Multimedia Appendix 1). Regarding treatment and prevention, the relationships include TREATS, ADMINISTERED_TO, USES, and PREVENTS, representing treatment drugs, surgeries, and preventive measures for breast cancer. Regarding influencing or associated factors, the relationships include ASSOCIATED_WITH, AFFECTS, and CAUSES, which represent diseases' impact and etiological factors. Regarding related diseases, the relationship COEXISTS_WITH represents the coexistence between different diseases. In the semantic patterns involving treatment (TREATS), the topp-TREATS-neop and topp-TREATS-podg have appeared over 1000 times.

Summary of SPO Triples

In terms of breast tumors, malignant neoplasms had the highest frequency, accounting for 42.3% (587/1387) of the total, followed by triple-negative breast neoplasms (56/1387, 4%) and human epidermal growth factor receptor 2 (*HER*2)–positive carcinoma of breast (54/1387, 4%; Table 1 and Multimedia Appendix 2).

Table . Summary of breast cancer subtypes and stages, treatment methods, and treatment drugs. The top 30 subtypes, treatment methods, and treatment drugs with higher frequencies in all data are presented for each group.

Group		Values, n (%)
Breast cancer subtypes and stages (n=1387)		
	Malignant neoplasm of breast	587 (42.3)
	Triple-negative breast neoplasms	56 (4)
	HER2[a]-positive carcinoma of breast	54 (3.9)
	Carcinoma breast stage IV	48 (3.5)
	Breast cancer metastatic	47 (3.4)
	Early-stage breast carcinoma	42 (3)
	Malignant neoplasms	31 (2.2)
	Neoplasm	30 (2.2)
	Metastatic triple-negative breast carcinoma	26 (1.9)
	High-risk cancer	24 (1.7)
	Neoplasm metastasis	21 (1.5)
	Advanced cancer	19 (1.4)
	Advanced breast carcinoma	19 (1.4)
	HER2-negative breast cancer	18 (1.3)
	Locally advanced malignant neoplasm	17 (1.2)
	Advanced malignant neoplasm	15 (1.1)
	Nonsmall cell lung carcinoma	15 (1.1)
	Noninfiltrating intraductal carcinoma	14 (1)
	Locally advanced breast cancer	13 (0.9)
	Breast cancer stage III	11 (0.8)
Treatment of breast cancer (n=1387)		
	Pharmacotherapy	267 (19.3)
	Neoadjuvant therapy	88 (6.3)
	Hormone therapy	68 (4.9)
	Chemotherapy (adjuvant)	54 (3.9)
	Therapeutic procedure	53 (3.8)
	Radiation therapy	48 (3.5)
	Treatment protocols	43 (3.1)
	Adjuvant therapy	36 (2.6)
	Breast-conserving surgery	35 (2.5)
	First-line treatment	31 (2.2)
	Single-agent therapy	27 (1.9)
	Mastectomy	27 (1.9)
	Operative surgical procedures	20 (1.4)
	Interventional procedure	16 (1.2)
	Radiotherapy (adjuvant)	14 (1)
	Excision of axillary lymph nodes group	13 (0.9)
	Combined modality therapy	12 (0.9)
	Excision	11 (0.8)
	Targeted therapy	11 (0.8)

Group		Values, n (%)
	Placebos	10 (0.7)
Drugs for breast cancer (n=1805)		
	Trastuzumab	209 (11.6)
	Capecitabine	88 (4.9)
	Paclitaxel	81 (4.5)
	Aromatase inhibitors	64 (3.5)
	Immunologic adjuvants	62 (3.4)
	Letrozole	58 (3.2)
	Bevacizumab	48 (2.7)
	Tamoxifen	40 (2.2)
	Gemcitabine	36 (2)
	Pertuzumab	36 (2)
	Fulvestrant	36 (2)
	Cyclophosphamide	32 (1.8)
	Pembrolizumab	30 (1.7)
	Docetaxel	27 (1.5)
	Taxane	27 (1.5)
	Ado-trastuzumab emtansine	22 (1.2)
	130-nm albumin-bound paclitaxel	22 (1.2)
	Carboplatin	22 (1.2)
	Eribulin	21 (1.2)
	Palbociclib	19 (1.1)
	Exemestane	19 (1.1)
	Everolimus	19 (1.1)
	Olaparib	18 (1)
	Talazoparib	17 (0.9)
	Pharmaceutical preparations	16 (0.9)
	Protein-tyrosine kinase inhibitor	15 (0.8)
	Cisplatin	14 (0.8)
	Lapatinib	14 (0.8)
	Fluorouracil	13 (0.7)
	Preservative free ingredient	13 (0.7)

[a]*HER*2: human epidermal growth factor receptor 2.

Pharmacotherapy is the most common treatment method, accounting for 19.2% (267/1387) of the overall frequency. Additionally, other high-frequency treatment modalities include neoadjuvant therapy (88/1387, 6%), hormone therapy (68/1387, 5%), adjuvant chemotherapy (54/1387, 4%), and radiation therapy (48/1387, 3%; Table 1 and Multimedia Appendix 3). In breast cancer treatment drugs, trastuzumab (209/1805, 11.6%), capecitabine (88/1805, 5%), paclitaxel (81/1805, 4%), aromatase inhibitors (64/1805, 4%), and immunologic adjuvants (62/1805, 3%) have a relatively high frequency of occurrence (Table 1 and Multimedia Appendix 4).

Breast Cancer Knowledge Graph

We visualized the SPO triples and displayed 3 subgroups: breast cancer treatment methods, therapeutic drugs, and relevant preventive measures. Figure 1 shows the relationship between different subtypes and stages of breast cancer and treatment methods. In different subtypes of breast cancer, the highest frequency is observed in malignant neoplasm of the breast, with pharmacotherapy having the highest frequency among various treatment modalities. Different subtypes simultaneously correspond to multiple treatment modalities; likewise, a single treatment modality corresponds to multiple breast cancer subtypes.

Figure 1. Relationship between different subtypes and stages of breast cancer and treatment methods. *HER2*: human epidermal growth factor receptor 2.

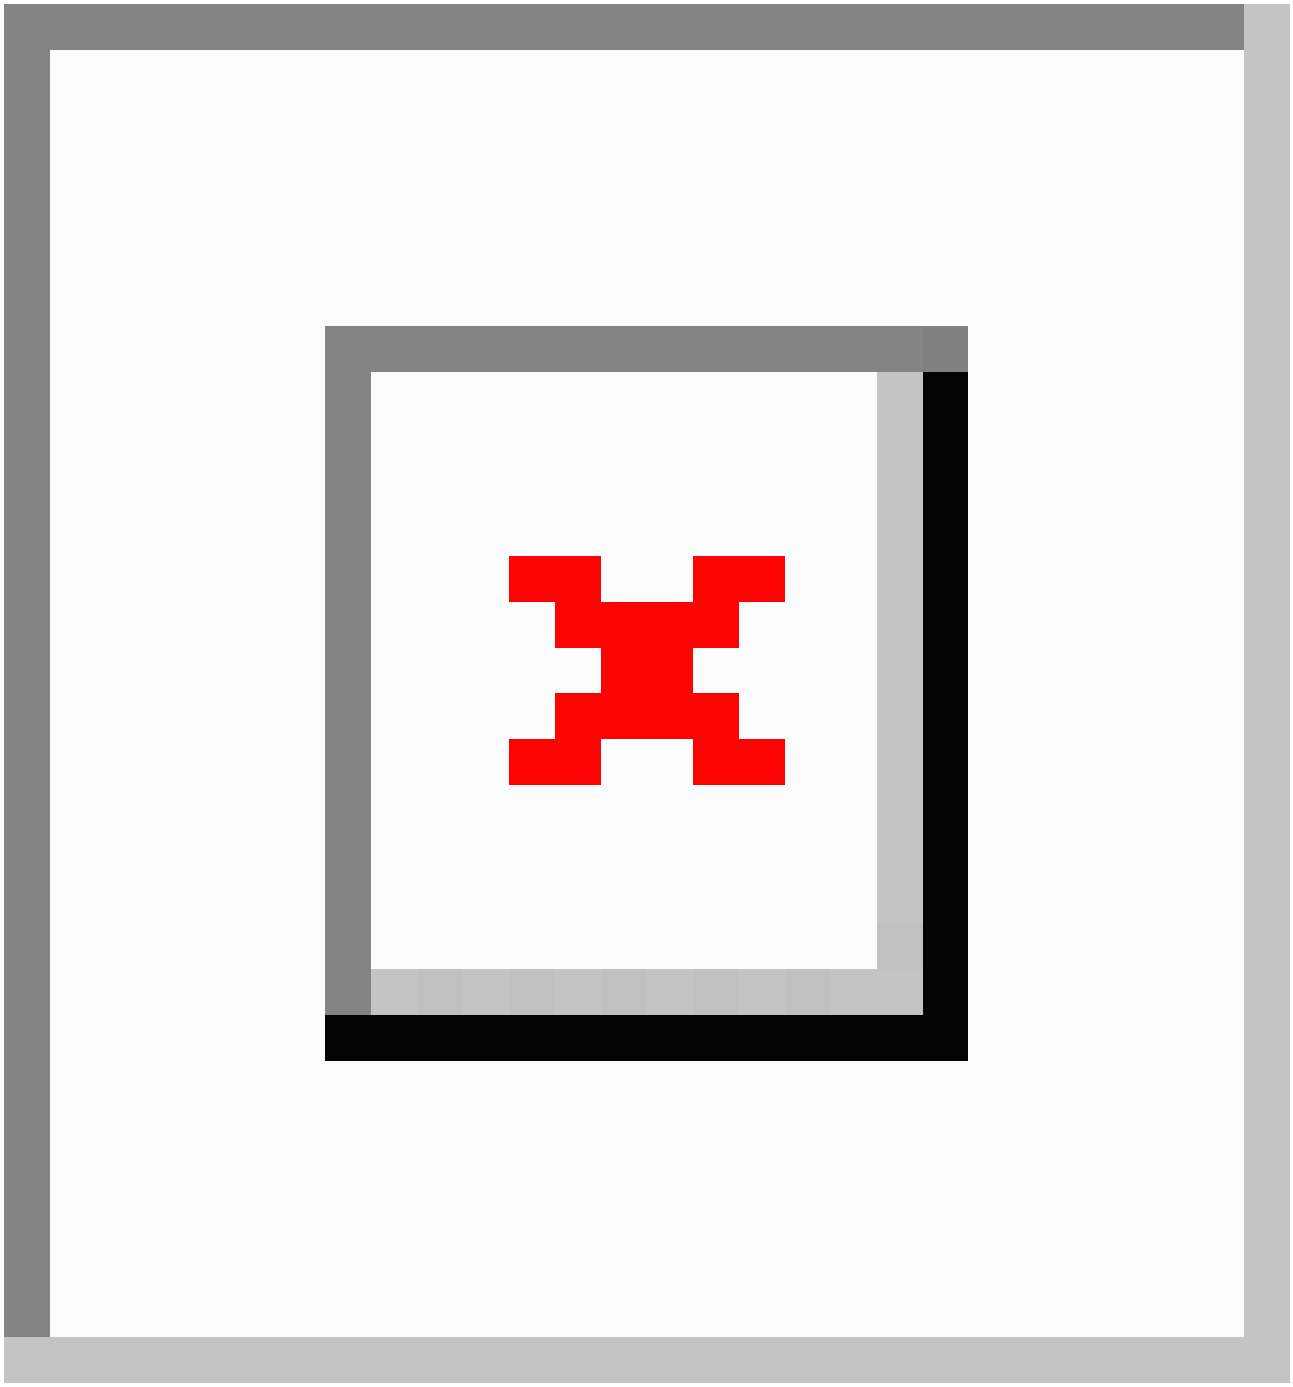

Figure 2 shows the relationship between different subtypes and stages of breast cancer and drugs. Among the therapeutic drugs for breast cancer, trastuzumab has the highest frequency and corresponds to the most types of breast cancer. Capecitabine, paclitaxel, aromatase inhibitors, and immunologic adjuvants also have relatively high frequencies. In comparison, immunologic adjuvants have the fewest connections with different types of breast cancer.

Figure 2. Relationship between different subtypes and stages of breast cancer and drugs. *HER2*: human epidermal growth factor receptor 2.

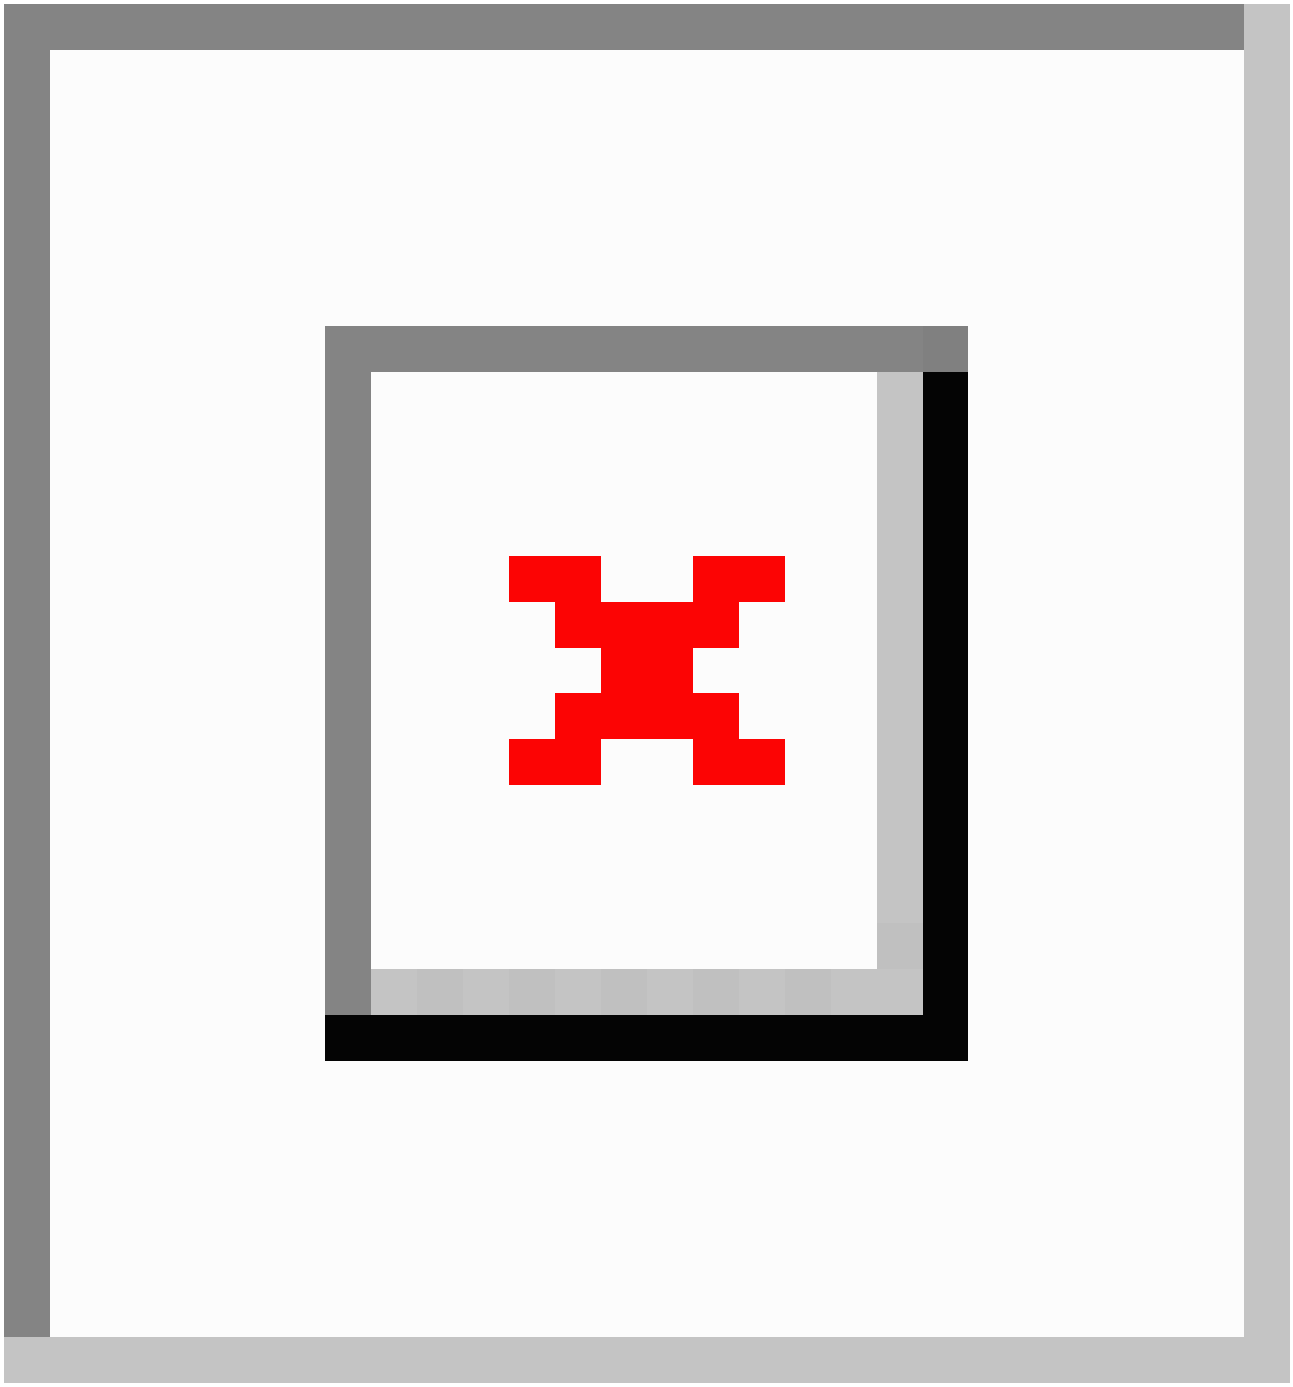

Figure 3 shows the relationship between breast cancer treatment and adverse reactions. Pharmacotherapy is associated with neuropathy, onycholysis, heart neutropenia failure, alopecia, febrile neutropenia, anemia, stomatitis, leukopenia, thrombocytopenia, premature menopause, and gastrointestinal dysfunction. Additionally, multiple nodes are connected, forming multiple pathways, such as pharmacotherapy-febrile neutropenia-adjuvant chemotherapy and pharmacotherapy-leukopenia-breast cancer therapeutic procedure-osteoporosis.

Figure 3. Relationship between breast cancer treatment and adverse reactions.

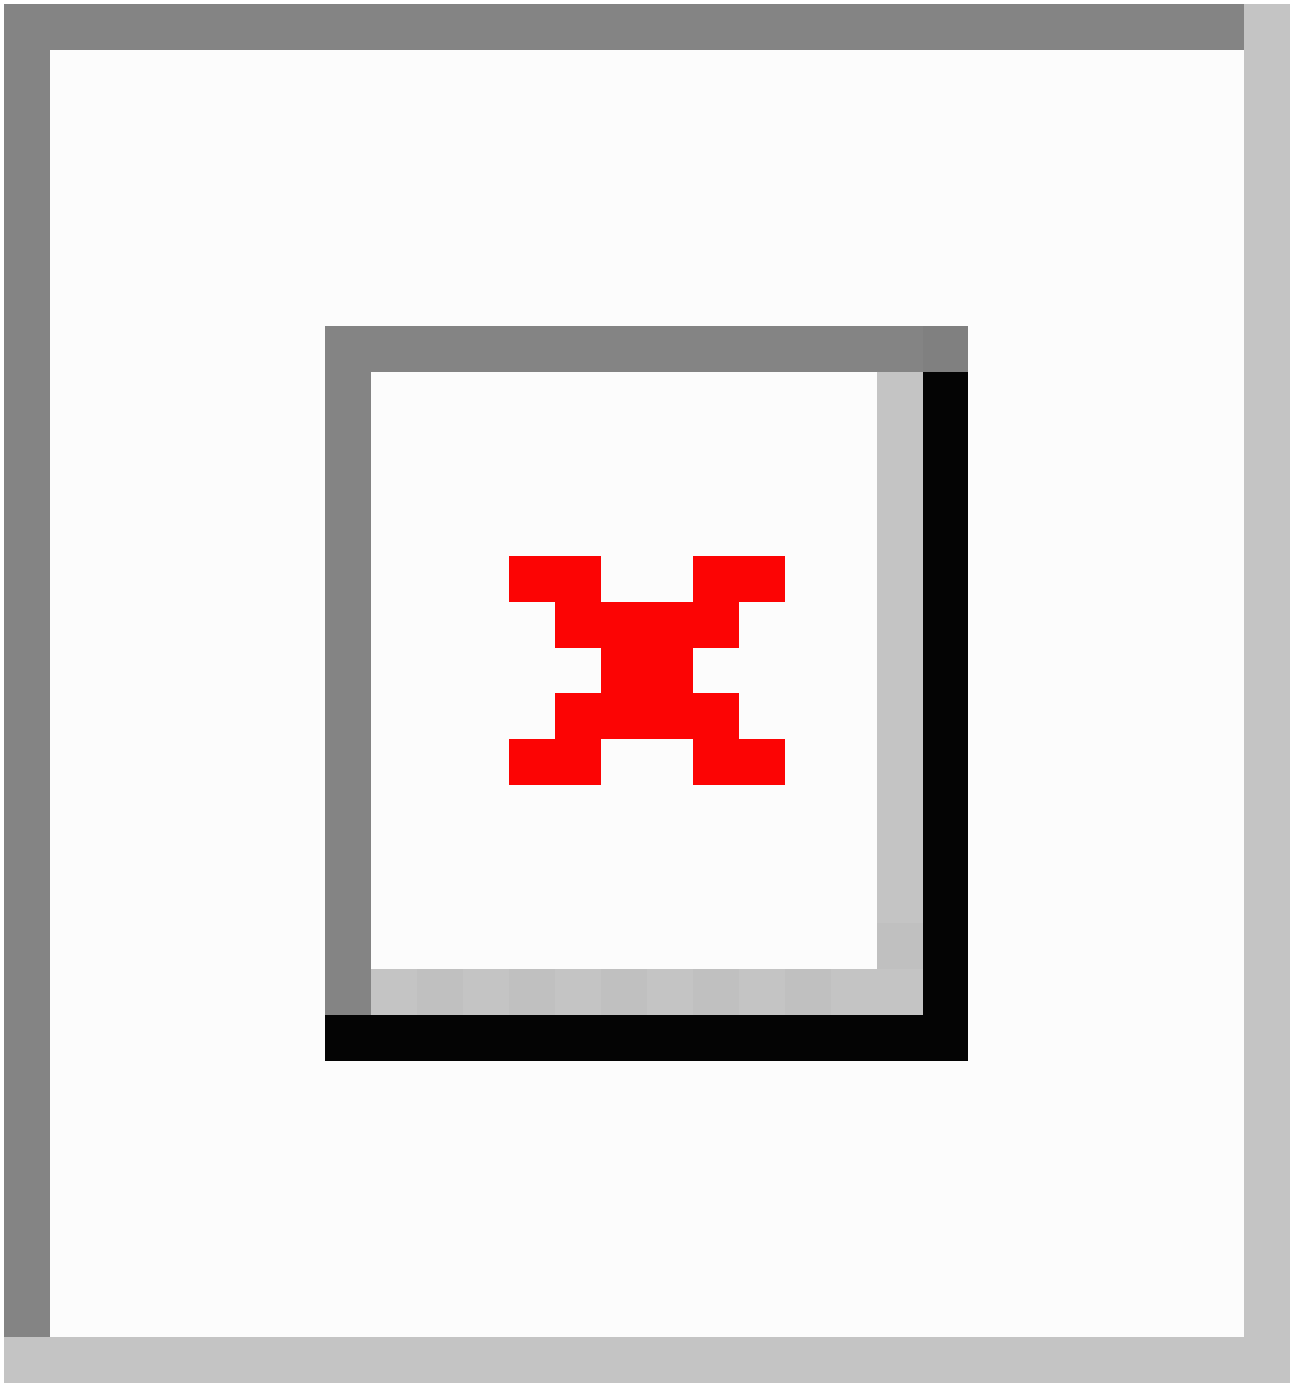

Figure 4 shows the relationship between adverse events after breast cancer treatment and preventive measures. Peripheral neuropathy is associated with cryotherapy, low-level laser therapy, compression procedure, acupuncture procedure, pharmacotherapy, and massage. Lymphedema is associated with resistance education, axillary lymph node dissection, physical therapy, excision of axillary lymph nodes group, and drainage of lymphatics. Early radiation dermatitis is associated with topical administration and bleomycin, cisplatin, or methotrexate protocol. In addition, there are some adverse reactions with relatively few treatment measures, such as stomatitis-diet, alopecia-scalp cooling.

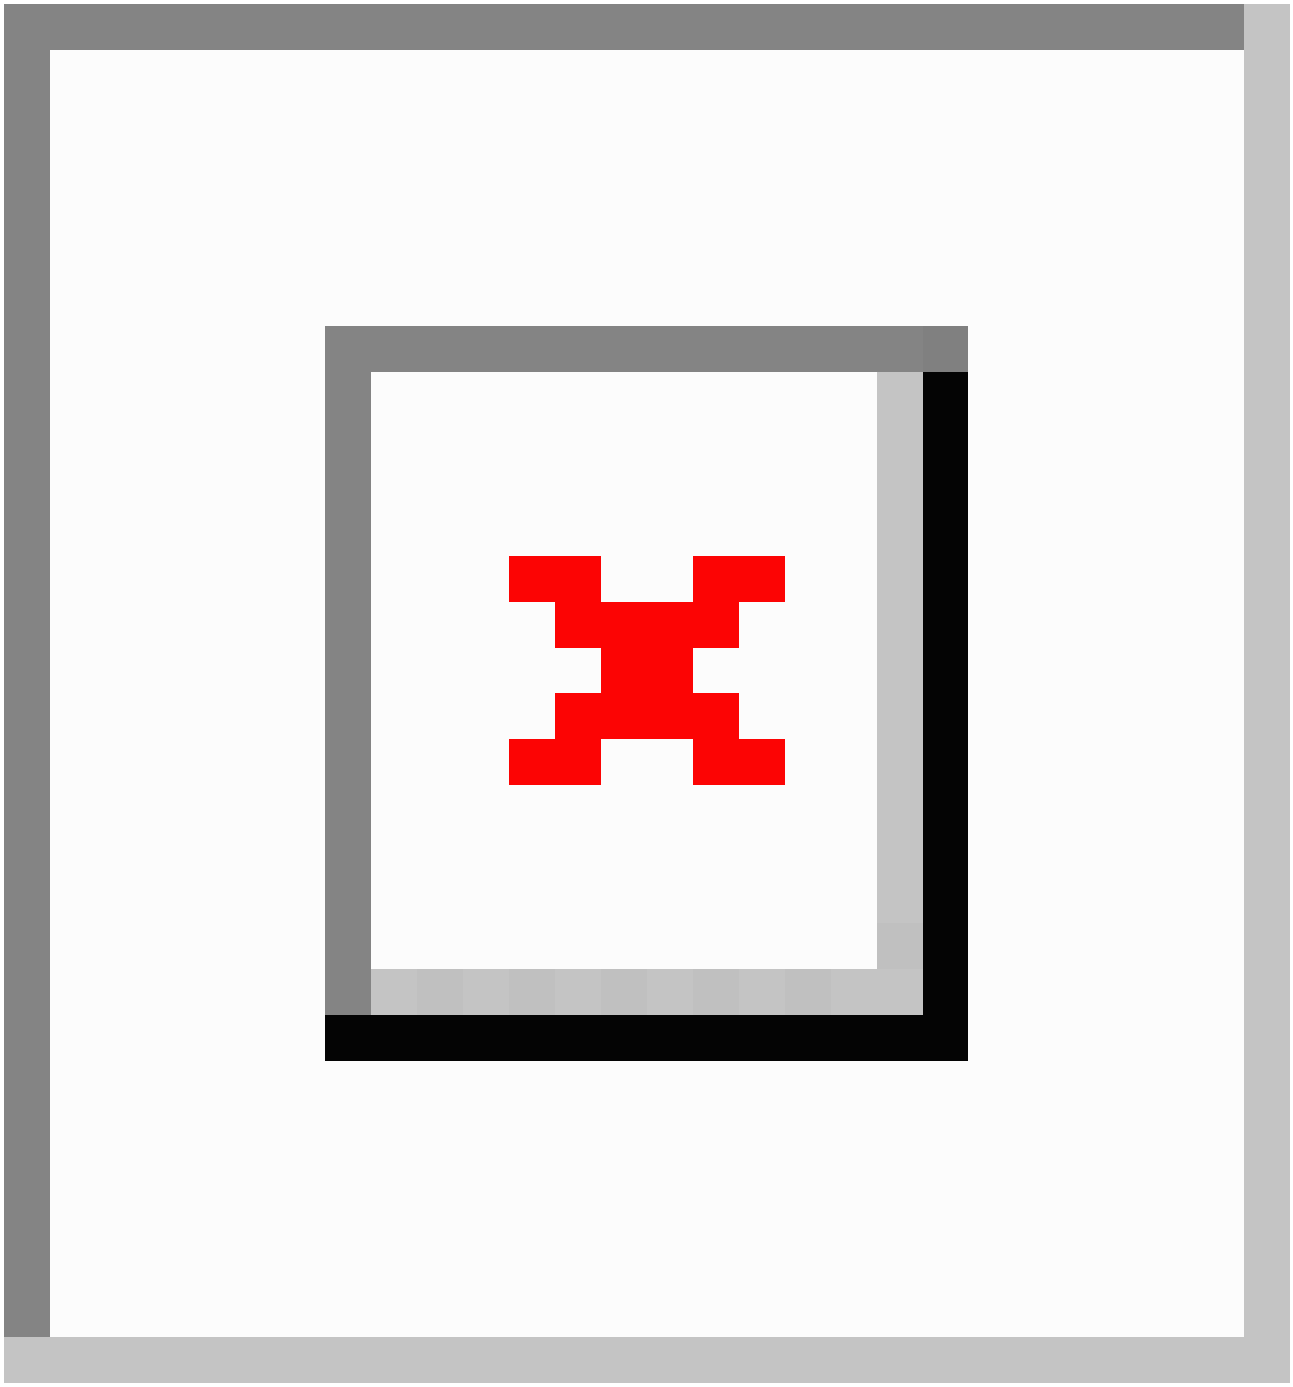
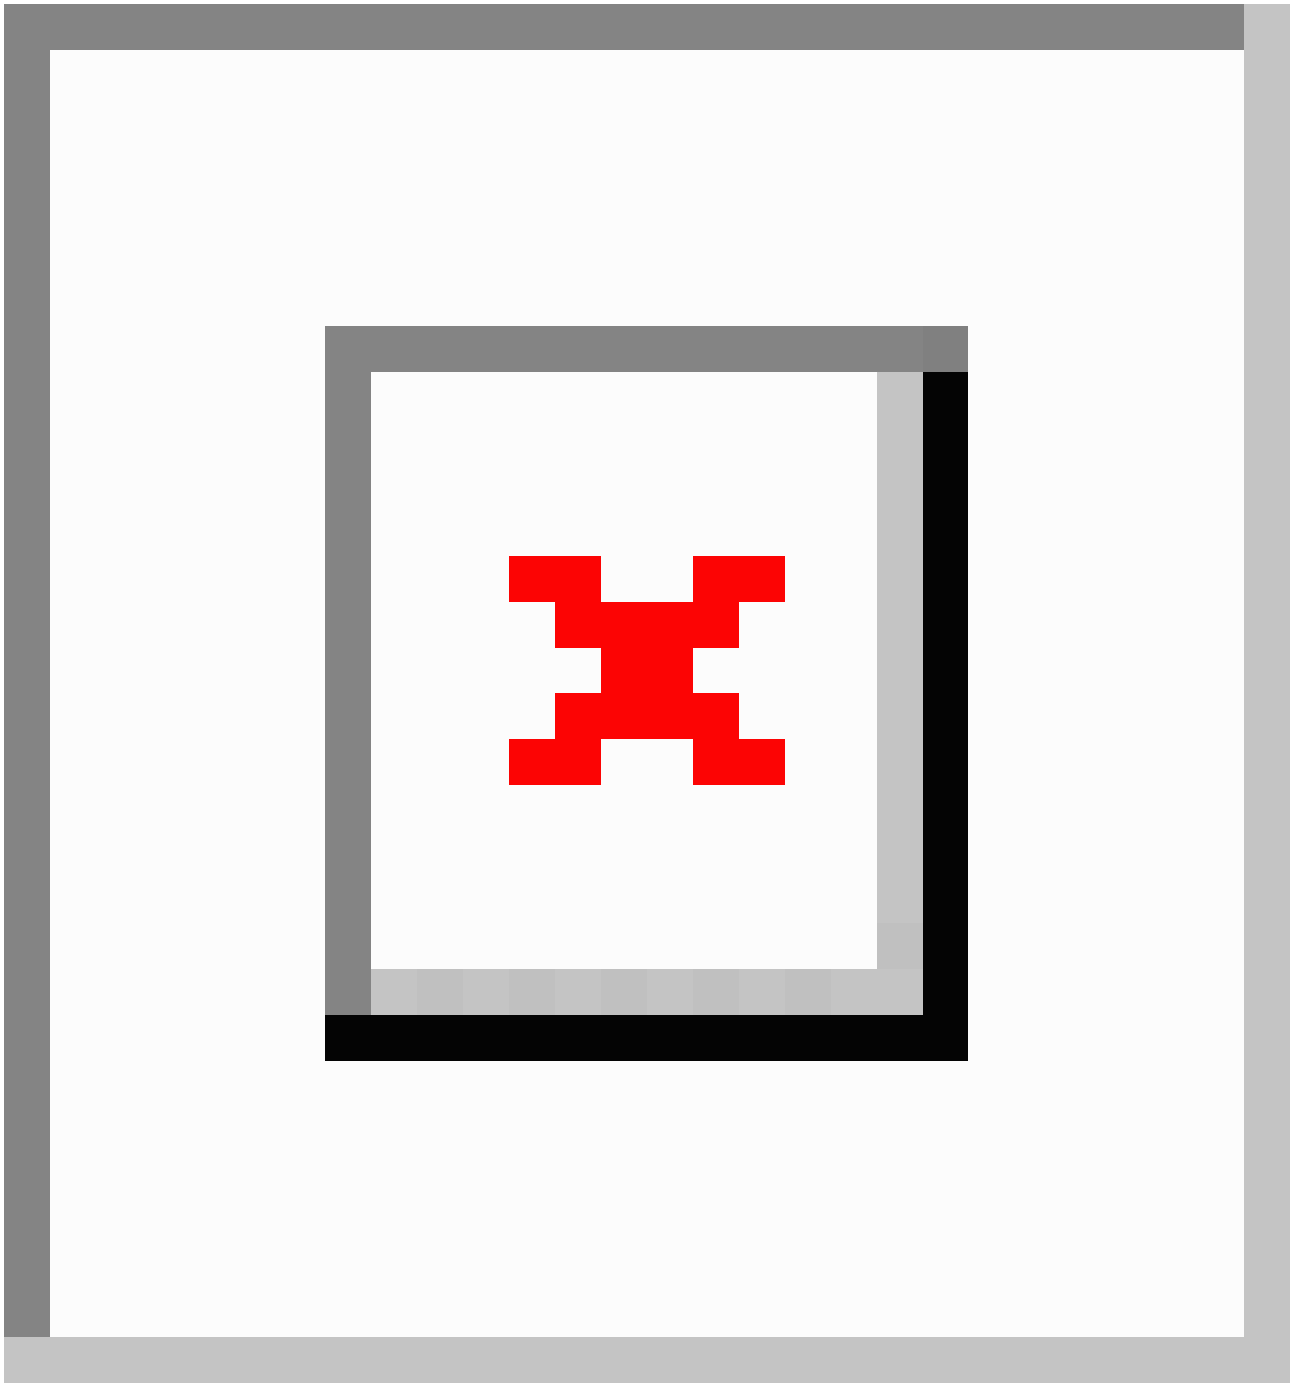
Figure 4. Relationship between adverse reactions after breast cancer treatment and preventive measures.



