
Legal Functional Framework

On behalf of the hospital, the RAD defines the framework of data use and access policies, security, and patient consent and privacy, and is in charge of the construction, organization, and enforcement of the NBDW regulatory framework. It works in conjunction with the hospital data protection officer, represented by an officer specifically dedicated to research data. Furthermore, the RAD structure requires documented monitoring to ensure a constant adaptation of the NBDW regulatory framework to answer to changes in legal standards. All projects are publicly described on the web [27] for all potential patients contributing data.

IT Stewardship and Interoperability

The ITD is in charge of the collection, storage aggregation, quality, and integrity of clinical data. This structure carries out a continuous process to conform to technical standards. Setting up the addition of new hospital data sources is an ongoing process that started in July 2018 and is still relevant.

The NBDW is set up on virtual machines. An Oracle database enables massive data storage, integrating multiple hospital data sources into a unique set of tables containing data on patients, consultations, diagnoses, laboratory results, medical notes, and inpatient drug administration. The NBDW uses eHOP [22,28] software to organize and query the database. eHOP is a platform developed by Rennes University using a public-private partnership on the enterprise application integration Enovacom Suite Version 2 (ESV2) of Enovacom (Orange Business Service-Santé). eHOP carries out the acquisition, transformation, and integration of the data coming from various HISs with different formats and standards (Health Level 7 [HL7]; Harmoniser et promouvoir l'informatique médicale [HPRIM]; PN13; Logical Observation Identifiers Names and Codes [LOINC]; and Word documents, PDF, CSV, and text). ESV2 provides an automatic, scheduled (daily, weekly, or monthly), and monitored data supply from the NBDW.

Scientific Data Stewardship and Mediated Access to BDW

Beginning in 2018, the CDC has had a specific team dedicated to the reuse of health data for research, relying on the expertise of public health doctors, data and computer scientists, epidemiologists, biostatisticians, and project managers promoting epidemiology analyses and providing support to clinical investigators and researchers in data access. In conjunction with the ITD, the CDC defines the standards necessary for data integration and data use practices, and ensures data control and the scientific quality of the analyses.

Target and Data Access

The end users of the NBDW are investigators (internal or external to CHUN) aiming to advance the institution's research. A per-project access is created for CHUN investigators through a standardized approval process consisting of 4 main steps (Figure 1). First, investigators register their request and submit a research protocol through a portal hosted by the CHUN intranet. Second, the CDC validation board, which meets once a week, analyzes three dimensions of the submitted research projects: compliance with ethical principles, scientific relevance, and feasibility. On completion of the approval process, the project is registered on an internal database for the completion of legal requirements. Third, the CDC processes all the necessary queries on the NBDW to select a group of patients relevant to the scientific question. During this step, ongoing collaboration with the investigator is necessary, in particular, to precisely define the scientific purpose, eligible population, and data of interest. Fourth, data are made available internally through a data mart, hosted by the CHUN intranet. The data mart system provides regulated, parsimonious (only the required data regarding the targeted population), and time-limited access to investigators. Data are completely deidentified. Moreover, investigators can make simple queries and seek data on patients contained in the data marts through eHOP, which is enriched with a set of tools for simple textual and structured data queries.

Projects requiring data management and extraction to integrate a research database are declared to the public registry of CHUN projects as a guarantee of transparency and to allow patient opposition. At this step, more complex methods for the extraction of information through natural language processing (NLP) [29], regular expression tools, or other structured data [30] may be applied. Finally, data extraction is constrained to strictly necessary data, following the parsimony principle, and only if access to data can be done in a secure environment.

In the case of a project supported by an external project leader from CHUN (academic or private partner), the same process as described above takes place with the exception of the following differences: the project might be supported by a clinical team that submits the research protocol through the portal; a partnership agreement must be signed between the hospital and the partner, and the data mart is only available through a specific virtual working space (data are still internally hosted).

Data Protection and Patient Consent

To comply with national and international privacy regulations, data integration is subjected to a deidentification algorithm. Data are stored in two independent and separate Oracle schemas to separate pseudonymized data from nominative or other directly reidentifying information to which access is strongly limited. Data separation is supplemented by access management and traceability of the actions carried out (ie, AuditLog). Most notably, the platform includes a functionality for collecting and applying patient consent to the use of personal data, ensuring compliance with French law and European General Data Protection Regulation requirements [31].

Regulatory Approval

In alignment with the French Data Protection Act (Loi Informatique et Libertés, 1978), the use of personal data for health research and evaluation requires compliance with a reference methodology, representing good practices. Without such compliance, personal data use must be authorized by the Commission Nationale de l'Informatique et des Libertés (CNIL; French National Commission for Information Technology and Civil Liberties). At the launch of the NBDW, no research methodology existed for data warehouses in the field. Therefore, approval from the CNIL was mandatory to initiate implementation. Submission to the CNIL covered legal responsibilities, data processing details, access, governance, and more. Comprehensive data access details were provided, extending to researchers whether affiliated with CHUN or not. Private entities are permitted to engage in research projects based on the NBDW, ensuring adherence to this resolution and French regulations. The Data Protection Impact Assessment for NBDW was an integral part of the submission to the CNIL, serving as a mandatory document. The authorization to set up and use the NBDW was granted on July 19, 2018, by the CNIL (resolution 2018 - 295).

Budget Planning and Sustainability

Estimating the costs associated with implementing and maintaining a data warehouse is challenging owing to several factors. First, the NBDW is part of an institutional strategy, making it difficult to consider it as a stand-alone entity. Second, implementing it involves the collaboration and coordination of multiple structures and experts, complicating the estimation of resource use. Third, hidden costs are difficult to anticipate and consider, including system failures and delays, unplanned license renewals and upgrades, adjustments to regulatory and legal requirements, unplanned changes in HISs, and infrastructure upgrades. We made an estimation by considering three budget lines—infrastructure, license, and human resources—and two different periods—completion in 5 years (2018 - 2022) and maintenance in 2 years (2022 and 2023)—for a total of €2.6 million (US $2.8 million).

In terms of sustainability, an annual operational budget is allocated for maintenance and updates. Specific needs for the integration of new hospital data sources are financed through project-based funding. Moreover, an economic model is currently being defined to incorporate additional charges for infrastructure costs in the case of external research projects.

Ethical Considerations

An ethics statement is included in the regulatory approval granted by CNIL with resolution number 2018 - 295 [32].

Implementation (Results)

Description of the Sources, Concepts, and Contents

The NBDW integrates multiple hospital data sources into a unique and structured set of tables containing data on patient demographic and administrative records, inpatient drug administration, inpatient constants and anthropometric scores and metrics, anatomic pathology notes, inpatient and outpatient medical laboratory results, narrative medical notes (including admission/discharge summaries, inpatient anesthesia notes, outpatient consultation notes, nurse notes), *International Classification of Diseases, 10th Revision* (*ICD-10*) and French Classification Commune des Actes Médicaux (CCAM; Common Classification of Medical Procedures) codes for inpatient diagnoses and procedures, and medical imaging reports. Table 1 shows principal concepts and contents according to different HIS data sources or software integrated up to now. Some data sources contain only narrative notes, and some sources contain both unstructured and structured data.

Table . Nantes University Hospital Biomedical Data Warehouse principal sources and concepts. Data extracted May 10, 2023.

Concepts	Software	Period	Patients, n	Documents, n	Documents in 2022, n	Structured data, n
Inpatient drug prescriptions	MILLENNIUM	2015-today	318,456	39,681,513	5,673,000	248,289,146
Cardiology narrative notes	CARDIOREPORT	2015-today	9278	38,041	6644	—[a]
Consultation clinical narrative notes	GAM-CLINICOM	2002-today	1,053,386	6,507,860	22,982	—
Constants and anthropometric data	MILLENNIUM	2015-today	440,250	3,306,589	638,969	61,142,757
Anatomic pathology notes	DIAMIC	2015-today	131,812	229,081	27,244	1246
Biology laboratory results	DXLAB	2012-today	701,804	10,752,384	1,672,218	155,825,060
Clinical narrative notes	MILLENNIUM	2015-today	569,114	3,967,073	907,573	5,395,233
ICD-10[b] and clinical procedure codes	CLINICOM	2006-today	725,802	5,318,712	401,607	105,246,620

[b]*ICD-10*: *International Classification of Diseases, 10th Revision.*

NBDW Figures and Populations

CHUN, a tertiary care hospital ranked seventh in France in terms of activity [33], provides care over a population catchment area of 1.4 million inhabitants. It provides follow-up and long-term health care for both in- and outpatients. It has 2993 hospital beds, delivers 4380 babies, and conducts more than 1 million consultations and external medical procedures per year [34]. It also carries out practical teaching for 1200 medical students, 800 medical residents, and over 2000 non–medical students.

The NDBW includes information on approximately 1.5 million patients admitted between 2003 and 2022 (Table 2). More than 1.2 million hospitalizations are associated with approximately

12.3 million *ICD-10*–coded diagnoses and 7.3 million clinical procedure codes. Together with more than 6.3 million external consultations, the NBDW contains more than 11 million textual documents. These narrative notes integrated as free-text documents can be interrogated and turned into structured data for research.

The yearly number of patients, hospitalizations, consultations, and narrative notes has increased over time (Multimedia Appendix 1) with growth rates between 2003 and 2019 ranging from 109% (hospitalizations) to 430% (outpatient consultations).

Table . Nantes University Hospital Biomedical Data Warehouse figures and contents, 2003 - 2022.

Contents	Since 2003, n	2022 only, n
Patients[a]	1,597,498	300,804
Hospitalizations[b]	2,635,809	183,361
Outpatient consultations	6,358,271	524,948
Clinical narrative notes[c]	11,634,761	826,670
Diagnoses[d]	12,251,148	956,688
Clinical procedures[e]	7,272,346	504,571

[a]Patients with ≥1 clinical narrative note or a structured document, including inpatient and patients admitted for outward consultations.

[b]Inpatient hospitalizations in medical, surgical, and obstetric services, including complete hospitalizations, day-hospital admissions, and recurring visits.

[c]Clinical narrative notes (with the exclusion of vital signs and anthropometric data; *International Classification of Diseases, 10th Revision* [*ICD-10*] and clinical procedure codes; laboratory results; inpatient drug administrations; and nurse transmissions).

[d]Medical diagnoses following the *ICD-10* for medical, surgical, and obstetric hospitalizations.

[e]Classification Commune des Actes Médicaux for medical, surgical, and obstetric hospitalizations.

Projects and Effectiveness Outcomes

The availability of NBDW data makes it possible to provide data in response to a wide array of scientific questions and the need for data in the analysis and management of care and organization. Prior to the creation of NBDW data, researchers were limited to the interrogation of medico-administrative–structured information out of the scope of data reuse consent. It only covered structured data such as *ICD-10* diagnoses associated with hospitalizations; medical procedures through CCAM codes; and, to a lesser extent owing to availability issues, laboratory results. Obtaining results from different queries performed independently on different HISs and data manager services was time-consuming if not impossible for both legal and technical reasons.

The NBDW currently facilitates queries of clinical concepts in both structured and unstructured free-text notes in an integrated environment and with respect to data protection policies and laws. BDW data requests may be divided into three different types of research projects according to their purpose: (1) optimize patient screening in both clinical trials and observational studies, (2) enrich case reports or electronic case report forms for disease surveillance, and (3) evaluate and improve clinical practices and resource management. To illustrate different types of studies, three concrete examples of data use are described in Multimedia Appendix 2 [35-37].

The first outcome to measure the effectiveness of the NBDW was defined as the number of studies supported through the project tracking portal (Figure 1). Since 2018, 577 requests have been made and treated by the CDC. Among them, 269 projects involved patients included thanks to NBDW queries and research tools (second outcome), and for 115 of them, data marts were created to give investigators access to data (third outcome).

Discussion

Lessons Learned

The development of clinical data warehouses has provided unprecedented access to a large amount of diverse data from clinical care. However, it requires a dedicated effort in terms of governance, data access rules with respect to patient consent and data protection, and technical challenges. The reorganization of structures within a functional research framework is the first factor in the success of the NBDW. Collaboration between departments has not only facilitated seamless communication but also engendered the innovation necessary to deal with the complexities of health care data management. It was an opportunity to test new IT technologies such as distributed infrastructure and anonymization techniques such as deidentification. The interaction between structures has also been a fundamental element in the process of obtaining BDW authorization from the CNIL. Indeed, the obtention of regulatory approval is the result of a long negotiation that required expertise in addressing legal, technical, and scientific research requirements (see Regulatory Approval section for more details).

The creation of the CDC, the result of multidisciplinary teamwork composed of computer scientists, NLP engineers, statisticians, physicians, epidemiologists, and project managers, has probably been the second factor of success. The weekly CDC validation boards, supported by the RAD and ITD structures, verify project compliance vis-à-vis three aspects: ethics, scientific relevance, and practical feasibility, giving support and access to the NBDW in a secure context. However, it is also a leading driver in the shift toward data-driven governance in hospitals.

Implementation of the NBDW has required a continuous and still relevant process to conform to new regulatory and technical standards, and to add new hospital sources and ongoing improvements. An important lesson learned was that each of the 269 NBDW projects in the past 5 years has been an opportunity to revisit the contents of the BDW, further the quality control process, and lead the data transformation process, creating data use value.

Establishing networks and working together is probably the best lesson learned. In France, some experiences have led to changes in health data foresight [28] and promoted the implementation of interregional [22] and national hubs. The NBDW has benefited from and contributed to the "Ouest Data Hub," a network of Western France university hospital data warehouses. The aim is both to facilitate the reproducibility of data analyses, share resources and best querying practices, and promote adapted and standardized terminologies and nomenclatures between centers. Moreover, BDWs use the same software for both integration and querying, allowing them to be interrogated using consistent queries and rules. This approach ensures a high level of interoperability and accessibility, facilitating seamless interaction and adherence to the Findable, Accessible, Interoperable, Reusable (FAIR) principles.

In hindsight, if this process were to be revisited, there are certain facets that we would address differently. Specifically, in the initial stages of implementing the NBDW, primary emphasis was placed on deploying the software and IT infrastructure recommended by the regional network, ODH, aimed at facilitating the establishment of the repository and its querying system. While acknowledging the benefits inherent in this strategy, a more thorough examination of alternative IT solutions is warranted to mitigate reliance on a singular approach and to streamline potential transitions to alternative and variated options.

Conclusions

In conclusion, conducting health studies using electronic health records requires careful attention to ensure accurate results owing to a lack of a systematic quality process. The data quality control procedure is a long and necessary process [17,38,39]. The future challenge will be the setting up of standardized and shared quality control pipelines to ensure quality results, not only at the local level but also in a regional and national context of future data sharing. By extending long-term investments in IT and data in care institutions, the development of NLP and text-mining tools will further accelerate the use of BDW, facilitating data-driven decision-making discussions from top management to patients.

Any research project and analysis of care-based research performed in health management institutions could benefit from the deployment of organized data access. The collaborative nature of data production and the information and privacy protection for patients require mediated and expert access to the BDW. It demonstrates that technical solutions are partial answers to better data-driven practices and must lead to a clear governance strategy

Abstract

Background: Falls had been identified as one of the nursing-sensitive indicators for nursing care in hospitals. With technological progress, health information systems make it possible for health care professionals to manage patient care better. However, there is a dearth of research on health information systems used to manage inpatient falls.

Objective: This study aimed to design and implement a novel hospital-based fall risk management information system (FRMIS) to prevent inpatient falls and improve nursing quality.

Methods: This implementation was conducted at a large academic medical center in central China. We established a nurse-led multidisciplinary fall prevention team in January 2016. The hospital's fall risk management problems were summarized by interviewing fall-related stakeholders, observing fall prevention workflow and post–fall care process, and investigating patients' satisfaction. The FRMIS was developed using an iterative design process, involving collaboration among health care professionals, software developers, and system architects. We used process indicators and outcome indicators to evaluate the implementation effect.

Results: The FRMIS includes a fall risk assessment platform, a fall risk warning platform, a fall preventive strategies platform, fall incident reporting, and a tracking improvement platform. Since the implementation of the FRMIS, the inpatient fall rate was significantly lower than that before implementation (P<.05). In addition, the percentage of major fall-related injuries was significantly lower than that before implementation. The implementation rate of fall-related process indicators and the reporting rate of high risk of falls were significantly different before and after system implementation (P<.05).

Conclusions: The FRMIS provides support to nursing staff in preventing falls among hospitalized patients while facilitating process control for nursing managers.

fall; hospital information system; patient safety; quality improvement; management; implementation

Introduction

Context

Falls are one of the nursing-sensitive indicators for nursing care [1], which are a leading cause of fatal and nonfatal health loss globally [2,3]. Reducing and preventing falls has become an international health priority. Falls—common adverse events reported in hospitals—have been identified as a nursing-sensitive quality indicator of patient care.

Given the growing technological progress, health IT may help enhance the quality and safety of provided care, facilitating the effectiveness and efficiency of the clinical workflow, and supporting the provision of integrated multidisciplinary care [4-11]. The hospital information system (HIS) is a promising

approach to improve care quality and safety in the complex hospital environment. Despite extensive literature on fall risk factors and preventive strategies [12-18], few studies have focused on health information systems for managing inpatient falls.

Problem Statement

To address these issues, we formed a nurse-led multidisciplinary fall prevention team in January 2016, including the hospital administrative staff, quality management specialists, physicians, nurses, pharmacists, and informatics staff. This team retrospectively analyzed 19 inpatient fall cases that occurred in 2015 (fall rate 0.015‰), ranking first among all in-hospital nursing adverse events. Among the fall cases, 30%-40% of patients had grade ≥3 injuries, which significantly exceeded the 3.978% proportion seen in similar hospitals during this period. Falls caused severe harm and financial burden to inpatients, with 3 patients experiencing severe head injuries and 2 having hip fractures. The longest hospital stay resulting from falls reached 36 days.

The hospital's fall risk management problems were summarized by interviewing fall-related stakeholders, observing fall prevention workflow and postfall care process, and investigating patients' satisfaction; these included (1) nonachievement of real-time fall risk assessment, real-time uploading, and information sharing; (2) absence of fall risk warning management; (3) complicated fall risk management workflow; (4) absence of process control in fall prevention (such as process control for different fall risk levels, process control for different time nodes, etc); and (5) lack of standardized pathways for inpatient fall incident reporting and improvement tracking.

Similar Interventions

Several studies have highlighted the benefits of using health information systems for patient fall management. For example, Giles et al [19] reported that data collected from nursing information systems can be used to identify high-fall-risk patients. Mei et al [20] designed an electronic patient fall reporting system in a US long-term residential care facility, which could improve the fall reporting process and subsequent quality improvement efforts. Katsulis et al [21] combined the Fall TIPS (Tailoring Interventions for Patient Safety) [22] with a clinical decision support system, which increased its ease of use over the paper version. Jacobsohn et al [23] developed an automated clinical decision support system for identifying and referring older adult emergency department patients at the risk of future falls. Mlaver et al [24] at the Brigham and Women's hospital developed a valuable electronic health record–embedded dashboard that collected inpatient fall risk data. However, the abovementioned fall information system only focused on a specific domain of fall management. So far, there is still no report about an HIS for overall fall risk management.

Aims and Objectives

This implementation aims to design and implement a fall risk management information system (FRMIS) to reduce falls among inpatients and improve nursing quality. Our goal is to create a culture of safety and reduce the incidence of falls hospital-wide, ensuring the well-being and security of all patients.

Methods

This study adhered to the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) checklist [25].

Blueprint Summary

This FRMIS consists of 4 major functional platforms to facilitate comprehensive fall prevention pathway management as shown in Textbox 1.

Textbox 1. The 4 major functional platforms of the fall risk management information system.

A fall risk assessment platform (Multimedia Appendix 1):

The assigned nurse uses a personal digital assistant to conduct fall risk assessments within 4 hours of patient admission. Upon completion, the personal digital assistant automatically compiles the Morse Fall Risk Score [26,27] and risk level, marking it in the electronic nursing record. All patients' Morse Fall Risk Scores are collected and shared in real time through the information platform. Simultaneously, nurses receive nursing guidelines specific to different fall risk levels. They implement corresponding fall prevention measures such as hanging “Fall Prevention” warning signs near high-risk patients' beds, distributing “Fall Prevention Information Sheets” to guide patients and their families on preventive measures, and documenting and passing on relevant information during shift changes. The head nurse conducts daily inspections and guidance on the accuracy of Morse fall assessments and the implementation of fall prevention measures, upon completion of departmental reviews.

A fall risk warning platform (Multimedia Appendix 1):

Patients at different fall risk levels are color-coded for easy identification: high-risk (Morse Fall Risk Score≥45), red; moderate (score approximately 25-44), yellow; and low (score approximately 0-24), green. The fall risk warning module comprehensively displays the daily number of high-risk falls, department distribution and ranking, percentage of the population at the risk of falls, specific bed locations, medical diagnoses, Morse Fall Risk Scores, and assessment times through charts and color-coded indicators. This provides nursing managers real-time insights into the key populations, departments, and information related to fall risk management, enabling proactive fall risk prevention and providing precise information support for effective fall prevention process control.

A fall preventive strategies platform (see Multimedia Appendix 1):

Evidence-based fall prevention strategies are developed, incorporating fall event analysis and expert discussions to extract key process monitoring indicators. An electronic fall prevention bundle strategies quality tracking checklist was established for accurate assessment of fall risk, increased awareness of preventive measures, enhanced handover process for high-risk patients, environmental safety, implementation of fall prevention knowledge training, and guidance on proper use of assistive devices. Nursing department and ward-level managers can use mobile devices (iPads) to conduct targeted goal management and quality inspections of fall prevention strategies. Real-time monitoring is conducted on key fall process indicators such as accuracy of Morse fall risk assessments, implementation of health education, adherence to handover procedures, and compliance with environmental safety measures.

A fall incident reporting and tracking platform (see Multimedia Appendix 1):

The platform regulates the reporting process for inpatient fall events. After a fall incident occurs, the ward head nurse promptly logs into the fall incident reporting platform to proactively report the incident. They provide details such as the time and location of the fall, the sequence of events, whether the patient was injured, the extent of the injury, and the emergency treatment process. Once the information platform receives the ward's report, it immediately sends text messages to the chief nurse and members of the nursing department's safety management team. On the platform, safety management team members can quickly trace the Morse Fall Risk Score, risk level, appropriateness of fall prevention interventions, timeliness of assessments, and any dynamic evaluations associated with that patient. After gaining a comprehensive understanding of the patient's relevant information, they visit the ward in a timely manner to conduct on-site inspections and tracking. They provide guidance to the department by applying root cause analysis to thoroughly analyze the fall event, identify the underlying causes, and propose areas of improvement directly on the web-based platform. Ward head nurses and the chief nurse can access expert guidance instantly on the platform and make necessary improvements based on the advice provided.

Technical Design

The FRMIS was developed using an iterative design process, involving collaboration among health care professionals, software developers, and system architects. The design aimed to create a user-friendly interface, incorporate data integration capabilities, and enable real-time reporting functionalities. In order to meet the usage needs of both PC and mobile devices, the development language selected for this system includes C#, jQuery, and Java; the development tools used were Visual Studio (Microsoft Corp) and Eclipse (The Eclipse Foundation), and the development platforms used were Windows and Android.

Target

The FRMIS was designed to assist nursing staff in preventing inpatient falls through IT, facilitating process control for nursing managers and ensuring patient safety.

Data

Our hospital has a dedicated computer center, which serves as the technical support department for network security. It is responsible for the construction and operation of hospital network security protection measures. The collection of various data in the FRMIS complies with relevant national laws and regulations. The data collection scope follows the principle of “minimum necessary” and adopts measures such as data desensitization, data encryption, and link encryption to prevent data leakage during the data collection process.

Interoperability

To maximize the effectiveness of the FRMIS, standardization of data elements and the development of interface systems to allow seamless data exchange between our HISs were necessary. The FRMIS used Health Level Seven Fast Healthcare Interoperability Resources (HL7FHIR) to enable seamless data exchange and streamline workflows.

Participating Entities

The FRMIS project has obtained the approval and support of hospital management, who have provided strong guarantees in terms of personnel, resources, funding, and working hours required for the implementation of the research plan. Our hospital is an advanced information management hospital with state-of-the-art scientific technologies. The computer center has rich experience in developing information management platforms; they have independently developed and implemented 19 hospital operational management systems. The FRMIS’s development was initiated by the nursing department, with the

assistance of the computer center to fulfill the corresponding requirements.

Budget Planning

The FRMIS development process lasted about 4 months, and the total development cost was approximately 500,000 Renminbi (approximately US $68,300). The subsequent maintenance costs were estimated to be 8% of the total development cost annually. Funding for the FRMIS's development and maintenance was provided by our hospital. The ownership of the FRMIS belongs to Tongji Hospital.

Sustainability

The FRMIS's implementation was carried out through the issuance of relevant policy documents by the nursing department, ensuring its clinical adoption. All risk assessment and incident reports concerning the inpatient falls were conducted through this information system thus far, replacing the previous paper-based forms. Over the past few years of using this system, our hospital's computer center staff has been maintaining and fixing occasional bugs that occur during clinical implementation of this system. The computer center staff also made necessary modifications and improvements to certain details as needed to enhance system functionality, optimize workflows, and adapt to evolving health care practices.

Statistical Analysis

Statistical comparisons were made on the fall incidence rate among inpatients and the reporting rate of high-fall-risk patients before and after FRMIS implementation. Data entry and statistical analysis were performed using SPSS (version 17.0; IBM Corp). The chi-square test was used to compare the differences in the fall incidence rate among inpatients, the rate of high-fall-risk patients, and the implementation rate of preventive fall quality bundle strategy indicators before and after FRMIS implementation. A value of $P<.05$ was considered statistically significant.

Ethics Approval

The study was approved by the institutional review board of Tongji hospital (protocol TJ-IRB20191209).

Implementation (Results)

Coverage

Our hospital is a large academic medical center in central China. In 2016, the hospital had a total of 4000 open beds, 106 nursing wards, and 53 specialized nursing units. The average daily admission rate ranges from 4500 to 5000 patients, with a total of 193,709 admitted patients throughout the year. The cumulative number of bed-days reached 1,756,946, of which 277,365 (15.79%) were for critical patients.

Outcomes

We carried out the process and outcome evaluation with regard to the FRMIS's implementation. The process evaluation indicators include (1) the accuracy rate of the Morse fall risk assessment: number of accurate Morse fall risk assessments / total number of Morse fall risk assessments inspected; (2) implementation rate of fall prevention health education: number of implemented health education check items / number of patients inspected × total number of fall prevention health education check items; (3) implementation rate of shift handoff: number of implemented shift handoff check items / number of patients inspected × total number of fall prevention shift handoff check items; (4) implementation rate of environment safety: number of implemented environment safety check items / the number of patients inspected × the total number of environment safety check items.

The staff of the quality control office in the nursing department reviewed the FRMIS on a daily basis to identify the clinical departments where high-fall-risk patients were distributed across the hospital. For departments with more than 5 high-fall-risk patients and a proportion exceeding 20% of the total patients, we assigned 2 supervisory staff from the quality control team. They used the electronic form "Fall Prevention Bundle Strategy Quality Tracking Form" (see Multimedia Appendix 1) on an iPad to conduct quality inspections on the nursing units for the high-fall-risk patient population, randomly checking the implementation rate of fall prevention bundle strategy indicators (fall risk assessment, fall-related health education, fall-related shift handoff, and environment safety). Before implementing the FRMIS, a total of 1250 patients were randomly sampled for inspection. After implementing FRMIS, a total of 1806 patients were randomly sampled for inspection. Additionally, a comparative analysis was performed on the hospitalization period between February and October 2017 (after FRMIS implementation, the total bed days occupied by inpatients was 1,323,667) and between February and October 2015 (before FRMIS implementation, the total bed days occupied by inpatients was 1,303,094) to evaluate the hospital-wide reporting rate of high-fall-risk cases, incidence rate of patient falls, and severity of fall-related injuries.

The results showed that since the FRMIS's implementation, the inpatient falls rate was significantly lower than that before implementation ($P<.001$), as shown in Table 1. In addition, the percentage of major fall-related injuries was significantly lower than that before implementation, as shown in Table 2. The implementation rate of fall-related process indicators and the reporting rate of high risk of falls were significantly different before and after system implementation ($P<.001$), as shown in Table 3.

Table 1. Comparison of fall-related outcome indicators.

	Before implementation (total bed days=1,303,094), n (%)	After implementation (total bed days=1,323,667), n (%)	Chi-square (*df*)	*P* value
High-fall-risk patients' reports	1036 (0.8)	3007 (2.3)	931.7 (1)	<.001
Fall incident reports	23 (0.02)	11 (0.01)	4.4 (1)	<.001

Table 2. Results of fall-related injuries.

	Cases of fall-related injury, n			
	No injury	Minor	Moderate	Major
Before implementation	15	28	12	2
After implementation	20	13	9	0

Table 3. Comparison of fall-related process indicators.

	Before implementation (n=1250), n (%)	After implementation (n=1806), n (%)	Chi-square (*df*)	*P* value
Fall risk assessment	1056 (84.48)	1709 (95.73)	88 (1)	<.001
Fall-related health education	1107 (88.56)	1769 (97.95)	117.5 (1)	<.001
Fall-related shift handoff	1114 (89.12)	1767 (97.84)	104 (1)	<.001
Environment safety	1127 (90.16)	1796 (99.45)	153 (1)	<.001

Lessons Learned

The FRMIS's development and implementation followed a structured process, starting with needs assessment and culminating in ongoing monitoring and improvement. With this multidisciplinary team and comprehensive approach, we were able to provide a more robust and effective fall risk management system for the entire hospital. The FRMIS addressed the shortcomings of paper-based reporting, such as untimely fall assessments, delayed reporting, information transmission delays, loss of assessment forms, and incomplete tracking information. The FRMIS achieved a holistic fall prevention strategy that spanned from risk assessment to postfall intervention, which brought several benefits to both patients and health care providers. The FRMIS alerted nursing staff about high-risk patients, enabling timely interventions and reducing fall occurrences. It also standardized the reporting process for fall events, allowing for efficient tracking and analysis of incidents.

Discussion

Principal Findings

This study has designed and implemented an FMRIS at the hospital level. The novel system provided a simple, intuitive, and highly operational prevention management model, encompassing fall risk assessment, high fall risk screening, forecasting, and monitoring. It significantly improved the procedural and standardized levels of fall management for hospitalized patients, having prompted nurses to proactively implement fall preventive interventions, conducted timely fall risk assessments, reduced underreporting of high-fall-risk patients, and increased the forecast rate of high-fall-risk patients.

Unlike previous studies that focus on a specific stage of fall management (such as risk identification [19] or fall incident reporting [28]) or patients in a specific department [23], our system catered to the entire process of fall risk management for all inpatients. The FRMIS showed promise in enhancing patient safety, reducing fall incidents, and improving overall care quality.

To facilitate the successful implementation of the FRMIS in clinical practice, we first developed the Standardized Management Guidelines for Preventing Inpatient Falls at the hospital-wide level. This policy document comprehensively revises and improves clinical fall prevention efforts, which include patient fall risk assessment, health education, fall preventive interventions, fall management workflow, fall incident reporting, and system record-keeping. The policy document was distributed in hard copy by the nursing department to all departments and also uploaded electronically on the hospital's Office Automation platform. It mandated each clinical department to conduct fall prevention training based on the guidelines, requiring all nurses' participation and proficiency. This document served as a supporting tool, providing nurses with guidance on how to use the FRMIS effectively in their clinical practice to prevent inpatient falls.

In addition, we conducted standardized nurse training through a web-based platform. Three main implementation strategies were used. First, we conducted diverse forms of training, including ward-, department-, and hospital-level fall prevention training, as well as case-based warning education, bedside simulation assessment, experience sharing sessions, and special lectures, to comprehensively implement the content of the Standardized Management Guidelines for Preventing Falls. Second, we performed objective evaluation. We incorporated simulated case examinations for patient fall prevention into the clinical skills evaluation of nurses, head nurse position evaluation, and their performance appraisal to comprehensively assess the level of knowledge of fall management guidelines and the emergency handling capabilities for patient fall incidents. Third, we achieved full participation among all nurses. The training rate and assessment results of nurses in the wards were included in the performance management projects of ward head nurses, achieving the participation of all nurses and comprehensive evaluation of standardized fall prevention training. Based on the strategies mentioned above, the FRMIS's implementation in clinical practice has been relatively successful.

Limitations

This study still has certain limitations that should be acknowledged. First, the FRMIS was specifically designed and implemented by our hospital's computer center. It is currently applicable to 3 different hospital campuses within our institution

but has not been widely disseminated to other hospitals or integrated with diverse HISs. Therefore, its applicability and effectiveness in different hospital contexts remains uncertain. Second, the FRMIS heavily relied on the voluntary reporting by clinical nurses. The accuracy of these fall risk reports needed to be individually verified by staff members in the quality control office of the nursing department. This process is currently manual and lacks automation, which may introduce delays and potential inconsistencies. In the future, further improvements could be made by integrating artificial intelligence (AI) technologies. By automatically extracting fall risk factors from patients' electronic medical records, the system could achieve automated risk stratification and reduce dependence on manual reporting.

Despite these limitations, it is important to note that this study represents a significant step toward enhancing inpatient fall risk management through the FRMIS implementation. Future research and development efforts could focus on expanding the system's applicability to other hospitals, integrating AI capabilities for automated risk assessment, and improving data accuracy and automation processes. These advancements would contribute to more comprehensive and intelligent fall risk management practices for inpatients.

Conclusions

The design and implementation of an FRMIS significantly contributed to the prevention and management of falls among inpatients. The FRMIS enhanced patient safety through IT, providing comprehensive support for fall prevention and ensuring efficient management of fall events in health care settings.

Acknowledgments

We sincerely thank the nursing management and the participating nurses of the Tongji hospital for their support and participation in this study. This study was partly funded by the Huazhong University of Science and Technology Independent Innovation Fund (2013YQ008, 2018KFYYXJJ016), Chinese Nursing Association Research Project (ZHKY202204), and China Nursing Management Research Fund (CNM-2020-03).

Data Availability

The data sets used or analyzed during this study available from the corresponding author on reasonable request.

Authors' Contributions

WY designed the study. JMY and HM collected the data. HM and DMJ analyzed the data. JMY wrote the original draft of the manuscript. WY and HM reviewed and edited the manuscript. WY applied for funding. All authors have read and agreed to the version of the manuscript intended for publication.

Abstract

Background: The increasing population of older adults has led to a rise in the demand for health care services, with chronic diseases being a major burden. Person-centered integrated care is required to address these challenges; hence, the Turkish Ministry of Health has initiated strategies to implement an integrated health care model for chronic disease management. We aim to present the design, development, nationwide implementation, and initial performance results of the national Disease Management Platform (DMP).

Objective: This paper's objective is to present the design decisions taken and technical solutions provided to ensure successful nationwide implementation by addressing several challenges, including interoperability with existing IT systems, integration with clinical workflow, enabling transition of care, ease of use by health care professionals, scalability, high performance, and adaptability.

Methods: The DMP is implemented as an integrated care solution that heavily uses clinical decision support services to coordinate effective screening and management of chronic diseases in adherence to evidence-based clinical guidelines and, hence, to increase the quality of health care delivery. The DMP is designed and implemented to be easily integrated with the existing regional and national health IT systems via conformance to international health IT standards, such as Health Level Seven Fast Healthcare Interoperability Resources. A repeatable cocreation strategy has been used to design and develop new disease modules to ensure extensibility while ensuring ease of use and seamless integration into the regular clinical workflow during patient encounters. The DMP is horizontally scalable in case of high load to ensure high performance.

Results: As of September 2023, the DMP has been used by 25,568 health professionals to perform 73,715,269 encounters for 16,058,904 unique citizens. It has been used to screen and monitor chronic diseases such as obesity, cardiovascular risk, diabetes, and hypertension, resulting in the diagnosis of 3,545,573 patients with obesity, 534,423 patients with high cardiovascular risk, 490,346 patients with diabetes, and 144,768 patients with hypertension.

Conclusions: It has been demonstrated that the platform can scale horizontally and efficiently provides services to thousands of family medicine practitioners without performance problems. The system seamlessly interoperates with existing health IT solutions and runs as a part of the clinical workflow of physicians at the point of care. By automatically accessing and processing patient data from various sources to provide personalized care plan guidance, it maximizes the effect of evidence-based decision support services by seamless integration with point-of-care electronic health record systems. As the system is built on international code systems and standards, adaptation and deployment to additional regional and national settings become easily possible. The nationwide DMP as an integrated care solution has been operational since January 2020, coordinating effective screening and management of chronic diseases in adherence to evidence-based clinical guidelines.

Introduction

As in the rest of the world, the aging population is increasing rapidly in Turkey. A recent TurkStat report predicts that by 2030, the older adult population will be 12.9%, rising to 22.6% in 2060 and 25.6% in 2080 [1]. Noncommunicable diseases are the leading cause of death and disability in Turkey, posing a significant burden [2]. The elevated health costs for older adults strain Turkey's health care system. To address this, the Turkish Ministry of Health (MOH) has implemented a national strategy emphasizing multidisciplinary teams, led by family physicians. The goal is to enhance early detection and manage complications of noncommunicable diseases through systematic screening programs under the national Disease Management Platform (DMP) project launched in late 2018.

The growing use of digital health solutions such as electronic health records (EHRs) presents an opportunity to enhance chronic disease management. Clinical decision support services (CDSSs) can assist in making patient-centered and evidence-based decisions [3,4]. Digital tools and systems that collect and use patient information to provide decision support for health care professionals (HCPs), including patient-specific assessments and recommendations, can promote adherence to national guidelines, ultimately resulting in enhanced quality of care [5-9]. Research demonstrated that computerized decision support tailored to the patient successfully improved decision-making [10,11]. Such tools enhanced the decision-making abilities of HCPs in various domains, including effective prescription decisions [12,13], adherence to guidelines for cardiac rehabilitation [14], management of hypertension and diabetes [15-21], cancer screening [22,23], and computerized order decisions [24,25].

Building on these results, the national DMP is designed as an integrated care platform for chronic disease management in Turkey in a family physician–centered manner. It aims to effectively implement clinical treatment protocols, ensuring easy adherence with decision support services. These services focus on early diagnosis, followed by structured treatment recommendations during routine follow-ups. The DMP enhances standardization of care, improving health care efficiency and quality. It also facilitates seamless transitions between primary care and specialist services, reducing costs, minimizing risks, eliminating redundant tests, and easing the burden on patients.

To ensure successful implementation of a DMP aimed at achieving these strategic objectives, several technical challenges need to be addressed. Our design decisions consider the crucial factor of integrating CDSSs seamlessly into clinicians' daily workflow [26,27]. Despite the potential of CDSSs for evidence-based medicine, significant effort is needed to realize these benefits [28]. The DMP must smoothly integrate with physicians' workflows, necessitating interoperability with existing health IT systems. CDSS guidance should be user-friendly, ensuring a natural flow for clinical protocol implementation. With a target audience of over 26,000 practitioners in Turkey, serving a population of over 85 million, the platform must ensure high performance and scalability. It should easily expand to address additional diseases within a reasonable timeframe and prioritize reusability and compliance with international health IT standards for versatile deployment.

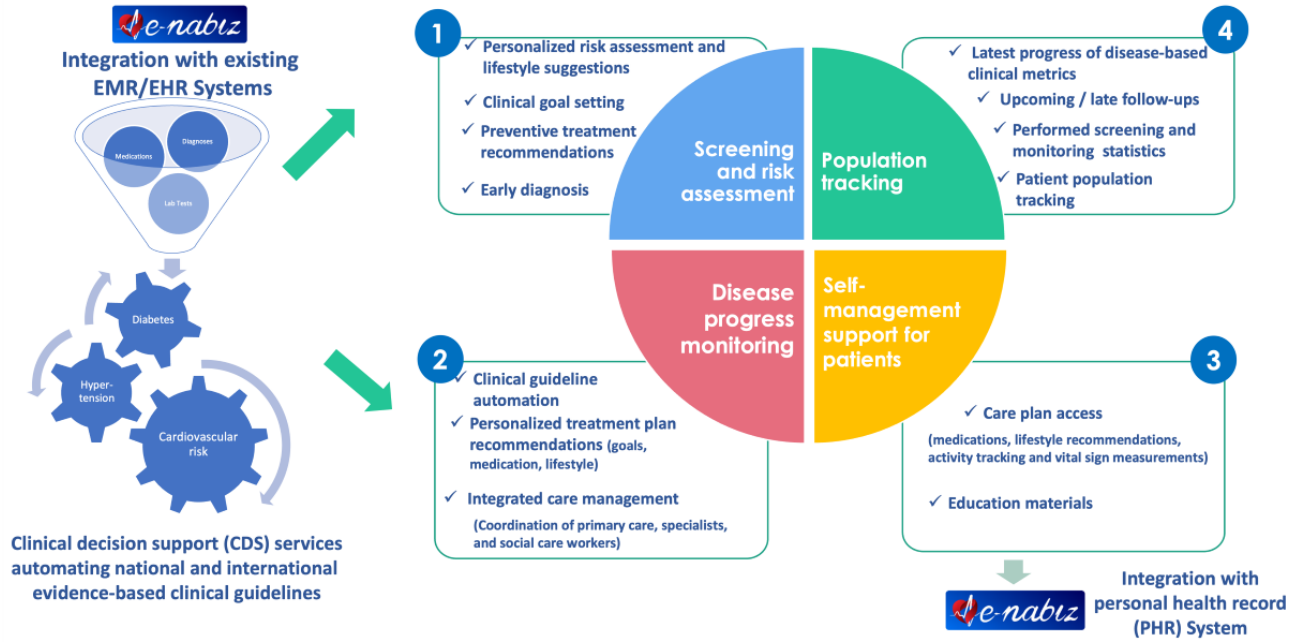
This paper outlines the design, development, nationwide implementation, and initial performance results of the national DMP in Turkey. The DMP can be categorized as a "2.3-Healthcare Provider Decision Support System" in terms of World Health Organization "Classification of digital health interventions" [29]. This implementation report will focus on the results of the deployment and implementation of the DMP in Turkey serving to more than 26,000 family medicine practitioners (FMPs) in the country. The objective is to share our experiences in building the DMP, as an implementation report in line with *iCHECK-DH: Guidelines and Checklist for the Reporting on Digital Health Implementations* [30]. We detail the design decisions and technical solutions aimed at ensuring interoperability with existing IT systems, integration with clinical workflow, enabling smooth transition of care, user-friendliness for HCPs, scalability, and adaptability in the *Methods* section. The *Implementation (Results)* section presents the outcomes of the nationwide implementation (number of users, number of screening and monitoring encounters, number of patients covered via these encounters, number of patients diagnosed as a result of screening encounters, and treatment goal achievements [such as blood pressure targets, hemoglobin A_{1c} {HbA_{1c}}, and cholesterol targets]), demonstrating how these objectives were achieved. Additionally, we outline current limitations and identify areas for future work to further enhance the clinical impact.

Methods

Overall System Architecture and Design Decisions

The DMP has been designed and implemented to enable the following 4 high-level features as summarized in Figure 1:

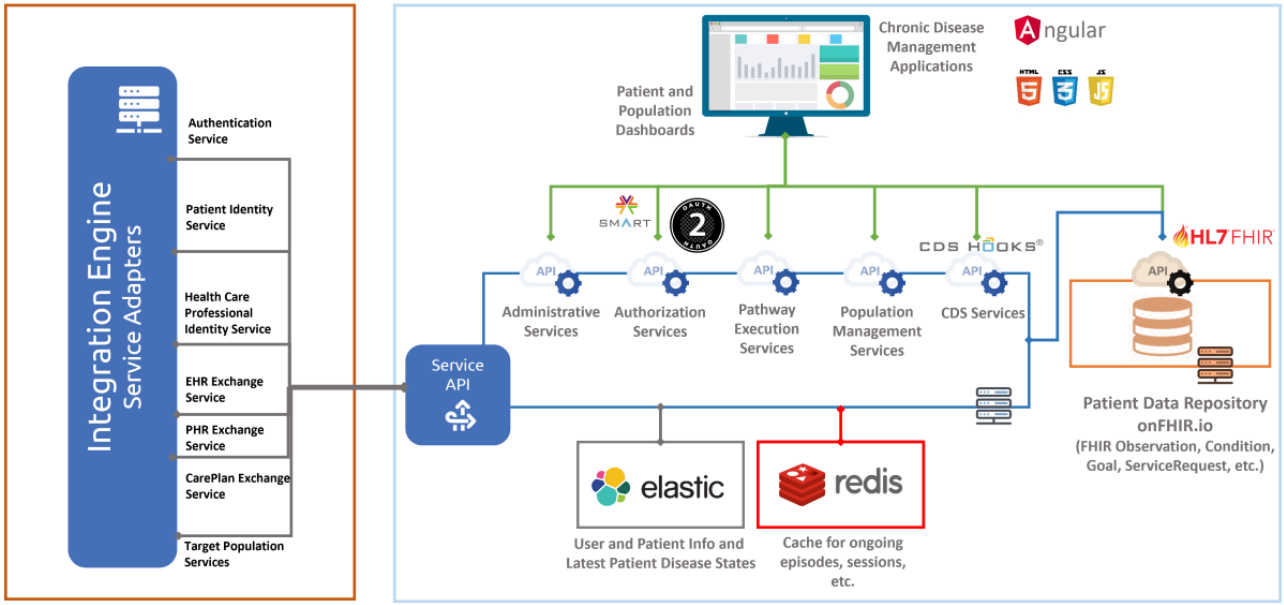
Figure 1. Overall aims of the disease management platform architecture. EHR: electronic health record; EMR: electronic medical record.



- Screening and risk assessment for healthy population: a web-based platform for FMPs facilitates screening for the healthy population. For instance, diabetes screening is required every 3 years for citizens aged over 40 years without a diabetes diagnosis. The full eligibility criteria for both screening and monitoring are presented in Multimedia Appendix 1. The system offers personalized risk assessments, early diagnosis, individualized goals, preventive treatment, and lifestyle suggestions aligned with national care pathways. Diagnosed patients enter the disease progress monitoring program, whereas undiagnosed individuals receive intensified screening based on risk and lifestyle recommendations.
- Disease progress monitoring: for diagnosed patients, the platform facilitates creating and updating personalized care plans during regular follow-up encounters, aligning with evidence-based national care pathways. It assesses laboratory results, conducts risk assessments, recommends personalized treatment goals and medications, suggests follow-up appointments, and refers to specialists when necessary for consultations and complication management. Patients in the monitoring program are categorized based on their control of clinical parameters, symptoms, and goal achievement status, guiding decisions on follow-up frequency, secondary care referrals, and medication plan updates.
- Self-management support for patients: a care plan with instructions for FMPs, specialists, and patients is shared with Turkey's e-Nabiz platform, the national EHR and personal health record (PHR) system. Patients can then access details about care plan activities, including medications, educational materials, self-measurement activities, and lifestyle recommendations.
- Population tracking: each FMP manages 2000 to 4000 patients based on their region's population. The population tracking module allows them to filter and manage patients for upcoming or overdue screening and monitoring encounters, access statistics on the screened population, send SMS invitations to patients, and monitor goal achievement for clinical parameters such as fasting plasma glucose, HbA_{1c}, and blood pressure.

The overall system architecture of the DMP is depicted in Figure 2.

Figure 2. High-level system architecture of the disease management platform. API: application programming interface; CDS: clinical decision support; EHR: electronic health record; FHIR: Fast Healthcare Interoperability Resources; HL7: Health Level Seven; PHR: personal health record.



Seamless Integration and Interoperability With Existing Systems

The DMP is designed and implemented for seamless integration with existing regional and national health IT systems. To achieve this, we have designed the core data model and data processing architecture of the DMP based on Health Level Seven (HL7) Fast Healthcare Interoperability Resources (FHIR) Release 4 [31]. FHIR has gained widespread adoption in the health care industry [32-36] and endorsed by country-wide implementations in the United States [34], United Kingdom [37], and Germany [38].

The DMP core data model conforms to HL7 FHIR Release 4 to encompass basic EHR components as well as resources for representing a patient's care plan. An open-source HL7 FHIR Repository, namely onFHIR.io [39], serves as the main component of the data management layer (Figure 2). onFHIR.io uses MongoDB as a database and provides real-time data subscription with the help of Apache Kafka. The DMP web application directly accesses patient and care plan data through RESTful interfaces provided by onFHIR.io, enabling fine-grained access control over all FHIR resources in compliance with the SMART on FHIR authorization guidelines and scopes [40].

In Turkey, the MOH operates e-Nabiz, a central national EHR infrastructure [41]. This system collects patient records as encounter summaries from nationwide health care providers, with patients also inputting vital signs and activity data. e-Nabiz codes data using international and national medical terminology, such as *International Classification of Diseases, Tenth Revision* (ICD-10). It is a document-based repository accessed through a Representational State Transfer application programming interface [42], and interoperability adapters in the DMP project (EHR exchange and PHR exchange services in Figure 2) communicate with it to retrieve patient data. These adapters transform proprietary XML formats to HL7 FHIR-based data models and store them in the Patient Data Repository. This transformation includes both structural and semantic mapping, incorporating a strategy of incremental synchronization. On initial DMP access, the patient's longitudinal EHR is mapped to FHIR, and subsequent encounters retrieve and transform only new, unsynchronized data.

To secure patient data access, clinicians authenticate to the DMP through the MOH's central authentication and authorization services using the OpenID Connect protocol. The DMP uses a role-based access control mechanism, catering to different disease management roles. Before data access and synchronization, a check ensures that the user has the required access rights via the MOH's central authentication service. If authorized, the DMP generates a patient-specific JavaScript Object Notation Web Token with corresponding permissions, serving as an OAuth2.0 bearer token for all interactions within the DMP.

In the DMP, FMPs perform screening and monitoring encounters based on predefined eligibility criteria. For instance, hypertension monitoring is required every 3 months for patients with a hypertension diagnosis and on antihypertensive medications. These criteria are executed in the e-Nabiz data warehouse, and both DMP and family medicine information systems retrieve target population lists through target population services (Figure 2). FMPs can easily identify if a visiting patient is on the screening or monitoring list via family medicine information systems, initiating a DMP encounter directly with a single sign-on integration.

The care plan created with the help of the DMP is stored as an HL7 FHIR *CarePlan* resource in the Patient Data Repository. It is shared with the e-Nabiz system via the Care Plan Exchange Service (Figure 2), enabling it to be accessible to the patient via e-Nabiz interfaces.

The DMP uses Elasticsearch technology for storing user information, basic patient attributes, and their current screening and monitoring statuses for each disease. Elasticsearch also serves as a system log repository. We have developed a Kibana

interface for monitoring system performance and geographical statistics. Redis is used as a caching system to temporally store information about ongoing encounters and user authorization access tokens.

Automation of National Care Pathways as a Clinical Workflow for FMPs

The interfaces of the DMP have been designed with ease of use in mind to allow for seamless integration into the regular clinical workflow. It is implemented as a cocreation activity with the involvement of system analysts, software engineers, and a clinical reference group set up by the MOH Department of Chronic Diseases and Elderly Health including multidisciplinary HCPs.

The national evidence-based care pathways have been collaboratively analyzed, leading to the identification of common steps, such as physical examination, medical history review, risk assessment, medication review, lab results review, diagnosis, clinical goal setting, pharmacological treatment planning, and nonpharmacological treatment planning. Each care pathway is designed modularly within the DMP as a series of pages corresponding to these common steps. These are organized as a flow of pages that is followed automatically based on patient parameters.

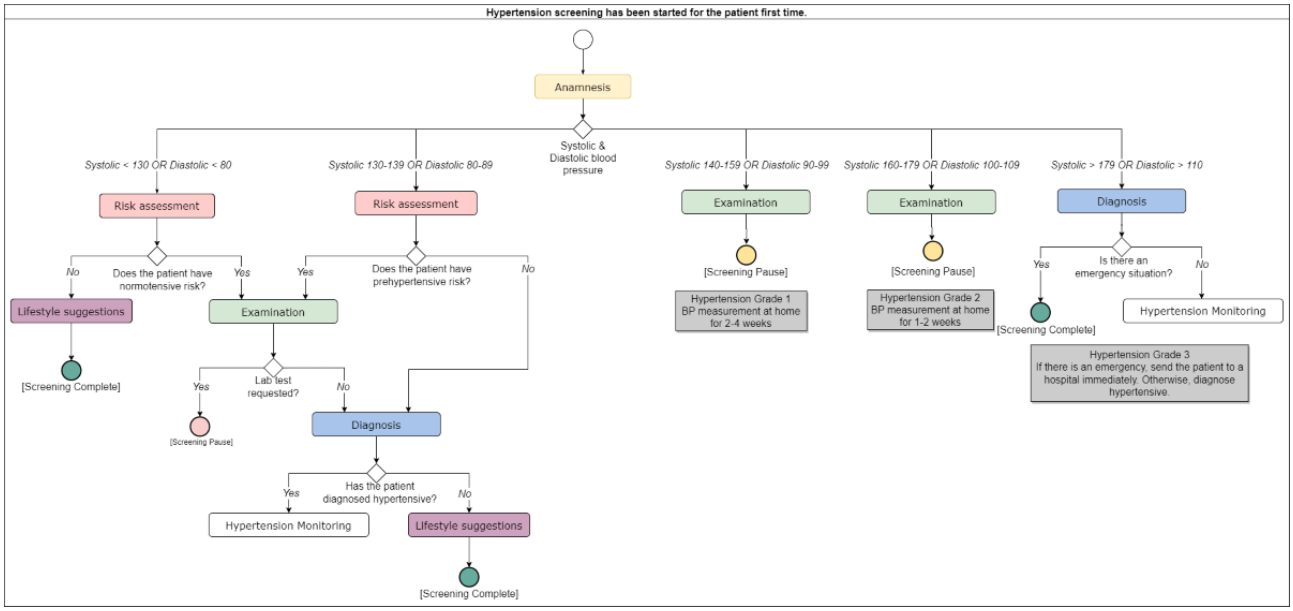
Each page is meticulously designed, specifying patient parameters for assessment. Most data come from the national EHR system, enabling clinicians to review prefilled pages with the latest parameters and make adjustments as needed. Validity periods for each parameter are identified, emphasizing recency, and they are enforced by the system and reminded to FMPs. Additionally, scaled assessments (eg, Mini Nutritional Assessment), risk assessments (eg, cardiovascular risk), and associated algorithms (eg, SCORE-Turkey) are also identified. Business rules within the pages are designed for personalized suggestions aligned with evidence-based care pathways.

All of these are thoroughly documented after discussions in cocreation workshops. Mock-up screens are designed, and flow diagrams are created to identify transition criteria between pages. These materials undergo further review and finalization in subsequent cocreation workshops. As an illustrative example, Figure 3 depicts a sample flow for hypertension screening.

After cocreation, each step's design becomes a web-based interface in the DMP application, developed with the Angular framework. A "Pathway Execution Service" state manager automates the flow diagram for disease screening or monitoring, adapting to patient parameters. This allows FMPs to use a wizard-like interface for encounters, facilitating adherence to national clinical pathways.

Transitions between disease modules are also modeled and implemented. For example, in hypertension screening, if a patient's fasting plasma glucose exceeds 110 mg/dL, the system prompts FMPs to consider a diabetes screening if not already monitored for diabetes. In response, the patient's diabetes screening schedule is automatically updated.

Figure 3. Hypertension screening flow. BP: blood pressure.



CDSS Implementation

CDSSs are a core component of DMP to enable patient-tailored recommendations. On the basis of the documented business rules from the design phase, we have designed CDSSs as automated processes. These processes link patient-specific data with evidence-based knowledge from national care pathways. We can categorize the CDSS implemented based on their functionality as follows:

- Risk assessment via scored algorithms (eg, SCORE-Turkey): FMPs are provided with explanatory guidance about scoring, referencing validated scoring assessment algorithms (see Figure 4).
- Diagnosis recommendations based on the patient's current condition and risk assessment: in screening operations, the CDSS recommends diagnoses to FMPs using predefined ICD-10 codes.

- Guidance for lab test ordering and interpretation: a personalized list of required lab tests is determined based on the patient's disease state, risks, and other comorbidities. The CDSS also provides notifications for when these lab tests should be renewed on expiration.
- Diagnosis and referral suggestions are recommended based on patient parameters such as lab results. For example, referral to a nephrologist is recommended when the estimated glomerular filtration rate result is below 60 mL/min/1.73 m^2.
- Treatment goals (eg, low-density lipoprotein cholesterol) are recommended based on the patient's risk, disease stage, and comorbidities. In Figure 5, an example screen for goal planning is presented. The physician can always manually update these targets based on their assessments.
- Medication suggestions are recommended for treatment planning based on disease stage, response to previous medications, existing medications, and comorbidities. Certain medications are marked as contraindications based on the existing comorbidities of the patient.
- Referral suggestions for preventive consultation visits are recommended, especially for complication management. For instance, a yearly retinopathy check with an ophthalmologist is advised during diabetes monitoring encounters.
- Follow-up visits are recommended based on the current status of the patient. For instance, screening in each 2 years is suggested for patients with low cardiovascular disease risk, whereas once a year screening is suggested for high-risk patients.
- Automated care pathway transitions for patients with multiple morbidities are personalized based on specific disease criteria. For instance, if a patient aged over 40 years has not had their cardiovascular risk score calculated, the DMP guides FMPs to continue with the cardiovascular risk module during hypertension or diabetes monitoring.

In the DMP, all CDSS implementations adhere to the CDS Hooks specifications [43]. As a standard published by HL7, it provides an API specification for CDS calls. Both input parameters and output suggestions are defined in reference to HL7 FHIR resources, facilitating plug-and-play interoperability with platforms that support HL7 FHIR. The CDS Hooks–compliant approach allows easy expansion with CDSSs created by external entities and to simplify deployment in different settings already adhering to HL7 FHIR.

Figure 4. An example screenshot from the Cardiovascular Risk Screening Module presenting individualized risk calculation. (The system is implemented in a multilingual manner supporting Turkish and English by default.) CVD: cardiovascular disease.

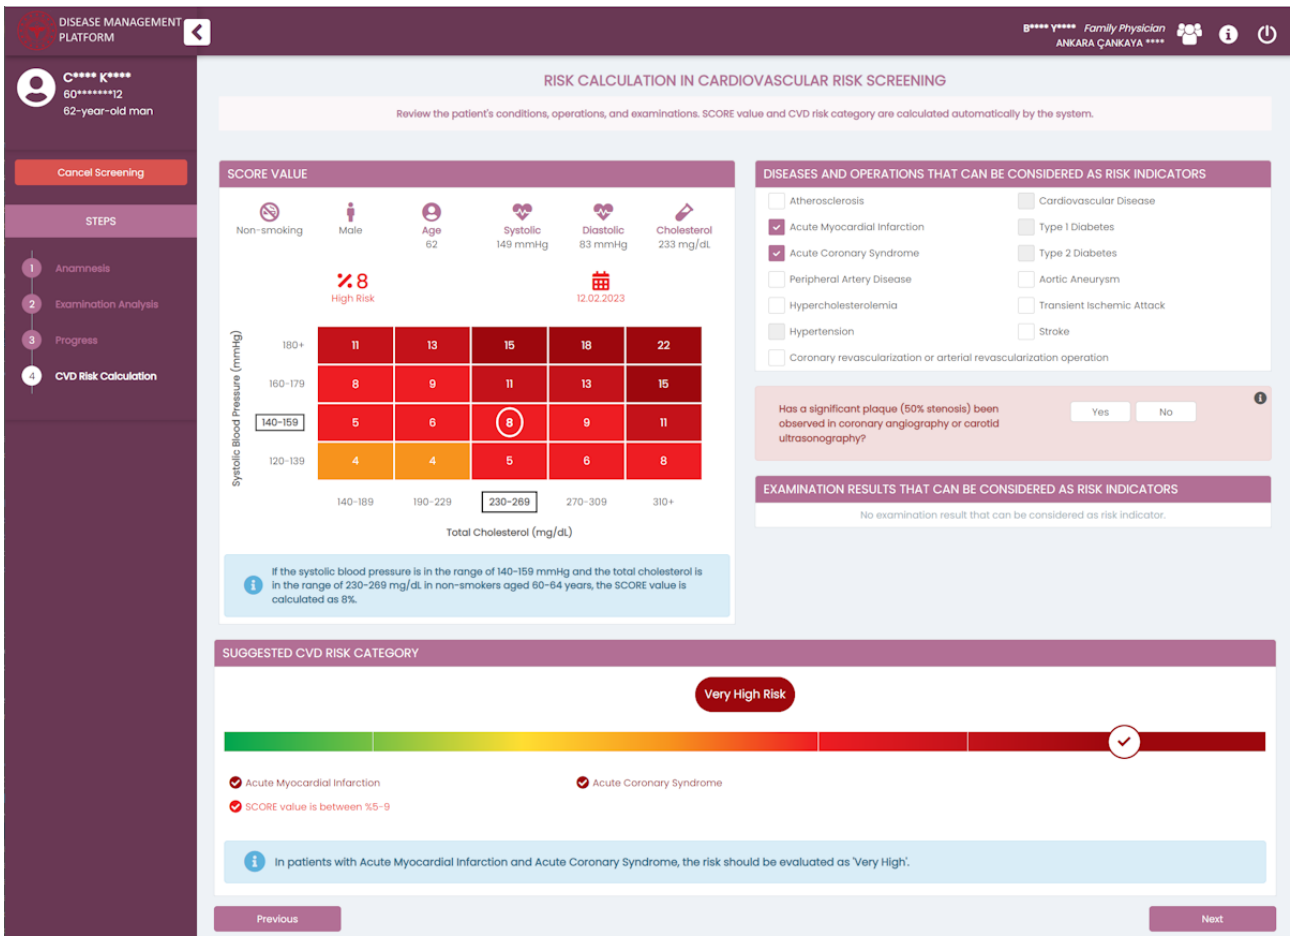


Figure 5. An example screenshot from the disease management platform presenting personalized lipid goals for the patient. HDL: high-density lipoprotein; LDL: low-density lipoprotein.

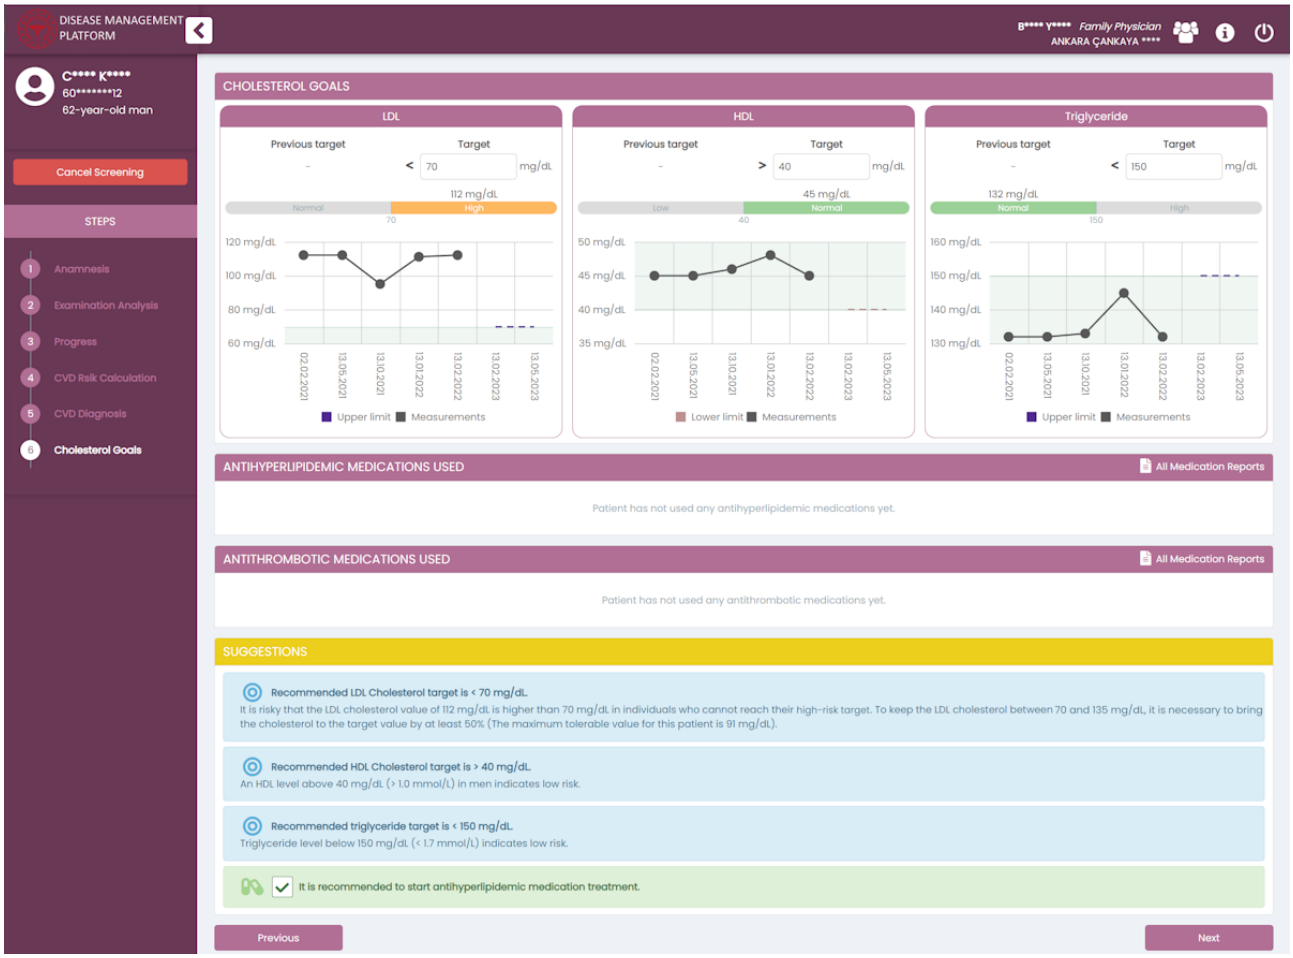

Ensuring Performance of the System

The DMP is designed for high horizontal scalability, using 2 servers for the web application and 3 for the Patient Data Repository, forming an onFHIR.io server cluster. Nginx acts as both a reverse proxy and a load balancer to distribute traffic across these backend servers. onFHIR.io servers connect to a horizontally scalable MongoDB cluster for data distribution and replication. Elasticsearch log and data store operate on a cluster hosted on 6 servers.

Testing, Piloting, and Deployment of Disease Modules

The system is developed by SRDC on behalf of the Turkish MOH with the support of Türksat and Innova. The final product is owned by the Turkish MOH. The initial version of the DMP, including modules for screening and monitoring of type 2 diabetes, hypertension, and cardiovascular risk management, was extensively tested by the clinical reference group. It underwent a 3-month pilot phase in 4 cities in late 2019. The pilot phase involved 14,351 encounters conducted by 219 FMPs for 5521 patients. Two more modules for obesity screening and monitoring, as well as older adult monitoring, were added to the system during this period. After the feedback is addressed and the system is retested, the system has been operationalized in whole Turkey by January 2020. On June 30, 2021, the MOH has published a directive incentivizing FMPs to conduct screening and monitoring for diabetes, hypertension, cardiovascular disease risk management, obesity, and older adult monitoring via the DMP. The system with incentivization calculations has been operational in whole Turkey since July 1, 2021.

Beyond existing modules, the system now includes monitoring modules for coronary artery disease, chronic kidney disease, stroke, chronic obstructive pulmonary disease, and asthma. The cocreation process, covering requirement analysis, mock-up design, implementation, and testing, took 3 months for each module, showcasing the process's repeatability for swift module additions. These new disease modules are not yet public in the operational system.

Implementation (Results)

The system is being used extensively throughout the whole country. As of September 18, 2023, a total of 73,715,269 screening and monitoring encounters have been performed by 25,568 users (24,627 FMPs and 941 FMP nurses) for 16,058,904 unique citizens. Among these citizens, 56.2% (n=9,025,104) are female and 43.8% (n=7,033,800) are male. The average number of DMP encounters per patient is 4.59. The distribution of encounters per DMP module and the breakdown between screening and monitoring is provided in Table 1.

In Turkey, there are 26,600 FMP units, with each unit using 1 FMP at a time. As of September 18, 2023, FMPs working at

26,210 (98.5%) unique FMP units have logged into the DMP at least once, and 22,982 (86.4%) FMP units have performed at least 1 encounter.

Table 2 details the nationwide coverage rates per disease module and encounter type as of September 18, 2023. It includes the cumulative target population size and the unique number of patients screened or monitored at least once. During this period, DMP screenings led to new diagnoses: 144,768 for hypertension, 490,346 for diabetes, 534,423 for high cardiovascular risk, and 3,545,573 for obesity. These individuals were diagnosed with these chronic diseases for the first time, following evidence-based clinical guidelines.

Age histograms of DMP patients who have been screened or monitored at least once are provided per sex in Figure 6.

Piloting studies occurred from October to December 2019, and the system has been fully operational nationwide since January 2020. Use notably increased with FMP salary incentivization calculations on July 1, 2021 (Figure 7), showing monthly encounter numbers by module from the start of 2021. Since then, encounters have steadily risen, with minor drops during summer holidays, and the distribution among DMP modules has remained consistent.

Figure 8 displays the distribution of total DMP encounters per city in Turkey, with colors intensifying as encounter numbers rise. Although higher numbers generally align with city populations, outliers exist, as seen in the top 10 performing cities outlined in Table 3. Despite Istanbul having Turkey's largest population, it only slightly surpasses Ankara in DMP encounters. This is mainly due to the high patient load per FMP in Istanbul. FMPs overseeing over 4000 citizens are exempt from DMP use due to their heavy workload. Table 3 also provides patient average age and encounter duration information.

The performance of the FMPs is assessed monthly. The cumulative targets and realized achievement rates for January 2023 are provided in Table 4. An achievement rate of 23.1% (4,508,841/19,546,041) for the entire population represents significant advancement compared with the 3.9% (511,198/13,117,900) achievement rate in July 2021.

The DMP system recommends personalized treatment goals such as systolic blood pressure, low-density lipoprotein cholesterol, and weight based on clinical guidelines. After a treatment goal is set, the DMP also assesses progress toward the goal in subsequent encounters. As of September 18, 2023, approximately 12.4 million of these treatment goals have been assessed, and the achievement rates are presented in Table 5. These assessments provide valuable information for FMPs caring for their patients.

At present, the performance of the FMPs is quantitatively calculated based on the number of performed encounters. However, the MOH envisions transitioning to a qualitative performance evaluation in midterm, where treatment goals and their achievement rates will play a significant role.

The system is highly performant and scalable. On a selected working day, February 14, 2023, the onFHIR.io HL7 FHIR Repository handled a total of 105.7 million FHIR interactions with an average response time of 31.3 milliseconds. During peak times of the day, the system can effortlessly manage up to 5000 FHIR interactions per second. Multimedia Appendix 2 illustrates the distribution and average response time of FHIR interactions on this day.

Among all FHIR requests, 57.4% (60.7 million) are search interactions, which are extensively used by the DMP web app to find, display, and forward specific clinical concept values to CDSS. Following search interactions, update interactions make up 33.2% (35.1 million) of the requests and are also used for resource creation when a provided resource ID is available. The average response times for read and search interactions are only 3.9 and 6.4 milliseconds, respectively. In the case of transactions and batch interactions, the average response times are even lower than update interaction alone, thanks to the parallelization of contained requests within onFHIR.io. As of September 18, 2023, onFHIR.io maintains a repository of 16.3 billion FHIR resources, totaling 22.4 terabytes in size, including care planning data by DMP and EHR/PHR data synchronized from e-Nabiz.

Table 1. Total screening and monitoring encounters per module.

Module	Screening (n=45,166,536), n (%)	Monitoring (n=28,548,733), n (%)	Total (n=73,715,269), n (%)
Hypertension	13,857,594 (30.7)	12,046,449 (42.2)	25,904,043 (35.1)
Obesity	18,029,994 (39.9)	800,480 (2.8)	18,830,474 (25.5)
Diabetes	8,914,193 (19.7)	5,071,646 (17.8)[a]	13,985,839 (19.0)
CVD[b] risk	4,364,755 (9.7)	9,182,814 (32.2)	13,547,569 (18.4)
Older adult	N/A[c]	1,447,344 (5.1)	1,447,344 (2.0)

[a]Only the patients monitored in primary care are listed; advanced obesity cases (a BMI over 40 kg/m^2 or a BMI between 30 and 40 kg/m^2 supported with additional comorbidities) are monitored in secondary and tertiary care.

[b]CVD: cardiovascular disease.

[c]N/A: not applicable.

Table 2. Coverage rate of citizens in target population lists.

Module and encounter type	All citizens in target population, n	Screened and monitored patients, n	Coverage rate (%)
Hypertension			
Screening	48,443,467	10,820,774	22.3
Monitoring	14,943,378	4,083,057	27.3
Obesity			
Screening	59,956,288	14,640,013	24.4
Monitoring	769,654[a]	383,920	49.9
Diabetes			
Screening	27,450,172	6,486,947	23.6
Monitoring	7,588,543	2,472,585	32.6
CVD[b] risk			
Screening	17,276,617	3,319,070	19.2
Monitoring	17,759,500	5,078,665	28.6
Older adult			
Monitoring	8,770,474	1,056,766	12.0

[a]Only those in the primary care obesity monitoring list, as explained in Table 1.

[b]CVD: cardiovascular disease.

Figure 6. Age histograms of disease management platform patients: female on the left and male on the right.

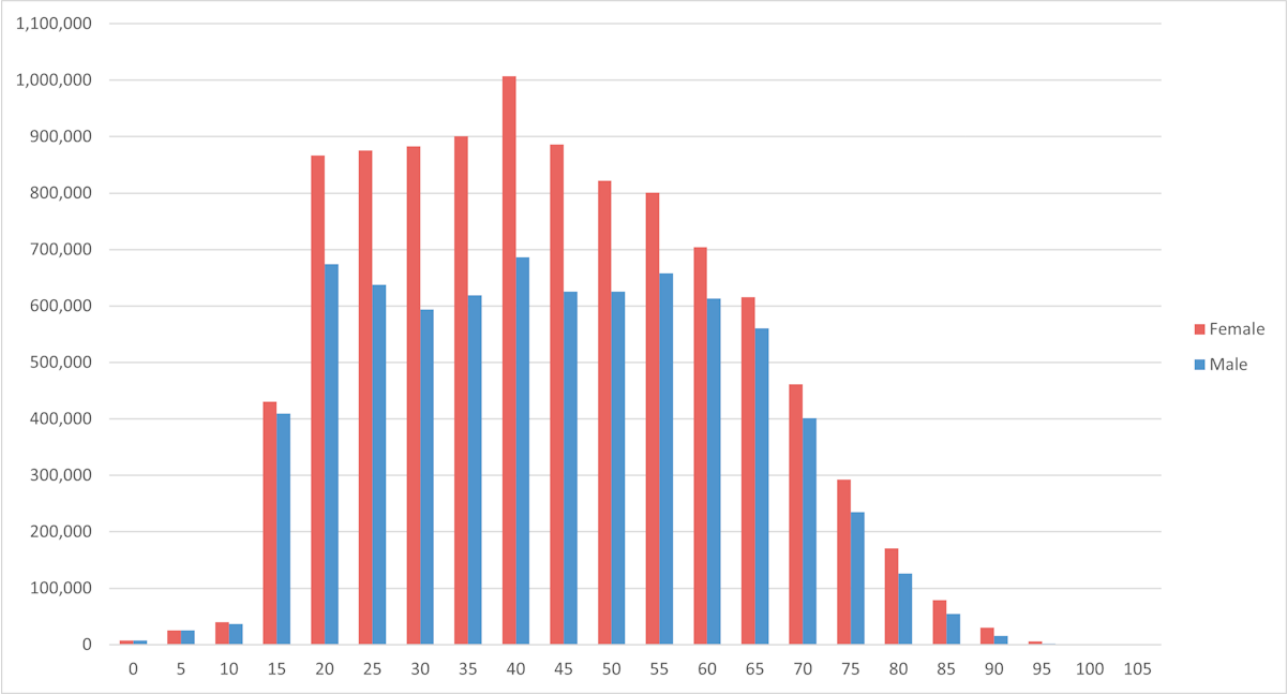

Figure 7. Disease management platform encounters per month by module. CVD: cardiovascular disease.

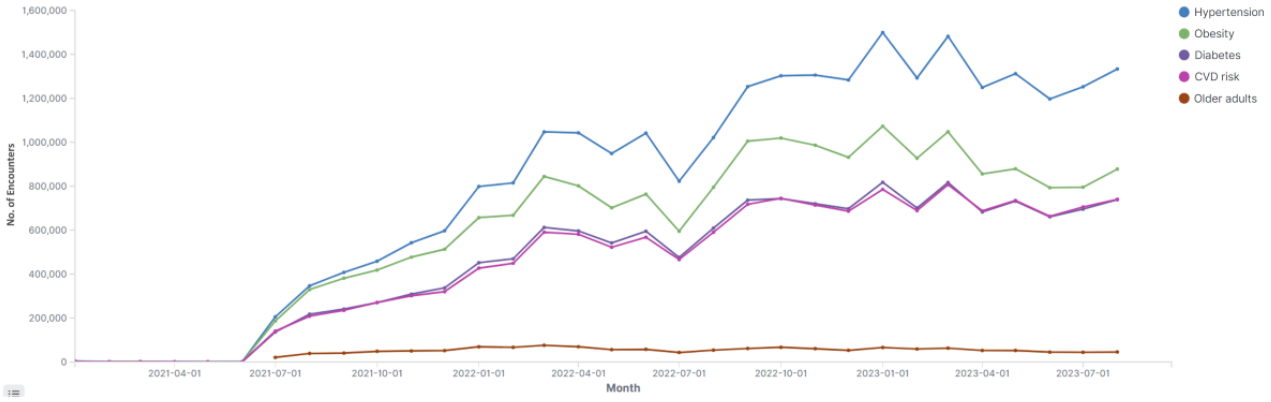

Figure 8. Encounters by city on a map.

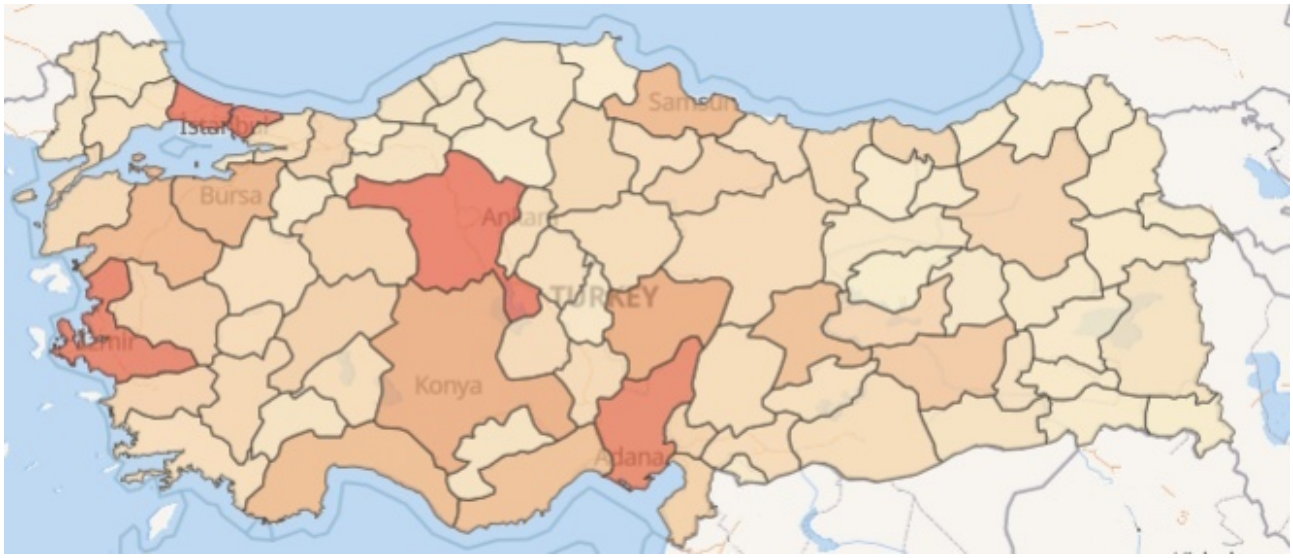

Table 3. Top 10 performing cities.

City	Total population[a]	Rank[b]	Number of encounters	Number of patients	Average age of patients (years)	Average duration (minutes)
Istanbul	15,907,951	1	4,974,972	1,286,640	50.5	1.21
Ankara	5,782,285	2	4,918,745	1,084,797	51.7	1.13
Izmir	4,462,056	3	4,395,653	937,607	53.4	1.18
Adana	2,274,106	7	3,531,441	709,075	51.3	0.99
Kayseri	1,441,523	15	2,633,349	479,849	51.7	1.06
Antalya	2,688,004	5	2,617,274	636,535	51.4	1.08
Konya	2,296,347	6	2,607,459	579,927	51.2	1.15
Bursa	3,194,720	4	2,408,817	525,016	52.3	1.18
Balikesir	1,257,590	17	2,322,111	425,171	55.7	1.13
Samsun	1,368,488	16	2,237,385	422,438	54.2	1.06

[a]2022 census data by the Turkish Statistical Institute (TurkStat).

[b]The rank of cities in Turkey by total population count.

Table 4. Screening and monitoring encounters per module in January 2023.

Module and encounter type	Monthly target	Number of encounters	Achievement rate (%)
Hypertension			
Screening	3,868,662	789,699	20.4
Monitoring	4,795,117	709,004	14.8
Obesity			
Screening	4,849,306	1,083,414	22.3
Monitoring	53,770	51,512	95.8
Diabetes			
Screening	898,665	670,502	74.6
Monitoring	2,128,955	279,071	13.1
CVD[a] risk			
Screening	742,634	262,419	35.3
Monitoring	1,488,004	589,523	39.6
Older adult			
Monitoring	720,928	73,697	10.2
Total	19,546,041	4,508,841	23.1

[a]CVD: cardiovascular disease.

Table 5. Achievement rates of treatment goals.

Treatment goal	Achievement rate (%)
Systolic BP[a]	88.8
Diastolic BP	94.2
Fasting glucose	52.0
HbA_{1c}[b]	61.5
LDL[c] cholesterol	14.8
HDL[d] cholesterol	63.2
Triglyceride	52.6
Weight	5.6
BMI	6.3
Waist circumference	2.9

[a]BP: blood pressure.

[b]HbA_{1c}: hemoglobin A_{1c}.

[c]LDL: low-density lipoprotein.

[d]HDL: high-density lipoprotein.

Discussion

Principle Findings and Lessons Learned

We have demonstrated that as of September 18, 2023, the DMP has been used by more than 25,000 users to conduct over 73 million screening and monitoring encounters for more than 16 million individuals. The national directive incentivizing FMPs to conduct screening and monitoring for chronic diseases is one of the contributing factors to this success.

We demonstrated the platform's efficient horizontal scalability, serving thousands of HCPs daily without performance issues. DMP screenings identified approximately 150,000 new hypertension cases, over 490,000 diabetes cases, more than 500,000 high cardiovascular risk cases, and over 3.5 million obesity cases. This allowed timely treatment in line with evidence-based guidelines.

We have shown that the system seamlessly interoperates with existing national EHR via HL7 FHIR. It enables accessing and processing patient data from various sources to provide personalized care plan guidance, maximizing the effectiveness

of evidence-based decision support services. The DMP has achieved all 5 levels of the 5S Model as proposed by Haynes [44] for the successful implementation of information services for evidence-based health care decisions. Continuous cocreation activity involving members of the Turkish MOH has contributed this success, along with the interoperability architecture based on international standards. On the other hand, we have collected feedback from FMPs to encourage us to also enable seamless integration with the national e-Prescription and national appointment system. FMPs need to manually input prescription and appointment recommendations into the other systems. Future plans include integrating these national systems directly to the DMP as well.

Although we have demonstrated that, through a repeatable and well-defined cocreation methodology, the system can be easily extended to address additional diseases, it still requires implementation effort from developers. We plan to extend the DMP system with administrative interfaces. This will enable subject matter experts from the MOH to create new disease screening and monitoring modules using form-based design interfaces.

Finally, although FMPs conduct screening and monitoring, specialists can view patient dashboards but cannot perform encounters; this can be easily enabled with the DMP's role-based access control mechanism, pending organizational decisions for national-scale implementation.

The system is operated as a part of national health IT ecosystem funded by the budget of the Turkish MOH. Open-source technologies have been used; hence, additional licensing fee has not incurred. Approximately 80% of the budget is spent for software development, 15% for project management, and 5% for training costs. Initial development phase has lasted 2 years. In the last 2.5 years, the system is under maintenance, and new disease modules have been developed.

Prospective Benefits and Impact

The system paves the way forward value-based care, where patient outcomes are monitored, and providers are incentivized for improving health. Currently, the DMP sets individual clinical goals (eg, HbA_{1c} and BMI) based on evidence-based guidelines. It monitors FMP performance in achieving these targets through close screening and monitoring. FMPs are presently incentivized based on screening and monitoring visits, but the system is ready to adopt value-based care by monitoring clinical targets.

DMP implementation opens opportunities to collect real-time research data, measuring the effectiveness of nationwide disease management protocols. Continuously gathering information about patients' disease status and recording outcomes from screening and monitoring visits, the generated data provide valuable insights into disease management.

Conclusions

This paper introduces a nationwide DMP designed for effective chronic disease screening and management, aligning with evidence-based clinical guidelines to enhance health care quality. With its user-friendly interfaces, it guides FMPs through personalized care planning with checklists for medication orders, referrals, lab tests, and risk screening. The system has been operational nationwide since January 2020. We have demonstrated seamless EHR integration, scalability, performance, and effectiveness in early diagnosis and meeting clinical targets. Future work includes a comprehensive study to analyze the direct clinical and cost-saving effects of the DMP on chronic disease management in Turkey.

Acknowledgments

The authors wish to acknowledge administrative and technical support by the following departments of the Turkish Ministry of Health: Department of Public Health Informatics, Department of Chronic Diseases and Elderly Health, Department of Healthy Nutrition and Active Life, Department of Data Management, and Department of Standards and Accreditation; Türksat, and Innova.

Abstract

Background: Telemedicine, a term that encompasses several applications and tasks, generally involves the remote management and treatment of patients by physicians. It is known as transversal telemedicine when practiced among health care professionals (HCPs).

Objective: We describe the experience of implementing our telemedicine Eumeda platform for HCPs over the last 10 years.

Methods: A web-based informatics platform was developed that had continuously updated hypertext created using advanced technology and the following features: security, data insertion, dedicated software for image analysis, and the ability to export data for statistical surveys. Customizable files called “modules” were designed and built for different fields of medicine, mainly in the ophthalmology subspecialty. Each module was used by HCPs with different authorization profiles.

Implementation (Results): Twelve representative modules for different projects are presented in this manuscript. These modules evolved over time, with varying degrees of interconnectivity, including the participation of a number of centers in 19 cities across Italy. The number of HCP operators involved in each single module ranged from 6 to 114 (average 21.8, SD 28.5). Data related to 2574 participants were inserted across all the modules. The average percentage of completed text/image fields in the 12 modules was 65.7%. All modules were evaluated in terms of access, acceptability, and medical efficacy. In their final evaluation, the participants judged the modules to be useful and efficient for clinical use.

Conclusions: Our results demonstrate the usefulness of the telemedicine platform for HCPs in terms of improved knowledge in medicine, patient care, scientific research, teaching, and the choice of therapies. It would be useful to start similar projects across various health care fields, considering that in the near future medicine as we know it will completely change.

(JMIR Med Inform 2024;12:e42847) doi:10.2196/42847

Introduction

Context

Medicine has typically involved physicians engaging face to face with patients. However, many teleconsultation projects have now been developed, particularly during the COVID-19 pandemic era, which has boosted teleconsultations in all medical specialties [1-4].

Alongside telemedicine between physicians and patients, there is also transversal telemedicine, which is conducted between health care professionals (HCPs). Our experience with this topic started in 1996 and has demonstrated the feasibility of training young ophthalmic vitreoretinal surgeons working in nonoptimal environments (postwar Bosnia), using telemedicine (via a satellite link) in Milan and Sarajevo [5,6]. Input from the above experiences [7,8] constituted the basis for our understanding of the needs of HCPs and the developmental direction of the dedicated telemedicine platform, giving users access, with appropriate personal authorization, from anywhere and at any time.

Problem Statement

The problem to be solved is the difficulty of sharing patients' clinical data and images among health personnel for efficient evaluation. This process should be multidisciplinary, involving actors such as physicians from different specialties, nurses, technicians, orthoptists, geneticists, residents, and tutors who need access to a common database holding key patient information.

Similar Interventions

Our scientific literature analysis identified a number of publications about implementation projects involving telemedicine platforms. These projects were mainly based on COVID-19 management and aimed to support different systems to provide health care in emergency conditions [9-11]. The purpose of these initiatives is to foster telecare and telemonitoring and to reduce the need for patients to visit hospitals or medical centers [12-17]. Our program is oriented in a different direction: the Eumeda web-based medical platform was developed for sharing patients' medical data among physicians. The platform has expanded its services to many HCPs. This paper describes how database modules for the clinical databank and trials, as well as second opinion services, were created and have now been implemented.

Methods

Aims and Objectives

The aim of this implementation program was to broaden the applications of our telemedicine platform with a transversal approach targeted at health care personnel. This process took place over the last 10 years with the creation of different projects aimed at clinical data collection, teleconsultation, and gathering second opinions. Various modules have been built for the platform (Textbox 1) for use by HCPs at different times. Twelve representative modules for different clinical projects are described in Table 1 [18-23].

We identified outcome measures and evaluated overall parameters for access, acceptability, and medical efficacy of the platform (Textbox 2).

Textbox 1. Building a module in 8 steps. The time required for the final release varies between modules (from 1 to 3 months for more complex ones). The original source code for the modules created belongs to the medical platform.

1. Initial agreement between the entity applying the module (university, company, institution, or representative association) and the manager of the medical platform (MP)

2. Signing of detailed operational form (with project requirements, such as the type of project, number of health care professionals and structures involved, and the importance of images) by the main users of the module and the scientific coordinator (who has knowledge of medicine planning and the potentiality and limits of medical informatics) of the MP

3. "Shoulder-to-shoulder" work by the scientific coordinator of the MP and main team programmer of the MP

4. Development of alpha software (not yet stable and still incomplete) to be shown to the entity that will use the module for changes and additions

5. Development of beta software with almost all functionalities

6. Massive data entry by the MP programmer to find bugs or software incompatibilities

7. Completion of beta software with automatic control functionalities (eg, alert icons to prevent inappropriate data from being entered, numerical limitations, and priorities to be respected in data entry or blocking of inappropriate saving) for users to check and identify any small changes required

8. Release of final version in a meeting with users, with explanatory text embedded in the module

Table 1. The left-hand column lists the 12 representative projects for which many modules have been built for the medical platform. The modules designed have been managed by health care personnel over the last 10 years in different locations in Italy.

Module	Description	Module type	Purpose	Timeframe of project activity	Holder	Sponsor
1	Teleconsultation in retinal diseases [18]	Second opinions[a]	Feasibility of second opinions among physicians	1 Month (during 2011)	Insubria University, Varese-Como	Comed Research nonprofit association, Milan
2	Age-related maculopathy [19]	Group[b] (10 locations)	Acceleration of anti–vascular endothelial growth factor therapy	19 Months (2011-2012)	T&C Srl, Milan, Italy	Novartis Pharma SpA, Origgio, Italy
3	Retinal pathology samples and correlated genes [20]	Data[c]	Collection of data on gene expression	4 Months (2012-2013)	Insubria University, Varese-Como	Insubria University, Varese-Como
4	Epiretinal macular membrane [21]	Data	Collection of data on disease morphology and functionality	10 Months (2015-2016)	Insubria University, Varese-Como	Insubria University, Varese-Como
5	Inherited eye diseases	Data	Collection of data on genetic eye diseases	2017-present	Ophthalmological Unit II, University of Naples	Ophthalmological Unit II, University of Naples; Rome Foundation
6	Retinal dystrophy due to rare *RPE65* gene mutation [22]	Group (9 locations)	Collection of data on disease	16 Months (2018-2020)	Ophthalmological Unit II, University of Naples	Retina Italia nonprofit association, Milan
7	Second opinions among resident physicians	Second opinions	Feasibility of second opinions in didactics	4 Months (during 2019)	Comed Research nonprofit association, Milan	Bayer Italy SpA, Milan
8	Instrumental data in multiple sclerosis	Group (2 locations)	Collection of multidisciplinary data on disease	2019-present	Neurological Unit, Insubria, University Varese-Como	Insubria University, Varese-Como
9	Epidemiological data on COVID-19 in workers	Group (2 locations)	Search for COVID-19 in throat, saliva, and tears	3 Months (during 2020)	SEA Company, Milan Linate-Malpensa Airports	SEA Company, Milan Linate-Milan Malpensa Airports
10	SARS-CoV-2 on throat and ocular surfaces [23]	Group (2 locations)	Search for SARS-CoV-2 in throat and tears in COVID-19 patients	1 Month (during 2020)	T&C Srl, Milan. Italy	Insubria University, Varese-Como
11	Potential malignant oral lesions	Group (2 locations)	Collection of data on disease	2021-present	Orthodontics Unit, Insubria University, Varese-Como	Insubria University, Varese-Como
12	Maculopathies and anti-aging medicine	Data	Collection of data on diseases and follow-up	2022-present	Claude Boscher, MD	Claude Boscher, MD

[a]Second opinions: second opinions from health care professionals at the same or a different institution.

[b]Group: shared database used by health care professionals at more than one institution.

[c]Data: shared database used by health care professionals at a single institution.

Textbox 2. Result options for the questionnaire for each health care professional, with relative scores. The final score is given by the sum of the partial scores (maximum 9, minimum 3). Scores equal to or higher than 6 are considered to indicate approval.

Access to the network by computer or mobile devices

- Poor: score of 1
- Good: score of 2
- Very good: score of 3

Acceptability of the procedures

- Poor: score of 1
- Good: score of 2
- Very good: score of 3

Medical efficacy

- Poor: score of 1
- Good: score of 2
- Very good: score of 3

Blueprint Summary

Design of Key Features and Roadmap

The design of the implementation program was oriented to develop three types of operational modules, integrated with one another where necessary: (1) a databank of diseases for clinical or scientific studies, (2) a database for groups of HCPs in different locations, giving them access to shared data from trial studies, and (3) a functionality enabling physicians to seek second opinions. The key points of the implemented modules were easy accessibility, complete acceptability for HCPs, data reliability, and overall medical efficacy considering all health specialties. The roadmap followed these principles and several new projects involving HCPs produced specific modules, which were created for the platform and take advantage of its benefits as a whole.

Technological Design and Infrastructure

Since 2010, the Eumeda platform has used continuously updated versions of PHP, an HTML-embedded web scripting language built to a high standard using advanced technology [24], which has the advantage of speed, flexibility, low use of resources, and compatibility with all web servers. PHP does not require a high level of machine resources to run and is therefore very fast and lends itself to applications with external integration.

Main Features of the Platform

Information technology services can be accessed via monitors or mobile devices and include current advanced technologies, such as the following: 24-7, 365-day-a-year access, easy data image insertion in electronic medical records, image comparison and overlapping, and SMS and email notification, when necessary, for fast interactivity.

Customizable Modules

The platform includes customizable files called “modules” that are designed and built for each project according to its needs in collaboration with professionals from different knowledge areas (Textbox 1). Each module functions to support the features and advantages of the entire platform. No data are sent directly to or from HCPs’ hardware. HCPs are able to see data in the central database, accessing this information remotely. All HCPs have a personal access code depending on their authorization level, enabling them to view, insert, or modify data in specific fields, close the electronic medical record (EMR) data temporarily or permanently, and export data for statistical surveys. The platform allows for individual and group interaction among HCPs at different sites. A remote “prompt assistance” service is provided for each module when necessary.

Module Functionality

Several functions can be activated, with open pop-ups showing the rationale of each study, its population, the provenance of resources, and the operating HCPs with various authorization profiles. The data entry procedure is quick, intuitive (Figure 1), and guided by many system alerts in the case of errors. When necessary, warning notifications are sent to users via SMS or email. Special software can be created, if requested, to support HCPs’ data evaluation and clinical decisions [25-27] (Figure 2). Data extraction for statistical surveys is immediate (Figure 1). At the end of each study period, the HCPs evaluated the project using a 3-point scoring system (Textbox 2).

Figure 1. Example of the main tasks and procedures for a module (module 6 in Table 1) on the medical platform: (1) entry to the system by the health care professional with their personal access key, after which they select the modules that they are qualified and authorized to use; (2) access to a list of operative centers with their own lists of patients and respective electronic medical records relating to the first and follow-up visits; (3) individual patient electronic medical record folder, which allows for the easy and quick insertion of data and multiple images at any time, as well as access to successive masks (a repository of images is available that allows image overlapping and comparison; Figure 3); (4) quick data extraction for statistical purposes.

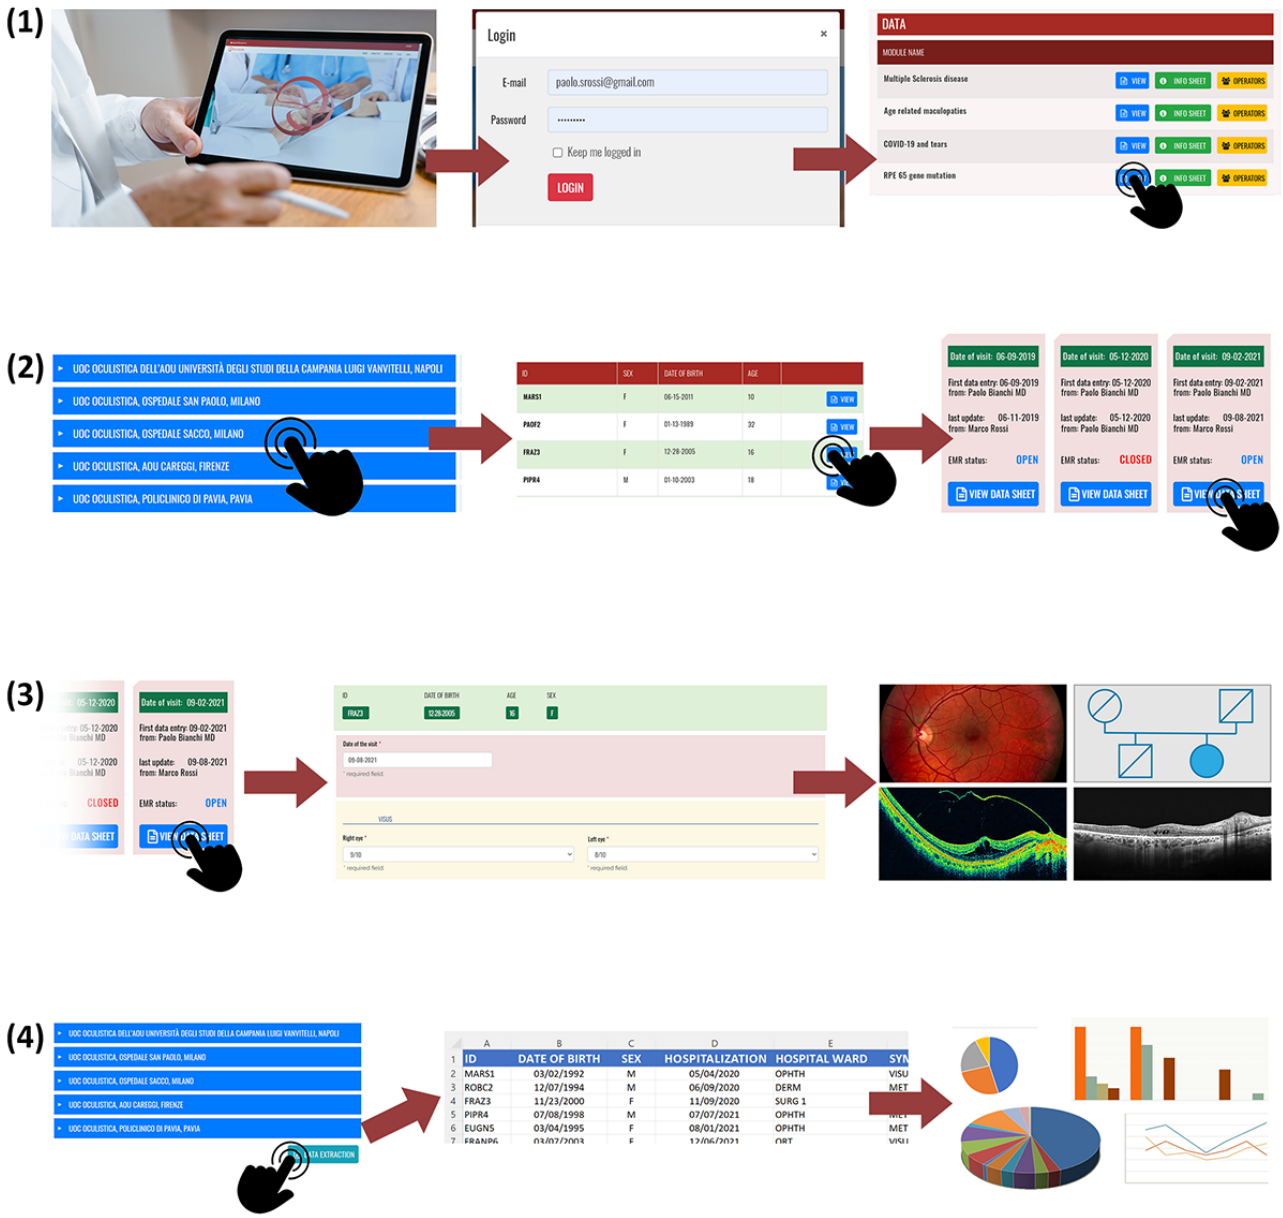

Figure 2. Examples of 2 special software programs designed to support health care professional activity. (1) For medical care decisions, each diagnostic variable of a disease is given a numeric value, and the software automatically provides a total score (shown by the arrow). If the value exceeds a defined score, the software advises general physicians to send the patient to an appropriate center at the next available appointment (module 2 in Table 1). (2) For tracking patients' clinical course, visual acuity data (or any other numerical data) are inserted into a patient's electronic medical record and the graph is updated in real time. The health care professional can see at a glance the functional course of the disease. RE: right eye; LE: left eye.

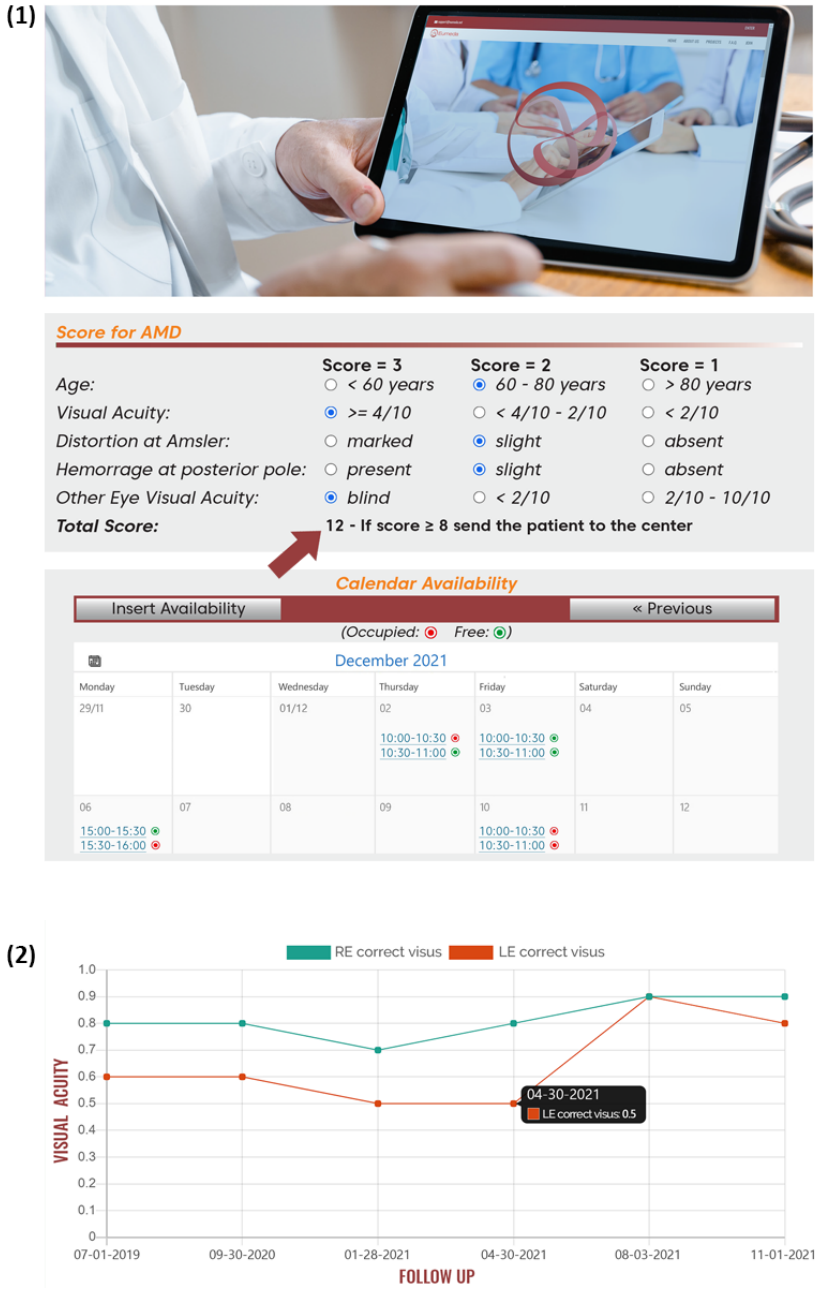
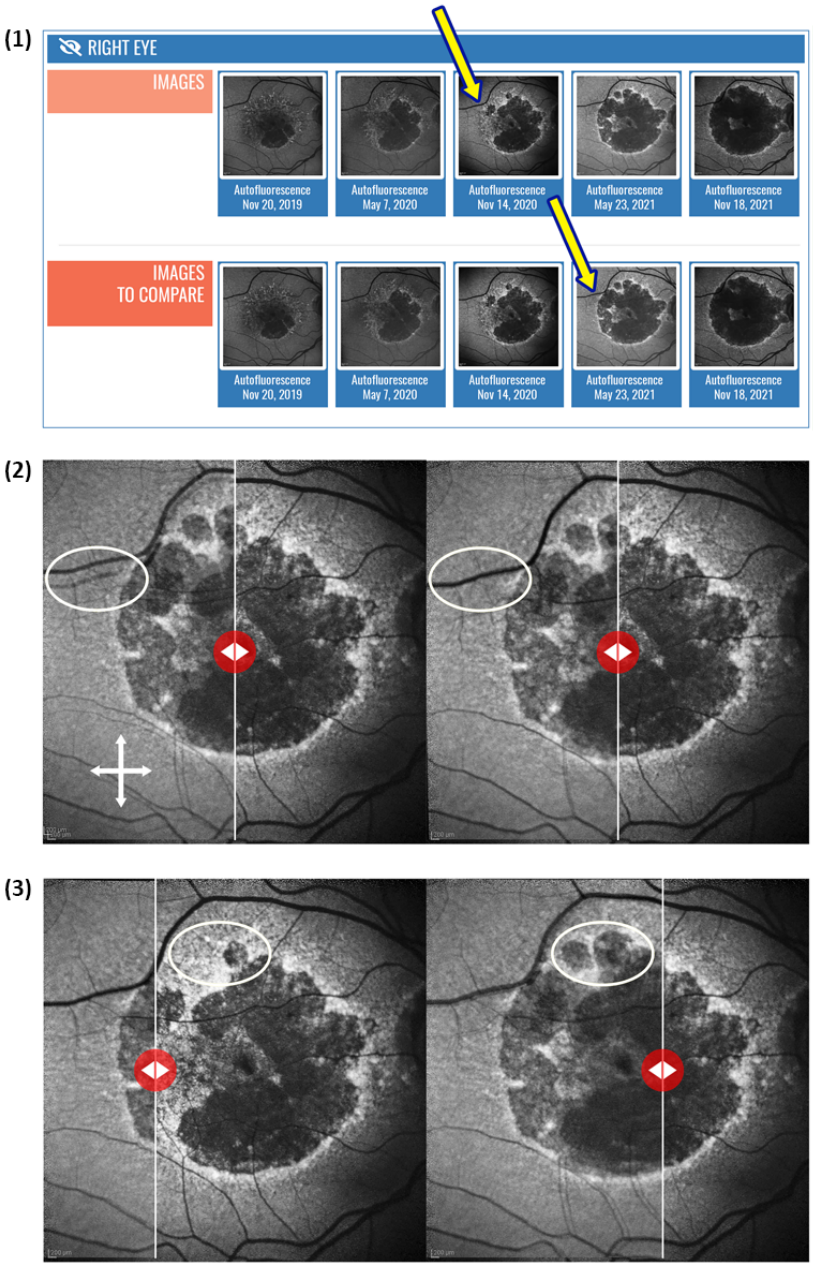


Images

Dedicated software allows the uploading of even high-resolution images and videos in a few seconds. A shared whiteboard for all images is available for each module. Image magnification and comparison software enables morphological changes to be observed over time in detail (Figure 3).

Figure 3. Example of image comparison: (1) selection of 2 images from a patient's electronic medical record (in this case, the patient had degenerative retinal maculopathy) uploaded at the 6-month follow-up (shown by the arrows); (2) creation of an overlap image that can be adjusted by clicking and moving the white cross; a special transparency application allows the images to be accurately superimposed on each other (shown by the white rings); (3) evaluation of morphological changes in the disease over time (within the white rings) by moving the overlap line back and forth (shown by the white line) using the red button.



Type of Technology

The Eumeda software platform is closed-source and owned by a private company that grants access through contracts. The platform was developed with the Wappler (Wappler.io) integrated development environment.

Targets

The target user base includes physicians of different specialties, nurses, technicians, orthoptists, geneticists, residents, and tutors, all of whom rely on access to a common database holding key patient information.

The target sites are hospitals, private offices, and medical hub centers working with spoke-peripheral centers. We involved medical structures equipped with technology and staff prepared to use hardware and software (Figure 4).

Figure 4. Locations of health care professionals (round dots) in Italy who have used the platform over the years (the map shows the Italian names of the cities). The Supervisory Center (SC) in Milan has responsibility for the data warehouse and help desk as well as a general coordination role.

Data

Data Location

All data were uploaded and stored in a data warehouse in Milan, Italy (Datasys Srl from 2001 to 2012; then Aruba Business Srl, provided by IRQ10 Srl, from 2013 until the present), to ensure data security and uninterrupted availability. Automated daily backups are a security measure guarding against the loss of data.

Data Entry Policy

HCPs must agree to the liability agreement, ownership agreement, and a code of conduct before using the platform. In all modules, data entry is performed in accordance with the guidelines of the Declaration of Helsinki and its subsequent revisions [28]. Informed consent forms are collected by the health facilities. In cases where data analysis included a therapeutic choice, approval from the relevant ethics committee or a qualified local committee was obtained, as in modules 6 and 11 in Table 1.

Data Security and Privacy

Data security and privacy are guaranteed by the latest generation of servers with secure backups. Data are protected on several levels: (1) individual HCPs receive access keys generated by the system; (2) subjects' personal data are encrypted and stored in a separate table in the cloud; (3) the system binds clinical data to personal data only when accessing hardware with a special algorithm; and (4) if necessary, a ready-to-use informed consent form can be downloaded for signature.

Responsibility for and Ownership of Data

According to European Union (EU) and Italian rules, liability for entered medical data, including cloud storage, lies with the HCP entering such data (acting as the "controller," as clearly defined in EU Regulation 679/16) and the manager of the medical platform and server farm (acting as "processors," as clearly defined in EU Regulation 679/16). Ownership of the data, including the purpose and methods for processing the data, belongs to the entity applying the module, who acts as the "controller."

Interoperability

The Eumeda software platform is not accessible from specific application programming interface clients by users, so it does not use data standards such as Health Level Seven. However, it implements the International Classification of Diseases, 10th

revision, system internally to classify pathologies. Clinical imaging is managed with current standard protocols.

Participating Entities

A nonprofit organization (Comed Research) initially implemented (from 2001) the projects. Subsequently, a joint venture between 2 for-profit companies (T&C Srl and TM95 Srl) managed the platform. These partners supply hardware, create software, or participate as web designers, hosting companies, or law firms. The funders of the implementation projects are public universities, hospitals and foundations, nonprofit medical associations, private companies, and physicians working in private offices (Table 1).

The society that created the main platform is the owner of all the implementations. The entities that applied the modules hold the ownership and the intellectual property.

Budget Planning

The total budget covered different phases according to implementation progression and project type for a period of 1 to 3 years. The costs included preliminary planning and the final draft (up to 30%), programming for final front view on the computer screen (30%), and user training (10%), as well as the pilot phase (5%), operation (10%), initial service (10%), and ongoing reports (5%). Selected projects could be conducted for free based on their importance or visibility for the platform.

Sustainability

The projects were initially funded (from 2001) by a nonprofit organization (Comed Research), which relies on donations from companies or nonprofit medical associations. Since January 1, 2017, the platform has been managed by a joint venture between 2 for-profit companies. The business model is based on the type and duration of the projects developed during the implementation phase, financed by different entities. The end of the project foresees the dissemination of the results with potential permanent effects.

Implementation (Results)

Coverage

The projects developed during the implementation phase have national coverage, encompassing a large number of Italian regions and their referent hospitals. The developed modules evolved over time, with varying degrees of interconnectivity, in different centers in 19 cities across Italy (Figure 4). In 2 modules (modules 1 and 2 in Table 1), HCPs from the referring regional areas were closely involved. The number of HCPs (at different levels) using individual modules ranged from 6 to 114 (average 21.8, SD 28.5).

Outcomes

Implementing the telemedicine platform allowed us to build several modules that could be used by HCPs at different times. The characteristics of 12 representative modules used over the last 10 years for different clinical projects are shown in Table 1.

Over time, our experience has led us to concentrate on three types of operational modules, integrated with one another if necessary: (1) a databank of diseases for clinical or scientific studies (eg, module 4; Table 1), (2) a database for groups of HCPs in different locations, giving them access to shared data (eg, module 6; Table 1), and (3) a functionality enabling physicians to seek second opinions (eg, module 7; Table 1).

The overall outcomes are reported in Table 2. Up to now, more than 250 HCPs have used the platform for several effective and operational projects. The total number of participants inserted in the modules is 2574. The percentage of data entered in the text or image fields for each module ranged from 20% to 95% (with an average of 65.7%). The evaluation score for each module was calculated as the sum of 3 partial scores (Textbox 2): out of all the modules, the first (module 1, the first to be created) was the one with the lowest evaluation score (Table 2). The average number of requests for technological support varied from 5 per month (in the case of simpler modules) to 9 (for more complex ones).

Table 2. Results pertaining to the designed modules shown in Table 1.

Module	Description	Centers involved, n	HCPs[a] involved, n	Participants whose data were inserted, n	Text/image fields for each EMR[b], n (fields that were filled in, %)	Beneficial effects	Evaluation score[c] (minimum positive score)
1	Teleconsultation in retinal diseases [18]	1 Retina center, 17 territorial offices	18	52	30 (60)	Useful teleconsultation among doctors	109 (108)
2	Age-related maculopathy [19]	11 Retina centers	114	678	65 (85)	Improvements in patients' functional final outcomes	803 (684)
3	Retinal pathology samples and correlated genes [20]	1 Ophthalmological center, 1 genetic center	11	12	65 (80)	Better understanding of molecular mechanisms	Not acquired
4	Epiretinal macular membrane [21]	2 Ophthalmologic centers, 1 human anatomy center	11	28	25 (65)	Identification of ultramicroscopic features of membranes	80 (66)
5	Inherited eye diseases[d]	1 Ophthalmological center, 1 genetic center	14	1145[e]	480[e] (20)	Increased knowledge of genetic eye diseases	In progress
6	Retinal dystrophy due to rare *RPE65* gene mutation [22]	9 Retinal-genetic centers	28	60	260 (65)	Identification of suitable patients for therapy	200 (168)
7	Second opinions among resident physicians[d]	4 University ophthalmological departments	19	110	12 (85)	Resident physicians' learning accelerated	140 (114)
8	Instrumental data in multiple sclerosis[d]	2 Neurological centers, 2 ophthalmological centers	6	58[e]	450[e] (18)	Recognition of the disease in the subclinical stage	In progress
9	Epidemiological data on COVID-19 in workers[d]	2 Care offices at 2 airports	9	298	30 (90)	Collection of useful diagnostic data on COVID-19 and how the disease is transmitted	75 (54)
10	SARS-CoV-2 on throat and ocular surfaces [23]	14 Medical units	20	108	34 (95)	Increased knowledge of COVID-19	165 (120)
11	Potential malignant oral lesions	4 Medical units	6	15[e]	50[e] (68)	Better prevention and therapy	In progress
12	Maculopathies and anti-aging medicine	1 Retina center	6	10[e]	110[e] (58)	Significantly better care	In progress

[a]HCP: health care professional (physicians from different specialties, nurses, technicians, orthoptists, geneticists, residents, tutors [employees were excluded]).

[b]EMR: electronic medical record (for each patient, considering first visit and all follow-ups).

[c]Sum of 3 partial scores for access, acceptability, and medical efficacy at end of the active working period (described in Textbox 2).

[d]Unpublished data.

[e]At the time of writing this paper.

Clinical fallout can be identified more easily with the use of this telemedicine platform because of the visibility of a database shared by HCPs (modules 3, 4, 5, 8, and 9; Table 2). Furthermore, data on rare diseases (collected from a large number of centers) can be used to identify patients who would benefit from expensive new therapies (module 6; Table 2). By sharing medical data, physicians and residents can learn better and faster (modules 1 and 7; Table 2), and the possibility of having a databank helps them to discover potential, as yet unknown disease complications (module 10; Table 2). Patient follow-up with dedicated software helps HCPs to locate better treatment options, identify preventive interventions (modules 2 , 11 and 12; Table 2) and track patients and their outcomes in real time.

Lessons Learned

Our program has multiple success factors that may be considered in future implementations or in the creation of similar telemedicine platforms and modules. First, the technological infrastructure of the platform is modern, highly versatile, and continuously updated by technical staff. The use of the latest generation of servers with secure, daily backups guarantees that no data loss occurs, while data security and privacy are protected on several levels, as specified in the Methods section. Second, data entry and retrieval in each module are immediate. Each module has different blocks of information that are well separated, including an explanation of the rationale of the study and practical guidance on how to insert data, as well as different HCP access profiles, patient IDs, EMRs, images, and statistical surveys. Third, no images are transmitted among HCPs. All images are stored on the main server and are viewed remotely without any deterioration. A dedicated procedure even allows the insertion of high-resolution images (through common connection links) immediately or very quickly. Rapid viewing is greatly appreciated by users, in addition to the possibility of enlarging, comparing, and superimposing, as well as being able to see in detail the morphological changes, even minimal ones, of a pathology over time (Figure 3). Lastly, different authorization profiles are given to HCPs, which enables them to access modules on the central server once they have agreed to abide by the terms of the liability and ownership agreements and the code of conduct, using personal passwords to view, change, or modify data and images. Module coordinators usually have total control of their respective modules and can compile statistical surveys using all the data, while other HCPs may only be able to enter data and images in accordance with their remit and authorized access level. A great amount of work has been undertaken to ensure that the user-friendly platform is up and running. A remote service is available by mail or telephone. All modules are visible both from monitors and mobile devices. In particular, the second opinion module may be suitable for use with mobile health (mHealth).

We consider the following points more as challenges than limits to implementation. The construction phase of each module is of critical importance, and a single medical interlocutor must be the voice of all HCPs (Textbox 1). The main mandatory factors involved in building a module include a scientific coordinator as the central figure and the participation of someone with both medical and IT skills. Finally, older HCPs tended to struggle with working on the platform, while the younger operators adapted quickly, were not disconcerted by the technology, and showed interest and satisfaction with the projects they carried out [29-34].

The presumed budgets of each project, divided into direct (eg, coordinators, IT programmers, law firms) and indirect (eg, travel, equipment, insurance) costs have been considered in the final balance.

The following recommendations may assist in overcoming many barriers to telemedicine practice among HCPs. First, the amount of preparatory work needed (Textbox 1) tends to be underestimated. Second, it is difficult to create systems for sharing text and images with appropriate levels of usability. Third, bureaucracy is often an obstacle, and self-regulation codes in telemedicine need official authorization. Fourth, a suitable “network culture” is still lacking in medicine, due to multiple technical and human factors. The success of telemedicine among HCPs requires participation, responsibility, and a desire for effective collaboration to develop knowledge for the benefit of professionals and patients.

Discussion

Principal Findings

The technological infrastructure of telemedicine intended strictly for HCPs is specific to this field, is not easy to implement, and must be customized for each individual project. Key persons such as scientific coordinators (with specific knowledge of medicine and IT) and program managers must be well chosen for projects to succeed. The results of our projects have shown a range of benefits, including increased medical efficacy and clinical knowledge, improved patient care, enhanced teaching and integration among hospitals, and a more effective choice of therapies. It is necessary for work to be carried out on organizational, bureaucratic, and network culture issues where these are not yet fully accepted and on sustainable business plans.

We identified some difficulties and limitations in our implementation project that may also be considered useful for future or similar telemedicine projects. Building a module in the absence of straightforward ideas forced us to make major changes during construction, meaning that the preliminary work completed had to be discarded and redone. All the software involved in the platform modules must be customized according to the needs of the HCPs, which requires time and hard work. Too many text or image fields to fill out and include in EMRs make the system difficult to use and produce a very large final database that is not fully used (as happened with module 5).

Conclusion

In conclusion, our experience was that both physicians and patients were always satisfied to be part of this “community of health” supported by groups of HCPs working for their benefit and making them feel cared for. The detailed description of our implementation program may be useful to shorten the learning curve for others seeking to implement similar projects in many fields of medicine, which must be able to adapt to the continuously changing nature of medicine now and in the future.

Acknowledgments

We would like to thank the hundreds of health care professionals who have used and contributed over time to the development of the platform. Special thanks go to all engineers, programmers, and other personnel who in their various capacities have worked to improve the platform over the last 10 years, especially Francesco Oggionni (IT professional) and Valerio Tartaglia (IT professional). We are grateful to Ferruccio Fazio, MD, former Italian minister of health, and Gianfranco Ferla, MD, for their support and advice. We would also like to thank Roberta Romagnolo (Lexikon) for editing the manuscript.

Abstract

Background: Recent years have witnessed an increase in the use of technology-enabled interventions for delivering mental health care in different settings. Technological solutions have been advocated to increase access to care, especially in primary health care settings in low- and middle-income countries, to facilitate task-sharing given the lack of trained mental health professionals.

Objective: This report describes the experiences and challenges faced during the development and implementation of technology-enabled interventions for mental health among adults and adolescents in rural and urban settings of India.

Methods: A detailed overview of the technological frameworks used in various studies, including the Systematic Medical Appraisal and Referral Treatment (SMART) Mental Health pilot study, SMART Mental Health cluster randomized controlled trial, and Adolescents' Resilience and Treatment Needs for Mental Health in Indian Slums (ARTEMIS) study, is provided. This includes the mobile apps that were used to collect data and the use of the database to store the data that were collected. Based on the experiences faced, the technological enhancements and adaptations made at the mobile app and database levels are described in detail.

Implementation (Results): Development of descriptive analytics at the database level; enabling offline and online data storage modalities; customizing the Open Medical Record System platform to suit the study requirements; modifying the encryption settings, thereby making the system more secure; and merging different apps for simultaneous data collection were some of the enhancements made across different projects.

Conclusions: Technology-enabled interventions prove to be a useful solution to cater to large populations in low-resource settings. The development of mobile apps is subject to the context and the area where they would be implemented. This paper outlines the need for careful testing using an iterative process that may support future research using similar technology.

Introduction

The burden of mental disorders [1] and the treatment gap due to untreated mental disorders in low- and middle-income countries (LMICs) such as India is estimated to range between 75% and 85% [2], with 1 in every 27 individuals being treated for depression [3]. Technological solutions have been advocated to increase access to care, especially in primary health care settings in LMICs, to facilitate task-sharing, given the lack of trained mental health professionals. Research has indicated the effectiveness of employing technologies for addressing complex health concerns among people with mental illnesses. However, the cost-effectiveness of technology-enabled interventions compared to in-person interventions has not yet been established [4].

Technology-enabled service delivery models have increased access to care and facilitated service monitoring, with mobile health (mHealth) being one such strategy. The World Health Organization (WHO) defines mHealth as "a medical and public health practice that is supported by mobile devices, such as mobile phones, patient monitoring devices, and other wireless devices" [5]. mHealth in the form of electronic decision support systems (EDSSs) has been widely adopted by service users and providers for monitoring health status and for diagnosing and managing a range of health conditions, including mental disorders and substance use [6]. mHealth use has increased with increasing penetration of mobile network connectivity [7].

This paper highlights the processes involved in the development and implementation of technology-enabled interventions employed in three projects across rural and urban settings in India among adults and adolescents: the Systematic Medical Appraisal and Referral Treatment (SMART) Mental Health (SMH) Pilot project [8], and two cluster randomized controlled trials (cRCTs), SMH trial [9] and the Adolescents' Resilience and Treatment Needs for Mental Health in Indian Slums (ARTEMIS) trial [10].

All three projects used EDSSs to facilitate the identification, diagnosis, and management of common mental disorders (CMDs), including depression, anxiety, psychological distress, and increased suicide risk. A task-sharing approach was used where nonphysician health workers known as Accredited Social Health Activists (ASHAs) and primary care doctors worked together to support people at high risk of CMDs [8-10].

This implementation report describes the experiences of using technology in implementing these three mental health projects, following implementation reporting guidelines [11].

Methods

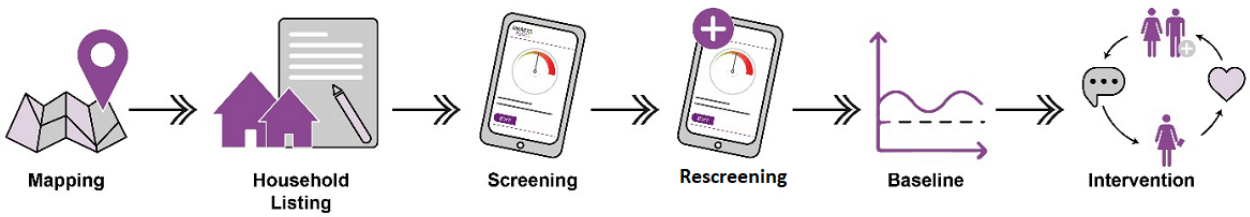
Aims and Objectives

This paper highlights the processes involved in the development and implementation of technology-enabled interventions employed in three projects across rural and urban settings among adults and adolescents in India.

Blueprint Summary

The overall technological framework of the SMH pilot study has two main components: a mobile app and a database. Different mobile apps were developed to collect data at divergent phases of the study (Figure 1). All apps were installed on 7-inch Android tablets for use by ASHAs/community women volunteers (CWVs), or primary health center (PHC) doctors. ASHAs are local women trained from the community with 8th-10th–grade education levels to support the implementation of health programs. While ASHAs work contractually, they are incentivized for their involvement in other projects. CWVs are women who reside in the same community where the study is being done. These CWVs were chosen from the slums and would have similar education level as ASHAs. They were trained on basic knowledge about mental health, along with the stigma and care of individuals with stress, depression, and increased suicide risk.

Figure 1. Different phases of the study.



The three studies underwent a formative phase, testing study tools and mobile apps while gauging user acceptance [12,13]. Iterations were made based on user feedback before the intervention phase. The technical team assessed the app and released a test version for research team testing. Once confirmed, a definitive version was used for data collection.

In the preintervention phase, geographical mapping and demarcation of the village boundaries were performed, followed by house listing to obtain accurate census data. Custom apps were developed for each step, including population screening for identifying individuals at risk of CMDs, which involved data collectors and ASHAs using specific screening tools. After screening, baseline data on various variables were collected before the intervention was implemented (Figure 1).

Technical Framework Design

The key components of the EDSS included the ASHA app, doctors app, and priority listing app (Table 1). Each ASHA had a finite set of individuals who lived in the geographical location covered by her. The tablets had encrypted, password-protected individual logins unique for every ASHA. Individuals screening positive were referred to primary care doctors for clinical diagnosis and treatment based on predetermined cut-off scores. The doctors used the WHO mhGAP-IG tool (version 1.0) [14] for diagnosing and treating people with CMDs, offering algorithm-based diagnoses and evidence-based treatment recommendations, including comorbidities. Doctors followed these recommendations, entering the type of care provided (pharmacological, psychological, referral, or combinations thereof) into their app. Doctors input the data to generate a traffic light–coded priorities list for ASHAs, indicating the status of screen-positive individuals in their area. Using color coding due to the low education levels of ASHAs, the list included pertinent questions on treatment adherence, social support, and stressors for each color category. The list was dynamic, changing based on doctors' updates during patient follow-up visits.

Table 1. Details of the apps used for the three studies and the target of the intervention.

App	Phase of the study	Users
SMART MH[a] (Pilot) and SMART MH trial focused on rural adults		
Listing app	Listing (household census data collection)	Data collectors
Screening app	Household screening for common mental disorders	ASHAs[b]
Baseline data collection app	Baseline: collected data on different variables and stressors triggering anxiety/depression	Data collectors
Intervention (ASHA app)	Intervention: for regular follow up of adults at high risk of CMDs[c] who sought care from the doctor or have yet to seek care	ASHAs
Intervention (doctor app)	Intervention: diagnosis and treatment for CMDs among adults	Primary care doctors
3M, 6M, and 12M app	Assessments at 3, 6, and 12 months of the intervention	Data collectors
ARTEMIS[d] trial focused on adolescents		
Listing app	Listing (household census data collection)	Data collectors
Screening app	Household screening for common mental disorders	Data collectors
Baseline data collection app	Baseline: collected data on different variables and stressors triggering anxiety/depression	Data collectors
Intervention (ASHA app)	Intervention: for regular follow up of adolescents who are at high risk of CMDs who sought care from the doctor or have yet to seek care	ASHAs
Intervention (doctor app)	Intervention: diagnosis and treatment for CMDs	Primary care doctors
3M, 6M, and 12 M app	Assessments at 3, 6, and 12 months of the intervention	Data collectors

[a]SMART MH: Systematic Medical Appraisal and Referral Treatment (SMART) Mental Health.

[b]ASHA: Accredited Social Health Activist.

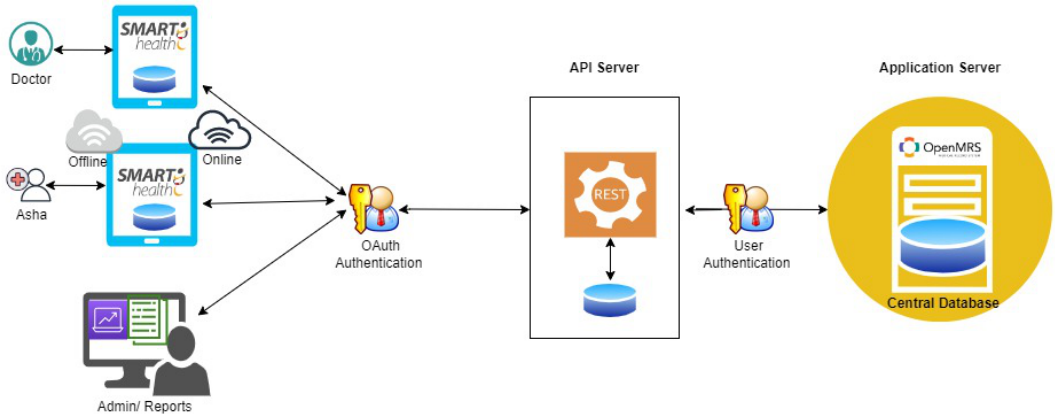
[c]CMD: common mental disorder.

[d]ARTEMIS: Adolescents' Resilience and Treatment Needs for Mental Health in Indian Slums.

Identifying an Electronic Medical Record System

All three projects utilized apps based on the Open Medical Record System (OpenMRS) [15], a community-driven open-source software for medical record storage and processing. OpenMRS is robust, scalable for large interventions, and customizable to study workflows and data collection needs. OpenMRS was chosen for these projects as it is freely available. Based on our earlier experience, the functionalities were suitable for our mental health projects [16]. Data collected on tablets underwent authentication and were transferred to the application programming interface (API) server, which were then sent to the application server housing the central OpenMRS database (Figure 2).

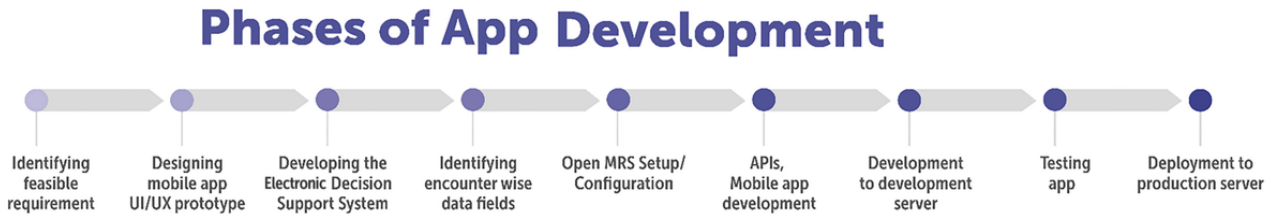
Figure 2. Workflow of data. API: application programming interface; Asha: Accredited Social Health Activist.



Phases of App Development

The apps went through different phases of development, enhancement, and adaptations across the three projects to suit the specific requirements of each project (Figure 3).

Figure 3. Phases of app development. API: application programming interface; MRS: Medical Record System; UI: user interface; UX: user experience.



Based on the scope of work (ie, a detailed document or description that outlines the specific tasks, activities, objectives, and deliverables associated with a particular project) received, the technological team assessed requirements and checked the feasibility of incorporating them.

The next step involved the design of the mobile app user interface (UI)/user experience (UX) prototype, which was an interactive mock-up of the mobile app. The prototype contained key UIs, screens, and simulated functions without any working code or final design elements. This provided a better understanding of the real-time UI and UX before production.

Subsequently, the EDSSs were designed according to standard existing diagnosis and management guidelines, which were programmed to develop the most appropriate apps. To identify encounter data fields, individual interactions by ASHAs/doctors were recorded as separate encounters in OpenMRS. Different study phases had distinct data points, necessitating a logical flow of questions. Specific roles were assigned, tailoring the data collection tools to individual responsibilities. For instance, the follow-ups for ASHAs used priority-listing questions, whereas the doctors app incorporated mhGAP tool queries. This ensured targeted and relevant data capture for each study participant.

The next step involved configuring project-specific technical details such as concepts, encounter types, visit frequencies, user roles, and API settings within OpenMRS. Additionally, custom tables were created to facilitate real-time reporting and analytics, ensuring efficient data management and analysis for the project.

The final step was the development of the mobile app and APIs, which was carried out as a multistage process. The set up followed the sequence of development, test stage, and production environments. The final prototype for the mobile app involved integrating the EDSS into the app. The SMH apps supported online/offline features. Standard security integrations were enabled while developing the mobile app in the local database in the three different environments. In the test environment, the integrated feature was assessed with test data to evaluate the impact of the load of data and the performance of the app. In the stage environment, this phase included an exact replica of a production environment for testing. In the production environment, the software or products were made live for use. Once the development of the app was complete and certified by the quality assurance team, it was deployed for the production environment. Screenshots of the app are provided in Figures 4-6.

Continuous modifications and maintenance of the app were applied across the projects' lifetimes.

Figure 4. App screenshot 1.

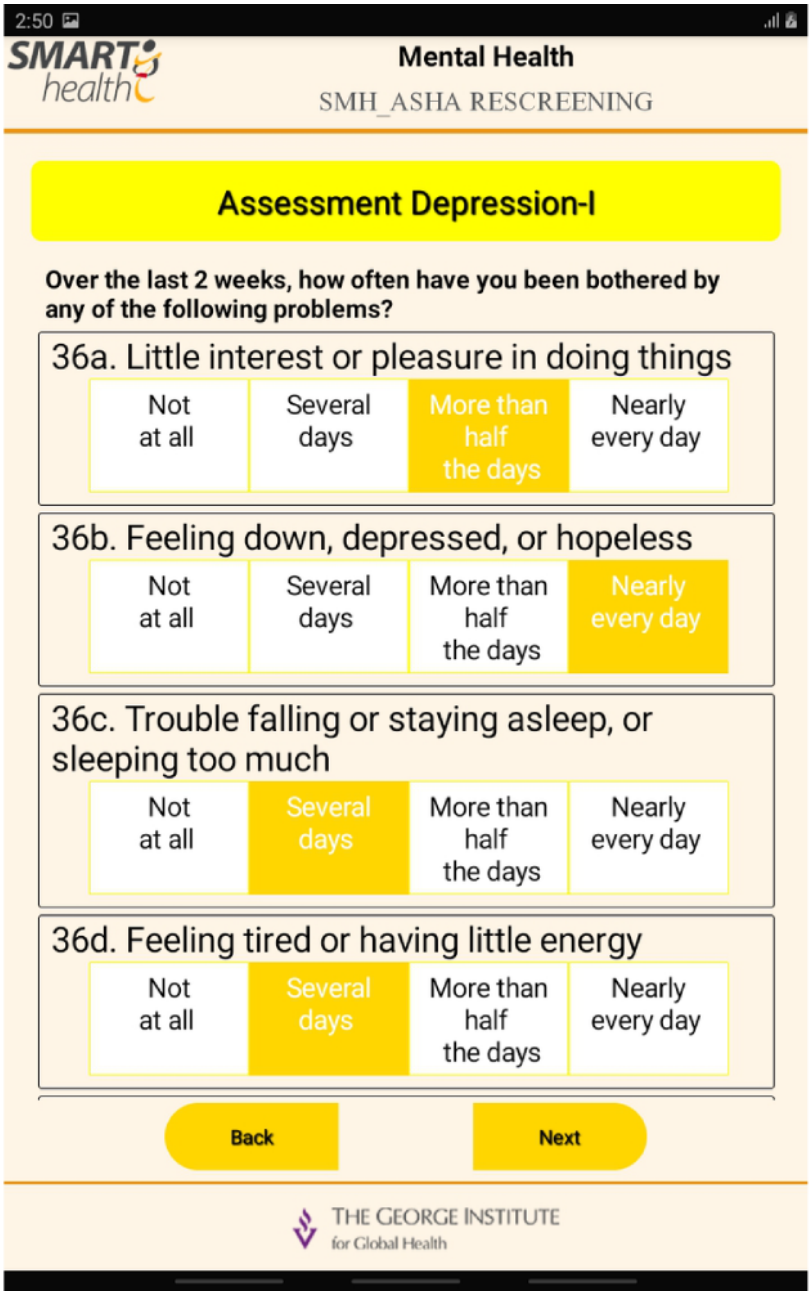


Figure 5. App screenshot 2.

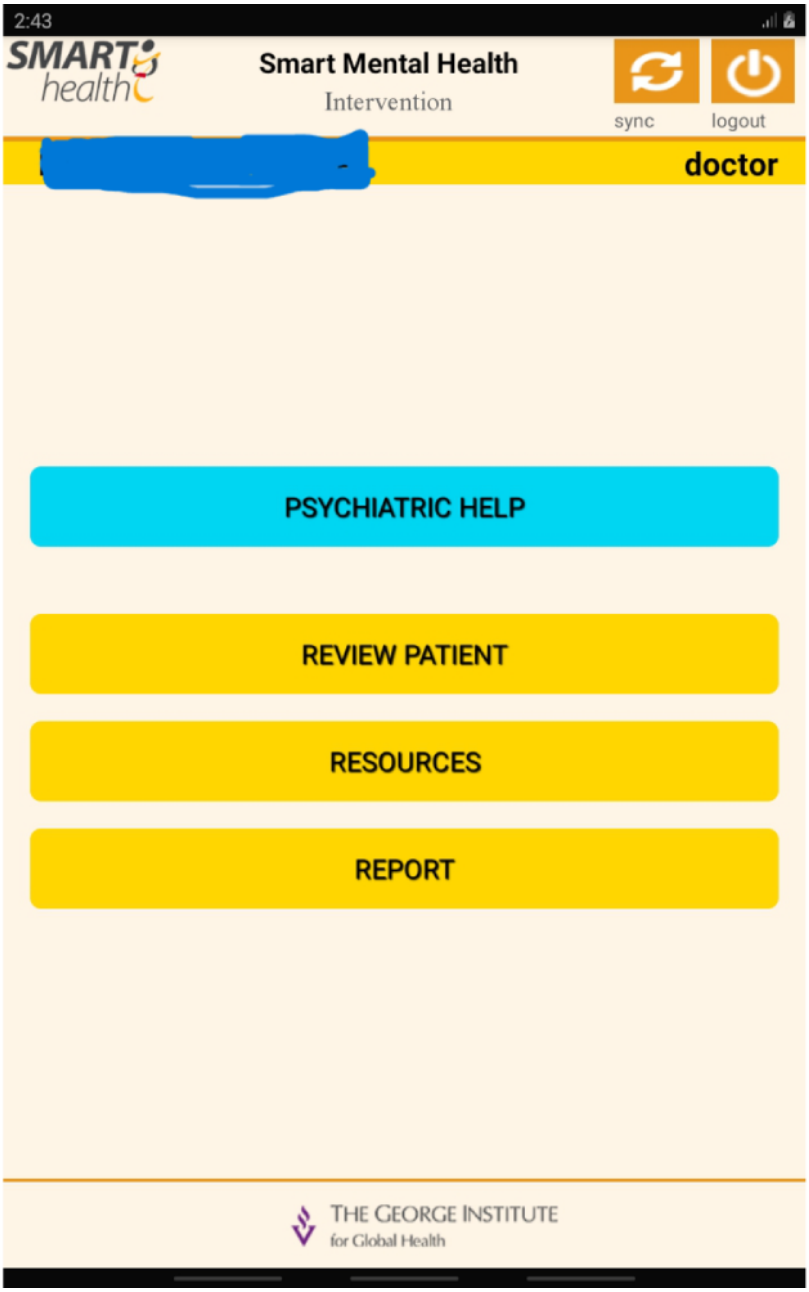

Figure 6. App screenshot 3.

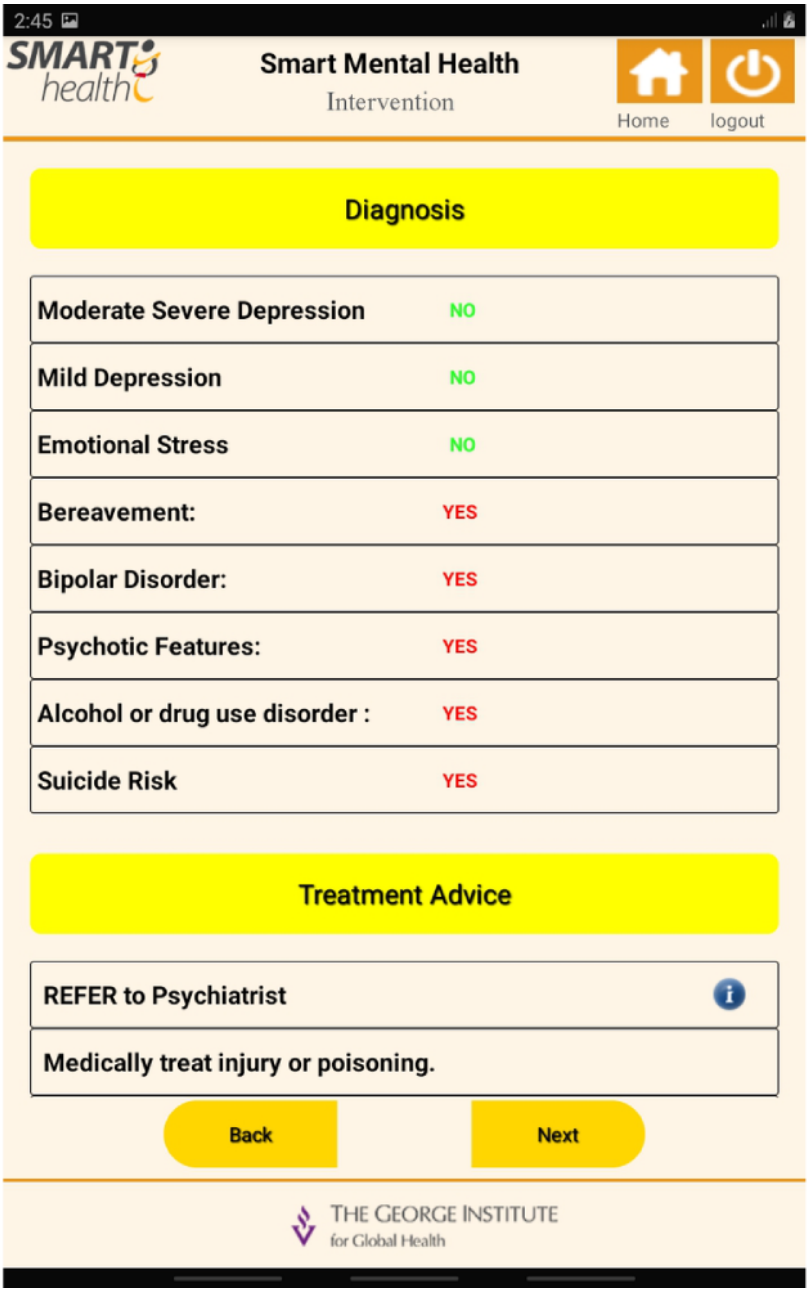

Target

The SMH Pilot was implemented in 42 villages across rural and tribal areas of Andhra Pradesh [8,17] with the goal of understanding the feasibility and acceptability of using mobile technology and task-sharing approaches to address CMDs. This project covered approximately 50,000 adults and informed the subsequent SMH Trial, which took place in villages across Haryana and Andhra Pradesh, screening 165,000 adults in 133 villages and 44 PHCs. Currently, ARTEMIS is being implemented among 70,000 adolescents (10-19 years old) in 60 urban slum clusters in Vijayawada (Andhra Pradesh) and New Delhi.

Ethical Considerations

All collected data are securely stored on central servers in Hyderabad, with restricted access limited to the project team. Participants provided written consent and received detailed information about data collection at various time points. The SMART Mental Health pilot study was approved by the Independent Ethics Review Committee of the Centre for Chronic Disease Control (IRB00006330) for studies CCDC_IEC_03_2014 and CCDC_IEC_02_2014 on October 1, 2014; the SMART Mental Health cluster randomized controlled trial was approved by the George Institute Ethics Committee (009/2018) on April 27, 2018; and the ARTEMIS trial was approved by the George Institute Ethics Committee (17/2020) on September 4, 2020. The study tools were approved by The George Institute Ethics Committee, and each participant was assigned a unique identification number at the study's outset. Data were consistently deidentified before any sharing, and only research staff and the study's implementation and statistical teams had access to the data, ensuring that confidentiality and ethical standards were maintained throughout the research process.

Participating Entities

The studies have received funding from various international organizations such as Wellcome Trust/Department of Biotechnology (India Alliance), National Health and Medical Research Council Australia, and the UK Medical Research Council. Importantly, these funders are not involved in data collection or analysis and do not have access to the data. Government agencies, although collaborators, also do not manage or analyze the data. The SMH app is under intellectual property rights of the developer, The George Institute India. Local government consultation occurred for support, but they have no role in data governance.

Budget Planning

A predefined budget was allocated to the development and implementation of the technological interventions. The main costs incurred included the cost of the server (INR 500,000=US $6862) and the time cost of an Android developer and a technical lead (INR 200,000=US $2868/month for the initial 6 months for development and then a 25% time cost for maintenance). The other costs included the procurement of tablets for data collection.

Interoperability

The apps used in the three studies followed the Health Level 7 (HL7)/Fast Healthcare Interoperability Resources (FHIR) standards for exchanging patient information between a server and mobile app in JavaScript Object Notation (JSON) format. HL7 has also developed other standards, including the HL7 Clinical Document Architecture. We used FHIR in our apps as it was designed to facilitate interoperability of health care systems, allowing different health care apps and devices to easily exchange and share data. As the FHIR standard is based on modern web technologies such as Representational State Transfer principles, JSON, and Extensible Markup Language, it provides a flexible and scalable approach to health care data exchange, making it easier for developers to build interoperable apps.

Sustainability

The study was developed and implemented in collaboration with the Andhra Pradesh and Haryana governments. The tool has been previously utilized in two studies with adults while undergoing several phases of enhancements and is currently being used in the ARTEMIS study with adolescents. Poststudy, the tool will be shared with government and other nongovernmental organizations interested in using it.

Implementation (Results)

Coverage

The overall coverage of the number of study participants, ASHAs/CWVs, and doctors reached in the three studies is detailed in Table 2.

Table 2. Coverage of participants across the three projects.

Project	Study participants reached, n	ASHAs[a]/CWVs[b] included, n	Doctors included, n
SMART MH[c] Pilot (2014 to 2019)	50,000 adults	40	14
SMART MH Trial (2018 to 2022)	165,000 adults	175	50
ARTEMIS[d] (2020-2024)	69,600 adolescents (10-19 years old)	104	27

[a]ASHA: Accredited Social Health Activist.

[b]CWV: community woman volunteer.

[c]SMART MH: Systematic Medical Appraisal and Referral Treatment Mental Health.

[d]ARTEMIS: Adolescents' Resilience and Treatment Needs for Mental Health in Indian Slums.

Outcomes and Technical Amendments Made to the Data Repository

OpenMRS indicated the overall number of instances that data were collected for each individual participant at different time points in the study. As OpenMRS has a report generation model, it was difficult to compare different data points for the same person or between participants across the same time point. Hence, an intermediary database was developed in house to facilitate the process of running customized reports, which enabled comparison of data at different time points. This process evolved following considerable testing at the backend to obtain the desired output in terms of data visualization. Some customizations were made to OpenMRS to suit study requirements (Table 3).

Table 3. Steps of configurations made to the Open Medical Record System (OpenMRS).

Configuration of OpenMRS modules	Features for the study
Creation of a concept dictionary	Every data point to be used for the study was created as a concept and given a short name
Role management	The roles of each user were fixed and were restricted based on the type of activity they were expected to do; for example, the project manager was only given access to user data management and downloading reports
User management	As per our project flow, the different users were allocated to each role, such as ASHAs[a], doctors, field staff/data collector, project manager, and administrator
Encounter management	Each entry into the tab for a specific user (ie, ASHA, doctor, data collector) was recorded as an encounter with a unique encounter ID, which helped to differentiate the number of encounters that had taken place for each study participant
Managing encounter types	Based on the different phases of the study, each phase was also considered as a separate encounter, such as the screening, rescreening, ASHA follow-up, and doctor follow-up phases
Manage observations	Each data point was considered as a separate observation
Managing persons	Demographic data for every app user (ASHA, doctor) or participant were stored as person details
Managing patients	In this feature, any additional personal identifiers/demographic details identified could be modified/configured
Cohort management	Specific cohorts were created for every phase of the project, matched to the user. This enabled the users to access data of people who were in their own cohort. This helped them to identify and follow up the individuals easily. This was done both for ASHAs and doctors, with each doctor in a particular PHC[b] having a defined set of ASHAs, who in turn had a defined set of high-risk individuals
Multilocation data management	This was a custom development made to the system to ensure the data of one location (state) were not merged with data from another location. This was relevant to the SMH[c] and ARTEMIS[d] trials, which involved two different geographical locations.

[a]ASHA: Accredited Social Health Activist.

[b]PHC: primary health center.

[c]SMH: Systematic Medical Appraisal and Referral Treatment Mental Health.

[d]ARTEMIS: Adolescents' Resilience and Treatment Needs for Mental Health in Indian Slums.

In India, internet connectivity varies, particularly in rural regions. To address this, the quality of connectivity was assessed in each study area and hotspots were identified. Offline and online data storage methods were implemented, allowing local storage on tablets in areas with poor connectivity. Data could later be uploaded to the central server once connectivity was restored. Additionally, networks at certain PHCs were improved, increasing the bandwidth to enable ASHAs and doctors to upload data when in proximity to these PHCs.

Lessons Learned

There were several lessons learned while designing and implementing these interventions, which resulted in several enhancements to the systems for improving UX and achieve the study outcomes. Following the SMH Pilot, issues were identified in the EDSS that needed to be corrected for the SMH and ARTEMIS trials (Table 4). During the project, unforeseen challenges arose due to the COVID-19 pandemic. Face-to-face training for health workers was impossible, leading to the preparation of training materials delivered with the assistance of field staff. Additionally, some tablets used by health workers broke down, necessitating replacements and revealing bugs in the app. The SMH cRCT project faced difficulties because of COVID-19, and different mitigation strategies were adopted to ensure implementation of the different stages of the project. However, due to the rapidly changing situation, those also had to be modified quickly. Considering all the issues encountered earlier, we tried to mitigate all these challenges encountered during the SMH pilot study and cRCT, leading to enhancement of the apps developed for the ARTEMIS project. To have a smooth transition from the test environment to the live environment, the technical team performed additional checks by testing the apps by the field staff and creating data that were uploaded to the server to confirm whether all the fields are being populated correctly. This helped in reducing the errors while data were being captured in live scenarios.

Table 4. Enhancements made to the electronic decision support system.

Issues that needed amendments	Solutions for the problems/issues
Daily monitoring of data at the field level and comparison of data across sites, localities, and users was very difficult. Monitoring of clinical data of patients was also difficult	Development of descriptive analytics at the database level while implementing the SMH[a] trial was done to ease monitoring of data. There were many enhancements made at that level, in terms of representing real-time data from different aspects of the study. This included identification of mental health service use, the burden of different mental health conditions, and comparison of different conditions, among other factors. These analytics could be viewed by comparisons made across regions, gender, and age groups. These were represented through pictorial modes such as graphs and pie charts (see Figure 7 for examples)
Monitoring an individual's mental health status over time was not possible	Analytics were developed to track the PHQ9[b] and GAD7[c] scores of an individual in the different phases of the study. Data captured periodically during monitoring could be viewed as graphs and charts based on the longitudinal data at the backend using analytics.
The performance of ASHAs[d] could not be tracked well	There were enhancements made to the ASHA app, which tracked the performance of each ASHA and provided data about the numbers of screenings and follow-ups performed, including the time taken for each. Random audio recordings of their interactions were also captured to ensure quality checks.
As the database is encrypted and stored in a password-protected, secure location, it is hard to gain access to data by reverse engineering or decoding	The app is protected with multifactor authentication using a password and lock pin as an enhancement to the existing setup.
User interface and functioning of the app were not clear	Several changes were made to the user interface, including a change of font size, color, and creating different section headers using attractive symbols/pictures, for better user experience
Enabling online training during COVID-19	Some of the training materials were embedded in the mobile apps to enable easier access for trainees using virtual modes during COVID-19.
Real-time monitoring of the activities of field staff was required to ensure increased data quality	Random audio recording of interaction of field staff with study participants or high-risk individuals was enabled. The time taken for each screening was also made available at the database level for these audio recordings. This helped the implementation team to monitor data collection and quality.
Merging of two apps, namely household listing and participant screening, into one app	This merger made it possible for simultaneous data collection for both listing and screening, which saved time for both the participant and field staff and reduced multiple visits to the same household for data collection.

Discussion

Principal Findings

This paper outlines the experience of employing technology in mental health service delivery across rural and urban India in three projects. We have highlighted the implementation challenges and app adaptations based on user feedback, offering insights valuable for technology-based mental health projects in resource-limited settings. Technology-enabled interventions have shown effectiveness in diagnosing, treating, and following up on various health conditions [18,19]. Most mHealth interventions used in India have been disease-specific and do not involve a health systems approach. One example of a more health system–focused app is the Government to Government web-based monitoring information system that has been set up by the Ministry of Health & Family Welfare, Government of India, to monitor the National Health Mission and other health programs. To increase effectiveness, these innovations should focus on creating new avenues to integrate tools that have encouraging and sustainable outcomes related to access, equity, quality, and responsiveness. The SMH app can be integrated with government systems after specific modifications. The use of electronic medical record systems and telemedicine are examples of some of the interventions implemented and found to be beneficial for health care delivery for large populations, especially in LMICs [16,19,20]. However, there is a need to understand the local context and setting while developing or enhancing any existing app, as some of the original features may not be relevant to the local context, making further adaptations critical.

One way to enhance the functional capabilities of apps such as SMH is to link the app with telemedicine facilities that amplify the ability to connect to remotely located consumers with specialists located in larger cities [13]. For example, machine learning has been applied for suicide prediction, matching patients to appropriate treatment, improving the efficacy of mental health care by clinicians, and monitoring patients for treatment adherence with the help of smartphones and sensors [21].

Another way to leverage technology in mental health is by using artificial intelligence. A recent systematic review recommended the use of artificial intelligence technologies as accurate and effective strategies in the diagnosis and treatment of mental health conditions [22]. Virtual reality technology has proven to be a useful and powerful tool in addiction research [23]. The user interacts with the virtual reality environment, offering an environment close to real life that is dynamic in nature and requires active participation. These environments can be used to develop psychotherapeutic interventions by adding a personal

touch, having predictable conditions with additional features such as embodiment, eye tracking, and other biological factors [24].

There is still substantial work to be done in terms of scaling up these interventions and understanding their feasibility and acceptability across different settings and populations. Use of novel strategies such as videogaming can be explored to implement mental health interventions that can be customized to specific populations [25]. Such techniques should be considered in future iterations of the technology platform [26,27].

Limitations

There were a few limitations in our apps. First, the mobile apps developed were limited to stress, depression, anxiety, and increased suicide risk; however, the principles of including other mental health conditions would be quite similar. Second, although the projects had a system of referring participants requiring specialist care to mental health professionals, it was beyond the scope of the projects to track the care provided by the mental health professionals through our app. This was because our app was developed through primary health system–focused application for use in low-resource settings and was not linked to any central electronic health record system as is possible in more developed health systems with more robust data capture and record-sharing capabilities, such as the National Health Service in the United Kingdom or health systems in Australia. Third, the current apps are compatible on Android platforms and could not be expanded to other operating systems. Finally, the apps developed were specifically created following consultations with local stakeholders; hence, their generalizability across other settings will need to be assessed after adaptation is complete.

Future Recommendations

Given our experiences, we have compiled a set of suggested recommendations for technology-based interventions in similar settings, which are presented in Textbox 1.

Textbox 1. Recommendations for technology-based interventions.

- Inclusion of the technical team from the outset when study protocols are being developed.
- All study-related tools and database designing should be finalized in consultation with relevant experts.
- A protocol that details the process of server support in terms of setup/maintenance needs should be developed and followed.
- The server needs to factor in the size of the data set and latest versions of operating systems in reducing any issues faced.
- App user interface/user experience should be designed and assessed for acceptability by targeted populations. The use of reports or data analytics for the study must be discussed and finalized as per study needs.
- Develop systems that can be used across any kind of device, are compatible for software or version upgrades, and are web-based and easily programmable.
- A technical guide with frequently asked questions outlining the various aspects of technology, such as navigation, problem-solving, and reporting of issues, should be developed to facilitate staff training.
- The infrastructure and the architecture of the app should be flexible for making modifications or scaling up the app. The scalability is measured by the number of requests an app can manage and support the app effectively. A decision needs to be taken in terms of adding resources to the computing system for scaling either horizontally (adding more machines to the existing pool) or vertically (adding more power to the existing machines). Both types of scaling are similar as they add computing resources to the infrastructure; however, there are distinct differences between the two in terms of implementation and performance.

Conclusion

In conclusion, the development of any health-related app is subject to the context and the area where it would be implemented. There is a need for careful testing using iterative processes, allocate human and budgetary resources that are adequate, and integrate apps with larger electronic health record systems that inform health systems.

Acknowledgments

We would like to acknowledge the entire Systematic Medical Appraisal and Referral Treatment (SMART) Mental Health team at the Andhra Pradesh, Haryana site and the staff of Adolescents' Resilience and Treatment Needs for Mental Health in Indian Slums (ARTEMIS) at the Vijayawada and Delhi sites who provided input while assessing the apps, which greatly helped in making specific enhancements to the apps. This work was supported by ARTEMIS (to SG, MG, and SK), Australian National Health and Medical Research Council (NHMRC) Global Alliances for Chronic Disease (GACD) (SMART for Common Mental Disorders in India; grant APP1143911), and UK Research and Innovation (UKRI)/Medical Research Council (MRC) grant (ARTEMIS; MR/S023224/1 to PKM). DP is partially or wholly supported through the SMART Mental Health NHMRC/GACD grant. PKM is the principal investigator on the ARTEMIS Project and coprincipal investigator on the SMART Mental Health Project and is partially supported by both projects. DP is supported by fellowships from the NHMRC of Australia (1,143,904) and the Heart Foundation of Australia (101,890). SKY is supported by the ARTEMIS Project (UKRI/MRC grant MR/S023224/1), SP is supported by the ARTEMIS Project and another project titled MentAL Health Risk Factors among Older AdolesceNts living in Urban Slums: An InTervention to Improve ResIlience (ANUMATI) funded by the Indian Council of Medical Research

(grant 2019-0531). MD is supported by SMART Mental Health funded by NHMRC Australia (grant APP1143911) and the International Study of Discrimination and Stigma Outcomes (INDIGO) Partnership Research Programme funded by the UK MRC (MR/R023697/1). The funding bodies played no role in the design of the study and in the conceptualization and writing of the manuscript.

Authors' Contributions

SK, SG, PKM: conceptualization. SK and SG: writing of first draft. MG, SK, SKY, SP, MD, DP, and PM: review & editing. All authors read and approved the final manuscript.

Conflicts of Interest

All authors are employees of The George Institute, which has a part-owned social enterprise, George Health Enterprises, with commercial relationships involving digital health innovations.

Implementation Report

A Mobile App (Concerto) to Empower Hospitalized Patients in a Swiss University Hospital: Development, Design, and Implementation Report

Abstract

Background: Patient empowerment can be associated with better health outcomes, especially in the management of chronic diseases. Digital health has the potential to promote patient empowerment.

Objective: Concerto is a mobile app designed to promote patient empowerment in an in-patient setting. This implementation report focuses on the lessons learned during its implementation.

Methods: The app was conceptualized and prototyped during a hackathon. Concerto uses hospital information system (HIS) data to offer the following key functionalities: a care schedule, targeted medical information, practical information, information about the on-duty care team, and a medical round preparation module. Funding was obtained following a feasibility study, and the app was developed and implemented in four pilot divisions of a Swiss University Hospital using institution-owned tablets.

Implementation (Results): The project lasted for 2 years with effective implementation in the four pilot divisions and was maintained within budget. The induced workload on caregivers impaired project sustainability and warranted a change in our implementation strategy. The presence of a killer function would have facilitated the deployment. Furthermore, our experience is in line with the well-accepted need for both high-quality user training and a suitable selection of superusers. Finally, by presenting HIS data directly to the patient, Concerto highlighted the data that are not fit for purpose and triggered data curation and standardization initiatives.

Conclusions: This implementation report presents a real-world example of designing, developing, and implementing a patient-empowering mobile app in a university hospital in-patient setting with a particular focus on the lessons learned. One limitation of the study is the lack of definition of a “key success” indicator.

patient empowerment; mobile apps; digital health; mobile health; implementation science; health care system; hospital information system; health promotion

Introduction

Context

During recent decades, medicine has been moving from a focus on paternalistic approaches toward a paradigm of patient-centeredness, highlighting patient partnership and participation. Patient empowerment refers to a metaconcept with no unique definition [1]. However, it is commonly accepted that empowered patients possess key capacities and resources to be able to (1) participate in shared decision-making, (2) manage their own health, and (3) self-empower themselves [1].

Patient Empowerment and Clinical Outcomes

Some studies have demonstrated a positive association between patient empowerment and improved clinical outcomes or their proxy. This is best documented in the context of chronic diseases, especially diabetes. Wong et al [2] compared serum glycated hemoglobin (HbA_{1C}) and low-density lipoprotein cholesterol (LDL-C) levels in a group following implementation of a patient empowerment program (PEP) or the standard of care, resulting in decreased LDL-C levels in the PEP group. Similarly, Lian et al [3] found a lower incidence of all-cause mortality, cardiovascular events, and diabetes mellitus complications following participation in a PEP. In a review of randomized controlled trials, a decrease in HbA_{1C} and blood pressure levels was associated with empowerment interventions for patients with diabetes in sub-Saharan Africa [4]. In a meta-analysis, Baldoni et al [5] reported an improvement in HbA_{1C} levels following collective empowerment strategies. In a systematic review, Shnaigat et al [6] identified patient activation, a concept related to empowerment, as a valid strategy to improve outcomes of patients with chronic obstructive pulmonary disease.

However, it is important to highlight that several studies also reported no beneficial effects of empowerment programs. A 2017 meta-analysis found no statistically significant positive effect of empowerment on HbA_{1C} levels, despite five included studies reporting positive results [7]. Santoso et al [8] reported a lack of evidence to demonstrate a positive association between women's empowerment and outcomes of child nutrition.

The lack of clear definitions and measures for empowerment may explain these controversial findings. Differences in program design could also contribute to this variability; therefore, further research identifying determinants for a successful intervention is needed. Indeed, the authors of the cited studies often reported the poor availability of high-quality research.

Digital Health and Patient Empowerment

With the variety of solutions that could be envisioned, digital health is seen as a promising tool to promote patient empowerment and, indirectly, outcomes. However, mixed results are seen in the related literature.

In a systematic review, Johansson et al [9] showed that online communities support patient empowerment. Sosa et al [10] reported that a text messaging–based empowering intervention following head and neck surgery was both highly appreciated by patients and feasible. Conversely, Ammenwerth et al [11] reported no clinically relevant effect of patient portals on patient empowerment or health-related outcomes in a systematic review. Vitger et al [12] failed to demonstrate a positive effect of digital interventions to support shared decision-making, which was likely due to the small number of high-quality studies available. Verweel et al [13] found limited evidence demonstrating a positive effect of a digital intervention for health literacy. Finally, Thomas et al [14] reported that the quality and adequacy of the content of patient-empowering mobile apps varied greatly, urging for a more rigorous design and further testing before implementation. To our knowledge, no study has directly shown a link between mobile health app–induced empowerment and direct health outcomes.

Overall, few high-quality studies assessing the effect of digital health interventions on patient empowerment are available. Research is needed to confirm or deny the high perceived potential of digital tools.

Concerto: A Mobile App Designed to Promote Patient Empowerment

Concerto is a mobile app designed to promote the empowerment of hospitalized patients. The app was initially designed during a hackathon in 2015 by a multidisciplinary team including health care and IT professionals as well as one patient. Building on the hackathon prototype and after a feasibility study, the Geneva University Hospitals (HUG) launched a project aiming at developing and implementing a fully functional mobile app delivered on institution-owned tablets in four pilot divisions (oncology, neurorehabilitation, orthopedics, and pediatrics) and assessing its effectiveness. Following this pilot study, the mobile app was further refined and deployed institution-wide based on a bring-your-own-device (BYOD) approach. This implementation report focuses on the pilot study only, with the objective to highlight the lessons learned. The report is structured following the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) guidelines [15].

Methods

Design and Agile Development

Building on the prototype developed during the hackathon, the foreseen functionalities of Concerto were first compared with patients' expectations using focus groups and a semiquantitative questionnaire. A feasibility study was then performed to assess the availability and quality of the necessary data in the hospital health information system (HIS), which has been developed mainly in-house during the last 30 years.

Based on the patients' insights, further described in Dietrich et al [16], version 1.0 of Concerto was specified and developed using an agile methodology with frequent user testing among hospitalized patients. The main functionalities of this version of Concerto included:

1. An up-to-date calendar on which patients can visualize their care schedule and better understand their daily planning with the aim to reduce the impact of these events and be better prepared for them.

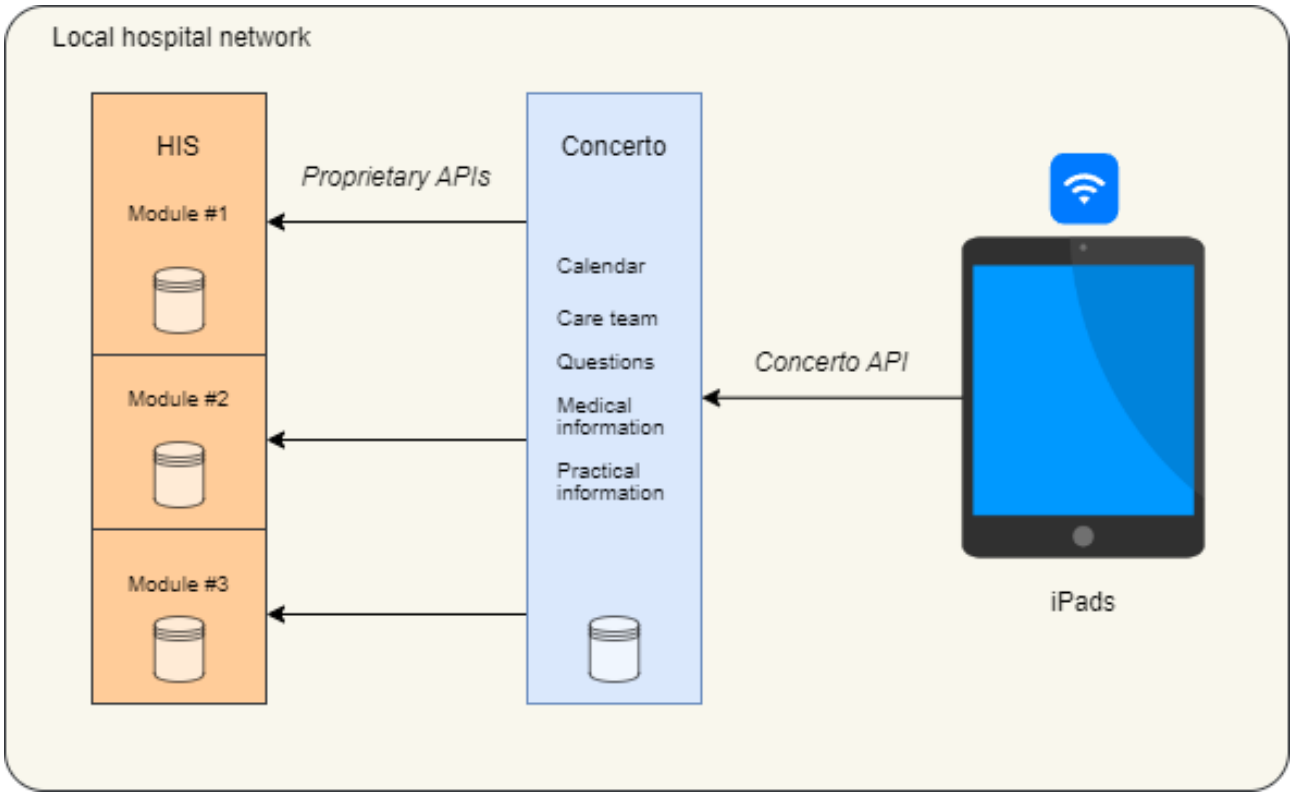
2. A care team module on which the patient can obtain information about their on-duty care team, including names and photographs, to better know the professionals they will meet during their stay and facilitate communication.
3. A “questions” module on which patients can prepare their questions for health care professionals during the medical round and thus elevate the level of communication.
4. An “information” module on which patients have access to targeted medical information. Expected benefits of this module were to achieve better situation awareness, better treatment adherence, and early detection of complications.
5. A “practical information” module on which patients can find useful information about their stay at the hospital to improve their overall experience.
6. A social network module on which patients can interact with HUG accounts.

In subsequent versions, a new module was added, allowing the patient to choose their meal directly on the app rather than via a form completed by the nurse. This module was designed to simultaneously improve the patient experience while decreasing the nurse workload.

The app was developed in web languages (an Angular project), encapsulated as an iOS app (with Apache Cordova), and deployed on institution-owned tablets using a mobile device management solution. The key arguments for internal development over acquisition of a commercial solution were that (1) a significant part of the development work was about interfacing with the HIS, and (2) to our knowledge, no adequate and mature commercial solution was available at the time, although such solutions have emerged since then.

The initial version of the app connected directly to the custom-made HUG HIS using its proprietary interfaces for the sake of development simplicity and to alleviate time constraints. Further versions of the app have used industry standards such as Health Level 7 Fast Healthcare Interoperability Resources, with the vision to enable Concerto to connect more easily to other HISs in the future. This update has required new developments on the HIS side and was not achievable during the pilot phase described in this report. Figure 1 presents the simplified architecture of Concerto.

Figure 1. Technical overview of Concerto. Through the hospital's private Wi-Fi, the patient's tablet connects to the Concerto server, which contains some patient-generated data and the business logic to provide the app data. The server connects to different modules of the hospital information system (HIS) to retrieve other data using diverse application programming interfaces (APIs).



Implementation

The definition of the logistics necessary to deliver Concerto on institution-managed tablets was an important part of the project. The following process was repeated for each patient: (1) setting up the tablet, including defining a personal passcode; (2) two-factor authentication in the Concerto app using the patient ID, scanned from the identification bracelet, and an SMS text messaging challenge; (3) on-demand charging; (4) disinfecting the tablet after the patient’s discharge; and (5) reinitializing and erasing the tablet. Tablets were charged and stored under key-secured storage in the nurse office. Each tablet was protected using individual cases. Hygiene procedures were validated by the Infection Prevention and Control Division of the HUG.

Once version 1.0 became available, caregivers of the different divisions were trained for 30 minutes during hands-on sessions

in which (1) the project and app were presented; (2) the logistics of the tablets were explained; and (3) most importantly, they had the opportunity to familiarize themselves with the tool. At least one caregiver was defined as a "superuser" on a voluntary basis and was implicated from the beginning of the project. The specific responsibilities of superusers included (1) acquiring deep knowledge of the app, (2) being the focal point for exchange with the project team, and (3) acting as the referent for day-to-day questions of caregivers. A typical division included 20 beds and comprised a pool of over 50 caregivers that were trained during different sessions. Importantly, as in many hospital projects, caregivers did not have dedicated time for the project. Therefore, they had to manage making themselves available during a normal day of work.

One unit was scheduled for launch every 2 weeks, with constant presence of one member of the Concerto team during the first few days. Only patients able to interact with a mobile app, as assessed by their caregivers, were offered to use the app. To this end, caregivers used a communication flyer describing the functionalities of the app, the modalities of its use, as well as data and privacy considerations.

Bugs, feedback, and general satisfaction were systematically consigned to fuel the improvement-and-fix backlog.

Data Considerations

At the stage presented during preparation of this report, Concerto worked mainly in "read-only" mode for personal health data available in the HIS and for insensitive, impersonal information. The information patients accessed from the HIS was part of their medical records. According to Swiss law, every patient owns the data contained in their medical record, except for personal notes of health care professionals, which were out of the scope of Concerto. Accordingly, Concerto facilitated access to data already owned by the patients.

The access to this sensitive personal information required a secure log-in based on the patient's ID number and a second-factor authentication with an SMS text challenge. The use of institution-owned devices allowed Concerto to access data in the hospital's local network, preventing unwanted access from the rest of the world.

The only personal information entered in Concerto included any questions patients may have had before interacting with their caregivers. This information was stored in the HIS and deleted after the hospital stay. Tablets were erased and reinitialized between patients, ensuring that no information leakage was possible between patients using the same tablet.

To summarize, Concerto facilitated the access to personal health information owned by the patient without the possibility to modify information from the app, and further allowed the patient to enter personal health information stored in the HIS that is inaccessible to others with all information systematically erased after the patient's hospital stay.

Overall, the project was compliant with the Swiss Law for Data Protection [17].

Funding and Budget Planning

The feasibility study and initial concept were self-funded by the eHealth and Telemedicine Division of the HUG, with the budget including salaries for a junior developer and a senior project manager.

The pilot project was then funded by private foundations based in Geneva, which included the salaries as well as necessary materials (tablets, covers, and software licenses).

Overall, the order of magnitude of the project costs ranged between US $150,000 and US $200,000, from which 25% was used for materials.

Ethical Considerations

This study is based on an internal project of a Swiss University Hospital, aiming for quality improvement. As such, no patient or participant was included specifically for this study. Moreover, no patient data of any kind were collected. Accordingly, this study does not qualify for a review by the Geneva Canton Ethics Board (Commission Cantonale d'Éthique de la Recherche sur l'Être Humain [18]). As there were no participants involved in the research, no consent, compensation scheme, or privacy and confidentiality considerations applies.

Implementation (Results)

Project Summary

Concerto was implemented in four pilot divisions; a typical division includes 20 beds and comprises a pool of over 50 caregivers.

The timeline of the various stages of the project is provided in Figure 2. From the initial hackathon to acquiring the funding, approximately 1 year was necessary to refine the concept with patients and assess the feasibility of the app. Following funding acquisition, 6 months of development were needed, followed by 6 months of piloting in the four selected hospital divisions. Overall, the project took 2 years.

The budget was respected. However, additional funding would have been welcome to help free the caregivers from their clinical duties to enable better implementation (see below for further discussion of this point).

The development team considered the agile development phase to be efficient and productive.

Critical to the development process, the organization of focus groups and one-on-one interviews with patients were facilitated owing to the clinical background of the project manager. The development team reported that early contacts with the IT division during the feasibility study helped to improve communication and hence efficiency. Finally, dedicated support of the management unlocked political stalling.

During the pilot phase, the app was proposed to all eligible patients (see the Implementation subsection of the Methods). The percentage of eligible patients was unfortunately not systematically monitored but varied according to the profile of hospitalized patients across the different divisions and over

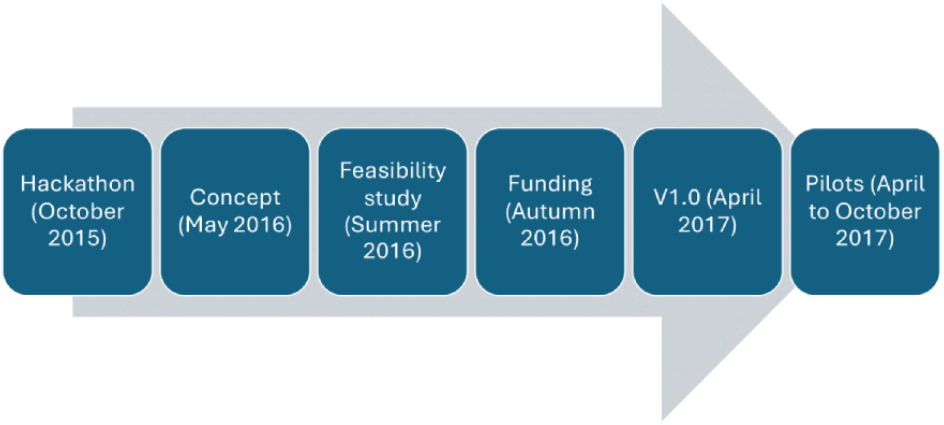
time. An eligibility rate below 50% of all hospitalized patients was common.

The percentage of acceptance was also not systematically collected. However, the project team recalled acceptance to be relatively less variable than the percentage of eligible patients and consistently high (over 80%).

The dropout rate should have also been monitored carefully to identify the reasons for dropping out.

Most importantly, navigating the logistics of the tablet emerged as a particular challenge for caregivers. Despite the support of the project team, this impaired the inclusion of patients and consequently use of the app. More precisely, caregivers reported difficulties in assisting patients with the log-in and reinitialization procedures, and all logistics steps were reported as being too time-consuming. Based on this finding, it was decided to stop the pilot phase and transition to a BYOD approach.

Figure 2. Timeline of the main phases of the project.



Lessons Learned and Determinants of Success and Failure

As often reported in the field, most challenges were encountered during the implementation (pilot) phase.

Our strategy to use institution-owned tablets added an important workload on the care teams because they were in charge of managing the tablet fleets in their divisions. This strategy was based on a rationale for cybersecurity and development; however, we underestimated the additional work it would generate for already overwhelmed caregivers. With such a strategy, it is our experience that protected and dedicated time for training caregivers is mandatory, at least for superusers. It is well recognized that the quality of training represents a key success factor for the implementation of electronic medical records (EMRs) [19]. Our impression is that this also applies to our project. Accordingly, our two first reported determinants of success are (1) having an implementation strategy that minimizes the impact on already overworked health care professionals and (2) including quality training time protected from the daily routine.

Similarly, we noticed that implementation was easier in care units in which the superuser was both convinced of the project's benefits and was an influential figure among their peers. Accordingly, our third observed determinant of success is that the presence of a "killer function," which on its own brings tremendous value, would have increased adoption by stakeholders. Even though such a function was not identified during patient focus groups, it was revealed during the implementation as the possibility for the patient to choose and order their own meals. Indeed, this function had the potential to both empower the patient and free up time for the caregivers. We consider that having such a functionality will be particularly relevant before the full-scale implementation.

The communication with the project's stakeholders was considered to be a key factor to maintain motivation and trust in the project. In particular, reactivity in fixing identified bugs or transparency about delays was appreciated.

Finally, we realized that the quality of the HIS medical information fueling Concerto was not always appropriate for display in a patient mobile app. This was either because the information was not timely or was incorrect in some cases, but most importantly because its label was too technical. This issue was associated with disadvantages such as a lack of confidence in the project as well as advantages such as a welcome transparency about HIS data, triggering continuous improvements. For example, specific agenda labels designed for patients were created in the HIS owing to the implementation of Concerto.

Discussion

This implementation report presents a real-world example of designing, developing, and implementing a patient-empowering mobile app in an in-patient setting of a Swiss public university hospital. The lessons learned, as presented in the Implementation (Results) section, are summarized in Table 1.

As described in the Introduction section, patient empowerment is a metaconcept. Hence, it is difficult to monitor with a single indicator. For this reason, a key success indicator was not defined at the beginning of this project, which has complicated its evaluation. This represents a limitation of this report, as an objective metric would have been important for complete evaluation. Simple monitoring metrics (eg, eligibility, number of users, and dropout and acceptance ratios) should have also

been collected and are planned for the next app version. A randomized controlled trial assessing the effectiveness of the Concerto mobile app on a patient situation awareness score has been designed and should be conducted in the near future. This trial will allow for better evaluation of the cost-effectiveness of such a project. Overall, data on the effectiveness of eHealth projects are often lacking, and the creation of a dedicated "Implementation Report" article type in *JMIR Medical Informatics* is helping to fill this gap.

The generalizability of our study is another limitation. Indeed, the innovation ecosystem and the EMR landscape at the HUG are very specific and different constraints may be experienced in other settings. However, we believe the reported lessons learned remain relevant in various environments.

In response to one of the main lessons learned with the pilot implementation of Concerto, a BYOD version of the app was developed. With this version, every patient was able to use the app on their personal devices, including computers, tablets, or smartphones. This decision was made to limit the workload on caregivers and improve the adoption rate. New functionalities such as the possibility for patients to choose their meal were also developed to answer unmet needs for both end users and stakeholders impacted by implementation of the app (ie, caregivers). Important challenges in terms of cybersecurity, interoperability, and compatibility had to be met with development of the BYOD version. These will be further described in a forthcoming implementation report focusing on this project phase.

Table 1. Main lessons learned and associated perceived relevance.

Lessons learned	Perceived relevance[a]
Minimize the workload of caregivers or, if possible, decrease it	5/5
Plan protected time for training end users	4/5
Select a convinced and influential superuser	3/5
Wait for a killer function before implementing the app	5/5
Maintain trust through reactivity and transparent communication	4/5

[a]Based on perceived experience, lessons learned were identified by the authors and their relevance was assessed by consensus using a score ranging from 1 (minimally important) to 5 (maximally important).

Acknowledgments

The Fondation Privée des Hôpitaux Universitaires de Genève was the main sponsor for the development and implementation of Concerto as described in this paper.

Authors' Contributions

DD was the project manager for Concerto during the project phases described in this report and wrote the manuscript. HBdV has been the project manager for Concerto after the project phases described in this implementation report and reviewed the manuscript. CPF has reviewed the manuscript. QL has been the lead developer of Concerto during the project phases described in this report and reviewed the manuscript.

Abstract

Background: Electronic medical record (EMR) systems are essential in health care for collecting and storing patient medical data. They provide critical information to doctors and caregivers, facilitating improved decision-making and patient care. Despite their significance, optimizing EMR systems is crucial for enhancing health care quality. Implementing the Observational Medical Outcomes Partnership (OMOP) shared data model represents a promising approach to improve EMR performance and overall health care outcomes.

Objective: This study aims to evaluate the effects of implementing the OMOP shared data model in EMR systems and to assess its impact on enhancing health care quality.

Methods: In this study, 3 distinct methodologies are used to explore various aspects of health care information systems. First, factor analysis is utilized to investigate the correlations between EMR systems and attitudes toward OMOP. Second, the best-worst method (BWM) is applied to determine the weights of criteria and subcriteria. Lastly, the decision-making trial and evaluation laboratory technique is used to illustrate the interactions and interdependencies among the identified criteria.

Results: In this research, we evaluated the AliHealth EMR system by surveying 98 users and practitioners to assess its effectiveness and user satisfaction. The study reveals that among all components, “EMR resolution” holds the highest importance with a weight of 0.31007783, highlighting its significant role in the evaluation. Conversely, “EMR ease of use” has the lowest weight of 0.1860467, indicating that stakeholders prioritize the resolution aspect over ease of use in their assessment of EMR systems.

Conclusions: The findings highlight that stakeholders prioritize certain aspects of EMR systems, with “EMR resolution” being the most valued component.

Introduction

Background

Today, electronic files are a standard tool for enhancing the efficiency and effectiveness of care services, thanks to their speed, accuracy, intelligent systems, reminders, and decision support. One of the most commonly used systems is the electronic medical record (EMR), a computerized system used by care providers, including hospitals and doctors’ offices [1,2]. It is designed for entering, storing, displaying, retrieving, and printing patients’ medical records. The system offers several

benefits, such as enhancing the quality of care provided to patients, better organizing information, and improving the timeliness, accuracy, and completeness of documentation [3]. Several factors drive health care providers and organizations to adopt EMR systems now or in the near future [4-6]. These include the ability to create and access patient records electronically, allowing patients to access their own files, preventing medication errors and allergic reactions, reducing medical errors, and providing immediate access to information across different locations. Additionally, EMR systems offer decision-support technology, streamline workflows, and enhance the overall efficiency of clinical processes. They also improve the quality of treatment and facilitate information sharing between general practitioners and specialists. Reducing medical errors and improving clinical data collection are key benefits of EMR systems. Health care providers and organizations increasingly recognize the need to adopt EMR systems to deliver more effective and efficient services [7]. However, the implementation of EMRs faces resistance, particularly from health care personnel, including doctors. To address this challenge, it is essential to create the necessary conditions for the acceptance of this system [8].

The acceptance of an EMR system is based on 2 major factors: perceived usefulness and perceived ease of use [9]. An individual's perception of the usefulness of information technology refers to the belief that using a particular technology will improve job performance or facilitate more efficient task execution within the organization [10]. This support may be reflected in reduced task completion time or the provision of timely information [11,12]. Perceived ease of use reflects the collective belief within an organization that a specific system is straightforward and requires minimal effort to operate [13-16]. In essence, tasks that are perceived as simpler are more likely to be embraced by users. The primary aim of this research is to explore the factors influencing the acceptance and use of the EMR system and the Observational Medical Outcomes Partnership (OMOP) using the Technology Acceptance Model. According to the Davis model [17-20], these factors include external variables (eg, user interface design, data quality, and health information within the EMR system), perceived usefulness, perceived ease of use, attitudes toward the system, and the behavioral intention to use the EMR system. In China, several EMR systems are widely used, driven by significant government investments and initiatives to enhance health care information technology infrastructure. Notable systems include WeDoctor (WeDoctor Holdings Co Ltd), AliHealth (Alibaba Health/Alibaba Group), Ping An Good Doctor (Ping An Healthcare and Technology), Winning Health Technology Group, and Neusoft Corporation. WeDoctor and AliHealth dominate the market by offering comprehensive services with a strong focus on interoperability and data integration. Ping An Good Doctor integrates its EMR system with its online health platform, facilitating remote consultations. Winning Health Technology Group and Neusoft Corporation focus on hospital management and clinical information systems, offering specialized solutions for various health care settings. We herein examined the AliHealth EMR system and surveyed 98 users and practitioners to evaluate its effectiveness and user satisfaction.

In this study, 3 distinct methodologies are used to explore various aspects of health care information systems. First, factor analysis (FA) is used to investigate the correlation between EMR systems and attitudes toward the OMOP. This approach aims to uncover underlying relationships and dependencies between these 2 key elements. Second, the best-worst method (BWM) is applied to determine the weight of criteria and subcriteria, offering a structured and quantitative assessment of their significance. Finally, the decision-making trial and evaluation laboratory (DEMATEL) method is applied to illustrate the interactions and interdependencies among the identified criteria, shedding light on the complex relationships within the health care information system landscape. Together, these methodologies provide a comprehensive understanding of the complex dynamics and factors influencing EMRs and health care information management. This approach differs from earlier studies in several ways. First, it significantly reduces the number of survey questions required to create a systematic causality diagram that decision makers can use. In the context of enhancing health care quality through the implementation of the OMOP shared data model in EMR systems, the integration of the BWM and DEMATEL is crucial for a thorough analysis. The BWM is first used to determine the relative importance of various criteria by comparing the best and worst criteria against all others, generating a weighted set of criteria. These weights are then used as inputs for the DEMATEL method, which maps out the cause-and-effect relationships among the criteria. Specifically, the numerical results from BWM prioritize the importance of factors, and DEMATEL quantifies the degree of influence each factor has over others, thereby creating a structured network of interdependencies. This integration allows for a nuanced understanding by using BWM-derived weights to adjust the influence degrees determined by DEMATEL, resulting in a refined model that better predicts and enhances health care outcomes through the OMOP model. The research contribution is summarized in 3 main stages:

- Determining the correlation between EMR systems and attitudes toward OMOP using FA.
- Establishing the weight of criteria and subcriteria using the BWM.
- Illustrating the interactions and dependencies among the criteria using the DEMATEL method.

The subsequent sections of this document are organized as follows: The "Literature Review" provides a concise summary of the current literature on EMRs, with a specific focus on the OMOP. The "Methods" section details the research methodology used in this study, including a comprehensive description of the chosen strategies and methodologies. The "Results" section presents demographic information and summarizes the conclusions of the study. The "Discussion" section examines the findings of the research. The "Conclusions" section presents the final outcomes of the article.

Literature Review

One of the most discussed aspects of eHealth today is EMRs. EMRs form the foundation of eHealth applications by storing patients' medical histories. They also include legal documents created in both in-house and outpatient settings [21]. The

electronic health record (EHR) system relies on these files for its data. Despite the widespread use of EMR systems in hospitals, many in the medical field still lack confidence in them [22]. Research on EMR systems in hospital settings remains limited. To address the personal, privacy, and security aspects affecting EMR adoption and utilization, Enaizan et al [23] introduced a decision support review framework. This framework is based on a multicriteria approach and K-means clustering, derived from insights gathered from Malaysian health care professionals. Although EHRs represent a significant technological advancement for health care, their adoption has been slow. Liou et al [24] highlighted this issue and proposed a theoretical framework to investigate and improve EHR utilization. Their framework uses the Technology-Organization-Environment model and the DEMATEL approach to create an Influence Network Relationship Map. This map integrates the core concepts of the Analytic Network Process with a modified Vlsekriterijumska Optimizacija i Kompromisno Resenje (VIKOR) method. This approach helps us better understand and utilize EHR technology. Oja et al [10] presented the process of converting EHR, claims, and prescription data into the OMOP format. They detailed the challenges and solutions associated with this conversion process.

EMRs are computerized medical information systems that capture, store, and display patient information. They assist doctors in conducting better, safer, and more efficient work, ultimately improving patient well-being. However, their adoption is still limited globally. Therefore, management information system scholars should investigate the increasing use of EMRs in the health care sector. Despite the potential of EMR systems to reduce administrative costs and medical errors, their adoption rates in physician practices have been slow. To address this, Zaidan et al [25] conducted a comparative study using multicriteria decision-making (MCDM) methods to assess and select open-source EMR software. The medical field is undergoing unprecedented transformation in many countries. Health care organizations are leveraging EMRs to enhance technology utilization, decision-making, and the search for medical solutions. There are employment opportunities for health care workers involved in the transition from paper to electronic records. EMR systems and other health information technologies rely heavily on critical users, particularly doctors. Therefore, the benefits of EMRs cannot be fully realized without user acceptance and approval. According to the literature review, effective criteria and subcriteria for evaluating attitudes toward the use of the OMOP system are listed in Table 1. The questionnaire used to assess attitudes toward the OMOP system included these components. Table 1 presents the criteria and subcriteria relevant to users' attitudes toward the EMR system. The questions were designed using a 5-point Likert scale, ranging from 1=low to 5=high importance, allowing respondents to rate each subcriterion based on their perspective. The criteria include the ease of use, the usefulness of OMOP, the EMR system itself, and the quality of care, each with associated subcriteria reflecting the system's usability, user-friendliness, and overall effectiveness.

Table 1. Effective criteria and subcriteria on the attitude of using OMOP[a].

Effective criteria and subcriteria on the attitude of using OMOP	Code	Mean
Ease of use [12,21,22,26]		
EMR[b] resolution	E1	4.61
EMR ease of use	E2	8.65
Easy to remember EMR	E3	9.66
User-friendliness of EMR	E4	6.64
Getting started with EMR is easy	E5	5.61
The usefulness of OMOP [12,21,22,26]		
EMR screen character resolution	U1	7.61
Appropriateness and consistency of terms used in EMR	U2	5.57
Appropriateness and consistency of the information used	U3	3.53
Ease of learning the operation of the OMOP system	U4	9.57
Features of the OMOP system	U5	5.52
EMR systems [12,21,22,26]		
Using an EMR is a good idea	EM1	3.64
Satisfaction with the use of EMR	EM2	1.65
Does EMR save money?	EM3	6.34
Does EMR save time?	EM4	1.68
The use of EMR is useful for users	EM5	6.35
Quality of care [12,21,22,26]		
OMOP quality	A1	4.62
Usability of OMOP	A2	2.62
Level of satisfaction with OMOP	A3	5.6
The flexibility of the OMOP system	A4	2.59
The power of the OMOP system	A5	7.59

Methods

Study Design and Overview

This methodology differs from previous studies in several key aspects. First, it significantly reduces the number of survey questions required to create a systematic causality diagram that decision makers can use. To thoroughly investigate the effectiveness of EMR systems and their relationship with attitudes toward the OMOP, a structured research methodology is essential. The research process is outlined in 3 key stages: The initial step involves establishing the relationship between EMR systems and users' attitudes toward OMOP. FA will be applied to identify the underlying variables that influence users' perceptions and satisfaction with OMOP within EMR systems. This method is crucial as it allows for the reduction of data complexity by identifying latent constructs that represent correlated variables. By understanding these correlations, we can better comprehend how different aspects of the EMR system influence users' attitudes toward OMOP, thereby providing a clearer picture of user satisfaction and areas needing improvement.

The second stage involves determining the importance of various criteria and subcriteria related to EMR systems using the BWM. BWM is an MCDM approach that derives criteria weights efficiently by comparing the best and worst criteria against all others. This step is essential for prioritizing the factors identified in the first stage and understanding their relative importance in shaping user attitudes. By assigning precise weights, BWM quantifies the impact of each criterion, enabling targeted improvements and informed strategic decision-making. The final stage involves analyzing the interactions and dependencies among the criteria using the DEMATEL method. DEMATEL is a powerful tool for visualizing and understanding causal relationships among complex criteria. This method is crucial as it reveals how different criteria influence one another, providing insights into the systemic structure of the EMR system. Understanding these interdependencies is essential for identifying key leverage points and developing strategies to enhance overall system performance and user satisfaction. To

summarize, the assessment framework is divided into 3 main stages:

- Determine the correlation between EMR systems and attitudes toward OMOP using FA.
- Determine the weight and importance of criteria and subcriteria using the BWM.
- Show how the criteria interact or depend on each other using the DEMATEL method.

The integration of BWM and DEMATEL results involves a systematic approach where the numerical outputs from each method inform and enhance the other. First, BWM is used to determine the relative importance (weights) of criteria and subcriteria by identifying the best and worst criteria through pairwise comparisons. These weights are then used as inputs for the DEMATEL method, which analyzes the interdependencies and causal relationships among the criteria. This combined approach allows for a comprehensive understanding of how different criteria influence each other and their overall impact on the system. By using the weighted criteria from BWM as a basis, DEMATEL provides a clearer understanding of how the most and least important criteria influence each other, refining the causal map of the system. The combined results offer a comprehensive view, where the weighted importance of criteria (from BWM) is contextualized within the network of influences and interactions (from DEMATEL). This integrated approach ensures that strategic decisions are both data driven and holistically informed. It allows for prioritizing factors not only based on their individual significance but also considering their dynamic interactions within the system.

DEMATEL is used to identify interrelationships and influences among criteria, revealing cause-effect chains, while BWM focuses on ranking and assigning precise weights to the criteria based on decision makers' preferences for the best and worst options. For example, DEMATEL helps determine which criteria have the most significant influence on others, while BWM quantifies these influences into specific weights. The weights derived from BWM and the influence matrix from DEMATEL are combined using a weight aggregation method. This process involves normalizing the weights from both methods and integrating them to form a consolidated weight for each criterion. This approach ensures that both the hierarchical influence identified by DEMATEL and the precision of BWM are captured. Once the combined weights are obtained, they can be applied to MCDM models. For example, in a selection problem, the integrated model uses the combined weights to evaluate and rank alternatives, ensuring a balanced consideration of interrelationships and priority weights. The combined results must be validated against other decision-making methods and through performance analysis tests to ensure their reliability and applicability in real-world scenarios. This step involves comparing the outcomes of the integrated model with those from using DEMATEL or BWM alone, highlighting improvements in decision accuracy and robustness.

Factor Analysis

FA is a statistical technique used to explore the latent structure of a data set. The primary goal of this study is to identify and examine the underlying factors that influence the observed variables. FA is commonly used in fields such as psychology, sociology, economics, and other social sciences [27].

FA is based on the principle that observed variables are influenced by a smaller set of latent factors. These latent factors are not directly observable but are inferred from patterns of correlations among variables. FA is a statistical technique that helps researchers understand the relationships between observed variables and the underlying factors that drive these relationships [25,28].

The BWM is an MCDM technique used to assess the relative weights or significance of selection criteria. This method involves selecting the best and worst criteria, with the best criteria representing those of greatest significance and the worst criteria representing those of least significance. In this study, BWM is used to determine the local weights for each criterion, as opposed to the analytic hierarchy process. Below, we provide a detailed explanation of the extended BWM calculation process [29-32].

BWM Method

Introducing the Best-Worst Method: A More Efficient Approach to Pairwise Comparisons

This new method requires fewer pairwise comparisons compared with the analytic hierarchy process. In hierarchical analysis, the number of pairwise comparisons is given by the formula $[m \times (m-1)]/2$, where m is the number of criteria or indicators being compared. By contrast, the BWM reduces the number of pairwise comparisons to $(2 \times m) - 3$, significantly decreasing the number of comparisons needed. The steps of this method are described in the following sections.

Step 1: Determining Research Criteria

In the first step, the decision matrix for the research problem is established, followed by the identification of the factors influencing the problem's objective.

Step 2.1: Choosing the Set of Decision Criteria

During this step, it is essential to identify the most significant and least significant criteria from among all the indicators, termed as the best and worst criteria, respectively. Next, comparisons should be made between the best criteria and the other criteria, as well as between the other criteria and the worst criteria, using 2 separate matrices. Responses to these comparisons should be provided on a numerical scale ranging from 1 to 9. Overall, experts or decision makers establish evaluation criteria that align with the decision-making problem $\{c_1, c_2, \ldots, c_n\}$.

Step 2.2: Eliminating the Best and Worst Candidates

Once experts or decision makers have established the q standards in step 1, the best and worst criteria are selected. This step is crucial as it significantly impacts the analysis and outcomes.

Step 2.3: Creating the Best-to-Others Vector

Pairwise comparisons with other criteria should be performed using the best criterion [33]. The best-to-others vector is expressed as follows [34]:

$$A_b=(a_{b1}, a_{b2}, ..., a_{bn})$$ **(1)**

where the value of the best criterion b, which is superior to criterion j, is represented by a_{bj}. By itself, the best criterion pairwise comparison must have a value of 1, or a_{bb}=1.

Step 2.4: Creating the Other-to-Worst Vector

This step involves generating the other-to-worst vector using the worst criterion as a reference for comparisons with the worst [35]. The decision maker evaluates the remaining criteria on a scale of 1-9 relative to the worst criterion. The other-to-worst vector is then formulated, as shown in equation 2, based on these comparisons between the worst criterion and the other criteria.

$$A_w=(a_{1w}, a_{2w}, \ldots, a_{nw})^T$$ **(2)**

where a_{jw} denotes how much the remaining criterion j is more important than the least important criterion w. By itself, the worse criterion pairwise comparison must have a value of 1, a_{ww}=1.

*Step 3: Determining the Ideal Weight for Each Criterion (w*1, w*2, …, w*n)*

During this stage, we construct the nonlinear optimization model of the BWM approach using the following equation [24,29]:

In this model,  .

When there are n criteria in total, the model can only compare pairs within a set of 4n–5 constraints in the solution of equation 6. Ultimately, the weights of all criteria combined are constrained to sum up to 1. In a nonempty collection, by assigning an appropriate value to ξ, a feasible solution space is created [29].

DEMATEL

Understanding and Applying the DEMATEL Technique for Complex Problem Solving

The DEMATEL technique, developed between 1971 and 1976, is designed to address intricate and complex problems. Its purpose is to enhance the understanding of complex issues and interrelated problems, ultimately offering a clear solution through a hierarchical structure [17-20,24,29-44]. The DEMATEL technique involves the following key procedures. Its primary objective is to identify causal relationship patterns among a set of criteria. This method assesses the strength of communication through scoring, explores feedback and its significance, and recognizes relationships that are not easily transferable [24,36].

Step 1: Creating a Direct Relation Matrix

The first step is to create a direct relationship matrix. In this step, the effectiveness of each criterion is evaluated individually. When opinions from multiple people are used, their arithmetic mean is calculated. The dimensions of the evaluation scale are then established to accurately reflect the magnitude of the impact. Semantic operational definitions and values are categorized into a scale from 0 to 4, representing varying degrees of influence. The potential values are low impact (1), medium impact (2), high impact (3), and very high impact (4) [24].

Experts (evaluators) complete this questionnaire (matrix), rating the relative importance of pairs of criteria. The values specified in step 1 are used to generate the direct relationship matrix. A direct relationship matrix $A = [a_{ij}]_{n*n}$ is then created by integrating the responses from the different experts. The initial average matrix, denoted as J, is constructed by calculating the mean scores provided by the respondents. This process determines each element in the matrix a_{ij}. The diagonal elements of the matrix are assigned a value of 0 [24].

Step 2: The Direct Influence Matrix Normalization

To normalize the direct correlation matrix, the formula $N=A/Z$ (ie, equation 4) is used. To calculate Z, the sum of all rows and columns is first found. The largest resulting number is chosen as Z. Then, all the entries of the direct correlation matrix are divided by Z.

Step 3: Computing the T (Matrix of Total Influence)

To calculate the total correlation matrix $T = [t_{ij}]_{n*n}$, an identity matrix I is formed We then subtract the identity matrix from the normalized matrix that  . Finally, we multiply the inverted matrix by the normal matrix. The total communication matrix is calculated from the relationship $T=N\times(I - N) - 1$. In other words

$$T = D + D^2 + \cdots + D^h = D(I - D)^{-1}$$ **(5)**

Step 4: Drawing the Network Relation Map Relationships

Column vectors R and S represent the T's column and row sums as equations 6 and 7 [24]:

where $[S_j]^T_{1*n} = [s_i]n*1$. If r_i represents the sum of matrix T's ith row, then r_i represents the total of factor i's that affects every other factor. The total of the direct and indirect effects that factor i has gotten from all of the other factors is represented by s_i, if s_i represents the column sum from matrix T. Additionally, $(r_i + s_i)$ provides an index of the strength of the effects that are imparted and received, meaning that $(r_i + s_i)$ represents the extent of factor i's overall effect in this system. The other factors are therefore influenced by factor i if $(r_i - s_i)$ is positive; conversely, if $(r_i - s_i)$ is negative, then factor i is generally influenced by the other factors [24,45,46].

Step 5: Creating a Causal Diagram

The summation of elements in each row (D) for every factor represents the impact of that factor on other elements within the system, reflecting the extent of influence exerted by the factor. Similarly, the summation of elements in each column

(R) for each factor indicates the degree to which that factor is influenced by other elements in the system, showing the extent of influence received by the factor.

Consequently, the horizontal vector ($D + R$) represents the overall influence of the specific factor within the system. In simpler terms, a higher $D + R$ value for a factor implies a greater level of interaction that the factor has with other factors in the system.

By contrast, the vertical vector ($D – R$) illustrates the influence of each factor. Generally, if $D – R$ is positive, the factor is considered a causal variable; if it is negative, it is regarded as an effect.

Step 6: Drawing the Cartesian Coordinate Diagram

In conclusion, a Cartesian coordinate system is constructed where the longitudinal axis represents $D + R$ values, and the transverse axis represents $D – R$ values. Each factor's position is defined by a point with coordinates ($D + R$, $D – R$) within this system. This approach results in a graphical diagram that visually represents the relationships and interactions among the factors in the system.

Ethics Approval

This study did not involve human participants or animals, and therefore, no ethics approval was required.

Implementation (Results)

Demographic Information

In the first phase of our study, we performed an FA on data collected from 98 hospital visitors, all of whom are users of the AliHealth EMR system. The demographic details of these participants are presented in Table 2. In the second phase, we conducted an MCDM survey with 10 experienced physicians and specialists, each with over 10 years of experience and advanced degrees. They were knowledgeable about electronic health topics, EMR systems, and OMOP. Our research aimed to investigate the impact of the OMOP on AliHealth users. OMOP is a public-private initiative designed to enhance methods and tools for analyzing health care data, particularly for postmarket surveillance of medical products. Its primary goal is to develop a common data model that standardizes the structure and content of observational health data, facilitating more efficient and reliable analysis across different data sources [47]. This model facilitates the integration of various data sets, enabling researchers to perform large-scale analyses and generate evidence on the safety and effectiveness of medical products. By examining the role of OMOP within the EMR system, we aim to understand how this standardized model enhances data integration and analysis capabilities. Our findings will contribute to ongoing efforts to improve health care outcomes through better data management and analytical tools, ultimately benefiting both health care providers and patients by ensuring safer and more effective medical treatments. Descriptive statistical measures have been used to assess the demographic characteristics of the participants, as illustrated in Table 2.

Table 2. Demographic characteristics of the respondents (N=98).

Characteristics	Values
Gender, n (%)	
Male	69 (70)
Female	29 (30)
Age (years), n (%)	
≤25	25 (26)
26-35	46 (47)
36-45	15 (15)
46-55	9 (9)
≥56	3 (3)
Marital status, n (%)	
Single	35 (36)
Married	63 (64)
Education, n (%)	
High school	17 (17)
Diploma	24 (24)

PhD	3 (3)
Use the online app, n/N (%)	
Everyday	18/55 (33)
2 or 3 times a week	29/89 (33)
Once a week	21/64 (33)
Once every 2 weeks	9/27 (33)
Once a month or less	21/64 (33)
See a doctor and update the medical record , n/N (%)	
Very little	10/30 (33)
Low	11/34 (32)
Medium	52/57 (91)
Much	14/43 (33)
Very much	12/37 (32)

FA Finding

Data are considered unsuitable for FA if the Kaiser-Meyer-Olkin (KMO) value is below 0.5. When the KMO value ranges between 0.5 and 0.69, FA should be approached with caution. However, if the KMO score is above 0.7, the correlations in the data are deemed suitable for FA. In this research, a KMO score of 0.766 indicates that the data are appropriate for analysis. Figure 1 illustrates the results of the partial least squares analysis, while Figure 2 displays the *t* value.

The path coefficients and their significance are given in Table 3.

Figure 1. Constructing a comprehensive research model using the partial least squares.

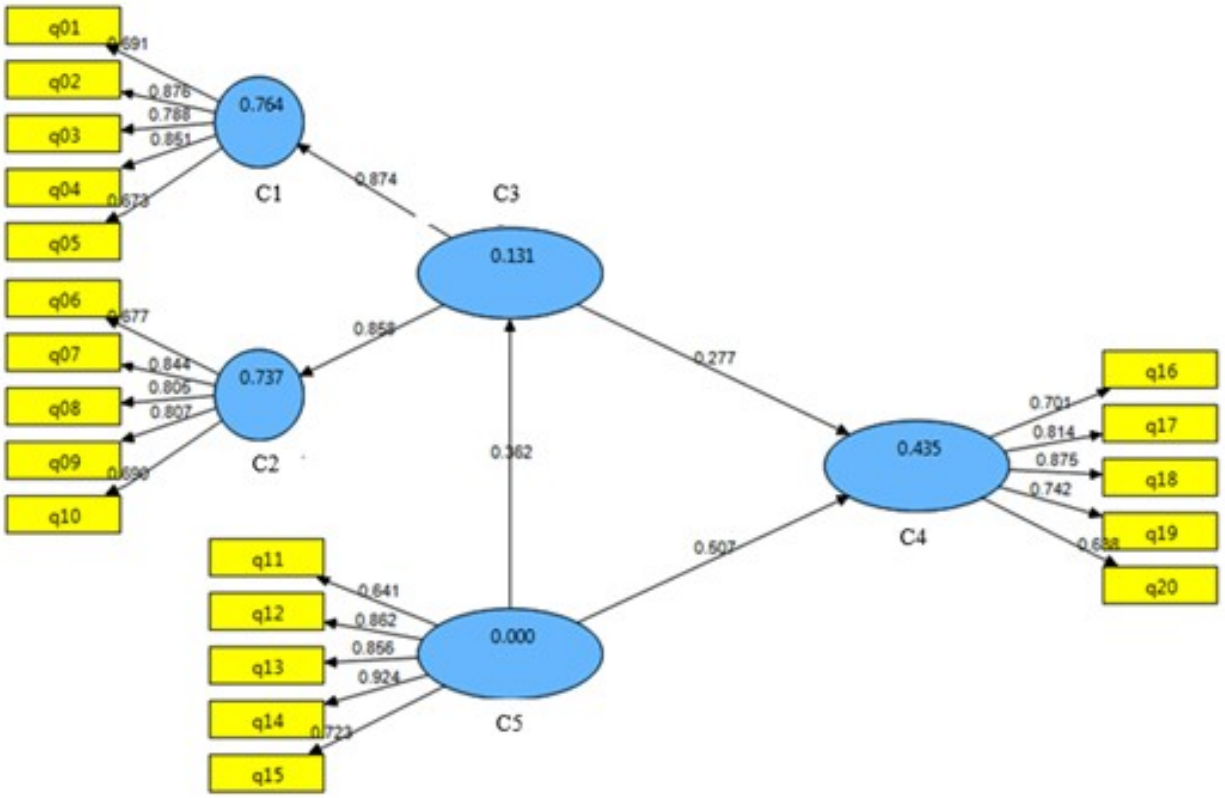

Figure 2. Utilizing the bootstrapping technique to derive T-statistics for the research model.

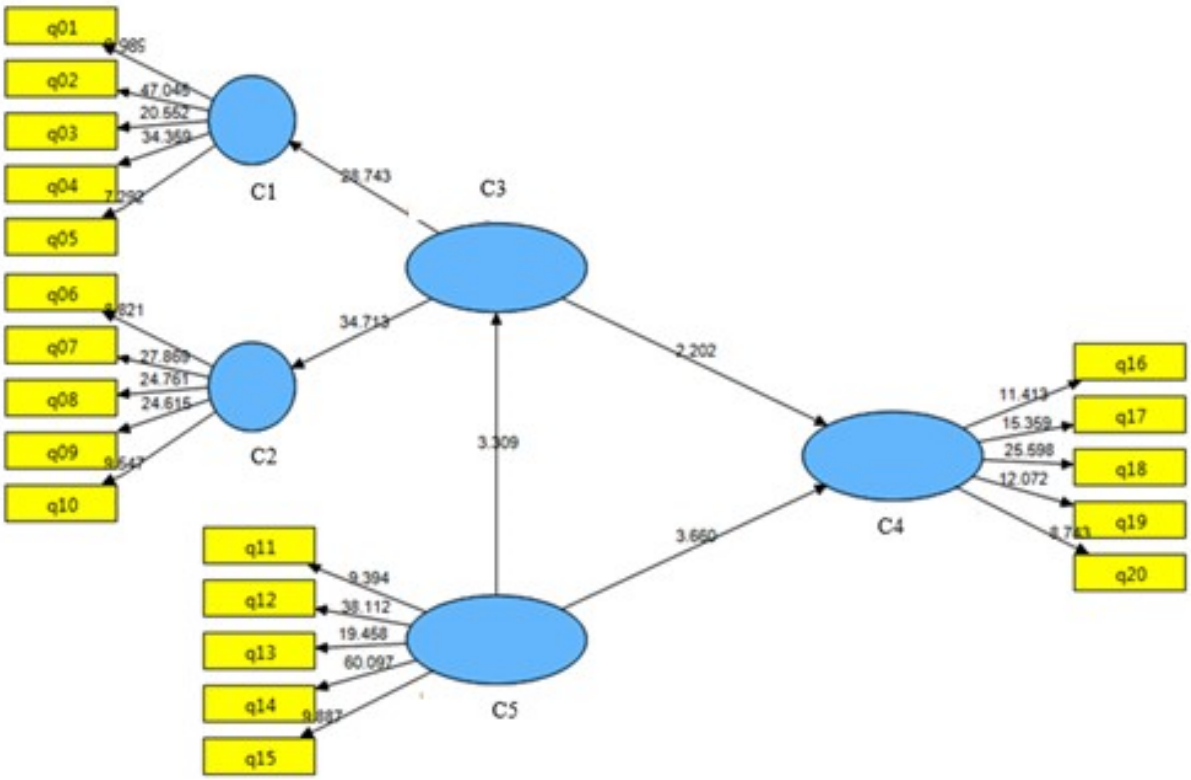

Table 3. Path coefficients.

t Value	Impact rate	Direction of the path
2.202	0.277	The effect of attitude toward the use of OMOP[a] on quality of care
34.713	0.858	The effect of attitude toward the use of OMOP on the usefulness of OMOP
28.743	0.874	The effect of attitude toward the use of OMOP on ease of use of OMOP
3.66	0.507	The effect of EMR[b] systems on quality of care
3.309	0.362	The effect of EMR systems on the attitude toward the use of OMOP

[a]OMOP: Observational Medical Outcomes Partnership.

[b]EMR: electronic medical record.

Table 3 reveals the strength of the relationships identified in the analysis. The correlation between EMR systems and attitudes toward OMOP usage is quantified at 0.362, with a test statistic of 3.309. This statistic exceeds the critical *t* value of 1.96 at the 5% significance level, confirming the statistical significance of the observed relationship. Therefore, with a 95% confidence level, a significant relationship between EMR systems and attitudes toward OMOP usage is established.

Similarly, the analysis reveals a relationship strength of 0.507 between EMR systems and quality of care, supported by a test statistic of 3.660. This result confirms a significant relationship between EMR systems and quality of care with 95% confidence.

Likewise, the correlation between the attitude toward OMOP usage and quality of care is 0.277, with a test statistic of 2.202. This statistic indicates a significant relationship between the attitude toward OMOP usage and quality of care with 95% confidence. Furthermore, the relationship strength between the attitude toward OMOP usage and the usefulness of OMOP is 0.858, with a test statistic of 34.713, which exceeds the critical *t* value at the 5% error level (1.96), confirming a significant relationship with 95% confidence. Therefore, a significant relationship is observed between the attitude toward OMOP usage and the usefulness of OMOP with 95% confidence. Additionally, the correlation between the attitude toward OMOP usage and the ease of use of OMOP is quantified at 0.874, with a test statistic of 28.743. This confirms a significant relationship between the attitude toward OMOP usage and the ease of use of OMOP with 95% confidence.

DEMATEL Findings

As outlined in the paper, the research questionnaire was developed using the DEMATEL technique and then administered to the participants. Table 4 presents the average opinions of the experts regarding the impact of each criterion (rows) on the other criteria (columns).

We use the formula  to normalize the components of Table 5.

Table 4. Average opinion of all experts.

Opinion	C1	C2	C3	C4	C5
C1	1.492	0.72	0.725	0.738	0.648
C2	0.867	1.707	0.96	1	0.779
C3	0.475	0.571	1.47	0.711	0.454
C4	0.693	0.825	0.872	1.723	0.852
C5	0.639	0.712	0.672	0.746	1.493

Table 5 shows the matrix after normalization.

Table 5. Normalized matrix.

Matrix	C1	C2	C3	C4	C5
C1	0.182	0.152	0.182	0.213	0
C2	0.152	0.273	0.273	0	0.303
C3	0.03	0.273	0	0.152	0.091
C4	0.333	0	0.242	0.214	0.121
C5	0	0.182	0.121	0.215	0.182

After computing the matrices mentioned above, the total relations matrix is derived using the following formula: 

In this formula, I is the unity matrix. The calculation results of the T matrix are shown in Table 6.

Table 6. The total relationship matrix (T).

Matrix	C1	C2	C3	C4	C5
C1	0.648	0.738	0.725	0.72	0.492
C2	0.779	1	0.96	0.707	0.867
C3	0.454	0.711	0.47	0.571	0.475
C4	0.852	0.723	0.872	0.825	0.693
C5	0.493	0.746	0.672	0.712	0.639

The next step is to obtain the sum of the rows and columns of the matrix *T*. We obtain the sum of rows and columns according to the following formula: and .

In the provided equation, *D* and *R* represent matrices of dimensions *n*×1 and 1×*n*, respectively. The next phase is evaluating the importance of indicators ($D_i + R_i$) and the correlation between criteria ($D_i - R_i$). If the difference between D_i and R_i is more than 0, the corresponding criterion is regarded as effective; conversely, if the difference between D_i and R_i is less than zero, the corresponding criterion is judged effective.

Table 7 and Figure 3 show the $D_i + R_i$ and $D_i - R_i$ and *XY* plots for importance, with their influence shown in Figure 4.

Table 7. Obtaining the importance and influence of criteria.

Matrix	Criteria	*D*	$D_i + R_i$	$D_i - R_i$
C1	The usefulness of OMOP[a]	3.324	6.49	0.157
C2	Ease of use of OMOP	4.314	7.849	0.778
C3	Attitude toward the use of OMOP	2.681	6.38	-1.018
C4	Quality of care	3.964	7.883	0.046

BWM Finding

The BWM is an effective MCDM technique used to determine the weights of criteria. The process begins by selecting the best and worst criteria based on expert judgment or specific research objectives. In this study, "The usefulness of OMOP (C1)" is identified as the best criterion, and "Electronic Medical Record Systems (C5)" is identified as the worst criterion. Following this, pairwise comparisons are performed between these criteria and all other criteria. The next step involves constructing a pairwise comparison matrix where comparisons are made between the best criterion (C1) and the other criteria, as well as between the worst criterion (C5) and the remaining criteria. Experts assign values based on how much better or worse one criterion is compared with another. An optimization model is then developed to minimize the maximum absolute differences between the derived weights and the optimal consistency ratio, ultimately determining the weights of the criteria. The weights assigned to the criteria in this analysis are as follows: "Usefulness of OMOP (C1)" has a weight of 0.3971, "Ease of use of OMOP (C2)" has a weight of 0.1985, "Attitude toward the use of OMOP (C3)" has a weight of 0.1489, "Quality of care (C4)" has a weight of 0.1538, and "Electronic medical record systems (C5)" has a weight of 0.1017. These weights reflect the relative importance of each criterion in the context of the research. The detailed results of the BWM analysis are presented in Table 8.

Table 8 shows the weights assigned to various factors related to the OMOP framework. The weights are as follows: W1 for "Usefulness of OMOP," W2 for "Ease of use of OMOP," W3 for "Attitude toward the use of OMOP," W4 for "Quality of care," and W5 for "Electronic medical record systems." Analysis of these weights reveals that W1 (Usefulness of OMOP) has the highest weight of 0.3971, indicating that this factor is considered the most important in the evaluation. By contrast, W5 (Electronic medical record systems) has the lowest weight of 0.1017, suggesting that it is considered less critical in this context. The weights provide a quantitative measure of the relative importance of each factor, with a higher weight indicating greater significance in the overall assessment of the OMOP framework. The process begins by selecting the best and worst criteria based on their relative importance, as reflected in their weights. After identifying these criteria, pairwise comparisons are conducted between the best and worst criteria and all other criteria. Following the pairwise comparisons, a linear programming model is formulated and solved to minimize the maximum deviation between the derived and optimal consistency ratios. Expert evaluations were aggregated using the simple weighted average method. The weights determined by this process are presented in Table 8.

Table 8. BWM_a result for subcriteria weight.

Criteria and subcriteria	Values
The usefulness of OMOP[b]	0.39708431
U1	0.31007783
U2	0.1860467
U3	0.23255837
U4	0.15503891

[a]BWM: best-worst method.

[b]OMOP: Observational Medical Outcomes Partnership.

These weights are shown in Multimedia Appendices 1 and 2 (the subcriteria weight is per Multimedia Appendix 2).

Table 8, along with Multimedia Appendices 1 and 2, assigns weights to various components related to the usefulness of OMOP. Among these components, “EMR resolution” has the highest weight, indicating its significant role in the evaluation. Conversely, “EMR ease of use” has the lowest weight, suggesting it is considered less critical in this context. The specific weight values are as follows: “EMR resolution” is assigned a weight of 0.31007783, while “EMR ease of use” has a weight of 0.1860467. This suggests that, in the assessment of EMR systems, stakeholders place the highest importance on the resolution aspect, while comparatively less weight is given to the ease of use of the EMR system. For the ease of use of OMOP, “EMR screen character resolution” holds the highest weight, highlighting its substantial importance in the assessment. Conversely, “Features of the OMOP system,” “Appropriateness and consistency of the information used,” and “Ease of learning the operation of the OMOP system” share the lowest weight, indicating a relatively lower significance for these aspects. The specific weight values are as follows: “EMR screen character resolution” has a weight of 0.19460294, while “Features of the OMOP system,” “Appropriateness and consistency of terms used in EMR,” and “Ease of learning the operation of the OMOP system” each have a weight of 0.12694036. This indicates that, in evaluating the EMR system within the OMOP framework, stakeholders consider the clarity and quality of screen character resolution to be the most important factor. By contrast, the features, terminology, and ease of learning are viewed as less influential.

For “Quality of care,” the component “Using an EMR is a good idea” has the highest weight, indicating that stakeholders place significant importance on the overall concept of using an EMR system. “Satisfaction with the use of EMR” follows closely, suggesting that user satisfaction is also a key consideration in the evaluation. By contrast, “Does EMR save time?” has the lowest weight, implying that the time-saving aspect is considered less critical in this context. The specific weight values are as

follows: "Using an EMR is a good idea" is assigned a weight of 0.38793627, indicating the highest priority. "Satisfaction with the use of EMR" has a weight of 0.19707721, reflecting its importance in stakeholder evaluations. "The use of EMR is useful for users" is assigned a weight of 0.18082109. By contrast, "Does EMR save money?" has a weight of 0.12694036, and "Does EMR save time?" has a weight of 0.10722507, suggesting that considerations related to time and cost savings are less emphasized compared with the perceived value and user satisfaction associated with EMR.

For "Electronic medical record systems," the component "OMOP quality" has the highest weight, reflecting the significant importance stakeholders place on the overall quality of the OMOP system. "The power of the OMOP system" is the next highest, indicating that the system's capability and strength are also crucial factors. Conversely, "Usability of OMOP," "Level of satisfaction with OMOP," and "The flexibility of the OMOP system" all share lower weights. This suggests that while usability, user satisfaction, and system flexibility are relevant, they are considered less critical compared with overall quality and system power in this context. The specific weight values are as follows: "OMOP quality" has a weight of 0.29528318, indicating a high priority for the overall quality of the OMOP system. "The power of the OMOP system" is assigned a weight of 0.19792768, reflecting its significant importance in the evaluation. By contrast, "Usability of OMOP," "Level of satisfaction with OMOP," and "The flexibility of the OMOP system" each have a weight of 0.07827498. This distribution suggests that stakeholders place greater emphasis on the overall quality and power of the OMOP system, while usability, satisfaction, and flexibility are considered relatively less critical in the evaluation process.

Discussion

Principal Findings

The primary objective of this research was to evaluate key components related to the usefulness, ease of use, quality of care, and EMR systems within the OMOP framework. The study aimed to identify the most critical factors influencing stakeholders' perceptions and priorities in these areas. The results, presented in Table 8 and Multimedia Appendices 1 and 2, highlight that "EMR resolution" and "OMOP quality" received the highest weights, indicating their significant importance in the assessment. Conversely, aspects such as "EMR ease of use" and "flexibility of the OMOP system" were considered less critical. Information technology plays a crucial role in enhancing data quality, which in turn improves patient care and safety. It is important for experts to define and explain the characteristics of health data quality so that system designers can identify appropriate methods to evaluate and improve these aspects during system revisions. This will contribute to better information quality in predictive and embedded systems. The findings of this study, particularly the emphasis on "EMR resolution" and "OMOP quality" as critical factors in evaluating the usefulness, ease of use, and quality of care within the OMOP framework, align well with existing literature. The focus on technical quality and the significance of detailed, high-resolution data for effective EMR use are consistently supported by multiple studies. For instance, the study by Kohane et al [48] on the impact of EMR systems on primary care practices underscores the importance of structural and process-related benefits that depend on high-resolution and quality EMR data to improve clinical outcomes. Additionally, the study by Lánczky and Győrffy [49] highlighted the usability of EMRs among health care professionals across various sectors, emphasizing the critical role of technical quality in facilitating efficient clinical workflows and decision-making processes. Effective EMR implementation in mental health settings depends on usability, acceptance, and alignment with clinical needs and workflows, although long-term outcomes remain unclear. Moreover, our study's conclusion that "EMR ease of use" and "flexibility of the OMOP system" were deemed less critical aligns with broader literature, which often underscores that user satisfaction is more strongly influenced by the quality and resolution of EMR data than by its ease of use. For example, a study [50] assessing the implementation of EMRs in mental health settings found that while ease of use is important, the perceived quality and accuracy of the data captured by the system were more significant in influencing user satisfaction and overall system acceptance.

The results related to the user interface reveal that users rated the clarity and quality of the EMR system screen, the appropriateness and consistency of the terms and information used, and the ease of learning its functions and capabilities as crucial factors. This indicates that, during the design and implementation of the EMR system, considerable attention has been given to external factors influencing system acceptance. When designing a new system, it is important to consider not only its functionality but also its appearance and all aspects that impact user interaction and satisfaction. Previous studies have found that more than 96.6% of doctors and midwives believe the EMR system is easy to operate, learn, and use [38-42]. In our study, the average user score for the ease of use of the system was 64.25. Regarding user attitudes toward EMR usage, polyclinic users exhibited a positive attitude with an average score of 66.84. This score is notably higher than the score (55.75) reported previously, indicating a favorable disposition toward the EMR system among polyclinic users. This positive attitude suggests that, with attention to other factors, there is potential to further enhance user satisfaction with the EMR system. In our study, the average behavioral preference score for the EMR system is 61.39. This score reflects users' preferences for the system, including its attractiveness, excitement, flexibility in adapting to changes, and overall power. These factors are related to users' perceptions of the system and are influenced by external factors associated with its implementation and use.

Conclusions

Based on the average scores for external factors such as data quality, clarity, and the user interface, it is evident that significant attention was given to these aspects during the design of the EMR system to ensure user satisfaction. Most users view the use of OMOP within the EMR system as beneficial, noting that this technology enhances productivity and fosters a positive attitude by improving task performance. This improvement can

be attributed to reducing task completion times and providing timely information. Over half of the EMR system users find it easy to use, believing that learning to operate the system requires minimal mental effort. Most users hold a positive attitude toward the EMR system. Consistent with these positive attitudes, the behavioral tendency to use the EMR system is also favorable. Future research should consider using the proposed integrated model to assess potential obstacles in the EMR system.

Abstract

Background: Medical errors are becoming a major problem for health care providers and those who design health policies. These errors cause patients' illnesses to worsen over time and can make recovery impossible. For the benefit of patients and the welfare of health care providers, a decrease in these errors is required to maintain safe, high-quality patient care.

Objective: This study aimed to improve the ability of health care professionals to diagnose diseases and reduce medical errors.

Methods: Data collection was performed at Dr George Mukhari Academic Hospital using convenience sampling. In total, 300 health care professionals were given a self-administered questionnaire, including doctors, dentists, pharmacists, physiologists, and nurses. To test the study hypotheses, multiple linear regression was used to evaluate empirical data.

Results: In the sample of 300 health care professionals, no significant correlation was found between medical error reduction (MER) and knowledge quality (KQ) (β=.043, *P*=.48). A nonsignificant negative relationship existed between MER and information quality (IQ) (β=–.080, *P*=.19). However, a significant positive relationship was observed between MER and electronic health records (EHR; β=.125, 95% CI 0.005-0.245, *P*=.042).

Conclusions: Increasing patient access to medical records for health care professionals may significantly improve patient health and well-being. The effectiveness of health care organizations' operations can also be increased through better health information systems. To lower medical errors and enhance patient outcomes, policy makers should provide financing and support for EHR adoption as a top priority. Health care administrators should also concentrate on providing staff with the training they need to operate these systems efficiently. Empirical surveys in other public and private hospitals can be used to further test the validated survey instrument.

Introduction

Background

Worldwide, the delivery of health care has been altered and improved through health information technology. In health care systems, patient administration and management have been facilitated by health information technology. The electronic health record (EHR) system is frequently cited as a vital piece of health information technology to raise the standard of patient care [1]. In the early 1970s, computerized patient EHR were first used to collect, save, and display patient data [2,3]. The ordering of tests, consultations, electronic prescriptions, decision support systems, digital imaging, telemedicine, and other clinical service units can all be included in EHRs, while preserving patient privacy and confidentiality [2].

According to Tegegne et al [4], both high-income and resource-constrained nations have the implementation of the EHR system on their priority agenda. Implementing an EHR is necessary to improve clinical judgment, patient information security, and privacy [1]. The EHR is thought to have the following potential advantages for the health care system: safety, patient information organization, care coordination, communication, patient history, quick access to medical information, and effectiveness of care [5,6]. Evidence also shows that EHR can improve data quality by storing patient data and performing medical tasks [7]. Furthermore, current studies on health information system (HIS) success are generally limited to exploring the driving factors at the HIS adoption level. However, the adoption of an HIS is not indicative of implementation success, as the value and potential of an HIS can only be realized when it is fully absorbed into the workflow by the organization and its users [8]. By comparing EHR adoption and assimilation, Upadhyay and Hu [9] provided empirical evidence that organizational assimilation over adoption can significantly improve patient treatment efficiency. Thus, this study aimed to explore how EHRs contribute to a decrease in medical errors using the expanded DeLone and McLean (D&M) Information System (IS) Success Model as the theoretical framework.

Thousands of people seek medical attention every day from a small group of doctors working in public health to improve the health of communities. Patient health care services must be provided more quickly to cater for the health needs for these communities. There are many problems with the public health care system, including long patient wait times, poor health care service, and inadequate infrastructure. Communities report that services provided by facilities fall short of fundamental standards of care and patient expectations despite government efforts to improve the quality of health care services [10]. In South Africa, more than half of the public health care facilities keep their records on paper, even though the country has adopted several EHR systems [11]. According to Rumball-Smith et al [5], using EHR to manage patient documentation could improve health care services. Despite their importance, medical records are common to be mishandled, resulting in patient files having medical records missing and the inability to get the correct treatment. Misplaced or absent records may have a negative effect on patients' quality of life [12]. It is currently acknowledged that modern productivity, efficiency, and effectiveness are necessary for the facilitation of medical care [13].

Losing a patient's medical records would be the worst-case situation because it could result in more issues, a wrong diagnosis, or, in severe circumstances, the patient's death [14]. In 1 case, where the woman gave birth to twins in the hospital, the Pietermaritzburg High Court ordered a KwaZulu-Natal district hospital to turn over medical information to the plaintiff's attorney in July 2006. In addition, hospital incompetence is said to have resulted in the patient losing 1 of the twins, and the surviving twin developing cerebral palsy. Medical records may occasionally be difficult to locate in the filing department due to a variety of issues, including documents being misfiled or misplaced [15]. These records, which are subsequently discovered in their offices, are occasionally misplaced by medical personnel. Furthermore, although the patient's status would have changed by the time the replacement record is found, the duplicate record would continue to exist.

This research developed a theoretical framework and a survey instrument consisting of questions to evaluate the efficacy of organizational EHR in day-to-day operations from the viewpoint of the nursing staff in residential adult care facilities. System quality, information quality (IQ), service quality (SQ), usability, user happiness, and net benefits were the 6 variables that made up the updated D&M IS Success Model that was part of the recommended study model.

The DeLone & McLean IS Success Model

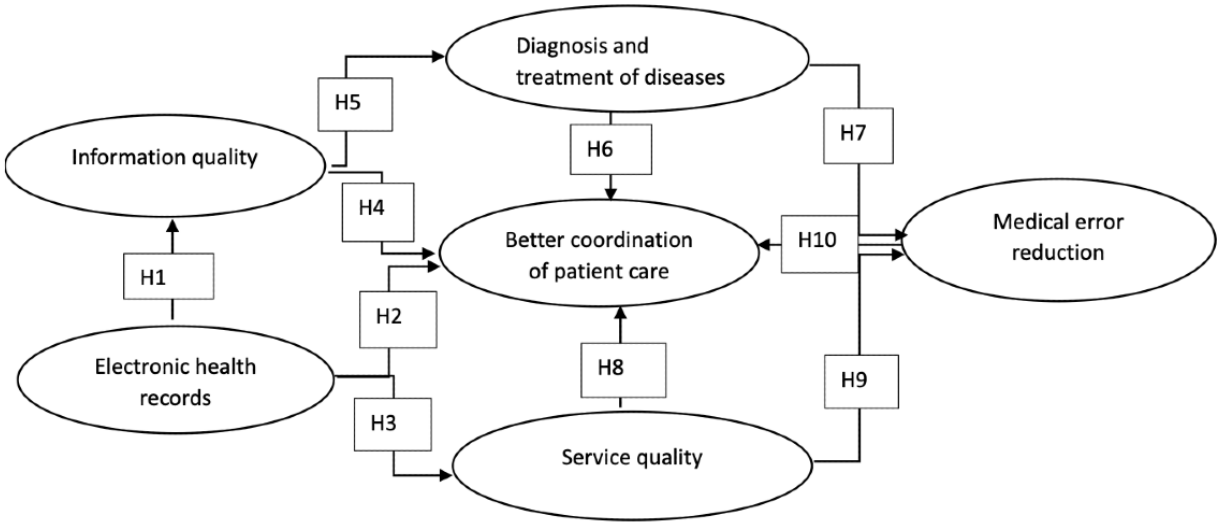
The D&M IS Success Model [16] has been 1 of the most popular measurement models in the IS industry when it comes to evaluating IS success. Numerous topics pertaining to the ongoing use of ISs have been investigated, with a focus on the model of IS success, which is theoretically based on DeLone and McLean's [16] work. Studies [17,18] have indicated that the D&M model is a reasonably developed theoretical model that is frequently used to predict people's behavior in a range of situations. Six interrelated IS success dimensions were identified using the original model. DeLone and McLean [16] proposed several factors that could be used to define IS success: system quality, output IQ, consumption (use) of the output, user response (user satisfaction), impact of the IS on user behavior (individual impact), and impact of the IS on organizational performance (organizational impact). This model indicated the causal and temporal relationships between the 6 characteristics and offered a system for categorizing the wide range of IS success measures. The D&M IS Success Model was updated 10 years later by DeLone and McLean, who combined organizational and individual impacts into a single impact variable known as "net benefit" and included SQ as a new dimension of measuring IS success [19]. The updated model [20] places strong emphasis on the value of gauging the effectiveness of IS variables.

The D&M IS Success Model [21] has been used to assess EHR implementations in numerous studies. It comprises elements of system quality, IQ, intention to use, satisfaction, actual use, and individual and organizational impacts. In the domain of health care, Jeyaraj [22] combined the Technology Acceptance Model (TAM) with the D&M IS Success Model. Consequently, he learned that having enough information available, having a well-designed interface, and having up-to-date information about the system are all crucial factors for an IS to succeed. The system's design is the most crucial element since success is determined by these factors. Noushi and Bedos [23] discovered certain guidelines that need to be followed while creating a new IS that may be used for patient work and diagnostics in a dental clinic setting. Based on the reviewed literature, this study sought to offer a research model to determine the effects of EHR on better coordination of patient care (BCP) in public hospitals. In the context of an HIS in a low- to middle-income country, the study validated the updated D&M IS Success Model. Following is a description of the research model and the proposed research model's hypotheses.

Research Model

The proposed research model is applied only to determine the effects of EHR on BCP in public hospitals. According to the objective of the study, the review of the literature, and the framework or TAM, the research model, as presented in Figure 1, adopted and incorporated the constructs of the D&M IS Success Model. A variable is defined as anything that has a quantity or quality that varies [24]. BCP was the dependent variable in this study's research model, which consisted of 3 independent variables or predictor factors. The independent variables in the study were EHR, IQ, medical error reduction (MER), diagnosis and treatment of diseases (DTD), and SQ. The model constructs are described in Figure 1.

Figure 1. Research model. H: hypothesis.



Hypothesis Development

Based on Figure 1, the 3 independent or predictor factors in the research model were:

- EHR: Digital copies of comprehensive patient records kept by health care professionals, containing information such as patients' medical history, diagnoses, and prescriptions
- IQ: The quality of information contained in the EHR system
- SQ: The quality of service provided by the health care facility, which can be influenced by factors such as the EHR system and the quality of information it contains

Every health care system aims to provide high-quality care [25]. Digital copies of thorough patient records that a health care professional keeps are called EHR or electronic medical records. According to Mitchell [26], EHR provide a comprehensive picture of a patient's medical history, improving care coordination. This history includes information about past medical conditions, prescription medications, allergies, and test results. The goal of an EHR is to guarantee that the patient receives care that is both effective and efficient. EHRs improve efficiency and accuracy, while making patient medical records easier to access and share. Furthermore, it improves treatment quality by allowing clinicians to quickly communicate, analyze data, and identify trends [9]. The following hypotheses were presented to investigate these relationships:

- Hypothesis (H)1: EHR have a significant positive influence on IQ.
- H2: EHR have a positive significant influence on BCP.
- H3: EHR have a positive significant influence on SQ.
- H4: IQ has a significant positive influence on BCP.
- H5: IQ has a significant positive influence on DTD.

The accurate diagnosis provided by this crucial information helps save time and money [12]. Patient data from the EHR system can be coordinated across numerous organizations because they are universally available. It is easier to read data between different EHR systems, since standardization of data according to a common set of standards is encouraged [27]. This major advantage of electronic records probably boosts the effectiveness of all health systems worldwide. Another crucial issue that health care facilities must address is preventive care [9]. More preventive treatment is expected to significantly improve patient outcomes. EHR systems are an excellent tool for helping preventive care initiatives. The following hypotheses were presented to investigate these relationships:

- H6: DTD has a significant positive influence on BCP.
- H7: DTD has a significant positive influence on MER.

Furthermore, EHR systems provide medical practitioners with more data so they can create campaigns for preventive health care [9,28]. EHR systems improve operational effectiveness and reduce error rates, immediately enhancing the standard and safety of patient care. EHR frequently encourage collaboration between organizations and the development of more robust institutions. EHR systems encourage improved hospital-wide communication and collaboration. For health care professionals, the issue of medical errors as an element of SQ has become crucial. According to Fraser et al [29] the SQ technique helps understand patient expectations and facilitates changes in medical practices, increasing patient happiness and compliance, while also improving the quality of the medical services

provided. The following hypotheses were presented to investigate these relationships:

- H8: SQ has a significant positive influence on BCP.
- H9: SQ has a significant positive influence on MER.
- H10: BCP has a significant positive influence on MER.

Methods

Research Design

The Dr George Mukhari Academic Hospital (DGMAH), a tertiary hospital located approximately 30 km north of Tshwane (Pretoria, South Africa), was the site of the study. Students in health sciences from the Sefako Makgatho Health Sciences University (SMU) use the DGMAH as a training hospital. It consists of 39 wards grouped together according to therapeutic specialties. A cross-sectional analytical research design was used for this investigation. Connelly [30] stated that all the data for a cross-sectional study should be gathered at once. Such studies are useful for recording the state of phenomena or the relationships between phenomena at a particular moment in time, since the phenomenon being studied is captured during a single data collection session. Data for the study were gathered at the DGMAH between August 2020 and July 2021. The sample size for this research was 300 medical health care professionals.

In this study, convenience sampling was the approach used in the participant selection process. Convenience samples are used in surveys where respondents are offered the choice to participate or not participate. This sampling is not probabilistic in any way. Probabilistic sampling involves selecting a sample using a probabilistic method without consulting the individuals selected [31]. Convenience sampling, according to Etikan et al [32], is a type of nonrandom sampling in which participants are selected from the target population only if they meet a specific set of pertinent practical requirements. Most often, convenience sampling is used to obtain information from subjects who are easy for the researcher to enroll into the study [32]. There are a number of inherent disadvantages to the convenience sampling technique. With this kind of sampling, biases in the sampling process and systematic errors could arise. In this sense, bias resulting from self-selection and noncoverage taints the convenience samples. Even though noncoverage is avoided and a sampling frame with a random pool of subjects is obtained, if empirical studies use nonprobability convenience samples, the researchers typically are unable to discharge self-selection, because individuals choose whether to complete the survey or participate in the interview at their own discretion. Furthermore, it is not possible to interpret the *P* value in a meaningful way. Alvi [33] further contended that the target population groups should be sufficiently inclusive to be further subdivided into an infinite number of categories that are relatively distinct from one another and therefore not representative of one another.

Teclaw et al [34] found that survey participants occasionally give up before completing the questionnaire. Therefore, it is imperative that the demographic information part of the survey be the first to be completed. Demographics are essential for comparison and descriptive reasons in any study. According to Teclaw et al [34], starting the survey with demographics enhances the item response rate. The goal of this research was to use EHR as a system to determine how IQ, MER, DTD, and SQ, which are independent variables, influence the dependent variable, BCP. Data were collected from the DGMAH, and the constructs were determined using the reviewed literature. Data were collected using a 5-point Likert scale (strongly disagree, disagree, neutral, agree, and strongly Agree). with items made up of demographic and background information, as well as D&M model variables. For the purposes of this study, the questionnaire items were adapted from conventional forms of the TAM, drawing on the relevant literature.

Ethical Considerations

The study was approved by the University of South Africa–College of Agriculture and Environmental Sciences (UNISA-CAES) Health Research Committee (reference number 2019/CAES/075). The DGMAH, Office of the Director of Clinical Services, gave its approval for the study to be carried out at the hospital. Each participant provided signed informed consent, which included details about the researcher, the purpose of the survey, its length, privacy protection protocols, and other information. The study's data were anonymized and deidentified.

Multiple Linear Regression

The rationale behind the selection of multiple linear regression in this study was its ability to evaluate the relationships between a single continuous dependent variable and multiple independent variables. This fit well with the study's goal of determining how different factors affect the reduction in medical errors. For that reason, multiple linear regression was used to investigate the relationship between the dependent variable (MER) and multiple independent variables (EHR, IQ, DTD, BCP, SQ). This method is appropriate when there is 1 continuous dependent variable hypothesized to be associated with 2 or more independent variables.

The specific variables included in the regression model were selected based on the research model and hypotheses developed from the literature review. The model aimed to test how EHR implementation influences MER, both directly and through potential mediating variables, such as IQ, DTD, SQ, and BCP.

Before conducting the regression, necessary assumption checks were performed:

- The Durbin-Watson statistic (2.119) indicated no significant autocorrelation in the residuals.
- The variance inflation factor (VIF) values were all below 5, suggesting no problematic multicollinearity.
- The histogram of standardized residuals followed a reasonably normal distribution.
- The Bartlett sphericity test ($P<.05$) and Kaiser-Meyer-Olkin (KMO) value ($0.727>0.5$) indicated sampling adequacy for factor analysis.

Data Analysis

SPSS Statistics (IBM Corp) was used to perform data analysis. A reliability test on the entire data set resulted in a Cronbach α value of .94, which confirmed the reliability of the data for further analysis. Data analysis and results were divided into 3

sections to cover descriptive analysis, factor analysis, and multiple regression analysis. In addition, quantitative data were analyzed to determine the causal relationship between the independent variables (EHR, IQ, MER, SQ, DTD) and the dependent variable (BCP). Inferential analysis was conducted that involved examining the nature of relationships between the variables under study using the Pearson correlation coefficient. Correlation and regression analyses were used in the inferential analysis. The data analyzed were presented using tables, correlation, regression, and ANOVA.

Results

Demographic Information

Table 1 displays the demographic profile of the survey participants. The sample was made up of 89 (29.7%) males and 211 (70.3%) females. Approximately 34% (n=102) of the respondents were in the 31-40–year age range, while 8.7% (n=26) were younger than 25 years. In addition, 243 (81.4%) were nurses, and 57 (18.6%) were medical professionals. Furthermore, 23 (5.0%) had less than a year's experience, 39 (13.0%) had 2-5 years' experience, 162 (5.4%) had 6-10 years' experience, and 76 (28.0%) had more than 10 years' experience. The structural model was put to the test on 35 items using the Bartlett sphericity test and KMO sample adequacy. Kaiser [35] argued that a KMO value below 0.5 is insufficient. The KMO value for this study was 0.727, indicating that the sample was sufficient and that factor analysis could be carried out. Furthermore, the Bartlett sphericity test was performed, and the result of $P<.05$ indicated that there was a statistically significant association between the variables.

Table 1. Demographic information.

Demographics	Participants (N=300), n (%)
Gender	
Male	89 (29.7)
Female	211 (70.3)
Age (years)	
<25	26 (8.7)
25-30	98 (32.6)
31-40	102 (34.0)
41-50	57 (19.0)
>50	17 (5.7)
Occupation	
Medical doctor	16 (5.0)
Pharmacist	12 (4.0)
Radiologist	10 (3.3)
Physiotherapist	9 (3.0)
Nurse	243 (81.4)
Dentist	10 (3.3)
Work experience (years)	
<1	23 (5.0)
2-5	39 (13.0)
6-10	162 (54.0)
>10	76 (28.0)

Reliability and Validity

To determine the internal consistency and relationship of the items on the scale, a reliability analysis was performed. Cronbach α was used to evaluate the dependability of 47 items. Cronbach α values exceeding 0.5 were considered as being within the acceptable range. The Cronbach α values of 7 variables were over 0.5 based on the indicated value, indicating strong consistency for those items. Items with values less than 0.5 were eliminated [36]. The reliability analysis of the 6 constructs is shown in Table 2.

Table 2. Reliability analysis.

Variable	Items, n	Cronbach α
DTD[a]	6	.783
BCP[b]	5	.852
MER[c]	5	.741
SQ[d]	5	.752
EHR[e]	5	.789
IQ[f]	5	.858

[a]DTD: diagnosis and treatment of diseases.

[b]BCP: better coordination of patient care.

[c]MER: medical error reduction.

[d]SQ: service quality.

[e]EHR: electronic health record.

[f]IQ: information quality.

Multiple Linear Regression

Ten variables were subjected to multiple linear regression to measure the success of the structural model in determining the effects of EHR on the reduction in medical errors in DTD in public hospitals. This resulted in an R^2 change, which showed an increase in variance accounted for by the new interaction term. The R^2 change increased by 0.159, indicating a 15.9% increase in the amount of variation that the extra interaction term could explain. It is important to note that the increase in variation was statistically significant (P<.05), indicating that EHR, SQ, and IQ all significantly have a significant positive influence on MER. Table 3 outlines the results of ANOVA for IQ, DTD, BCP, SQ, and EHR as mediating variables of MER.

The relative importance of each construct was represented by the model's standardized coefficients. The findings showed that there is no statistically significant relationship between MER and knowledge quality (KQ; β=.043, t=0.705, P<.05). MER and IQ had a negative and statistically insignificant relationship according to the predictor variables (β=–.080, t=–1.320, P<.05). However, there was a statistically significant relationship between MER and EHR (β=.125, t=2.043, P<.05). In general, the results showed a strong statistically significant correlation between the dependent variable MER and the predictors IQ, DTD, BCP, SQ, and EHR.

In this study, IQ, SQ, DTD, BCP, and EHR were all analyzed using hierarchical multiple regression. Table 4 represents the outcomes of the moderated regression analysis that are displayed in Figure 2, which shows the histogram of residuals in the regression model for the dependent variable, MER. The residual histogram was found to be reasonably normal and to be close to the normal curve.

Table 3. Summary of the regression model for analysis of success factors for model 1.[a]

Success factor	Value
R	0.399
R^2	0.159
Adjusted R^2 (SE)	0.154 (0.47074)
Change statistics	
R^2 change	0.159
F change	28.055
df1	2
df2	295
Significant F change	0
Durbin-Watson autocorrelation	2.119

[a]Predictors: (constant), information quality (IQ), electronic health record (EHR), diagnosis and treatment of (DTD), service quality (SQ), and better coordination of patient care and (BCP); dependent variable: medical error reduction (MER).

Table 4. Regression coefficients of variables included in the optimized model.

Variable[a]	Unstandardized coefficient, B (SE)	Standardized coefficient, β	*t* test (*df*)	Significance	95% CI	Collinearity statistics	
						Tolerance	VIF[b]
(Constant)	3.903 (0.482)		8.100	0.000	2.954 to 4.851		
SQ[c]	0.035 (0.050)	.043	0.705 (0.600)	0.481	–0.064 to 0.135	0.976	1.024
IQ[d]	–0.061 (0.046)	–.080	–1.320 (–0.988)	0.188	–0.154 to 0.030	0.986	1.014
EHR[e]	0.136 (0.066)	.125	2.043 (2.890)	0.042	–0.005 to 0.067	0.975	1.026
BCP[f]	0.030 (0.207)	.016	0.144 (2.548)	0.085	–0.077 to 0.133	0.964	1.011
DTD[g]	0.181 (0.149)	.137	2.216 (3.118)	0.025	–0.112 to 0.171	0.971	1.028

[a]Dependent variable: medical error reduction (MER).

Hypotheses

Multiple regression testing was performed to examine the effects of EHR on BCP in public hospitals, as well as to evaluate the statistical significance of each hypothesis. Of the 10 hypotheses, 6 (H1, H2, H4, H5, H7, and H10) were statistically significant in determining the effects of EHR on BCP in public hospitals according to the study's findings, with $P<.05$. The results of the hypothesis testing are summarized in Table 5.

Table 5. Summary of the results of hypothesis testing.

Hypothesis (H)		Results	Outcome
H1	EHR[a]→IQ[b]	*P*=.028<.05, β=.354	Accepted
H2	EHR→BCP[c]	*P*=.010<.05, β=–.391	Accepted
H3	EHR→SQ[d]	*P*=.226>.05, β=.109	Rejected
H4	IQ→BCP	*P*=.010<.05, β=–.391	Accepted
H5	IQ→DTD[e]	*P*=.021<.05, β=.329	Accepted
H6	DTD→BCP	*P*=.229>.05, β=–.129	Rejected
H7	DTD→MER[f]	*P*=.002<.05, β=.415	Accepted
H8	SQ→BCP	*P*=.224>.05, β=.100	Rejected
H9	SQ→MER	*P*=.990>.05, β=.001	Rejected
H10	BCP→MER	*P*=.021<.05, β=.329	Accepted

[a]EHR: electronic health record.

[b]IQ: information quality.

[c]BCP: better coordination of patient care.

[d]SQ: service quality.

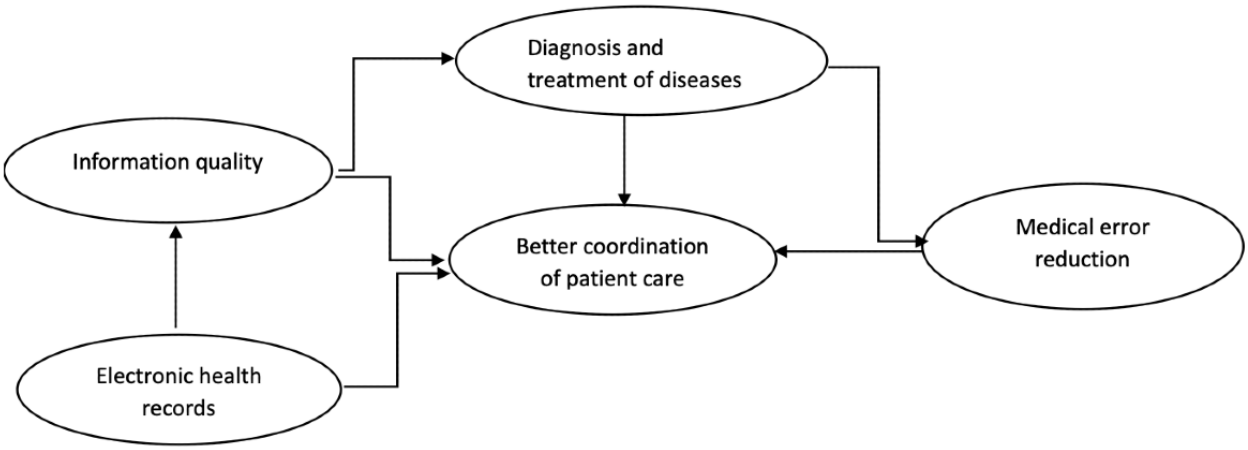
[e]DTD: diagnosis and treatment of diseases.

[f]MER: medical error reduction.

Final Research Model

The final proposed research model was reviewed by removing the rejected hypotheses that were not significant and keeping the variables supported by the accepted hypotheses based on the findings of the hypothesis testing and the significance level. These variables included MER rates, EHR, and IQ. Figure 3 shows the revised recommended model to examine the variables to determine the effects of EHR on BCP in public hospitals.

Figure 3. Revised research model.



Discussion

Principal Findings

Developing a proposed model for reducing medical errors based on the updated D&M IS Success Model as the underpinning theory was the goal of this study. Empirical research was conducted on the suggested model, with medical professionals chosen from the DGMAH as participants. The 5 components of the suggested conceptual model were as follows: MER as the dependent variable, improved BCP, DTD, SQ, and EHR. Based on the validation procedure, the model was updated and changed. Of 10 hypotheses, 6 (H1, H2, H4, H5, H7, and H10) were statistically significant in predicting the effects of EHR on BCP in public hospitals according to the study's results (*P*<.05). The use of EHRs was found to improve patient care coordination and IQ in a statistically significant way. EHR systems are intended to facilitate effective coordination of patient care by practitioners and support evidence-based decision-making [19]. The benefits of implementing EHRs, such as better patient outcomes, more patient safety measures, and lower costs, have also been noted in the literature [19].

The results of this study underline the notion that EHR-based clinical data offer several benefits over traditional medical records. As a result, they greatly improve overall health quality.

They also become readily accessible through a range of communication channels [37]. This ensures that medical personnel treat patients correctly and greatly improves patient outcomes (H1, H2, H4). Additionally, the findings are consistent with those of previous studies [9], which indicated that EHR systems improve patient care quality and increase patient safety, specifically through gains in operational efficiency and a reduction in errors. Fraser et al [29] indicated that the EHR system also tends to promote stronger institutions and cooperation between organizations.

However, other studies have supported the findings of H5 and H7 by demonstrating that EHR systems encourage greater information exchange and interorganizational cooperation [38]. This outcome was in line with most of the earlier research [25]. Preventive treatment is considered crucial to improving patient outcomes and reducing medical expenditures for both individuals and the health system, particularly in regions that are susceptible to certain disease epidemics. The findings aligned with those of Tsai et al [39], who suggested that EHR systems can facilitate the creation of novel and evidence-based treatment objectives, in addition to enhancing data analytics and identifying strategies to improve patient outcomes. The study's conclusions imply that by enhancing the capacity of health care organizations to communicate with patients, particularly those who require preventive care measures, the use of EHR systems can help improve preventive care. EHR in clinics can help medical professionals diagnose patients, treat them, and perform other tasks more accurately [29]. According to research by O'Donnell et al [40], physicians who are older and less tech savvy would likely be against the adoption of new technology. In this study, 5.6% of participants were older than 50 years and 19% were 41-50 years old. Therefore, it may be said that most of the participants were in the age range of 21-40 years. Based on the results, it appears that most participants were eager to use EHRs.

In supporting the findings of H10, Motsi and Chimbo [15] found that their survey results were in line with the conclusions, stating that the primary duty of all health care providers is to provide medical care. A well-known indicator of the effectiveness of hospital health services is patient satisfaction. Patient satisfaction is a critical indicator used to evaluate the quality of health care services rendered [25]. These results also support those of a study by Mohd and Chakravarty [41], who showed that patient-perspective evaluation of health service delivery has gained popularity and is now a fundamental component of all health systems because it serves as a useful gauge of service delivery effectiveness, especially in public health facilities. In this investigation, H3, H6, H8, and H9 were rejected. To further validate the results of the rejected hypotheses, more studies should be conducted in other public hospitals.

The insignificant relationship between SQ and BCP (H8 rejected) could potentially be explained by the fact that SQ encompasses many factors beyond just care coordination. Although high SQ is desirable, it may not directly lead to better coordination if other systemic issues exist. This highlights the need for a multifaceted approach targeting different aspects of health care delivery. The lack of a significant relationship between SQ and MER (H9 rejected) is somewhat surprising, as one would expect higher SQ to correspond with fewer errors. However, it underscores the fact that medical errors can stem from a complex interplay of factors, such as staffing levels, training, and communication protocols, rather than just SQ perceptions. Dedicated interventions focused on error prevention may be needed. The rejected H6 suggests that although accurate DTD is crucial, it alone may not automatically translate into BCP if there are disconnects in the overall continuum of care processes. Improving DTD must go hand in hand with enhancements in teamwork, information sharing, and smooth care transitions.

To effectively leverage the benefits of EHR for improving patient care coordination, a multipronged systems-based approach is recommended. This entails concurrently targeting electronic records, IQ, care coordination processes, accurate diagnosis/treatment, and error reduction through integrated efforts rather than siloed initiatives. Providing comprehensive training and clinical decision support tools can enable health care professionals to optimize EHR use for precise diagnosis, treatment planning, and error prevention. Clear protocols and accountability measures must be implemented to ensure seamless flow of information from EHR across the entire continuum of care, enabling truly coordinated services. Regular assessment of SQ from the patient's perspective through surveys is crucial, and the feedback obtained should drive quality improvement initiatives. Interdisciplinary quality assurance teams should be established to conduct root cause analyses of medical errors and devise preventive strategies that go beyond just SQ aspects. Furthermore, updating health care policies and funding models to incentivize the adoption of integrated EHR systems and prioritize care coordination activities is vital for sustainable progress in this domain.

Limitations

Although the results offer useful information for assessing the impact of EHR on BCP in public hospitals, the generalizability of the findings was hampered by the study's use of a single academic hospital as its study unit. In this study, the effects of organizational factors were not considered. Even though the results are significant, it is imperative that the proposed framework be assessed in light of many theories in further studies, even if it only includes constructs from 1 model. Further research is required to determine their impact on EHRs and on BCP in public hospitals. Organizational culture, managerial support, and implementation readiness are additional variables that should be considered.

The researchers were unable to compare the findings of the study in private hospitals, as the sample only consisted of health care professionals working at a public hospital. A comparative analysis between public and private hospitals may shed light on how and the extent to which organizational and environmental factors influence the implementation of EHR adoption. The fact that a self-report questionnaire was used to gather data may also have limited the accuracy of the responses. Credibility concerns could have been raised by the health care professionals' answers if they had an unclear understanding of EHR. Interviews ought to be used in future studies. The capacity to collect rich, thorough data; elicit and explain participant

responses; customize the interview to the requirements of the research project; build rapport and trust with participants; and be careful when researching sensitive subjects are just a few of the benefits that come with conducting interviews.

Conclusion

The purpose of this study was to determine how EHRs' impact improves patient care coordination in public hospitals. The study proposed a model to determine the factors associated with improved patient care coordination. The study examined data collected from 300 health care professionals at the DGMAH using a cross-sectional analytical research design, and 6 of the 10 hypotheses were found to be supported by the data. The study's findings indicate that EHR are statistically significant in 2 areas: better IQ and BCP. It was found that better DTD, as well as BCP, are significantly impacted by the quality of information. However, it was observed that improved patient care coordination has a positive and considerable influence on reducing medical errors but has no discernible effect on disease diagnosis and treatment. In terms of SQ, it was found that there is no correlation between decreased medical errors and BCP. The government should move more quickly to put policies into effect to increase the eagerness of medical personnel to practice.

In this study the D&M IS Success Model served as the underpinning theory for the development of a framework for MER influenced by the integration of EHR. To address the current issues of health care costs for treatment patients, this framework offers a solution that enables quick access to patient records for more coordinated, efficient care in low- to -middle-income countries, especially in Africa. In addition, this study's findings will assist stakeholders in better understanding the importance behind the integration of the eHealth system with the full implementation of electronic records in South African public hospitals. This understanding will help the department of health and stakeholders to make informed decisions regarding the integration of eHealth with electronic records, which has been implemented at a snail's pace. In addition, by expanding the body of knowledge, the study advances the field of academia in eHealth and health informatics. Furthermore, the study also contributes to the body of knowledge in both the fields of e-HIS governance.

Acknowledgments

We would like to express our deepest gratitude to every single health care professional who filled out the survey and contributed to this research at Dr George Mukhari Academic Hospital.

Abstract

Background: The optimization of patient care pathways is crucial for hospital managers in the context of a scarcity of medical resources. Assuming unlimited capacities, the pathway of a patient would only be governed by pure medical logic to meet at best the patient's needs. However, logistical limitations (eg, resources such as inpatient beds) are often associated with delayed treatments and may ultimately affect patient pathways. This is especially true for unscheduled patients—when a patient in the emergency department needs to be admitted to another medical unit without disturbing the flow of planned hospitalizations.

Objective: In this study, we proposed a new framework to automatically detect activities in patient pathways that may be unrelated to patients' needs but rather induced by logistical limitations.

Methods: The scientific contribution lies in a method that transforms a database of historical pathways with bias into 2 databases: a labeled pathway database where each activity is labeled as relevant (related to a patient's needs) or irrelevant (induced by logistical limitations) and a corrected pathway database where each activity corresponds to the activity that would occur assuming unlimited resources. The labeling algorithm was assessed through medical expertise. In total, 2 case studies quantified the impact of our method of preprocessing health care data using process mining and discrete event simulation.

Results: Focusing on unscheduled patient pathways, we collected data covering 12 months of activity at the Groupe Hospitalier Bretagne Sud in France. Our algorithm had 87% accuracy and demonstrated its usefulness for preprocessing traces and obtaining a clean database. The 2 case studies showed the importance of our preprocessing step before any analysis. The process graphs of the processed data had, on average, 40% (SD 10%) fewer variants than the raw data. The simulation revealed that 30% of the medical units had >1 bed difference in capacity between the processed and raw data.

Conclusions: Patient pathway data reflect the actual activity of hospitals that is governed by medical requirements and logistical limitations. Before using these data, these limitations should be identified and corrected. We anticipate that our approach can be generalized to obtain unbiased analyses of patient pathways for other hospitals.

Introduction

Context

Bed management is a critical task for hospitals to provide coherent care pathways. Daily bed management consists of finding beds for patients coming from the emergency department (ED) in appropriate medical units without canceling planned hospitalizations. Therefore, bed management involves 2 distinct flows: unscheduled flow (life-threatening emergencies and patients coming to the ED) and scheduled flow (planned hospitalizations). Despite the complexity of the task, bed management is most often organized without the help of any decision support tools and involves multiple phone calls to find a bed in a medical unit matching the patient's needs [1]. When medical units are facing high occupation rates, it is not always possible to find a bed to match patient needs.

In these situations, patients are either kept in the short-stay hospitalization unit of the ED or transferred to an overflow medical unit to wait for a bed. Consequently, the medical units visited by a patient do not always correspond to their medical needs. For example, a patient from the ED can be transferred to a surgery unit and then to a cardiology unit. This is the pathway observed in the data. The patient did not receive any surgical treatment. He was admitted to the surgery unit waiting for a cardiology unit bed. Therefore, the location of the patient does not always match the cause of hospitalization. The succession of medical units is called a patient pathway. Unscheduled pathways describe the pathways of patients coming from the ED. In this work, we only considered patients who visited the ED and were subsequently hospitalized.

The study of patient pathways reveals several challenges due to the variety of pathways, the lack of complete guidelines and references, and the heterogeneity of patient management between hospitals (due to equipment and organizational differences). Unscheduled pathways are difficult to explain because management rules or clear indicators are not available to identify them. In addition, the high number of pathway variants makes individual studies of each pathway impossible (eg, >1000 variants for French hospitals of average size) [2]. Process mining is an interesting tool for studying a set of pathways with several variants because a pathway can be seen as a patient care process [2,3]. Nevertheless, a large variance in pathways leads to uninterpretable process graphs. Strategies exist to make a process graph easier to read, such as trace clustering or graph size reduction using filters or aggregation [2], but these methods cannot identify which activities are relevant and which activities are induced by logistical limitations.

In this study, we sought to develop a method to assess observed pathways extracted from a hospital information system. We wanted to identify which medical units matched the cause of hospitalization (relevant) or not (irrelevant) in a patient pathway. The medical relevance or the relevance of treatments was not evaluated, nor was the choice of the bed manager. Only the relevance of the patient's location was evaluated. An *irrelevant* medical unit means that the patient would have been hospitalized in another unit if there were an infinite number of beds. The identification of such irrelevance is important to avoid any misinterpretation of further analysis results. In this paper, we often use the word *bias* to denote a wrong, inaccurate, or incomplete interpretation of a real situation because the data do not represent reality. We use the expression *bias in pathways* or *data bias* to refer to data that represent pathways that do not always correspond to patients' medical needs.

Related Work

We did not find proper literature on the task of assessing pathways but, rather, heterogeneous papers dealing with bias or phases of a pathway. In 1989, Selker et al [4] designed the "Delay Tool," which detects medically unnecessary hospital days. It is based on a taxonomy of delays. Each stay was manually evaluated using patient records with the Delay Tool method. In an article on the prediction of the disposition of ED patients, El-Bouri et al [5] considered the fact that ED patients can be admitted to an inpatient unit inappropriate for their diagnosis. Patients were filtered according to whether their primary diagnosis code for the ED visit clearly corresponded to the admission inpatient unit. Their aim was to avoid learning from biased data. These methods require a thesaurus of all possible diagnoses linked to appropriate wards. To study patient pathways, Franck et al [6] designed a generic framework to model pathways and distinguished 3 different phases: (1) a waiting phase—the patient waits in the ED (unscheduled) or at home (scheduled) to be admitted to the relevant medical unit, (2) an acute phase—the patient receives care in the medical unit, and (3) a rehabilitative phase—rehabilitative care of the patient. They also differentiated scheduled patients from unscheduled patients. To analyze the clinical pathways, they defined relevant pathways for each type of patient by considering only the acute phase and substitution options. To identify the relevant pathways and substitutions, they used process mining on administrative data. This method is very accurate but time-consuming given that a relevant pathway and substitutions must be defined for each pathology. They applied this method exclusively to patients with stroke.

Data quality in health research is a shared problem, and solutions have been proposed to improve several dimensions of quality [7]. However, methods are often not suggested to correct specific bias in health care data due to missing details about a piece of information.

Patient pathways can be seen as processes, with the succession of medical units being the succession of events. Therefore, pathways can be studied using process mining techniques. "The goal of process mining is to use event data to extract process-related information" [8]. The first rough representation of patient pathways using process discovery algorithms provides a spaghettilike process model. Indeed, process discovery algorithms are not successful with event logs that involve numerous variants and many events [2]. A typical solution to untangle a spaghettilike model is to cluster the whole set of traces (trace clustering) and represent each cluster using a process model that should be smaller and more comprehensive. The main challenges of the clustering of patient pathways are the integration of medical knowledge (medical logic) and the evaluation of the resulting clusters. In the literature, several

methods for trace clustering have been proposed. Some of these methods are distance-based clustering algorithms. The core of these methods is to compute distances between traces to apply classic clustering algorithms (trace clustering [9], trace clustering based on conserved patterns [10], context-aware clustering [11], and the method by Delias et al [12]). Others are model based; these methods gradually build a process model that represents a cluster, and a trace is assigned to the cluster with the nearest process model (sequence clustering [13], active trace clustering [14], disjunctive workflow schema [15], graph-based approach and Markov models [16], and behavioral topic analysis [17]). In terms of cluster evaluation, different metrics are used. Some metrics analyze cluster intrahomogeneity, and others analyze the complexity of the process model of each cluster. There is no consensus on these metrics, and they do not guarantee that the clusters computed using the algorithm have an expert logic. Hence, trace clustering does not give us complete satisfaction in characterizing pathways. Another approach for simplifying process models was proposed by Fahland and Van der Aalst [18] based on unfolding.

Some data preparation techniques can also reduce the "spaghettiness" of process models. Data preparation is an unavoidable step in a process mining project and impacts on the resulting process graph, as highlighted by De Roock and Martin [19] in their most recent state-of-the-art study. Several methods have been suggested in the literature to simplify process models. Semantic log purging was proposed by Ly et al [20] in 2012 to clean log data. This method is based on the identification of "fundamental constraints that a process has to obey" thanks to experts. Only a qualitative evaluation and 1 experiment using 1 dataset were performed. Van Zelst et al [21] reviewed the literature on event abstraction in process mining. However, this technique is not related to the problem addressed in this study because our dataset did not provide information on the granularity of events. Several papers address the issue of time stamp inaccuracy.

Martin et al [22] proposed interactive data cleaning. Dixit et al [23] created a method to detect and repair event ordering mistakes. Rogge-Solti et al [24] presented a similar approach to repairing missing events based on alignment. In addition, these researchers created a method for time repairing.

To rigorously prepare the data and event log, different frameworks have been developed. Andrews et al [25] applied the Cross-Industry Standard Process for Data Mining method to identify data quality issues. The data quality dimensions used in data mining are also useful for assessing data quality in process mining. Nevertheless, the researchers do not consider dimensions specific to processes, such as trace coherence. Therefore, the fourth step, namely, prestudy process mining analysis, is important to assess this dimension. Bose et al [26] noted 27 event log quality issues based on 4 categories (missing data, incorrect data, imprecise data, and irrelevant data) and 9 components of an event log (case, event, belongs to, case attributes, event attributes, position, activity name, time stamp, and resource). The researchers also distinguished 4 process characteristics: (1) voluminous data, which refers to a large number of cases or events; (2) case heterogeneity, which refers to a large number of distinct traces; (3) event granularity, which refers to a large number of distinct activities; and (4) process flexibility and concept drifts. The issues caused by case heterogeneity are a part of the problem we attempted to address in this study. Van Eck et al [27] suggested PM^2, a process mining project methodology. Data processing is the third step and consists of creating views (creating the event log), aggregating events, enriching logs (addition of attributes), and filtering logs. Vanbrabant et al [28] presented a data quality framework based on 3 previous frameworks and applied it to a case study—pretreatment of ED data before simulation. These researchers divided quality problems into hierarchical classes. Verhulst [29] defined very precisely the different data quality dimensions for process mining and their scoring methods. All these papers on data preparation are general to process mining datasets and do not answer the question of pathway bias.

Process mining is not the only method used to analyze patient pathways, and this method can be combined with other methods such as discrete event simulation (DES). Prodel et al [30,31] developed a framework to automatically convert a process model discovered using process mining into a simulation model of clinical pathways. Abohamad et al [32] used process mining to discover ED processes and then used DES to study bottlenecks. Wood and Murch [33] modeled patient pathways using Markov chains to study transfer delays between medical units and discharge delays. Karakra et al [34] also used a DES to model an ED and added a real-time connection to real-time patient data to create a digital twin. The digital twin of the patient enables the monitoring of their pathway and activities as well as near-future predictions. Some models reproduce an entire hospital. Holm et al [35] used a DES to model an entire hospital and patient flows through the wards and determine bed use. Demir et al [36] used a similar model to anticipate an increase in the number of patients and adapt resources. Ordu et al [37] achieved an even more complete model of a hospital and patient flows.

To conclude, this review of the literature reveals that process mining and simulation are the principal methods used to study patient pathways. Process mining is a standard tool for discovering patient pathways (or other health care processes), but important limitations are noted in the literature, especially the complexity of the model graphs. Data preparation techniques and clustering methods are suggested to compensate for this issue. Some methods are based on expert interviews or expert knowledge integration. This is similar to our construction of rules. Several papers focus on time stamp correction or missing events or labels, but none of the studies focus on our problem of biased events. Simulations do not consider input data quality. In this study, we focused on enriching the log by adding an attribute that can define an event as relevant or irrelevant.

Objectives

The objective of this paper was twofold: (1) building a framework to model and analyze patient pathways and (2) proposing a method to automatically identify bias in patient pathway data. In other words, this method turns a database of observed pathways with bias into 2 databases: one database includes labeled pathways (identified bias), and one database

includes corrected pathways (without bias). Such a method is intended to ease the preprocessing of real data for data analysts or hospital managers who seek a clean database with unbiased medical pathways.

The scientific contributions of this paper are as follows:

1. This study provides a new framework to model patient pathways considering hospital management constraints (eg, bed occupancy and resource availability). This framework is used to assess patient pathways.
2. This study develops a new method to automatically label and correct pathways based on hospital data. Pathway labeling aims to identify the steps in a patient pathway due to a difficult bed management, and path correction aims to correct irrelevant activities. The labeling algorithm was assessed by comparing its outputs with experts' answers.
3. Two case studies are reported: (1) a quantitative comparison of the observed pathway database and the corrected pathway database was performed based on process mining using process model comparison and classical process mining indicators, and (2) a DES model based on the observed pathway database and the corrected pathway database was used to evaluate the impacts of data correction on the occupation of medical units.

Methods

Unscheduled Hospital Pathway Modeling Framework

Formal Definition of the Framework for the Study Patient Pathway

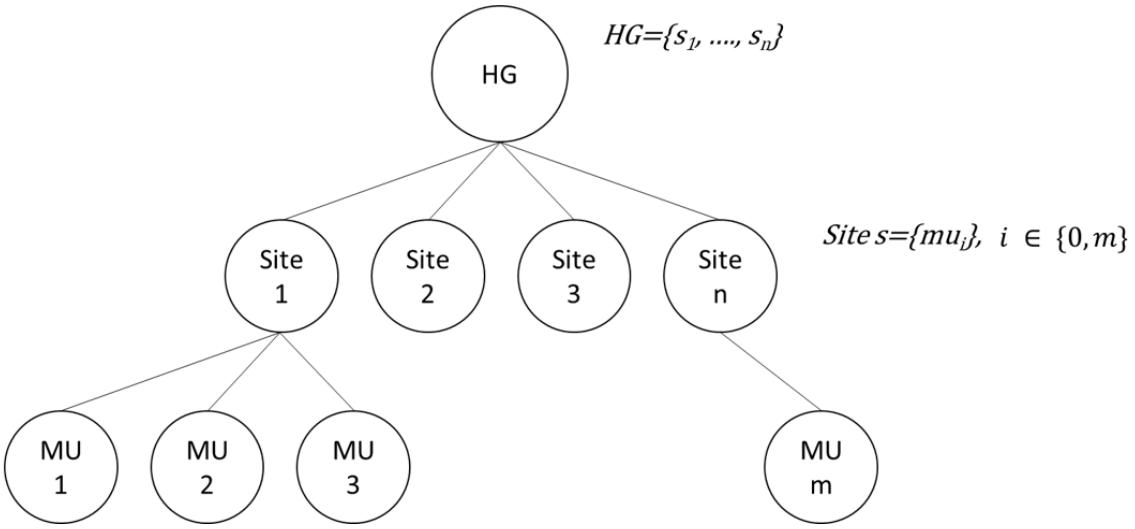
Overview

In this section, we propose a set of definitions that will be used to formalize the unscheduled hospital pathway modeling framework.

In this study, we were interested in the medicine, surgery, obstetrics, and odontology (MCO). In French, the initials MCO stand for *Médecine, Chirurgie, Obstétrique et Odontologie* (medicine, surgery, obstetrics, and odontology). The medical units belong to a *hospital* that itself can belong to a *hospital group*. Figure 1 represents the dependencies among the hospital group, site, and medical unit. Here, we are interested in the pathways inside the same hospital group, which we call the *MCO-stay*. Multimedia Appendix 1 provides detailed definitions of the aforementioned concepts.

The hospital pathways are defined using a process mining formalism [8].

Figure 1. Hospital group (HG; {s1,..., sn}) structure. MU: medical unit.



Definition 1 (Event)

Let E be the event universe (ie, the set of all possible event identifiers), E^* be the set of all sequences over E, and T be the time domain. We assume that events are defined by several attributes; however, the case ID, time stamp, and activity name are mandatory for case identification, trace ordering, and event labeling, respectively.

Let AN be a set of attribute names. For any event $e \in E$ and name $z \in AN$, $\#_n(e)$ is the value of the attribute z for event e. We consider $\#_{activity} \in E \rightarrow A$ and $\#_{time} \in E \rightarrow T$ functions that assign an activity name from a finite set of process activities A and a time stamp, respectively, to each event. For convenience, we assume the following standard attributes: (1) $\#_{activity}(e)$ is the activity associated with event e, (2) $\#_{time}(e)$ is the time stamp of event e, and (3) $\#_{trans}(e)$ is the transaction type associated with event e (eg, schedule, start, complete, and suspend).

The transaction type attribute $\#_{trans}(e)$ refers to the life cycle of activities. In most situations, activities take time. Therefore, events may point out, for example, the start or completion of activities.

Definition 2 (Trace)

A trace is a finite sequence of events denoted as $\sigma = < e_1, e_2, ..., e_n > \forall e_i \in E^*$ such that each event appears only once: $e_i \neq e_j$ for $1 \leq i < j \leq |\sigma|$.

Specifically, $|\sigma|$ denotes the length of the trace. In this case, $|\sigma| = n$.

Definition 3 (Stage)

In a trace, several events can have the same activity name. In the following, the subset of events with the same activity name that contains a single start event and a single completion event subsequent to the start event is referred to as a stage.

Let e_i and e_m such that (1) $\#_{activity}(e_i) = \#_{activity}(e_m)$=a; (2) $\#_{trans}(e_i)$=start and $\#_{trans}(e_m)$=complete; (3) $\#_{time}(e_i)=t_i \leq \#_{time}(e_m)=t_m$; and (4) e_j such that $\#_{time}(e_j)=t_j \geq t_i$, $t_j \leq t_m$, $\#_{activity}(e_j)$=a, and $\#_{trans}(e_j)$=complete or $\#_{trans}(e_j)$=start.

$$\text{Stage} = \{e_j | \#_{activity}(e_j) = a \text{ and } t_i \leq t_j \leq t_m\}$$

The duration of a stage is defined as the time between the start of the stage and its completion:

$$\#_{duration}(s) = \#_{time}(e_m) - \#_{time}(e_i)$$

In the following, we will note e_{x1}, e_{x2},..., e_{xi} as all the events that compose stage *x*.

Furthermore, the duration of the trace σ of length *n* is determined as follows:

$$duration(\sigma) = \#_{time}(e_n) - \#_{time}(e_1)$$

In our study framework, a trace always begins at the ED stage and ends at the last unit of the MCO stay (the unit before the MCO discharge).

Definition 4 (Event Log)

An event log is a set of traces representing the execution of the underlying process. An event can only occur in 1 trace; however, events from different traces can share the same activity.

Definition 5 (Patient Pathway)

A patient pathway describes the succession of medical events inside a health care facility. In this work, each pathway is linked to an MCO stay.

A patient pathway is a set (p, s, σ, d) where $p \in$ N is the identifier of the patient, $s \in$ N is the identifier of the MCO stay, σ is the trace of the MCO stay, and d is the MCO discharge disposition.

We consider two types of pathways:

1. Scheduled pathways
   : these pathways are planned before patient admission.
2. Unscheduled pathways
   : neither the admissions nor the pathways are planned. The patients are hospitalized from the ED or admitted to a specific unit for life-threatening emergencies.

Definition 6 (Relevance of Stage)

A stage of a patient pathway is relevant if it is adequate that, at this moment, the patient is still hospitalized (first condition) and if the patient is in the medical unit intended to care for their pathology (second condition).

We consider 3 levels of relevance: level 2 (both conditions are met), level 1 (the second condition is not met; ie, the patient is not hospitalized in the ideal medical unit for their pathology), and level 0 (no condition is met, and there is no medical reason that justifies the patient being still hospitalized in this discipline).

Definition 7 (Bias)

In our context, a bias in the data is noted when some details about a piece of information are missing, which leads to a misinterpretation of a situation.

For example, a pathway {ED, Surgery, Geriatrics} without additional information suggests that the patient needs surgery after the ED followed by geriatric care. The bias is that the patient just stays in surgery while waiting for a bed in geriatrics.

Definition 8 (Activity Labels)

In this study, we consider 2 levels of activity names.

In level 1, *U* is the set of labels corresponding to all the names or IDs of the medical units constituting the hospital group. Consequently, an event activity is a medical unit that a patient has visited.

$$GH = \{mu_1, ..., mu_n\}$$

$$U = \{id(mu_i)\} \text{ with } i \in [1, n]$$

$$\#_{activity}(e_x) = id(mu_m)$$

In level 2, let *L* be the set of labels corresponding to the relevance levels. *A* is the set of labels corresponding to the product of *U* and *L*:

$$L = \{\text{level 0, level 1, level 2}\}$$

$$A = U \times L$$

$$\#_{activity}(e_x) = (id(mu_m), \text{level l})$$

Hence, level 1 characterizes the activity of an event based on the ID of the medical unit, and level 2 adds a level of relevance. For more convenient reading, in the following sections, the activity of an event will be noted using the name of the medical unit.

Motivation

The pathway of a patient is governed not only by pure medical logic (health care needs) but also by logistical limitations. In other words, the pathway of a patient depends not only on their medical needs but also on the availability of inpatient beds and the possibility of discharge. Therefore, a patient can go to an unsuitable medical unit (unit *b*) because of a lack of beds in the suitable unit (unit *a*). The patient can later be transferred to unit *a*. Discharge also has an impact on patient pathways. Indeed, patients do not always immediately leave the hospital when they are medically fit for discharge because they are waiting for a discharge disposition. The challenge is to automatically identify these irrelevant steps in any MCO pathway. Indeed, these pathways are not clearly identified in the electronic health records (EHRs), and there is no generally applicable thesaurus of ideal pathways and no clear indicator of the adequacy of a unit in the EHR. The same medical unit can have different functions (see Textbox 1 for an example), and identical patients in terms of pathology can have different pathways according to hospital occupancy [6].

Our objective was to find a function (an algorithm) that evaluates the relevance of each stage. It is important to understand the word *relevance* as defined in the previous sections (*Definition 6: Relevance of Stage* section). Medical practices or medications were not judged here. Only the relevance of the patient's location was evaluated. In our framework, an input trace with event labels comprising only the activity name is converted into an output trace with event labels comprising the activity name and the level of relevance.

Textbox 1. Example of the different roles that a medical unit can play in a patient pathway.

Examples

- Emergency department (ED) to neurology: acute care in neurology
- ED to neurology to neurovascular intensive care: waiting in neurology for a bed in neurovascular intensive care
- ED to neurovascular intensive care to neurology: waiting for a discharge solution in neurology

Definition of the Function Evaluating the Relevance of Stages

Let $\sigma =< e_{11}, e_{12}, e_{nx} > \forall e_{xi}, \#_{activity}(e_{xi}) \in U$, and $\sigma' =< e'_{11}, e'_{12},..., e'_{nx} > \forall e'_{xi}, \#_{activity}(e'_{xi}) \in A$.

σ and σ' are 2 traces of the same case: σ is the *historical trace* and σ' is the *labeled trace*.

$f: \sigma \rightarrow \sigma'$ with $|\{e'_i|\#_{act}e'_i = a\}|_{\forall e'_j \in \sigma'} \geq |\{e_i|\#_{act}e_i = a\}|_{\forall ei \in \sigma}$

The function *f* identifies the relevance levels of each stage in a trace. A stage can be divided into several phases with distinct levels of relevance. Therefore, the number of events that correspond to activity *a* in the trace σ is smaller or equal to the number of events that correspond to the activity *a* in trace σ'.

Example

This paragraph illustrates the definitions and the transformation of a pathway using the function *f*. In the following fictive example, the hospital group is named Groupe Hospitalier Bretagne Sud (GHBS) and is composed of 2 sites, named Scorff and Villeneuve. One patient arrived on January 4 at 5:36 AM at the ED of the Scorff Hospital. At 10:13 AM, he was admitted to the observation unit (OU), but the patient was actually waiting for a bed in the geriatric unit. On January 5 at 9:45 AM, the patient was transferred to the geriatric unit of the Villeneuve Hospital, another site of the hospital group. He arrived at 10:15 AM. On January 10 at 2 PM, the patient was medically fit for discharge. On January 12 at 1:30 PM, the patient was discharged, and he returned home with additional community nursing services. Figure 2 illustrates the pathway of the patient according to the framework defined previously.

The pathway of patient *00000056098* can be formalized as follows:

$\sigma =< e_{11}, e_{12}, e_{21}, e_{22}, e_{31}, e_{32} >$ with

$\#_{activity}(e_{11}) = ED, \#_{trans}(e_{11}) = start$

$\#_{activity}(e_{12}) = ED, \#_{trans}(e_{12}) = end$

$\#_{activity}(e_{21}) = OU, \#_{trans}(e_{21}) = start$

$\#_{activity}(e_{22}) = OU, \#_{trans}(e_{22}) = end$

$\#_{activity}(e_{31}) = GERIATRICS, \#_{trans}(e_{31}) = start$

$\#_{activity}(e_{32}) = GERIATRICS, \#_{trans}(e_{32}) = end$

The function *f* takes the trace σ as input and returns the trace $\sigma' =< e'_{11}, e'_{12}, e'_{21}, e'_{22}, e'_{31}, e'_{32} >$ with the following features:

$\#_{activity}(e'_{11}) = (ED, level2), \#_{trans}(e'_{11}) = start$

$\#_{activity}(e'_{12}) = (ED, level3), \#_{trans}(e'_{12}) = end$

$\#_{activity}(e'_{21}) = (OU, level1), \#_{trans}(e'_{21}) = start$

$\#_{activity}(e'_{22}) = (OU, level1), \#_{trans}(e'_{22}) = end$

$\#_{activity}(e'_{31}) = (GERIATRICS, level2), \#_{trans}(e'_{31}) = start$

$\#_{activity}(e'_{32}) = (GERIATRICS, level2), \#_{trans}(e'_{32}) = end$

$\#_{activity}(e'_{41}) = (GERIATRICS, level0), \#_{trans}(e'_{41}) = start$

$\#_{activity}(e'_{42}) = (GERIATRICS, level0), \#_{trans}(e'_{42}) = end$

The succession of stages is described by level-2 activity labels. The initial stage *Geriatrics* has been divided into a relevant phase (level 2) and an irrelevant phase (level 0).

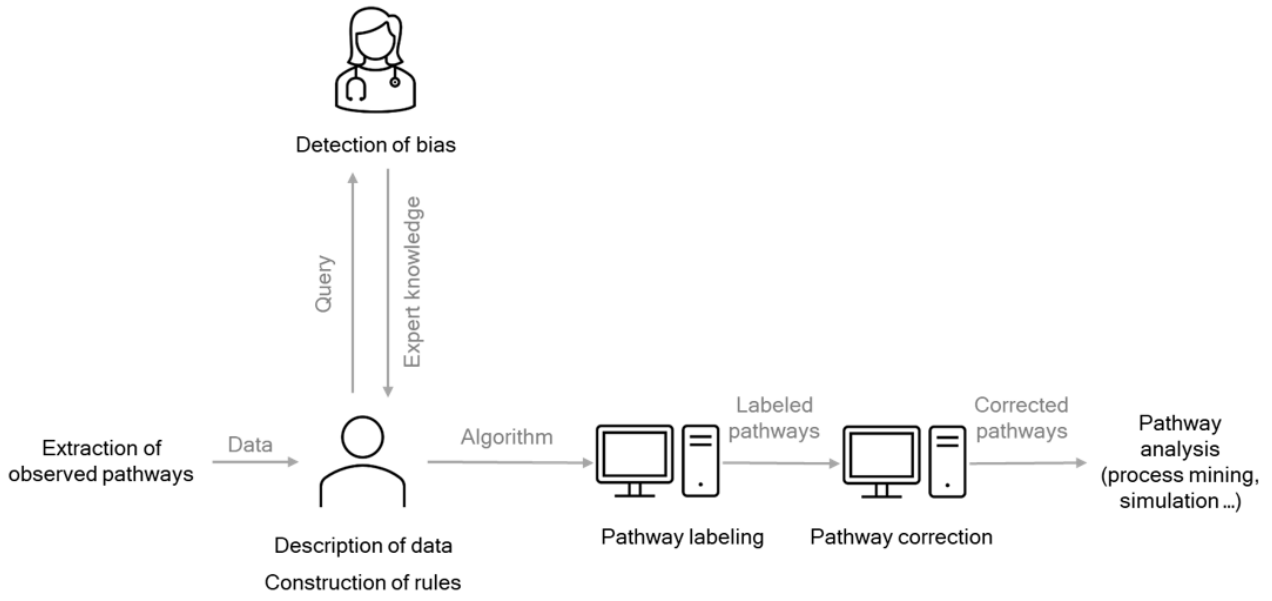
Automatic Pathway Labeling and Correction

Overview

In this section, the method for identifying bias in patient pathway data and the method for building an algorithm to label the stages of the pathways as relevant or irrelevant are described. We then present an algorithm for automatically transforming a historical trace into a labeled trace and an algorithm for automatically transforming a labeled trace into a corrected trace. These algorithms are based on a symbolic approach. In other words, the rules are *if*, *then* propositions. Our approach can be visualized in Figure 3.

Figure 3. Pathway-labeling method.



Identification of Bias and Rule Definition

Overview

The methodology for identifying the bias and then defining the rules consists of three steps, which are described as follows:

1. Description of the pathway dataset: the objective was to distinguish the different pathways and identify frequent and rare patterns.
2. Identification of bias with expert interpretation: the objective was to analyze the patterns with experts to determine the bias.
3. Definition of rules: the rules are defined based on the experts' analysis.

The first step can be achieved by computing the frequency and representativeness of each pathway variant and the number of events per variant, grouping some events, and computing the

new variants to identify repetitive patterns. The second step enables us to identify bias through discussions with experts. Preferably, the discussions are conducted with several physicians to obtain different opinions. The third step requires the translation of the analyses of physicians into rules. A rule deduces whether an event is relevant from the EHR data. According to our definition of relevance (cf Definition 6), we consider three levels: (1) level 0, in which the stage is completely irrelevant (none of the conditions are met); (2) level 1, in which the stage is not totally relevant (only the first condition is met); and (3) level 2, in which the stage is relevant (both conditions are met). The aim of the rules is to identify in a pathway the phases with various levels of relevance. We remind the reader that only the hospitalization ward (patient location) is evaluated.

Example

A rule states that, if the first stage of the trace lasts <10 units, then the stage is completely irrelevant (level 0).

Let $\sigma =< e_{11}, e_{12}, e_{21}, e_{22} >$ be a trace with 2 activities a_1 and a_2 such that the following conditions are met: (1) *#activity*(e_{11}) = *#activity*(e_{12})=a1; (2) *#activity*(e_{21}) = *#activity*(e_{22})=a2; and (3) *#time*(e_{11})=0, (4) *#time*(e_{12})=7, and (5) *#time*(e_{21})=7, *#time*(e_{22})=20.

The first stage is a_1 and lasts 7 units; therefore, e_{11} and e_{12} are labeled as level 0.

Algorithm 1: Pathway Labeling

Once the rules have been defined, algorithm 1 (Textbox 2) labels a pathway according to these rules (lines 6-9). A level of 1 or 0 is assigned if a stage is identified as irrelevant, and a level of 2 is assigned if the stage is relevant (lines 7-9). A stage can be labeled through several rules. In this case, the worst label is applied (ie, level 0 has a priority over level 1, and level 1 has a priority over level 2 [lines 10-12]).

We want to emphasize that this algorithm is purely based on logic and administrative rules. It does not include medical reasoning and is, therefore, inaccurate. However, the aim of the next section is to evaluate this inaccuracy (ie, the number of errors between an algorithm with simple rules and the complex reasoning of an expert [expert knowledge]).

Textbox 2. Algorithm 1—pathway labeling.

1: Let e_x be an event of the historical pathway

2: Let e'_x be an event of the labeled pathway

3: Let t_1 be the start date of the stay.

4: Let t_n be the end date of the stay.

5: Let $\sigma =< e_{11}, e_{12},..., e_{n1}, e_{n2} >$ be the trace representing the historical pathway.

6: Let L be a list that stores the result of each rule.

7: for each rule r_k do

8: Add $r_k(\sigma)$ to L

9: end for

10: for each $e_x \in \sigma$ do

11: Apply the modification of each rule that has changed e_x. The lowest relevance level has priority.

12: end for

13: Return $\sigma' =< e'_{11}, e'_{12},..., e'_{m1}, e'_{m2} >$, the labeled trace.

Algorithm 2: Pathway Correction

We also implemented an algorithm to correct the pathways labeled using algorithm 1 (Textbox 3). The idea is to transform the observed pathway into a theoretical pathway by correcting irrelevant stages. The different corrections applied to a labeled pathway are deduced from the rules. The irrelevant activities are replaced with the relevant activities (lines 4-6). Only the label of an event is changed, and the time stamp remains the same. At the end of the correction, subsequent identical activities are merged (lines 7-13). For example, let us note a stage (activity name, relevance level, start, or end). The pathway *<(ED, level2, t1, t2), (OU, level1, t2, t3), (Geriatrics, level2, t3, t4)>* is corrected and becomes *<(ED, t1, t2), (Geriatrics, t2, t3), (Geriatrics, t3, t4)>*. In addition, the pathway can be merged to become *<(ED, t1, t2), (Geriatrics, t2, t4)>*.

Textbox 3. Algorithm 2—pathway correction.

1: Let $\sigma' = < e'_{11}, e'_{12}, ..., e'_{m1}, e'_{m2} >$ be the labeled trace.

2: Let r be the rule applied at e'_x.

3: Let $\sigma'' = < e''_{11}, e''_{12}, ..., e''_{m1}, e''_{m2} >$ be a copy of σ'.

4: for each $e''_x \in \sigma''$ do

5: $\#_{activity}(e''_x)$ = the corrected activity according to the rules of correction

6: end for

7: for each $e''_x \in \sigma''$ with $t_x < t_m$ do

8: if $\#_{activity}(e''_{x1}) = \#_{activity}(e''_{x+1,1})$ then

9: $\#_{time}(e''_{x2}) = \#_{time}(e''_{x+1,2})$ with $\#_{trans}(e''_{x+1,2})$ = complete and all the events of stage $x+1$ are deleted from σ''

10: end if

11: end for

12: Return $\sigma'' = < e''_{11}, e''_{12}, ..., e''_{p1}, e''_{p2} >$, the corrected trace.