We performed a relationship visualization to gain a better understanding of the association between types of breast cancer, treatments, drugs, and genes. Figure 5 intuitively reflects the high frequency of malignant neoplasm of the breast, pharmacotherapy, and trastuzumab. In addition, breast malignant tumors are associated with multiple genes, such as the phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha (*PIK3CA*) gene, platelet-derived growth factor receptor beta (*PDGFRB*) gene, phosphatase and tensin homolog (*PTEN*) gene, and erb-B2 receptor tyrosine kinase 2 (*ERBB2*) gene.

Figure 5. Relationship between types of breast cancer, treatments, drugs, and genes.



Discussion

Principal Findings

The knowledge graphs constructed in this study help researchers understand the research hot spots in breast cancer over the past 5 years. The complex network involving treatment methods, drugs, adverse reactions, preventive measures, and genes in breast cancer can assist clinicians in making decisions that comprehensively consider multiple aspects, ultimately aiding in decisions that are the most beneficial to patients. Additionally, the knowledge graph allows for personalized considerations based on specific genes for individualized patients.

This study found that from 2018 to 2022, breast malignancies appeared most frequently in the literature and were the primary concern for researchers. Research interest in triple-negative breast neoplasms is higher than in other subtypes. This phenomenon may be due to the higher risk of recurrence and poor prognosis in patients with early-stage triple-negative breast neoplasms [10], making it a subject of greater concern to clinicians and researchers. Among treatment modalities, pharmacotherapy receives the highest attention. Pharmacotherapy for breast cancer primarily involves chemotherapy, endocrine therapy, and targeted therapy [27]. Compared to traditional surgery and radiotherapy, pharmacotherapy can more precisely intervene in the growth and division of cancer cells by targeting specific molecules or

cellular structures, which reduces damage to normal cells and allows for the formulation of personalized treatment plans based on the patient's genotype and molecular characteristics [28]. Medications circulating through the bloodstream can also act on cancer cells throughout the body, preventing cancer cell metastasis. These advantages of pharmacotherapy may be related to the heightened emphasis on pharmacotherapy over the past 5 years. Trastuzumab receives the highest attention in breast cancer pharmacotherapy; it is a specific cancer-targeting medication used in the treatment of cancers characterized by elevated levels of HER2 protein [29].

Pharmacotherapy is associated with various adverse reactions, including neutropenia, neuropathy, onycholysis, heart failure, alopecia, and febrile neutropenia. Among these adverse reactions, peripheral neuropathy and lymphedema have the most corresponding preventive and treatment measures, with lymphedema being a common complication after surgery [30]. However, there is limited research on how to prevent and treat the potential adverse reactions of pharmacotherapy, and further studies are needed. Various adverse effects of breast cancer treatment may reduce patients' adherence to treatment. Therefore, when clinicians choose different treatments and drugs, they should pay close attention to their potential adverse reactions and how to prevent or mitigate them.

In existing knowledge graphs related to breast cancer, one study from China constructed a knowledge graph using electronic medical records, clinical guidelines, and expert opinions, primarily focusing on breast cancer diagnosis [18]. Another study by Chinese scholars also used data from various sources, including clinical guidelines, medical encyclopedias, and electronic medical records, to construct a knowledge graph primarily applied to medical knowledge question-answering and medical record retrieval [19]. These studies used data from multiple sources, including structured, unstructured, and semistructured data. Data extraction and accuracy face challenges. Therefore, they used neural network models for training and calculated a series of metrics to ensure data accuracy. For instance, they utilized BERT + Bi-LSTM+ CRF for textual data to achieve named entity recognition. In this study, SemMedDB was used as the data source, and the database was constructed by extracting semantic information from PubMed using SemRep, which demonstrated good performance in a biomedical text [21].

In summary, the knowledge graph constructed in this study for breast cancer treatment and prevention encompasses information on different stages, subtypes of breast cancer, treatment modalities, medications, adverse reactions, and preventive measures. This knowledge forms a complex network, providing clinical practitioners with a comprehensive and referenced knowledge base. We recommend that clinical practitioners apply our research findings in several aspects. First, clinicians can gain insights into the current state of breast cancer treatment and prevention research through our study. Additionally, there is a relative lack of preventive measures and strategies for mitigating postoperative and postmedication adverse reactions compared to breast cancer treatment, and more efforts are needed in these areas. Furthermore, our research can assist clinicians in making comprehensive decisions. For instance, when selecting a treatment approach for patients, the knowledge graph facilitates linking to available medications, associated adverse reactions, and measures to mitigate or prevent adverse effects.

Our research still has several limitations. First, SemRep, as a natural language processing program based on the UMLS, still exhibits shortcomings. Despite the extensive coverage and scale of the UMLS Metathesaurus, it has a relatively limited ability to recognize entities. There are still areas for improvement in processing natural language texts [20]. Second, clinical researchers often prefer causal relationships rather than pure correlations; however, our study can only reveal the connections between pieces of information and cannot determine the magnitude and direction of their effects. Third, with the release of new literature, the knowledge graph also needs to be updated promptly, increasing the burden on researchers. Future improvements should focus on automating the mining of literature data to ensure timely updates to the knowledge graph for breast cancer prevention and treatment, thereby alleviating the burden on researchers.

Conclusions

This study successfully constructed a knowledge graph for breast cancer prevention and treatment by integrating relevant literature from the past 5 years and conducting knowledge discovery. Through this knowledge graph, researchers can learn about breast cancer treatment methods, medications, and adverse reactions to preventive treatments and gain insights into the relationships between different pieces of knowledge.

Acknowledgments

The authors would like to thank Feng Xixi, associate chief physician and member of the Chronic Disease Special Committee of the Chengdu City Preventive Medicine Association, for her suggestions at the initial stage of the study.

Abstract

Background: Activities of daily living (ADL) are essential for independence and personal well-being, reflecting an individual's functional status. Impairment in executing these tasks can limit autonomy and negatively affect quality of life. The assessment of physical function during ADL is crucial for the prevention and rehabilitation of movement limitations. Still, its traditional evaluation based on subjective observation has limitations in precision and objectivity.

Objective: The primary objective of this study is to use innovative technology, specifically wearable inertial sensors combined with artificial intelligence techniques, to objectively and accurately evaluate human performance in ADL. It is proposed to overcome the limitations of traditional methods by implementing systems that allow dynamic and noninvasive monitoring of movements during daily activities. The approach seeks to provide an effective tool for the early detection of dysfunctions and the personalization of treatment and rehabilitation plans, thus promoting an improvement in the quality of life of individuals.

Methods: To monitor movements, wearable inertial sensors were developed, which include accelerometers and triaxial gyroscopes. The developed sensors were used to create a proprietary database with 6 movements related to the shoulder and 3 related to the back. We registered 53,165 activity records in the database (consisting of accelerometer and gyroscope measurements), which were reduced to 52,600 after processing to remove null or abnormal values. Finally, 4 deep learning (DL) models were created by combining various processing layers to explore different approaches in ADL recognition.

Results: The results revealed high performance of the 4 proposed models, with levels of accuracy, precision, recall, and F_1-score ranging between 95% and 97% for all classes and an average loss of 0.10. These results indicate the great capacity of the models to accurately identify a variety of activities, with a good balance between precision and recall. Both the convolutional and bidirectional approaches achieved slightly superior results, although the bidirectional model reached convergence in a smaller number of epochs.

Conclusions: The DL models implemented have demonstrated solid performance, indicating an effective ability to identify and classify various daily activities related to the shoulder and lumbar region. These results were achieved with minimal sensorization—being noninvasive and practically imperceptible to the user—which does not affect their daily routine and promotes acceptance and adherence to continuous monitoring, thus improving the reliability of the data collected. This research has the potential to have a significant impact on the clinical evaluation and rehabilitation of patients with movement limitations, by providing an objective and advanced tool to detect key movement patterns and joint dysfunctions.

Introduction

Activities of daily living (ADL) are the most basic tasks of the person, as they enable them to function with a minimum of autonomy. ADL are crucial for maintaining quality of life and personal well-being, serving as indicators of functional status [1-3]. ADL are an indicator of a person's functional status and include basic physical tasks such as moving, eating, dressing, maintaining personal hygiene, and grooming, as well as more complex and instrumental activities such as working, shopping, cleaning, exercising, and participating in recreational activities [2-4]. Impaired physical function can limit the execution of these tasks, affecting personal goals and independent living. This condition can affect the individual's ability to achieve personal goals and maintain an independent quality of life [2,5,6]. Therefore, it is necessary to assess this deterioration during the execution of ADL in different preventive, clinical, or rehabilitation contexts [6-8].

The functional assessment of ADL is complex, so it is advisable to approach it based on the evaluation of fundamental movement patterns on which these ADL are developed [9-11]. The shoulder and lumbar region are key joint complexes in this regard. Specifically, the shoulder joint is essential in many basic ADL, providing the mobility and stability necessary to perform actions in all planes of movement. It is essential to position the hand in space in a way that allows one to reach objects, eat, button a shirt, unbutton a bra, or comb one's hair [9,12-14]. The movement patterns most used in its assessment are scapula-humeral elevation in the sagittal and frontal plane and rotations at different elevation angles [9,13,14]. Similarly, the lumbar region is a joint complex that has a close relationship with basic movement patterns such as flexion and extension of the trunk in the sagittal plane but also in extremely important actions such as sitting and standing up [10,15-18]. Various ADL derive from this fundamental movement pattern, the most studied being the gestures of sitting and getting up from a chair, bending or crouching, and lifting an object or weight [15-17,19].

The precise evaluation, control, and monitoring of ADL performance are fundamental tasks, although not simple, in the development of effective intervention tools in these clinical and rehabilitation contexts. Traditionally, the assessment of ADL has been based on direct observation and subjective evaluation by therapists, which entails biases, errors, and lack of precision in the results [6,20-22]. In contrast, recent advancements in technology, including wearable health monitoring devices, smart clothing sensors, and mobility assistance devices, enable the objective assessment and quantification of personal performance during ADL [23-27]. This technology includes wearable devices, motion sensors, and 2D or 3D motion capture systems, which allow complex movements and functionality of key joints, such as the shoulder or lumbar region, to be accurately recorded and analyzed during the performance of ADL [4,9,15]. However, limitations such as its high acquisition and implementation cost, its specialized technical knowledge, its lack of transparency and complexity, or its lack of validation and reliability hinder its applicability in the specific clinical or rehabilitation context [4,9,24,25].

A promising solution to overcome the aforementioned limitations is the use of wearable inertial sensors [28-34]. These have been gaining substantial scientific interest due to their potential to provide real-time information on kinematic aspects of human movement through continuous, dynamic, and minimally invasive monitoring. In the clinical and rehabilitation field, this technology has emerged as a simple and low-cost alternative to obtain precise information on accelerations, angular velocities, and trajectories in the different planes of movement during the execution of different basic ADL. This technology offers several advantages. It allows for a more accurate and objective assessment of the functionality of key joint complexes, identifying specific areas of weakness or limitation in movement during ADL and providing quantitative data on the person's progress over time [28,35,36]. On the other hand, it favors the motivation of patients, by being able to visualize their evolution, thus improving treatment adherence [28,31,37].

However, inertial sensors have some limitations. Despite being light and small, these devices may not be entirely transparent for users, especially due to the high number of sensors that, in many cases, must be used to obtain data that accurately interpret human movement [30,38,39].

Compared with the traditional approach of most studies that only use wearable inertial sensors to monitor kinematic aspects of human movement, the use of artificial intelligence (AI) techniques has been gaining popularity, by helping to improve the process of assessing and supervising different body movements using inertial sensors, in addition to reducing the number of sensors necessary for this [40-42].

In Yen at al [40], a wearable device consisting of a microcontroller and an inertial sensor placed on the participant's waist is presented. The signals collected by the accelerometer and gyroscope were used to train a 1D convolutional neural network–based feature learning model, enabling the identification of 6 ADL. The results demonstrated high accuracy in both external and study data, validating the effectiveness of the proposed method.

The study by Huynh-The et al [41] introduces an innovative method for recognizing ADL- and sports-related activities using wearable sensors. This method involves converting inertial data into color images, facilitating the learning of highly discriminative features using convolutional neural networks. Experimental results showed recognition accuracy of over 95%, outperforming other deep learning (DL)–based approaches for human activity recognition (HAR).

In Ronald et al [43], a novel DL model inspired by the Inception-ResNet architecture is presented for HAR tasks. The proposed model, trained on data collected from smartphones and inertial sensors capturing accelerometer, gyroscope, magnetometer, GPS, temperature, and heart rate signals, achieved remarkable performance across different data sets, demonstrating its flexibility and adaptability to varying signal types and quantities.

Meanwhile, Poulose et al [44] address the challenges of HAR in health care systems by proposing an approach based on a human image threshing machine using smartphone camera images. The human image threshing system uses mask region–based convolutional neural networks for human detection and a DL model for activity classification, achieving a precision of 98.53% and surpassing conventional sensor-based HAR approaches.

This study is based on the combination of accelerometer and gyroscope signals with AI techniques for the assessment of the shoulder and lumbar spine. AI algorithms can process the data captured by inertial sensors and perform sophisticated analyses to detect patterns, identify alterations in movement, and provide relevant clinical information. This facilitates a more complete and accurate evaluation of the joint movement of the shoulder or lower back, allowing a better understanding of dysfunctions and personalization of treatment and rehabilitation plans. The key contributions made by this study are summarized as follows:

1. Accelerometer and gyroscope signals with AI integration for enhanced ADL assessment: This combination shows great potential for the assessment of shoulder and lumbar region motion in basic ADL performance, providing an objective and advanced perspective in clinical evaluation and rehabilitation. However, validly and reliably demonstrating its use as a control and evaluation tool for ADL performance, in gestures such as eating, combing hair, dressing, sitting, or standing, still appears as an unresolved research challenge. Therefore, in this study, we aim to address the automatic detection and monitoring, using AI techniques, of the patient's basic ADL related to the shoulder and back.
2. Enhanced activity recognition precision: Our study relies on direct capture of inertial sensor signals, potentially offering a more precise and less image quality–dependent solution.
3. Efficient sensors use: For signal capture, only 2 sensors are used. Furthermore, it is intended to achieve this objective through minimal, noninvasive, and practically transparent sensorization for the user, improving adherence to the monitoring process and facilitating the integration of technology into the individual's daily life at a low cost.
4. Direct inertial data approach: Our study focuses on the direct use of accelerometer and gyroscope data without requiring additional conversion for model training.
5. Broad scope and versatility: It covers a wide range of activities, showcasing its versatility and adaptability.

We believe that this novel approach will make a significant contribution to this field of research, as it can be used in the prevention, clinical, or rehabilitation contexts of the shoulder and lumbar region.

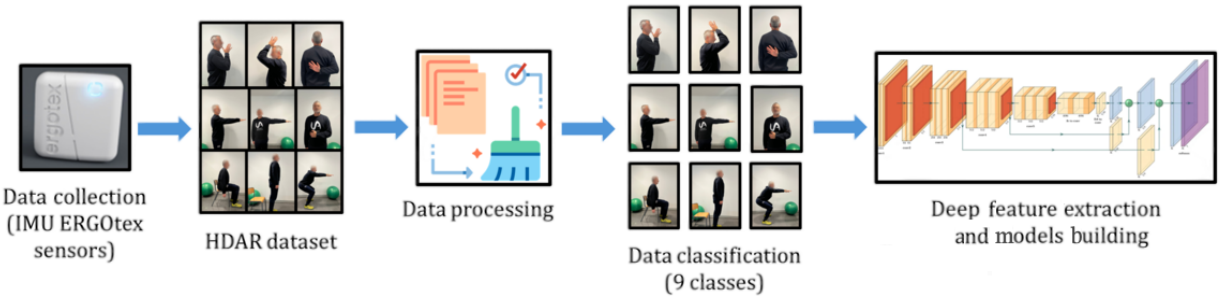
The remainder of the paper is organized as follows: the *Methods* section addresses how the database was generated, the processing layers used, and the architecture of the 4 developed DL models, as well as the parameters selected for their training and optimization. In the *Results* section, the evaluation outcomes obtained by the 4 DL models are presented, analyzed, and compared. Finally, the *Discussion* section presents a discussion of the principal findings and conclusions regarding our study.

Methods

Overview

This research work focuses on the detection and automatic monitoring of ADL using AI models (DL models) and wearable inertial sensors to prevent or diagnose injuries, as well as supervise rehabilitation processes. Figure 1 presents an overview of the methodology proposed. In the following subsections, each step is explained in depth.

Figure 1. System overview. HDAR: Human Daily Activities Recognition ; IMU: inertial measurement unit.



Ethical Considerations

This study has been conducted in strict accordance with the ethical principles outlined in the Declaration of Helsinki. Approval for this research was obtained from the Ethics Committee of the University of Alicante (protocol code UA-2023-11-16).

Prior to commencement, participants provided written informed consent. Respect for participants, including their autonomy, confidentiality, and well-being, has been ensured.

All collected data have undergone a rigorous anonymization process, safeguarding the privacy of the individuals involved in the research. Protective measures were implemented in

accordance with institutional guidelines to ensure the security of participant information throughout the study.

Participants involved in human subjects research were not provided with any form of compensation. This decision was made to uphold transparency and fairness in the research process and to minimize potential biases associated with compensation.

Data Collection

A total of 9 ADLs were included in the study, 6 of them related to the shoulder (eating [E], combing hair [CH], fastening the bra [FB], opening the door [OD], reaching for an object [RO], and buttoning up [BU]) and 3 related to the back (sitting [S], standing up [SU], and half squat [HS]). Figure 2 graphically shows these movements.

Figure 2. Graphic description of activities of daily living movements. In the top row (from left to right): eating, combing hair, and fastening the bra. In the middle row (from left to right): opening the door, reaching for an object, and buttoning up. Bottom row (left to right): sitting, standing up, and half squat.

To monitor movements, we used 2 self-developed inertial measurement unit ERGOtex model sensors [45,46]. This inertial measurement unit ERGOtex sensor comprises 3 triaxial accelerometers (±2 g, controlled noise at 100 µg/√Hz), triaxial gyroscopes (±1000 deg/s, sensitivity error within ±1%, and low noise level, at ±4 mdeg/s/√Hz), and magnetometers, encapsulated in a device (weight=8 g, dimensions=23×21×10 mm). The ICM-20602 MEMS MotionTracking (TDK Corp) device was selected for its high-performance specifications, critical for the reliability of the device. The incorporation of a 1K-byte FIFO buffer reduces serial bus congestion, enhancing measurement consistency and optimizing device power use. It operates at a sampling rate of 20 Hz, has an autonomy of 8 hours, and can be attached to the skin using double-sided tape or secured elsewhere using an elastic strap. These enhancements guarantee reliable response times and sensitivity levels, crucial for maintaining data accuracy (Figure 3).

Figure 3. ERGOtex inertial measurement unit sensors were developed for movement identification.

The inertial sensors were attached to the skin over the sacrum (S1) and the distal part of the upper extremity (close to the wrist). Primarily designed for monitoring spine posture and arm, this device records acceleration data across all 3 axes. Internal integration of the acceleration signal occurs within the device, transmitting data instantly via Bluetooth (frequency=2.4 GHz) to a smartphone or tablet equipped with the preinstalled app. This application enables immediate data visualization and facilitates export to a spreadsheet in comma-separated text format (CSV).

The database generated initially had 53,165 records of all activities. The records were grouped into batches of time series (of different lengths) that represented the different movements. Each record was made up of 12 attributes or numerical variables, corresponding to the value obtained by the accelerometer and gyroscope of each sensor during the execution of the movement according to its 3 axes (Acx, Acy, Acz, Gyx, Gyy, Gyz). After the processing stage, where null, missing, and abnormal values were eliminated, the database was reduced to 52,600 records (RO: n=6423, FB: n=6956, E: n=6216, OD: n=6472, SU: n=3678, CH: n=6010, BU: n=5915, HS: n=6630, and S: n=4300).

DL Models

Processing Layers

To create the DL models, different processing layers that perform the transformation, regularization, feature extraction, regularization, and dependency capture operations were combined. The basics of each of them are presented below.

1D Convolution Layer for Feature Extraction

A 1D convolutional layer is specifically designed to process data that follows a 1D structure, such as time series or text sequences. In the case of a 1D time series, the 1D convolution operation follows a similar process as a standard convolutional layer but is performed along 1 dimension instead of 2 [47]. The convolution operation is the key component of this type of layer. During the 1D convolution operation, a filter (kernel) of defined size slides along the time series, multiplying the filter values by the corresponding values in the time series and summing them to produce a single value at the output. This process is repeated for each filter position throughout the time series, thus generating a feature map that highlights relevant patterns in the data sequences. The 1D convolutional layer is essential for the automatic identification of patterns in time series, allowing efficient extraction of important features during the training process. By reducing the number of parameters and avoiding overfitting, 1D convolution helps capture the temporal structure of data and improve model performance in time series prediction or classification tasks [48]. Given an input 1D time series X and a set of filters F, the convolution operation is performed as follows (equation 1):

where Y_i is the output value at the feature map position i, X_{i+j} is the time series value at position $i+j$, * denotes the convolution operation, and b_i is the bias associated with the output F_j, and m is the filter size.

Long Short-Term Memory Layer for Modeling Temporal Dependencies

Long short-term memory (LSTM) layers are a type of recurrent layer designed to overcome the limitations of traditional recurrent neural networks in capturing long-term dependencies in temporal sequences [49]. Its design is based on the idea of using internal memory structures controlled by gates to manage information over time and make decisions about what information to retain and discard. In an LSTM, 3 main gates are introduced: the forget gate, which decides what information should be discarded from the previous memory; the input gate, which decides what new information should be stored in memory; and the output gate, which determines what memory information should be used to generate the output of the layer. These gates are controlled by activation functions and adjustable weights during training.

An overview of the fundamental equations of an LSTM cell is presented below, which describe how an LSTM cell manages information and gates to process and retain relevant information over time in a temporal sequence, given one input at a time step t, denoted as x_t, and the outputs of the previous time step [h_{t-1}] (LSTM cell output) and C_{t-1} (LSTM cell state).

Forget gate (f_t): decides what information should be discarded or forgotten from the cell state (equation 2)

Input gate (i_t): decide what new information to store in the cell state (equations 3 and 4)

The forgotten information and new information are then combined to update the state of the cell (equation 5).

Output gate (o_t): finally, the final activation at the current position (h_t) is calculated with the output gate (o_t), which regulates the amount of information to be output (equation 6)

Where σ is the sigmoid function; *tanh* is the hyperbolic tangent function; W_i,W_C and W_o are weight matrices that are learned during training; and b_f, b_i, b_c, and b_o are biases. [h_{t-1},x_t] denotes the concatenation of h_{t-1} and x_t before applying the linear operation.

Dropout Regularization Layer

The Dropout layer is a regularization strategy that prevents overfitting by introducing variability into the network during training [50]. This technique randomly turns off a percentage of units in each iteration, temporarily removing them and forcing the network to learn more robust representations. Based on the assembly concept, it simulates the presence or absence of units, improving effectiveness and reducing dependence on specific units. In addition to its impact on generalization, the Dropout layer acts as an effective regularization mechanism, improving modeling efficiency and performance by preventing overoptimization and facilitating generalization to unseen data [51,52].

Flatten and Fully Connected (Dense) Transformation Layers

The Flatten layer aims to transform 2D or 3D data into a 1D format, allowing for a more manageable representation and facilitating the transition from convolutional layers to dense layers [53]. Given a 3D input matrix where m, n, and p are the spatial dimensions, the Flatten layer converts this matrix into a 1D vector X' of size $m * n * p$.

The fully connected (FC) or Dense layer connects all neurons in 1 layer to all neurons in the next layer [48]. It performs linear transformations on the data followed by nonlinear activation functions, allowing complex representations to be learned. If X is the input of the Dense layer, W is the weight matrix, and b is the bias vector, the output Y is calculated as (equation 8):

where σ is the activation function.

1D MaxPooling Layer for Feature Reduction

The 1D MaxPooling layer is a technique used in neural networks to reduce the spatial dimensionality of data by retaining only the maximum values in specific regions [54,55]. In the context of 1D time series, 1D MaxPooling is used to summarize the most relevant information and reduce the computational cost by decreasing the number of parameters in the network. Given a 1D input data set X with elements and a pooling window of size p, the output Y is calculated by taking the maximum value in each window. Mathematically, this can be expressed as (equation 9):

where i is the index of the pooling window. This process is repeated until the entire length of the entry is covered.

Proposed Architecture

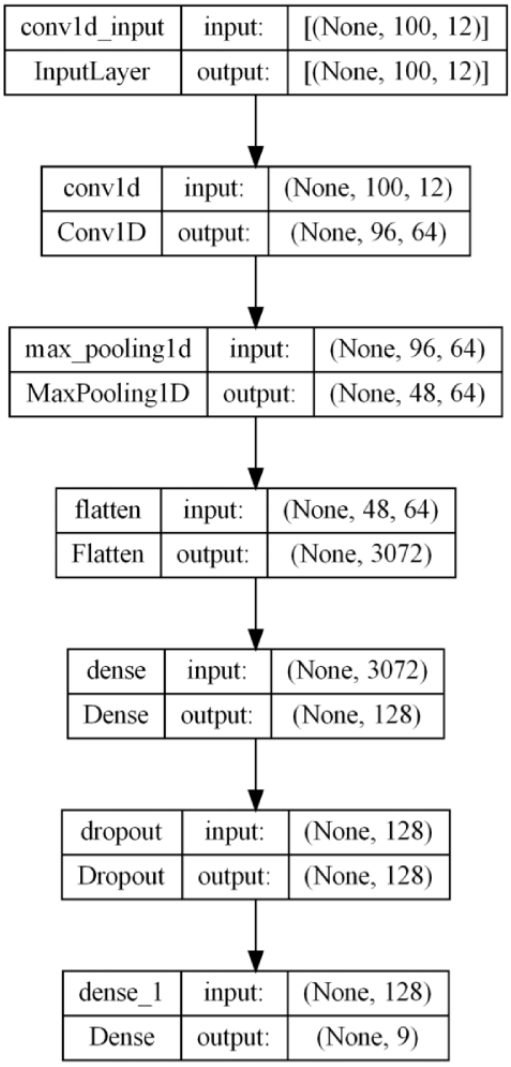
Overview

The processing layers described above were combined to create 4 DL models of different complexity. Each model was designed to explore and exploit different approaches in data processing for the ADL recognition task. The architectures and distinctive features of each of these models are detailed below.

Convolutional Approach

The first proposed architecture uses a convolutional approach. It is composed of 3 main layers: a 1D convolutional layer, a pooling layer, and an FC layer (Figure 4). The convolutional layer, with 64 filters and a kernel size of 5, performs local feature extraction. Next, the pooling layer with pool size 2 is applied to reduce the dimensionality and preserve the most relevant features. Subsequently, a Flatten layer is used to convert the output into a 1D vector before connecting it to an FC layer with 128 neurons and a rectified lineal unit (ReLU) activation function. ReLU is a nonlinear activation function commonly used in neural networks to introduce nonlinearities and aid in model convergence [56]. Finally, a Dropout layer with a rate of 40% is incorporated to prevent overfitting. The output layer uses the Softmax function and is designed for multiclass classification. The output layer uses the Softmax function, which is commonly used in multiclass classification tasks to compute the probabilities of each class outcome and facilitate decision-making based on the highest probability class [57].

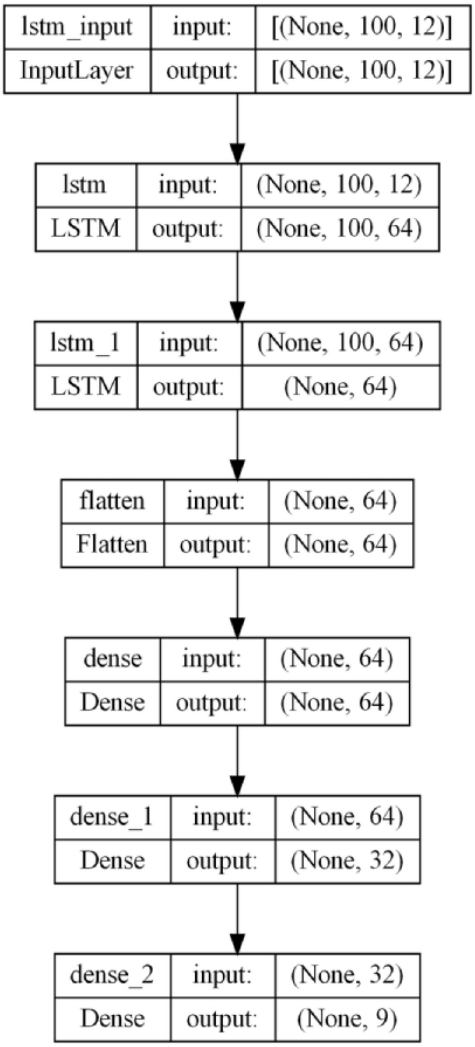
Figure 4. Model architecture based on a convolutional approach.



Deep LSTM Approach

The second architecture is based on a deep LSTM networking approach. It includes 2 LSTM layers, both with 64 units, followed by a Flatten layer. Then, 2 FC layers, with 64 and 32 neurons, respectively, and ReLU activation function are incorporated. The output layer uses the Softmax function for multiclass classification (Figure 5). This architecture deepens into the LSTM network with multiple layers, allowing more complex temporal patterns to be learned. The complexity increases compared with the convolutional model due to the deepening of the LSTM layers and the increase in FC connections. This approach seeks to capture more elaborate temporal dependencies in time series data.