Evaluation of the Performance of the Labeling Algorithm

This subsection describes the method used to assess the labeling algorithm. Because there is no reference to compare the results of the algorithm with a ground truth, the evaluation of the algorithm has to be made by comparing its results with the analyses of experts. The methodology used for this study is inspired by the framework developed by the French think tank Ethik IA for its humane oversight board (Ethik-IA, unpublished data, April 2021). A representative sample of patient pathways was analyzed by 2 experts. They had access to information from the electronic patient records. Each expert performed the analysis separately. The results of the first expert were compared with those of the second expert. When the results did not match, the medical experts discussed them to find a common answer. Their answers were then compared with the algorithms' answers. For each difference, a discussion with the experts allowed us to determine whether the algorithm was wrong and, if so, qualify the errors.

The method presented in this paper is general and can be applied at any hospital. In the next section, we apply these methods to a real case study to create rules to label and correct a real dataset extracted from a hospital database, and we evaluate the accuracy of these rules.

Ethical Considerations

This study was approved by the French Data Protection Authority (*Commission Nationale de l'Informatique et des Libertés*) under the number 922243. French and European rules about access to health care data for research were respected and ethical standards also.

Results

Data

This work was performed with the GHBS, a French hospital group located in the Lorient area. It has 2 general hospital sites with an ED and 6 other sites. In total, there were 89,791 ED visits and 108,875 hospitalizations and sessions (values for 2021). This study was based on data collected at the GHBS. Data were retrospectively collected for the period from July 2020 to July 2021. The data cover 12 months of activity and only adults, 54,850 different ED visits and 41,161 unique patients, including 19,905 MCO stays. Multiple MCO stays of the same patient were treated as separate instances. Three sources of data were used: (1) electronic patient records, (2) administrative health care databases, and (3) data from the software used for rehabilitation and home hospitalization. Only structured data were used to save time in the data analyses; no plug-and-play natural language processing tool was available for our data. The pediatric and obstetric pathways were excluded from the study dataset, as were the pathways with only a visit to the ED.

Identification of Bias and Rule Definition

In this section, we detail the results obtained using our method to identify bias from our data.

Results of Step 1: Description of the Pathway Dataset

In our dataset, there were 19,905 pathways and 1013 trace variants. Some variants were very frequent, such as (ED, OU) representing 22.75% (4528/19,905) of the pathways, and others were very rare, such as (ED, neurology intensive care, cardiology) occurring just once.

We observed that most pathways had only 1 stage after the ED visit (60/1013, 5.92% of the variants and 15,699/19,905, 78.87% of the pathways). Pathways with >3 stages after the ED were rare. They appeared between 1 and 3 times in the dataset and represented 0.98% (195/19,905) of the pathways but 18.85% (191/1013) of the variants. Therefore, the diversity of pathways was mainly due to pathways with many activities. We identified five types of pathways at the GHBS: (1) mono-disease pathways, which include 1 necessary medical unit; (2) pathways for patients who were seriously ill, which include transfer to an intensive care unit (ICU); (3) older person pathways, which include geriatric units; (4) frequent and processed pathways,

which include strokes; and (5) multi-disease and complex pathways, which include several medical units.

The most frequent medical units were OUs, polyvalent medicine units, geriatric medicine units, postemergency units, surgery units, and specialized medical units. By categorizing the medical units into 4 groups (ED, medicine, surgery, and ICU), we obtained 165 patterns, and the 10 most frequent structures of the pathways are listed in Table 1.

Within the pathways (MEDICINE, MEDICINE), several patterns were frequently observed. Pathways such as heart failure or stroke pathways were normally composed of 2 steps after the ED: admission to a cardiology (or neurology, respectively) ICU followed by cardiology (or neurology, respectively). The second type of pattern is the pathway with an admission to a polyvalent unit before an admission to a specialized unit or another polyvalent unit. In this case, a polyvalent unit is a medical unit, such as an OU, polyvalent medicine unit, or postemergency unit, where patients with multiple diseases or who do not require specialized treatment are treated. We also observed a few transfers between specialized units. Finally, patients could be transferred between the weekly hospitalization unit and the full hospitalization unit.

For most of the pathways that followed the pattern (SURGERY, MEDICINE), the activity of surgery was noted as an overflow bed. For the few others, a surgical act was performed before a transfer for medical reasons to a medicine unit.

The pattern (MEDICINE, SURGERY) mainly concerned an admission to an OU (while waiting for surgery) followed by a surgery unit. In the other pathways, patients were first admitted to a specialized unit (eg, hepatogastroenterology) before surgery.

Hence, we obtained four patterns for the pathways in 2 steps: (1) a polyvalent unit followed by a specialized unit (pattern 1), (2) a surgery unit followed by a medical unit (pattern 2), (3) a daily or weekly hospitalization unit followed by a full hospitalization unit of the same specialty (pattern 3), and (4) a specialized unit followed by another specialized unit (pattern 4).

Table 1. Main structures of historical pathways and occurrence differences for corrected pathways.

Variant	Occurrence (%)	
	Historical	Corrected
ED[a], MEDICINE	68.68	68.57
ED, MEDICINE, MEDICINE	10.67	7.24
ED, SURGERY	9.66	10.90
ED, SURGERY, MEDICINE	2.88	0.33
ED, MEDICINE, SURGERY	1.7	0.63
ED, MEDICINE, MEDICINE, MEDICINE	1.2	0.80
ED, ICU[b], MEDICINE	0.88	1.05
ED, ICU	0.53	0.56
ED, SURGERY, SURGERY	0.47	0.16
ED, ED, MED	0.39	0.22
ED	—[c]	7.18

[a]ED: emergency department.

[b]ICU: intensive care unit.

[c]Not present in historical pathways.

Results of Step 2: Interpretation of Patterns by Experts

We discussed the patterns identified in the first step with the experts. According to the experts, pattern 1 (a polyvalent unit followed by another unit) usually indicates that the polyvalent unit is used as a buffer. In fact, when beds are lacking, patients can be admitted to a polyvalent unit to begin their treatment while waiting for a bed in the ideal unit. The second pattern has the same explanation—a patient requiring medical treatment is placed in a surgery unit while waiting for a bed in the ideal unit. Pattern 3 (transfers between daily or weekly hospitalization units and full hospitalization units) is explained by a lack of beds in the full hospitalization unit. The last pattern (transfers between specialized units) has no general explanation. Occasionally, a specialized unit can also be used as a buffer, but the transfer can also be medically explained.

The length of stay (LoS) was also an aspect of the pathway discussed with the experts. Some pathways are too long because patients cannot be discharged as soon as they are medically fit for MCO discharge. The delay is mainly due to a back home impossible without community care or a lack of beds in rehabilitation centers. LoS can be compared with a national reference. In France, the national reference is the average LoS used for hospital stay invoicing (*durée moyenne de séjour* in French). It is defined for each diagnosis-related group. However, each pathway is unique, and an LoS above the national reference does not guarantee that the stay was too long because of discharge difficulties. For example, longer stays for patients

receiving palliative care are frequent and normal. Occasionally, the diagnosis-related group does not correctly report the seriousness of the patient because the patient was transferred to another hospital.

The LoS in the ED was also discussed. According to the experts, the LoS in the ED is occasionally too long because patients are waiting to be hospitalized. The ED LoS should not exceed 5 to 10 hours.

Results of Step 3: Rule Construction

From these observations and discussions, we deduced several dimensions to investigate in a pathway:

1. Time spent in the ED: ED LoS can be prolonged because of a lack of inpatient beds in acute care units. Rule 1 evaluates whether the time spent in the ED is too long.
2. LoS: the LoS can be prolonged because of a delayed discharge. Rules 2 and 3 evaluate this condition.
3. Overflow bed: occasionally, patients are admitted to a medical unit but are treated by the physicians of another unit. The location of the patient is entered (ie, the activity name) in the hospital data, and the unit medically responsible for the patient is also indicated. For example, when a patient is in surgery and awaits a bed in cardiology, the activity is surgery and the medically responsible unit is cardiology.
4. Sequence of activities: a typical pattern is the transfer between a polyvalent unit and a specialized unit. According to physician experience, when the transfer occurs within 1 week, in general, the polyvalent unit stage is irrelevant. In rule 5, the threshold is 7 and a half days to consider the transfer time. Rule 6 is dedicated to the OU because, in our dataset, a transfer in the OU is labeled as "back home within 24 h," "observation," or "awaiting bed." The label "awaiting bed" indicates an irrelevant stage because the patient should have been transferred immediately to the appropriate unit.

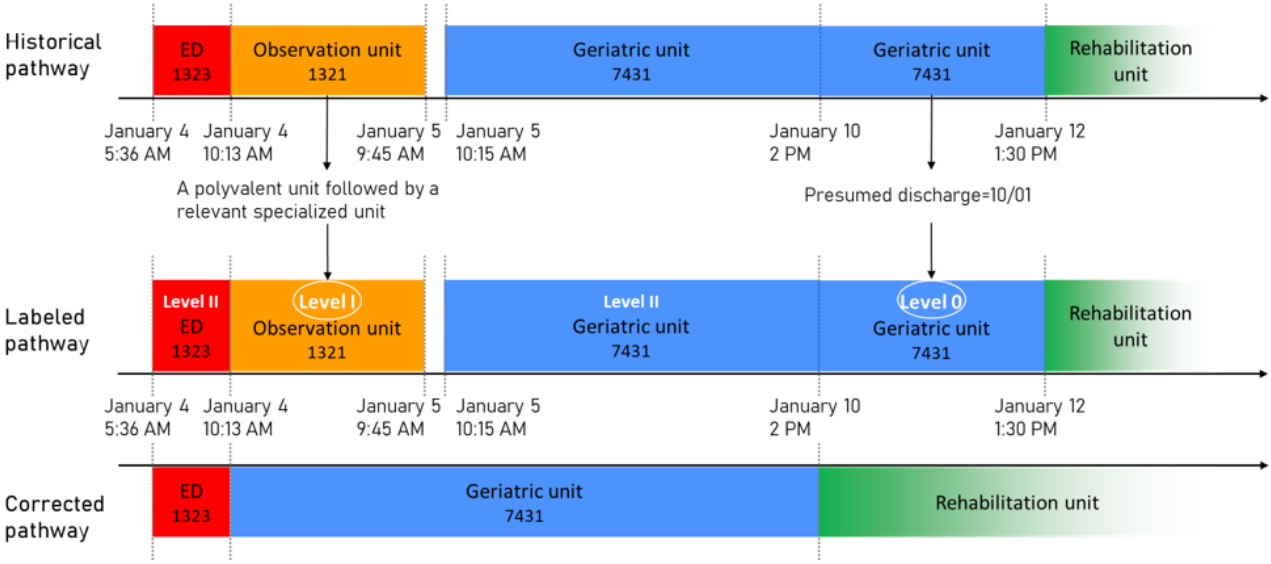
The challenge was to identify which structured data could be used to investigate these different dimensions and, therefore, to create the rules. We detail the rules obtained from our dataset in Multimedia Appendix 2, as well as the algorithms of the 7 rules.

From these rules, we deduced how to correct the labeled pathways. The different corrections are listed in Table S1 in Multimedia Appendix 2.

Example

Figure 4 illustrates the labeling and correction of a pathway. In total, 2 phases are considered irrelevant by the algorithm: the OU (rule 6) and the end of the stay in the geriatric unit (rule 3). To correct the pathway, the time spent in the OU is replaced by the time spent in the geriatric unit, which is the relevant stage following the OU, and the patient is discharged earlier at the presumed discharge date.

Figure 4. Example of the correction of a pathway. ED: emergency department.



Accuracy of the Labeling Algorithm

A total of 118 different pathways were analyzed by 6 different duos of physicians from the GHBS (only 1/12, 8% had previously participated in the discussion to define the rules) and compared with the algorithm output. Only rules 3, 4, 5, 6, and 7 could be evaluated because the physicians could not reach a consensus on either the ideal LoS or the ideal length of ED visit within the allotted time. The physicians had access to the patient's pathway, their age, the chief complaint, the diagnoses, the national LoS reference for the diagnosis-related groups, the discharge destination, and requests for rehabilitation and home hospitalization. They also had access to patient records if more information was needed.

We counted the number of errors per stage (except for the first ED visit) and per pathway. For example, the pathway (ED, OU, CARDIOLOGY) has 2 stages (we do not count the ED), and the experts assessed that OU was not relevant and that CARDIOLOGY was relevant, but the algorithm assessed that the 2 stages were relevant. Therefore, we identified 1 pathway error per 1 pathway and 1 stage error per 2 stages. Table 2 presents the results of the evaluation of the 118 pathways. The algorithm failed to evaluate 19.5% (23/118) of the pathways

and 12.9% (30/232) of the stages. Among these errors, false-positive errors were 5 and 3 times more important, respectively, than false-negative errors. This means that the main error of the algorithm was considering a pathway or a stage as relevant when it was actually irrelevant.

The main errors were related to medical knowledge. When patients were hospitalized in a specialized medical unit (eg, oncology) but pertained to another specialized medical unit (eg, cardiology), the algorithm did not detect this irrelevance. Similarly, hospitalization in the general ICU before transfer to the cardiology ICU was occasionally irrelevant but not detected by the algorithm. In addition, the algorithm considered that a polyvalent unit following a specialized unit was irrelevant; however, in some cases, it was wrong.

Table 2. Performance of the algorithm based on rules 3, 4, 5, 6, and 7.

	Actual values		Precision	Recall
	Positive [a]	Negative [b]		
Pathways			0.75	0.93
Predicted values				
Positive	56	19		
Negative	4	39

Predicted values				
Positive	162	22		
Negative	8	40		

[a]Relevant pathway or stage (level 2).

[b]Irrelevant pathway or stage (level 0 and level 1).

Preprocessing of Pathway Data

In this section, we use only rules 3 to 7 to preprocess our data given that rules 1 and 2 could not be assessed. We evaluated 19,832 pathways, including 24,989 stages (excluding the first ED stage). Of these 19,832 pathways, 2669 (13.46%) were evaluated as irrelevant, and 11.21% (2802/24,989) of stages were also evaluated as irrelevant. Considering the error margin, between 2162 and 3176 pathways were irrelevant, and between 2438 and 3166 stages were irrelevant. The main irrelevant movements detected by the algorithm were overflow bed in surgery, overflow bed in polyvalent units, and waiting time in the OU. The 19,832 historical pathways included 986 (4.97%) variants. Once corrected, 792 variants were noted. Table 1 details the distribution of the structures of the variants. We observed that the *ED, MEDICINE, MEDICINE* and *ED, SURGERY, MEDICINE* traces were less frequent than before correction, which is due to the correction of the overflow beds. The trace ED appeared because the OU stage was assessed as irrelevant for several *ED, OU* (included in *ED, MEDICINE*) traces.

Statistical Analysis of Relevant and Irrelevant Pathways

Once the pathways were labeled, we compared the relevant pathways with the irrelevant pathways to understand the causes of irrelevance in the pathways. Several causes were already known among medical and administrative staff: bed occupation rates, ED crowding, age, and discharge destination. We tested these hypotheses using 4 bivariate analyses. The 4 variables to explain were an ED LoS of >5 hours, an ED LoS of >10 hours, the presence of overflow beds, and delayed discharge. For categorical variables, the proportions were compared using a chi-square test. For quantitative variables, the distributions were compared using a 2-tailed Student *t* test. We studied different explanatory variables: weekday corresponds to the start of the ED visit or admission to the inpatient unit; the arrival period is divided into 4 periods (morning from 7 AM to noon, afternoon from noon to 5 PM, night from 5 PM to 11 PM, and deep night from 11 PM to 7 AM); the next historical stage is the inpatient unit where the patient was admitted, and the next corrected stage is where the patient should have been admitted (based on the evaluation of the pathways); the last stage is the medical unit from which the patient was discharged; and the ED crowds are the number of patients present in the ED when the patient arrives.

Table 3 reports the bivariate analyses. Tables S2 and S3 in Multimedia Appendix 3 provide the detailed results. Several observations can be made from the statistical analysis. First, the seasons and the irrelevance of the next stage are not significant for a delay in the ED of >5 hours, but they are significant for a delay of >10 hours. Second, counterintuitively, fewer irrelevant post-ED admissions occur for long ED delays. This finding is probably because patients who stay in the ED for a long time are ultimately admitted to a relevant unit. Third, the weekday of patient arrival influences the ED delay. On Mondays, more patients wait >5 hours, and the proportion decreases throughout the week and increases again on Sundays. This phenomenon is caused not only by the greater number of patients admitted on Monday but also by the difficulty in hospitalizing patients during the weekend. Therefore, on Sunday, many patients are waiting for hospitalization. Fourth, this is the same observation and explanation for the overflow beds; more patients are admitted to an irrelevant unit on Sunday. Fifth, crowding in the ED was less important for the longest ED delays. Indeed, patients arriving at night or late at night are less

likely to be transferred to an inpatient unit, and this is also the period during which fewer patients arrive at the ED. Sixth, a greater number of patients are admitted to irrelevant units when the ED is more crowded. Seventh, increased age is a factor of long delays in accessing the ED. Eighth, similar features are noted for the occupation rate of the next stage. Ninth, the next corrected stages had an occupation rate (95%) higher than that of the next historical stages (92%). Tenth, age does not impact the risk of being in an overflow bed. Eleventh, the season has an impact on discharge delays. Specifically, in summer, more discharges are delayed, perhaps because the health care supply is lower during the summer holidays. Twelfth, the proportion of delayed discharges varies according to the destination of the discharge. Discharges at a psychiatric center have the highest rate of delay (97/203, 47.8% of delayed stays), followed by discharges at rehabilitation centers (1285/3294, 39.01% of delayed stays). Delayed discharges for death correspond to requests for palliative care at home or at another center that were not accepted in time. Thirteenth, age does not affect the risk of delayed discharge.

The period of study was impacted by the COVID-19 pandemic. These results could be more robust with access to a longer period of study (3 years instead of 1), and the seasons variably could be assessed several times during a longer time frame. Furthermore, the quality of the data was imperfect, especially for the computation of the occupation rate. Therefore, the results should not be extrapolated to other periods or hospitals. However, the analysis allowed us to compare the relevant and irrelevant pathways because they were derived from the same dataset. Hence, we can conclude that significant differences (P<.001 for most of the features) were observed between relevant and irrelevant pathways. Logistic factors such as the day of the week, the hour of arrival, medical unit occupation, and the discharge destination influence the risk of overflow.

[a]The analysis was performed exclusively using the data from the principal site (Scorff) because emergency department crowds and age differ between the principal site and the smaller site (Villeneuve).

[b]ED: emergency department.

[c]The next historical stage is the inpatient unit where the patient was admitted, and the next corrected stage is where the patient should have been admitted (based on the evaluation of the pathways). Occupation rate is the number of patients already present in the unit over its capacity.

[d]We compared the set of pathways without an overflow stage and the set of pathways with at least one overflow stage.

[e]In each pathway, the ED crowds were only computed for the first medical unit subsequent to the ED stage.

[f]We compared the sets of relevant and irrelevant stages.

Synthesis of Patient Pathway Labels

To summarize this section, from the analysis of the structure of the patient pathways and expert knowledge, we built 7 rules that detect irrelevant stages in a patient pathway (description of the dataset and construction of rules). On the basis of these rules, we used a pathway-labeling algorithm that labels the stages of a pathway according to 3 levels of relevance (pathway labeling). We then used a pathway correction algorithm that transforms a labeled pathway into an ideal pathway (pathway correction). The evaluation of our algorithm showed that it exhibits 87% accuracy. In our dataset, 13.46% (2669/19,832) of the pathways were labeled as irrelevant. Finally, a statistical comparison between relevant and irrelevant pathways demonstrated that logistic constraints influence the quality of patient pathways.

The next 2 sections show the importance of this preprocessing step before analyzing patient pathways using process mining and of using these data for hospital management.

Case Study 1: Analysis of Patient Pathways Using Process Mining

Motivation

The first case study investigates the impact of our preprocessing technique on process discovery. We evaluated the ability of our preprocessing method to simplify process graphs. We compared the process graph of an event log comprising historical traces with the process graph of an event log comprising corrected traces. We used the ProM framework (version 6.12; ProM Tools) [38] to discover the graphs and estimate different metrics. The process graphs were computed using the Fodina algorithm [39], which outputs a causal graph that was transformed into a Petri net with the plug-in "Convert Causal net (C-Net) to Petri net" (F. Mannhardt).

Metrics

The metrics were computed using the plug-in "Show Petri-net Metrics" (HMW Verbek). This plug-in computes (1) the extended Cardoso metric (ECaM), (2) the extended Cyclomatic metric (ECyM), (3) the structuredness [40], and (4) the density [41].

The ECaM counts the splits (XOR, OR, or AND) in the net and penalizes each of them. The ECyM is the difference between the number of edges and vertices plus the number of strongly connected components. According to Lassen and Van der Aalst [40], a high ECaM score can be caused by a "high degree of fan-out from places," and numerous parallelisms can increase the ECyM. Structuredness recognizes different types of structures and scores each structure by giving it a penalty value. Finally, the density relates the number of arcs to the number of all possible arcs for a given number of nodes. Therefore, these 4 metrics quantify the different structural characteristics of a graph.

Quantitative Analysis

The process graph discovered from the whole dataset of pathways is spaghettilike because the number of variants is large with or without correction (986 vs 792). To avoid spaghettilike effects, we reduced the analysis to 1 medical unit (ie, the event log included only the traces that contained this activity). Table 4 shows the metrics calculated for 5 medical units. As expected, the corrected event log contains fewer variants and activities than the historical event log. Consequently, the number of arcs, places, and transitions on the graph also decreases. The historical graph density is greater than the corrected graph density. This finding indicates that the corrected graph is more compact than the historical graph. The ECaM and ECyM of the corrected graph are lower than those of the historical graph. Indeed, we can observe more places with many output transitions and more parallelisms in the historical Petri net. Finally, the structuredness of the historical graph is also greater than the structuredness of the corrected graph except for the neurology unit. This means that more complex structures or more unstructured components are observed in the historical graphs than in the corrected graph. The neurology exception can be explained by the fact that a state machine is identified in the historical graph but only an unstructured component is identified in the corrected graph. In conclusion, the corrected Petri nets can be considered simpler than the historical Petri nets.

Table 4. Comparison of the historical and corrected process graph.

Process graph	Variants, N	Activities, N	Arcs, N	Places, N	Transitions, N	Density	ECaM[a]	ECyM[b]	Structuredness

Corrected	16	8	37	10	18	0.10	17	24	1602

[a]ECaM: extended Cardoso metric.

[b]ECyM: extended Cyclomatic metric.

Qualitative Analysis

A qualitative analysis can also be performed (see Multimedia Appendix 4 for the pictures of the graphs). The cardiology historical graph (Figure S1 in Multimedia Appendix 4) shows that several activities can occur before admission to cardiology, but it is not easy to distinguish between groups of patients. The corrected graph is easier to read, and four groups of patients can be identified: (1) serious patients who need intensive or continuous care before being admitted to cardiology, (2) patients who need to be permanently monitored for cardiac examination, (3) patients who need pulmonology care before cardiology care, and (4) patients who do not need other care before transfer and are directly admitted to cardiology (with eventually a step in the OU before).

The historical graph of the polyvalent medicine unit (Figure S2 in Multimedia Appendix 4) is complex to read, and several specialized units are present but not related to the polyvalent unit in the graph. The corrected graph is much simpler to read. Three groups of stays are identified: (1) stays with intensive or continuous care before admission to polyvalent medicine, (2) stays with direct admission, and (3) stays with a step in the OU or seasonal unit before admission to polyvalent medicine.

Equivalent analyses can be performed on other medical units (Figures S3, S4 and S5 in Multimedia Appendix 4). The neurology graph (Figure S3 in Multimedia Appendix 4) is less simple than the other graphs, possibly because patients going to neurology have complex pathways or because the correction of neurology pathways requires particular rules. However, the corrected graph is again more interpretable than the historical one.

Case Study 2: Estimation of Ward Capacity Through Simulation

Motivation

Computer simulations can be used to estimate the number of beds necessary in each medical unit to admit unscheduled patients and help solve capacity planning problems. Indeed, the actual number of patients admitted to each medical unit does not include all the patients not admitted because of a lack of beds, and the number of the patients who should not be admitted to each unit is considered. Hence, it does not reflect the real need for beds. To solve this problem, pathway correction can be used. This method can be useful for estimating capacities when building or renovating a hospital or for organizing medical teams.

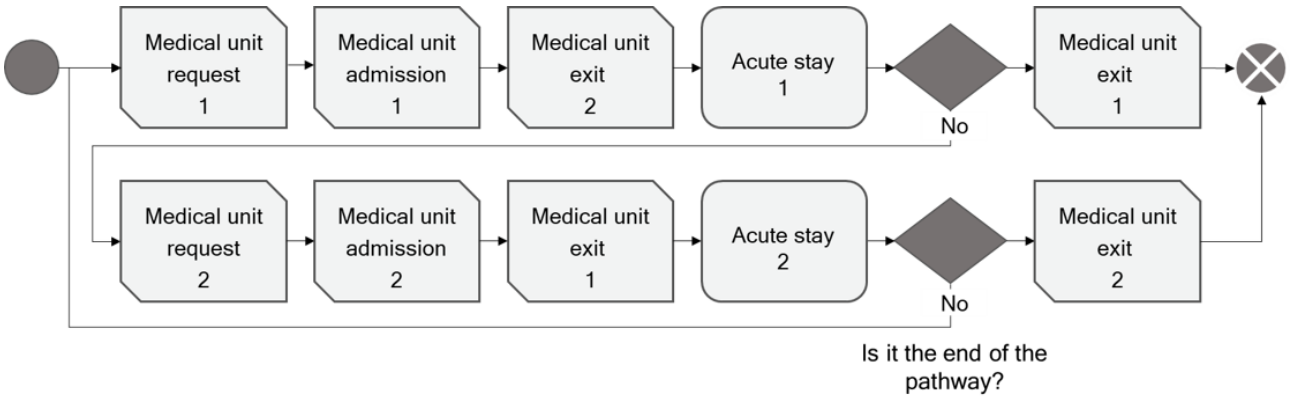
DES Model

In this case study, we simulate patient flow through the medical units of one hospital to compute the level of occupation of the medical units. We compared a simulation with the historical pathways (scenario 1) and a simulation with the corrected pathways (scenario 2). To do so, we modeled the medical units and patient flow using the AnyLogic software (The AnyLogic Company). Figure 5 shows the DES model.

The model represents 1 general hospital and 20 full hospitalization units. Each patient has a succession of units to follow. The model simulates the admissions of patients to medical units, their stays, and their discharges. A patient exits the simulation when they have completed their pathway. To simulate the source of patients, we used the dataset described in section Data (only patients from the main general hospital site [named Scorff] were included). We filtered the dataset based on the following criterion: only the pathways with at most 3

activities (ED visits plus 1 or 2 units) were included. We excluded pathways with weekly or daily units, the rare variants (coverage percentage of <0.001), and patients from sites other than Scorff. The corrected pathway dataset was filtered to keep only the stays included.

Figure 5. Modeling of patient flows through medical units.



Experimental Settings

The capacities of the medical units were set to infinity to calculate how many unscheduled patients needed to be admitted to each unit each day. The LoS in each unit was randomly generated according to a probability law. To choose this probability law, we compared several distributions (normal, β, γ, log-normal, Weibull, and exponentiated Weibull) and fitted them on the stays of our dataset (between 150 and 5000 stays per medical unit). The log-normal distribution best fit the LoSs in each unit. The parameters of the log-normal distributions were adjusted for each unit by fitting the distribution to the real values. The log-normal distribution tends to generate more extreme values than those observed in reality; thus, the LoS was limited to 28 days in a unit and 24 hours in the ED. The simulated patients' arrival dates were fixed and equal to the real patients' arrival dates. The simulated patients either followed the historical pathways (scenario 1) or the corrected pathways (scenario 2). The simulation duration was 1 year, and the simulation run included 13,366 pathways.

To choose the warm-up time, we monitored the mean number of present patients in each medical unit over the simulation time. After 50 days, a stable situation was reached (Figure S6 in Multimedia Appendix 5). The warm-up time was set to 2 months. The number of replications was chosen to have an error of <10%. In total, 15 replications allowed this target to be reached and a reasonable simulation time to be reached—approximately 1 minute is required for 1 run, and the 15 replications take 10 minutes. The results are the mean values of 15 replications.

The simulation model was validated by comparing the mean LoS of each medical unit from the simulation results to those from the real dataset. This was the only source of randomness in the model as the simulated patients arrive according to the real dataset and follow a deterministic pathway. The mean absolute error was 0.6 days, which is <10% of the mean length of a hospital stay (Table S4 in Multimedia Appendix 5).

Results of DES

Table 5 shows the mean number of acute patients present in each unit in both scenarios. For several units, the number of patients differed between scenario 1 and scenario 2. For example, the polyvalent medicine unit had, on average, 2 patients less with corrected pathways, and the neurovascular unit had 1 more patient. We also observed that, globally, there were fewer patients present at the same time with the corrected pathways compared with the historic pathways. Indeed, there were fewer stages in the corrected pathways because some were judged as irrelevant; therefore, in the simulation, the patients stayed less time in the hospital.

In conclusion, preprocessing pathway data is important for addressing capacity planning problems in hospitals. In this example, we observed that using historic pathways can lead to biased numeric interpretations for the capacity planning of medical units.

Table 5. Mean number of acute patients in medical units over 1 year.

Medical unit	Scenario 1	Scenario 2	Difference
3O surgery[a], mean (95% CI)	7.6 (7.3-7.9)	1.1 (0.9-1.2)	–6.5
Orthopedic surgery, mean (95% CI)	10.1 (9.9-10.3)	13.3 (13.0-13.5)	3.1
Visceral surgery, mean (95% CI)	6.5 (6.0-7.1)	5.9 (5.4-6.3)	–0.7
Pulmonology, mean (95% CI)	14.2 (14.0-14.4)	14.3 (14.1-14.6)	0.1
Cardiology ICU[b], mean (95% CI)	2.0 (1.8-2.2)	2.0 (1.8-2.2)	0.0
Cardiology, mean (95% CI)	10.1 (9.8-10.3)	10.1 (9.9-10.3)	0.1
Postemergency unit, mean (95% CI)	17.0 (16.7-17.3)	14.5 (14.3-14.7)	–2.5
Polyvalent medicine, mean (95% CI)	35.5 (35.5-35.5)	33.9 (33.9-33.9)	–1.7
Neurology ICU, mean (95% CI)	3.0 (2.7-3.3)	3.0 (2.7-3.3)	0.0
Neurovascular, mean (95% CI)	3.9 (3.8-4.1)	5.1 (4.8-5.5)	1.2
Neurology, mean (95% CI)	3.7 (3.7-3.7)	3.1 (3.1-3.1)	–0.7
Hepatogastroenterology, mean (95% CI)	13.3 (12.9-13.6)	13.7 (13.5-13.8)	0.4
Rheumatology, mean (95% CI)	11.4 (11.2-11.6)	11.3 (11.3-11.3)	–0.1
Observation unit, mean (95% CI)	8.7 (8.4-9.0)	6.5 (6.1-6.9)	–2.2
Geriatric medicine, mean (95% CI)	39.3 (39.0-39.5)	38.7 (38.5-38.9)	–0.5
ICU, mean (95% CI)	1.8 (1.5-2.1)	2.0 (1.7-2.3)	0.2
Seasonal unit[c], mean (95% CI)	2.9 (2.5-3.2)	2.0 (1.7-2.3)	–0.9
Oncology hematology, mean (95% CI)	5.0 (4.7-5.3)	5.2 (4.8-5.6)	0.2
Nephrology endocrinology, mean (95% CI)	3.5 (2.9-4.0)	3.4 (3.0-3.8)	–0.1
CCU[d], mean (95% CI)	0.6 (0.3-0.9)	0.6 (0.3-0.9)	0.0
Total patients, N	200	190	–10

[a]Ear, nose, and throat; ophthalmologic; and orthopedic surgery.

[b]ICU: intensive care unit.

[c]The seasonal unit is only open during the winter months. Therefore, the occupation figures computed over a year do not reflect reality.

[d]CCU: continuing care unit.

Discussion

Principal Findings

A framework and a methodology to study patient pathways were presented in this paper. They were used to develop a pathway-labeling algorithm that automatically detects whether a patient pathway is irrelevant (ie, contains stages due to resource limitations [as defined in the *Definition 6: Relevance of Stage* section]). Two main methods are available to achieve such a task: (1) building a thesaurus with medical experts (or using supervised learning) that links the main diagnosis (or the chief complaint) with an ideal pathway and (2) building a symbolic algorithm. The first method is the most accurate but is very time-consuming. This method would require hours of work with experts to build a thesaurus or annotate data for training a machine. None of these methods provide general results because the thesaurus and rules need to be adapted to each hospital. We chose the second option, an algorithm based on logic and administrative data, because it can be built quickly and is easily adaptable to organizational changes. We provided a general method to build this algorithm. We applied our algorithm to our dataset, and we were able to estimate the gap between our algorithm and an expert assessment. Our results demonstrate that a nonnegligible gap exists (13% to 19% of errors); however, we believe that the error rate was small enough for globally evaluated pathways. The estimation of this error also enabled us to identify the source of errors of the algorithm. On the basis of this labeling, a correction of the pathways was then performed to represent pathways that would be considered ideal.

We also demonstrated that resource limitations impact the choice of pathway using a statistical analysis that compared relevant and irrelevant pathways. The factors identified as increasing difficulties in managing patient flows could be included in hospitals' strategies to improve patient pathways.

The 2 case studies illustrate the importance of preprocessing patient pathway data before any analysis. Studying and representing patient pathways using process mining is complicated (*Related Work* section). By focusing on pathways with a common medical unit, we demonstrated that a corrected graph is more interpretable than a historical graph. Hence, our algorithm is an efficient preprocessing tool for the analysis of

patient pathways using process mining. The simulation of patient pathways is useful for testing bed management changes, but numeric results can be false if the input data include bias. In our example, the determination of the mean number of beds required for acute patients differed for the historic and corrected pathways. Some medical units need fewer beds, and others need more beds.

Pathway labeling should be applied before any analysis, such as process mining (case study 1), simulation (case study 2), or training of machine learning models to predict hospital pathways. In another work, we studied the prediction of the medical unit where a patient will be admitted after an ED visit. If raw data are used to train a machine learning model, the training will be biased. Indeed, the model will learn, for example, that some patients who do not need surgical treatment should be transferred to surgery. In contrast, if the model is trained using relevant pathways, it will learn the ideal medical unit for the patients [42].

Limitations

We proposed a general method to study patient pathways and identify bias in the data. However, our approach could only be tested in 1 dataset because of legal constraints. Therefore, additional studies with other hospitals should be performed to validate the generalizability of our approach. Our labeling algorithm is not 100% accurate. To avoid errors, more rules could be created by exploiting textual data using natural language processing. Indeed, to build our algorithm, we only used structured data because of the unavailability of an adequate tool to treat textual data in our hospital.

Conclusions

This work suggests a new approach to preprocess data on pathways of unscheduled patients. To our knowledge, there are no other studies that have evaluated nonspecific disease pathways. Our approach has the advantages of being explicable, simple to implement, and adaptable to each hospital.

Future research could develop process discovery techniques that consider the relevance labels of the activities.

Acknowledgments

The authors thank the Groupe Hospitalier Bretagne Sud, especially the Groupe Hospitalier Bretagne Sud Information System Department teams and the SIB Company Data Department teams, for providing access to electronic health records for this study. The authors would like to thank the physicians who helped them construct and validate their algorithms, including Dr Bry, Dr Chevallier, Dr Dollon, Dr La Combe, Dr Le Corf, Dr Girard, Dr Henry, Dr Laurichesse, Dr Le Merlay, Dr Lenoir, Dr Luquet, Dr Maigre, and Dr Vaillant. The authors also thank Dr Quiguer for her advice and Professor Saulnier for his help with the statistical analyses. This work was funded by the company Enovacom.

Abstract

Background: Recently, the growing demand for pediatric sedation services outside the operating room has imposed a heavy burden on pediatric centers in China. There is an urgent need to develop a novel system for improved sedation services.

Objective: This study aimed to develop and implement a computerized system, the Pediatric Sedation Assessment and Management System (PSAMS), to streamline pediatric sedation services at a major children's hospital in Southwest China.

Methods: PSAMS was designed to reflect the actual workflow of pediatric sedation. It consists of 3 main components: server-hosted software; client applications on tablets and computers; and specialized devices like gun-type scanners, desktop label printers, and pulse oximeters. With the participation of a multidisciplinary team, PSAMS was developed and refined during its application in the sedation process. This study analyzed data from the first 2 years after the system's deployment.

Implementation (Results): From January 2020 to December 2021, a total of 127,325 sedations were performed on 85,281 patients using the PSAMS database. Besides basic variables imported from Hospital Information Systems (HIS), the PSAMS database currently contains 33 additional variables that capture comprehensive information from presedation assessment to postprocedural recovery. The recorded data from PSAMS indicates a one-time sedation success rate of 97.1% (50,752/52,282) in 2020 and 97.5% (73,184/75,043) in 2021. The observed adverse events rate was 3.5% (95% CI 3.4% - 3.7%) in 2020 and 2.8% (95% CI 2.7%-2.9%) in 2021.

Conclusions: PSAMS streamlined the entire sedation workflow, reduced the burden of data collection, and laid a foundation for future cooperation of multiple pediatric health care centers.

KEYWORDS

electronic data capture; information systems; pediatric sedation; sedation management; workflow optimization

Introduction

Context

Procedural sedation in infants and children is in great demand for anxiety, pain, and motor control. Over the past decades, pediatric sedation has evolved into a multispecialty practice, with guidelines established by the American Society of Anesthesiologists (ASA), the American Academy of Pediatrics, and the International Committee for the Advancement of Procedural Sedation . However, there is currently no universally accepted optimal strategy for pediatric procedural sedation. Factors such as medical resources, patient volume, and health insurance systems may contribute to variations in criteria for administering sedation, methods for monitoring depth of sedation, qualifications of professionals performing sedation, and the choice of sedative agents [1-3]. The Children's Hospital of Chongqing Medical University (CHCMU) is the largest pediatric center in Southwest China. The CHCMU had 1400 inpatient beds in 2019, which increased to 2480 in 2021, with more than 3 million outpatient visits annually [4]. The huge patient volume at CHCMU highlights the need for an electronic data capture and management system (EDCMS) that seamlessly integrates multiple sedation steps. Such a system ensures reliability and consistency, reduces documentation time, and allows more time and resources to be devoted to sedation services [4,5]. In addition, the system can flag high-risk patients (eg, ASA III patients) and monitor their sedation process in real time, facilitating quicker detection of potential risks. Smaller hospitals may also find this system beneficial, as it can enhance work efficiency and enable proper data management for comprehensive assessment and tracking of all records.

After a 2-month pilot deployment, the feasibility of the current system was proven, and it has been fully implemented since January 2020.

Problem Statement

The demand for procedural sedation has significantly risen due to increased awareness of its importance [6-8]. Nevertheless, the current anesthesia system employed inside the operating room is incompatible with pediatric sedation outside the operating room. Other challenges include insufficient data collection and nonuniform management, which were initially deemed unavoidable owing to the large number of patients and limited pediatric personnel and resources for pediatric care. Moreover, a low ratio of medical personnel to patient is a long-standing issue for procedural sedation in many limited-income countries in Africa and Asia [9] as well as in many European countries [10].

Similar Interventions

Traditional tools, such as Research Electronic Data Capture (REDCap) [11], were developed for data collection and lacked the features necessary to manage sedation services. Similarly, anesthesia systems designed for the surgical settings do not align with the requirements of outpatient sedation services. The newly implemented Pediatric Sedation Assessment and Management System (PSAMS) was designed to meet the unique needs of pediatric sedation services, optimizing both data management and clinical workflow.

Methods

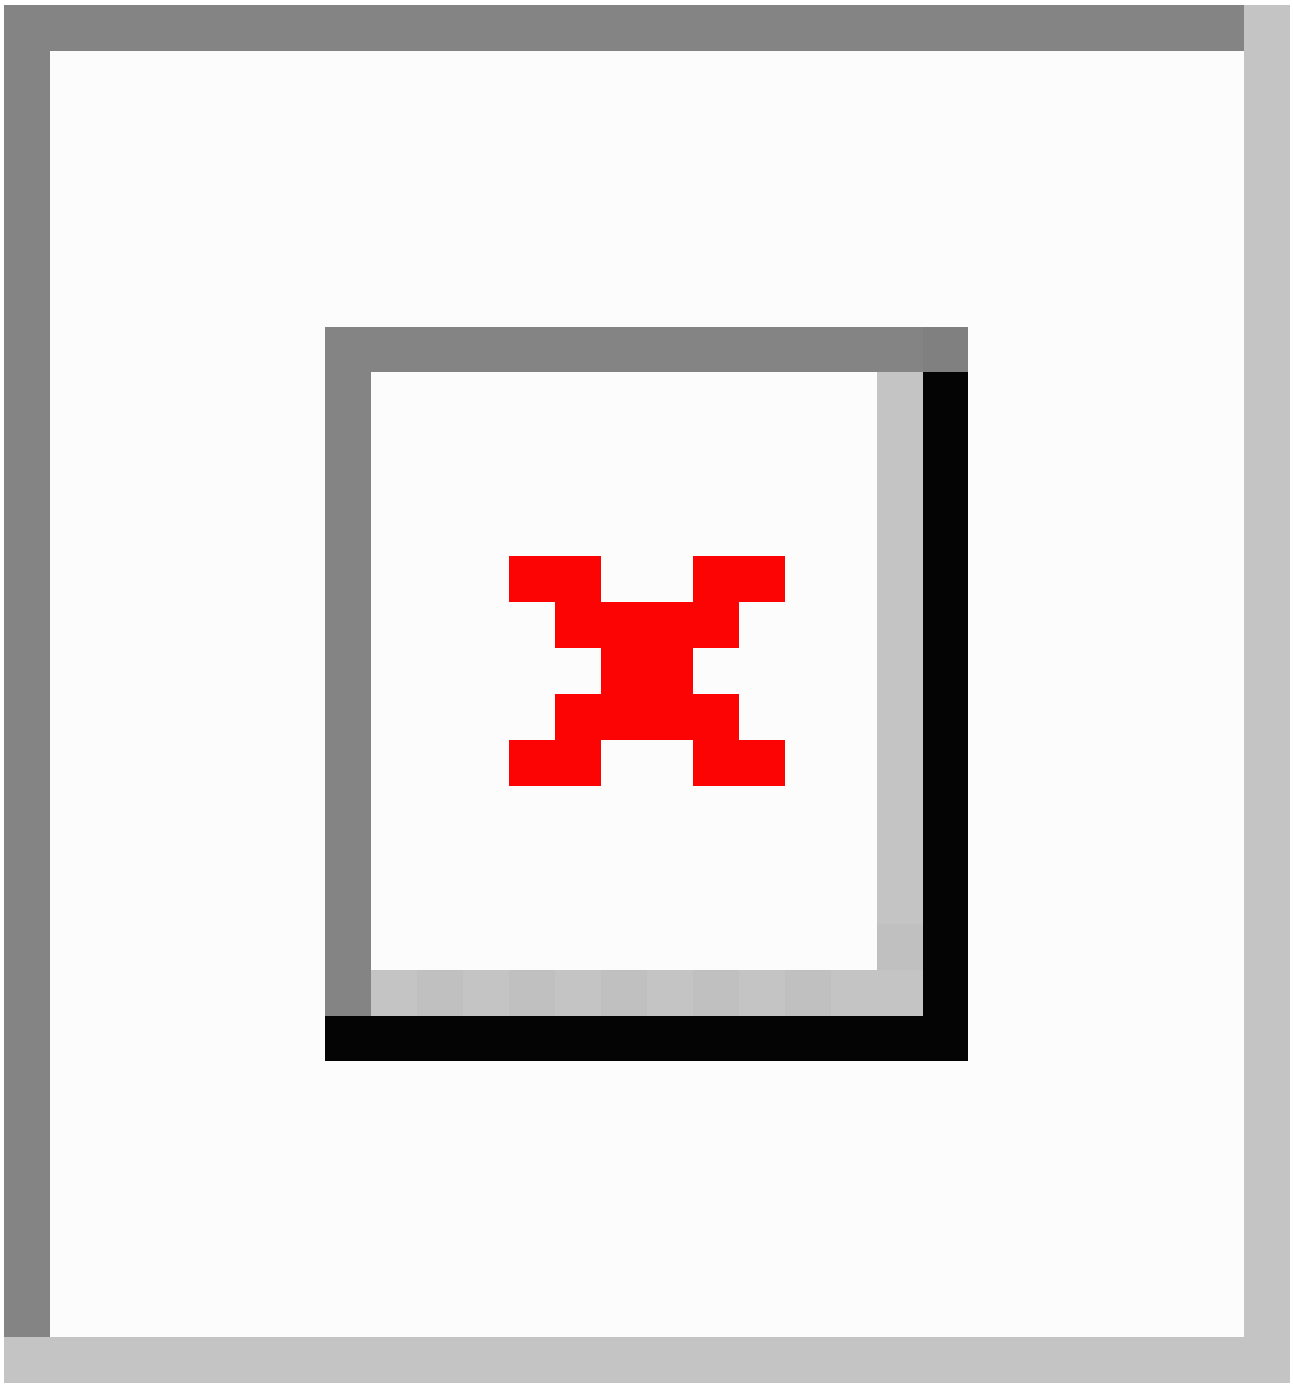
Aims and Objectives

In this study, we aimed to develop a system that could meet the needs of pediatric sedation services and optimize both data management and clinical workflow. First, we introduced the development and implementation of the PSAMS. Second, we analyzed the one-time sedation success rate and the incidence of adverse events based on the data collected by the PSAMS.

Blueprint Summary

PSAMS was developed at the CHCMU based on the following principles: (1) user-friendly interfaces and features for anesthesiologists and nurses; (2) high accuracy with carefully designed error-proofing techniques; (3) interoperability and integration with the Hospital Information System (HIS); (4) compatible scalability reserved for future updates and to accommodate different deployments; and (5) solid security assurance on patients' privacy. This system comprises 3 main parts: the software hosted on a server; clients distributed on portable tablets and computers; and devices, including gun-type scanners, desktop label printers, and pulse oximeters (Figure 1). This study adhered to the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) guidelines (Checklist 1) [12].

Figure 1. Devices and user interfaces of the Pediatric Sedation Assessment and Management System (PSAMS). All tasks are assigned to 4 roles by PSAMS: nurse A, anesthesiologist, nurse B, and nurse C. PSAMS is distributed on computers and portable tablets, and every user interface is specifically designed based on the different tasks of each user role. A large display in the sedation center provides a real-time update summary and statistics generated by PSAMS.



Technical Design

The in-depth technical details of the construction of the PSAMS are available from the correspondence author upon reasonable request. Briefly, most of the system was written in C++; the Qt framework was used for application and graphical user interface development, and Java was used for back-end data processing. MySQL was applied as the database management system.

Target

PSAMS has demonstrated great feasibility since its full implementation in 4 sedation centers of CHCMU in 2 districts of Chongqing from January 2020. PSAMS can be easily customized and adapted to other health care systems to provide sedation services for all pediatric patients (≤18 years of age). As of December 2022, it has been adopted by other health care centers in China, including Shenzhen Children's Hospital in Guangdong Province and Zhengzhou Children's Hospital in Henan Province, following team training and pilot implementation.

Ethical Considerations

This study was approved by the Institutional Review Board of the Children's Hospital of Chongqing Medical University (file

number 2022, 220), and all data analyzed in this study were collected in accordance with its regulations. Informed consent was waived due to the retrospective observational nature of the study. Data will be stored on the hospital's internal servers and managed by the hospital.

Data

A comprehensive approach was implemented to ensure data quality. For data validation and verification, we designed and used prestructured data entry as drop-down menus or checkboxes. Other mandatory basic information fields were automatically synchronized with the HIS. Each data entry was immediately validated against predefined ranges or criteria. If an anomalous entry was detected (eg, 32 °C for body temperature or 400 kg for body weight), PSAMS would send notifications and remind the user to confirm the entry while recording the incident in the system's running log, which also served as a dataset for analyzing error patterns and system performance issues over time. To further improve data integrity and support clinical decision making, PSAMS included advanced tools for automated dose calculation and sedation regimen recommendations, while aligning with best clinical practices. For example, the regimen recommendation tool was developed based on sedation practice and expert guidelines, allowing the anesthesiologist to accept or modify recommendations based on real-world scenarios. The regimen recommendation tool incorporated expert knowledge through a set of predefined rules considering factors such as age, weight, diagnosis, and procedure type. All tools were regularly updated and maintained based on user feedback and updated guidelines (Figure S1 in Multimedia Appendix 1). For adverse events reporting, the adverse event reporting tool from the World SIVA International Sedation Task Force [13] was integrated into PSAMS to facilitate early detection and provide standardized records.

Interoperability

The PSAMS is integrated with the HIS, which applies the *International Classification of Diseases, Tenth Revision*. This interoperability ensures seamless data exchange and standardized coding for diagnoses, enhancing the accuracy and efficiency of medical records management within the system.

Participating Entities

The multidisciplinary team included anesthesiologists and nurses from the Department of Anesthesiology, staff from the Department of Health Information Management, and software engineers. The Department of Health Information Management provided server, network, and HIS integration support. The software engineers created a prototype and refined the system based on feedback from the anesthesiologists and nurses during clinical practice. The funding body did not participate in the study design, implementation, or data governance.

Budget Planning

Approximately 54% of the budget was spent on software development, 10% on change management, 25% on project management, 5% on user training, and 6% on product deployment. The development phase took 1 year in addition to a 2-month pilot deployment.

Sustainability

PSAMS has been integrated into the HIS and used in several pediatric centers for procedural sedation. Therefore, PSAMS was maintained through the hospital budget and the remaining funds were dedicated to the active development and improvement of PSAMS.

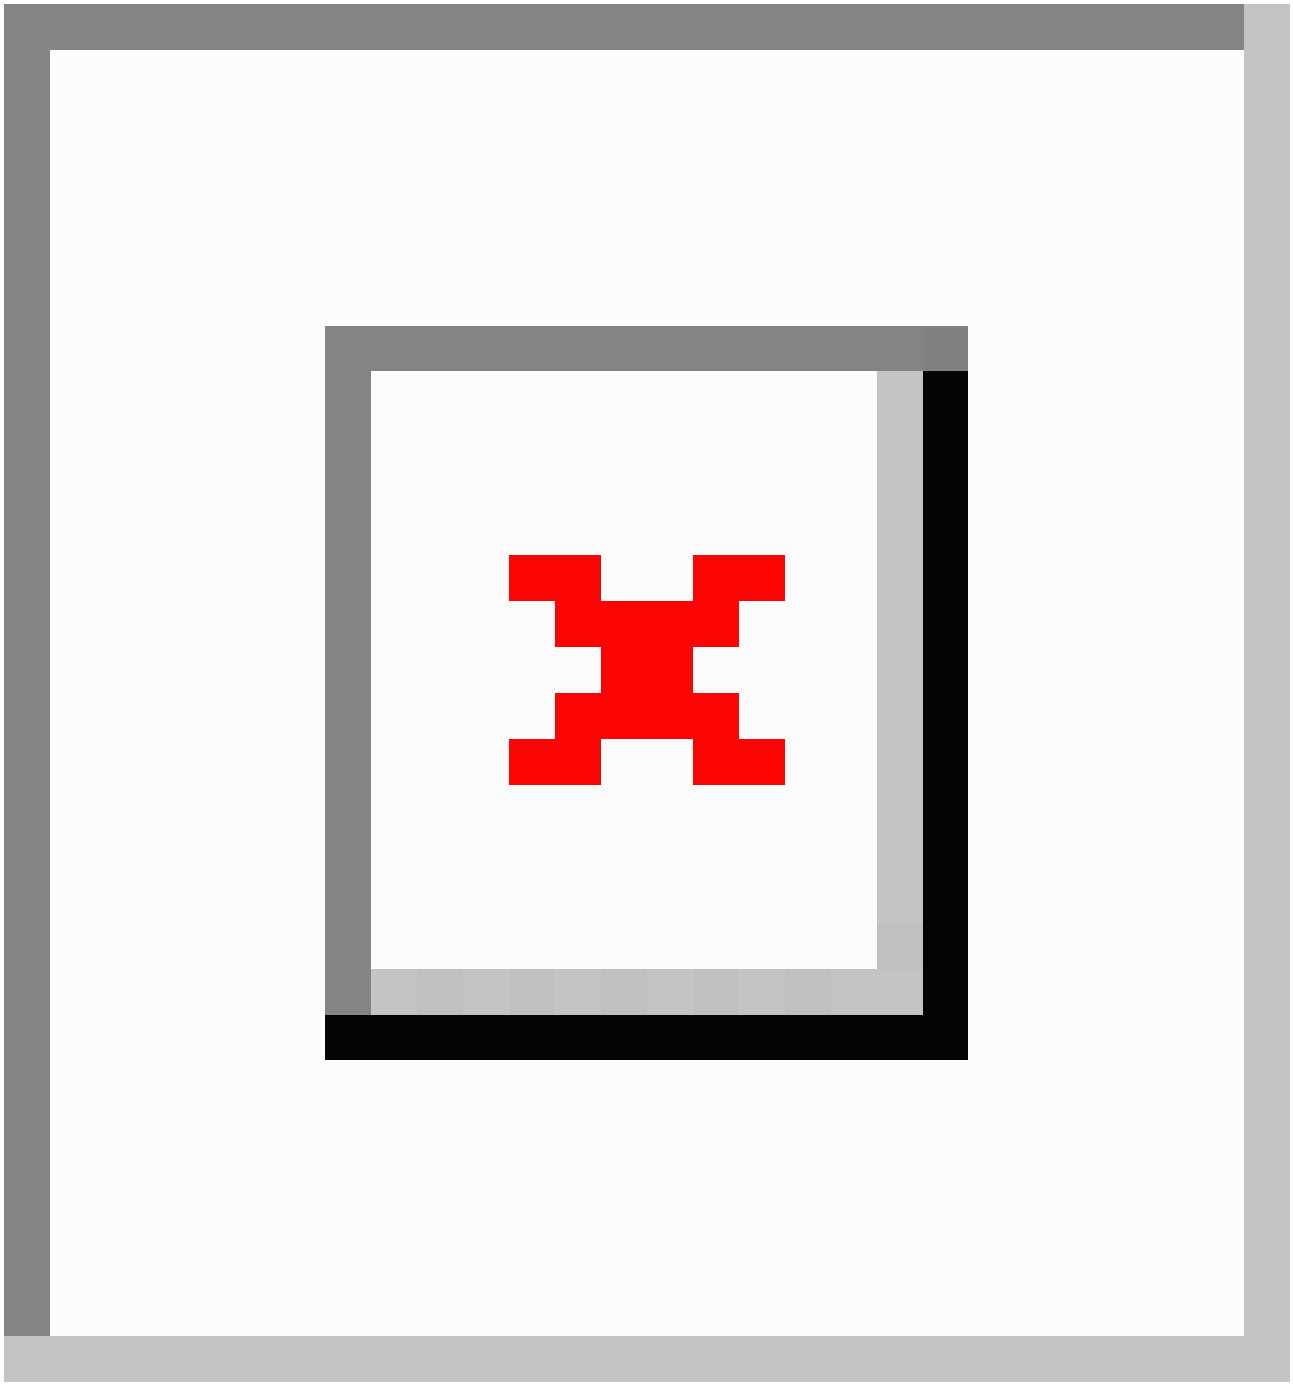
Implementation (Results)

Implementation of PSAMS

Figure 2 shows the PSAMS-mediated sedation workflow. Patients arriving at the nurses' station were registered by nurse A using a gun-type barcode scanner. This allowed automatic registration and synchronization of basic patient information (eg, name, age, gender, and ID) from the HIS. Previously, this process required manual entry of multiple forms, which typically took at least several minutes per patient. Following registration, nurse A quickly measured the patients' body weight, temperature, pulse, and saturation of peripheral oxygen (SpO_2), and completed the guidance sheet in PSAMS. The anesthesiologist then performed a presedation assessment based on physical examination and directed history (Table S1 in Multimedia Appendix 1). All relevant medical records were readily accessible via synchronization with the HIS, which was a significant improvement over the previous workflow, where data were isolated and difficult to retrieve. Patients deemed suitable for sedation who had signed informed consent were then directed to designated waiting or sedation areas.

From sedation to postprocedure recovery, pulse rate, and oxygen saturation were routinely recorded for ASA I and II patients at 4 time points: drug administration, sedation depth evaluation, procedure completion, and recovery from the procedure. Patients with ASA III and above received continuous monitoring of pulse rate and oxygen saturation by an experienced nurse with advanced life-support skills. PSAMS also tracked each step of the sedation process, displaying patient status on nurse dashboard panels, enabling nurse B to efficiently manage the patient queue and address any adverse events or complications promptly. In the case of an adverse event occurrence, PSAMS instantly alerted all screens within the sedation center, allowing the emergency team to quickly identify the potential reason and take appropriate measures to manage the adverse events. Meanwhile, the sedation records of the patients were immediately archived, synchronized, and reported to the department. Nurse C administered the drugs and logged the details into PSAMS. After the procedure, nurse C repeated the physical examinations and evaluated the recovery status. Overall, PSAMS had integrated previously independent sedation steps into a unified workflow, while maintaining and prioritizing important information, including vital parameters and sedation status at each stage.

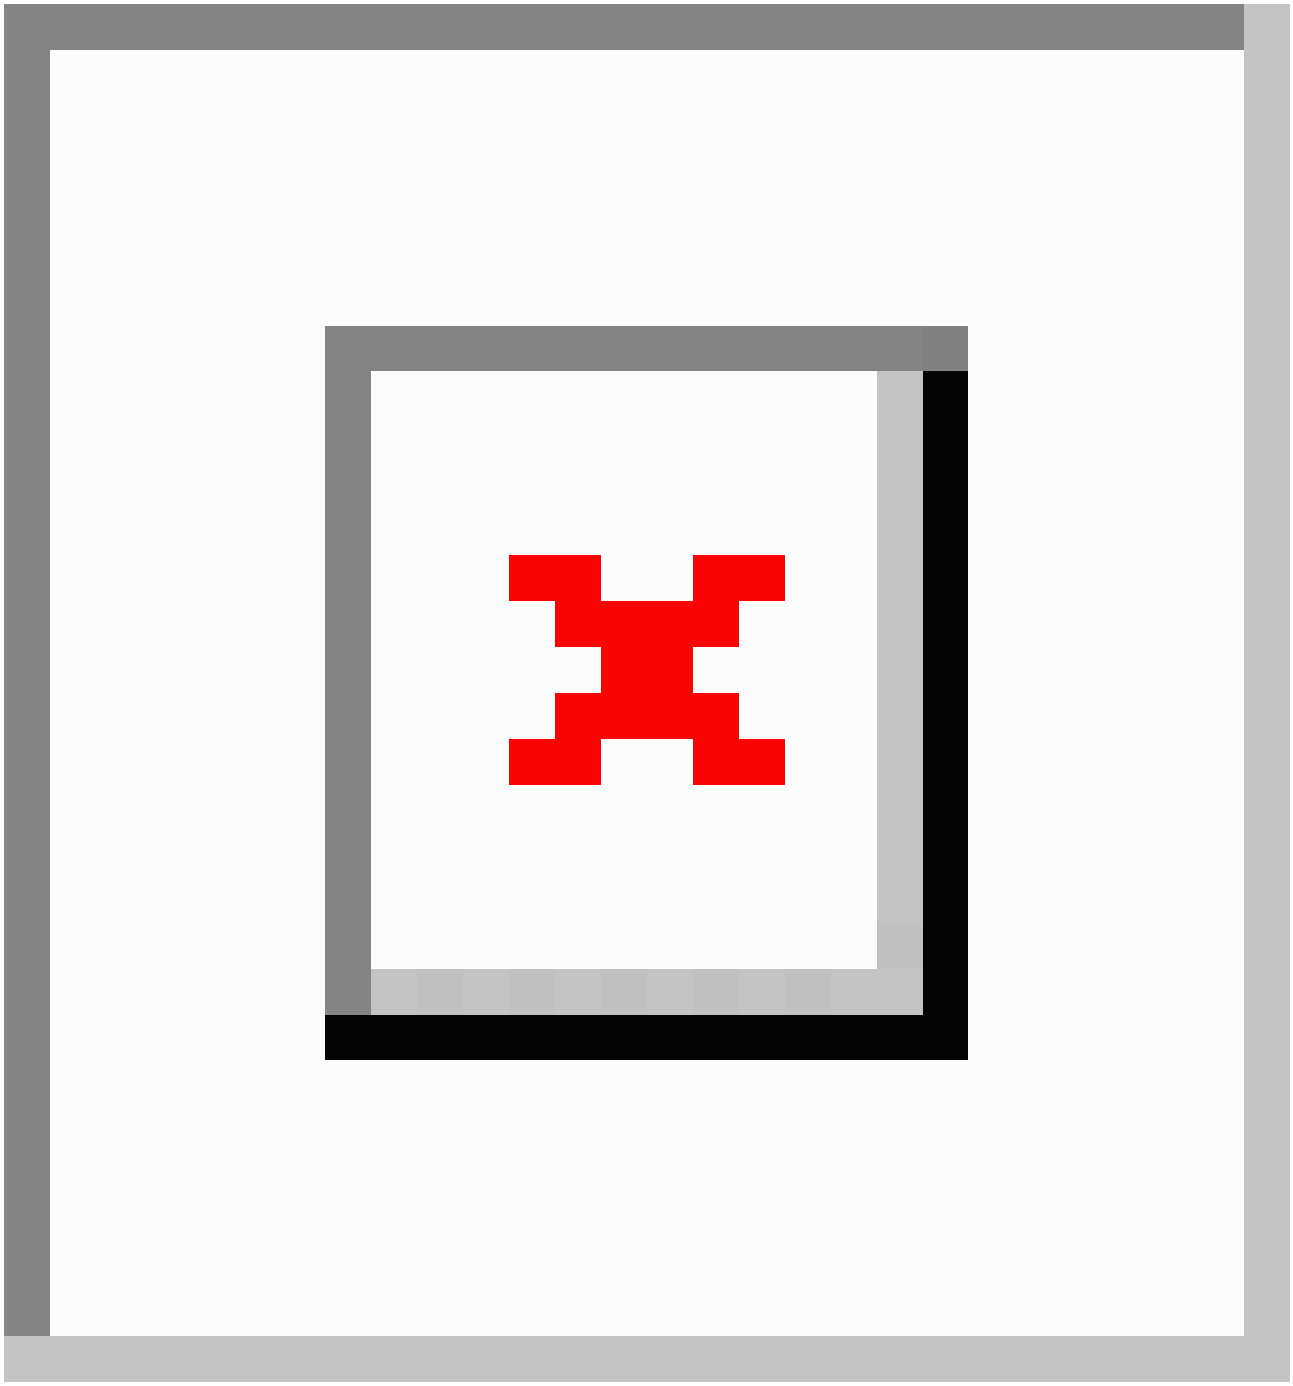
Figure 2. Complete sedation workflow mediated by the Pediatric Sedation Assessment and Management System in Children's Hospital of Chongqing Medical University. HIS: Hospital Information System; PR:pulse rate; SpO_2: saturation of peripheral oxygen.



Overview of the Current Database of PSAMS

For a 2-year deployment from 2020 to 2021, a total of 127,325 sedations were performed in 85,281 patients (Figure 3A and B). In all, patients came from 31 provinces and municipalities in China (Table S2 in Multimedia Appendix 1). The year 2020 saw fewer sedations due to the COVID-19 pandemic, and February was notably affected by the Chinese lunar new year. We included 43 variables from presedation assessment (eg, body weight, temperature, and pulse) to postprocedural recovery (eg, postprocedural pulse, SpO_2, and recovery time) for every single record (Table S3 in Multimedia Appendix 1). Of the 43 variables, 19 were complete in all records (Figure 3). High missing rates in some variables were due to the fact that most sedations did not require further intervention.

Figure 3. Overview of the sedation database from 2020 to 2021. (A) Calendar heatmap showing daily performed sedations from 2020 to 2021; (B) monthly summary of sedations from 2020 to 2021; (C) missing rate of each included variable in the database of the Pediatric Sedation Assessment and Management System. ASA: American Society of Anesthesiologists; SpO_2: saturation of peripheral oxygen.



The demographic characteristics and ASA levels of the patients are summarized in Table 1. The mean age was 2.2 (SD 1.7) years, and the mean weight was 11.7 (SD 4.8) kg. The proportion of male patients (n=76,001, 59.7%) was higher than that of female patients (n=51,324, 40.3%). .

Table . Demographic characteristics and the American Society of Anesthesiologists (ASA) levels.

Demographic characteristics		Total (N=127,325)	Year 2020 (n=52,282, 41.1%)	Year 2021 (n=75,043, 58.9%)
Age (year)				
	Mean (SD)	2.2 (1.7)	2.1 (1.8)	2.3 (1.7)
	Range	0.0-18.0	0.0-17.9	0.0-18.0

Sedative Choice, Procedures, Success Rate, and Adverse Events

PSAMS comprehensively collected and maintained information regarding the one-time sedation success rate and adverse events. The one-time sedation success was defined as achieving appropriate sedation depth with a single drug administration without adverse events. The most commonly used sedation regimen was dexmedetomidine combined with chloral hydrate (n=85,337, 67%) with a one-time sedation success rate of 96.6% (82,427/85,337; Table S4 in Multimedia Appendix 1). The most common procedure performed after sedation was magnetic resonance imaging (MRI; n=27,416, 21.5%), with the highest one-time sedation success rate of 99.7% (27,327/27,416; Figure S2 in Multimedia Appendix 1). The overall one-time sedation success rate was 97.1% (50,752/52,282) in 2020, which increased to 97.5% (73,184/75,043) in 2021. However, we were unable to summarize the one-time sedation success rate in 2019 and earlier because of the large volume of disorganized documents generated from the paper-based workflow and limited availability of personnel. Adverse events were recorded and reported using the adverse event reporting tool from the World SIVA International Sedation Task Force [13]. Most minimal risk adverse events, such as vomiting and hypersalivation, were not tracked and recorded by the PSAMS due to incompatibility with the monitoring devices. Minor risk adverse events were reported in 3397 sedations, where only 2 major adverse events were reported (Table 2).

Table . Adverse events reported in the Pediatric Sedation Assessment and Management System from 2020 to 2021.

Adverse events		Total (N=3962), n (%; 95% CI)	2020 (n=1843), n (%; 95% CI)	2021 (n=2119), n (%; 95% CI)
Minimal adverse events				
	Vomiting/retching	2 (0.1; 0-0.1)	1 (0; 0-0.2)	1 (0.1; 0-0.1)
	Subclinical respiratory depression	—[a]	—	—

Discussion

Principal Results

We developed the PSAMS through a multidisciplinary collaboration. To the best of our knowledge, This is the first EDCMS, specifically designed and used for pediatric sedation in China. PSAMS is deeply integrated with HIS. Thus, anesthesiologists could systematically determine a patient's medical status and optimize the sedation techniques. In case of an adverse outcome or complication, PSAMS immediately called for backup assistance and reported the event. All the generated data were recorded and tracked by PSAMS. When transitioning to PSAMS, the biggest challenge for users was adapting to the new system, which was resolved after a 2-week training program. During this time, users encountered specific problems, such as unfamiliarity with the interface navigation, difficulty entering and saving data, or not knowing how to use the built-in tools. To address these challenges, we provided targeted support in the form of quick reference guides and on-demand lectures to facilitate a smoother transition. Meanwhile, PSAMS continues to be updated to improve usability and better meet the needs of users based on their feedback. Due to the previous poorly documented paper-based system, quantitatively comparison was unavailable, and a preliminary survey was conducted to evaluate the improvement after PSAMS implementation. Most users (19 out of 22 nurses and all 5 anesthesiologists) reported a reduction in administrative burdens, convenient access to patient data, and a smoother workflow, which allowed more focus on patient care per se. Overall, PSAMS has streamlined the entire workflow and aligned each member of the sedation team within a cohesive and structured process to ensure high-quality and efficient pediatric sedation.

Limitations and Lessons Learned

PSAMS has several limitations. First, we did not perform real-time monitoring of every patient's vital parameters, such as body temperature, respiration rate, pulse, and blood pressure, during the entire sedation process. In our clinical practice, current physiological monitoring systems failed to function while transferring patients and during examinations. To overcome this hurdle, new wearable monitoring devices, a highly networked information system, and a robust computing resource are necessary to achieve real-time monitoring. We are actively engaged in developing innovative wearable devices that integrate seamlessly with PSAMS and improve server performance with advanced algorithms and models. Second, many minimal adverse events were not recorded, and we believe that PSAMS can fill in this missing information after the implementation of new devices. Third, this study was performed at a single center; however, efforts are being made to extend PSAMS to other health care centers in China to prove its generalizability. Nevertheless, necessary adjustments and training are still required to ensure successful deployment of PSAMS in various settings. Additionally, PSAMS is vulnerable to mishandled data from the HIS, which means that the current system cannot yet verify the data imported from other databases.

In summary, valuable lessons have been learned from the PSAMS program. The key success factor is ensuring smooth communication within the multidisciplinary team, which keeps development on track and enables the realization of practical and user-friendly features. Additionally, allocating sufficient time for user training in advance is essential, as it accelerates the transition from the previous paper-based workflow. Finally, maintaining device redundancy is crucial, as devices such as pulse oximeters and tablets can be accidentally damaged during long-term deployment.

Comparison With Prior Work

The advent of EDCMS and its integration with HIS has transitioned paper-based clinical workflow to an electronic one, significantly improved efficiency and data quality [14]. However, commonly used EDCMSs, such as REDCap, which provides hundreds of preconfigured forms to facilitate data capture, unfortunately, are not suitable for clinical sedation practice [15]. In our previous paper-based workflow, each step was separate, with no system for integrating and processing the information in one place. Nurses manually signed piles of medical paperwork, recorded patient status on notepads, and entered the information into a computer. Anesthesiologists performed sedation and spent more time preparing presedation assessment because of the cumbersome information exchange. The previous paper-based workflow had several limitations, such as the lack of a computerized system to integrate and process information in one place, cumbersome information exchange, and the inability to have a complete view of the entire sedation process. Consequently, nurses and anesthesiologists were compelled to allocate a significant proportion of their time on administrative tasks rather than patient care, and adverse events could be difficult to identify and were even ignored. Therefore, the application of well-computerized systems has been proposed as an effective way to reduce errors and improve the health care services [16,17].

Moreover, previous sedation databases only recorded data regarding sedation implementation, and the data were updated after a complete sedation workflow [18]. PSAMS included data from presedation assessment to postprocedural recovery and discharge and updated the database in a real-time manner. Consequently, the quickly accumulating data collected by PSAMS provided new insights into pediatric sedation.

At our institution, the most common procedure performed after sedation was MRI (n=27,416, 21.5%). Similarly, a retrospective analysis of 109,947 entries for MRI from the Pediatric Sedation Research Consortium, a large multicenter corroboration database containing more than 600,000 sedations, found that MRI was one of the most common imaging procedures requiring sedation [19]. Procedures like MRI and computed tomography (CT) scans require patients to remain still during imaging to ensure scanning quality, which can be difficult for children [20]. In fact, dexmedetomidine is used as a sole drug for noninvasive procedures, such as MRI and CT scans [21]. However, at our institution, we found that the dexmedetomidine alone cannot induce ideal sedation depth and often causes the children to awaken during or even before the MRI procedure. Therefore, a combination of rapidly titratable drugs and rapid onset drugs has been proposed as a standard regimen to improve sedation efficacy in China [4].

Conclusions

In summary, we developed and applied PSAMS for pediatric sedation to meet the increasing demands. This is the first assessment and management system tailored for pediatric sedation. We are actively maintaining and improving PSAMS to optimize individualized sedation protocols, despite the heavy workload.

Abstract

Background: Headaches, including migraines, are one of the most common causes of disability and account for nearly 20% - 30% of referrals from primary care to neurology. In primary care, electronic health record–based alerts offer a mechanism to influence health care provider behaviors, manage neurology referrals, and optimize headache care.

Objective: This project aimed to evaluate the impact of an electronic alert implemented in primary care on patients' overall headache management.

Methods: We conducted a stratified cluster-randomized study across 38 primary care clinic sites between December 2021 to December 2022 at a large integrated health care delivery system in the United States. Clinics were stratified into 6 blocks based on region and patient-to–health care provider ratios and then 1:1 randomized within each block into either the control or intervention. Health care providers practicing at intervention clinics received an interruptive alert in the electronic health record. The primary end point was a change in headache burden, measured using the Headache Impact Test 6 scale, from baseline to 6 months. Secondary outcomes included changes in headache frequency and intensity, access to care, and resource use. We analyzed the difference-in-differences between the arms at follow-up at the individual patient level.

Results: We enrolled 203 adult patients with a confirmed headache diagnosis. At baseline, the average Headache Impact Test 6 scores in each arm were not significantly different (intervention: mean 63, SD 6.9; control: mean 61.8, SD 6.6; *P*=.21). We observed a significant reduction in the headache burden only in the intervention arm at follow-up (3.5 points; *P*=.009). The reduction in the headache burden was not statistically different between groups (difference-in-differences estimate –1.89, 95% CI –5 to 1.31; *P*=.25). Similarly, secondary outcomes were not significantly different between groups. Only 11.32% (303/2677) of alerts were acted upon.

Conclusions: The use of an interruptive electronic alert did not significantly improve headache outcomes. Low use of alerts by health care providers prompts future alterations of the alert and exploration of alternative approaches.

KEYWORDS

headache management; migraine management; electronic health record–based alerts; primary care; clinician decision support tools; electronic health record; EHR

Introduction

Headache disorders are a major public health concern, with migraine being the second most common cause of disability [1]. The frequency of headaches is nearly twice as common in women, adults aged 18 - 44 years, people with low family income (<US $35,000), and Native Americans [2]. Patients with migraines and chronic headaches experience greater than normal use of emergency department (ED) services, with headaches accounting for approximately 3% of all ED visits annually [2]. Headaches also directly impact workplace productivity, with an economic impact estimated to be $19.3 billion in 2019 [3].

Headaches account for up to 30% of referrals from primary care to neurology. Of these, nearly 50% of patients are ultimately diagnosed with migraines, and the majority have never adequately trialed first-line therapy prior to referral [4-7]. Barriers to primary care management of headaches include time constraints, access challenges, and lack of expertise to accurately diagnose and give appropriate treatment [8,9]. These barriers result in high referrals to specialized care, an easier option than drug initiation titration, monitoring, and adjustments. This leads to prolonged wait times, resulting in patients often remaining unmanaged and seeking care in urgent or emergent settings for episodic management [10,11].

The Geisinger system was an early adopter of the electronic health record (EHR) system (beginning in 1996), with its EHR implemented across all sites of care. The use of clinician decision support tools in the form of alerts within the EHR has increased exponentially in recent years [12]. These alerts have been used across different disease states within primary care to provide useful information to clinicians, shape their behaviors, and positively impact patient safety and outcomes [12-14]. Considering the utility of alerts and the challenges described above, we instituted an EHR-based, clinician-facing, interruptive alert that provides real-time guidance on managing patients with headaches to improve headache care before neurology referral. This includes assistance in collecting information about headache characteristics, guidance on medication management, and the opportunity to e-consult with neurology providers. The purpose of this pragmatic randomized controlled trial was to evaluate the impact of the alert on the management of primary headache disorders in primary care settings. We hypothesized that an electronic alert for the management of headaches improves patient-reported headache burden at 6 months among patients with headache managed in primary care.

Methods

Setting

Geisinger is an integrated health care delivery system located in central and northeastern Pennsylvania, serving more than 1 million patients yearly. Geisinger maintains 44 primary care and over 100 specialty clinics, which include 8 neurology practices with 43 neurology physicians all using the same EHR system.

Study Design

We conducted a prospective stratified cluster-randomized controlled trial across 38 primary care sites to assess the impact of an interruptive electronic alert on the management of primary headache disorders. Eligible patients were enrolled and followed for 6 months post index encounter to evaluate headache management-related outcomes. It was uploaded to ClinicalTrials.gov and can be found using the registration number NCT05067725. The trial followed CONSORT (Consolidated Standards of Reporting Trials) reporting guidelines for randomized trials. We have also reported the e-CONSORT per the journal requirements [15].

Site Randomization and Patient Enrollment

In total, 38 of 44 primary care clinic sites were selected for randomization based on their ability to participate. The sites were first stratified into 9 possible blocks based on 2 criteria: geographical location (west, central, or northeast) and patient-to–health care provider ratio (low, moderate, or high). Note that 3 of the 9 possible blocks did not contain any sites, leaving only 6 blocks for this study. Within each block, simple randomization was then used to assign each site to either the intervention or control arm, using a 1:1 ratio. A Microsoft Excel 365 (Microsoft Corporation) random number generator was used to generate the simple randomization allocation sequence. Patients received the treatment to which their site had been assigned, making this a cluster-randomized study with sites as clusters (Multimedia Appendix 1).

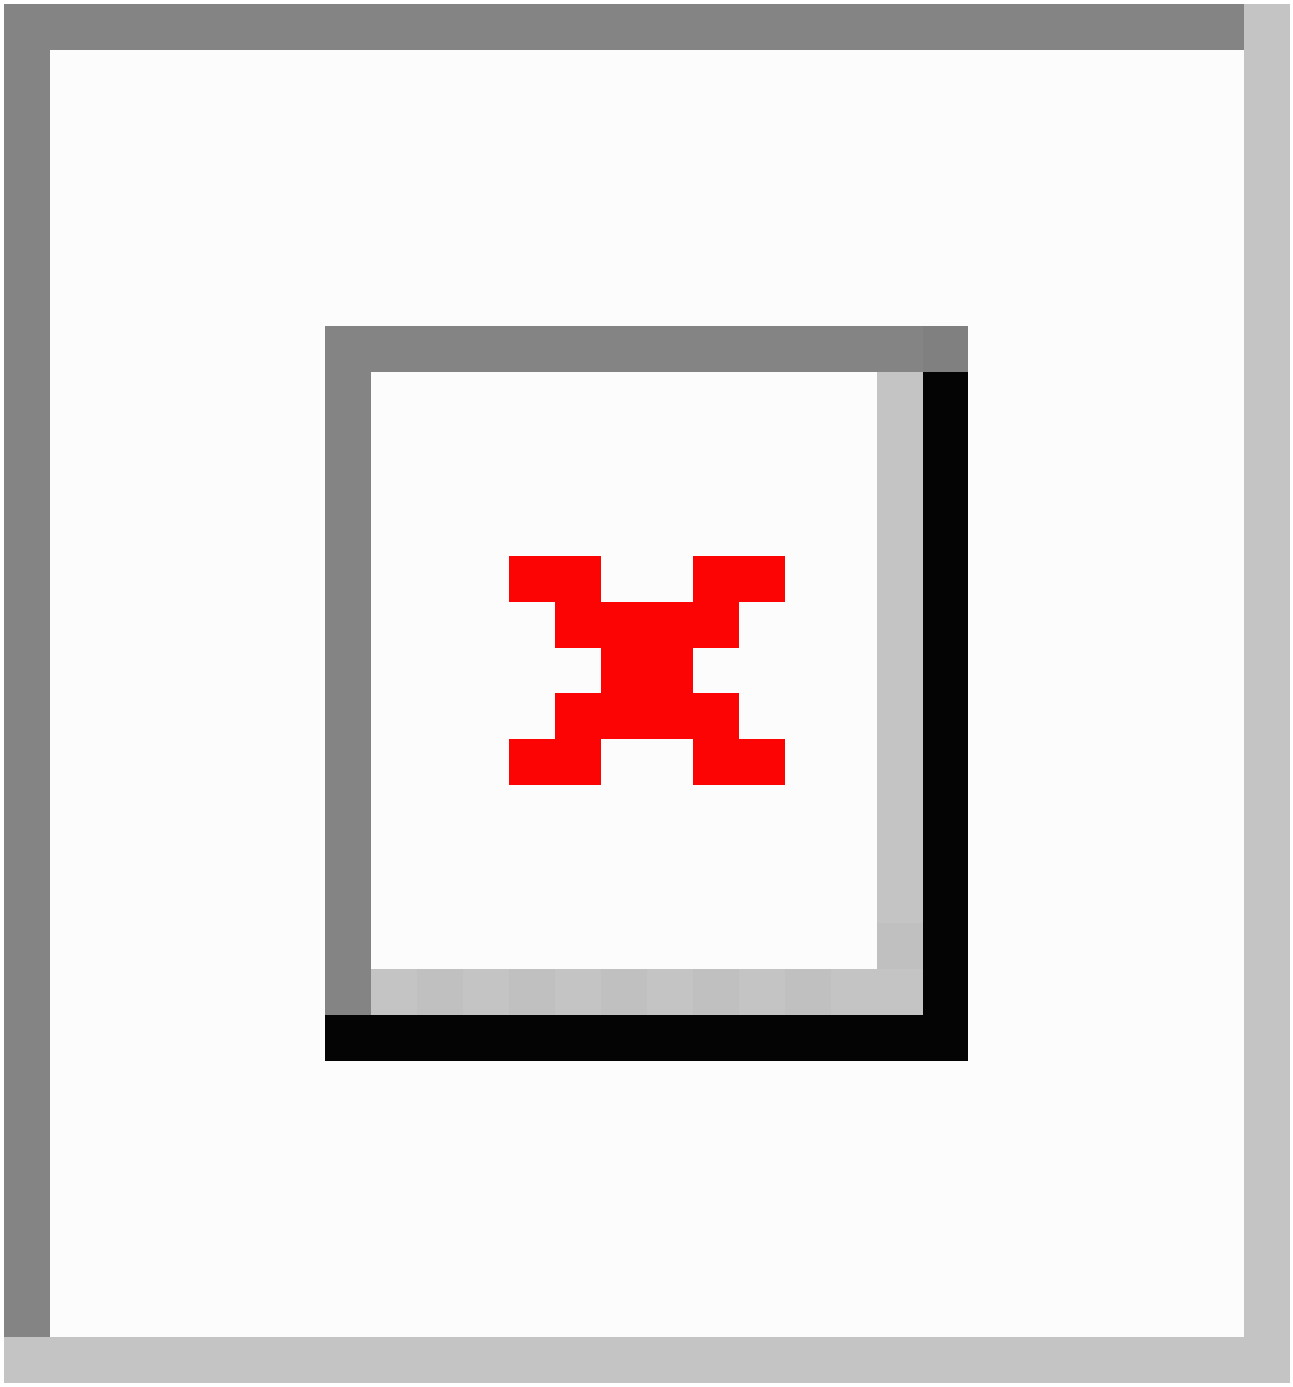
Patient Selection and Enrollment

Patients were eligible if (1) the criteria for the alert were met, which included an in-person or telemedicine encounter and a headache diagnosis or chief complaint of headache (Multimedia Appendix 2); (2) they were aged 18 years or older; and (3) postvisit criteria were met, which included a confirmed diagnosis of primary headache disorder by manual medical record review and a minimum baseline Headache Impact Test 6 (HIT-6) score of 50 or higher or headache frequency of 12 days or greater in the last 3 months. Clinical input and the scale guidance document were used to determine thresholds for HIT-6 scores and headache frequency [16]. Manual medical record reviews were conducted by study team members (HA, AP, and SP) under the guidance of the neurologist (SF) to confirm headache diagnosis. Types of headaches in the analytic sample included migraine, chronic daily, tension-type, cluster, or medication overuse headaches, collectively grouped as “headaches.” Patients were excluded if they had a serious systemic illness (eg, headaches due to hypertensive emergencies, hepatic or renal failure, or cardiac failure), secondary headaches (eg, concussion), were pregnant, or were actively followed with neurology [17]. Patients with serious systemic illness were excluded from our study as it would have been difficult to distinguish whether headaches observed among them were due to primary or secondary factors.

Within 2 weeks after their scheduled visit, eligible patients were contacted by the Survey Research and Recruitment Core to collect baseline measures (which determined minimum headache eligibility) and to gain verbal consent. Patient contact was

attempted 7 times. Figure 1 represents this study's process of patient selection, enrollment, and follow-up.

Figure 1. Patient selection, enrollment, and follow-up.



Intervention

A clinician-facing interruptive EHR-based alert in the form of a Best Practice Advisory was built based on input from an expert panel of neurologists, primary care providers (PCPs), pharmacists, and informaticians. PCPs include primary care physicians and advanced practitioners such as nurse practitioners and physician assistants. The first iteration of the alert was developed based on input received from the needs assessment conducted with the PCPs. This version was piloted at 2 primary care sites over 3 months [18]. Face-to-face education of PCPs at the pilot sites was undertaken to familiarize health care providers with the utility of the alert [18]. A simple pre-post assessment of the 900 eligible patient encounters during this pilot phase demonstrated a significant reduction in neurology referrals post implementation of the electronic alert. Following the pilot implementation, feedback was collected from 10 PCPs at these sites about the structure, verbiage, and utility of the electronic alert. Subsequent modifications were made based on this feedback before full implementation.

The Best Practice Advisory consisted of four parts: (1) a questionnaire to assist the PCP in characterizing the patient's headache (Multimedia Appendix 3); (2) a "SmartSet" guide for ordering medications, imaging, laboratories, and referrals using evidence-based guidelines (Multimedia Appendix 3); (3) a

hyperlink to allow for electronic consultation with a neurologist; and (4) a link to the "synopsis" which provided a summary of prior patient headache care. The "SmartSet" guide could be accessed directly within the alert by clicking on the "Open Express Lane" button to facilitate quick ordering for health care providers. The alert appeared within the EHR when a PCP entered a headache diagnosis for an in-person or telemedicine encounter. All actions taken in the alert were recorded, although health care providers could dismiss them without any action. Suppression criteria were built to lock out and avoid repeated firing of the alert. The alert was suppressed for 24 hours if the dismissal reason was headache-controlled and for 365 days for PCP long-term management. The alert could also be dismissed by acknowledging that the health care provider was previewing the patients' medical record, in this case, the alert would refire during the same encounter.

An invisible or silent alert was activated at control sites that would be triggered by identical criteria to the intervention arm, however, this alert was not visible to the clinicians, so no suppression criteria were developed for control sites. The silent alert was developed to help generate a list of eligible patients for the control group that would be comparable to those identified in the intervention arm.

Before full implementation, the primary care leadership team was encouraged to disseminate information about the tool to PCPs in the intervention cohort through local departmental meetings and direct emails, including text and short video instructions.

Data Collection

Data sources included the EHR and survey results from patients at baseline, 3 months, and 6 months. The surveys conducted by the Survey Research and Recruitment Core included 6 questions from the HIT-6 questionnaire, which measures headache impact on a participant's ability to function in day-to-day life [19]; 1 question on pain intensity; 1 on the frequency of headaches; 3 from the Migraine Treatment Optimization Questionnaire (M-TOQ), which determines if a medication treatment for a participant is optimal; and 2 asking for sociodemographic information that could not be pulled from the EHR [20]. The M-TOQ questions were modified for our study by replacing the word "migraine" with "headache." Prior to study enrollment, the survey was piloted among a sample (n=10) of patients from pilot sites to ensure appropriateness and check for face validity. Patients had the option to opt-out at any time during this study. See Multimedia Appendix 4 for the full survey guide.

Study Outcomes

Primary Outcome—Headache Burden

Headache burden was assessed using the HIT-6 scale [7]. The scale ranged from 36 to 78, and a score of 50 or greater represented a greater impact and disruption of life caused by headache [21,22]. The primary end point was the comparison of changes in HIT-6 scores between arms from baseline to 6 months.

Secondary Outcomes

Secondary outcomes included headache frequency, defined as the self-reported frequency of headache days over the previous 3 months; average headache pain intensity defined by pain on a 10-point analog scale over the same period (0=no pain at all to 10=the worst pain ever); access to care, defined as the proportion of patients referred to neurology; resource utilization, defined as the proportion of patients with an ED-visit (all-cause and headache specific); and medication management, defined as the proportion of patients that initiated preventive or abortive medications for headache [7,23]. Referral to neurology was used as a surrogate measure to represent access to neurological care considering that the availability of a timely neurology appointment impacts the volume of referrals.

Implementation Outcomes

We assessed the adoption of the alert among health care providers through actions within the alert. Positive adoption was any activity where the health care provider interacted with the components of the alert such as completing the headache questionnaire, using the SmartSet, or using the synopsis. We also reviewed feedback provided by PCPs from reports generated by a committee that oversees all EHR-based alerts.

Several modifications to the initial analysis plan were implemented following go-live but before analysis. We omitted some secondary outcomes, including time to initiation of treatment in treatment naïve patients and M-TOQ outcomes. The data on the M-TOQ were only available at baseline eliminating any pre-post analysis, and the time to initiation of medication in naïve patients was dropped in favor of initiation of treatment in all patients as a binary outcome. We added a referral to neurology due to its relevance to clinical practice. All these changes were updated on the ClinicalTrials.gov website to ensure reporting transparency. We also updated our analytical approach from generalized linear models with robust SEs in the analytical plan to generalized estimating equations (GEE), a specialized generalized linear model approach. After further internal discussion, we felt given that the outcomes data were longitudinal and correlated due to clustering, GEE were better suited.

Sample Size Calculation

A minimum difference of equal to or greater than a 2.3-point (SD 4.3) reduction on the HIT-6 scale represents a clinically important and significant change [22]. We needed to enroll at least a total of 66 patients per arm to detect this change with 80% power at a significance level of .05 and an intraclass correlation of 0.02. The sample size was calculated using an online calculator developed by the University of California San Francisco [24].

Statistical Analysis

The total number of patients in each arm was counted to ensure a balanced distribution of patient numbers. Descriptive statistics were computed for continuous variables as means or medians with SD or IQRs, and as frequency and percentages for categorical variables when appropriate for baseline patient-reported outcomes and socioeconomic and demographic characteristics (ie, sex, age, race, ethnicity, insurance, education,

and income). Appropriate statistical tests were used to compare differences in these characteristics between the 2 groups and within groups: 2-tailed independent *t* tests or paired *t* tests were used for continuous data, χ^2 for categorical data, and Mann-Whitney for nonnormal categorical or continuous data.

We constructed GEE for all outcome comparisons between groups, adjusting for effects of treatment, phase (baseline, 6 months), treatment-by-phase interaction, and demographics while accounting for clustering of patients per primary care site. The GEE model with log link was used, considering the skewness of data observed for headache days and pain scores (Multimedia Appendix 5). For all the binary variables, a log link with binomial distribution was used, while an identity link with normal distribution was used for HIT-6 scores. As a first step, we performed an unadjusted GEE model with this study's groups as only a univariate analysis. Multivariable (adjusted) models only included demographic variables that were significantly different between groups (P<.05). For the GEE analysis, we reported odds ratios or estimates and associated CIs. All analyses were conducted using SAS Enterprise Guide software (version 8.3 for Windows; SAS Institute Inc).

The analysis was conducted based on the principle of "intention-to-treat (ITT)" analysis. All patients who consented and met the inclusion criteria were included in the analysis per the group they were recruited into. The analysis was performed to assess the difference in outcomes at the individual patient level. For missing data via survey collection, we applied a last observation carried forward (LOCF) technique to maximize the number of observations available for analysis [25]. The results from the LOCF technique were further compared to those from the measured data to assess the impact of loss to follow-up.

Ethical Considerations

This study was an evaluation of a quality improvement initiative that was undertaken at Geisinger with the intent to affect clinical practice. As a result, it was determined as "not human subjects research" by Geisinger's institutional review board (2021 - 0729).

Results

Overview

The alert was fired for a total of 9239 times in 3183 patients (intervention arm: 2677 times in 1507 patients; control arm: 6562 times in 1676 patients) between December 2021 and February 2022. We excluded 1828 patients for not meeting eligibility criteria. We manually verified the diagnosis of primary headache among 729 of the remaining 1355 patients who were eligible for consent and baseline survey assessment. We obtained verbal consent from 221 patients at baseline but only enrolled the 203 patients that either had an HIT-6 score of ≥50 or a headache frequency of >12 days, as per our inclusion criteria (Figure 1). At the end of 6 months, follow-up patient-reported data were available for 88/203 (43.3%) patients.

All baseline characteristics were similar between groups for patients enrolled in this study except for mean age, which was higher in the intervention group (mean 43, SD 14.4 y vs mean 39, SD 14.4 y, P=.04; Table 1). There was no difference in the HIT-6 scores, headache frequency and intensity, or patient-reported use of medications at baseline between groups (HIT-6 scores: mean 63, SD 6.9 vs mean 61.8, SD 6.6; headache days in the past 3 months: median 20.5, IQR 10.0 - 45.0 vs median 20, IQR 10.0 - 45.0; pain scores: median 7, IQR 6.0 - 8.0 vs median 7, IQR 5.0 - 8.0; reported use of preventive or abortive medications: 63/98, 64% vs 57/105, 54.2%). The majority of the patients were female, were White, were non-Hispanic, had a commercial insurance plan, had an educational qualification of greater than high school, and had an annual household income between US $50,000 to US $100,000. Similarly, there was no statistically significant difference in the baseline characteristics observed between groups for patients that completed the 6-month follow-up.

Table . Patient characteristics at baseline.

[b]HIT-6: Headache Impact Test 6.

Primary Outcome—Headache Burden

HIT-6 scores improved significantly from baseline in the intervention arm at 6 months (3.5 points; *P*=.009) but not in the control group (1.40 points; *P*=.23); additionally, the improvements from baseline did not differ significantly between groups (Table 2). The intracluster correlation coefficient observed was 0.411 for HIT-6 scores.

Table . Adjusted primary and secondary outcomes of headache burden, frequency, and intensity.

Outcome and arm	Phase	n	Mean (SD)	Change, mean (SD)	D-I-D[a] estimate, regression coefficients (95% CI)	*P* value
HIT-6[b] score					–1.84 (–5 to 1.31)	.25
Intervention				–3.5 (7.9)[c]

[b]HIT-6: Headache Impact Test 6.

[c]*P*=.01.

Secondary Outcomes

Change in the number of headache days and pain score did not differ between groups (Table 2). Similarly, compared to baseline, there was no difference in the proportion of patients being referred to neurology, using ED for all-cause or headache-specific reasons, or initiating new abortive or preventative treatment in the 6 months post intervention (Table 3).

Table . Percent change in the proportion of patients from baseline to 6 months and adjusted odds ratio estimates for resource use and access to care (note: a negative or positive percentage denotes a decrease or increase post recruitment).

Outcome and arm	Phase	Use, n (%)	Percent change	D-I-D[a] estimate, odds ratio (95% CI)	*P* value
ED [b] use (all-cause)				1.4 (0.58 to 3.36)	.46
Intervention (n=98)			–2.0

Results from the LOCF models for HIT-6 scores, headache days, and pain intensity are listed in Table 4. Findings from the LOCF models were similar to those from the base models presented in Table 2. It was observed that there was a similar significant improvement in HIT-6 scores in the intervention arm, and a reduction in the headache days in the control arm from baseline to 6 months, however, the difference between groups was not statistically significant.

Table . Adjusted primary and secondary outcomes of headache burden, frequency, and intensity using the LOCF[a] method.

Outcome and arm	Phase	N	Mean (SD)	Change, mean (SD)	D-I-D[b] estimate, regression coefficients (95% CI)	*P* value
HIT-6 score					–1.01 (–2.87 to 0.85)	.29

Implementation Outcomes

Of the 2677 alert firings in the intervention arm, 2228 (83.23%) were overridden or dismissed, 146 (5.45%) were ignored, and 303 (11.32%) action was taken. Of the 205 PCPs exposed to the intervention alert, 15 provided feedback, 3 found the alert helpful, and 12 expressed dissatisfaction due to alert firing on inappropriate patients or noting the alert was disruptive to workflow. A manual medical record review of 1355 patients revealed that 729 (53.80%) had a confirmed diagnosis of primary headache disorder. The remaining 626 (46.20%) either did not have a confirmed diagnosis of primary headache disorder or were already followed by neurology for headaches.

Discussion

In this pragmatic clinical trial across 38 clinics, we found no benefit of the electronic alert as designed on headache outcomes. As the alert was based on evidence-based guidelines for diagnosis and treatment, it seems unlikely that the content of the alert was poor and more likely that the lack of impact was due to gaps in implementation.

This is the first study to offer a clinician decision support tool that guided PCPs in diagnosing and appropriately treating patients with different types of primary headache disorders using an episodic electronic alert. Most of the research studies to date focus on a single type of headache disorder, chronic headaches, or migraines [23,26]. As initial preventative treatment for the most common headache types is similar, our alert was designed to be used across them as a one-stop access to help diagnose and treat headaches and e-consult with neurologists if required.

Even though we did notice improvements in several outcome measures in both the intervention and control arms from baseline to 6-month follow-up, on a between-groups comparison, the effects did not hold. A similar trend for improvement from baseline in outcomes such as HIT-6 scores and headache days was observed when an LOCF approach was used, but the effect

did not hold for between-group comparisons. Using our pragmatic design, we were able to distinguish between expected improvements in headaches over time and those attributed to the intervention using a comparator group, with largely similar characteristics except by age at baseline [27]. Past research studies that have evaluated the impact of headache management programs and found improvement in patients' headache burden and resource use have often used a pre-post study design which makes attribution of success to the intervention difficult [17,23]. Our results have substantial implications, as identification of the ineffectiveness of these types of alerts is necessary to determine which should remain active and which should be either deactivated or revised. Only a well-designed test of comparison with a suitable counter-factual arm (ie, control) can distinguish improvements due to bias (eg, regression to the mean) versus the intervention itself.

The total number of unique patients for whom the alert fired was relatively similar between groups, but the alert fired 2.2 times more frequently in the control arm. This is to be expected, as in the interventional arm, the interruptive alert that was visible to the health care providers could be suppressed for the duration of the encounter by acknowledging a reason for dismissal, as opposed to the silent or invisible alert in the control arm. Health care providers also noted several challenges with alert firing such as confusion with multiple components of the alert, concerns over alert firing for inappropriate patients and appearing at times other than during direct patient contact, and trouble dismissing the alert, highlighting flaws with the existing alert design. Medical record reviews illustrated that health care providers often list headaches as not just chief complaints but also visit diagnoses, due to headaches often being a symptom of other underlying conditions. The inaccurate use of headache as a visit diagnosis led to the alert's misfiring in nearly 40% of our patients. It also complicates the firing logic for decision support tools such as ours. Research shows that the nonspecificity of alerts may desensitize clinicians and lead to habituation, thereby lessening their likelihood to follow alert recommendations or guidance [28,29]. Furthermore, even when firing appropriately, health care providers reported the location of the alert to be disruptive to their normal workflow. Some of the challenges mentioned could be attributed to the health care providers not having received sufficient education about the alert. The majority of the health care providers did not recall having seen or received any education about the alert despite efforts to disseminate this information through emails, fact sheets, and videos. This highlights an implementation gap and the need for a more engaged educational outreach in primary care settings.

Much of the feedback and low adoption found in our study affirms prior reports of alert fatigue experienced by health care providers in primary care settings and is likely to be the main contributor to the lack of significant impact [30]. With only 11.32% (303/2677) of alerts being acted upon, we can expect only this fraction to benefit from the intervention. Yet, research does not support the notion that prior alert exposure has a carry-forward impact on the care of future patients; suggesting that future recognition of patients and bypassing of alerts does not have a strong persistence of effect on health care provider action behaviors [28,29,31].

The lack of positive outcomes within the intervention arm was unexpected, considering the detailed human-centered design-build, the engagement of pilot PCPs, and the early feedback received, which was affirmative for the intervention. Slight modifications to the verbiage within the alert were undertaken based on feedback from the pilot health care providers before its full-scale implementation. Despite this, we noted low use of the features present within the alert and additional adoption challenges that were not fully uncovered in the pilot period. These results are similar to other studies published using human-centered design, which failed to translate into adoption and outcome differences [32-35]. These studies have found that better engagement by pilot health care providers does not always translate to all health care providers at the time of scaling interventions. Additionally, differences in the mechanism used for delivering training between the pilot and full implementation phase also impact the uptake of the intervention [32-35]. Furthermore, the positive findings and feedback from the pilot phase could be influenced by commitment and congruence bias in addition to observation and measurement bias resulting in a Hawthorne effect of the intervention [36].

Considering the challenges identified in this study, post completion we made significant modifications to the tool. First, we redesigned the identification of the patients to make it more specific (but less sensitive) to the targeted patient population. We repositioned the alert to fire at the time of neurology referral as opposed to when assigning a visit diagnosis or chief complaint. We also recognize that an EHR-only intervention is not the only mechanism to address incomplete headache care, and a pilot initiative involving pharmacist-based medication management has been launched. Research is currently underway to assess the impact of this pilot.

We recognize several limitations to our study. First, given the single-site design of this study, generalizability to other sites is limited and likely influenced by variations in practice environments and standards of practice. Our use of an alert was largely driven by our integrative health care environment, the ubiquitous use of EHR across primary care and specialty health care providers, and the low cost and light maintenance of the alert. Second, while an LOCF method was used to reduce the effect of a type II error, the high attrition rate observed might have affected the magnitude of the impact. We recognize that other interventions to address the optimal treatment of headaches do exist and are worthy of consideration. Programs that involved greater manpower and dedicated professionals for follow-up and management observed significant improvement in their patients' headache burden and headache-related disability or reduced resource use, and attributed their success to the dedicated personnel [23,26]. Alternatively, programs that solely relied on physician education or leveraging existing clinical pathways, while at times cost-saving, did not significantly improve patients' headache burden or quality of life [7,21]. Most of these existing studies have been standalone initiatives that focused on headache-specific work groups with limited generalizability of results, some of which are no longer in effect

due to resource and infrastructure constraints. Our objective was to sustainably change the culture of practice surrounding headache care without creating new standalone avenues. In conclusion, our study found that the implementation of an interruptive electronic alert in primary care to aid diagnosis and management of primary headache disorders did not improve headache care for patients. Low adoption of the tool by the health care providers has prompted the development of alternative population health–based approaches to improve headache management.

Acknowledgments

We would like to thank Neil R Holland, MBBS, MBA, MSMEd; Aubrielle C Smith-Masri, PharmD; Alex Skitolsky, BA, MFA; Maria Kobylinski, MD; the Survey Research and Recruitment Core (SRRC) at Geisinger; and the primary care providers and patients at Geisinger for their contributions to this study. We would also like to thank Duncan Dobbins, BSPF, PharmD for his creation of our paper's table of contents image.

Authors' Contributions

Conception and design were done by AP, EAW, LW, and SF. Acquisition of data was handled by AP, VAH, HA, and SP. Analysis and interpretation of data were performed by AP, JB, MS, and JG. All authors (AP, EAW, VAH, JB, MS, LW, HA, SP, JG, and SF) drafted this paper, revised it for intellectual content, and gave final approval of this completed paper.

Abstract

Background: With the capability to render prediagnoses, consumer wearables have the potential to affect subsequent diagnoses and the level of care in the health care delivery setting. Despite this, postmarket surveillance of consumer wearables has been hindered by the lack of codified terms in electronic health records (EHRs) to capture wearable use.

Objective: We sought to develop a weak supervision–based approach to demonstrate the feasibility and efficacy of EHR-based postmarket surveillance on consumer wearables that render atrial fibrillation (AF) prediagnoses.

Methods: We applied data programming, where labeling heuristics are expressed as code-based labeling functions, to detect incidents of AF prediagnoses. A labeler model was then derived from the predictions of the labeling functions using the Snorkel framework. The labeler model was applied to clinical notes to probabilistically label them, and the labeled notes were then used as a training set to fine-tune a classifier called Clinical-Longformer. The resulting classifier identified patients with an AF prediagnosis. A retrospective cohort study was conducted, where the baseline characteristics and subsequent care patterns of patients identified by the classifier were compared against those who did not receive a prediagnosis.

Results: The labeler model derived from the labeling functions showed high accuracy (0.92; F_1-score=0.77) on the training set. The classifier trained on the probabilistically labeled notes accurately identified patients with an AF prediagnosis (0.95; F_1-score=0.83). The cohort study conducted using the constructed system carried enough statistical power to verify the key findings of the Apple Heart Study, which enrolled a much larger number of participants, where patients who received a prediagnosis tended to be older, male, and White with higher CHA_2DS_2-VASc (congestive heart failure, hypertension, age ≥75 years, diabetes, stroke, vascular disease, age 65-74 years, sex category) scores (P<.001). We also made a novel discovery that patients with a prediagnosis were more likely to use anticoagulants (525/1037, 50.63% vs 5936/16,560, 35.85%) and have an eventual AF diagnosis (305/1037, 29.41% vs 262/16,560, 1.58%). At the index diagnosis, the existence of a prediagnosis did not distinguish patients based on clinical characteristics, but did correlate with anticoagulant prescription (P=.004 for apixaban and P=.01 for rivaroxaban).

Conclusions: Our work establishes the feasibility and efficacy of an EHR-based surveillance system for consumer wearables that render AF prediagnoses. Further work is necessary to generalize these findings for patient populations at other sites.

Introduction

Background

Consumer-facing devices such as the Apple Watch [1] and Fitbit [2] now have the capability to notify users with a *prediagnosis* such as atrial fibrillation (AF). As these notifications may incentivize patients to seek follow-up medical care, wearables now have the potential to affect diagnosis rates and initiate cascades of medical care [3,4]. Although these devices undergo premarket validation to obtain Food and Drug Administration (FDA) clearance [5], limited information exists on their postmarket use and clinical utility.

To conduct *postmarket surveillance* on consumer wearables, electronic health records (EHRs) should capture wearable use, in particular those incidents where patients received prediagnosis notifications. However, EHRs are often built around medical diagnosis codes used for billing purposes [6,7], which do not contain terms for describing wearable use. Prescription wearables should have ordering information, but this does not capture how the wearables are used. Therefore, unstructured data such as clinical notes must be parsed to obtain the wearable use information.

Deep learning–based natural language processing (NLP) methods [8-10] have been shown to outperform traditional approaches on clinical note classification tasks [11,12]. However, these deep learning–based classifiers require large, hand-labeled training sets that are costly to generate. For EHR-based postmarket surveillance to be widely implemented, a scalable approach is necessary to reduce the labeling burden.

Objectives

We aimed to demonstrate the feasibility and efficacy of postmarket surveillance on consumer wearables that render AF prediagnoses. The first aim of this study was to evaluate the efficacy of a weakly supervised approach to heuristically generate labels for a training set. A *labeler model* derived from programmatically expressed heuristics probabilistically assigns labels to clinical notes regarding whether the note contains a mention of the patient receiving a prediagnosis from a wearable. The second aim was to evaluate the performance of a *classifier* fine-tuned on the training set labeled by the labeler model, which identifies mentions of an AF prediagnosis in a note. The third aim was to summarize the clinical characteristics of patients identified by the classifier and compare them to patients who were not alerted to a prediagnosis.

Methods

Cohort Identification

We used the Stanford Medicine Research Data Repository (STARR) data set [13], which contains EHR-derived records from the inpatient, outpatient, and emergency department visits at Stanford Health Care and the Lucile Packard Children's Hospital. We retrieved all clinical notes from the STARR data set that contain a mention of a wearable device (Textbox 1), resulting in 86,260 notes from 34,329 unique patients. Following the FDA guidance for pertinent cardiovascular algorithms [5], we excluded patients younger than 22 years of age when the note was written, leaving 78,323 notes from 30,133 unique patients. We further limited the data set to notes written on or after January 1, 2019, since the first consumer-facing AF detection feature became available in December 2018 [14]. The resulting cohort comprised 56,924 notes from 21,332 unique patients.

Textbox 1. Search terms for wearable devices.

Apple watch, iwatch, applewatch, fitbit, fit bit, fit-bit, galaxy watch, samsung watch, google watch, kardia, alivecor, alive cor, wearable, smart watch, and smartwatch

To evaluate the performance of the labeler model and the classifier, we constructed a test set by manually labeling 600 notes. Specifically, we randomly selected 600 unique patients and then selected 1 note for each patient that contained *action terms* (Textbox 2) in the vicinity (30 characters) of a wearable mention. This was to filter out nonrelevant wearable descriptions (eg, boilerplate texts recommending the use of wearables during meditation), so that resulting notes are enriched with relevant use cases.

Textbox 2. Action terms used to enrich sample relevance.

Alert, notify, warn, observe, identify, detect, note, record, capture, show, report, give, alarm, register, read, tell, have, had, see, saw, receive, get, got, notice, check, and confirm

These notes were then labeled independently by 2 data scientists, and differences were adjudicated by 2 physicians. A clinical note was labeled as positive when the patient received an automated AF notification from the wearable, or when the patient initiated an on-demand measurement (eg, electrocardiogram strip) that resulted in an AF prediagnosis. There were no instances where the 2 physicians disagreed on the label. The resulting test set contained 105 positive notes (prevalence=0.18).

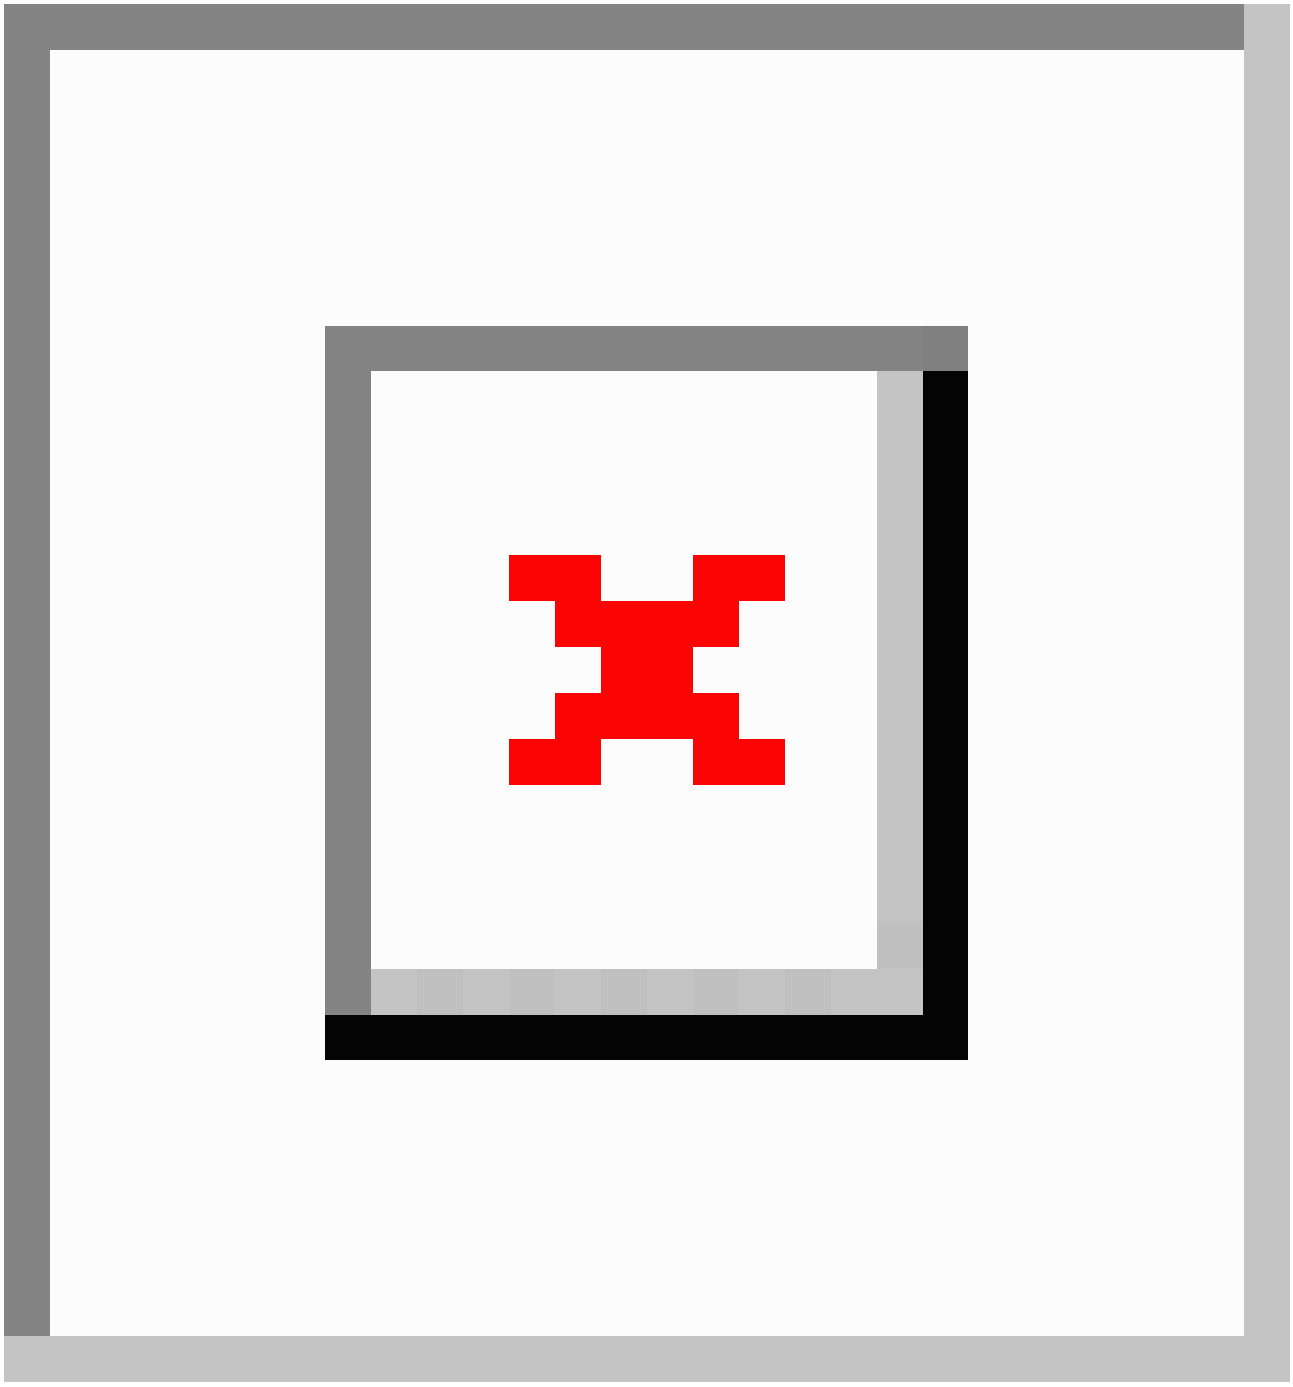
In addition to the test set, we prepared a development set of 600 notes that was used to aid the development of the labeler model. This set was manually labeled by a single data scientist, using a labeling guideline (Multimedia Appendix 1) that was developed as part of the test set generation. The development set contained 100 positive notes (prevalence=0.17).

Labeler Model Derivation

We then derived a labeler model that used weak supervision to probabilistically assign labels for the training set. Specifically,

as shown in Figure 1, we used data programming [15], where labeling heuristics are expressed as code-based *labeling functions*. Using the encoded heuristics, the labeling functions make predictions as to which label a clinical note should be assigned. Predictions from these labeling functions are then combined to develop a generative *labeler model*.

Figure 1. Labeler model generation process. Labeling heuristics were expressed as code-based labeling functions. Snorkel [16] then applied the labeling functions to the sample clinical notes and fit a generative model on the predictions of the labeling functions. The resulting labeler model probabilistically assigns a label to a clinical note based on whether the note mentions the patient receiving an AF prediagnosis from the wearable device. AF: atrial fibrillation.



We used the Snorkel framework [16] to implement data programming. A preprocessing framework [17] was applied to our notes to split them into sentences using the spaCy [18] framework, with a specialized tokenizer to recognize terms specific to medical literature. Thus parsed grammatical information was made available to the labeling functions as metadata.

We then used the development set to understand how the AF prediagnosis was described, and we expressed each pattern as a labeling function. The development process was iterative, where the Snorkel framework allowed us to observe the predictive values of the labeling functions on development set records. Each function could then be further optimized to reduce the differences between predictive values and actual labels, leading to overall performance improvement on the development

set. Textbox 3 shows all the terms that were identified as denoting AF. Negations were properly handled.

Once developed, we applied the labeling functions on the samples and then instructed Snorkel to fit a generative model on the output. Specifically, we used 10-fold cross-validation on the test set and chose the labeler model with the best F_1-score. This model was then applied to the entire corpus of 56,924 notes to probabilistically assign labels.

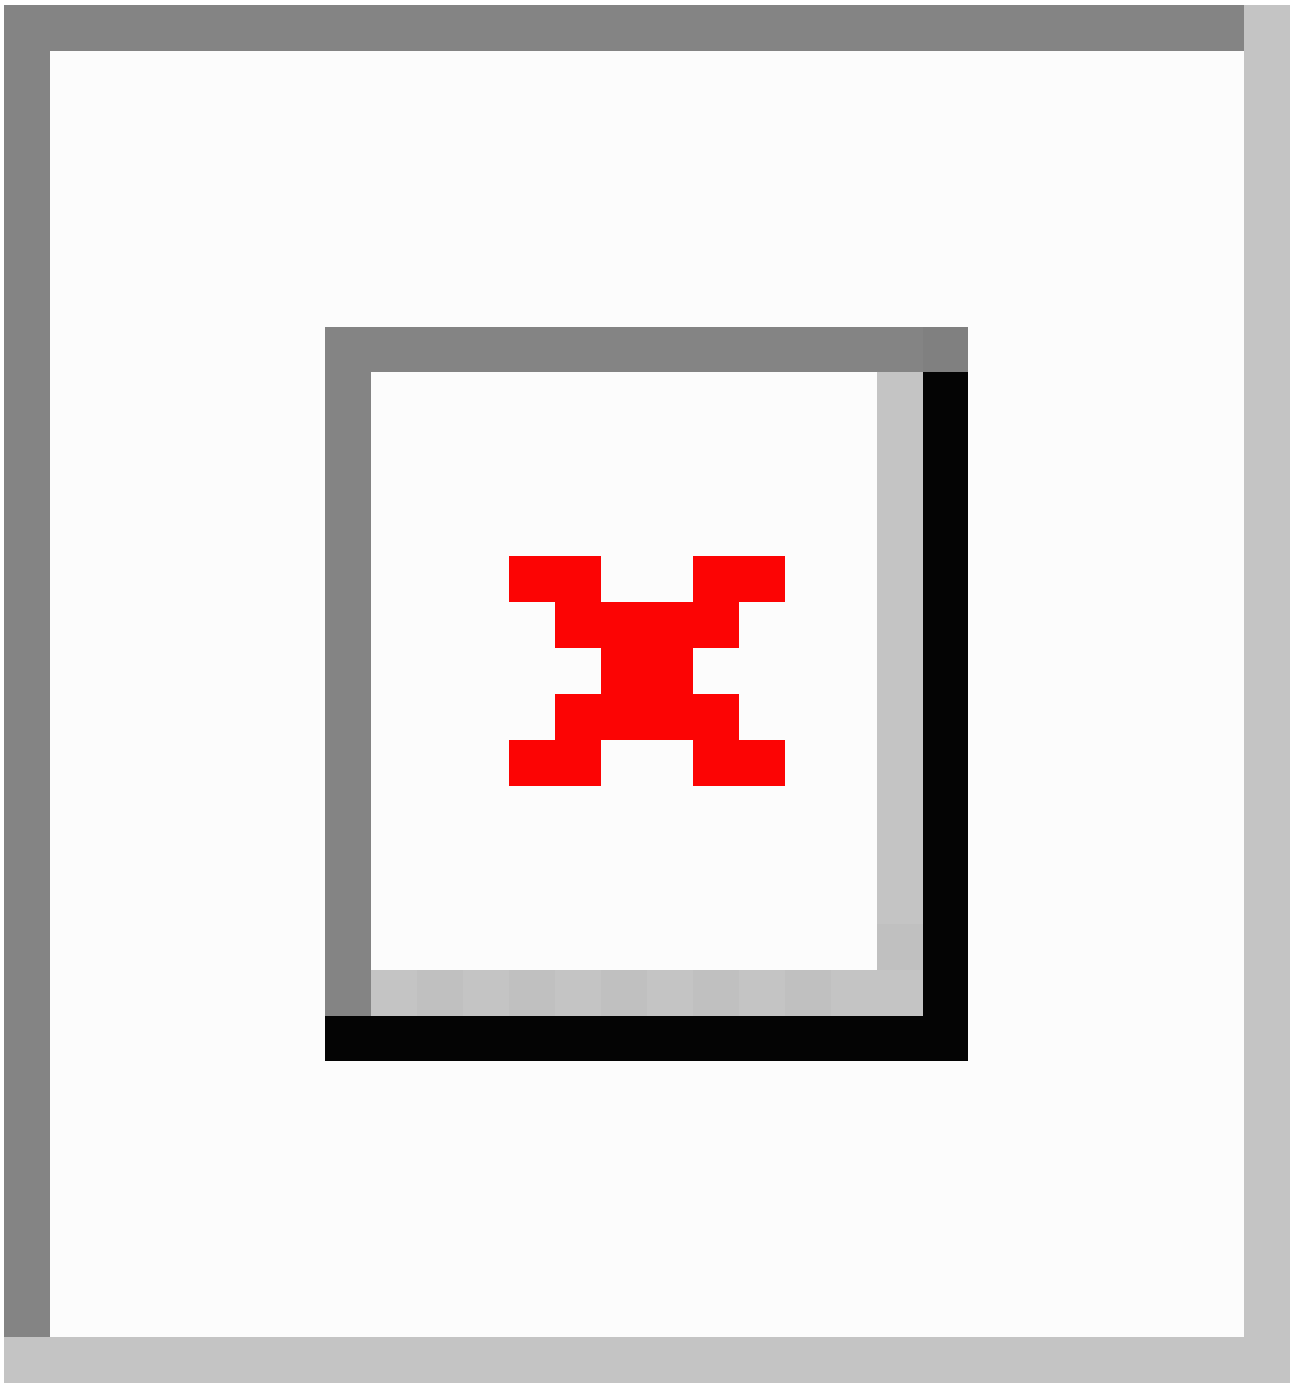
Textbox 3. Terms denoting atrial fibrillation.

Af, afib, a-fib, a.fib, arrhythmia, paf, atrial fibrillation, a. fib, a fib, atrial fib, atrial arrhythmia, irregular heartbeat, irregular hr, irregular rhythm, irregular pulse, irreg hr, irregular heart beat, irregular heart rhythm, irregular heart rate, irreg heart rhythm, irreg heart beat, irreg heart rate, abnormal ekg rhythm, paroxysmal atrial fibrillation, a. fib, a - fib, pafib, abnormal heart rhythm, abnormal rhythm, abnormal HR, and arrhythmia

Classifier Fine-Tuning

Notes that were probabilistically labeled by the labeler model were then used to fine-tune a large, NLP-based classifier: Clinical-Longformer [12] (Figure 2). The resulting classifier takes plain note text as the input and classifies the note as positive (ie, includes mention of a patient receiving an AF notification, or patient-initiated cardiac testing or electrocardiogram resulting in an AF prediagnosis) or negative. When a classifier is tuned on the labeler model output, it enables generalizing beyond the labeling heuristics encoded in the labeling functions, such that the classifier can recognize more patterns.

Figure 2. Classifier generation process. The labeler model was used to probabilistically assign labels for a large number of unlabeled clinical notes, which were then used to fine-tune a classifier to detect whether a patient received an AF prediagnosis from a wearable device. AF: atrial fibrillation; NLP: natural language processing.



Specifically, we fine-tuned the pretrained Clinical-Longformer for the sequence classification task, with varying training set sizes. For a single fine-tuning run, we chose the snapshot with the best F_1-score on the test set as the representative. The Adam optimizer was used, with the learning rate ramping up to 1×10^{-5} followed by linear decay over 3 epochs. Clinical-Longformer has a maximum input length of 4096 subword tokens: 94% (53,509/56,924) of our notes fit this criterion, and notes with more tokens were trimmed. Fine-tuning other NLP-based classifiers (eg, ClinicalBERT [11], which takes a smaller number of input tokens [512 or fewer]) resulted in abysmal performance numbers (F_1-score=0.21), hinting that they could not be properly fine-tuned on our lengthy clinical notes.

The test set was never presented to the classifier during the fine-tuning process. Since our data set was highly skewed toward negative samples, we stratified the training set to maintain a 1:2 ratio between the positive and negative notes. All samples were chosen randomly.

The classifier with the best F_1-score was then run across the entire set of 56,924 clinical notes to identify all incidents of AF prediagnoses.

Retrospective Cohort Study

Using the classifier, we identified patients who received an AF prediagnosis and performed 3 retrospective cohort studies comparing the characteristics of patients who received a prediagnosis to those who did not, using the same STARR data set.

First, we considered all the patients in the cohort regardless of their prior AF diagnosis. We compared the demographics, CHA_2DS_2-VASc (congestive heart failure, hypertension, age ≥75 years, diabetes, stroke, vascular disease, age 65-74 years, sex category) [19] score, and its related comorbidities on the date the index note was created. We defined the oldest note with a prediagnosis as the index note since it was the most likely to drive downstream medical intervention. When a patient had not received any prediagnosis, the oldest note with mention of a wearable was chosen as the index.

Second, we focused on patients who did not have a prior AF diagnosis. A patient was filtered out if the patient had received an AF diagnosis, defined as an ambulatory or inpatient encounter with SNOMED code 313217 and its descendants, prior to the index note. We then compared the same demographics and comorbidities between those who received a prediagnosis and those who did not, on the date the index note was created.

Lastly, we further confined the analysis to patients who received a clinician-assigned AF diagnosis within 60 days from the index note. Same as before, we excluded patients who had a prior AF diagnosis before the index note. Patients were then grouped based on whether they had received an AF prediagnosis from a wearable and characterized on the date they received the index AF diagnosis. In addition to the demographics and comorbidities, we also compared anticoagulant medication (Textbox 4), rhythm management medication (Textbox 5), and cardioversion rates between the 2 groups. Only the index prescription and procedure that took place within 60 days from the index diagnosis were considered.

Textbox 4. Anticoagulant medications analyzed in this study.

Warfarin

Direct oral anticoagulants

- Apixaban, dabigatran, rivaroxaban, edoxaban, and betrixaban

Textbox 5. Rhythm management medications analyzed in this study.

Class I antiarrhythmics

- Propafenone, disopyramide, quinidine, mexiletine, and flecainide

Class II antiarrhythmics

- Metoprolol, carvedilol, labetalol, nadolol, propranolol, carteolol, penbutolol, pindolol, atenolol, betaxolol, bisoprolol, esmolol, nebivolol, and timolol

Class III antiarrhythmics

- Sotalol and dofetilide

Class IV antiarrhythmics

- Verapamil, diltiazem, nicardipine, amlodipine, felodipine, nifedipine, isradipine, and nisoldipine

Others

- Digoxin

Statistical Analysis

When compiling patient race and ethnicity information, we used the 5 categories of race defined by the US Census and denoted Hispanic as a dedicated ethnicity. A total of 11.12% (2371/21,327) of the patients were missing race and ethnicity information, so we categorized them as belonging to the *undisclosed* category.

For hypothesis testing, we used the 1-tailed Welch *t* test for continuous variables and χ^2 test for categorical variables. One-tailed tests were chosen over 2-tailed tests since clinical contexts helped establish the comparison direction, providing for a stricter analysis. Statistical analysis was performed using *Pandas* [20] 1.3.0 and *SciPy* [21] 1.7.0, running on Python 3.9.6 configured through Conda 4.5.11.

Ethical Considerations

The STARR data set is derived from consented patients only. Patients were not compensated for participation. Data analyzed in this study were not deidentified, but its analysis was conducted in a HIPAA (Health Insurance Portability and Accountability Act)–compliant, high-security environment. The Stanford University Institutional Review Board approved this study (62865).

Results

Labeler Model Performance

In total, 8 labeling functions were developed. Most (7/8, 88%) labeling functions used the grammatical information present in the metadata, whereas 1 (12%) used a simple dictionary-based lookup. Table 1 provides the performance of each labeling function, followed by the combined labeler model.

Since each labeling function was geared toward identifying positive samples that follow a specific pattern, each labeling function exhibited substantially higher precision than recall. By combining these labeling functions into 1 generative labeler model, we improved recall (0.72). The high labeler model accuracy (0.92) also showed that the model correctly classified negative samples. After running the labeler model on the set of 56,924 clinical notes, 5829 notes were flagged as positive, a substantial increase from the 105 positive notes identified through manual labeling.

Table . Labeling function (LF) and labeler model performance[a].

Function or model	Target pattern	Example	Precision[b]	Recall[c]	F_1-score[d]	Accuracy[e]
LF1	Simple dictionary lookup	"AF" and "wearable" and "notification"	0.90	0.33	0.51	0.87

[a]Averages taken from 10-fold cross-validation on the test set of 600 manually labeled notes. Italic numbers indicate the best observed performance for each metric.

[b]Precision = true positive / (true positive + false positive).

[c]Recall = true positive / (true positive + false negative).

[d]F_1-score = 2 × precision × recall / (precision + recall).

[e]Accuracy = (true positive + true negative) / (positive + negative).

[f]AF: atrial fibrillation.

[g]Prep: preposition.

[h]N/A: not available.

Classifier Performance

Here, we report the performance of the classifier that was fine-tuned using the clinical notes labeled by the labeler model. Table 2 shows the average performance of the classifier on the test set, across varying training set sizes. The training set size was capped at 15,000 to maintain the 1:2 positive-to-negative ratio (the labeler model labeled 5829 notes as positive). Regardless of the training set size, the test set was excluded from the input to the fine-tuning process.

Table . Classifier performance across varying training set sizes[a].

Training set size	Precision[b]	Recall[c]	F_1-score[d]	Accuracy[e]
600	0.37	0.68	0.48	0.73
5000	0.79	*0.85*	0.81	0.93
10,000	0.84	0.81	*0.83*	*0.94*
15,000	*0.85*	0.81	*0.83*	*0.94*

[a]For each training set, average values are reported across 3 runs with different random seeds. For each run, the classifier snapshot with highest F_1-score was used. Italic numbers indicate the best performance observed for each metric.

[b]Precision = true positive / (true positive + false positive).

[c]Recall = true positive / (true positive + false negative).

[d]F_1-score = 2 × precision × recall / (precision + recall).

[e]Accuracy = (true positive + true negative) / (positive + negative).

Table 2 demonstrates how classifier performance benefits from the weakly supervised approach. In particular, a training set size of 600 emulated the hypothetical scenario where the size of the training set is limited due to manual labeling overhead. Such a small data set was not enough to adequately fine-tune Clinical-Longformer (F_1-score=0.48).

As the training set size increased, the classifier obtained better performance, reaching the best average F_1-score of 0.83. When compared to the labeler model in Table 1 (recall=0.72), the classifier significantly improved recall (0.81), demonstrating that the classifier managed to generalize beyond the rules specified by the labeling functions.

Figures 3 and 4 show the comparisons of the best-performing (by F_1-score) classifiers from each training set size.

Figure 3. Classifier receiver operating characteristic (ROC) curve across varying training set sizes. For each training set, the best-performing (by F_1-score) run was chosen among 3 runs with different random seeds. For each run, the best-performing classifier snapshot was chosen.

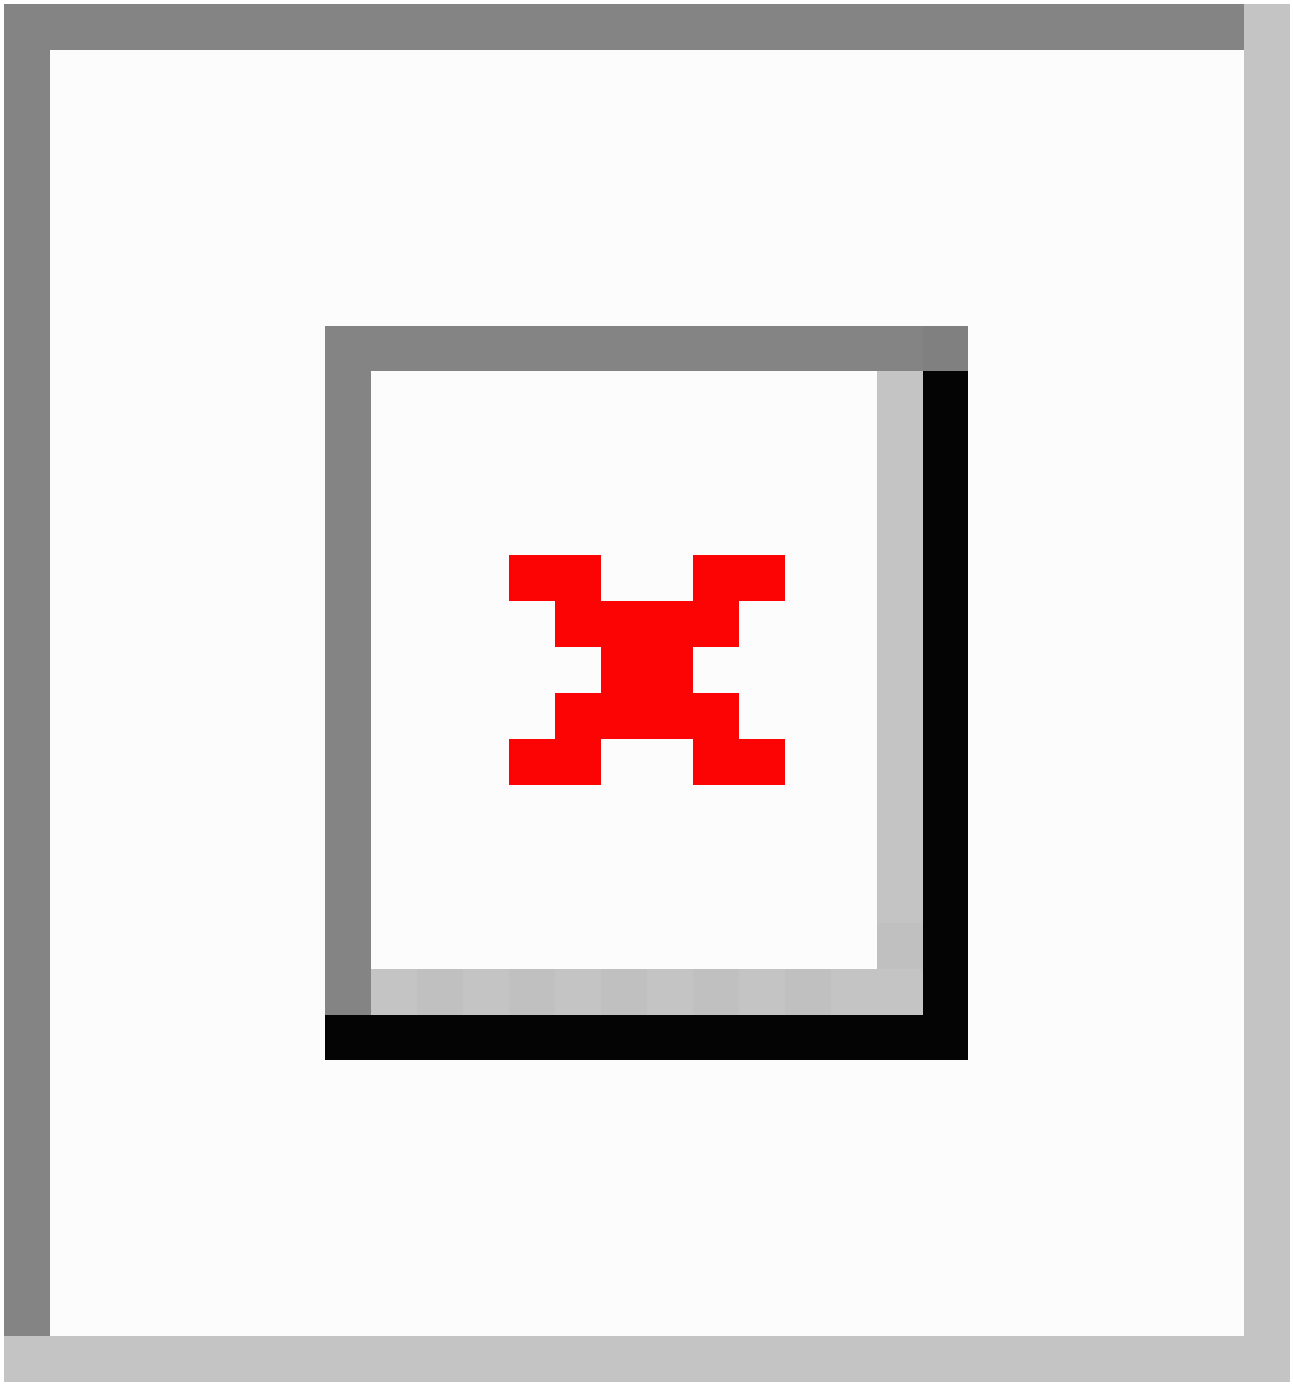

Figure 4. Classifier precision-recall curve across varying training set sizes. For each training set, the best-performing (by F_1-score) run was chosen among 3 runs with different random seeds. For each run, the best-performing classifier snapshot was chosen.

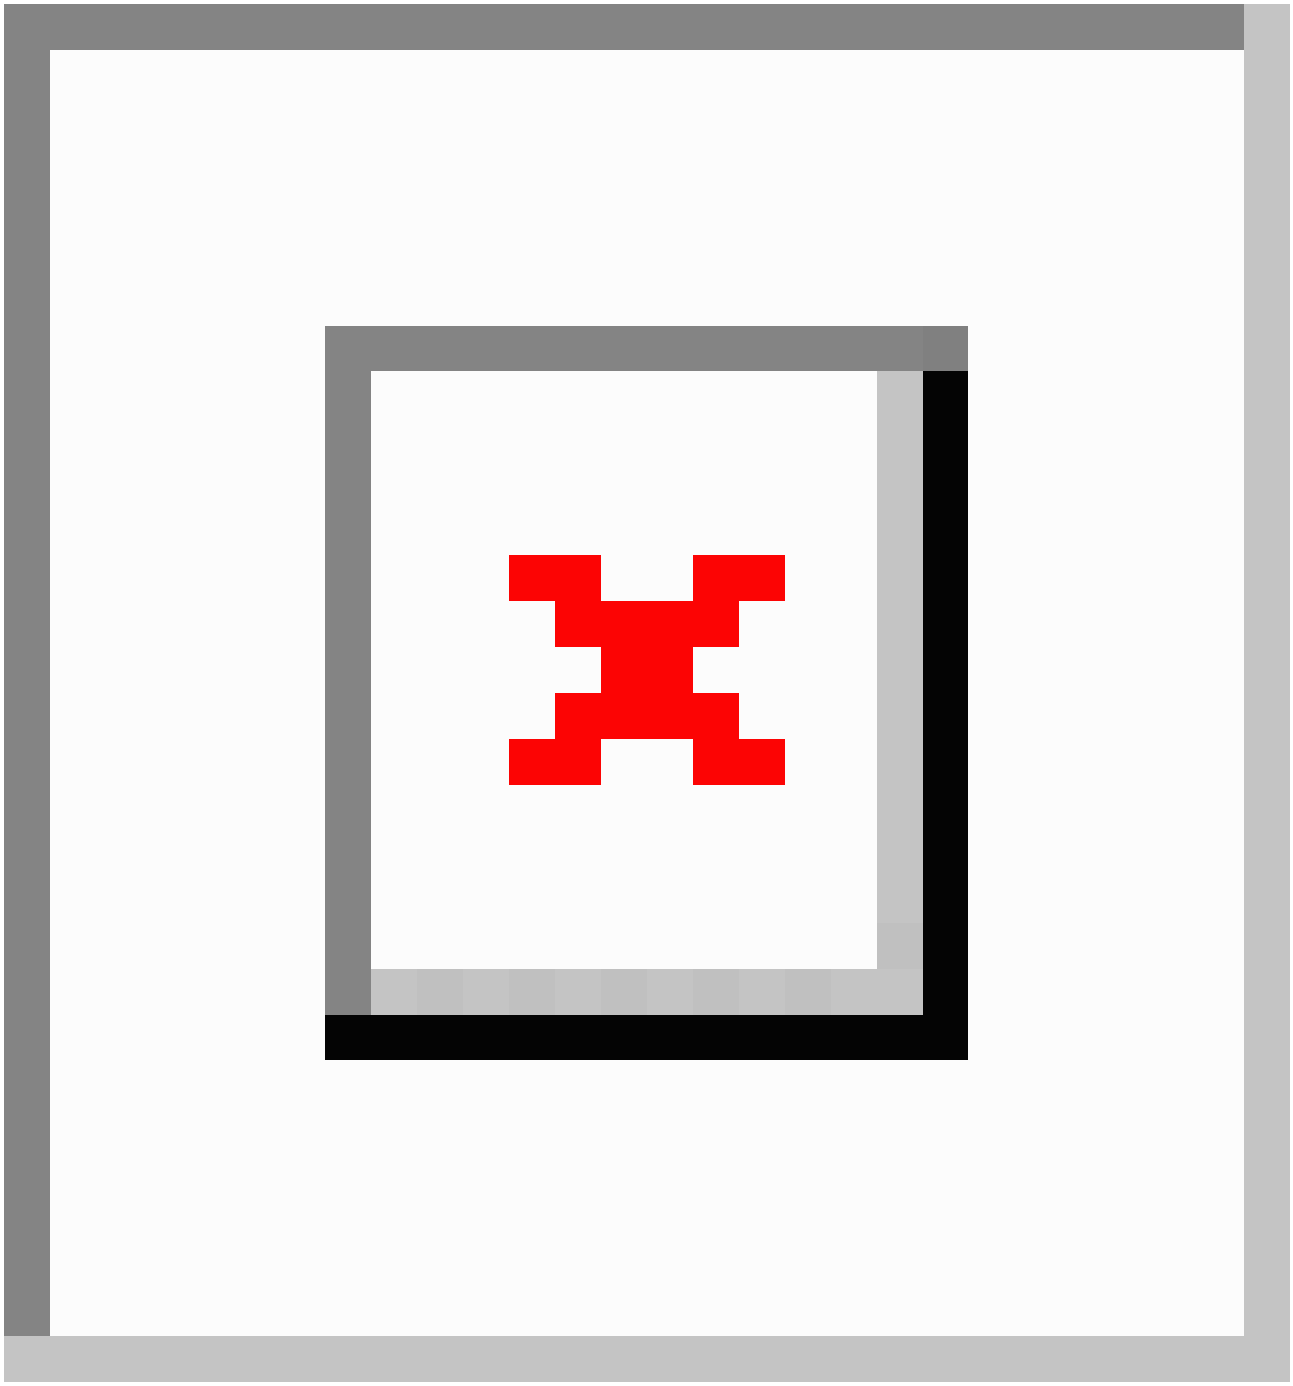

The receiver operating characteristic curve (Figure 3) shows that even the best classifier with a training set size of 600 performed worse than classifiers from larger data set sizes. In the precision-recall curve (Figure 4), the classifier lost substantial precision for small gains in recall, further hinting that the classifier was not properly trained.

Across all training set sizes and runs, the best-performing classifier achieved an F_1-score of 0.85 (accuracy=0.95). Running this classifier on 56,924 clinical notes identified 6515 notes as containing an AF prediagnosis across 2279 unique patients.

Cohort Study: All Patients

Table 3 summarizes the characteristics of the entire cohort regardless of their prior AF diagnosis, reflecting the characteristics of generic patients that used wearables. In all, 5 patients were missing sex information and were not included in the analysis.

Table . Characteristics of all patients[a].

Characteristics			With a prediagnosis (n=2279)	Without a prediagnosis (n=19,048)	*P* value
Demographics					
	Age (y), mean (SD)		63.85 (14.21)	53.53 (16.70)	<.001[b]
	Race and ethnicity, n (%)				<.001[b]
		Asian	295 (12.94)	3143 (16.5)	
		Black	53 (2.33)	619 (3.25)	
		Hispanic	96 (4.21)	1731 (9.09)	
		White	1613 (70.78)	11,240 (59.01)	
		Others	13 (0.57)	153 (0.8)	
		Undisclosed	209 (9.17)	2162 (11.35)	
	Sex, n (%)				<.001[b]
		Male	1384 (60.73)	7739 (40.63)	
		Female	895 (39.27)	11,309 (59.37)	
Comorbidities, n (%)					
	Congestive heart failure		341 (14.96)	1434 (7.53)	<.001[b]
	Hypertension		1267 (55.59)	6796 (35.68)	<.001[b]
	Diabetes mellitus		101 (4.43)	1018 (5.34)	.07
	Vascular disease		251 (11.01)	1582 (8.31)	<.001[b]
CHA_2DS_2-VASc[c] score, mean (SD)			2.12 (1.55)	1.61 (1.35)	<.001[b]

[a]Measured on the date of the index note.

[b]Statistically significant at α=.05.

[c]CHA_2DS_2-VASc: congestive heart failure, hypertension, age ≥75 years, diabetes, stroke, vascular disease, age 65-74 years, sex category.

Patients who received an AF prediagnosis from a wearable tended to be older, with more comorbidities except for diabetes mellitus. White and male individuals constituted a larger portion of patients with a prediagnosis, who also exhibited higher CHA_2DS_2-VASc scores.

Cohort Study: Patients Without a Prior AF Diagnosis

Table 4 then compares the characteristics of patients who had no AF diagnosis prior to the index note, highlighting the efficacy of wearables on the undiagnosed population.

Table . Characteristics of patients without a prior atrial fibrillation diagnosis[a].

Characteristics			With a prediagnosis (n=1037)	Without a prediagnosis (n=16,560)	*P* value
Demographics					
	Age (y), mean (SD)		60.16 (15.65)	51.54 (16.28)	<.001[b]
	Race and ethnicity, n (%)				<.001[b]
		Asian	127 (12.25)	2890 (17.45)	
		Black	28 (2.7)	553 (3.34)	
		Hispanic	55 (5.3)	1598 (9.65)	
		White	723 (69.72)	9414 (56.85)	
		Others	3 (0.29)	136 (0.82)	
		Undisclosed	101 (9.74)	1969 (11.89)	
	Sex, n (%)				<.001[b]
		Male	595 (57.38)	6241 (37.69)	
		Female	442 (42.62)	10,319 (62.31)	
Comorbidities, n (%)					
	Congestive heart failure		85 (8.2)	696 (4.2)	<.001[b]
	Hypertension		461 (44.46)	5082 (30.69)	<.001[b]
	Diabetes mellitus		42 (4.05)	805 (4.86)	.27
	Vascular disease		95 (9.16)	1090 (6.58)	.002[b]
CHA_2DS_2-VASc[c] score, mean (SD)			1.78 (1.44)	1.46 (1.23)	<.001[b]

[a]Measured on the date of the index note.

[b]Statistically significant at α=.05.

[c]CHA_2DS_2-VASc: congestive heart failure, hypertension, age ≥75 years, diabetes, stroke, vascular disease, age 65-74 years, sex category.

These patients exhibited similar characteristics to the overall cohort, where those who received an AF prediagnosis tended to be older, White, and male, with more comorbidities except for diabetes mellitus. In particular, 50.63% (525/1037) of the patients who received a prediagnosis had CHA_2DS_2-VASc scores of 2 or higher, warranting anticoagulation therapy [22]. In contrast, among the patients without a prediagnosis, only 35.85% (5936/16,560) had CHA_2DS_2-VASc scores of 2 or higher.

Cohort Study: Patients With a Clinician-Assigned AF Diagnosis

Among those patients who did not have a prior AF diagnosis, 29.41% (305/1037) of the patients with a wearable-assigned prediagnosis received a clinician-assigned AF diagnosis within 60 days from the index prediagnosis. The average duration from prediagnosis to diagnosis was 4.74 days. In contrast, only 1.58% (262/16,560) of those patients without a prediagnosis received a clinician-assigned AF diagnosis.

Table 5 compares the clinical characteristics of those patients who received an AF diagnosis, based on whether they had received a wearable-assigned prediagnosis prior to the diagnosis.

None of the patient characteristics reported in Table 5 differed significantly between those with an AF prediagnosis and those without (all *P*>.05). However, anticoagulant prescriptions differed based on AF prediagnoses, where more patients with a prediagnosis were prescribed apixaban and rivaroxaban.

Table . Characteristics of patients with a clinician-assigned atrial fibrillation diagnosis[a].

Characteristics		With a prediagnosis (n=305)	Without a prediagnosis (n=262)	*P* value

Discussion

Principal Findings

In this study, we applied a weak supervision–based approach to demonstrate the feasibility and efficacy of an EHR-based postmarket surveillance system for consumer wearables that render AF prediagnoses.