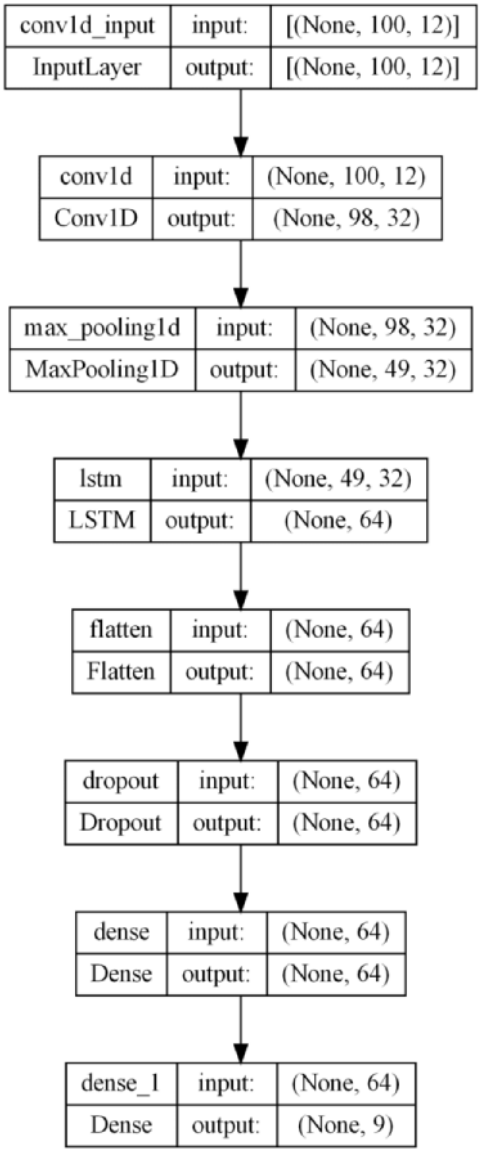
Figure 5. Model architecture based on a deep LSTM approach. LSTM: long short-term memory.



Hybrid Approach: 1D Convolutional + LSTM

The third architecture adopts a hybrid approach combining convolutional layers and LSTM networks (Figure 6). It starts with a 1D convolutional layer with 32 filters and kernel size 3, followed by an LSTM layer with 64 units. Subsequently, a pooling layer and a Flatten layer are applied. A Dropout layer (30%) is introduced to prevent overfitting before connecting to an FC layer with 64 neurons and ReLU activation. The output layer uses Softmax for multiclass classification. This architecture seeks to take advantage of the ability of convolutional layers to extract local features and the ability of LSTMs to model long-term temporal dependencies, offering a combination of both capabilities. Its complexity lies in the integration of 2 different approaches to improve the representation and understanding of time series data.

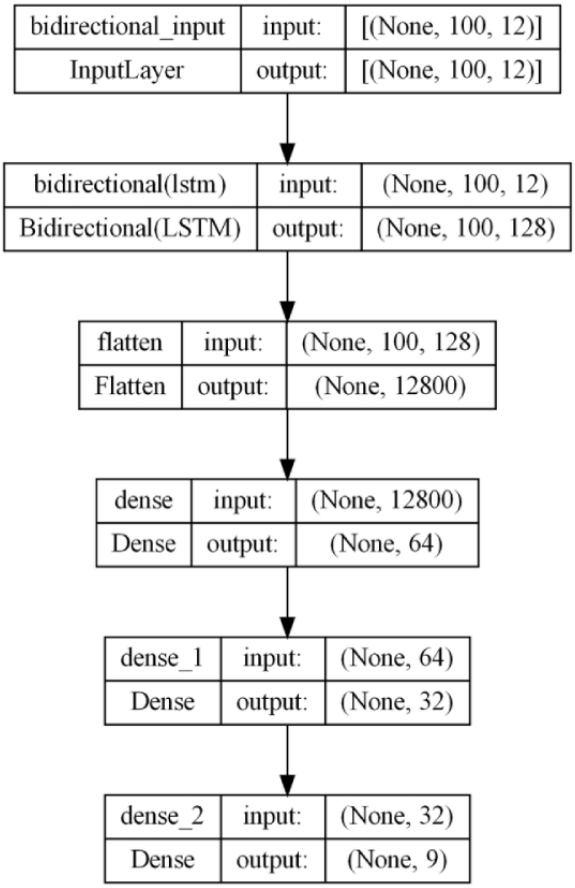
Figure 6. Model architecture based on a hybrid approach (convolutional + LSTM). LSTM: long short-term memory.



Bidirectional LSTM Approach

The fourth architecture adopts a bidirectional approach using LSTM layers (Figure 7). It starts with a bidirectional LSTM layer with 64 units to capture temporal patterns in both directions. Then, a Flatten layer is applied before connecting with 2 FC layers of 64 and 32 neurons, respectively, with ReLU activation function. The output layer uses Softmax for multiclass classification. This architecture represents a more sophisticated and complex model by taking advantage of the ability of bidirectional LSTMs to capture both forward and backward temporal dependencies.

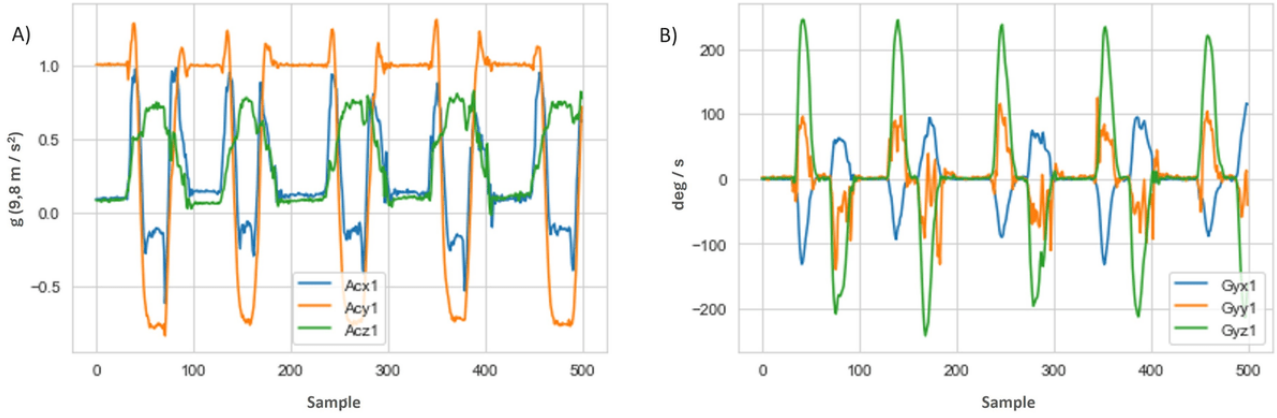
Figure 7. Model architecture based on a bidirectional LSTM approach. LSTM: long short-term memory.



Selection of Parameters for Training and Optimization of Models

For a better understanding of the data and selection of the hyperparameters of the AI model, the accelerometry and gyroscope values of each movement were analyzed separately (Figure 8). Based on this, the temporal sequences were divided into windows of 100 records with a 10-record overlap between adjacent windows.

Figure 8. Time series of eating activity: (A) accelerometer and (B) gyroscope.



Each model was trained over 150 epochs, representing a complete iteration through the training data. The model weights were updated every 1024 records (batch size), and training was stopped if the validation accuracy did not improve for 15 consecutive epochs (early stopping) to prevent overfitting.

As the optimization algorithm during training, Adam was used. Its primary goal is to adjust the network's weights and biases so that the model's loss function is minimized. Adam enhances the standard gradient descent technique by adjusting the learning rate for each parameter individually, potentially leading to faster convergence and better model performance.

Additionally, an L2 regularization term with a strength of 0.0015 was also applied to mitigate overfitting. This term controls the excessive growth of weights during training by adding a penalty term to the model's loss function. The regularization strength determines how much large weights are penalized. By penalizing large weights, L2 regularization helps smooth out the model's

decisions and prevents it from fitting too closely to the training data.

Categorical cross-entropy was used as the loss function. This function measures the discrepancy between the probability distributions predicted by the model and the actual distributions. The primary evaluation metric was accuracy, indicating the proportion of the model's predictions in the test set that were correct.

Results

Evaluation Metrics

The experiment was performed on a personal computer with Microsoft Windows 10, an Intel(R) Core(TM) i5-4210U CPU @ 1.70GHz-2.40 GHz, 6 GB RAM, and no GPU. All software was implemented using the Python programming language and the TensorFlow library in the Spyder development environment. After preparing the data, the DL models were trained using 70% of the data, and the remaining 30% was used to evaluate their performance. For this, popular evaluation metrics were used in classification problems, including precision, recall, F_1-score, and accuracy.

Accuracy (equation 10) refers to the proportion of correct predictions, true positives (TPs) and true negatives (TNs) in relation to the total predictions made by the model, which include false positives (FPs) and false negatives (FNs).

Precision (equation 11) represents the proportion of positive predictions that were correct. It is calculated as the number of TPs divided by the sum of TPs and FPs.

Recall (equation 12) refers to the proportion of TP cases that were correctly identified by the model, calculated as the number of TPs divided by the sum of TPs and FNs.

F_1-score (equation 13) is a measure that combines precision and recall. It is calculated as the harmonic mean between precision and recall and provides a more balanced assessment of model performance, particularly useful when there is an imbalance in the class distribution in the data.

Evaluation Outcomes

The obtained results show the high performance of the 4 proposed models, with accuracy, precision, recall, and F_1-score ranging between 95% and 97% for all cases (Table 1), while the loss function indicates an error rate of approximately 0.10 for the models. The high accuracy, precision, and recall suggest an ability to accurately identify multiple classes of activities, while the high F_1-score indicates a good balance between precision and recall. These results suggest that the models have effectively learned the relationships in the training, enabling them to identify patterns and generalize effectively to data they have not encountered during training, demonstrating strong and reliable predictive capabilities.

Table 1. Evaluation metrics of the designed deep learning models.

Models	Accuracy (%)	Precision (%)	Recall (%)	F_1-score (%)
CNN[a]	97.11	97.19	97.14	97.14
Deep LSTM[d]	95.52	95.64	95.58	95.54
CNN+LSTM	96.19	96.19	96.14	96.14
Bidirectional LSTM	97.56	97.51	97.52	97.51

[a]CNN: convolutional neural network.

[b]LSTM: long short-term memory.

When comparing different modeling approaches, it is evident that both the convolutional and bidirectional methods yield similar results across all evaluated metrics. This suggests that, despite the bidirectional approach's inherent complexity in processing sequences in both directions, it does not offer a significant improvement over the simpler convolutional method. The convolutional model may have struck an optimal balance between learnability and generalization, enabling it to match or even surpass more complex models in terms of accuracy. However, it is worth noting that the bidirectional model achieved convergence in a smaller number of epochs (n=30; Figure 9), which is particularly valuable when rapid training and model responsiveness are required.

It is also noteworthy that more complex models, such as deep LSTM and the hybrid approach, exhibit slightly inferior results compared with the convolutional approach. This observation may stem from several factors. First, the generalization ability of these models may be compromised due to the inherent complexity of their architectures and sensitivity to weight initialization. Additionally, the nature of the data and the suitability of different modeling approaches to capture the relevant characteristics of the time series should be considered. The activities represented in the data may benefit more from a simpler, more straightforward approach, such as convolutional, rather than more complex methods that may be prone to capturing irrelevant features or noise in the data.

At the activity or class level, the confusion matrix provides a detailed breakdown of the model predictions for each class compared with the real class. Referring to the confusion matrix of the model with the best performance (Figure 10), it is observed that the majority of the predictions align with the main diagonal of the matrix, indicating that, for the most part, the classes are classified correctly. However, the activity of eating exhibits the most erroneous predictions, primarily being confused with the activities of opening a door and combing one's hair. This confusion may arise due to overlapping movements and shared characteristics, such as acceleration and rotation patterns, making it challenging for the model to distinguish between them. Moreover, variations in the sequence of movements and the context in which these activities are performed may lead to different interpretations by the model. Variability in the execution of activities and differences in movements between individuals can also contribute to confusion among these classes.

Figure 9. Training sessions progress over iterations.

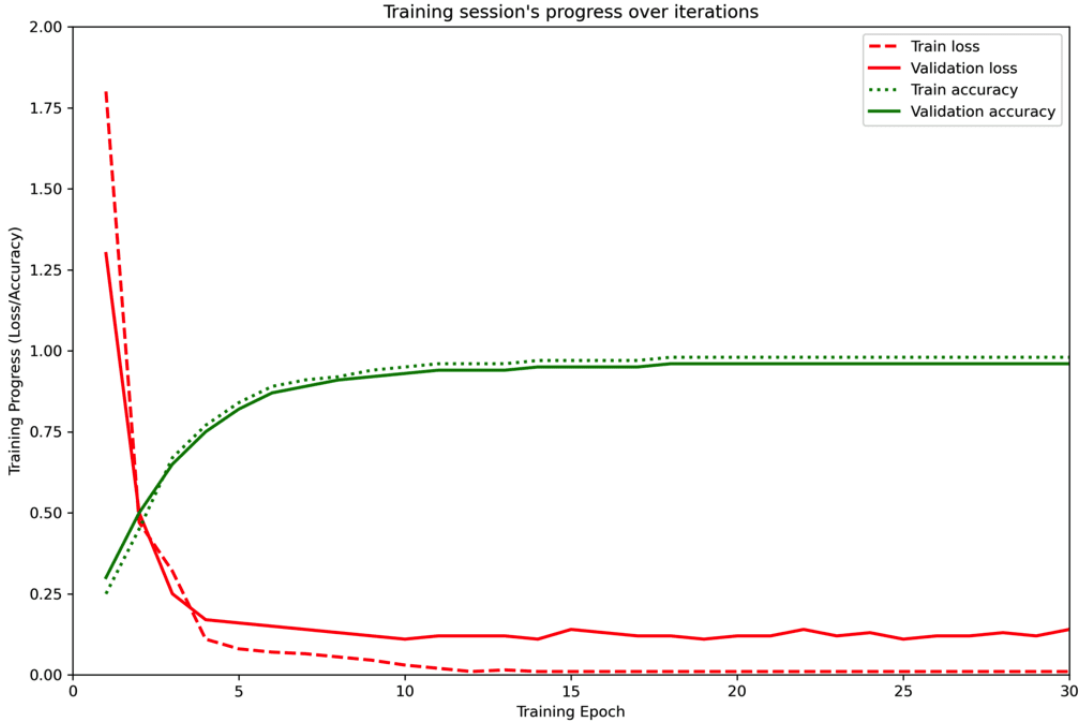


Figure 10. Confusion matrix of the winning model based on the bidirectional approach: (left) standard and (right) normalized. BU: buttoning up; CH: combing hair; E: eating; FB: fastening the bra; HS: half squat; OD: opening the door; RO: reaching for an object; S: sitting SU: standing up.

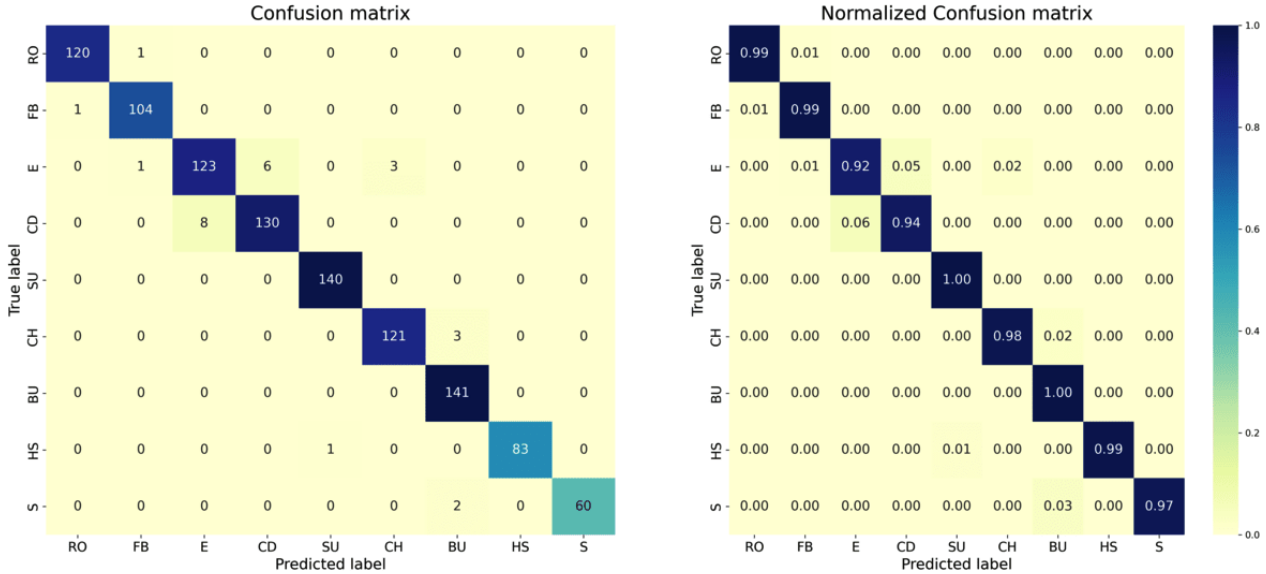

Discussion

Background

ADL are fundamental tasks that enable individuals to function with a minimum of autonomy and maintain their quality of life. Precise evaluation of ADL, especially in clinical and rehabilitation contexts, is crucial for understanding individuals' functional status and designing effective interventions. Traditionally, the assessment of ADL has relied on direct observation and subjective evaluation by therapists, which can lead to biases and errors. Innovative technology, including wearable inertial sensors and AI, offers new opportunities for objective and quantitative evaluation of ADL performance.

Principal Findings

This study presents an innovative initiative by combining wearable inertial sensors with AI techniques to evaluate human movement in ADL. The implemented AI models have demonstrated solid performance, exhibiting high accuracy, precision, recall, and F_1-score (ranging between 95% and 97%), indicating an effective ability to identify and classify a variety of daily activities related to the shoulder and lumbar region. Furthermore, these results have been achieved through minimal sensorization, which is noninvasive and practically imperceptible to the user, thus minimizing interference with their daily life. This feature is crucial as it promotes user acceptance and adherence to continuous monitoring, contributing to the reliability of the collected data.

Comparison to Prior Work

This study presents significant improvements in the identification and monitoring of activities of ADL compared with other existing methods. Unlike most previous approaches that primarily focus on activities involving the lumbar region (sitting, lying down, standing up, etc), our proposal allows for the precise identification of complex movements involving both the lumbar region and the shoulder. This is achieved using only 2 low-cost inertial sensors, contrasting with other solutions that require a higher degree of sensorization or bulkier devices. This minimally invasive monitoring enables individuals to perform daily activities naturally, promoting a more authentic representation of movement.

The information provided by the sensors is used by DL algorithms for movement identification, without requiring additional processing. This enables immediate analysis of movement patterns during the performance of everyday activities, avoiding the delay associated with data processing needed in image-based motion capture systems, which tend to be more expensive and complex to set up and maintain.

Furthermore, the use of inertial sensors offers versatility and adaptability, making them suitable for monitoring a wide range of ADL in different environments and contexts. They provide valuable information on movement patterns and functional abilities that may not be effectively captured or may be more difficult to capture by traditional 2D and 3D motion capture systems, which are more limited by factors such as image quality, potential obstructions in the line of sight between the camera and the person, or the need to use a greater number of cameras or sensors to capture all movement details.

Limitations and Strengths of This Study

This study demonstrates notable strengths in its methodology and approach. It uses the integration of inertial sensors and AI to improve the assessment of shoulder and lumbar motion during basic ADL performance, providing an objective and advanced perspective for clinical evaluation and rehabilitation. Although challenges persist in validating its use across various ADL gestures, such as eating or dressing, our focus on automatic detection and monitoring using AI techniques addresses this gap. Furthermore, by directly capturing inertial sensor signals and using only 2 sensors, our approach ensures enhanced activity recognition precision and efficiency. This strategy facilitates seamless integration into individuals' daily lives at a low cost, promoting improved adherence to monitoring. Additionally, our study's direct use of accelerometer and gyroscope data without conversion for model training emphasizes its versatility and broad scope, highlighting its adaptability across a wide range of activities.

However, it is essential to acknowledge potential limitations to encourage further research and refinement. One limitation lies in the scope of activities monitored, which primarily focuses on specific muscle groups. Future research should aim to expand the scope of using AI and wearable inertial sensors beyond the assessment of shoulder and lumbar motion, broadening the range of monitored ADL. Given this limitation, it would be interesting to conduct in the future more extensive studies that encompass a broader range of ADL and other more distal body segments. For instance, investigations could explore the application of these technologies in assessing motion patterns related to limb motion (ie, elbow and wrist, or knee and ankle movements), offering valuable insights into biomechanical segmentary dynamics and enhancing our understanding of musculoskeletal movement patterns through AI approaches. Despite this limitation, the study sets a solid foundation for future endeavors in this field, showcasing its potential for advancement and application in clinical and rehabilitative settings.

Conclusions

This research has the potential to significantly impact the clinical evaluation and rehabilitation of patients with movement limitations, offering an objective and advanced tool to detect key movement patterns and joint dysfunctions. Such information can assist professionals in tailoring treatment plans to be more precise and personalized, addressing specific areas of weakness, and designing interventions to improve the patient's functionality and quality of life.

Acknowledgments

This research was funded by the Valencian Innovation Agency of Spain (grant INNVA1/2020/81).

Data Availability

The datasets generated during this study are not publicly available due to ethical restrictions but are available from the corresponding author on reasonable request.

Authors' Contributions

DRF and JCT designed the research. JCT and MGJ collected and supervised the data. ADR analyzed the data and developed and evaluated the deep learning models. All authors drafted the manuscript. DRF and JCT critically reviewed the manuscript. DRF had primary responsibility for the final content. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The problem list (PL) is a repository of diagnoses for patients' medical conditions and health-related issues. Unfortunately, over time, our PLs have become overloaded with duplications, conflicting entries, and no-longer-valid diagnoses. The lack of a standardized structure for review adds to the challenges of clinical use. Previously, our default electronic health record (EHR) organized the PL primarily via alphabetization, with other options available, for example, organization by clinical systems or priority settings. The system's PL was built with limited groupers, resulting in many diagnoses that were inconsistent with the expected clinical systems or not associated with any clinical systems at all. As a consequence of these limited EHR configuration options, our PL organization has poorly supported clinical use over time, particularly as the number of diagnoses on the PL has increased.

Objective: We aimed to measure the accuracy of sorting PL diagnoses into PL system groupers based on Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) concept groupers implemented in our EHR.

Methods: We transformed and developed 21 system- or condition-based groupers, using 1211 SNOMED CT hierarchal concepts refined with Boolean logic, to reorganize the PL in our EHR. To evaluate the clinical utility of our new groupers, we extracted all diagnoses on the PLs from a convenience sample of 50 patients with 3 or more encounters in the previous year. To provide a spectrum of clinical diagnoses, we included patients from all ages and divided them by sex in a deidentified format. Two physicians independently determined whether each diagnosis was correctly attributed to the expected clinical system grouper. Discrepancies were discussed, and if no consensus was reached, they were adjudicated by a third physician. Descriptive statistics and Cohen κ statistics for interrater reliability were calculated.

Results: Our 50-patient sample had a total of 869 diagnoses (range 4-59; median 12, IQR 9-24). The reviewers initially agreed on 821 system attributions. Of the remaining 48 items, 16 required adjudication with the tie-breaking third physician. The calculated κ statistic was 0.7. The PL groupers appropriately associated diagnoses to the expected clinical system with a sensitivity of 97.6%, a specificity of 58.7%, a positive predictive value of 96.8%, and an F_1-score of 0.972.

Conclusions: We found that PL organization by clinical specialty or condition using SNOMED CT concept groupers accurately reflects clinical systems. Our system groupers were subsequently adopted by our vendor EHR in their foundation system for PL organization.

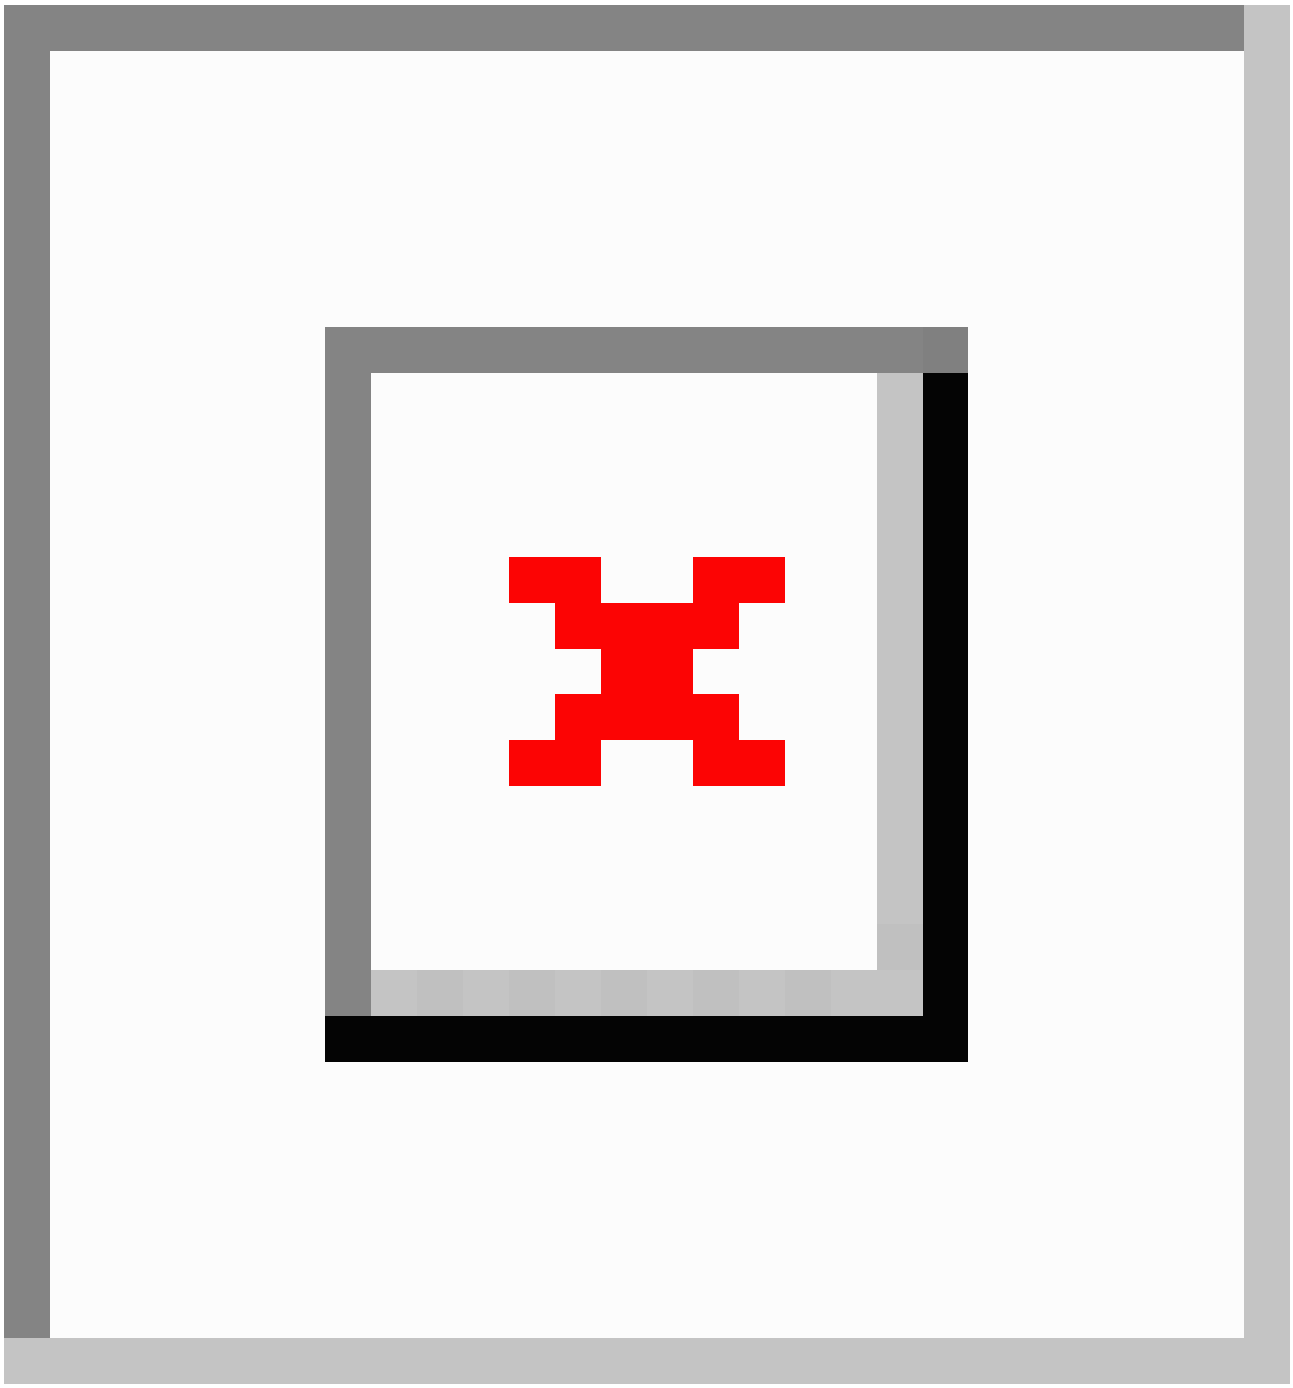
Introduction

The electronic health record (EHR) problem list (PL) is a dynamic repository of a patient's current and historical conditions as well as other health-related issues. As such, it supports communication across a wide range of potential caregivers and clinical environments. An accurate PL serves as a foundation for clinical care and population health management, with multiple derivative secondary processes, including phenotype extraction and disease prediction.

Understanding the history of the PL helps to illustrate why this construct has become the default format for summarizing patients' clinical history. In the 1960s, Lawrence L Weed, MD, proposed the concepts of the problem-oriented medical record; the PL; and the Subjective, Objective, Assessment, and Plan (SOAP) notes for documentation [1]. The idea was to colocate clinical problems with clinical results to focus on systematically addressing all of a patient's diagnoses [2]. Although the SOAP note became the standard format for clinical notes, the PL has encountered more inconsistent use, struggling with problems of inaccuracy, missing diagnoses, not being updated, and bloating [3]. In 2009, the HITECH (Health Information Technology Economic and Clinical Health) Act codified the requirement for an up-to-date PL for meaningful use [4]. Until recently, our vendor EHR had relied on relatively ineffective organization strategies for the PL.

With no one owner, the PLs have become disorganized and cluttered with duplications, conflicting entries, and no-longer-valid diagnoses that contribute to information overload and bloat, obscuring the patient's clinical picture [5]. In its former state, our EHR PL was organized primarily alphabetically, with other options based on primary specialty or priority, all of which have limited clinical utility, especially as the number of diagnoses on the PL increases (Figure 1) . For example, for one patient, we found active diagnoses of lung nodule (Respiratory System), then lung cancer (Oncology System), and then lung cancer with brain metastases (Oncology System). These diagnoses were all related to the same problem but were added sequentially with previous diagnoses that were no longer clinically relevant and were not removed.

Figure 1. Appearance of a problem list before and after grouping algorithm application. Items were reorganized into 21 system groupers using Boolean logic with the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) codes; they were then translated into the *International Classification of Diseases, Tenth Version* (*ICD-10*) codes. Groupers were based on a combination of traditional medical specialty categories, clinically relevant care coordination, and procedure-based groupings, some of which were themselves combined due to overlapping diagnostic coverage. The final order of the problem list items was determined by Epic System's base hierarchy. CMS: The Centers for Medicare and Medicaid Services; HCC: Hierarchical Condition Category; HHS: US Department of Health and Human Services; FEN/GI: Fluids, Electrolytes, Nutrition/Gastrointestinal; GFR=Glomerular Filtration Rate.



There are several major terminology standards that capture patient diagnoses, symptoms, and other health-related conditions, two of which are the *International Classification of Diseases* (*ICD*) [6] and the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) [7]. The World Health Organization maintains *ICD* codes, which are designed to classify diseases, conditions, and other health-related issues [8,9]. Organized into 21 chapters, they use an alphanumeric classification format to identify diseases, injuries, and factors influencing health. The United States uses an additional Clinical Modifier for further specificity [10]. The *ICD* codes are used in various clinical and nonclinical settings, including disease description, treatment selection, billing, and research applications [11]. There are 78,044 total codes in the 2024 code set, according to the Centers for Medicare and Medicaid Services [12].

Currently managed by Systematized Nomenclature of Medicine (SNOMED) International (previously known as the International

Health Terminology Standards Development Organization [IHTSDO]), SNOMED CT was designed to be a US standard for health information exchange. It functions as a highly granular ontology used to describe clinical observations and findings [13]. SNOMED CT uses a polyhierarchal (parent-child) format organized around a general root concept (eg, a clinical finding, procedure, situation with explicit context, or event) with increased granularity achieved by differentiating more specific descriptions of that root concept. This process allows for the representation of specific clinical content in a machine-readable format [14,15]. Updated monthly, the total number of concepts is 512,087 (as of April 1, 2024 [16]) and continues to increase over time.

Though required for billing, the *ICD, Tenth Revision* (*ICD-10)* terminology is not used directly in clinical care, as many code names are not consistent with clinical vernacular. For example, code Z91.038 "Allergy status to unspecified drugs, medicaments and biological substances" is not as intuitive as "Allergy to insect stings." For this example, our third-party vendor, Intelligent Medical Objects (IMO), transforms the *ICD-10* codes into clinically relevant human-readable concepts. IMO additionally maps at least 1 SNOMED CT concept for each diagnosis, attached as metadata, upon which the PL groupers can be organized. Although SNOMED CT concepts are mapped to *ICD-10* codes [17,18], as with most ontologies, there are gaps in clinical concept coverage.

PL organization and cleanup is challenging for many reasons, including there being no single owner of a patient's PL [19] and its maintenance and cleanup being secondary to other direct clinical care priorities. The tools in the EHR for cleanup are limited to a single patient and do not allow for automated processing or opportunities to categorize or define the state of the PL or large-scale maintenance at the population level. Multiple interventions, including reconfiguration of the EHR PL and re-education, have been met with limited success [20]. Despite these attempts, PL bloat and inaccuracy are widely recognized as issues affecting clinical care and secondary downstream uses of the data [3]. We have come to recognize that curating a clinically relevant and updated PL is a difficult challenge; our primary option for improving its organization was to extend and improve SNOMED CT groupers.

In this paper, we present a PL reorganization developed around clinical specialty groupings using SNOMED CT codes and Boolean logic. We describe the evaluation of the new PL groupers for clinical accuracy and efficiency using a convenience set of patients and their diagnoses. This system allows for future characterization of the PLs at the patient and population levels; it also provides potential for automated cleanup options in the future.

Methods

SNOMED CT Grouper Development and Evaluation

Author EMH extended and extensively modified 19 previously defined groupers initially developed by Heidi Twedt, MD, and added 2 newly defined system- or condition-based groupers, one for pediatric and one for transplant-specific conditions (Table 1). System groupers included traditional medical specialty categories as well as clinically relevant care coordination and procedure-based groupings. Some specialties were combined due to overlapping diagnosis domains (eg, "Respiratory and Allergy" and "Orthopedic and Musculoskeletal" domains). The primary focus was for the system grouper diagnoses to be organized around clinical use. For example, "acute myocardial infarction" and "venous thromboembolism" were sorted into the "Cardiovascular and Peripheral Vascular" grouper, while addiction issues, such as "alcohol use disorder," were sorted into the "Behavioral Health" grouper.

Table . List of system groupers with example diagnoses.

Condition or specialty grouper	Example diagnosis	Notable deviations
1. Care Coordination	Physical deconditioning, food insecurity, risk for falls	Includes health-related social needs
2. Oncology	Malignancies and radiation therapy diagnoses	Excludes dermatology cancers and includes treatment complications
3. Cardiovascular and Peripheral Vascular	Atrial fibrillation and deep vein thrombosis	Excludes cerebral vascular diagnoses
4. Respiratory and Allergy	Asthma and peanut allergy	—[a]
5. Endocrine	Diabetes mellitus, gout, and hypothyroidism	—
6. Behavioral Health	Schizophrenia and opioid use disorder	—
7. Transplant	Living-related kidney transplant and graft versus host disease	Includes transplant complications
8. Infectious Disease, Immune, or Lymphatic	Pneumonia and immune deficiencies	—
9. Blood	Anemia	—
10. Neurology or Sleep	Seizure and sleep disorders	Excludes chronic pain
11. Ears, Nose, Throat (ENT)	Nasal polyps, cleft palate, and hearing loss	—
12. Fluids, Electrolytes, Nutrition, and Gastrointestinal	Hyponatremia and Crohns disease	—
13. Obstetrics and Gynecology	Ovarian cysts; hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome; and dense breast tissue	Female-specific diagnoses
14. Genitourinary and Nephrology	Ureteral calculus and prostatitis	Includes male-specific genitourinary issues
15. Dermatology	Atopic dermatitis and melanoma	Includes all dermatology-specific cancers (eg, squamous or basal cell carcinoma)
16. Rheumatology	Rheumatoid arthritis	—
17. Orthopedic and Musculoskeletal	Hip fracture	—
18. Ophthalmology or Eye	Uveitis	Includes complications of eye from other diseases
19. Genetics	Trisomy 21	Includes all nonspecific system genomic issues
20. Pediatrics	28-week prematurity	Includes developmental disorders
21. Surgery, Trauma, Wound, and Pain	Gunshot wound and complex regional pain syndrome	—
22. Other	Edema and medication management	Includes any diagnosis that does not fit into another grouper

[a]Not applicable.

Due to its polyhierarchal framework, all child-related SNOMED CT concepts include all related downstream concepts, unless excluded by the Boolean logic. In this format, fewer SNOMED CT concepts can represent many derivative *ICD-10* codes more comprehensively than could be achieved by directly curating *ICD-10* codes. For example, 167 SNOMED CT concepts within the Neurology grouper were mapped to 9243 IMO *ICD-10* diagnoses. Our default EHR PLs were reorganized according to this system-based methodology in the order presented in Table 1.

Using our EHR vendor's built-in tools for grouper build, author EMH iteratively refined the groupers to be consistent with clinical systems using 1211 SNOMED CT concepts. System groupers included the highest parent concept that was appropriate with logic to exclude child-related SNOMED CT concepts not clinically appropriate for a system. For example, squamous cell carcinoma and skin cancers in general are managed clinically by dermatology. In the build for the Oncology grouper, therefore, all dermatologic cancers were excluded and instead added to the Dermatology grouper. As another example, our Cardiovascular grouper includes peripheral vascular diseases like "deep venous thrombosis" but excludes cerebral vascular concepts. This allows diagnoses like "cerebral avascular malformation" to be presented within our Neurology grouper. Both examples highlight the focus of this grouper organization to support clinical specialty coordination of diagnoses.

Multisystem disorders were grouped according to the specialty that would typically manage each disease entity. For example, systemic lupus erythematosus was grouped under "Rheumatology." If a diagnosis's SNOMED CT concept was too broad to be captured by one of the 21 groupers, it defaulted

into the "Other" category. For example, "edema" is a clinical finding that can be reasonably attributed to multiple diseases. As such, it does not have a specific condition or specialty and instead falls into the "Other" category.

To evaluate the effectiveness of specialty sorting, we used a convenience sample of 50 patients randomly identified in January 2022. These patients had at least 3 encounters in the previous year and were selected across all age groups, ranging from newborn to geriatric patients, with an equal ratio of sexes (Table 2). The encounter criteria ensured that identified patients had multiple recent opportunities to have their PLs updated. The PLs for these patients were extracted through screen capture software by author EMH to develop a cohort with no patient identifiers. Standard EHR PL functionality included system grouper name, time frame since the problem was added to the PL, and a limited free-text overview if included with the entry. These study PL entries were reconfigured into a study document with labels indicating sequential patient number, patient age, and patient sex.

Two of the authors, both family medicine physicians (TT and RS), independently examined each patient's PL to determine the clinical accuracy of system groupings for all diagnoses (Table 3). For any items whose system attribution they questioned, the reviewers identified the SNOMED CT code attached to the *ICD-10* code. Diagnoses that were deemed correctly grouped into the appropriate system grouper were considered true positives, while those that were incorrectly grouped were considered false positives. All diagnoses in the dropout "Other" category were examined by their associated SNOMED CT code for options for attribution to a defined system grouper. A diagnosis for which the SNOMED CT code was too vague or not specific enough to be grouped was considered a true negative. Any diagnosis that had a SNOMED code that could have been placed in a relevant system grouper but was not was considered a false negative.

Table . Patient demographics and baseline descriptive statistics. A total of 50 patients, subdivided by age and sex, with descriptive statistics, were reported for each age range.

Age ranges (years)	Gender			Problems			
	Total, n (%)	Male, n (%)	Female, n (%)	Total, n	Mean	Median	Min-Max
<1	6 (12)	3 (50)	3 (50)	72	12.0	10	6-20
1-17	7 (14)	3 (42.9)	4 (57.1)	157	22.4	26	4-35
18-64	24 (48)	11 (45.8)	13 (54.2)	342	14.3	10	4-43
≥65	13 (26)	8 (61.5)	5 (38.5)	298	22.9	21	4-59
All ages	50 (100)	25 (50)	25 (50)	869	17.4	12	4-59

Table . Description of metrics used to determine the effectiveness of automated system grouping. Two reviewers examined individual problem list items and their assigned grouping, placing each into a category.

Assessment category	Definition	Example
True positive (correct system association)	Diagnosis falls into the right disease system—the SNOMED[a] grouper is specific and attributable.	"Community-acquired pneumonia" in the Infectious Disease system
False positive (incorrect system association)	Diagnosis falls in the wrong system grouper.	"Diaphragmatic stimulation by cardiac pacemaker" grouped under "Central Hypoventilation Syndrome".
True negative (Other—correct system association)	The SNOMED grouper associated with a diagnosis is not specific enough to be in anything but the Other category.	"Anticoagulated" placed with the SNOMED grouper "Drug therapy finding". This is not specific enough to be attributed to just anticoagulation status.
False negative (Other—incorrect system association)	Diagnosis belongs to a specified system grouper but falls into the Other category due to logic deficits in the grouper.	"Genetic disorder" falling into the "Other" category until the VCG Grouper is corrected.

[a]SNOMED: Systematized Nomenclature of Medicine.

Each diagnosis was independently categorized according to the scheme in Table 3; then the reviewers compared their determinations. A third independent clinician (author LN) served as a tie-breaker for those PL items for which an agreement was not reached. We calculated descriptive statistics to summarize the volume of diagnoses for the 50 test patients and performance metrics to assess the accuracy and validity of the groupers. The correlation coefficient (κ statistic) was calculated for the degree of agreement between reviewers and for SNOMED CT grouper attributions.

This work was performed using Epic Systems (version May 2021; Verona, WI) initially deployed with ambulatory applications in July 2012 and inpatient applications in June 2013 within the Duke University Health System.

Ethical Considerations

All patient data were anonymized with all demographic identifiers removed except for age. This study was approved by the Duke University Internal Review Board for exempt status (IRB #PRO-00108903).

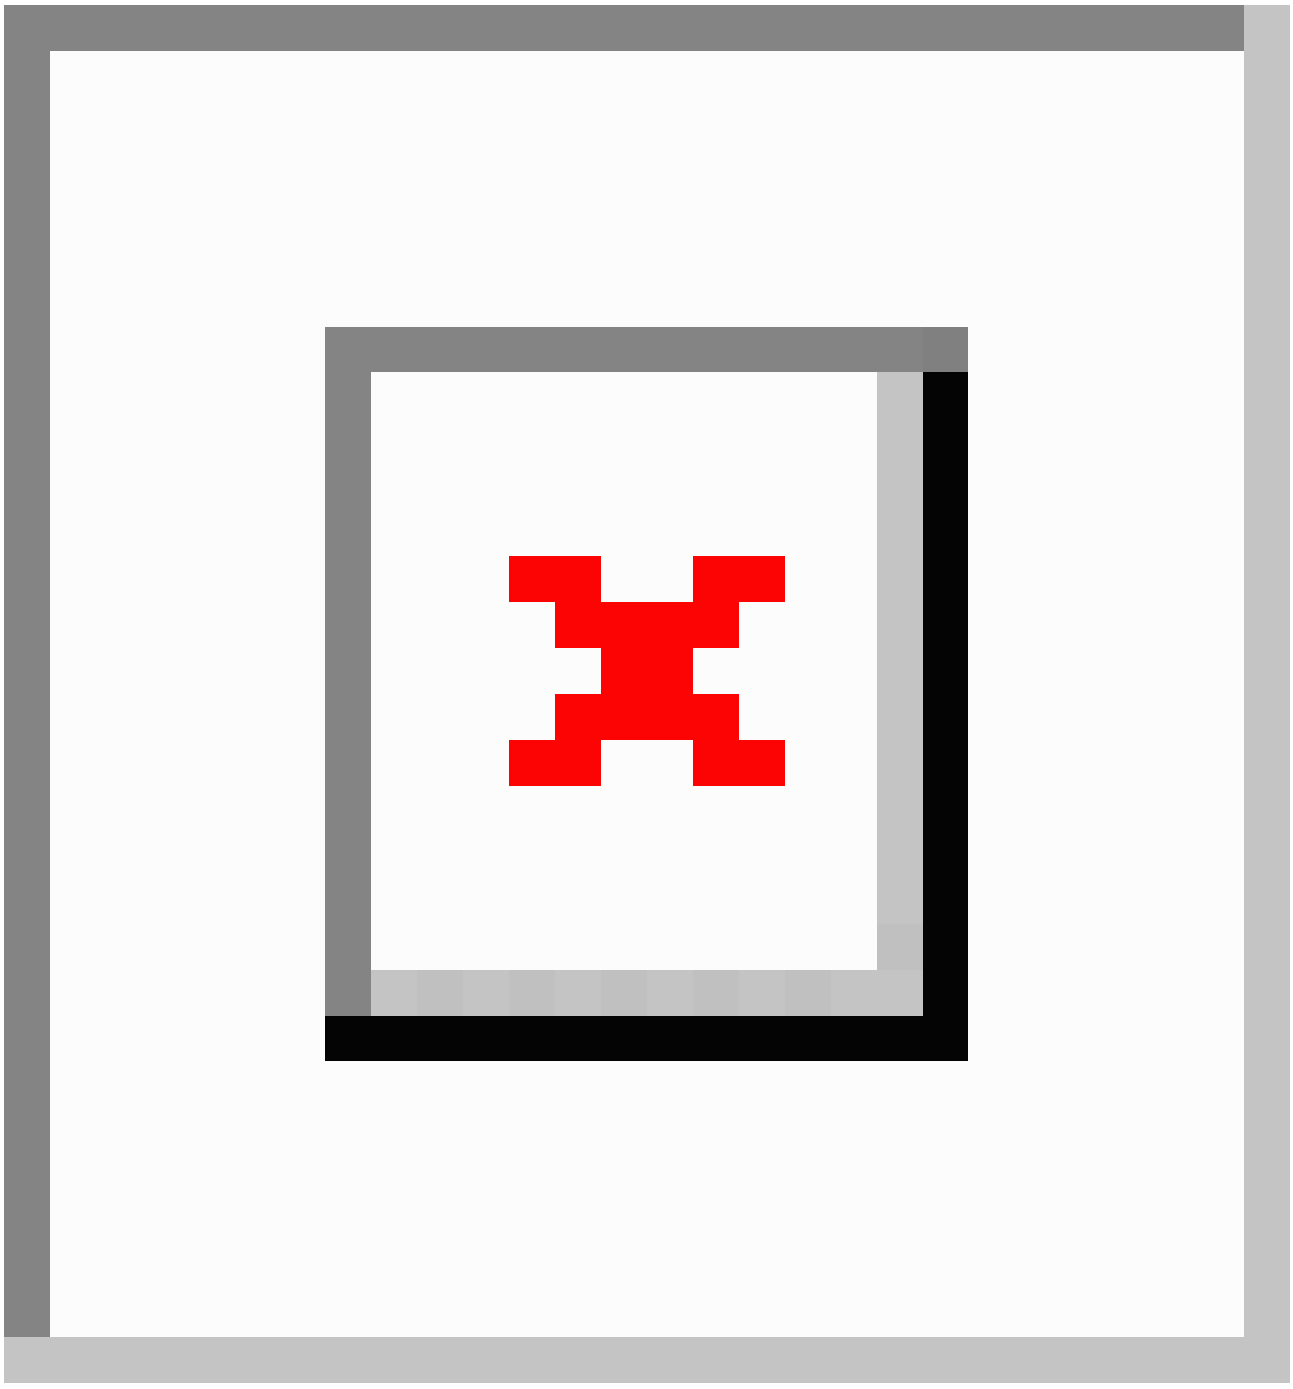
Results

Across the 50 patients, aged 14 days to 93 years, there were a total of 869 (range 4-59) diagnoses identified, with a median of 12 diagnoses per patient. Table 2 includes the breakdown of the volume of PL entries across age and sex.

After their independent evaluations of the PLs, the reviewers initially agreed on 821 (94.4%) of the 869 total problems (Cohen κ coefficient of 0.7, indicating moderate agreement [21]). Of the remaining 48 diagnoses, they subsequently agreed on 32 for a revised agreement rate of 98.2%. The remaining 16 were adjudicated by author LN for attribution.

Based on the definitions presented in Table 3, Figure 2 describes our results. Our final attribution evaluation found that the diagnoses were correctly attributed to a system grouper (ie, sensitivity) in 97.6% of cases, and the nonspecific diagnoses were correctly placed in the "Other" category (ie, specificity) in 58.7% of cases. The positive predictive value, or the correct grouper accuracy rate, was 96.8%. We found 37 (4.3%) true negatives, representing concepts without a SNOMED CT code or diagnoses too general to be attributed to a clinical system. The calculated F_1-Score was 0.972.

Figure 2. Two clinicians' review of problem list sorting algorithm. FN: false negative; FP: false positive; PPV: positive predictive value; NPV: negative predictive value; TN: true negative; TP: true positive; Sn: sensitivity; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms; Sp: specificity.



Discussion

Overview

The PL is the repository of medical diagnoses intended to reflect the patient's clinical conditions. Without groupings reflective of the larger specialty formats of clinical care, the PL can become overloaded and difficult to use as a tool to communicate a patient's clinical status across encounters. We developed 21 SNOMED CT groupers for system concepts to standardize the organization of our EHR PL based on 1211 concepts (Table 1). We chose to evaluate these PL groupers across all ages and sexes to provide a more representative sample of diagnoses across our EHR patient population, recognizing that this is only a subset of the total potential diagnoses. Taking advantage of the hierarchal logic of the SNOMED CT concepts refined with Boolean logic allowed for more than 95% of the diagnoses to be attributed to a system grouper [22,23].

We established the effectiveness of these SNOMED CT groupers in organizing the PL by clinical system related to clinical specialty or condition. We propose that this standardized format for PL organization permits the sharing and reproduction of concepts across other health systems and EHRs.

Comparison to Prior Work

Other groups have used conceptually similar methods with SNOMED CT codes for clinical phenotyping [22]. However, those code sets are typically more narrow in scope for a more specific clinical description. The United Medical Language System Clinical Observations Recordings and Encoding Problem List Subset is meant to "facilitate the use of SNOMED CT as the primary coding terminology for PLs or other summary level clinical documentation" [24]. Compared to these other SNOMED CT code sets, our implementation includes broader clinical coordination groupings (eg, surgical, transplant, care coordination, and infectious disease) that are more reflective of the PL clinical care needs within our institution. Our work here builds upon those efforts and applies them at the system level, which is more accessible for clinical use.

Limitations

We noted some limitations and challenges in using SNOMED CT concepts for this build. Despite ongoing international mapping efforts [17,18], SNOMED CT concepts are not fully representative of all the *ICD-10* codes because of differences in original intended uses [8,13] and baseline granularity [25,26]. For example, the *ICD-10* code "Encounter for pre-transplant evaluation for chronic liver disease" is mapped to the SNOMED CT concept "patient encounter status," as there is no other comparable SNOMED CT coding option. Estimates for the proportions of completely mapped concepts or codes are found in studies reviewing the automation of mapping SNOMED CT and *ICD-10* codes; one study estimated the proportion of complete mappings to *ICD-10-Clinical Modification* (*ICD-10-CM*) at 74% in 2012 [25], and another one estimated the proportion of complete mappings to *ICD-10-Procedure Coding System* (*ICD-10-PCS*) (used to capture inpatient procedures) to be about 86% in 2017 [27].

There were many *ICD-10* diagnoses that were too broad to easily match a SNOMED CT system grouper. "Fatigue" is a good example of an inherently vague constitutional or multisystemic symptom that does not have a clearly identifiable system-level grouper in our schema. For these diagnoses, the "Other" category was used to capture the remaining nonspecific diagnoses. It is important to note that this category is not the same as the *ICD-10* options for "Not Otherwise Specified" (NOS) or "Not Elsewhere Classifiable" (NEC) codes for lesser defined diagnoses. For example, "Pneumonia due to other infectious organisms, NEC" still falls into our "Infectious Disease, Immune, Lymphatic" grouper.

We also note that the mappings are not completely represented across all specialties in terms of the breadth of coverage of concepts. For example, we found more SNOMED CT cardiology-specific concepts and fewer pediatric-specific concepts. These differences may reflect the relative volume of cardiology diagnoses in the general population. The more specific diagnosis of "Encounter for assessment of implantable cardioverter-defibrillator" was mapped to an appropriate SNOMED CT concept and was correctly placed into our cardiovascular system grouper. However, the pediatric diagnosis "Concern about growth" was only mapped to the SNOMED CT code "Finding reported by subject or history provider," which was too broad to be added to the Pediatric grouper only, consequently falling into the "Other" category. Specialties such as pediatrics also require greater levels of specificity for their diagnoses than is always possible with the SNOMED CT concepts currently available.

There were also multiple *ICD-10* codes mapped to the same SNOMED CT code that made attribution to a system grouper challenging. For example, the diagnoses "Diaphragmatic stimulation by pacemaker" and "Disorder of cardiac pacemaker system" mapped to the same SNOMED CT code of "Disorder of cardiac pacemaker system," placing them into the Cardiovascular grouper, although the former would ideally be attributed to the Pulmonary grouper.

As we consider the future challenges of algorithm-based PL sorting, it will be important to investigate the implications of updating ontologies as the World Health Organization has already published the 11th edition of *ICD* (*ICD-11)* with 35 countries now implementing it [28]. We do not suspect that *ICD-11* will replace SNOMED CT as an ontology organization method, as SNOMED CT maintains greater flexibility for clinical use. Health systems are always evolving, and it will be important to consider how such algorithms and their applications will evolve within them.

Conclusions

We leveraged a PL sorting algorithm based on the clinical system–based SNOMED CT groupers to create a standardized PL format in our EHR, reorganizing the diagnoses, symptoms, and medical problems for better clinical utility. We found subjective positive outcomes for our clinical users who reported streamlining their clinical review processes and easier ability to identify similar and duplicate diagnoses. This may be especially helpful for patients with complex issues and many associated diagnoses. A structured PL also enables a shift from patient-level evaluation to potentially population-level assessments and cleanup automation.

As with improvements in the provider experience, automated PL maintenance may also impact researchers leveraging PL diagnoses for machine learning and other similar research. Such possibilities underscore the need for accurate and updated PL diagnoses to achieve and maintain high-fidelity outputs. It will be important to further evaluate methods to automate the maintenance of accurate Pls and best influence care delivery.

Acknowledgments

The authors would also like to acknowledge the support of Tres Brown from the Duke Health Technology System's Maestro Care Electronic Health Records (EHR) Application Team. This work was done while authors RS and TT were Clinical Informatics Fellows at Duke University.

This work was partially funded by a grant from the Duke Institute for Health Innovation.

Data Availability

The authors have uploaded the groupers to GitHub and will share if emailed directly.

Authors' Contributions

All the authors of this manuscript participated in and contributed equally to the conceptualization, design, and evaluation of the program list (PL) grouper categorization. EHM used the previous work of Heidi Twedt, MD, at Stanford (172 concepts across 19 systems and conditions) to develop the final set by extending 8 systems' coverage (eg, "Pulmonary" to "Pulmonary and Allergy"), adding 2 system groupers, and extending them to a total of 1211 concepts with the Boolean logic. Authors RS and EMH primarily authored the manuscript with other authors contributing to editing. Epic Systems incorporated these groupers into their standard development for PL organization by system as default in November of 2022. EMH will continue to make yearly updates to the groupers.

Abstract

Background: Dermoscopy is a growing field that uses microscopy to allow dermatologists and primary care physicians to identify skin lesions. For a given skin lesion, a wide variety of differential diagnoses exist, which may be challenging for inexperienced users to name and understand.

Objective: In this study, we describe the creation of the dermoscopy differential diagnosis explorer (D3X), an ontology linking dermoscopic patterns to differential diagnoses.

Methods: Existing ontologies that were incorporated into D3X include the elements of visuals ontology and dermoscopy elements of visuals ontology, which connect visual features to dermoscopic patterns. A list of differential diagnoses for each pattern was generated from the literature and in consultation with domain experts. Open-source images were incorporated from DermNet, Dermoscopedia, and open-access research papers.

Results: D3X was encoded in the OWL 2 web ontology language and includes 3041 logical axioms, 1519 classes, 103 object properties, and 20 data properties. We compared D3X with publicly available ontologies in the dermatology domain using a semiotic theory–driven metric to measure the innate qualities of D3X with others. The results indicate that D3X is adequately comparable with other ontologies of the dermatology domain.

Conclusions: The D3X ontology is a resource that can link and integrate dermoscopic differential diagnoses and supplementary information with existing ontology-based resources. Future directions include developing a web application based on D3X for dermoscopy education and clinical practice.

Introduction

Dermoscopy is a noninvasive, in vivo microscopic technique used to examine skin lesions by detecting morphological features that may not be seen by the naked eye [1-4]. Studies have demonstrated that dermoscopy improves the diagnosis of both pigmented skin lesions [3,5-7] and nonpigmented skin lesions [8], including neoplasms [9] and infectious and inflammatory skin diseases [4,10]. Notably, the diagnostic accuracy of dermoscopy is dependent on the examiner's experience, as dermoscopy by untrained or less experienced examiners was found to be no better than clinical inspection without dermoscopy [6]. Learning dermoscopy is not just relevant to dermatologists, but also for physicians in other medical specialties. Patients with new or changing skin lesions often first consult their primary care physician (PCP) rather than a dermatologist. Dermoscopy has shown to be an effective tool for the assessment and triage of pigmented skin lesions in primary care, with improved diagnostic accuracy and referral accuracy to dermatologists [11-13]. However, dermoscopy training for PCPs is currently highly variable, with many PCPs citing a lack of training as a key barrier to the use of dermoscopy [14-16]. Furthermore, short dermoscopy training programs [14] may be insufficient to establish long-term competency in dermoscopy, with poor continuing use of dermoscopy and the need for refresher sessions [17]. The need for dermoscopy training among plastic surgeons has recently been documented as well [18]. Thus, the development of machine-based tools for dermoscopy may enhance clinical practice for dermatology providers and other medical professionals.

The use of standard terminologies organized through taxonomies has a long history with the life sciences, starting with Carl Linnaeus' taxonomy [19]: a classification system to name and group species according to their shared characteristics. Centuries later and with advances in computing infrastructure, these types of classification systems have continued to be of interest to the science community. An ontology is "a representational artifact comprising a taxonomy as proper part, whose representational units are intended to designate some combination of universals, defined classes, and certain relations between them" [20]. Essentially, an ontology is a graphical representation of linked concepts to formalize a schema (Tbox) for data (Abox). The formalization leverages semantic links (Rbox) between the concepts to give data more meaning and to aggregate related data of any heterogeneous format. This ensures the normalization of heterogeneous data. Furthermore, with semantics, ontologies could support machine reasoning to generate references via deductive reasoning. As related to the medical field, ontologies can extend the computability of standard controlled terminologies to provide descriptive and composite representations of medical information (such as features related to various diagnoses). Ontologies represent the data in a machine-readable format to give computing tools more context, making them highly valuable for artificial intelligence.

Within the dermatology domain, some existing ontologies aim to describe cutaneous disorders. For example, the dermatology lexicon (DERMLEX) was created with the American Academy of Dermatology with a nosology, anatomical distributions, classical signs, and therapeutic procedures; however, maintenance was discontinued in 2009 [21,22]. More recently, the human dermatological disease ontology (DERMO) was developed to classify cutaneous diseases by etiology, anatomical location or cell type, and phenotype consistent with current clinical practice [23,24]. Some other dermatology-specific ontologies exist, including the skin physiology ontology (SPO; last updated in 2008) [25], but notably, none of these ontologies connect cutaneous disorders to metaphoric terms like "strawberry pattern" which may be difficult for a machine to understand. Similarly, none of the aforementioned ontologies specifically address dermoscopy, which is a specialized technique that may have special considerations when used in diagnosis. For instance, the colors of certain lesions are best seen under polarized light [26]. As such, there is a need to develop an ontology that adequately addresses the field of dermoscopy, with the capability of processing both descriptive and metaphoric terminology.

In our previous work, we developed the elements of visuals ontology (EVO) to decompose the fundamental features of visualizations, such as shapes, colors, and textures. The dermoscopy elements of visuals ontology (DEVO) then applied the visual features described in EVO to dermoscopic terminology [27]. For instance, DEVO characterizes dermoscopic metaphoric terms such as "shiny white streaks" and "leaflike areas" by shapes, colors, and textures, along with other features involved. Discussion with domain experts revealed that while DEVO is capable of responding to queries to find visual features associated with metaphoric terms and vice versa, linking the dermoscopic terms to differential diagnoses would significantly enhance its clinical utility. A list of differential diagnoses indicates many possible diagnoses that share similar features to the patient's symptoms and signs. These differential diagnoses can then be narrowed down to aid the clinician in identifying the final diagnosis. As dermatology is a technical field, the landscape of differential diagnoses is wide and difficult to parse [28]. In this study, we describe the extension of EVO and DEVO to create the dermoscopy differential diagnosis explorer (D3X), an ontology linking metaphoric terms to differential diagnoses. We further propose a use case integrating D3X into a web application in dermoscopy education and clinical practice.

Ethical Considerations

This article adheres to the Committee on Publication Ethics guidelines. This research did not involve human subjects.

Integration of Existing Ontologies

Overview

A common practice in the development of ontologies [29] is to reuse existing ontologies' components to ensure semantic interoperability. We used the following ontologies to build the D3X ontology.

About EVO

EVO is a foundational ontology model that describes the basic constituents of visualizations: shapes, colors, strokes (lines), size, perceived texture, etc. It also represents the dimensional extended 9-intersection model, a mathematical model for spatial relationships between elements [30]. Further, EVO imports and reuses controlled terminologies and standards from the W3C scalable vector graphics, Wikidata, phenotype and trait ontology, and the simple knowledge organization system to supplement our core representational model of visualizations. EVO is hosted on GitHub for public release and is coded in the OWL 2 web ontology language.

About DEVO

DEVO is an extension of EVO that reuses the foundational understanding of visualizations for the dermoscopy domain. DEVO incorporates some of the controlled terminologies—"metaphoric" and "descriptive"—that are used in practice by dermatologists, with a focus on the metaphoric terminologies. With DEVO, we developed a core model that encodes and describes the "visual language" of the dermoscopic terms' definitions. Further, one important outcome of this work was a computable representational model of an agreed understanding of visual elements of dermoscopic patterns, which we used as a framework to generate differential diagnoses. Similarly, DEVO was coded in OWL 2 and is hosted on GitHub for public consumption.

Miscellaneous Ontologies and Vocabularies

We also aligned D3X with commonly used top-level ontologies. The information artifact ontology (IAO) [31] is part of the open biological and biomedical ontology (OBO) foundry. IAO represents a general abstraction of informational objects (like documents and components within those documents—eg, figures, images). Like many OBO foundry ontologies, IAO uses the basic formal ontology and relation ontology as part of its architecture model. We minimally reused some of the term entities and properties like IAO:image and "denoted by." We also reused the software ontology (SWO) [32] for its licensing entity terms—SWO:license and "has license"—to describe the licensing information for any imaging resource of skin lesions. Lastly, we used Schema.org's [33] schema::image to link image resources.

Development of D3X

To generate a list of differential diagnoses, we started with the metaphoric terms defined in DEVO from the third consensus conference conducted by the International Society of Dermoscopy [34]. We then searched the literature [34-36] for corresponding differential diagnoses for each term and consulted 2 domain experts to independently edit the list of diagnoses for accuracy. These differential diagnoses were later encoded using Protégé [37] in our ontology. Following this, we reviewed open-source resources (DermNet, Dermoscopedia, and open-access research papers) for a collection of hosted images that matched individual differential diagnoses. We tracked the provenance information and associated data (caption, description, etc) in a spreadsheet as a central organized resource that mapped the images for each diagnosis to the concept diagnosis used in D3X. To streamline the data transfer process, we developed a management code to transfer data from the spreadsheet to the ontology. The source code is available on our GitHub repository, using the OWL API to facilitate efficient custom import. This approach allowed centralized data collection and also enabled an ad-hoc import and data creation pipeline.

Semiotic Evaluation

Semiotic theory is the study of signs and symbols, and considering ontologies are symbolic representations of a specific domain, we used a metric suite grounded in that theoretical framework [38]. Semiotic theory is composed of 3 basic qualities: *syntactic*, *semantic*, and *pragmatic*. Essentially, in the context of ontologies, the metric suite components refer to aspects of the ontology artifact—*syntactic* concerning encoding adherence and standards; *semantic* concerning the effective use of human-friendly labels for entities and concepts; and *pragmatic* concerning function. Each of these qualities is quantified based on a computation of representative quantifiable features of an ontology file (eg, the number of classes, the average number of word senses for labels, etc). This is described in detail in previously published works [38]. This suite helps to measure some of the intrinsic qualities of our ontology concerning other ontologies in the same domain. We used publicly available ontologies from the skin and dermatology domain—DERMLEX, DERMO, and SPO—that are found in the National Center for Biomedical Ontology (NCBO) BioPortal. We used a command line version of our tool OntoKeeper [39] to quickly generate scores from the metric suite and then calculated *z* scores to determine how D3X fares in terms of intrinsic quality with other ontologies of the dermatology domain.