We first derived a labeler model from labeling heuristics expressed as labeling functions, which showed high accuracy (0.92; F_1-score=0.77) on the test set. We then fine-tuned a classifier on labeler model output, to accurately identify AF prediagnoses (0.95; F_1-score=0.83).

Further, using the classifier output, we identified patients who received an AF prediagnosis from a wearable and conducted a retrospective analysis to compare the baseline characteristics and subsequent clinical treatment of these patients against those who did not receive a prediagnosis.

Across the entire cohort, patients with a prediagnosis were older with more comorbidities. The race and sex composition of these patients also differed from those who did not receive a prediagnosis (*P*<.001).

Focusing on the subgroup of patients without a prior AF diagnosis (Table 4), we observed that a higher percentage of patients (525/1037, 50.63% vs 5936/16,560, 35.85%) who received a wearable-assigned prediagnosis exhibited CHA_2DS_2-VASc scores that warranted a recommendation for anticoagulation therapy [22]. This increased likelihood for anticoagulation therapy could be attributed to an early prediagnosis from the wearable.

In the same subgroup, patients who received a prediagnosis were 18.61 times more likely to receive a clinician-assigned AF diagnosis than those who did not. The existence of a prediagnosis was not correlated with patient demographics, comorbidities, or AF subtype at the index diagnosis (Table 5) but did correlate with anticoagulant prescription, where patients with an AF prediagnosis were more frequently prescribed apixaban (*P*=.004) and rivaroxaban (*P*=.01).

Comparison With Prior Work

Given that more consumer wearables will be introduced with increasing prediagnostic capabilities, a surveillance framework for wearable devices is urgently needed to properly assess their impact on downstream health care [3,4]. However, publications sponsored by wearable vendors focused mostly on ascertaining the accuracy of the prediagnostic algorithm itself [1,2].

On the other hand, publications that sought to conduct postmarket surveillance relied solely on manual chart review [3,4], which is hard to scale. In a prior study on wearable notifications, clinician review of 534 clinical notes yielded only 41 patients with an AF prediagnosis [3]. With a weakly supervised approach, our clinician review of 600 notes (ie, the test set) allowed the subsequent identification of 2279 patients with a prediagnosis.

Such an improvement in recall enhanced the statistical power of our analysis. First, our cohort study findings that showed patients with an AF prediagnosis tended to be older, male, and White with higher CHA_2DS_2-VASc scores matches the key findings of the Apple Heart Study [1], which enrolled a much larger number of participants (n=419,297). Second, we were able to make a novel discovery in that a wearable-assigned prediagnosis increases the likelihood of patients receiving anticoagulation therapy and an eventual AF diagnosis, and we identified statistically meaningful anticoagulant prescription differences.

Prior work has applied various methods of weakly supervised learning to some form of medical surveillance [16,17,23-25]. Most relevantly, Callahan et al [23] implemented a surveillance framework for hip implants, and Sanyal et al [25] implemented one for insulin pumps. To the best of our knowledge, however, our work is the first to apply a weakly supervised approach to consumer wearable surveillance. Without prescription records, consumer wearable surveillance can be challenging to scale.

Limitations

We acknowledge that the STARR data set is confined to a small health care system in a single geographic region, which is known [13] to serve populations with higher percentages of male, White, and older individuals. We recommend other institutions to monitor their patient population by developing their own surveillance framework using our weakly supervised methodology. In fact, work is already underway to adapt this approach for use at Palo Alto Veterans Affairs.

We could not establish causality between prediagnoses and patient characteristics. The fact that patients who are older, with more comorbidities; White; and male had a higher likelihood

of receiving an AF prediagnosis may very well reflect that they are health conscious and use wearables more frequently.

Conclusions

By providing prediagnoses, consumer wearables have the potential to affect subsequent diagnoses and downstream health care. Postmarket surveillance of wearables is necessary to understand the impact but is hindered by the lack of codified terms in EHRs to capture wearable use. By applying a weakly supervised methodology to efficiently identify wearable-assigned AF prediagnoses from clinical notes, we demonstrate that such a surveillance system could be built.

The cohort study conducted using the constructed system carried enough statistical power to verify the key findings of the Apple Heart Study, which enrolled a much larger number of patients, where patients who received a prediagnosis tended to be older, male, and White with higher CHA_2DS_2-VASc scores. We also made a novel discovery in that a prediagnosis from a wearable increases the likelihood for anticoagulant prescription and an eventual AF diagnosis. At the index diagnosis, the existence of a prediagnosis from a wearable did not distinguish patients based on clinical characteristics but did correlate with anticoagulant prescription.

Our work establishes the feasibility and efficacy of an EHR-based surveillance system for consumer wearable devices. Further work is necessary to generalize these findings for patient populations at other sites.

Authors' Contributions

RMY, BTV, KNP, JAF, and NHS contributed to concept and design. JAF contributed to the acquisition of data. RMY, BTV, KNP, JAF, AZ, TP, and ND contributed to the analysis and interpretation of data. RMY and BTV contributed to the drafting of the manuscript. RMY, KNP, JAF, AZ, TP, ND, and NHS contributed to critical revision of the manuscript for important intellectual content. RMY contributed to statistical analysis. NHS contributed to the provision of patients or study materials, obtaining funding, and supervision. JAF and NHS contributed to administrative, technical, or logistic support.

Conflicts of Interest

KNP receives research grants from the American Heart Association and the American College of Cardiology and is a consultant for Evidently and 100Plus. JAF is a research consultant for Snorkel AI.

Abstract

Background: The use of chronic disease information systems in hospitals and communities plays a significant role in disease prevention, control, and monitoring. However, there are several limitations to these systems, including that the platforms are generally isolated, the patient health information and medical resources are not effectively integrated, and the "Internet Plus Healthcare" technology model is not implemented throughout the patient consultation process.

Objective: The aim of this study was to evaluate the efficiency of the application of a hospital case management information system in a general hospital in the context of chronic respiratory diseases as a model case.

Methods: A chronic disease management information system was developed for use in general hospitals based on internet technology, a chronic disease case management model, and an overall quality management model. Using this system, the case managers provided sophisticated inpatient, outpatient, and home medical services for patients with chronic respiratory diseases. Chronic respiratory disease case management quality indicators (number of managed cases, number of patients accepting routine follow-up services, follow-up visit rate, pulmonary function test rate, admission rate for acute exacerbations, chronic respiratory diseases knowledge awareness rate, and patient satisfaction) were evaluated before (2019 - 2020) and after (2021 - 2022) implementation of the chronic disease management information system.

Results: Before implementation of the chronic disease management information system, 1808 cases were managed in the general hospital, and an average of 603 (SD 137) people were provided with routine follow-up services. After use of the information system, 5868 cases were managed and 2056 (SD 211) patients were routinely followed-up, representing a significant increase of 3.2 and 3.4 times the respective values before use (U=342.779; P<.001). With respect to the quality of case management, compared to the indicators measured before use, the achievement rate of follow-up examination increased by 50.2%, the achievement rate of the pulmonary function test increased by 26.2%, the awareness rate of chronic respiratory disease knowledge increased by 20.1%, the retention rate increased by 16.3%, and the patient satisfaction rate increased by 9.6% (all P<.001), while the admission rate of acute exacerbation decreased by 42.4% (P<.001) after use of the chronic disease management information system.

Conclusions: Use of a chronic disease management information system improves the quality of chronic respiratory disease case management and reduces the admission rate of patients owing to acute exacerbations of their diseases.

Introduction

Chronic obstructive pulmonary disease (COPD) and asthma are examples of common chronic respiratory diseases. The prevalence of COPD among people 40 years and older in China is estimated to be 13.7%, with the total number of patients reaching nearly 100 million. The lengthy disease cycle, recurrent acute exacerbations, and low control rate were found to have a significant impact on the prognosis and quality of life of middle-aged and older patients with COPD [1,2]. Therefore, to decrease the morbidity and disability rates and enhance the quality of life of all patients with chronic respiratory diseases, it is crucial to investigate effective prevention and treatment methods and establish a life cycle management model for chronic respiratory diseases.

Since the development of information technology, the internet and medical technology have been applied to the management of chronic diseases [3]. The chronic disease information systems adopted in hospitals and communities, along with mobile medical apps, can enhance the self-management capabilities of patients and play a significant role in disease prevention, control, and monitoring [4-9]. However, the existing platforms are generally isolated, the patient health information and medical resources are not effectively integrated, and the Internet Plus Healthcare technology model is not implemented throughout the patient consultation process [3,9].

Yulin First People's Hospital developed a chronic disease management information system based on the hospital information system (HIS) to fully and effectively utilize the medical resources in hospitals and to better support and adapt the system to the needs of patients with chronic diseases. In this study, we evaluated the impact of the use of this system on the efficacy of case management for patients with chronic respiratory diseases.

Methods

Chronic Respiratory Diseases Case Management Model Prior to Implementation of the Chronic Disease Management Information System

Yulin First People's Hospital is a public grade-3 general hospital with 2460 open beds, a specialty clinic in the Department of Pulmonary and Critical Care Medicine, and 180 beds in the Inpatient Department. Chronic respiratory diseases case management was initiated in 2019, which did not involve the use of an information system and was implemented by a chronic respiratory diseases case management team led by two nurses qualified as case managers, one chief physician, two supervisor nurses, and one technician. Under this system, patients with COPD, bronchial asthma, bronchiectasis, pulmonary thromboembolism, lung cancer, and lung nodules were managed using the traditional inpatient-outpatient-home chronic respiratory diseases case management model, including 1024 cases managed from 2019 to 2020. Except for medical prescriptions and electronic medical records, the patient case management information such as the basic information form, follow-up form, patient enrollment form, inpatient follow-up register, patient medication and inhalation device use records, smoking cessation and vaccination records, and pulmonary rehabilitation and health education records was managed using Microsoft Excel forms that were regularly printed for filing.

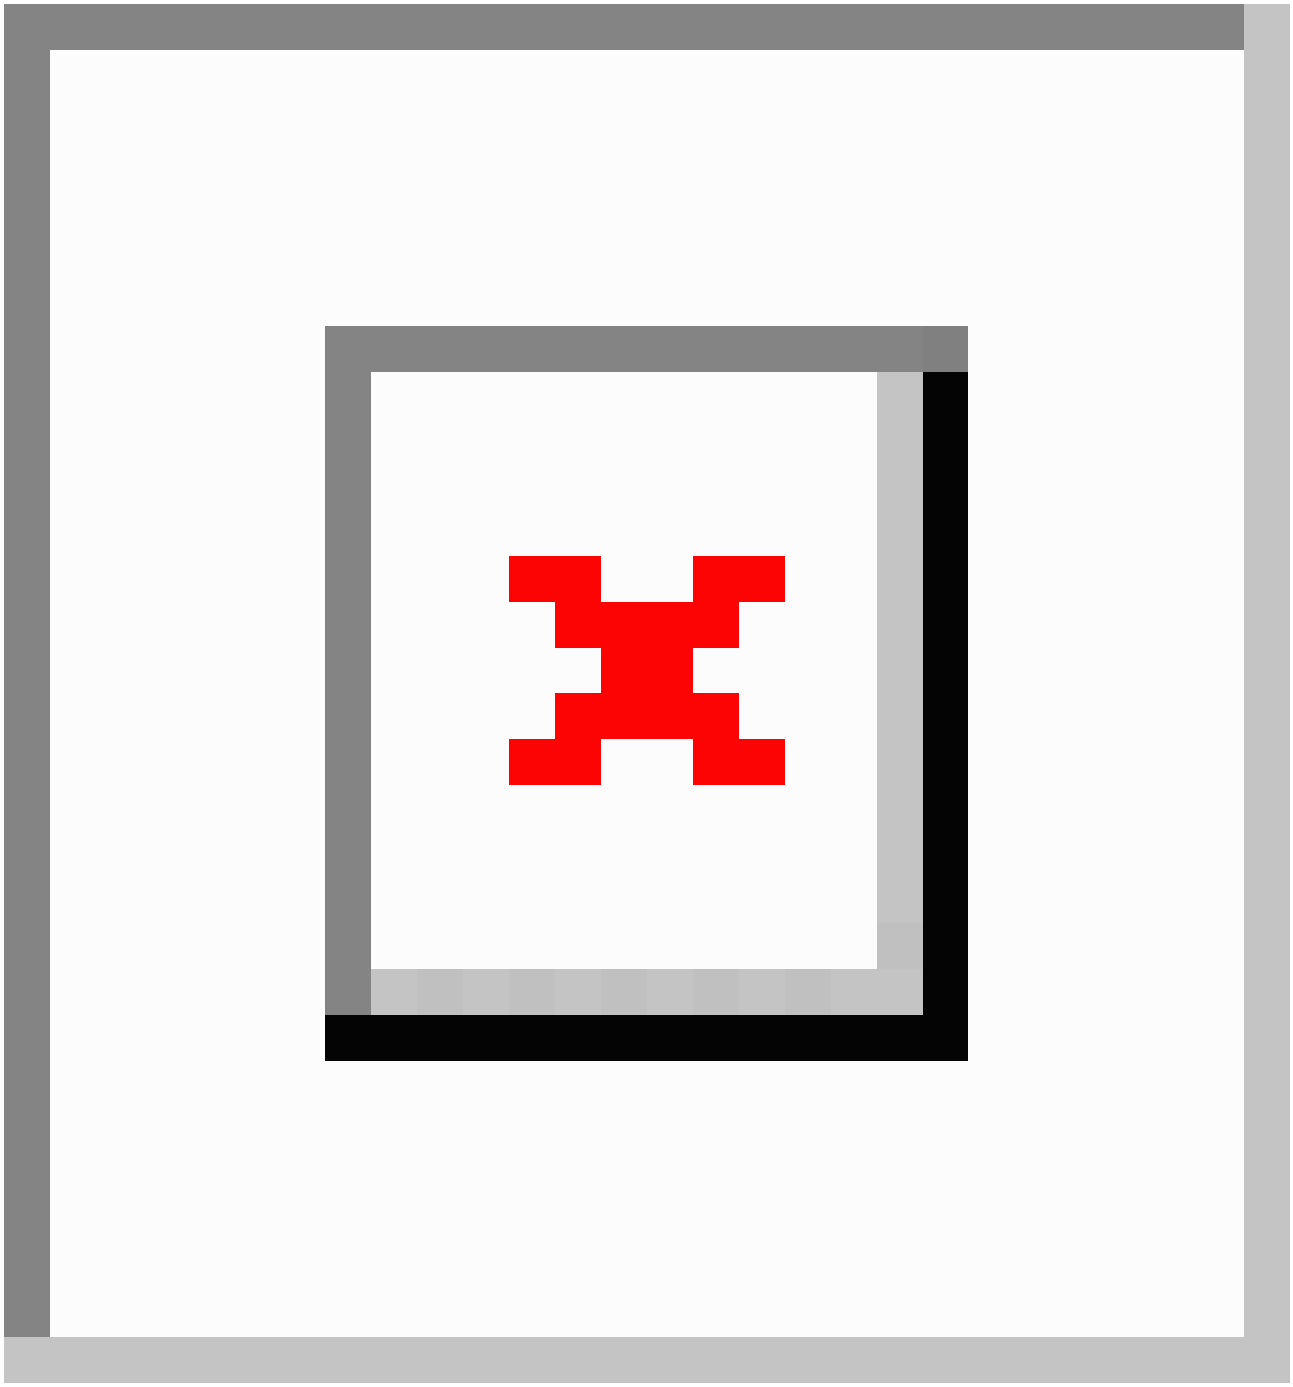
Establishment of a Management Information System for Chronic Diseases

The information carrier forming the basis of the management information system is constituted by the model of internet technology, chronic disease case management models, and overall quality management. The key technology is to establish a scientific, refined, and feasible follow-up pathway according to the methods and procedures of chronic disease case management based on the guidelines for the diagnosis and treatment of single chronic diseases. The closed-loop management of the clinical pathway was conducted in accordance with the Deming cycle (plan-do-check-act), and dynamic monitoring of single-disease health-sensitive and quality-sensitive indicators was carried out. The successfully developed system was installed on the hospital server to connect personal terminals (medical terminals and customer apps) to the existing HIS, which includes electronic medical records and medical advice.

Using the single-disease path assessment or plan scale as a framework, the system can automatically collect and integrate the majority of the medical information of patients with chronic respiratory diseases and provide these patients with inpatient, outpatient, and home intelligent medical services. Patients with chronic diseases who enroll in use of the system can use the app to schedule appointments for medical guidance, payment, and result queries; receive health guidance information; perform self-health assessments; write a treatment diary; and obtain medical communication materials.

The medical terminal consists of five functional modules: user entry, data statistics and query, quality control, knowledge base, and module management. As the core of the system, the user entry module can manage case information in seven steps: enrollment, assessment, planning, implementation, feedback, evaluation, and settlement [10-14]. Each step has a corresponding assessment record scale as well as the health-sensitive and quality-sensitive indicators. The structure of the HIS-based chronic disease management information system is shown in Figure 1.

Figure 1. Main structure of the hospital information system–based chronic disease management information system. *ICD*: *International Classification of Diseases*.



Implementation of the Chronic Disease Information Management System

Overview

Using the chronic disease management information system, two full-time case managers oversaw the case management of 2747 patients diagnosed with six diseases among chronic respiratory diseases between 2021 and 2022. The operation process was broken down into enrollment, assessment, planning, implementation, evaluation, feedback, and settlement stages.

Enrollment

Case managers entered the system through the medical app, selected a disease and an enrolled patient from the list of patients (the system automatically captures the patient's name and ID number according to the *International Classification of Diseases* [*ICD*] code) in accordance with the chronic respiratory diseases diagnostic criteria to sign the enrollment contract and determine the relationship between the personal information and data [15-19].

Assessment

The system can be seamlessly integrated with multiple workstations on the HIS to automatically capture the basic

information, electronic medical records, medical advice, and inspection materials, and can generate questionnaires or assessment scales for patients with chronic respiratory diseases such as the COPD Assessment Test, Asthma Control Test, modified Medical Research Council scale, form for lung function test results, inhalation device technique evaluation form, 6-minute walk test record, rehabilitation assessment form, health promotion form, and nutritional assessment form. The above materials can be added or removed based on the requirements for individual patients.

Planning

The case managers drafted the follow-up plan based on the patient assessment criteria and included the patients on the 1-, 3-, 6-, and 12-month follow-up lists. If the patient satisfied the self-management and indicator control requirements after follow-up, they could be settled and included in the annual follow-up cohort. Case managers can set up follow-up warning and treatment, involving the return visit plan, health education, follow-up content, pathway, and time, and notify the patients and nurses on day 7 and at months 1, 3, 6, and 12 after discharge. The nurses should promptly deal with patients who miss their scheduled follow-up visit.

Implementation

During the inpatient or outpatient care, supervising physicians, nurses, and patients collaborated with each other to implement the treatment. Case managers monitored the patients, evaluated them, documented the results, interpreted various test indicators, and provided health guidance. The chronic disease management information system acquired the corresponding data for chronic disease–sensitive indicators from outpatient and inpatient orders and medical records automatically. The chronic respiratory diseases management team reviewed the patients' conditions and the dynamics of chronic disease–sensitive indicators to make accurate decisions based on the current situation. The outpatient physicians obtained the single-disease package advice and personalized prescriptions to modify the diagnosis and treatment scheme.

Evaluation

Case managers highlighted evaluation and health education. First, they assessed and examined the content of the previous education and recorded and analyzed the patients' conditions, medication, diet, nutrition, rehabilitation exercises, and self-management. Second, they prepared the personalized health education plan, return visit plan, and rehabilitation plan, and used standardized courseware, educational videos, and health prescriptions to provide the patients with one-on-one health guidance. Finally, they sent the management tasks and educational contents to the phones of the patients for consolidating the learning in the hospital, as an outpatient, and at home.

Feedback

Patients can access their biochemical, physical, and chemical data as well as chronic disease–sensitive indicators in the hospital, as an outpatient, and at home for self-health management. Case managers can also perform online assessment, appraisal, and guidance via telephone, WeChat, and the chronic disease information system and record the data. Client mobile terminals can receive SMS text message alerts and the main interface of the chronic disease information system would display reminders of follow-up and return visits within ±7 days.

Settlement

If a patient was out of contact for 3 months, died, or refused to accept the treatment, case managers could settle the case.

Evaluation of the Effect of Implementing the Chronic Disease Management Information System

Evaluation Method

In accordance with case quality management indicators [20], two full-time case managers collected and evaluated data in the process of the follow-up procedure. To reduce the potential for evaluation bias, the case managers consistently communicated and learned to standardize the evaluation method. The cases were divided based on different chronic respiratory diseases case management models (ie, before and after use of the chronic disease information system). The following case management quality indicators were evaluated under the noninformation system management model (2019 - 2020) and under the chronic disease management information system model (2021 - 2022): number of managed cases, number of patients accepting routine follow-up services, follow-up visit rate, pulmonary function test rate, admission rate for acute exacerbations, chronic respiratory diseases knowledge awareness rate, and patient satisfaction. Excel sheets were used to acquire data prior to incorporation of the chronic disease management information system into the new information system.

Evaluation Indicators

The annual number of cases was calculated as the sum of the number of newly enrolled patients and the number of initially enrolled patients. The number of cases was calculated as the sum of the number of cases in different years. The number of routine follow-up visits represents the number of patients who completed the treatment plan. The follow-up visit rate was calculated as the number of completed follow-up visits in the year divided by the number of planned follow-up visits in the same year. The pulmonary function test rate was calculated as the number of pulmonary function tests completed for patients scheduled for follow-up during the year divided by the number of pulmonary function tests for patients scheduled for follow-up during the year. The admission rate for acute exacerbations was calculated as the number of recorded patients admitted to the hospital due to acute exacerbations divided by the total number of patients recorded. The chronic respiratory diseases knowledge awareness rate was determined by the number of people having sufficient knowledge divided by the total number of people tested. This knowledge indicator was based on the self-prepared chronic respiratory diseases knowledge test scale, which consists of 10 items determined using the Delphi method (following expert consultation) through review of the literature, including common symptoms, disease hazards, treatment medication, diet, living habits, exercise, negative habits affecting the disease, regular review items, effective methods for cough and sputum removal, appointments, and follow-ups. The content of the

questionnaire was refined by disease type, and the reviewers included 11 personnel with the title of Deputy Chief Nurse or above in the Internal Medicine Department of the hospital. The expert authority coefficients were 0.85 and 0.87 and the coordination coefficients were 0.50 and 0.67 for the two rounds of review, respectively; the χ^2 test showed a statistically significant value of P=.01. Patient satisfaction was assessed with a self-made questionnaire that showed good internal reliability (Cronbach α=0.78) and content validity (0.86). The questionnaire items included the reminder of return visits, practicability of health education content, and service attitude of medical staff; the full-time case managers surveyed the patients (or their caregivers) at the time of return visits after the third quarter of each year. Satisfaction items were rated using a 5-point Likert scale with a score of 1 - 5, and a mean ≥4 points for an individual indicated satisfaction. Patient satisfaction was then calculated as the number of satisfied patients divided by the total number of managed patients.

Statistical Analysis

SPSS 16.0 software was used for data analysis. The Mann-Whitney U test was performed to compare continuous variables between groups and the χ^2 test was performed to compare categorical variables between groups. P<.05 indicated that the difference was statistically significant.

Ethical Considerations

The study was conducted in accordance with the principles of the Declaration of Helsinki. This study received approval from the Ethics Committee of Yulin First People's Hospital (approval number: YLSY-IRB-RP-2024005). The study did not interfere with routine diagnosis and treatment, did not affect patients' medical rights, and did not pose any additional risks to patients. Therefore, after discussion with the Ethics Committee of Yulin First People's Hospital, it was decided to waive the requirement for informed consent from patients. Patients' personal privacy and data confidentiality have been upheld throughout the study.

Results

Characteristics of Patient Populations Before and After Implementation of the Information System

There was no significant difference in age and gender distributions in the patient populations that received care before and after implementation of the chronic disease management information system (Table 1).

Table . General characteristics of the patient populations under case management before and after use of the chronic disease management information system.

Characteristic		Before use (n=1024)	After use (n=2747)	χ^2 value	*df*	*P* value
Gender, n (%)				1.046	1	.31
	Men	677 (66.1)	1767 (64.3)			
	Women	347 (33.9)	980 (35.7)			
Age group (years), n (%)				0.997	3	.80
	<30	26 (2.6)	73 (2.7)			
	30-59	370 (36.1)	1013 (36.9)			
	60-79	510 (49.8)	118 (11.5)			
	>80	1322 (48.1)	339 (12.3)			

Comparison of Workload Before and After Implementation of the Information Management System

Before use of the system, 1808 cases were managed, with a mean of 603 (SD 137) cases having routine follow-up visits. After use of the system, 5868 cases were managed, with a mean of 2056 (SD 211) routine follow-up visits. Therefore, the number of managed cases and the number of follow-up visits significantly increased by 3.2 and 3.4 times, respectively, after use of the system (U=342.779; P<.001).

Comparison of Quality Indicators of Managed Cases Before and After Implementation of the Information System

The quality indicators in the two groups are summarized in Table 2. Compared with the corresponding indicators before use of the system, the follow-up visit rate increased by 50.2%, the pulmonary function test rate increased by 26.2%, the chronic respiratory diseases knowledge awareness rate increased by 20.1%, the retention rate increased by 16.3%, and the patient satisfaction increased by 9.6%; moreover, the admission rate for acute exacerbations decreased by 42.4%.

Table . Comparison of case management quality indicators before and after implementation of the chronic diseases information management system.

Quality indicators	Before use (n=1024), n (%)	After use (n=2747), n (%)	χ^2 value (*df*=1)	*P* value
Subsequent visit rate	209 (20.4)	1939 (70.6)	7.660	<.001
Lung function test achievement rate	190 (18.6)	1231 (44.8)	2.190	<.001
CRD[a] knowledge awareness rate	443 (43.3)	1742 (63.4)	1.243	<.001
Retention rate	787 (76.9)	2560 (93.2)	1.995	<.001
Acute exacerbation admission rate	663 (64.7)	613 (22.3)	5.999	<.001
Patient satisfaction	862 (84.2)	2577 (93.8)	86.190	.01

[a]CRD: chronic respiratory disease.

Discussion

Principal Findings

The main purpose of this study was to build a chronic disease management information system and apply it to the case management of chronic respiratory diseases. Our evaluation showed that the chronic disease management information system not only improves the efficiency and quality of case management but also has a benefit for maintaining the stability of the condition for patients with respiratory diseases, reduces the number of acute disease exacerbations, increases the rate of outpatient return, and improves patients' adherence with disease self-management. Thus, a chronic disease management information system is worth popularizing and applying widely.

Value of the HIS-Based Chronic Disease Management Information System

Chronic diseases constitute a significant public health issue in China. Public hospitals play important roles in the health service system, particularly large-scale public hospitals with the most advanced technologies, equipment, and enormous medical human resources, which can greatly aid in the diagnosis and treatment of diseases and also serve as important hubs for the graded treatment of chronic diseases. Moreover, a significant number of patients with chronic diseases visit large hospitals, making them important sources of big data on chronic diseases [21]. Adoption of an HIS-based chronic disease management information system can make full use of and exert the advantages of large-scale public hospitals in terms of labor, technology, and equipment in the diagnosis, treatment, and prevention of chronic diseases; enhance the cohesiveness of the case management team in chronic disease management; and achieve prehospital, in-hospital, and posthospital continuity of care for patients with chronic diseases. Overall, use of a chronic disease management information system can enhance the quality and efficiency of chronic disease management and lay a good foundation for teaching and research on chronic diseases.

Improved Efficiency of Case Management

China was relatively late in applying case management practices, and chronic disease management has traditionally been primarily conducted offline [14,20] or supplemented by management with apps and WeChat [7,8]. Traditional case management methods require case managers to manually search, record, store, query, count, and analyze information. This manual process necessitates substantial time and makes it challenging to realize a comprehensive, systematic, and dynamic understanding of patient information, resulting in a small number of managed cases and follow-up visits. With the application of information technology, use of an HIS-based chronic disease monitoring and case management system can automatically extract and integrate patient information, thereby increasing the efficiency of chronic disease management and reduce costs [4,22]. In this study, two case managers played leading roles both before and after implementation of the information system; however, compared with the situation before the use of the system, the numbers of both managed cases and of follow-up visits increased, reaching 3.2 and 3.4 times the preimplementation values, respectively. The information system can automatically obtain a patient's name and ID number based on the *ICD* code, which can expand the range of enrollment screening and appoint the register of patients as planned. In addition, the information system can automatically obtain outpatient, inpatient, and home medical information for the postillness life cycle management of patients. Moreover, the intuitive, clear, and dynamic indicator charts on the system can save a significant amount of time for diagnosis and treatment by medical staff, while the paperless office and online data-sharing functions can essentially solve the problem of managing files by case managers to ultimately enhance efficiency.

Improved Quality of Case Management

According to evidence-based medicine, the seven steps of case management represent the optimal clinical pathway [10-14,22]. In this study, the concept of an Internet-Plus medical service was introduced; that is, the chronic disease management information system was established based on the HIS data and case management model [22] and the function of a mobile medical terminal app was incorporated in the system [6,7]. Compared with the noninformation system case management model, this system has several advantages. First, owing to the swift management mode, it can overcome the limitations of time and space [4-8]. Second, multichannel health education and communication can enhance patients' knowledge and skills, as well as their compliance with self-management, based on diversified forms of image data such as graphics and audio [6,22]. Third, the use of intelligent management can remind

doctors and patients to complete management work and follow-up visits as planned, and to perform intelligent pushes of patient outcome indicators to improve confidence in the treatment [22]. Fourth, this system enables information sharing and big data analysis, as well as multidisciplinary diagnosis and treatment based on the matching of doctor-patient responsibility management, which can be more conducive to the precise health management of patients.

Compared with the traditional case management model, information-based case management significantly increased the follow-up visit rate, lung function test rate, chronic respiratory diseases knowledge awareness rate of patients, patient satisfaction rate, and retention rate. Among these indicators, the follow-up visit rate and lung function test rate represent aspects related to the patients' own management of their condition [1]. The results of this study are consistent with previous findings related to information-based management of chronic diseases in China, demonstrating that such a management system was more conducive to planned, systematic, and personalized education and follow-up by the case management team, thereby promoting the virtuous cycle of compliance with self-management and reducing the number of acute exacerbations among patients with chronic respiratory diseases, ultimately enhancing the precision of medical resource allocation and hospital management [22,23].

Helping Patients With COPD Maintain Stability of Their Condition

The admission rate for acute exacerbations serves as a common indicator of the quality of the treatment of chronic respiratory diseases [23]. The deployment of a clinical pathway–based hospital case management information system significantly reduced the admission rate for acute exacerbations and enhanced the quality of treatment for chronic respiratory diseases, indicating its high clinical significance. There are several reasons for these observed benefits. First, home care and self-management are essential in the management of chronic respiratory diseases. The information-based case management model improved the patients' knowledge and skills along with their compliance with self-management. Consequently, the standardized self-management process helped to reduce the number of acute exacerbations of chronic respiratory diseases and thus lowered the admission rate. Second, the information-based case management model increased the regular return rate, which allowed the medical staff to identify the potential risk factors for acute exacerbations in a timely manner, deal with them when they occur, and prepare personalized treatment plans and precise health management schemes. This consequently enabled adjustment of treatment schemes in real time, reduced the number of admissions due to acute exacerbations, and lowered the readmission rate. For hospitals interested in implementing a similar model, we suggest first conducting a detailed review of the current situation prior to making adequate changes based on the relevant disease and patient populations.

Consequently, the HIS-based case information management model could improve efficiency, enhance the quality of case management, and aid in stabilizing the conditions of patients with chronic respiratory diseases. In contrast to the hospital case management information system reported by Yuan et al [22], the system described in this study includes a personal terminal app. Previous studies confirmed that a stand-alone mobile health app could improve patient compliance and disease control [6-8]; thus, whether this system can be used to manage specialized disease cohorts for patients with chronic diseases remains to be determined. In this study, the effect on the retention rate of patients was confirmed; however, the overall operational indicators for the diagnosis and treatment of chronic diseases should be further determined.

Conclusion

With the advancement of information technology, the internet and medical technology have been applied to the management of chronic diseases. As an information-based platform for the case management of patients with chronic respiratory diseases, a newly developed chronic disease management information system was introduced in this study. This system is capable of designing the follow-up time registration, follow-up content, approaches, methods, quality control, and feedback process for a single chronic respiratory disease via the single-disease clinical pathway following the case management process (enrollment, assessment, planning, implementation, feedback, and evaluation). Use of this system can encourage patients with chronic respiratory diseases to adhere to regular follow-up and form an outpatient-inpatient-home chronic disease management strategy. This can help in reducing the admission rate for acute exacerbations, increase the return visit rate, and improve the correctness and compliance of home self-management of patients with chronic respiratory diseases. Owing to these benefits, wide adoption of such information systems for the management of chronic diseases can offer substantial economic and social value.

Abstract

Background: After strict COVID-19–related restrictions were lifted, health systems globally were overwhelmed. Much has been discussed about how health systems could better prepare for future pandemics; however, primary health care (PHC) has been largely ignored.

Objective: We aimed to investigate what combined policies PHC could apply to strengthen the health care system via a bottom-up approach, so as to better respond to a public health emergency.

Methods: We developed a system dynamics model to replicate Shanghai's response when COVID-19–related restrictions were lifted. We then simulated an alternative PHC-based integrated health system and tested the following three interventions: first contact in PHC with telemedicine services, recommendation to secondary care, and return to PHC for recovery.

Results: The simulation results showed that each selected intervention could alleviate hospital overwhelm. Increasing the rate of first contact in PHC with telemedicine increased hospital bed availability by 6% to 12% and reduced the cumulative number of deaths by 35%. More precise recommendations had a limited impact on hospital overwhelm (<1%), but the simulation results showed that underrecommendation (rate: 80%) would result in a 19% increase in cumulative deaths. Increasing the rate of return to PHC from 5% to 20% improved hospital bed availability by 6% to 16% and reduced the cumulative number of deaths by 46%. Moreover, combining all 3 interventions had a multiplier effect; bed availability increased by 683%, and the cumulative number of deaths dropped by 75%.

Conclusions: Rather than focusing on the allocation of medical resources in secondary care, we determined that an optimal PHC-based integrated strategy would be to have a 60% rate of first contact in PHC, a 110% recommendation rate, and a 20% rate of return to PHC. This could increase health system resilience during public health emergencies.

Introduction

The World Health Organization (WHO) announced the end of the COVID-19 public health emergency of international concern on May 5, 2023. Over the past 3 years, the COVID-19 epidemic has resulted in more than 765 million infections and 6.92 million deaths globally and has involved ongoing outbreaks, infection control via restrictions, the lifting of restrictions, and large-scale infections [1]. The limitations of health care systems worldwide regarding the response to mass infections and admissions have been exposed, and these limitations exist in countries classified as high-performing and resilient countries, as well as in resource-limited countries [2-4]. Although most governments have prudently considered the appropriate time to relax restriction policies, health care systems have unavoidably been overwhelmed, and some even collapsed once restrictions were lifted [5].

Much has been discussed regarding how health care systems could have better prepared for COVID-19 and how to prepare for future pandemics. Topics of discussion include adequate health care workforces and facilities [6], better intensive care unit capacity [7], early intervention to avoid local transmission

[8], and the broader application of telemedicine [9]. Some scholars have advocated for the integration and coordination of the health system, including public health and clinical medicine. The role of primary health care (PHC) in COVID-19 management has received attention [10-13], but this attention is obviously insufficient when compared with the attention given to the professional treatment capabilities of large hospitals. In particular, there is a lack of empirical research on the role of PHC. After touring 5 cities in China, the WHO provided recommendations that were predominantly focused on secondary care and epidemiological tracking and control, and the role of PHC was missed again [14].

Distinguishing itself from secondary care for specialist treatment, PHC is regarded as the most inclusive, effective, and efficient approach to enhancing people's physical and mental health. PHC has great value in a strong, coordinated response to a public health crisis [10,15]. Recent studies show that a strong PHC foundation could effectively mitigate an epidemic. One such case is that of Singapore, which promptly instituted aggressive containment measures by establishing public health preparedness clinics that were supported in a sustained manner by the PHC network [16]. In contrast, PHC resources in the African Union are exceedingly scarce, which resulted in insufficient engagement when dealing with COVID-19 [17-20]. Even in countries with adequate PHC resources, such as the United Kingdom, the health system did not respond quickly and struggled to meet medical demands under a large-scale epidemic [21]. Legido-Quigley and colleagues [7] argued that well-developed integration was a key factor of services influencing resilience during the COVID-19 pandemic in high-performing health systems. Prompt communication and coordination among PHC, public health, and secondary care are essential [22].

At the end of 2022, COVID-19–related restrictions were lifted in China, and an epidemic wave caused by the highly transmissible Omicron SARS-CoV-2 variant placed health services in the country under extreme pressure, especially in metropolises. In Shanghai, which is the most populous metropolis in China and has a permanent population of 25 million, it is extremely difficult to deal with the spread of epidemic infections. At the end of 2022, Shanghai adopted an expansion strategy that involved allocating medical resources in secondary care institutions in a manner that favored patients with SARS-CoV-2 infection. At the same time, Shanghai, as a pilot city, was one of the first cities to promote a hierarchical diagnosis and treatment system based on PHC. As such, Shanghai provides an extremely rare opportunity to explore how the health system of a metropolis can actively respond to large-scale infections, as well as the key role of PHC in this system. In this study, we simulated the large-scale infections that occurred in Shanghai at the end of 2022 by using a simulated environment, wherein we reproduced Shanghai's response to the challenges of the fast-spreading epidemic. We then tested an alternative strategy that used a PHC-based integrated health system.

Methods

Ethical Considerations

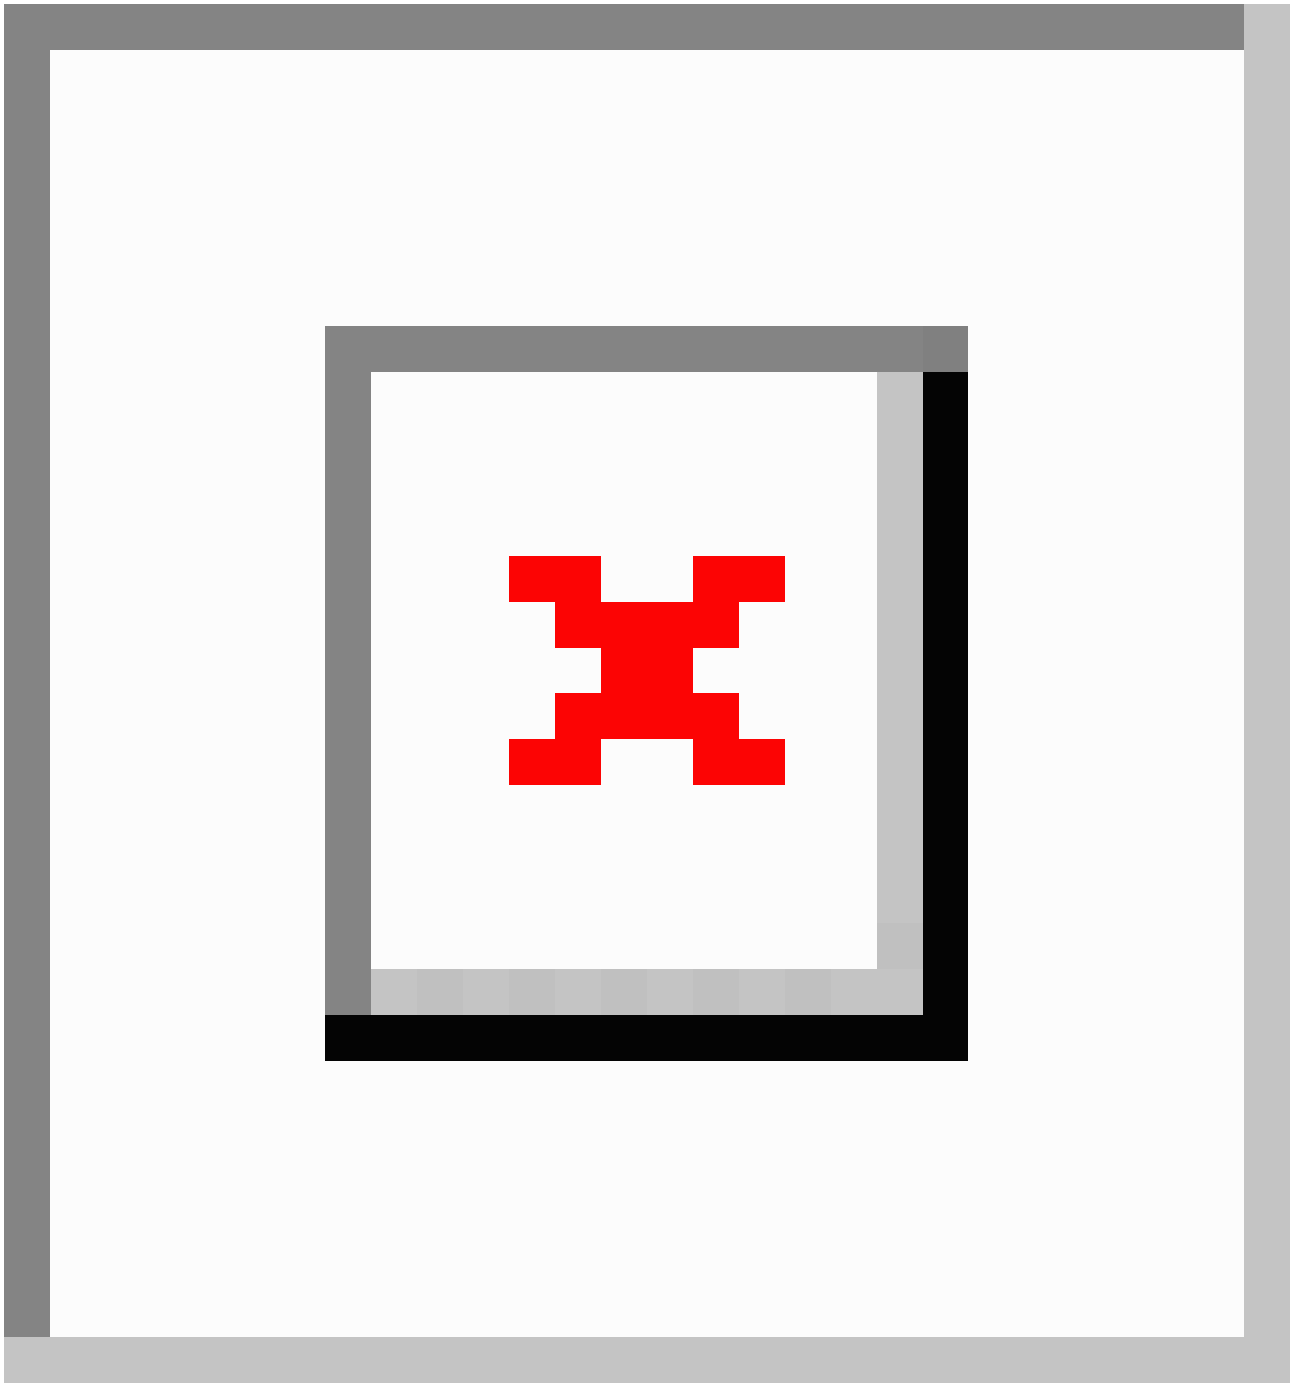
Ethics board review was not required, as this study only involved modeling and simulations. All modeling data came from public sources or published papers and did not involve ethical issues.

Study Design

System dynamics was applied in this study to simulate the mass infections and the health system performance in Shanghai. System dynamics models are established based on the feedback structures (loops) centered around the issue of concern [23,24]. The nonlinear dynamic behaviors derived from these feedback loops shed light on the underlying mechanisms that generate problematic system behaviors, which helps with understanding complex systems and finding fundamental solutions [25]. The use of system dynamics models is a suitable method for investigating public health issues that feature high-complexity systems [26,27]. In recent years, system dynamics has been widely used to model issues related to COVID-19 [28-31].

We developed a system dynamics–based model to replicate the health system in Shanghai after COVID-19–related policies were lifted. The following indicators of an overwhelmed health system were used: physician availability (the percentage of patients arriving at the hospital who could be treated) and bed availability (the percentage of patients needing hospitalization who could be admitted) in secondary hospitals. Shanghai's response to the soaring medical demands was to reallocate medical resources from other divisions to increase the supply of hospital physicians and beds for patients with COVID-19. This policy increased the capacity of secondary hospitals such that more patients could be treated and hospitalized. We also used the system dynamics model to establish a PHC-based integrated health system as an alternative option for addressing hospital overwhelm. The following three critical policy interventions were tested: first contact in PHC, identification of high-risk patients and recommendation to secondary care hospitals, and referral for a return to PHC for follow-up and recovery at the community level (Figure 1). Telemedicine services were also considered in PHC, with which more first contacts could be handled and the capacity of PHC to handle patients could be increased.

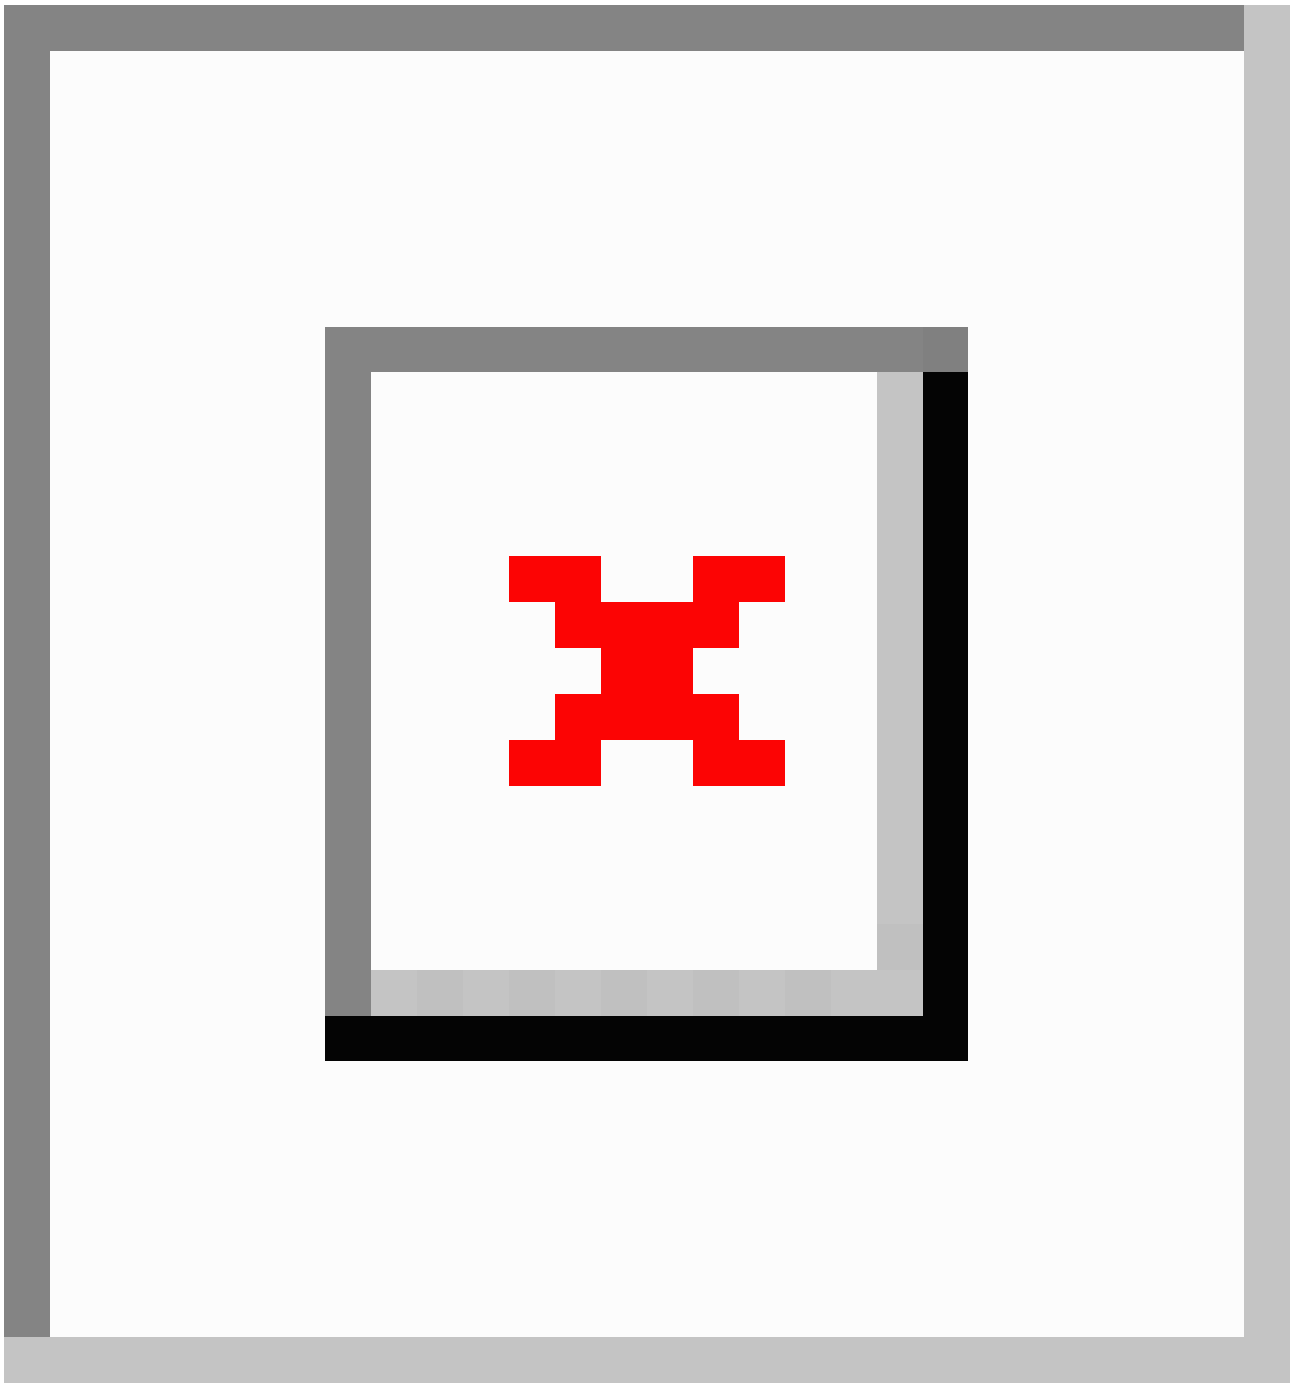
Figure 1. PHC-based health system. PHC: primary health care.



Model Structure

The Shanghai model includes the following two parts: the epidemic dynamics representing the mass infections that occurred when COVID-19 restrictions were lifted in Shanghai and the health care system response, as shown in Figure 2.

Figure 2. Shanghai system dynamics model of a PHC-based integrated system. *A*: infected population without symptoms; D: death; *E*: infected population during the incubation period; GB: getting better; GW: getting worse; HR: home recovery; *I*: infected population with symptoms; PHC: primary health care; R: recover; *RA*: population in *A* that has recovered; *S*: susceptible population without vaccination; *SV*: susceptible population with vaccination.



In Figure 2, the left part depicts an extension of the traditional Susceptible-Exposed-Infectious-Removed model, which we used to model the spread of COVID-19 in Shanghai and compute the number of symptomatic cases, of which a large proportion would require medical services. We disaggregated the total population into the following six groups.

SV and *S* represent the susceptible population with vaccination and the susceptible population without vaccination, respectively. The transformation of *SV* to *S* represents the waning effectiveness of COVID-19 vaccines, where ω is the waning effect of vaccination.

E represents the infected population during the incubation period. The transformation of *SV* to *E* and *S* to *E* represents the spread of the virus, where c is the contact rate, β is the transmission probability, and θ_1 is the effectiveness rate of vaccination against infection.

I and *A* represent the infected population with symptoms and the infected population without symptoms, respectively. α is the percentage of asymptomatic cases, and τ is the incubation period.

RA represents the population in *A* that has recovered. γ_1 is the recovery fraction among asymptomatic cases.

Patients with symptoms (ie, those from population *I*) link the left and right parts of the model. Some patients will recover at home, and others will visit a physician. Among those visiting a physician, some will first contact a PHC institution, while others will contact a secondary hospital directly. PHC institutions and secondary hospitals each have a specific capacity, and when this capacity is reached, new, excess patients cannot be treated and will have to return home. With regard to patients treated in PHC institutions and secondary hospitals, those with mild symptoms will be given prescriptions and sent home to recover. With regard to patients needing further treatment when presenting at the PHC level, general practitioners will recommend them to a secondary hospital; some patients will be hospitalized and become inpatients if hospital beds are available. Over time, some inpatients will recover, whereas others will develop severe illness and eventually recover or die. Patients who recover at home will either improve or worsen, as will untreated and treated patients from PHC institutions and secondary hospitals. The proportion of patients whose condition worsens is highest for untreated patients and lowest for treated patients. Some recovering inpatients in secondary care hospitals might recover at the community level if PHC can provide follow-up health management services. The model equations and parameter settings are detailed in sections 1 and 2 in Multimedia Appendix 1.

Data Source and Model Validation

We previously developed and validated a model of reopening in Shanghai that accounts for the epidemiological dynamics of the first Omicron wave in this metropolis during the first half of 2022 [32]. The model we established in this study was based on that previous model and was used to simulate the second Omicron wave, specifically the time when most intervention prevention control measures were lifted at the end of 2022. Data related to the spread of Omicron in Shanghai, such as the contact rate, transmission possibility, asymptomatic rate, incubation period, and recovery fraction, were obtained from previous literature about COVID-19 and, especially, Omicron (further details are reported in section 2 and Table S1 in Multimedia Appendix 1). Data related to individuals' behaviors, such as the rate of first contact in PHC and the rate of recovery at home, were set according to estimations based on our investigation of PHC, hospitals, and the community. Sensitivity tests for these parameters were conducted to check the robustness of the model (section 3.2 in Multimedia Appendix 1).

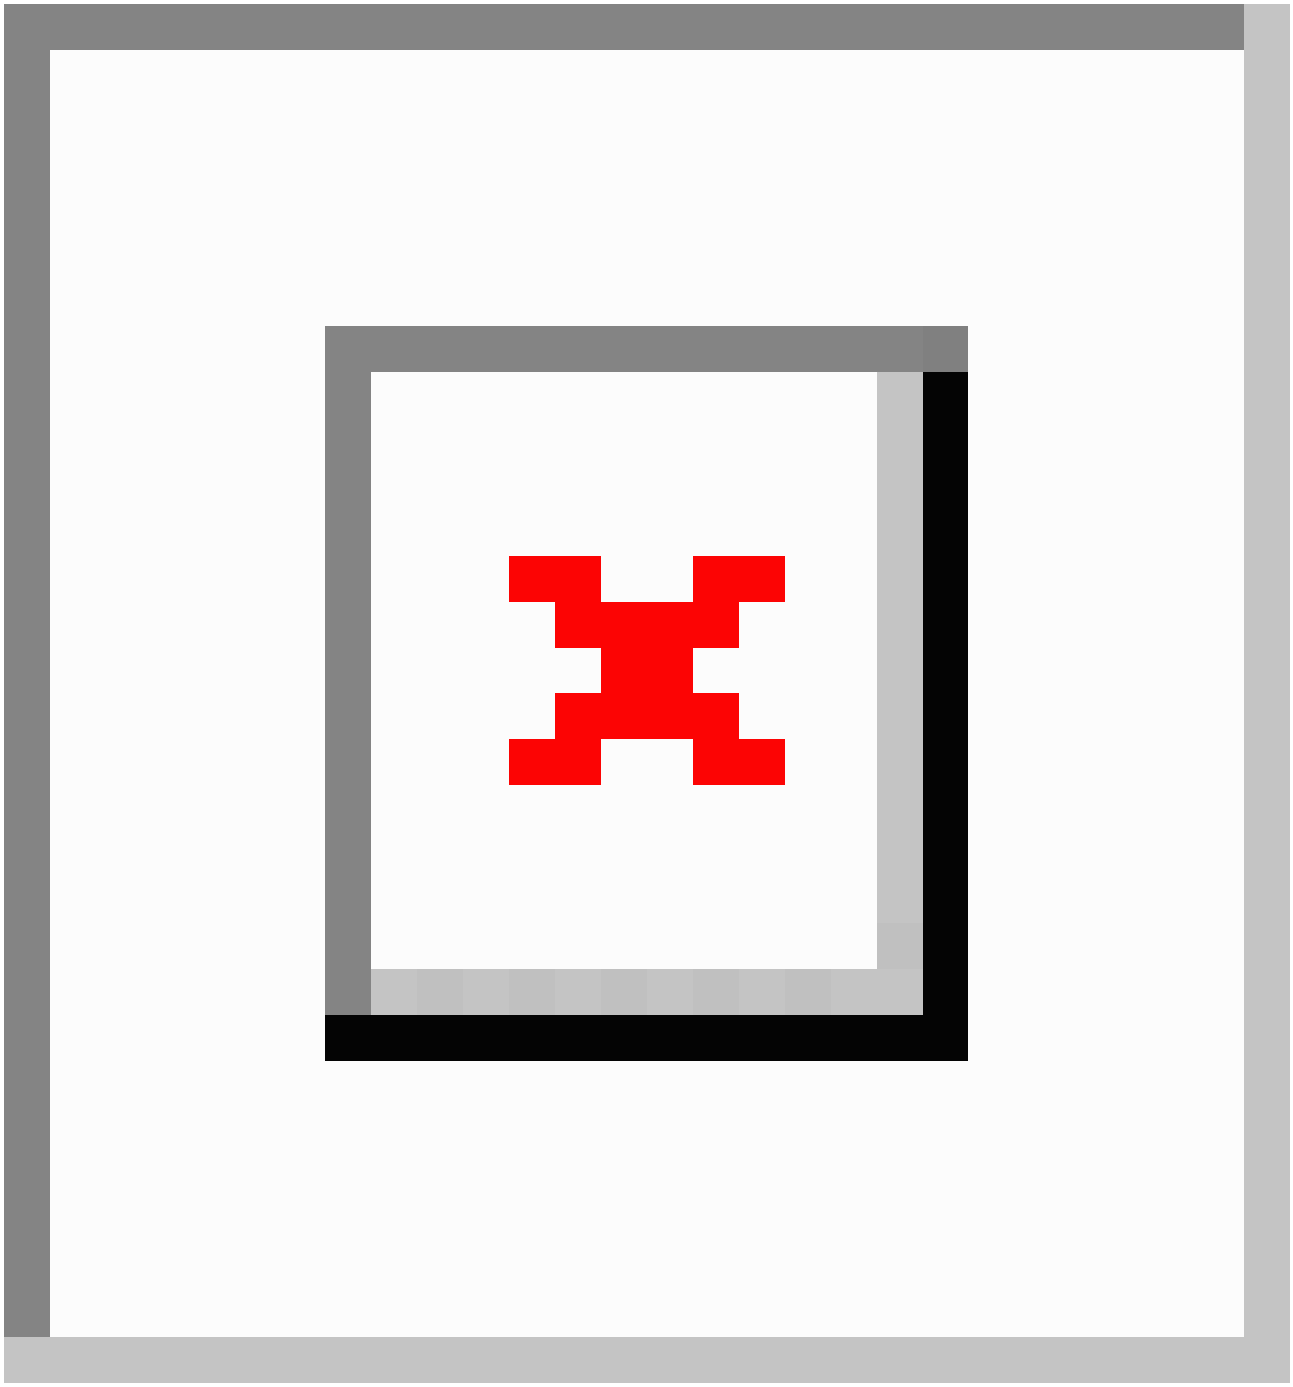
The validation of model behavior usually involves the comparison of simulation results with real-world data. Because mass COVID-19 testing was no longer required, accurate infection data were no longer available; news reports on viral infections and the level of pressure on medical resources were used as references. The model results revealed patterns that were similar to the actual situation during the second Omicron wave in Shanghai, thereby confirming the validity of the model (further details are reported in section 3 in Multimedia Appendix 1). As a result, we determined that this model could provide a simulated environment to facilitate the exploration of effective policies regarding the response to mass infections in a metropolis.

Results

Scenario 1: Medical Resource Reallocation in Secondary Care

When the strict intervention prevention controls were lifted, the policy focus changed from preventing the spread of COVID-19 to the timely treatment of patients with COVID-19. When facing massive increases in infections, physicians' availability could decline to as low as 55% if no interventions were adopted. In the case of Shanghai, a series of measures was taken to deal with the impact of large-scale infections on hospitals. When hospital physician capacity and hospital bed capacity were increased by 70% of the original capacities, the lowest physician availability and bed availability changed to approximately 85% and 70%, respectively. Moreover, bed shortages lasted approximately 8 days, which was around one-third of the bed shortage time for the scenario with no capacity extension. The peak number of severe cases decreased, as more patients could be treated promptly. Consequently, the cumulative number of deaths decreased to less than half of that for the scenario without additional resources, as shown in Figure 3.

Figure 3. Expanding capacity to meet soaring demand. Base: baseline; Ext cap 30: 30% capacity extension; Ext cap 50: 50% capacity extension; Ext cap 70: 70% capacity extension.

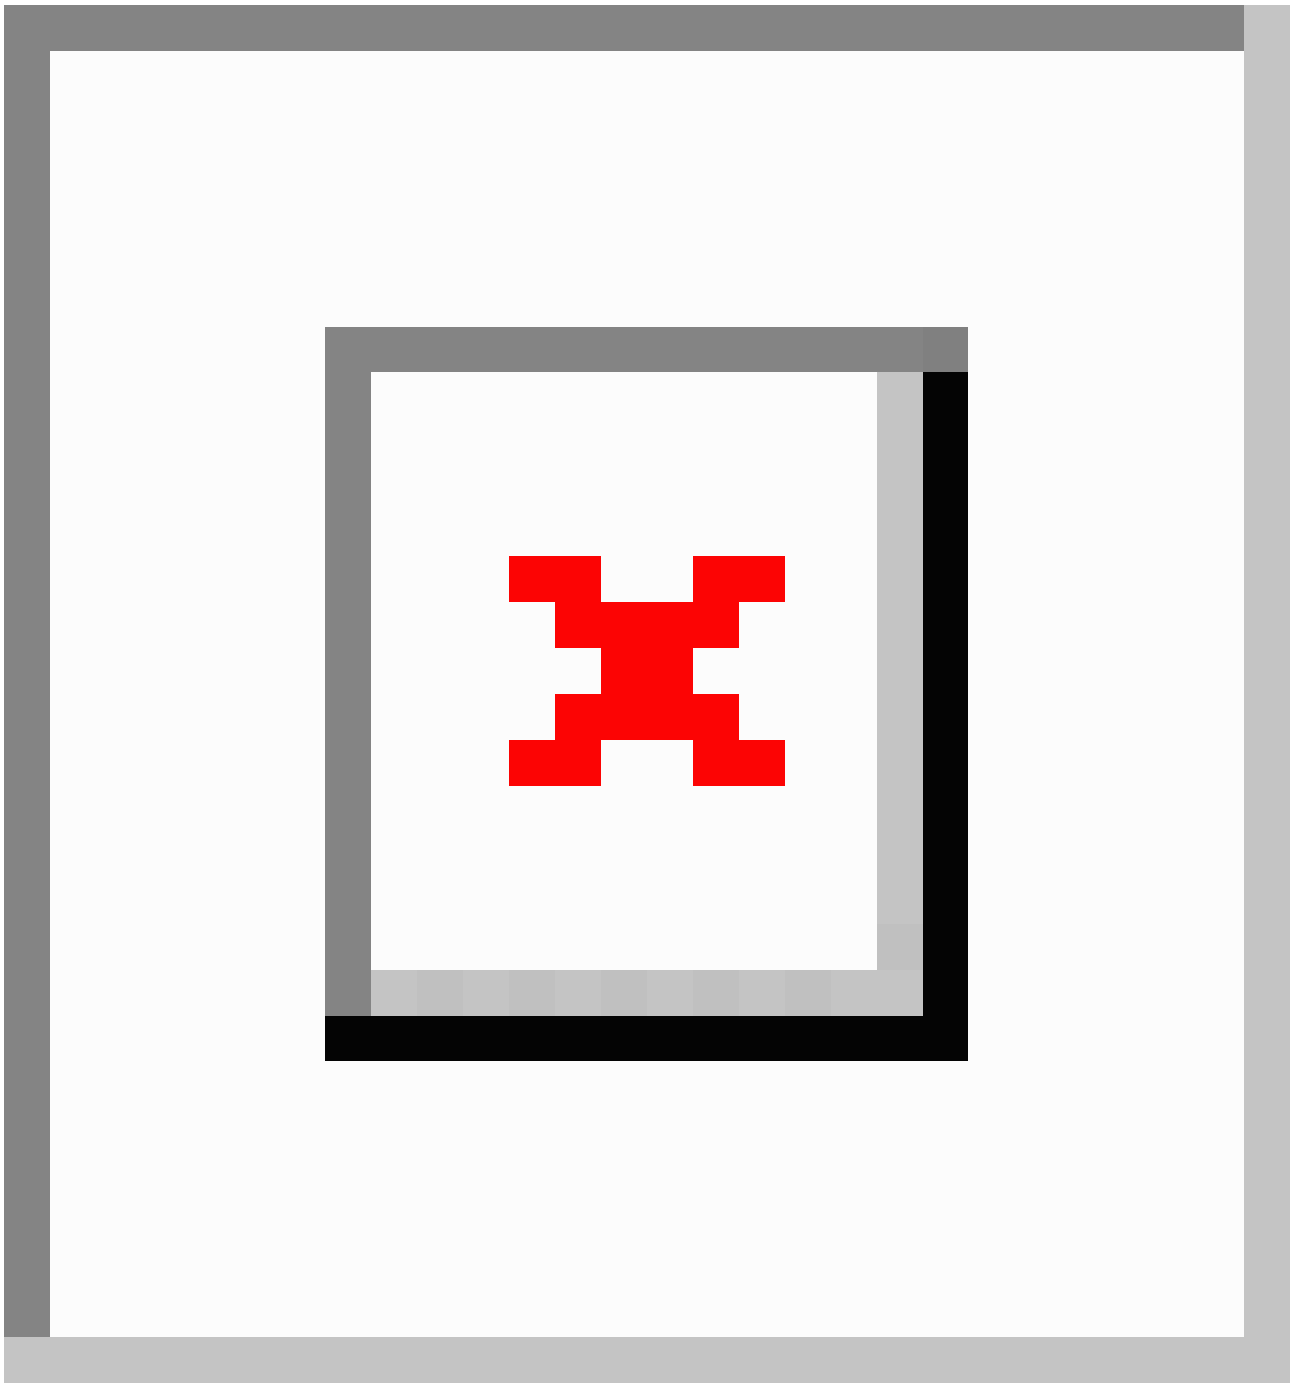


Scenario 2: PHC-Based Integrated Health Care System

Scenario 2.1: Increasing the Rate of First Contact in PHC Plus PHC Telemedicine

Facing huge increases in the number of patients, we examined ways to increase the rate of first contact in PHC, in which PHC telemedicine services were also considered. Under such circumstances, 6 scenarios were simulated, with the rate of first contact in PHC with and without telemedicine services set to 40%, 50%, and 60%. Figure 4 shows that replacing the worst scenario (40% rate of first contact in PHC without telemedicine) with the best scenario (60% rate of first contact in PHC with telemedicine) increased the lowest level of secondary hospital physician availability and that of secondary hospital bed availability by 32% (from 51% to 67%) and 111% (from 9% to 19%), respectively. Moreover, the duration of bed shortages dropped from approximately 30 days to approximately 20 days. Because more patients were promptly treated in the best scenario, the number of cumulative deaths decreased from 24,740 in the worst scenario to 15,837—a 56% decrease.

Figure 4. Scenarios with various rates of first contacts in primary health care with and without telemedicine. PHC FC 40: 40% rate of first contact in primary health care without telemedicine; PHC FC 50: 50% rate of first contact in primary health care without telemedicine; PHC FC 60: 60% rate of first contact in primary health care without telemedicine; PHC FC 40 + Telem 2: 40% rate of first contact in primary health care with telemedicine; PHC FC 50 + Telem 2: 50% rate of first contact in primary health care with telemedicine; PHC FC 60 + Telem 2: 60% rate of first contact in primary health care with telemedicine.

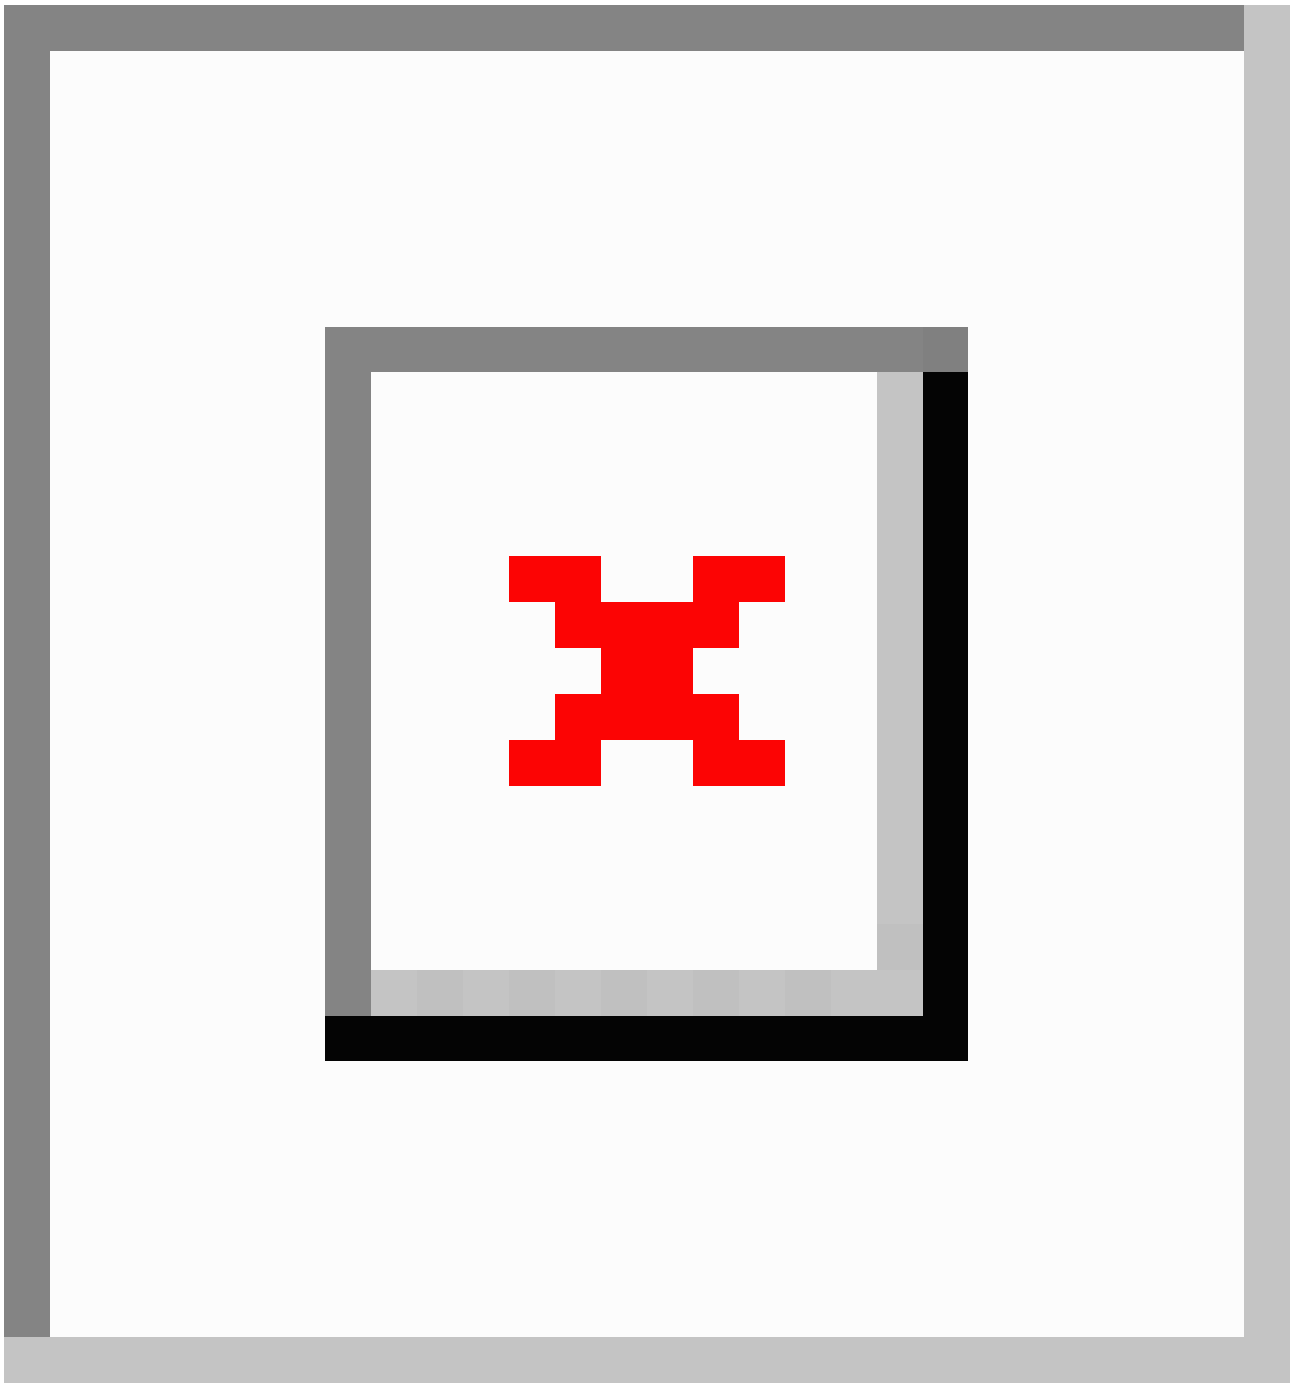


Scenario 2.2: Referral Recommendation Rate for High-Risk Patients

Two of the main tasks of general practitioners in PHC are to identify high-risk patients and provide referral recommendations to secondary care, which are related to the professional capabilities of general practitioners. We simulated the following four scenarios: (1) a recommendation rate of 80%, meaning that 20% of patients requiring advanced treatment in a hospital were not identified (ie, underrecommendation); (2) a recommendation rate of 100% without underrecommendation or overrecommendation, which is an ideal scenario; (3) a recommendation rate of 120%, meaning that 20% of patients were overreferred to secondary care; and (4) a recommendation rate of 100% but with underrecommendation and overrecommendation happening at the same time. Underrecommendation and overrecommendation, respectively, slightly increased and decreased the physician availability and bed availability. However, with underrecommendation, in which 20% of patients who needed to be treated in a hospital were not referred, some patients developed severe illness due to improper

treatment, leading to more severe cases and more cumulative deaths, as shown in Figure 5.

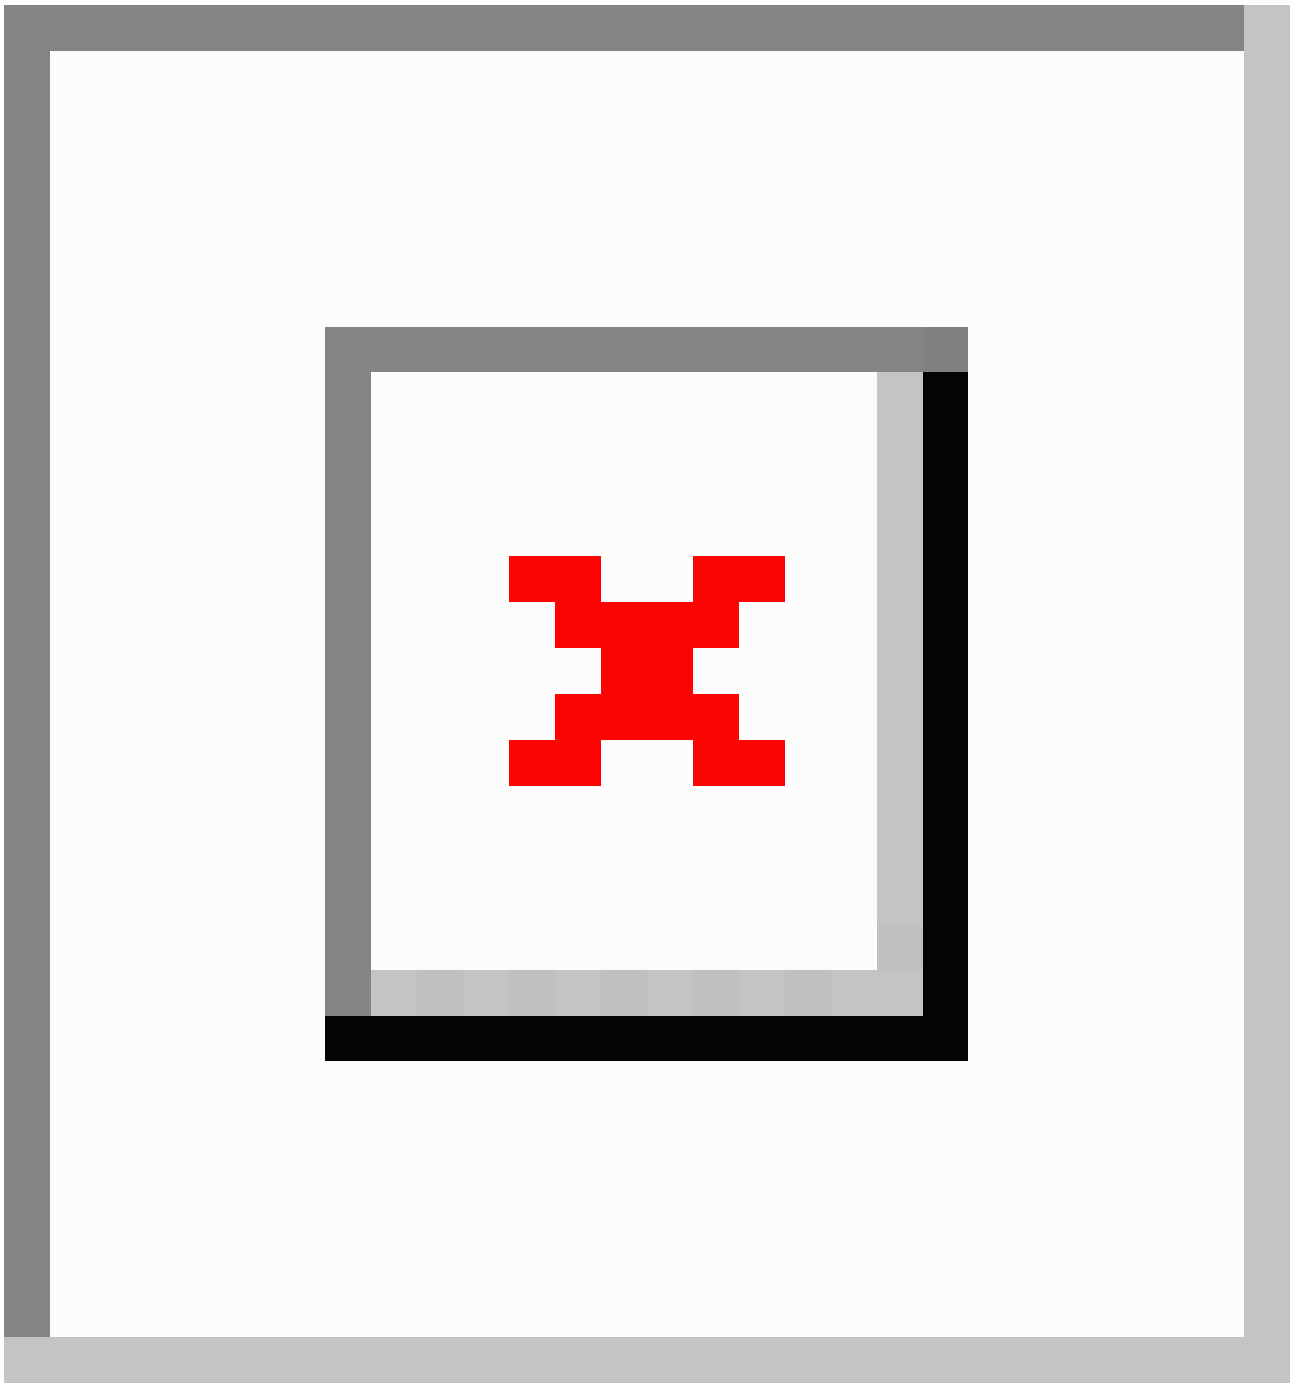
Figure 5. Scenarios involving general practitioners in primary health care with differing capabilities for identifying high-risk patients. “Ideal” refers to no underrecommendation and no overrecommendation. “Nonideal” refers to underrecommendation and overrecommendation happening at the same time.



Scenario 2.3: Follow-Up Health Management Services in PHC

When facing bed shortages, some patients with mild symptoms who are nearly recovered can be transferred to recover in the community if PHC can provide follow-up health management services. We simulated four scenarios under which 5%, 10%, 15%, and 20% of hospital inpatients were transferred back to PHC to recover. As shown in Figure 6, physician availability was not affected, but hospital bed availability improved. When 20% of inpatients could recover in the community, the lowest bed availability level reached approximately 20%, whereas this level reached 7% in the scenario where only 5% of inpatients were referred to PHC to recover. Moreover, the number of days with bed shortages was nearly halved. As a result, the peak number of severe cases decreased from 16,897 to 14,737, and the cumulative number of deaths dropped from 28,008 to 14,344.

Figure 6. Scenarios with different percentages of patients returning to primary health care for recovery. Health mngt 05: 5% rate of health management in the community; Health mngt 10: 10% rate of health management in the community; Health mngt 15: 15% rate of health management in the community; Health mngt 20: 20% rate of health management in the community.

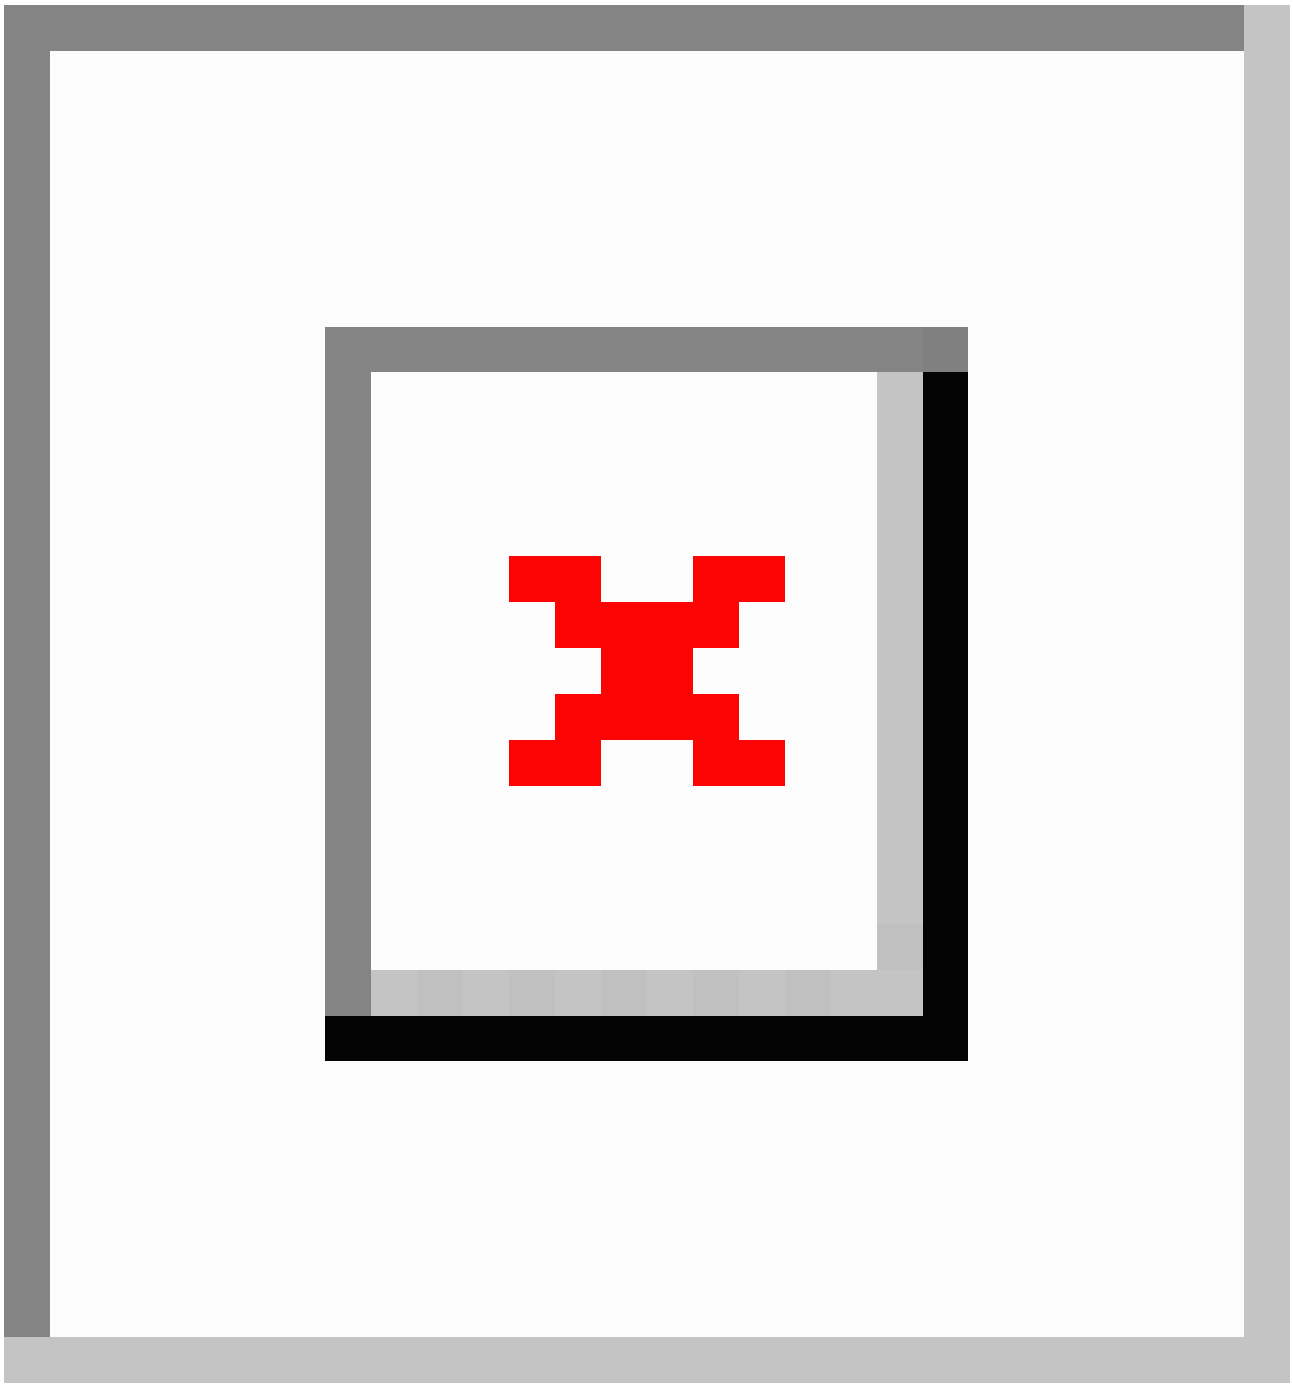


Scenario 2.4: Mixed Policy Interventions

We integrated the above three policy interventions to investigate the overall impact of a PHC-based system, as shown in Figure 7. The model simulation results showed that the lowest level of hospital physician availability ranged from 51% in the worst case (40% rate of first contact in PHC without telemedicine) to 69% in the best case (60% rate of first contact in PHC with telemedicine). The lowest level of hospital bed availability varied even more, ranging from 6% in the worst case (40% rate of first contact in PHC without telemedicine and 5% rate of health management in the community) to 51% in the best case (60% rate of first contact in PHC with telemedicine, recommendation rate of 80%, and 20% rate of health management in the community). With regard to the number of severe cases, the worst case peaked at 20,876 severe cases (40% rate of first contact in PHC without telemedicine, underrecommendation rate of 20%, and 5% rate of health management in the community), and the best case peaked at 11,984 severe cases (60% rate of first contact in PHC with telemedicine, recommendation rate of 100%, and 20% rate of health management in the community)—a decrease of approximately 75%. As for cumulative deaths, the worst case was 37,369 deaths, and the best case was only 7946 deaths—a 79% reduction. Furthermore, we identified the following relatively optimal policy intervention mix: a 60% rate of first

contact in PHC with telemedicine services, a 20% rate of referral to return to PHC, and a recommendation rate of 100% to 120%.

Figure 7. Overall impact of integrated primary health care (PHC). The red, orange, green, and blue areas represent PHC with or without telemedicine, the rate of FC in PHC, the rate of PHC recommendation to secondary care, and the rate of referral to return to PHC, respectively. The gray areas represent the biggest medical resource gaps, including hospital physician availability and hospital bed availability, and the resulting peak number of SCs and cumulative deaths. FC: first contact; SC: severe case.



Discussion

Principal Findings

The experience of hospital overwhelm during the COVID-19 pandemic highlights the need to reflect on existing health systems and search for more proactive solutions during an epidemic. In this study, we constructed a simulated policy environment to replicate Shanghai's response to the mass SARS-CoV-2 infections that occurred once restrictions were lifted. Specifically, the Shanghai Municipal Health Commission deployed medical resources in secondary care hospitals, in a manner that favored patients with SARS-CoV-2 infection, as quickly as possible. This strategy included increasing the availability of beds and reallocating more medical staff from other departments to promptly treat critically ill patients and prevent deaths. This efficient and decisive response allowed Shanghai to avoid the large-scale congestion and overwhelm of the health care system. However, Shanghai's strategy worked under the assumptions that advanced medical resources would

be available and could be deployed, and the strategy largely depended on the government's strong decision-making and coordination capabilities. At the same time, we realize that relying on PHC to alleviate congestion is an important strategy to achieve the effective allocation of medical resources, rather than only relying on temporary expansion in secondary care [33].

We proposed an alternative PHC-based strategy and tested this in a simulated policy simulation environment. We tested the rate of first contact in PHC, the rate of identifying high-risk patients for recommendation to a specialist, and the rate of return to PHC for recovery. According to the simulation results, increasing the rate of first contact in PHC could effectively alleviate the shortage of specialists in large hospitals. Additionally, telemedicine application in PHC contributed substantially to reducing congestion within hospitals engaged in COVID-19 treatment. In our model, a 60% rate of first contact in PHC with telemedicine could increase the lowest level of secondary hospital physician availability from 51% to 67% and reduce the number of cumulative deaths by 9630. The value of first contact in PHC for patients is receiving immediate medical treatment to avoid severe illness or death caused by delays in treatment, as well as reducing the shortage of medical resources in secondary hospitals. COVID-19 has accelerated the development of telemedicine. Alexander and colleagues [34] used a nationally representative audit of outpatient care to characterize primary care delivery in the United States and found that the pandemic was associated with a >25% decrease in primary care volume, which has been offset in part by increases in the delivery of telemedicine. Some believe that the boom in telemedicine during the COVID-19 pandemic could worsen health disparities [35], especially for racial and ethnic minority groups; those living in rural areas; and individuals with limited English proficiency, low literacy, or low income [36]. Nevertheless, telemedicine is an inevitable future developmental trend.

The rate of identifying high-risk patients is a crucial indicator of PHC worker capacity. We found that underidentification could result in more severe illness and more deaths, whereas overidentification could increase congestion in hospitals to some degree. For example, in the scenario with a 50% rate of first contact in PHC with telemedicine, a 120% recommendation rate reduced hospital specialist availability from 61% to 60%, whereas an 80% recommendation rate increased hospital specialist availability from 61% to 63%. A similar impact was observed on hospital bed availability. However, underrecommendation resulted in some patients (ie, those needing further treatment) failing to seek timely medical care and thus higher rates of severe illness and an increase of 3265 cumulative deaths. According to the simulation results, the effect of accurately identifying high-risk patients is limited in the existing system, possibly due to a low rate of first contact in PHC. Unlike countries in Europe and North America, China has a loose medical referral system rather than a strict referral system based on first contact in PHC [37]. China established its PHC system after the new health care reform in 2009 [38]. In October 2016, the Chinese government launched the Healthy China 2030 initiative, in which a critical component is developing a patient referral model [39]. In contrast, gatekeeping systems can ensure the efficient use of scarce medical resources in secondary care; to date, there has been no action plan to enforce the patient referral model [37]. The rate of first contact in PHC has remained at approximately 30% to 50% for the past 10 years. However, in scenarios where PHC first contact–based referral is strictly implemented, such as in the United Kingdom [40], we believe that accurate risk identification in PHC is important.

We also considered the rate of return to PHC for recovery in the community, which can accelerate bed turnover in secondary hospitals. The model simulation results showed that increasing the rate of return to PHC from 5% to 20% would increase bed availability from 6% to 16%, thereby reducing the number of cumulative deaths by approximately 13,000. According to the WHO, referral is a bidirectional process that acknowledges not only the role of the specialist but also the critical role of PHC workers in coordinating patient care over the longer term [41]. In May 2023, Shanghai issued an important document—*Implementation Plan to Further Enhance the City's Community Health Service Capabilities*—focusing on strengthening 4 functions in community health centers—PHC, health management, rehabilitation, and nursing—as well as the primary public health network [42]. COVID-19 has definitely brought challenges to PHC, but it has also provided new opportunities.

Interestingly, we also found a multiplier effect with combined policy interventions. For example, offering telemedicine services, increasing the rate of first contact in PHC from 40% to 60%, and raising the rate of referral to return to PHC from 5% to 20% respectively increased bed availability by 16.67%, 50%, and 167%. However, when combined, these policies increased the lowest bed availability level by 683%. Optimal policy intervention combinations are widely applied in health, climate change, and economics (eg, funding instruments). Policy mixing implies a focus on trade-off interactions and interdependencies among different policies, as they affect the extent to which the intended policy outcomes are achieved. It provides a window of opportunity to reconsider basic and often hidden assumptions to better deal with complex, multilevel, multiactor realities [43]. In this study, we identified a relatively optimal policy combination (ie, a 60% rate of first contact in PHC, a 110% recommendation rate, and a 20% rate of return to PHC) that could establish a strong PHC foundation and increase health system resilience by reducing medical resource gaps in responding to public health emergencies. The interplay of policies and instruments, as well as the deliberate design of policy mixes and portfolios of interventions, has received surprisingly little practical and theoretical attention so far and is vastly underrated [44].

Using the scenario of reopening in Shanghai, we built a health care system for metropolises to deal with large-scale infections and verified the role of PHC through a system simulation model. However, our study has some limitations. First, real-world data were missed, especially epidemiological data, as mass COVID-19 testing was canceled. We validated our model based on information from news reports indicating the development of the Omicron wave and web-based information. Second, data

related to individuals' behaviors, such as the rate of first contact in PHC and the rate of recovery at home, are not available. We estimated these parameters according to our investigation of PHC institutions, hospitals, and communities. Third, this study simulated a PHC-based integrated health system responding to large-scale infections (including parameters such as first-contact rate, referral rate, and recovery fraction), but our models did not tell us how the integrated system could be improved. More attention should be paid to integrated health systems in the near future by conducting more case studies or implementation research.

Conclusions

Rather than focusing on secondary care, in this study, we proposed an alternative—strengthening the health system via a bottom-up approach by using PHC as a foundation to better respond to a public health emergency. Per our PHC-based health system, an optimal PHC-based integrated strategy would be to have a 60% rate of first contact in PHC, a 110% recommendation rate, and a 20% rate of return to PHC, which could increase health system resilience during public health emergencies. A robust PHC-based integrated health system, in addition to the temporary deployment of medical resources in secondary care, could maximize the use of limited medical resources to actively respond to large-scale increases in infections. This study provides an optimal solution for constructing a PHC-based integrated health system to respond to large-scale infections. We acknowledge that there is a long way to go to achieve an integrated health system, as getting PHC to communicate and interact seamlessly with secondary care is extremely challenging globally. We advocate increasing investments in PHC to promote its overall development and conducting more research on integrated health systems in the near future.

Abstract

Background: The Health Information Technology for Economic and Clinical Health Act of 2009 was legislated to reduce health care costs, improve quality, and increase patient safety. Providers and organizations were incentivized to exhibit meaningful use of certified electronic health record (EHR) systems in order to achieve this objective. EHR adoption is an expensive investment, given the resources and capital that are invested. Due to the cost of the investment, a return on the EHR adoption investment is expected.

Objective: This study performed a value analysis of EHRs. The objective of this study was to investigate the relationship between EHR adoption levels and financial and clinical outcomes by combining both financial and clinical outcomes into one conceptual model.

Methods: We examined the multivariate relationships between different levels of EHR adoption and financial and clinical outcomes, along with the time variant control variables, using moderation analysis with a longitudinal fixed effects model. Since it is unknown as to when hospitals begin experiencing improvements in financial outcomes, additional analysis was conducted using a 1- or 2-year lag for profit margin ratios.

Results: A total of 5768 hospital-year observations were analyzed over the course of 4 years. According to the results of the moderation analysis, as the readmission rate increases by 1 unit, the effect of a 1-unit increase in EHR adoption level on the operating margin decreases by 5.38%. Hospitals with higher readmission payment adjustment factors have lower penalties.

Conclusions: This study fills the gap in the literature by evaluating individual relationships between EHR adoption levels and financial and clinical outcomes, in addition to evaluating the relationship between EHR adoption level and financial outcomes, with clinical outcomes as moderators. This study provided statistically significant evidence ($P<.05$), indicating that there is a relationship between EHR adoption level and operating margins when this relationship is moderated by readmission rates, meaning hospitals that have adopted EHRs could see a reduction in their readmission rates and an increase in operating margins. This finding could further be supported by evaluating more recent data to analyze whether hospitals increasing their level of EHR adoption would decrease readmission rates, resulting in an increase in operating margins. Hospitals would incur lower penalties as a result of improved readmission rates, which would contribute toward improved operating margins.

Introduction

Overview

The Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 was legislated to reduce health care costs, improve quality, and increase patient safety [1]. Providers and organizations were incentivized to exhibit meaningful use of certified electronic health record (EHR) systems in order to achieve this objective [1]. The HITECH Act was based on the "triple aim" of health care, which consisted of reducing costs, improving the experience of care, and improving population health, and the HITECH Act contributed to the importance of EHRs [2]. Physicians and hospitals that adopted and used certified EHRs as described in federally defined "meaningful use" criteria were awarded approximately US $27 billion in incentives [3] for eligible providers.

EHR adoption is an expensive investment, given the resources and capital that are invested [4,5]. Due to the cost of the investment, a return on the EHR adoption investment is expected. Usually, a return on adoption is measured by calculating net profit and dividing the net profit by net investment [6]. Calculating a return on investment for EHR adoption requires considering the size of the organization, the extent of the EHR adoption, and profit or improvement in terms of both the financial and clinical outcomes perspectives. Given the complex process of calculating return on investment for EHR adoption, this study evaluates return on investment in terms of how it yields value to the adopting entity. Value from the health care perspective has been described in terms of dollars (financial), productivity (clinical), effectiveness (clinical) [7], cost savings (financial) [8], improvement in clinical decisions (clinical; Rudin et al [9]), supporting triage decisions (clinical; Rudin et al [9]), supporting collaborations among the providers (clinical; Rudin et al [9]), increased productivity (financial and clinical) [9], etc. However, a gap exists in that the return on investment is not analyzed in terms of financial and clinical outcomes combined. Additionally, current literature does not review EHR adoption in terms of level of EHR adoption but rather as a binary variable of "adopted" or "not adopted." This study addresses these gaps by including a combination of both financial and clinical outcomes in a conceptual model and reviewing EHR adoption in terms of levels of EHR adoption.

The value of health IT, of which EHRs are a subset, can depend on the stakeholder and context [10-12]. Looking at value from the stakeholder perspective, for the hospital, EHR value may be reviewed in terms of improved revenue and reduced cost (outcomes); for patients, value may be to improve health and prevent illness (outcomes); for providers, value may be to reduce errors and provide efficient care (process and outcomes); and for government, it may be to improve population health through timely public health reporting and population well-being (process and outcomes) [7]. Hence, given the frequent use of different outcome categories in the literature used to measure value, this study focuses on outcomes as the main value construct and investigates value in terms of different tangible outcomes, such as financial and clinical outcomes. This study examined how EHR adoption levels are associated with value in terms of financial and clinical outcomes combined in 1 model. To address this question, this study investigated the relationship between EHR adoption levels and financial and clinical outcomes by combining both financial and clinical outcomes into 1 conceptual model.

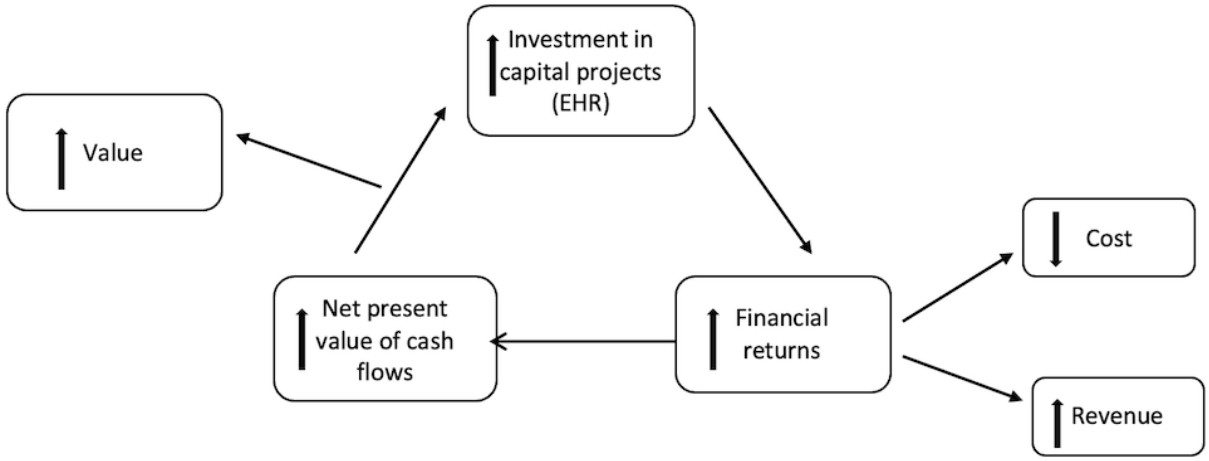
Conceptual Framework and Hypotheses

This study used the corporate financial theory of the firm [13] to guide the evaluation of the relationship between EHR adoption and financial and clinical outcomes. The corporate financial theory of the firm (Figure 1) indicates that the value of the firm, or in this case, the health care entity, is expected to be in alignment with the discounted cash flows from the investments, such as EHRs [13]. This theory indicates that a capital investment, such as EHR adoption, increases the value of the firm as it contributes toward an increase in the net present value of cash flows [13]. Multiple studies have supported the notion that EHR investments improve the value of a hospital through improved financial outcomes by way of a reduction in cost or improved revenues [4,14,15].

A study conducted by Collum et al [4] used this theory to determine an association between EHR adoption and financial outcomes (measured as profit margins and return on assets). The findings from this study indicated that financial returns depend on how long it takes for a hospital's EHR system to achieve full functionality [4], meaning it is important to consider the time variable when reviewing the outcomes of EHR adoption.

Additionally, there have been several studies that have analyzed the relationship between EHR adoption and financial outcomes without using the corporate financial theory of the firm as their guiding framework. Some of the studies from the current literature exhibited a trend that EHR adoption and financial outcomes have a nonlinear relationship [16,17], and some of the studies indicated that EHR adoption resulted in improved financial outcomes for health care organizations that adopted it over time [14,18].

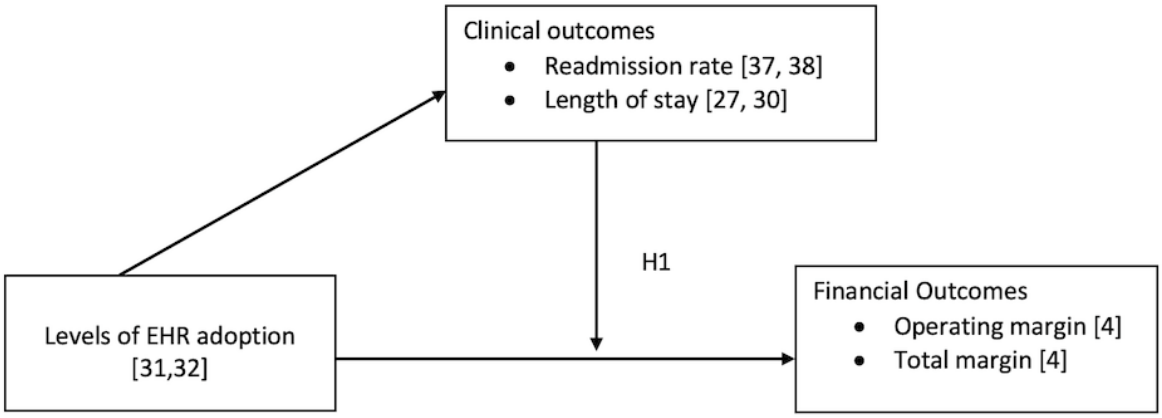
Figure 1. The corporate financial theory of the firm. EHR: electronic health record.



The literature suggests that improvement in costs and revenues is the result of improved clinical outcomes such as reduction of redundant tests [19], reduction of medication and hospital bed-related costs [20], improved ability to capture charges [15], and improved decision support systems [21]. Since this study focuses on combining both financial and clinical outcomes into 1 conceptual model, for the purpose of this study, the capital project investment (EHR adoption in this case) and improvement in financial returns (financial outcomes), tenets of the corporate financial theory of the firm, with an addition of the clinical outcomes, are integrated into a conceptual framework.

The purpose of this conceptual framework (Figure 2 [4,22-27]) is to determine if the previously stated overarching research question of "How is electronic health record adoption associated with value in terms of financial and clinical outcomes?" is supported by the following hypothesis: "The relationship between levels of EHR adoption and financial outcomes (both operating margin and total margin) is moderated by clinical outcomes (readmission rate and length of stay [LOS]) that are also affected by levels of EHR adoption (Figure 2).

Figure 2. Electronic health record (EHR) value analysis conceptual framework.



Methods

Data for this study were retrieved from multiple sources, including the Health Care Provider Cost Reporting Information System, the American Hospital Association (AHA) Annual Survey, the AHA IT Supplement Survey, and Health Care Analytics from Leavitt Partners. The study used a longitudinal design from 2014 to 2017 with 5897 hospital-year observations. Measures were divided into 2 groups: financial and clinical. Financial outcome variables were measured or operationalized using 2 variables (operating margin and total margin) that have been used in the health care literature to measure the profitability of hospitals after EHR adoption. The variables describing clinical outcomes are LOS and readmission rates, as these variables have an impact on the financial performance of the hospital [28,29]. The variables describing the financial outcomes are operating margin and total margin, as these measures include both costs and revenues described in the corporate financial theory of the firm [4,13]. The dependent variables used in this study (operating margins, total margins, LOS, and readmission rates) are not comprehensive in terms of measuring financial

and clinical outcomes for a hospital; however, for the purpose of this study, these variables are considered sufficient, given their potential association with one another.

Dependent Variables

Financial Outcome Variables

In order to gain an understanding of the financial performance of acute care hospitals, profitability ratios are the most frequently used measures [30]; hence, this study included operating margin and total margin as variables representing financial outcomes. Operating margin captures the expenses and revenues related to hospital operations. Total margin measures or captures operating and nonoperating expenses and revenues. The operating margin was calculated by dividing net patient revenues less total operating expenses by net patient revenues and multiplying the ratio by 100. The total margin variable is calculated by dividing net income by total patient revenue. The financial outcome variables are retrieved from the AHA Annual Survey (2014-2017).

Clinical Outcome Variables

Clinical outcomes were measured using LOS and readmission rates. Daniel et al [22] and Schreiber and Shaha [31] reported an intersection of financial and clinical outcomes as a result of EHR adoption and focused on LOS. These studies reported an improvement in LOS due to EHR adoption, resulting in lower plan premiums for patients [22] and costs [31]. Readmission rates are a part of the value-based purchasing program, and depending on the readmission rate, hospitals are penalized on a yearly basis, hence impacting hospital costs [28]. The readmission rates were measured for 6 conditions or procedures, as patients with these conditions are more likely to be readmitted to the hospital. These conditions are: acute myocardial infarction, chronic obstructive pulmonary disease, heart failure, pneumonia, coronary artery bypass graft surgery, and elective primary total hip arthroplasty and total knee arthroplasty [32]. LOS captures the number of days a patient spent in the hospital. Readmission rates indicate whether patients are readmitted to the hospital within 30 days of being discharged. The average LOS and readmission rates can be considered to be indicators of clinical quality outcomes by way of clinical quality measures [28]. Ben-Assuli et al [33] and Lee et al [34] have indicated improvements in average LOS and readmission rates as results of EHR adoption. To confirm these findings for the most recent data, this study analyzes how EHR adoption influences both average (LOS) and readmission rates for the selected sample.

The LOS variable is measured as the average number of days a patient stays in one hospital. The readmission rate variable is measured as the readmission rate payment adjustment factor. The full-year payment adjustment factor is based on data from the fiscal year Hospital Readmissions Reduction Program performance period (ie, July 1, 2014, to June 30, 2017). The minimum payment adjustment factor is 0.97 (ie, 3% maximum penalty). The maximum payment adjustment factor is 1 (ie, no penalty). Hospitals with higher payment adjustment factors have lower penalties [32].

Independent Variables

The level of EHR adoption is considered the major explanatory variable in this study. Hospitals are required to report the extent of adoption of each of the 28 EHR functions to the AHA IT Supplement Survey. The 28 EHR functions can be characterized into 5 different categories: clinical documentation, results viewing, computerized order entry, decision support, and bar coding. Hospitals indicate if each function is implemented in all units, 1 unit, or is in some stage of planning. A study conducted by Everson et al [23] emphasizes the reliability and validity of measuring hospital adoption of EHR with these 28 items.

In order to look at the extent of EHR adoption, Adler-Milstein et al [24] created a continuous EHR adoption measure for each hospital in each year in which they responded to the AHA IT Supplement Survey. The continuous measure was constructed as follows: for each function that was implemented in all units, a hospital received 2 points, and for each function that was implemented in at least 1 unit, a hospital received 1 point. According to the calculations, the total possible EHR adoption score ranged from 0 to 56. In order to improve interpretability, the measure was scaled by dividing each hospital's total score by 56, which yielded an EHR score ranging from 0 to 1. This strategy will be replicated in this study and applied to the EHR adoption level [24].

Control Variables

Control variables for this study include time-variant variables such as competition and payer mix. Control variables are identified based on elements that may influence the level of EHR adoption or hospital financial and clinical outcomes [4]. Since this study uses panel data, which accounts for changes in financial outcomes within hospitals due to changes in levels of EHR adoption, it is not essential to control for time-invariant hospital characteristics such as size of the hospital, ownership, system affiliation, and teaching status. For the purpose of this study, time-variant components that may change over the years, such as competition and payer mix, are considered control variables [4].

The competition construct was operationalized using the Herfindahl-Hirschman Index (HHI), which measures the concentration of an industry in a designated market. HHI was measured in terms of discharges for the health service area. Payer mix was measured using the proportion of inpatient days that were related to Medicare and Medicaid patients (Medicare percentage = total facility Medicare days/total inpatient days, and Medicaid percentage = total facility Medicaid days/total inpatient days). The AHA Annual Survey was used to collect the HHI and payer mix data.

Analysis

The unit of analysis for this study is at the hospital level. To demonstrate the appropriateness of the variables, univariate statistics and bivariate analyses were conducted. Bivariate statistics were generated for both independent and dependent variables of interest. Pairwise correlation analysis was conducted at the significance level of $P<.05$ in order to examine pairwise correlation coefficients between the continuous variables.

Multivariate relationships between different levels of EHR adoption and financial and clinical outcomes, along with the time-variant control variables, were examined using moderation analysis with a longitudinal fixed effects model [35]. Since it is unknown as to when hospitals begin experiencing improvements in financial outcomes, additional analysis was conducted using a 1- or 2-year lag for profit margin ratios [4]. Statistical significance was noted at the significance levels of $P<.10$, $P<.05$, and $P<.01$, and all statistical analyses were conducted in Stata (version 16; StataCorp).

Longitudinal Fixed Effects Moderation Analysis Model

A longitudinal fixed effects model with moderation analysis was used to analyze the multivariate relationships between different levels of EHR adoption and financial and clinical outcomes, along with the time variant control variables.

$$y_{it} = \beta_1 X_{it1} + \beta_2 X_{it2} + \beta_3 X_{it1} X_{it2} + Z_{it}\lambda + \alpha_i + \mu_{it}$$

In this equation, y_{it} is the dependent variable (financial or clinical outcomes), i = hospital, and t = time. β_1 is the coefficient for the main independent variable (levels of EHR adoption), X_{it1}. β_2 is the coefficient for the moderator variable (clinical outcomes), X_{it2}. β_3 is the coefficient for the interaction of the independent variable (levels of EHR adoption) and moderator variable (clinical outcomes), $X_{it1}X_{it2}$. $Z_{it}\lambda$ represents all control variables (competition, payer mix, and years of observation). α_i is the unknown intercept for a vector of hospitals. And μ_{it} is the error term.

The hypothesis, that the relationship between EHR adoption and financial outcomes is moderated by clinical outcomes, was tested using multiple models. The models and their use are outlined in Textbox 1.

Textbox 1. Analytic models and their use.

Model 1

Determine the association between levels of electronic health record (EHR) adoption and operating margin moderated by length of stay (LOS) with the operating margins from the same year.

Model 2

Determine the association between levels of EHR adoption and operating margin moderated by readmission rates with the operating margins from the same year.

Model 3

Determine the association between levels of EHR adoption and total margin moderated by LOS with the total margins from the same year.

Model 4

Determine the association between levels of EHR adoption and total margin moderated by readmission rates with the total margins from the same year.

Model 5

Determine the association between levels of EHR adoption and operating margin moderated by LOS with a 1-year lag in the operating margins.

Model 6

Determine the association between levels of EHR adoption and operating margin moderated by LOS with a 2-year lag in the operating margins.

Model 7

Determine the association between levels of EHR adoption and operating margin moderated by readmission rates with a 1-year lag in the operating margins.

Model 8

Determine the association between levels of EHR adoption and operating margin moderated by readmission rates with a 2-year lag in the operating margins.

Model 9

Determine the association between levels of EHR adoption and total margin moderated by LOS with a 1-year lag in the total margins.

Model 10

Determine the association between levels of EHR adoption and total margin moderated by LOS with a 2-year lag in the total margins.

Model 11

Determine the association between levels of EHR adoption and total margin moderated by readmission rates with a 1-year lag in the total margins.

Model 12

Determine the association between levels of EHR adoption and total margin moderated by readmission rates with a 2-year lag in the total margins.

Ethical Considerations

This study was approved by the University of Alabama at Birmingham institutional review board (300003241).

Results

Overview

Descriptive statistics of acute care hospitals for the years 2014-2017 are displayed in Table 1. For acute care hospitals, average EHR adoption levels showed little variability across each observed year (approximately 0.89 for each observed year). Hospitals observed a steady decrease in average operating margin from 2014 (0.07%) to 2017 (0.057%). The average total margin across hospitals showed a decrease for 2015 (0.005%) compared with 2014 (1.014%), followed by a steady increase across years 2016 (1.136%) and 2017 (0.951%). An increase in LOS was observed for the years 2016 and 2017 (approximately 7.9 days for the year 2017 vs 3.9 days for the year 2014). Average readmission rates remained somewhat steady across all 4 observation years (approximately 0.99 for each observed year).

Table 1. Descriptive statistics of variables (N=5678 hospital-year observations).

Variables	2014 (n=1420)	2015 (n=1453)	2016 (n=1393)	2017 (n=1412)

[a]EHR: electronic health record.

[b]HHI: Herfindahl-Hirschman Index.

For time-variant control variables, the average HHI in terms of discharges across all 4 years was approximately 0.093. HHI values range from 0 to 1, where an HHI value closer to 1 means monopolistic markets, or more market share, and an HHI value closer to 0 means highly competitive markets, or less market share. For the sample used in this study, the markets appear to be highly competitive. In terms of payer mix, the Medicare percentage was similar across all 4 years (average of 0.52). Similarly, the Medicaid percentage was also similar across all 4 years (average of 0.20).

For organizational characteristics, bed size was somewhat similar across all hospitals for all observed years (approximately 255 beds per hospital). In terms of ownership status of the sample hospitals, a majority of the hospitals were nongovernment, not-for-profit hospitals (1105/1421, 78%), followed by investor-owned for-profit hospitals (294/1421, 20%) and government nonfederal hospitals (22/1421, 1.5%). In terms of system affiliation, approximately half the hospitals were affiliated with a system, and the other half were not. For teaching status, a majority of the hospitals did not hold a teaching status (861/1421, 61%).

According to the bivariate statistical analysis (Table 2), at the significance level of $P<.05$, levels of EHR adoption exhibit a positive correlation with operating margin at a magnitude of 0.0978. At the significance level of $P<.05$, readmission rate and levels of EHR adoption are negatively correlated at the magnitude of 0.0321. Even though the magnitudes are close to

0, these relationships are statistically significant at the significance level of $P<.05$.

EHR: Length of Stay (Operating Margin and Total Margin)

Model 1 analyzed the relationship between EHR adoption levels and operating margins without any lags in operating margins, with LOS as a moderating variable for acute care hospitals. For Model 1, the prob>F was greater than 0.05, meaning this model did not provide a statistical explanation for the proposed relationship between EHR adoption levels and operating margins with LOS as a moderating variable.

Model 5 analyzed the relationship between EHR adoption levels and operating margins with a 1-year lag in operating margins, with LOS as the moderating variable for acute care hospitals. The prob>F was less than .05 for this model; however, the analysis did not provide statistically significant evidence to support the relationship between EHR adoption levels and operating margins with a 1-year lag in operating margins, with LOS as a moderating variable. The nonsignificant results indicated a direct positive association between EHR adoption levels and operating margins and LOS; however, when LOS acts as a moderating variable, the indirect relationship between EHR adoption levels and operating margins was negative.

Model 6 analyzed the relationship between EHR adoption levels and operating margins with a 2-year lag in operating margins, with LOS as a moderating variable for acute care hospitals. Even though the prob>F was less than .05 for this model, the analysis did not provide statistically significant evidence to support the relationship between EHR adoption levels and

operating margins with a 1-year lag in operating margins, with LOS as a moderating variable. The nonsignificant results indicated a direct positive association between EHR adoption levels and operating margins with a 2-year lag, which was expected. Additionally, the nonsignificant results indicated a direct negative association between EHR adoption levels and LOS, which is consistent with the findings from the literature. However, when LOS is introduced as a moderating variable, the nonsignificant results indicate a negative indirect relationship between EHR adoption levels and operating margins with a 2-year lag.

Model 3 analyzed the relationship between EHR adoption levels and total margins without any lags in total margins, with LOS as a moderating variable for acute care hospitals. The prob>F was greater than 0.05, meaning the models did not provide a statistically significant explanation for the proposed relationship between EHR adoption levels and total margins without any lags in total margins, with LOS as a moderating variable.

Model 9 analyzed the relationship between EHR adoption levels and total margins with a 1-year lag in total margins, with LOS as a moderating variable for acute care hospitals. For Model 9, the prob>F was greater than 0.05, meaning this model could not accurately predict the relationship between EHR adoption levels and total margins with a 1-year lag in total margins, with LOS as a moderating variable.

Model 10 analyzed the relationship between EHR adoption levels and total margins with a 2-year lag in total margins, with LOS as a moderating variable for acute care hospitals. For Model 10, the prob>F was greater than 0.05, which indicates that this model could not accurately predict the relationship between EHR adoption levels and total margins with a 2-year lag in total margins, with LOS as a moderating variable.

EHR: Readmission Rate (Operating Margin and Total Margin)

Model 2 analyzed the relationship between EHR adoption levels and operating margins without any lags in operating margins, with readmission rates as a moderating variable for acute care hospitals. Hospitals with higher readmission payment adjustment factors have lower penalties [32]. This was the only model in which the results from the analysis provided statistically significant evidence to support the proposed relationship. At the significance level of $P<.05$, EHR adoption levels were positively associated with operating margins. Similarly, at the significance level of $P<.05$, readmission rates were positively associated with an increase in operating margin. However, when readmission rates are introduced as a moderating variable, the magnitude of the relationship between levels of EHR adoption and operating margins is negative.

Model 7 analyzed the relationship between EHR adoption levels and operating margins with a 1-year lag in operating margins, with readmission rates as a moderating variable for acute care hospitals. For Model 7, the prob>F was less than .05 for this model; however, the analysis did not provide statistically significant evidence to support the relationship between EHR adoption levels and operating margins with a 1-year lag in operating margins, with readmission rates as a moderating variable. The nonsignificant results indicate a direct positive association between EHR adoption levels and operating margins with a 1-year lag and readmission rates, which is consistent with the findings from Model 2. However, when readmission rates act as a moderating variable, the nonsignificant results indicate a positive relationship between levels of EHR adoption and operating margins with a 1-year lag, which was the opposite of the results from Model 2.

Model 8 analyzed the relationship between EHR adoption levels and operating margins with a 2-year lag in operating margins, with readmission rates as a moderating variable for acute care hospitals. The prob>F was less than .05 for this model; however, the analysis did not provide statistically significant evidence to support the relationship between EHR adoption levels and operating margins with a 2-year lag in operating margins, with readmission rates as a moderating variable. Similar to Model 7, the nonsignificant results indicated a direct positive association between EHR adoption levels and operating margins with a 2-year lag and readmission rates, which was consistent with the findings from Model 2. However, when readmission rates act as a moderating variable, the nonsignificant results indicated a positive relationship between levels of EHR adoption and operating margins with a 2-year lag, which was the opposite of the results from Model 2.

Model 4 analyzed the relationship between EHR adoption levels and total margins without any lags in total margins, with readmission rates as a moderating variable for acute care hospitals. The prob>F was greater than 0.05, meaning this model could not provide a statistically significant explanation for the proposed relationship between EHR adoption levels and total margins without any lags in total margins, with readmission rates as a moderating variable.

Model 11 analyzed the relationship between EHR adoption levels and total margins with a 1-year lag in total margins, with readmission rates as a moderating variable for acute care hospitals. For Model 11, the prob>F was greater than 0.05, which indicates that this model could not accurately predict the relationship between EHR adoption levels and total margins with a 1-year lag in total margins, with readmission rates as a moderating variable.

Model 12 analyzed the relationship between EHR adoption levels and total margins with a 2-year lag in total margins, with readmission rates as a moderating variable for acute care hospitals. The prob>F was greater than 0.05, meaning this model could not provide a statistically significant explanation for the proposed relationship between EHR adoption levels and total margins with a 2-year lag in total margins, with readmission rates as a moderating variable.

Results from the regression analysis with fixed effects are displayed in Tables 3 and 4. Table 3 includes results from the regression analysis with financial and clinical outcomes from the same year. Hospitals receive their reimbursement and penalties associated with readmission rates and LOS approximately 1 to 2 years after the actual outcomes occur. In order to accommodate this situation, operating margin and total margin ratios were calculated with a 1- and 2-year lag. Table 4

presents results with lags in profit margins for acute care hospitals.

The results from Table 3 for model 2 suggest that, at the significance level of $P<.05$, a 1-unit increase in EHR adoption was associated with an increase of approximately 5.34% in the operating margin.

Table 4 displays results from the analyses with the added lag effect in operating and total margins. According to the results displayed in Table 4, it can be inferred that at the significance levels of $P<.05$, $P<.10$, or $P<.001$, there is not enough evidence to support models 5-8 from this study. For models 9-12, the models did not provide a statistical explanation for the proposed relationships. In other words, the models discussed above could not accurately predict the proposed relationships.

Discussion

Overview

The objective of this study was to determine how EHR adoption level contributes to financial and clinical outcomes for acute care hospitals.

To understand the relationship between EHR adoption level and financial outcomes, moderated by clinical outcomes, this study used a fixed effects moderation analysis model. We hypothesized that there would be a positive association between EHR adoption level and operating and total margins, with LOS and readmission rates as moderating variables.

According to the results displayed in Table 3, for models 1, 3, and 4, the prob>F was greater than .05, meaning the models did not provide a statistical explanation for the proposed relationships in these models. In other words, the models discussed above could not accurately predict the proposed relationships, and there is no evidence that EHR adoption levels have a linear relationship with or explain variance in the operating margins, total margins, and LOS.

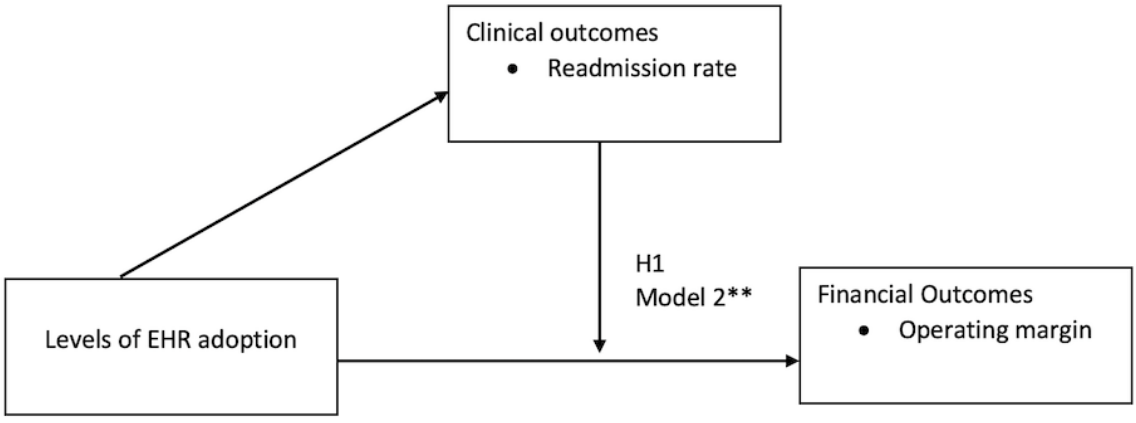
Even though the results are inverse of what was predicted in the hypothesis, these findings indicated that the relationship between EHR adoption levels and operating margins was statistically significant when it was moderated by the readmission rates variable at the significance level of $P<.05$. According to the results of the moderation analysis, as the readmission rate increases by 1 unit, the effect of a 1-unit increase in EHR adoption level on the operating margin decreases by 5.38%. In other words, when the hospital incurred lower penalties for readmissions, the operating margins increased. The minimum payment adjustment factor is 0.97 (ie, 3% maximum penalty). The maximum payment adjustment factor is 1 (ie, no penalty), and hospitals with higher payment adjustment factors have lower penalties and, in turn, larger operating margins [32].

In order to confirm any lagged effect (the timeline of hospitals receiving penalties or incentives for EHR adoption being not clear), this study included additional models that accounted for 1- and 2-year lag in the profit margin ratios (models 5-12). The results, however, did not provide any statistically significant evidence supporting a positive relationship between EHR adoption level and profit margin ratios when the lag effect was included in the model.

Findings from current literature indicate an improvement in LOS as a result of EHR adoption (not necessarily adoption level) yielding increased compensation for the loss of patient days from Center for Medicare and Medicaid Services [25]; however, for this study, none of the tested models provided a statistical explanation for the proposed relationships between EHR adoption and profit margins with LOS as moderating variables.

Even though this finding is opposite of what was proposed in the hypothesis, this finding provides statistically significant evidence that levels of EHR adoption change operating margins when readmission rates are taken into account (Figure 3). Analyzing more recent data could indicate a decrease in readmission rates as a result of increased levels of EHR adoption, yielding an increase in operating margins. The relationship between EHR adoption level and operating margins has not been previously evaluated using readmission rates as moderating variables. Hence, this finding from this study is a unique contribution to the current literature.

Figure 3. Electronic health record (EHR) value analysis framework with results. ***P*<.05.



Limitations of This Study

Regardless of the valuable contribution of the buildout of the conceptual model and the results from the analysis, this study has limitations. First, there is always a risk when using secondary data to conduct research that was not the intent when the data were collected, as this could result in inconsistency in the data collection methods due to the possibility of human error [36].

Second, this study used data from the Medicare Cost Reports to operationalize the readmission rate variable. This particular measure is reported on a 3-year rolling basis, meaning the data analyzed included a rolling average of 3 years of readmission rate data for each hospital [32]. This study operationalized the readmission rate data for specific years in order to evaluate their relationship with levels of EHR adoption and financial outcomes, which can be considered a limitation.

Conclusion

The HITECH Act has played an important role in EHRs becoming an integral part of the modern health system over the last 10 years. The goal of enacting the HITECH Act of 2009 was to reduce health care costs, improve the quality of the care provided, and increase patient safety for providers and organizations that exhibited meaningful use of certified EHR systems [1,37]. Given the cost and complexity of EHR adoption, analyzing its value from various and seemingly atypical perspectives is essential.

The current literature does a good job of providing perspectives on EHR value relative to individual financial and clinical outcomes, but it falls short in providing a collective value analysis. This study fills the gap in the literature by evaluating individual relationships between EHR adoption levels and financial and clinical outcomes, in addition to evaluating the relationship between EHR adoption level and financial outcomes, with clinical outcomes as moderators.

This study provided statistically significant evidence, indicating that there is a relationship between EHR adoption level and operating margins when this relationship is moderated by readmission rates. This finding could further be supported by evaluating more recent data to analyze whether hospitals increasing their level of EHR adoption would decrease readmission rates, resulting in an increase in operating margins. Hospitals would incur lower penalties as a result of improved readmission rates, which would contribute toward improved operating margins.

Abstract

Background: Generative artificial intelligence tools and applications (GenAI) are being increasingly used in health care. Physicians, specialists, and other providers have started primarily using GenAI as an aid or tool to gather knowledge, provide information, train, or generate suggestive dialogue between physicians and patients or between physicians and patients' families or friends. However, unless the use of GenAI is oriented to be helpful in clinical service encounters that can improve the accuracy of diagnosis, treatment, and patient outcomes, the expected potential will not be achieved. As adoption continues, it is essential to validate the effectiveness of the infusion of GenAI as an intelligent technology in service encounters to understand the gap in actual clinical service use of GenAI.

Objective: This study synthesizes preliminary evidence on how GenAI assists, guides, and automates clinical service rendering and encounters in health care The review scope was limited to articles published in peer-reviewed medical journals.

Methods: We screened and selected 0.38% (161/42,459) of articles published between January 1, 2020, and May 31, 2023, identified from PubMed. We followed the protocols outlined in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines to select highly relevant studies with at least 1 element on clinical use, evaluation, and validation to provide evidence of GenAI use in clinical services. The articles were classified based on their relevance to clinical service functions or activities using the descriptive and analytical information presented in the articles.

Results: Of 161 articles, 141 (87.6%) reported using GenAI to assist services through knowledge access, collation, and filtering. GenAI was used for disease detection (19/161, 11.8%), diagnosis (14/161, 8.7%), and screening processes (12/161, 7.5%) in the areas of radiology (17/161, 10.6%), cardiology (12/161, 7.5%), gastrointestinal medicine (4/161, 2.5%), and diabetes (6/161, 3.7%). The literature synthesis in this study suggests that GenAI is mainly used for diagnostic processes, improvement of diagnosis accuracy, and screening and diagnostic purposes using knowledge access. Although this solves the problem of knowledge access and may improve diagnostic accuracy, it is oriented toward higher value creation in health care.

Conclusions: GenAI informs rather than assisting or automating clinical service functions in health care. There is potential in clinical service, but it has yet to be actualized for GenAI. More clinical service–level evidence that GenAI is used to streamline some functions or provides more automated help than only information retrieval is needed. To transform health care as purported, more studies related to GenAI applications must automate and guide human-performed services and keep up with the optimism that forward-thinking health care organizations will take advantage of GenAI.

KEYWORDS

generative artificial intelligence tools and applications; GenAI; service; clinical; health care; transformation; digital

Introduction

Background

Generative artificial intelligence tools and applications (GenAI) systems automatically learn patterns and structures from text, images, sounds, animation, models, or other media inputs to generate new data with similar characteristics [1]. GenAI is used to search, write, and create models, computer codes, and art forms without human assistance. GenAI has emerged significantly in the current decade to help every industry through different products such as ChatGPT, Bing Chat, Bard, LLaMA, Stable Diffusion, Midjourney, and DALL-E [2-5]. Almost all industries share an optimistic vision, with significant investment in using GenAI to transform aspects of value chains [6-10]. However, similar to many other technology hypes, whether this optimism will translate to value outcomes or be a "fad or fashion" remains to be tested over time.

The adoption of GenAI in health care is emerging. Studies point to the use of GenAI in service interactions involving breast cancer diagnoses [11], bariatric surgery [12], cardiopulmonary resuscitation [13], and breast cancer radiologic decision-making [14]. GenAI has the potential to transform by performing tasks at higher quality than humans, which may reduce errors associated with humans in expert domains such as cancer detection [15] and neurological clinical decisions [16]. The rise of GenAI is also referred to as the "second machine age" [17], whereby "instead of machines performing mechanical work they are taking on cognitive work exclusively in the human domain" [17]. Although these instances are encouraging, how exactly GenAI helps in health care processes needs to be articulated and evaluated to provide an understanding of use and value linkages [18,19]. Thus, we asked the following research questions (RQs) in this study: (1) How is GenAI used across different aspects of health care services? (RQ 1) and (2) What is the preliminary evidence of GenAI use across health care services? (RQ 2).

It is essential to explore these 2 RQs for several reasons. Exploring GenAI's use in health care services is essential for realizing its potential benefits, addressing ethical concerns, and continually improving its applications to enhance patient care and the health care ecosystem. This impact spans different areas. For instance, GenAI can help analyze data to provide personalized treatment and tailor interventions. It has shown promise in improving diagnostic accuracy, with higher levels of accuracy in the interpretation of images and scans. AI applications can enhance patient engagement by providing personalized health recommendations, reminders for medications, and real-time monitoring of vital signs. On the provider side, GenAI can save costs by streamlining administrative tasks and improving efficiency, early disease detection, and preventive care. Similarly, knowing the preliminary evidence of GenAI use across health care services is crucial for making informed decisions, ensuring regulatory compliance, building trust, guiding research initiatives, and addressing ethical considerations. This sets the stage for the responsible and effective integration of GenAI into the health care landscape.

The impact of GenAI in health care depends on various factors, including the specific application, quality of data used for training, ethical considerations, and regulatory framework in place. Continuous monitoring, evaluation, and responsible deployment are essential to maximize the positive impact and mitigate potential negative consequences. For instance, artificial intelligence (AI) assists pathologists in diagnosing diseases from pathology slides, leading to faster and more accurate diagnoses and improving patient outcomes [20]. Analysis of oncology literature, clinical trial data, and patient records can help oncologists identify personalized, evidence-based treatment options for patients with cancer, potentially improving treatment decisions [21]. AI has been applied to analyze medical images for conditions such as diabetic retinopathy, aiding in early detection and intervention [22]. AI analyzes clinical and molecular data to help physicians make more informed decisions about cancer treatment and steer them toward personalized and effective therapies [23].

Concerns about using GenAI remain because of algorithmic bias in predictive models that causes discrimination, unequal distribution of health care resources, and exacerbated health disparities [24]. Data privacy and the need for clear guidelines on AI in health care remain a gap, with reported misuse [25]. Misinterpretations or errors in algorithms can lead to incorrect diagnoses, specifically for image readings, which underscores the importance of human oversight in critical health care decisions [26]. Furthermore, implementing and maintaining AI systems can be costly, and overreliance on technology without sufficient human oversight may result in overlooking critical clinical nuances and potentially compromising patient care [27]. Therefore, it is essential to note that the impact of AI on health care is a dynamic and evolving field. Regular updates and scrutiny of the latest research and applications are necessary to understand the positive and negative aspects of GenAI in health care.

Using a literature scoping, review, and synthesis approach in this study, we evaluated the proportionate evidence of using GenAI to assist, guide, and automate clinical service functions. Technologies in general help standardize [28], provide flexibility [29], increase experience and satisfaction through relational benefits [30], induce higher switching costs [31], and enhance the overall quality [32] and value [33] of services. However, high technology may reduce personal touch, trust, and loyalty in service settings [34-38]. Complex technologies may introduce anxiety, confusion, and isolation [39] or disconnection, disruption, and passivity stressors [13] that can erode satisfaction, loyalty, and retention in service settings [28,40-42]. Given the mixed evidence in previous research on the role of technology in services [28,43,44], it is timely to assess to what extent GenAI may even have a role in shaping or disrupting health care services. Overall, the ground realities of the potential for emerging GenAI to benefit health care services rather than just being another knowledge and collation tool need to be assessed and reported to influence further research and practice activities.

Objectives

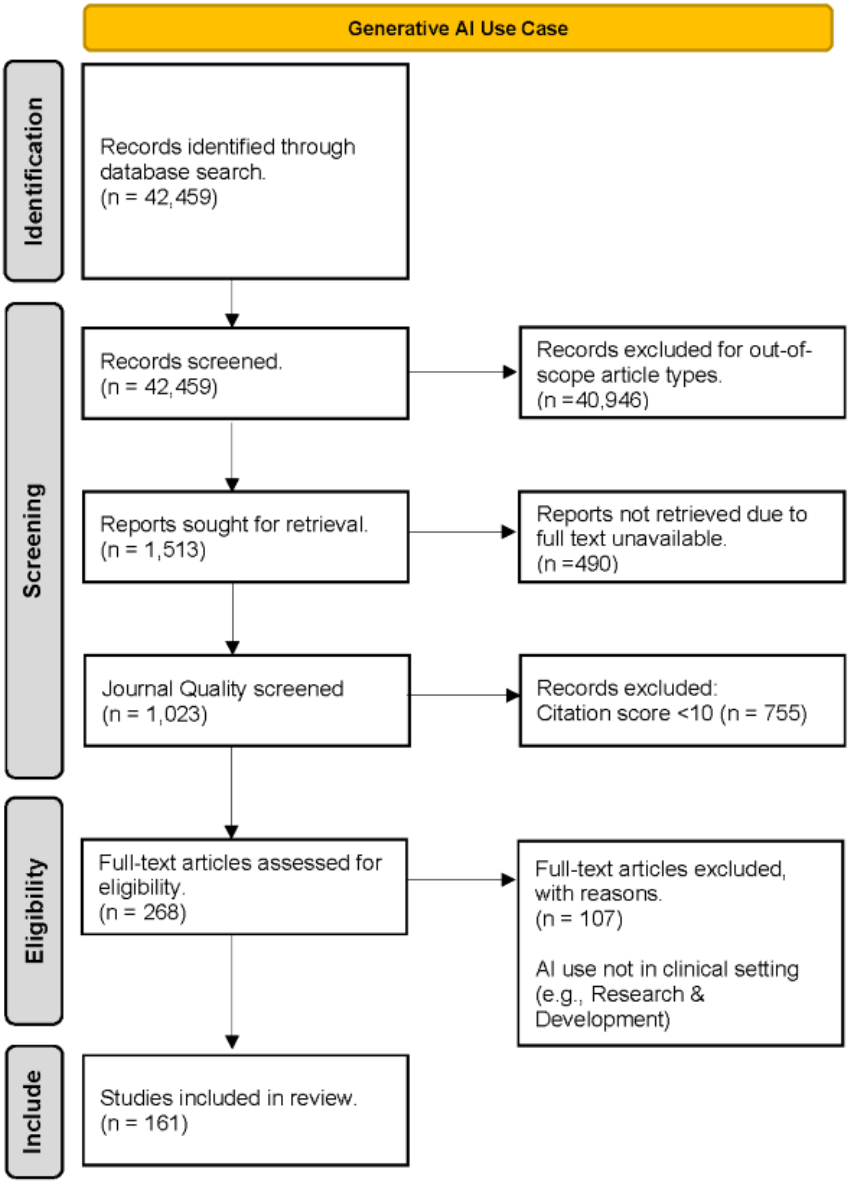
This study took a deep dive to review and synthesize preliminary evidence on how GenAI is used to assist, guide, and automate activities or functions during clinical service encounters in health care, with plausible indications for differential use. More evidence on the actual use is needed to assert that GenAI plays a considerable role in the digital transformation of health care. Therefore, this study aims to identify how GenAI is used in clinical settings by systematically reviewing preliminary evidence on its applications to assist, guide, and automate clinical activities or functions.

Methods

Article Search and Selection Strategy

This study aims to identify how physicians use GenAI in clinical settings, as evidenced in published studies. The design of this study adheres to the protocols outlined in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [45,46]. Figure 1 provides a flowchart of this study's article search and inclusion process.

Figure 1. Literature screening process for relevant articles on generative artificial intelligence (AI) tools and applications.



We focused our search exclusively on PubMed to ensure the credibility of this study's medical or clinical service settings. PubMed is part of the National Library of Medicine and a trusted national source of peer-reviewed publications on medical devices, software applications, and techniques used in the clinical setting. We performed keyword searches to retrieve relevant GenAI publications in PubMed that used "artificial intelligence" anywhere in the text of the article written in English. The sampling period of the publications was from January 1, 2020, to May 31, 2023. The search yielded 42,459 results in the first round of identification of articles for evaluation.

Within PubMed's classification system for articles, we used the "article type" that described the material presented in the article (eg, review, clinical trial, retracted publication, or letter). We

used this article type feature in the PubMed classification system to identify peer-reviewed articles and other relevant types of publications that are pertinent to our study. A total of 52.02% (22,086/42,459) of the returned articles did not have an article type assigned from the 75 article types in PubMed's classification system and were excluded from the study sample. We included clinical, multicenter, case report, news, evaluation, and validation studies. We excluded article types that were out of scope, such as uncategorized articles, government-funded studies, reviews, editorials, errata, opinion articles, nonscientific articles, retracted publications, and supplementary files. We also excluded preprint article types that were unlikely to have attracted attention. Errata or retracted publications (404/42,459, 0.95%), supplementary files (117/42,459, 0.28%), and 50 article types that had too few search returns (243/42,459, 0.57%) were also excluded.

The screening stage excluded review articles (6732/42,459, 15.86%) with an objective that was neither aligned with nor redundant to this study's goal. Opinion articles such as editorials, letters, and commentaries were excluded (2455/42,459, 5.78%). Articles whose funding came from the government or a government agency were not considered because of a conflict of interest for the researchers of the evaluated study (8936/42,459, 21.05%), and preprint articles (77/42,459, 0.2%) were excluded because of lack of availability to the public. We also considered the full text availability of the article, and 32.39% (490/1513) of the articles were excluded in the eligibility stage.

The resulting set of records included 1023 publications. To ensure the credibility of the publication source, we used CiteScore (Elsevier) [47] as a citation index to remove publication sources whose influence is limited. Any publication source whose citation index was unavailable or <10 was removed, resulting in 268 records.

In total, 2 raters, 1 author (DY) and 1 graduate assistant (BB), evaluated 161 articles. The 2 raters' agreement was 91.93%, and the expected agreement was 82.99%. The κ score was 0.5252 (SE 0.0544; *Z* score=9.66; probability>Z score=0.0000). The author and the graduate student performed manual coding by reading the paper's title, abstract, and introduction paragraph to gain a preliminary understanding of the study. After reading the abstract and introduction paragraph, each rater classified each article according to the definition of the 3 classes. For articles that were difficult to understand, the rater read the article further to gain a better understanding of the article. We defined clinical service settings to include the life cycle of physician encounters with patients for the diagnosis, prognosis, and management of health conditions. The research and development of drug discovery, for instance, was not considered. This process eliminated 107 records. The final data set of articles considered for this study was 161.

Ethical Considerations

The data collected for this study were obtained from publicly available sources. The study did not involve any interaction with users. Therefore, ethics approval was not required for this study.

Data Extraction and Categorization Process

We adopted a modified thematic synthesis approach for data analysis that involved coding the text, developing descriptive themes, and generating analytical themes [48]. Initially, each author coded each line of text extracted from the articles, assigning it to different dimensions. This line-by-line coding process facilitated identifying and capturing critical article information and concepts. Next, each author developed descriptive themes by grouping related codes and identifying common patterns or topics emerging from the coded data. These descriptive themes provided a broad overview of the various aspects of AI in the clinical service context. Building on the descriptive themes, each author generated analytical pieces to deepen the understanding and interpretation of the data. The analytical themes involved exploring relationships, connections, and implications within and across the articles, allowing for the extraction of meaningful insights.

Throughout the analysis process, all the authors engaged in extensive discussions to refine and finalize the results of the thematic synthesis. By collectively examining and interpreting the data, the research team ensured the robustness and reliability of the synthesized findings. Similar dimensions were then merged to generate the following 3 meaningful dimensions (assist, guide, and automate) and for relevance to the study objectives, as shown in Textbox 1. The researchers manually coded each article into several groups. They then tried to synthesize them into 1 of the 3 categories of *assist*, *guide*, and *automate* by looking at the title, abstract, and introduction (where applicable).

Textbox 1. Use of generative artificial intelligence tools and applications in clinical services in the reviewed articles (N=161).

Assist

- Improve diagnostic accuracy or reduce error by accessing knowledge during clinical services (141/161, 87.6%) [49-96]
- Activities:
  - Disease detection (19/161, 11.8%) [58,63,67,69,71,73,77,90,97-107]
  - Diagnosis (14/161, 8.7%) [100,108-120]
  - Screening (12/161, 7.5%) [65,86,87,93,121-128]
- Service areas:
  - Radiology (17/161, 10.6%) [49-63,65,66]
  - Cardiology (12/161, 7.5%) [67-72,74,76-79,129]
  - Gastrointestinal medicine (4/161, 2.5%) [81-84]
  - Diabetes (6/161, 3.7%) [86-91]
- Approaches and methods:
  - Deep learning (34/161, 21.1%) [49,59,60,62,63,65,68,71,79,89,100,107,108,111,115,123,125,130-145]
  - Machine learning (9/161, 5.6%) [53,55,83,91,110,146-149]
  - Image analysis (13/161, 8.1%) [68,88,104,110,111,114,116,119,133,135,138,150,151]

Guide

- Recommend treatment options, step-by-step instructions, or checklists to improve clinical services (13/161, 8.1%) [64,80,85,96,152-160]
- Personalized treatment plans (1/161, 0.6%) [64]
- Monitoring and managing (1/161, 0.6%) [96]

Automate

- Minimize or eliminate human provider involvement in clinical services or follow-ups (7/161, 4.3%) [94,95,161-165]

In addition to manual coding by human researchers, we used ChatGPT (version 3.5; OpenAI) for automatic coding. ChatGPT-3.5 was used for speed and cost. ChatGPT-4 is less accessible to users who do not have the funds to pay for its monthly subscription. ChatGPT-3.5 training used one-shot learning using the standard user interface with the "foundational" mode, and no fine-tuning was performed. Future studies may use focused data sets for fine-tuning to improve classification accuracy. However, our study demonstrates that classification accuracy is high and robust even without fine-tuning. This procedure was implemented to check for any subjective bias and demonstrate AI's potential use to complement the human coding process. The abstracts and introductions of these 161 articles were fed into ChatGPT using in-context or a few short learning processes that fine-tune a pair of domain-specific inputs and outputs to train, thereby enhancing the relevance and accuracy of ChatGPT's automated coding output [166,167].

For instance, a sample of input we used in the study was the abstract, which summarizes the article. The output is the categories identified by the experts. ChatGPT learns how to code a set of articles by repeating the pair of inputs and outputs. One-shot learning, which consists of a single pair of inputs and outputs in general, performs as well as >2 samples and zero-shot learning. The benefits of in-context learning (ICL) in ChatGPT include enhanced relevance, where the foundational model becomes better at generating content for domain-specific tasks without additional training of the full model; controlled output such as developing a single word matching the desired coding category or variable; and reduced biases inherent in manual coding. We used the definitions provided in Textbox 1 to train and restrict ChatGPT to choose only 1 of the 3 use-case categories. We further compared ChatGPT's classification with expert coding and found a high level of agreement between the 2, with a κ score of 0.94.