Results

Development of D3X

The D3X ontology was encoded in the OWL 2 web ontology language. In terms of the size of the ontology, there are 3041 logical axioms, 1519 classes, 103 object properties, and 20 data properties. Imported image data are encoded as 387 instances. Figure 1 displays a sample series of screenshots showing Kaposi sarcoma, as an example entity, linked to DEVO's rainbow pattern, standard medical terminologies (eg, Systematized Nomenclature of Medicine–Clinical Terms [SNOMED CT], National Cancer Institute [NCI] Thesaurus), and the open-sourced image example. For ongoing data management, we host the spreadsheet with image data (n=364 images) and the OWL API software code to allow for an automated process of adding new image data. The software will pull the data from the spreadsheet and will add and export a version of our ontology that has the image instance data. Both the spreadsheet and the software are available on our GitHub repository [32]. As more dermoscopy images become available for the public domain, we will include them in our spreadsheet and generate an encoded export with the new instance data. D3X uses our pre-existing work of DEVO and also leverages terminology from the IAO, SWO, and Schema.org. Figure 2 shows a global

overview of the D3X ontology and the various linked terminologies that compose the entire model.

Figure 1. Sample screenshot of the D3X ontology through Protégé showing related metadata and information about Kaposi sarcoma. D3X: dermoscopy differential diagnosis explorer; DDX: differential diagnosis.

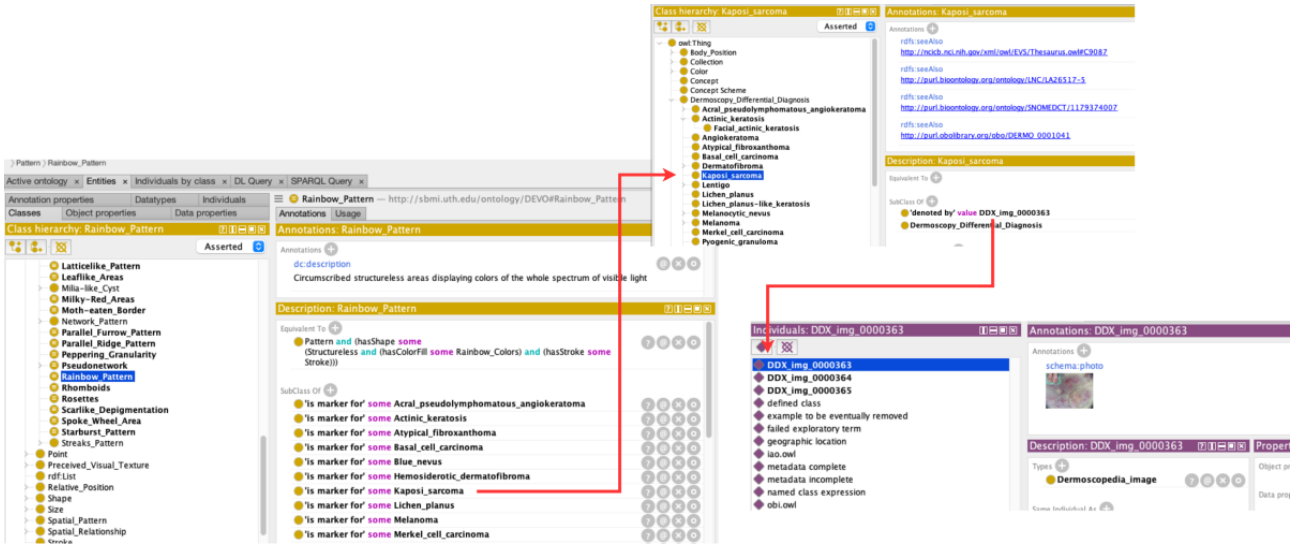

Figure 2. Global overview of the D3X ontology and linked ontologies, including the DEVO, BFO, IAO, and SWO. BFO: basic formal ontology; D3X: dermoscopy differential diagnosis explorer; DEVO: dermoscopy elements of visuals ontology; IAO: information artifact ontology; rdfs: resource description framework schema; RO: relation ontology; SWO: software ontology.

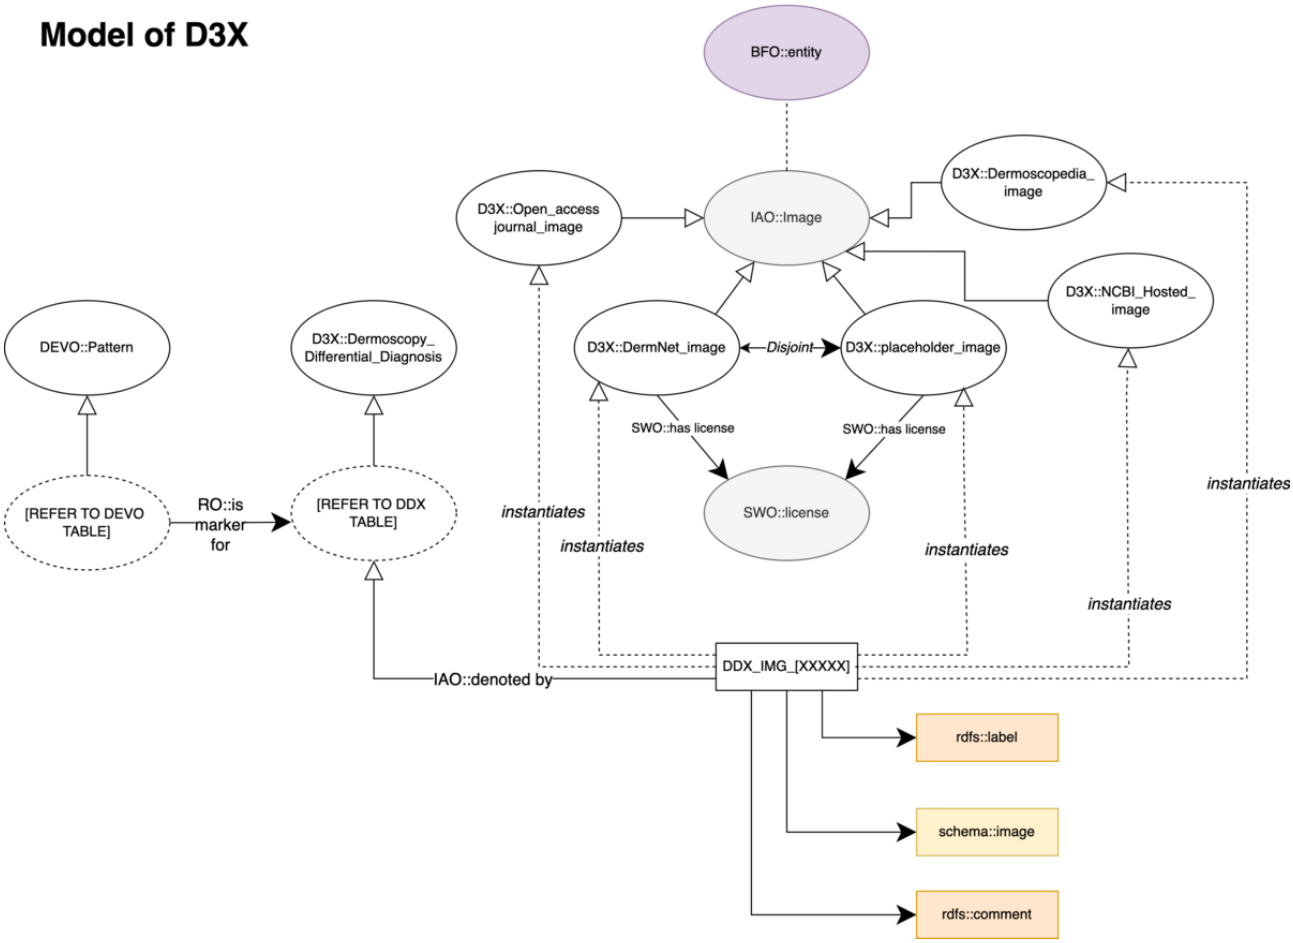

Each dermoscopy sample image is represented as a single instance data value with a unique ID (DDX_IMG_[DIGITS]). As an instance data value representing the digital image, it links to the exact file on the web using schema:image from Schema.org. Caption information is used as an annotation for RDF:comment (RDF: resource description framework) and rdf:label (rdf: resource description framework). The instance data value is an instantiation of a specific image class from the

following sources: IAO—open access journal images, DermNet images, National Center for Biotechnology Information–hosted images, and Dermoscopedia images. For some of them, the "has licenses" predicate links to a license, signifying that any instance of this image class has some license agreement (eg, Creative Commons). The licensing terminology is derived from the SWO and is hosted on our GitHub repository as an external import.

With D3X, we declared a new dermoscopy differential diagnosis class. This class provides a list of associated diagnoses for skin lesions. Each of the dermoscopy differential diagnosis classes is linked to a pattern from DEVO. The pattern in DEVO ontologically describes each dermoscopic pattern (metaphoric term) using visual elements, such as lines, shapes, colors, and spatial relationships. Table S1 in Multimedia Appendix 1 provides a comprehensive list of the metaphoric patterns listed in DEVO and their corresponding differential diagnoses in D3X. Each pattern in DEVO is linked to its differential diagnoses using OBO's "is marker for" (eg, angular lines > is a marker for > Lentigo_maligna). Additionally, the instance images described above are linked to the differential diagnoses using "denoted by," such that each diagnosis is provided with at least one visual example. Lastly, for each of the dermoscopy differential diagnosis classes, there are associated annotations that link the class to the other standardized ontologies like the Medical Dictionary for Regulatory Activities (MedDRA), SNOMED CT, NCI Thesaurus, and LOINC (logical observation identifier names and codes). MedRA covered 63% (n=25) of the classes, while SNOMED CT and NCI Thesaurus covered 53% (n=21) and 55% (n=22) of the classes, respectively. The remaining, like DERMO and LOINC, covered 15% (n=6) and 3% (n=1) of the classes.

Semiotic Evaluation

Semiotic theory is composed of 3 basic qualities: *syntactic*, *semantic*, and *pragmatic*. Table 1 displays the *z* scores for each of the qualities and subqualities of D3X compared to other publicly available ontologies in the dermatology domain. Examining the *syntactic* quality of D3X (z=0.17), while it lacks diverse syntactic *richness* (z=–0.74) in comparison with its other domain counterparts, D3X does adhere to syntactic *lawfulness* (z=0.49). D3X compares satisfactorily with other ontologies in the *semantic* quality (z=0.77). Although the semantic *clarity* subquality was below average than its peers (z=–0.91; the ambiguity of labels), D3X does better with semantic *consistency* (z=0.56; the number of essentially unique labels) and semantic *interpretability* (z=0.65; whether the label has meaning). The *pragmatic* quality is composed of 1 score: *comprehensiveness*, a measure of the coverage of the domain scope of the ontology based on the number of entities encoded, which was nearly below average for D3X (z=–0.66). Lastly, the overall score of D3X (z=0.58) points to a somewhat better overall quality score than DERMLEX and SPO (z=–1.41 and 0.00, respectively). Although DERMO had a slightly higher overall quality than D3X (z=0.83), its score is still within 1 SD of the D3X ontology score, so the quality of D3X appears at least comparable to that of the other ontologies within its own domain.

Table 1. Semiotic comparison of D3X[a] to other dermatology ontologies: the DERMLEX[b], DERMO[c], and SPO[d] using *z* scores.

Quality and subquality	Mean (SD)	D3X-z	DERMLEX-z	DERMO-z	SPO-z
Syntactic	0.57 (0.11)	0.17[e]	–1.33	0.08	1.09[e]
Richness	0.26 (0.11)	–0.74	0.62[e]	–0.96	1.08[e]
Lawfulness	0.87 (0.25)	0.49	–1.50	0.51[e]	0.51 [e]
Semantic	0.85 (0.13)	0.77[e]	–1.38	0.70[e]	–0.08
Clarity	0.99 (0.01)	–0.91	0.91[e]	0.82[e]	–0.82
Consistency	0.73 (0.49)	0.56[e]	–1.50	0.43	0.51[e]
Interpretability	0.87 (0.21)	0.65[e]	0.65[e]	0.16	–1.46
Pragmatic	0.11 (0.15)	–0.66	1.44[e]	–0.09[e]	–0.69
Comprehensiveness	0.11 (0.15)	–0.66	1.44[e]	–0.09[e]	–0.69
Overall score	0.52 (0.03)	0.58 [e]	–1.41	0.83[e]	0.00

[a]D3X: dermoscopy differential diagnosis explorer.

[b]DERMLEX: dermatology lexicon.

[d]SPO: skin physiology ontology.

[e]These values indicate the 2 highest values for each quality and subquality.

Discussion

Principal Results and Limitations

D3X is an ontology that connects dermoscopic patterns (metaphoric terms) with differential diagnoses. It is an extension of the DEVO to describe patterns based on their visual elements, which is in turn an extension of the EVO. D3X also leverages terminology from IAO, SWO, Relation Ontology, and Schema.org, and its differential diagnoses are linked to MedDRA, SNOMED CT, and NCI Thesaurus. Using the semiotic theory framework proposed by Burton-Jones et al [38], we measured D3X in comparison with similar publicly available ontologies to assess its intrinsic quality. Our assessment indicates that while comparably better to the other ontologies of the same domain in its overall score, D3X does lack diverse syntactic *richness* and could improve its semantic *clarity* (despite a better overall semantic quality score than its ilk) and pragmatic *comprehensiveness*. Leveraging additional OWL 2 syntactic features could improve the syntactic richness. However, since the purpose of our ontology is to retrieve and aggregate information and metadata about dermoscopic features, some of the more sophisticated OWL 2 features like symmetry, inverse, etc, may not be necessary for our use case. As for the pragmatic score, it might improve over time as we collect more instance data of images to link to our ontology. Further, our assessment was limited to 3 ontologies as there are no other publicly available ontologies that deal solely with a dermatology subject. Additionally, OntoKeeper uses a subset of scores as the social quality (composed of *authority* and *history*), and the pragmatic subscores of *accuracy* and *relevancy* are difficult to compute, so they are not listed in our semiotic analysis [39]. Despite this, the quality scores are sufficient for an application ontology, since the role of this artifact is to aggregate and consolidate skin diagnostic information—an area where it is likely to shine.

The aforementioned evaluation included DERMLEX, DERMO, and the SPO. DERMLEX was originally created by the American Academy of Dermatology to describe dermatological diagnosis and related domain vocabularies, aligned to *International Classification of Diseases, Ninth Revision* (*ICD-9*). However, the upkeep ended in 2009 [22]. DERMO is another ontology that also aims to describe dermatological diseases, but unlike DERMLEX, it is aligned to *International Classification of Diseases, Tenth Revision* (*ICD-10*). The latest version was last released in 2015, according to the NCBO BioPortal record [23]. Not much is known about SPO, other than a presence on NCBO BioPortal and the latest release dating back to 2008 [25]. Compared to these existing works, D3X yields richer semantics and applicability by the OWL2 encoding in EVO and DEVO that describes lesions using primitive visualization elements. Another advantage of this work is the use of semantic web properties of our work, namely the linking of heterogeneous resources (external entities, images, metadata, etc). This allows D3X to be an application-driven artifact that can be integrated into software tools, and other analytical and educational tools. According to researchers, terminologies enriched with semantics will yield opportunities to develop innovative tools and applications [40]. We further discuss our vision in the subsequent sections (see Proposed Web Application and Use Case). Overall, we presume this work provides a richer ontological artifact compared to similar ontologies of the same domain.

Aside from our aforementioned application use case, this work can advance machine learning models for dermoscopy diagnosis support. There has been some preliminary evidence that machine learning models can be supported or improved by ontologies [41-43]. Potentially, the combined stack of EVO, DEVO, and D3X could augment tools that analyze real-world entities (eg, lesions). In Figure 3, we illustrate a hypothetical example where a software application segments signals from an entity using machine learning in a sensor array to detect shape, color, and pattern data. The structured information from the sensor array could then be linked to an ontological knowledge base system that expresses meaning and context.

Data Upkeep and Management Plan

Noted earlier, we produced a basic management system to allow for continued integration of data and information from external sources to be added to D3X. Continued data management is an issue with some ontology and controlled terminology resources. By having this basic management system, we can ensure that D3X will be up to date with little resources and time needed to integrate new diagnostic information and metadata. Figure 4 shows the basic management pipeline, with the tools needed, hosted on our GitHub repository under the ddx_data_management folder. In the aforementioned figure, any new or updated digital resources (images, web page text, knowledge graph, and ontology resources) will be added to a centralized spreadsheet for the human-friendly organization of data for diagnosis information. The management software will import the spreadsheet and parse the data for the D3X ontology. The final output of the software is the D3X ontology with the updated linked information. Future plans could include using shapes constraint language (SHACL) to ensure the quality of the data is validated, and further development of data management software to facilitate ease of use.

Proposed Web Application and Use Case

For use in clinical practice, an ontology-based software application could be designed using D3X to guide the identification of differential diagnoses. After the user performs dermoscopy on a skin lesion, they can open the web application and select various features about the lesion, which will then suggest differential diagnoses. A mock-up for the use case of Kaposi sarcoma is shown in Figure 5. The user can select options for the first 3 boxes ("dermoscopy," "feature," and the chosen feature [eg, "color"], with multi-select functionality available for the latter). The web application would then generate the relevant patterns and a list of differential diagnoses. Thus, if the user indicates that under polarized light, red, pink, blue, violet, and white colors were visualized, this corresponds to a "rainbow pattern," which is associated with Kaposi sarcoma, among other differential diagnoses. Clicking on each differential diagnosis will then display any relevant dermoscopic images in the "viewer," as well as a description under "details" with a link to learn more about the condition. By reviewing images and descriptions of these differential diagnoses, this would ideally help the user narrow down the list and identify the most likely diagnosis. This web application was independently reviewed by 2 domain experts who agreed that the format was understandable to the user; they also stated that the information provided would be useful in clinical practice as a quick search for differential diagnoses. Of note, the aforementioned example illustrates a query based on features or patterns, but the web application would also be capable of querying based on diagnoses (eg, "what dermoscopy patterns are associated with Kaposi sarcoma?"). This would be more useful in an educational setting for those who want to gain an understanding of dermoscopic patterns and the features comprising each pattern. Furthermore, we proposed the development of a web application harnessing D3X capable of carrying out the following queries: (1) given dermoscopic features or patterns, output a list of differential diagnoses; and (2) given a differential diagnosis, output associated features and patterns. Along with a description of each differential diagnosis, the application would also display images from DermNet, Dermoscopedia, National Center for Biotechnology Information Hosted, or open-access journals for ease of understanding the relationship between each differential diagnosis and its visual elements. There is a growing body of literature on machine learning models for automated diagnosis of dermoscopic images, such as convolutional neural networks (CNNs) [9]. Both ontologies and CNNs fall under the artificial intelligence umbrella, but ontologies relate to knowledge representation, while CNN is statistical machine learning. These

are fundamentally different approaches to power artificial intelligence that are difficult to compare directly. While automated diagnosis via CNNs is a very promising area of study, research has largely focused on the diagnosis of melanoma [44-46], with few studies including pigmented nonmelanocytic lesions [47,48] and largely ignoring nonpigmented lesions. D3X labels dermoscopic patterns of pigmented and nonpigmented lesions, so it may apply to a broader range of patient visits. Additionally, the likelihood of provider acceptance of automated diagnosis systems is unclear. With our proposed web application, providers would be able to input search criteria themselves and see a list of differential diagnoses, rather than a binary output for 1 diagnosis (eg, melanoma) suggested by the machine, which may not be as likely to be accepted by physicians.

Figure 5. Mock-up of a web application harnessing the D3X ontology to perform queries for differential diagnoses associated with dermoscopic features and patterns, with Kaposi sarcoma as a use case. In discussion with domain experts, we chose not to integrate diagnostic rules into D3X, as experienced dermoscopy users could assess the list of differential diagnoses fairly quickly and decide on the most likely diagnosis using their clinical expertise. If the user is relatively inexperienced, they may gain more understanding by reading the description of each differential diagnosis, viewing the images, and accessing additional information by clicking “learn more” in the web application. Nevertheless, in the future, it may be useful to integrate diagnostic rules into D3X for more sophisticated suggestions

of differential diagnoses (eg, ranking the most to least likely differential diagnoses in a prioritized list). Another limitation is that there are dermoscopic terms and differential diagnoses not included in D3X, given that we built D3X from the terms mentioned in the International Society of Dermoscopy's third consensus conference [34]. Similarly, while we aimed to include images from a variety of external sources, we acknowledge that they may not be fully representative of all patient skin tones. Our work is only a starting point, as we plan to continue updating D3X and anticipate that its library will become more comprehensive with time.

To conclude, the web application based on D3X has great potential for use in several areas. First, it could be included alongside formal dermoscopy training as a supplementary educational tool for dermatology trainees and providers in other specialties (PCPs, plastic surgeons). Given that providers may require ongoing dermoscopy refresher sessions to feel fully comfortable even after completing an initial training program [17], this web application could be a helpful reference to deepen understanding of dermoscopic patterns associated with different skin conditions. Furthermore, in a clinical setting, providers could quickly query the web application for a list of differential diagnoses after dermoscopic examination of a lesion, which would aid in the identification of their patient's diagnosis. This may be useful for inexperienced and experienced dermoscopy users alike, as it is intended to augment, not replace, the provider's clinical reasoning. The next steps include using our proposed interface to build a functional web application. Creating the web application could reveal additional flaws in the design that require clarification, and we would continue to improve aspects of D3X and the web application in an iterative process. After a beta version of the web application is finalized, we would aim to conduct user testing to evaluate the user experience as well as clinical or educational utility among physicians.

Conclusions

We introduce and discuss the design and development of the D3X ontology as a resource that can link and integrate dermoscopic differential diagnoses and supplementary information with existing ontology-based resources (MedDRA, SNOMED CT, and NCI). We repurposed a previous work of the EVO and DEVO to construct and support D3X, along with other supplementary standardized ontologies, like IAO and SWO. Using the semiotic theoretical framework to compare D3X with other dermatology-related ontologies, its overall quality score was similar to existing ontologies' scores. One of the outcomes of this work is providing a means to aggregate and link dermoscopic patterns to differential diagnoses, thereby enhancing understanding of dermoscopy for educational and clinical use. This outcome has fueled our next objective in developing a web-based application that can query D3X and fetch the linked information for the user. Currently, D3X and its resources are available on GitHub for public release and use.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) is a chronic condition among the main causes of morbidity and mortality worldwide, representing a burden on health care systems. Scientific literature highlights that nutrition is pivotal in respiratory inflammatory processes connected to COPD, including exacerbations. Patients with COPD have an increased risk of developing nutrition-related comorbidities, such as diabetes, cardiovascular diseases, and malnutrition. Moreover, these patients often manifest sarcopenia and cachexia. Therefore, an adequate nutritional assessment and therapy are essential to help individuals with COPD in managing the progress of the disease. However, the role of nutrition in pulmonary rehabilitation (PR) programs is often underestimated due to a lack of resources and dedicated services, mostly because pneumologists may lack the specialized training for such a discipline.

Objective: This work proposes a novel knowledge-based decision support system to support pneumologists in considering nutritional aspects in PR. The system provides clinicians with patient-tailored dietary recommendations leveraging expert knowledge.

Methods: The expert knowledge—acquired from experts and clinical literature—was formalized in domain ontologies and rules, which were developed leveraging the support of Italian clinicians with expertise in the rehabilitation of patients with COPD. Thus, by following an agile ontology engineering methodology, the relevant formal ontologies were developed to act as a backbone for an application targeted at pneumologists. The recommendations provided by the decision support system were validated by a group of nutrition experts, whereas the acceptability of such an application in the context of PR was evaluated by pneumologists.

Results: A total of 7 dieticians (mean age 46.60, SD 13.35 years) were interviewed to assess their level of agreement with the decision support system's recommendations by evaluating 5 patients' health conditions. The preliminary results indicate that the system performed more than adequately (with an overall average score of 4.23, SD 0.52 out of 5 points), providing meaningful and safe recommendations in compliance with clinical practice. With regard to the acceptability of the system by lung specialists (mean age 44.71, SD 11.94 years), the usefulness and relevance of the proposed solution were extremely positive—the scores on each of the perceived usefulness subscales of the technology acceptance model 3 were 4.86 (SD 0.38) out of 5 points, whereas the score on the intention to use subscale was 4.14 (SD 0.38) out of 5 points.

Conclusions: Although designed for the Italian clinical context, the proposed system can be adapted for any other national clinical context by modifying the domain ontologies, thus providing a multidisciplinary approach to the management of patients with COPD.

Introduction

Background

Chronic obstructive pulmonary disease (COPD) is one of the leading causes of morbidity and mortality worldwide. In Italy, 3.2% of the population in 2019 had a diagnosis of COPD, and such numbers are expected to increase in the next years due to the worsening of risk factors [1]. COPD is characterized by chronic inflammation in the lungs and airflow obstruction. Starting from the respiratory system, COPD has several systemic effects, including skeletal muscle wasting (which limits exercise capacity), increased risk of cardiovascular disease, osteoporosis, depression, and anxiety [2]. Pulmonary rehabilitation (PR) is an evidence-based, nonpharmacological intervention that helps people with COPD improve their health condition and quality of life by increasing exercise capacity and reducing symptoms of dyspnea and fatigue [3]. PR is based on a multidisciplinary approach and includes several components, among which nutritional status evaluation is considered relevant.

However, as highlighted recently by the American Thoracic Society, the scarcity of resources often limits the nutritional component, which, in some settings, can be accessible only outside the PR program [4]. Moreover, even though the influence of nutrition on COPD has been recognized and a relationship between some nutrients and pulmonary functions has been identified, PR programs often do not formally include patient-specific dietary recommendations. Therefore, more studies are required to drive the implementation of tailored nutritional strategies [5].

The Role of Nutrition in Patients With COPD: Evidence

The relationship between COPD and nutrition has been investigated by many authors, who have put together a set of evidence that underlines the role of nutrients in PR and the disease exacerbations. The results of the systematic review and meta-analysis by Collins et al [6] demonstrated that nutritional support, primarily in the form of oral nutritional supplements, improves total energy intake, anthropometric measurements, and grip strength in patients with COPD. This work highlighted how dietary changes supported protein and energy intake in patients with COPD, resulting in weight gain and a moderate increase in muscle strength—which can significantly impact respiratory muscle strength, walking distance, and quality of life. Another systematic review [7] found that nutritional supplementation improves body weight gain in patients with COPD, especially when malnourished, in terms of body composition, respiratory muscle strength, and quality of life.

Inadequate nutritional intake, higher daily energy expenditure, weight loss, and fat-free mass (FFM) depletion affect the functional capacity of patients with COPD. The progression of the disease also contributes to an increased respiratory muscle load, hypoxemia, physical inactivity, and release of inflammation mediators [8]. In addition, Liu et al [9] explored the associations among COPD, diet, and inflammation, identifying a correlation between diet and COPD inflammatory status. By calculating the Diet Inflammatory Index in COPD, they observed that COPD was more prevalent in patients with a worse Diet Inflammatory Index.

A systematic review of factors influencing the risk of developing COPD [10] concluded that the Western diet, characterized by the consumption of processed meat and alcohol and a low intake of fruit and vegetables, is associated with the prevalence of COPD. A cross-sectional study [11] assessed the nutritional status of outpatients with COPD and found a significant association between malnutrition and COPD—most of the patients did not have an adequate daily food intake and showed a lower quality of life, highlighting the need for a more tailored nutritional intervention for managing malnutrition in patients with COPD with cachexia. In COPD, low FFM and sarcopenia are predictive factors of mortality [12]. Considering that literature data demonstrate that the presence of malnutrition and, above all, a low FFM index is associated with an increased risk of mortality, Schols et al [13] identified different nutritional risk profiles based on nutritional phenotypes that appear to be predictors of outcome independent of impaired respiratory function. These nutritional phenotypes included obesity, sarcopenic obesity, sarcopenia, and cachexia and required at least three items for their identification: (1) BMI and body circumference, (2) bioelectrical impedance analysis, and (3) history of unintentional weight loss. A recent study [14] demonstrated that patients with COPD with sarcopenia and sarcopenic obesity had worse muscle strength than patients with healthy body weight, claiming that body composition is associated with physical functions. Patients with COPD with obesity have a higher risk of developing comorbidities such as diabetes and metabolic and cardiovascular diseases in addition to typical COPD symptoms.

Research Challenge: Nutritional Status to Prevent COPD Exacerbation

The evidence reported previously indicates that clinicians and dietitians must evaluate the nutritional status and body composition of patients when giving nutritional advice or diet recommendations to patients with COPD with obesity to foster an adequate intake of macro- and micronutrients and control obesity as well [15].

Malnutrition plays a pivotal role among the challenges that must be faced in treating COPD. The study by Mete et al [16] affirms that malnutrition and risk of malnutrition are very frequent conditions among patients with COPD and, together with a significantly lower BMI, are associated with disease severity, as highlighted by pulmonary function tests. In clinical practice, sarcopenia assessment is not part of the standard of care, implying a loss of personalized treatment that should be essential to improve health outcomes related to the disease [17]. The current literature illustrates that screening for sarcopenia and tailored nutrition intervention in patients with COPD could cost-effectively achieve better health outcomes [18,19]. Functional capacity, respiratory muscle strength, and quality of life can all be improved through nutritional supplementation and a better assessment of nutritional status.

The future nutrition challenges require the identification of specific targets of intervention, considering body composition, nutritional status, and inflammation in addition to the strictly clinical aspects. Nowadays, diet is not always an integral part of COPD therapeutic strategy [20]. Moreover, different studies have highlighted the necessity of new methods to assess malnutrition and evaluate nutritional status in patients with COPD, not considering the BMI alone [21] as it misses important changes in body composition.

This new vision places nutritional intervention as an integral part of COPD management, not only in the advanced and early stages but also to prevent the evolution toward respiratory failure. Creating a decision support system (DSS) that brings together data and knowledge in the nutritional field to identify the different nutritional phenotypes and suggest specific dietary recommendations could be useful to meet these challenges. In particular, this DSS could become a valuable tool for pulmonologists to develop nutritional interventions as an integral part of the COPD therapeutic strategy even in the absence of specific resources.

Objective of This Study

Digital health care applications are already used to improve PR models, mainly for self-management; modification of lifestyle factors; and modification of risk factors, such as smoking cessation and fostering physical activity [22]. However, to the best of our knowledge, there are only a few applications focused on nutritional aspects associated with COPD. This work leveraged clinical expert knowledge—formalized into domain ontologies—from the Italian health care context to develop a DSS to support pneumologists in considering nutritional aspects in PR to avoid the disease's exacerbation and provide patients with tailored dietary guidelines. The application exploiting the DSS fits the context of a preprototype according to the World Health Organization (WHO) guidelines for the monitoring and evaluation of digital health interventions [23].

Related Work

Overview

Ontology-based technologies have been adopted for both clinical DSSs and patient-centered DSSs. Regarding the ontological formalization of requisites and tailored suggestions for patients with COPD in DSSs, no work has tackled this issue in PR—except for an early version of the system we propose in this work [24]. Nonetheless, the use of ontologies to formalize COPD has been established in some works. Moreover, specific digital applications for patients with COPD have been developed in the past years. This section presents works relevant to the fields of ontology-based clinical and patient-centered DSSs and digital applications specifically developed for patients with COPD.

Ontologies and Ontology-Based Systems for COPD Management

COPD has been formalized in ontologies or knowledge bases since the early 2010s. The COPD ontology by Greenberg et al [25] was developed to support COPD longitudinal research and clinical trials, leveraging a preexisting model dedicated to representing subpopulations of patients. Cano et al [26] developed a knowledge base devoted to collecting clinical experimental data; the COPD Knowledge Base can semantically map data to physiological and molecular data to support clinical decision-making through a predictive mathematical model.

Ontologies can play a pivotal role in diagnostic systems. In the case of COPD, Rayner et al [27] developed an ontology for the early diagnosis of the illness. The ontological model takes advantage of clinical tests and patients' data (eg, spirometry, forced expiratory volume in the first second [FEV1], age, and smoking status) and tests its robustness against a large data set of patients. The model proved able to categorize patients as "Unlikely COPD," "Probable COPD," and "Definite COPD" cases.

As ontology-enabled reasoning processes are appreciated in the context of clinical decision-making, the adoption of formal models in health care systems aimed at managing chronic conditions—including systems for patients with COPD—has also been established. CHRONIOUS [28] is an open and ubiquitous system that exploits ontology-based inferential reasoning to adapt the platform's services, including monitoring patients' conditions—which is also performed leveraging wearable sensors. Lasierra et al [29] developed an ontology-based telemonitoring system aimed at monitoring patients with chronic diseases at home. The ontology layer (Home Ontology for Integrated Management in Home-Based Scenarios) represents the patient profile, vital signs, and chronic conditions (including COPD) to observe the patient's evolution and plan activities. Similarly, Ajami and McHeick [30] developed a domain ontology encompassing environmental features, patient data, clinical status and diseases (including COPD), and devices to monitor and identify patients' conditions. This DSS aimed to foster patients' adherence to a healthy lifestyle and identify and avoid possibly dangerous situations.

Digital Applications for Patients With COPD

Digital applications may offer solutions to both clinicians—to ease the process of assessment and support clinical decisions—and patients—mainly to support them in the management of the disease. Digital applications currently available for patients with COPD are mainly telemedicine and telerehabilitation solutions. Most of them are focused on educational programs, symptom tracking, behavior change,

support for medication or treatment, and activity report [31]. In some cases, as both research prototypes [32] and commercial products [33], the educational programs include specific sections on nutrition, in which helpful tips and recommendations are provided to manage symptoms during meal consumption and help maintain a balanced diet. However, such applications do not provide personalized information tailored to the patient's nutritional status. In such cases, the applications targeted at health care professionals comprise the "clinician side" of telemedicine platforms (ie, monitoring dashboard allowing for remote visualization of patients' data and applications for remote teleconsulting).

Differently from the aforementioned solutions, the DSS proposed in this work tackles the role of nutritional therapy in the PR of patients with COPD—an aspect neglected in existing DSSs.

Methods

A DSS was developed to tackle the aims described in the Introduction section and the research challenge described in the Objective of This Study section, thus supporting pneumologists in suggesting specific dietary recommendations for patients with COPD. The DSS leverages expert knowledge in the form of ontologies and, through automatic inference processes, is expected to provide guidelines to prepare a tailored dietary plan.

The development of the ontology underlying the DSS leveraged expert clinical knowledge to maximize its acceptability. Contrary to purely data-driven approaches, ontologies formalize information to enable a system to perform inferences (based on the knowledge formalized in the ontology). The inference process simulates human inference capabilities [34] so that ontology-based approaches are perceived as transparent. Thus, ontologies are widely adopted in several artificial intelligence and health-related applications [35].

However, the development of a domain ontology is not a trivial task—it is a process that may involve several activities (eg, the acquisition of knowledge, its conceptualization, the survey of existing models that can be reused, the development of the model in a formal language, and the testing of the developed ontology [36]). The ontology engineered for the proposed DSS was developed following the Agile, Simplified, and Collaborative Ontology Engineering Methodology (AgiSCOnt) [37] engineering methodology, which involves knowledge elicitation techniques and domain experts in the development phase of the ontology. This collaborative ontology engineering methodology adopts unstructured interviews, scientific literature surveys, and discussions to elicit the necessary knowledge to minimize the impact of the "knowledge elicitation bottleneck" (ie, it takes longer to gather knowledge from experts and documentation than to write the software [38]). Its collaborative and agile features and validation [37] were the reasons behind the adoption of AgiSCOnt in this work.

The methodology involves three phases:

1. *Domain analysis and conceptualization*, which includes the identification of the knowledge to be included and the preparation of competency questions (CQs) [39] that the ontology is expected to answer; it enables the conceptualization of the domain (which results in a conceptual map) and the preliminary identification of existing ontological resources that can be reused.
2. *Development and testing*, which involves the selection of the ontological languages to formalize the conceptualization developed in the previous step and the identification of ontology design patterns (ie, "micro-ontologies" that can be reused to model recurrent problems in ontology engineering [40]). This step results in the prototypization of the ontology, which undergoes a preliminary test to assess the validity of its inferences.
3. *Ontology use and updating*, which includes activities such as use of the developed ontology in an application, extended validation, and feedback collection. The following subsections delve into the engineering process.

The development of this ontology involved the following team members: 1 ontologist with experience in modeling using agile ontology engineering methodologies, 1 biomedical engineer with previous experience in ontology engineering and knowledge of COPD, 2 senior dieticians with clinical experience with patients with COPD, and 1 senior pneumologist. The team was composed of clinical personnel from universities (dieticians) and a research and cure center (Scientific Institute for Research, Hospitalisation and Health Care) with a specialization in COPD (pneumologist) and yearly experience treating such patients. The team delved into nutrition and diet's role in tackling this disease, with examples from the literature and clinical trials in which the clinical personnel was involved. The discussion was then oriented to identify some of the issues that the ontology was expected to answer (ie, the CQs).

Ethical Considerations

This study does not include human subjects research (no human subjects experimentation or intervention was conducted) and so does not require institutional review board approval.

Results

This section describes the development of the COPD and Nutrition domain ontology for the DSS and the ontology-based application for clinical personnel.

The COPD and Nutrition Domain Ontology

Domain Analysis and Conceptualization

The considerations reported in The Role of Nutrition in Patients With COPD: Evidence and Research Challenge: Nutritional Status to Prevent COPD Exacerbation sections were gathered by the team in this phase. Leveraging the objective (ie, providing clinical personnel with support in identifying tailored nutritional recommendations for patients with COPD), the team decided that the ontology should focus on representing the patients' health condition and the stage of their COPD. On the basis of their expertise, clinicians pointed out that the purpose of the ontology should be to illustrate, for each patient, a tailored percentage of macro- and micronutrients they are advised to consume on a daily basis to avoid exacerbations, as well as to provide nutritional guidance. The summary of the entities and

expected outputs of the ontology is provided in Textbox 1, listing the CQs and their answers.

Textbox 1. The list of competency questions and answers for the Chronic Obstructive Pulmonary Disease (COPD) and Nutrition ontology engineering process.

What information identifies a patient? What basic information is used to identify the patient? What clinical information is used to identify the patient?

- A patient is identified by an ID and gender. Each patient is associated with 1 health condition and 1 anthropometric phenotype (defined via BMI cutoffs). Each patient can be classified as a patient with sarcopenia or cachexia or as a patient without sarcopenia or cachexia.

How is COPD evaluated?

- COPD is evaluated according to the criteria defined in the gold standard—it can be mild, moderate, severe, and very severe. The criterion to be analyzed is the forced expiratory volume in the first second.

How is sarcopenia evaluated?

- The status of sarcopenia is evaluated according to clinical standards (operational definition of sarcopenia). The first criterion comprises low muscle strength, the second criterion comprises a low muscle quantity or quality, and the third criterion comprises low physical performance. The presence of the first criterion alone indicates probable sarcopenia, the presence of both the first and second criteria indicates diagnosed sarcopenia, and the presence of all 3 criteria indicates severe sarcopenia.

How is cachexia evaluated?

- Cachexia is evaluated by means of biochemical indicators according to the study by Evans et al [41]. Albuminemia, iron transport, and polymerase chain reaction (PCR) criteria must be copresent to indicate a cachexia diagnosis.

Which data characterize the patient's health condition? How is the nutritional risk index assessed?

- Patients' health condition must indicate the stage of COPD and the nutritional risk index profile characterizing the patient. Each health condition must illustrate anthropometric measures (current weight, usual weight, height in meters, and BMI), physical performance indicators (hand grip and gait speed), and biochemical indicators (albuminemia, PCR, resistance, reactance, and iron transport). The nutritional risk index assessment is performed following clinical standards.

What recommendations are given to clinical personnel?

- The recommendations provided to clinical personnel indicate (for each patient) the basal metabolic rate and the corrected caloric intake, the daily macronutrient shares (protein, minimum and maximum share of carbohydrates, minimum and maximum share of fats, minimum and maximum share of fiber, maximum share of sugar, and maximum share of saturated fats), the amount of cholesterol and sodium, and whether the patient should increase their caloric intake by means of branched-chain amino acid or energy-protein supplementations.

How are recommendation values calculated?

- The indications provided in the patient's recommendation are calculated according to clinical standards and differentiated according to the patient's gender, stage of COPD, and anthropometric phenotype.

In this phase, the pneumologist specialized in clinical nutrition and a clinical dietitian defined the phenotypes and their nutritional requirements based on anthropometric and clinical parameters and comorbidities according to national and international guidelines. For the definition of each anthropometric phenotype, COPD stage (defined via FEV1 and forced vital capacity and in particular FEV1–to–forced vital capacity ratio [42,43]; Table 1) and the presence of sarcopenia or cachexia were considered. A total of 5 metabolic phenotypes for patients with COPD were developed (underweight, normal weight, overweight, first-degree obesity, and second-degree obesity), and each can be characterized by the presence of sarcopenia, cachexia, or none of the 2 conditions (Table 2).

Moreover, nutritional risk was assessed by means of the nutritional risk index (NRI) formula [44] as follows:

(1)

Thus, patients were classified according to this formula (Table 3).

The diagnosis of sarcopenia was based on the analysis of specific patients' value indicators. The first one was the appendicular skeletal muscular mass, which is calculated according to the work by Sergi et al [45]:

(2)

Appendicular skeletal muscular mass and other indicators allow for the classification of patients' sarcopenic condition according to the 3 criteria in Table 4 [46].

If the first criterion applied, then the patient was *probable* sarcopenic; if the first and second criteria applied, then the patient was *diagnosed* sarcopenic; if all 3 criteria applied, then the patient was *severe* sarcopenic.

A similar approach was adopted to identify whether a patient was cachectic. If a patient's polymerase chain reaction was >10, the level of iron transport was <150, the level of albuminemia was <3.5, and the patient was sarcopenic, then they were also cachectic [41]. As such, it is safe to infer that cachexia is a particular case of sarcopenia.

Calculation of nutritional recommendations was performed using the "if-then" type rules produced by clinical personnel considering reference values reported in scientific literature and national and international guidelines. The COPD DSS provides the following nutritional information and recommendations: (1) basal metabolic rate (BMR), (2) total daily energy requirement (kcal), (3) meal frequency, (4) indication for energy-protein supplementation (yes or no), (5) indication for branched-chain amino acid (BCAA) supplementation (yes or no), (6) protein intake (percentage and grams), (7) carbohydrate intake (percentage and grams), (8) lipid intake (percentage and grams), (9) sugar intake (maximum percentage and grams), (10) saturated fat intake (maximum percentage and grams), (11) cholesterol intake (maximum milligrams), (12) fiber intake (minimum and maximum grams), (13) sodium intake (maximum milligrams), and (14) calcium intake (milligrams).

For BMR calculation, Harris-Benedict or Mifflin predictive equations based on sex, age, weight, and height were considered. The Harris-Benedict equation was preferred for patients who were underweight or had normal weight, whereas the Mifflin equation was used for patients with COPD with overweight or obesity [47-49]. According to the COPD stage, different correction factors to BMR were applied (Multimedia Appendix 1)—for patients who were underweight, had a normal weight, were overweight, or had first- or second-class obesity presenting with COPD at the first or second stage and who were nonsarcopenic and noncachectic or sarcopenic, a 1.5 correction factor was used to calculate total daily energy requirement; for the same categories of patients presenting with COPD at the third or fourth stage, a correction factor of 1.8 was preferred to counteract the important energy expenditure due to the respiratory work of these patients. Only for patients with cachexia a 1.8 correction factor was always applied regardless of BMI and COPD stage.

The impact of physical activity was deemed marginal for the correction factor's definition as patients with COPD are a vulnerable population presenting with comorbidities that limit their capacity to perform physical activity. As seen in the pathological lung mechanics of patients with COPD, dynamic hyperinflation influences the proper operation of the chest's horizontal and vertical diameters that expand during inspiration due to the activation of the external intercostal muscles and the diaphragmatic contraction. This impairment plays a role in how much exercise a patient with COPD can tolerate. As shown in individuals with severe-stage COPD and weight loss related to COPD, respiratory muscle weakness exacerbates the breathing mechanism. Increased dyspnea and decreased exercise tolerance are directly related to this respiratory muscle weakening. Moreover, it has been observed that patients with COPD are characterized by higher levels of physical inactivity [50]. As far as protein requirement was concerned, clinical experts decided to provide different recommendations according to real or ideal weight or BMI or focusing on FFM considering specific body composition or COPD stage to give personalized recommendations to not compromise health and nutritional status as well as prevent further decrease in metabolically active lean mass [12]. For this reason, cachectic phenotype, regardless of BMI and COPD stage, was always given a high percentage of protein intake. BCAA was suggested when energy requirements but not protein requirements were met through diet. Differently, protein-caloric supplements were indicated when neither energy nor protein requirements were satisfied through food intake [51]. Phenotypes characterized by cachexia, regardless of BMI, underweight sarcopenic and normal-weight phenotype, and COPD stage, were always recommended BCAA and energy-protein supplementation in consideration of their health status. For the same reason, BCAA supplementation was always suggested for sarcopenic phenotypes [52]. As far as carbohydrate metabolism was concerned, and in line with the lower levels reported in the reference values of nutrients and energy for the Italian population [13,47], a carbohydrate intake of 45% to 50% of total daily calories and a maximum sugar intake of 15% of total calories were indicated except for individuals with type 2 diabetes mellitus, for whom a maximum of 10% of total calories was indicated to be reached through sugar intake. A lower recommendation for carbohydrate intake permits the promotion of protein and lipid intake, which are functional for respiratory work and to prevent further weight or lean mass loss. Regarding dietary fiber, it was decided that providing a lower indication than that provided by the Livelli di Assunzione di Riferimento di Nutrienti ed energia (LARN; National Recommended Energy and Nutrient Intake Levels) was preferred to encourage the intake of energy and protein foods, especially considering the difficulties met by patients with COPD in feeding and the early sense of satiety as a result of high-fiber food intake. Compared to the LARN, a higher intake of lipids was recommended, especially for phenotypes presenting with a partial pressure of carbon dioxide of >50 mm Hg, a measure of carbon dioxide in arterial or venous blood [53]. For saturated fats, a maximum intake of 10% of total daily calories was suggested according to LARN guidelines. Regarding cholesterol intake, a LARN nutritional goal for prevention, a maximum of 300 mg per day was recommended except for patients with high cholesterol levels, for whom the target was lowered to 200 mg per day. Hypercholesterolemia was defined as elevated total or low-density lipoprotein cholesterol levels or low levels of high-density lipoprotein cholesterol. Regarding micronutrients, sodium and calcium intake was considered. According to the recent WHO report on sodium intake [54], a maximum intake of <2000 mg per day of sodium (<5 g per day of salt) was recommended. A slightly higher recommendation than that of the LARN was given for calcium to prevent or counteract osteoporosis [55]. Finally, given the difficulties in feeding and early satiety observed, an indication for fractioned meals was given to meet energy and nutritional requirements throughout the day with small and frequent meals.

All the parameters involved in the evaluations presented previously (ie, FEV1; partial pressure of carbon dioxide; resistance; reactance; iron transport; albuminemia; polymerase chain reaction; hand grip; gait speed; and general patient

information such as age, gender, height in meters, current weight, and usual weight) are usually acquired during patient assessment (such as spirometry and blood tests). AgiSCOnt's outputs for the domain analysis phase consisted of the conceptual map reported in Figure 1 and a list of CQs (Textbox 1).

Table 1. The cutoffs identifying the chronic obstructive pulmonary disease (COPD) stages based on the forced expiratory volume in the first second (FEV1) values.

COPD stage number	COPD stage name	FEV1 (%)
I	Mild	≥80
II	Moderate	≥50 to <80
III	Severe	≥30 to <50
IV	Very severe	<30

Table 2. World Health Organization cutoffs for nutritional status categories based on BMI.

Nutritional status	BMI (kg/m^2)
Underweight	<18.5
Healthy weight	≥18.5 to ≤24.9
Overweight (preobesity)	≥25.0 to <29.9
Obesity degree I	≥30.0 to <34.9
Obesity degree II	≥35.0 to <39.9
Obesity degree III	≥40

Table 3. The cutoffs identifying the 4 levels of nutritional risk based on the nutritional risk index (NRI).

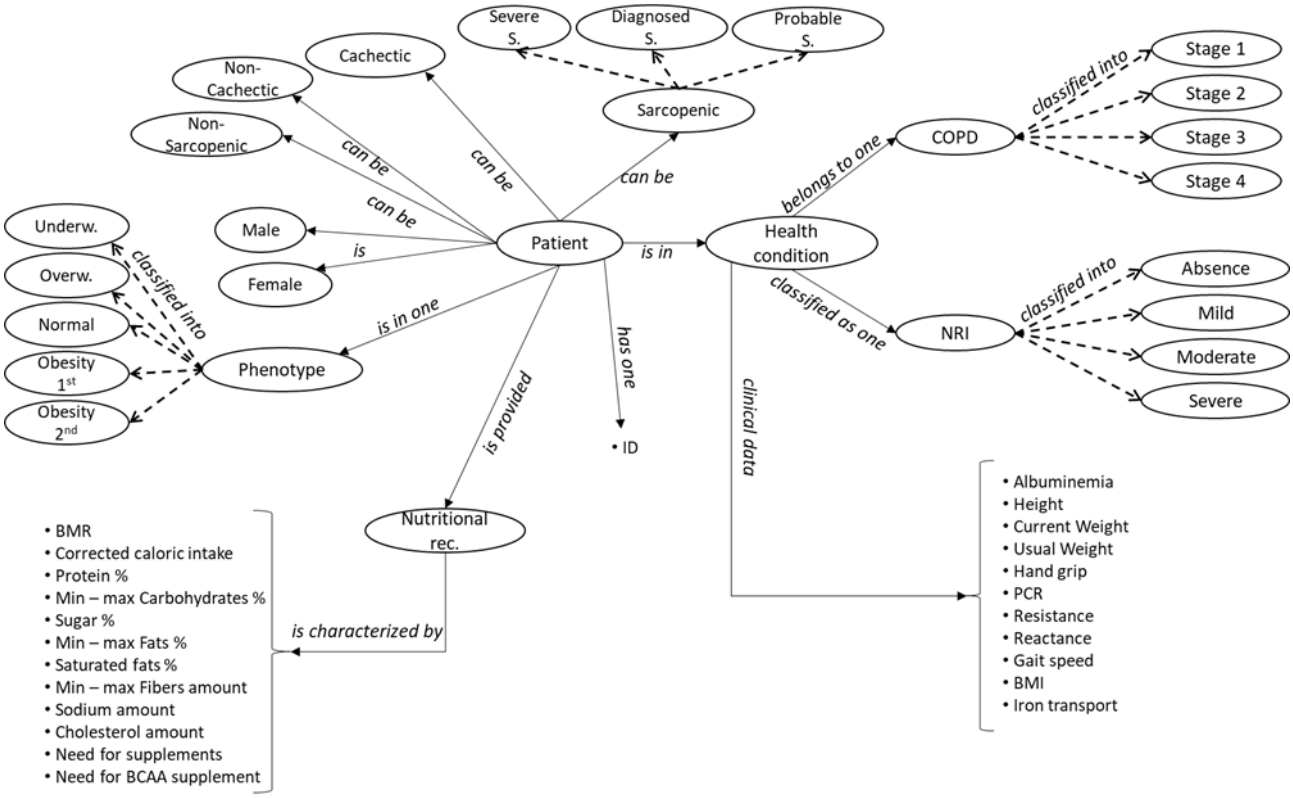
NRI	Index
Absence of risk	>100
Mild risk	≥97.5 to ≤100
Moderate risk	≥83.5 to <97.5
Severe risk	<83.5

Table 4. Criteria for the classification of sarcopenia in patients.

Criteria	Cutoff for male patients	Cutoff for female patients
Low muscular strength—hand grip	<27 kg	<16 kg
Low muscular quantity	ASMM[a]<20 kg; ASMM/height^2<7 kg/m^2	ASMM<15 kg; ASMM/height^2<5.5 kg/m^2
Poor physical performance	≤0.8 m/s	≤0.8 m/s

[a]ASMM: appendicular skeletal muscular mass.

Figure 1. An excerpt of the conceptual map developed by the team involved in the ontology engineering process for the clinical chronic obstructive pulmonary disease (COPD) and nutrition ontology. BCAA: branched-chain amino acid; BMR: basal metabolic rate; NRI: nutritional risk index; PCR: polymerase chain reaction.



Development and Testing

The development phase adopted the conceptual map and CQs produced in the previous phase to guide the entire development process and discuss whether to model some concepts pertaining to the patients or their health conditions. The ontology editor Protégé (Stanford Center for Biomedical Informatics Research) [56] that supports Resource Description Framework [57] and Web Ontology Language [58] with a DL (description logic) profile [59] was adopted. Clinicians explicitly asked any significant advancement in the development of TBox and Abox (eg, patient modeling, health condition characterization, and recommendation modeling) to be illustrated to ensure that undesired entailments were not modeled in the ontology. From a reuse perspective, no ontology able to describe the conceptualization reached in this study was found; the only ontology design pattern reused in this ontology was the one that relates a copd:Patient to their copd:Health_Condition via the copd:isInHealthCondition object property [60]. The developed ontology (prefixed with copd:), discussed in this subsection, is accessible in Multimedia Appendix 2.

The development started with the identification of concepts that could be translated into owl:Classes. The concept of copd:Patient is pivotal in this ontology. Each patient is defined by exactly 1 patient ID, is given at least 1 nutritional recommendation individual, and is characterized by a health condition individual.

Each patient needs to be classified as copd:Female or copd:Male—disjoint classes—and as copd:Cachectic (or its complement copd:non-Cachectic) or copd:Sarcopenic (or its complement copd:non-Sarcopenic). Sarcopenia and cachexia are modeled as attributes of the patient and not of their health condition. The clinical personnel deemed essential to state that these 2 conditions have systemic status; therefore, they characterize the individual as a whole. The class copd:Sarcopenic is further detailed into the subclasses copd:Probable_Sarcopenic, copd:Diagnosed_Sarcopenic, and copd:Severe_Sarcopenic to reflect the operational definition standard provided by clinicians (presented in the previous subsection).

In the same way, the copd:Anthropometric_Phenotypes are characteristics of the copd:Patients, and this class lists 5 subclasses for the representation of the phenotypes.

Similarly to copd:Patient, the development of the TBox pertaining to the patient's health condition was discussed among the team members—each health condition is characterized by an NRI profile, but in general, a copd:Health_Condition is not necessarily characterized by COPD. The terms adopted in the conceptual map to sketch the relationships among copd:Health_Condition, copd:Nutritional_Risk_Index_Profile, and copd:COPD_HC were found indicative of the clinicians' perspective—both NRI and COPD are considered particular attributes of a health condition (ie, there could be health conditions characterized only by an NRI profile but lacking COPD). Therefore, the classes copd:Nutritional_Risk_Index_Profile and copd:COPD_HC were modeled as rdfs:subclassOf copd:Health_Condition. This decision was also encouraged by the fact that the datatype properties copd:FEV1 and copd:nutritionalRiskIndex have copd:Health_Condition as the domain.

The copd:Nutritional_Risk_Index_Profile and copd:COPD_HC subclasses are characterized by restrictions that allow for the classification of individual health conditions whose copd:nutritionalRiskIndex and copd:FEV1 object values fall under specific restrictions.

Each copd:Health_Condition is described by a set of datatype properties, which represent the clinical data elicited in the previous phase and are required to enable the patient's classification and recommendations. Each owl:Individual belonging to this class also materializes inferred triples related to the copd:AppendicularSkeletalMuscleMass, the copd:ResistiveIndex, and the copd:nutritionRiskIndex. While the copd:nutritionalRiskIndex is calculated using semantic web rule language (SWRL) rules and used to classify each copd:Health_Condition into one of the NRI's subclasses, the copd:ResistiveIndex is a piece of information necessary to calculate the copd:AppendicularSkeletalMuscleMass (both are inferred as the result of 2 different SWRL rules). Figure 2 illustrates an example of copd:Health_Condition completed with all its datatype properties (both asserted and inferred).

The ontology makes use of 39 datatype properties and 2 object properties (copd:isInHealthCondition and copd:hasRecommendation)—almost all datatype properties were used to provide values for the patient's health condition and nutritional recommendation.

The ontology also contains 79 SWRL rules, which are largely used to represent the tuples in Multimedia Appendix 1, depicting the conditions that determine the shares and amounts of nutrients characterizing a patient's diet (see the full ontology in Multimedia Appendix 2). The equations adopted to calculate the BMR and the corrected caloric intake were adapted with SWRL using mathematical built-ins [61]. Taking as an example a copd:Overweight, copd:non-Sarcopenic, and copd:non-Cachectic male patient characterized by copd:Stage2 disease, the BMR is inferred through the following rule (for each male patient not characterized by sarcopenia or cachexia, calculate the BMR using the Harris-Benedict equation and round the result):

Male(?p), Overweight(?p), (not (Cachectic))(?p), (not (Sarcopenic))(?p), hasRecommendation(?p, ?rec), isInHealthCondition(?p, ?hc), age(?hc, ?age), currentWeight(?hc, ?kg), height_meters(?hc, ?m), multiply(?a, ?kg, 13.75), multiply(?b, ?m, 5, ?100), multiply(?c, 6.78, ?age), add(?d, 66.5, ?a, ?b), subtract (?e, ?d, ?c), round(?f, ?e) -> regularRecommendedCaloricIntake(?rec, ?f)

Then, the correction is applied (for each male patient not characterized by sarcopenia or cachexia with stage-1 or stage-2 COPD, correct the BMR calculated using the Harris-Benedict equation by multiplying it by 1.5):

(Normal_Weight or Obesity_1st_Degree or Overweight or Underweight)(?p), hasRecommendation(?p, ?rec), isInHealthCondition(?p, ?hc), (Stage1 or Stage2)(?hc), (not (Cachectic))(?p), (not (Sarcopenic))(?p), regularRecommendedCaloricIntake(?rec, ?reg), multiply(?corin, ?reg, 1.5), round(?f, ?corin) -> correctedRecommendedCaloricIntake(?rec, ?f)

The definition of the share of protein that a patient with COPD needs is calculated by identifying the amount (in grams) of protein. With the sole exception of patients with cachexia—who are given a 25% protein share for clinical reasons—for each patient, the daily quantity of protein is calculated according to their weight (for each patient with normal or overweight status and not characterized by sarcopenia or cachexia, obtain the amount of protein in grams by multiplying their current weight by 1.2):

(Normal_Weight or Overweight)(?p), (not (Cachectic))(?p), (not (Sarcopenic))(?p), hasRecommendation(?p, ?rec), isInHealthCondition (?p, ?hc), currentWeight (?hc, ?w), multiply (?pgra, ?w, 1.2) -> proteinsGrams (?rec, ?pgra)

This amount is then converted into calories, bearing in mind that 1 protein is equal to 4 kcal, and then the daily protein share is calculated. This approach also enables the possibility to correct the amount of protein for particular classes of patients; for example, dieticians indicated that patients classified as copd:non-Sarcopenic, copd:non-Cachectic, and copd:Underweight should have their protein share calculated considering a different BMI (which is set to a higher value to fight their underweight condition and is established at 22.5 kg/m^2).

As mentioned previously, the ontology provides enough SWRL rules to model all the information identified by the domain experts and elicited in Multimedia Appendix 1. As established by the development step in AgiSCOnt, the ontology underwent a test with data from 6 patients provided by clinicians. The test was divided into 2 steps. The first was dedicated to assessing whether the ontology provided a correct classification of the patients (ie, whether it identified copd:Sarcopenic and copd:Cachectic status for each patient and whether the stage of COPD and the copd:Nutritional_Risk_Index_Profile were correctly inferred). Thus, by querying the ontology using SPARQL (World Wide Web Consortium) [62], it was possible to assess the accuracy of the inferences (reported in Table 5).

The pneumologist and dieticians verified the correctness of the classification for each patient. All 6 individuals representing patients were found to be correctly classified. The second phase dealt with the retrieval of nutritional suggestions and their evaluation by the clinical personnel with the aim of assessing the validity of the SWRL rules modeled in the COPD and Nutrition ontology. The ontology was queried using SPARQL to retrieve all the nutrient minimum and maximum shares and quantities deemed important for patients with COPD (the results of the query are reported in Multimedia Appendix 3). Each copd:Nutritional_Recommendation and its inferred nutrient values were evaluated by clinical personnel and were found to be correct—although, for some values such as the copd:proteinShare and copd:fiberMINamount, a rounding of the decimal was suggested by dieticians.

Figure 2. The complete datatype property set for a copd:Health_Condition. The datatype properties with a yellow background represent inferred values.

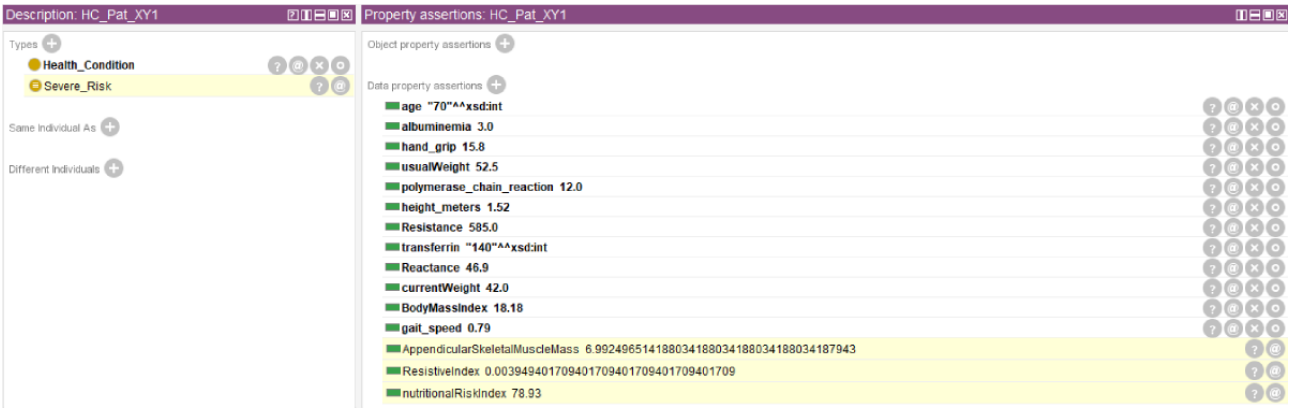


Table 5. An excerpt of the results retrieved for the query investigating, for each patient, their ID, their status (whether they had sarcopenia or cachexia), the stage of chronic obstructive pulmonary disease (COPD), and their nutritional risk index profile. For patients characterized by sarcopenia, all the subclasses of copd:Sarcopenic are illustrated so that clinical personnel can easily see the importance of this condition.

Ontology Use and Updating

The COPD and Nutrition ontology described in the previous subsection is a tested prototype able to classify patients properly and provide clinicians with nutrition-related recommendations. To support clinical personnel, the ontology-based DSS needs to be integrated into digital applications, enabling clinicians to access its functionalities intuitively and easily (as described in the following section). This would also enable the assessment of the usefulness and accuracy of the inferences by leveraging on clinicians outside the development team.

The Application for Clinical Personnel

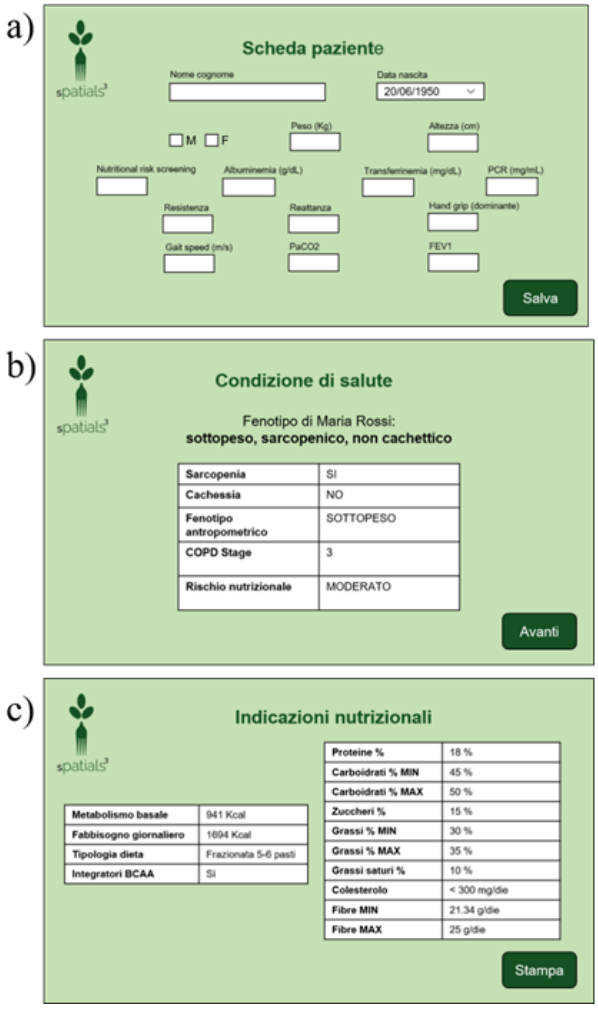
The clinician application was developed to run on a Windows PC or laptop and allows the lung specialist to obtain an overview of the patient's nutritional condition and generate tailored dietary recommendations. To achieve this, the application is connected to the DSS (hosted on a semantic repository) with permission to modify the ontology, reason over new input data, and obtain a new set of dietary recommendations. The application and DSS communication are based on SPARQL queries running over the Stardog reasoner. The entire architecture has already been tested in previous work [24,63].