As mentioned previously, the manual coding process involved the raters coding and evaluating each article. After each rater coded the article, the results were compared and discussed to further refine the classification definition and derive consensus on the final assignment of the article classification. This "gold standard" classification was compared with automatic coding performed by ChatGPT (version 3.5). Automatic coding was performed by ChatGPT-3.5. Classification training was performed using one-shot ICL. ChatGPT learns how to classify articles by being fed a pair of articles and classification labels. For example, a user can feed a prompt or use control tokens to indicate an article abstract and the label associated with the article. In our context, 3 articles and labels were fed to the interface. After this initial prompt session of training on 3 classification labels, subsequent interactions of providing only

the article abstract with a prompt asking for a class label would return ChatGPT's prompt completion. Alternatively, training could involve >1 example of the article and its label, which would then be called *few-shot learning*. To summarize, 161 articles were coded by ChatGPT-3.5 based on a single instance of ICL.

Results

Findings From the Synthesis on the Use of GenAI to Assist in Different Aspects of Health Care Services

GenAI can improve clinical services in 3 ways. First, of the 161 articles, 141 (87.6%) reported using GenAI to assist services through knowledge access, collation, and filtering. The assistance of GenAI was used for disease detection (19/161, 11.8%) [58,63,67,69,71,73,77,90,97-107], diagnosis (14/161, 8.7%) [100,108-120], and screening processes (12/161, 7.5%) [65,86,87,93,121-127,168,169] in the areas of radiology (17/161, 10.6%) [49-63,65,66], cardiology (12/161, 7.5%) [67-72,74,76-79,129], gastrointestinal medicine (4/161, 2.5%) [81-84], and diabetes (6/161, 3.7%) [86-91]. Thus, although the use of GenAI has percolated across almost all disease-relevant and main service–relevant areas in health care, it is mainly for assisting through knowledge access, collation, and filtering.

The use of GenAI in disease diagnosis has long-term implications. For instance, identifying "referrable" diabetic retinopathy using routinely collected data would help in population health planning and prevention [86-90]; however, rigorous testing and validation of the applications are critical before clinical implementation [94]. Similarly, using GenAI in remote care helps improve glycemia and weight loss [95], yet challenges related to variable patient uptake and increased clinician participation necessitated by shared decision-making must be considered [96]. In radiology services, prediction models using deep learning and machine learning methods for predictive accuracy and as diagnostic aids have shown potential, and natural language processing has been used to improve readability by generating captions; however, studies report using high-quality images, highlighting the need for a future standardized pipeline for data collection and imaging detection.

In cardiology, AI analysis allows for early detection, population-level screening, and automated evaluation. It expands the reach of electrocardiography to clinical settings in which immediate interrogation of anatomy and cardiac function is needed and to locations with limited resources [67-69,71,73-75,95]. Nevertheless, there is evidence suggesting that integrating AI with patient data, including social determinants of health, enables disease prediction and early disease identification, which could lead to more precise and timely diagnoses, improving patient outcomes.

GenAI aids in diagnostic accuracy, although its focus on higher value creation in health care is limited. The articles in this review reported that they used deep learning (34/161, 21.1%) [49,59,60,62,63,65,68,71,79,89,100,107,108,111,115,123,125,130-145], machine learning (9/161, 5.6%) [53,55,83,91,110,146-149], and image analysis approaches of GenAI during the assistance process (13/161, 8.1%) [68,88,104,110,111,114,116,119,133,135,138,150,151]. Knowledge access using GenAI has the potential to enable more options and flexibility in serving patients.

Evidence of GenAI Use for Guiding or Automation Services

Only 8.1% (13/161) of the studies provided insights into how GenAI is used to guide some services by seeking recommended treatment options, step-by-step instructions, or checklists to improve clinical services [64,80,85,96,152-160]. Of the 161 studies, 1 (0.6%) study sought personalized treatment plans and discussed monitored and managed service processes using GenAI [96]. Although this use category is nascent, GenAI can help provide speed efficiency and customized solutions in health services as in other contexts [37,127,170].

Finally, only 4.3% (7/161) of the articles indicated the use of GenAI to automate any service functions that could minimize or eliminate human provider involvement. When used appropriately, automation provides a predictable, reliable, and faster experience everywhere, every time for all customers, which will be a standardized way to provide several health care services [94,95,161-165].

The use of GenAI in some instances of service automation and guidance may be in its infancy but is encouraging. Providers are trying to explore unique ways to use AI, which requires a set of steps such as understanding the current workflow and the changes needed or aspirational workflows and aligning or designing GenAI to help in the workflow. This is similar to modifying restaurant food delivery options to suit drive-in rather than sit-in options. The providers need some work to fully automate, streamline, or re-engineer the service functions using GenAI in the future.

Summary of Findings

To summarize our findings, in this study, we conducted a systematic scoping review of the literature on how GenAI is used in clinical settings by synthesizing evidence on its application to assist, guide, and automate clinical activities and functions. Of the 161 articles, 141 (87.6%) reported using GenAI to assist services through knowledge access, collation, and filtering. The assistance of GenAI was used for disease detection (19/161, 11.8%), diagnosis (14/161, 8.7%), and screening processes (12/161, 7.5%) in the areas of radiology (17/161, 10.6%), cardiology (12/161, 7.5%), gastrointestinal medicine (4/161, 2.5%), and diabetes (6/161, 3.7%). Thus, we conclude that GenAI mainly informs rather than assisting and automating service functions. Presumably, the potential in clinical service is there, but it has yet to be actualized for GenAI.

Robustness Check Using Additional Database Search

To ensure the comprehensiveness and robustness of our findings, we expanded the search to Web of Science using similar keywords and strategies (suggested by the review team). We used the same keyword, "artificial intelligence," in all text fields over the sampling period between January 1, 2020, and November 27, 2023. Our search was restricted to peer-reviewed academic journal articles written in English. We used the Web of Science–provided "Highly Cited Papers" criterion as a

filtering mechanism to follow influential papers. Given the nonclinical context of the journals in the database, we believe that filtering based on the article's importance is reasonable. Initial search results included 1958 articles from the Web of Science Core Collection. The preliminary analysis of the annual breakdown comprised 414 articles in 2023, a total of 651 articles in 2022, a total of 519 articles in 2021, and a total of 374 articles in 2020. The search results were further reduced by removing PubMed articles for redundancy, resulting in 1221 articles.

Next, Web of Science journals include medical, nonmedical, and other clinical journals. Thus, we used simple keywords for filtering nonmedical and clinical contexts. We used the keywords "medical" and "health" mentioned in the abstract, which led to 133 articles. Finally, we read the abstracts and titles to exclude survey or meta-review and nonclinical studies. This process further narrowed down the selection to 51 relevant articles. Using ChatGPT-3.5 on November 27, 2023, we applied one-shot learning by providing 3 class definitions. We asked ChatGPT-3.5 to classify the article's abstract, with 63% (32/51) in the *assist* category, 29% (15/51) in the *guide* category, and 8% (4/51) in the *automated* category. Diagnostic assistance articles dominated, similar to the results from PubMed. However, the other categories—prescriptive guidance and clinical service recommendations—were slightly higher. This difference is explained by the nonmedical and clinical nature of the journals included in the database. The "applied" nature of the journals is more likely to explore prescriptive guidance and clinical service recommendation use cases.

Discussion

Principal Findings

This study asked RQs about how GenAI is used, with evidence, to shape health care services. It showed that 11.8% (19/161) of the studies were on automation and guidance, whereas 87.6% (141/161) reflected the assistance role of GenAI. These findings are essential to discuss and distinguish between the optimism and actual use of GenAI in health care.

Study Implications

The aspiration that GenAI has the potential to change health care significantly needs a careful revisit. Health care organizations need to assess the actual ground use for GenAI and prepare for and understand the exciting possibilities with a cautious approach rather than overly high expectations. Concerns related to the cost, privacy, misuse, and regulatory aspects of implementing and using GenAI [24-26] will become more pronounced, particularly when there is a perceived overreliance without clear promising results or actual practical use [26].

The literature synthesis in this study suggests that GenAI is mainly used for screening and diagnostic purposes using knowledge access; diagnostic processes such as predicted disease outcomes, survival, or disease classification; and improvement of the accuracy of diagnosis. This solves the problem of knowledge being available and accessible in time in a well-articulated manner to provide or render the services. This could help health care providers make more accurate and timely diagnoses, leading to earlier treatment and better patient outcomes. Such knowledge distillation helps improve diagnostic accuracy through GenAI, which can provide enough knowledge to physicians during service encounters; however, this is not hugely oriented toward higher value creation in health care.

The research synthesis also suggests that there has been some use of GenAI during different steps and aspects of guiding the service delivery processes. Still, such use could be more encouraging and significant across the board. Plausibly, GenAI can analyze large amounts of disparate data from patients to suggest personalized medicine—which may help inform treatment plans for individuals. Service delivery needs some guidance or step-by-step help to be efficient and meet the duration or time requirements to render the clinical service on time, which GenAI may solve. However, we have not yet found strong evidence for such use by any health system.

Currently, the automation of service functions using GenAI has only seen minimal instances and is yet to see widespread implementation. Automation helps offset some manual activities. However, automation may help in service functions' cost, efficiency, and flexibility while maintaining some standards across similar services.

Similarly, although we did not consider this area in the synthesis as it was out of the scope of services, GenAI can also be used in drug development and clinical trial pathways—a value proposition yet to be seen in practice. However, we do not undermine that many laboratories and pharmaceutical companies have used machine learning and AI tools and techniques in drug development and clinical trials. However, reported commercial GenAI use has not come to the limelight.

Some other plausible uses of GenAI in health care include managing supply chain data, managing medical equipment assets, maintaining gadgets and equipment, and building a robust intelligent information infrastructure to support several other activities. For example, active efforts are being undertaken to incorporate GenAI, especially in administrative use cases such as the In Basket patient messaging applications. However, assessing the clinical accuracy of such tools remains a concern.

In addition, we must incorporate user-centered design and sociotechnical frameworks into designing and building GenAI for health care use cases, for instance, to explore how GenAI can prevent a common pitfall of developing models opportunistically—based on data availability or end-point labels, adopting a user-centered design framework is vital for GenAI tools [171]. Similarly, scientific or research-oriented use of GenAI for knowledge search, articulation, or synthesis is helpful [172]. However, how far that will translate to the transformative clinical health care delivery processes while creating higher-order organizational capabilities to create value remains a concern [173].

Limitations of the Study and Scope for Future Research

Several limitations and constraints affect the interpretation and generalizability of the findings of this study. Some of these limitations indicate the need for future research in relevant areas that we discuss further. First, the study's findings were

constrained by the availability of relevant and high-quality publications and the exclusion of preprints and unpublished data to limit the specifically designed scope of the study on using GenAI in health care clinical services, which influences the comprehensiveness and accuracy of the review. There also might be a tendency for studies with positive or significant results to be published, leading to a potential publication bias. In addition, harmful or neutral findings may not be adequately represented in the review, influencing the overall assessment of GenAI's effectiveness in health care. Research should focus on patient-centered outcomes, including patient satisfaction and engagement and the impact of GenAI on the patient-provider relationship. Understanding the patient perspective is crucial for successfully integrating AI technologies into health care.

Second, the field of GenAI in health care is rapidly advancing, and new technologies and applications are continuously emerging. The findings of this study might not capture the most recent developments, and the ’conclusions of this study may become outdated quickly, specifically when some technologies have the potential to be adopted beyond institutional mechanisms, such as using GenAI mobile apps to scan images for retinopathy. Furthermore, an in-depth analysis of specific GenAI applications may open newer directions, and future research should focus on specific GenAI applications to provide detailed insights into their effectiveness and limitations. This could include applications such as diagnostic tools, treatment planning algorithms, and predictive analytics. Such heterogeneity of GenAI in health care encompasses a wide range of applications, and investigating these could make it challenging to draw overarching conclusions about GenAI’s impact on clinical services.

Third, this review may not comprehensively address ethical considerations and potential biases in the use of GenAI in health care. Ethical issues related to data privacy, algorithmic bias, and the responsible deployment of AI technologies may require more in-depth exploration. Future research should systematically explore the ethical considerations associated with GenAI use in health care. This includes issues related to data privacy, consent, transparency, and the ethical deployment of AI algorithms in clinical settings. Finally, more data, papers, articles, and longitudinal developments on some applications may enrich this study and enhance its current limited generalizability. Longitudinal studies are needed to track the impact of GenAI in health care over an extended period. This will help researchers understand the sustained effects, identify potential challenges that may arise over time, and assess the scalability and adaptability of these technologies.

Future studies could undertake comparative effectiveness research to assess how GenAI compares with traditional approaches in health care. Understanding the relative advantages and disadvantages will contribute to evidence-based decision-making. In addition, it is not clear what and how to measure the GenAI applications’ effectiveness in clinical services, leading to a call for standardized study metrics that can incorporate outcome measures and evaluation frameworks. Future research should investigate how the integration of GenAI into clinical health care services affects the workflow of health care providers. This includes understanding the time savings, challenges, and potential improvements in decision-making processes. By addressing these areas, future research can contribute to a more comprehensive understanding of the role, challenges, and potential benefits of GenAI in clinical health care services.

Actionable Policy and Practice Recommendations

The proliferation of technology often outpaces the development of appropriate regulatory and policy frameworks that are necessary for guiding proper dissemination. Our call is that, given that GenAI is emerging, policy agencies and health care organizations play a role in proactively guiding the use of GenAI in health care organizations.

What are some actionable steps for stakeholders, including health care organizations and policy makers, to navigate the integration of GenAI in health care? For health care organizations, the steps may include conducting a technology assessment vis-à-vis goals to achieve outcomes from GenAI. Evaluating the existing infrastructure and technological capabilities within the health care organization to determine readiness for GenAI integration is a first step. This will provide an understanding of the current state of technology and ensure that the necessary upgrades or modifications can be implemented to support GenAI applications, thus garnering the benefits of GenAI.

The second step is to invest in staff training and education through the development of training programs to enhance the skills of health care professionals in understanding and using GenAI technologies. Well-trained staff is essential for the effective and ethical implementation of GenAI, fostering a culture of continuous learning and adaptability. Third, health care organizations need to develop and communicate clear protocols and guidelines for the use of GenAI in different health care services, outlining ethical considerations, data privacy measures, and accountability standards. Transparent protocols help ensure the responsible and standardized use of GenAI, fostering trust among health care professionals and patients.

Fourth, health care organizations need to engage in research on GenAI through collaboration with research institutions and industry partners to participate actively in studies evaluating the effectiveness and impact of GenAI applications in specific health care domains. Involvement in research contributes to the evidence base, informs best practices, and positions the organization as a leader in health care innovation. Finally, as mentioned previously, implementing the gradual integration of GenAI rather than jumping into irrational decisions is a caution. All health systems need to gradually plan and introduce GenAI technologies, starting with pilot programs in specific departments or use cases. Gradual integration allows for careful monitoring of performance, identification of potential challenges, and iterative improvement before broader implementation.

For policy makers, much work must be done at the regulatory framework level to realize GenAI better. Policy makers must establish clear and adaptive regulatory frameworks that address the unique challenges GenAI poses in health care, ensuring patient safety, data privacy, and ethical use. There is a concern

that bias in GenAI algorithms could lead to discrimination in care delivery across patients, and the role of policy guidelines in this aspect to train and use GenAI appropriately is critical. Policy frameworks must be developed to ensure less risk, safe and ethical use, and responsible effectiveness of GenAI. Policy and industry partnerships among experts to determine relevant frameworks are vital to guide the future of GenAI to help transform health care. Robust regulations will provide a foundation for the responsible and standardized integration of GenAI technologies. An underlying challenge of GenAI is integrating it across different legacy IT systems, which involves developing and adopting interoperability standards to ensure seamless communication and data exchange between different GenAI applications and existing health care systems. Interoperability enhances efficiency, reduces redundancy, and facilitates the integration of diverse GenAI solutions. In this process, creating incentives for responsible innovation for ethical considerations and the continuous improvement of GenAI applications will drive a culture of responsibility and quality improvement, aligning technological advancements with societal needs.

Policy-level efforts also need to be oriented to allocate resources to enhance health care infrastructure, including robust connectivity and data storage capabilities, to support the data-intensive nature of GenAI applications. Adequate infrastructure is crucial for the reliable and secure functioning of GenAI in health care. Many of these enhancements may require collaboration between public health care systems, private organizations, and academia to leverage collective expertise and resources for GenAI research, development, and implementation. Finally, policies that address potential biases in GenAI applications and ensure equitable access to these technologies across diverse populations are necessary to help with proactive measures to prevent the exacerbation of existing health care disparities through the adoption of GenAI.

Conclusions

GenAI is both a tool and a complex technology. Complexity is the basis for GenAI, and thus, the use of GenAI in health care creates a set of unparalleled challenges. GenAI is costly to implement and integrate across all aspects of a health system [174]. In envisioning the future of GenAI in health care, we glimpse a transformative landscape in which technology and compassion converge for the betterment of humanity. As we stand at the intersection of innovation and responsibility, the prospect of GenAI holds immense promise in revolutionizing health care, shaping a future in which personalized, efficient, and equitable clinical services are not just aspirations but tangible realities. Our vision embraces a symbiotic relationship between technology and human touch, recognizing that the power of GenAI lies not only in its computational prowess but also in its potential to amplify the capabilities of health care professionals. Picture a world in which diagnostic accuracy is elevated, treatment plans are truly personalized, and each patient's journey is marked by precision and empathy.

Crucially, this vision hinges on responsible adoption. We envisage a future in which regulatory frameworks ensure the ethical use of GenAI, safeguard patient privacy, and uphold the principles of equity. It is a future in which interdisciplinary collaboration flourishes, bridging the expertise of health care providers, policy makers, technologists, and ethicists to navigate the complexities of this evolving landscape.

In the future, the impact of AI on human lives will be profound. Patients experience a health care system that not only heals but also understands, a system in which the integration of GenAI contributes to quicker diagnoses, more effective treatments, and improved outcomes. The human experience is at the forefront—GenAI becomes a tool for health care professionals to better connect with patients and spend more time understanding their unique needs, fears, and hopes. As we embark on this journey, it is crucial to remember that the heart of health care lies in the compassion, empathy, and wisdom of its human stewards. GenAI catalyzes empowerment, freeing health care professionals from mundane tasks to engage in meaningful interactions. It fosters a health care culture in which technology serves humanity, and the collective mission is to enhance the quality of care and life.

In embracing this vision, we are not just architects of technological progress but also custodians of a future in which GenAI and human touch coalesce to redefine health care possibilities. Let our strides be guided by a commitment to responsible innovation, a dedication to inclusivity, and an unwavering focus on the well-being of those we serve. The future of GenAI in health care is not just a scientific evolution, but it is a narrative of healing; compassion; and a shared commitment to a healthier, more humane world. However, without enough evidence, we are skeptical about the current euphoria regarding GenAI in health care.

This systematic narrative review of the preliminary evidence of using GenAI in health care clinical services provides valuable insights into the evolving landscape of AI applications in health care. The existing literature synthesis reveals promising advancements and critical considerations for integrating GenAI into clinical settings. The positive evidence underscores the potential of GenAI to revolutionize health care by offering personalized treatment plans, enhancing diagnostic accuracy, and contributing to the development of innovative therapeutic solutions. The applications of GenAI in areas such as pathology assistance, oncology decision support, and medical imaging interpretation showcase its capacity to augment health care professionals' capabilities and improve patient outcomes.

However, this review also highlights several limitations and challenges that warrant careful consideration. Issues such as the quality of available data, the rapid pace of technological evolution, and the potential for algorithmic bias highlight the complexities associated with adopting GenAI in health care. Ethical concerns, data privacy considerations, and the need for transparent guidelines underscore the importance of a thoughtful and measured approach to integration.

As we navigate the preliminary evidence, it becomes evident that a collaborative effort is required among health care organizations, policy makers, researchers, and technology developers. Establishing clear regulatory frameworks, fostering interdisciplinary collaboration, and prioritizing ethical considerations are crucial steps in ensuring the responsible

deployment of GenAI. Addressing the identified limitations through targeted research initiatives, ongoing evaluation, and continuous improvement will be essential for maximizing the benefits of GenAI while mitigating potential risks.

Moving forward, it is imperative to recognize that integrating GenAI into health care is dynamic and evolving. Future research should focus on refining our understanding of the long-term impact, patient-centered outcomes, and scalability of GenAI applications. By collectively addressing the challenges outlined in this review, stakeholders can contribute to a health care landscape in which GenAI is a powerful ally in delivering personalized, efficient, and equitable clinical services.

Acknowledgments

JK expressly acknowledges the Health Administration Research Consortium at the Business School of the University of Colorado Denver for providing a platform for the stimulating discussion and insights on this topic. The authors acknowledge Mr Bhanukesh Balabhadrapatruni, graduate student fellow at the Health Administration Research Consortium, for assisting with data categorization and citation listing. AM thanks the participants from the Society of Physician Entrepreneurs for their input about artificial intelligence in health care. VP thanks Dr Ron Li at Stanford Medicine for insights and a stimulating discussion on this topic. We used the generative AI tool ChatGPT (version 3.5; OpenAI) for automatic coding and checking the accuracy of the human coding process used to categorize the articles reviewed and synthesized in this study [166,167].

Abstract

Background: Although Ethiopia has made remarkable progress in the uptake of the District Health Information System version 2 (DHIS2) for national aggregate data reporting, there has been no comprehensive assessment of the maturity level of the system.

Objective: This study aims to assess the maturity level of DHIS2 implementation in Ethiopia and propose a road map that could guide the progress toward a higher level of maturity. We also aim to assess the current maturity status, implementation gaps, and future directions of DHIS2 implementation in Ethiopia. The assessment focused on digital health system governance, skilled human resources, information and communication technology (ICT) infrastructure, interoperability, and data quality and use.

Methods: A collaborative assessment was conducted with the engagement of key stakeholders through consultative workshops using the Stages of Continuous Improvement tool to measure maturity levels in 5 core domains, 13 components, and 39 subcomponents. A 5-point scale (1=emerging, 2=repeatable, 3=defined, 4=managed, and 5=optimized) was used to measure the DHIS2 implementation maturity level.

Results: The national DHIS2 implementation's maturity level is currently at the defined stage (score=2.81) and planned to move to the manageable stage (score=4.09) by 2025. The domain-wise maturity score indicated that except for ICT infrastructure, which is at the repeatable stage (score=2.14), the remaining 4 domains are at the defined stage (score=3). The development of a standardized and basic DHIS2 process at the national level, the development of a 10-year strategic plan to guide the implementation of digital health systems including DHIS2, and the presence of the required competencies at the facility level to accomplish

specific DHIS2-related tasks are the major strength of the Ministry of Health of Ethiopia so far. The lack of workforce competency guidelines to support the implementation of DHIS2; the unavailability of core competencies (knowledge, skills, and abilities) required to accomplish DHIS2 tasks at all levels of the health system; and ICT infrastructures such as communication network and internet connectivity at the district, zonal, and regional levels are the major hindrances to effective DHIS2 implementation in the country.

Conclusions: On the basis of the Stages of Continuous Improvement maturity model toolkit, the implementation status of DHIS2 in Ethiopia is at the defined stage, with the ICT infrastructure domain being at the lowest stage as compared to the other 4 domains. By 2025, the maturity status is planned to move from the defined stage to the managed stage by improving the identified gaps. Various action points are suggested to address the identified gaps and reach the stated maturity level. The responsible body, necessary resources, and methods of verification required to reach the specified maturity level are also listed.

(JMIR Med Inform 2024;12:e50375) doi:10.2196/50375

Introduction

Background

Health information systems (HISs) have become an essential component of evidence-based decision-making and health service delivery worldwide [1,2]. Over the past years, countries have recognized the importance of reliable health data to track key health issues and outcomes, leading to significant investments in HISs in both high- and low-income nations. Therefore, the global community has recognized that reliable health data are vital for the development of national health systems. This has been further highlighted in the 2030 Agenda of Sustainable Development Goals [3,4], which recognizes the potential of information and communication technology (ICT) to accelerate human progress, bridge the digital divide, and develop knowledge societies [5].

In low- and middle-income countries (LMICs), various national governments and some global partners, such as the World Health Organization (WHO) and United Nations International Children's Emergency Fund, have made substantial investments in strengthening their HISs [6]. In particular, Ethiopia has made remarkable achievements in implementing HIS over the years. In 2006, the Ministry of Health (MOH) undertook a Health Management Information System reform with a focus on data management, human resources, and ICT (Planning and Programming Department, unpublished data, May 2006) [7]. The MOH standardized the indicators, recording and reporting forms, procedures, and reporting channels to improve performance [8].

Moreover, the MOH has implemented different digital health initiatives, including District Health Information System version 2 (DHIS2), electronic community HIS, electronic medical record systems, electronic community-based health insurance, logistic management information system, human resource information system, master facility registries, and electronic public health emergency management system. Maturity assessment of such digital health systems is essential to guide policy makers in strategizing and prioritizing initiatives [7].

Despite the remarkable progress made in Ethiopia, a comprehensive maturity assessment is yet to be conducted to determine the maturity level of the system and to inform policy makers about potential future interventions. DHIS2 is an open-source digital health platform developed by the University of Oslo in 2006 to manage HISs. Its first implementation was in India in 2006, and its first national rollout was in Kenya in 2010 [9]. Since 2010, LMICs worldwide have adopted this software. In Ethiopia, DHIS2 has been implemented since 2018 [7]. Since then, the MOH has made significant achievements in the development and implementation of DHIS2, such as the deployment of web-based or offline instances, full ownership of DHIS2 customization and implementation, upgrading DHIS2 to version 2.30 with apps developed in-house such as those for disease and public health emergency management report, data visualization applications (scorecard, bottleneck analysis, action tracker, and custom reports), creating metadata, data set customization, incorporating reporting functionality, and new features for decision-making by integrating data quality checks and dashboards [10].

Currently, the MOH uses DHIS2 for planning, reporting, analysis, and dissemination of data for all health programs. It accurately and timely collects and aggregates data such as routine health facility data, staffing, equipment, infrastructure, population estimates, disease outbreaks, survey or audit data, patient satisfaction surveys, and longitudinal patient records. DHIS2 stores, analyzes, and evaluates both aggregate and event-based data at a health facility level [7]. Therefore, DHIS2 is accepted as a primary source of information for planning and decision-making in Ethiopia's health system. However, despite its implementation, the maturity level of DHIS2 has not yet been assessed. A maturity assessment is used to measure the current maturity status of a certain HIS to identify the strengths and improvement points and accordingly prioritize the next steps to reach higher maturity levels [11].

In Ethiopia, the Stages of Continuous Improvement (SOCI) tool was used to assess the current maturity status and improvement of the overall HIS. The assessment report indicated that the overall maturity level of the Ethiopian HIS is between the "repeatable" and "defined" maturity stages [12]. The report recommends maturity assessment of individual digital health systems (eg, DHIS2), which have a wide impact and coverage in the country.

Objective

This study aims to assess the maturity level of DHIS2 implementation in Ethiopia and propose a road map that could guide the progress toward a higher level of maturity. The assessment could help identify the current capabilities; set a baseline for measuring improvement; identify strengths, weaknesses, opportunities, and threats; identify factors influencing achievements; set new pathways for improvements; and foster a culture of excellence in Ethiopia.

Methods

Assessment Setting

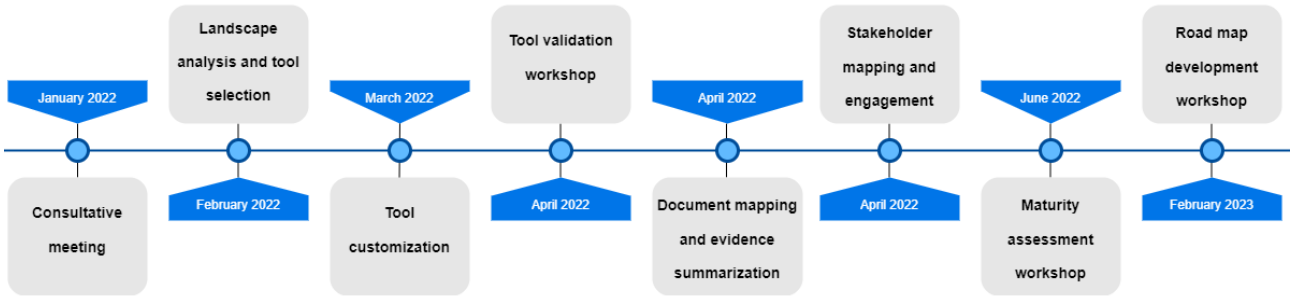
The maturity assessment of DHIS2 implementation was conducted in Ethiopia. It is a landlocked country in East Africa, with a population of 118 million and a 3-tier health care system consisting of primary health care units (health posts, health centers, and primary hospitals), general hospitals, and tertiary hospitals. The country has implemented DHIS2 since 2018. Since then, the country has made significant achievements in the customization and implementation of DHIS2 [10].

Assessment Procedure

Overview

A multimethod approach study was conducted in Ethiopia to assess the maturity level of the DHIS2 implementation. The assessment process proposed in the users' guide for the HIS interoperability maturity assessment was followed to conduct the DHIS2 maturity assessment [13]. First, we conducted various consultative meetings to develop an activity plan for the maturity assessment. Then, we conducted a landscape analysis of various maturity assessment tools to select an appropriate tool for customization. Next, tool customization, followed by a validation workshop, was conducted. The purpose of the workshop was to validate the customized tool for its clarity and appropriateness in the Ethiopian context. Then, we mapped the stakeholders and conducted a maturity assessment workshop. Finally, a road map development workshop was conducted to improve DHIS2 implementation in Ethiopia. Figure 1 shows a diagrammatic representation of the assessment procedure.

Figure 1. Diagrammatic representation of the assessment procedure.



Conducting Consultative Meetings

After the proposal to conduct a maturity assessment for DHIS2 was approved, the researchers conducted several consultative meetings with the MOH and Digital Health Activity, a partner of the MOH that supports Ethiopia in improving health care services through the implementation of digital health solutions. The first meeting was conducted on January 14, 2022, to discuss a drafted activity plan for the entire assessment procedure. The activity plan was presented in the presence of focal persons from the MOH and project facilitators from Digital Health Activity. Several useful inputs were provided to improve the activity plan. The key activities included a landscape analysis; a panel discussion among domain experts to select and customize the maturity assessment tool; a tool validation workshop involving domain experts, partners, and stakeholders to standardize the customized maturity assessment tool; a national workshop involving the MOH, partners, universities, and stakeholders; and data collection and analysis.

Landscape Analysis and Tool Selection

The researchers conducted a rigorous review of existing maturity assessment toolkits and peer reviewed publications from January 11, 2022, to February 15, 2022, to select an appropriate tool. Several tools were reviewed, including the Information Systems for Health Maturity Assessment Toolkit (IS4H) [14], the Global Digital Health Index [15], the Digital Maturity Assessment Tool [16], the HIS Interoperability Maturity Toolkit [17], the Hospital Information System Maturity Model [17], and the SOCI toolkit [18].

After reviewing each potential assessment model and conducting several discussion meetings, 2 models were shortlisted, considering their relevance, comprehensiveness, validity, credibility, and feasibility: IS4H and SOCI. IS4H is a maturity assessment model that describes the method, tool, and questions for assessing the organizational capacity of digital health systems. The model was developed by the Pan American Health Organization and WHO. In contrast, SOCI was developed by the US Centers for Disease Control and Prevention, the Health Data Collaborative Digital Health and Interoperability Working Group, and the United States Agency for International Development–funded Monitoring and Evaluation to Assess and Use Results Evaluation to help countries assess, plan, and prioritize interventions and investments to strengthen an HIS.

After rigorous deliberations regarding the strengths and limitations and comparing the shortlisted models (Multimedia Appendix 1) in a discussion among experts from the MOH, partners, and universities, SOCI was selected as the final model to assess DHIS2 implementation maturity.

Tool Customization

The assessment measures the current and desired HIS status across 5 core domains, 13 components, and 39 subcomponents and road map improvements [18]. The assessment tool measures maturity level based on 5 stages—emerging, defined, repeatable, managed, and optimized, with scores ranging from 1 to 5. Table 1 shows the definitions of each stage of the SOCI tool.

The tool was designed in 2 formats: an Excel (Microsoft Corp)–based and an app-based version of the tool available through the DHIS2 platform. In our case, we customized the Excel-based tool in March 2022 to assess the DHIS2 implementation maturity status. The customization focused on changing the generic HIS to the DHIS2 context. Throughout the Excel-based tool, we have modified the HIS concept to the DHIS2 context without altering the purpose and the core domains, components, and subcomponents of SOCI.

Table 1. The 5 stages of the Stages of Continuous Improvement tool and their definitions.

Stage	Scale	Definition
Emerging	1	Formal processes, capabilities, experience, or understanding of HIS[a] issues or activities are limited or emerging. Formal processes are not documented, and functional capabilities are at the development stage. Success depends on individual effort.
Repeatable	2	Basic processes are in place, based on previous activities or existing and accessible policies. The need for standardized processes and automated functional capabilities is known. There are efforts to document the current processes.
Defined	3	There are approved documented processes and guidelines tailored to District HIS version 2 activities. There is increased collaboration and knowledge sharing. Innovative methods and tools can be implemented and used to extend the functional capabilities.
Managed	4	Activities are under control using established processes. Requirements or goals have been developed, and a feedback process is in place to ensure that they are met. Detailed measures for processes and products are being collected.
Optimized	5	Best practices are being applied, and the system is capable of learning and adapting. The system uses experiences and feedback to rectify problems and continuously improve processes and capabilities. Future challenges are anticipated, and a plan is in place to address them through innovation and new technology. Processes are in place to ensure reviews and incorporation of relevant innovation.

[a]HIS: health information system.

Tool Validation Workshop

A validation workshop involving 18 high-level digital health experts was conducted on April 28 and 29, 2022, to standardize and validate a customized SOCI tool, with participants forming 2 groups to validate each domain, component, and subcomponent and provide constructive feedback. Following the workshop, the feedback was incorporated, which resulted in a validated and standardized SOCI tool.

Document Mapping and Evidence Summarization

The assessors used evidence from the policies and guidelines available in the Ethiopian MOH resource library to evaluate the DHIS2 implementation maturity status [19]. This supporting evidence was mapped in April 2022 based on the content and topics related to the specific component, which served as a reference for the assessors.

Stakeholder Mapping and Engagement

Potential stakeholders were identified in April 2022 after a discussion with the MOH, and those who were working on and supporting DHIS2 were selected, including national and international partners and agencies such as Ethiopian Food and Drug Administration; Ethiopian Pharmaceuticals Supply Agency; Ethiopian Public Health Institute; United Nations International Children's Emergency Fund; United States Agency for International Development; Water, Education, Economic Empowerment, Medical Care, and Alliance; Program for Appropriate Technology in Health; Bill and Melinda Gates Foundation; WHO; Population Services International; HIS Program; Institute of Chartered Accountant of Pakistan; African Medical and Research Foundation; Children's Investment Fund Foundation; Last 10 Kilometers; Data Use Partnership; Transform Primary Health Care; Project Hope; and Clinton Health Access Initiative. All directorates under the MOH, regional health bureaus, and universities were officially invited to participate in the maturity assessment, and most of the selected stakeholders agreed to participate.

Maturity Assessment Workshop

A total of 35 digital health experts were invited to participate in the maturity assessment workshop, of which only 29 (83%) participated. The workshop was conducted from June 15, 2022, to June 17, 2022, with participants representing the stakeholders identified in the mapping exercise. The workshop began with an opening remark by the Health Information Technology Director stating the workshop's objectives and the aim of the assessment, followed by a presentation on the basics, rationale, methods, and reasons for maturity assessment by the University of Gondar team. The maturity assessment tool selection process, landscape analysis, steps followed, and activities performed were presented. Participants were categorized into 2 major groups based on their expertise and experiences and oriented on how to conduct the assessment using the adopted maturity assessment toolkit, SOCI. Each team assessed DHIS2 based on the 5 domains of SOCI, with chairpersons and secretaries facilitating and documenting the assessment scores and justification for each result. Disagreements in scoring between the groups were resolved through discussions. The average score of the 39 subcomponents was summed as the total score for each component, the average score of the 13 components was

summed as the total score for each domain, and the average score of the 5 domains was considered as the total score of the current DHIS2 implementation maturity. Finally, the assessment scores, strengths, and gaps in the DHIS2 implementation were presented and discussed, and feedback was incorporated to refine the assessment results.

Road Map Development Workshop

Of the 45 digital health experts invited to the road map workshop, only 38 (84%) participated. The workshop was conducted from January 30, 2023, to February 2, 2023. The workshop aimed to improve the maturity level of DHIS2 implementation. In total, 38 high-level digital health system experts—12 from the MOH, 9 from Regional Health Bureaus, 2 from agencies, 10 donors or partners, and 5 from Capacity Building and Mentorship Program Universities—participated. The workshop was hands-on, with at least 90% of the time spent in brainstorming and discussion. This approach allowed for better experience, more retention, and more realistic evaluation of the roadmap development. The sessions were continuously linked to the strategic challenges faced by the MOH or health sector, and solutions were discussed and suggested to provide practical solutions for DHIS2 maturity challenges.

During the workshop, key issues related to the 5 domains, 13 components, and 39 subcomponents of the SOCI tool were addressed for the road mapping of DHIS2 implementation. Various discussions were conducted to uncover the strengths and gaps of DHIS2 implementation; identify specific limitations that hinder the capability and implementation of the road map of DHIS2; analyze how DHIS2 is implemented; explore various ways of future improvements on DHIS2 including alternative concepts, tools, and technologies; and scrutinize various governance documents, tools, system documentation, manuals, and other resources to assess the maturity road map of DHIS2.

Each participant integrated knowledge, cognitive strategies, and behaviors as a guide in the group work, and the road map tool was presented and discussed. A detailed road map for each domain and respective components and subcomponents was presented, and major gaps and methods to address them were discussed. A 2-year target was set, and a list of high-impact interventions was identified to address the gaps. Considerations and means of verifications were established; the primarily responsible body was identified; and finally, the road map was developed.

Ethical Considerations

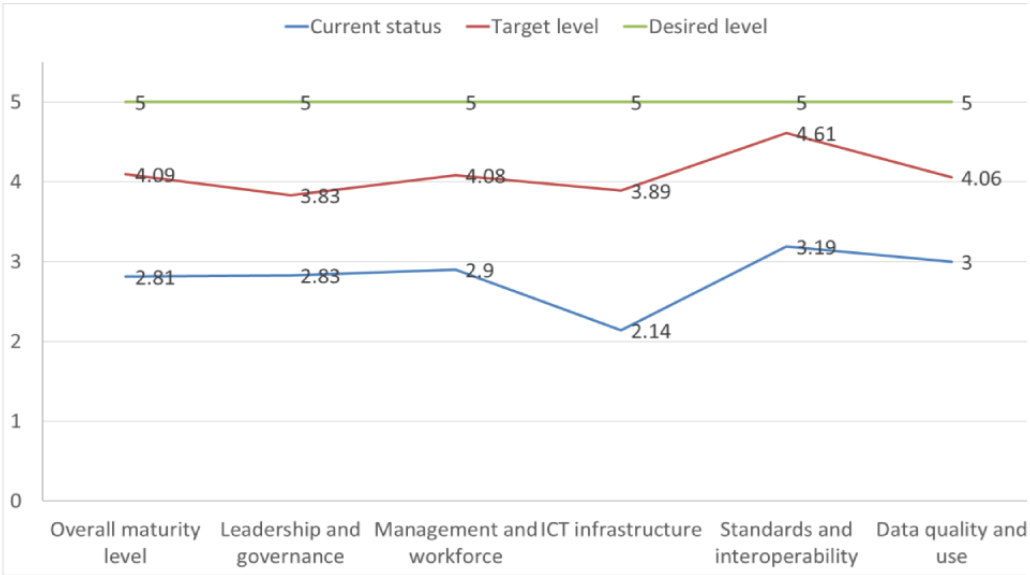
The maturity assessment was conducted in a workshop where participants completed the assessment in groups. There was no individual assessment. No personal identification was used in the assessment. Participation was voluntary. Participants were informed to express their ideas freely during the group discussion.

Implementation (Results)

Overall Current and Target Maturity Levels

The overall DHIS2 implementation in the country is currently at the “defined” stage, with a score of 2.81, and the goal is set to reach the “managed” stage of maturity, with a score of 4.09 by 2025 (Figure 2). Except for the ICT infrastructure domain, which is at the “repeatable” stage, with a score of 2.14, the other 4 domains are at the “defined” stage, with a score of approximately 3. The MOH’s strengths include the development of a standardized and basic DHIS2 process at the national level, the development of a 10-year strategic plan to guide the implementation of digital health systems, and the presence of required competencies at the facility level. However, the lack of workforce competency guidelines, the unavailability of the core competencies required to accomplish DHIS2 tasks at all levels of the health system, and ICT infrastructure challenges are the major hindrances to effectively implementing DHIS2. DHIS2 implementation is also in the “emerging” stage in terms of interoperability and data use components. Multimedia Appendix 2 provides the maturity levels of each domain, component, and subcomponent for the DHIS2 implementation.

Figure 2. A line graph showing the overall national maturity levels and targets of District Health Information System version 2 implementation. ICT: information and communication technology.



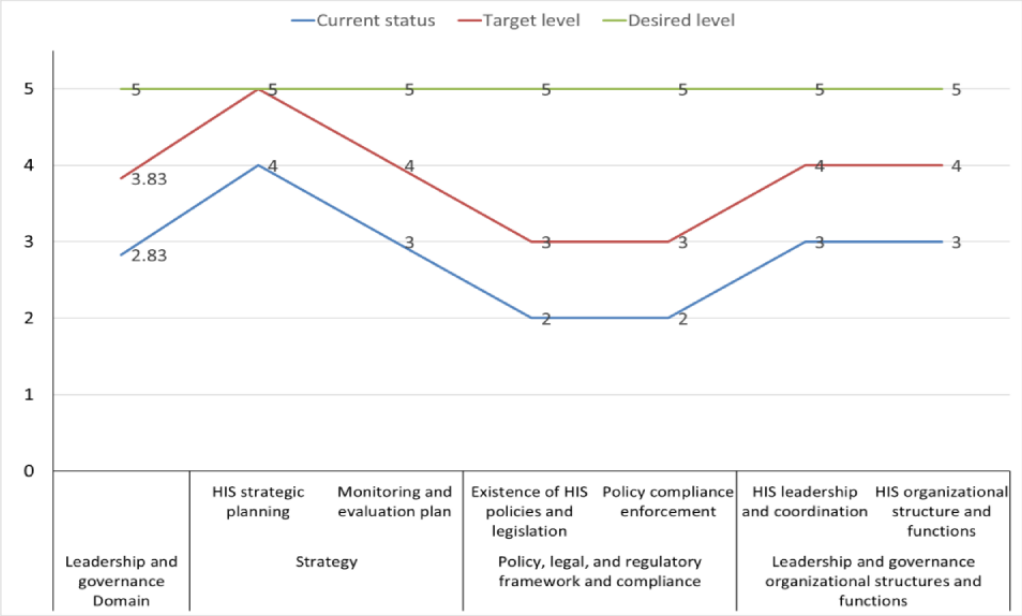
Domain-Wise Implementation Status and Improvement Road Map

Leadership and Governance

The target maturity level for the DHIS2 leadership and governance domain is to move from the defined (score=2.83) to the managed (score=3.83) stage. The "strategic planning" component is intended to move from the managed (score=3.5) to the optimized (score=4.5) maturity stage. The "policy, legal, and regulatory framework, and the compliance" component is intended to progress from the repeatable (score=2) to the defined (score=3) maturity stage, whereas the "leadership, governance, organizational structures, and functions" component is intended to move from the defined (score=3) to the managed (score=4) maturity stage (Figure 3). The MOH has a well-defined and budgeted strategy for HIS that includes DHIS2. In addition, there is a national-level cross-agency coordination group that oversees DHIS2 implementation. However, there are no well-defined mechanisms and regulatory bodies to ensure adherence to organizational policies, procedures, and best practices related to the digital health system. Multimedia Appendix 3 provides detailed information about the strengths and gaps of the ministry regarding DHIS2 implementation with respect to the "leadership and governance" domain.

The bodies responsible for performing the suggested activities (Multimedia Appendix 3) for the subcomponents are the MOH, Ethiopian Food and Drug Administration, regional health bureaus, subregional health administration authorities, and all line agencies. The resources needed to perform the operations indicated for the leadership and governance domain are adequate time, sufficient number of competent workforces, and adequate funds.

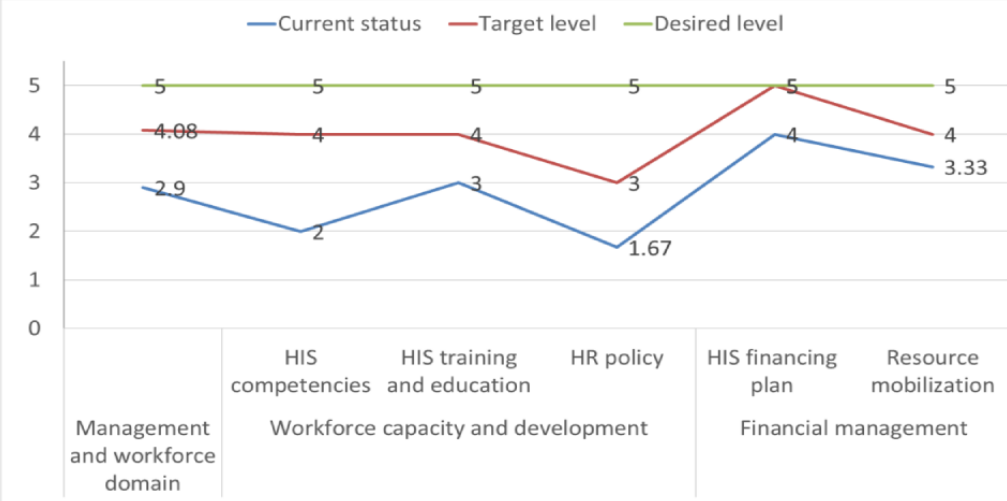
Figure 3. District Health Information System version 2 leadership and governance maturity level and targets. HIS: health information system.



Management and Workforce

The DHIS2 "management and workforce" domain is targeted to improve from the defined (score=2.9) to the managed (score=4) maturity stage. Financial management and workforce capacity and development are the 2 components that are expected to advance from the managed (score=3.6) to the optimized (score=4.5) stage and the repeatable (score=2.2) to the managed (score=3.67) stage, respectively (Figure 4). The DHIS2 academy-level training, collaboration with institutions, and customized training are identified as promising workforce competency initiatives. However, irregular DHIS2 workforce capability assessments and analyses, unclear career paths and roles, insufficient infrastructure, lack of regular feedback, and unmet staffing needs were identified as challenges (Multimedia Appendix 4). The MOH, Human Resource Directorate, Regional Health Bureau, higher institutions, associations, and civil service are responsible for preforming the planned activities. Financial and human resources, infrastructure, and connectivity are required resources. Verification methods included competency assessments, finance and monitoring and evaluation reports, and improvement at the job evaluation grading level.

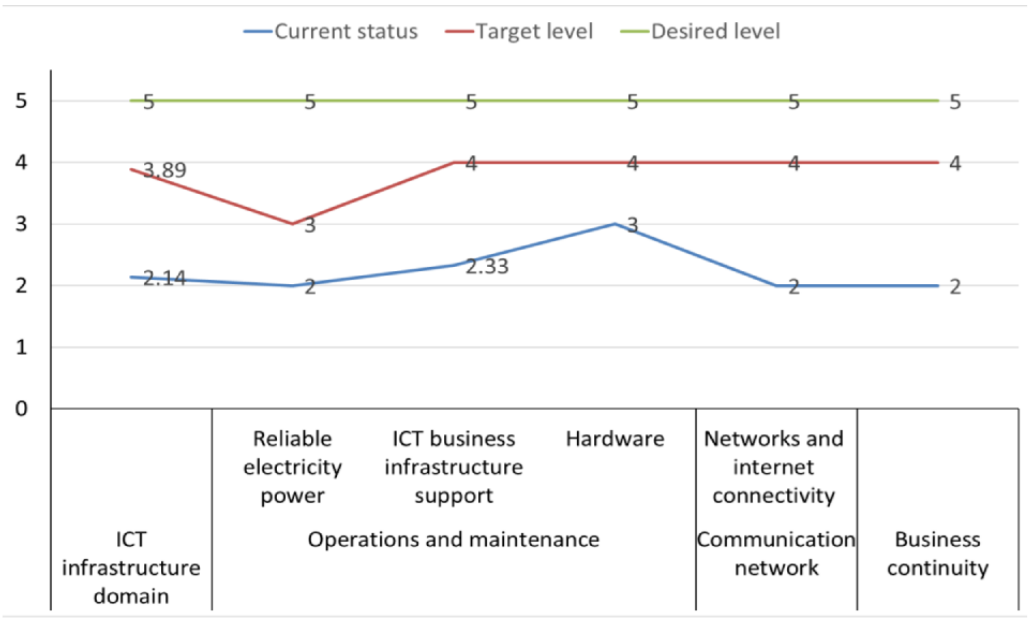
Figure 4. A line graph indicating the national District Health Information System version 2 management and workforce domain maturity level and targets. HIS: health information system; HR: human resource.



ICT Infrastructure

The information and communication domain's projected maturity levels ranged from repeatable (score=2.14) to managed (score=3.89), with a plan in place to elevate operations and maintenance from the repeatable (score=2.44) to the managed (score=3.67) level. Upgrading the local area network and wide area network components from the repeatable (score=2) to the managed (score=4) level is also planned. Similarly, the business continuity element is slated for transformation from the repeatable (score=2) to the managed (score=4) level (Figure 5). The national MOH has collected data about electricity or power access, sources, and reliability to support DHIS2 infrastructure; however, it is limited at higher levels. The MOH has also developed the facility hardware and software specifications, with some national and subnational offices having adequate hardware. Maintenance and installation of DHIS2 infrastructure are currently handled through an ad hoc mechanism (ie, there is no regular maintenance and installation). Maintenance and installation are conducted when the need arises. Simultaneously, several challenges impede the effectiveness of DHIS2 implementation under this domain, such as unstable electricity, insufficient hardware, outdated infrastructure, and limited and unstable network and internet connectivity. In addition, business continuity plans are at the emerging stage, not harmonized across DHIS2 health sector needs, and infrequently reviewed and revised (Multimedia Appendix 5). The MOH, including the chief executive officer, Regional Health Bureaus, digital health, and ICT and health infrastructure departments, is responsible for executing the planned actions in the ICT infrastructure sector. Financial resources, electrical engineers, network specialists, maintenance professionals, ICT spare parts (eg, hard drives and RAM), and other ICT accessories are all essential for achieving the predetermined goals. The methods of verification in the ICT infrastructure field include evaluation reports, network assessments, and support requests, which are measured against predetermined indicators for support from the support system.

Figure 5. A line graph indicating the national District Health Information System version 2 information and communication technology (ICT) infrastructure maturity level and targets.



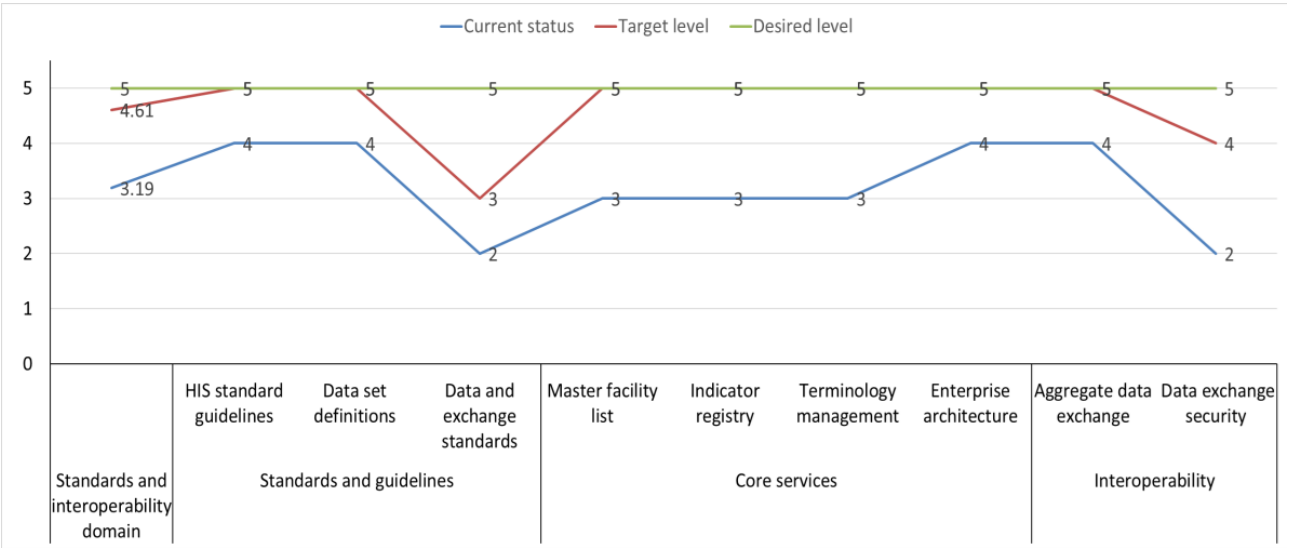
Standards and Interoperability

The "standards and interoperability" domain is an indispensable element in ensuring the success of any HIS as it facilitates the exchange of data across various systems while ensuring the accuracy of data capture and reporting. The domain's anticipated maturity levels ranged from defined (score=3.19) to optimized (score=4.61), with several components expected to move from the defined to the managed or optimized levels. The components of "standards and guidelines" are planned to have a maturity level ranging from defined (score=3.33) to managed (score=4.33), whereas the "core services" components are expected to move from the defined (score=3.25) to the optimized (score=5) level. In addition, there is a strategy to enhance the maturity level of the "interoperability and data exchange" components from defined (score=3) to optimized (score=4.5; Figure 6).

There are several strengths of the "standards and interoperability" domain, including the regular review and harmonization of indicators with international standards, the availability of different types of data exchange mechanisms, and well-documented indicator reference guides and formulas within DHIS2. The eHealth architecture includes an interoperability layer and defined shared services, and data exchange is piloted between DHIS2 and the Master Facility Registry. Vaccines, tracer drugs, and Rapid Diagnostic Test kits are available as indicators or data elements, and essential IT security measures such as virtual private networks, antivirus software, authentication, authorization, and firewalls are in place. Despite the ongoing efforts to improve standards and interoperability, there are still some gaps and areas for improvement. Although the national standard disease definitions, Health Management Information System recording and reporting guidelines, and electronic health record standards are in place, automated patient data exchange using internationally recognized standards between DHIS2 and other systems is not yet implemented. In addition, an interoperability laboratory for new exchange partners to test or onboard and a certification process do not exist yet. The DHIS2 data management and exchange standards are not integrated into the national health plan (Multimedia Appendix 6).

Technical expertise and financial resources are required to ensure the successful implementation and continued improvement in the "standards and interoperability" domain. The MOH and its partners are responsible for implementing the standards and interoperability-related activities. In addition, there must be a commitment to integrate DHIS2 data management and exchange standards into the national health plan and establish an interoperability laboratory for new exchange partners to test or onboard and a certification process.

Figure 6. A line graph indicating the national District Health Information System version 2 interoperability and standard maturity level and targets.



Data Quality and Use

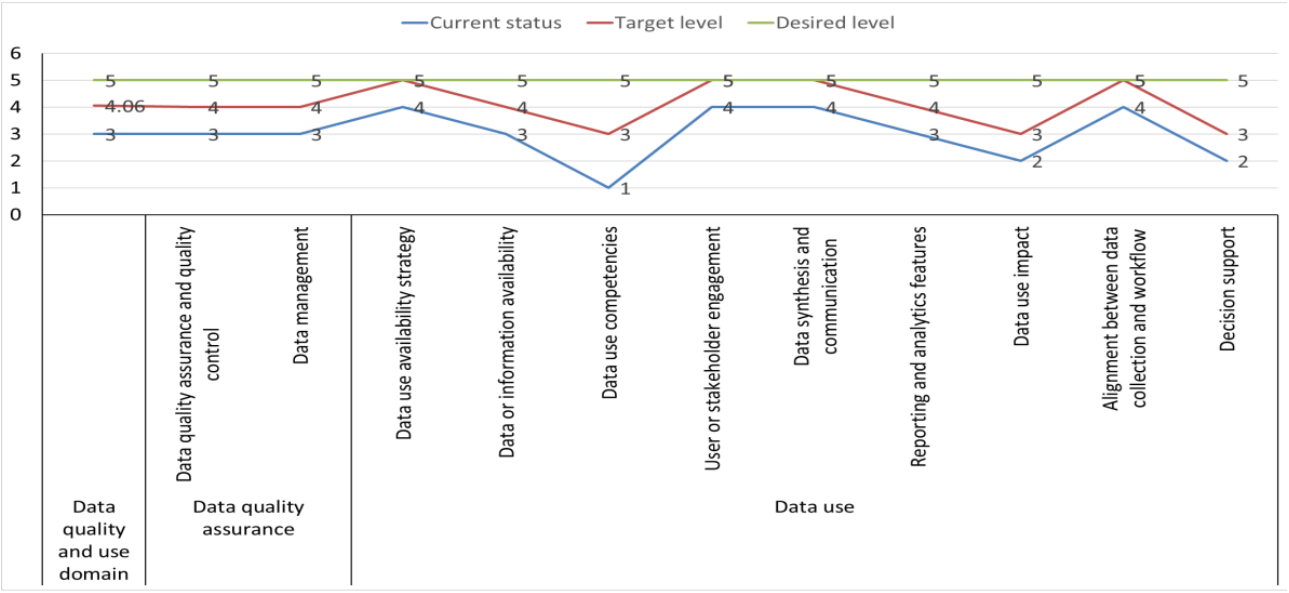
The anticipated maturity levels of the "data quality and use" domain ranged from defined (score=3) to managed (score=4.06), with planned improvements in the maturity level of data quality assurance components from the defined (score=3) to the managed (score=4) stage and data use components from the defined (score=3) to the managed (score=4.11) stage (Figure 7).

The assessment identified the strengths and gaps in this domain. The following strengths were identified: data quality assessment and auditing are performed regularly, manuals for data management and accessibility exist, and analytics and findings are shared with stakeholders on a quarterly basis. In addition, DHIS2 automated data reporting is implemented at all health facilities nationally, including sex-disaggregated data, where applicable. In contrast, there is no evidence of a national data quality governing body that meets regularly to ensure that data quality is maintained. Furthermore, the standard operating procedures and supervision for data management are inadequate. There is also a lack of common measurement metrics or indexes to monitor the progress of data or information use (Multimedia Appendix 7).

The means of verification for the "data quality and use" domain include documentation, data quality audit reports, regular technical working group minutes, practices of data exchange between systems, supervision reports, and regularly reviewed standard operating procedures. The MOH and its partners are

responsible for implementing the standards- and interoperability-related activities in this domain. Technical expertise and financial resources are required to complete the tasks mentioned in the areas of standards and interoperability.

Figure 7. A line graph showing the national District Health Information System version 2 data quality and use maturity level and targets.



Discussion

Principal Findings

Overview

The maturity assessment aims to determine the current implementation status of DHIS2 and set a road map for improvement. The results show that the DHIS2 implementation status has an average score of 2.81, indicating that it is closer to the defined (stage 3) level. This suggests that there is a standardized and basic DHIS2 process at the national level. However, the implementation of DHIS2 is limited by the lack of guidelines for relevant workforce competencies. The competencies required for DHIS2 tasks, such as knowledge and skills, are not specific to DHIS2 activities. The biggest hindrance to DHIS2 implementation in Ethiopia is the ICT infrastructure, including network and internet connectivity. This finding is consistent with the HIS maturity assessments conducted by the MOH of Ethiopia [12] and WHO [20]. It is also consistent with other African countries, such as Cape Verde, Ghana, Mali, Nigeria, and Benin, where the HIS is at the "desired" level of maturity [20].

Leadership and Governance

According to this assessment, the "leadership and governance" domain is currently closer to the defined stage of maturity, with an average score of 2.83. This indicates that the monitoring and evaluation of DHIS2 implementation lacks a clear definition as well as adherence to organizational policies, procedures, and best practices related to the digital health system. This issue is not unique to Ethiopia, as it is also prevalent in many African countries [21,22]. Situational analysis of the Africa Health Strategy 2016 to 2030 revealed that most member states have poor HIS strategies [23]. Ethiopia has just started implementing strategies to facilitate the implementation of digital health systems including DHIS2 [24]. Furthermore, various studies conducted by organizations such as WHO and the Health Metrics Network have shown that health policy is one of the weakest components of digital health and HISs in many countries, particularly LMICs [25-31]. Weak leadership and insufficient coordination are major threats to HIS implementation in LMICs [32-34]. To address these challenges, strengthening the governance and regulation of technologies, including data privacy and security and accreditation of health apps for consumers, should be prioritized for good HIS governance and leadership [35]. A robust governance framework is essential to promote HIS accountability through monitoring and regular, transparent reviews of progress and performance (MOH, unpublished data, September 2022). By prioritizing these areas, Ethiopia should work toward achieving a more effective and sustainable DHIS2 system, ultimately leading to better health care outcomes for its populations.

Management and Workforce

Regarding the "management and workforce" domain, the assessment revealed that DHIS2 implementation in Ethiopia has reached the defined stage (score=2.9). This suggests that there is a lack of regular workforce capability assessments, unclear career paths, and insufficient infrastructure, hindering the effective management and workforce practice of DHIS2 functions at the national level. The importance of effective HIS management and workforce cannot be overstated, as it is crucial for evidence-based decision-making, health service planning, and the delivery of high-quality care [36,37]. Consequently, there has been a growing interest in developing a competent HIS workforce in Africa and beyond [35,38,39]. Financing is also vital for the maintenance, development, promotion, and expansion of DHIS2, necessitating the need for an integrated system of health collaborations and programs [38,40-43]. However, studies in Ethiopia have revealed several challenges, such as poor management and governance of human resource health and weak regulatory capacity for HRH [38,44]. The MOH

has developed a 10-year HIS human resource development road map (2020-2030) and policy on eHealth architecture [45] to address these challenges. This road map provides guidance about the future need for human resources, ensuring proper national HIS support.

Regarding the "ICT infrastructure" domain, the DHIS2 implementation is currently at the repeatable stage (score=2.14). However, there are challenges such as unstandardized measurements of power outages, outdated infrastructure, and limited and unstable network and internet connectivity that hinder its effectiveness. Despite the objectives of the information revolution road map of the country to improve health care delivery through the appropriate use of ICTs, health care facilities in Ethiopia still face issues such as inadequate power sources, poor planning for replacing outdated and damaged equipment, and a lack of business continuity plan related to power supply [38,44,46]. Similar challenges have been reported in other African countries such as Kenya [47], Botswana [48], and Cameroon [49].

ICT Infrastructure

Establishing hardware and networking standards and guidelines for procurement would ensure the incorporation of related technological advancements without any hindrance to the interoperability of systems [50,51]. On the basis of the study findings, it is evident that the main determinants of DHIS2 information use are the availability of computers, communication networks, internet services, trained staff, and legislation [52]. In Africa, there is a need for an ample supply of computers, networks, internet services, and other accessories as well as training staff to boost ICT infrastructural prerequisites for the proper functioning of DHIS2 [53]. Particularly in Ethiopia, communication gaps between the internet service providers and health institutions, lack of follow-up and lack of technical support from the MOH and regional health bureaus, lack of regular network and internet connectivity assessment and reporting methods, and redundant internet or wide area network connection options are among the major challenges [44].

Standards and Interoperability

"Standards and interoperability" is another domain of DHIS2 implementation that is at the defined stage (score=3). Despite the availability of eHealth architecture that guides the interoperability of digital health systems, limited documentation has been found in Ethiopia outlining the standards for data exchange [45]. Health data exchange and harmonization rely on registry services, but in Ethiopia, there are limitations in the regular update and feedback process of the implemented core services. A client registry has not been developed, and Ethiopia does not have a national digital identification program [44]. Consistent with the call for developing standardized indicators by the World Health Assembly Resolution 63.16 [54], the Ethiopian MOH publishes health and health-related indicators annually [55], which is crucial for facilitating personal and aggregate data exchange.

Data Quality and Use

DHIS2 implementation has reached the defined stage (score=3) of maturity in terms of data quality and use. This means that there are regular data quality assessments and audits; quarterly dissemination of analytics and findings to the stakeholders; and automated data reporting using DHIS2, including sex-disaggregated data, where applicable, at all health facilities. However, there are still gaps in the national data quality governing body meeting conducted on an irregular basis to maintain data quality. Furthermore, there is a lack of common measurement metrics or indexes to monitor the progress of data or information use. Researchers agree that this lack of data quality and use is a major problem in LMICs [56,57] and needs to be addressed to solve the complex global health challenges. Thus, efforts to build a culture of data quality and use should be prioritized to ensure the effective use of data for improved health outcomes.

Limitations

This assessment has some limitations. The assessment was conducted among participants with different levels of experience and knowledge regarding DHIS2 implementation in Ethiopia. Therefore, the rating might be affected by this variation. We have attempted to minimize this limitation by letting participants have more time to discuss their differences and reach consensus. We did not collect data about DHIS2 implementation at the health facility level due to resource limitations. Therefore, the actual implementation status might not be reflected. However, we have attempted to involve participants who closely support and monitor DHIS2 implementation at the facility level.

Conclusions and Recommendations

The study used the SOCI maturity model toolkit to assess the maturity level of DHIS2 implementation in Ethiopia. The study found that DHIS2 implementation was at the defined stage of maturity in 4 of 5 domains, with a plan to move to the managed level (score=4.09) by 2025 by addressing the identified gaps.

The development of a standardized and basic DHIS2 process at the national level and the development of a 10-year strategic plan to guide the implementation of digital health systems, including DHIS2, were identified as strengths. However, the lack of workforce competency guidelines to support the implementation of DHIS2 and the gaps in knowledge and skills required to accomplish DHIS2 tasks at all levels of the health system were found to be the challenges in successfully implementing DHIS2.

The study also found that the country was in the emerging phase in terms of interoperability and data use components. Therefore, we recommend the following:

1. Clearly defined regulatory body, processes, and procedures to ensure compliance with DHIS2 standards, policies, and regulations should be established nationally. A process to review, validate, and enforce the implementation of policies, legislation, and regulations in DHIS2 should be regularized and updated as necessary to reflect the changes within the health domain. Metrics regarding DHIS2 compliance and

noncompliance should be collected, recorded, and reported regularly.

2. A platform to review DHIS2 users' competencies should be established to ensure continuous performance improvement and alignment with health care goals. This can be achieved through annual knowledge and skill evaluations and certification of the workforce. Planning, human capacity requirements, and availability related to digital health systems such as DHIS2 should be continuously improved based on the national digital health strategic plan.
3. Clear national plans and procedures for network management should be established. A dedicated network support team should be put in place at least at the district level. This will sustain the implementation of DHIS2 in the relevant facilities and offices at all levels. In addition, connectivity gaps should be documented and addressed as part of a standard process.
4. Integration of the DHIS2 data exchange and management process into the national HIS or health plan should be tracked, monitored, and reviewed through a standardized process. Moreover, it would be beneficial to have an interoperability laboratory for new exchange partners to test or for onboarding and to have a certification process.
5. Computerized alerts and reminders to managers, care providers, and patients; clinical guidelines; condition-specific order sets; focused patient data reports and summaries; documentation templates; diagnostic support; and contextually relevant reference information, among other tools, should be provided by integrating decision support apps into the DHIS2 system.

Overall, the recommendations aimed to improve the DHIS2 implementation in Ethiopia by addressing the identified gaps and enhancing the strengths. By implementing these recommendations, the country can improve the efficiency and effectiveness of its HIS, which can lead to better health outcomes for its population. However, the successful implementation of the recommendations depends on the prioritization and the capacity of the ministry and its stakeholders to allocate the necessary budget and resources.

Acknowledgments

The authors would like to thank the participants involved in the District Health Information System version 2 implementation maturity assessment process.

Abstract

Background: With the aging population on the rise, the demand for effective health care solutions to address adverse drug events is becoming increasingly urgent. Telemedicine has emerged as a promising solution for strengthening health care delivery in home care settings and mitigating drug errors. Due to the indispensable role of family caregivers in daily patient care, integrating digital health tools has the potential to streamline medication management processes and enhance the overall quality of patient care.

Objective: This study aims to explore health care professionals' perspectives on the use of a medication and care support system (MCSS) and collect recommendations for designing a similar tool for family caregivers.

Methods: Fifteen interviews with health care professionals in a home care center were conducted. Thematic analysis was used, and 5 key themes highlighting the importance of using the MCSS tool to improve medication management in home care were identified.

Results: All participants emphasized the necessity of direct communication between health care professionals and family caregivers and stated that family caregivers need comprehensive information about medication administration, patient conditions, and symptoms. Furthermore, the health care professionals recommended features and functions customized for family caregivers.

Conclusions: This study underscored the importance of clear communication between health care professionals and family caregivers and the provision of comprehensive instructions to promote safe medication practices. By equipping family caregivers with essential information via a tool similar to the MCSS, a proactive approach to preventing errors and improving outcomes is advocated.

Introduction

Background

As the population ages, the demand for effective care solutions in home care intensifies, necessitating innovative approaches to medical care services [1]. According to studies [2,3], older adults often face complex health conditions and cognitive impairments; thus, drug therapy becomes more complex, and with an increasing number of new prescription drugs being approved and patients requiring more potent and sophisticated treatments, the likelihood of errors also increases. Studies show high rates of medication errors, with 23% to 92% in outpatient settings and nearly 50% after discharge, highlighting the need for effective interventions [4-6] Recently, the role of family caregivers in supporting older adults with daily activities,

including medication management, has become vital. Recognizing this, there is a growing trend to develop digital supportive systems that lighten the burden on family caregivers while enhancing the well-being of the older adults under their care. Family caregivers often struggle with the challenges of managing multiple responsibilities, navigating complex medication regimens, and ensuring adherence to promote medication without harm, all while managing their loved ones' cognitive conditions. In response to this pressing need, there is a call for proactive measures aimed at empowering family caregivers with tools and resources tailored to their unique needs [7-11].

In the realm of health care, eHealth refers to the integration of digital technologies and information and communications technologies into health care systems and processes. This integration aims to improve the delivery of health care services, enhance patient care, and streamline administrative tasks [12,13].

The adoption of eHealth solutions enables better coordination, data-driven decision-making, and personalized medicine, benefiting health care professionals, providers, patients, and family caregivers alike. Health care professionals gain improved access to patient data and tools for remote consultation, whereas providers streamline administrative tasks and enhance care delivery and patients, together with family caregivers, benefit from increased engagement, remote monitoring, and personalized interventions, leading to better health outcomes [1,14-16]. eHealth solutions empower patients to actively participate in their care, access educational resources, and engage in teleconsultations with health care professionals from the comfort of their homes. Moreover, digital health streamlines administrative tasks and improves care coordination and communication among multidisciplinary teams [17-20]. Building on these advancements, the role of eHealth solutions in home care has become increasingly important, particularly in countries such as Sweden, where a growing aging population receives care in their homes.

Home Care in Sweden and the Medication and Care Support System

Home care in Sweden is a vital component of the country's health care system, aiming to provide support and assistance to individuals who require medical or personal care in their own homes. Home care services in Sweden are organized and provided by municipal authorities, intending to promote independence, autonomy, and quality of life for individuals who may have difficulties and challenges with daily activities due to illness, disability, or aging [21,22].

Despite its well-structured and person-centered approach, several challenges persist for both patients and their family caregivers. One prominent challenge is the increasingly complex nature of medication management, particularly for older adults with multiple chronic conditions or cognitive impairments. Ensuring adherence to medication regimens, preventing medication errors, and managing potential drug interactions can pose significant hurdles. In addition, the evolving needs of individuals requiring home care demand a higher level of coordination and integration among health care providers, family caregivers, and support services, often leading to fragmented care delivery and gaps in communication [3,23,24].

Among these challenges, the implementation of a medication management system emerges as a crucial solution to enhance the efficiency, safety, and quality of care within the home care context. By leveraging technology and tailored support mechanisms, a medication and care support system (MCSS) can assist health care professionals in the process of medication management. Moreover, a medication management system can facilitate seamless communication and collaboration among health care professionals and family caregivers, fostering a more integrated and holistic approach to care delivery [25,26]. By addressing the complexities of medication management and promoting collaboration among stakeholders, an MCSS has the potential to enhance the effectiveness and sustainability of home care services, enabling individuals to age in place with dignity and independence [27,28]. One example of a digital tool that embodies this collaborative approach to medication management is the MCSS developed by Vitec Appva [29] and widely implemented in Sweden's home care services. The MCSS supports health care professionals in home care in medication administration, dosage tracking, and medication reconciliation, thereby reducing the risk of adverse drug events (ADEs) and promoting medication adherence. In addition to its core functions, the MCSS is extensively used by health care professionals across most home care settings in Sweden for task management, including inputting signing lists and tracking the completion of assigned duties. It is also used to simply see what the health care professionals need to do and sign off once they have completed it. It plays a crucial role in medication management in home care. With the widespread adoption of smartphones and tablets, health care professionals can access MCSS platforms from anywhere, allowing for real-time monitoring of medication schedules, reminders, administration logs, and communication tools [29]. The nurses have access to the MCSS through both a mobile app and a web platform (Figure 1 [29]). These tools allow them to customize and oversee various activities related to medication administration and patient care. With the mobile app, health care professionals can conveniently access the system from their smartphones or tablets, enabling them to stay connected and manage tasks on the go. Similarly, the web platform provides a robust interface accessible from computers or laptops, offering additional functionalities for detailed monitoring and analysis. This dual accessibility empowers nurses to tailor their approach to medication management, effectively monitor patient activities regardless of their location or device preference, assist in administrative tasks, and maintain the security of medical information [29].

Figure 1. Mobile and web-based medication and care support system platform. The figure was inspired by the MCCS developed by Vitec Appva [30].

However, despite the significant benefits offered by these digital solutions, challenges in medication management still persist. Studies [2,16,30,31] have shown that, even with the availability of advanced digital tools, family caregivers continue to deal with medication mismanagement in their complex caregiving responsibilities and limited communication with health care professionals. While health care professionals use the MCSS as a tool to administer medications and effectively communicate with each other, there remains a notable gap in research regarding whether a tool similar to the MCSS can also be leveraged by family caregivers to manage multiple medications, thereby mitigating medication errors in home care practices.

Studies [3,32-36] indicate that, as the population ages and drug therapy becomes more complex—with more new prescription drugs being approved and patients requiring increasingly potent and sophisticated treatments—the likelihood of errors also increases. Studies have revealed alarming statistics on medication errors and ADEs, demonstrating their profound impact on patient safety, health care providers, and health care systems. Studies [32-36] have discussed medication errors, their causes, prevention methods, and risk management strategies within the pharmacy and health care industry context. They have highlighted the importance of medication therapy as a valuable tool in treating various health conditions but also acknowledged the risks associated with its misuse. Examples of medication errors outlined in the studies include administering the wrong drug, wrong strength, or wrong dose; confusion over similar–looking or sounding drugs; incorrect routes of administration; miscalculations; and errors in prescribing and transcription. Key findings indicate that significant risk factors for medication errors include patient age of ≥60 years, inexperienced caregivers, polypharmacy (≥5 drugs), comorbidities, and multiple prescribers, which are critical to address for improving patient safety in home care [28]. In addition, a study [32] on 16,963 emergency department visits found that 3.4% were due to ADEs, with 15.1% leading to hospitalization, ADEs extending hospital stays by nearly 2 days, and medication errors adding almost 5 extra days, significantly increasing health care costs. This study emphasized the importance of implementing strategies to prevent medication errors, such as improving medication safety protocols, enhancing care delivery training, using technology for error detection and prevention, and fostering a culture of open communication and reporting within health care organizations. It underscored the need for constant caution and proactive measures to mitigate the risks associated with medication errors and ensure patient safety.

Aim of the Study

This project aimed to investigate health care professionals' perspectives on the use of the MCSS and gather recommendations for designing a similar tool for family caregivers. The focus was on identifying the necessary information and features essential for both health care professionals and family caregivers.

Methods

Study Design

In this study, an exploratory qualitative approach was adopted to investigate health care professionals' experience of using the MCSS and recommendations for designing a similar tool for family caregivers in home care settings. To gather comprehensive insights, the researchers explored the perspectives and recommendations of health care professionals actively using the MCSS in health care delivery within home care settings [25,37,38]. The research methodology used an inductive approach, focusing on deriving insights and conclusions from collected data. Thematic analysis was conducted according to the guidelines by Braun and Clarke [38], systematically identifying recurring themes and patterns in the interview data.

Study Setting and Participants

The interviews involved a total of 15 health care professionals and took place between February 2024 and May 2024 in Sweden. In this study, we involved health care professionals

working in home care in the Nora municipality. The Nora municipality is located in the northern part of Örebro County and has approximately 10,700 inhabitants. The municipality is responsible for, among other things, home care for people who need continued health care at home. Nurses, assistant nurses, and care assistants work in home health care [39]. The study participants' characteristics encompassed various factors, including demographic details, age distribution, tenure in home care, and experience with MCSS use. Factors such as diversity of perspectives, expertise, and experiences were considered.

The head of Nora Home Care was contacted and assisted with obtaining access to potential participants among the home care employees. Subsequently, the researchers personally met with these employees to provide a thorough explanation of the study's purpose. Following this, interested employees who met the study's inclusion criteria conveyed their willingness to participate via email. The participants' eligibility was determined by their expertise in medication administration, encompassing individuals such as registered nurses, nurse assistants, care assistants, and therapists employed at Nora Home Care actively using MCSS for >2 years. These criteria helped ensure that participants possessed relevant and comprehensive experiences, perspectives, and recommendations related to the research topic while maintaining the quality and validity of the study findings [36,37,40]. The researchers sent out emails to potential participants with further details about the study objectives and attached the invitation letter along with the letter of consent. In addition, a QR code linked to a Google Form was included to facilitate scheduling for interview dates and times. Participants' characteristics are presented in Table 1.

Table 1. Participant characteristics.

	Age category (y)	Occupation	Years of experience in home care	Years of MCSS[a] use
Participant 1	45-55	Registered nurse	10-20	5-10
Participant 2	45-55	Registered nurse	30-40	5-10
Participant 3	45-55	Registered nurse	20-30	5-10
Participant 4	30-40	Occupational therapist	10-15	5-10
Participant 5	20-30	Nurse assistant	5-10	5-10
Participant 6	40-50	Nurse assistant	20-40	5-10
Participant 7	55-65	Nurse assistant	40-50	5-10
Participant 8	40-50	Nurse assistant	10-15	5-10
Participant 9	40-50	Nurse assistant	10-15	5-10
Participant 10	45-55	Nurse assistant	10-20	5-10
Participant 11	25-35	Nurse assistant	5-10	5-10
Participant 12	35-45	Nurse assistant	10-15	5-10
Participant 13	40-50	Nurse assistant	5-10	5-10
Participant 14	20-30	Carre assistant	2-5	2-5
Participant 15	35-45	Care assistant	2-5	2-5

[a]MCSS: medication and care support system.

Data Collection

Fifteen interviews with health professionals administering medication in home care settings were conducted. Their responses centered on various aspects of medication management, including their own experiences, the role of family caregivers, the use of the MCSS tool, necessary information for caregivers, information needed by health care professionals in the MCSS from family caregivers, and recommended features for improving the tool and for designing a similar tool for family caregivers.

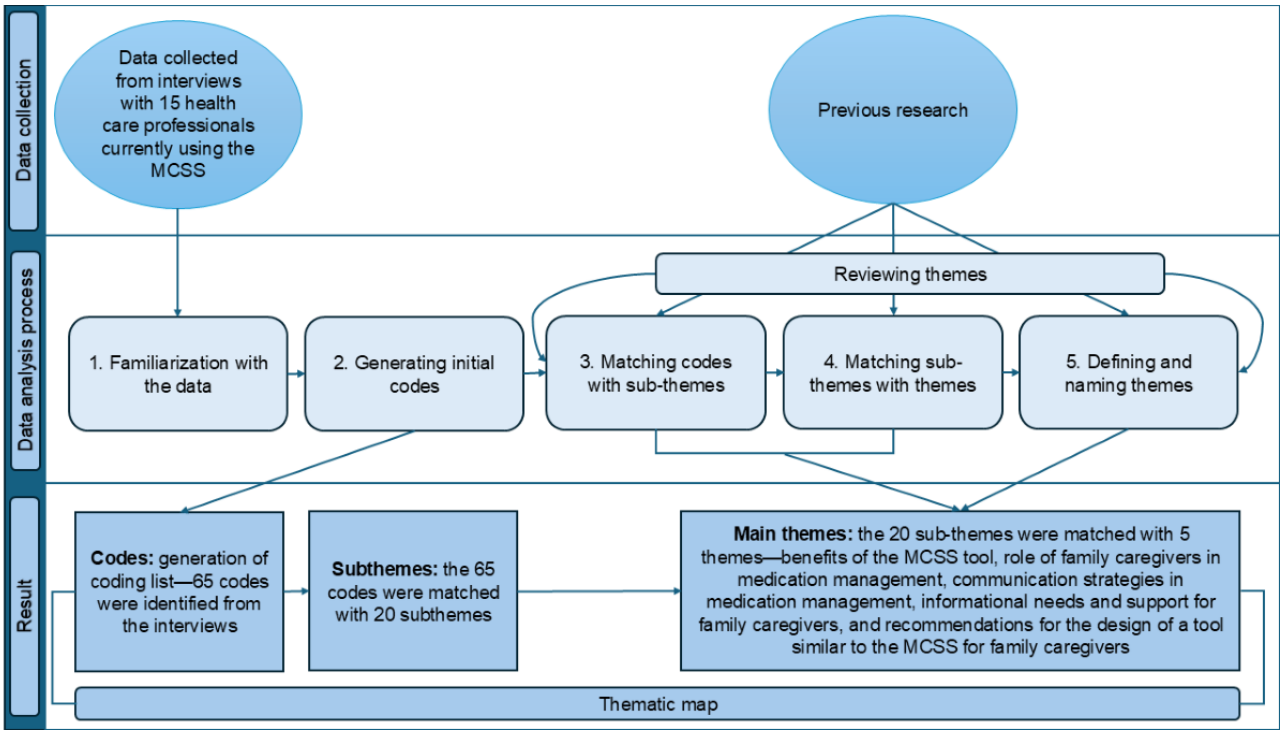
A pilot interview with a group of 3 nurses was conducted to assess the clarity of the research aim and interview questions. Feedback from the pilot test informed any necessary revisions. Each participant was required to sign an informed consent form before the interviews started. The interviews were recorded, and notes were taken to ensure the accuracy and comprehensiveness of the information gathered. Each interview lasted approximately 30 to 40 minutes. Given that our study included 15 participants, we closely monitored the data during collection and analysis to ensure that no new themes or insights were emerging. This point of saturation was reached when additional interviews did not produce any new or relevant information. The interviews were transcribed verbatim.

Data Analysis

Thematic analysis was chosen as the method to analyze the data due to its inherent flexibility and systematic framework for interpreting data from qualitative research approaches. This approach facilitated the identification of recurring patterns or themes within the dataset, allowing for a nuanced exploration of the participants' perspectives and experiences. The thematic analysis procedure, as outlined in Figure 2, inspired by the work by Matt et al [41], was guided by the step-by-step approach by Braun and Clarke [38], providing a structured methodological framework for conducting the analysis. This methodology

ensured a comprehensive examination of the data, enabling the extraction of meaningful insights that contributed to addressing the research questions effectively.

Figure 2. Data analysis process. MCSS: medication and care support system.



The analysis began with familiarization with the data, where the first author immersed herself in the data to gain a comprehensive overview. This first step involved reading through all the transcripts of the interviews multiple times to become familiar with their content. During this phase, the author took notes, highlighted sections, and looked for recurring patterns. This step was crucial for gaining insights into the data's context. The second step was to generate initial codes, which started by identifying specific segments that were relevant to the research question and objectives. The first author assigned initial codes to label them based on their content. The third step included matching codes with subthemes—during this step, both authors reviewed the initial codes and began to group them into clusters that reflected subthemes. A total of 20 identified subthemes represented a more specific aspect of the data compared to the broader themes. In this step, the authors examined relationships between codes and identified patterns that suggested subthemes. The fourth step was matching subthemes with themes, in which the authors combined related subthemes into broader themes that captured significant patterns in the data. The authors reviewed how subthemes fit together to form comprehensive themes that represented the major findings of the research. The last step was to describe what the themes represented and choose concise and descriptive names for the themes that accurately reflected their content. The data analysis was an iterative process involving creating new codes, subthemes, and themes based on emerging evidence.

Ethical Considerations

This research was carried out in Sweden. According to the Swedish Ethical Review Act, the research in our submitted manuscript does not require ethics approval as it does not handle sensitive personal information (as understood by the European General Data Protection Regulation). However, ethical requirements still apply. Consequently, prospective study participants were contacted after receiving an email invitation outlining the study's purpose. Arrangements for interviews were made via email, SMS text message, or phone call accommodating participants' preferred timing and location. Each interview session began with a comprehensive explanation of the study's aim, interview process, and participant rights. Before participation, all individuals provided written and verbal consent, with formal documentation signed by both the participant and the researchers. This consent form detailed study objectives, potential risks, confidentiality, and the right to withdraw. Participants were assured of anonymity and informed about how their data would be handled [42,43]. No compensation was provided to the participants in this study.

Results

Overview

Altogether, 5 overarching themes, 20 subthemes, and 65 codes were generated (Textbox 1 and Figures 3-7). These will be showcased alongside their corresponding summarized meaning units, with participants identified by their designated number following their quotations.

Textbox 1. An overview of the themes and subthemes.

Benefits of the medication and care support system tool

- Verification and cross-referencing of patient details and medication lists
- Ensuring adherence to prescribed schedules
- Monitoring medication intake and signing off on administration
- Electronic medication reminders and signing lists
- Digital access to medication schedules and administration records

Role of family caregivers in medication management

- Perceived benefits of family members administering medications
- Concerns about family caregivers' lack of training and experience
- Examples of medication mismanagement by family caregivers

Communication strategies in medication management

- Communication features between health care professionals and family caregivers
- Pretrip communication between health care professionals and family caregivers
- Communication during and after trips, primarily via phone calls
- Lack of direct communication during medication management periods

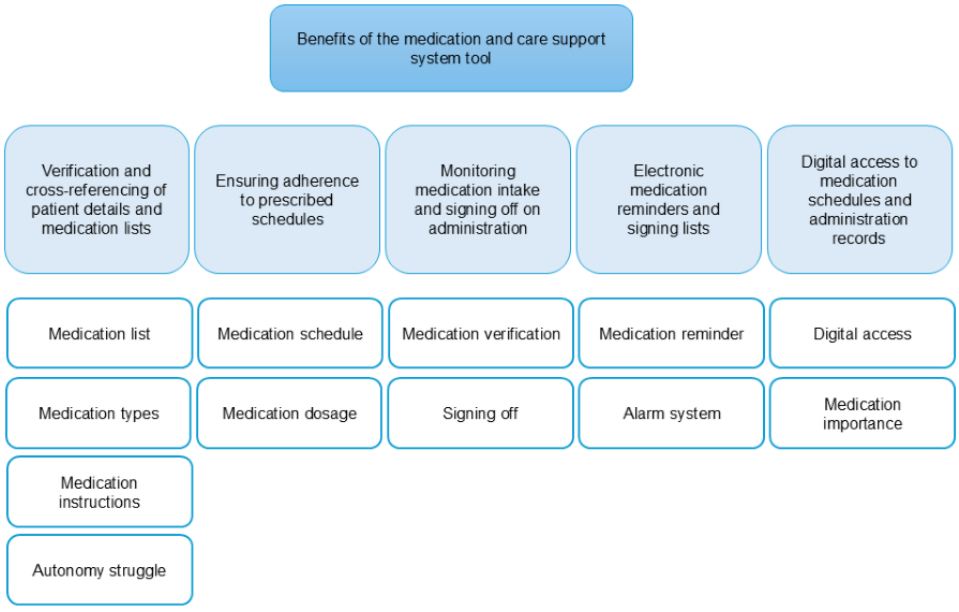
Informational needs and support for family caregivers

- Necessary information for safe medication administration
- Importance of clearly communicating medication schedules, dosages, and potential side effects
- Preferences for written information to supplement oral communication

Recommendations for the design of a tool similar to the MCSS for family caregivers

- Key features and functions of a similar MCSS for family caregivers
- Importance of a clear and simple user interface
- Privacy features to restrict access to sensitive information
- Customization options for focusing on individual patients

Figure 3. A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom.



Theme 1: Benefits of the MCSS Tool

Overview

A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom (Figure 3). The participants mentioned that the MCSS tool presents a comprehensive solution designed to streamline the medication administration process. They revealed that its functionality lies in the abilities outlined in the following sections.

Verification and Cross-Referencing of Patient Details and Medication Lists

The MCSS tool helps health care professionals verify patients' details on the app and cross-reference them with medication lists at the patients' home to ensure accuracy and consistency in medication administration:

> *We use MCCS in the municipality to ensure and know that the care recipients have received their prescribed medication. It is a way to verify that it has been done or check exactly as prescribed in the system.* [Participant 1]

> *When I arrive at the patient's [home], I open the app and go to the person who is supposed to receive medication. I verify that the name and person match, and I check the prescription list they have in their binder at home, cross-referencing it with what is displayed in the Appva MCSS app.* [Participant 6]

Ensuring Adherence to Prescribed Schedules

The participants expressed that the MCSS takes into account any specific instructions for medication timing and dosage to maintain adherence to the treatment plan. Participants discussed that this feature provides a way to track and manage medication schedules effectively for different household members. Similarly, by selecting the correct person within the app, one can view details about prescribed medications, including which medicines should be administered, the dosage instructions, and the specific times when each medication should be taken:

> *You enter the app under the right person. Then you can also check the prescription action that is available at everyone's home. It states which medicine to give, how to give it, and at what time.* [Participant 5]

The participants also described how occupational therapists and physiotherapists use the MCSS to organize training sessions and provide feedback. They mentioned that, during home training visits, the occupational therapists collaborate with physiotherapists to address patients' training needs:

> *The process, it's about when we're at home for training visits. We can say that physiotherapists are meeting someone who has a training need where staff need to be present. Then we go through what type of training program [they have], then we put in the MCSS description of the training and how often, how long approximately during the day, and then we provide feedback to both patients and staff.* [Participant 4]

Monitoring Medication Intake and Signing off on Administration

The participants discussed the MCSS's ability to monitor medication intake, and they sign off on administration on the app to confirm that the medication has been given as prescribed:

> *Once I have retrieved the medication, I observe that the person has taken or swallowed it. If I have administered the medication myself, I then sign off to confirm that it is complete.* [Participant 6]

Electronic Medication Reminders and Signing Lists

The participants appreciated the implementation of electronic medication reminders within the system that prompt health care professionals about scheduled doses. They also highlighted the importance of electronic signing lists through the MCSS to track medication administration accurately and discussed that this system promotes self-awareness by flagging instances in which medication is not taken or documented properly, ensuring optimal care:

> *An alert may come up. I can see that the patient or care recipient may not have taken their medication. Perhaps they have taken it, but it's not signed for. This is to ensure good self-awareness in medication management...* [Participant 1]

Digital Access to Medication Schedules and Administration Records

The participants emphasized the value of digital access to medication schedules and administration records, enabling health care professionals to have comprehensive and up-to-date information about medication management:

> *Is a digital platform that facilitates the management of medication and care for our patients. Through MCSS, we can schedule medication, keep track of dosages, and improve communication among healthcare professionals. Within the system, you can see whether medications have been administered or not.* [Participant 10]

Following the exploration of the benefits provided by the MCSS tool, it is equally important to examine the crucial role that family caregivers play in medication management. This next section delves into the perceived benefits and challenges faced by family caregivers, highlighting their experiences and the potential risks associated with their involvement in administering medications.

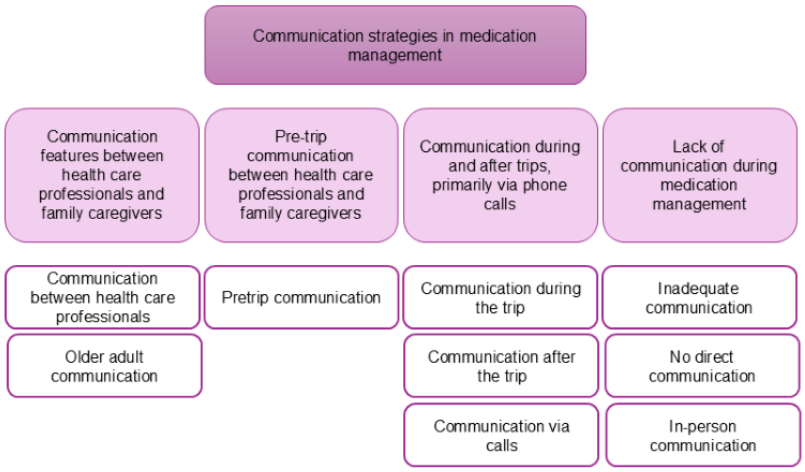
Theme 2: Role of Family Caregivers in Medication Management

Overview

A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom (Figure 4). The participants described how family members may step in to take on tasks typically performed by health care professionals and acknowledged the significant role of family members in the care of the patients. However,

the participants exposed some challenges that arose when family caregivers had the responsibility of administering medication.

Figure 4. A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom.



Perceived Benefits of Family Members Administering Medications

Participants recognized the value of family members assisting with medication administration and acknowledged that this involvement fosters a sense of collaboration and shared responsibility in the patient's care:

> *In general, it is considered good that relatives take responsibility for administering medications. It allows the patient to have autonomy and independence. That one is not so dependent on the assistance of healthcare personnel.* [Participant 1]

> *Actually, relatives take over what the staff usually do when they take care of the patient themselves. It can be temporary, for example, I am visiting my mom now at lunch and I will stay until 3 o'clock so I will give her medication at 2 o'clock.* [Participant 2]

Concerns About Family Caregivers' Lack of Training and Experience

Despite the benefits, the participants expressed concerns about the potential risks associated with family members administering medications. They noted the lack of formal training and expertise among family caregivers, which could lead to errors or omissions in medication administration:

> *Yes, it's quite a big responsibility that family members take on. It's important that they receive enough information, so they know which medications to give and at what times. There may also be a medication that shouldn't be administered if the person's condition is worse or changes in a certain way. It's quite a significant responsibility to assume...It actually carries the same risks as healthcare professionals. But the risk becomes greater because family members are inexperienced and cannot read medication lists. They don't have the training that healthcare professionals have.* [Participant 3]

Examples of Medication Mismanagement by Family Caregivers

Participants shared examples in which medication mismanagement occurred when family caregivers were responsible for administration. These examples included cases in which medications were not taken as prescribed or doses were missed altogether. They also speculated that the family caregivers may not have fully understood the patient's cognitive state or failed to double-check medication adherence. They also noted that those incidents highlighted the importance and need for clear communication and caution in medication management even when delegated to family members:

> *There was one incident that comes to mind where a woman we sent home with her medication, as her relatives had informed us, she would be going home to her daughter and taking her medication with her. But when she returned home after about a week, she hadn't taken any of her medication. She had medication three times a day...In this situation, I think that perhaps the relatives hadn't realized that the person wasn't entirely clear in her thinking. Or maybe they didn't double-check properly...but in this case, the person hadn't taken their medication. So, she brought half of the pill dispenser back home.* [Participant 6]

> *It has happened to me actually. I sent medication to a patient with dementia. And the family was supposed to take responsibility for the medication. We sent the medication box that he should take, and it was only medication for two days, but the patient took all the medication. We don't know if he took all the medications or if he threw them away...This is a bit of a problem if the family members know nothing about the medication. There are always problems with family members and patients when they are going to leave or visit.* [Participant 9]

Building on the discussion of family caregivers' roles in medication management, it is essential to consider how communication strategies impact this process. The following

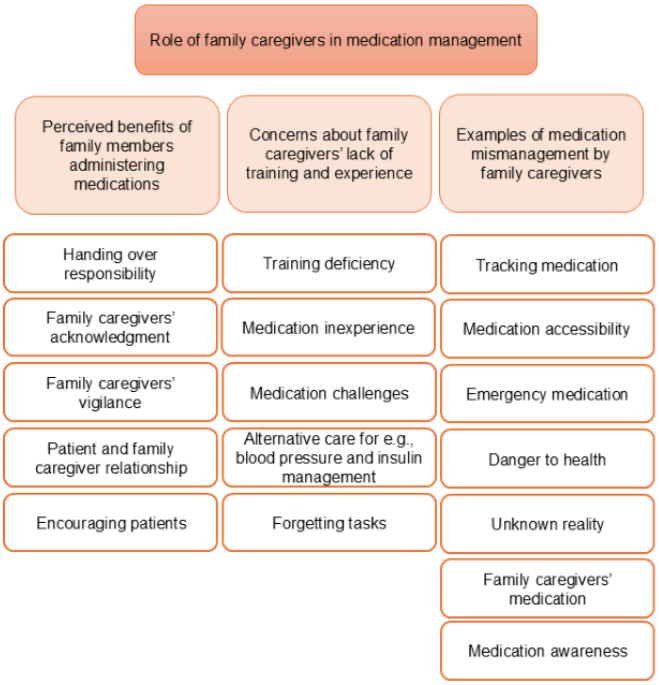
section explores the various communication features and challenges between health care professionals and family caregivers, focusing on the critical moments before, during, and after trips and the implications of inadequate direct communication during the medication management period.

Theme 3: Communication Strategies in Medication Management

Overview

A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom (Figure 5). The participants described communication strategies used between health care professionals and family caregivers typically occurring before, during, and after trips, primarily in person or through phone calls. However, the participants mentioned that they had been contacted only before the trips but never been contacted while the patient was away, whereas both family caregivers and care recipients are encouraged to communicate with health care professionals whenever they have questions if they find any changes or seek advice regarding medication management.

Figure 5. A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom.



Communication Features Between Health Care Professionals and Family Caregivers

The participants discussed the situation regarding communication between health care professionals and family caregivers:

> *Currently, we communicate with family members regarding medication administration through phone calls and in-person meetings before they travel with the patient.* [Participant 11]

Pretrip Communication Between Health Care Professionals and Family Caregivers

The participants discussed the importance of communication between health care professionals and caregivers before a trip. They mentioned that, typically, communication occurs before the trip, where caregivers inform health care professionals about their travel plans and inquire about managing medications during their absence:

> *Yes, we plan together if someone is going away for two weeks, we say, so then it's the nurse who is informed and dispenses medications for the entire period.* [Participant 3]

Communication During and After Trips, Primarily via Phone Calls

The participants highlighted a lack of ongoing communication during and after trips. They expressed that, during trips, there was no communication with family caregivers and the same happened afterward except for health care professionals possibly asking how it went. In addition, participants explained that, after trips, communication remained minimal and mentioned that this approach may not provide timely updates and not ensure that everyone involved is informed about the medication regimen while many changes may occur during the absence of the patient:

> *But during and after, we don't have any direct communication in that way. Instead, the entire responsibility is left, and it's explained beforehand. During that time, we have no communication with them, and not afterward either. Except that one can ask how it went.* [Participant 5]

Lack of Direct Communication During Medication Management Periods

The participants acknowledged challenges related to trusting family caregivers to manage medications correctly. They

mentioned the difficulty in verifying whether medications were taken properly, especially when the responsibility is entirely on the family caregiver because they cannot sign off on the medication:

> *It's a bit tricky for us as healthcare professionals; we don't receive any information about the patient, whether they have taken medication at the right time, or they haven't taken all their medications.* [Participant 9]

> *Often challenges related to them not having enough medication support. Since we are not with them, we don't know how it works for them.* [Participant 10]

The participants continued to discuss the importance of planning travels well in advance to ensure smooth coordination; otherwise, it resulted in patients not having enough medication before the trip. They mentioned the challenges regarding the fact that, in such cases, arrangements need to be made for the patient to receive the medication dispenser at the pharmacy where their family caregiver lives:

> *Also, another challenge is that when family members want to take care of the medications, they usually order upcoming medication not in good time, they always say it at the last minute, and it usually takes time to fix. It can affect the patient's illness, for example, when they are not close.* [Participant 11]

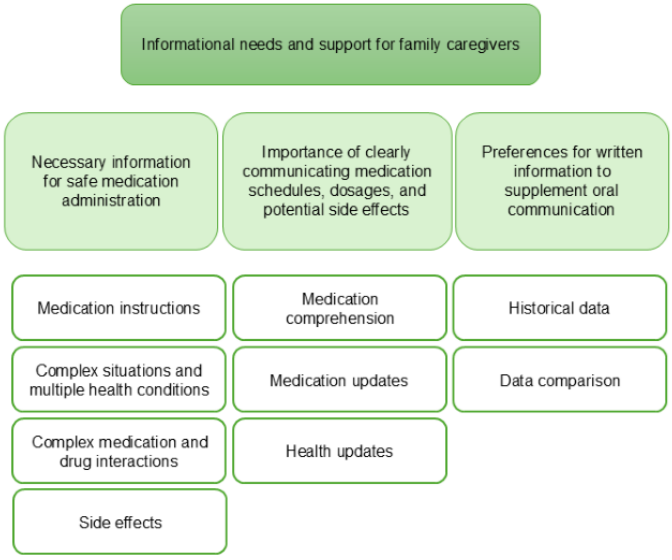
Effective communication is crucial, but ensuring that family caregivers have the right information is equally important. The next section delves into the informational needs of family caregivers, emphasizing the significance of clear instructions and understanding medication schedules and potential side effects and the preference for written materials to support oral communication.

Theme 4: Informational Needs and Support for Family Caregivers

Overview

A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom (Figure 6). The participants highlighted the need for detailed information about medication administration. They stressed the importance of providing written instructions, especially for complex situations, to ensure that family members can effectively assist with medication management.

Figure 6. A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom.



Necessary Information for Safe Medication Administration

The participants emphasized the importance of having updated information regarding any changes or updates to medication prescriptions to ensure that family caregivers and health care professionals administer the correct medications according to the latest prescriptions:

> *They can see there, for example, at nine o'clock it should be this APO on the bag, and then at twelve, it should be insulin and APO, like that.* [Participant 5]

> *They should know why they're taking the medication, which medication it is, and what illness it's for.* [Participant 12]

Participants highlighted the importance of family caregivers being updated on any changes in the medication list, such as medication names or any changes in patients' conditions that needed to be reported to health care professionals through the MCSS. They expressed that this information is crucial to health care practices to ensure that everyone is informed and involved in the patient's care:

> *Yes, one thing that can be difficult is when it says that they should give a certain medication with certain names, and then a similar product with a different name has come from the pharmacy. Then it's hard to know what it is I should give... You have to update them if there have been any changes. I always try to inform them when I can. When the patient themselves doesn't have such a good memory or understanding*

of their health condition, then I usually contact relatives and inform them. [Participant 2]

Importance of Clearly Communicating Medication Schedules, Dosages, and Potential Side Effects

The participants stressed that clear communication of medication schedules and dosages is crucial for safe administration and that the information does not need to be too much to read. They expressed that family caregivers and patients need to understand only when and how to take each medication to ensure adherence to the prescribed regimen:

> *To have information about medication, regimens, dosages, potential side effects, and what to do in case of medical emergencies. Communicating these details clearly and regularly is important to ensure safe and effective care.* [Participant 10]

They also emphasized that communicating potential side effects of medications is essential for family caregivers and patients should be aware of possible adverse reactions so that they can monitor them and seek medical attention if necessary:

> *When the patient is about to feel nauseous and vomit, maybe you understand what to do then with the medications. And sometimes that type of information needs to be written down as well, so it can be given to relatives, not just verbally; it can be a lot of information at once.* [Participant 3]
>
> *The family members have to be informed about what can sometimes happen to patients after taking such medication.* [Participant 9]

Preferences for Written Information to Supplement Oral Communication

Participants highlighted the written instructions on how to administer each medication, including dosage, route, and any special instructions or preparations that are necessary to avoid errors and make good decisions in administration:

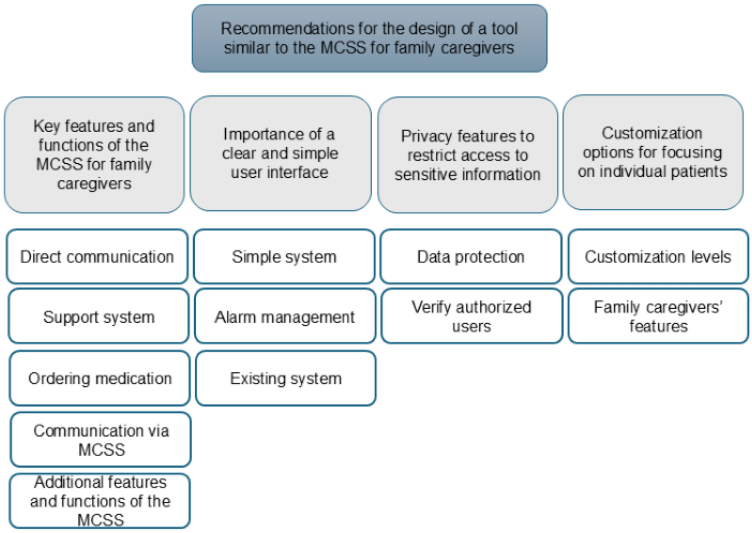
> *I recommend that all information exchanged between healthcare professionals, relatives, and patients should be in written form rather than on the phone, as it can cause misunderstandings...Relatives receive the same information about medications as the patient does, including the illness...* [Participant 13]

Building on the importance of clear communication and information, it is essential to consider how technology can support family caregivers in managing medication. The following section explores recommendations for the design of a tool similar to the MCSS, highlighting the need for key features such as a user-friendly interface, strong privacy protections, and customizable options to meet the unique needs of individual patients.

Theme 5: Recommendations for the Design of a Tool Similar to the MCSS for Family Caregivers

A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom (Figure 7). The participants recommended the design of a system similar to the MCSS for the managing of medication and health care information by family caregivers.

Figure 7. A hierarchical structure displaying the themes at the top followed by the subthemes in the middle and the corresponding codes at the bottom. MCSS: medication and care support system.



Key Features and Functions of a Similar MCSS for Family Caregivers

On the basis of the existing MCSS, participants highlighted specific features and their roles that can help family caregivers effectively manage medication.

Alarm System or Medication Reminder

Participants emphasized the importance of a reminder function within the system to prevent missed doses or overdoses. They suggested that reminders could be sent via SMS text messages or notifications to ensure timely medication administration:

> *I'm thinking that perhaps one could implement receiving a text message or something to a relative's phone when it's time for medication.* [Participant 6]

> *Electronic medication reminders are important, digital signing lists that show if medications have been administered; this gives relatives the opportunity to communicate directly with healthcare staff...These features help to increase the efficiency and safety of medication administration, as well as promote collaboration and communication between healthcare professionals and relatives.* [Participant 10]

Medication List (Dosage and Schedule)

Participants highlighted the need for easy access to a comprehensive list of medications, including both regular and as-needed (nonregular) medications. They suggested that the system should provide clear instructions regarding dosage, timing, and potential interactions to assist family caregivers in managing medications effectively:

> *If family caregivers can go in and get an overview when the care recipient has medication that you want to sign for. So, I think MCSS would help there...It's about seeing the times when medication should be given. If it's every hour or an hour before it's completely okay...Family caregivers should log in and check for as-needed medications, to see when and how often they can be given...* [Participant 1]

> *I'm thinking that as we have with MCSS, they can see there, for example, at nine o'clock it should be this APO in the bag, and then at twelve it should be insulin and APO like that.* [Participant 5]

As-Needed Medication Access

The discussion focused on the importance of medication access and patient safety. However, participants described a situation in which a family member is responsible for administering scheduled medication to a patient but access to additional medication (as needed) is restricted. If the patient suddenly needed medication during this time, the family member might not be able to provide it, leading to frustration or danger to patients:

> *...When a relative who is with a patient has received both a pharmacy bag and doses from the healthcare staff to be given at the next scheduled time, which the relatives will be responsible for and the rest is locked up in a cabinet at the patient's home and then that period begins when the patient feels unwell and needs medication, and then they don't have access to them, such as as-needed medication. So, it can be frustrating for them...In the worst cases, we lock up medications to have better control.* [Participant 2]

Participants discussed the crucial importance of medication management, particularly concerning narcotics, in home patient care. They noted that these medications are securely stored and only accessible to health care professionals due to their high vigilance requirement to avoid the potential risks associated with narcotics. This limited access can pose challenges during emergencies when family caregivers are responsible for medication administration.

Medication Instructions

Participants suggested that the system should provide detailed information about each medication, including its purpose, administration instructions, and potential side effects. They emphasized the importance of clear communication to reassure family caregivers and ensure safe medication administration:

> *Yes, perhaps relatives would need to have a description of what the medication is for in MCSS because it provides a sense of security to know what I am putting into my mouth, so that there can also be some help text provided not to give in these symptoms, for example. Or consider always giving with food or not with food and such things...Or if there's a particular pill that is important to give at an exact time, one could have extra instruction for such matters, because we don't have that now, as the staff can manage it when it's not needed in the same way now. But for relatives, it would be very good; it would reassure them in that case; it would be a completely new function.* [Participant 3]

Signing off and Medication Confirmation

Participants discussed the importance of a feature that allows family caregivers to confirm medication administration. This confirmation could serve as a record for monitoring adherence and tracking progress, providing reassurance for both caregivers and health care professionals:

> *I believe that signing list for training and rehabilitation is the best feature of relatives. Then it's also the case that we have used it, sometimes I have probably used it just to get a confirmation that it's carried out. It becomes a reassurance for us when we delegate training or rehabilitation, that we see that it's being done in the way we've agreed upon with patients and relatives.* [Participant 4]

> *And that it becomes clear for them too that they could simultaneously sign so that we still get an overview that their medication has been given at the same time so that they can also check themselves that the medication has indeed been given and that they have signed that they have given it.* [Participant 5]

Preordering Medication

Participants suggested that the family caregiver's system should include a feature for preordering medications, particularly for travel preparation. This would ensure that family caregivers have an adequate supply of medications on hand even when they are away from home:

> *Yes, the other functions, like ordering medication, because when they are not around, they have to have enough medication otherwise it's difficult to deliver medication where they are.* [Participant 2]

Importance of a Clear and Simple User Interface

Participants advocated for the importance of a system that is easy to navigate, particularly for individuals lacking technical expertise, older family caregivers, or busy working individuals.

They suggested that it should display only essential information to avoid overwhelming users:

> *It shouldn't be anything complicated, it's just that the time and date are written. It doesn't need to be anything difficult...Sometimes they may think it's too much information; it should be a bit simple. If it's just a medication bag, maybe there should just be an option to press or sign, or if you're giving insulin. That it's something simple. It can also be older people who find such things difficult.* [Participant 7]

> *And it would be a system that is easier for them because some don't have any technical training.* [Participant 11]

Privacy Features to Restrict Access to Sensitive Information

The participants expressed the importance of ensuring privacy, security, and personalized access to health care information through the system. They emphasized that the system should prevent unauthorized access; only authorized individuals such as close relatives should have access to the system and specific patient data:

> *The functions to hide are the personal identification number, or so that someone else cannot log in...It's just that only closest relatives receive all the information, for example, the personal identification number and what medication it is.* [Participant 8]

Customization Options for Focusing on Individual Patients

The participants stressed the significance of customization options for focusing on specific patients, particularly for family caregivers. They highlighted the importance of ensuring that family caregivers only have access to information relevant to their particular patient rather than being able to view data for all patients, as health care professionals can:

> *Then the system must be installed on their phones. And then they should only have access to that patient and no one else.* [Participant 2]

Discussion

Principal Findings and Comparison With Prior Work

This study delved into 15 health care professionals' perspectives regarding medication management for older adults receiving home care, with a specific focus on exploring the current digital support tool being used (MCSS). This study aimed to explore health care professionals' perspectives and gather recommendations regarding the design of a similar tool for family caregivers. The findings identified 5 key themes: benefits of the MCSS, role of family caregivers in medication management, communication strategies in medication management, informational needs and support for family caregivers, and recommendations for the design of a tool similar to the MCSS for family caregivers.

Similarly, this study found 10 key MCSS features—alarm system or medication reminder, medication list, medication dosage and schedule, as-needed medication access, medication instructions, signing off and medication confirmation, preordering medication, user-friendly interfaces, privacy features, and customization options—that are crucial for family caregivers to manage medication and have direct communication with health care professionals.

The essential features of the MCSS not only support effective medication management for family caregivers but also reflect the broader impact of the system, as highlighted by the findings, which confirm the MCSS's role in simplifying medication administration processes and facilitating direct communication with health care professionals. All participants expressed that the MCSS offers the benefits of verifying patient details, ensuring adherence to prescribed schedules, and providing electronic reminders and direct communication with health care professionals. In addition to the benefits of the MCSS tool, the crucial role of family caregivers, also known as informal caregivers, in providing unpaid support to patients cannot be overlooked. Studies [16,19,44] have shown that family caregivers offer a wide array of unpaid assistance. On the basis of these studies, family caregivers play a crucial role in medication management, particularly as health care systems increasingly rely on them to support patient care at home. These studies emphasize the growing responsibilities of family caregivers, especially in palliative care settings, where they are often tasked with managing complex medication regimens. These studies [14,19,44] highlight the fact that family caregivers are often responsible for ensuring that medication is administered correctly, managing complex medication schedules, and addressing any side effects or interactions. However, these responsibilities can be overwhelming, especially when caregivers lack formal training or adequate support. These studies highlight the need for robust support systems to ensure that family caregivers effectively handle these responsibilities. In our study, participants acknowledged the significant responsibility shouldered by family caregivers in administering medications and the need for a support system. In addition, our study highlighted insufficient communication between health care professionals and family caregivers. As the primary communication occurred before handing over medication responsibility to family caregivers during trips with patients, participants noted challenges in maintaining communication during and after the trips. The MCSS can help ease these challenges by providing tools that streamline medication management, offer clear instructions, and facilitate ongoing communication with health care professionals.

Beyond communication challenges, participants also expressed concerns regarding the lack of training and experience among family caregivers in medication administration, which led to instances of medication mismanagement. This underscored the importance of addressing educational gaps by providing an adequate support system to family caregivers to ensure safe medication practices, as was mentioned in previous studies [28,44,45]. To address this challenge identified both in these studies and in our study, the MCSS should include comprehensive training modules that help family caregivers understand how to use the system effectively. These modules could be delivered through the app or via web-based tutorials,

ensuring that family caregivers feel confident in managing medications.

Moreover, challenges related to verifying medication administration under family caregiver responsibility were expressed. The participants highlighted the importance of the MCSS, which is built with the ability to ensure proper medication administration and provide electronic reminders. They discussed that the system provides detailed medication information and sends reminders when it is time to administer medication or when time passes. In addition, previous studies have described the importance of a digital system that provides comprehensive written instructions [28,29,45] for safe medication administration and clear communication regarding medication schedules, dosages, and potential side effects. The findings of these studies align closely with our study's findings regarding the role and support needs of family caregivers and the importance of support tools that provide comprehensive and accessible information for medication management. Using a digital system among family caregivers was suggested as a crucial approach to promoting proper medication adherence and reducing the likelihood of errors associated with ADEs. These results are aligned with the results of previous studies that highlight the crucial role of digital tools in reducing medication errors and improving patient care. These studies demonstrate that telehealth interventions and telemedicine can enhance caregiver support and reduce medication management errors [10,17,20,28,46,47]. These studies emphasize the integration of telehealth for monitoring chronic conditions, reinforcing the need for a comprehensive system that supports caregivers in managing complex medication regimes. In addition, these studies discuss the prevalence of medication errors and adverse events, which our study aligns with by advocating for enhanced MCSS features to mitigate these issues.

Building on this, the participants highlighted how specific features, such as confirmation processes, could address the challenges identified in previous studies and further enhance the MCSS's effectiveness in managing medication errors and adverse events.

Our study identified that the design of an MCSS similar to that used by health care professionals is necessary for family caregivers to bridge the communication gap and improve medication management. However, while our study explored health care professionals' perspectives on this issue, more studies are needed to investigate this subject from family caregivers' and patients' perspectives. In addition, the design recommendations should be verified based on family caregivers' and patients' input.

Limitations of the Study

Some of the limitations of this study include the small sample of participants. While the in-depth nature of the interviews provided rich insights, the limited sample size may restrict the generalizability of the findings to broader populations of health care professionals working in diverse home care contexts. Future research should aim to increase the sample size to enhance the representativeness of the findings, strengthen the generalizability of the results, and ensure the broader applicability of the findings. Another notable weakness is the lack of inclusion of patient and family caregivers' perspectives in the study. By primarily focusing on health care professionals' viewpoints, this research overlooks the experiences and preferences of older adults receiving home care and of their family caregivers. By engaging patients and family caregivers in future studies, their perspectives and needs can be considered. Future research should prioritize incorporating the viewpoints of both patients and their family caregivers and the development, implementation, and evaluation of such interventions to assess their effectiveness and feasibility in real-world contexts.

Conclusions

This study delved into the complexities of medication management among older adults in home care, focusing on health care professionals' perspectives and the use of the MCSS. Through interviews, this study uncovered critical themes and recommendations, emphasizing the need to address gaps in medication management practices, particularly concerning similar support tools for family caregivers. In conclusion, incorporating the recommended design features, such as customizable interfaces and enhanced privacy controls, into the MCSS can improve usability and effectiveness for family caregivers. These enhancements are expected to facilitate better medication management, reduce errors, and strengthen communication with health care professionals. By equipping family caregivers with essential information via a tool similar to the MCSS, a proactive approach to preventing errors and improving outcomes is advocated. However, the impact of these improvements should be verified in future studies to confirm their effectiveness and address any emerging challenges.

Acknowledgments

The authors would like to thank Nora Home Care for helping with the recruitment of participants. In addition, they would like to thank all the study participants for their time and valuable insights. The use of generative artificial intelligence technology such as Grammarly (Grammarly Inc) and ChatGPT-3.5 (OpenAI) in this study was to enhance the grammatical accuracy and vocabulary richness of the data; specifically, it facilitated the incorporation of medical terminology that may not have been included in the researchers' vocabulary. This approach ensured that participants could express themselves using familiar medical terms, thereby improving the quality and authenticity of the data collected. This use of generative artificial intelligence aligns with ethical considerations as it helped maintain the integrity of participants' language while ensuring that their contributions were accurately represented in the study [42,43,48]. In addition, the tools were used in the preparation of the manuscript to harmonize the text. After using these tools, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication. The authors received no specific funding for this work.

Authors' Contributions

Both authors were involved in the design of the study. Data collection and initial data analysis were conducted by AA. The analysis was then reviewed and refined by ND. Both authors contributed to the subsequent writing and reviewing of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Artificial intelligence (AI) is rapidly being adopted to build products and aid in the decision-making process across industries. However, AI systems have been shown to exhibit and even amplify biases, causing a growing concern among people worldwide. Thus, investigating methods of measuring and mitigating bias within these AI-powered tools is necessary.

Objective: In natural language processing applications, the word embedding association test (WEAT) is a popular method of measuring bias in input embeddings, a common area of measure bias in AI. However, certain limitations of the WEAT have been identified (ie, their nonrobust measure of bias and their reliance on predefined and limited groups of words or sentences), which may lead to inadequate measurements and evaluations of bias. Thus, this study takes a new approach at modifying this popular measure of bias, with a focus on making it more robust and applicable in other domains.

Methods: In this study, we introduce the SD-WEAT, which is a modified version of the WEAT that uses the SD of multiple permutations of the WEATs to calculate bias in input embeddings. With the SD-WEAT, we evaluated the biases and stability of several language embedding models, including Global Vectors for Word Representation (GloVe), Word2Vec, and bidirectional encoder representations from transformers (BERT).

Results: This method produces results comparable to those of the WEAT, with strong correlations between the methods' bias scores or effect sizes (r=0.786) and P values (r=0.776), while addressing some of its largest limitations. More specifically, the SD-WEAT is more accessible, as it removes the need to predefine attribute groups, and because the SD-WEAT measures bias over multiple runs rather than one, it reduces the impact of outliers and sample size. Furthermore, the SD-WEAT was found to be more consistent and reliable than its predecessor.

Conclusions: Thus, the SD-WEAT shows promise for robustly measuring bias in the input embeddings fed to AI language models.

Introduction

Background

When considering the bias in artificial intelligence (AI) and how it can be mitigated, it is key to understand how to measure the bias of interest in order to properly determine the effectiveness of the mitigation technique. One common area for measuring bias in AI is with regard to the input embeddings of the AI model. Input embeddings are how the training and input data are numerically represented in order to make the data understandable to the model. Word and sentence embeddings are 2 common types of input embeddings, and these are likely to capture societal attitudes and display semantic biases [1]. For example, word embeddings may make biased associations between different genders and certain occupations (ie, nurse and female; doctor and male). Thus, in natural language processing (NLP) applications, such as large language models like ChatGPT and LLaMA, addressing bias in this area is of great importance. Several existing methods for measuring bias in input embeddings include the word embedding association test (WEAT), the Sentence Encoder Association Test (SEAT), and the Embedding Coherence Test [2-4]. The WEAT, for instance, has been rather influential, with its derivative, the SEAT, being used by several studies investigating methods of mitigating bias, including Sent-Debias and Auto-Debias [5,6]. Furthermore, the WEAT has been used to assess the stability of word embedding methods (WEMs) [7].

WEAT: The Word Embedding Association Test

The WEAT was created in 2017 to assess bias within the semantic representations of words in AI, or word embeddings [2], which represent words as a vector based on the textual context in which the word is found. This metric works by considering 2 sets of target terms (eg, science and art terms) and 2 sets of attribute terms (eg, male and female terms). The null hypothesis is that there is no difference between the sets of target words and their relative similarity to the sets of attribute words. Bias is quantified by computing the probability that a permutation of attribute words would produce the observed difference in sample means and, thus, determining the unlikelihood of the null hypothesis [2].

The WEAT was developed to be a statistical test analogous to the implicit association test (IAT), which asked participants to pair concepts or words that they implicitly associate [8]. A total of 10 WEATs were developed based on the documented human biases highlighted by the IAT. In the first WEAT study, Global Vectors for Word Representation (GloVe) word embeddings were used to numerically represent the selected words for each test and, in turn, compute bias scores (see the Methods section for more information about the WEAT's method of assessing bias). GloVe is an unsupervised learning algorithm for obtaining vector representations for words [9]. The GloVe model was trained on aggregated word-word cooccurrence statistics from a large English language corpus. The resulting word representations capture meaningful linear substructures, allowing for excellent performance on word analogy, word similarity, and named entity recognition tasks [9].

While the WEAT has become somewhat of a standard measure of bias in input embeddings, there are several limitations of using it to measure an AI language model's bias. First, the WEAT demands 2 distinct term groups for both targets and attributes, which can be challenging without prior knowledge to segregate, especially for nonbinary terms. For instance, age-related terms might include categories like infants, youth, middle-aged, and seniors, complicating differentiation. The WEAT struggles to consider the nuances across such multiple subgroups, limiting its effectiveness in scenarios where terms don't neatly divide into binary categories. Second, the current groups of terms could be incomplete, potentially introducing unwanted bias. Finally, the original bias calculation (ie, the effect size) is not that robust, and as such, it may be affected by the size or contents of the target or attribute groups. Thus, there is some room to improve this measure of bias, which leads to the focus of this study.

SEAT: The Sentence Encoder Association Test

The SEAT is a generalization of the WEAT to phrases and sentences, rather than single or compound words [3]. In more detail, this measure of bias modifies the original WEATs by inserting the words into simple sentence templates such as "This is a[n]<word > ." Furthermore, new tests were created to measure additional race- and sex-related stereotypical biases. In the SEAT study, multiple sentence encoders were evaluated, including those for popular language models, such as ELMo [10], GPT [11], and bidirectional encoder representations from transformers (BERT) [12]. In the SEAT, bias is measured the same as in the WEAT.

With sentence encoders becoming increasingly popular in NLP applications, the SEAT is a useful extension of the WEAT for measuring bias within sentence representations. Based on the SEAT study's results, sentence embeddings typically display less bias than word embeddings, and more recent sentence encoders (such as those for GPT and BERT) exhibit less bias than previous models (such as GloVe) [3]. However, the SEAT still shares the same major limitations as the WEAT, with the need to have predefined, binary sets of targets and attributes, for instance.

Applications of WEAT and SEAT

The WEAT [2] has been influential in the investigation and development of techniques for mitigating bias in AI systems, with its sentence-level extension, the SEAT [3], being used to measure and evaluate biases present in sentence presentations before and after applying debiasing techniques. More specifically, the SEAT has been used to evaluate the performance of Sent-Debias and Auto-Debias [5,6]. On the one hand, Sent-Debias [5] is a method of debiasing sentence embeddings, while on the other hand, Auto-Debias [6] is an automatic method of mitigating social biases in pretrained language models that alters the model's parameters through fine-tuning. Both methods used 6 SEAT benchmarks to measure the bias present in the sentence embeddings for various language models, both before and after their application.

The WEAT has also been used in the study of the stability of WEMs. In 2021, Borah et al [7] developed a metric for stability and evaluated a collection of WEMs, including fastText [13], GloVe [9], and Word2Vec [14], on a collection of downstream tasks, including fairness evaluation. For this task, they used the WEAT's bias score to assess the stability of the WEMs, noting a relationship between these scores and those of their developed stability metric. Thus, the WEAT can be used to determine the stability of a WEM, which is significant because stability is necessary to produce similar results across multiple experiments.

Objective

Altogether, with the WEAT's ability to assess the stability of WEMs and the SEAT's use in evaluating the performance of recent debiasing techniques such as Sent-Debias and Auto-Debias, it is evident that the WEAT has a large influence in this area of measuring bias in input embeddings. However, certain limitations of the WEAT and SEAT have been identified (ie, their nonrobust measure of bias and their reliance on predefined, binary groups of words or sentences), which may lead to inadequate measurements and evaluations of bias. Thus, this study takes a new approach at modifying this popular measure of bias, with a focus on making it more robust and applicable in other domains. Moreover, we aim to make a more flexible and user-friendly approach to measuring bias in input embeddings, where the user is not required to segregate terms to achieve a reliable bias assessment result.

Methods

WEAT Method

The WEAT's measure of bias, the effect size, is calculated similarly to Cohen *d*; with target sets *X* and *Y* and attribute sets *A* and *B*, the WEAT's effect size (*d*) is a normalized measure of how separated the 2 distributions of associations between the target and attribute are. In the formula for the effect size (Textbox 1), *s(w,A,B)* measures the association of a target word (*w*) with the attribute words (Textbox 2).

Textbox 1. Word embedding association test effect size.

$$d=\text{mean}_{x\in X} s(x,A,B)-\text{mean}_{y\in Y} s(y,A,B)\,\text{std\_dev}_{w\in X\cup Y} s(w,A,B)$$

Textbox 2. Word embedding association test association measure.

$$s(w,A,B)=\text{mean}_{a\in A}\cos(\vec{w},\vec{a})-\text{mean}_{b\in B}\cos(\vec{w},\vec{b})$$

To measure the significance of the associations between targets and attributes and determine the unlikelihood of the null hypothesis, the WEAT defines a 1-sided *P* value test with the test statistic *s*(*X*,*Y*,*A*,*B*). The test statistic (Textbox 3) measures the differential association of the 2 sets of target words with the attribute. Textbox 4 shows how the *P* value is calculated, with $(X_i,Y_i)_i$ denoting all the partitions of $X\cup Y$ into 2 sets of equal size.

Textbox 3. The word embedding association test's test statistic.

$$s(X,Y,A,B)=\sum_{x\in X} s(x,A,B)-\sum_{y\in Y} s(y,A,B)$$

Textbox 4. Word embedding association test P value.

$$\text{Pr}_i[s(X_i,Y_i,A,B)>s(X,Y,A,B)]$$

SD-WEAT Method

In this study, we introduce the SD-WEAT, a more robust and balanced method for exploring and assessing bias. Instead of using predefined word sets and using the effect size as the bias measurement score, the words are randomly replaced and the SD of multiple effect sizes is computed. This removes the need to predefine the word groups, allowing for the avoidance of biased groups of words. Furthermore, the results are more robust, as the SD is calculated over multiple runs rather than one. Together, this should allow the SD-WEAT to be a more simplistic and accessible measure of bias in input embeddings.

Multiple experiments were conducted to explore the uses of these modifications to the WEAT. In each experiment, GloVe word embeddings were used to numerically represent the words for each test, following suit from the original WEAT study. More specifically, we used the GloVe model "glove.840B.300d" from the Stanford NLP Group [15], which was trained on 840 billion tokens from Common Crawl data, has a vocab size of 2.2 million, and generates 300-dimension vectors. Moreover, other input embedding methods, including those of BERT [12], Sci-BERT [16], and BioBERT [17], have been evaluated in order to explore the differences of their biases, which may potentially come from their training datasets or techniques.

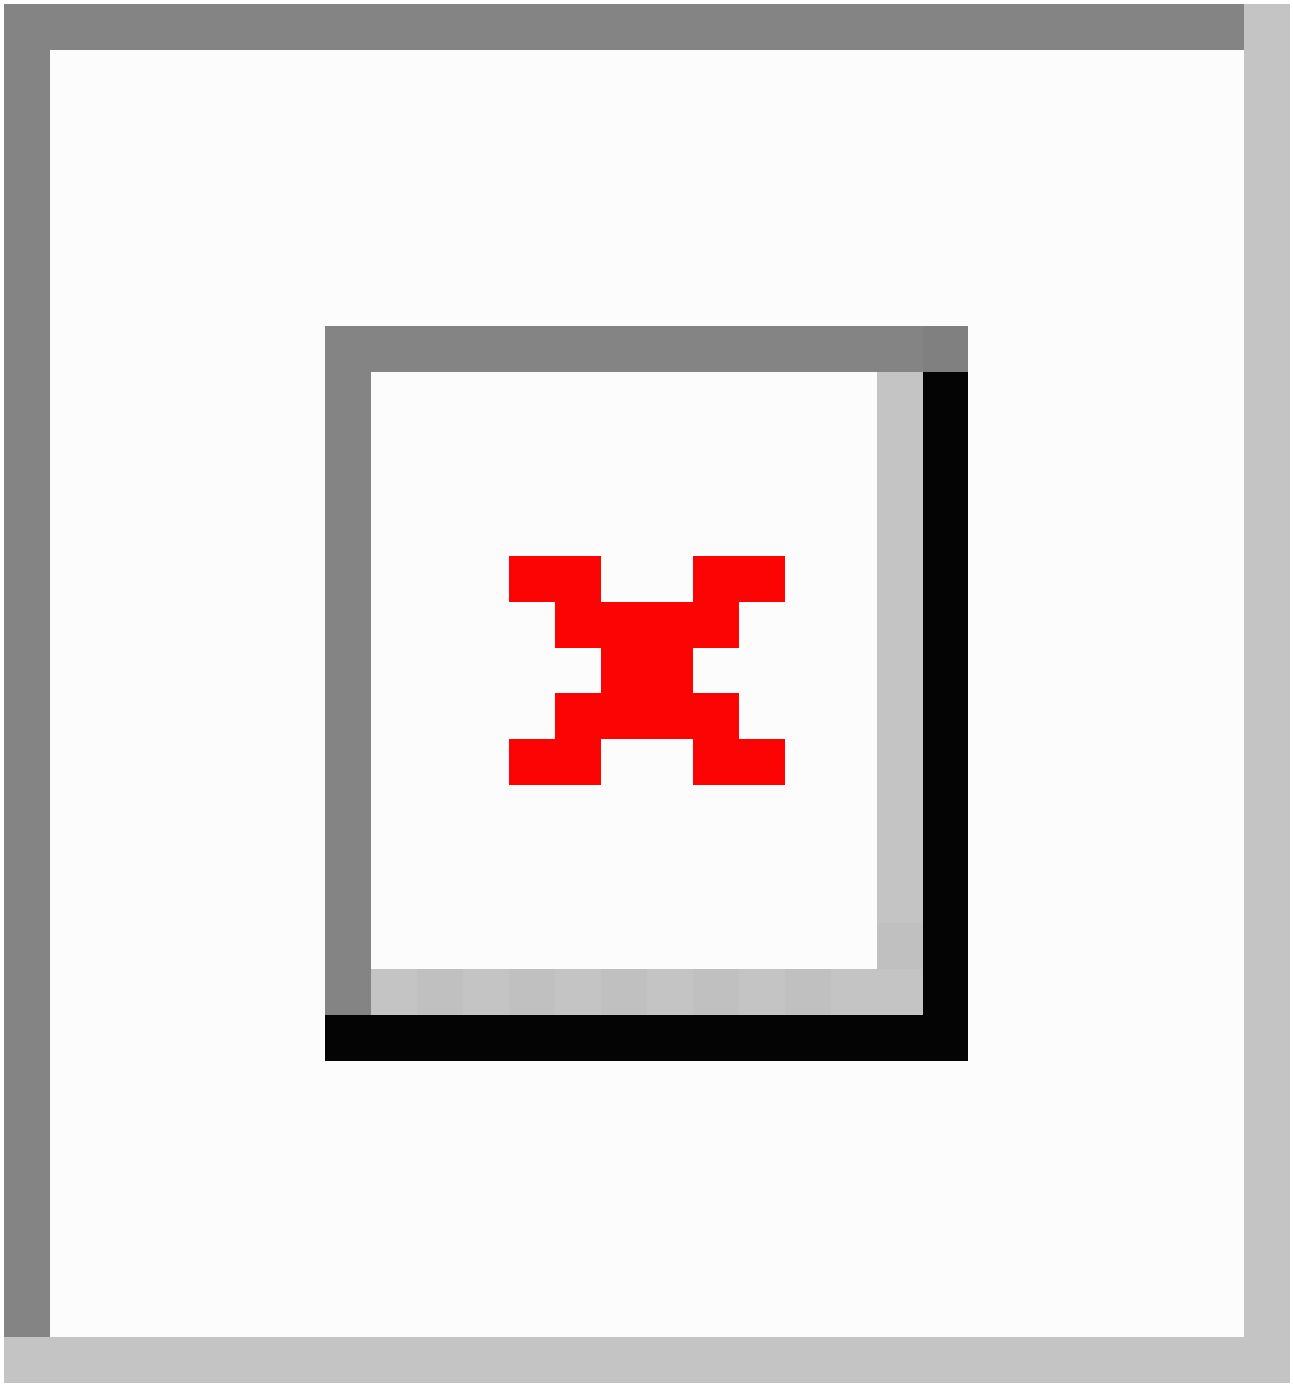
Due to the significance of the attribute sets in both the WEAT's null hypothesis and effect size calculation, it was decided to focus 2 experiments around replacing the attribute sets. The primary experiment, hereafter named "SD-WEAT," used the original 10 benchmark datasets used by the WEAT, but the attribute sets were replaced with random word sets from the combined original attribute sets. The secondary experiment, hereafter named "SD-WEAT-Negative-Control," used the original target data in the 10 benchmark datasets, but the attribute sets were replaced with random word sets derived from the GloVe dictionary.

In the SD-WEAT, for each of the 10 WEATs, the 2 sets of attribute words were pooled together into one list, and then, 100 new tests were constructed, pulling 4 words from said list to form 2 new attribute sets (of 2 words each). For example, the benchmark WEAT-7, which examines a form of gender bias, contains attribute sets with male (eg, "male," "man," "boy," etc) and female (eg, "female," "woman," "girl," etc) terms. The SD-WEAT forms 100 new tests with attribute sets containing words randomly selected from the combination of these term lists, and as a result, the new attribute sets for one of these tests may resemble the following: (1) "male" and "female"; and (2) "woman" and "boy." Assuming a normal distribution of attribute set permutations, the SD-WEAT should be capable of assessing bias between the target and attribute concepts in a more robust manner, and this should open the door for assessing bias over multiple attribute groups at once. For instance, in the case of racial bias, the SD-WEAT should be able to assess bias over multiple racial groups such as Asian, Black, or White; the different permutations could be examined at an individual level to further assess bias in this multilevel context. This concept will be further explored in future studies.

On the other hand, in the SD-WEAT-Negative-Control, a large list of words was derived from GloVe, and then, 10,000 new tests were constructed, pulling 4 words from said list to form 2 new attribute sets (of 2 words each). Because the GloVe dictionary contains multitudes more words than the original attribute sets, a larger number of tests were constructed than before, allowing for 100 groups of 100 tests to analyze the variance across groups. For each experiment, GloVe word

embeddings and a Bag-of-Words model were used to complete each test, and the SD of all the collected effect sizes was computed. Figure 1A and B illustrates the process of creating the new tests for the SD-WEAT and SD-WEAT-Negative-Control, respectively.

Figure 1. SD-WEAT experiment design. GloVe: Global Vectors for Word Representation. WEAT: word embedding association test.



Textbox 5 shows how the SD-WEAT quantifies bias, using the effect size (*d*) from the WEAT (see Textbox 1). SD was chosen over other metrics (such as average), because with a normal distribution of attribute permutations, it is expected that the average of all effect sizes is close to zero. The significance of the SD-WEAT results was also calculated. In more detail, *z* scores were calculated for each of the 10 WEAT benchmarks, using Textbox 6. Here, x is the SD-WEAT score, while μ and σ are the average and SD of the SDs for the 100 groups of 100 effect sizes in the SD-WEAT-Negative-Control, respectively. Since the WEAT uses a 1-sided, right-tailed test, *P* values were calculated from the *z* scores with the right-tailed methodology.

Textbox 5. SD-word embedding association test bias calculation.

x=SD_WEAT

{x}control=(SD(d1,d2,…,d100)1,…,SD(d1,d2,…,d100)100)

μ=mean(x_control)

σ=SD(x_control)

Embedding Method Comparison

To explore the differences of biases between various input embedding methods, several additional methods were evaluated, including BERT, SciBERT, and BioBERT. BERT, which stands for *bidirectional encoder representations from transformers*, is a language model that was pretrained using data from the Toronto Book Corpus and English Wikipedia with the tasks of masked language model and next sentence prediction [12]. Compared to GloVe, which was pretrained using data from Common Crawl and generates context-free representations for each word [9], BERT uses the context on either side of a word to generate that word's representation. Since the WEATs are only composed of single or compound words rather than sentences, it is expected that the representations for these words will not be influenced by context, and thus, this controls one factor that could potentially contribute to differences in bias between these 2 embedding methods. However, it is expected that differences in bias between GloVe and BERT will emerge based on the differences in their algorithms as well as their training datasets.

SciBERT and BioBERT take inspiration from BERT, using a similar architecture but modifying the model's training process. On the one hand, SciBERT was pretrained on a large corpus of scientific texts (specifically, 1.14 million papers from Semantic Scholar) rather than the more general texts used for pretraining BERT [16]. SciBERT also uses a new vocabulary based on this scientific corpus. On the other hand, BioBERT continues to pretrain BERT with a large collection of PubMed abstracts (keeping the BERT pretraining datasets), resulting in a model that performs well on biomedical tasks [17]. There is great interest in using these models in regulatory science research efforts, and thus, they were included in this analysis. The BERT, SciBERT, and BioBERT models were each obtained from the Hugging Face repository. In more detail, these 3 models are listed in Hugging Face as "bert-based-cased" [18], "allenai/scibert_scivocab_cased" [19], and "dmis-lab/biobert-v1.1" [20], respectively.

Stability of Embedding Methods

The WEAT has also been used to assess the stability of WEMs, including fastText, GloVe, and Word2Vec. In more detail, Borah et al [7] trained 3 sets of embeddings for each WEM with a Wikipedia article dataset containing approximately 46 million tokens, changing the seed for each embedding set. The 9 trained embedding sets (3 for each WEM) were then evaluated with the WEAT benchmarks, and the highest and lowest WEAT scores for each benchmark were reported for each of the 3 WEMs. The stability of the WEM is based on the range of WEAT scores; WEMs that produced more similar WEAT scores for each benchmark are more stable than those that produced more different WEAT scores. Based on their results, fastText was found to be the most stable, and Word2Vec was found to be the least stable, with GloVe somewhere in the middle [7]. This aligns with their previous findings, and thus, there is a relationship between WEAT scores and the stability of WEMs.

Our study adopts a similar, yet modified, methodology to assess the stability of the same 3 WEMs, as well as BERT, with both the WEAT and SD-WEAT. In more detail, we began by obtaining the dataset. Without access to the dataset used by the referenced study, we downloaded a Wikipedia dataset (on November 3, 2023) that was uploaded to Hugging Face, specifically the version labeled "20220301.en" [21]. The raw dataset contains over 6 million documents (articles) and 138 million sentences. To conserve computational resources and time, 3 random samples were taken from this dataset, each containing 1% of the total number of documents, or 64,587 to be exact. For the fastText, GloVe, and Word2Vec methods, these 3 sample datasets were processed similarly to those in the referenced study. More specifically, the Wikipedia articles were broken down into sentences using the "punkt" tokenizer from the Natural Language Toolkit (NLTK) package for Python. Then, the sentences were broken down into lists of words, removing stop words and converting all text to lowercase. After processing, each sample dataset contains approximately 1.4 million sentences and 19 million words (tokens). For BERT, which is a sentence embedding method, a different approach had to be taken. The BERT model required a BERT tokenizer, so instead of using a pretrained NLTK tokenizer, a collection of BERT tokenizers was trained using the raw sample datasets. The "bert-base-cased" tokenizer was used to initialize the training, and the vocabulary size was set to 32,000. Three tokenizers were trained per sample dataset, changing the seed for each, resulting in 9 unique BERT tokenizers.

Next, the models were trained. For the fastText and Word2Vec methods, the Gensim package for Python and the "FastText" [22] and "Word2Vec" [23] models were used, and for the GloVe method, the Glove-Python package [24] was used. The parameters for these models were set based on those used in the referenced study, with the vector size set to 300, the context window size set to 5, and the number of epochs set to 5. For each WEM, 3 models were trained per sample dataset, changing the seed parameter for each, resulting in 9 models per WEM. On the other hand, for BERT, the "BertForMaskedLM" model [25] from the Hugging Face package for Python was used. This model uses BERT's default vector size of 768, with the number of epochs set to 5. In total, 9 BERT models were trained, one

for each of the BERT tokenizers that were trained. Since BERT is fundamentally different than the other embedding methods, it is expected that results for these models will differ than those of the WEMs; however, the comparison between the WEAT and SD-WEAT may be useful in the examination of the SD-WEAT's strengths.

Finally, with 9 models each for fastText, GloVe, Word2Vec, and BERT (or 3 models per each of the 3 sample datasets), the stability of these embedding methods could be evaluated. Each model was assessed with the WEAT and SD-WEAT benchmarks, and the variation within these scores could be used to determine the stability of the method. Furthermore, variations within the scores for a specific benchmark can be noted to analyze the areas that have a greater impact on stability than others.

Results

SD-WEAT is Correlated With WEAT in Bias Evaluation

Figure 2A illustrates and compares the bias measurement scores for the WEAT and SD-WEAT on the 10 WEAT benchmarks with the GloVe model (see Table 1 for a more detailed breakdown of the results). As shown in Figure 2A, the effect sizes (r=0.786) and P values (r=0.776) for the 10 WEAT benchmarks between 2 approaches were highly correlated. The results demonstrate that the SD-WEAT can effectively measure bias in binary-group attribute terms, providing similar performance as the original WEAT.

Figure 2. SD-WEAT and WEAT comparison. (A) WEAT versus SD-WEAT bias scores on the 10 WEAT benchmarks. (B) WEAT versus SD-WEAT bias scores on similar benchmarks (WEAT-4 and 5). WEAT: word embedding association test.

[d]The columns labeled “SD-W” contain the results for the SD-WEAT.

Additional patterns could be noted between the WEAT and SD-WEAT. Taking a closer look at the WEAT-4 and 5, both shared a similar focus, with the same target sets of European or African names (16 terms each) and different attribute sets formed with some combination of pleasant or unpleasant terms (25 and 8 terms each, respectively). Figure 2B depicts the WEAT and SD-WEAT scores of WEAT-4 and 5, respectively, where the SD-WEAT showed a much closer gap between 2 benchmarks. This suggested that, given the same target terms, the WEAT score was more vulnerable by the size of attribute terms, whereas the SD-WEAT can provide a more consistent effect score for bias assessment.

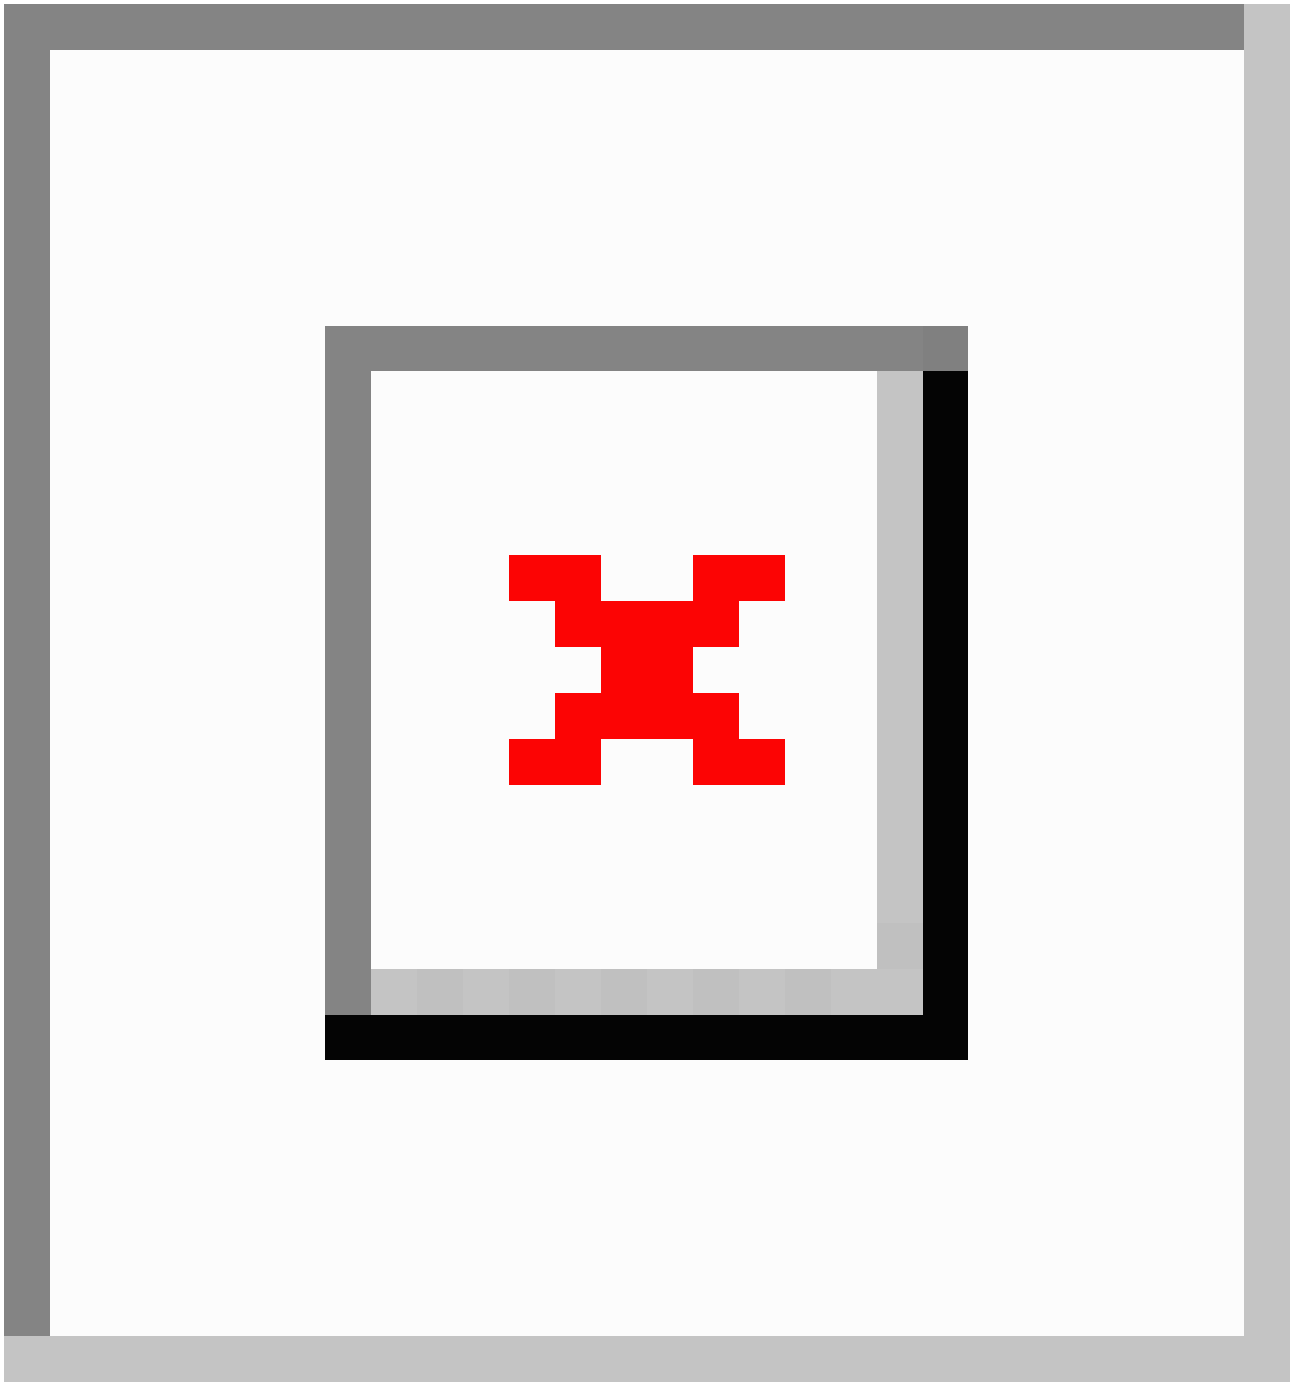
SD-WEAT’s Attribute Set Size Did Not Affect Bias Evaluation

In the primary SD-WEAT experiments, the replaced attribute sets consisted of 2 words each, which was the minimum required to measure the effect score. To examine the impact of the

attribute size, we also conducted the SD-WEAT experiments with 3- and 5-word attribute sets, keeping other parameters unchanged. Due to the original size of WEAT benchmark datasets, attribute sizes larger than 5 were not tested.