The application is based on a simple and intuitive graphical user interface (GUI). Its flow is as follows:

1. The clinician logs in to the application either to create a new patient profile or to modify an existing one. The Patient Profile (Scheda Paziente) panel (Figure 3A) has several fields corresponding to the input information needed by the DSS to represent the user's health condition. These include personal data and the results of the patient assessment.
2. Once the new patient profile is saved, the application sends a SPARQL query INSERT to upload the new information into the ontology. The DSS reasons over the new data to obtain the patient's classification and the nutritional recommendations. The output is sent back to the application in the form of a JSON file to populate the GUI panels.

3. The Health Condition (Condizione di Salute) panel, shown in Figure 3B, shows the classification results: metabolic phenotype, presence of sarcopenia and cachexia, anthropometric phenotype, COPD stage, and NRI.
4. The subsequent panel, the Nutritional Recommendations (Indicazioni Nutrizionali), shown in Figure 3C, summarizes the nutritional recommendations, indicating basal metabolism, daily intake, type of diet, suggested BCAA supplement, percentage, and grams of micro- and macronutrients.
5. The clinician can save the recommendations in a PDF file or print them to share them with the dietician to support them in preparing a diet for the patient.

Figure 3. The 3 main graphical user interface panels of the clinician application: (A) patient profile, (B) health condition, and (C) nutritional recommendations.



Preliminary Validation With Clinical Personnel

Overview

Before the implementation in a real use-case scenario, we performed an expert validation of the DSS as a preliminary but necessary step. In total, 2 experiments were performed—considering the multidisciplinary nature of the tool, it was necessary to validate 2 aspects of the DSS with 2 different groups of clinicians.

Therefore, each experiment was carried out by a specific group of clinical experts: (1) a group of nutrition experts validated the recommendations generated by the DSS, and (2) a group of specialists in respiratory diseases evaluated the acceptability of the digital application in clinical practice based on the COPD DSS.

Procedure

Participants were recruited through email invitations among the national experts in nutrition and pulmonology, identified by searching the literature and professional networks. Once they expressed willingness to participate in the study, they signed a written informed consent form and agreed to the data treatment according to the General Data Protection Regulation. In total, 2 experimenters scheduled the web-based video calls—one for each participant—between November 2022 and January 2023. During the test, the experimenters briefly introduced the aim of the system and the main steps of the validation and recorded the participants' answers to brief ad hoc questionnaires and spontaneous comments. Descriptive statistics were calculated for each variable, and the spontaneous comments were analyzed and categorized based on their content.

Experiment 1: Validation of the DSS Recommendations

The first experiment focused on validating the nutritional recommendations generated by the DSS. A total of 7 nutrition experts participated in the validation. The experimenters showed the participants the profiles of 5 real patients and the inferred recommendations. The patient profiles were obtained from real clinical cases provided by the clinicians involved in the project. Each profile included the patient ID, age, gender, and health condition containing all the clinical parameters needed as input to the system.

After presenting the patient's condition, the experimenter showed the recommendations generated by the DSS, which included the patient's inferred classification (metabolic phenotype, presence of sarcopenia or cachexia, anthropometric phenotype, COPD stage, and NRI) and the nutritional recommendations with information on metabolism and suggested quantities of macro- and micronutrients. An example of a patient profile used during the experiment is presented in Figure 4, whereas all the patient profiles used during the evaluation are available in Multimedia Appendix 3. Participants were granted up to 15 minutes to observe the presented patient's health condition. During this time, participants were free to perform calculations using the data shown, ask questions (if necessary) to the experimenter, and consult external sources (eg, books and papers). After the 15-minute period, for each patient, we asked the participants to rate on a scale from 1 to 5 how much they agreed with the recommendation; in case of a score of <5, we asked the participant to provide a brief explanation. We also collected spontaneous comments that emerged during the experiment. The maximum duration of the experiment for each participant was 1 hour and 15 minutes.

Figure 4. An example of a patient profile provided to clinicians (on the left) and the inferences drawn by the ontology-based decision support system (on the right).

21.457	25.0	2.4 grams per day, 6 grams of salt per day	1500	no

Experiment 2: Acceptability Evaluation

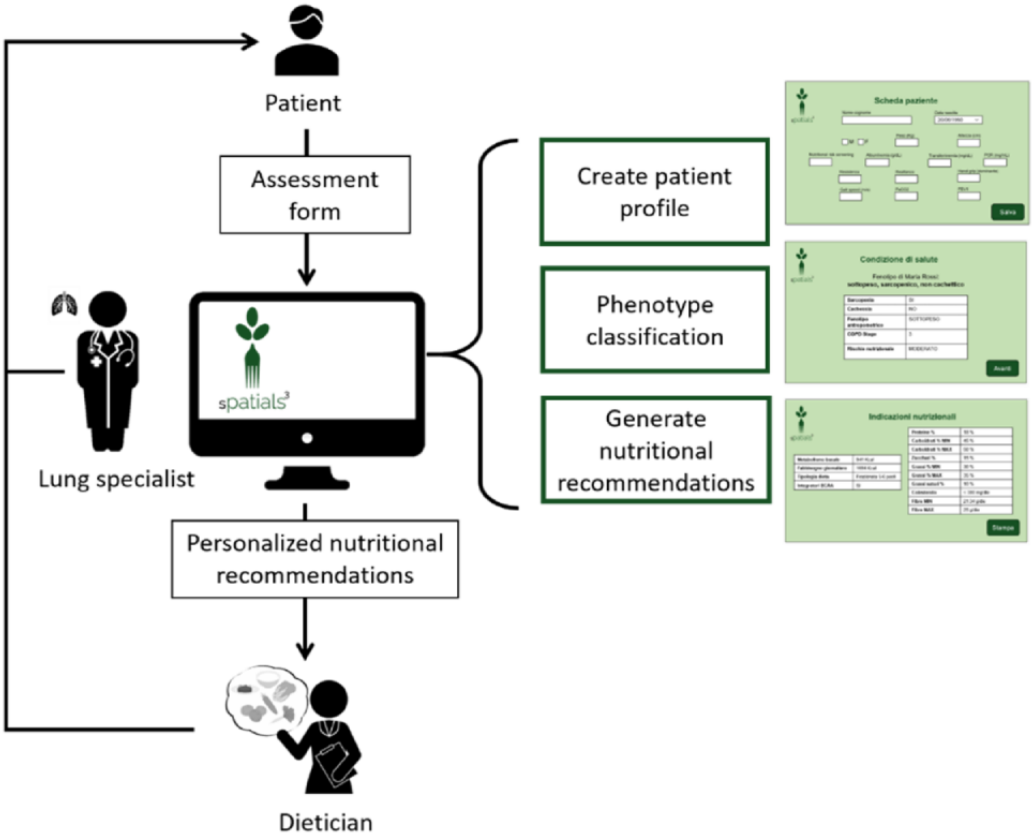
The second evaluation focused on assessing the overall system acceptability, including the DSS and a digital application working as a GUI for inserting patient data and retrieving personalized recommendations. A total of 7 lung specialists agreed to participate in the experiment. The experimenter explained to each participant the expected process of use of the system and the application data flow in a daily clinical routine, as summarized in Figure 5. The lung specialists performed the patient assessment; inserted the clinical data to generate the patient profile on the application GUI, as described in the Application for Clinical Personnel section; and generated the nutritional recommendations**.**

Participants were granted 10 minutes to assess the application, ask the experimenters questions, or ask to be presented with the data flow again.

After this time, the experimenter administered an ad hoc questionnaire based on the subscales of the technology acceptance model by Davis [64] and its subsequent amendments [65] focused on perceived usefulness and intention to use. The participants had to rate on a scale from 1 to 5 the level of agreement with the following statements: (1) "I think that the proposed system is useful for clinicians"; (2) "I think that by using this application could enhance the treatment of individuals with COPD"; and (3) "if I had this application at work, I would use it."

We also asked them to specify at least one reason why the application could be useful or not.

Figure 5. The process of use of the chronic obstructive pulmonary disease decision support system allowing the professionals to generate nutritional recommendations for a specific patient and some screenshots of the main graphical user interface panels (patient profile, patient classification, and nutritional recommendations).



Results

Experiment 1 Results: Validation of the DSS Recommendations

A total of 7 experts (mean age 46.60, SD 13.35 years; n=7, 100% female) participated in the first validation phase. They were all dieticians with an average of 25.57 (SD 11.49) years of professional experience. The level of agreement with each recommendation is reported in Table 6 in terms of mean, SD, and minimum and maximum score.

The comments provided by each participant were analyzed and categorized according to their content. The categorization and frequency of the comments and the patient profiles that originated them are reported in Table 7.

Table 6. Validation—level of agreement scores (mean and SD) for each patient profile (BB, FG, LA, TM, and XY2 are the patient IDs) expressed by each participant; mean and SD for each patient profile.

	Scores (1-5)							Values, mean (SD)
BB	5	4	5	5	3	4	5	4.43 (0.79)
FG	5	1	4	2	3	4	4	3.29 (1.38)
LA	5	4	5	5	4	4	4	4.43 (0.53)
TM	5	4	5	5	3	4	5	4.43 (0.79)
XY2	5	4	5	5	4	4	5	4.57 (0.53)

Table 7. The list of comments provided by clinicians categorized according to their content (category and comment) and linked to the patients that originated them (patient IDs); the frequency of each comment is reported in parentheses.

Category	Comment	Patient ID (frequency)
Quantity	"Too high-calorie uptake"	BB (1), FG (6), TM (1), and ANM (1)
Quantity	"Too high protein uptake"	FG (2) and LA (2)
Quantity	"Consider reducing simple sugars from 15 to 10%"	FG (1), LA (1), TM (2), and ANM (1)
Assessment	"I suggest including the physical activity level during the assessment and adjust correction factors accordingly"	All (2)

Experiment 2 Results: Acceptability Evaluation

A total of 7 experts (mean age 44.71, SD 11.94 years; n=7, 100% female) participated in the second validation phase. Of the 7 experts, 5 (71%) were lung specialists, 1 (14%) was a specialized lung physician, and 1 (14%) was a surgeon of the respiratory system. They had, on average, 14.73 (SD 9.67) years of professional experience, ranging from a minimum of 1 year for the specialized physician to 31 years. The acceptability score for the 3 subscales of perceived usefulness and intention to use was >4 points out of 5, as reported in Table 8.

Our system was considered useful for clinical practice because (1) it promotes the importance and facilitates the inclusion of the nutritional aspect in PR, as stated by 43% (3/7) of the participants; (2) it quickly provides a complete overview of the patient's condition, according to 57% (4/7) of the participants; and (3) it fosters the multidisciplinary collaboration between lung specialists and dieticians. In addition, 86% (6/7) of the participants spontaneously commented on the ease of use of the application GUI that allowed the clinician to insert the patient assessment and obtain the nutritional recommendations.

Table 8. Acceptability—technology acceptance model subscale scores reported by each participant for perceived usefulness (PU1 and PU2) and intention to use (INT); mean and SD are reported for each subscale.

	Scores (1-5)							Values, mean (SD)
INT	4	4	4	5	4	4	4	4.86 (0.38)
PU1	5	5	5	5	4	5	5	4.86 (0.38)
PU2	5	5	5	5	5	5	4	4.14 (0.38)

Discussion

Principal Findings

We performed 2 types of evaluation with 2 different experiments aimed at validating the nutritional recommendations generated by our system by nutrition experts and assessing the system's acceptability by lung specialists. The first validation—performed by 7 nutrition experts—demonstrated that our system is able to provide meaningful and safe recommendations overall in compliance with clinical practice. In 80% (4/5) of the cases, the level of agreement between the human and the "digital" expert was approximately 4.5 points out of 5. In one case (patient FG), the experts did not completely agree with the recommendations, reporting a score of 3.29, which is not considered a disagreement. However, such a score was associated with the case of a critical patient who, in addition to COPD, had second-degree obesity. This is because our system is highly specialized in treating patients with COPD, who need a higher energy intake to cope with impaired respiratory functionality. In such critical cases, the active involvement of the clinician in the process becomes essential. For instance, the clinician may adjust the nutritional recommendations for the patient to lose weight while monitoring them. It is crucial that such a patient does not lose muscular mass instead of fat mass.

The comments were positive overall and could be considered more as suggestions than criticisms. The presence of small disagreements among experts (eg, regarding the calculation of the quantity of macro- and micronutrients) confirms the need for maintaining "the clinician in the loop," as prescribed by the AgiSCOnt methodology adopted for the development of our DSS. In fact, although our system provides a useful and easy way of generating recommendations, each clinical case should be carefully considered, and slight modifications should be made by the clinician themselves in person.

The same considerations apply to the spontaneous comments, summarized in Table 7. The main concerns were about the percentage of simple sugars, which, for 4 patients, could be reduced from 15% to 10%. The guidelines indicate 15% as the maximum value, which should be adjusted by the clinician based on the percentage of other macronutrients. The other comments revealed a slight disagreement on the overall energy and protein intake, which was sometimes considered too high. However, our system is specifically focused on COPD; therefore, a higher intake was justified by the need to compensate for impaired respiratory function. Our group of experts was representative of the Italian clinical scenario, in which the influence of COPD on a patient's nutrition is sometimes neglected. Therefore, such a result strengthens the rationale of our work, which provides a system able to help professionals and clinical care facilities, which often lack specialized services, identify particular needs toward more personalized and effective care.

The second evaluation demonstrated the acceptability of our system by a group of final users (ie, lung specialists involved daily in the assessment and therapy of patients with COPD). The usefulness of our system was confirmed and was especially

related to the possibility of strengthening the consideration of nutritional aspects as part of PR standard practice. This is considered crucial by most specialists and the scientific community; however, due to organizational issues, it is not always considered [4]. Another crucial aspect that emerged was related to the importance of a multidisciplinary approach, and our system could especially help ease the cooperation between lung and nutrition specialists. At the same time, it could help lung professionals in extending their knowledge by considering aspects not strictly related to their expertise. Finally, all participants expressed their willingness to have such a system available in their daily clinical routine. They also considered it easy to use as the GUI was clear and the process was intuitive.

Limitations

This work is not without limitations. First, our system was designed for the Italian context. The DSS is based on the national nutritional guidelines—it was necessary to follow a recognized standard, which may be different from one country to another. Similarly, the dietary recommendations are based on the Italian diet. This was necessary to provide a tool that can be effectively used by our target users (ie, lung specialists treating patients with COPD in the Italian health care system). The DSS's modularity allows it to overcome such a limitation easily—the DSS could be adapted to include nutritional recommendations for other countries. The second limitation is about the participants of our validation experiments. The first experiment was based on the evaluation of 5 patient profiles by a group of nutrition experts. The number of patients examined was identified as the best compromise between a comprehensive representation of the clinical context and organizational aspects. Despite being few, the proposed patient profiles covered most of the potential real clinical cases. Regarding the acceptability evaluation, the main limitation resides in the fact that participants were homogeneous in terms of age (most of them were aged 45-50 years), culture, geographical location, and language (all of them were Italian). Such sociocultural factors are known to impact digital health technology use [66]; however, as previously stated, our work at this stage is focused on the Italian scenario, and therefore, our sample can be considered representative of the final population of target users.

Future Work

As recently noted, most digital health applications remain limited to pilot studies—mainly because they fail in the proposed aims or face significant implementational barriers [67]. From a digital health application perspective, our experiments aimed to verify the stability of the developed solution—in line with the WHO's guidelines [23]. In particular, the validations verified the performance consistency, the proposed solution's overall feasibility, and the digital tool's efficacy. Considering the early stage of the DSS and its application, we need to further investigate the implementation protocols and to acquire long-term proof of the efficacy of the tool among pneumologists and patients with COPD (ie, the acceptability of the tool needs to be verified with a larger sample of end users and in a real clinical setting so that more pneumologists can provide feedback regarding the tool's perceived usefulness, ease of use, and satisfaction; moreover, the effectiveness of the proposed diets should be tested with patients with COPD). To achieve these objectives, more extensive experimentation with larger samples of participants (clinical nutritionists, dieticians, and pneumologists) is necessary. Moreover, the involvement of clinical personnel can support the identification of implementation protocols suitable for the adoption of the digital tool in clinical practice. In this way, the application's level of maturity could move from early to mild (according to the WHO [23]), where its effectiveness can be tested in a nonresearch (uncontrolled) setting.

To support the prompt identification of barriers and implementational challenges, reporting the development of the COPD DSS within a framework for the definition of digital health application implementation can be useful. In particular, the Guidelines and Checklist for the Reporting on Digital Health Implementations [67], by providing a list of 20 items to be monitored, can foster the identification of issues in the Technical design phase in the Interoperability and Data management areas.

In this regard, the availability of data and the implementation of the application within the health system are another relevant node to be investigated. Although the current version of the digital application is still in its prototypical phase, scaling up the application to the regional or national level (ie, *coverage* in the Guidelines and Checklist for the Reporting on Digital Health Implementations) is essential to ensure its use in clinical practice. Therefore, toward this aim, strategies for collecting the outputs and making them available in patients' data (or electronic health records) need to be investigated. In this regard, scientific literature offers some interesting approaches grounded in the Italian health care system that could be considered to make the COPD DSS interoperable with existing tools [68-70]. As the COPD DSS leverages ontologies to represent its data, this technology can be used to achieve semantic interoperability of the information [68], moving a step toward the longitudinal collection of health data about patients [70] while ensuring data protection according to the national and European laws [69].

Finally, from an ontological perspective, the domain ontology regarding COPD presented in this work could benefit from mapping with existing (and larger) biomedical standard ontologies to increase its shareability (eg, the WHO's International Classification of Diseases and International Classification of Functioning, Disability and Health, as well as upper biomedical ontologies)—a best practice of ontology engineering [71]. Moreover, considering that the proposed system can be adapted to any other national clinical context by modifying the domain ontologies, a possible future research direction consists of involving international clinicians to increase the knowledge formalized in the ontologies so that it is possible for the DSS to cover the specific nutritional indications of different countries.

Conclusions

The role of nutrition in the management of patients with COPD is often underestimated, although scientific evidence points toward the important role that diet plays in PR. The nutritional status of patients with COPD is essential to prevent exacerbations and avoid comorbidities, but attention to the patient's body composition and nutritional status is often

secondary in clinical practice. This may be partially because lung specialists may lack specialized training in clinical nutrition, although they recognize the relevance of dietary recommendations in PR.

An ontology-based DSS was developed to support pneumologists in considering nutritional aspects. The DSS formalizes expert knowledge in computable models able to infer patient-tailored nutritional recommendations, leveraging a set of information to capture the nutritional and physical status of the patient; therefore, by applying rules, it can support the classification of patients with COPD and provide tailored recommendations indicating the percentages and amounts of micro- and macronutrients that should make up their diet. The domain ontologies act as the backbone of a clinician-dedicated application.

The application was validated to assess the clinical compliance of the DSS's recommendations and the acceptability of such an application in clinical practice by lung specialists. For both validations, the proposed system performed more than adequately—in particular, pneumologists underlined the role that such an application may play in achieving a multidisciplinary approach in PR. This paper concludes by investigating future research directions to implement the COPD DSS further into a fully-fledged digital health application.

Abstract

Background: Out-of-hours primary care (OOH-PC) is challenging due to high workloads, workforce shortages, and long waiting and transportation times for patients. Use of video enables triage professionals to visually assess patients, potentially ending more contacts in a telephone triage contact instead of referring patients to more resource-demanding clinic consultations or home visits. Thus, video use may help reduce use of health care resources in OOH-PC.

Objective: This study aimed to investigate video use in telephone triage contacts to OOH-PC in Denmark by studying rate of use and potential associations between video use and patient- and contact-related characteristics and between video use and triage outcomes and follow-up contacts. We hypothesized that video use could serve to reduce use of health care resources in OOH-PC.

Methods: This register-based study included all telephone triage contacts to OOH-PC in 4 of the 5 Danish regions from March 15, 2020, to December 1, 2021. We linked data from the OOH-PC electronic registration systems to national registers and identified telephone triage contacts with video use (video contact) and without video use (telephone contact). Calculating crude incidence rate ratios and adjusted incidence rate ratios (aIRRs), we investigated the association between patient- and contact-related characteristics and video contacts and measured the frequency of different triage outcomes and follow-up contacts after video contact compared to telephone contact.

Results: Of 2,900,566 identified telephone triage contacts to OOH-PC, 9.5% (n=275,203) were conducted as video contacts. The frequency of video contact was unevenly distributed across patient- and contact-related characteristics; it was used more often for employed young patients without comorbidities who contacted OOH-PC more than 4 hours before the opening hours of daytime general practice. Compared to telephone contacts, notably more video contacts ended with advice and self-care (aIRR 1.21, 95% CI 1.21-1.21) and no follow-up contact (aIRR 1.08, 95% CI 1.08-1.09).

Conclusions: This study supports our hypothesis that video contacts could reduce use of health care resources in OOH-PC. Video use lowered the frequency of referrals to a clinic consultation or a home visit and also lowered the frequency of follow-up contacts. However, the results could be biased due to confounding by indication, reflecting that triage GPs use video for a specific set of reasons for encounters.

Introduction

General practice serves as a gatekeeper to secondary care in many countries [1]. However, the services in out-of-hours primary care (OOH-PC) are challenging due to high workloads, workforce shortages, and long waiting and transportation times for patients. This development has received much political attention and has caused public debate and reorganization [2,3].

Existing health care systems are currently undergoing a digital transformation, which was pushed by the COVID-19 pandemic [4-9]. As a central part of this digitization, video consultations have been implemented broadly in general practice [5,8-12]. Many countries have introduced video as part of telephone triage in OOH-PC [12-14]. Video use enables triage professionals to visually assess patients, which may imply that more contacts can be ended in a telephone triage contact instead of referring patients to clinic consultations or home visits, which demand more resources. Thereby, video use might reduce use of health care resources related to clinic consultations and home visits.

Research has shown that patients welcome the use of video in general practice in the daytime and also after hours [4,14-16]. However, in daytime general practice, general practitioners (GPs) experience both benefits of (eg, care delivery) and barriers to (eg, technical difficulties, varying suitability for different

health problems and patient groups) video use [6,10,16-19]. Two qualitative studies indicated that video use in OOH-PC is beneficial to both triage professionals (eg, it improved patient assessment and reassurance) [13,14] and patients (eg, it led to better reassurance and higher satisfaction) [14]. Two register-based studies found that video use in OOH-PC increased during the COVID-19 pandemic [12,20]. However, little is still known about video use and its effects. This study aimed to investigate video use in telephone triage contacts to OOH-PC in Denmark by studying rate of use and potential associations between video use and patient- and contact-related characteristics and between video use and triage outcomes and follow-up contacts.

Methods

Design and Population

We conducted a register-based study of video use in telephone triage contacts to OOH-PC in 4 of the 5 Danish regions (North Denmark Region, Central Denmark Region, Region of Southern Denmark, and Region Zealand). As the Capital Region of Denmark runs a different OOH-PC system than the other 4 regions, this region was not included in this study. We included all telephone contacts from March 15, 2020, to December 1, 2021, and followed each patient for 7 days to record the outcomes. In Region Zealand, telephone contacts were included from March 1, 2021, because this region started using video from this date.

Setting

Denmark has free public health care for its residents. The health care system is centrally regulated, but most services are provided by the local governments of the 5 regions. Outside office hours, Danish GPs and GP trainees cover shifts in the regional OOH-PC service, which is open on weekdays from 4 PM to 8 AM and 24 hours during weekends and holidays. GPs and GP trainees in their last year of specialist training (hereinafter referred to jointly as triage GPs) perform telephone triage and determine the triage outcome: telephone triage with video use (video contacts) or telephone triage without video use (telephone contacts), clinic consultation, home visit, or hospital admission. The triage GPs assesses whether the problem is suitable for a video contact. If so and if the patient approves, a video link is sent to the patient via text message. When the link is activated, the triage GP can see the patient, but the patient cannot see the triage GP. Triage GPs are paid a fee for service using remuneration codes.

Outcome Measures

The following outcome measures were defined: the proportion of video contacts (number of video contacts per 100 telephone contacts); the association between video contact and patient- and contact-related characteristics (sex and age of the patient, cohabitation status, comorbidity, educational level, ethnicity, income, urbanization, employment status, region, and time of contact); the frequency of triage outcomes (advice and self-care, referral to clinic consultation, home visit, or hospital admission) and their association with video contact; and the frequency of follow-up contacts in daytime general practice or OOH-PC within 7 days or a hospital admission within 1 day and their association with video contact.

Data Collection

We used data from the OOH-PC electronic registration system, which provided information on date, time, region, type of contact (telephone contact or video contact), and triage outcome (advice and self-care, referral to clinic consultation, home visit, or hospital admission). We constructed a "time of contact" variable, which was defined by its relation to the next opening time of daytime general practice and dichotomized into >4 hours or ≤4 hours, as the option to refer a patient to their regular GP may influence the triage decision.

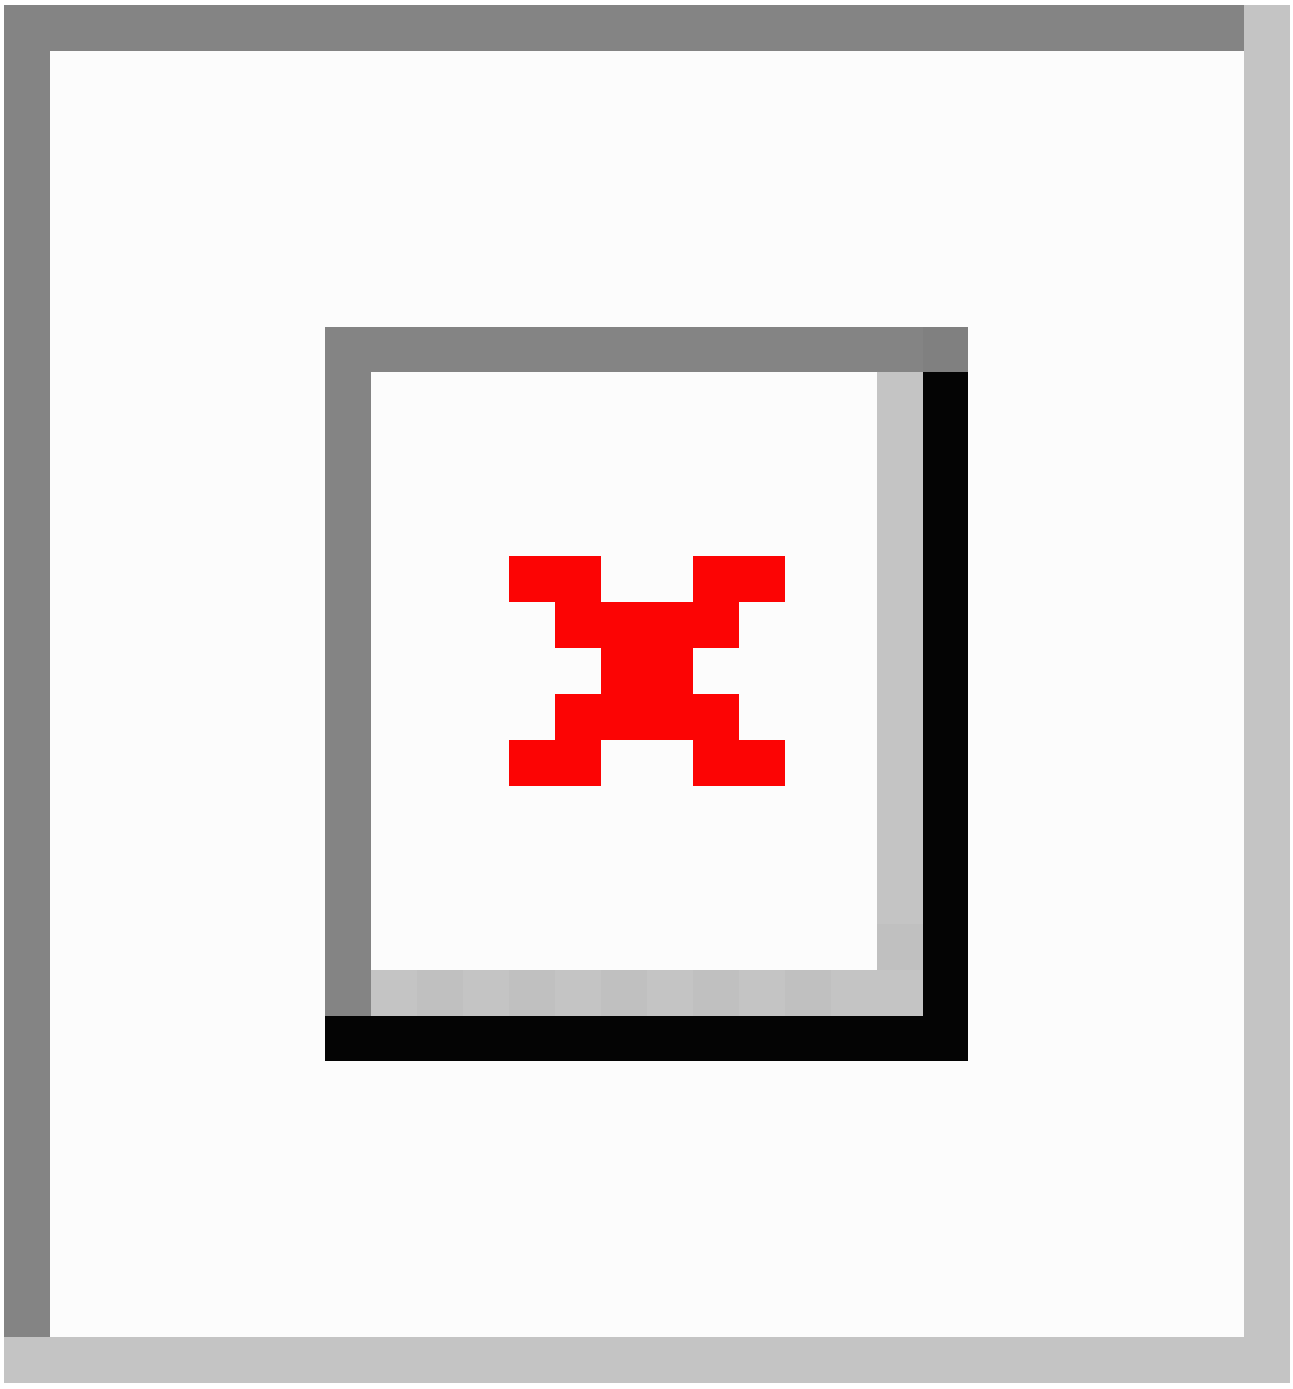
To investigate follow-up contacts, we linked data from the OOH-PC registration system to 2 Danish national registers using each patient's unique personal identification number [21]. The Danish National Health Service Register [22] provided information on date and type of contact to daytime general practice (telephone contacts, video contacts, clinic consultations, or home visits). The Danish National Patient Registry [23] provided information on date of contact to the hospital (emergency department visits and unscheduled hospital admissions) and comorbidity. Comorbidity was defined as the number of diagnoses from the Charlson Comorbidity Index that were recorded as diagnosis codes in hospital charts. Data on socioeconomic characteristics of the patients (sex, age, cohabitation status, educational level, ethnicity, income, urbanization, and employment status) were obtained from Statistics Denmark [24]. All covariates (except for age, sex, and comorbidity) were reported at the household level. For example, household educational level was determined by the member with the longest education. Hence, it was possible to avoid excluding contacts involving children because of missing values. We included only persons with registered socioeconomic characteristics.

Data Analyses

People with more than 25 contacts to OOH-PC during the study period (comprising 98,126/2,900,566 contacts, 3.4%) were excluded from the data analyses since they were considered outliers. Likewise, people aged >104 years (162/2,900,566 contacts, 0%) and patients with missing covariates (18,740/2,900,566 contacts, 0.7%) were excluded.

Descriptive analyses were used to describe the study population. To ensure convergence of the regressions, we used Poisson regression models to measure the association between patient- and contact-related characteristics and video contacts, and we calculated incidence rate ratios (IRRs) and 95% CIs [25]. Results are presented as a forest plot (Figure 1). Using a Poisson regression model, we also calculated crude and adjusted IRRs (aIRRs) of triage outcomes and follow-up contacts after a video contact compared to after a telephone contact. IRRs were adjusted for patient- and contact-related characteristics. Stata (version 17; StataCorp) was used to analyze all data. Reporting of results was conducted in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement.

Figure 1. Forest plot presenting the association between patient- and contact-related characteristics and the likelihood of having a video contact (incidence rate ratios [IRRs] with 95% CIs). An IRR >1 indicates a higher use of video contacts compared to the reference group, marked in the right column of the figure. Conversely, an IRR <1 indicates a lower use of video contacts.