The result of this comparative analysis was illustrated in Figure 3. As shown, there was little difference among using 2-, 3-, or 5-word attribute sets. For each attribute size, the correlation between the WEAT's effect size and the SD-WEAT's SD is relatively unchanged. Thus, with the SD-WEAT methodology, using any attribute size could provide consistent results.

Figure 3. SD-WEAT attribute size analysis (WEAT vs SD-WEAT: bias score). Red, blue, and yellow represent the SD-WEAT with 2, 3, and 5 words, respectively. WEAT: word embedding association test.



Using SD-WEAT to Evaluate Various Embedding Methods

The WEAT and SD-WEAT experiments were further analyzed with BERT, SciBERT, and BioBERT, along with the original embedding method, GloVe, that the WEAT used. Table 1 contains the results. The columns labeled "W" contain the results for the WEAT, while those labeled "SD-W" contain those for the SD-WEAT. Both the bias scores (effect sizes) and *P* values are provided.

Based on the results of this analysis, the 3 BERT input embedding methods typically achieve lower WEAT and SD-WEAT scores compared to the GloVe method, indicating

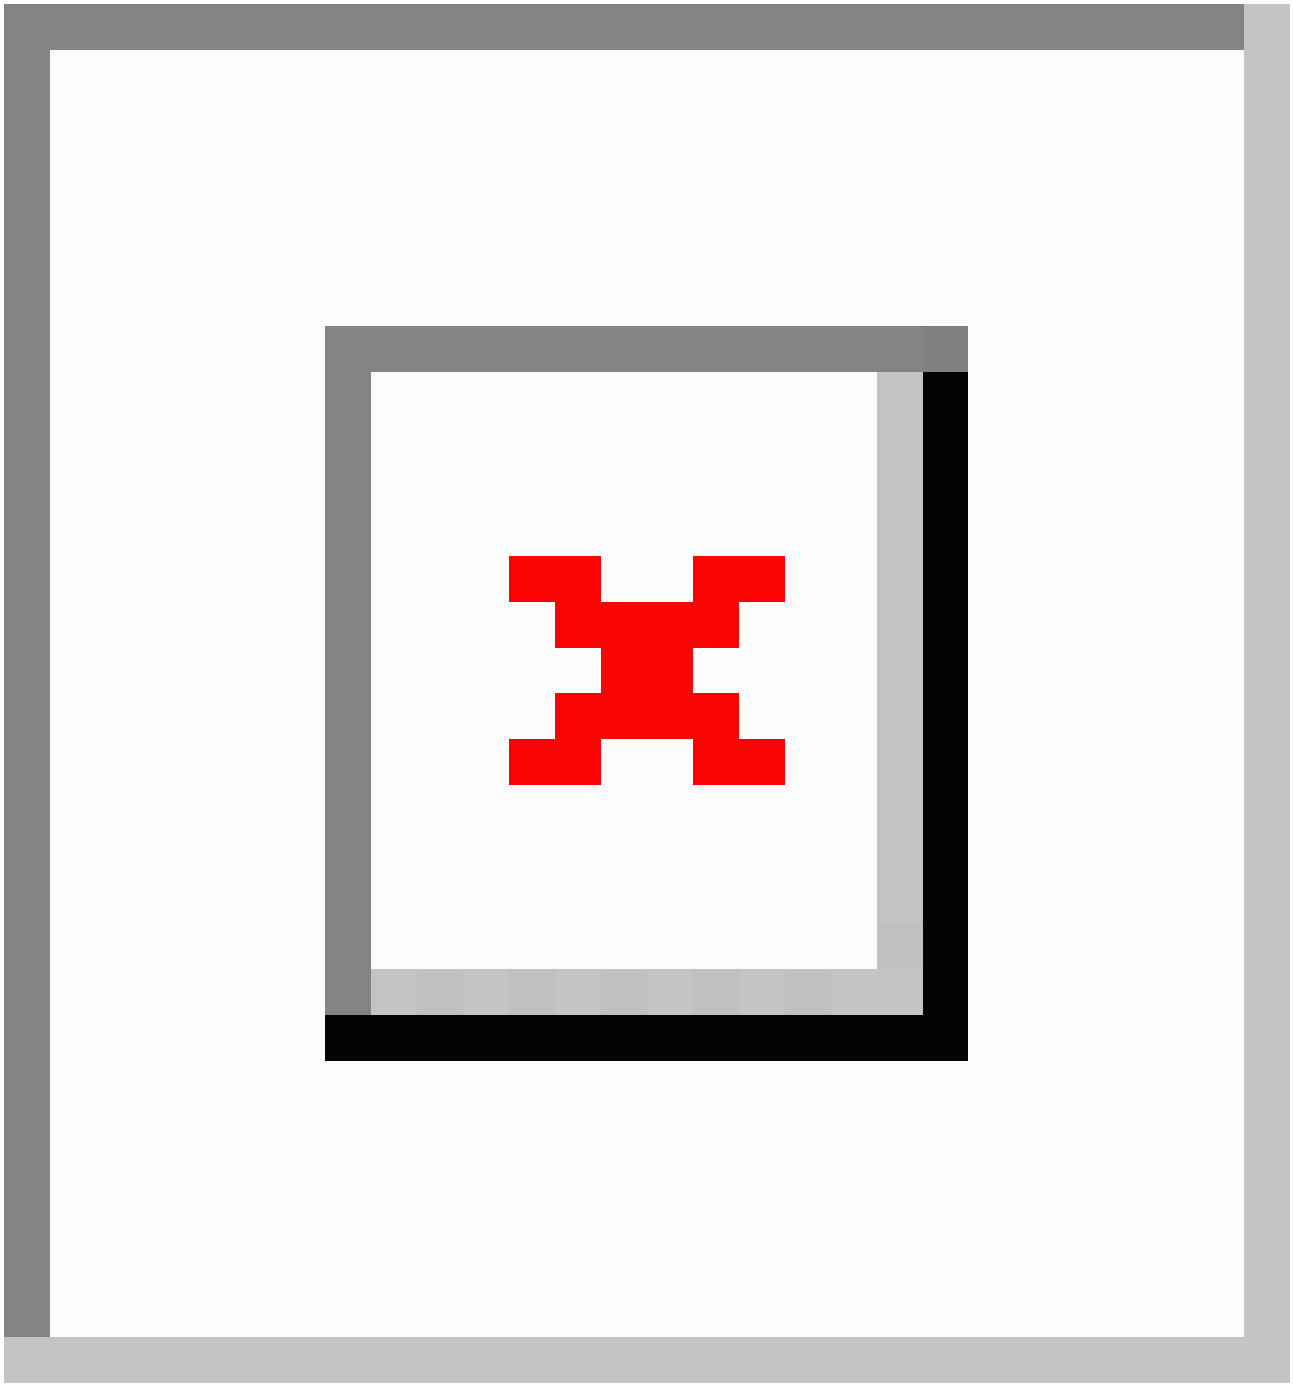
that these methods make less biased associations. Because the BERT embeddings should not be influenced by additional context with the lone words present within the WEAT benchmarks, this shows that the methods' algorithms or training datasets are likely the cause of their differences in bias. The 3 BERT models have training datasets with more objective language (ie, Wikipedia and scientific articles), which could explain why they produce lower WEAT and SD-WEAT scores than the GloVe method. Furthermore, it can be noted that the various BERT models perform differently than one another. For instance, unlike the other BERT models, BioBERT produces a significant result for WEAT-9, which focuses on the associations between mental and physical diseases and temporary and permanent terms, indicating that the attribute terms used in this specific benchmark have a significantly greater impact than random words. BioBERT was trained on biomedical data, and this could be why it performs so differently for this biomedical task.

Using SD-WEAT to Assess the Stability of Embedding Methods

The stability of fastText, GloVe, Word2Vec, and BERT was evaluated using the WEAT and SD-WEAT. Multimedia Appendix 1 shows the variability in the WEAT and SD-WEAT scores obtained for each WEAT benchmark over 9 training iterations per embedding method. The subfigures in the left column are box plots showing the spread of the scores, while the subfigures in the right column are bar charts showing the SD of these scores. At a glance, the box plots show that there is less variability in the SD-WEAT scores than the WEAT scores for each benchmark, confirmed by the lower SDs in the bar charts. Furthermore, based on the sizes of the box plots, some embedding methods appear more stable than others. For instance, fastText appears to have less variability in the WEAT and SD-WEAT scores than GloVe, Word2Vec, and BERT, indicating that this method may be the most stable of the ones evaluated.

Figure 4 compares the stability of each embedding method based on the SD of the WEAT and SD-WEAT scores over the 10 WEAT benchmarks. Recall that for each embedding method, 9 models were trained. Thus, the SD of the WEAT and SD-WEAT scores was calculated for each set of 9 models for each WEAT benchmark. Since SD is a measure of variation, lower values can be more stable. Again, fastText appears to be the most stable embedding method based on the WEAT and SD-WEAT scores. Furthermore, based on the results, there is less variability in the SD-WEAT scores than the WEAT scores.

Figure 4. Stability of word embedding methods: BERT: bidirectional encoder representations from transformers; GloVe: Global Vectors for Word Representation; WEAT versus SD-WEAT. WEAT: word embedding association test.



Overall, these findings are somewhat different than those of the referenced study, which found fastText to be the most stable and Word2Vec to be the least stable out of the 3 WEMs based on WEAT scores. In our case, fastText was indeed the most stable for the WEAT, but GloVe produced the most variable results. This difference may be a result of the difference in dataset size or contents, as we opted to use 3 smaller random samples than one larger one. This study also analyzed the stability of BERT, a sentence embedding method. However, based on the results, this method produces more variable WEAT and SD-WEAT scores than other methods, which may be a result of the fundamental differences of this model compared to the others. Moreover, some of this instability may be due to the small training sample, as the original BERT model was trained on much more data. Nonetheless, we found that all the models showed less variability with regard to the SD-WEAT than the WEAT. This shows a major strength of the SD-WEAT; this measure of bias is much more consistent and reliable than its predecessor.

Discussion

Overview

In this paper, we explored the methodology of measuring bias in the input embeddings of language embedding models, developing a novel approach, called SD-WEAT, for enhancing

bias assessment for complex term groups. This method addresses several limitations of its predecessor, the WEAT, resulting in a more robust and consistent measure of bias. Furthermore, with the SD-WEAT, it is now possible to assess bias over multilevel attribute groups, such as age, race, region, etc, in addition to binary attribute groups.

Future Directions and Limitations

In the future, new benchmarks can be established to measure bias among demographic groups or topics and a full list of attribute terms without segregation. For instance, a benchmark can be developed with target sets comprised of sex-linked medical terms and an attribute set of gender terms in order to estimate the level of bias between sex and medical conditions. In addition, by analyzing the individual trials that produced the highest bias effect, the medical terms that have the greatest association with one sex over the other can be identified. These applications may provide new insight into how these language embedding models can be applied into health care and regulatory science fields.

One limitation of the SD-WEAT is the increased computation resources due to having to generate and execute multiple runs to calculate the final bias effect score. However, the impact is rather minimal, only needing to examine the embedding method's biases once or periodically.

Advantages of SD-WEAT

The SD-WEAT not only enables the bias assessment over multilevel group terms but also enhances the bias assessment for binary group terms by avoiding unnecessary groupings of words. In some cases, it may be difficult to determine whether an intermediate word should belong to a certain grouping. Moreover, the SD-WEAT more robustly measures bias through the utilization of the SD of multiple effect sizes, and it has been found to be a more consistent and reliable measure of bias than its predecessor. As such, the SD-WEAT is a more robust and user-friendly measure of bias in input embeddings for AI language models.

Conclusions

To conclude, we introduced the SD-WEAT, a novel algorithm based on the WEAT, to enhance the bias assessment for complex term groups in language embedding models. In the future, the SD-WEAT could be applied in a regulatory science application and provide new insights to measure biases of common embedding models with regard to multilevel attribute groups, such as age, race, and region.

Abstract

Background: Obtaining and describing semiology efficiently and classifying seizure types correctly are crucial for the diagnosis and treatment of epilepsy. Nevertheless, there exists an inadequacy in related informatics resources and decision support tools.

Objective: We developed a symptom entity extraction tool and an epilepsy semiology ontology (ESO) and used machine learning to achieve an automated binary classification of epilepsy in this study.

Methods: Using present history data of electronic health records from the Southwest Epilepsy Center in China, we constructed an ESO and a symptom-entity extraction tool to extract seizure duration, seizure symptoms, and seizure frequency from the unstructured text by combining manual annotation with natural language processing techniques. In addition, we achieved automatic classification of patients in the study cohort with high accuracy based on the extracted seizure feature data using multiple machine learning methods.

Results: Data included present history from 10,925 cases between 2010 and 2020. Six annotators labeled a total of 2500 texts to obtain 5844 words of semiology and construct an ESO with 702 terms. Based on the ontology, the extraction tool achieved an accuracy rate of 85% in symptom extraction. Furthermore, we trained a stacking ensemble learning model combining XGBoost and random forest with an F_1-score of 75.03%. The random forest model had the highest area under the curve (0.985).

Conclusions: This work demonstrated the feasibility of natural language processing–assisted structural extraction of epilepsy medical record texts and downstream tasks, providing open ontology resources for subsequent related work.

Introduction

Epilepsy is a major chronic neurological disorder that affects approximately 70 million people and severely reduces the quality of life of patients and their families [1]. Obtaining a correct and complete seizure semiology efficiently is essential for the diagnosis and classification of seizures. However, this process is difficult to achieve. First, the symptoms of seizures are stereotypical but variable, and the same seizure course is in fact a complex combination of multiple symptomatologic elements in time and space. Furthermore, the type of seizure an individual patient experiences can change over the course of the disease [2,3]. Second, seizures have sudden onset, resulting in a short period of time for patients or witnesses to recognize and observe them, and history taking often relies on experienced and careful questioning by epilepsy specialists rather than recording the patient's statements directly [4,5]. Finally, epilepsy specialists are scarce and unevenly distributed worldwide. Nonneurologists, medical students, caregivers, and community workers play important roles in epilepsy care but lack appropriate tools to tease out epilepsy histories and determine classifications [6-9].

In recent years, natural language processing (NLP) has been widely used in the structured processing of clinical text data and development of intelligent diagnostic tools in neurology [10]. NLP methods have been used to automatically extract details from electronic health records (EHRs) of patients with epilepsy, such as categorical diagnosis, abnormal electroencephalogram (EEG) and imaging results, and medications prescribed [11-13]. These data are also used to

accomplish tasks such as automated identification of cohorts of drug-resistant patients and long-term prognostic tracking [14,15]. However, the complexity of epilepsy symptom elements remains a challenge for entity recognition and automatic extraction classification.

Therefore, ontologies were introduced to address this complexity. The concept of ontology is derived from philosophy and is used for formal, structured, domain-specific, and human- and computer-interpretable representations of entities and relationships. It has been widely used in computers, bioinformatics, and medical informatics [16,17]. Application ontology can be used in the medical field to represent established knowledge within a domain and maintain a standardized vocabulary across multiple locations, datasets, and consortiums, allowing for automated computation and decision-making based on structured data. Application ontologies can also be combined with NLP techniques to disambiguate textual concepts and build tools for the knowledge extracted from EHRs [10,18]. This work demonstrated the feasibility of NLP-assisted structural extraction of epilepsy medical record texts and downstream tasks, providing open ontology resources for subsequent related work.

Methods

Dataset

Electronic medical record data were obtained from patients with an *International Classification of Diseases, Tenth Revision* (*ICD-10*) epilepsy diagnosis (G40 or G40.x) who were hospitalized at West China Hospital of Sichuan University and assigned an epilepsy diagnosis between 2010 and 2020. The seizure type of inpatients was determined by discharge diagnosis.

The text information of the current medical history records the details of the occurrence, evolution, diagnosis, and treatment of the patient's disease; is written in chronological order; and is divided into the following parts: onset of the disease, including the time and place of onset; antecedent symptoms; probable causes or triggers; characteristics of the main symptoms and their development and change (describing the location, nature, duration, degree, factors of relief or aggravation, and evolution of the main symptoms in sequential order); accompanying symptoms; diagnosis and treatment since the onset of the disease; and the patient's general condition since the onset of the disease.

Ethical Considerations

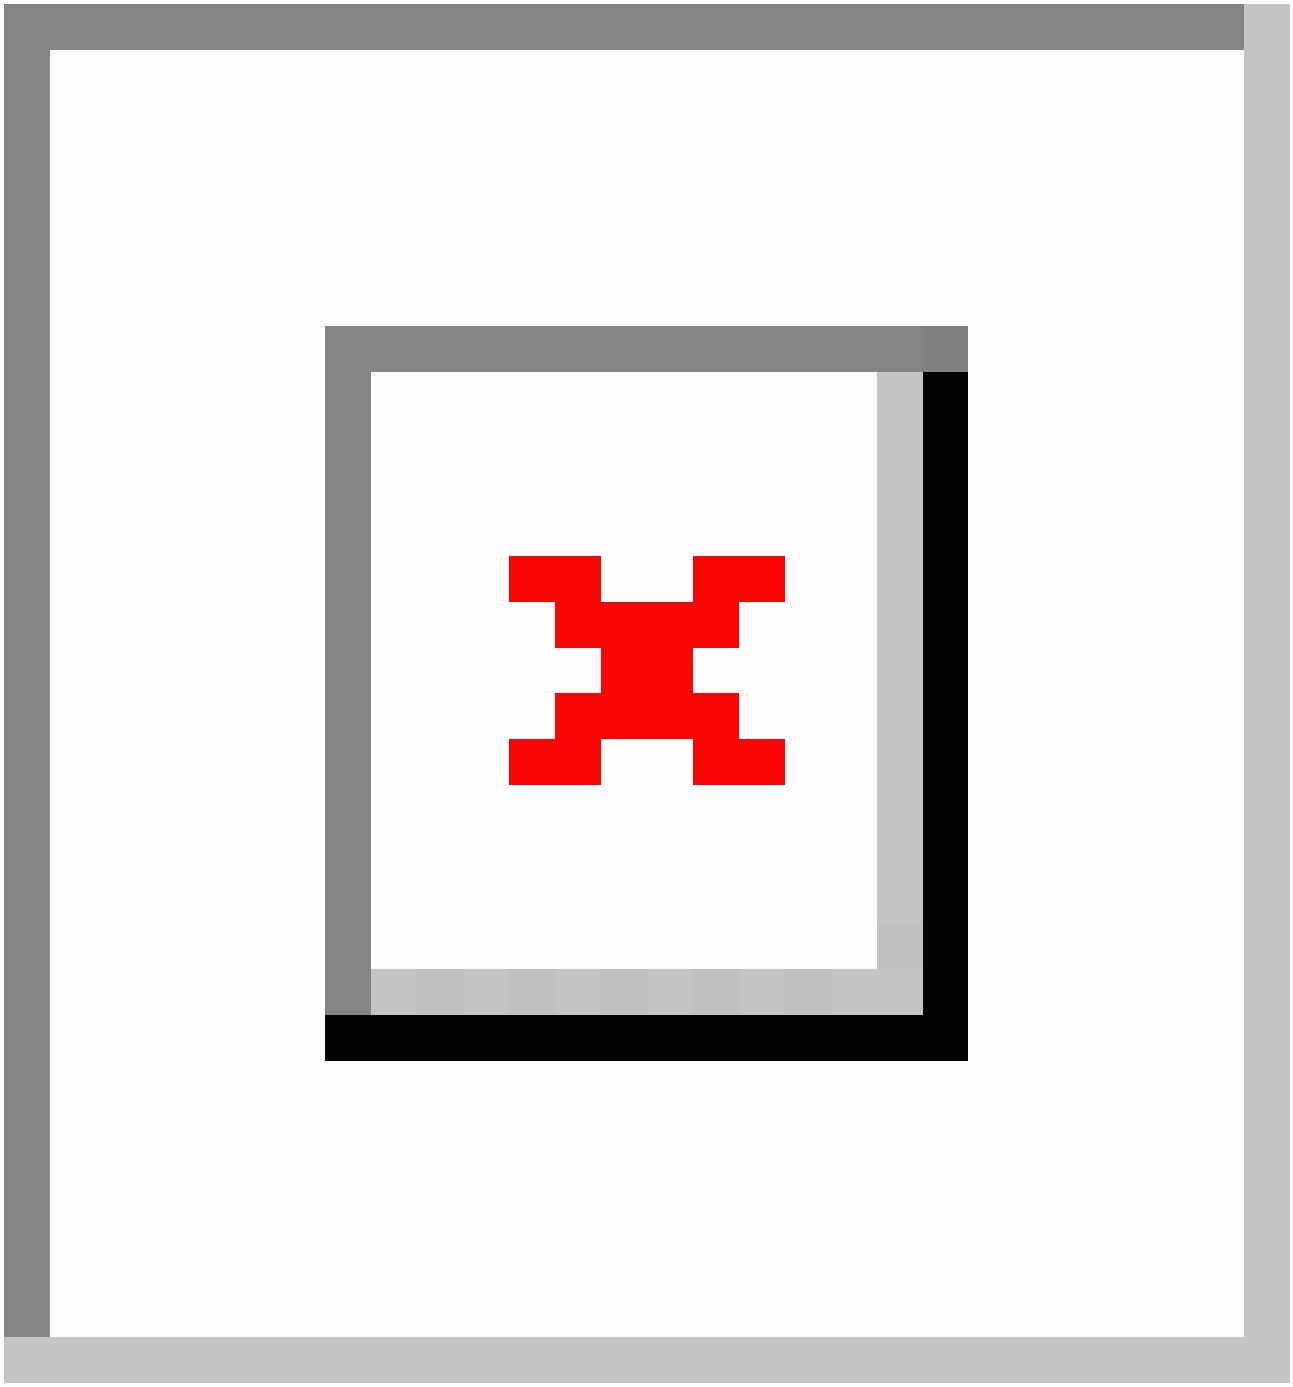
The study was reviewed and approved by the Ethics Committee of West China Hospital of Sichuan University (2022(1083)). Since the data were obtained from previous medical records, we have received approval from the ethics committee for a waiver of informed consent. The study data were deidentified, and the privacy and personal information of the subjects were protected.

Framework for Standardizing Seizure Information

We proposed a seizure extraction framework for mining and structuring important information related to seizures from the presenting medical histories of patients with epilepsy (Figure 1). The framework requires the extraction of the following information:

1. Time stamp: The important point in time at which the patient's condition has changed since today.
2. Location: Seizure site refers to the anatomical parts of the body corresponding to the symptom performance.
3. Symptom: Symptom performance refers to the symptoms and signs that appear during the seizure.
4. Duration of seizure event (episode time): Duration of epileptic events within the seizure episode.
5. Status: Occurrence state refers to the state corresponding to the symptom performance, including "with," "without," or "unknown."
6. Frequency: The frequency of seizures, for example: once a month, and so forth.

Figure 1. Example of the standardized framework.



Labeling Process

Six annotators completed the labeling process. Four of them, junior physicians (SB, LS, LJ, and YD) specializing in epilepsy or epilepsy researchers, were responsible for independently extracting seizure-related information from 2500 raw texts of presenting medical histories according to a standardized framework. Two senior physicians (HL and WL) specializing in epilepsy were responsible for discussing and formulating the framework of the annotation and the rules that should be followed during annotation to ensure reliability, providing uniform training to the annotators, and manually reviewing the final results of the annotation. Annotation rules included the following:

When a particular Chinese phrase used to describe the seizure process was a fixed collocation, the phrase was extracted as a whole without separating the verb and the object (usually a location) in it individually, in order to avoid a decrease in the specificity of the extraction.

Due to the specificity of the commonly used symptomatology phrases in the Chinese section, it is important to ensure that the symptomatic manifestations are extracted at the coarsest possible granularity, that is, descriptive phrases that include seizure state and seizure site are avoided. However, phrases should not be disassembled when they cannot be clearly recognized as symptoms, such as lip smacking (oropharyngeal automatisms) and hand rubbing (hand automatisms), and the anatomical part of the phrase should be retained. It should also be confirmed

that all seizure symptomatology is extracted from seizures and not from other symptoms accompanying epilepsy. Cognitive decline, such as memory and attention, should not be included in labeling.

Do not standardize the presentation of the extracted information and keep it as original as possible.

To assess the consistency of the annotations by the 4 annotators, 50 identical medical records were included without their knowledge. Two senior physicians provided reference standards for the annotation of the 50 medical records. We used Fleiss's κ to calculate interannotator agreement. By convention, κ value above 0.80 indicates "near-perfect" agreement.

Bilingual Ontology Construction for Seizure Semiology

Compared with other parts of the seizure information framework, epileptic semiology expression and the diversity of expression extraction tasks are more challenging, especially for Chinese EHRs of epilepsy. Therefore, we constructed a bilingual ontology to share the lexicon obtained from manual extraction and annotation. It can be further used, evaluated, and refined for future Chinese epilepsy history extraction tasks.

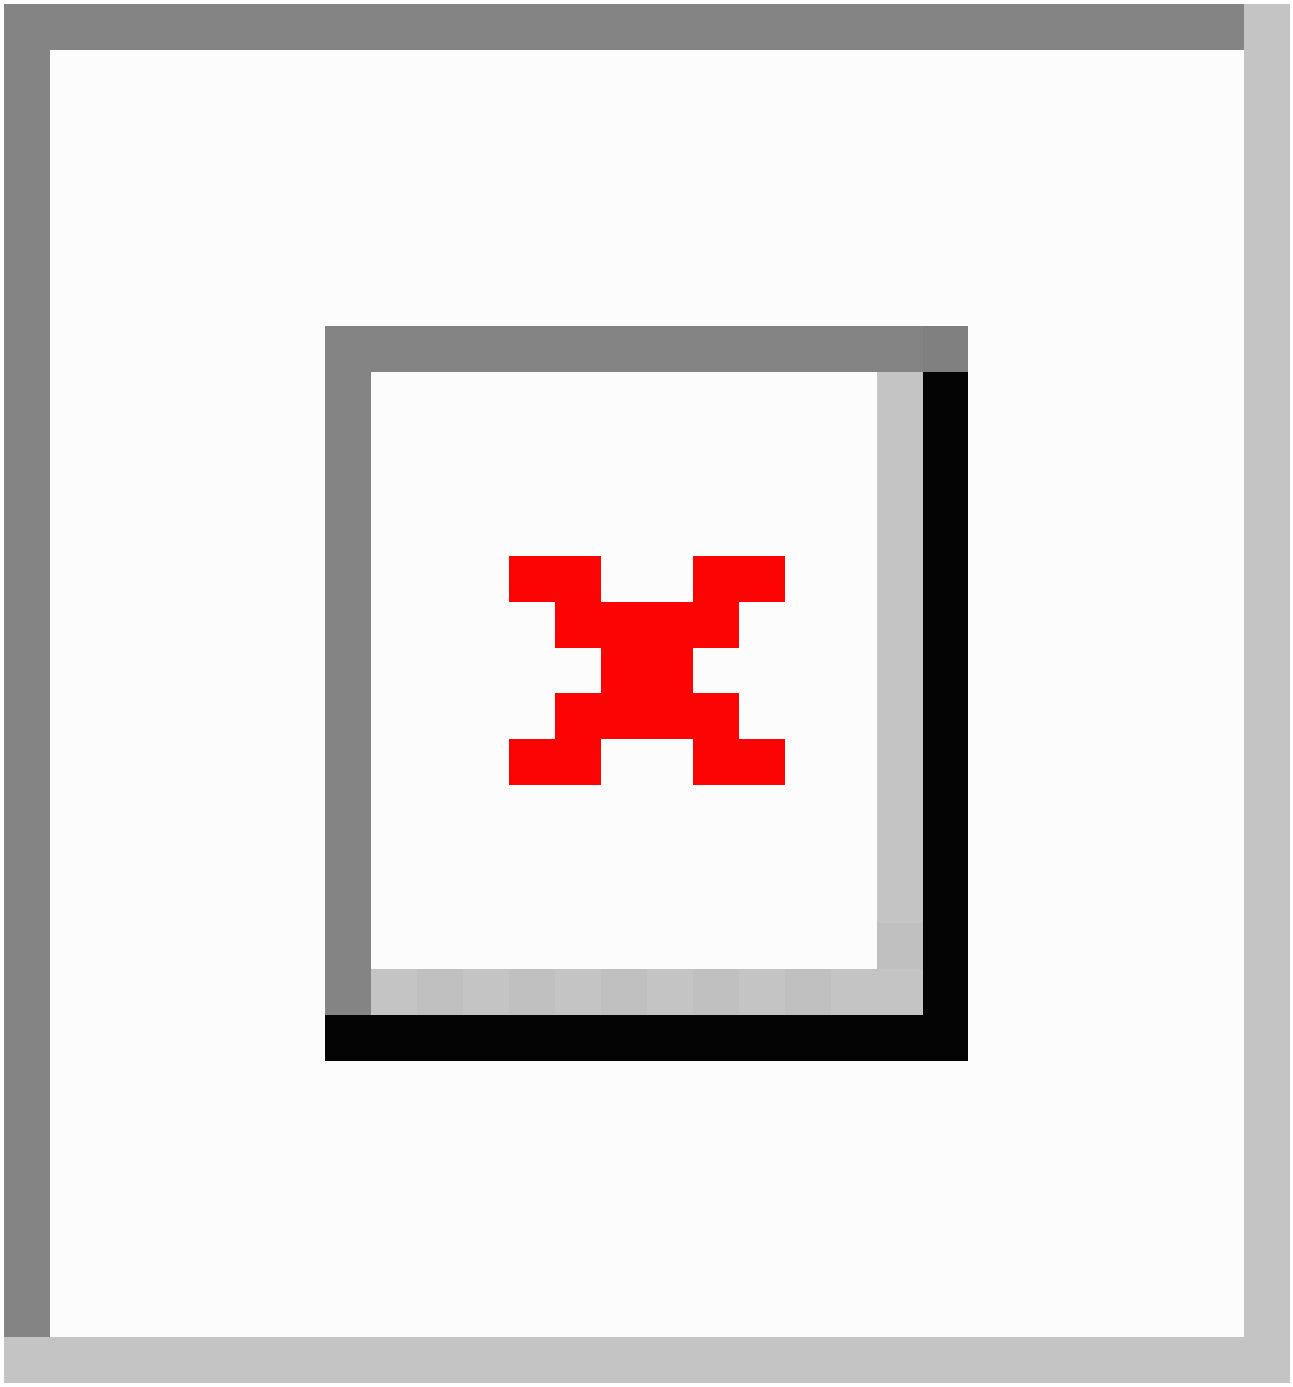
We defined the scope of this domain of ontology as epileptic semiology by reference, reused the more authoritative epilepsy-related ontologies and terminology sets as standard terminology, referred to the basic formalized ontology (BFO) as the top-level ontology, and hierarchically arranged the entities according to their domain-neutral framework. Then, we deemphasized the annotated symptoms collected in the annotation phase to eliminate redundancy and placed them into the corresponding terms as their synonymous expression properties. We used Protégé as the editor of the ontology and uploaded it in Ontology Web Language (OWL) as the first version of the world's largest ontology browser, BioPortal.

Extraction Process and Evaluation of Extraction Results

We used some NLP tools to structure the extraction of current medical history from EHRs. We imported the organized dictionaries of symptom performance, symptom nature, seizure frequency, and seizure site into the Jieba tokenizer and initialized the Part-of-Speech Tagger (Postagger) and Dependency Parser (Parser) of the pyltp [19] plug-in using existing models (pos.model, parser.model). pyltp provides a series of Chinese NLP tools, and users can use these tools for Chinese text segmentation, part-of-speech tagging, parsing, and so on.

Specifically, in the data preprocessing stage, we first imported organized dictionaries of symptom presentation, symptom type, seizure frequency, and seizure location. These dictionaries are used for subsequent segmentation and feature extraction. We used Postagger to tag the parts of speech of the tokenized results and Parser to analyze the dependency relations of the words in the current sentence or context. Next, we performed text segmentation and annotation, using Jieba Segmenter to segment the medical history text in the EHR. Jieba Segmenter is able to accurately slice and dice the text based on the imported dictionaries. Postagger was called to lexically annotate the segmentation results by identifying the lexical properties of each word. The dependencies between words are analyzed using Parser to determine the syntactic structure between words. Then, to extract symptom information, we iteratively processed the participle results by combining a list of negatives, a list of transitive or logical connectives, and a list of temporal adverbs. These normalized lists allowed us to accurately identify positive and negative symptom information. In each sentence, information such as the location, type, duration, and frequency of symptom episodes was extracted. Finally, the extracted information such as positive and negative symptoms, location, nature, duration, and frequency of episodes was structured and stored in the output dictionary according to the temporal nodes. The overall process flow is illustrated in Figure 2.

Figure 2. Extraction modeling workflow.



The software and programming languages used included Python 3.8.8, pyltp 0.2.0, pandas 1.4.2, and Jieba 0.42.1.

After the extraction was completed, we randomly selected 200 cases from all the results for manual inspection to comprehensively assess the extraction capability and obtain the accuracy for 6 aspects separately: time stamp, symptom, location, episode time, status, and frequency.

Seizure Classification Based on Machine Learning

Our work aimed to build a binary classification model capable of distinguishing between generalized and focal seizures. The analysis process, based on supervised machine learning, consisted of the following steps: data preprocessing, feature selection, algorithm selection, parameter tuning, and performance evaluation.

Data Preprocessing

Our extraction tool was used to retrieve semiology data of the patients. After preprocessing 16,587 records by *ICD* coding combined with regular expression matching, 10,098 records were excluded because they did not receive a clear classification (60%).

A total of 6489 medical history text records with a diagnosis of generalized or focal seizure were retained, including 2632 records of generalized epilepsy and 3857 records of focal epilepsy. After communication with clinicians, 103 symptom words were defined to cover the main symptoms that can occur

in patients with epilepsy. We used text-matching techniques to map the symptom descriptions in each record to these 103 symptom words. Specifically, for each record, if a symptom word was mentioned in the text, we marked the corresponding symptom word as 1; if it was not mentioned, it was marked as 0. For example, if a record mentioned "Clonic" but not "Foaming at Mouth," then the field for "Clonic" was set to 1, and the field for "Foaming at Mouth" was set to 0.

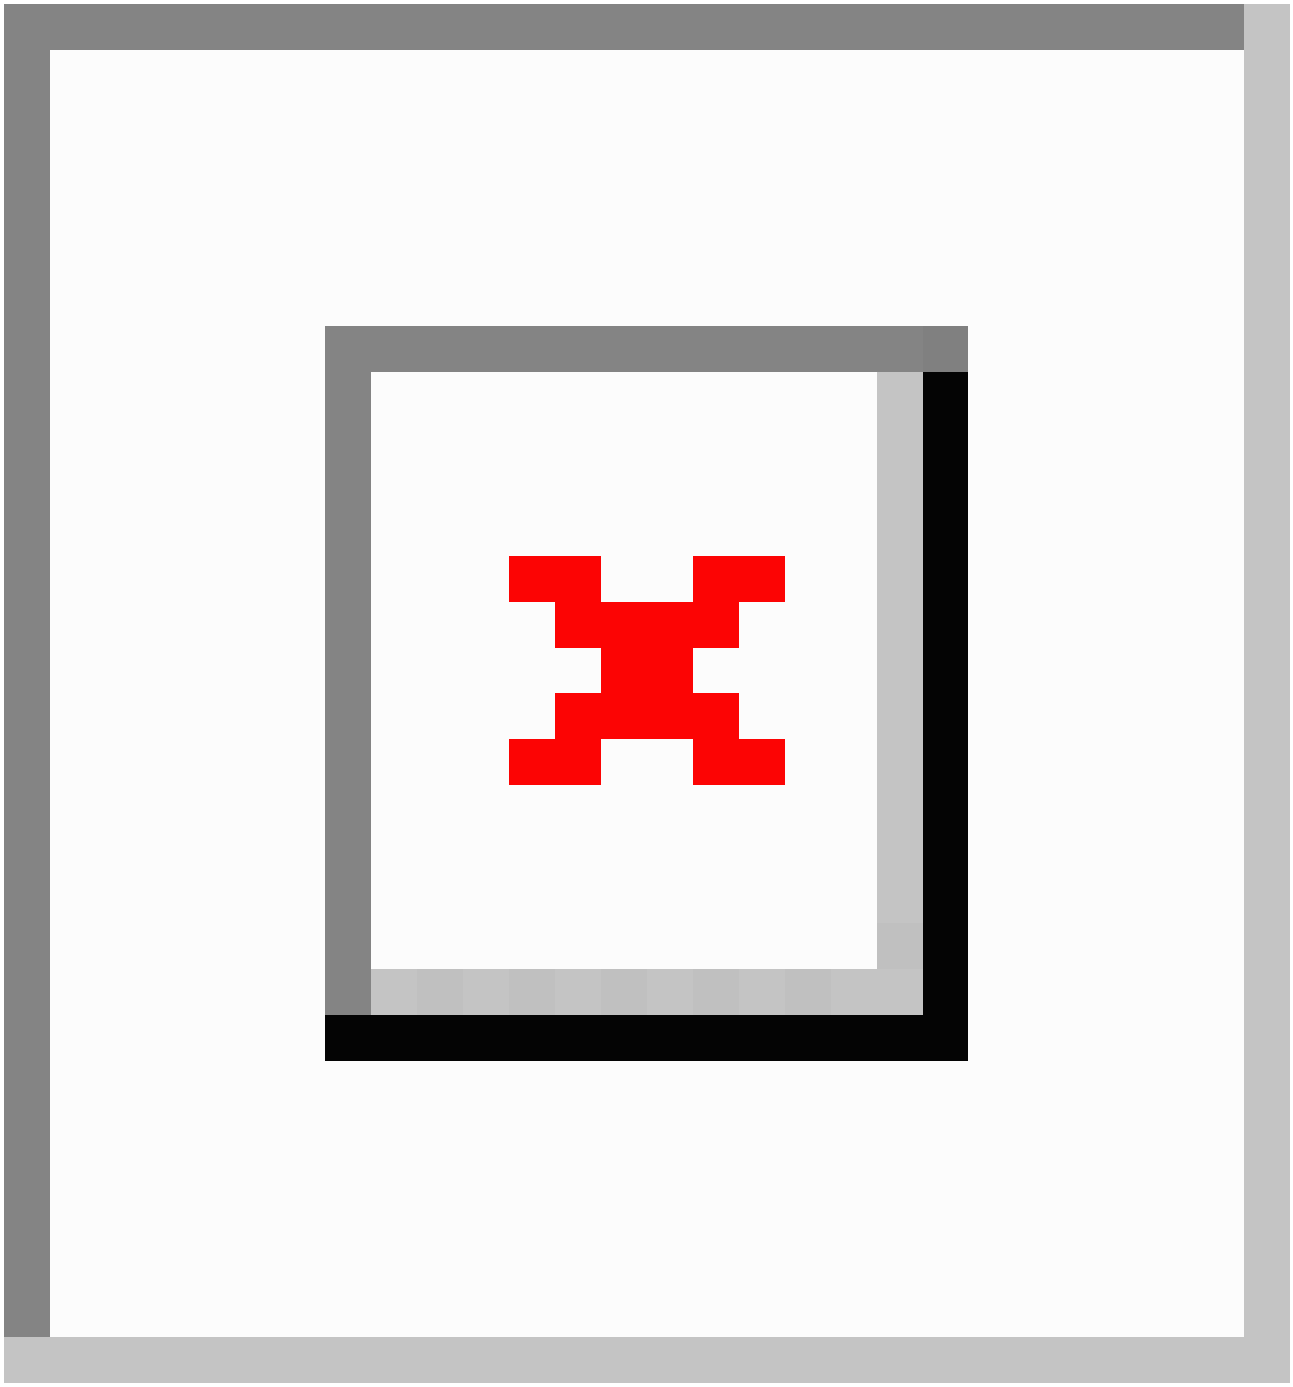
Feature Selection

We used several feature selection techniques to identify the most relevant features for the classification task. Specifically, we used recursive feature elimination, random forest–based feature importance, mutual information, and the SelectKBest method using the ANOVA *F* value. Each method was systematically applied to the feature matrix (X) and the label vector (y) to generate a reduced set of features. We varied the number of retained features (k) across multiple values to evaluate its impact on model performance. In addition, we examined the effects of different sample ratios on the model's performance.

Algorithm Selection and Parameter Tuning

Subsequently, we divided the preprocessed dataset into training and testing sets at a 7:3 ratio. We used 4 types of models as base models: decision tree [20], random forest [21], XGBoost [22], and LightGBM [23]. Using grid search algorithms and k-fold cross-validation, we optimized the hyperparameters of the models with training to enhance the model accuracy. Specific parameters are detailed in Multimedia Appendix 1. We also introduced the stacking ensemble learning method, which was conducted in 2 stages, as illustrated in Figure 3. In the first stage, we performed 5-fold cross-validation. Specifically, we divided the training dataset into 5 parts, with 4 serving as the training set for base model training and the remaining part serving as the validation set for generating new training data. Simultaneously, we predicted the entire test set (test_data) to create a new test dataset. In the second stage, we used the training and testing sets generated from the first stage as inputs for further training and prediction using the logistic regression model, resulting in the final outcome. In this study, we combined the XGBoost model with the random forest and LightGBM models for combined training and testing.

Figure 3. Stacking integration learning process. EHR: electronic health record.



Performance Evaluation

Finally, we used the test set to evaluate the precision, recall, F_1-scores, and the area under the receiver operating characteristic curve (ROC) value of the model. We designated "generalized epilepsy" as label A and "focal epilepsy" as label B. TP(*A*) represents true positives, FP(*A*) represents false positives, and FN(*A*) represents false negatives for label A, and similarly for label B.

Precision is defined by the following formula:

(1)Precision=12(TP(A)TP(A)+FP(A)+TP(B)TP(B)+FP(B))

Recall is defined by the following formula:

(2)Recall=12(TP(A)TP(A)+FN(A)+TP(B)TP(B)+FN(B))

The F_1-score (F_1) is defined by the following formula:

(3)F1=2×Precision×RecallPrecision+Recall

For the classification analysis of seizure, the following software or programming language versions were used: Python 3.8.8, NumPy 1.24.3, pandas 1.4.2, scikit-learn 1.3.2, XGBoost 2.0.1, and LightGBM 4.1.0.

Bilingual Ontology Construction for Seizure Semiology

Compared with other parts of the seizure information framework, epileptic semiology expression and the diversity of expression extraction tasks are more challenging, especially for Chinese EHRs of epilepsy. Therefore, we constructed a bilingual ontology to share the lexicon obtained from manual extraction and annotation. In developing epilepsy semiology ontology

(ESO), we followed 5 of the 7 steps of the Stanford methodology: (1) defining the domain and scope of the ontology, (2) reusing existing ontologies to the extent possible, (3) enumerating ontology terms, (4) defining classes and class hierarchies, and (5) defining class attributes (Multimedia Appendix 2).

In the first step, epileptologists and the ontology development team met biweekly to define the scope of the ontology and to ensure that the goals remained constant throughout its development. In steps 2 and 3, we standardized terminology by referring to existing, more authoritative epilepsy-related ontologies and terminology sets. In the fourth step, we adopted the BFO as the top-level ontology. In the fifth step, we de-emphasized the annotated symptoms collected in the annotation phase to eliminate redundancy and placed them into the corresponding terms as their synonymous expression properties. Finally, we rendered the ontology using the OWL in the Protégé ontology editor and uploaded it to the world's largest ontology browser, Bioportal, as a first version.

Results

Patient Cohort

The study cohort included 10,925 patients and 10,658 texts of presenting medical histories. The patient cohort included 42% (4588/10,925) females and 58% (6337/10,925) males with a mean age of 31.45 (age range: 1 - 92) years. The presenting medical history texts were independently written and completed by 117 physicians. Fifty-seven percent (6227/10,925) of the patients in the patient cohort ultimately received a definitive diagnostic classification of seizures at the time of discharge, with 32% (1992/6227) of patients having focal epilepsy and 26% (1619/6227) having generalized epilepsy.

Assessment of Labeling Quality Control Results and Extraction Capacity

In the annotation phase, we assigned 50 identical texts to the annotators without their knowledge to test the consistency of their annotations. The κ-value of the 4 annotators was 0.862, indicating a high degree of consistency.

After completing the extraction using the model, we manually inspected a random sample of 200 notes from the extraction results (which included 235 seizures) to assess the extraction performance of the model. The extraction results for the 5 dimensions are shown in Table 1.

Table . Extraction performance.

	Time stamp	Location	Symptom	Episode time	Status	Frequency
Total number of elements by reviewer annotation, "gold standard"	235	512	1325	183	1325	106
Total number of elements by algorithm report	196	516	1219	175	1302	93
Number of correct algorithm-reported elements	181	507	1126	145	1254	84
Recall, n/N (%)	181/235 (77)	507/512 (99)	1126/1325 (85)	145/183 (79)	1254/1325 (95)	84/106 (79)
Precision, n/N (%)	181/196 (92)	507/512 (98)	1126/1219 (92)	145/175 (82)	1254/1302 (96)	84/93 (90)
F_1-score	0.83	0.98	0.88	0.80	0.95	0.84

Epilepsy Semiology Ontology

The overall hierarchical structure of ESO adheres to the architecture of the top-level ontology BFO, which supports semantic interoperability between ontologies, starting from "continuant" and "occurrent" under "entity."

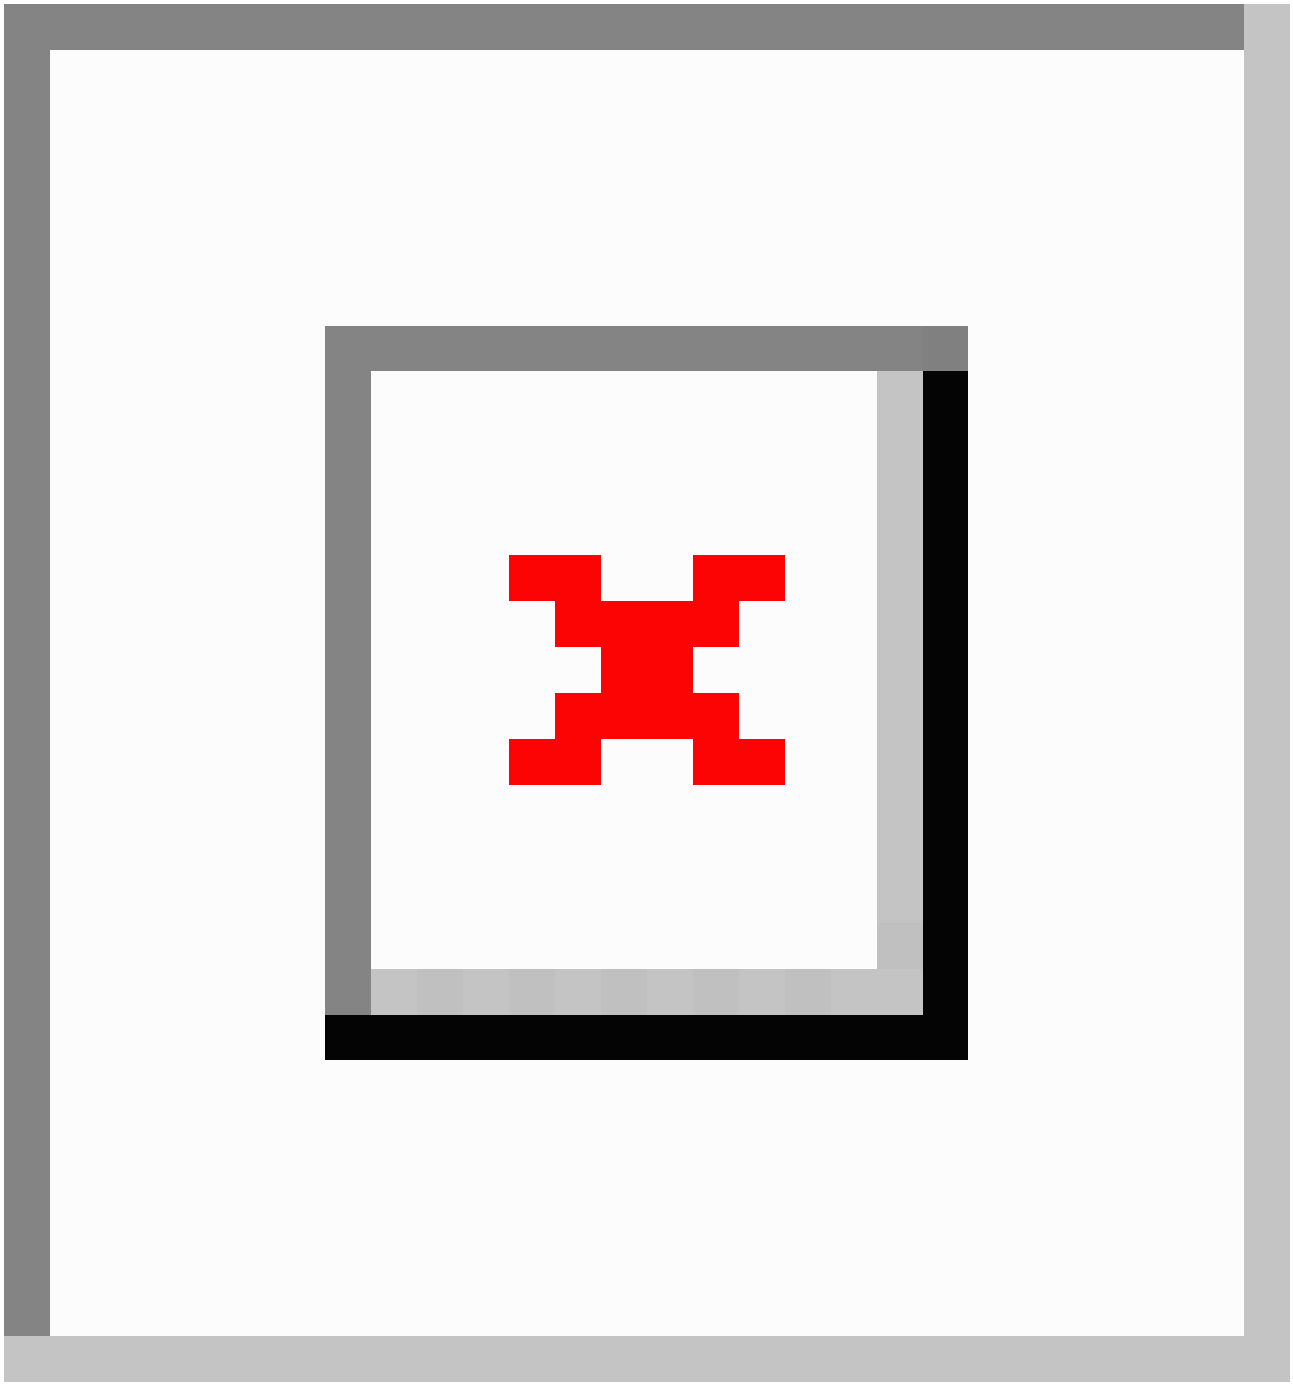
The ESO contains a total of 176 terms, most of which are based on the nominal entity "anatomical entity" and the process "physiological pathological process," with a maximum depth of 10 layers. According to the principle of ontology reuse, we partially reused and rearranged the concepts of "pathophysiological process" and its leaf nodes in epilepsy and seizure ontology (EPSO) [24] and also referred to the existing semiology terminology collection of the International League Against Epilepsy, which includes a total of 132 epilepsy semiology terms. In terms of seizure sites, we referred to the "Bodily Feature" section of Systemized Nomenclature of Medicine Clinical Terms (SNOMED CT) [25] and EPSO, which contains a total of 32 seizure-site terms. The purpose, scope, language, and users are listed in Multimedia Appendix 3.

As an important step in implementing the medical record extraction function of the application ontology, we added Chinese translations and synonyms of symptom performance as entity attributes (Multimedia Appendix 3). After annotating 2500 medical records, we obtained 5844 words of semiology. After de-emphasizing and removing nonepileptic seizure symptoms (usually abnormal general conditions and comorbid symptoms), we obtained 702 terms, 75 primary terms, and their synonyms. Among them, there were more than 30 synonyms for holding, dropping, and vocalization.

Performance of Seizure Classification

In the feature selection process, we found that choosing 103 features among the 4 feature selection methods gave the best results, and we also observed that choosing different sample ratios for training had little impact on the model performance (Multimedia Appendix 4). On this basis, we optimized the parameters and trained 4 foundational models—decision tree, random forest, XGBoost, and LightGBM—to distinguish between generalized and focal epilepsy. Figure 4A-E illustrates the contribution of each symptom feature to the predictive decisions of these models. Notably, "clonic," "tonic," "unresponsive to call," "eyes rolled up," "foaming at mouth," and "fall" are pivotal in differentiating seizure types.

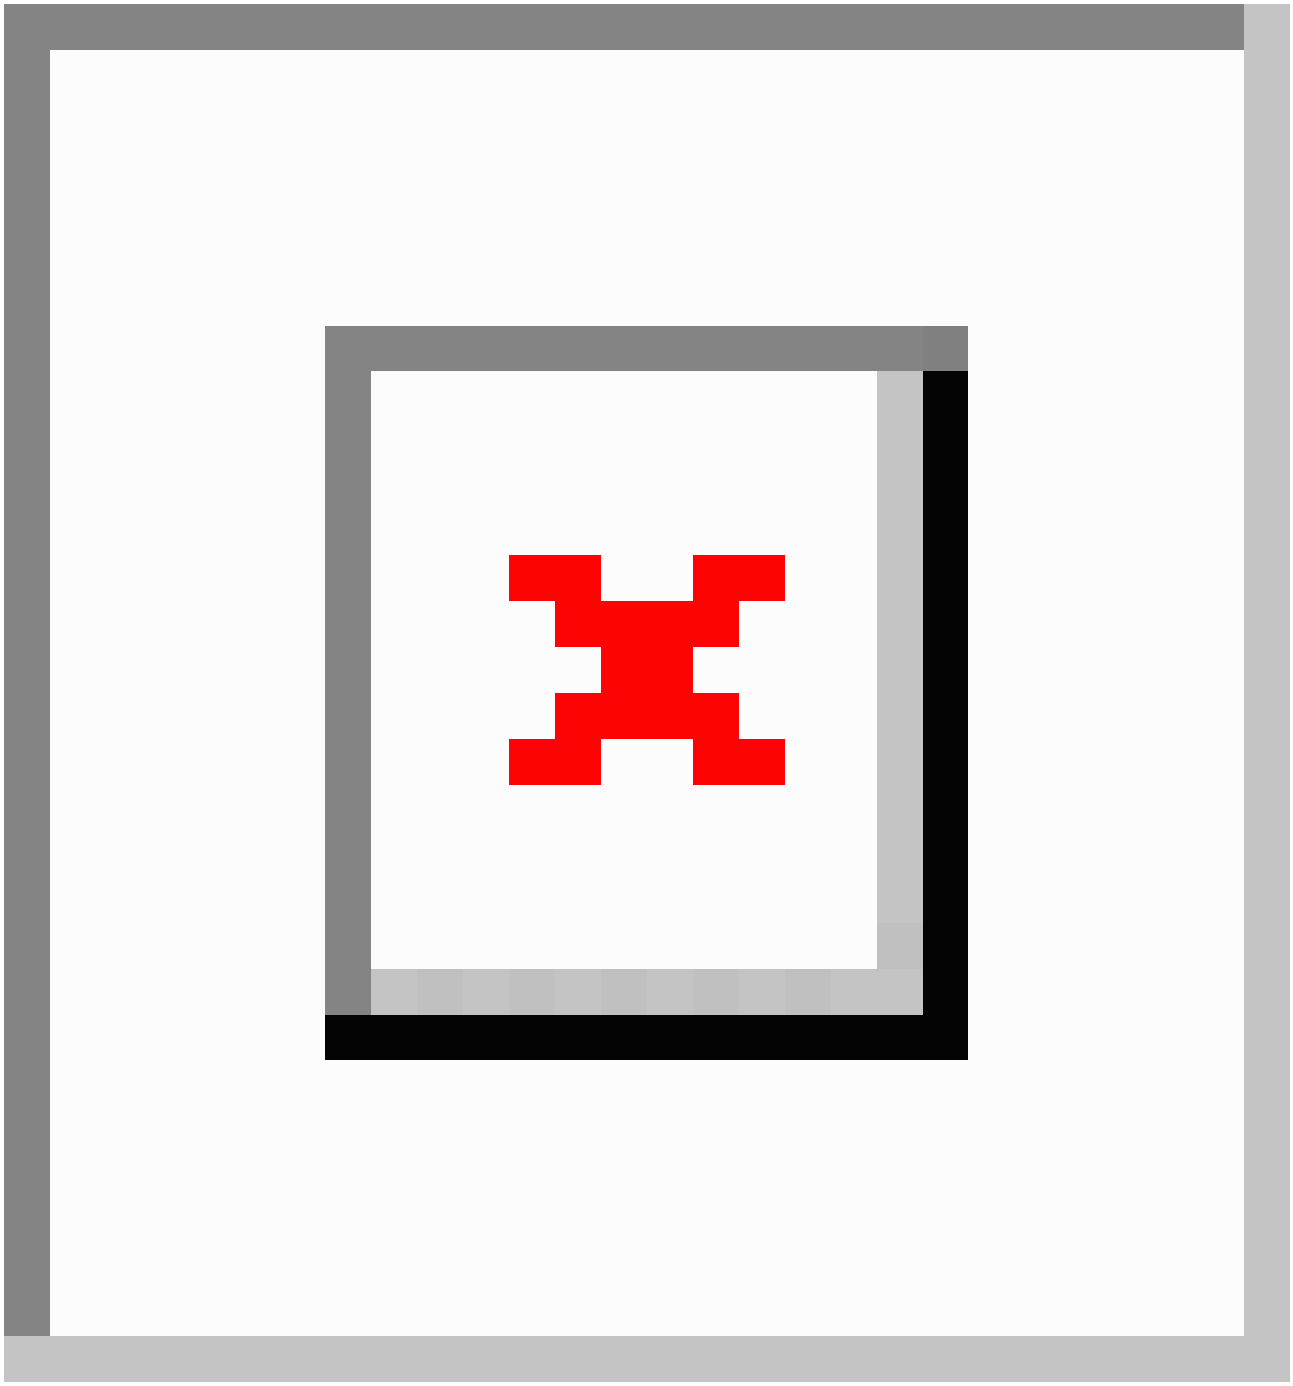
Figure 4. Distribution of important features of the base model. (A) Decision tree model important features. (B) Random forest model important features. (C) XGBoost model important features. (D) LightGBM model important features. (E) important features of the base model Wayne chart.



In addition, we trained a stacking ensemble learning model. As shown in Figure 5A-C, the stacking ensemble model outperformed the other base models in terms of precision, recall, and F_1-score. Among them, the ensemble model combining XGBoost and random forest yielded the best results, with the highest F_1-score (75.03%). We also compared the ROCs of the various models represented by different colors. Notably, the random forest model and XGBoost+random forest ensemble model outperformed the other models, as indicated by the orange and blue lines, respectively. As shown in Figure 5D, the random forest model had the highest area under the curve (AUC)—0.984—whereas the XGBoost+random forest ensemble

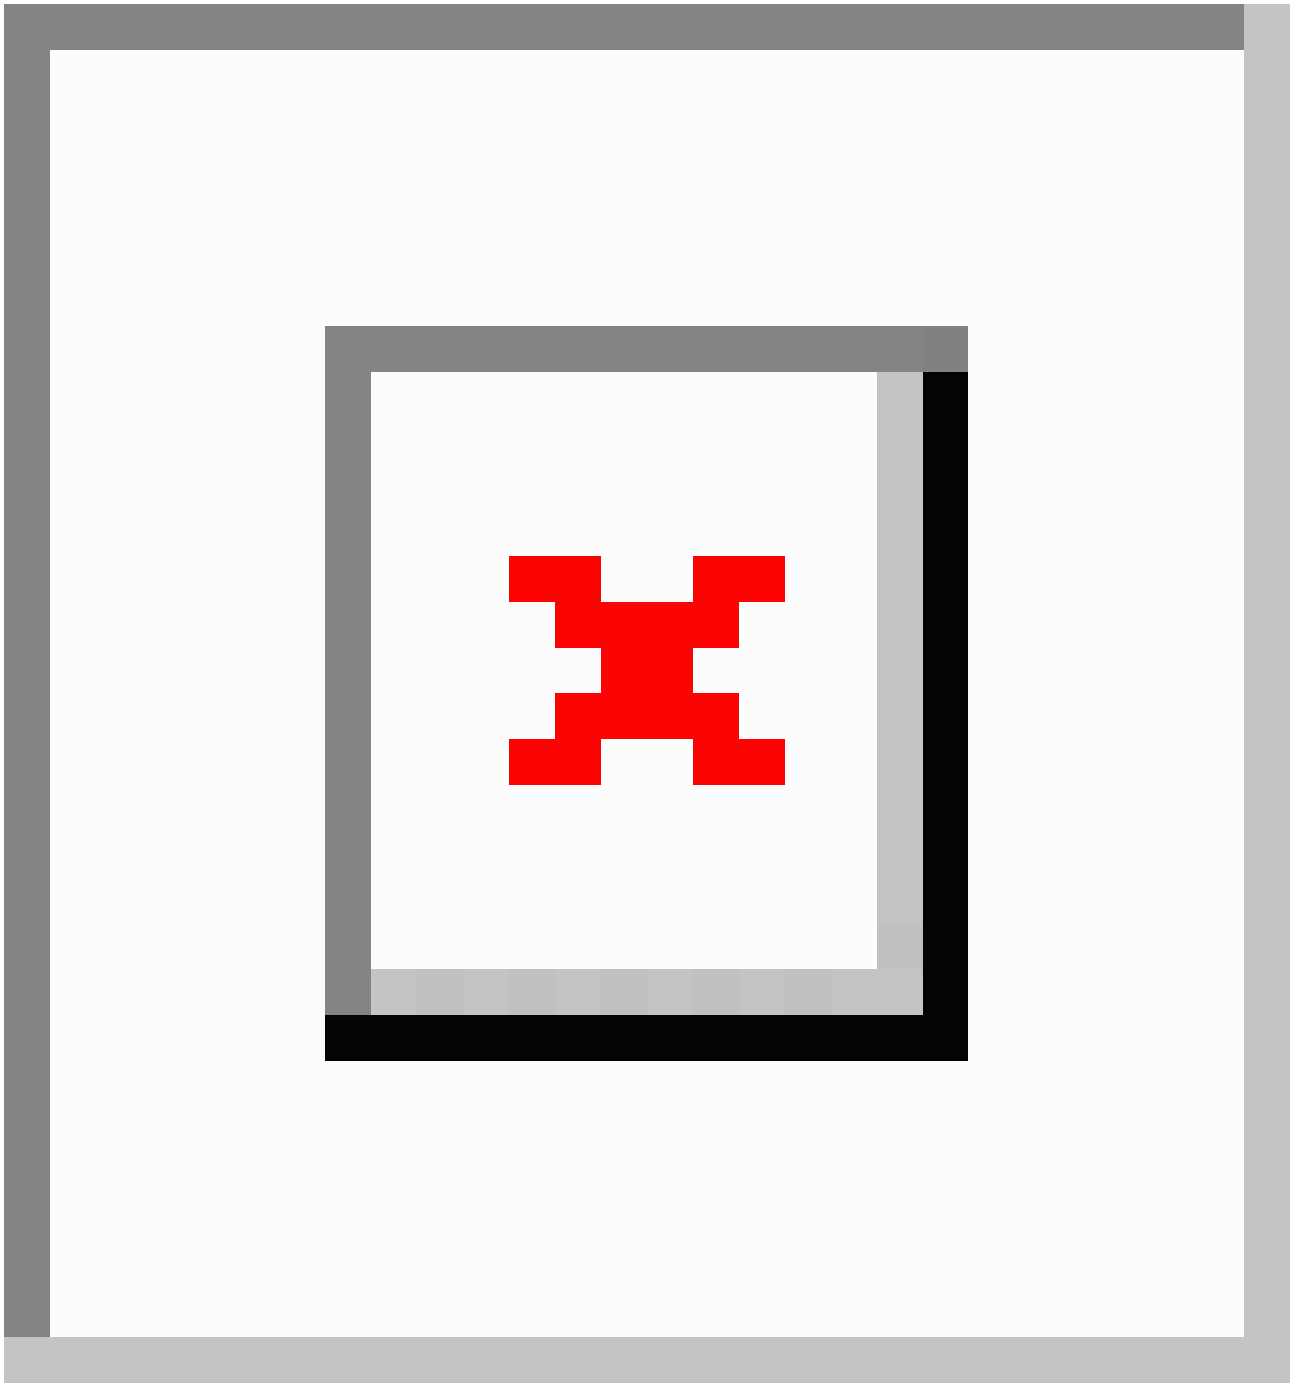
model had an AUC of 0.919, with the AUCs of the other models falling below these 2.

Figure 5. Comparison of model evaluations plotted against ROCs. (A) Comparison of precision across models. (B) Comparison of recall across models. (C) Comparison of F_1-scores across models. (D) Comparison of ROCs across models. AUC: area under the curve; ROC: receiver operating characteristic curve.



Ultimately, we selected the ensemble model combining XGBoost and random forest for predicting seizure classification and visualized its confusion matrix. As shown in Figure 6, the model has a precision of 0.68 for predicting "generalized epilepsy" and a precision of 0.80 for predicting "focal epilepsy."

Figure 6. XGBoost+random forest confusion matrix plot.



Discussion

Principal Findings

In this study, the first Chinese-English ontology of epilepsy semiology was established, the first non–English-structured extraction of epilepsy history text was achieved by combining manual annotation and NLP techniques, and automatic seizure classification was further accomplished based on the data extracted by the tool.

Comparison to Prior Work

Ninety percent of the disease burden caused by epilepsy is borne by resource-limited countries. China has more than 12% of patients with epilepsy worldwide [26,27]. The Global Burden of Disease study reported that, in 2019, China's disability-adjusted life years (DALYs) due to epilepsy accounted for 10% of the global DALYs and 94% of the DALYs in East Asia [28]. However, the development of Chinese language EHR processing tools for epilepsy has been delayed because of the lack of high-quality corpora such as relevant terminology sets. English ontologies and terminology systems, including SNOMED CT, Unified Medical Language System, and EPSO [26], are limited by the problems of diverse descriptions of Chinese medical entities, fuzzy boundaries, and the existence of nested relationships. Therefore, it is more difficult to support clinical terminology extraction from Chinese medical records after "Chinese-ization" [29]. The technical challenges of Chinese NLP lie in its complex word-splitting process, high-frequency

ambiguity phenomenon, and flexible and variable sentence construction [30]. By contrast, English NLP is relatively simple to process because of its clear separation of words by spaces, more standardized syntactic structures, and abundant processing resources. Despite these differences, the gap between Chinese and English NLP technologies is gradually narrowing as deep learning and pretrained language models continue to advance and multilingual processing capabilities are significantly enhanced. In this study, the ontology and extraction tool constructed based on the corpus of the Southwest Epilepsy Center can better serve the grassroots areas in western China, where the burden of epilepsy is high and medical resources are relatively scarce, thereby bridging the world's health disparities for people with epilepsy [26,31].

In this study, for the first time, the symptom elements of epileptic seizures were extracted at an ultrafine granularity, the accuracy of the extraction of the features reached 0.85, and the classification of generalized and focal seizures relying on the symptom features alone reached an AUC of 0.985. We also found that the key features in the classifier corresponded to the "red flag" symptoms used by human experts, yielding a list of symptoms including "clonic," "tonic," "unresponsive to call," "eyes rolled up," "foaming at mouth" and "fall," which are the same basic key features as those categorized by human experts' guidelines [2]. To the best of our knowledge, this is the first time that a present history of epilepsy has been extracted and automatically categorized with symptom element granularity [32,33]. Barbour et al [34] created regular expressions manually as well as creating false-positive filters and disambiguated them using conditional matching to extract entities such as seizure type, with internally tested F_1-values ranging from 0.86 to 0.90. Vulpius et al [35] extracted seizure epilepsy types primarily by manually constructing dictionaries.

However, these 2 studies were based only on existing unstructured diagnostic texts rather than indirect inference through medical history texts, and only automated extraction, rather than automated classification based on symptom features, was achieved. In our seizure classification task, we used a stacking integration technique to combine the XGBoost and random forest models (AUC=0.919). Despite the higher AUC of the random forest model, it may have lower precision or recall in some categories, resulting in a less favorable F_1-score than the stacking method. The stacking method, on the other hand, by combining the advantages of both random forest and XGBoost, may achieve a more balanced performance across all categories, thereby improving the F_1-score.

Although downstream tasks for seizure classification currently exist, most rely on a single-model architecture, such as support vector machine, linear model, or XGBoost [35,36]. However, by pooling multiple underlying models using stacking techniques, it is possible to improve model performance and reduce the risk of overfitting, which in turn improves the model's generalization capabilities.

Future Directions

Beyond the initial diagnosis and classification of seizure, our study has the potential to identify specific types of epilepsy. For example, the classification of adolescent myoclonic epilepsy may change over the course of a single patient's illness, with a predominance of absence and myoclonic seizures initially, followed by intensification of generalized tonic-clonic seizures in adulthood or after practice tasks [3]. This type of epilepsy is difficult to recognize because of changes from pediatric and adult neurologists. Plug-ins based on extraction and classification models can be developed to alert epileptologists to consider this particular type.

In addition, accurate extraction of seizure duration and frequency has been used in epilepsy research to help clinical researchers accurately screen retrospective cohorts in vast multicenter electronic health information databases, for example, by accelerating the speed of patient recruitment and data collection, screening of rare epilepsy cohorts [37], and screening of persistent status epilepticus in children [38]. The extracted data also enable the dynamic and automated monitoring of postmedication efficacy, epidemiological statistics, and medical economics studies on a larger scale. In the future, we will consider the use of deep learning models and the addition of multimodal features such as imaging and EEG in the seizure classification task to achieve a more accurate and dynamically changing classification capability based on the patient's journey. With further improvements in extraction and classification accuracy, automated symptom-based classification will be uniquely suited to help primary care physicians and other specialists accurately classify epilepsy and select appropriate medications. In conclusion, this work demonstrates the feasibility of NLP-assisted structured extraction of epilepsy history text and downstream tasks in Chinese and provides an open ontology resource for subsequent related work.

Limitations

This study also has some limitations. First, including the fact that the data source was only from a single center, we have not yet verified its transferability to other regions in China. Second, we have not yet applied the ontology to real clinical scenarios, such as assisting clinicians in structured and efficient registration of epilepsy history. Third, the accuracy of dependent syntax analysis is crucial to the effectiveness of information extraction, and the flexibility of Chinese grammar adds to the difficulty of the analysis. Fourth, although current deep learning techniques have gained momentum to improve the situation, they also require finer tuning and extensive contextual adaptation testing. Fifth, our ontology remains in its initial iteration. There is currently no systematic approach to quality assessment and verification. We will continue to expand and refine the ontology data. In the future, other dimensions and modalities should be added to the features, including EEG and imaging, to further improve the accuracy of classification and the completion of more downstream tasks.

Conclusions

Clinically significant seizure information was successfully extracted from Chinese medical histories using NLP. This innovative approach represents a powerful tool for clinical research, with numerous potential applications, particularly for disorders characterized by complex clinical symptoms, such as seizure disorders. During this process, we constructed a bilingual

ontology of seizure symptomatology comprising 702 terms. Furthermore, leveraging the extracted symptomatology information, we trained a binary classification model for generalized versus focal epilepsy using the stacking ensemble learning method. This demonstrates the feasibility of performing downstream tasks, such as seizure classification, based on the extracted information.

Acknowledgments

We are very grateful to Bairong Shen and Xingyun Liu from the Institute of Systems Genetics of West China Hospital for their guidance on ontology construction. This work was financially supported by TianYuan Special Funds of the National Natural Science Foundation of China (No. 12026607) and Sichuan Science and Technology Program (2023YFS0047).

Authors' Contributions

YX and LC contributed to study conception and design. YT, HL, and WL participated in data acquisition and curation. SB, LS, LJ, YD, HL, and WL participated in the data labeling process. YX and ZH contributed to ontology construction. YX, MH, SB, and LS participated in the analysis of data and extraction process. Abstract

Background: Electronic medical records store extensive patient data and serve as a comprehensive repository, including textual medical records like surgical and imaging reports. Their utility in clinical decision support systems is substantial, but the widespread use of ambiguous and unstandardized abbreviations in clinical documents poses challenges for natural language processing in clinical decision support systems. Efficient abbreviation disambiguation methods are needed for effective information extraction.

Objective: This study aims to enhance the one-to-all (OTA) framework for clinical abbreviation expansion, which uses a single model to predict multiple abbreviation meanings. The objective is to improve OTA by developing context-candidate pairs and optimizing word embeddings in Bidirectional Encoder Representations From Transformers (BERT), evaluating the model's efficacy in expanding clinical abbreviations using real data.

Methods: Three datasets were used: Medical Subject Headings Word Sense Disambiguation, University of Minnesota, and Chia-Yi Christian Hospital from Ditmanson Medical Foundation Chia-Yi Christian Hospital. Texts containing polysemous abbreviations were preprocessed and formatted for BERT. The study involved fine-tuning pretrained models, ClinicalBERT and BlueBERT, generating dataset pairs for training and testing based on Huang et al's method.

Results: BlueBERT achieved macro- and microaccuracies of 95.41% and 95.16%, respectively, on the Medical Subject Headings Word Sense Disambiguation dataset. It improved macroaccuracy by 0.54% - 1.53% compared to two baselines, long short-term memory and deepBioWSD with random embedding. On the University of Minnesota dataset, BlueBERT recorded macro- and microaccuracies of 98.40% and 98.22%, respectively. Against the baselines of Word2Vec + support vector machine and BioWordVec + support vector machine, BlueBERT demonstrated a macroaccuracy improvement of 2.61% - 4.13%.

Conclusions: This research preliminarily validated the effectiveness of the OTA method for abbreviation disambiguation in medical texts, demonstrating the potential to enhance both clinical staff efficiency and research effectiveness.

KEYWORDS

word sense disambiguation; electronic medical records; abbreviation expansion; text mining; natural language processing

Introduction

The advent of electronic medical records (EMRs) has revolutionized data management in medical institutions by enabling the storage and collection of extensive patient data. EMRs integrate records and reports from various hospital departments, documenting diverse patient conditions and providing a comprehensive repository of information, including previous laboratory and examination reports, hospitalization and surgical procedure records, and medication histories [1-3]. EMRs contain two types of data: structured, such as physiological measurements, laboratory results, diagnostic and drug codes, and assessment scales, and unstructured, primarily consisting of textual medical records like surgical and imaging reports, pathology reports, and discharge summaries [4-10].

Recent studies have leveraged natural language processing (NLP) tools, including MetaMap, MedLEE, and Clinical Text Analysis and Knowledge Extraction System (cTAKES), to extract valuable patient information from EMRs' clinical text [11-14]. These applications range from identifying specific medical concepts to complex analyses, such as discerning relationships between medical conditions or predicting patient outcomes and disease progression [10,15-19]. However, the prevalent use of abbreviations in clinical documents poses significant challenges for NLP in clinical decision support systems, as abbreviations often have multiple meanings depending on their context, and unstandardized or local abbreviations further complicate text interpretation [20,21]. This ambiguity impedes the extraction of meaningful information, affecting clinical decision support system

performance and highlighting the need for effective methods for abbreviation disambiguation in clinical NLP applications.

Abbreviation disambiguation in NLP involves identifying the correct expansion of an abbreviation based on its context [22,23]. In this process, one-to-one (OTO) and one-to-all (OTA) approaches are two distinct strategies for resolving the meaning of abbreviations [24]. The OTO approach involves training a separate machine learning model for each specific abbreviation, learning its unique patterns and contextual cues to disambiguate its meaning. In contrast, the OTA approach uses a single machine learning model trained to disambiguate all abbreviations across various contexts.

The OTA approach in abbreviation disambiguation offers several advantages over the OTO approach. OTA is easier to scale, requiring the maintenance and updating of only a single model, whereas OTO necessitates multiple models for each abbreviation, making it less scalable. OTA is more efficient in terms of computational resources and ensures a uniform disambiguation approach, reducing inconsistencies. Additionally, OTA simplifies model management, streamlining changes and improvements. By learning general patterns and contextual cues applicable to various abbreviations, OTA enhances overall context understanding, making it suitable for applications with diverse abbreviation needs. This flexibility makes OTA particularly useful in the biomedical domain, where abbreviations can have varied meanings in different contexts.

This study aims to enhance the application of the OTA abbreviation disambiguation framework for clinical abbreviation expansion. We propose constructing an OTA disambiguation model by creating context-candidate pairs and refining word embeddings using Bidirectional Encoder Representations From Transformers (BERT) [25]. The model's effectiveness was assessed based on its predictive performance on real clinical data for the task of clinical abbreviation expansion.

Methods

Data

This study conducted experimental evaluations using 3 datasets: 2 publicly available datasets and 1 independently collected from a regional hospital in Taiwan. The first dataset, the Medical Subject Headings Word Sense Disambiguation (MSH WSD) dataset, was extracted from MEDLINE abstracts [26]. The MSH WSD dataset comprises 203 polysemous words and is divided into three sections: abbreviation set, term set, and term/abbreviation set. The abbreviation set, containing 106 ambiguous acronyms, was selected as one of our investigated datasets. The second dataset, originating from the University of Minnesota (UMN), comprises deidentified clinical text sourced from the university's hospitals [27]. The UMN dataset includes 440 frequently used abbreviations and acronyms, carefully selected from a pool of 352,267 dictated clinical notes. These two datasets are valuable resources for both NLP and medical informatics, particularly for disambiguation tasks within the health care domain [20,28,29].

Lastly, the Chia-Yi Christian Hospital (CYCH) dataset aggregates present illness data from patients at the Neurology Department of Ditmanson Medical Foundation Chia-Yi Christian Hospital. Abbreviation disambiguation results were validated by a neurologist. We narrowed the scope of abbreviations for evaluation and asked the doctor to mark the answers in advance. Specifically, we selected five frequently appearing abbreviations—ER, DM, CVA, PM, and PA—from both the UMN and CYCH datasets. We verified that the correct interpretations of abbreviations in the CYCH clinical documents matched the candidate sets for the UMN abbreviations. Due to manpower constraints, we limited our extraction to the first 1000 abbreviations for annotation by a physician. After removing one erroneous data entry and two initially overlooked abbreviations, we had a total of 998 sentences that included the five selected abbreviations. All 3 datasets were preprocessed and organized into the same format for subsequent model construction and evaluation. As shown in Table 1, the text "...He is status post a BK amputation on the right side and..." is partitioned into three parts: left, right, and target. Left denotes the text to the left of the target abbreviation, right represents the text to the right, and target indicates the target abbreviation. The remaining two fields include the correct expansion word for the target abbreviation (label) and the collection of all incorrect candidate expansion words (negs).

Table . Data schema after data preprocessing and an example sample text.

Field	Description	Example
Index	Document ID	1
Target	The target abbreviation	BK
Left	The text to the left of the target abbreviation	...He is status post a
Right	The text to the right of the target abbreviation	amputation on the right side and...
Label	The correct expansion word for the target abbreviation	below knee
Neg	The collection of all incorrect candidate expansion words. If there are multiple, separate them with commas.	BK(virus)

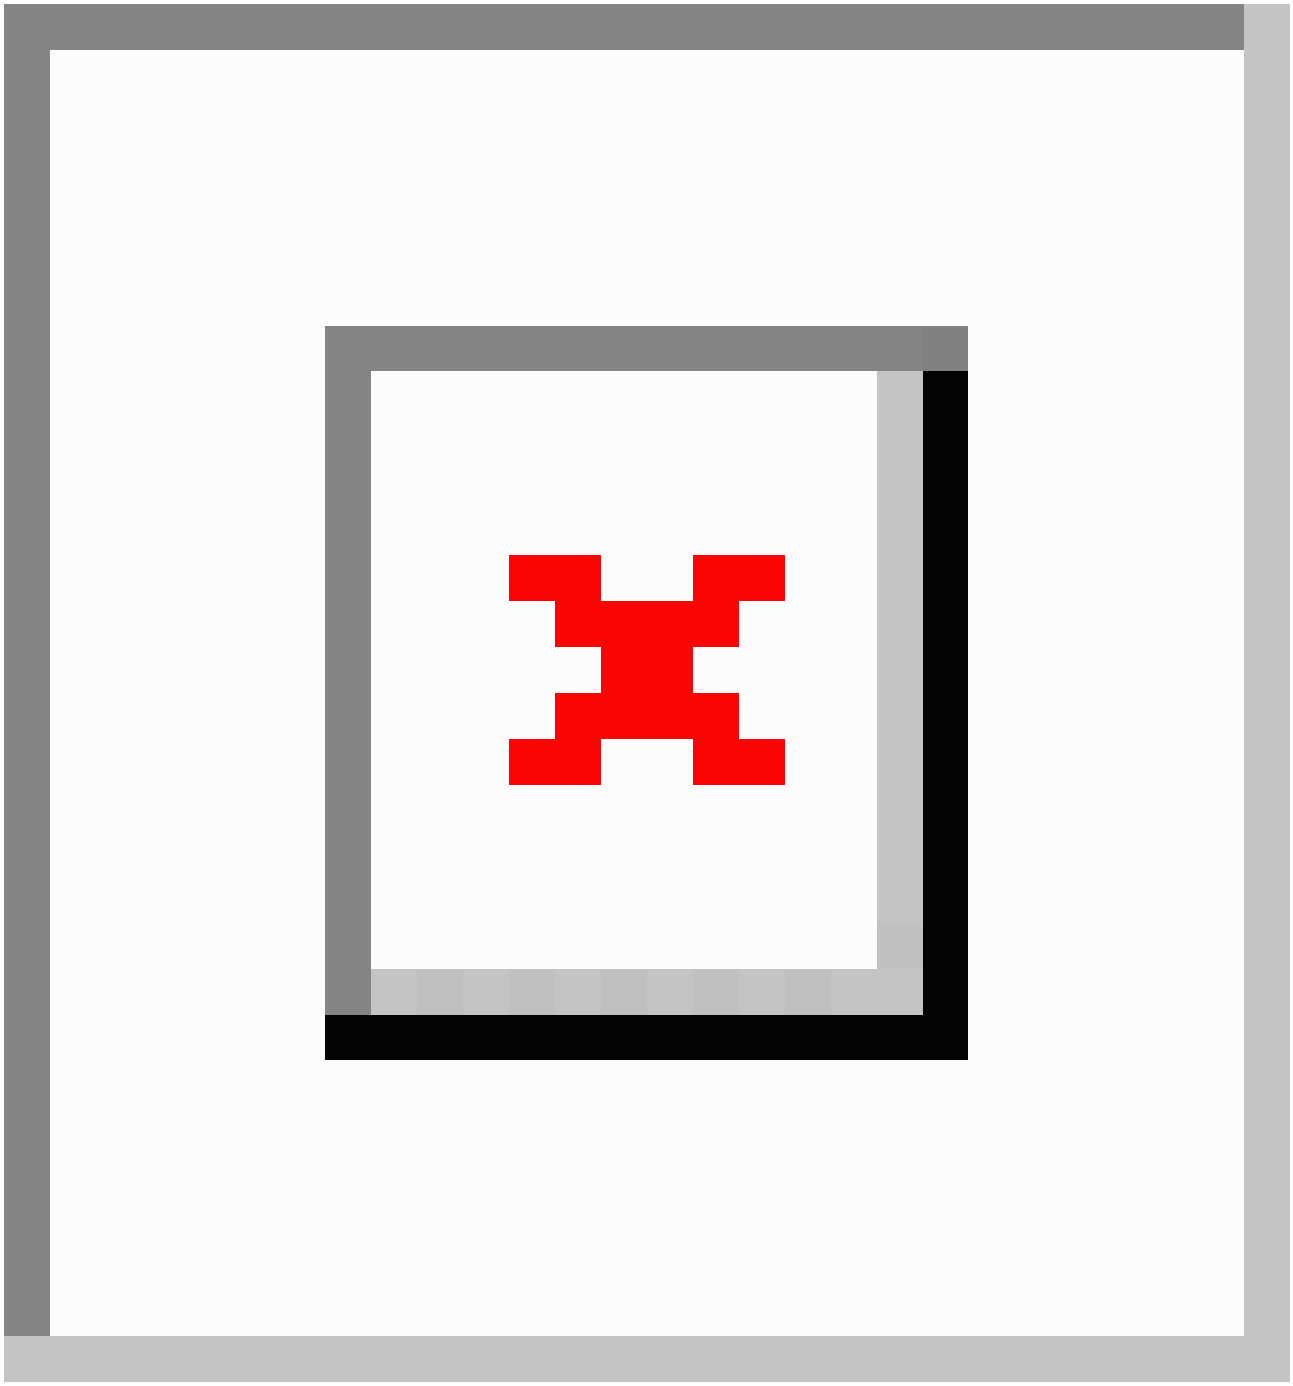
Ethical Considerations

The study protocol received formal approval from the Ditmanson Medical Foundation Chia-Yi Christian Hospital Institutional Review Board (2022074). Patient identifiers were replaced by a unique study identification number to ensure confidentiality. Informed consent was thus exempted.

The Proposed Framework

Figure 1 illustrates the proposed framework. We begin by retrieving text containing polysemous abbreviations from the 3 investigated datasets. The polysemous abbreviations are kept in their original form and marked accordingly. Subsequent steps involve common text preprocessing techniques, such as converting text to lowercase and removing certain special symbols. The preprocessed text is then adjusted to meet the input format required by BERT. Finally, the processed text is divided into training and testing sets. Three existing pretrained BERT-based models, including BERT-base-uncased [25], ClinicalBERT [30], and BlueBERT [31], are chosen and fine-tuned using these datasets, and prediction results are subsequently generated for evaluation. BERT-base-uncased is specifically used due to the common inconsistencies in capitalization within clinical texts, where lowercase letters are frequently used, even at the beginning of sentences or in abbreviations.

Figure 1. Research framework. BERT: Bidirectional Encoder Representations From Transformers; CYCH: Chia-Yi Christian Hospital; MSH WSD: Medical Subject Headings Word Sense Disambiguation; UMN: University of Minnesota.



Text Preprocessing

This study converts the text into the context-candidate pair format and adjusts the word embedding values for BERT input. Specifically, we apply GlossBERT [32] to train our model using the samples consisting of abbreviations and all of their candidate expansions. If an abbreviation has *n* candidate expansions, with only one correct answer, we produce *n* samples. This includes one sample marked as the correct expansion (indicated as 1) and *n* – 1 samples marked as incorrect expansions (indicated as 0).

Before training, we use BERT's tokenizer to convert text into WordPieces, breaking words such as "amputation" into ['amp', '##utation']. Special tokens are then added: [CLS] at the start, [SEP] to separate sentences or differentiate sections, and [PAD] to equalize sequence lengths for batch processing. For instance, when processing the sentence "He is status post a BK amputation..." with "BK" having expansions "BK(virus)" and "below knee," we generate two sequences: "[CLS] He is status post a BK amputation... [SEP] BK(virus) [SEP], 0" and "[CLS] He is status post a BK amputation... [SEP] below knee [SEP], 1."

Due to BERT's token limit of 512, sequences exceeding this are truncated. We manage sequence lengths by first converting text into WordPieces and adding necessary tokens. If the combined length of a sequence and its expansions exceeds BERT's limit, we employ a first in, first out (FIFO) strategy to ensure compliance with the token restriction.

BERT Tuning

Due to the limited dataset size, retraining a full BERT encoder was not feasible for this study. Instead, we fine-tuned existing pretrained models to assess our abbreviation disambiguation method. We selected two health care–related models, ClinicalBERT and BlueBERT, along with a generic BERT-base-uncased model as a baseline.

We adapted these models by adding a fully connected output layer. This layer consists of two linear layers and a rectified linear unit activation function, simplified as:

$$(1) y=f(\sum i=1 n w k x i+b k)$$

where wk represents the weights applied to inputs xi, and bk is the bias term.

The output layer's parameters are set as (50, 2), reflecting the size of the output from the previous layer and the number of classes (1 or 0). During prediction, the model calculates probabilities for each class. We focus primarily on the accuracy of the predictions for class 1, applying a softmax operation to enhance decision-making based on class 1's probability scores. This process optimizes our approach to evaluating the effectiveness of the trained models in context-sensitive disambiguation tasks.

Experimental Setup and Performance Measure

In our experimental evaluation, we aim to compare our proposed approach with several representative methods from prior studies on abbreviation disambiguation, focusing on model adaptability and performance across various datasets. The structure of our study is divided into two main parts.

Experiment 1 assesses the prediction performance of abbreviation expansion using both our proposed approach and baseline models (both OTO and OTA). We utilized two public datasets: MSH WSD and UMN. For MSH WSD, the OTO baselines included *k*-nearest neighbors [33], naive Bayes [26], and long short-term memory (LSTM) [34] models. For the UMN dataset, we referred to Wu et al [35] who used a combination of Word2Vec + support vector machine (SVM) as the OTO baseline. We further adapted this approach by substituting the original Word2Vec model with BioWordVec [36] (BioWordVec + SVM), which offers biomedical word embeddings via fastText, to better suit our study's focus on clinical data. Each clinical note was represented as a 200-dimensional vector. For the OTA baseline models, we implemented non–sense-based methods using BERT/XLNet, as described by Kim et al [37], which include $\text{deepBioWSD}_{\text{random embeddings}}$ and $\text{deepBioWSD}_{\text{pretrained sense embeddings}}$. Additionally, we employed sense-based methods using bidirectional LSTM, outlined by Pesaranghader et al [38], specifically masked language modeling and permutation language modeling.

Experiment 2 evaluates the prediction performance of abbreviation disambiguation within the CYCH dataset, aiming to address abbreviation ambiguity in clinical contexts. This involved training models using the UMN dataset and testing them on the CYCH dataset. The experiment was designed to test how well the fine-tuning of pretrained models could adapt to a new hospital setting, using a combination of internal and external datasets to assess accuracy in a real-world clinical environment.

We conducted experiment 2 under two distinct scenarios to assess the adaptability and effectiveness of our model in handling abbreviation disambiguation. In the first scenario, we excluded CYCH text, utilizing only the UMN dataset for training. This approach tested the model's ability to generalize from an external dataset to a new environment, applying it subsequently to 998 entries from the CYCH dataset. In the second scenario, we incorporated a small subset of CYCH text into the training process. This was designed to explore incremental learning, where the model adapts to new data while retaining previously learned information, thereby enhancing its predictive performance with minimal data and brief training periods.

Moreover, to maintain consistency and validity in our training process, it was crucial to ensure that all context-candidate pairs appeared in the training set. Consequently, the dataset was carefully screened before splitting, opting for a simple 9:1 ratio between the training and test sets instead of using cross-validation. To evaluate the model's performance, we employed metrics such as accuracy, microaccuracy, and macroaccuracy. These metrics were derived from the confusion matrix for each abbreviation, providing detailed insights into the model's efficacy across different contexts.

Results

Experiment 1

The results for experiment 1, using the MSH WSD dataset, are summarized in Table 2. For the OTO baselines, *k*-nearest neighbors achieved a macroaccuracy of 94.34%, with microaccuracy data unavailable. The naive Bayes method recorded a macroaccuracy of 93.86%, but microaccuracy was not reported. The LSTM method displayed both macro- and microaccuracy scores, which were 94.87% and 94.78%, respectively. For the OTA baselines, the sense-based deepBioWSD$_{\text{random embeddings}}$ [38] achieved macro- and microaccuracy scores of 93.88% and 93.71%, respectively. The deepBioWSD$_{\text{pretrained sense embeddings}}$ [38] improved prediction performance, with macro- and microaccuracy scores of 96.82% and 96.24%, respectively. Meanwhile, the non–sense-based methods, masked language modeling and permutation language modeling [37], recorded macroaccuracies of 95.89% and 96.83%, respectively, with microaccuracy not reported.

The BERT-base-uncased achieved macro- and microaccuracy scores of 93.64% and 93.38%, respectively. ClinicalBERT recorded a macroaccuracy of 94.77% and a microaccuracy of 94.59%. BlueBERT displayed a competitive performance with macro- and microaccuracies of 95.41% and 95.16%, respectively, on par with other evaluated methods. BlueBERT's macroaccuracy was only slightly lower than the highest performing models, deepBioWSD$_{\text{pretrained sense embeddings}}$ (96.82%) and permutation language modeling (96.83%), but higher than deepBioWSD$_{\text{random embeddings}}$ (93.88%). This demonstrates BlueBERT's robustness and effectiveness in sequence classification within this study.

The abbreviation disambiguation results for the UMN dataset, presented in Table 3, highlight the performance of various models. BlueBERT excelled, achieving macro- and microaccuracies of 98.4% and 98.22%, respectively, indicating its strong potential for disambiguation tasks. BERT-base-uncased and ClinicalBERT also showed strong performance, though slightly less than BlueBERT. In contrast, OTO-based models like Word2Vec + SVM and BioWordVec + SVM had lower accuracy scores, underscoring the advanced capabilities of the BERT models.

Table . Abbreviation disambiguation results (Medical Subject Headings Word Sense Disambiguation).

Method		Macroaccuracy (%)	Microaccuracy (%)
One-to-one			
	k-nearest neighbors [33]	94.34	—[a]
	Naive Bayes [26]	93.86	—
	Long short-term memory [34]	94.87	94.78
One-to-all			
	deepBioWSD$_{\text{random embeddings}}$ [38]	93.88	93.71
	deepBioWSD$_{\text{pretrained sense embeddings}}$ [38]	96.82	96.24
	Masked language modeling [37]	95.89	—
	Permutation language modeling [37]	96.83	—
	BERT-base-uncased	93.64	93.38
	ClinicalBERT	94.77	94.59
	BlueBERT	95.41	95.16

[a]Not applicable.

Table . Abbreviation disambiguation results (University of Minnesota).

Method (work)		Macroaccuracy (%)	Microaccuracy (%)
One-to-one			
	Word2Vec + SVM[a] [35]	95.79	—[b]
	BioWordVec + SVM	94.27	—
One-to-all			
	Masked language modeling [37]	98.39	—
	Permutation language modeling [37]	98.28	—
	BERT-base-uncased	97.59	97.27
	ClinicalBERT	98.27	98.01
	BlueBERT	98.40	98.22

[a]SVM: support vector machine.

[b]Not applicable.

Overall, the proposed OTA method, especially when implemented using the pretrained BlueBERT model, outperformed the OTO-based approaches. The OTA method's reliance on a single model, as opposed to the multiple models required by OTO methods, improves maintainability and scalability.

Experiment 2

Table 4 displays the abbreviation disambiguation results for the CYCH dataset using BlueBERT. The table compares accuracy percentages for each abbreviation when trained exclusively on external data versus including incremental amounts of CYCH data (5 and 10 samples, respectively). For example, the model recorded a 62.07% accuracy for the abbreviation DM when trained without CYCH data. With the inclusion of CYCH data, the accuracy slightly improved to 70.27% with 5 samples but then slightly decreased to 100% with 10 samples. This trend of initial improvement followed by a marginal decline was observed for other abbreviations as well. Notably, the abbreviation PA showed a substantial increase in performance; it had 0% accuracy when trained without CYCH data but reached 100% accuracy when trained with either 5 or 10 CYCH samples.

Table . Abbreviation disambiguation results of the Chia-Yi Christian Hospital (CYCH) dataset.

Abbreviation	Training without CYCH data, accuracy (%)	Training with CYCH data	
		Accuracy, includes 5 documents (%)	Accuracy, includes 10 documents (%)
ER	97.91	98.03	97.75
DM	62.07	70.27	100
CVA	96.20	98.65	100
PM	77.27	100	100
PA	0.00	100	100

Discussion

Automatic abbreviation disambiguation is crucial in clinical settings as it enhances the clarity and readability of medical records. By accurately interpreting abbreviations, it ensures that health care professionals have a precise understanding of patient information, facilitating accurate diagnoses and effective treatment plans. This automation also speeds up data processing, supports decision-making, and reduces errors, thereby improving overall health care delivery and patient safety.

Traditional OTO methods for abbreviation expansion involve constructing independent models for each abbreviation. Although this method offers high accuracy, it presents challenges in terms of maintenance and generalizability, complicating clinical applications due to the high number of models and associated maintenance costs. In contrast, this study proposes an approach that reduces the number of required models and offers better performance in clinical abbreviation restoration, thereby lowering both the operational and maintenance costs.

Compared to OTO, the OTA approach provides greater scalability, efficiency, and consistency, with a unified model that is easier to maintain and update. However, OTA approaches can be costly in terms of model retraining. Kim et al [37] highlighted that retraining the encoder necessitated high-end GPUs and substantial memory, requiring up to 14 days. Our study adopted a tuning approach using existing pretrained models, substantially cutting down training time to

approximately an hour and a half by utilizing free online resources like the K80 GPU through Kaggle Notebook. This method effectively reduces both hardware and time costs, especially beneficial in clinical settings where frequent model updates may be necessary.

This study further demonstrates the practicality of this method in various hospital scenarios, particularly addressing cross-hospital and interdepartmental issues. Our incremental learning approach has been shown to significantly improve prediction results, thereby saving considerable retraining costs.

This study has the following limitations. First, although it preliminarily validates the exceptional effectiveness of the OTA method for abbreviation disambiguation in medical texts, the evaluation is limited by the size of the datasets used. More extensive and comprehensive clinical data are required before application to further validate this method. Second, our study is constrained by the maximum sequence length restriction of the BERT model. Longer clinical notes exceeding the 512-token limit must be truncated, risking the loss of information. Analysis shows that about 16.85% of the MSH WSD dataset and only 0.03% of the UMN dataset exceed this limit. The experimental results indicate superior accuracy for the UMN dataset; however, the performance for the MSH WSD dataset is lower, likely due to significant truncation of longer texts.

Additionally, in generating context-candidate pairs, we retain all candidates and use a FIFO approach for trimming the context. If an abbreviation appears at both the beginning and end of a context and exceeds the token limit, the FIFO method may remove the initial occurrence. Conversely, a last in, first out method could remove an abbreviation appearing at the end. If the same abbreviation carries different meanings in different parts of the text, identical context-candidate pairs may be created post trimming, potentially distorting model training and leading to incorrect predictions.

This study presents an innovative approach to the disambiguation and expansion of abbreviations in clinical medical texts by utilizing context-candidate pairs and the BERT model. This method enhances the readability of medical texts, improving the efficiency of clinical staff who review EMRs and saving time for cross-disciplinary researchers analyzing clinical data, thereby increasing the effectiveness of their studies. Given that clinical medical texts are replete with abbreviations, accurate disambiguation is essential for improving text clarity and usability. Automating this process greatly assists both medical professionals and researchers. The successful application of this model on the investigated datasets underscores its effectiveness and establishes it as a valuable reference for future research in clinical abbreviation expansion.

Abstract

Background: Diagnosis codes and prescription data are used in algorithms to identify postherpetic neuralgia (PHN), a debilitating complication of herpes zoster (HZ). Because of the questionable accuracy of codes and prescription data, manual chart review is sometimes used to identify PHN in electronic health records (EHRs), which can be costly and time-consuming.

Objective: This study aims to develop and validate a natural language processing (NLP) algorithm for automatically identifying PHN from unstructured EHR data and to compare its performance with that of code-based methods.

Methods: This retrospective study used EHR data from Kaiser Permanente Southern California, a large integrated health care system that serves over 4.8 million members. The source population included members aged ≥50 years who received an incident HZ diagnosis and accompanying antiviral prescription between 2018 and 2020 and had ≥1 encounter within 90 - 180 days of the incident HZ diagnosis. The study team manually reviewed the EHR and identified PHN cases. For NLP development and validation, 500 and 800 random samples from the source population were selected, respectively. The sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), F-score, and Matthews correlation coefficient (MCC) of NLP and the code-based methods were evaluated using chart-reviewed results as the reference standard.

Results: The NLP algorithm identified PHN cases with a 90.9% sensitivity, 98.5% specificity, 82% PPV, and 99.3% NPV. The composite scores of the NLP algorithm were 0.89 (F-score) and 0.85 (MCC). The prevalences of PHN in the validation data were 6.9% (reference standard), 7.6% (NLP), and 5.4% - 13.1% (code-based). The code-based methods achieved a 52.7% - 61.8% sensitivity, 89.8% - 98.4% specificity, 27.6% - 72.1% PPV, and 96.3% - 97.1% NPV. The F-scores and MCCs ranged between 0.45 and 0.59 and between 0.32 and 0.61, respectively.

Conclusions: The automated NLP-based approach identified PHN cases from the EHR with good accuracy. This method could be useful in population-based PHN research.

KEYWORDS

postherpetic neuralgia; herpes zoster; natural language processing; electronic health record; real-world data; artificial intelligence; development; validation; diagnosis; EHR; algorithm; EHR data; sensitivity; specificity; validation data; neuralgia; recombinant zoster vaccine

Introduction

Herpes zoster (HZ) or shingles is a painful dermatomal vesicular disease that results from the reactivation of the latent varicella-zoster virus in the nerve ganglia [1]. Nearly all adults have the varicella-zoster virus dormant in their nervous system [2], and the estimated lifetime risk of HZ was approximately 30% prior to the availability of the zoster vaccine [3]. HZ usually begins with a prodromal stage of discomfort, followed by a painful, itchy rash on one unilateral dermatome that lasts 2 to 4 weeks [4]. Patients with HZ may develop postherpetic neuralgia (PHN)—dermatomal pain persisting at least 90 days after the appearance of the acute HZ rash [3,5]. PHN is the most common complication of HZ and greatly lowers patients' quality of life [3].

Population-based studies using real-world data are cost-effective ways to address many questions about PHN [3]. However, accurately identifying PHN is difficult. Clinical trials rely on

predetermined follow-up visits, which are difficult to replicate in real-world settings [6,7]. Due to time and resource constraints, prospective studies have mainly been limited to hundreds of patients with HZ and smaller numbers of PHN cases [3]. Retrospective studies of PHN have relied heavily on diagnosis codes [8-13], which lack accuracy [3,14], or manual chart review [14-16], which is costly and time-consuming. Moreover, despite the widespread use of code-based algorithms, only a few publications included PHN algorithm validation results [8,10].

Natural language processing (NLP), a subfield of artificial intelligence, has been used to identify and extract information from unstructured clinical data. We previously developed NLP methods to identify HZ ophthalmicus and HZ ophthalmicus with eye involvement, which are also common HZ complications [17,18]. In this study, we developed and validated an NLP algorithm to identify PHN. Using manual chart-reviewed results as a reference standard, we compared the performance of the NLP algorithm with that of 5 previously published code-based algorithms.

Methods

Setting

This study was conducted at Kaiser Permanente Southern California (KPSC), an integrated health care system with 16 hospitals and 197 medical offices that serves over 4.8 million members. The prepaid health plan incentivizes members to use services at KPSC facilities. The electronic health record (EHR) system at KPSC stores all aspects of member care, including sociodemographic characteristics, medical encounters, diagnoses, laboratory tests, pharmacy use, immunization records, membership history, and billing and claims.

PHN Case Definition

PHN was defined as pain or discomfort consistent with the HZ episode ≥90 days after the initial HZ diagnosis; the symptoms were at the location of the initial HZ rash and were not due to other obvious causes [19-21].

Data Sets

This study used EHR data of patients aged ≥50 years who each had an incident HZ diagnosis and associated antiviral prescription between 2018 and 2020 at KPSC. All patients had to have at least 1 year of membership prior to the index (incident HZ diagnosis) date so that comorbidities and health care use could be ascertained. Among patients with ≥1 encounter during the 90 - 180 days after the incident HZ diagnosis, trained research associates reviewed their EHRs based on the PHN abstraction instructions (Multimedia Appendix 1). An infectious disease physician (BKA) reviewed all possible or unclear cases. From these reviewed cases, we randomly selected 500 cases for NLP development and 800 cases for NLP validation. Because the NLP work was done concurrently with the manual review, the development data set was collected at an earlier stage, when the reviewed cohort had a greater proportion of Asian and recombinant zoster vaccine–vaccinated patients.

Reference Standard

Among the 800 cases in the validation data set, BKA reviewed 37 HZ cases that research associates had identified as unclear PHN cases. Because reviewers sometimes missed positive mentions of PHN, BKA rereviewed cases in the validation set where NLP results differed from reviewer results. Nine cases were corrected from negative to positive PHN. These manually reviewed results served as the reference standard for assessing the performance of PHN identification algorithms.

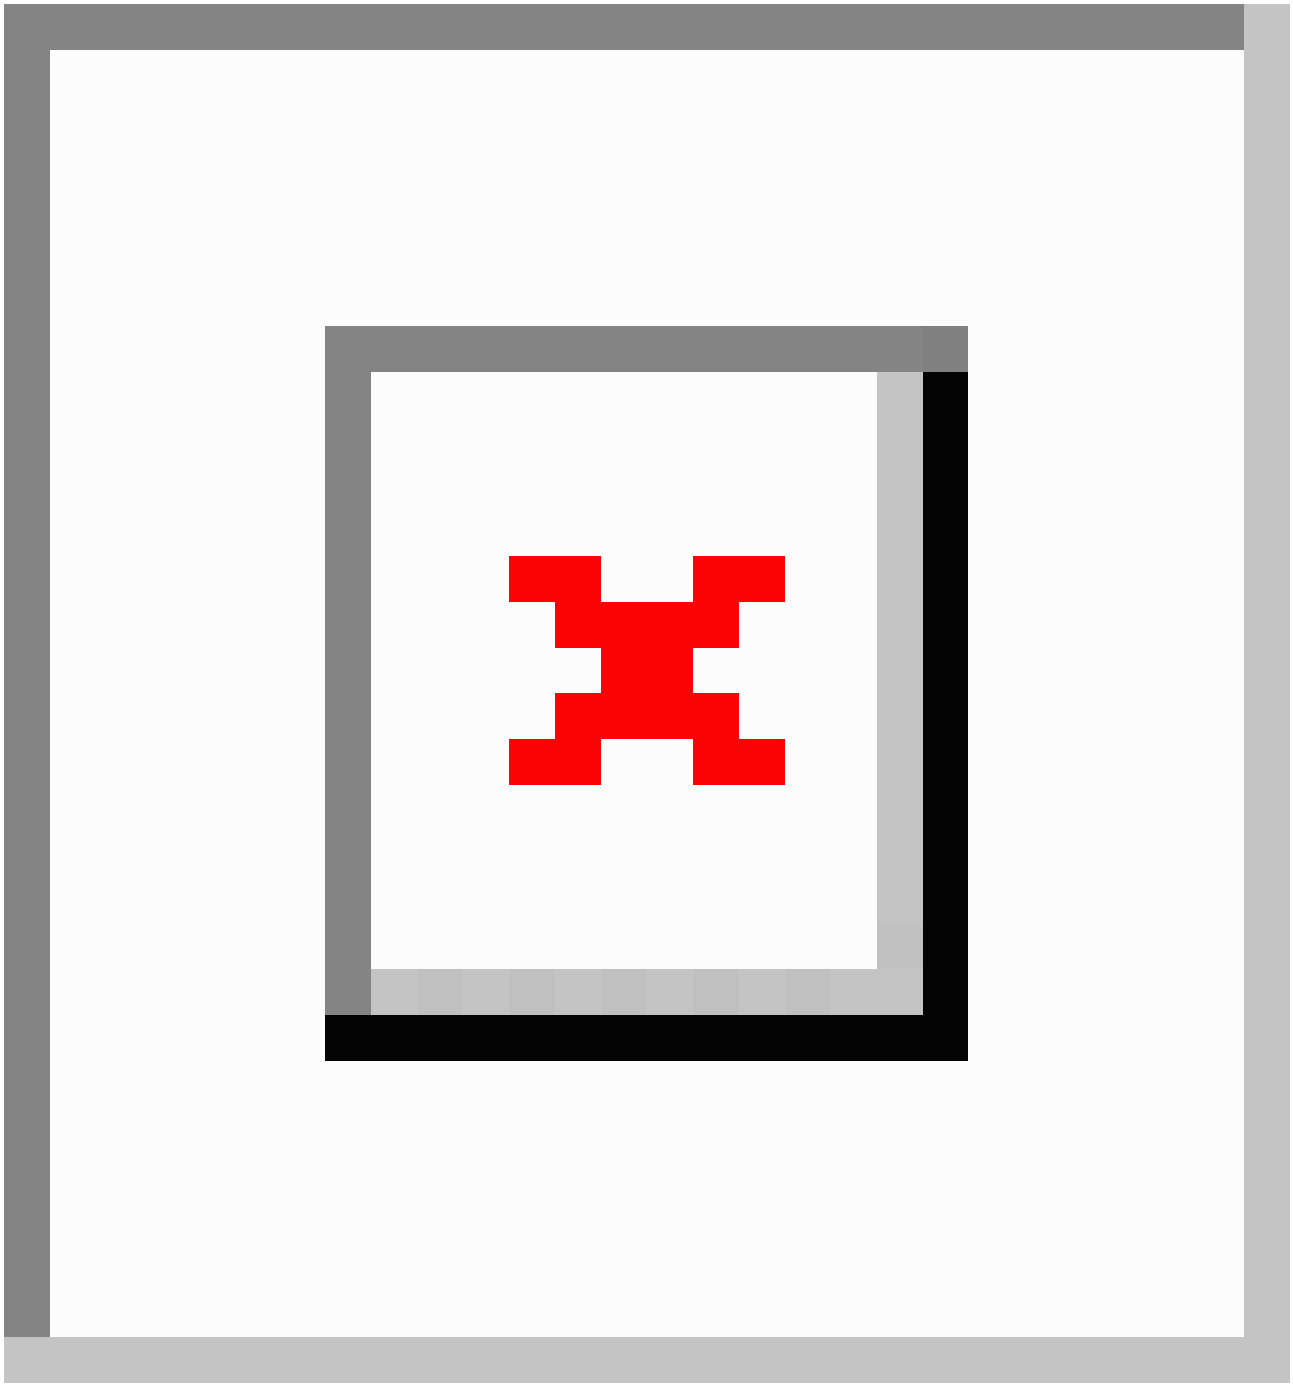
NLP Algorithm Development

We developed the NLP algorithm based on our previous work [17,18,22-26]. Multimedia Appendix 2 describes the steps for preprocessing text and generating nomenclature. We created the rule-based NLP algorithm using the Linguamatics I2E software (Linguamatics, an IQVIA company). Each note was searched at different levels: section (eg, “Physical Exam,” “Assessment/Plan”), cross-sentence, intrasentence, and phrase. A distance-based relationship algorithm was applied to identify related terms based on the number of words or sentences between them. The relationship search identified the words or phrases (eg, negated, uncertain, and hypothetical statements) that modified the concepts of interest.

Figure 1 depicts an overview of the NLP algorithm. We separated the extracted clinical texts into 3 time periods: index (acute HZ) period (−7 to 21 d from incident HZ diagnosis date), transitional (subacute HZ) period (22 to 89 d), and risk (defined PHN) period (90 to 180 d). We developed search queries to identify the HZ anatomic locations in the index episode and PHN-related evidence in the transitional and risk periods. Supporting evidence of PHN included explicit mention of ongoing PHN, symptom location and causality, and PHN listed in the assessment and plan section. Counterevidence of PHN included differential diagnoses, recurrent HZ, and resolved PHN. We excluded sections and statements that may have been copied forward as historical information.

The PHN decision algorithm was implemented in Python language, which incorporated the evidence from the NLP search queries and classified each case based on decision rules. To exclude the copy-pasted results, the NLP program ran search queries on both the transitional and risk periods and compared the results to locate identical sequences of text. The algorithm considered the time sequences of identified evidence. The symptom location during the risk period was compared with the index HZ location. Because adjacent dermatomes might be difficult to distinguish clinically, symptom location during the index and risk periods had to occur in the same or surrounding dermatomes (eg, face and neck). Based on the development data set, we tested and updated the algorithm.

Figure 1. Diagram of NLP algorithm. HZ: herpes zoster; NLP: natural language processing; PHN: postherpetic neuralgia.



Implementation of Published PHN Identification Algorithms

We selected and implemented 5 code-based PHN identification algorithms based on the variety of their algorithms, the journal category and impact factor, the publication year, the total citations, and the size of the study (Table 1). The first code-based method (C1: Yanni et al [27]) exclusively used PHN-related diagnosis codes (Multimedia Appendix 3). The remaining 4 algorithms (C2: Klompas et al [8]; C3: Klein et al [10]; C4: Forbes et al [9]; C5: Munoz-Quiles et al [11]) used additional structured data, such as diagnosis codes for HZ, neuralgia, and chronic pain; prescriptions for analgesics, antidepressants, and anticonvulsants; and clinical visit data.

Table . List of sources for selected code-based methods.

Method	Herpes zoster cases, n	Journal category	Journal (IF[a])	Year	TC[b]
C1 [27]	21,146	General medicine	BMJ Open (2.9)	2018	67
C2 [8]	2089	General medicine	Mayo Clinic Proceeding (8.9)	2011	125
C3 [10]	62,205	Immunology	Vaccine (5.5)	2019	32
C4 [9]	119,413	Neurology	Neurology (10.1)	2016	155
C5 [11]	87,086	Infectious diseases	Journal of Infection (28.2)	2018	38

[a]IF: impact factor based on Journal Citation Report released in 2023.

[b]TC: total citations based on Google Scholar as of July 1, 2024.

Validation and Analysis

The results generated from the various algorithms were evaluated against the chart-reviewed reference standard validation data set. We counted the numbers of true-positive (TP), false-positive (FP), true-negative (TN), and false-negative (FN) cases to calculate the performance metrics: sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), F-score [28], and Matthews correlation coefficient (MCC) [29].

The F-score is a combination metric in machine learning and NLP research. It is defined as a weighted harmonic mean of sensitivity and PPV, where the parameter β represents the relative importance of sensitivity versus PPV.

$$F-score=(\beta 2+1)*PPV*sensitivity\beta 2*PPV+sensitivity$$

Since a minority of patients with HZ will develop PHN and FNs and sensitivity are more important than PPV, we chose β=2 to favor sensitivity over PPV. The F-score's value ranges from 0 to 1, with higher values suggesting better prediction. However, because the F-score does not include TN in its formula, MCC has been proposed as a better overall measurement than the F-score as well as the area under the receiver operating characteristic curve in binary classification [29,30]. The MCC formula considers all 4 confusion matrix categories, with values between −1 to 1, where ±1 denotes perfect agreement or disagreement between actuals and predictions, and 0 indicates randomness.

$$MCC=TP*TN-FP*FN(TP+FP)*(TP+FN)*(TN+FP)*(TN+FN)$$

The prevalence proportion of PHN was calculated as the number of identified PHN cases per 100 cases of HZ.

Ethical Considerations

The KPSC institutional review board approved this study (institutional review board number: 12270). A waiver of informed consent was granted for this study because this was a data-only minimal-risk study.

Results

Study Population

The characteristics of the study population are presented in Table 2. The mean (SD) ages of the development and validation data sets were 69.5 (9.1) and 70.0 (9.8) years, respectively, with 329 (65.8%) and 542 (67.8%) being female. The development data set had a higher proportion of Asian (177/500, 35.4% vs 110/796, 13.8%) and recombinant zoster vaccine–vaccinated patients (61/500, 12.2% vs 28/800, 3.5%). There were no significant differences between the development and validation data sets in terms of clinical visits and comorbidities prior to the index date. In the development and validation data sets, approximately one-third of the patients had diabetes (159/500, 31.8% and 262/796, 32.8%, respectively), while less than one-quarter had chronic pulmonary disease (88/500, 17.6% and 163/800, 20.4%) and depression (103/500, 20.6% and 189/800, 23.6%). The development data had a higher proportion of patients with cancer as compared with the validation data (52/500, 10.4% vs 54/800, 6.8%).

Table . Characteristics of patients in the development and validation data sets.

Characteristics		Patients		*P* value[a]
		Development (n=500)	Validation (n=800)	
Age (year), mean (SD)		69.5 (9.1)	70.0 (9.8)	.47

		Development (n=500)	Validation (n=800)	
	1-dose vaccinated	32 (6.4)	9 (1.1)	
	Fully (2-dose) vaccinated	29 (5.8)	19 (2.4)	

[a]χ^2 test was used for categorical variables, and Wilcoxon test was used for continuous variables.

[b]HZ: herpes zoster.

Validation Data Set

In the validation data set, the numbers of clinical notes in the index, transitional, and risk periods were 12,158, 14,446, and 18,895, respectively. The percentages of HZ- or PHN-relevant notes were 26.2%, 8.2%, and 3.2%, respectively for the index, transitional, and risk periods. Most of the HZ index visits occurred in primary care, urgent care, emergency departments, and hospital settings (Multimedia Appendix 4). After the index period, HZ-related mentions were much less frequently documented in urgent care visit notes, but more frequently documented in specialist visit notes (41 specialties).

Application of NLP on Validation Data Set

Out of the 800 patients in the validation data set, the NLP algorithm identified 796 patients with HZ who had at least 1 note with HZ- or PHN-related terms in the index period. Among the 4 remaining patients, 2 patients had their index HZ diagnosed outside KPSC and had no follow-up visits in the index period. For the remaining 2 patients, HZ-related symptoms were documented, but no mention of HZ or PHN was made in the clinical notes. Among these 796 patients, the NLP algorithm identified the HZ anatomic location for 751 (94.3%) patients, and among them, 611 (81.3%) had laterality information (Multimedia Appendix 5). In the transitional and risk periods, the NLP algorithm identified positive mentions of any pain or discomfort in 370 (46.3%) and 425 (53.1%) patients, respectively.

Validation Results

In the validation data set, the NLP algorithm achieved a 90.9% sensitivity, 98.5% specificity, 82% PPV, and 99.3% NPV (Table 3). The composite scores of the NLP algorithm were 0.89 (F-score) and 0.85 (MCC). Of the 800 patients in the validation data set, 55 (6.9%) were chart-confirmed as PHN. The prevalence proportion of PHN identified by the NLP algorithm was 7.6%.

Table . Performance characteristics of natural language processing and code-based methods for identifying postherpetic neuralgia as compared with chart-confirmed reference standard.

Method	PHN[a] (%)	TP[b]	TN[c]	FN[d]	FP[e]	Sensitivity (%)	Specificity (%)	PPV[f] (%)	NPV[g] (%)	F-score	MCC[h]
NLP[i]	7.6	50	734	5	11	90.9	98.5	82.0	99.3	0.89	0.85
C1	5.4	31	733	24	12	56.4	98.4	72.1	96.8	0.59	0.61
C2	10.9	34	692	21	53	61.8	92.9	39.1	97.1	0.55	0.44
C3	5.5	31	732	24	13	56.4	98.3	70.5	96.8	0.59	0.61
C4	13.1	29	669	26	76	52.7	89.8	27.6	96.3	0.45	0.32
C5	9.3	31	702	24	43	56.4	94.2	41.9	96.7	0.53	0.44

[a]PHN: postherpetic neuralgia.

[b]TP: true-positive.

[c]TN: true-negative.

[d]FN: false-negative.

[e]FP: false-positive.

[f]PPV: positive predictive value.

[g]NPV: negative predictive value.

[h]MCC: Matthews correlation coefficient.

[i]NLP: natural language processing.

Error Analysis of NLP Validation Results

Error analysis of the FN and FP cases is presented in Table 4. Some of the NLP-related errors were caused by the selection of data sources. For 2 FN cases, NLP incorrectly classified them as PHN negative when statements were found indicating HZ-associated pain had resolved even though additional evidence showed the patients still had other PHN-related symptoms. The FP cases were caused by copied-and-pasted text, incorrect causality attribution of symptoms, misclassified recurrent HZ cases as PHN, and unclear clinical documentation.

Table . Error analysis of natural language processing false-negatives and false-positives.

Type of NLP[a] error		Description	Number of cases
False-negative			5
	EHR[b] data source	• Case 1: We did not include one free text table (formatted messages) from the Epic EHR. • Case 2: PHN[c] was mentioned in a clinical note from the hematology department, which was excluded from NLP processing.	2
	Unclear documentation	• HZ[d] or PHN was not stated in the clinical note, which was required by NLP to reduce false-positive hits.	1
	Symptom	• While the patient stated that HZ-associated pain had resolved, documents also indicated that the patient still had other PHN-related symptoms (prickling sensation and itchy).	2
False-positive			11
	EHR data source	• We included Epic's SmartData elements, which lacked specificity for PHN identification.	2
	Unclear documentation	• In 2 cases, the text was copied from the clinical notes in the index period. The NLP copy-and-paste detection algorithm was only applied to the clinical notes in the transitional period. • In another 2 cases, PHN and PHN-related medications were listed in the assessment and plan sections. However, it was unclear whether the patient had ongoing symptoms.	4
	Acute HZ	• NLP misclassified 2 acute HZ cases that occurred in the risk period as PHN.	2
	Causality	• Case 1: Pain thought to be due to chalazion based on information in follow-up visits. • Case 2: PHN was listed in the assessment section and tramadol and gabapentin were listed in the plan section. However, the medications were likely for lumbosacral radiculopathy.	2
	Symptom	• The patient reported generalized symptoms (nausea) since HZ, but there was no mention of concomitant sensory changes such as pain, thus the case did not meet our PHN definition.	1

[a]NLP: natural language processing.

[b]EHR: electronic health record.

[c]PHN: postherpetic neuralgia.

[d]HZ: herpes zoster.

Code-Based Methods

The prevalence proportions of PHN identified by code-based methods ranged from 5.4% to 13.1%. The code-based methods achieved a 52.7% - 61.8% sensitivity, 89.8% - 98.4% specificity, 27.6% - 72.1% PPV, and 96.3% - 97.1% NPV. The F-scores and MCCs ranged between 0.45 and 0.59 and between 0.32 and 0.61, respectively. The more sophisticated algorithms were no better than the PHN diagnosis code–only method as measured by the F-score or MCC. Although each component of the code-based methods identified PHN cases, most of them did not contribute to identifying additional true PHN cases beyond those identified by PHN diagnosis codes, and those that did have much lower PPVs (C4.3: 10.3%, C4.2: 26.1% and C2.2: 37.7%) than the PHN diagnosis code–only method (C1, PPV 72.1%) (Table 5). We re-reviewed all FP cases from code-based methods C1 and C3 and randomly sampled the remaining FP cases from approaches C2, C4, and C5. Among the 20 reviewed FP cases, we found that none were true PHN cases.

Table . Postherpetic neuralgia cases identified by code-based methods.

Method			PHN[a] diagnosis code used	PHN, n (%)	TP[b] (PPV[c]), n (%)	Supplementary TP[d]
C1[e]			✓	43 (5.4)[f]	31 (72.1)[f]	—[g]

[a]PHN: postherpetic neuralgia.

[b]TP: true-positive.

[c]PPV: positive predictive value.

[d]Supplementary contributions to the number of correctly identified positive cases, apart from method C1.

[e]Method C1 only used PHN diagnosis codes.

[f]Overall performance.

[g]Not applicable.

Discussion

Principal Findings

We developed and validated NLP algorithms to identify PHN using various clinical data sources from EHRs. Compared with the chart-reviewed reference standard, the NLP algorithms showed high accuracy. This study demonstrates the feasibility of population-based PHN studies using EHR data with an automated method.

Using manual review to identify PHN cases is often infeasible for population-based research because a large volume of clinical notes would need to be reviewed. In contrast, the size of the study population and length of follow-up have little impact on running the NLP algorithm. Moreover, our NLP algorithm can readily capture PHN at varied time intervals, providing an efficient method to assess the long-term impact of PHN and compare results with studies using different PHN risk windows. Furthermore, studies can use NLP alone or with manual review confirmation. For example, a manual review of the NLP-positive cases (n=61) could increase the specificity and PPV to 100% and improve the F-score from 0.89 to 0.93 and MCC from 0.85 to 0.95; this is more efficient than a manual review of all 800 HZ cases.

Implementing NLP on EHR data presents challenges. In this study, data sources accounted for one-quarter of NLP errors (2 FNs and 2 FPs). First, clinical data were stored in a variety of locations within our institution's complex EHR system, which contains over 900,000 database tables. It is often difficult to locate the database table storing the data displayed in the EHR user interface. One FN case resulted from not including a previously unknown table. Second, selecting data sources for NLP processing is often a tradeoff. One FN and 2 FP cases resulted from including or excluding certain data sources. EHRs have also made it easy to create lengthy and bloated notes [31,32]. According to recent research, over half of clinical note content is duplicated or copied from earlier notes [32-34]. Clinicians may copy from prior visit notes to improve recall and clinical reasoning [35]. However, these replicated contents may lack temporal or contextual information, making them difficult to identify manually and challenging for NLP.

Because PHN-related symptoms such as pain and discomfort are common in a variety of medical conditions with numerous plausible causes, identifying PHN necessitates integrating the NLP-identified PHN symptoms with their associated anatomic location, temporality, and causality. These elements, however, are not always explicitly stated in clinical documents. About half of the NLP FP cases were from incorrectly attributing the complaint or treatment to PHN. These FP cases were partially explained by the NLP algorithm's preference for sensitivity over specificity.

Another popular method of PHN identification is using coded data from administrative claims or EHR, which could include a large sample size at a low cost. However, many of the code-based PHN identification algorithms have not been validated [3]. We implemented and validated 5 code-based algorithms, including 1 that solely uses PHN diagnosis codes (C1) and 2 that had previously been validated (C2 and C3). To maximize their sensitivity, algorithms C2-C5 used the "OR" statement to combine various criteria. The downside of using the "OR" logic is the loss of PPV. Algorithms C2-C5 all had worse PPV than the diagnosis codes–only algorithm (C1). However, in our study, the sensitivity of these algorithms ranged from 53% to 62%, with only C2 outperforming C1 (62% vs 56%). Algorithms C2-C5 had lower PPVs (28% - 71%) than C1 (72%). With such limited sensitivities, these algorithms may miss roughly half of the PHN cases. In our study, aside from the PHN diagnosis codes, the other diagnosis codes and prescription data had little impact on true case identification, instead adding complexity and increasing FPs.

Studies have used the similarity of the PHN proportions to construct the validity of their case-finding algorithms [8-11]. Administrative database studies reported PHN (pain persisting for ≥90 days) prevalences of 3% - 14% (Multimedia Appendix 6) [3], which are comparable to the 5.4% - 13.1% prevalences of the code-based approaches in our study. The broad range of prevalences identified in previous code-based studies could be caused by variations in study design, population, and data source [3]. However, the code-based approaches in this study had the same population and data source. Only the variation in algorithms could cause such a wide disparity.

We expanded the validations conducted for the 2 previously validated algorithms, which were performed on EHR data. The C2 (Klompas et al [8]) algorithm was only validated with the 30-day definition in the original study, and it had 86% sensitivity and 78% PPV. In our study, algorithm C2 with the 90-day definition had notably lower sensitivity (62%) and PPV (39%). One main contributor to the variability in performance is the difference in the temporal criteria. According to Yawn [36], up to 75% of pain present at 30 days disappears at 90 days, and the prevalence of PHN decreased by sixfold when the definition was changed from 30 days to 90 days. As prevalence decreases, so do the sensitivity and PPV [37,38]. The same trends were also reported in the original C2 paper; the PPVs for different PHN search criteria using the 30-day definition (29% - 95%) were nearly double that of using the 90-day definition (15% - 52%). The discrepancy in C2 algorithm performance between the original study and this study could be further explained by the differences in case definition. Our case definition for PHN is based on persistent PHN-related symptoms and causal attribution, not diagnosis code or medication. Algorithm C2 used ongoing symptoms or renewal of medication for HZ. The use of medications to identify PHN has some drawbacks, as PHN-related medications have a wide range of indications. For example, gabapentin, a first-line therapy for PHN, has over 20 approved and off-label uses [39]. Furthermore, prescriptions can be refilled in the absence of active PHN symptoms for various non-PHN disorders.

The original C3 (Klein et al [10]) algorithm was only validated on potential PHN cases identified by its 4 component criteria, rather than randomly selected HZ cases; only PPVs were reported. In this study, the 4 criteria of the C3 algorithm had PPVs ranging from 71% to 100%, which is consistent with the previous study's findings (PPVs ranging from 73% to 96%). The C3 algorithm was one of the best-performing code-based algorithms based on F-score and MCC. However, its low sensitivity (56%) and PPV (71%) indicate considerable misclassification. The lower overall PPV is partly due to the "OR" logic of the 4 criteria. Because Klein et al [10] did not describe the case definition or chart review rules, we were unable to assess their impact on the performance differences between the original C3 study and this study.

The substantial misclassification of coded methods as observed in this study could have a substantial impact on measuring incidence, identifying risk factors, and assessing vaccine effectiveness. Code-based method studies (C4 and C5) had identified depression, diabetes mellitus, heart failure, and chronic obstructive pulmonary disease as risk factors for PHN. It is conceivable that the link between depression and PHN is caused by using anticonvulsants and tricyclic antidepressants to identify PHN. The inclusion of prescriptions for pain medications and chronic pain codes may contribute to the association of diabetes mellitus [40], heart failure [41], and chronic obstructive pulmonary disease [42] with PHN.

Study Strengths and Limitations

This study was conducted within a large integrated health care system with comprehensive EHRs. Because the health plan provides strong incentives for members to use its facilities,

clinical documentation is expected to be more detailed. We developed NLP algorithms to identify PHN from various unstructured data sources within EHRs, such as clinical notes, which contain a wealth of information but differ greatly in structure, content, and quality. The algorithms were highly accurate, as evidenced by our validation. Compared with studies based on self-reported pain scores collected through surveys, EHR-based studies measure the health care burden of PHN, which is more clinically relevant. This study also has limitations. The reference standard relied on the review of EHRs which could be erroneous and incomplete [14]. Moreover, rereviewing cases in the validation set where NLP results differed from research associates' results may result in bias in favor of higher performance of the NLP algorithm. On the other hand, reconciling discrepant results improved the quality of the reference standard. Additionally, diagnosis codes, prescriptions, clinical documentation language, and style can differ between institutions and physicians. Our NLP method may perform differently in other test data sets.

Conclusions

PHN-related diagnosis codes have low sensitivity for identifying PHN cases. Additional diagnosis codes and prescription data did little to improve sensitivity while significantly lowering the PPV. Using clinical text from the EHR, the NLP-based method identified PHN cases with high accuracy. Our NLP method can be used in EHR-based studies to identify PHN risk factors and evaluate the effectiveness of vaccinations and treatments against PHN.

Acknowledgments

Abstract

Background: Collaborative documentation (CD) is a behavioral health practice involving shared writing of clinic visit notes by providers and consumers. Despite widespread dissemination of CD, research on its effectiveness or impact on person-centered care (PCC) has been limited. Principles of PCC planning, a recovery-based approach to service planning that operationalizes PCC, can inform the measurement of person-centeredness within clinical documentation.

Objective: This study aims to use the clinical informatics approach of natural language processing (NLP) to examine the impact of CD on person-centeredness in clinic visit notes. Using a dictionary-based approach, this study conducts a textual analysis of clinic notes from a community mental health center before and after staff were trained in CD.

Methods: This study used visit notes (n=1981) from 10 providers in a community mental health center 6 months before and after training in CD. LIWC-22 was used to assess all notes using the Linguistic Inquiry and Word Count (LIWC) dictionary, which categorizes over 5000 linguistic and psychological words. Twelve LIWC categories were selected and mapped onto PCC planning principles through the consensus of 3 domain experts. The LIWC-22 contextualizer was used to extract sentence fragments from notes corresponding to LIWC categories. Then, fixed-effects modeling was used to identify differences in notes before and after CD training while accounting for nesting within the provider.

Results: Sentence fragments identified by the contextualizing process illustrated how visit notes demonstrated PCC. The fixed effects analysis found a significant positive shift toward person-centeredness; this was observed in 6 of the selected LIWC categories post CD. Specifically, there was a notable increase in words associated with achievement (β=.774, *P*<.001), power (β=.831, *P*<.001), money (β=.204, *P*<.001), physical health (β=.427, *P*=.03), while leisure words decreased (β=−.166, *P*=.002).

Conclusions: By using a dictionary-based approach, the study identified how CD might influence the integration of PCC principles within clinical notes. Although the results were mixed, the findings highlight the potential effectiveness of CD in enhancing person-centeredness in clinic notes. By leveraging NLP techniques, this research illuminated the value of narrative clinical notes in assessing the quality of care in behavioral health contexts. These findings underscore the promise of NLP for quality assurance in health care settings and emphasize the need for refining algorithms to more accurately measure PCC.

Introduction

Collaborative documentation (CD) is a specified behavioral health practice where clinicians complete visit notes jointly with consumers during the session [1]. Through deliberate clinical strategies, such as sharing the computer screen, reading visit notes aloud, and actively seeking consumer's input into the content of the session note [2], CD is a person-centered strategy that aims to engage and empower individuals and facilitate a mutual agreement on treatment progress, service goals, and session activities. Both as a means to promote person-centered care (PCC) and make health information more accessible and transparent to consumers, the practice of CD is being widely

disseminated through formal and informal training for community mental health providers [3].

PCC, also referred to as patient-centered care, is a paradigm shift in health care that is defined by the Institute of Medicine as care that is responsive to individual client preferences, needs, and values [4]. A key part of behavioral health reform, PCC moves away from disease-centered treatment to a more holistic approach that engages individuals as active, empowered partners in their care. Person-centered care planning (PCCP) is a recovery-oriented practice that integrates principles of PCC into the service planning process. PCCP orients service planning and documentation to the unique personal life goals of the consumer [5], and provides a framework for operationalizing PCC in practice through six core principles, which are as follows: (1) PCC is based on the person's own unique life goals and aspirations; (2) PCC is oriented toward promoting recovery rather than only minimizing illness and symptoms; (3) PCC articulates the person's own role and the role of both paid practitioners and natural supports in assisting the person to achieve his or her own goals; (4) PCC focuses and builds on the person's capacities, strengths, and interests; (5) PCC emphasizes the use of natural community settings rather than segregated program settings; and (6) PCC anticipates and allow for uncertainty, setbacks, and disagreements as inevitable steps on the path to greater self-determination [6].

While CD has emerged as a recognized person-centered practice strategy by fully engaging the consumer in decisions about their care, there remains a very limited evidence base demonstrating its clinical effectiveness, including its impact on PCC. Existing research demonstrates that CD is aligned with consumer preferences; a recent scoping review found that the ability to read their visit notes improved consumers' experience in mental health care, including their ability to remember their plans of care, understand their treatment, and trust decisions made with providers [7]. In community mental health, the use of CD specifically has been found to strengthen the therapeutic alliance [8], and improve service engagement, both in terms of visit attendance and medication adherence [1].

Despite this preliminary support for CD, more work is needed to examine its impact on quality of care. Adding urgency to this knowledge gap, regulatory changes to the 21st Century Cures Act now mandate organizations to make electronic health and mental health information, including many types of visit notes, accessible online to service users [9]. As a consequence, best practices for using visit notes to support the provision of high-quality PCC are needed.

Clinical informatics, which provides highly efficient ways to mine data within the electronic health record (EHR), is a promising methodological approach to examining the impact of CD on clinical quality. Although behavioral health has lagged behind medical settings in the adoption of EHRs, now the majority of behavioral health settings document visit notes via the EHR [10]. The shift from paper records to EHRs provides an unprecedented opportunity for clinical informatics to inform quality improvement in behavioral health care. Visit notes include nuanced information about care processes, session content, provider perspective, and the consumer experience that are not captured in other more structured fields of the EHR, offering valuable insight into clinical quality that has not yet been systematically targeted in mental health services research [11]. Researchers have applied manual content analysis to visit notes to evaluate dimensions of PCC [12,13], but these efforts are inevitably limited in scope and dependent on the interpretive lens of the researcher [14].

One clinical informatics strategy that can parse large volumes of unstructured narrative information into quantitative data is natural language processing (NLP) [15]. While some text mining approaches use words as the unit of analysis, NLP is able to capture the complexity of unstructured narrative using underlying metadata, which examines how words relate to each other in a sentence and the semantic context of a sentence [16]. The method involves syntactic processing, information extraction, and capturing meaning and relationships across concepts. NLP has been predominantly used for detecting pathology and predicting behavior [17] including measuring the following: alcohol misuse in trauma patients [18], suicidal behavior [19], adverse childhood experiences among VA patients [20], smoking status [21], and sentiment at discharge [22]. Recent studies have used this method to measure quality and safety in nursing care [23], identify integrated care elements within primary care [24], and detect changes in clinical documentation after opening notes to service users [25], however, there have been fewer studies that have used NLP to analyze indicators of mental health care quality, including PCC. By providing a framework to systematically categorize and compare the contents of clinical notes, NLP is well poised to provide novel insight into how CD affects clinical quality and PCC.

The dictionary-based approach in NLP is a method that uses a predefined lexicon to identify and extract certain types of words or phrases within a given text. This approach is often used in tasks such as part-of-speech tagging, named entity recognition, and sentiment analysis. In the dictionary-based approach, the dictionary consists of a list of words or phrases along with their associated tags or labels. For example, in part-of-speech tagging, the dictionary might contain a list of common nouns, verbs, and adjectives, each with a corresponding tag that indicates the word's part of speech. One of the benefits of the dictionary-based approach is its simplicity and ease of implementation, as it targets only a predefined lexicon, or set of words, and does not require the use of complex algorithms or machine learning models. One of the most dictionary-based approaches is LIWC (Linguistic Inquiry and Word Count), and LIWC analysis has been found to be particularly useful for identifying and analyzing the emotional state of individuals in mental health–related text data [26]. Despite its potential, such as its application in oncology settings to examine the changes in clinical notes after patient access [27], the dictionary-based approach has not yet been applied to clinical notes in behavioral health care settings for its change after CD.

This study examines the effect of CD on the person-centeredness of documentation within a community mental health setting using a quasi-experimental pretest-posttest design. The study adapted a well-established dictionary to conduct sentiment

analysis of provider clinic visit notes before and after providers were trained in CD.

Methods

Ethical Considerations

This study (IRB-FY2022-5838) was granted an exemption by the New York University Institutional Review Board.

Data Source

The study setting was a community mental health center, which provided a range of services to people with severe mental illnesses including outpatient therapy, assertive community treatment, community support programs, and psychiatric rehabilitation. The data set, or corpus, is visit notes completed by providers trained in CD. Providers were trained in CD by MTM Services [28], a leader in CD training. Their training consisted of tailored in-person workshops, technical assistance, and a "train the trainer" series designed for practice sustainability. The clinic training consisted of 8 hours of web-based training and customized consultation support for implementation.

The visit notes were clinical narrative documents completed when the provider had an in-person contact with a service user. Visit notes document the following: (1) sessions focused on developing or revising the service plan, a narrative clinical document completed every 6 months with the service user detailing goals, strengths and barriers, short-term objectives, supports, professional/ billable services, and natural support and self-directed actions, and (2) a visit focused on progress made towards completing the steps in the service plan. Inclusion criteria for providers were that they were: full-time employees of the clinic; provided services to adults with severe mental illnesses; trained in CD; and had been employed in their position a year prior and the year after being trained.

This study sampled all visit notes completed by participating providers 6 months prior to CD training and all visit notes completed during the sixth month following training (with a month lag for implementation time) between July 1, 2015, and March 10, 2020. Based on anticipated documentation rates of a clinic note being generated by each visit, we recruited 10 providers, generating a total of 1981 visit notes. On average, 198.1 notes were included per provider with a standard deviation of 37.8. Sampled notes were deidentified but linked to providers through unique identifiers. In addition to the session narrative, each note was comprised of the following sections: (1) Provider ID, (2) Time and Date of Service, (3) Therapy Modality, and (4) Length of Stay.

Analytic Strategy

We used LIWC-22 to compute the scores for PCC-related sentiment and linguistic categories [29] in each sampled note. The LIWC method is a text analysis tool that uses linguistic algorithms to identify and categorize words in a text according to their psychological properties. The method is based on the LIWC dictionary, which contains over 5000 words and word stems organized into linguistic and psychological categories. In this study, 3 domain experts used a consensus approach to select LIWC categories that mapped onto the 6 principles of PCC [6] with several of the categories mapping onto more than one domain. This iterative process involved 8 rounds of independent coding by 3 raters using Excel, followed by discussions to resolve discrepancies and achieve consensus on the final coding of all data points. According to the Cohen κ measure, raters had an average interrater agreement of 88% across the LIWC categories [30]. Out of a possible 107 LIWC categories, we selected 12 categories. The selected LIWC domains and their associated PCC principles are summarized in Tables 1 and 2 [6,30].

Table . Mapping PCCP[a] principles onto LIWC[b] categories.

PCCP principles	LIWC categories
PCCP is based on the person's own unique life goals and aspirations.	Lifestyle (leisure, home, work, money, religion), social referents (family, friend)
PCCP is oriented toward promoting recovery rather than only minimizing illness and symptoms.	Health (physical, wellness)
PCCP articulates the person's own role and the role of both paid practitioners and natural supports in assisting the person to achieve his or her own goals.	Social referents (family, friend), physical (physical, wellness)
PCCP focuses and builds on the person's capacities, strengths, and interests.	Drives (achievement, affiliation, power), lifestyle (leisure, home, work, money, religion)
PCCP emphasizes the use of natural community settings rather than segregated program settings.	Lifestyle (leisure, home, work, money, religion)
PCCP anticipates and allows for uncertainty, setbacks, and disagreements as inevitable steps on the path to greater self-determination.	Drives (affiliation, achievement, power)

[a]PCCP: person-centered care planning.

[b]LIWC: Linguistic Inquiry and Word Count.

Table . Sample fragments from clinic notes generated by contextualizing LIWC[a] subcategories.

LIWC subcategories		Clinic note excerpt
Drives		
	Achievement	• Was able to identify her strengths, abilities, and self-identified progress in therapy reports that she has been engaging more socially with friends and that she has been trying to express herself
	Affiliation	• Unexpected death of her pet was huge stressor that triggers increases in intensity of depression improvement with community resources and social networking due to becoming more integrated with his new community and within his daughter's school district
	Power	• The client reports with a positive outlook that she feels more in control and is excited to receive praise for using her therapy learning • Had no outbursts or over reactions recently and feels proud of her assertive but in control manner
Lifestyle		
	Home	• Highlighting that he doesn't like the apartment "being so quiet" when his son is gone… • The client has increased productivity at home with baking and wrapping presents.
	Leisure	• She is also making self-care more of a priority, "I scheduled a cruise and it's just my sister and I going" • Progress is that he has begun basketball
	Money	• She admits that she has no savings of her own but she knows that she will get alimony • He has figured out a plan to pay for housing
	Religion	• Topics of no control include people's religious actions and beliefs, elements within his own church and community, as well as the political culture • She reported that she has been supported by her church and increased her faith significantly
	Work	• He continues to apply for jobs and is now working with workforce development. • Not working currently, sent about a couple of job applications, continues with college course work
Physical		
	Physical	• Strengthen his tongue and swallowing skills, will occur to help reduce his concern regarding health issues • Barriers to maintaining treatment plans goals, because her varying blood sugars have caused severe mood swings

LIWC subcategories		Clinic note excerpt
	Wellness	• Emily is making progress in her goals to increase positive self-worth and applying healthy coping skills • Trouble with motivation at times and needing to clear his mind, discussed option of yoga and mindfulness
Social referents		
	Family	• Has been spending time with her family and working to express her feelings and needs when appropriate • Progress is that she has figured out how to resolve some of her parenting issues
	Friend	• States that she feels she can "cut loose and have fun" with her friends • Regards to her recent trip to [place] which she really enjoyed she made new friends

[a]LIWC: Linguistic Inquiry and Word Count.

Analysis

Using the LIWC categories described above, we compared notes pre and post CD training to examine differences in PCC. The complete visit note was used as the unit of analysis. For data preprocessing, we cleaned the data and converted the information into a structured format that made it amenable to identifying patterns in the data. The LIWC-22 dictionary is case-insensitive and allows for matching 2-word phrases. The LIWC-22 software removes extra whitespace characters by default. While irrelevant words are not explicitly defined in the dictionary, we removed section headings (eg, Location) from the clinical notes before processing the text to eliminate some irrelevant words. Negated phrases (eg, "not happy") are not treated differently from nonnegated phrases in the standard scoring. To address this limitation, we included an additional analysis in Multimedia Appendix 1 that controls for the negations score.

To validate the team's selection of LIWC categories, we first used the Contextualizer function of LIWC-22 to generate sentence fragments containing words related to each LIWC domain included in the analysis. We then analyzed changes in the clinical note before and after CD training, using the complete visit note as the unit of analysis. To calculate changes in the content characteristics of clinical notes before and after CD training, we calculated frequency scores of each LIWC category for every clinical note since this study focuses on examining the presence of words from the LIWC dictionary.

Instead of using LIWC scores based on percentages, we used frequency scores. This decision was made based on previous research indicating that CD enhances the length of clinical notes in terms of word and character count [31]. Additionally, we used frequencies to assess the presence of PCC-related language in clinical notes. Our primary interest was to capture whether clinicians used PCC-related words in their documentation, even if these words did not constitute a large proportion of the total text. By focusing on word frequencies, we aimed to mitigate the potential impact of note length inflation due to CD practices, such as copy-and-pasting or using templates [32,33]. The LIWC frequency scores are calculated by the following steps. First, we calculated LIWC scores, which are determined by the percentage of words in a text that belong to specific linguistic categories. Then, to find the frequency of each category within a clinical note, the respective LIWC percentage is multiplied by the total word count of the note. For example, an LIWC value of 1.02 for achievement indicates that the note contains 1.02 words related to achievement per the LIWC dictionary.

We used a fixed effects model that included the provider as a categorical variable. The changes in the notes before and after CD training were calculated while accounting for nesting within the therapist using individual fixed-effects models. This approach allowed us to examine whether the changes in PCC language use before and after the CD training varied across the 10 providers in our sample. To further investigate these differences, we calculated the intraclass correlation coefficient (ICC) and conducted paired sample *t* tests for each provider (Multimedia Appendix 2). The LIWC version 22 was used for dictionary-based sentiment analysis and STATA (version 17.0; Statacorp) was used for statistical analyses.

Results

Contextualizing LIWC Categories

The sentences generated by the Contextualizer function illustrated how the LIWC categories mapped onto the PCCP principles (see Table 2). The drives subcategories (achievement, affiliation, and power) reflected a strength-based approach by describing the positive changes made by the client; greater self-determination by feeling more in control; and interests by capturing how a client feels connected to community, people, and pets. The lifestyle subcategories (home, leisure, money, religion, and work) captured the unique details of the person's life that are needed to individualize treatment, including their beliefs, values, and preferences which inform their personal life goals. Examples included going on a cruise as part of self-care and seeking employment. Lifestyle categories also illustrated

people's interests such as playing sports and describing their life in the community such as attending church. Physical categories (physical and wellness) demonstrated a more holistic approach to the client by paying attention to how physical health affects mental health and also to a focus on recovery by including activities that promote wellness such as yoga and health coping skills. The social referents category (family and friend) demonstrated the role family and friends play as natural supports such as going on vacation with your sister or having fun with your friends.

Changes in LIWC Categories

Overall, there was a significant positive change in 4 of the selected LIWC categories indicating person-centeredness after the providers had been trained in CD. As shown in Table 3, the fixed effects regression analysis found the following among the 12 selected characteristics: an increased use in 4 categories, decreased use in 4 categories, and no change in use in 4 categories, while controlling for length of sessions at the therapist level. Within the drives category, we observed a significant increase in words associated with achievement (β=.774, *P*<.001, ICC=0.146) and power (β=.831, *P*<.001, ICC=0.072), with the ICC values indicating that 14.6% and 7.2% of the variance in these word categories, respectively, could be attributed to differences between therapists. In the lifestyle category, there was an increase in the use of words related to home (β=.047, *P*=.35, ICC=0.060) and work (β=.047, *P*=.12, ICC=0.285), but these changes are not statistically significant. The ICC values suggest that 6.0 and 28.5% of the variance in these word categories, respectively, could be attributed to differences between therapists. On the other hand, leisure and religion-associated words showed a significant decrease (β=−.166, *P*=.002, ICC=0.033; β=−.105, *P*<.001, ICC=0.031, respectively), while words associated with money displayed substantial increases (β=.204, *P*<.001, ICC=0.035). The ICC values for these categories indicate that 3.3%, 3.1%, and 3.5% of the variance, respectively, could be attributed to differences between therapists. In the health category, there was a notable increase in the use of physical health–related words (β=.427, *P*=.03, ICC=0.159), with 15.9% of the variance attributable to differences between therapists. In contrast, wellness-related words decreased significantly (β=−.427, *P*<.001, ICC=0.211), with 21.1% of the variance attributable to differences between therapists. In the social referents category, the use of family-related words did not show any significant change (β=−.016, *P*=.89, ICC=0.085), with 8.5% of the variance attributable to differences between therapists. However, the frequency of friend-related words decreased significantly (β=−.084, *P*=.005, ICC=0.028), with only 2.8% of the variance attributable to differences between therapists.

Table . Person-centeredness before and after collaborative documentation (CD). Coefficients were reported. Standard errors are in parentheses. β denotes coefficients of fixed-effects models. Fixed-effects estimates were based on models from the STATA module "xtreg" commands, clustered by therapist and with controls for length of session (minutes).

Category		Sample words	Frequency mean		Fixed effects		
			Before CD	After CD	ICC[a]	β (SE)	*P* value
Drives							
	Achievement	work, better, best, working	4.04	5.09	0.146	.774 (0.129)	<.001
	Affiliation	we, our, us, help	4.28	4.24	0.212	.086 (0.138)	.53
	Power	wn, order, allow, power	1.75	2.66	0.072	.831 (0.094)	<.001
Lifestyle							
	Home	home, house, room, bed	0.66	0.77	0.060	.047 (0.051)	.35
	Leisure	game, fun, play, party	0.78	0.62	0.033	−.166 (0.053)	.002

	Work	work, school, working, class	6.20	6.68	0.285	.234 (0.152)	.12
Health							
	Physical	medic, food, patients, eye	5.43	5.90	0.159	.427 (0.193)	.03
	Wellness	healthy, gym, supported, diet	0.93	0.59	0.211	−.416 (0.057)	<.001
Social referents							
	Family	parent, mother, father, baby	2.24	2.09	0.085	−.016 (0.116)	.89
	Friend	friend, boyfriend, girlfriend, dude	0.26	0.18	0.028	−.084 (0.03)	.005

[a]ICC: intraclass correlation coefficient.

Discussion

Principal Findings

The contextualizing analysis provided insight into the documentation content reflecting the selected LIWC categories and demonstrated how person-centered principles can be integrated into clinical documentation. Using LIWC categories illustrated how providers described their clients in ways that gave a sense of their lives beyond their mental health. These details included what they care about and how that related to their personal goals (getting a job, financial situation, going on a cruise, or attending church), their life beyond the clinic in the community (their home life, family and friends, and their community). The sentences also showed when clinicians used a strengths-based approach, the nature and content of their clinic notes changed in ways that moved beyond symptoms [34].

The quantitative results indicating whether there was an increase in person-centeredness of clinical documentation as indicated by relevant LIWC categories were mixed, with a significant increase in half the subcategories. The most pronounced positive increase was within the drives category, with words associated with power and achievement increasing. In terms of PCC, this indicates providers made more reference to self-determination, including how the client has made progress, and their strengths. Lifestyle categories, which include words related to hobbies and other social activities were more mixed, showing that providers were not consistent in increasing their focus on personal life goals or taking a holistic view of the client. In health, there was a significant increase in references to physical health but a decrease in references to wellness. This may reflect the increasing efforts to integrate health into their clinical interventions [35], but does not indicate a more recovery-oriented focus. Finally, in terms of social referents, there was no change in family references, which may be due to the fact that family inclusion is a common best practice of PCC [36,37], and a decrease in references to friends, often considered a source of natural supports within PCC.

Existing work has suggested that CD can improve important indicators of PCC, including service engagement and the quality of the working alliance [1,8], but research has yet not illuminated how this practice impacts care processes, including how person-centered principles are integrated into clinical interventions. Through analysis of session notes, this study found an increase in strengths-based approaches to clinical documentation following CD training, which may also reflect a shift towards interventions that emphasize self-determination. In addition to expanding the limited evidence base around the impact of CD on clinical quality, this study uniquely describes the mechanisms through which CD supports alliance building and engagement in care.

To meet the much-documented challenges of measuring PCC [38,39], a core component of health care reform, this study sought to harness the richness of clinical narrative data using a machine learning algorithm. While some studies have used NLP to study psychotherapy sessions [25], this is one of the first to mine narrative psychosocial documentation in behavioral health settings. Overall, this methodological approach has considerable potential to sample large quantities of documentation to measure different aspects of care quality, including PCC. NLP can be used both by researchers to examine how quality of care predicts clinical outcomes and by clinics to promote and document quality improvement.

Despite this potential, there are considerable challenges in calibrating algorithms so that they can accurately capture more nuanced aspects of care, such as person-centeredness. This study chose to use a well-validated dictionary designed to capture psychological concepts within narrative data. Although the study team was able to map existing LIWC categories onto established principles of PCC, the algorithm was not explicitly designed to measure these constructs, which may have contributed to the lack of positive findings within certain subcategories. Furthermore, the LIWC dictionary's focus on single words limits the algorithm's ability to capture more nuanced meanings that occur when words are evaluated within the larger context of surrounding phrases or sentences. This suggests the need to develop an algorithm focused specifically on PCC.

This study showed the potential for using NLP techniques to measure the quality of care within behavioral health settings. As more care standards demand that clinics demonstrate PCC [40] within mental health, there is a pressing need for feasible methods to capture this quality dimension. Being able to use at the aggregate level note data that reflects more nuanced and individualized aspects of care would help clinics document and report PCC.

In addition, our study highlights the value of clinical notes for research in behavioral health settings. Clinical notes have been harnessed for research purposes but have mainly been confined to hospital settings due to the scarcity of publicly available data [41]. The nature of psychosocial documentation differs from other clinical notes, which require different analytics and models and there is a need for publicly available data sets for analyzing psychotherapy notes in the United States. Furthermore, mental health notes often contain identifiable and sensitive information different from other clinical notes for physical illnesses, so an in-depth discussion on ethics, privacy, and deidentification and the development of techniques such as word embedding models to improve the privacy of clinical notes [42,43] for mental health notes is required.

Limitations

The study was limited to the scope of the LIWC categories rather than an algorithm developed specifically to capture PCC and therefore, was not able to measure the concept in its entirety. Furthermore, the analysis limited itself to categories with a positive valence rather than also measuring the inverse of PCC. Although well validated, the LIWC can still fail to capture the meaning of words and mis-categorize them but as it is used more, the algorithm will continue to be trained and improved. Overall, while documentation is an important indicator of PCC, it does not directly capture the interpersonal interactions between the provider and the clinician which shape a client's experience of PCC.

While our fixed effects model controlled for Provider ID and Date of Service, we were unable to account for potential differences in therapy modality or length of stay. In our study setting, the therapy modality primarily consisted of individual psychotherapy sessions excluding 2 notes (1 group therapy and 1 family therapy) resulting in insufficient variation to control for this variable. Additionally, our current data set did not include sufficient information on length of stay to include this variable in the model. Future research could benefit from examining the influence of therapy modality and longitudinal factors on PCC language use in clinical documentation.

It is important to acknowledge that while our study demonstrates an increase in person-centered content within clinic visit notes following the implementation of the CD, we did not directly assess whether the increased PCC in the clinic visit notes was associated with improved PCC practices. Future research should investigate the relationship between the presence of PCC in clinical notes and its impact on PCC practices and outcomes.

Conclusion

This study is an important first step in using NLP to measure the quality of care through narrative clinical notes in behavioral health settings. We were able to identify key PCC principles within the notes using a dictionary-based approach and examine whether CD changes the way providers document with respect to PCC. This demonstrates the potential for NLP to be used by both researchers and clinics as a quality improvement tool and the importance of further developing algorithms that can capture the nuances of PCC.

Abstract

Background: Large language models (LLMs) have achieved great progress in natural language processing tasks and demonstrated the potential for use in clinical applications. Despite their capabilities, LLMs in the medical domain are prone to generating hallucinations (not fully reliable responses). Hallucinations in LLMs' responses create substantial risks, potentially threatening patients' physical safety. Thus, to perceive and prevent this safety risk, it is essential to evaluate LLMs in the medical domain and build a systematic evaluation.

Objective: We developed a comprehensive evaluation system, MedGPTEval, composed of criteria, medical data sets in Chinese, and publicly available benchmarks.

Methods: First, a set of evaluation criteria was designed based on a comprehensive literature review. Second, existing candidate criteria were optimized by using a Delphi method with 5 experts in medicine and engineering. Third, 3 clinical experts designed medical data sets to interact with LLMs. Finally, benchmarking experiments were conducted on the data sets. The responses generated by chatbots based on LLMs were recorded for blind evaluations by 5 licensed medical experts. The evaluation criteria that were obtained covered medical professional capabilities, social comprehensive capabilities, contextual capabilities, and computational robustness, with 16 detailed indicators. The medical data sets include 27 medical dialogues and 7 case reports in Chinese. Three chatbots were evaluated: ChatGPT by OpenAI; ERNIE Bot by Baidu, Inc; and Doctor PuJiang (Dr PJ) by Shanghai Artificial Intelligence Laboratory.

Results: Dr PJ outperformed ChatGPT and ERNIE Bot in the multiple-turn medical dialogues and case report scenarios. Dr PJ also outperformed ChatGPT in the semantic consistency rate and complete error rate category, indicating better robustness. However, Dr PJ had slightly lower scores in medical professional capabilities compared with ChatGPT in the multiple-turn dialogue scenario.

Conclusions: MedGPTEval provides comprehensive criteria to evaluate chatbots by LLMs in the medical domain, open-source data sets, and benchmarks assessing 3 LLMs. Experimental results demonstrate that Dr PJ outperforms ChatGPT and ERNIE Bot in social and professional contexts. Therefore, such an assessment system can be easily adopted by researchers in this community to augment an open-source data set.

ChatGPT; LLM; assessment; data set; benchmark; medicine

Introduction

The development of large language models (LLMs) has revolutionized natural language processing, raising significant interest in LLMs as a solution for complex tasks such as instruction execution and elaborate question-answering in various domains [1]. Among these domains, the medical field has received significant attention because of its actual demands. Recently, progress has been achieved in medical education [2], patient care management [3], medical exams [4], and other medical applications.

Despite their capabilities, LLMs are prone to generating hallucinations (not fully reliable responses) [5,6]. Hallucinations in LLMs' responses create substantial risks, potentially

threatening patient's physical safety and leading to serious medical malpractice. Thus, to perceive and prevent this safety risk, we must conduct an exhaustive evaluation of LLMs in the medical domain and build a systematic evaluation.

However, conducting an exhaustive evaluation for LLMs is not trivial. First, LLMs lack robustness; that is, their performance is highly sensitive to prompts. White et al [7] showed that a meticulously crafted and thoroughly tested prompt could greatly improve performance and produce superior results. Thus, the robustness of LLMs must be evaluated through in-depth research. Second, the evaluation criteria of LLMs are critical. Recent evaluations have been mainly based on automatic metrics [8-10] (eg, bilingual evaluation understudy, Recall-Oriented Understudy for Gisting Evaluation, and accuracy) in popular applications such as machine translation and text summarization. Despite their high efficiency, these automatic metrics are insufficient for using LLMs in real-world medical scenarios. Other factors such as the logical coherence of responses, social characteristics like tone, and the ability to understand contextual information are essential influential factors [6,11-17].

To conduct an exhaustive study, we developed a comprehensive assessment system, MedGPTEval, composed of criteria, medical data sets in Chinese, and publicly available benchmarks. First, 5 interdisciplinary experts in medicine and engineering summarized existing criteria based on a comprehensive literature review on the assessment of medical applications. The experts have rich research experience in artificial intelligence (AI) or big data, but specific subdisciplines and majors may vary, including AI and health care management, AI and clinical medicine, AI and medical imaging, clinical medicine and big data, AI, medical imaging, and computer vision. Second, these candidate criteria were optimized using a Delphi method. In the realms of health care [18,19] and the foresight of interdisciplinary future-built environments [20], the Delphi method has emerged as an efficacious instrument for amalgamating the insights of experts across diverse domains, fostering consensus, and refining standards. This approach serves to harmonize the interests of all pivotal stakeholders, thereby amplifying the efficacy and transparency of value-based outcomes [19]. The obtained evaluation criteria cover medical professional capabilities, social comprehensive capabilities, contextual capabilities, and computational robustness, with 16 detailed indicators. Third, 3 clinical experts designed medical data sets to interact with LLMs, including 27 medical dialogues and 7 case reports in Chinese. The case data set is adapted and constructed based on real clinical cases. We have adopted multiple rounds of internal review and expert review processes, and have conducted verification consistent with actual clinical scenarios to ensure the accuracy and practicality of the data. Finally, benchmarking experiments were conducted on the data sets. The responses generated by LLMs were recorded for blind evaluations by 5 licensed medical experts practicing medicine.

In the benchmarking experiments, 3 chatbots by LLMs were selected for evaluation. First, ChatGPT, an LLM created by OpenAI, has gained global popularity owing to its exceptional language capabilities [2]. However, ChatGPT has not been specifically trained for the medical domain [21]. Second, ERNIE Bot is an LLM developed by Baidu, Inc, a Chinese computer technology company [22]. It has been primarily trained on Chinese text and predominantly supports the Chinese language for general purposes. Third, Doctor PuJiang (Dr PJ) is an LLM created by the medical research group of the Shanghai Artificial Intelligence Laboratory. Dr PJ has been trained based on massive Chinese medical corpora and supports various application scenarios, such as diagnosis, triage, and medical question-answering. Note that ChatGPT and ERNIE Bot are general-purpose conversational AI systems, while Dr PJ is an LLM fine-tuned specifically for medical use. To promote research on the evaluation of medical LLMs, we conducted benchmarking experiments on the proposed medical data sets in Chinese. Experimental results show that Dr PJ outperformed ChatGPT and ERNIE Bot in both the multi-turn medical dialogues (scores of 13.95 vs 13.41 vs 12.56 out of 16) and the case report scenarios (scores of 10.14 vs 8.71 vs 8.0 out of 13).

The scale of the data set remains limited. We urge researchers in this community to join this open project via email (xujie@pjlab.org.cn). MedGPTEval is open to researchers, that is, people affiliated with a research organization (in academia or industry), as well as to people whose technical and professional expertise is relevant to the social aspects of the project.

The contribution of this work is 2-fold:

1. By conducting a thorough study of LLMs used in the medical context and collaborating with domain experts, we established comprehensive evaluation criteria to assess the medical responses of LLMs.
2. Based on the criteria, we released a set of open-source data sets for the evaluation of medical responses in Chinese and conducted benchmark experiments on 3 chatbots, including ChatGPT.

Methods

Evaluation Criteria

The evaluation criteria for assessing the LLMs were summarized by a thorough literature review. The evaluation criteria were then optimized using the Delphi method [23]. The general process involved sending the criteria to designated experts in the field and obtaining their opinions on linguistic embellishment, ambiguity, and readability. After generalizing and corrections, we provided anonymous feedback to each expert. This cycle of seeking opinions, refining focus, and giving feedback was repeated until a unanimous consensus was reached. A team of 5 interdisciplinary experts in medicine and engineering collaborated to determine the final evaluation aspects, specific details, and scoring standards. All members of the team held doctoral degrees in their specialties, with titles of associate professor or above, including 2 clinical medicine specialists, 2 computer specialists, and 1 medical management specialist.

Medical Data Sets in Chinese

To apply the evaluation criteria, 3 licensed medical experts with over 10 years of extensive clinical experience worked together to create a set of medical data sets in Chinese, including the multiple-turn dialogue data set and the case report data set. The

case report data set necessitated a singular round of questioning and encompasses an elaborate medical record of the patient, including age, gender, medical history (personal and familial), symptoms, medication history, and other relevant information. In addition, the medical problem consulted had to be clearly described. In contrast, the data set with multiple-turn dialogue was derived through an iterative process comprising four rounds. The initial round was initiated with the patient's symptoms, followed by supplementary descriptions of medication, examination, or other symptom-related queries. The data set with multiple-turn dialogue required careful consideration to assess contextual relevance.

Benchmark

The generations of LLMs' responses were recorded by an impartial programmer to ensure an unbiased evaluation. During the evaluation process, the LLMs' responses were concealed from a different group of 5 clinical medical experts who were licensed practitioners. They have similar years of clinical experience, and we have unified training on assessment processes and criteria to account for the impact of differences in clinical practice on the assessment process. The clinical fundamental response performances of 3 LLMs (ChatGPT, ERNIE Bot, and Dr PJ) were then compared based on the assessment criteria outlined above and on the proposed medical data sets. The data sets proposed by 5 clinical medical experts based on actual clinical experience and clinical confusion, and determined through peer review and discussion were used to evaluate the medical and social capabilities of the LLMs, while the multiple-turn dialogue data set was used to additionally assess their contextual abilities. The maximum scores available for LLMs in the multiple-turn dialogue data set and the case report data set were 16 and 13, respectively, where a higher score indicated superior performance. Furthermore, the computational robustness of the LLMs was assessed using extended data sets derived from the multiple-turn dialogue data set. Lastly, a subset of the case reports was randomly selected and comprehensively reviewed by five medical experts. The benchmark assessment methods are summarized in Table 1.

Table . Summary of benchmark assessment.

Data sets and assessment aspects		Assessment approaches
Medical dialogue		
	Medical professional capabilities, social comprehensive capabilities, contextual capabilities	Maximum score of 16
	Computational robustness	Percentage
Case report		
	Medical professional capabilities, social comprehensive capabilities	Maximum score of 13
	Computational robustness	Percentage
	Comprehensive review	Comments

Ethical Considerations

This study does not include human participants (ie, no human subject experimentation or intervention was conducted) and does not require institutional review board approval.

Results

Comprehensive Assessment Criteria

The draft evaluation criteria for assessing the LLMs were summarized by a thorough literature review [6,7,11-14,16,17,24] from 4 aspects: medical professional capabilities, social comprehensive capabilities, contextual capabilities, and computational robustness. All 5 interdisciplinary experts made suggestions for fine-tuning the assessment method, and they reached a consensus using the Delphi method to make it more scientifically rigorous and easier to read [23].

Medical Professional Capabilities

The professional comprehensive capabilities of LLMs' answers were evaluated using 6 indicators [7,12,17]: (1) accuracy, requiring that there are no medical errors in the answers and that the answers do not provide any harmful information to patients (accuracy can also include the evaluation of safety); (2) informativeness, where a 3-point Likert scale was used to evaluate the informativeness of the answers (0: incomplete; 1: adequate; 2: comprehensive); (3) expansiveness, meaning that the answers contain useful information besides the medical knowledge included in the question; (4) logic, with a 3-point Likert scale (0: the answer is irrelevant to the topic; 1: off topic, the answer does not directly address the topic but is still relevant; 2: on topic, the answer addresses the topic directly and positively); (5) prohibitiveness, where the LLMs correctly identify medical vocabulary or prohibited vocabulary; and (6) sensitivity, ensuring that LLMs' answers do not contain any politically sensitive expressions. Note that if the score for either knowledge accuracy or logical correlation is 0, the score for the overall professional comprehensive capabilities is set to 0.

Social Comprehensive Capabilities

We conducted an overall evaluation of the social comprehensive performances using 4 indicators [6,11,12,14]: (1) comprehension, where a binary scale is used to evaluate the readability of the answers (0: awkward sounding—all answers are professional and not explanatory; 1: understandable—intuitive and easy to understand); (2) tone, which pertains to the appropriate use of mood/tone in the generated responses by the LLMs, including the use of mood

particles, symbols, emotional rhythm, and emotional intensity; (3) empathy, where the accuracy of the scenario analysis is considered, including emotional understanding and reasoning; and (4) social decorum, using a 3-point Likert scale to evaluate the social decorum (0: rude–not matching any friendly social keywords or displaying malicious language attacks; 1: general—matching 1-2 keywords; 2: graceful—matching 3 or more keywords).

Contextual Capabilities

Three indicators were used to access the contextual capabilities [13,24] only in the multiple-turn dialogue data set, as follows: (1) repeated answer, which means that no duplicate answers should appear in the responses generated by LLMs; (2) anaphora matching, which involves correctly identifying and matching the abbreviations or aliases of medical professional terms used in the dialogue; and (3) key information, where LLMs can recognize and include all relevant information from the question in their response, particularly those that have been repeated 2 or more times in the questions. The content performance criteria used for scoring are outlined in Table 2.

Table . Summary of evaluation aspects, indicators, criteria, and data sets.

Evaluation aspects		Data sets	Evaluation criteria	Score
Medical professional capabilities		Both		
	Accuracy[a]		No medical knowledge errors are present in the answer	1
	Informativeness		Comprehensive: answers include additional information beyond the expectations	2
	Expansiveness		Answers include content from aspects other than medical knowledge included in the question	1
	Logic[a]		On topic: the answers address the topic directly and positively	2
	Prohibitiveness		The model can correctly identify medical or prohibited terms	1
	Sensitivity		There is no political sensitivity expressed in the answers of chatbots by LLM[b]	1
Social comprehensive capabilities		Both		
	Comprehension		Understandable: the answers are intuitive and easy to understand	1
	Tone		The answers use correct modal particles and symbols	1
	Empathy		The answers can accurately empathize with the patient	1
	Social decorum		Appropriate: matching 3 or more keywords	2
Contextual capabilities		Multiple-turn dialogue		
	Repeated answer		The model has no duplicate answers	1
	Anaphora matching		The model can identify medical professional abbreviations and aliases	1
	Key information		The model can identify key information that appears 2 or more times	1

[a]Highest priority. If the score of an item is 0, no further evaluation was conducted on either medical professional capability.

[b]LLM: large language model.

Computational Robustness

To evaluate the robustness of the LLMs, 5 extended data sets were created based on first-round questions in the multiple-turn dialogue data set described above. Specifically, the following strategies were used to rephrase each original question and create 10 rephrasing questions: (1) rephrasing the question or sentence but maintaining the semantics (data set A), (2) rephrasing the question or sentence and changing the semantics (data set B), (3) rephrasing the question or sentence by introducing punctuation errors (data set C), (4) rephrasing the question or sentence by introducing grammatical errors (data set D), and (5) rephrasing the question or sentence by introducing spelling errors (data set E). Data sets A-E were used to evaluate the robustness of the LLMs from different common scenarios, which could be classified into 3 anomaly categories. Specifically, data set A was used for the adversarial success rate, data set B for the noise success rate, and data set C-E for the input error success rate.

For each data set, the original and rephrased questions were inputted into the LLMs, and 3 metrics were calculated according to the LLMs' answers as follows [16,17]: (1) the semantic consistency rate (R_1) represents the proportion of the answer able to maintain the same semantics when inputting a rephrasing question, (2) the semantically inconsistent but medically sound rate (R_2) means that the semantics of the answer has changed but is medically sound when inputting the rephrased question, and (3) the complete error rate (R_3) means that the semantics of the answer have changed and that there is a medical error when inputting a rephrasing question.

Medical Data Sets in Chinese

Two medical data sets in Chinese were created: medical multiple-turn dialogues and case reports. The data sets [25] include a total of 34 cases, with 27 cases for multiple-turn dialogue and 7 case reports. Data sets included medical scenarios, questions, suspected diagnoses given by LLMs, disease types, and classification of medical questions. The medical questions were sorted into 6 categories: clinical manifestations, treatment, ancillary tests, lifestyle habits, etiology, and prognosis. Most questions focused on patients' self-reported symptoms and their treatments. The data sets contain 14 types of diseases: systemic diseases, digestive system diseases, brain diseases, heart diseases, bone diseases, chest diseases, vascular diseases, eye diseases, uterine diseases, urinary system diseases, nasopharyngeal diseases, oral diseases, skin diseases, and accidental injuries. Some specific common diseases featured in the data sets are metabolic diseases like diabetes mellitus, gastrointestinal diseases such as gastritis and hyperacidity, and critical diseases like Parkinson disease and heart failure.

Benchmarks Based on ChatGPT, ERNIE Bot, and Dr PJ

Analysis of the Results in Two Medical Scenarios

As shown in Table 3, three assessment aspects were covered in the multiple-turn dialogue evaluation: medical professional capabilities, social comprehensive capabilities, and contextual capabilities. Table 3 shows the total scores of each assessment and the scores of specific indicators. Dr PJ outperformed ChatGPT and ERNIE Bot, with total scores of 13.95, 13.41, and 12.56, respectively. ChatGPT achieved a slightly higher score of 6.30 in medical professional capabilities, compared to 6.25 for Dr PJ and 5.63 for ERNIE Bot. Although ChatGPT performed better in the assessment of medical professional capabilities, Dr PJ had a higher score for accuracy, meaning that the answers were harmless and that Dr PJ performed better in the evaluation of safety. As for social comprehensive capabilities, ChatGPT, ERNIE, and Dr PJ achieved scores of 4.26, 4.33, and 4.70, respectively. Dr PJ achieved a score of 3.00 for context relevance, while ChatGPT and ERNIE Bot achieved scores of 2.85 and 2.59, respectively.

As shown in Table 4, two assessment aspects were covered in the case report evaluation: medical professional capabilities and social comprehensive capabilities. Dr PJ outperformed ChatGPT and ERNIE Bot, with total scores of 10.14, 8.71, and 8.00, respectively. As for medical professional capabilities, Dr PJ achieved 6.86, higher than that of ChatGPT (6.43) and ERNIE Bot (5.71). Similarly, Dr PJ had the highest score (1.00) for accuracy in the evaluation of medical professional capabilities. In addition, Dr PJ had the same scores as ChatGPT regarding informativeness and expansiveness. As for social comprehensive capabilities, the scores for Dr PJ, ChatGPT, and ERNIE Bot were 3.29, 2.29, and 2.29, respectively. Specific scores for each indicator can be found in Table 4.

Table . The content performances of chatbots in medical scenarios on multiple-turn dialogues.

Evaluation indicators	Chatbots		
	ChatGPT	ERNIE Bot	Doctor PuJiang
Total score (maximum score: 16)	13.41	12.56	13.95
Medical professional capabilities (maximum score: 8)	6.30	5.63	6.25
Accuracy	0.91	0.79	0.94
Informativeness	1.40	1.22	1.31
Expansiveness	0.19	0.12	0.17
Logic	1.81	1.50	1.84
Prohibitiveness	1.00	1.00	1.00
Sensitivity	1.00	1.00	1.00
Social comprehensive capabilities (maximum score: 5)	4.26	4.33	4.70
Comprehension	0.96	0.96	0.96
Tone	0.96	1.00	1.00
Empathy	0.70	0.70	0.85
Social decorum	1.63	1.67	1.89
Contextual capabilities (maximum score: 3)	2.85	2.59	3.00
Repeated answer	0.96	0.81	1.00
Anaphora matching	0.96	0.85	1.00
Key information	0.93	0.93	1.00

Table . The content performances of chatbots in medical scenarios with the case report.

Evaluation indicators	Chatbots		
	ChatGPT	ERNIE bot	Doctor PuJiang
Total score (maximum score: 13)	8.71	8.00	10.14
Medical professional capabilities (maximum score: 8)	6.43	5.71	6.86
Accuracy	0.86	0.71	1.00
Informativeness	1.43	1.14	1.43
Expansiveness	0.43	0.43	0.43
Logic	1.71	1.43	2.00
Prohibitiveness	1.00	1.00	1.00
Sensitivity	1.00	1.00	1.00
Social comprehensive capabilities (maximum score: 5)	2.29	2.29	3.29
Comprehension	1.00	1.00	1.00
Tone	0.29	0.14	0.71
Empathy	0.00	0.14	0.29
Social decorum	1.00	1.00	1.29

Comprehensive Review of Detailed Case Reports

The comments of 2 case reports by 5 medical experts are shown in Multimedia Appendix 1. Overall, all 3 LLMs performed well in correctly understanding patients' questions. They could comprehend the questions asked by patients and respond with logical answers. However, Dr PJ outperformed the others in terms of sociality. Additionally, Dr PJ answered the questions in an orderly manner, with clear and intuitive serial numbers listed.

Computational Robustness Performance

The results in Table 5 show that Dr PJ outperformed ChatGPT and ERNIE Bot in the semantic consistency rate, with a higher adversarial success rate, noise success rate, and input error success rate. This indicates that Dr PJ was the best at

maintaining the same semantics of the model answers when questions were paraphrased. Furthermore, in the complete error rate category, both Dr PJ and ERNIE Bot had lower error rates than ChatGPT, suggesting that the semantics of the answer changed when the question was altered. Dr PJ also had a low probability of medical errors.

Table . The robustness of 3 chatbots for the medical consultation detailed answer task.

Chatbots, anomaly category, and data set		R_1[a] (%)	R_2[b] (%)	R_3[c] (%)
ChatGPT				
ASR[d]				
	Data set A	15	65	20
NSR[e]				
	Data set B	15	55	30
IESR[f]				
	Data set C	0	100	0
	Data set D	30	40	30
	Data set E	20	80	0
ERNIE Bot				
ASR				
	Data set A	10	85	5
NSR				
	Data set B	0	100	0
IESR				
	Data set C	0	100	0
	Data set D	20	80	0
	Data set E	20	80	0
Doctor PuJiang				
ASR				
	Data set A	15	80	5
NSR				
	Data set B	35	65	0
IESR				
	Data set C	60	40	0
	Data set D	50	40	10
	Data set E	80	20	0

[a]R_1: semantic consistency rate.

[b]R_2: semantically inconsistent but medically sound.

[c]R_3: complete error rate.

[d]ASR: adversarial success rate.

[e]NSR: noise success rate.

[f]IESR: input error success rate.

Discussion

Principal Findings

In this study, we introduced a set of comprehensive evaluation criteria for assessing LLMs' performances in medical contexts, considering aspects such as medical professional capabilities, social comprehensive capabilities, contextual capabilities, and computational robustness. We compared ChatGPT and ERNIE Bot with Dr PJ in 2 medical scenarios: multi-turn dialogues and case reports. Experimental results show that Dr PJ outperformed ChatGPT and ERNIE Bot in handling various forms of the same question in these 2 scenarios.

Recently, LLMs have achieved rapid advancements and demonstrated technical potential. However, only a few

question-and-answer evaluation methods have been developed for nonmedical fields or accuracy aspects. Liu et al [26] presented a research summary for ChatGPT/GPT-4 suggesting that there are several evaluation aspects to consider, such as engineering performance, scenario, user feedback, and negative impacts. Similarly, West [17] evaluated the accuracy of ChatGPT-3.5 and ChatGPT-4 in answering conceptual physics questions by assessing correctness, confidence, error type, and stability. Further, Tan et al [16] compared responses from 6 English and 2 multilingual data sets, totaling 190,000 cases, and they discovered that ChatGPT outperformed similar models in most results but struggled with questions requiring numerical or time-based answers. However, the team's evaluation metrics such as the minimal functionality test, invariance test, and directional expectation test [16] are primarily focused on model performances and stability. Unlike general question-answering domains, medical data sets require a more comprehensive evaluation approach. It is essential to not only focus on the LLMs' performances but also consider the physical and psychological state of the questioner, as well as potential patients seeking medical assistance from a medical professional's perspective. As a result, we propose content evaluation criteria including both medical and social capabilities. Simultaneously, in a recent publication comparing physicians versus LLMs' responses to patient questions, the researchers assessed the quality of information and empathy of the responses on a 5-point scale [27]. Moreover, a recent study on radiation oncology physics showed that GPT-4 performed better in answering highly specialized radiation oncology physics questions after labeling. However, results were obtained where human expertise won out, suggesting the importance of the diversity of expertise and contextual inference capabilities [13]. Correspondingly, contextual capabilities are incorporated as a crucial component to evaluate LLMs' contextual inference professionally and objectively. We believe that the comprehensiveness of Chinese data sets is equally important. For example, our latest proposed medical data sets in Chinese include common and critical diseases from 14 different clinical departments. Furthermore, our open-source data sets can facilitate a fairer evaluation process and expedite the global assessment and advancement of LLMs applied to medical data sets in Chinese.

Many current models are data hungry and necessitate labor-intensive labeling [28]. The advent of medical knowledge graphs and foundation models, which enable training without labeled data and professional medical knowledge, has driven the application of AI throughout the clinical workflow, including triage, diagnosis, and clinical management [4,29,30]. Inspired by these advancements, we developed Dr PJ, an LLM based on massive medical data sets in Chinese. Given the highly specialized nature of medical care, training LLMs in this field requires strict supervision to ensure medical professionalism. Simultaneously, humanistic care, a fundamental aspect of doctor-patient communication, is crucial for human-computer interaction [31]. Unlike ChatGPT and ERNIE Bot, which are general AI models pretrained on general internet data, Dr PJ was built for medical applications and has been trained using medical texts. When applying these models to multiple-turn dialogues, our model achieved the highest total score. This result shows that the higher medical expertise score of ChatGPT resulted from informativeness and expansiveness, while our model achieved better accuracy and medical safety. Additionally, we evaluated the robustness of models by changing the method of inputs or the order of words. In the real world, patients may enter their symptoms in different ways or may remember diseases or drugs incorrectly. The word order may also influence the natural language understanding [32]. Therefore, it is important to measure the robustness of medical models to deal with various inputs. Dr PJ had higher semantic consistency and a lower complete error rate compared to ChatGPT, indicating better robustness. Although the developers of OpenAI believe that ChatGPT performs well in translation, it does not perform stably in different modes of questioning. This indicates that the language barrier in foundation models is an important factor to consider.

Limitations

Limitations remain in the evaluation system and LLM development. First, the evaluation criteria primarily rely on subjective scoring by a group of medical professionals. Although this approach aligns with the principles of the medical domain, it can introduce a certain bias into the results, and the human-scoring system can waste time and human resources. Second, our data set mainly focuses on Chinese medicine, which has language and cultural limitations. This may have some impact on the generalizability of the findings. Expanding the scope of the data set in future studies would be a worthwhile research direction to enhance the reliability and generalizability of the study.

Future Directions

To improve evaluation efficiency and reduce bias, future work on the combination of automated model evaluation is needed. Moreover, the scale of medical data sets for evaluation is still limited, so we encourage research collaborations to help expand the current evaluation data set with more Chinese medical data sets to construct a more comprehensive evaluation data set. In addition, foundation models with a greater number of parameters have the potential to yield better accuracy. We can also potentially enhance the model performance by training the model with more complex parameters. Finally, note that using different prompts may have an impact on model output [33]. Therefore, evaluations of different prompting strategies for models should be conducted to select those suitable for medical scenarios.

Conclusions

This work proposed an assessment system, composed of a set of evaluation criteria, open-source medical data sets in Chinese, and a benchmark of 3 chatbots. Medical experts evaluated the LLMs and found that 3 chatbots (ChatGPT, ERNIE Bot, and Dr PJ) could understand patients' questions and provide logical answers. Through a comparison using the proposed evaluation criteria, we found that Dr PJ outperformed the other 2 models with more accurate medical knowledge and humanistic care. Overall, the study results underscore the need for continuous research and development in LLMs to ensure their safe and effective use in medical scenarios.

Abstract

Background: Biomedical natural language processing tasks are best performed with English models, and translation tools have undergone major improvements. On the other hand, building annotated biomedical data sets remains a challenge.

Objective: The aim of our study is to determine whether the use of English tools to extract and normalize French medical concepts based on translations provides comparable performance to that of French models trained on a set of annotated French clinical notes.

Methods: We compared 2 methods: 1 involving French-language models and 1 involving English-language models. For the native French method, the named entity recognition and normalization steps were performed separately. For the translated English method, after the first translation step, we compared a 2-step method and a terminology-oriented method that performs extraction and normalization at the same time. We used French, English, and bilingual annotated data sets to evaluate all stages (named entity recognition, normalization, and translation) of our algorithms.

Results: The native French method outperformed the translated English method, with an overall F_1-score of 0.51 (95% CI 0.47-0.55), compared with 0.39 (95% CI 0.34-0.44) and 0.38 (95% CI 0.36-0.40) for the 2 English methods tested.

Conclusions: Despite recent improvements in translation models, there is a significant difference in performance between the 2 approaches in favor of the native French method, which is more effective on French medical texts, even with few annotated documents.

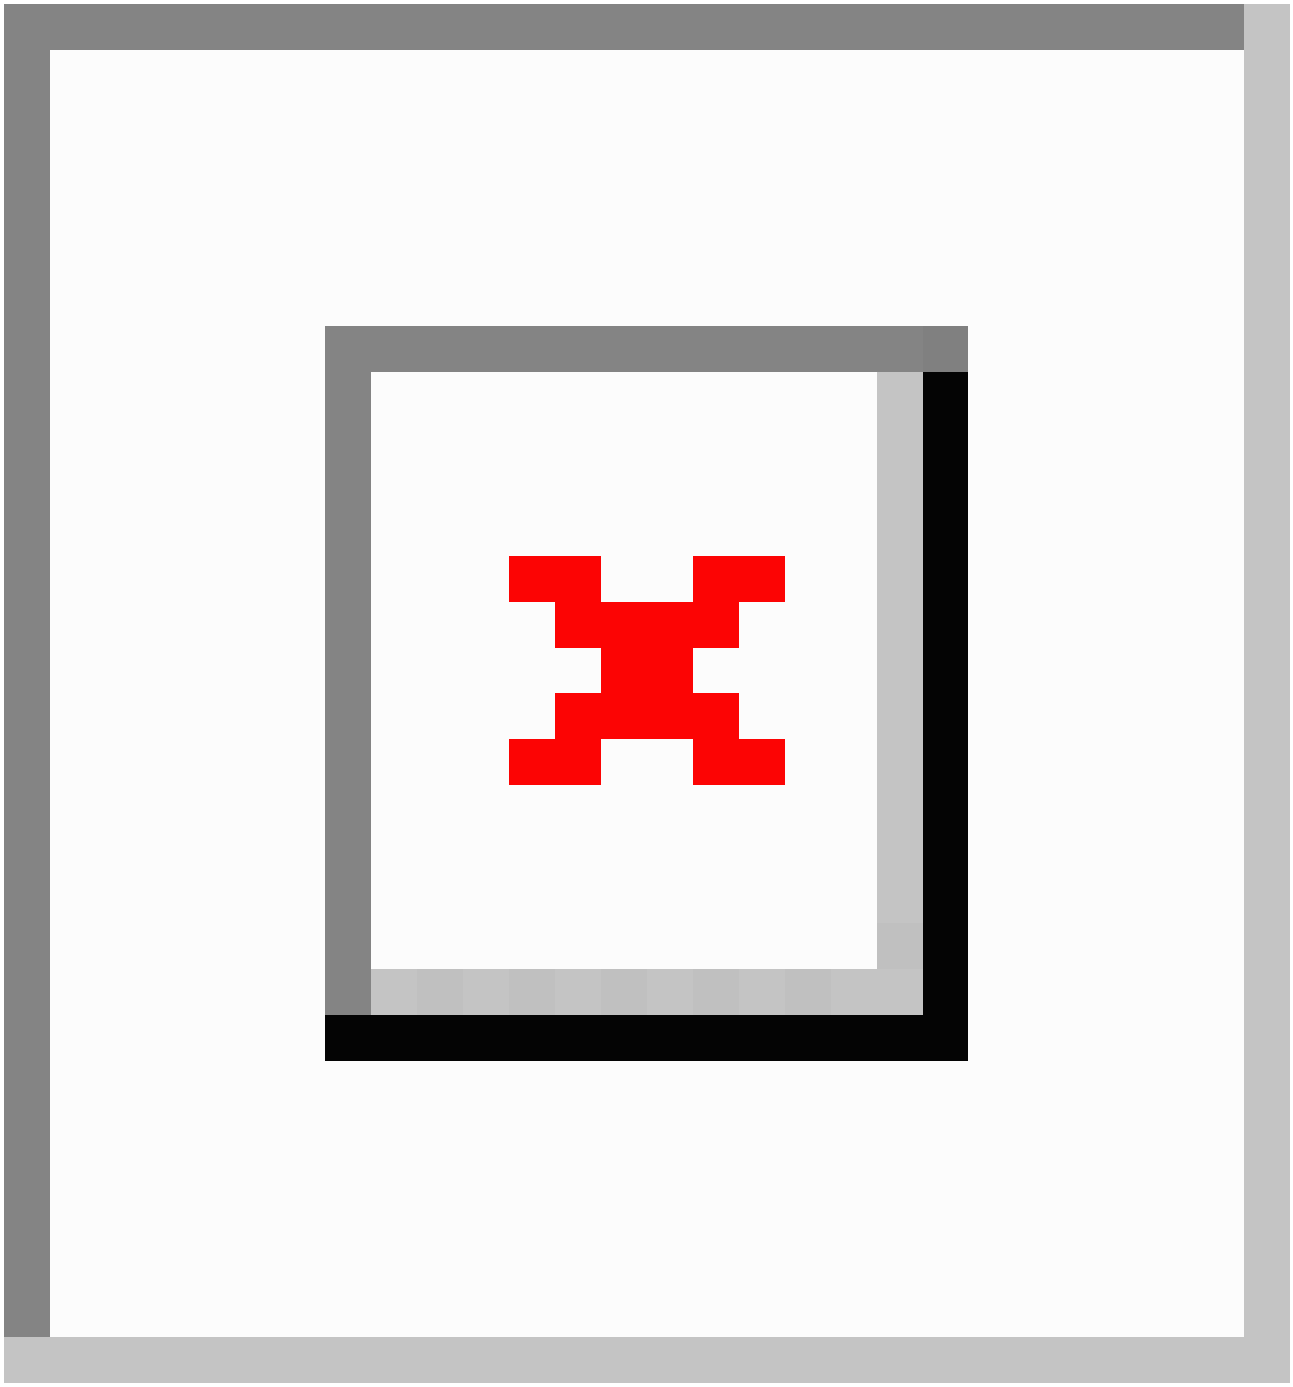
Introduction

Named entity recognition (NER) and term normalization are important steps in biomedical natural language processing (NLP). NER is used to extract key information from textual medical reports, and normalization consists of matching a specific term to its formal reference in a shared terminology such as the United Medical Language System (UMLS) Metathesaurus [1]. Major improvements have been made recently in these areas, particularly for English, as a huge amount of data is available in the literature and resources. Modern automatic language processing relies heavily on pretrained language models, which enable efficient semantic representation of texts. The development of algorithms such as transformers [2,3] has led to significant progress in this field.

In Figure 1, the term “mention level” indicates that the analysis is carried out at the level of a word or small group of words: first at the NER stage (in blue) and then during normalization (in green); finally, all mentions with normalized concept unique identifiers (CUIs) are aggregated at the “document level” (orange part). The sets of aggregated CUIs per document predicted by the native French and translated English approaches are then compared to the manually annotated gold standard.

Figure 1. Overall objective of the method: translating plain text to the CUI codes of the UMLS Metathesaurus, document by document. CHEM: Chemicals & Drugs; CUI: concept unique identifier; DISO: Disorders; PROC: Procedures; UMLS: United Medical Language System.



In many languages other than English, efforts remain to be made to obtain such results, notably due to a much smaller quantity of accessible data [4]. In this context, our work explores the relevance of a translation step for the recognition and normalization of medical concepts in French biomedical documents. We compared 2 methods: (1) a native French approach where only annotated documents and resources in French are used and (2) a translation-based approach where documents are translated into English, in order to take advantage of existing tools and resources for this language that would allow the extraction of concepts mentioned in unpublished French texts without new training data (zero-shot), as proposed in van Mulligen et al [5].

We evaluated and discussed the results on several French biomedical corpora, including a new set of 42 annotated hospitalization reports with 4 entity groups. We evaluated the normalization task at the document level, in order to avoid a cross-language alignment step at evaluation time, which would add a potential level of error and thus make the results more difficult to interpret (see word alignment in Gao and Vogel [6] and Vogel et al [7]). This normalization was carried out by mapping all terms to their CUI in the UMLS Metathesaurus [1]. Figure 1 summarizes these various stages, from the raw French text and the translated English text to the aggregation and comparison of CUIs at the document level. Our code is available on GitHub [8].

The various stages of our algorithms rely heavily on transformers language models [2]. These models currently represent the state of the art for many NLP tasks, such as machine translation, NER, classification, and text normalization (also known as entity binding). Once trained, these models can represent any specific language, such as biomedical or legal. The power of these models comes from their neural architecture but also largely depends on the amount of data they are trained on. In the biomedical field, 2 main types of data are available: public articles (eg PubMed) and clinical electronic medical record databases (eg MIMIC-III [9]), and the most powerful models are, for example, BioBERT [10], which has been trained on the whole of PubMed in English, and ClinicalBERT [11], which has been trained on PubMed and MIMIC-III. In French, the variety of models is less extensive, with CamemBERT [12] and FlauBERT [13] for the general domain and no specific model available for the biomedical domain.

In Figure 2, axis 1 (green axis on the left) corresponds to the native French branch with a NER step based on a FastText model trained from scratch on French clinical notes and a CamemBERT model. A multilingual Bidirectional Encoder Representations From Transformers (BERT) model was then used for the normalization step, with 2 models tested: a deep multilingual normalization model [14] and CODER [15] with the full version. Axes 2.1 and 2.2 (the 2 purple axes on the right) correspond to the translated English branches, with a first translation step performed by the OPUS-MT-FR-EN model [16] for both. Axis 2.1 (left) was conducted with decoupled NER and normalization steps: FastText trained from PubMed and MIMIC-III [17] for NER, and deep multilingual normalization [14] or CODER [15] with the English version for normalization. Axis 2.2 (right) used a single system for the NER and normalization stages: MedCAT [18].

In addition to particularly powerful English-language pretrained models, universal biomedical terminologies (ie, the UMLS Metathesaurus) also contain many more English terms than other languages. For example, the UMLS Metathesaurus [1] contains at least 10 times more English terms than French terms, which may enable rule-based models to perform better in English. As mentioned above, each reference concept in the UMLS Metathesaurus [1] is assigned a CUI, associated with a set of synonyms, possibly in several languages, and a semantic group, such as *Disorders*, *Chemicals & Drugs*, *Procedure*, *Anatomy*, etc.

In parallel, the performance of machine translation has also improved thanks to the same type of transformer-based language models, and recent years have seen the emergence of high-quality machine translations, such as OPUS-MT developed by Tiedemann et al [16], Google Translate, and others. These 2 observations have led several research teams to add a translation step in order to analyze medical texts, for example, to extract relevant mentions in ultrasound reports [19,20] or in the case of the standardization of medical concepts [14,15,21]. Work in the general (nonmedical) domain has also focused on alignment between named entities in parallel bilingual texts [22,23].

Figure 2. Diagram of different experiments comparing French and English language models without and with intermediate translation steps. Methods

Approaches

Overview

Figure 2 shows the main approaches and models used in our study. We explored 1 "native French approach axis" (axis 1 in Figure 2), based on French linguistic models learned from and applied to French annotated data, and 2 "translated English approach axes" (axes 2.1 and 2.2), based on a translation step and concept extraction tools in English. We compared the performance of all axes with the average of the document-level CUI prediction precisions for all documents.

Native French Approach

Axis 1 consisted of 2 stages: a NER stage and a normalization stage. For the NER stage, we used the nested NER algorithm. Next, a normalization step was performed by 2 different algorithms: a deep multilingual normalization model [14] and CODER [15] with the *CODER all* version.

Translated-English Approach

First, axes 2.1 and 2.2 consisted of a translation step, performed by the state-of-the-art OPUS-MT-FR-EN [16] or Google

Translate algorithm. Second, similar to axis 1, axis 2.1 was based on a NER step and a normalization step. The NER step was performed by the same algorithm but trained on the National NLP Clinical Challenges (N2C2) 2019 data set [24] without manual annotation realignment; for the normalization step, we used the same deep multilingual algorithm [14] and the English version of CODER [15] based on a BioBERT model [10]. This axis allows us to compare 2 methods whose difference lies solely in the translation step.

Axis 2.2 was based on the MedCAT [18] algorithm, which performs NER and normalization simultaneously. In this case, we compared the native French method with a state-of-the-art, ready-to-use English system, which is not available in French.

Data Sets

For all our experiments, we chose to focus on 4 semantic groups of the UMLS Metathesaurus [1]: *Chemical & Drugs* ("CHEM"); *Devices* ("DEVI"), corresponding to medical devices such as pacemakers, catheters, etc; *Disorders* ("DISO"), corresponding to all signs, symptoms, results (eg, positive or negative results of biological tests), and diseases; and *Procedures* ("PROC"), corresponding to all diagnostic and therapeutic procedures such as imaging, biological tests, operative procedures, etc, as well as the corresponding number of documents.

Table 1 shows the data sets used for all our experiments and the corresponding number of documents. First, 2 French data sets were used for the final evaluation, as well as for training the axis-1 models. QUAERO is a freely available corpus [25] based on pharmacological notes with 2 subcorpora: MEDLINE (short sentences from PubMed abstracts) and EMEA (drug package inserts). We also annotated a new data set of real-life clinical notes from the Assistance Publique Hôpitaux de Paris data warehouse, described in Section S1 in Multimedia Appendix 1.

Table . Overview of all data sets used. When a data set is used for both training and testing, 80% of the data set is used for training and 20% is used for testing. Thus, for the EMEA data set, 30 documents were used for training and 8 for testing, 34 French notes were used for training and 8 for testing, and so on.

[c]NER: named entity recognition.

Second, we used the N2C2 2019 corpus [24] with annotated CUIs, on which we automatically added semantic group information from the UMLS Metathesaurus [1], to train the axis-2.1 system and evaluate the NER and English normalization algorithms. We also used the Mantra data set [26], a multilingual reference corpus for biomedical concept recognition.

Finally, we refined and tested the translation algorithms on the Workshop on Machine Translation biomedical corpora of 2016 [27] and 2019 [28]. A detailed description of the number of respective entities in the data sets can be found in Table S1 in Multimedia Appendix 1.

The annotation methods for the French corpus are detailed in Section S1 and Figure S1 in Multimedia Appendix 1. The distribution of entities for this annotation is detailed in Table S1 in Multimedia Appendix 1.

Translation

We used and compared 2 main algorithms for the translation step: the OPUS-MT-FR-EN model [16], which we tested without and with *fine-tuning* on the 2 biomedical translation corpora of 2016 and 2019 [27,28], and Google Translate as a comparison model.

NER Algorithm

For this step, we used the algorithm of Wajsbürt [29] described in Gérardin et al [30]. This model is based on the representation of a BERT transformer [3] and calculates the scores of all possible concepts to be predicted in the text. The extracted concepts are delimited by 3 values: start, end, and label. More precisely, the encoding of the text corresponds to the last 4 layers of BERT, FastText integration, and a max-pool Char-CNN [31] representation of the word. The decoding step is then performed by a 3-layer long short-term memory [32] with learning weights [33], similar to the method in Yu et al [34]. A sigmoid function was added to the vertex. Values (start, end, and label) with a score greater than 0.5 were retained for prediction. The loss function was a binary cross-entropy, and we used the Adam optimizer [35].

In our experiments, for the native French axis (axis 1 in Figure 2), the pretrained embeddings used to train the model were based on a FastText model [36], trained from scratch on 5 gigabytes of clinical text, and a CamemBERT-large model [12] *fine-tuned* on this same data set. For English axis 2.1, the pretrained models were BioWordVec [17] and ClinicalBERT [11].

Normalization Algorithms

Overview

This stage of our experiments was essential for comparing a method in native French and one translated into English, and it consisted of matching each mention extracted from the text to its associated CUI in the UMLS Metathesaurus [1]. We compared 3 models for this step, described below: the deep multilingual normalization algorithm developed by Wajsbürt et al [14]; CODER [15]; and the MedCAT [18] model, which performs both NER and normalization.

These 3 models require no training data set other than the UMLS Metathesaurus.

Deep Multilingual Normalization

This algorithm by Wajsbürt et al [14] considers the normalization task as a highly multiclass classification problem with cosine similarity and a softmax function as the last layer. The model is based on contextual integration, using the pretrained multilingual BERT model [3], and works in 2 steps. In the first step, the BERT model is fine-tuned and the French UMLS terms and their corresponding English synonyms are learned. Then, in the second step, the BERT model is frozen and the representation of all English-only terms (ie, those present only in English in the UMLS Metathesaurus [1]) is learned. The same training is used for the native French and translated English approaches. This model was trained with the 2021 version of the UMLS Metathesaurus [1], corresponding to the version used for annotating the French corpus. The model was thus trained on over 4 million concepts corresponding to 2 million CUIs.

CODER

The CODER algorithm [15] was developed by contrastive learning on the basis of the medical knowledge graph of the UMLS Metathesaurus [1], with concept similarities being calculated from the representation of terms and relations in this knowledge graph. Contrastive learning is used to learn embeddings through multisimilarity loss [37]. The authors have developed 2 versions: a multilingual version based on the multilingual BERT [3] and an English version based on the pretrained BioBERT model [10]. We used the multilingual version for axis 1 (native French approach) and the English version for axis 2.1. Both types of this model (*CODER all* and *CODER en*) were trained with the 2020 version of UMLS (publicly available models). *CODER all* [15] was trained on over 4 million concepts corresponding to 2 million CUIs, and *CODER en* was trained on over 3 million terms and 2 million CUIs.

For the deep multilingual model and the CODER model, in order to improve performance in terms of accuracy, we chose to add semantic group information (ie, *Chemical & Drugs*, *Devices*, *Disorders*, and *Procedures*) to the model output: that is, from the first *k* CUIs chosen from a mention, we selected the first from the corresponding group.

The MedCAT algorithm is described in detail in Section S1 in Multimedia Appendix 1.

Ethical Considerations

The study and its experimental protocol were approved by the Assistance Publique Hôpitaux de Paris Scientific and Ethical Committee (IRB00011591, decision CSE 20-0093). Patients were informed that their electronic health record information could be reused after an anonymization process, and those who objected to the reuse of their data were excluded. All methods were applied in accordance with the relevant guidelines (*Commission nationale de l'informatique et des libertés* reference methodology MR-004 [38]).

Results

The sections below present the performance results for each stage. The N2C2 2019 challenge corpus [24] enabled us to evaluate the performance of our English models on clinical data, and the Biomedical Translation 2016 shared task [27] allowed us to evaluate our translation performance on biomedical data with a BLEU score [39].

NER Performances

To be able to compare our approaches in native French and translated English, we used the same NER model, trained and tested on each of the data sets described above. Table 2 shows the corresponding results. Overall F_1-scores were similar across data sets: from 0.72 to 0.77.

Table . Named entity recognition (NER) performance for each model. For all experiments, we used the same NER algorithm but with different pretrained models. The best performance values are italicized.

Groups	Data sets and models

Normalization Performances

This section presents only the normalization performance based on the gold standard's entity mentions, without the intermediate steps. The results are summarized in Table 3. The deep multilingual algorithm performed better for all corpora tested, with an improvement in F_1-score from +0.6 to +0.11. By way of comparison, the winning team of the 2019 N2C2 had achieved an accuracy of 0.85 using the N2C2 data set directly to train their algorithm [24]. In our context of comparing algorithms between 2 languages, the normalization algorithms were not trained on data other than the UMLS Metathesaurus. MedCAT's performance (shown in Table S2 in Multimedia Appendix 1) cannot be directly compared with that of other models, as this method performed both NER and normalization in a single step. However, we note that this algorithm performed as well as axis 2.1 in terms of overall performance, as shown in Table 4.

Table . Performance of the normalization step. Model results were calculated from the annotated data sets, focusing on the 4 semantic groups of interest: *Chemical & Drugs*, *Devices*, *Disorders*, and *Procedures*. The best performance values are italicized.

Algorithms	Data set models

[a]NER: named entity recognition.

Translation Performances

For both translation models, the respective BLEU scores [39] were calculated on the shared 2016 Biomedical Translation Task [27]. The chosen BLEU algorithm was the weighted geometric mean of the n-gram precisions per sentence.

A fine-tuned version of OPUS-MT-FR-EN [16] was also tested on the 2016 and 2019 Biomedical Translation shared tasks. For fine-tuning, we used the following hyperparameters: a maximum sequence length of 128 (mainly for computational memory reasons), a learning rate of 2×10^{-5}, and a weight decay of 0.01, and we varied the number of epochs up to 15 epochs (the error function curve stops decaying after 10 epochs). The Google Translate model could not be used for our clinical score experiments for reasons of confidentiality.

Table 5 presents the BLEU scores for the 3 models, showing that fine-tuning the OPUS-MT-FR-EN model [16] on biomedical data sets gave the best results, with a BLEU score [39] of 0.51. This was the model used to calculate the overall performance of axes 2.1 and 2.2.

Table . Translation performances: BLEU scores of the translation models. The best performance value is italicized.

Models	WMT[a] Biomed 2016 test
Google Translate	0.42
OPUS-MT-FR-EN	0.31
OPUS-MT-FR-EN FT[b]	*0.51*

[a]WMT: Workshop on Machine Translation.

[b]OPUS-MT-FR-EN FT corresponds to the OPUS-MT-FR-EN model [16] *fine-tuned* on biomedical translated corpus from the WMT Biomedical Translation Tasks in 2016 [27] and 2019 [28].

Overall Performances From Raw Text to CUI Predictions

This section presents the overall performance of the 3 axes, in an end-to-end pipeline. For axis 2, the results are those obtained with the best normalization algorithm (presented in Table 3). The model used for translation is the OPUS-MT-FR-EN [16] fine-tuned model. The results are presented in Table 4, with the best results obtained by the native French approach on the EMEA corpus [25] and French clinical notes. The 95% CIs were calculated using the empirical bootstrap method [40].

Discussion

Principal Findings

In this paper, we compared 2 approaches for extracting medical concepts from clinical notes: a French approach based on a French language model and a translated English approach, where we compared 2 state-of-the-art English biomedical language models, after a translation step. The main advantages of our experiment are that it is reproducible and that we were able to analyze the performance of each step of the algorithm: NER, normalization, and translation, and to test several models for each step.

The Quality of the Translation Is Not Sufficient

We showed that the native French approach outperformed the 2 translated English approaches, even with a small French training data set. This analysis confirms that, where possible, an annotated data set improves feature extraction. The evaluation of each intermediate step showed that the performance of each module was similar in French and English. We can therefore conclude that it is rather the translation phase itself that is of insufficient quality to allow the use of English as a proxy without a loss of performance. This is confirmed by the translation performance calculations, where the calculated BLEU scores were relatively low, although improved by a fine-tuning step.

In conclusion, although translation is commonly used for entity extraction or term normalization in languages other than English

[5,20,41-43], due to the availability of turnkey models that do not require additional annotation by a clinician, we showed that this induces a significant performance loss.

Commercial application programming interface–based translation services could not be used for our task due to data confidentiality issues. However, the OPUS-MT model is considered state of the art, it is adjustable to domain-specific data, and the translation results presented in Table 5 confirm the absence of performance difference between this model and the Google Translate model.

Although our experiments were carried out on a single language, the French-English pair is one of the best performers in recent translation benchmarks [16]. Other languages are unlikely to produce significantly better results.

Error Analysis

In these experiments, the overall results may appear low, but the task is still complex, especially because the UMLS Metathesaurus [1] contains many synonyms with different CUIs. To better understand this, we performed an error analysis on the normalization task only, as shown in Table S3 in Multimedia Appendix 1, with a physician's evaluation, on a sample of 100 errors for both models. We calculated that 24% (24/100) and 39% (39/100) of the terms found by the deep normalization algorithm [14] and CODER [15], respectively, were in fact synonyms but had 2 different UMLS CUIs. This highlights the difficulty of achieving normalization on the UMLS Metathesaurus. The UMLS Metathesaurus indeed groups together numerous terminologies whose mapping between terms is often imperfect, implying that certain synonyms, as shown here, do not have the same CUI, as pointed out by Cimino [44] and Jiménez-Ruiz et al [45]. For example, "cardiac ultrasound" has the CUI of C1655737, whereas "echocardiography" has another CUI of C0013516; similarly, "H/O: thromboembolism" has a CUI of C0455533, whereas "history of thromboembolism" has a CUI of C1997787, and so on.

Moreover, to be more precise, each axis had its own errors: overall, the errors in axis 2 were essentially due to the loss of information in translation. One notable error was literal translation: for example, "dispersed lupus erythematous" instead of "systemic lupus erythematosus," or "crepitant" instead of "crackles." This loss of translation led to more errors in the extraction of named entities.

In addition to the loss of translation information, axis 2.1 was also penalized by the NER step, due to the difference between the training set (N2C2 notes) and the test set (the translated French notes; the aim being to compare the performance of English-language turnkey models with the performance of French-language models from an annotated set). Axis 2.1, for example, omitted the names of certain drugs more often.

Finally, both axes were penalized by abbreviations. These were often badly translated (for example, the abbreviation "MFIU" for "mort foetale in utero," meaning "intrauterine fetal death," was not translated), which penalized axis 2. Nevertheless, if they were indeed extracted by NER steps in axis 1, they were not correctly normalized due to the absence of a corresponding CUI in the UMLS Metathesaurus.

Limitations

This work has several limitations. First, the actual French clinical notes contained very few terms in the *Devices* semantic group, which prevented the NER algorithm from finding them in the test data set. However, this drawback, which penalized the native French approach, still allowed us to draw a conclusion for the results. Furthermore, in this study, we did not take into account attributes of the extracted terms such as negation, hypothetical attribute, or belonging to a person other than the patient for comparison purposes, as the QUAERO [25] and N2C2 2019 [24] data sets did not have this labeled information.

Acknowledgments

The authors would like to thank the Assistance Publique Hôpitaux de Paris (AP-HP) data warehouse, which provided the data and the computing power to carry out this study under good conditions. We wish to thank all the medical colleges, including internal medicine, rheumatology, dermatology, nephrology, pneumology, hepato-gastroenterology, hematology, endocrinology, gynecology, infectiology, cardiology, oncology, emergency, and intensive care units, that gave their permission for the use of the clinical data.

Data Availability

The data sets analyzed as part of this study are not accessible to the public due to the confidentiality of data from patient files, even after deidentification. However, access to raw data from the Assistance Publique Hôpitaux de Paris (AP-HP) data warehouse can be granted by following the procedure described on its website [46]: by contacting the ethical and scientific committee at secretariat.cse@aphp.fr. Prior validation of access by the local institutional review committee is required. In the case of non-APHP researchers, a collaboration contract must also be signed.

Authors' Contributions

CG contributed to conceptualization, data curation, formal analysis, investigation, methodology, software, validation, original drafting, writing—original version, and writing—revision and editing the manuscript. Abstract

Background: Physicians are hesitant to forgo the opportunity of entering unstructured clinical notes for structured data entry in electronic health records. Does free text increase informational value in comparison with structured data?

Objective: This study aims to compare information from unstructured text-based chief complaints harvested and processed by a natural language processing (NLP) algorithm with clinician-entered structured diagnoses in terms of their potential utility for automated improvement of patient workflows.

Methods: Electronic health records of 293,298 patient visits at the emergency department of a Swiss university hospital from January 2014 to October 2021 were analyzed. Using emergency department overcrowding as a case in point, we compared supervised NLP-based keyword dictionaries of symptom clusters from unstructured clinical notes and clinician-entered chief complaints from a structured drop-down menu with the following 2 outcomes: hospitalization and high Emergency Severity Index (ESI) score.

Results: Of 12 symptom clusters, the NLP cluster was substantial in predicting hospitalization in 11 (92%) clusters; 8 (67%) clusters remained significant even after controlling for the cluster of clinician-determined chief complaints in the model. All 12 NLP symptom clusters were significant in predicting a low ESI score, of which 9 (75%) remained significant when controlling for clinician-determined chief complaints. The correlation between NLP clusters and chief complaints was low (r=−0.04 to 0.6), indicating complementarity of information.

Conclusions: The NLP-derived features and clinicians' knowledge were complementary in explaining patient outcome heterogeneity. They can provide an efficient approach to patient flow management, for example, in an emergency medicine setting. We further demonstrated the feasibility of creating extensive and precise keyword dictionaries with NLP by medical experts without requiring programming knowledge. Using the dictionary, we could classify short and unstructured clinical texts into diagnostic categories defined by the clinician.

KEYWORDS

electronic health records; free text; natural language processing; NLP; artificial intelligence; AI

Introduction

Organizational challenges, such as overcrowding in emergency departments (EDs), directly impact patient outcomes. The digitization of health records offers an opportunity to integrate artificial intelligence (AI) into patient management. However, health care workers often prefer to write unstructured text rather than entering structured data [1,2]. This raises the question of how future electronic health records (EHRs) should be designed: what additional value does free text provide?

We propose adding an additional dimension alongside the classic predictive task performed with text—inference to infer characteristics from text entries. Most studies using text analysis with patient records show promising results in predicting patient outcomes, such as in-hospital mortality, unplanned re-admission after 30 days, and prolonged length of hospital stay [3,4]. The benefits of unstructured text in EHRs for the improvement of prediction models have been demonstrated, as underscored by the extensive review by Seinen et al [5]. Indeed, 20% of the trials that were reported were conducted within a hospital ED environment. However, the analysis of the reported studies focused on demonstrating an improvement in predicting clinical outcomes, such as death or rehospitalization. We extend this approach by using the text not primarily to predict outcomes but to explain the correlation of patient subgroups with clinical outcomes. For instance, we show if certain symptoms documented in the ED triage are associated with a higher probability of an inpatient stay. Our results indicate that the information captured by clinical text-based notes is complementary to traditional structured data and can provide clinicians with valuable information about patients.

Overcrowding in the ED is an important case in point where AI supporting the optimization of patient workflows may substantially improve outcomes. It is a recognized challenge facing many EDs worldwide [6,7], adversely impacting patient outcomes [8]. These negative effects are evident during ED resource overload, such as during the COVID-19 pandemic [9]. More recently, senior public health officials in England have attributed up to 500 excess deaths per week during the recent winter months to delays caused by National Health Service capacity constraints [10,11]. Therefore, electronically enabled targeted patient selection could help speed up triage and reduce ED overcrowding. However, the optimal structure of EHRs remains controversial, particularly because clinicians tend to prefer the flexibility of entering unstructured text to structured data entry [12].

By comparing data extracted from 2 fields—1 derived from a structured drop-down menu indicating leading symptoms for ED admission and the other containing unstructured text—we can demonstrate that free text contains additional information beyond structured data and that these 2 types of data complement each other. With our semisupervised topic allocation method, we demonstrate the ability to capture more comprehensive information about a patient's symptom cluster compared with relying solely on a manually attributed single chief complaint. Moreover, we present a transparent approach for extracting topics from short clinical texts based on natural language processing (NLP)–supported annotated clinical libraries, which can be fed into predictive models. In addition to being transparent, our method is language independent and easy to implement for clinical researchers (although the dictionaries we constructed are in German, researchers can easily use our method to construct their own topic dictionaries in any language).

Our approach is based on constructing a dictionary with keywords that define a topic. In contrast to dictionary approaches, unsupervised topic models, such as the latent Dirichlet allocation [13], are often used. However, finding topics in short-text samples using these models is challenging [14]. Moreover, unsupervised models might not capture topics that are of interest to the researcher because these models differentiate between topics based on their statistical difference. For instance, it could be that latent Dirichlet allocation defines topics based on words about the age and gender of the patients because these are the most distinctive features. However, the researcher may be interested in the diagnosis, which is more challenging to classify.

In contrast, supervised machine learning methods require creating a manually classified training data set. The algorithm learns how to classify future data into topics based on the training set. When dealing with a high volume of topics, both human classification and the algorithm's training run the risk of creating noise. Similarly, regression approaches for supervised classifications are not suitable for many topics. Therefore, we chose a dictionary approach based on keywords. To facilitate the selection of the keywords, we developed a preselection of words based on a measure of their semantic similarity. As our presorting of words uses word embeddings, we consider our approach as a hybrid between dictionary- and machine learning–based approaches [15].

Our approach, combined with clinical notes, allow us to address 2 questions:

- What additional information does the free text provide on the patient being admitted compared with the suspected diagnosis from the drop-down menu?
- Could this additional information be useful for clinical or organizational purposes?

Methods

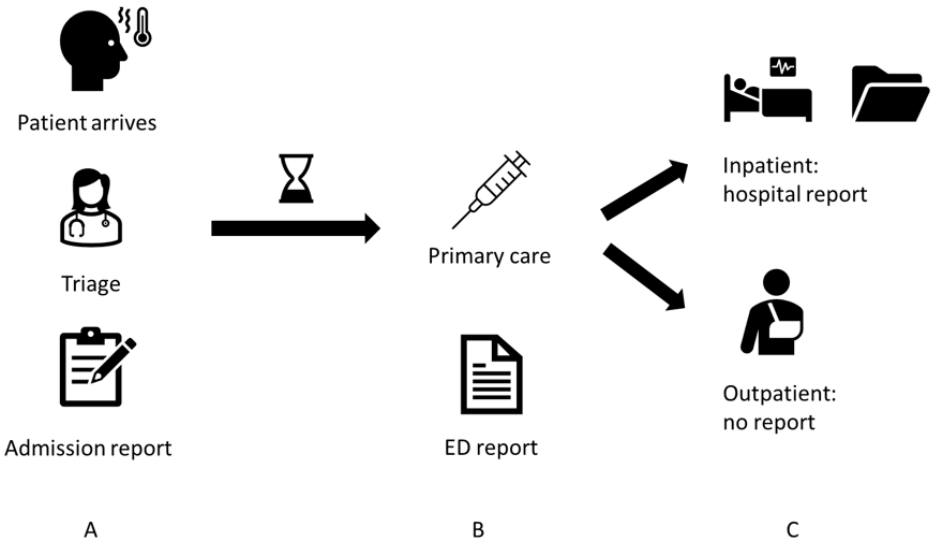
Data

We used data from the ED's admission report. Figure 1 provides a contextual representation of this data type in relation to patient flow and other documents associated with patients. In step 1, patients present themselves at the ED and are admitted in the system. A medical professional conducts the triage by quickly assessing the main symptoms and their severity using the Emergency Severity Index (ESI) score, resulting in an admission report. This report is for the internal patient management within the ED and contains basic patient information (age, gender, and so on) along with the chief complaints and symptoms.

After a waiting time (which depends on the triage score), the patient receives primary care from a medical professional, which

is documented in the ED report. The ED report summarizes the patient's entire stay at the ED and is issued at the end of the patient care from the ED. In the third step, the patient is either discharged into ambulatory care (which does not create any further documents) or is transferred to inpatient care, which results in the classic medical records.

Figure 1. Patient flow in emergency department (ED) and associated reports.



For our analysis, we used the first type of document: the internal ED admission report. Unlike the other types of documents, this report is issued before treatment and provides an opportunity to manage patient flow. Although the ED report from step 2 could also be used for inpatient management, this proves challenging in practice because inpatient care is very heterogeneous and depends on many factors, including different organizational structures in every hospital department. In contrast, the ED admission reports can be used for homogeneous organization within the ED.

Our initial data set contained 293,298 patient visits to the ED of the University Hospital of Zurich, Switzerland, from January 1, 2014, to October 31, 2021 (in German; received in the Excel [Microsoft Corporation] format). For each visit, the data set includes a short text from the triage with the patient's symptoms, along with our 2 outcomes of interest (triage score "ESI," which we further explain below, and type of discharge), basic patient characteristics (patient visit pseudo ID, age, gender, admission type [self, ambulance, or police], and admission reason [accident or illness]), ED organizational variables (average number of patients in ED; average patient waiting time; night, late, or early shift; and treating ED team [internal medicine, surgery, neurology, neurosurgery, or psychiatry]), and the visit's time stamp. The summary statistics of these variables are presented in Table 1.

After excluding cases with no records in the string variable "suspected diagnosis" on admission on which NLP analysis was to be performed, the data set comprised 256,329 (87.4%) of the initial data set of 293,298 patient visits. We only used 2019 to 2021 for comparison as these visits had a recorded chief complaint, reducing the data set to the final sample of 52,222 patient visits. Patients directly admitted to the shock room (ie, ESI score=1) were not considered in our analysis, as no additional triage was performed upon admission. The data structure of our analysis is summarized in Figure 2, and the recorded variables are presented in Textbox 1.

The ESI is an internationally established 5-level triage algorithm widely used in EDs and is based on the acuity as well as the resource intensity of anticipated emergency care, with level 1 denoting acute life-threatening conditions, such as massive trauma warranting immediate, life-saving care, and level 5 denoting non–time-critical conditions of low complexity [13]. Cases triaged as ESI 4 or 5 (approximately 16% of patients) are usually fast-tracked to specialized treatment rooms because the medical resources required to treat these patients are low, and thus, they can be managed in parallel by a dedicated team, which reduces ED congestion. ESI 2 or 3 typically require a more thorough workup. Hence, for the outcome variable "low ESI," we decided to set the cutoff at ESI<4, that is, patients with "low ESI" had been triaged with a score of 2 or 3. Furthermore, the data set included free-text fields (strings), namely, the suspected diagnosis at admission and the diagnosis at discharge.

In the admission process, the clinician performing triage records the patient's symptoms in written form in 2 to 3 sentences. The purpose of this free text is to preregister the patient in the ED and enable all team members to become aware of the impending clinical problems. To our knowledge, all the larger EDs in German-speaking countries with full EHR note the reason for admission in the form of a short, unstructured text upon notification of a pending ED admission.

From May 28, 2019, onward, the symptoms were additionally recorded as so-called chief complaints from a drop-down menu (ordinal variable). The difference between the free text and the chief complaint was that the chief complaint was a fixed category selected from a drop-down menu and was primarily intended to serve administrative and statistical purposes, that is, to allow for post hoc analysis of the patient composition of the ED.

During the entire study period, the list of chief complaints (n=99) varied over time or contained doublets, which we grouped into 58 symptom topics. For patient visits with a

selected chief complaint from the drop-down option "Diverse," it was unclear if a leading symptom had been attributed at triage; hence, we did not include them in the list of chief complaints (referred to as lead symptoms [LS]). Furthermore, we grouped 5 chief complaints with very low occurrences, such as "drowning accident" or "flu vaccine," into our class "diverse." However, we did not use this group in further analysis because of the heterogeneity of the symptoms included. The lead symptom topics were then aggregated into 12 clusters by the authors according to clinical judgment. The complete list of LS can be found in Table S1 in Multimedia Appendix 1.

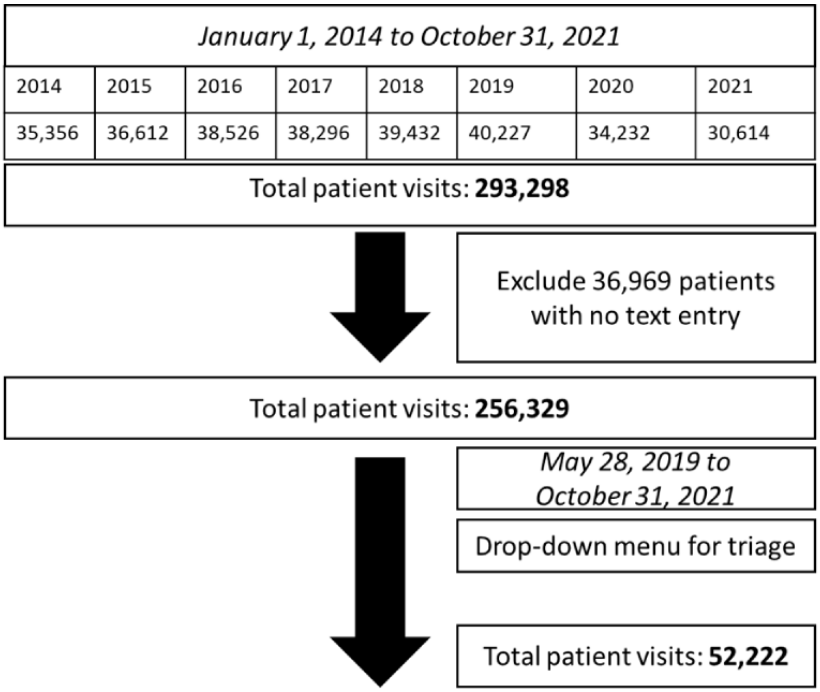
A total of 65 variables from 2014 to 2018 and 69 variables from 2019 to 2021 (including the chief complaint) were recorded in the initial data set. A total of 65 variables from 2014 to 2018 were constant throughout 2014 to 2021 and were retained for preprocessing. The final data table used for the analysis contained the variables listed in Table 1, in addition to the patient ID, year and weekday of the consultation derived from the admission time stamp, the treating ED team (internal medicine, surgery, neurology, or psychiatry), as well as the LS clusters from the drop-down menu and the NLP-extracted topic clusters that were obtained from the field "suspected diagnoses," discussed in detail in *Analysis: Topic Allocation* section. In addition, the table contained the outcomes "inpatient" and "ESI score<4" as binary variables. Two further outcomes were considered, namely, readmission within 30 days and waiting time>30 minutes, but were discarded owing to doubts regarding the quality and consistency of the entered data. We retained the outcomes "inpatient" and "ESI score<4" owing to their direct association with the immediacy of the outcome in the patient pathway within the ED, ensuring robust data quality.

Table 1. Summary statistics of the patient population (n=52,222)[a].

Variable	Values
Age (y), mean (SD)	46.5 (19.7)
Female, n (%)	23,782 (45.54)
Emergency Severity Index score (out of 5), mean (SD)	3.3 (0.6)
Fast track, n (%)	8264 (15.82)
Number of patients in the emergency department, mean (SD)	19.8 (8.3)
Early shift, n (%)	21,644 (41.45)
With emergency medical service, n (%)	9020 (17.27)
With police, n (%)	188 (0.36)
Accident, n (%)	16,845 (32.26)
Inpatient, n (%)	14,112 (27.02)
Night shift, n (%)	7915 (15.16)
Late shift, n (%)	22,663 (43.4)

[a]The total sample contains patient visits for the period from May 28, 2019, to October 31, 2021.

Figure 2. Data structure.



Textbox 1. Variables recorded for our analysis.

Triage

- Suspected diagnosis (free text) and Emergency Severity Index score

Type of discharge

- Hospitalization, ambulatory treatment, or patient has run away

Patient characteristics

- Patient visit pseudo ID, age, gender, admission type (self, ambulance, or police), and admission reason (accident or illness)

Organizational

- Average number of patients in emergency department (ED); average patient waiting time; night, late, or early shift; and treating ED team (internal medicine, surgery, neurology, or psychiatry)

Time

- Time stamp

Analysis: Topic Allocation

We selected the field "suspected diagnosis" to extract the symptoms or complaints that led to ED admission according to the oral report received by the ED physician in charge, as mentioned previously. This field comprises a short-text string entered by the ED physician upon receiving information about the patient's expected arrival at the ED. This information can be transmitted to the ED physician by a referring physician or ambulance well in advance of a patient's arrival. The text is entered before the patient triage is performed by the triage ED nurse. As a clinical note, the physician's text entry is part of the EHR. The information contained in the string "suspected diagnoses" is supposed to be similar to the selected chief complaint from the drop-down menu "lead symptom." Indeed, the latter variable was added later (in 2019) to facilitate the administrative analysis of causes for ED admission, as an analysis using unstructured text was not possible by the hospital administration. Both fields are supposed to contain the medical reason, or chief complaint, leading to ED admission.

We constructed a measure of the semantic distance of all words in the corpus by training a word embedding. Word embeddings are matrices in which each column represents a word and its relative distance to other words (eg, the distance between blood and red is smaller than that between blood and green). Hence, it is possible to find the most similar words for a given keyword using the smallest distance measured with the cosine similarity. To train the word embedding, we used word2vec with the entire text corpus and the continuous bag-of-words algorithm from the Python library Gensim [16], with an embedding size of 300 computed with 100 epochs.

To construct our topic dictionaries, we proceeded in 4 steps, as shown in Figure 3. First, we manually defined topics and selected between 2 and 20 initial seed words (henceforth "keywords") by reading some of the texts and using prior medical knowledge. A smaller number of keywords were used for the design of the topic "infection" (n=1). A larger number of initial keywords were used for the design of the topics "intoxication" (n=40) and "skin" (n=28). In step 2, we then searched for up to 50 of the semantically closest words for each initial list. With the help of the word embedding, it is possible to search for the words that maximize the cosine similarity for the seed keywords. In addition, we only considered keywords that occurred at least 10 times. This list of similar words allowed us to efficiently increase the dictionary for each topic. In step 3, we manually chose words from the preselection of similar words to the seed word, resulting in a separate dictionary per topic (step 4). In some instances, the dictionary used combinations of words. For instance, the topic "chest pain" was allocated to combinations of words such as "pain" or "pressure" with the words "chest" or "thorax."

This table presents the distribution of the diagnosis topics obtained with the NLP-based text annotation before and after the spherical feature annotation. The total number of cases was 52,222, and 20.38% could not be attributed with a diagnosis topic.

The summary of the increase in tags per topic cluster through the NLP-based expansion of our topics library is presented in Table 2. The first column shows the percentage of the sample tagged with a topic using the original keyword approach. The proportion of clinical topics ranged from 0.72% for COVID-19 to 31.6% for trauma-related visits. It should be noted that patient visits can be allocated with multiple topics. The next column shows the share of visits with the spherically increased dictionary, with the percentage increase in topic shares in the last column. Overall, the spherical dictionary enhancement decreased the number of nontagged visits by nearly 25%, from 27.08% of the sample to 20.24%. For the individual topics, the additional keywords increased their share, ranging from 5.29% for trauma to 286.35% for general administrative visits.

In the second procedure, we automatically increased the number of keywords for each topic dictionary. This process is shown in Figure 4, which can be imagined as constructing a multidimensional sphere using the initial keywords. The additional keywords were then located within that sphere.

The "spherical" dictionary enhancement consists of the following steps:

- Compute all distances between the keywords and retain the largest distance (ie, the distance between the 2 least similar words). For each keyword, this distance is the radius of a circle in the embedding space (steps 1 and 2).
- For each of the initial keywords, identify the n-closest words (not in the topic dictionary) using the cosine similarity (step 3).
- Retain these additional words if their distance to all other initial keywords is smaller than the maximum distance computed in the first step, that is, if the new words are in the intersection of all circles (step 4).

Using the abovementioned approach, we could tag 79.76% (41,653/52,222) of the final sample. The remaining texts could not be tagged because they either belonged to small topics that we did not define or because these texts did not contain words that are present in the dictionary.

Once the dictionaries for each topic are constructed, they can be used for additional patient visits and for similar data sets, which makes the approach easily scalable.

Figure 3. Topic dictionaries with semimanual keyword selection. (A) The researcher selects an initial seed word for a topic. (B) Using word embeddings, a list of semantically similar words from the corpus is generated. (C) The researcher manually selects words that are associated with the topic. (D) The topic dictionary is created.

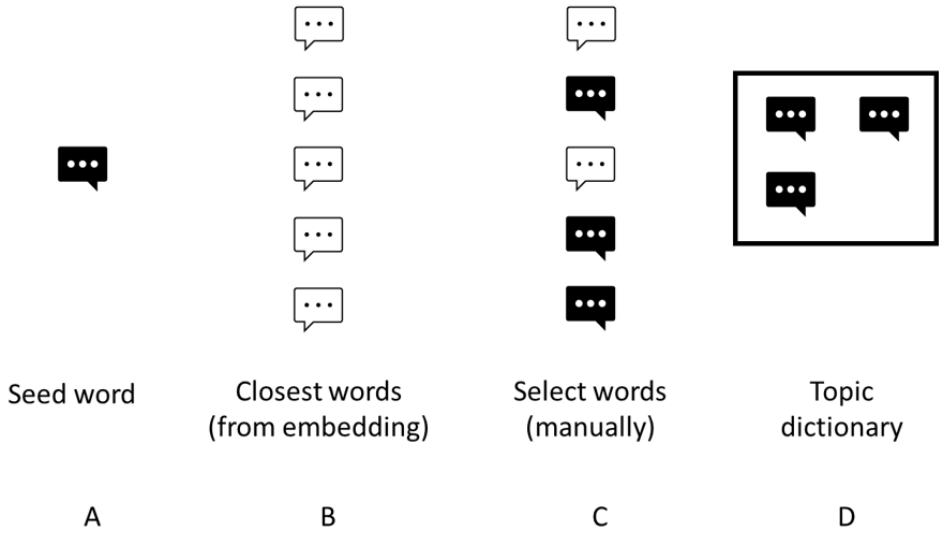


Table 2. Spherical feature annotation and increase in topic share (n=52,222)[a].

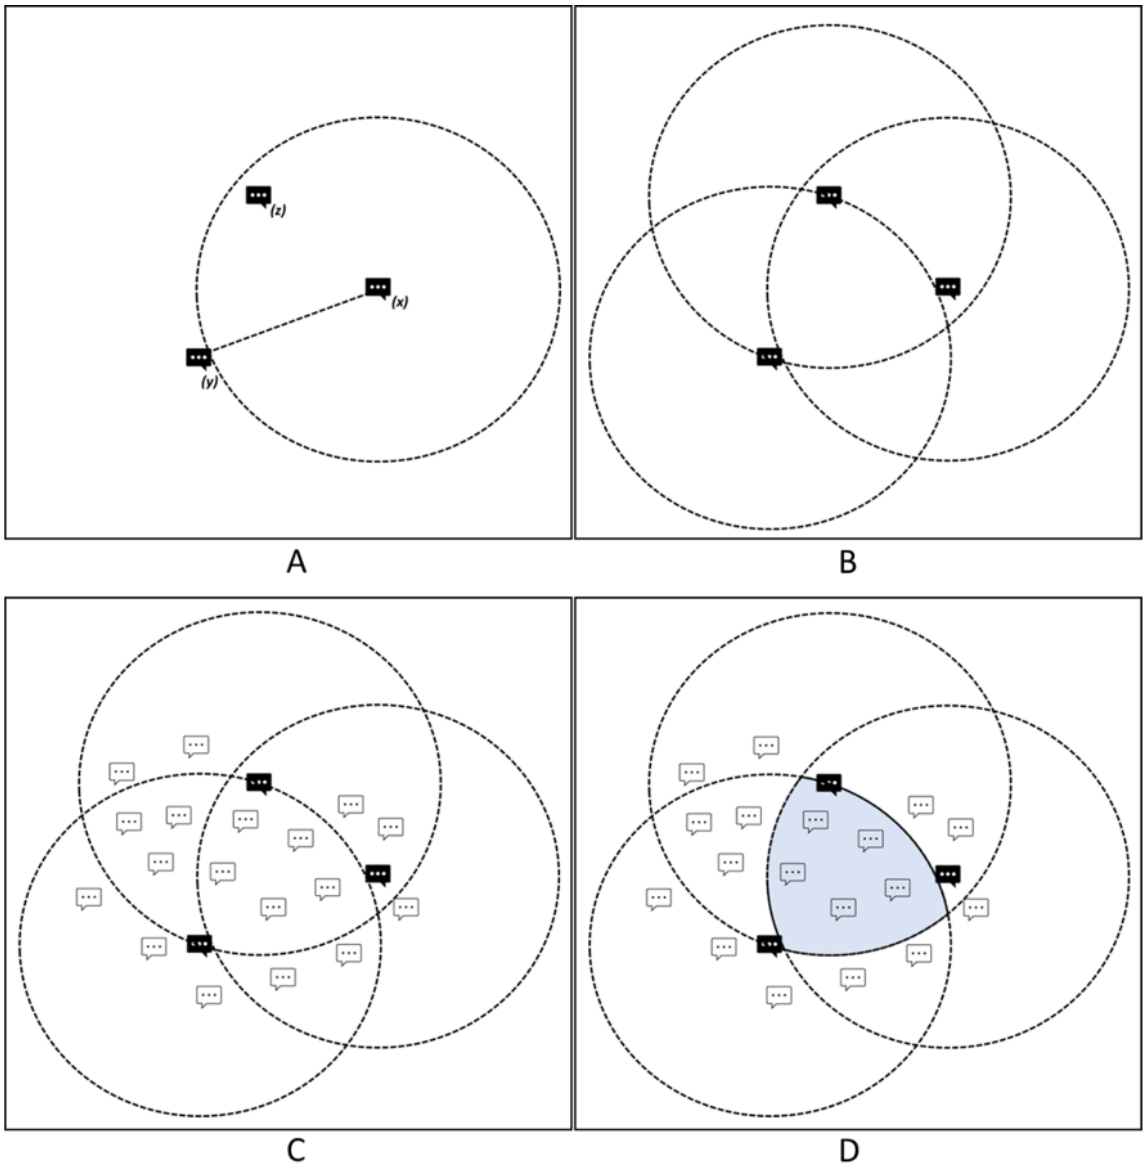
Clinical topic NLP[b]	Records tagged initially, n (%)	Records tagged NLP-augmented, n (%)	Increase in tagged patient records, n (%)[c]
COVID-19	375 (0.72)	405 (0.78)	30 (8)
General symptom	6401 (12.26)	6867 (13.15)	466 (7.28)
General administration	315 (0.6)	1217 (2.33)	902 (286.35)
Systemic clinical	3219 (6.16)	3519 (6.74)	300 (9.32)
Gastrointestinal	3421 (6.55)	4159 (7.96)	738 (21.57)
Respiratory	4040 (6.55)	4159 (7.96)	738 (21.57)
Cardiovascular	2683 (5.14)	5219 (9.99)	2536 (94.52)
Neurological	414 (7.93)	4485 (8.59)	345 (8.33)
Eye; ear, nose, and throat; and derma	1818 (3.48)	2061 (3.95)	243 (13.37)
Gynecology and urology	2712 (5.19)	3004 (5.75)	292 (10.77)
Trauma	16,516 (31.63)	17,389 (33.3)	873 (5.29)
General psychiatric	1989 (3.81)	2627 (5.03)	638 (32.08)
No tag	14,141 (27.08)	10,569 (20.24)	–3572 (–25.26)

[a]This table presents the distribution of the diagnosis topics obtained with the NLP-based text annotation before and after the spherical feature annotation.

[b]NLP: natural language processing.

[c]Percent of initially recorded tags.

Figure 4. Spherical dictionary enhancement. (A) Step A uses the largest distance between 2 words that are already in the topic. The circle around the word (x) shows the region in the embedding space with words closer to (x) than the maximum distance. (B) The same region is circled around the other 2 words (y) and (z). (C) The other words in the embedding space that were initially not included in the topic. (D) The intersection of the 3 circles defines the area in the embedding space where the distance of each word is smaller than the maximum distance.



Ethical Considerations

A waiver from the cantonal ethics committee was obtained before the commencement of this study (BASEC-Nr. Req-2019-00671).

Results

In the first step, we performed a descriptive analysis of the topics. To this end, we first excluded cases without a manually selected LS for further analysis and obtained a data set with 52,222 entries. Of the 52,222 patient visits included in our final analysis, 5994 (11.48%) had a manually recorded chief complaint that was not otherwise specified (eg, “Diverse”) and could not be classified as a symptom Of the 52,222 entries, 10,569 (20.24%) were not tagged with an NLP topic.

The distribution of all NLP topics is shown in Table 3. The distribution ranged from 0.05% of patient visits tagged with the NLP topic “dementia” to 9.89% for “wound.” The largest cluster of aggregated NLP symptom-related topics was “trauma,” with 33.1% of visits, and the smallest was “COVID,” with 0.8% of visits. The distribution of chief complaints can be found in Table S1 in Multimedia Appendix 1. In total, the distribution ranged from 0.01% of patient visits for the recorded chief complaints “melaena,” “hearing problems,” and “contact with chemicals” to 14.6% for “COVID.” The largest cluster of aggregated chief complaints was “trauma” with 23.6% and the smallest was “general organizational” with 1.2% of visits.

For comparability, we grouped all LS and NLP topics into 12 identical symptom clusters, which can be found in Table 4.

Table 3. Clusters for natural language processing–extracted topics (n=52,222)[a].

Cluster and subcluster detail	Values, n (%)
COVID-19	401 (0.77)
General symptoms	6852 (13.12)
Fever	2440 (4.67)
Pain	4505 (8.63)

Trauma	12,337	17,302	0.54	0.79
General psychiatric	1610	2625	0.60	0.78
No tag	5994	10,644	0.07	0.28

[a]This table presents the number of tagged cases for each chief cluster with both the natural language processing–based method and based on the chief complaint tag.

[b]LS: lead symptom.

[c]NLP: natural language processing.

[d]Correlation between LS and NLP.

[e]The number of overlapping LS and NLP tags divided by the total number of LS tags.

In addition to the NLP symptom-related topics, 4 modulating NLP topics, “acute,” “chronic,” “nonsevere,” and “severe,” were recorded, also based on keywords (ie, words in the text indicating severity). The purpose of the modulating topics is to provide more information on severity and control for this dimension in the further analysis.

We found that the correlation between LS clusters and NLP clusters was low (Table 4). Similarly, consistency varies relative to the LS. We also calculated the consistency of the NLP tags relative to the LS groups (the LS groups are the denominator; being more established, we use them as a benchmark). For most clusters, the consistency is approximately 50%, with trauma and psychiatric diagnosis having the highest consistency of 78% and 79%, respectively, and general administration and COVID-19 having the lowest consistency of 4% and 5%, respectively.

Compared with the LS clusters, our NLP topics have the advantage that a patient visit can be tagged to multiple topics. Table S2 in Multimedia Appendix 1 shows the number of NLP topics for each LS cluster. Of the 46,228 patient visits where we could assign a manually recorded chief complaint, 8950 (19.36%) were not tagged with an NLP topic. In contrast, 33.48% (15,477/46,228) of the visits were tagged with at least 2 NLP topics.

We estimated 3 models using logistic regression to show the association of the different symptom groups with the ESI and inpatient indicators:

$$\text{Model 1: } Y_i = \alpha + \beta X_i + \gamma Z_i + \varepsilon_i \textbf{ (1)}$$

$$\text{Model 2: } Y_i = \alpha + \beta X_i + \delta W_i + \varepsilon_i \textbf{ (2)}$$

$$\text{Model 3: } Y_i = \alpha + \beta X_i + \gamma Z_i + \delta W_i + \varepsilon_i \textbf{ (3)}$$

where Y_i is either the ESI or inpatient indicator variable for patient visit i, α the intercept, X_i is a vector of demographic and organizational variables for patient visit I (age; gender; admission type; admission reason; average number of patients in ED; average patient waiting time; night, late, or early shift; and treating ED team), Z_i is a vector of the NLP-derived symptom clusters, W_i is a vector of the lead symptom–derived cluster (based on the drop-down menu), and ε_i is the error term.

Tables 5 and 6 present the results. Column 1 shows the NLP-derived groups, with coefficients ranging between 5% and 13% increased or decreased probability of a high ESI score or 5% to 19% increased or decreased probability for hospitalization. The drop-down–based LS in column 2 has similar but slightly larger coefficients. Column 3 shows both variables, as in model 3, in this specification, the coefficients are mostly complementary, meaning that if a patient shows the same symptom in both the NLP and LS measures, the probabilities can be added. Note that this is not owing to multicollinearity because both coefficients remain significant in most cases.

Table 5. Linear probability model on "Inpatient"[a].

[j]P<.10.

Of the 12 symptom clusters, 11 (92%) in column 1 had a significant regression coefficient for hospitalization (all but "general organizational"). Eight clusters remained significant even when including the cluster of clinician-determined chief complaints in the model. In the model explaining "inpatient," in 10 (83%) out of the 12 symptom cluster pairs, the coefficients of the NLP topic clusters showed the same algebraic sign as the chief complaint clusters. In contrast, for 2 symptom cluster pairs, they did not ("general symptoms" and "trauma"). A change in the algebraic sign of either the chief complaint cluster

or the NLP topics cluster occurred in 4 cluster pairs when both NLP topics and chief complaints were included in the model ("COVID," "general symptoms," "general organizational," and "respiratory"). We obtained similar results when analyzing the low ESI scores. However, a change in the algebraic sign of a coefficient within solely 1 pair of symptom clusters was noted ("trauma"). Interestingly, the clusters "cardiovascular," "neurological," and "trauma" were significantly associated with nonhospitalization, of which "neurological" and "trauma" but not "cardiovascular" were also significantly associated with a lower ESI score.

As a robustness check, we used each of the 3 model specifications to predict the ESI indicator and the inpatient indicator. Using the respective sets of variables of each specification, we used a logistic regression with a 2:1 train-test split to predict both outcomes. Table 7 shows the F_1-score and area under the curve (AUC) score of these predictions. The results show that the 3 specifications have similar predictive power (an AUC of 0.82-0.84 for "inpatient" and an AUC of 0.90-0.92 for ESI indicator).

The inference and prediction results show that the added value of text in this setting is not by increasing the predictive power of the model, where the outcomes are existing process outcomes (eg, discharge type of severity). Instead, unstructured text allows clinicians to access more granular information to optimize patient flows, which cannot be reflected in the inpatient and ESI indicator outcomes.

In a more granular analysis, we estimated models 1 to 3 with the individual NLP topics and the individual LS groups instead of the clusters previously used. The analysis corroborated our clinical presumptions that, for example, age, admission by an ambulance, and "sepsis" as an NLP topic, as well as "chest pain" for a chief complaint, were associated with low ESI scores (2 or 3) or hospital admission. In contrast, the NLP topic or chief complaint cluster "follow-up" was not. The complete results are provided in Tables S3-S6 in Multimedia Appendix 1.

Table 7. Prediction of hospitalization ("Inpatient") and low Emergency Severity Index (ESI) score of 2 or 3 ("Low ESI score").

Variable and model	F_1-score on ones	AUC[a]
Inpatient		
Model 1: NLP[b] clusters	0.57	0.82
Model 2: LS[c] clusters	0.57	0.83
Model 3: NLP+LS clusters	0.59	0.84
Low ESI score		
Model 1: NLP clusters	0.86	0.92
Model 2: LS clusters	0.84	0.90
Model 3: NLP+LS clusters	0.87	0.92

[a]AUC: area under the curve.

[b]NLP: natural language processing.

[c]LS: lead symptom.

Discussion

Principal Findings

Our analysis of patient records showed the additional information extracted from unstructured text and its potential usefulness in the clinical context. We demonstrated that the information extracted from NLP features and the physician's categorization of chief complaints was *complementary*. Indeed, the correlation and consistency between the chief complaint and NLP-derived clusters were low (Table 4). This finding indicates that the free text from the NLP clusters provides additional information than that contained in the symptom clusters from the structured chief complaints.

The complementarity of the information is further emphasized by the results summarized in Tables 5 and 6, and most coefficients remained significant when both types of indicators were included in the model, suggesting that different aspects of patient information appear to be encoded by the 2 approaches. These results support our hypothesis that NLP-derived libraries capture greater depth and breadth of information than a single chief complaint and underscore the relevance of including information captured in unstructured text to address patient populations.

Surprisingly, the "cardiovascular" and "trauma" clusters were not significant features for predicting hospitalization, with "trauma" also significant for predicting a *higher* ESI score. In contrast, the "systemic" cluster, which included sepsis, anaphylaxis, and neoplastic disease, was significant for predicting hospitalization and a lower ESI score, consistent with clinical expectations. Although symptoms suggestive of cardiac dysfunction and trauma may warrant urgent clinical risk assessment, most patients with such complaints would not require hospitalization. Therefore, early allocation of hospital beds for these subgroups is unlikely to reduce overcrowding. Targeting patients with systemic symptoms, in contrast, is likely to do so.

We also proposed a method for analyzing unstructured clinical notes. Our approach has the advantages of speed, simplicity of

implementation, and transparency. The speed at which supervised libraries can be assembled is a strength of the proposed approach. A limitation of implementing supervised NLP algorithms in routine decision support is that they are often resource intensive [17]. In our application, it took an untrained clinician only a few days to assemble the entire library.

Furthermore, using NLP as a tool traditionally requires expertise and the ability to master NLP applications. In fields that require years to decades of training, such as health care, professionals cannot be routinely trained to excel in programming. Thus, a further major barrier to the successful implementation of NLP applications in health care is often the usability of NLP applications [18]. Moreover, the flexibility of the method allows easy adaptation of the created dictionaries to analyze new data sets.

Trust is one of the key benefits of clinician involvement in developing proprietary AI models. Indeed, lack of trust is a recognized major limitation that hinders the potential benefits of using AI in routine clinical practice for organizations and patients [19,20]. Owing to the supervised approach, annotated library compilation is comprehensible and transparent; hence, it is trustworthy for clinicians. This may also become an important advantage if regulation on the implementation of AI use in health care tightens in the future.

The limitation of this study is that our approach still requires manual coding. However, future developments in AI may facilitate this step even further. In addition, human bias was possible because the library was compiled manually. In general, an AI-based text analysis does not achieve perfect precision. However, we primarily advocate using free-text analysis for organizational, not clinical, decision support. Therefore, this limitation is not clinically relevant. A further limitation may lie in the fact that the low correlation between the NLP and chief complaint clusters could stem from errors originating from the manual grouping or NLP clustering. However, we believe these results are plausible. Indeed, the chief complaints “fever” and “pain” were included in the cluster “general symptoms,” as were the NLP-extracted tags “fever” and “pain.” However, as only 1 chief complaint could allocated to a patient, during the COVID-19 pandemic, most patients presenting with fever or influenza-like pain would have most likely been categorized as presenting with the chief complaint “COVID.”

Conclusions

Health care workers on the one side and EHR engineers as well as hospital administration on the other side are caught in a long, ongoing conflict over the extent of structuring the data entered into EHR. Health care workers often argue that entering structured data is a cumbersome task and that the information archived can be of little use in daily clinical practice. In contrast, administrators and EHR engineers often advocate that structuring data is the only reliable solution, enabling a meaningful analysis of the data. Technological advances may help resolve this conflict.

We were able to demonstrate the importance of maintaining free text in EHR. Indeed, using the chief complaints attributed by a physician from a drop-down menu and a corresponding free-text field as a case in point, we were able to show that free text contains a wealth of information that is not routinely captured by structured data.

Moreover, we developed an approach that could enable the information captured in free text to be easily extracted and processed by hospital informatics systems and fed into a workflow, possibly improving the efficiency of patient management.

Therefore, future EHRs should include the possibility of entering free text.

Abstract

Background: Inpatient falls are a substantial concern for health care providers and are associated with negative outcomes for patients. Automated detection of falls using machine learning (ML) algorithms may aid in improving patient safety and reducing the occurrence of falls.

Objective: This study aims to develop and evaluate an ML algorithm for inpatient fall detection using multidisciplinary progress record notes and a pretrained Bidirectional Encoder Representation from Transformers (BERT) language model.

Methods: A cohort of 4323 adult patients admitted to 3 acute care hospitals in Calgary, Alberta, Canada from 2016 to 2021 were randomly sampled. Trained reviewers determined falls from patient charts, which were linked to electronic medical records and administrative data. The BERT-based language model was pretrained on clinical notes, and a fall detection algorithm was developed based on a neural network binary classification architecture.

Results: To address various use scenarios, we developed 3 different Alberta hospital notes-specific BERT models: a high sensitivity model (sensitivity 97.7, IQR 87.7-99.9), a high positive predictive value model (positive predictive value 85.7, IQR 57.2-98.2), and the high F_1-score model (F_1=64.4). Our proposed method outperformed 3 classical ML algorithms and an International Classification of Diseases code–based algorithm for fall detection, showing its potential for improved performance in diverse clinical settings.

Conclusions: The developed algorithm provides an automated and accurate method for inpatient fall detection using multidisciplinary progress record notes and a pretrained BERT language model. This method could be implemented in clinical practice to improve patient safety and reduce the occurrence of falls in hospitals.

Introduction

Background

Inpatient falls detrimentally impact patients, leading to extended hospital stays and distress among families and caregivers [1-5]. Studies reflect a varying incidence rate of such falls, with 250,000 annually in England and Wales alone [1], and evidence showing 7.5% of patients experience at least 1 fall during hospitalization [2]. Acute care hospitals also report a range of 1 to 9 falls per 1000 bed days, underscoring the pervasive nature of this problem [4]. Patients who fall may experience injuries that increase the risk of comorbidity or even disability [6,7]. They may also experience psychological effects such as anxiety, depression, or loss of confidence, which can affect their recovery and quality of life [8].

Manual chart review is regarded as one of the most common methods to identify inpatient falls [9]. This process involves the thorough examination of patient medical records to gather relevant information on the details of falls. Existing strategies include the Harvard Medical Practice Study [10] and the Global Trigger Tool [11]. Alternative methodologies, such as Patient Safety Indicators, based on International Classification of Diseases (ICD) codes, are used to identify adverse events (AEs), leveraging systematized health care data for detection [12-14]. However, these methodologies, while widely used, present challenges due to the time-consuming nature of ICD coding and manual chart reviews, potentially causing delays in recording and detecting AEs [15,16].

Free text data in electronic medical records (EMRs) offer rich, up-to-date insights into patients' health status, medications, and various narrative content. Despite its wealth of information, the unstructured nature of this data necessitates chart reviews, a labor-intensive process, to identify inpatient falls [17]. There has been an increasing interest in recent years in applying natural language processing (NLP) techniques to electronic clinical notes to automate disease identification and create clinical support decision systems [18-24].

Previous NLP studies in the detection of patient fall including rule-based algorithms [25,26] and machine learning (ML) methods [27-30] have been explored, but they often struggle with the variety and complexity of clinical language.

The deep learning model Bidirectional Encoder Representation from Transformers (BERT) [31] can effectively address these challenges. It uses transformer architecture to understand text contextually, handling linguistic complexity, abbreviations, and data gaps, thereby augmenting text understanding from EMR [20]. The use of transformer-based methods to understand EMR text data has emerged as a promising new trend in automatic clinical text analysis [32].

Objectives

In this study, we intend to pretrain an existing model, BioClinical BERT [33], with free text data from Alberta hospital EMRs to develop an Alberta hospital notes-specific BERT model (AHN-BERT). The pretrained language model would serve as a feature extraction layer in a neural network to identify inpatient falls. We hypothesize that fine-tuning BERT on local hospital data will enable more accurate fall detection compared with generic models. Additionally, we expect AHN-BERT will outperform conventional rule-based and ML approaches, as well as ICD code methods, in detecting falls from unstructured EMR notes in near real time. By evaluating AHN-BERT against current techniques, we hope to demonstrate the value of transfer learning with BERT for improved efficiency and generalizability in surfacing patient safety events from clinical text. Ultimately, our goal is to advance the detection of inpatient falls, allowing for more detailed and accurate patient safety interventions. An improved fall detection system could potentially enable health care providers to swiftly implement preventive measures, reducing the incidence and severity of falls. Additionally, through the facilitation of access and analysis of fall-related data, our system could become an invaluable resource for researchers investigating fall prevention and associated subjects.

Methods

Overview

In our methodology, we emphasized a detailed and transparent approach, covering all aspects from data collection to model validation. This comprehensive process, reflecting best practices in research reporting [34], ensures clarity and precision in our multivariable prediction model, providing an in-depth understanding of its performance and applicability.

Source of Data

Our study is a retrospective analysis. We used a stratified random sample of adult patients admitted to acute care hospitals in Calgary, Alberta. We linked the extracted EMR data to Sunrise Clinical Manager (SCM) records and ICD-coded discharge abstract database (DAD) using an established mechanism [35]. Both tables are stored and managed by the Oracle database.

The chart reviewer team consists of 6 registered nurses with 1 to 10 years of experience using SCM for clinical care. The nurses followed a training procedure, and 1 trained nurse became the project lead for quality assurance. The training involved learning the condition definitions and practicing reviewing each chart systematically. Reviewers examined the entire record for specified conditions and consulted each other with questions. In the process of training and quality assurance, we tested interrater reliability using Conger, Fleiss, and Light κ methods, with 2 nurses reviewing the same set of 10 charts for consensus on AEs. Where agreement was poor ($\kappa<0.60$), retraining occurred until high agreement ($\kappa>0.80$) was achieved [36]. Reviewers then proceeded independently with REDCap tool (Vanderbilt University).

The chart review data served as the reference standard to develop and evaluate our fall detection model. We focused on multidisciplinary progress records (MPRs) for fall detection, as chart review data showed most falls (115/155, 73.7%) were documented in MPRs by nursing staff. We created supervised data sets for the classification task to identify optimal fall detection timing, including 1-day (fall day MRPs notes), 2-day (fall day + day after), 3-day (fall day + 2 days after), and full hospitalization MRPs. All supervised data sets were labeled to

indicate whether notes were associated with inpatient falls. For the training of our model, we used both cases (falls) and controls (nonfalls) at a ratio of 1:29. This was done to ensure the model was exposed to a balanced representation of both scenarios. Our test set mirrored the real-world data distribution to enable an accurate evaluation of model performance. In addition, we constructed an unsupervised corpus specifically for language model pretraining. This corpus comprises free-text note data and does not rely on any predetermined labels or annotations.

Participants

At the time of the study, a total of 4393 charts were reviewed, among which we identified a total of 155 records as falls and 4238 records as no falls. The study included only the first admission of each patient, even if they had multiple hospitalizations within the study period. We exclusively focused on adults 18 to 100 years of age, thereby excluding minors and centenarians. Furthermore, if a patient had multiple fall incidents, only the most recent record was considered, although no such cases were identified during the study. The temporal framework for the study encompassed a decade, from 2010 to 2020. Exclusion criteria were also clearly defined: patients without unstructured note data or those who could not be linked using our established data linkage mechanism were omitted from the study.

Missing Data and Data Cleaning

Our study implemented rigorous data cleaning to ensure data integrity. After conducting a conflict review and excluding records with inconsistencies in fall status documentation (17 records checked for both falls and no falls), failed data linkage (1 record), temporal conflicts between fall and admission dates (5 records), and missing MPR documentations (47 records), the final clean data set totaled 4323 records (142 falls and 4181 no falls).

Outcome and Variables

The desired outcome of our proposed framework is to predict whether a patient's daily progress note contains hints about inpatient falls. The input to our model is each patient's n-day note. We use a BERT model to represent the textual data in numerical format, also known as contextualized word embeddings.

The input text is represented by 768-dimensional feature vectors, which can be considered as 768 variables. However, due to the distributed representation of neural language models, each variable does not represent a single word. Instead, individual variables preserve contextual information segments for each word, constituting meaningful vector representations of the entire input text.

On a related note, we have also collected and analyzed several demographic and clinical variables for our patient cohort from DAD database. Although not directly used in our predictive modeling, these variables furnish invaluable insights into the characteristics of our study population and contribute to the overall richness of our research data. These include age at the time of admission, sex, the incidence of intensive care unit visits during the hospital stays, the length of the hospital stays, and the hospital's geographical location. The latter was particularly focused on 3 acute care hospitals based in Calgary, Alberta: hospitals "A," "B," and "C." These variables help us understand the context in which the patient notes were written and may influence the interpretation of the model's results.

Sample Size

We included all patient data that has been reviewed by the reviewer team and filtered out from the inclusion-exclusion criteria.

Model Development

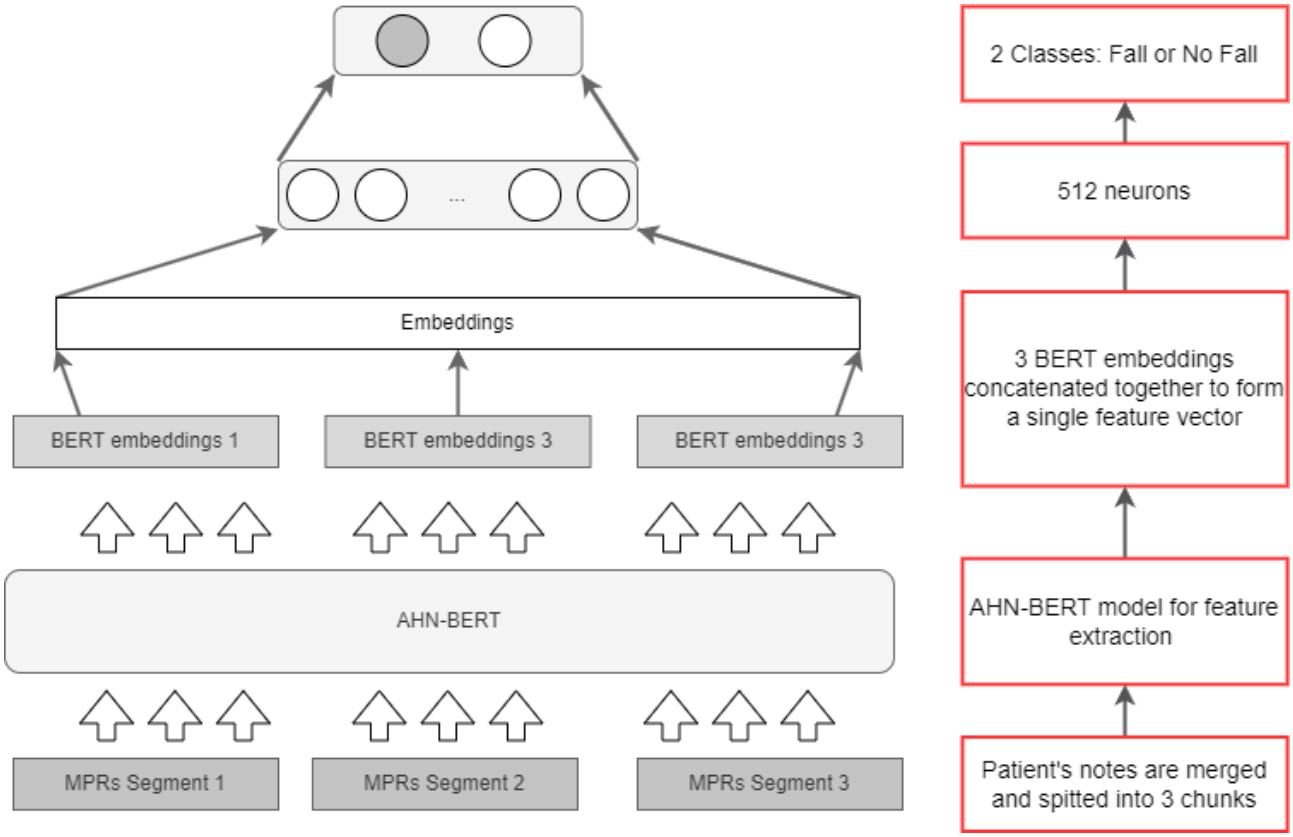
To conform to the BERT input length limit, MPR notes exceeding 400 tokens were programmatically split into segments under 400 words, preserving contextual information. All notes underwent preprocessing including removal of extraneous headers, signatures, whitespaces, and escape characters using regular expressions, and duplicate sentences were eliminated.

Our model architecture comprises 2 key components, an Alberta hospital note-specific BERT model for contextual feature extraction from clinical text, which we term AHN-BERT, and a feedforward neural network classifier to detect falls from the extracted features (as Figure 1).

AHN-BERT was initialized with weights from BioClinical BERT and further pretrained on our corpus of unsupervised hospital notes to adapt to local clinical terminology and language patterns. To prevent bias from overly lengthy documents, notes were filtered to be between 50 and 5000 tokens prior to pretraining. AHN-BERT was pretrained using a masked language modeling technique on 15% of randomly selected input tokens, enabling learning of contextual representations of clinical text without explicit labels. For feature extraction, AHN-BERT processes up to 3 concatenated note segments under 400 tokens. The resulting "[CLS]" vectors summarizing the semantic content of each segment are aggregated via concatenation to represent the full note's contextual information [37].

A feedforward neural network is used as the classifier, taking the concatenated features as input. The network comprises fully connected layers to map the features into class probabilities for fall detection. Dropout regularization is implemented in the classifier to prevent overfitting to the training data. Sigmoid activation in the output layer provides posterior probabilities for the binary fall classification task.

Figure 1. Proposed model architecture. AHN-BERT: Alberta hospital notes-specific BERT; BERT: Bidirectional Encoder Representation from Transformers; MPR: multidisciplinary progress record.



Model Assessment

First, to determine the optimal timeframe for note selection that best represents inpatient falls, we compared model performance using 1-day, 2-day, 3-day, and complete patient note data sets. Since the exact time lapse between an inpatient fall and corresponding documentation is variable, we evaluated these distinct time intervals in a data-driven approach to identify the optimal period for note selection. We used the same model architecture and pretrained AHN-BERT for all data sets, comparing training and validation loss convergence and evaluation metrics to assess performance.

Second, we tuned the classification probability threshold to balance model sensitivity and precision. The threshold denotes the cutoff for determining class membership based on predicted probabilities. By optimizing the threshold, we controlled the tradeoff between correctly identifying true positives and avoiding false positives. We developed three distinct models by threshold tuning for different purposes: (1) a high-sensitivity model that maximizes sensitivity by optimizing the threshold, (2) a high positive predictive value (PPV) model that maximizes PPV through threshold optimization, and (3) a high F_1-score model that balances sensitivity and PPV by optimizing the threshold, serving as a general-purpose model.

Third, we conducted a comparative evaluation between our top-performing neural network model and several other approaches, including 2 alternative BERT-based models, 3 conventional ML models, and an ICD-code–based algorithm. The 2 additional BERT-based models used original pretrained BERT and BioClinical BERT as feature extractors. For the 3 conventional ML models (support vector machine, logistic regression, and decision tree classifiers), we used bag-of-words features and term frequency-inverse document frequency weighting. These models were trained and compared on the 1-day MPRs data set. The ICD-code algorithm was applied to the same patient cohort but relied on administrative diagnosis codes rather than clinical notes. It aimed to demonstrate the efficacy of standard diagnostic codes for identifying falls compared with our neural network model. Falls were identified by the presence of ICD-10 codes W00-W20 when not listed as the primary diagnosis.

Statistical Analysis

The characteristics of the patients included in the study were thoroughly evaluated. These characteristics encompassed age, sex, the incidence of intensive care unit visits, the length of their hospital stay, and their originating hospitals. We summarized categorical variables as frequencies and percentages, while continuous variables were expressed as medians and IQRs. The χ^2 test was used for categorical variables to determine statistical differences, while the Wilcoxon rank-sum test was used for continuous variables. A P value threshold of 5% or lower was set to denote statistical significance.

To evaluate our ML model, we calculated several statistical metrics such as sensitivity, specificity, PPV, negative predictive value, accuracy, and F_1-score.

Computational Environment

Our study harnessed a high-performance computing environment, primarily driven by an NVIDIA GeForce RTX

3080 GPU with 16GB of memory, vital for pretraining and fine-tuning our language model. The statistical analysis and experiment leveraged Python 3.8, and libraries such as NumPy [38], Scikit-learn [39], Pandas [40], and PyTorch [41] for tasks like data processing and modeling.

Ethics Approval

This study was approved by the Conjoint Health Research Ethics Board at the University of Calgary (REB21-0416). Patient consent was waived as part of the ethics board review process.

Results

Participants

Our final study cohort contains 4323 individuals, with 142 (3.28%) patients identified by chart reviewers as having falls recorded in their medical charts during their hospital stay. The remaining 4181 (96.7%) did not fall. All patients were successfully linked to the SCM and DAD by unique identification number and admission date. Table 1 presents the descriptive statistics in general. Multimedia Appendix 1 further stratifies Table 1 into respective hospitals (Multimedia Appendix 1).

Table 1. Descriptive statistics of the study cohort.

	Total (n=4323)	Confirmed fall (n=142)[a]	No fall (n=4181)[b]	*P* value[c]
Age, median (IQRs[d])	62.0 (48.5-75.5)	71.0 (59.6-82.4)	61.0 (47.5-74.5)	<001
Sex (male), n (%)	2169 (50.2)	73 (51.4)	2096 (50.1)	.77
ICU[e] visit, n (%)	163 (3.8)	19 (13.4)	144 (3.4)	<.001
Length of hospital stay (days), median (IQRs)	3.0 (0.5-5.5)	12.0 (1.5-22.5)	3.0 (0.5-5.5)	<.001
Hospitals, n (%)[f]				.04
Hospital “A”	3548 (82.1)	104 (73.2)	3444 (82.4)	
Hospital “B”	651 (15.1)	34 (23.9)	617 (14.8)	
Hospital “C”	124 (2.8)	4 (2.9)	120 (2.8)	

[a]A term used in the study to refer to patients who fell during their hospital stay and were confirmed to have fallen through medical records or other documentation.

[b]A term used in the study to refer to patients who did not fall during their hospital stay.

[c]A measure indicating the statistical significance (P<.05) of the observed difference between groups.

[d]A measure of statistical dispersion representing the difference between the 75th and 25th percentiles of a data set.

[e]ICU: intensive care unit.

[f]Three different hospitals were included in the study: hospitals A, B, and C.

Model and Framework Assessment

First, to determine the optimal timeframe, we compared 1-day, 2-day, 3-day, and complete note data sets using the same model architecture and AHN-BERT pretrained embeddings. We trained each model for 200 epochs, with the primary goal of comparing their overall performance on the test sets. Evaluating performance metrics and training convergence, the 1-day data set was most effective and efficient, achieving 93.0% sensitivity and 83.0% specificity.

Second, we optimized the classification threshold to balance sensitivity and precision. These models maximize sensitivity, PPV, and F_1-score respectively. As results are shown in Table 2, our proposed architecture with AHN-BERT achieved overall the highest metrics among the comparison.

Third, the comparative assessment showed our approach outperformed 2 alternative BERT models, 3 classical ML models (support vector machine, logistic regression, and decision tree), and an ICD-code algorithm. The BERT models used original BERT and BioClinical BERT embeddings, while the ML models used bag-of-words and term frequency-inverse document frequency on the 1-day data set. The ICD method relied on administrative codes rather than text. Our neural network model demonstrated superior inpatient fall detection across different methods and data sources.

Our high sensitivity model exhibited 97.7% sensitivity, enabling near-perfect capture of relevant notes, along with 82.3% accuracy, but a low 26.8% F_1-score. The high PPV model achieved 97.5% accuracy, 85.7 % PPV, and 27.9 % sensitivity. The high F_1-model balanced 66.7% sensitivity and 60.5% PPV to optimize 64.4% F_1-score and 97.7% accuracy. In comparison, the ICD-based method had 27.9% sensitivity, while traditional classifiers achieved 51.2%-76.7% sensitivities and 8.3-15.8 PPVs.

The result of the probability-based threshold adjustment in accordance with PPV, sensitivity, and F_1-score is shown in Figure 2. By adjusting the classification threshold, we can control the trade-off between sensitivity and precision (as Figure 3).

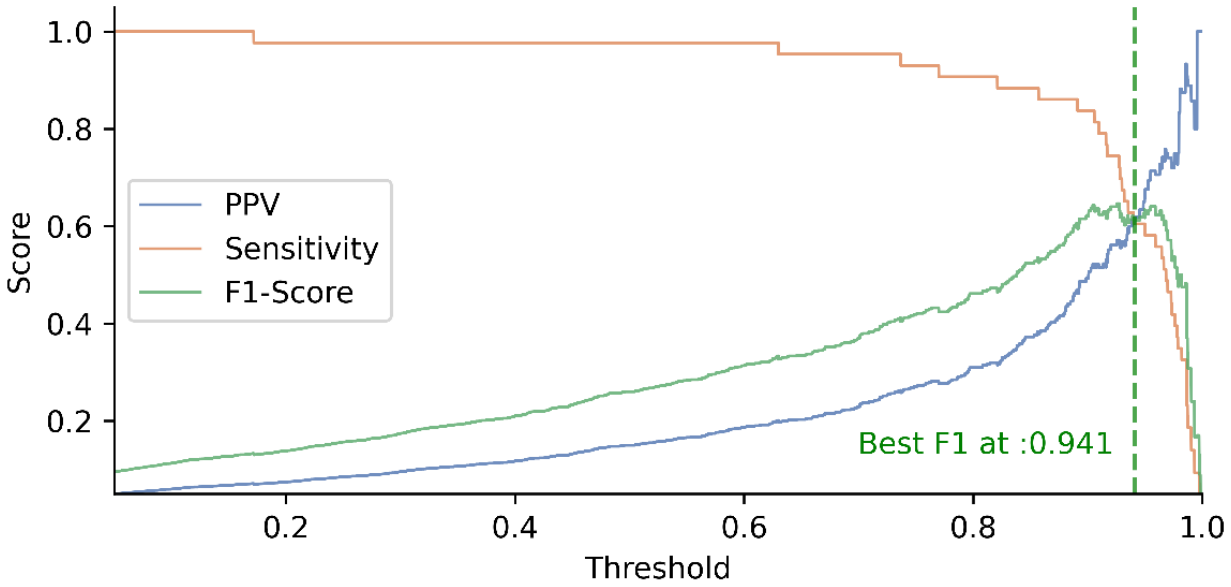

Figure 3. Percision-recall curve. PPV: positive predictive value.

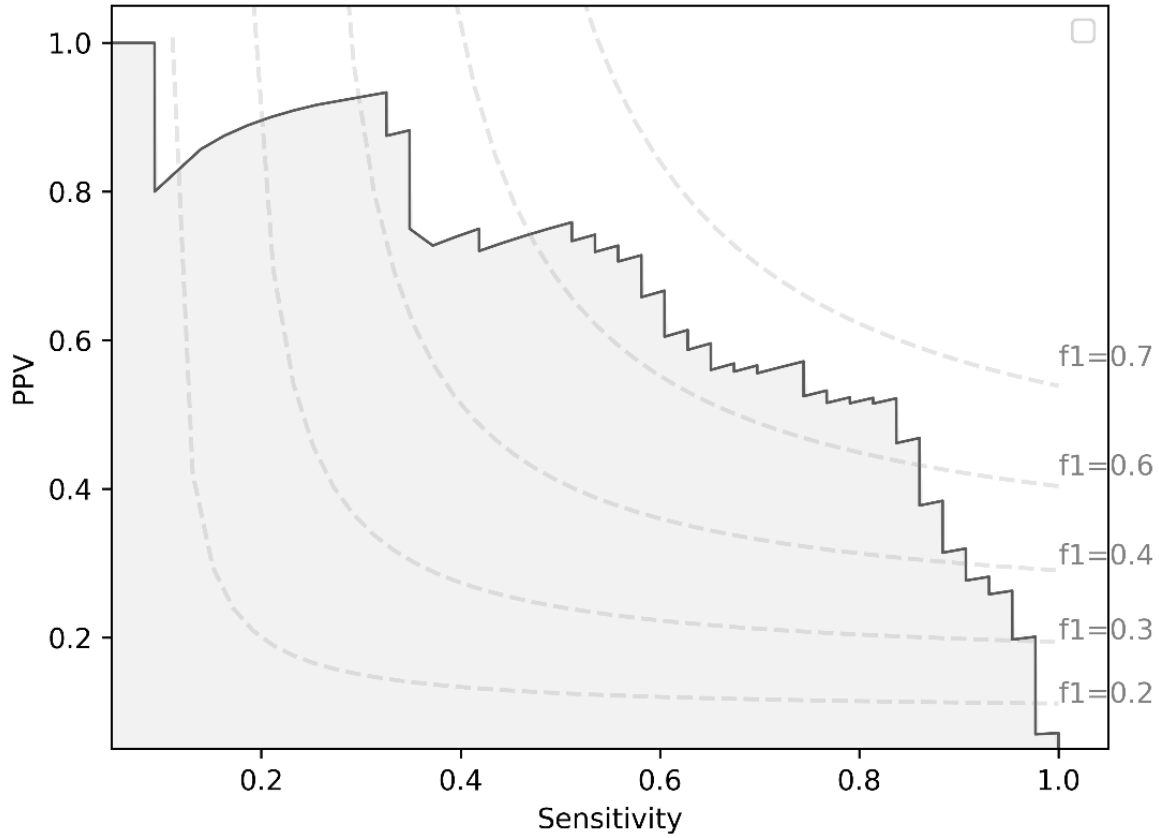

Discussion

Principal Results

In our study, we illustrate how a BERT-based model substantially outperforms the ICD-based algorithm in fall detection within the hospital setting. This superiority stems from the model's ability to process EMR text data in real time, enabling rapid identification of falls. In contrast, ICD codes are assigned retrospectively, leading to delays in fall detection and intervention. Using BERT's advanced NLP facilitates accurate, efficient, and generalizable analysis of clinical notes for surveillance applications.

Specifically, our proposed AHN-BERT model surpasses generic BERT, conventional ML, and ICD-codes. Fine-tuning BERT on local hospital notes better captures local domain-specific language and context, boosting performance. Additionally, combining high-sensitivity and high-PPV models enables optimized 2-stage fall detection by adjusting decision thresholds to balance false positives and negatives. This provides flexibility for different use cases and challenging tasks.

Furthermore, our study provides valuable insights into the optimal time frame for defining falls empirically. This comparison sheds light on the potential benefits of using a finer-grained time interval, which could improve the generalizability and applicability of the model across different populations and settings. Understanding the optimal period for detecting fall incidents can guide the development and implementation of targeted public health interventions. Health surveillance data can be used to evaluate the effectiveness of these interventions and inform future strategies for fall prevention and management. By determining the most suitable time interval for defining fall incidents, health surveillance systems can better allocate resources to areas with a higher risk of falls. This may result in more efficient and effective public health efforts, improving health outcomes for at-risk populations.

Applications

Our models leverage unstructured EMR data to accurately detect inpatient falls, enabling health care systems to enact tailored prevention measures and reduce fall-associated injuries. The automation of extensive clinical documentation review accelerates health care surveillance and quality improvement processes.

Regarding research applications, our algorithms can extract comprehensive fall data from EMR text to support developing evidence-based interventions.

The proposed framework has broad applicability beyond fall detection for tasks like diagnosis prediction, medication adherence monitoring, and adverse drug event identification. This adaptability improves health care outcomes, patient safety, and quality of care.

Strength and Limitations

In our research, the AHN-BERT model has shown remarkable superiority over traditional ICD-based algorithms in fall detection within hospital environments. This enhanced performance is primarily attributed to the model's proficiency in processing and understanding the nuances of EMRs text data. Unlike ICD codes, which can sometimes result in undercoding

or loss of information, the nursing notes processed by our model are more closely aligned with the actual circumstances of inpatient falls. The ability of AHN-BERT to immediately and accurately process this data is a substantial advancement, ensuring that fall detection is not only more precise but also more reflective of the true clinical scenario. Additionally, the combination of high-sensitivity and high-PPV models in our 2-stage fall detection system allows for adjustable decision thresholds, thus balancing false positives and negatives and providing flexibility across different scenarios.

However, the model faces challenges in balancing high sensitivity with a high PPV due to the imbalanced nature of clinical data. The rarity of AEs like falls leads to a higher rate of false positives, as seen in our data set with a significant imbalance ratio. Our test data set, characterized by a significant 29:1 imbalance, aligns more closely with real-world clinical scenarios than balanced data sets used in some prior studies [27], which, while yielding promising results, may not fully represent practical conditions. This intentional choice ensures that our model's performance is tested under conditions typical of rare events like falls, thereby enhancing its relevance and utility in actual clinical settings.

Second, the effectiveness of our models depends on the quality and comprehensiveness of documentation. If fall events or associated risk factors are not well documented, our model, like any data-driven model, may have difficulty detecting them. This underscores the importance of careful, detailed clinical documentation to enhance the effectiveness of monitoring applications. In addition, our study also assumes a certain level of linguistic and terminological consistency within the EMR data. Variations in documentation styles across different health care providers could potentially impact the model's performance, suggesting that future models should incorporate strategies, for example, pretraining the ML, to mitigate such discrepancies. Last, the differentiation between a history of falls and inpatient falls presents a challenge, as it could potentially lead to false positive predictions if falls that occurred prior to hospitalization are documented in the notes. Although the BERT model's contextual understanding can partially alleviate this issue, we acknowledge that more improvements are needed. As part of our future work, we aim to further refine our model to better handle such complexities.

Conclusions

This study developed and evaluated BERT-based NLP models for the automated detection of falls from electronic clinical notes. The developed models provided a more accurate and timely way to detect falls than traditional ML and ICD-codes–based methods. Moreover, we provided a masked language model technique to pretrain a pre-existing BERT model using clinical text data gathered from various health care facilities in Calgary, Alberta, creating a more local institution-specific and effective AHN-BERT model. By using self-supervised language modeling strategies, we can bypass steps that were regarded as vital in standard ML methods, such as the necessity for thorough text preprocessing, complex feature engineering, and a considerable amount of labeled data. In addition, by exploring the optimal period for fall incident detection and selecting 1-day notes for our final architecture, our model contributes to enhanced patient safety and care with less noise.

Acknowledgments

YX and CAE received research support funding from Canadian Institutes of Health Research through grant number DC0190GP. GW was supported by the Canadian Institutes of Health Research postdoctoral fellowship, O'Brien Institute for Public Health Postdoctoral Scholarship, Cumming School of Medicine Postdoctoral Scholarship at the University of Calgary, and the Network of Alberta Health Economists Postdoctoral Fellowship at the University of Alberta.

Authors' Contributions

YX, CAE, HQ, GW, and CC were responsible for the study planning, conceptualization, and coordination. SL, EAM, and GW managed data retrieval, data linkage, and data quality assurance. The design and development of the neural network architecture were carried out by CC and YX. CC conducted clinical note preprocessing, analysis, and model evaluation. The reference standard development and chart review study design was executed by YX, CAE, NS, DAS, and GW. SL and CC drafted the manuscript and GW drafted the Methods (Study Cohort and Data Sources). GW, JP, DAS, EAM, CAE, NS, and YX participated in discussions and provided comments on the manuscript. All authors contributed to the revision and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The rehabilitation of a patient who had a stroke requires precise, personalized treatment plans. Natural language processing (NLP) offers the potential to extract valuable exercise information from clinical notes, aiding in the development of more effective rehabilitation strategies.

Objective: This study aims to develop and evaluate a variety of NLP algorithms to extract and categorize physical rehabilitation exercise information from the clinical notes of patients who had a stroke treated at the University of Pittsburgh Medical Center.

Methods: A cohort of 13,605 patients diagnosed with stroke was identified, and their clinical notes containing rehabilitation therapy notes were retrieved. A comprehensive clinical ontology was created to represent various aspects of physical rehabilitation exercises. State-of-the-art NLP algorithms were then developed and compared, including rule-based, machine learning–based algorithms (support vector machine, logistic regression, gradient boosting, and AdaBoost) and large language model (LLM)–based algorithms (ChatGPT [OpenAI]). The study focused on key performance metrics, particularly F_1-scores, to evaluate algorithm effectiveness.

Results: The analysis was conducted on a data set comprising 23,724 notes with detailed demographic and clinical characteristics. The rule-based NLP algorithm demonstrated superior performance in most areas, particularly in detecting the "Right Side" location with an F_1-score of 0.975, outperforming gradient boosting by 0.063. Gradient boosting excelled in "Lower Extremity" location detection (F_1-score: 0.978), surpassing rule-based NLP by 0.023. It also showed notable performance in the "Passive Range of Motion" detection with an F_1-score of 0.970, a 0.032 improvement over rule-based NLP. The rule-based algorithm efficiently handled "Duration," "Sets," and "Reps" with F_1-scores up to 0.65. LLM-based NLP, particularly ChatGPT with few-shot prompts, achieved high recall but generally lower precision and F_1-scores. However, it notably excelled in "Backward Plane" motion detection, achieving an F_1-score of 0.846, surpassing the rule-based algorithm's 0.720.

Conclusions: The study successfully developed and evaluated multiple NLP algorithms, revealing the strengths and weaknesses of each in extracting physical rehabilitation exercise information from clinical notes. The detailed ontology and the robust performance of the rule-based and gradient boosting algorithms demonstrate significant potential for enhancing precision

rehabilitation. These findings contribute to the ongoing efforts to integrate advanced NLP techniques into health care, moving toward predictive models that can recommend personalized rehabilitation treatments for optimal patient outcomes.

Introduction

Precision medicine is a promising field of research that aims to provide personalized treatment plans for patients [1]. Recent years have seen a rise in interest in this field, as advances in machine learning and data collection techniques have greatly facilitated this research [2]. However, the principles of precision medicine have primarily been applied to the development of medications, and relatively little research has been conducted on their applications in other areas [3]. For instance, although rehabilitation clinics require individualized treatment procedures for patients, little research has been conducted on methods that use data analysis and machine learning to facilitate the design of such procedures [4]. Although the application of precision medicine to physical therapy has proven effective in improving the health of patients, current methods of creating personalized treatments rarely use automated approaches to facilitate decision support [5]. Thus, there is a need for tools to assist in the development of personalized treatments in physical therapy [6]. In the treatment of patients who had a stroke, the lack of decision support tools is especially pronounced, as the available treatments for this condition have not led to consistent outcomes across patient populations [7].

To develop decision support tools for the design of precision rehabilitation treatments for patients who had a stroke, it would be necessary to use electronic health record data to develop a predictive model of existing treatment options and their impact on patient outcomes [8]. However, physical therapy procedures are typically described in unstructured clinical notes, meaning that simple data extraction methods such as database queries cannot be applied to obtain sufficient information. Additionally, the language used to describe these procedures can differ between clinicians, locations, and periods [9]. More advanced natural language processing (NLP) algorithms are required to extract this information from clinical notes, but such a method has not yet been developed for this application.

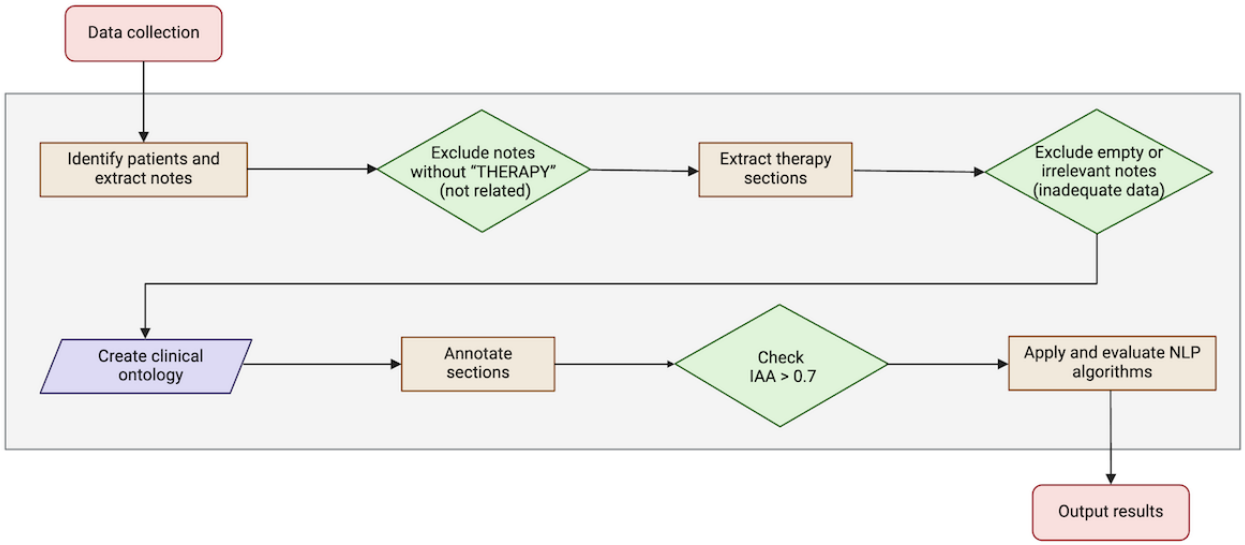
In this paper, we aim to develop and evaluate NLP algorithms to extract physical rehabilitation exercise information from the clinical notes in the electronic health record. Our specific contributions are as follows. First, we created a novel and comprehensive clinical ontology to represent physical rehabilitation exercise information, which includes the type of motion, side of the body, location on the body, the plane of motion, duration, information on sets and reps, exercise purpose, exercise type, and body position. Second, we developed and compared a variety of NLP algorithms leveraging state-of-the-art techniques, including rule-based NLP algorithms, machine learning–based NLP algorithms (ie, support vector machine [SVM], logistic regression [LR], gradient boosting, and AdaBoost), and large language model (LLM)–based NLP algorithms (ie, ChatGPT [OpenAI] [10]) for the extraction of physical rehabilitation exercise from clinical notes. We are among the first to evaluate the capabilities of ChatGPT in extracting useful information from clinical notes.

Methods

Overview

Figure 1 illustrates the data flow and the various stages of the research process. Each of these stages will be described in detail in the following sections.

Figure 1. Flowchart illustrating the data flow throughout the study. IIA: interannotator agreement (IAA); NLP: natural language processing.



Data Collection

The study identified a cohort of patients diagnosed with stroke between January 1, 2016, and December 31, 2016, at University of Pittsburgh Medical Center (UPMC). For these patients, clinical encounter notes created between January 1, 2016, and December 31, 2018, were extracted from the institutional data warehouse. Table 1 provides the demographic characteristics of the patients included in this data set.

Table 1. Demographic information of patients included in the unfiltered data set (N=13,605).

Demographics	Values
Age (years), mean (SD)	75 (16)
Gender, n (%)	
Female	6931 (51)
Male	6673 (49)
Race, n (%)	
Asian	64 (0.5)
Black	1325 (9.7)
White	11,661 (86)
Other	153 (1.1)
Not specified	402 (3)
Ethnicity, n (%)	
Hispanic or Latinx	64 (0.5)
Not Hispanic or Latinx	12,471 (92)
Not specified	984 (7.2)

Ethical Considerations

The study was approved by the University of Pittsburgh's institutional review board (#21040204).

Clinical Ontology for Physical Rehabilitation Exercise

To determine the relevance and hierarchy of extracted information, we developed a clinical ontology consisting of 9 categories of concepts relating to exercise descriptions, informed by consultation with clinical experts (PD, BA, and AB) in the field of physical therapy. In developing our clinical ontology, we also consulted established frameworks such as the International Classification of Functioning, Disability, and Health (ICF) [11] and the Systematized Nomenclature of Medicine—Clinical Terms (SNOMED CT) [12]. These comprehensive systems offered valuable insights into the structuring and categorization of health-related concepts, which we adapted for the specific context of physical rehabilitation exercises. Additionally, our ontology incorporates principles from the Unified Medical Language System (UMLS) [13] to ensure compatibility and interoperability with other health care informatics systems.

Each category was given a set of values, as well as examples of how those values might be expressed in clinical notes. The categories are type of motion, side of the body, location on the body, the plane of motion, duration, information on sets and reps, exercise purpose, exercise type, and body position. The ontology also includes examples of indications that the mentioned exercise was not performed during the visit corresponding to the clinical note. This ontology was used to inform both the structure of the annotations and the methods used to extract relevant documents from the data set.

The ontology reflects the complexity and nuance of physical rehabilitation exercises by incorporating terms and categories that are sensitive to the variations and specificities observed in clinical settings. This approach ensures that the ontology not only represents the theoretical model of rehabilitation exercises but also aligns with the practical, real-world application and documentation by health care professionals. Table 2 displays the 9 categories for 3 exercise descriptions (performed in-office, home exercise program, and not performed), with sets and reps split into separate rows and including negations and out-of-office exercises at the bottom.

Table 2. Summary of the clinical ontology used for annotations.

Category	Data type	Concepts
Exercise description	Enumerated	Performed in-office, home exercise program, not performed
Type of motion	Enumerated	ROM[a], active ROM, active-assisted ROM, and passive ROM
Side of body	Enumerated	Right, left, bilateral, unilateral, contralateral, and ipsilateral
Location on body	Enumerated	Upper extremity (arms), lower extremity (legs), hip, thigh, knee, ankle, foot, heel, toe, shoulder, scapula, elbow, forearm, wrist, hand, thumb, head, neck, chest, abdomen, and lower back
Plane of motion	Enumerated	Flexion, extension, abduction, adduction, internal rotation, external rotation, lateral flexion, horizontal abduction, horizontal adduction, protraction, retraction, elevation, depression, inversion, eversion, pronation, supination, plantarflexion, dorsiflexion, radial deviation, ulnar deviation, upward rotation, downward rotation, opposition, forward, backward, lateral, medial, scaption, rotation, closure, clockwise, counterclockwise, distraction, all planes, anterior, posterior, horizontal, vertical, diagonal, and gravity elimination
Duration (seconds)	Integer	N/A[b]
Number of sets	Integer	N/A
Number of reps	Integer	N/A
Exercise purpose	Enumerated	Strength, fine motor, motor control, perception, simulated, power, endurance, joint mobility, joint alignment, muscle flexibility, cardio, pulmonary, agility, and vestibular
Exercise type	Enumerated	Upper extremity strength, lower extremity strength, trunk or core strength, scapular strength, ROM, flexibility or mobility, balance or vestibular, gait training, cardio or aerobic, and functional mobility
Body position	Binary	Weight bearing and non-weight bearing
Negation or hypothetical	Binary	Held or not performed and home exercise program

[a]ROM: range of motion.

[b]N/A: not applicable.

Preprocessing and Section Extraction

Physical therapeutic procedures were usually documented in the section "THERAPY." Therefore, we first filtered out the notes that did not contain a physical therapy visit by excluding files whose names lacked the string "THERAPY." From the resulting set of files, the section on therapeutic procedures was extracted using a regular expression, if such a section existed. This resulted in a total of 23,724 notes, some of which were empty or lacked pertinent information.

The method of section extraction has a few minor limitations. Because the regular expression used to locate these sections assumes a structure in the notes that is not always present, it is possible that a file may contain additional text from other sections of the original note in rare instances. All sections used in the creation of the gold-standard labels were manually examined to ensure the absence of these errors. It is also possible that some therapeutic procedures' sections are completely omitted from the note due to copy-and-paste errors made by their authors.

Because many of the extracted sections were very brief or lacked relevant information, we developed a method to create a more robust set of sections by extracting keywords. Initially, concepts were organized into 9 categories based on the clinical ontology. Each category was then assigned a list of keywords. A section was considered to mention a category if it contained at least 1 of the keywords. Consequently, each section was assigned a score between 0 and 9 based on the number of categories mentioned. All sections with a score of 9 and a random selection of notes with a score of 8 were extracted to generate 300 enriched sections that were anticipated to be relatively dense in information. In addition, 300 random sections were selected,

excluding those with a length of fewer than 200 characters in order to reduce the likelihood of omissions.