Ethical Considerations

The Committee on Health Research Ethics in the Central Denmark Region approved the data collection from the electronic patient records in the OOH-PC registration system (1-45-70-22-22) without informed consent from participants or any provision for them to opt out. The study was listed in the record of processing activities at the Research Unit for General Practice in Aarhus in accordance with the provisions of the General Data Protection Regulation (GDPR). All data on participants were deidentified. Finally, conduct of the study was endorsed by the regional association of GPs.

Results

Study Population

During the study period, 2,900,566 telephone triage contacts to OOH-PC were identified (Table 1). Patient- and contact-related characteristics varied between telephone and video contacts; the largest variation was seen for patient age, comorbidity, employment status, region, and time of contact.

Table . Distribution of patient- and contact-related characteristics (N=2,900,566).

Characteristics		Telephone contacts (n=2,625,363, 90.5%), n (%)	Video contacts (n=275,203, 9.5%), n (%)	Total (n=2,900,566, 100%), n (%)

Proportion of Video Contacts

During the study period, 9.5% (275,203/2,900,566) of telephone triage contacts to OOH-PC were video contacts. After the introduction of video, a range of 5%-15% video contacts was achieved within weeks across all regions. This level remained stable throughout the study period (data not shown).

Association Between Video Contact and Patient- and Contact-Related Characteristics

The frequency of video contacts was unevenly distributed across patient- and contact-related characteristics. The strongest associations were seen for age, comorbidity, employment status, region, and time of contact (Figure 1). Patients aged <20 years had a notably higher frequency of video contacts than patients aged 21 to 40 years (aIRR range: 2.39-1.31). This was also the case for employed compared to unemployed patients (aIRR 1.21). The frequency of video contacts was significantly higher for contacts to OOH-PC at more than 4 hours before the opening of daytime general practice (aIRR 1.40; reference: ≤4 hours), and was more frequent in the Region of Southern Denmark (aIRR 1.55; reference: North Denmark Region). In contrast, the frequency of video contacts was significantly lower for patients >40 years (aIRR range: 0.40-0.90; reference: 21-40 years), patients with comorbidities (aIRR range 0.59-0.90; reference: no comorbidities), and retired patients (aIRR 0.66; reference: unemployed). The frequency of video contacts was also significantly lower in Region Zealand (aIRR 0.73; reference: North Denmark Region).

Triage Outcomes

Patients receiving a video contact had a significantly higher frequency of ending the contact with advice and self-care compared to patients receiving a telephone contact (aIRR 1.21, 95% CI 1.21-1.21) (Table 2). Conversely, patients receiving a video contact had a significant lower frequency of being referred to a clinic consultation (aIRR 0.59, 95% CI 0.59-0.60) or a home visit compared to patients receiving a telephone contact (aIRR 0.31, 95% CI 0.29-0.32). The frequency of being admitted to a hospital was significantly higher after a video contact compared to a telephone contact (aIRR 1.20, 95% CI 1.17-1.23).

Table . Frequency of triage outcomes and their association with video contacts (incidence rate ratio).

Outcome	Telephone contacts (n=2,625,363), n (%)	Video contacts (n=275,203), n (%)	Total (n=2,900,566), n (%)	Incidence rate ratio (95% CI)	
				Crude	Adjusted[a]
Advice and self-care	1,663,681 (63.4)	215,484 (78.3)	1,879,567 (64.8)	1.24 (1.23-1.24)	1.21 (1.21-1.21)
Clinic consultation	712,255 (27.1)	49,262 (17.9)	759,948 (26.2)	0.66 (0.66-0.67)	0.59 (0.59-0.60)
Home visit	165,052 (6.3)	1926 (0.7)	168,233 (5.8)	0.12 (0.11-0.12)	0.31 (0.29-0.32)
Hospital admission	84,375 (3.2)	8531 (3.1)	92,818 (3.2)	0.95 (0.93-0.97)	1.20 (1.17-1.23)

[a]Adjusted for patient sex, age, cohabitation status, comorbidity, educational level, ethnicity, income, urbanization, employment status, region, and time of contact.

Follow-Up Contacts

In general, patients receiving a video contact had a significantly higher frequency of no follow-up contact compared to patients receiving a telephone contact (aIRR 1.09, 95% CI 1.08-1.09) (Table 3). For those who had a follow-up contact, the patients who received a video contact had a significantly higher frequency of having a follow-up contact with their regular GP compared to those receiving a telephone contact (aIRR 1.02, 95% CI 1.01-1.03). Conversely, patients receiving a video contact had a significant lower frequency of a follow-up contact in OOH-PC (aIRR 0.96, 95% CI 0.95-0.97) or at the hospital (aIRR 0.75, 95% CI 0.74-0.76) compared to patients receiving a telephone contact.

Table . Frequency of follow-up contacts and association between use of video contacts and subsequent follow-up contacts (incidence rate ratio).

Type of follow-up contact	Telephone contacts (n=2,625,363), n (%)	Video contacts (n=275,203), n (%)	Total (n=2,900,566)	Incidence rate ratio (95% CI)	
				Crude	Adjusted[a]
No follow-up	1,097,402 (41.8)	137,601 (50)	1,232,741 (42.5)	1.20 (1.19-1.20)	1.09 (1.08-1.09)

[e]All nonscheduled hospital contacts (emergency department visits and hospital admissions) within 1 day from the index contact to OOH-PC.

Discussion

Principal Results

Video was used in 9.5% (275,203/2,900,566) of all telephone triage contacts to OOH-PC. Video contacts were unevenly distributed across patient- and contact-related characteristics; video contacts were more often used for patients who were employed, young, without comorbidities, and contacting OOH-PC more than 4 hours before the opening hours of daytime general practice. Compared to telephone contacts, significantly more video contacts ended with advice and self-care and significantly fewer had follow-up contacts.

Strengths and Limitations

This study was based on a large data set, including codes for remuneration by GPs. The economic incentive for GPs to register all services provided contributed to the completeness of the data, though validity has not been studied [22].

Our study also had some limitations. First, we had no information on the reasons for encounters (RFEs), as this is not systematically registered in OOH-PC contacts. In each telephone triage contact, the triage GP assessed the relevance of video use based on the current RFE balanced against the specific patient- and contact-related characteristics. Therefore, telephone contacts and video contacts had different diagnostic scope, which could have influenced the differences found in triage outcome and follow-up contacts through confounding by indication. Second, we followed each patient for 7 days to record follow-up contacts to OOH-PC and to daytime general practice, as previously described in the literature [26]. This led to an overestimation of follow-up contacts, as we could not link these follow-up contacts to the index contact in OOH-PC using the RFE. However, any overestimation would be independent of type of contact. Finally, we used the Charlson Comorbidity Index to define comorbidity based on hospital diagnosis codes. This approach might have led to an underestimation of comorbidity [27], as patients with mild chronic diseases are often treated solely in general practice.

Several factors must be considered when generalizing the results of this study. First, the study period was defined according to the date of initiation of video contact in each of the regions. Therefore, the regions were included in different periods of the COVID-19 pandemic, and they had different contact patterns to primary care both inside and outside office hours [8,12,20,28] and probably also different distributions of triage outcomes. Second, triage GPs perform telephone triage with no decision support tool in Danish OOH-PC; this is unlike most countries with comparable OOH-PC services, which often use other health care professionals with decision support systems [3]. Compared to other triage professionals, GPs may be able to triage more patients via video contact. Lastly, Danish triage GPs were remunerated on a fee-for-service basis. As the fee for a video contact was higher than the fee for a telephone contact, this could have been an incentive to aim for a higher share of video contacts in this setting compared to countries with other payment structures.

Comparison With Prior Work

We found a 9.5% rate of use of video contacts to OOH-PC. To our knowledge, no previous studies used a data collection period of this length to report on video use in OOH-PC. Studies on

changing contact patterns in OOH-PC during the COVID-19 pandemic have found an overall increase in telehealth consultations (email, video, or telephone) [8,12,28]. Video use in daytime general practice has previously been reported to range from 1% to 6.4% [15,29-32]. However, as patient populations and RFEs are known to differ between daytime general practice and OOH-PC [33], these results cannot be compared with our findings. Furthermore, video contacts in OOH-PC guide triage professionals in the assessment of patients and in improving patient reassurance [13,14]. In contrast, video contact has often been used as a substitute for clinic consultations in daytime general practice for practical reasons, for example, to reduce travel time or limit the risk of contamination, but both patients and GPs seem to prefer in-person consultations in the postpandemic era [10,13,18].

Our study showed that video contacts were used more often for employed young patients without comorbidities. To the best of our knowledge, this is the first study to report on associations between patient- and contact-related characteristics and video contacts in OOH-PC. Studies conducted in daytime general practice have found higher video rates of use during COVID-19 lockdown periods [34] and among people from socioeconomically advantaged areas [34,35]. Previous studies have reported inconsistent results on the association between patient age and video use, as higher use has been reported for both younger [32,35] and older patients [30]. Moreover, daytime video use seems to be associated with patients with high morbidity [36] compared to patients with low morbidity. These findings are not in line with our study results, which could be due to differences in patient populations between daytime general practice and OOH-PC [33]. Furthermore, some previous studies were conducted during the peak of the COVID-19 pandemic, and different countries have different health care systems and had different approaches to tackling the pandemic.

We found that video contacts more often ended with advice and self-care and no follow-up contact compared to telephone contacts. Two qualitative studies investigating the effect of video contacts on the patient flow in daytime general practice found that GPs experience uncertainties when referring patients to secondary care after a video contact [9,37]. A UK study on follow-up contact after using a video contact service (used by hospitals, daytime general practices, and other services) found no significant difference in the number of subsequent referrals compared to telephone contacts [38]. However, these studies focused on video use in the daytime rather than on telephone triage in OOH-PC.

Implications for Practice and Future Research

Our study suggests that video contacts could help reduce the use of health care resources in the OOH-PC setting by lowering the number of subsequent clinic consultations and home visits. More studies are needed on the effect of video contact on patient flow. First, further research is needed to investigate the impact of video contact in relation to different RFEs. Second, future studies should explore if the findings of this study are maintained in the postpandemic period and across different OOH-PC organizations. Third, future studies should investigate if the video option might generate more contacts to OOH-PC overall. Fourth, our study indicates an association between video contacts and specific patient characteristics: video was more often used for employed young patients without comorbidities. This finding contrasts with most studies in daytime general practice and should be further investigated. Finally, it is important to note that we did not study costs associated with video use and its effects on resource use. Therefore, future studies should investigate the costs as well.

Conclusion

This study supports our hypothesis that video contacts could reduce use of health care resources in OOH-PC. Video use lowered the frequency of referrals to a clinic consultation or home visit and also lowered the frequency of follow-up contacts. However, the results could be biased due to confounding by indication, reflecting that triage GPs use video for a specific set of RFEs.

Acknowledgments

We gratefully acknowledge the financial support for this study provided by the Danish Health Insurance Foundation (Sygeforsikringen danmark), the General Practice Research Foundation of the Central Denmark Region (Praksisforskningsfonden), and the Department of Public Health, Aarhus University. The funding bodies had no role in the study design, data collection, data analysis, data interpretation, writing of the manuscript, or submission of the final article.

Authors' Contributions

All authors contributed to the study design, interpretation of results, and drafting and revising of the manuscript. MAN and CHV conducted the data management and the statistical analysis. All authors have agreed to the final submitted version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The Hispanic community represents a sizeable community that experiences inequities in the US health care system. As the system has moved toward digital health platforms, evaluating the potential impact on Hispanic communities is critical.

Objective: The study aimed to investigate demographic, socioeconomic, and behavioral factors contributing to low telehealth use in Hispanic communities.

Methods: We used a retrospective observation study design to examine the study objectives. The COVID-19 Research Database Consortium provided the Analytics IQ PeopleCore consumer data and Office Alley claims data. The study period was from March 2020 to April 2021. Multiple logistic regression was used to determine the odds of using telehealth services.

Results: We examined 3,478,287 unique Hispanic patients, 16.6% (577,396) of whom used telehealth. Results suggested that patients aged between 18 and 44 years were more likely to use telehealth (odds ratio [OR] 1.07, 95% CI 1.05-1.1; *P*<.001) than patients aged older than 65 years. Across all age groups, patients with high incomes were at least 20% more likely to use telehealth than patients with lower incomes (*P*<.001); patients who had a primary care physician (*P*=.01), exhibited high medical usage (*P*<.001), or were interested in exercise (*P*=.03) were more likely to use telehealth; patients who had unhealthy behaviors such as smoking and alcohol consumption were less likely to use telehealth (*P*<.001). Male patients were less likely than female patients to use telehealth among patients aged 65 years and older (OR 0.94, 95% CI 0.93-0.95; *P*<.001), while male patients aged between 18 and 44 years were more likely to use telehealth (OR 1.05, 95% CI 1.03-1.07; *P*<.001). Among patients younger than 65 years, full-time employment was positively associated with telehealth use (*P*<.001). Patients aged between 18 and 44 years with high school or less education were 2% less likely to use telehealth (OR 0.98, 95% CI 0.97-0.99; *P*=.005). Results also revealed a positive association with using WebMD (WebMD LLC) among patients aged older than 44 years (*P*<.001), while there was a negative association with electronic prescriptions among those who were aged between 18 and 44 years (*P*=.009) and aged between 45 and 64 years (*P*=.004).

Conclusions: This study demonstrates that telehealth use among Hispanic communities is dependent upon factors such as age, gender, education, socioeconomic status, current health care engagement, and health behaviors. To address these challenges, we advocate for interdisciplinary approaches that involve medical professionals, insurance providers, and community-based services actively engaging with Hispanic communities and promoting telehealth use. We propose the following recommendations: enhance access to health insurance, improve access to primary care providers, and allocate fiscal and educational resources to support telehealth use. As telehealth increasingly shapes health care delivery, it is vital for professionals to facilitate the use of all available avenues for accessing care.

Introduction

Health inequities among people of racial and ethnic minority groups are a significant concern across the United States of America. The Hispanic or Latino (hereafter “Hispanic”) population is a community that experiences inequities in access to care. However, health inequities in the United States of America are primarily compared between non-Hispanic White and non-Hispanic Black populations, with some positioning of

the Hispanic population. Therefore, we must highlight the needs of the Hispanic community as a matter of priority. A previous study suggested that health inequities between non-Hispanic Black and Hispanic people are similar in health risks and outcomes [1]. Boen and Hummer [1] attributed much of the similarities to the influence of socioeconomic status and stress in these communities. Social determinants of health significantly impact the health and wellness of people of color. In addition, the inequity in health outcomes is confounded by challenges in access to care. Gaining access to and using health care services is essential to mitigating adverse health outcomes and promoting equity in quality care [2]. Low access to health care services is due to a complexity of factors, which include a lack of insurance, education, and fiscal resources [2]. Non-Hispanic White women and men experienced greater usage of care, 83% and 74%, respectively; among Hispanic individuals, women had higher usage rates than men, 68% and 50%, respectively; however, they still fall short of their non-Hispanic White counterparts [2].

While there are considerable efforts to decrease inequities in health care access, recent events such as the proliferation of technology in health care and the global COVID-19 pandemic eclipse equity in access efforts. COVID-19 accelerated the use of telehealth, which was essential to access health care information and services [3]. Telehealth was highly encouraged to mitigate the ill effects of the contagion and support lockdown measures. While other racial and ethnic communities experienced telehealth growth, the Hispanic population experienced relatively lower amounts of telehealth increases and had a disproportioned rise in the use of health care resources [4-7]. When compared to non-Hispanic White individuals, Hispanic patients had lower usage of telehealth services (27% and 6.8%, respectively) [8]. Telehealth usage among Hispanic people fell below that of their non-Hispanic Black counterparts. Hispanic people showed lower adjusted odds of using telehealth when compared to non-Hispanic Black persons before and during the pandemic [9,10]. However, Hispanic patients and people in low-income positions had increased levels of telehealth use during the pandemic [11]. People who experience inequities in access are more likely to have unmet health care needs and have a higher prevalence of morbidity and mortality rates [12]. The lack of telehealth usage was a critical issue during this time. Qian et al [13] found higher rates of COVID-19 cases in regions with low telehealth use. Given the lack of telehealth usage and reduced access to in-person services during the pandemic, it is reasonable to assume that overall health outcomes were compromised.

Research suggested that telehealth use differed by demographics such as gender, age, and education [14]. Studies have noted gender differences in telehealth use, as male participants are less likely to use telehealth than female participants [3,9,15,16]. Among racial and ethnic groups, Hispanic patients often opt for in-person rather than telehealth visits [5,10]. Whether a patient has access to and knowledge to use telehealth depends on socioeconomic factors [5]. Ramirez et al [5] observed that the Hispanic community had lower telehealth use due to cultural perceptions, inadequate financial resources, and digital literacy barriers. Health inequities are concerning, as research suggests that health outcomes are favorable across racial and ethnic groups when services are used [17,18]. The persistence of inequity in health care suggests that access to care is complex and should consider economic and social factors. To effectively incorporate factors influencing care, we comprehensively assess the components contributing to lower usage among Hispanic people. This study aims to examine the socioeconomic, demographic, and behavioral factors that influence telehealth use among people who identify as Hispanic.

Methods

Data Source

The study period was from March 2020 to April 2021. The COVID-19 Research Database Consortium provided access to the Office Ally and Analytics IQ PeopleCore consumer databases. The Office Ally database provided access to US claims data from 100 million unique patients and 3.4 billion medical claims. The Analytics IQ PeopleCore consumer database provides individual-level data across demographics, behaviors, and economic indicators and is a national representation of 242.5 million US adults aged 19 years and older. We joined the Office Ally claims data with Analytics IQ PeopleCore consumer data through an identifier, which enabled us to retrieve patient claims data during the study period and examine telehealth usage from socioeconomic and behavioral perspectives, as shown in the “Results” section.

Ethical Considerations

The COVID-19 Research Database was established by complying with regulatory standards to protect patient privacy. The COVID-19 Research Database received a waiver of patient consent certified from the Western Institutional Review Board for using HIPAA (Health Insurance Portability and Accountability Act)–certified deidentified data on April 20, 2020 [19]. The Western Institutional Review Board granted exemption status for HIPAA-limited data sets and non-HIPAA–covered data on May 14, 2020. This exemption covers all research performed in the COVID-19 Research Database. In addition, researchers with approved study proposals are granted access only to specific data sets necessary to answer their research question or questions. Only deidentified and limited data sets are made available through the database and certified before access is granted. Individual project institutional board approval was optional.

Results

Overview

We retrieved 16.43 million Office Ally claim records of Hispanic patients during the study period, and 3,478,287 unique Hispanic patients were included to investigate telehealth usage. A descriptive summary of the patients included in the analyses is in Table 1. Telehealth claims were identified by screening for the procedure modifier codes 95, GT, and GQ. Among the patients, 16.6% (578,945/3,478,287) had one or more telehealth claims during the study period. Female patients had slightly higher telehealth usage (338,795/1,958,350, 17.3%) than male patients (240,150/1,519,937, 15.8%).

Table . Characteristics of participants in the study (N=3,478,287).

Characteristics		Value
Sex, n (%)		
	Female	1,958,350 (56.3)
	Male	1,519,937 (43.7)
Age group (years), n (%)		
	18-44	1,133,417 (32.6)
	45-64	1,326,391 (38.1)
	65+	1,018,479 (29.3)
Education qualification, n (%)		
	Bachelor or higher	922,435 (26.5)
	High school or less	2,555,852 (73.5)
Employment status, n (%)		
	Unemployed	1,227,541 (35.3)
	Part-time	634, 818 (18.2)
	Full-time	1,615,928 (46.5)
Household annual income (US $), n (%)		
	Low: <46,000 (1st quartile)	941,294 (27.1)
	Medium: 46,000-144,000	1,670,747 (48)
	High: >114,000 (4th quartile)	866,246 (24.9)
Having a primary care doctor, n (%)		
	Yes	2,782,591 (80)
	No	695,696 (20)
Exhibit high medical use, n (%)		
	Yes	671,349 (19.3)
	No	2,806,938 (80.7)
Interest in exercise, n (%)		
	Yes	700,691 (20.1)
	No	2,777,596 (79.9)
Measure of alcohol consumption, n (%)		
	No consumption	353,921 (10.2)
	Some consumption	2,855,276 (82.1)
	High consumption	269,090 (7.7)
Frequency of smoking, n (%)		
	Never	413,982 (11.9)
	Some	2,919,447 (83.9)
	Daily	144,858 (4.2)
Using electronic prescription services, n (%)		
	Yes	578,768 (16.6)
	No	2,899,519 (83.4)
Using WebMD, n (%)		
	Yes	828,260 (23.8)
	No	2,650,027 (76.2)
Total number of claims during the study period, mean (SD)		4.73 (4.71)

Logistic Regression Analysis

The data were aggregated at the patient level to investigate telehealth use and determine whether a patient used telehealth during the study period. A patient with one or more telehealth claims during the study period was assigned a value of 1 for the dependent variable; otherwise, the value was assigned as 0. Categorical variables were created to stratify patients into groups by their demographics and socioeconomic status, as listed in Table 1. We conducted a multiple logistic regression to determine the odds of patients using telehealth. Each patient's total number of claims during the study period was included as an offset variable in the logistic regression to control its potential impact on the dependent variable. Results suggested that compared to patients aged older than 65 years, patients aged between 18 and 44 years are 1.07 times (odds ratio [OR] 1.07, 95% CI 1.05-1.1; *P*<.001) likely to use telehealth, while patients aged between 45 and 64 years showed a nonsignificant difference (*P*=.49).

Results from our logistic regression analysis of the 3 age groups are shown in Table 2. Male patients in the older group (aged older than 65 years) are 6% less likely to use telehealth (OR 0.94, 95% CI 0.93-0.95; *P*<.001), while male patients in the young group (aged between 18 and 44 years) are 5% more likely to use telehealth (OR 1.05, 95% CI 1.03-1.07; *P*<.001). Patients with a primary care doctor (*P*=.01) or high medical usage (*P*<.001) are significantly more likely to use telehealth, especially in the patients aged older than 65 years group. Patients who use WebMD (WebMD LLC) are significantly (*P*<.001) more likely to use telehealth among those who are aged older than 44 years. In comparison, the negative association with electronic prescriptions is significant among those who are aged between 18 and 44 years (*P*=.009) and aged between 45 and 64 years (*P*=.004). Patients aged between 18 and 44 years with high school or less education are 2% less likely to use telehealth (OR 0.98, 95% CI 0.97-0.99; *P*=.005). Patients with high incomes across all age groups were more likely to use telehealth than patients with lower incomes, as follows: aged between 18 and 44 years (OR 1.25, 95% CI 1.23-1.28; *P*<.001), aged between 45 and 64 years (OR 1.33, 95% CI 1.3-1.35; *P*<.001), and aged older than 65 years (OR 1.2, 95% CI 1.18-1.22; *P*<.001). Patients younger than 65 years with full-time employment (*P*<.001) are significantly more likely to use telehealth.

Patients with unhealthy behaviors such as alcohol use and smoking are significantly less likely to use telehealth (*P*<.001). In the patients older than 65 years group, patients with high alcohol consumption are 39% less likely to use telehealth than patients with no alcohol consumption (OR 0.61, 95%CI 0.56-0.65; *P*<.001). Patients aged 65 years and older who smoke daily are 36% less likely to use telehealth than patients who never smoke (OR 0.64, 95% CI 0.6-0.69; *P*<.001). Meanwhile, patients interested in exercise were significantly more likely to use telehealth (*P*=.03).

Table . Odds ratios from logistic regression analysis by age groups.

Variables		Aged 65+ years	Aged between 45 and 64 years	Aged between 18 and 44 years
Sex: male (reference: female)				
	Odds ratio (95% CI)	0.94 (0.93-0.95)	0.99 (0.98-1.01)	1.05 (1.03-1.07)

Discussion

Overview

This study found that among Hispanic people, male participants aged between 18 and 44 years were more likely to use telehealth than female participants, but male participants aged older than 44 years were less likely to use telehealth than female participants. Across all age groups, people with high incomes, people with primary care physicians, current users of the health care system, people who used WebMD, and people who reported full-time employment were more likely to use telehealth. Patients aged between 18 and 44 years with high school or less education were 2% less likely to use telehealth. There was a negative association with electronic prescriptions among those aged between 18 and 44 years and aged between 45 and 64 years. In addition, regardless of age, people with unhealthy behaviors, such as smoking, alcohol consumption, and a lack of interest in exercise, were less likely to use telehealth services.

Telehealth and Demographic Factors

The presented analyses represent factors contributing to telehealth use among Hispanic people. Like other studies, people aged older than 65 years were less likely to use telehealth than people in younger age groups [3,9]. Male participants in the aged older than 65 years group were 6% less likely to use telehealth, while male participants in the youngest group were 5% more likely to use telehealth. Saeed and Masters [16] indicated that female participants have higher telehealth usage due to caregiver burdens that make attending in-person visits more challenging. Furthermore, our findings indicate that the positive influence of health care use factors (eg, having a primary care doctor, medical usage, and use of WebMD) and the detrimental effects of unhealthy behaviors (alcohol consumption and smoking) are more pronounced among patients aged older than 65 years compared to younger age groups. Our findings suggest the necessity of considering various age groups when examining usage differences between age and gender groups.

Telehealth and Socioeconomic Factors

This study's results on educational background align with other studies that suggested that people with more than a high school diploma have higher telehealth usage [18]. A lack of education contributes to low health and digital literacy and interferes with a person's inability to access and use health-related information [20,21]. This study suggests that people with a primary care physician and those using the health care system (medical usage) are more likely to use telehealth [9,22]. These characteristics describe people who already have access to the health care system and are perhaps representative of the segment of the Hispanic population that experiences more health-related equity [23]. This has implications for increasing convenient access to care rather than increasing access for people who do not already have access to care. Research suggested that a primary care physician was critical to accessing traditional, in-person services. Having access to a primary care physician provides an avenue to get telehealth services; therefore, we can reasonably speculate that people who have access to in-person health care will have access to telehealth [16,24]. People who live in low-income communities are particularly vulnerable due to a lack of resources [14]. Darrat et al [15] suggested that among people with incomes less than US $30,000 annually, 29% lacked a smartphone, 44% did not have home broadband access, and 46% did not own a computer. The lack of internet access exacerbates the inequity in service access [18]. Jain et al [25] suggested that 84% of telehealth users had broadband internet access [26]. A study by Chau et al [27] indicated that 30% of Hispanic people do not have a computer in their home and are 10 years behind non-Hispanic White people with regard to broadband internet access. Researchers suggested that cultural perspectives influence technology use even when Hispanic individuals have similar technologies [2,26,28]. The results of this study indicate that Hispanic persons who used the internet for health information, such as WebMD, were more likely to use telehealth services; however, there was no relationship with electronic prescription behavior. Haun et al [29] also suggested no statistically significant relationship exists between telehealth use and electronic prescription behavior, as the provider, not the patient, initiates this service. Among Hispanic patients who used telehealth, they had the highest rate of missed telehealth visits at 42% [3]. A study by Ghaddar et al [6] suggested that 60% of Hispanic individuals access the internet or send or receive emails. However, only 24% communicate electronically with health care providers, and 40% report having low digital literacy [6].

Telehealth and Health Behaviors

In this study, people with unhealthy behaviors, such as smoking, alcohol consumption, and a lack of interest in exercise, had significantly lower odds of using telehealth across all age groups. Researchers suggested that smoking disproportionately affects people of low income and educational status, and alcohol misuse is increasing among people of color and people older than 60 years [30,31]. Health behaviors often include factors such as smoking, drinking, and physical activity and contribute to health inequity [32,33]. In addition, health behaviors have a significant effect on health care usage [34,35]. The association between telehealth use and smoking and alcohol is not conclusive in the body of literature. Jaffe et al [36] suggested that smoking has no relationship with exercise behavior, alcohol use, smoking, or telehealth. They suggested that 12% of people who smoked had a telehealth visit, as compared to 61% of people who never smoked and had a telehealth visit; however, it was not statistically significant (P=.45) [36]. The authors also suggested that alcohol consumption was not a deterrent to telehealth use, as 69% of alcohol users experienced a telehealth visit. A study by Wegermann et al [3] indicated that there were minimal to no differences in telehealth use among people who reported alcohol use or smoking. However, another study by Kim [37] indicated that exercise and alcohol use were associated with telehealth acceptance, whereas smoking status was not. A study by Jagielo et al [38] noted that during the COVID-19 pandemic, the stay-at-home order was more predictive of telehealth use than race or ethnicity among smokers. Among people with alcohol use disorders, researchers reported no differences in preference for telehealth or in-person treatment [39,40]. While beyond the scope of this study, it is imperative to note the rapid usage of telehealth and other digital technologies for smoking and alcohol cessation programs and exercise promotion. Given the aforementioned socioeconomic status of people who engaged in unhealthy behaviors, it is not surprising that challenges were noted in access to technology, digital literacy, and quiet session locations [30].

Recommendations

Glasgow et al [41] suggested that socioeconomic factors, cultural perceptions, and patient preferences significantly impact health care use. By considering patient health behaviors and preferences, providers and decision-makers can support "individual health and public health through enhanced care" [41] and gain a comprehensive understanding of the complex factors contributing to low telehealth access. We make several recommendations based on the results of this and other studies. First, primary care providers serve as the point of care and cost-efficient entry into the health care system [42]. Primary care supports access to other physician specialties, and its services are relatively more amenable to telehealth compared

to other physician specialties (42% and 35%, respectively); 73% of primary care services could be offered through telehealth [43]. Community-based primary care clinics can close the health equity gap [44]. Primary care clinics are uniquely positioned to engage communities in the sociocontent of their environment and culture. Using this strategy, local clinics can promote culturally relevant educational strategies and encourage positive behavior change for health outcomes. Second, as we consider supporting telehealth in primary care, it is imperative that we support a digital public health infrastructure. Primary care providers serving people vulnerable to health inequities report that the lack of digital access remains a barrier. Chang et al [14] suggested that primary care providers report that as much as 70% of their patients lack digital or internet access, and 50% are uncomfortable with the technology. Digital access provides a gateway to education and employment; thus, with effective interventions, we can mitigate this social determinant of health [45]. This suggests that discussions about including digital access in the public health infrastructure and as a social determinant of health warrant priority consideration [46].

Limitations

This study used a unique population-based data source. This allowed us to examine the Hispanic population in the Office Ally and Analytics IQ databases. We studied socioeconomic, health behavior, and demographic factors in the Hispanic community and determined the odds of using telehealth during a public health crisis. The results may not be reproducible, as the data collection was during COVID-19, and patients may not have gained proficiency with the technology or lack internet access. The study used the COVID-19 Research Database and is subject to the limitations of administrative databases. The validity of the data is dependant upon the facilities to report accurate data and code visits correctly in the Office Ally database. Analytics IQ PeopleCore consumer data rely on the accuracy of reporting by the consumer. In this study, the Hispanic population considered all persons of Hispanic or Latino identification. In addition, data were not available on geography (rural and urban), access to home internet, and the ability to read and write English proficiently. In future research, it is imperative to account for variances in usage patterns between urban and rural populations, given the potential impacts of geographic disparities, technological infrastructure, and internet accessibility on health care usage. Future studies should consider measures of English health literacy and its association with health care access. Furthermore, future studies should consider patient and provider relationships in local communities to explore additional information not captured in surveys and claims data that explicates attitudes and challenges with telehealth access and use.

Conclusions

Telehealth supports favorable health outcomes across populations. However, without equity in usage, these benefits are not realized across communities. This study highlights that telehealth use among Hispanic communities can be influenced by demographic, socioeconomic, and health behavioral factors. Telehealth use among Hispanic communities is dependent upon several important factors, such as age, gender, education, socioeconomic status, current health care engagement, and health behaviors. To overcome these barriers, we recommend interdisciplinary strategies that call for medical professionals, insurance providers, and community-based services to engage meaningfully with Hispanic communities to support telehealth use. As telehealth becomes increasingly prevalent in our society, it is imperative that we support this method for accessing the health care system.

Acknowledgments

We thank the COVID-19 Research Database Consortium for their support of the study. The research was supported by the Bill and Melinda Gates Foundation. The content is exclusively the responsibility of the authors and does not necessarily represent the official views of the Bill and Melinda Gates Foundation and the COVID-19 Research Database Consortium.

Data Availability

The data sets generated and/or analyzed during the current study are not publicly available due to the consortium restrictions and governance policies. The database can be accessed by academic, scientific, and medical researchers at COVID-19 Research Database's website. Potential users must register as approved researchers and submit a proposal, including a request to access a specific database. The submitted proposal will be reviewed by the scientific steering committee and a privacy and governance review board. If approved, access will be granted to install the database environment where researchers must conduct the analysis.

Authors' Contributions

CW contributed to the study's conception and design, interpretation of results, and drafting and revising of the work. DS contributed to the study's design, interpretation, analysis, and revising of the data. HC contributed to the writing and editing of the manuscript. All authors approved the final version of the manuscript.

Conflicts of Interest

None declared.