Gold-Standard Data Set Creation

Gold standard labels were developed by 2 clinical experts in the field of physical therapy (PD and BA) under the supervision of a senior clinical expert in physical therapy (AB). Each annotator was given a set of guidelines on how to label sections and was told to refer to the clinical ontology for examples of each concept to label. Instructions were given to label explicit mentions of each concept, and inferences were only to be made when specified. For example, the concepts under the categories exercise type and positioning were each given several common keywords that indicate exercises that relate to them. The annotators were given identical batches of 20 randomly selected sections to annotate, and the interannotator agreement was calculated using Fleiss κ. This process was repeated for a total of 3 batches, after which all 3 annotators achieved an interannotator agreement greater than 0.7. Throughout this process, the annotation guidelines were revised, and the structure of the labels was finalized. Once sufficient agreement was reached, 50 sections from the enriched set and 50 more from the random set were given to each annotator, totaling 300 distinct annotated sections. These sections were then split randomly into a training set consisting of 125 sections from each of the original sets and a test set consisting of the remaining 50 sections. The details of this corpus are included in Textbox 1, which outlines the total word count, the number of distinct words, and 2 examples of the data.

Textbox 1. Summary of the annotated corpus.

Total words: 74,104

Total distinct words: 2371

Deidentified note example 1:

- "1: AROM right elbow flx/ext HEP (right arm supported on table) 2: AROM right wrist flx/ext HEP 3: AROM right forearm pronation/supination HEP 4: Thumb opposition HEP 5: Seated AAROM table slide??"

Deidentified note example 2:

- "1: foam balance (heel/toe rocking): x 30 2: step taps with 2 taps from foam 12""" block: x 20 B/L 3: tandem walking: 25' x 2 4: backward walking: 25' x 2 5: foam Lunges: x 20 B/L 6: Dips 4""" stair: 2x10 B/L 7: side stepping green TB 10 ft x5 each direction 9: bridging with LLE leg lift 1""" off mat x10 10: tandem stance on foam x 1' 11: Nustep: L5 x 10' (LEs only)"

Rule-Based NLP

The first NLP method we developed was a named entity recognition (NER) algorithm using MedTagger (OHNLP), which is a software that uses rule-based methods to segment documents and extract named entity information with regular expressions [14]. We used this tool to detect the categories outlined in the ontology by creating explainable rules to extract the physical rehabilitation exercise information and compare it against the gold-standard labels. For each rule defined in the algorithm, MedTagger identified spans of text that matched the expression as well as the corresponding category and concept predicted for that text. We initiated the rules using simple keywords in the clinical ontology as defined in Table 2 and then refined the rules using the training set of the gold-standard notes.

Machine Learning–Based NLP

In addition to attempting to automate the annotation of clinical notes with exercise information, several sequence-level binary classification methods were explored to predict whether a specific concept is mentioned in a given span of text at least once according to the gold-standard labels. Here, a sequence is defined as a string of text within a section that describes an individual exercise. As the therapeutic procedures are documented as numbered lists, it is assumed that each enumerated item that contains text constitutes a single procedure for the purpose of this study. The aim was to extract these procedures from sections and then classify each according to which concepts they mention.

For this task, the sequences provided in the gold-standard data were used as raw input, and targets were defined using the labels that were associated with each sequence. These labels consisted of 101 concepts as given by the clinical ontology in Table 2, excluding duration, sets, and reps since these are numeric types unfit for binary classification tasks. Because the postprocessed output from MedTagger was formatted in a similar manner to the gold-standard data for ease of comparison, a similar method was used to create predictions and directly score MedTagger against the true labels for this task. In this manner, we compared our rule-based NLP algorithm against several other methods by redefining the information extraction task as a sequence classification task. The labels of all predicted spans of text were assigned to the section containing it.

A total of 4 machine learning models were trained to perform binary classification on sections, including SVM [15], LR [16], gradient boosting [17], and AdaBoost [18]. We built different machine learning models for different physical rehabilitation exercise concept extraction tasks. This resulted in 101 distinct SVM, LR, gradient boosting, and AdaBoost models each trained to predict a distinct concept. Each model was created using the *scikit-learn* [19] library in Python (version 3; Python Software Foundation). The input for each model was given in a simple uncased bag-of-words vector space fitted to the training set. The LR was performed with a learning rate of 1×10^{-4} and balanced class weights. The SVM model used a polynomial kernel with a degree of 2 and also used balanced class weights. The AdaBoost and gradient boosting were performed with the default parameters provided by *scikit-learn*, with 100 and 50

estimators, respectively. All unspecified hyperparameters were kept at the default values used by *scikit-learn*.

LLM-Based NLP

Recently, LLMs have gained much interest due to their promising results across many NLP tasks and straightforward development pipelines. To measure a baseline for the performance of LLMs on this data set, this study used OpenAI's ChatGPT, specifically GPT-3.5-turbo [20], which serves as the NLP backend for the first release of ChatGPT. This study accessed ChatGPT through the Microsoft Azure secure cloud service with an approved institutional review board.

For each of the concepts to be identified, a separate prompt was created asking the model to identify whether or not that concept is mentioned in the given sections. We note that the sections used in this exercise were fully deidentified and contained no sensitive information. One of the primary advantages of using LLMs to perform NLP tasks is that they can yield results comparable to other methods with much less time spent on fine-tuning and other manual design tasks. Therefore, in order to evaluate the practicality of using this method in an application with constraints on time or available machine learning expertise, prompts were automatically generated using a template and the name assigned to each label. Two simple prompting techniques were compared: a few-shot prompting technique that included example dialogue for 2 positive examples and 2 negative examples [21] and a zero-shot prompt that omitted any examples [22]. Prompts were created by providing a list of dialogue strings that can be attributed to the user providing the prompt, the model giving the response, and a third party giving instructions to the model, hereafter named System. The following is an example of a few-shot prompt that was automatically generated and sent to ChatGPT.

> *System: You are an assistant assigned to determine if a given text segment from a medical record contains mentions of Active Range of Motion. You must answer yes or no.*
>
> *User: 7: [PERSONALNAME] maze - AROM LUE - 3 rep*
>
> *Model: Yes.*
>
> *User: 23: / Supine on mat / dowel rod no wt above head for triceps*
>
> *Model: No.*
>
> *User: 2: AROM Right wrist ext/flex - 20 x*
>
> *Model: Yes.*
>
> *User: 24: SL HS activation- with tapping and suspended to limit friction x10 DEFERRED*
>
> *Model: No.*
>
> *User: 14: SLR- 2x10 deferred to HEP*

Prompts were made in this manner using 4 dialogue exchanges, switching out the last line for the section to be classified. Any concepts that were labeled fewer than 2 times were excluded from the experiment because not enough examples could be generated for the few-shot prompt. A total of 3 additional concepts were excluded relating to whether a procedure was performed in-office, at home, or not at all, as well as the 3 numeric concepts. This left a total of 82 concepts to be extracted.

Results

Because the clinical ontology covered a broad range of concepts within this domain, many of these concepts were very sparse in our data. More than half of the 101 concepts were present in fewer than 10 exercise descriptions in the train or test sets; these concepts have been omitted from the results. Table 3 contains a breakdown of the F_1-scores for each machine learning method, as well as the performance of the rule-based NLP algorithm on the NER task, for each of the remaining 40 concepts. See Multimedia Appendix 1 for the results on all concepts. The best-performing machine learning model is shown in bold for each concept.

Table 3. Binary F_1-scores of each algorithm on the test set (50 documents).

[a]RBNLP: rule-based natural language processing.

[b]NER: named entity recognition.

[c]LR: logistic regression.

[d]SVM: support vector machine.

[e]The best performance for each entity.

[f]N/A: not applicable.

[g]ROM: range of motion.

The rule-based NLP's performance on the sequence classification task was similar to its performance on the NER task. Instances of higher performance in sequence classification compared to NER can be partially explained by mismatches in predicted spans and their labels affecting NER accuracy, yet still allowing for correct overall text section classification. The rule-based algorithm tied with or outperformed the other models on half of the concepts in Table 3. Among the machine learning models, gradient boosting performed nearly as well, achieving the highest F_1-score on 18 concepts.

In addition to these concepts, the rule-based NLP algorithm also predicted the spans of durations, sets, and reps. Since these categories do not have any specific concepts assigned to them, the number presented in each span was used instead as a comparison against the true label, converting minutes to seconds where applicable. This resulted in F_1-scores of 0.65, 0.58, and 0.88, respectively. It is important to note that we limited the experiments for "Duration," "Sets," and "Reps" exclusively to rule-based algorithms because these categories inherently involve numeric data, which align well with the deterministic and pattern-based nature of rule-based approaches.

Gradient boosting demonstrated the best performance for identifying range of motion (ROM) concepts and determining the location of exercise (performed in-office, home exercise program, and not performed) with F_1-scores of 0.863 for active ROM; 0.857 for active-assisted ROM; and 0.977, 0.986, and 0.950, respectively, for the locations. The rule-based natural language processing algorithm outperformed machine learning models in detecting sides of the body with F_1-scores of 0.975 for the right side and 0.937 for the left side, and it also performed the best on most exercise types, except for balance or vestibular and gait training concepts, which were classified best by gradient boosting with F_1-scores of 0.939 and 0.860, respectively. The LR obtained a strictly higher score than other methods in the weight-bearing exercise concept with an F_1-score of 0.876. The AdaBoost got a strictly higher score on 3 concepts, notably on non–weight bearing positioning with an F_1-score of 0.946. The SVM model did not score higher than other models but had 3 ties, indicating competitive performance.

These findings indicate that the rule-based approach is particularly effective for certain types of exercises, with superior performance in most categories. However, gradient boosting demonstrated strength in more complex categorizations such as balance or vestibular and gait training, where understanding nuanced differences is crucial.

For the LLM-based NLP, the results show that both zero-shot prompts and few-shot prompts result in high recall scores that sometimes exceed other methods. However, precision was quite low for most concepts, and F_1-scores did not exceed every other method for any concept. However, ChatGPT did occasionally outperform some of the simpler machine learning models and, on 1 occasion, even outperformed the rule-based algorithm (on the backward plane of motion concept). The average precision over all 82 concepts tested was 0.33 for the zero-shot approach and 0.27 for the few-shot approach. The average recall was 0.8 for the zero-shot approach and 0.82 for the few-shot approach. This resulted in average F_1-scores of 0.37 and 0.35, respectively, indicating that the zero-shot approach was slightly better on average than the few-shot approach. However, the few-shot approach performed the best for all but 10 concepts. The reason the zero-shot method performed better on average is thus due to the fact that it shows significant improvement on a few specific concepts, such as hip, scapula, hand, abduction, and extension.

Discussion

Observations

As indicated by the high performance of the machine learning models on many of the concepts, the task of extracting information from exercise descriptions was not complex. Although some of these concepts could be extracted effectively using straightforward rules or a small machine learning model, there were also many cases where clinical notes appeared ambiguous without context. For instance, the abbreviation "SL" could be interpreted as "single leg" or "side-lying" depending on the exercise being described. In addition, "L" could mean "left" or "lateral," which explains why the rule-based NLP algorithm performed slightly worse when classifying left versus right. The use of single letters as abbreviations, especially "A" as a shorthand for "anterior," could cause issues in machine learning algorithms without careful consideration. It would be possible to increase the performance of the rule-based algorithm by further tuning the rules to search for context clues at other points in the document, but this could potentially cause the rules to overfit the training set. Of particular interest are the numeric data present in duration, sets, and reps. These are particularly tricky to extract since they are expressed in a wide variety of ways by different physicians. It can be difficult to define what sets and reps are depending on the exercise, and sometimes one or both are not well-defined at all. Additionally, the use of apostrophes and quotes can either indicate measurements of time or distance, once again requiring context to disambiguate. Mentions of distance were not annotated in the gold-standard labels, but it is important in measuring the intensity of some exercises, so we plan to include it in the future.

Some of the misclassifications of the rule-based algorithm are due to inaccuracies in the gold-standard data set. For instance, many false positives produced by the rule-based algorithm appeared to be concepts that were missed by the annotators. There were also a few minor errors that could be explained by a mouse slip, including a span of text being assigned the wrong concept or a span excluding the last letter in a word. There were also some spelling mistakes in the notes themselves; common instances were explicitly mentioned in the rules to increase precision. Preprocessing clinical notes to correct spelling mistakes might be useful to improve results, although this creates a risk of incorrect changes being made to uncommon words. All of these errors were not particularly common throughout the labels, but they could have a significant effect on concepts that are already uncommon in the data.

Another obstacle that obscured some of the signals in the data came from the deidentification process. In addition to removing names, addresses, and other protected information from these documents, many other tokens and phrases were mistakenly removed, including equipment names and numbers denoting indices in a list. These were replaced with placeholder tokens such as "[ADDRESS]" or "[PERSONALNAME]." The low precision of the deidentification process caused some relevant information to be obfuscated or entirely erased from notes.

During the data annotation, we found that many of the concepts identified as relevant in this domain were not well documented in the data we extracted for annotation. This could be due in part to the fact that the data were only collected from patients who had a stroke, but this is not expected to be the main reason because patients who had a stroke can have a wide variety of musculoskeletal problems, resulting in a correspondingly wide variety of treatments being mentioned in clinical notes [23]. The other reason the data set lacks many of these concepts could be that they are rarely mentioned in these particular sections of clinical notes, either because they are not common enough to appear in many records at all or because they are mentioned more often in other sections. Thus, future research could focus on improving extraction methods to focus more on these uncommon concepts or include information from outside of the exercise descriptions.

In addition to ChatGPT for the LLM-based NLP approach, we also fine-tuned a Bidirectional Encoder Representations from Transformers (BERT) model with the task of categorizing the physical rehabilitation exercise concept. The BioClinicalBERT model [24] was used, which was pretrained on Medical Information Mart for Intensive Care-III (MIMIC-III) [25]. However, the amount of data collected seemed insufficient to make the model perform comparably to simpler methods. The model with the highest F_1-score on the validation set had an average F_1-score of 0.05 across all concepts on the test set. It accurately predicted in-office exercise performance with an F_1-score of 0.72. However, the performance on the remaining 100 concepts ranged only from 0 to 0.35. Therefore, we did not include this approach in the experimental comparison.

Limitations and Future Work

One limitation in this research was the necessary exclusion of "Duration," "Number of Sets," and "Number of Reps" from our machine learning–based NLP analysis due to their numeric nature, rendering them unsuitable for binary classification tasks. In future work, we plan to incorporate regression models or specialized classification techniques capable of handling numeric data. We also plan to expand our research to include additional variables such as stroke duration and severity, recognizing their potential to significantly enhance the prediction accuracy and effectiveness of rehabilitation strategies.

Furthermore, another limitation of this study is that we did not consider technique names and their association with specific motion types in rehabilitation exercise notes. For instance, we encountered the text "1: Standing AAROM PNF exercise D1/D2 flexion - 20 x" during annotation but did not annotate the technique name PNF (proprioceptive neuromuscular facilitation). To address this, in future work, we intend to develop a supplementary module for our algorithm that can effectively extract and map popular technique names to their corresponding motion types and categories, thereby enhancing the comprehensiveness and applicability of the algorithm.

Moreover, we plan to implement a robust standardized extraction protocol in the next version of our algorithm to mitigate the omission of therapeutic procedure sections due to copy-and-paste errors. This protocol will include multiple checks for consistency and completeness and will be assessed through a pilot study to ensure its reliability and accuracy. To enhance our model's generalizability amid varied note-writing practices across rehabilitation facilities, future research will also focus on diversifying data sources, refining adaptability to diverse writing styles and terminologies, and conducting extensive validation studies in a range of settings to improve performance. Through continuous monitoring and refinement of our extraction process, we are committed to enhancing the reliability and validity of our data, thereby strengthening the overall quality and impact of our research.

Conclusions

In this study, we developed and evaluated several NLP algorithms to extract physical rehabilitation exercise information from clinical notes of patients who had stroke. We first created a novel and comprehensive clinical ontology to represent physical rehabilitation exercise in clinical notes and then developed a variety of NLP algorithms leveraging state-of-the-art techniques, including rule-based NLP algorithms, machine learning–based NLP algorithms, and LLM-based NLP algorithms. The experiments on the clinical notes of a cohort of patients who had a stroke showed that the rule-based NLP algorithm had the best performance for most of the physical rehabilitation exercise concepts. Among all machine learning models, gradient boosting achieved the best performance on a majority of concepts. On the other hand, the rule-based NLP performed well for extracting handled durations, sets, and reps, while gradient boosting excelled in ROM and location detection. The LLM-based NLP achieved high recall with zero-shot and few-shot prompts but low precision and F_1-scores. It occasionally outperformed simpler models and once bet the rule-based algorithm.

Abstract

Background: Large language models (LLMs) have shown remarkable capabilities in natural language processing (NLP), especially in domains where labeled data are scarce or expensive, such as the clinical domain. However, to unlock the clinical knowledge hidden in these LLMs, we need to design effective prompts that can guide them to perform specific clinical NLP tasks without any task-specific training data. This is known as in-context learning, which is an art and science that requires understanding the strengths and weaknesses of different LLMs and prompt engineering approaches.

Objective: The objective of this study is to assess the effectiveness of various prompt engineering techniques, including 2 newly introduced types—heuristic and ensemble prompts, for zero-shot and few-shot clinical information extraction using pretrained language models.

Methods: This comprehensive experimental study evaluated different prompt types (simple prefix, simple cloze, chain of thought, anticipatory, heuristic, and ensemble) across 5 clinical NLP tasks: clinical sense disambiguation, biomedical evidence extraction, coreference resolution, medication status extraction, and medication attribute extraction. The performance of these prompts was assessed using 3 state-of-the-art language models: GPT-3.5 (OpenAI), Gemini (Google), and LLaMA-2 (Meta). The study contrasted zero-shot with few-shot prompting and explored the effectiveness of ensemble approaches.

Results: The study revealed that task-specific prompt tailoring is vital for the high performance of LLMs for zero-shot clinical NLP. In clinical sense disambiguation, GPT-3.5 achieved an accuracy of 0.96 with heuristic prompts and 0.94 in biomedical evidence extraction. Heuristic prompts, alongside chain of thought prompts, were highly effective across tasks. Few-shot prompting improved performance in complex scenarios, and ensemble approaches capitalized on multiple prompt strengths. GPT-3.5 consistently outperformed Gemini and LLaMA-2 across tasks and prompt types.

Conclusions: This study provides a rigorous evaluation of prompt engineering methodologies and introduces innovative techniques for clinical information extraction, demonstrating the potential of in-context learning in the clinical domain. These findings offer clear guidelines for future prompt-based clinical NLP research, facilitating engagement by non-NLP experts in clinical NLP advancements. To the best of our knowledge, this is one of the first works on the empirical evaluation of different prompt engineering approaches for clinical NLP in this era of generative artificial intelligence, and we hope that it will inspire and inform future research in this area.

Introduction

Clinical information extraction (IE) is the task of identifying and extracting relevant information from clinical narratives, such as clinical notes, radiology reports, or pathology reports. Clinical IE has many applications in health care, such as improving diagnosis, treatment, and decision-making; facilitating clinical research; and enhancing patient care [1,2]. However, clinical IE faces several challenges, such as the scarcity and heterogeneity of annotated data, the complexity and variability of clinical language, and the need for domain knowledge and expertise.

Zero-shot IE is a promising paradigm that aims to overcome these challenges by leveraging large pretrained language models (LMs) that can perform IE tasks without any task-specific training data [3]. In-context learning is a framework for zero-shot and few-shot learning, where a large pretrained LM takes a context and directly decodes the output without any retraining or fine-tuning [4]. In-context learning relies on prompt engineering, which is the process of crafting informative and contextually relevant instructions or queries as inputs to LMs to guide their output for specific tasks [5]. The use of prompt engineering lies in its ability to leverage the powerful capabilities of large LMs (LLMs), such as GPT-3.5 (OpenAI) [6], Gemini (Google) [7], LLaMA-2 (Meta) [8], even in scenarios where limited or no task-specific training data are available. In clinical natural language processing (NLP), where labeled data sets tend to be scarce, expensive, and time-consuming to create, splintered across institutions, and constrained by data use agreements, prompt engineering becomes even more crucial to unlock the potential of state-of-the-art LLMs for clinical NLP tasks.

While prompt engineering has been widely explored for general NLP tasks, its application and impact in clinical NLP remain relatively unexplored. Most of the existing literature on prompt engineering in the health care domain focuses on biomedical NLP tasks rather than clinical NLP tasks that involve processing real-world clinical notes. For instance, Chen et al [9] used a fixed template as the prompt to measure the performance of LLMs on biomedical NLP tasks but did not investigate different kinds of prompting methods. Wang et al [10] gave a comprehensive survey of prompt engineering for health care NLP applications such as question-answering systems, text summarization, and machine translation. However, they did not compare and evaluate different types of prompts for specific clinical NLP tasks and how the performance varies across different LLMs. There is a lack of systematic and comprehensive studies on how to engineer prompts for clinical NLP tasks, and the existing literature predominantly focuses on general NLP problems. This creates a notable gap in the research, warranting a dedicated investigation into the design and development of effective prompts specifically for clinical NLP. Currently, researchers in the field lack a comprehensive understanding of the types of prompts that exist, their relative effectiveness, and the challenges associated with their implementation in clinical settings.

The main research question and objectives of this study are to investigate how to engineer prompts for clinical NLP tasks, identify best practices, and address the challenges in this emerging field. By doing so, we aim to propose a guideline for future prompt-based clinical NLP studies. In this work, we present a comprehensive empirical evaluation study on prompt engineering for 5 diverse clinical NLP tasks, namely, clinical sense disambiguation, biomedical evidence extraction, coreference resolution, medication status extraction, and medication attribute extraction [11,12]. By systematically evaluating different types of prompts proposed in recent literature, including prefix [13], cloze [14], chain of thought [15], and anticipatory prompts [16], we gain insights into their performance and suitability for each task. Two new types of prompting approaches were also introduced: (1) heuristic prompts and (2) ensemble prompts. The rationale behind these novel prompts is to leverage the existing knowledge and expertise in rule-based NLP, which has been prominent and has shown significant results in the clinical domain [17]. We hypothesize that heuristic prompts, which are based on rules derived from domain knowledge and linguistic patterns, can capture the salient features and constraints of the clinical IE tasks. We also conjecture that ensemble prompts, which are composed of multiple types of prompts, can benefit from the complementary strengths and mitigate the weaknesses of each individual prompt.

One of the key aspects of prompt engineering is the number of examples or shots that are provided to the model along with the prompt. Few-shot prompting is a technique that provides the model with a few examples of input-output pairs, while zero-shot prompting does not provide any examples [3,18]. By contrasting these strategies, we aim to shed light on the most efficient and effective ways to leverage prompt engineering in clinical NLP. Finally, we propose a prompt engineering framework to build and deploy zero-shot NLP models for the clinical domain. This study covers 3 state-of-the-art LMs, including GPT-3.5, Gemini, and LLaMA-2, to assess the generalizability of the findings across various models. This work yields novel insights and guidelines for prompt engineering specifically for clinical NLP tasks.

Methods

Tasks

We selected 5 distinct clinical NLP tasks representing diverse categories of natural language understanding: clinical sense disambiguation (text classification) [19], biomedical evidence extraction (named entity recognition) [20], coreference resolution [21], medication status extraction (named entity recognition+classification) [22], and medication attribute

extraction (named entity recognition+relation extraction) [23]. Table 1 provides a succinct overview of each task, an example scenario, and the corresponding prompt type used for each task.

Table 1. Task descriptions.

Task	NLP[a] task category	Description	Example prompt
Clinical sense disambiguation	Text classification	This task involves identifying the correct meaning of clinical abbreviations within a given context.	What is the meaning of the abbreviation CR[b] in the context of cardiology?
Biomedical evidence extraction	Text extraction	In this task, interventions are extracted from biomedical abstracts.	Identify the psychological interventions in the given text?
Coreference resolution	Coreference resolution	The goal here is to identify all mentions in clinical text that refer to the same entity.	Identify the antecedent for the patient in the clinical note.
Medication status extraction	NER[c]+classification	This task involves identifying whether a medication is currently being taken, not taken, or unknown.	What is the current status of [24] in the treatment of [25]?
Medication attribute extraction	NER+RE[d]	The objective here is to identify specific attributes of a medication, such as dosage and frequency.	What is the recommended dosage of [26] for [27] and how often?

[a]NLP: natural language processing.

[b]CR: cardiac resuscitation.

[c]NER: named entity recognition.

[d]RE: relation extraction.

Data Sets and Evaluation

The prompts were evaluated on 3 LLMs, GPT-3.5, Gemini, and LLaMA-2, under both zero-shot and few-shot prompting conditions, using precise experimental settings and parameters. To simplify the evaluation process and facilitate clear comparisons, we adopted accuracy as the sole evaluation metric for all tasks. Accuracy is defined as the proportion of correct outputs generated by the LLM for each task, using a resolver that maps the output to the label space. Table 2 shows the data sets and sample size for each clinical NLP task. The data sets are as follows:

- Clinical abbreviation sense inventories: This is a data set of clinical abbreviations, senses, and instances [28]. It contains 41 acronyms from 18,164 notes, along with their expanded forms and contexts. We used a randomly sampled subset from this data set for clinical sense disambiguation, coreference resolution, medication status extraction, and medication attribute extraction tasks (Table 2).
- Evidence-based medicine-NLP: This is a data set of evidence-based medicine annotations for NLP [29]. It contains 187 abstracts and 20 annotated abstracts, with interventions extracted from the text. We used this data set for the biomedical evidence extraction task.

Table 2. Evaluation data sets and samples for different tasks.

Task	Data set	Data set example	Samples
Clinical sense disambiguation	CASI[a]	The abbreviation "CR[b]" can refer to "cardiac resuscitation" or "computed radiography."	11 acronyms from 55 notes
Biomedical evidence extraction	EBM[c]-NLP[d]	Identifying panic, avoidance, and agoraphobia (psychological interventions)	187 abstracts and 20 annotated abstracts
Coreference resolution	CASI	Resolving references to "the patient" or "the study" within a clinical trial report.	105 annotated examples
Medication status extraction	CASI	Identifying that a patient is currently taking insulin for diabetes.	105 annotated examples with 340 medication status pairs
Medication attribute extraction	CASI	Identifying dosage, frequency, and route of a medication for a patient.	105 annotated examples with 313 medications and 533 attributes

[a]CASI: clinical abbreviation sense inventories.

[b]CR: cardiac resuscitation.

[c]EBM: evidence-based medicine.

[d]NLP: natural language processing.

All experiments were carried out in different system settings. All GPT-3.5 experiments were conducted using the GPT-3.5 Turbo application programming interface as of the September 2023 update. The LLaMA-2 model was directly accessed for

our experiments. Gemini was accessed using the Gemini application (previously BARD)—Google's generative artificial intelligence conversational system. These varied system settings and access methods were taken into account to ensure the reliability and validity of our experimental results, given the differing architectures and capabilities of each LLM.

In evaluating the prompt-based approaches on GPT-3.5, Gemini, and LLaMA-2, we have also incorporated traditional NLP baselines to provide a comprehensive understanding of the LLMs' performance in a broader context. These baselines include well-established models such as Bidirectional Encoder Representations From Transformers (BERT) [30], Embeddings From Language Models (ELMO) [31], and PubMedBERT-Conditional Random Field (PubMedBERT-CRF) [32], which have previously set the standard in clinical NLP tasks. By comparing the outputs of LLMs against these baselines, we aim to offer a clear perspective on the advancements LLMs represent in the field. This comparative analysis is crucial for appreciating the extent to which prompt engineering techniques can leverage the inherent capabilities of LLMs, marking a significant evolution from traditional approaches to more dynamic and contextually aware methodologies in clinical NLP.

Prompt Creation Process

A rigorous process was followed to create suitable prompts for each task. These prompts were carefully crafted to match the specific context and objectives of each task. There is no established method for prompt design and selection as of now. Therefore, we adopted an iterative approach where prompts, which are created by health care experts, go through a verification and improvement process in an iterative cycle, which involved design, experimentation, and evaluation, as depicted in Figure 1.

Figure 1. Iterative prompt design process: a schematic diagram of the iterative prompt creation process for clinical NLP tasks. The process consists of 3 steps: sampling, prompt designing, and deployment. The sampling step involves defining the task and collecting data and annotations. The prompt designing step involves creating and refining prompts using different types and language models. The deployment step involves selecting the best model and deploying the model for clinical use. LLM: large language model; NER: named entity recognition; NLP: natural language processing; RE: relation extraction.

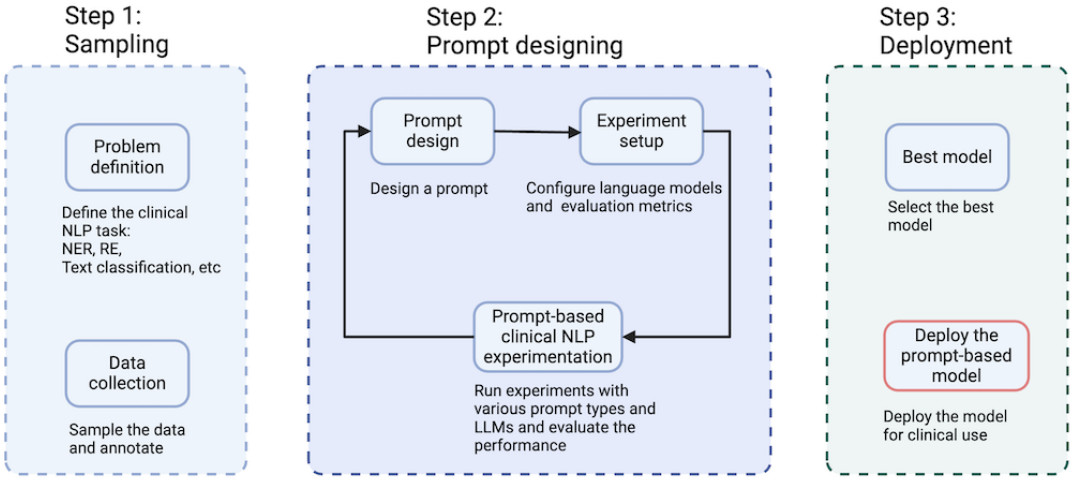

Figure 1 illustrates the 3 main steps of our prompt creation process: sampling, prompt designing, and deployment. In the sampling step (step 1), we defined the clinical NLP task (eg, named entity recognition, relation extraction, and text classification) and collected a sample of data and annotations as an evaluation for the task. In the prompt designing step (step 2), a prompt was designed for the task using one of the prompt types (eg, simple prefix prompt, simple cloze prompt, heuristic prompt, chain of thought prompt, question prompt, and anticipatory prompt). We also optionally performed few-shot prompting by providing some examples along with the prompt. The LLMs and the evaluation metrics for the experiment setup were then configured. We ran experiments with various prompt types and LLMs and evaluated their performance on the task. Based on the results, we refined or modified the prompt design until we achieved satisfactory performance or reached a limit. In the deployment step (step 3), the best prompt-based models were selected based on their performance metrics, and the model was deployed for the corresponding task.

Prompt Engineering Techniques

Overview

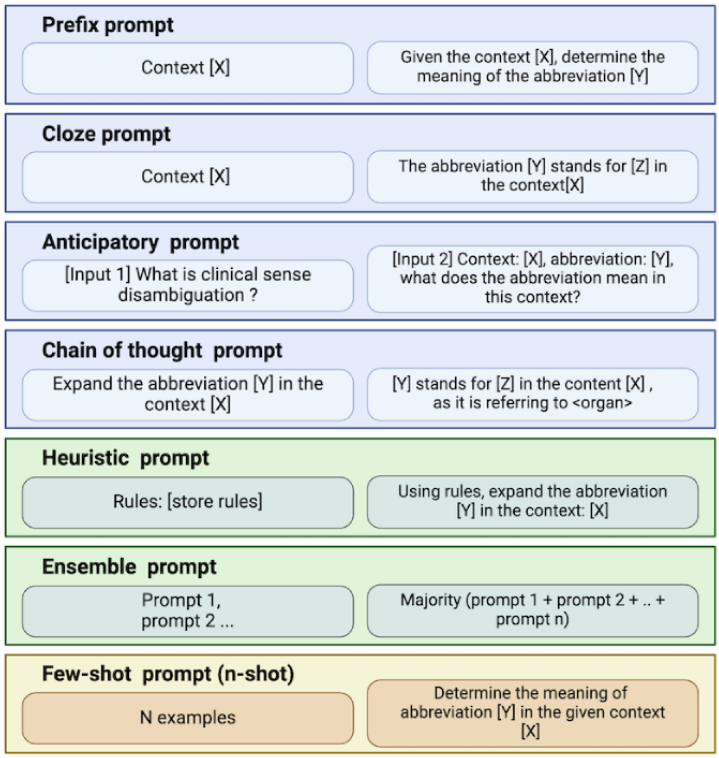
Prompt engineering is the process of designing and creating prompts that elicit desired responses from LLMs. Prompts can be categorized into different types based on their structure, function, and complexity.

Each prompt consists of a natural language query that is designed to elicit a specific response from the pretrained LLM. The prompts are categorized into 7 types, as illustrated in Figure 2 (all prompts have been included in Multimedia Appendix 1). Prefix prompts are the simplest type of prompts, which prepend a word or phrase indicating the type or format or tone of response for control and relevance. Cloze prompts are based on the idea of fill in the blank exercises, which create a masked token in the input text and ask the LLM to predict the missing word or phrase [3]. Anticipatory prompts are the prompts anticipating the next question or command based on experience or knowledge, guiding the conversation. Chain of thought

prompting involves a series of intermediate natural language reasoning steps that lead to the final output [15].

In addition to the existing types of prompts, 2 new novel prompts were also designed: heuristic prompts and ensemble prompts, which will be discussed in the following sections.

Figure 2. Types of prompts: examples of 7 types of prompts that we used to query the pretrained language model for different clinical information extraction tasks. [X]: context; [Y]: abbreviation; [Z]: expanded form.



Heuristic Prompts

Heuristic prompts are rule-based prompts that decompose complex queries into smaller, more manageable components for comprehensive answers. Adopting the principles of traditional rule-based NLP, which relies on manually crafted, rule-based algorithms for specific clinical NLP applications, we have integrated these concepts into our heuristic prompts approach. These prompts use a set of predefined rules to guide the LLM in expanding abbreviations within a given context. For instance, a heuristic prompt might use the rule that an abbreviation is typically capitalized, followed by a period, and preceded by an article or a noun. This approach contrasts with chain of thought prompts, which focus on elucidating the reasoning or logic behind an output. Instead, heuristic prompts leverage a series of predefined rules to direct the LLM in executing a specific task.

Mathematically, we can express a heuristic prompt as $H(x)$, a function applied to an input sequence x. This function is defined as a series of rule-based transformations T_i, where i indicates the specific rule applied. The output of this function, denoted as y_H, is then:

$$y_H=H(x)=T_n(T_{\{n-1\}}(\ldots T_1(x)))$$

Here, each transformation T_i applies a specific heuristic rule to modify the input sequence, making it more suitable for processing by LLMs.

From an algorithmic standpoint, heuristic prompts are implemented by defining a set of rules $R=\{R_1, R_2, \ldots, R_m\}$. Each rule R_j is a function that applies a specific heuristic criterion to an input token or sequence of tokens. Algorithmically, the heuristic prompting process can be summarized as follows:

By merging the precision and specificity of traditional rule-based NLP methods with the advanced capabilities of LLMs, the heuristic prompts offer a robust and accurate system for clinical information processing and analysis.

Ensemble Prompts

Ensemble prompts are prompts that combine multiple prompts using majority voting for aggregated outputs. They use various types of prompts to generate multiple responses to the same input, subsequently selecting the most commonly occurring output as the final answer. For instance, an ensemble prompt might use 3 different prefix prompts, or a combination of other prompt types, to produce 3 potential expansions for an abbreviation. The most frequently appearing expansion is then chosen. For the sake of simplicity, we amalgamated the outputs from all 5 different prompt types using a majority voting approach.

Mathematically, consider a set of m different prompting methods $P_1, P_2, \ldots, P_m$ applied to the same input x. Each method generates

an output y_i for i=1,2, ..., m. The ensemble prompt's output y_E is then the mode of these outputs:

y_E=mode (y_1, y_2, ..., y_m)

Algorithmically, the ensemble prompting process is as follows:

The rationale behind an ensemble prompt is that by integrating multiple types of prompts, we can use the strengths and counterbalance the weaknesses of each individual prompt, offering a robust and potentially more accurate response. Some prompts may be more effective for specific tasks or models, while others might be more resilient to noise or ambiguity. Majority voting allows us to choose the most likely correct or coherent output from the variety generated by different prompt types.

Results

Overview

In this section, we present the results of our experiments on prompt engineering for zero-shot clinical IE. Various prompt types were evaluated across 5 clinical NLP tasks, aiming to understand how different prompts influence the accuracy of different LLMs. Zero-shot and few-shot prompting strategies were also compared, exploring how the addition of context affects the model performance. Furthermore, we tested an ensemble approach that combines the outputs of different prompt types using majority voting. Finally, the impact of different LLMs on task performance was analyzed, and some interesting patterns were observed. Table 3 illustrates that different prompt types have different levels of effectiveness for different tasks and LLMs. We can also observe some general trends across the tasks and models.

Table 3. Performance comparison of different prompt types and language models.

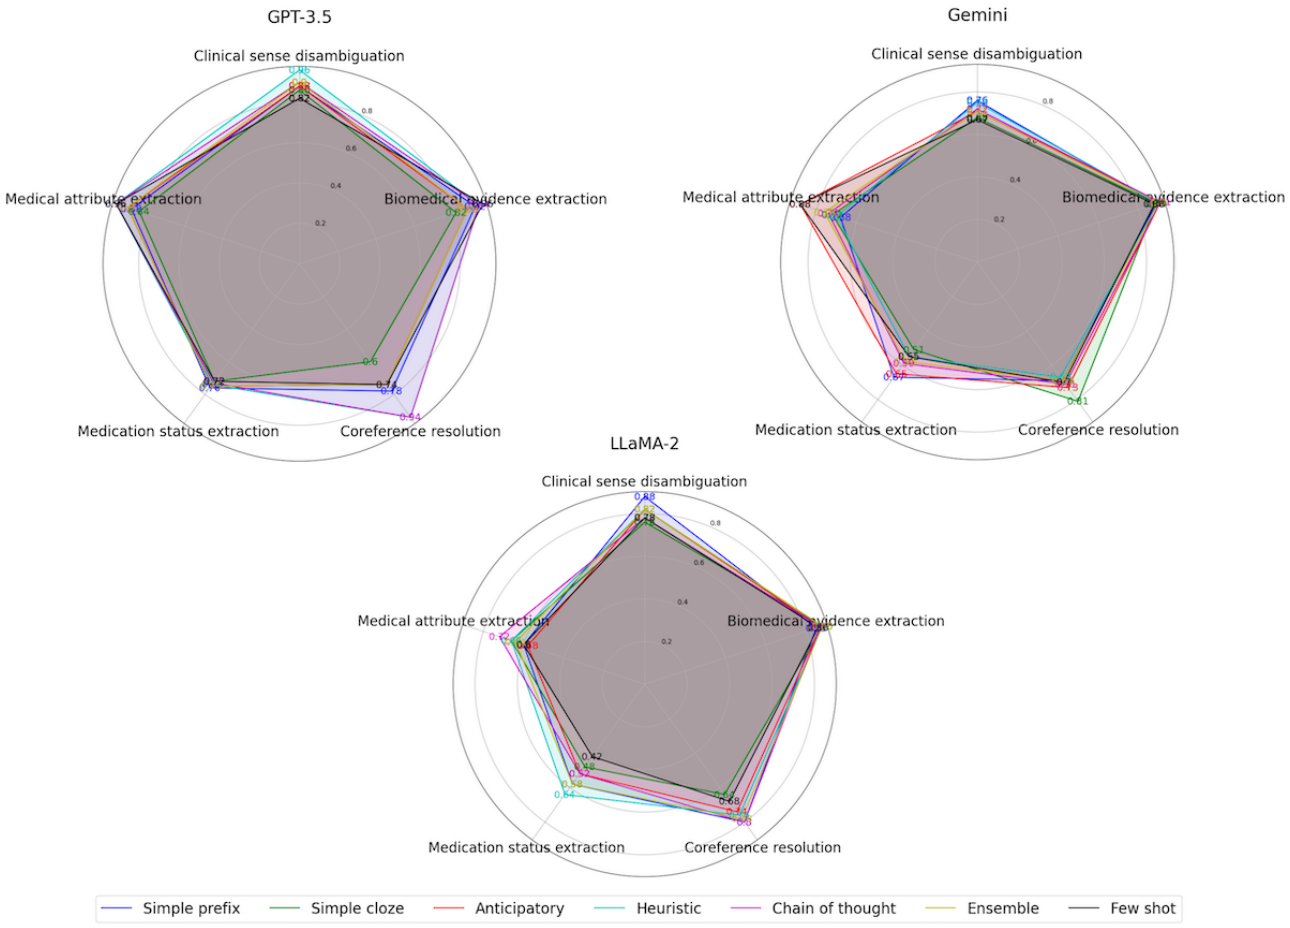
Prompt Optimization and Evaluation

For clinical sense disambiguation, the heuristic and prefix prompts consistently achieved the highest performance across all LLMs, significantly outperforming baselines such as BERT [30] and ELMO, with GPT-3.5 achieving an accuracy of 0.96, showcasing its advanced understanding of clinical context using appropriate prompting strategies. For biomedical evidence extraction, the heuristic and chain of thought prompts excelled across all LLMs in zero-shot setting. This indicates that these prompt types were able to provide enough information and constraints for the model to extract the evidence from the clinical note. GPT-3.5 achieved an accuracy of 0.94 with these prompt types, which was higher than any other model or prompt type combination. For coreference resolution, the chain of thought prompt type performed best among all prompt types with 2 LLMs—GPT-3.5 and LLaMA-2. This indicates that this prompt type was able to provide enough structure and logic for the model to resolve the coreference in the clinical note. GPT-3.5 displayed high accuracy with this prompt type, achieving an

accuracy of 0.94. For medication status extraction, simple prefix and heuristic prompts yielded good results across all LLMs. These prompt types were able to provide enough introduction or rules for the model to extract the status of the medication in relation to the patient or condition. GPT-3.5 excelled with these prompt types, achieving an accuracy of 0.76 and 0.74, respectively. For medication attribute extraction, we found that the chain of thought and heuristic prompts were effective across all LLMs. These prompt types were able to provide enough reasoning or rules for the model to extract and label the attributes of medications from clinical notes. Anticipatory prompts, however, had the best accuracy for Gemini among all the prompts. GPT-3.5 achieved an accuracy of 0.96 with these prompt types, which was higher than any other model or prompt type combination.

Thus, we can see that task-specific prompt tailoring is crucial for achieving high accuracy. Different tasks require different levels of information and constraints to guide the LLM to produce the desired output. The experiments show that heuristic, prefix, and chain of thought prompts are generally very effective for guiding the LLM to produce clear and unambiguous outputs. As shown in Figure 3, it is clear that GPT-3.5 is a superior and versatile LLM that can handle various clinical NLP tasks in zero-shot settings, outperforming other models in most cases.

Figure 3. Graphical comparison of prompt types in the 5 clinical natural language processing tasks used in this study.



Overall, the prompt-based approach has demonstrated remarkable superiority over traditional baseline models across all the 5 tasks. For clinical sense disambiguation, GPT-3.5's heuristic prompts achieved a remarkable accuracy of 0.96, showcasing a notable improvement over baselines such as BERT (0.42) and ELMO (0.55). In biomedical evidence extraction, GPT-3.5 again set a high standard with an accuracy of 0.94 using heuristic prompts, far surpassing the baseline performance of PubMedBERT-CRF at 0.35. Coreference resolution saw GPT-3.5 reaching an accuracy of 0.94 with chain of thought prompts, eclipsing the performance of existing methods such as Toshniwal et al [34] (0.69). In medication status extraction, GPT-3.5 outperformed the baseline ScispaCy (0.52) with an accuracy of 0.76 using simple prefix prompts. Finally, for medication attribute extraction, GPT-3.5's heuristic prompts achieved an impressive accuracy of 0.96, significantly higher than the ScispaCy baseline (0.70). These figures not only showcase the potential of LLMs in clinical settings but also set a foundation for future research to build upon, exploring even more sophisticated prompt engineering strategies and their implications for health care informatics.

Zero-Shot Versus Few-Shot Prompting

The performance of zero-shot prompting and few-shot prompting strategies was compared for each clinical NLP task. The same prompt types and LLMs were used as in the previous experiments, but some context was added to the input in the form of examples or explanations. Two examples or

explanations were used for each task (2-shot) depending on the complexity and variability of the task. Table 3 shows that few-shot prompting consistently improved the accuracy of all combinations for all tasks except for clinical sense disambiguation and medication attribute extraction, where some zero-shot prompt types performed better. We also observed some general trends across the tasks and models.

We found that few-shot prompting enhanced accuracy by providing limited context that aided complex scenario understanding. The improvement was more pronounced compared to simple cloze prompts, which had lower accuracy in most of the tasks. We also found that some zero-shot prompt types were very effective for certain tasks, even outperforming few-shot prompting. These prompt types used a rule-based or reasoning approach to generate sentences that contained definitions or examples of the target words or concepts, which helped the LLM to understand and match the context. For example, heuristic prompts achieved higher accuracy than few-shot prompting for clinical sense disambiguation and medication attribute extraction, while chain of thought prompts achieved higher accuracy than few-shot prompting for coreference resolution and medication attribute extraction. Alternatively, the clinical evidence extraction task likely benefits from additional context provided by few-shot examples, which can guide the model more effectively than the broader inferences made in zero-shot scenarios. This suggests that tasks requiring deeper contextual understanding might be better suited to few-shot learning approaches.

From these results, we can infer that LLMs can be effectively used for clinical NLP in a no-data scenario, where we do not have many publicly available data sets, by using appropriate zero-shot prompt types that guide the LLM to produce clear and unambiguous outputs. However, few-shot prompting can also improve the performance of LLMs by providing some context that helps the LLM to handle complex scenarios.

Other Observations

Ensemble Approaches

We experimented with an ensemble approach by combining outputs from multiple prompts using majority voting. The ensemble approach was not the best-performing strategy for any of the tasks, but it was better than the low-performing prompts. The ensemble approach was able to benefit from the diversity and complementarity of different prompt types and avoid some of the pitfalls of individual prompts. For example, for clinical sense disambiguation, the ensemble approach achieved an accuracy of 0.9 with GPT-3.5, which was the second best–performing prompt type. Similarly, for medication attribute extraction, the ensemble approach achieved an accuracy of 0.9 with GPT-3.5 and 0.76 with Gemini, which were close to the best single prompt type (anticipatory). However, the ensemble approach also had some drawbacks, such as inconsistency and noise. For tasks that required more specific or consistent outputs, such as coreference resolution, the ensemble approach did not improve the accuracy over the best single prompt type and sometimes even decreased it. This suggests that the ensemble approach may introduce ambiguity for tasks that require more precise or coherent outputs.

While the ensemble approach aims to reduce the variance introduced by individual prompt idiosyncrasies, our specific implementation observed instances where the combination of diverse prompt types introduced additional complexity. This complexity occasionally manifested as inconsistency and noise in the outputs contrary to our objective of achieving higher performance. Future iterations of this approach may include refinement of the prompt selection process to enhance consistency and further reduce noise in the aggregated outputs.

Impact of LLMs

Variations in performance were observed among different LLMs (Table 3). We found that GPT-3.5 generally outperformed Gemini and LLaMA-2 on most tasks. This suggests that GPT-3.5 has a better generalization ability and can handle a variety of clinical NLP tasks with different prompt types. However, Gemini and LLaMA-2 also showed some advantages over GPT-3.5 on certain tasks and prompt types. For example, Gemini achieved the highest accuracy of 0.81 with simple cloze prompts and LLaMA-2 achieved the highest accuracy of 0.8 with simple prefix prompts for coreference resolution. This indicates that Gemini and LLaMA-2 may have some domain-specific knowledge that can benefit certain clinical NLP tasks for specific prompt types.

Persona Patterns

Persona patterns are a way of asking the LLM to act like a persona or a system that is relevant to the task or domain. For example, one can ask the LLM to "act as a clinical NLP expert." This can help the LLM to generate outputs that are more appropriate and consistent with the persona or system. For example, one can use the following prompt for clinical sense disambiguation:

> *Act as a clinical NLP expert. Disambiguate the word "cold" in the following sentence: "She had a cold for three days."*

We experimented with persona patterns for different tasks and LLMs and found that they can improve the accuracy and quality of the outputs. Persona patterns can help the LLM to focus on the relevant information and constraints for the task and avoid generating outputs that are irrelevant or contradictory to the persona or system.

Randomness in Output

Most LLMs do not produce the output in the same format every time. There is inherent randomness in the outputs the LLMs produce. Hence, the prompts need to be specific in the way they are done for the task. Prompts are powerful when they are specific and if we use them in the right way.

Randomness in output can be beneficial or detrimental for different tasks and scenarios. In the clinical domain, randomness can introduce noise and errors in the outputs, which can make them less accurate and reliable for the users. For example, for tasks that involve extracting factual information, such as biomedical evidence extraction and medication status extraction, randomness can cause the LM to produce outputs that are inconsistent or contradictory with the input or context.

Guidelines and Suggestions for Optimal Prompt Selection

In recognizing the evolving nature of clinical NLP, we expand our discussion to contemplate the adaptability of our recommended prompt types and LM combinations across a wider spectrum of clinical tasks and narratives. This speculative analysis aims to bridge the gap between our current findings and their applicability to unexplored clinical NLP challenges, setting a foundation for future research to validate and refine these recommendations. In this section, we synthesize the main findings from our experiments and offer some practical advice for prompt engineering for zero-shot and few-shot clinical IE. We propose the following steps for selecting optimal prompts for different tasks and scenarios:

The first step is to identify the type of clinical NLP task, which can be broadly categorized into three types: (1) classification, (2) extraction, and (3) resolution. Classification tasks involve assigning a label or category to a word, phrase, or sentence in a clinical note, such as clinical sense disambiguation or medication status extraction. Extraction tasks involve identifying and extracting relevant information from a clinical note, such as biomedical evidence extraction or medication attribute extraction. Resolution tasks involve linking or matching entities or concepts in a clinical note, such as coreference resolution.

The second step is to choose the prompt type that is most suitable for the task type. We found that different prompt types have different strengths and weaknesses for different task types, depending on the level of information and constraints they provide to the LLM. Table 4 summarizes our findings and recommendations for optimal prompt selection for each task type.

The third step is to choose the LLM that is most compatible with the chosen prompt type. We found that different LLMs have different capabilities and limitations for different prompt types, depending on their generalization ability and domain-specific knowledge. Table 5 summarizes our findings and recommendations for optimal LLM selection for each prompt type.

The fourth step is to evaluate the performance of the chosen prompt type and LLM combination on the clinical NLP task using appropriate metrics such as accuracy, precision, recall, or F_1-score. If the performance is satisfactory, then the prompt engineering process is complete. If not, then the process can be repeated by choosing a different prompt type or LLM or by modifying the existing prompt to improve its effectiveness.

Table 4. Optimal prompt types for different clinical natural language processing task types.

Task type	Prompt type
Classification	Heuristic or prefix
Extraction	Heuristic or chain of thought
Resolution	Chain of thought

Table 5. Optimal language models for different prompt types.

Prompt type	Language model
Heuristic	GPT-3.5
Prefix	GPT-3.5 or LLaMA-2
Cloze	Gemini or LLaMA-2
Chain of thought	GPT-3.5
Anticipatory	Gemini

Discussion

Principal Findings

In this paper, we have presented a novel approach to zero-shot and few-shot clinical IE using prompt engineering. Various prompt types were evaluated across 5 clinical NLP tasks: clinical sense disambiguation, biomedical evidence extraction, coreference resolution, medication status extraction, and medication attribute extraction. The performance of different LLMs, GPT-3.5, Gemini, and LLaMA-2, was also compared. Our main findings are as follows:

1. Task-specific prompt tailoring is crucial for achieving high accuracy. Different tasks require different levels of information and constraints to guide the LLM to produce the desired output. Therefore, it is important to design prompts that are relevant and specific to the task at hand and avoid using generic or vague prompts that may confuse the model or lead to erroneous outputs.
2. Heuristic prompts are generally very effective for guiding the LLM to produce clear and unambiguous outputs. These prompts use a rule-based approach to generate sentences that contain definitions or examples of the target words or concepts, which help the model to understand and match the context. Heuristic prompts are especially useful for tasks that involve disambiguation, extraction, or classification of entities or relations.
3. Chain of thought prompts are also effective for guiding the LLM to produce logical and coherent outputs. These prompts use a multistep approach to generate sentences that contain a series of questions and answers that resolve the

task in the context. Chain of thought prompts are especially useful for tasks that involve reasoning, inference, or coreference resolution.

4. Few-shot prompting can improve the performance of LLMs by providing some context that helps the model to handle complex scenarios. Few-shot prompting can be done by adding some examples or explanations to the input depending on the complexity and variability of the task. Few-shot prompting can enhance accuracy by providing limited context that aids complex scenario understanding. The improvement is more pronounced compared to simple prefix and cloze prompts, which had lower accuracy in most of the tasks.
5. Ensemble approaches can also improve the performance of LLMs by combining outputs from multiple prompts using majority voting. Ensemble approaches can leverage the strengths of each prompt type and reduce the errors of individual prompts. Ensemble approaches are especially effective for tasks that require multiple types of information or reasoning, such as biomedical evidence extraction and medication attribute extraction.

It is noteworthy that context size has a significant impact on the performance of LLMs in zero-shot IE [36]. In the scope of this study, we have avoided the context size dependence on performance, as it is a complex issue that requires careful consideration.

This study serves as an initial exploration into the efficacy of prompt engineering in clinical NLP, providing foundational insights rather than exhaustive guidelines. Given the rapid advancements in generative artificial intelligence and the complexity of clinical narratives, we advocate for continuous empirical testing of these prompt strategies across diverse clinical tasks and data sets. This approach will not only validate the generalizability of our findings but also uncover new avenues for enhancing the accuracy and applicability of LLMs in clinical settings.

Limitations

In this study, we primarily focused on exploring the capabilities and versatility of generative LLMs in the context of zero-shot and few-shot learning for clinical NLP tasks. Our approach also has some limitations that we acknowledge in this work. First, it relies on the quality and availability of pretrained LLMs, which may vary depending on the domain and task. As LLMs are rapidly evolving, some parts of the prompt engineering discipline may be timeless, while some parts may evolve and adapt over time as different capabilities of models evolve. Second, it requires a lot of experimentation and iteration to optimize prompts for different applications, which may be iterative and time-consuming. However, once optimal prompts are identified, the approach offers time savings in subsequent applications by reusing these prompts or making minor adjustments for similar tasks. We may not have explored all the possible combinations and variations of prompts that could potentially improve the performance of the clinical NLP tasks. Third, the LLMs do not release the details of the data set that they were trained on. Hence, the high accuracy could be because the models would have already seen the data during training and not because of the effectiveness of the prompts.

Future Work

We plan to address these challenges and limitations in our future work. We aim to develop more systematic and automated methods for prompt design and evaluation, such as using prompt-tuning or meta-learning techniques. We also aim to incorporate more domain knowledge or external resources into the prompts or the LLMs, such as using ontologies, knowledge graphs, or databases. We also aim to incorporate more quality control or error correction mechanisms into the prompts or the LLMs, such as using adversarial examples, confidence scores, or human feedback.

Conclusions

In this paper, we have benchmarked different prompt engineering techniques for both zero-shot and few-shot clinical NLP tasks. Two new types of prompts, heuristic and ensemble prompts, were also conceptualized and proposed. We have demonstrated that prompt engineering can enable the use of pretrained LMs for various clinical NLP tasks without requiring any fine-tuning or additional data. We have shown that task-specific prompt tailoring, heuristic prompts, chain of thought prompts, few-shot prompting, and ensemble approaches can improve the accuracy and quality of the outputs. We have also shown that GPT-3.5 is very adaptable and precise across all tasks and prompt types, while Gemini and LLaMA-2 may have some domain-specific advantages for certain tasks and prompt types.

We believe that a prompt-based approach has several benefits over existing methods for clinical IE. It reduces the cost and time in the initial phases of clinical NLP application development, where prompt-based methods offer a streamlined alternative to the conventional data preparation and model training processes. It is flexible and adaptable, as it can be applied to various clinical NLP tasks with different prompt types and LLMs. It is interpretable and explainable, as it uses natural language prompts that can be easily understood and modified by humans.

Abstract

Background: In the evolving field of health care, multimodal generative artificial intelligence (AI) systems, such as ChatGPT-4 with vision (ChatGPT-4V), represent a significant advancement, as they integrate visual data with text data. This integration has the potential to revolutionize clinical diagnostics by offering more comprehensive analysis capabilities. However, the impact on diagnostic accuracy of using image data to augment ChatGPT-4 remains unclear.

Objective: This study aims to assess the impact of adding image data on ChatGPT-4's diagnostic accuracy and provide insights into how image data integration can enhance the accuracy of multimodal AI in medical diagnostics. Specifically, this study endeavored to compare the diagnostic accuracy between ChatGPT-4V, which processed both text and image data, and its counterpart, ChatGPT-4, which only uses text data.

Methods: We identified a total of 557 case reports published in the *American Journal of Case Reports* from January 2022 to March 2023. After excluding cases that were nondiagnostic, pediatric, and lacking image data, we included 363 case descriptions with their final diagnoses and associated images. We compared the diagnostic accuracy of ChatGPT-4V and ChatGPT-4 without vision based on their ability to include the final diagnoses within differential diagnosis lists. Two independent physicians evaluated their accuracy, with a third resolving any discrepancies, ensuring a rigorous and objective analysis.

Results: The integration of image data into ChatGPT-4V did not significantly enhance diagnostic accuracy, showing that final diagnoses were included in the top 10 differential diagnosis lists at a rate of 85.1% (n=309), comparable to the rate of 87.9% (n=319) for the text-only version (P=.33). Notably, ChatGPT-4V's performance in correctly identifying the top diagnosis was inferior, at 44.4% (n=161), compared with 55.9% (n=203) for the text-only version (P=.002, χ^2 test). Additionally, ChatGPT-4's self-reports showed that image data accounted for 30% of the weight in developing the differential diagnosis lists in more than half of cases.

Conclusions: Our findings reveal that currently, ChatGPT-4V predominantly relies on textual data, limiting its ability to fully use the diagnostic potential of visual information. This study underscores the need for further development of multimodal generative AI systems to effectively integrate and use clinical image data. Enhancing the diagnostic performance of such AI systems through improved multimodal data integration could significantly benefit patient care by providing more accurate and comprehensive diagnostic insights. Future research should focus on overcoming these limitations, paving the way for the practical application of advanced AI in medicine.

Introduction

Diagnostic Excellence

Diagnostic excellence involves accurately and efficiently diagnosing a wide range of conditions [1]. Achieving this requires a multifaceted approach [2], including effective collaboration among medical professionals, patients, families, and clinical decision support systems (CDSSs). Each plays a pivotal role, as follows: medical professionals bring their expertise and judgment, patients and families provide essential health information and context, and CDSSs offer data-driven insights, enhancing the collective decision-making process.

CDSSs for Diagnostic Excellence

CDSSs are computer-based tools that assist medical professionals in a wide range of clinical decisions, including diagnosis, treatment planning, medication ordering, preventive care, and patient education [3]. Research has shown that CDSS interventions significantly improve diagnostic accuracy [4], a key aspect of diagnostic excellence [5]. For instance, interventions involving a CDSS in the diagnosis of common chronic diseases demonstrated significant improvements [6]. Accurate diagnosis entails more than identifying a disease; it involves understanding the patient's unique health context, ensuring timely and appropriate treatment, reducing misdiagnosis risk, and ultimately improving patient outcomes [7]. In the rapidly evolving health care environment, maintaining high standards of diagnostic precision becomes increasingly crucial.

Artificial Intelligence in Medicine

CDSSs are broadly categorized into 2 types [3]: knowledge-based systems, which are grounded in medical guidelines and expert knowledge; and non–knowledge-based systems, using artificial intelligence (AI) or statistical pattern recognition for clinical data analysis.

The integration of AI into clinical settings is advancing rapidly. AI systems in medicine range from assisting in diagnostic imaging and analysis to optimizing patient treatment plans [8,9]. These systems are being increasingly adopted in hospitals and clinics [10], significantly contributing to enhanced diagnostic accuracy and efficiency.

However, the integration of AI into clinical settings brings transformative potential but also faces several hurdles. Challenges include ensuring data privacy [11], addressing the lack of large and diverse training data sets, and maintaining the interpretability of AI-generated recommendations to align with ethical standards [12,13]. Real-world obstacles, such as resistance from health care professionals due to trust issues in AI's diagnostic suggestions, underscore the complexity of AI integration into clinical practice.

Advancements in Large Language Models

A notable advancement in AI is the use of large language models (LLMs). As a subset of non–knowledge-based systems, LLMs are specialized forms of generative AI systems that process and generate human-like text based on extensive textual data training [14]. They are adept at tasks like translation, summarization, and even creative writing. In clinical practice, generative AI systems using LLMs have shown promise in summarizing patient history, integrating medical records, analyzing complex data streams, and enhancing communication between patients and medical professionals [15,16], demonstrating their utility in handling complex medical language and concepts. Such advancements not only improve the efficiency of medical documentation but also offer novel approaches to generating differential diagnoses, showcasing the innovative application of LLMs in clinical settings.

Multimodal Artificial Intelligence in Diagnostics

Integrating multimodal data, including text and images, presents technical challenges. Successful integration in other fields, such as autonomous driving technologies that combine multisensory observation data to navigate [17], offers a potential model for health care. Recent developments in generative AI systems, including Google Gemini (previous Google Bard [18]) and ChatGPT-4 with vision (ChatGPT-4V), have enabled the processing of both text and image data. This integration is essential for providing a comprehensive clinical overview. Although effectively combining data from different data sources remains a challenge, the development of multimodal AI models that incorporate data across modalities enabled broad applications that include personalized medicine and digital health [19]. For example, a multimodal model developed from the combination of images and health records could classify pulmonary embolism [20]. Another multimodal model could differentiate between common respiratory failure [21]. Among publicly available generative AI systems, the ChatGPT series, particularly ChatGPT-4V, developed by OpenAI and released in September 2023, stands out [22,23]. It accepts both text and image data [24,25], demonstrating impressive performance in various applications.

Preliminary studies in various fields, including medicine [26-28] and others [29-31] have shown the effectiveness of ChatGPT-4V. Some of these studies have highlighted its efficacy in interpreting medical images [26,28], though they were limited in scope. However, clinical image data includes a wide range of elements, from physical examinations to various investigation results. The full impact of image data integration on diagnostic accuracy is yet to be thoroughly explored.

Study Objectives

This study directly addressed the gaps identified in the current understanding of multimodal AI's application in clinical diagnostics. By comparing the diagnostic accuracy of

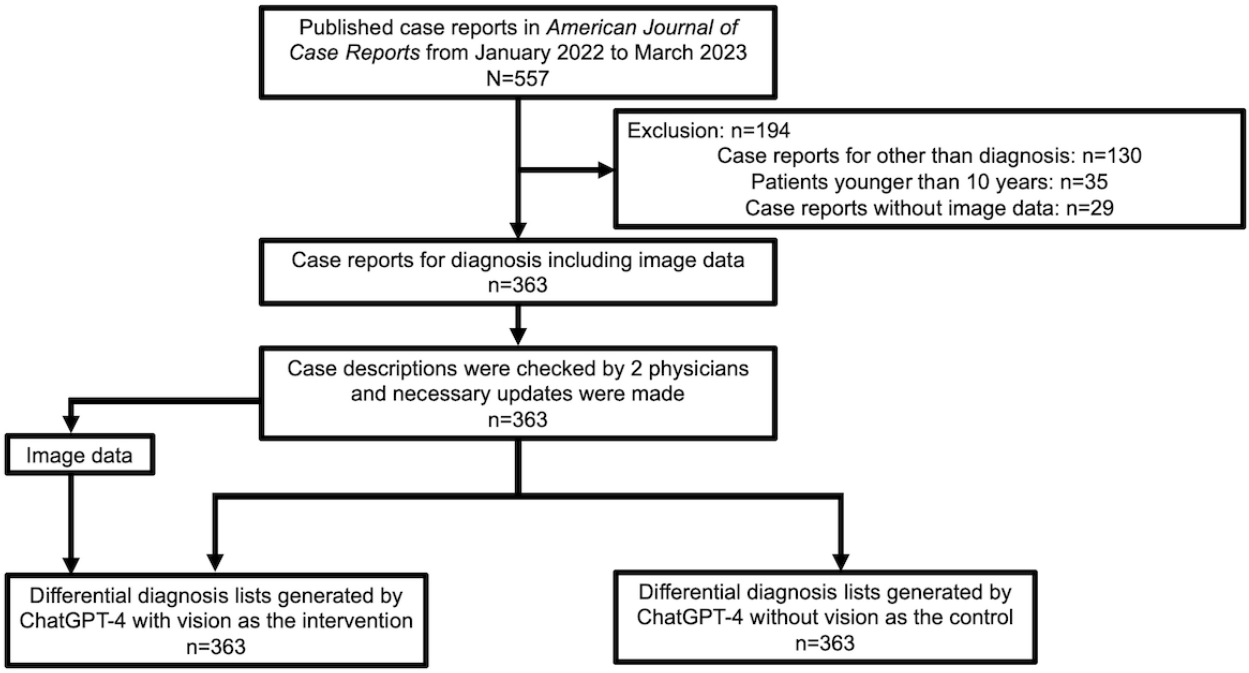
ChatGPT-4V and without vision across detailed case reports, and examining the impact of image data integration, we aimed to provide concrete evidence on the value and challenges of incorporating generative AI into clinical flows. Our objectives were shaped by the need to better understand how multimodal AI can be optimized to support diagnostic excellence, ultimately contributing to the advancement of medical diagnostics through technology.

Methods

Overview

We conducted an experimental study to assess the diagnostic accuracy of multimodal generative AI systems using data from a large number of case reports. This study was conducted in the Department of Diagnostic and Generalist Medicine (General Internal Medicine) at Dokkyo Medical University. This study involved several steps: preparing the data set and control, preparing image data, generating differential diagnosis lists by ChatGPT-4V, and evaluating the diagnostic accuracy of these differential diagnosis lists. A flow chart of the study's methodology is presented in Figure 1.

Figure 1. Study design.



Ethical Considerations

This study used published case reports, and thus ethical committee approval was not applicable.

Preparing Data Set and Control

We used the data set from our previous study (T Hirosawa, Y Harada, K Mizuta, T Sakamoto, K Tokomasu, T Shimizu, unpublished data, November 2023). The data set comprised case descriptions and final diagnoses, sourced from the *American Journal of Case Reports*, spanning January 2022 to March 2023. This peer-reviewed journal covers diagnostically challenging case reports from various medical fields. A total of 557 case reports were identified. The exclusion criteria were carefully chosen based on previous studies for CDSSs [32] and ChatGPT-4V [28] to ensure the focus remained on diagnostically challenging adult cases with relevant image data. Specifically, cases were excluded for the following reasons: nondiagnosis (130 cases), patients younger than 10 years (35 cases), and the absence of image data (29 cases). The included case reports were refined into case descriptions by the primary researcher (TH) and double-checked by another researcher (YH). From the included case reports, we extracted a case description until the final diagnosis was made in the "case report" section. We removed sentences that directly assessed the diagnosis to minimize bias in generating differential diagnoses. This step ensures that the differential diagnoses generated by ChatGPT-4 are based solely on the unbiased clinical presentation of the case. After brush-up, we formatted these case descriptions for input into ChatGPT-4. A typical case description included demographic information, chief complaints, history of present illness, results of physical examinations, and investigative findings leading to diagnoses. The final diagnoses were typically determined by the authors of the case reports. For example, in a case report titled "Levofloxacin-Associated Bullous Pemphigoid in a Hemodialysis Patient After Kidney Transplant Failure" [33] we extracted from "A 27-year-old female with hemodialysis was admitted for evaluation of a worsening bullous rash and shortness of breath over the last 3 days..." to "...Although the swab PCR test for VZV and HSV was negative, there was still concern about disseminated herpes zoster, as the patient was immunosuppressed" as a case description.

Additionally, the final diagnosis was levofloxacin-associated bullous pemphigoid.

In the next step, we used ChatGPT-4 without vision to develop the top 10 differential diagnosis lists based on the data of case descriptions. Two expert physicians independently evaluated whether the final diagnosis was included in the lists, and any discrepancies were resolved through discussion. Therefore, the differential diagnosis lists and data of physicians' evaluation of the lists from a total of 363 case reports were included as the control in this study.

Preparing Image Data

All figures and tables of included case descriptions were standardized to a resolution of 96 dots per inch in JPEG format to balance detail with file size, facilitating efficient processing by ChatGPT-4V without compromising the quality necessary for accurate diagnostic inference. When multiple figures or tables were present in a case description, they were compiled into a single JPEG file, each annotated with a file number in the upper-left corner. If image data exceeded the upload size limit, the images were resized to half their original size while preserving image quality, using the Preview application (version 11.0; Apple Inc) on a Mac computer.

Generating Differential Diagnosis Lists by ChatGPT-4V

We used ChatGPT-4V, a multimodal generative AI system developed by OpenAI, from October 30, 2023, to November 9, 2023. Additional training or reinforcement for diagnosis was not performed. The prompt was constructed as follows: "Identify the top 10 suspected illnesses based on the attached files with file names indicated in the left upper corner of each image, and the provided case description. List these illnesses using only their names, without providing any reasoning AND describe the proportion of the case description and the provided files to develop your suspected illness list (case description + all files = 100%): (copy and paste the case descriptions)." This design was intended to explicitly guide ChatGPT-4V to not only generate a list of possible diagnoses but also reflect on how each type of data influenced its conclusions, providing insights into the AI's diagnostics process. Apart from the prompt and file names, the text data input to ChatGPT-4V remained the same as the control, ChatGPT-4 without vision. The first generated list was used as the differential diagnosis list. The chat history was cleared before entering each new case description. Moreover, the data control settings for chat history were disabled. The details of ChatGPT-4V and ChatGPT-4 without vision are shown in Table 1.

Table 1. The details of ChatGPT-4 with vision and ChatGPT-4 without vision in this study.

Details	ChatGPT-4 with vision (intervention) [24]	ChatGPT-4 without vision (control) [22]
Short name	ChatGPT-4V	ChatGPT-4
Prompt	Identify the top 10 suspected illnesses based on the attached files with file names indicated in the left upper corner of each image, and the provided case description. List these illnesses using only their names, without providing any reasoning AND describe the proportion of the case description and the provided files to develop your suspected illness list (case description + all files =100%): (copy and paste the case descriptions)	Tell me the top 10 suspected illnesses for the following case: (copy and paste the case descriptions)
Text input	Same case descriptions with the above prompt and referred file number	Same case descriptions with the above prompt
Image input	Image data in JPEG format with a resolution of 96 dots per inch	No image data
Output	The top 10 differential diagnosis lists and the proportion of weight between text data and image data contributing to development of the differential diagnosis list	The top 10 differential diagnosis lists
Evaluations	By 2 independent physicians; any discrepancies were resolved by another physician	By 2 independent physicians; any discrepancies were resolved by another physician
Release date	September 2023	March 2023
Access date	From October 30, 2023, to November 9, 2023	From June 22, 2023, to June 29, 2023
Data control for chat history	Off	Off

Evaluation for Differential Diagnosis Lists by Physicians

Two expert physicians, TI and T Suzuki, independently evaluated whether the final diagnoses were included in the differential diagnosis lists. The evaluation was binary, with 1 indicating inclusion and 0 indicating exclusion. A score of 1 indicated that the differential closely matched the final diagnoses. This close match was defined not merely by the presence of the correct diagnosis within the list but by the relevance and clinical appropriateness of the differentials in relation to the final diagnosis. A score of 1 indicated that AI-generated differentials were clinically relevant and could potentially lead to appropriate interventions, thereby aligning with patient safety and standards [34]. Additionally, evaluators ranked the match of differential to the final diagnoses.

Conversely, a score of 0 was given if the differential diagnosis list significantly differed from the final diagnosis, indicating a lack of clinical relevance or potential misdirection in a real-world diagnostic scenario. Any discrepancies were resolved by another expert physician (KT), ensuring objective and consistent evaluation across all included case reports.

Outcome

The study assessed the diagnostic accuracy of ChatGPT-4V, as an intervention and compared it to ChatGPT-4 without vision as a control. The primary outcome was defined as the ratio of cases where the final diagnoses were included within the top 10 differential diagnosis lists. The secondary outcome is defined as the ratio of cases where the final diagnoses were included as top diagnosis. These outcomes were chosen to quantitatively measure diagnostic accuracy and the effectiveness of image data integration in enhancing ChatGPT-4's diagnostics.

Additionally, we assessed the contributing weight between text data (case descriptions) and image data (files) in developing the differential diagnosis lists, as reported by ChatGPT-4V. The total contribution from both elements was set to 100%. Specifically, we analyzed how much the text and image data individually contributed to the formulation of the differential diagnosis list. For example, if the text data (case description) contributed 60% and the image data contributed 40%, the total would sum up to 100%. This method allowed for a comprehensive understanding of the relative impact of textual and image data on AI diagnostics.

Statistical Analysis

For analysis, R (version 4.2.2; R Foundation for Statistical Computing) was used. We present continuous variables as medians and IQRs to accurately reflect the distribution of data. We presented categorical or binary variables as numbers and percentages. Additionally, we used χ^2 tests to compare categorical variables, setting the significance level at a *P* value <.05. The choice of χ^2 tests for comparing categorical variables was based on their ability to handle binary and categorical data effectively, providing a robust measure of association between diagnostic outcomes and ChatGPT-4 with or without vision.

To quantify the impact of each factor on the likelihood of accurate diagnosis inclusion, an univariable logistic regression model was applied. This model allows for the exploration of potential predictors of diagnostic accuracy, offering insights into how different data types contribute to ChatGPT-4's diagnostic processes. For the logistic regression model, the primary and secondary outcomes were treated as binary dependent variables: presence (1) or absence (0) of the correct diagnosis within the top 10 differential diagnosis lists and as the top diagnosis, respectively. Independent variables included the proportion of image data weight, the presence (1) or absence (0) of specific types of image data (eg, computed tomography [CT] images, pathological specimens, laboratory data, magnetic resonance imaging [MRI] scans, and X-ray images), and the number of characters in the text data. Odds ratios (ORs) and associated 95% CIs were used to estimate the relative risks of potential predictors of the final diagnosis included within the top 10 differential diagnosis lists in the univariable logistic regression model.

Results

Case Descriptions and Image Data Profile

A total of 363 case descriptions with additional image data, such as figures or tables, were included. ChatGPT-4V generated the differential diagnosis lists for all case descriptions. Representative final diagnosis, image data, and differential diagnosis lists generated by ChatGPT-4V and ChatGPT-4 without vision are shown in Table 2. The cases included in this study, along with the differential diagnosis lists generated by ChatGPT-4V and without vision, are shown in Multimedia Appendix 1.

Table 2. Representative final diagnoses, image data, and differential diagnosis lists generated by ChatGPT-4 with vision and ChatGPT-4 without vision.

Final diagnoses	ChatGPT-4 with vision (intervention)			ChatGPT-4 without vision (control)
	Image data	Image data weight[a], %	Differential diagnosis lists	Differential diagnosis lists
Olanzapine intoxication	Laboratory data	20%	1. Hospital-acquired pneumonia 2. Sepsis 3. Acute kidney injury 4. Respiratory failure 5. Intensive care unit delirium 6. Hypotension 7. Opioid intoxication 8. Benzodiazepine intoxication 9. Hyperglycemia 10. Cardiovascular complications after surgery	1. Zolpidem overdose or prolonged effect 2. Benzodiazepine overdose 3. Olanzapine overdose or side effect 4. Interaction between zolpidem and olanzapine 5. Delirium 6. Other drug overdose 7. Severe sepsis 8. Neuroleptic malignant syndrome 9. Acute cholinergic crisis 10. Acute stroke
Secondary syphilis	Laboratory data and X-ray images	40%	1. Osteoarthritis 2. Rheumatoid arthritis 3. Gout 4. Pseudogout 5. Systemic lupus erythematosus 6. Psoriatic arthritis 7. Reactive arthritis 8. Osteoporosis 9. Septic arthritis 10. Ankylosing spondylitis	1. Secondary syphilis 2. Reactive arthritis 3. Rheumatoid arthritis 4. Osteoarthritis 5. Gout/pseudogout 6. Psoriatic arthritis 7. Lyme disease 8. Systemic lupus erythematosus 9. Infectious arthritis 10. Vasculitis (eg, granulomatosis with polyangiitis and microscopic polyangiitis)
Sarcomatoid carcinoma	Computed tomography image and pathological specimens	30%	1. Colorectal cancer 2. Adenocarcinoma of the colon 3. Malignant mesothelioma 4. Gastrointestinal stromal tumor 5. Carcinoid tumor of the appendix 6. Lymphoma 7. Desmoid tumor 8. Metastatic carcinoma 9. Leiomyosarcoma 10. Neuroendocrine tumor of the colon	1. Colorectal carcinoma 2. Metastatic malignancy to the colon 3. Peritoneal mesothelioma 4. Sarcomatoid carcinoma 5. Malignant mixed Mullerian tumor (carcinosarcoma) 6. Gastrointestinal stromal tumor 7. Leiomyosarcoma 8. Colonic lymphoma 9. Malignant peripheral nerve sheath tumors 10. Undifferentiated/unclassified malignancies

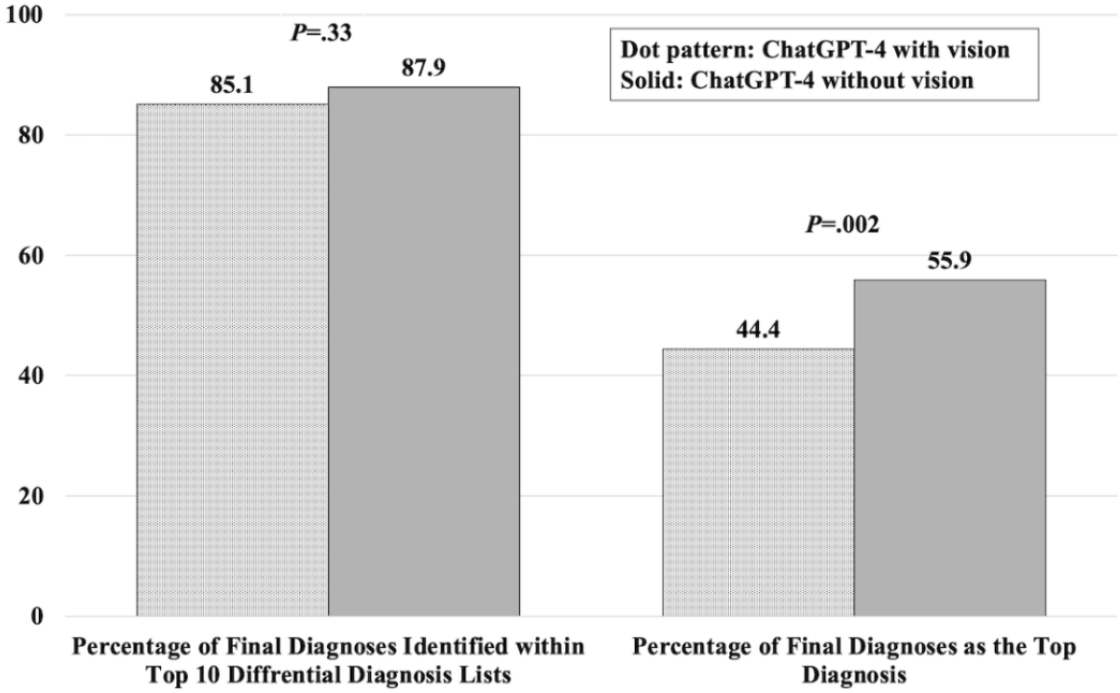
[a]The proportion of image data weight contributing to development of the differential-diagnosis lists.

Among these, the 25th percentile, median, and 75th percentile number of characters in the text data were 1971, 2683, and 3442, respectively. The maximum and minimum number of characters in text data were 7148 and 465, respectively. Regarding image data, CT images, pathological specimens, laboratory data, MRI scans, and X-ray images were included in 163, 124, 98, 77, and 70 case descriptions, respectively. The details of image data are shown in Multimedia Appendix 2.

Diagnostic Performance

For the primary outcome, the rate of final diagnoses within the top 10 differential diagnosis lists generated by ChatGPT-4V was 85.1% (n=363), compared with 87.9% (n=363) by ChatGPT-4 without vision (*P*=.33). For the secondary outcome, the rate of final diagnoses as the top diagnoses generated by ChatGPT-4V was 44.4% (n=363), inferior to 55.9% (n=363) by ChatGPT-4 without vision (*P*=.002). Figure 2 shows the rate of final diagnoses within the top 10 differential diagnosis lists and as the top diagnoses generated by ChatGPT-4V and without vision.

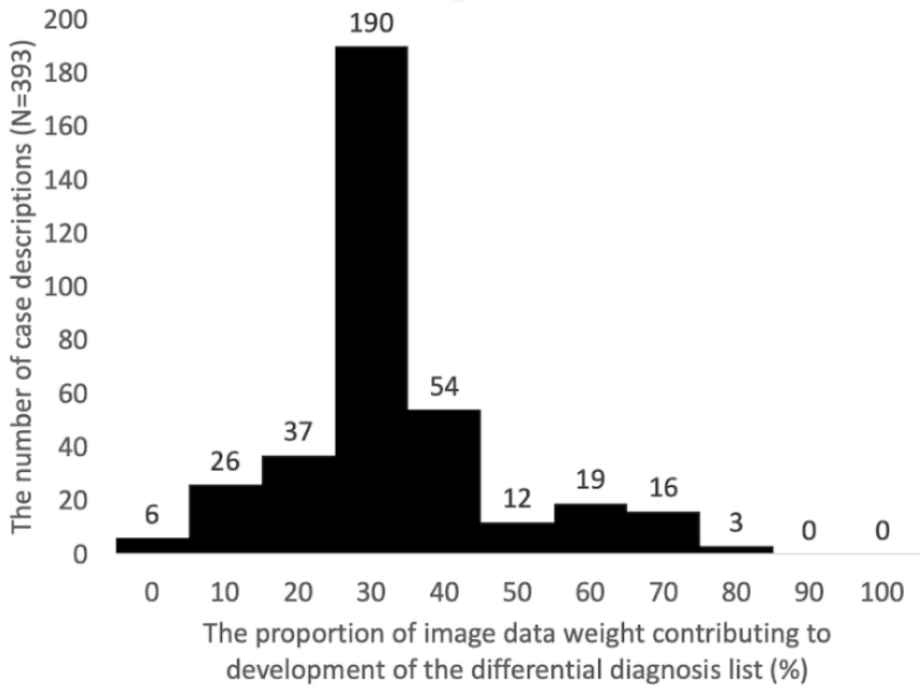
Figure 2. The rate of final diagnoses within the top 10 differential diagnosis lists and as the top diagnoses generated by ChatGPT-4 with vision and without vision.



The Contributing Weight Between Text and Image Data in Developing the Differential Diagnosis Lists

The 25th percentile, median, and 75th percentile proportions of image data weight contributing to the development of the differential diagnosis lists were 30%, 30%, and 40%, respectively, indicating a consistent reliance on image data across a significant portion of cases. The maximum and minimum proportion of image data weight contributing to the development of the differential diagnosis lists were 80% and 0%, respectively, highlighting the wide range of reliance on image data across different case reports. Specifically, in 190 case descriptions of the total 363 included case reports (190/363, 52.3%), the proportion of image data weight contributing to the development of the lists was reported to be 30%. Figure 3 shows the proportion of image data weight contributing to the development of the differential diagnosis lists.

Figure 3. The proportion of image data weight contributing to the development of the differential diagnosis lists by ChatGPT-4 with vision.



The ORs of Variables for Predicting the Outcomes

Laboratory data independently predicted the inclusion of the final diagnoses within the top 10 differential diagnosis lists by ChatGPT-4V: OR 0.52 (95% CI 0.29-0.97; *P*=.03). Additionally, MRI scans were also found to be independent predictive factors: OR 3.87 (95% CI 1.51-13.11; *P*=.01). These results were derived from univariable logistic regression models. Other variables, including the proportion of image data weight contributing to the development of the differential diagnosis lists, CT images, pathological specimens, X-ray images, and the number of characters in text data, were not associated with the final diagnoses included within the top 10 differential diagnosis lists by ChatGPT-4V, as shown in Figure 4.

Additionally, MRI scans (OR 1.93, 95% CI 1.16-3.22; *P*=.01) were independent predictive factors for the final diagnoses as top diagnoses by ChatGPT-4V. Other variables were not associated with the secondary outcome, as shown in Figure 5.

Figure 4. Odds ratios of variables for predicting the final diagnoses included within the top 10 differential diagnosis lists by ChatGPT-4 with vision in univariable regression model. *P* values are derived from the univariable logistic regression model. CT: computed tomography; MRI: magnetic resonance imaging.

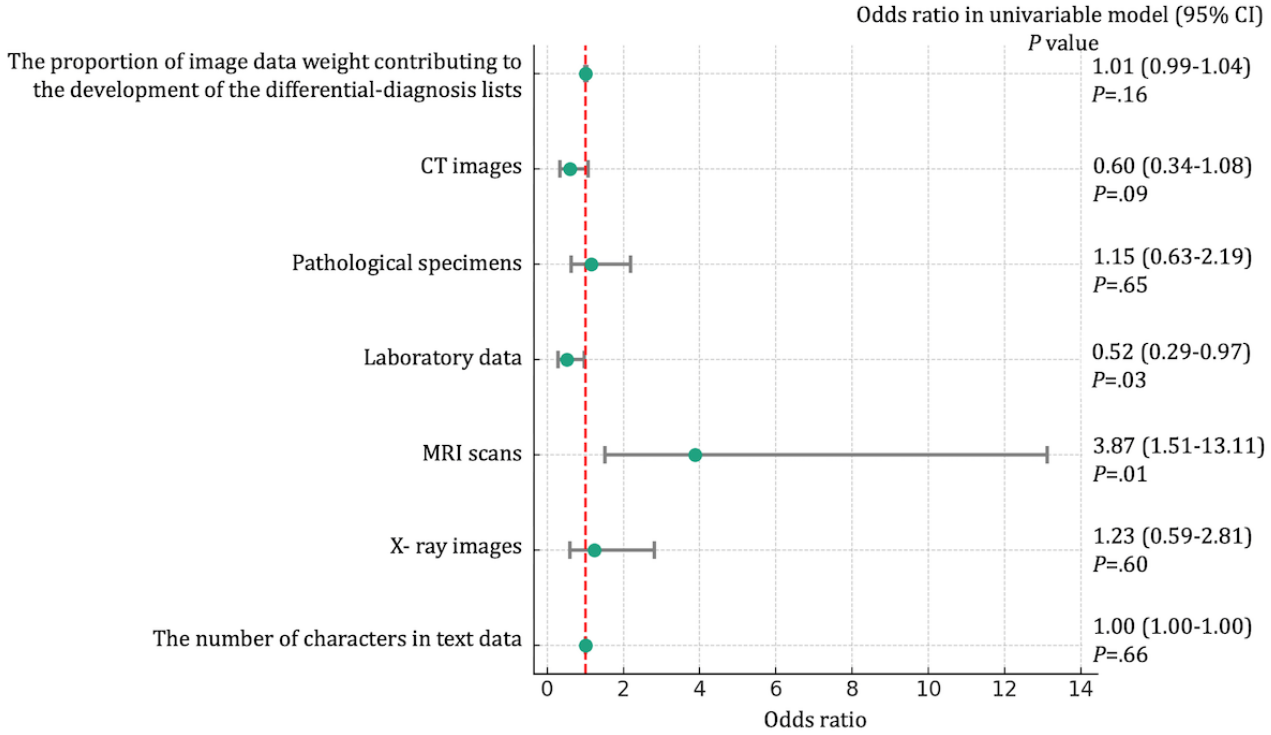


Figure 5. Odds ratios of variables for predicting the final diagnoses as top diagnoses by ChatGPT-4 with vision in univariable regression model. *P* values are derived from the univariable logistic regression model. CT: computed tomography; MRI: magnetic resonance imaging.

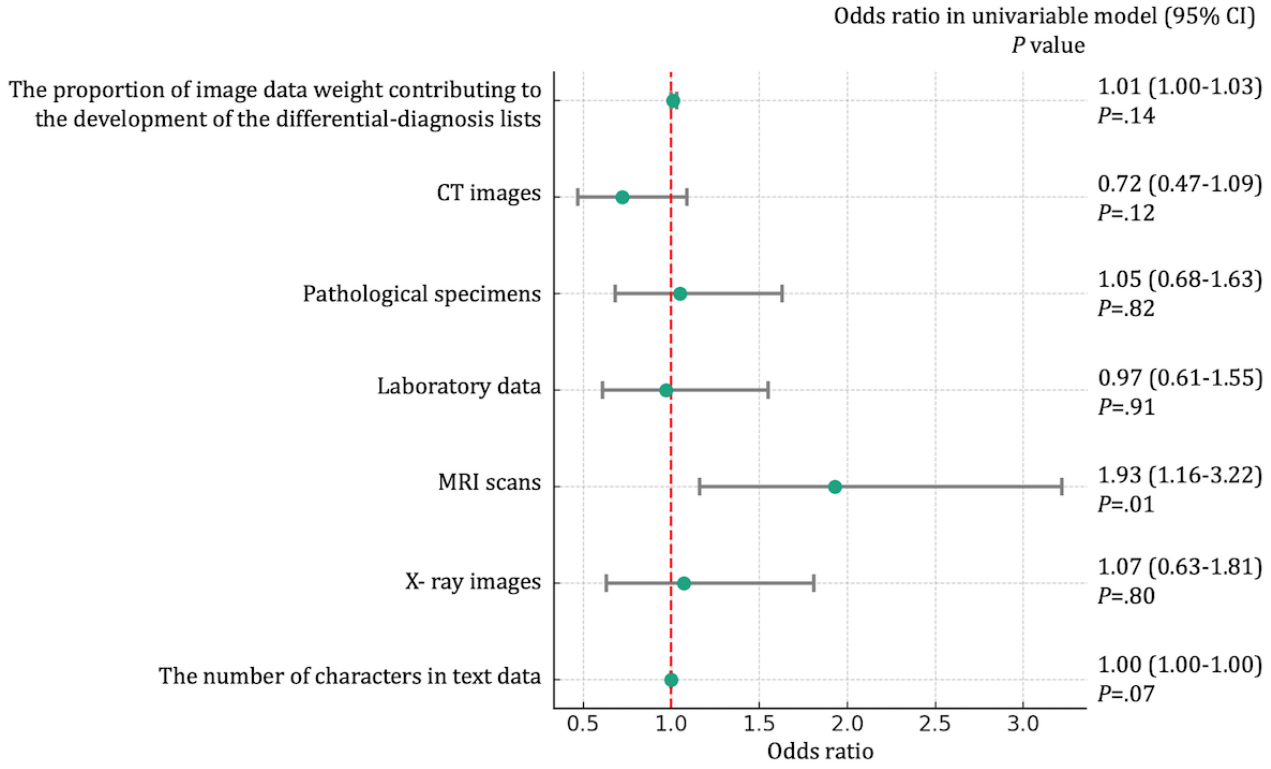

Discussion

Principal Results

This study showed several key findings regarding the diagnostic capabilities of ChatGPT-4 with and without vision. The incorporation of image data into ChatGPT-4V did not yield a significant improvement in diagnostic accuracy compared with that without vision. This was evident in the rates of final diagnoses within the top 10 differential diagnosis lists generated by ChatGPT-4V, where ChatGPT-4 without vision actually demonstrated comparable performance. Conversely, the rate of final diagnoses as the top diagnoses generated by ChatGPT-4V was inferior to that without vision. While ChatGPT-4V accepts a wide range of medical images, from physical examinations to various investigation results, its potential to enhance diagnostic accuracy appears underused. This underuse of image processing capabilities could be attributed to the current AI model's limitations in processing and integrating complex image data with textual data. Additionally, the AI system's training regimen, which might have emphasized text data over image data, could have resulted in a bias toward text-based analysis. Future iterations of AI systems should focus on enhancing the model's ability to discern and integrate key diagnostic features from both text and images.

In the univariable logistic regression model, these findings suggest that while the integration of image data by ChatGPT-4V did not uniformly improve diagnostic accuracy across all cases, specific types of image data, particularly MRI scans, play a crucial role in certain diagnostic contexts. MRI scans were associated with significantly higher rates of primary and secondary outcomes. Conversely, laboratory data were associated with significantly lower rates of the primary outcome. These results suggest that MRI scans are typically focused on specific body locations to target particular organs. For example, the inclusion of brain MRI scans led ChatGPT-4V to focus its differential diagnoses on cerebral diseases. The characteristics of MRI scans to focus on anatomical regions could be used to enhance the diagnostic performance of ChatGPT-4V in identifying specific conditions. Moreover, the laboratory data, often presented in tables, typically cover a broader spectrum of information than the case descriptions. For instance, in the case of infectious diseases with elevated blood glucose levels which were included only in the table, ChatGPT-4V considered hyperglycemic condition in addition to the final diagnoses. Incorporating additional laboratory data into the textual analysis could broaden the differential diagnosis lists, potentially reducing the primary outcome. The logistic regression analysis thus provides valuable insights into how different data formats influence the AI's diagnostic capabilities, guiding future improvements in AI design and training to better leverage these inputs.

Focusing on the proportion of image data weight contributing to the development of the differential diagnosis lists, a notable observation emerges regarding ChatGPT-4V's reliance. In more than half of the outputs, image data accounted for 30% of the weight in developing the differential diagnosis lists. This finding leads us to consider the system's internal decision-making process. It is important to consider that the accuracy of the proportion of image data weight in representing the actual process of integrating text and image input in ChatGPT-4V remains uncertain. Despite the consideration, the proportion of image data weight further indicates a dominant dependence on text data. It raises the possibility that ChatGPT-4V may not be

integrating text and image inputs in a balanced way. The implication here is that even with its capability to process image data, the system's diagnostic output might still be mainly influenced by text data.

Given these findings, this unexpected outcome leads us to question why additional image data did not contribute to improvements in diagnostic accuracy. Exploring the reasons behind these results, one plausible explanation emerges related to the potential biases in ChatGPT-4V's use of image data. The biases would be rooted in its training regimen. Rather than aiding in diagnosis, this image data could introduce complexity, leading ChatGPT-4V to rely more on text-based analysis and less on visual clues.

This study highlights the challenges in harnessing the full potential of multimodal AI in medical diagnostics. The findings indicate that despite the advanced capabilities of ChatGPT-4V, its integration of image data is not yet optimizing diagnostic outcomes. This would be partly because of the system's inherent design and training, which could predispose it to prioritize text over image data, despite the latter's potential richness in clinical information. This revelation is crucial for the ongoing development of AI in health care, highlighting a pivotal area for improvement. As AI continues to evolve, focusing on the harmonious integration of text and image data will be essential. This study paves the way for future innovations, guiding efforts to refine multimodal AI systems for more accurate, efficient, and reliable medical diagnostics. Future research should particularly explore the development of more sophisticated methods for image analysis and the optimization of multimodal data integration, aiming to improve the current reliance on text data and enhance the diagnostic power of AI in health care settings.

The findings from our study also raise important considerations for the practical application of AI in health care. While AI systems like ChatGPT-4V hold promise for supporting clinical decision-making, their current limitations necessitate a cautious approach to integration into clinical workflows. For instance, AI could serve as a supporting tool for preliminary analysis, helping triage or providing a second opinion in diagnostic challenges, thereby augmenting the expertise of health care professionals rather than replacing it. Health care professionals should be aware of these systems' strengths and weaknesses, leveraging them as support tools rather than definitive diagnostic solutions.

Limitations

There were several limitations in this study. A major limitation of our study was the reliance on selected image data excerpted from case reports [35], rather than whole slices of image data from clinical settings. This limitation partly arose because the current ChatGPT-4V can only process partial slices of image data [27]. This approach, while necessary for concise reporting in cases, may not accurately reflect the complexity and variability encountered in real-world clinical practice. Moreover, we excluded video files. Although generative AI systems currently do not accept video files, their inclusion could potentially improve diagnostic accuracy. Future research should explore incorporating more comprehensive image data sets and video data, technologies permitting, to enhance the AI system's diagnostic capabilities. Furthermore, the study's reliance on data derived from case reports may not encompass the diversity of real-world clinical scenarios [36]. The specificity of data sources inevitably impacts the generalizability of our findings, highlighting a significant challenge in extending our results to different health care settings and populations. Future studies should consider including complete data from real-patient scenarios with various situations.

Beyond these specific limitations, our study underscores broader concerns regarding the integration of AI in health care, particularly the potential bias inherent in the data sets used to train generative AI systems like ChatGPT-4. These biases may impact the generalizability of the AI's diagnostic and predictive capabilities across diverse populations and clinical settings. The absence of regulatory approval for generative AI systems in clinical practice further complicates their potential adoption, while inconsistencies in ChatGPT-4V interpretations of medical imaging underscore the current limitations of these technologies in performing medical functions [25].

Furthermore, the interpretability and explainability of AI-generated diagnoses remain significant hurdles [16]. The deployment of AI in health care settings also raises practical challenges related to the training of health care professionals in AI use and the integration of AI tools into existing clinical workflows. Ensuring that health care workers are adequately prepared to interpret AI-generated insights and make informed decisions is crucial for the successful adoption of AI technologies.

Last, the rapid evolution of AI technology presents unique challenges, as advancements may quickly outpace the findings of our study. The pace at which AI technologies evolve means that our conclusions may become outdated as new capabilities emerge. This highlights the importance of ongoing research and adaptation in the field of AI and health care, ensuring that studies remain relevant and that AI tools are continually evaluated and updated to reflect the latest technological advancements.

Comparison With Prior Work

Compared with a previous preliminary study for ChatGPT-4V, this study showed higher performance. The previous study assessed the proficiency of ChatGPT-4V for selected medical images from open-source libraries and repositories [27]. The study reported that only 21.7% (n=15) of cases were correctly interpreted with the correct advice. This inconsistency was partly because of the methodological differences between the 2 studies, particularly in terms of data set preparation and evaluation criteria. While the previous study mainly focused on a limited data set with simple prompts and evaluated the system's interpretation and medical advice quality, our study introduced a more comprehensive data set with a rich clinical context. Additionally, we evaluated the diagnostic accuracy, rather than merely assessing interpretation and advice, thereby providing a deeper insight into the AI system's utility in clinical decision-making.

Another study evaluated the performance of ChatGPT-4V for selected clinical cases from the website, including image data [26]. The study showed that ChatGPT-4V heavily relies on the patients' medical history. This result was consistent with this study that additional image data did not improve the diagnostic accuracy. The result was also consistent with this study that approximately half of the outputs reported that the proportion of image data weight contributing to the development of the differential diagnosis lists was 30%.

A critical distinction between our study and previous works is our comparative analysis of ChatGPT-4 with and without vision capabilities. This unique approach allowed us to highlight the impact of image data on diagnostic accuracy, revealing that while ChatGPT-4's vision component does not significantly enhance diagnostic accuracy, it does not detract from it either. This finding is crucial for understanding the role of integrated image data in AI-assisted diagnosis and highlights the potential of AI systems to support health care professionals by providing a comprehensive analysis that includes both text and image data.

Conclusions

The rates of final diagnoses within the differential diagnosis lists generated by ChatGPT-4V did not show improvement over those generated without vision. The rate of final diagnoses as the top diagnosis generated by ChatGPT-4V was inferior to that without vision. Despite its multimodal data processing capabilities, ChatGPT-4V appears to prioritize text data, which may limit its effectiveness in medical diagnostic applications, as highlighted by its system card [25]. The implications of our study for the advancement of multimodal AI systems in health care are profound. It uncovers a pivotal aspect of AI development that requires attention: the nuanced integration and weighted analysis of diverse data types. To emulate the complex reasoning of medical professionals, AI systems must advance beyond simple data incorporation toward a sophisticated synthesis that enhances diagnostic accuracy. For future improvements, we recommend the following: enhanced clinical data fusion techniques; interpretability of AI decisions; and collaborative development efforts with AI developers and medical professionals. In clinical practice, more sophisticated multimodal AI systems have the potential to enhance in providing timely, contextually rich differential diagnoses, serving as educational aids for medical trainees, and enhancing patient care by supporting remote or underserved areas. Through these enhancements, AI tools can ultimately improve patient outcomes.

Abstract

Background: Vaccines serve as a crucial public health tool, although vaccine hesitancy continues to pose a significant threat to full vaccine uptake and, consequently, community health. Understanding and tracking vaccine hesitancy is essential for effective public health interventions; however, traditional survey methods present various limitations.

Objective: This study aimed to create a real-time, natural language processing (NLP)–based tool to assess vaccine sentiment and hesitancy across 3 prominent social media platforms.

Methods: We mined and curated discussions in English from Twitter (subsequently rebranded as X), Reddit, and YouTube social media platforms posted between January 1, 2011, and October 31, 2021, concerning human papillomavirus; measles, mumps, and rubella; and unspecified vaccines. We tested multiple NLP algorithms to classify vaccine sentiment into positive, neutral, or negative and to classify vaccine hesitancy using the World Health Organization's (WHO) 3Cs (confidence, complacency, and convenience) hesitancy model, conceptualizing an online dashboard to illustrate and contextualize trends.

Results: We compiled over 86 million discussions. Our top-performing NLP models displayed accuracies ranging from 0.51 to 0.78 for sentiment classification and from 0.69 to 0.91 for hesitancy classification. Explorative analysis on our platform highlighted variations in online activity about vaccine sentiment and hesitancy, suggesting unique patterns for different vaccines.

Conclusions: Our innovative system performs real-time analysis of sentiment and hesitancy on 3 vaccine topics across major social networks, providing crucial trend insights to assist campaigns aimed at enhancing vaccine uptake and public health.

Introduction

Vaccine is an essential public health intervention that has saved millions of lives and achieved a substantial global reduction in cases, hospitalizations, and health care costs associated with vaccine-preventable diseases (VPDs) [1-3]. Yet, despite their value, vaccine hesitancy persists as a barrier to full vaccine uptake. The World Health Organization (WHO) defines vaccine hesitancy as the delay or refusal of vaccination, even when vaccination services are accessible [4]. Additionally, the WHO identifies vaccine hesitancy as one of the top 10 global health threats [5]. Delay or refusal of vaccines due to vaccine hesitancy can have broad-reaching implications; unvaccinated individuals not only put themselves at risk of VPDs, such as COVID-19,

but also pose a threat to the broader community or even global health [6]. This phenomenon has been documented since the advent of vaccines in over 90% of the countries [7]. Considering the case of measles, mumps, and rubella (MMR), it is crucial to uphold community protection or herd immunity, necessitating widespread vaccination to protect those unable to receive the vaccine [8]. A former London study successfully raised MMR vaccination rates from 80% to 94% in under 2 years through incentivized care packages and innovative technology use, approaching the desired herd immunity target [9].

There is a myriad of reasons for vaccine hesitancy, including personal or familial beliefs, concerns about adverse reactions or efficacy, and skepticism toward government and vaccine manufacturers [6,10-17]. This intricate web of motivations makes vaccine hesitancy a complex public health challenge [18].

Understanding vaccine hesitancy is crucial for developing effective interventions, public health education, and vaccination promotion strategies [19-22]. While surveys have traditionally served as a valuable tool for gathering public opinions on vaccination, they possess inherent limitations such as static data collection, resource intensiveness, and potential time lag [23-29]. To address these limitations, real-time tracking of vaccine hesitancy activities and trends offers public health professionals' valuable insights. This approach helps identify critical intervention points before the vaccination uptake wanes, allowing for more targeted and timely communication efforts.

The emergence of social media platforms has enabled billions of users to engage in discussions, information sharing, and opinion expression on various subjects, including health-related topics [30]. While this presents an unprecedented opportunity for public health improvement, it also poses a significant risk linked to the dissemination of vaccine-related misinformation and disinformation [31]. Previous research has used semiautomatic methods such as manual coding and hashtag or keyword analysis to study social media vaccine discussions [32-35]. Nevertheless, these approaches may sometimes encounter potential challenges with scalability and precision. Natural language processing (NLP) is an automated method designed to effectively and accurately decipher the wealth of information in natural language text, addressing challenges such as ambiguities and probabilistic parsing, and enabling applications such as information extraction and discourse analysis [36]. This technique has emerged as a promising solution, holding the potential to mitigate these challenges and improve the precision of vaccine-related public sentiment analysis [37,38].

To address these challenges, this study's principal aim was to create an NLP system for real-time monitoring of vaccine sentiment and hesitancy across English-language social media platforms targeting the US market. Our 3-fold contributions are (1) developing one of the first real-time monitoring systems for social media vaccine discussions that covers 3 major social media platforms and 3 vaccine topic groups [39]; (2) comprehensively evaluating multiple machine learning–based NLP models for social media post classification tasks, thus establishing a benchmark for future research; and (3) analyzing decade-long trends of sentiment and hesitancy and linked real-world events to corresponding points on the trends for multiple vaccine targets.

Methods

Overview

We followed a systematic approach to monitor vaccine sentiment and hesitancy posts on Twitter (subsequently rebranded as X), Reddit, and YouTube. We selected Twitter, Reddit, and YouTube as they are the primary social media platforms offering substantial volumes of posts through application programming interface (API) access [40-43]. We focused exclusively on English language posts given the widespread use of English in the largest market countries for our target vaccines and with regard to the accessibility of English language social media. Other platforms and languages, such as Facebook and Spanish [44], may be of interest for future studies; however, these served as a first approach to research. Figure 1 illustrates our workflow, including data annotation, NLP algorithms, and an online dashboard.

First, we categorized vaccine sentiment into positive, negative, and neutral, which were the labels also used in other sentiment analyses using social media data [45,46]. Then, we aligned vaccine hesitancy with the WHO's 3Cs (confidence, complacency, and convenience) vaccine hesitancy model, described in further detail in the *3Cs Vaccine Hesitancy Annotation* section [4]. The definitions of post sentiment and vaccine hesitancy are comprehensively presented in Table 1. We collected data using vaccine-specific search queries (see Table S1 in Multimedia Appendix 1) for relevant posts from the 3 social media platforms. To ensure the quality and reliability of the data, we collaborated with medical experts to create annotated corpora aligned with the information model. These corpora were then used to train NLP algorithms to automatically extract vaccine sentiment and hesitancy content. Finally, we developed an online dashboard to provide real-time insights into vaccine sentiment and hesitancy trends. Our study focuses on evaluating the vaccine sentiment and hesitancy of human papillomavirus (HPV), MMR, and general or unspecified vaccines. The critical role of the vaccines is exemplified by the HPV vaccine, which has effectively reduced prevalent HPV infections and precancerous lesions, underlining the importance of global implementation [47], and the MMR vaccine is renowned for its safety and efficacy, which has greatly mitigated endemic diseases in the United States [48]. Despite these successes, challenges such as insufficient vaccination coverage, increasing hesitancy, and the resurgence of mumps, attributed to waning immunity and antigenic variation, persist worldwide. Throughout the COVID-19 pandemic up to 2022, HPV and MMR were the vaccines that maintained the greatest negative impact on routine vaccinations in the United States, suggesting a need for proactive efforts to increase vaccination coverage to prevent associated health complications and costs [49].

Figure 1. The overview of study design and classifications used to evaluate vaccine-related posts. 3Cs: confidence, complacency, and convenience; ML: machine learning; WHO: World Health Organization.

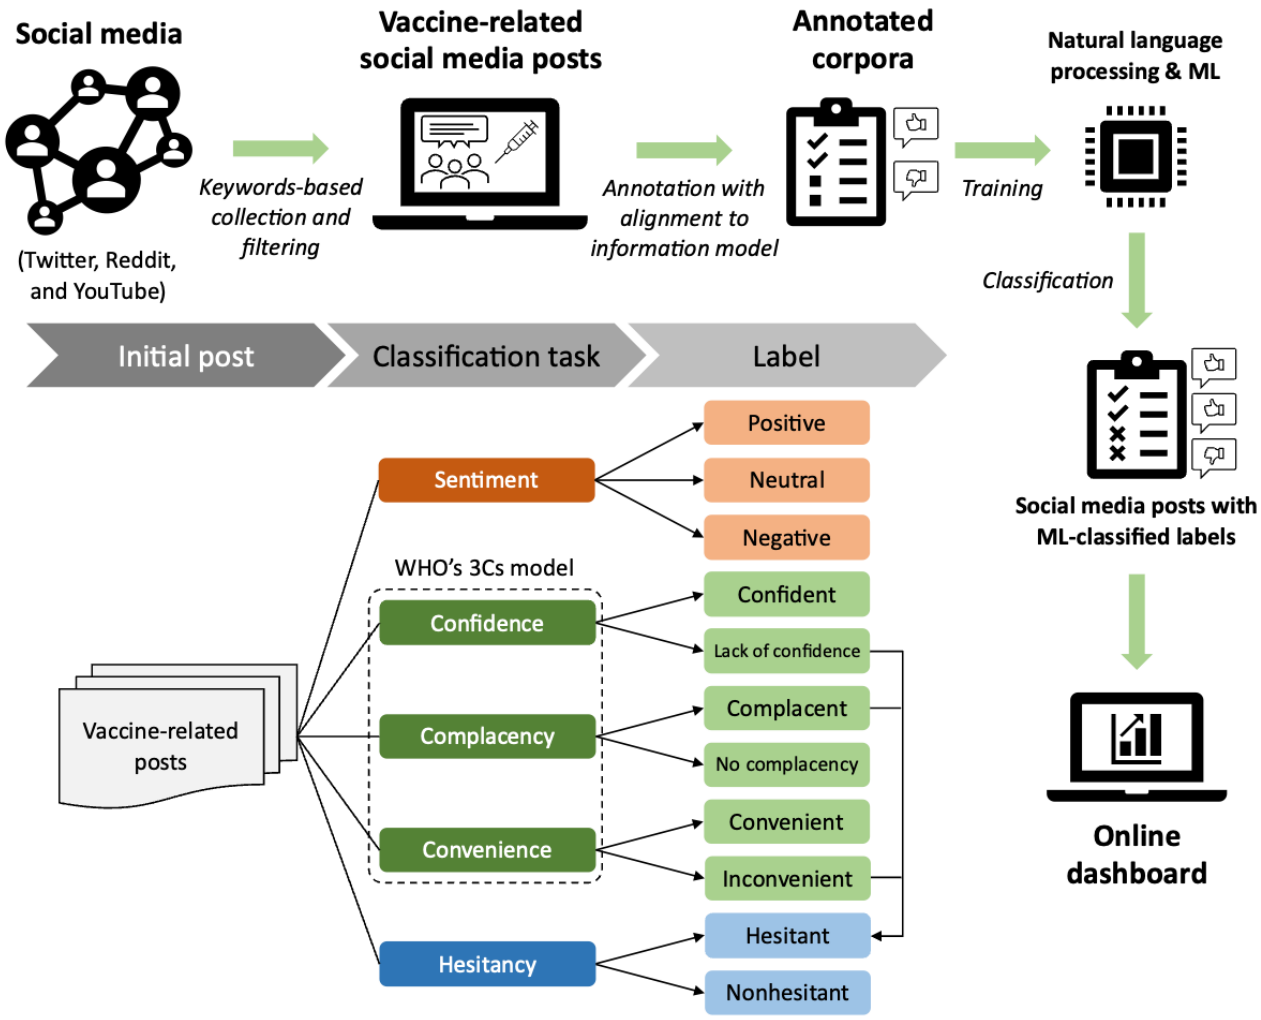

Table 1. Definitions of post sentiment and hesitancy.

Classification task and label	Definition
Sentiment	
Positive	Posts that mention, report, or share positive news, opinions, or stories about vaccines or vaccination.
Neutral	Posts that are related to vaccines or vaccination topics but contain no sentiment, the sentiment is unclear, or they contain both negative and positive sentiments.
Negative	Posts that mention, report, or share negative news, opinions, or stories about vaccines or vaccination, which may discourage vaccination.
Confidence	
Confident	Posts reflecting a trust in the effectiveness and safety of vaccines, the vaccine delivery system, or policy makers' motivations.
Lack of confidence	Posts reflecting a lack of trust in the effectiveness and safety of vaccines, the vaccine delivery system, or policy makers' motivations.
Complacency	
Complacent	Posts where the perceived risks of VPDs[a] are low and vaccination is deemed as an unnecessary preventive action.
No complacency	Posts where the perceived risks of VPDs are high and vaccination is deemed as a necessary preventive action.
Convenience	
Convenient	Posts where physical availability, affordability and willingness to pay, geographical accessibility, ability to understand (language and health literacy), and appeal of immunization services do not affect uptake.
Inconvenient	Posts where physical availability, affordability and willingness to pay, geographical accessibility, ability to understand (language and health literacy), and appeal of immunization services affect uptake.
Hesitancy	
Hesitant	The post is labeled as lack of confidence, complacent, or inconvenient.
Nonhesitant	The post is not labeled as lack of confidence, complacent, or inconvenient.

[a]VPD: vaccine-preventable disease.

Social Media Data Collection

The systematic collection of social media data spanned from January 1, 2011, to October 31, 2021, across 3 platforms—Twitter, Reddit, and YouTube. During initial exploratory analysis, we recognized variations in text nature and query logic across these platforms, leading us to tailor our search queries for each platform to collect relevant posts while excluding irrelevant ones. Table S1 in Multimedia Appendix 1 lists the customized queries on each platform for each vaccine topic group, which include both inclusion and exclusion keywords. We retrieved the results (relevant posts) using the APIs provided by the 3 platforms. Details about the software versions are described in the Multimedia Appendix 1. To clarify ethical considerations and data privacy issues, when gathering data from Twitter, YouTube, and Reddit, we adhered to their API's data privacy policies and ensured the deidentification of all posts and videos by assigning them a unique random ID.

Ethical Considerations

Ethics board review was not required, as all modelling data came from public sources and there were no ethical issues. The data privacy policies of the application program interfaces (APIs) of Twitter, YouTube, and Reddit were followed when gathering data. We ensured the deidentification of all posts and videos by assigning them a unique random ID.

Data Annotation

From the retrieved results, approximately 90 million posts, we randomly selected 60,000 social media discussions. These posts were manually annotated to build both training and evaluation data sets, which were used for building the text classifiers. We selected 20,000 posts for annotation, including 10,000 tweets, 5000 Reddit posts, and 5000 YouTube comments for each vaccine topic group, including HPV vaccine, MMR vaccine, and general or unspecified vaccines. During annotator training, 4 annotators with a medical training background were recruited for the annotation. An annotation guideline was developed. All annotators first annotated the same 1000 tweets, 1000 Reddit posts, and 1000 YouTube posts independently, and then discussed collectively for any discrepancies. After all discrepancies were resolved through discussions, these annotators began to annotate the rest of the social media posts. A 2-fold annotation strategy was used, where first, we annotated the sentiment of the post as positive, neutral, or negative, assigning only 1 category to each post; and second, we annotated vaccine hesitancy based on the constructs of the WHO 3Cs model, which include confidence, complacency, and convenience (Figure 1). These annotation categories also define each classification task.

Sentiment Annotation

The annotation task involved assigning 1 of 3 sentiment labels to each post, which constituted a multiple-class classification problem. The labels and corresponding illustrative examples are defined in Textbox 1.

Textbox 1. Definitions and examples of sentiment labels.

- Positive: posts that mention, report, or share positive news, opinions, or stories about vaccines or vaccination.
  - Example: "HPV vaccine, prevents against the two HPV types, 16 and 18, which cause 70% of cervical cancers"
  - Example: "Get vaccinated against HPV to protect you in the future for now!"
- Neutral: posts that are related to vaccines or vaccination topics but contain no sentiment, the sentiment is unclear, or they contain both negative and positive sentiments.
  - Example: "The following report is specifically for the MMR vaccine, but you can browse around for others"
  - Example: "I just learned that there are more than 50 strains of HPV...I always thought the vaccine prevented all strains."
- Negative: posts that mention, report, or share negative news, opinions, or stories about vaccines or vaccination, which may discourage vaccination.
  - Example: "According to a report, thousands of kids suffer permanent injury or death by getting vaccines"
  - Example: "Believe it? Vaccines have killed 1000 more kids than any measles!"

3Cs Vaccine Hesitancy Annotation

The annotation task involved assigning multiple labels to each post according to the 3Cs model constructs. Annotators checked each construct to determine whether the post was related to it separately. If any of the constructs were labeled as "lack of confidence," "complacent," or "inconvenient," we considered the post as vaccine hesitant; otherwise, it was considered vaccine nonhesitant. Definitions and examples for each 3Cs model construct are provided in Textbox 2.

Table S2 in Multimedia Appendix 1 provides examples of specific social media posts with annotations for the different categories. The distribution of annotated posts in each sentiment and 3Cs construct for each platform and vaccine topic group is shown in Table S3 in Multimedia Appendix 1.

Textbox 2. Definitions and examples of World Health Organization's 3Cs (confidence, complacency, and convenience) model.

- Lack of confidence: posts reflecting a lack of trust in the effectiveness and safety of vaccines, the vaccine delivery system, or policy makers' motivations.
  - Example: "Fully vaccinated are 30 times more likely to get COVID-19, and 10 times more likely to require hospitalization."
  - Example: "The vaccine label includes all these events. Concerns have been raised about reports of deaths occurring in individuals after receiving that vaccine."
- Complacency: posts where the perceived risks of vaccine-preventable diseases are low, and vaccination is deemed as an unnecessary preventive action.
  - Example: "Why do adults need to know about the measles vaccine? The measles is a benign disease and there is no need for vaccines."
  - Example: "I wasn't vaccinated against a preventable disease. It's not always just a life-or-death dichotomy - I recovered."
- Inconvenience or convenience: posts where physical availability, affordability and willingness to pay, geographical accessibility, ability to understand (language and health literacy), and appeal of immunization services affect uptake.
- Example: "I am 30-year-old man and am looking for an HPV vaccine. Unfortunately, my insurance only covers it for women. I am particularly at risk for certain cancers. I really don't understand how insurance companies are allowed to make the gender distinction when the FDA approved it for both."

Text Classification Algorithms

Overview

To classify the sentiment and hesitancy of social media posts, we compared the performance of 5 text classification algorithms—logistic regression (LR) [50], support vector machine (SVM) [51], random forest [52], extreme gradient boosting (XGBoost) [53], and Snorkel [54]. Each of these models has unique characteristics, which are summarized below.

LR Algorithm

LR is a classic statistical methodology that models a binary dependent variable using a logistic function. It is favored in medical research due to its ability to determine the odds ratio, indicating the potential change in outcome probabilities [55].

SVM Algorithm

SVM is one of the most robust classification methods based on statistical learning frameworks. It finds a hyperplane in an N-dimensional space that distinctly classifies data points. In

medical text mining, SVM combined with other algorithms has demonstrated effective performance in extracting and recognizing entities in clinical text, contributing notably to improved patient care [56].

Random Forest Algorithm

Random forest is a classifier that uses ensemble learning to combine decision tree classifiers through bagging or bootstrap aggregating. It has been applied to highly ranked features obtained through suitable ranker algorithms and has shown promising results in medical data classification tasks, enhancing the prediction accuracy for various diseases [57].

XGBoost Algorithm

XGBoost is an ensemble of algorithms that turn weak learners into strong learners by focusing on where the individual models went wrong. In gradient boosting, individual weak models train upon the difference between the classification and the actual results. It has been effective in mining and classifying suggestive sentences from online customer reviews by combining them with a word-embedding approach [58].

Snorkel Algorithm

Snorkel is a system that enables users to train models without hand labeling all training data by writing their labeling functions. Using Snorkel enables the extraction of chemical reaction relationships from biomedical literature abstracts, supporting the understanding of biological processes without requiring a large, labeled training data set [59].

We extracted the term frequency–inverse document frequency vector for each word in all text classification algorithms using *scikit-learn*'s *TfidfTransformer* function with default parameter settings. Term frequency–inverse document frequency evaluates how relevant a word is to a text in a collection of texts [60]. If the model encounters a new post with words or symbols not included in its original bag of words, it will effectively ignore those words during the transformation process. To ensure a balanced training set, the 3 class-balancing methods implemented by Python *imblearn* package applied were (1) random oversampling, (2) synthetic minority over-sampling technique (SMOTE) [61], and (3) SVM-based SMOTE [62] (with the default parameter settings, specifically k_neighbors=5, as they exhibited the optimal performance within the developer's data set [61]). SMOTE randomly selects a minority class instance, finds one of its nearest minority class neighbors, and then synthesizes an instance between these 2 instances in the feature space. SVM-based SMOTE uses support vectors to determine the decision boundaries and then synthesizes a minority class instance along the decision boundary.

NLP Evaluation

The evaluation data sets were created from the annotated corpora and randomly divided into training, validation, and test sets in a 6:2:2 ratio to assess the performance of the 5 text classification algorithms. The models were trained on the training sets, optimized on the validation sets, and then evaluated on the test sets. The following key metrics were calculated to evaluate the models:

A true positive occurs when the model accurately classifies the positive class (positive, negative, or neutral for sentiment; true for 3Cs model constructs). A true negative occurs when the model accurately classifies the negative class (nonpositive, nonnegative, or nonneutral for sentiment; false for 3Cs model constructs). A false positive is an incorrect positive classification, while a false negative is an incorrect negative classification. As the sentiment and hesitancy labels in Tweets, Reddit posts, and YouTube comments are imbalanced, we optimized our models based on F_1-scores, which balance precision and recall, rather than accuracy. The purpose of optimizing a model based on F_1-scores when dealing with imbalanced labels is to achieve a better balance between precision and recall, thereby improving the overall performance of the model. This is especially important in imbalanced data sets where the cost of misclassification can be high.

Dashboard Development

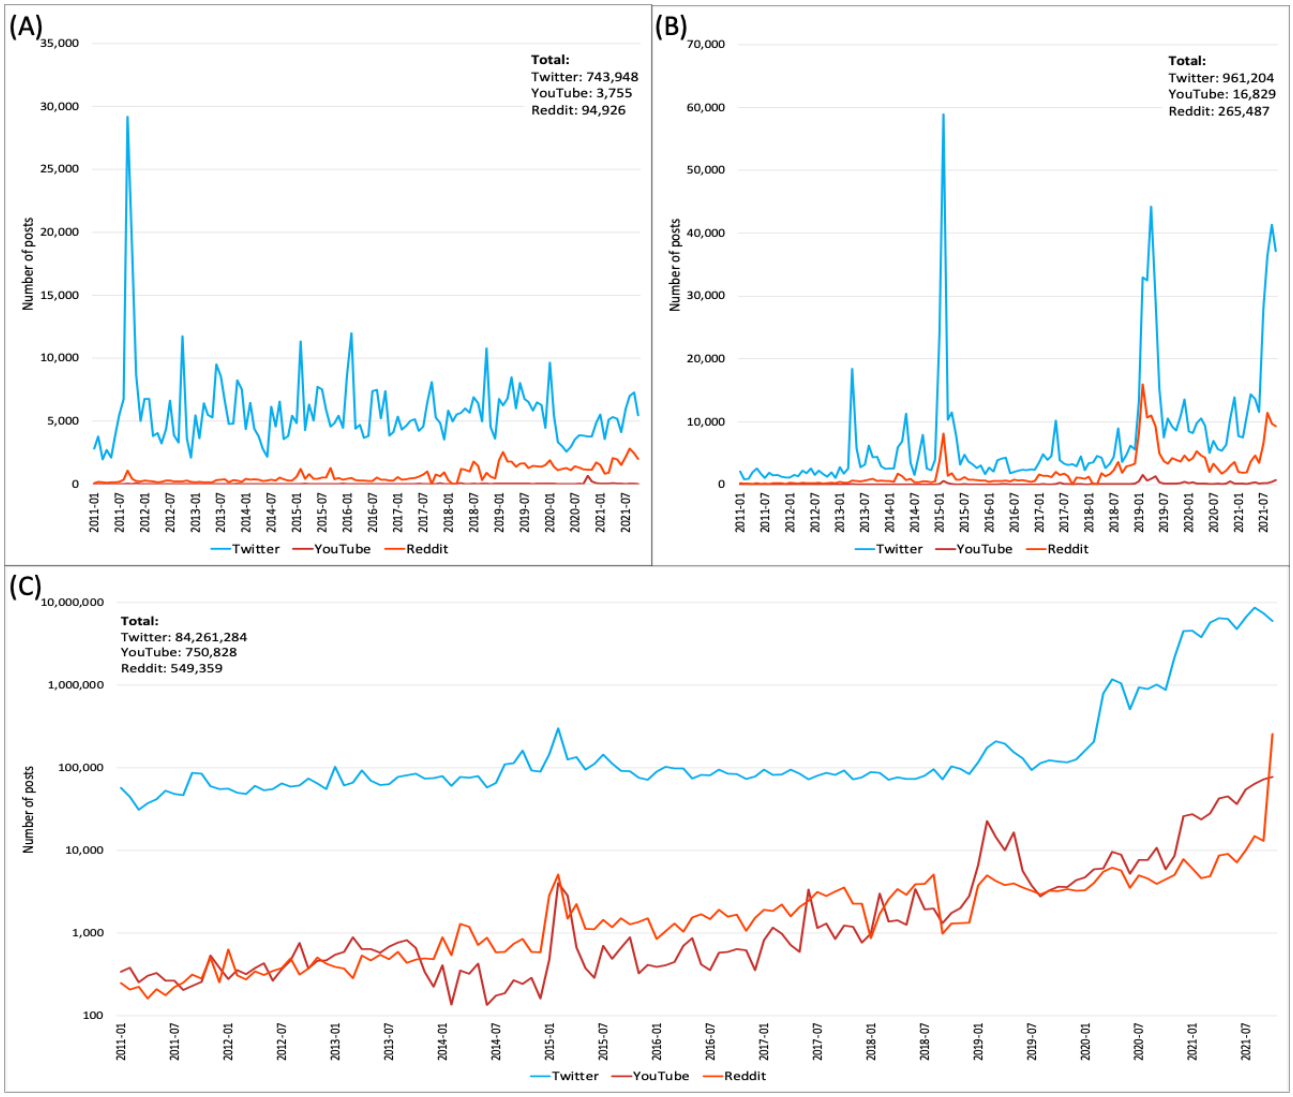
We designed a user-friendly, web-based visualization dashboard [39] for real-time analysis of trends in vaccine sentiment and hesitancy over time and geography (Figure S1A-C in Multimedia Appendix 1). The dashboard also allows for comparisons of sentiment and hesitancy across different social media platforms and vaccine topic groups (Figure S1D in Multimedia Appendix 1). The NLP models were optimized based on their F_1-scores to address the imbalanced labels of sentiment and hesitancy in tweets, Reddit posts, and YouTube comments. The selected models are applied to all unlabeled data collected from 2011 to 2021. Technical details are described and represented in Figure S2 in Multimedia Appendix 1.

Results

Social Media Data Collection Summary

From January 1, 2011, to October 31, 2021, we collected 86 million posts from Twitter, 0.9 million from Reddit, and 76,000 from YouTube, which were related to vaccines. The most widely discussed topic across all 3 platforms was the general or unspecified vaccine, followed by the MMR and then HPV vaccines. We observed a substantial increase in the general vaccine-related discussions on Twitter and Reddit starting in early 2020, coinciding with the onset of the COVID-19 pandemic. The collected social media data and growth trends are plotted in Figure 2.

Figure 2. The long and short-term trends of collected vaccine-related social media post data across 3 different platforms for different vaccine topic groups: (A) human papillomavirus (HPV); (B) measles, mumps, and rubella (MMR); and (C) general or unspecified vaccine.



NLP Performance on Vaccine Sentiment and Hesitancy

We tested all combinations of the 5 NLP algorithms. The performances in sentiment classification, hesitancy classification, and 3Cs classifications are presented in Table 2. The best-performing algorithms (according to F_1-scores) and detailed performance scores for different classification tasks are shown in Tables S4-S8 in Multimedia Appendix 1. In sentiment classification, LR outperformed other algorithms in 7 out of 9 platform–vaccine topic group combinations, with overall accuracies ranging from 0.51 to 0.78 (Table S4 in Multimedia Appendix 1). The macroaveraged F_1-scores of negative, neutral, and positive sentiment classifications across different platforms and vaccine topic groups were 0.43, 0.67, and 0.53, respectively. In hesitancy classification, LR outperformed other algorithms in 6 platform–vaccine topic group combinations, with overall accuracies ranging from 0.69 to 0.91 (Table S5 in Multimedia Appendix 1). The macroaveraged F_1-scores of nonhesitancy and hesitancy classifications were 0.86 and 0.40, respectively. Notably, Reddit users had fewer negative sentiment posts, resulting in lower performance in classifying negative sentiment. In addition, as Reddit had fewer hesitancy posts, classifying hesitancy was more challenging than on Twitter and YouTube.

Our evaluation of various algorithms and class-balancing methods for each platform and vaccine topic group revealed that Snorkel performed best in 3 platform–vaccine topic group combinations in vaccine hesitancy classifications, with overall accuracies ranging from 0.69 to 0.98 (Table S6 in Multimedia Appendix 1). The macroaveraged F_1-scores for lack of confidence and nonlack of confidence classifications were 0.88 and 0.45, respectively. Similarly, for complacency classifications, Snorkel outperformed other algorithms in 4 platform–vaccine topic group combinations, with overall accuracies ranging from 0.64 to 0.99 (Table S7 in Multimedia Appendix 1). The macroaveraged F_1-scores for noncomplacency and complacency classifications were 0.89 and 0.49, respectively. Inconvenience classifications were significantly improved with Snorkel in 8 platform–vaccine topic group combinations, with overall accuracies ranging from 0.89 to 0.99 (Table S8 in Multimedia Appendix 1). However, the results are biased as there were limited posts with convenience information on all 3 social media platforms, which may impact generalizability. The macroaveraged F_1-scores for

noninconvenience and inconvenience classifications were 0.98 and 0.38, respectively. Our findings demonstrate that advanced text classification algorithms such as XGBoost and Snorkel outperformed other algorithms in highly class-imbalanced situations, even when different class-balancing methods were applied.

We have created a web-based dashboard building upon those best-performing NLP algorithms to extract vaccine sentiment and hesitancy from social media posts. The dashboard summarizes posts from the 3 social media platforms and allows users to analyze temporal trends and geographic clustering easily. It offers different views, including 3 social media platform–centric views and a comparison view that enables users to compare selected vaccine topic groups and sentiment or hesitancy (Figure S1 in Multimedia Appendix 1).

When analyzing the sentiment of HPV vaccine posts across 3 social media platforms from January 2011 to October 2021 (Figure 3A), we observed that the ratio of positive sentiment was generally higher than that of neutral and negative sentiment. We also compared vaccine sentiment across 3 social media platforms for MMR vaccines from January 2011 to October 2021 (Figure 3B). Overall, posts expressed positive sentiment toward MMR, with most being neutral. Taking the hesitancy of MMR vaccine as an example, the overall trend shows that the social media posts across 3 social media platforms have a higher ratio of nonhesitancy than hesitancy (Figure 3C).

Table 2. NLP[a] performance (measured by F1-scores and accuracy) on vaccine sentiment and hesitancy.

Performance	Twitter			Reddit			YouTube		
	HPV[b]	MMR[c]	General[d]	HPV	MMR	General	HPV	MMR	General
Sentiment									
Positive F_1-score	0.87	0.57	0.47	0.67	0.50	0.35	0.58	0.53	0.19
Neutral F_1-score	0.71	0.67	0.83	0.67	0.65	0.86	0.51	0.59	0.51
Negative F_1-score	0.41	0.53	0.43	0.32	0.26	0.21	0.60	0.49	0.59
Accuracy	0.78	0.61	0.73	0.63	0.55	0.75	0.56	0.55	0.51
Confidence									
Confident F_1-score	0.35	0.31	0.52	0.35	0.62	0.56	0.44	0.29	0.63
Lack of confidence F_1-score	0.88	0.95	0.79	0.86	0.74	0.84	0.89	0.99	0.98
Accuracy	0.80	0.90	0.71	0.77	0.69	0.77	0.82	0.98	0.95
Complacency									
Complacent F_1-score	0.47	0.36	0.41	0.43	0.68	0.60	0.33	0.50	0.60
No complacency F_1-score	0.94	0.91	0.81	0.93	0.59	0.96	0.91	1.00	0.97
Accuracy	0.89	0.84	0.71	0.88	0.64	0.93	0.84	0.99	0.95
Convenience									
Convenient F_1-score	0.96	0.99	0.99	0.94	0.95	0.98	0.98	1.00	0.99
Inconvenient F_1-score	0.48	0.18	0.55	0.67	0.17	0.50	0.17	0.50	0.20
Accuracy	0.92	0.98	0.98	0.89	0.91	0.97	0.96	0.99	0.98
Hesitancy									
Hesitant F_1-score	0.40	0.44	0.38	0.19	0.23	0.20	0.58	0.53	0.61
Nonhesitant F_1-score	0.94	0.90	0.89	0.87	0.81	0.95	0.81	0.83	0.76
Accuracy	0.90	0.83	0.82	0.78	0.69	0.91	0.73	0.75	0.70

Discussion

Principal Findings

Our analysis of temporal trends in vaccine-related sentiment on social media platforms yielded valuable insights into the dynamics of public perception. A total of 5 different classification algorithms were subjected to tests for performance in sentiment and hesitancy classifications, revealing that advanced text classification algorithms such as XGBoost and Snorkel outperformed others in classifying hesitancy, complacency, and other factors, while LR had a superior performance for sentiment classification. The superior performance of LR could potentially be attributed to its enhanced ability to effectively handle binary classification

challenges and manage noise variables [63]. As the use of artificial intelligence platforms is increasingly becoming accessible for public use, it is crucial to gain an understanding of their accuracy and limitations. Traditional machine learning algorithms have the ability to predict outcomes but often lack transparency. Hence, enhancing public understanding and advancing toward explainable artificial intelligence is vital for error rectification and improved model efficacy for social media research [64].

When evaluating trends for the HPV vaccine, overall positive sentiment outweighed neutral and negative sentiment (Figure 3A), a notable exception occurred in March 2013. During this period, posts with negative sentiment on all 3 platforms surpassed those with 34% (2270/6582) positive and 24% (1581/6582) neutral sentiment, constituting 41% (2731/6582) of the total. This spike in negative sentiment can be attributed to news articles published in March 2013; for example, "Worried Parents Balk At HPV Vaccine For Daughters" by National Public Radio [65] and "Side Effect Fears Stop Parents from Getting HPV Vaccine for Daughters" by CBS News [66]. These articles highlighted concerns and fears about the HPV vaccine. Afterward, specific studies were conducted and published to further investigate these concerns and fears [67,68]. Notably, the HPV vaccines have been found to be safe in several studies and strongly recommended by the Centers for Disease Control and Prevention (CDC), etc [69,70].

Conversely, overall, posts expressed more neutral sentiment toward MMR than positive sentiment (Figure 3B), with an exception in November 2017. During this month, 51% (2844/5619) of posts expressed positive sentiment and 47% (2636/5619) were neutral. We found that a mumps outbreak was observed right before November 2017, which may have encouraged people to discuss the importance of MMR vaccination. News articles highlighted this outbreak, for example, "Third dose of mumps vaccine could help stop outbreaks, researchers say" by PBS News Hour [71] and "CDC recommends booster shot of MMR vaccine during mumps outbreaks" by CNN [72] mentioned the outbreak and recommended the booster shot of MMR vaccine.

When tracking vaccine hesitancy, we found that the social media posts with a higher ratio of hesitancy were only observed in August 2014 (Figure 3C). During this month, some examples of articles could be associated with vaccine hesitancy: "Journal questions validity of autism and vaccine study" by CNN [73] and "Whistleblower Claims CDC Covered Up Data Showing Vaccine-Autism Link" by TIME [74]. While speculation, particularly among antivaccination subpopulations, continues to surround the discredited study linking MMR vaccines with autism, it is crucial to emphasize that this link has been unequivocally debunked by subsequent research, and organizations such as the CDC and WHO have clarified that no such association exists [75-77]. Nonetheless, these news articles, considered by some as antivaccine propaganda, may partially explain the observed trends in MMR vaccine hesitancy during August 2014.

Strengths and Limitations

In this study, we introduced an NLP-powered online monitoring tool for tracking vaccine-related discussions on multiple social media platforms, covering 3 vaccine topic groups. Our system provides several features that distinguish it from existing tools. It uses NLP algorithms to perform sentiment analysis on social media posts and facilitates the tracking of temporal trends and geographic clustering of vaccine sentiment and hesitancy through visualization. In addition, our system enables users to compare vaccine sentiment and hesitancy across different social media platforms. We have publicly shared our annotated social media vaccine corpora, and we have evaluated several text classification algorithms, providing a benchmark for future research. One of the hypothetical use cases is that our NLP-based tool's application spans from gauging vaccine sentiment during disease outbreaks to when a new vaccine is introduced. During an outbreak, the tool effectively analyzed sentiments toward measles vaccination, facilitating adjustments in public health campaigns.

While our proposed method uses the coarse-grained sentiment model (ie, represents the sentiment as a positive or negative class), fine-grained sentiment models, unlike traditional independent dimensional approaches, beneficially incorporate relations between dimensions, such as valence and arousal, into deep neural networks, thereby providing more nuanced, real-valued sentiment analysis and enhancing prediction accuracy [78-81]. These models prove particularly valuable in language-specific applications and are capable of classifying emotion categories and simultaneously predicting valence, arousal, and dominance scores for specific sentences, providing more nuanced sentiment analysis compared with simple positive or negative classifications.

Beyond the limitations inherent in the sentiment model, our approach also encounters constraints due to the use of traditional machine learning algorithms. Deep learning methods for word or sentiment embedding offer enhanced performance in sentiment analysis tasks by integrating external knowledge such as sentiment polarity and emotional semantics into word vectors [82-87]. They leverage neural networks and multitask learning to create task-specific embeddings, improving the accuracy of tasks such as sentiment and emotion analysis and sarcasm and stress detection [82-84,86]. Furthermore, these methods can adapt to the dynamic nature of language, handling out-of-vocabulary words and context-specific word meanings, proving more accurate and comprehensive than traditional word embeddings [86,87]. In future iterations, we plan to enrich our tool by integrating cutting-edge methods, alongside a more robust evaluation method such as time series cross-validation [88].

While previous studies have used NLP for sentiment analysis on COVID-19 vaccination and information exposure analysis regarding the HPV vaccine using Twitter data sets [40,89], and have investigated the temporal and geographic variations in public perceptions of the HPV vaccine [90], our tool extends its functionality to include a broader spectrum of platforms for tracking different vaccine sentiment and hesitancy on social media. Despite the scientific evidence supporting the safety and

efficacy of vaccines, vaccine hesitancy sentiments on social media can impact public confidence regarding vaccination [91]. Our tool is designed to quickly identify surges in vaccine hesitancy and thereby could be a tool to assist public health professionals in responding promptly with accurate information and effective vaccine promotion strategies.

However, it is essential to acknowledge the inherent limitations of using social media as a public health surveillance tool. These limitations include geography and language restrictions, as well as potential population, age, and gender biases, given that social media users may not represent the general population [92-94]. The user diversity across various social media platforms might partly account for the variation in sentiment and hesitancy label distributions. For example, YouTube has a high volume of users, but Twitter had the most activity in our study because people may view YouTube videos without leaving comments [93]. Moreover, owners of YouTube channels also have the option to disable comments on their uploaded videos. In addition, YouTube comments are highly tied to the content of the videos that the model might not have access to, leading to misinterpretations of sentiment and hesitancy. These biases and variabilities could partly account for the lower prediction accuracy observed for YouTube. Therefore, caution should be exercised when interpreting findings based on social media data, particularly considering the varying distributions of sentiment and hesitancy across different social media platforms in our study. Another limitation pertains to the absence of a weighting system in the dashboard. Currently, the impact of each post, considering variables such as the number of views or reposts, is not considered. In addition, private interactions, specifically on sites such as Facebook, might go unnoticed and this lack of access to private dialogues could limit the comprehensiveness of the responses we capture. Finally, there is the possibility of shifts in user behavior to emerging social media platforms, such as TikTok, introducing additional population bias if such platforms are not included in further analyses.

Conclusions

This study successfully developed an innovative real-time monitoring system for analyzing vaccine sentiment and hesitancy across 3 major social media platforms. This system uses NLP and machine learning to mine and classify social media discussions on vaccines, providing valuable insights into public sentiment and hesitancy trends. The application of this tool presents significant implications for public health strategies, aiding in promptly identifying and mitigating vaccine misinformation, enhancing vaccine uptake, and assisting in the execution of targeted health campaigns. Moreover, it encourages health care professionals to foster an evidence-based discourse around vaccines, thus counteracting misinformation and improving public health outcomes.

Abstract

Background: Named entity recognition (NER) is a fundamental task in natural language processing. However, it is typically preceded by named entity annotation, which poses several challenges, especially in the clinical domain. For instance, determining entity boundaries is one of the most common sources of disagreements between annotators due to questions such as whether modifiers or peripheral words should be annotated. If unresolved, these can induce inconsistency in the produced corpora, yet, on the other hand, strict guidelines or adjudication sessions can further prolong an already slow and convoluted process.

Objective: The aim of this study is to address these challenges by evaluating 2 novel annotation methodologies, *lenient span* and *point annotation*, aiming to mitigate the difficulty of precisely determining entity boundaries.

Methods: We evaluate their effects through an annotation case study on a Japanese medical case report data set. We compare annotation time, annotator agreement, and the quality of the produced labeling and assess the impact on the performance of an NER system trained on the annotated corpus.

Results: We saw significant improvements in the labeling process efficiency, with up to a 25% reduction in overall annotation time and even a 10% improvement in annotator agreement compared to the traditional boundary-strict approach. However, even the best-achieved NER model presented some drop in performance compared to the traditional annotation methodology.

Conclusions: Our findings demonstrate a balance between annotation speed and model performance. Although disregarding boundary information affects model performance to some extent, this is counterbalanced by significant reductions in the annotator's workload and notable improvements in the speed of the annotation process. These benefits may prove valuable in various applications, offering an attractive compromise for developers and researchers.

Introduction

Overview

The electronic health record (EHR) can be an important source of data for health-related research as it contains information on a patient's condition and complaints, performed procedures and administered drugs, the outcome of the treatment, and more [1].

Clinical narratives are a fundamental part of EHRs. Due to their free and unstructured format, natural language processing (NLP) methods are essential for extracting the information from such documents in a way that is comprehensible and useful for

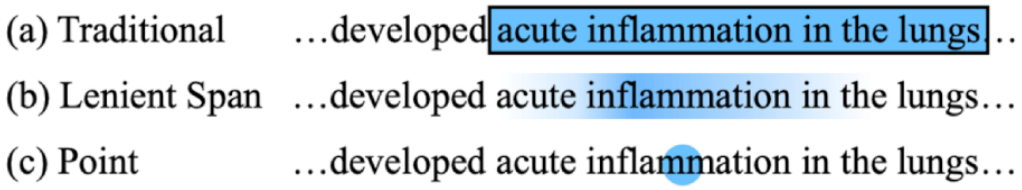
computer systems. Although machine learning–based NLP systems can achieve high performance, these often require large amounts of in-domain annotated data for proper training [2]. Recent few-shot approaches empowered by large language models (LLMs) have also been shown to be performant. Yet, these can also benefit from fine-tuning with in-domain examples, yielding notable improvements [3].

Named entity (NE) annotation, as an inherently manual process, allied to the sheer volume of data that must be meticulously labeled to produce an accurate model, makes it an exhausting and time-consuming task [4]. Particularly when annotating clinical data, workers must possess not only linguistic understanding but specialized medical knowledge is also required. Recruiting such a capable workforce can make the process rather costly [5].

Furthermore, annotation is accompanied by a set of practical issues. For instance, it is natural that contributors disagree on how certain information is annotated or even whether it should be annotated [6]. Determining entity boundaries, meaning where a concept starts and ends, is one of the primary sources of conflict during the process, as so-called *boundary words*, such as articles or adjectives, can induce ambiguity [7].

Especially in medical texts, it is common for annotators to be unsure whether adjectives or modifiers should be included in the annotation. For example, in the sentence presented in Figure 1, some may annotate only the core symptom (“inflammation”).

Figure 1. Example of different annotation paradigms. Traditional annotation (a) requires precisely labeling the beginning and end of the span, while boundary-free (b and c) methods focus on only identifying the core term.



Conversely, others may consider adding all modifiers necessary for a complete encapsulation of the condition.

While entity boundary definition is a problem that affects all languages, scriptio continua languages (which do not have spaces between words), such as Japanese, Chinese, and Korean, are particularly impacted due to the increased difficulty in separating concepts and modifiers.

One can employ strict annotation guidelines to delineate precisely how information should be annotated and even implement adjudication sessions to resolve disagreements. Yet, these can increase the workload and complexity of an already slow and convoluted process.

As an alternative to mitigate such issues, we propose to reformulate the annotation task by eliminating the need to define specific span boundaries when annotating an NE. By demanding less precision from the annotators, we expect to minimize the required decision-making during labeling, thus, improving annotation speed and relieving conflicts.

Although this approach may reduce annotation quality, named entity recognition (NER) performance should not be significantly impacted, as previous research found that models are resilient to a certain amount of boundary imprecision in their training data [8].

In this paper, we leverage this phenomenon by introducing 2 *boundary-free* annotation methodologies: *lenient span*, which relieves the emphasis on entity boundary precision, and *point*, which uses a single position to represent the annotation. Figure 1 presents a visual comparison between the methodologies. We performed a case study to evaluate the efficiency of the proposed methods when annotating a corpus of Japanese medical case reports to create training data for an NER system.

Our contributions are summarized as follows. We present 2 novel boundary-free annotation methodologies, evaluate the efficiency of the annotation process by metrics of annotation time and annotator agreement, and analyze the impact on the performance of an NER system trained with annotated corpora.

Related Work

Annotation Efficiency Improvements

Attempts to improve the annotation workflow are a common theme in NER-related research.

Preannotation depicts the automatic labeling of the text prior to the annotator work [9]. This technique can not only reduce the required annotation time and workload required but also minimize errors [10]. Active learning (AL) [11] can further optimize automatic labeling by iteratively incorporating the data produced during the annotation process to retrain the preannotation model. Kholghi et al [12] ascertained that AL reduced the annotation time by up to 35% (5.6/16 hours) during experiments.

While these are well-established approaches, recent studies also explore alternative ideas. Tokunaga et al [13] analyzed eye-tracking data during NE annotation to identify characteristics that can help design effective features for an annotation tool. Saxena et al [14] introduced a hybrid search-enhanced software that allows users to look for similar terms and annotate related information simultaneously, shortening work time when compared to standard tools.

In recent years, generative LLMs have transformed NLP research and applications, becoming state-of-the-art NLP techniques. While the potential of LLMs to improve the text annotation workflow has also been evaluated in a few different studies [15-17], Tan et al [18] point out that their effectiveness is still strongly affected by model hallucinations and the gap in performance between proprietary and open-source LLMs.

Although crowdsourcing platforms allow the convenient annotation of vast amounts of data [19], they do not improve

task execution or reduce the workload of an individual worker. In addition, as Snow et al [20] noted, inconsistent or low-quality annotations require effective quality control measures. Li [21] found that LLMs can be used to improve the quality of annotation generated by crowdsourcing. Yet LLM annotation quality is still shy of what can be produced manually; thus, combining the automated technique and human effort is still the best approach to creating a high-quality data set [22].

Entity Boundary Imprecision

When addressing boundary imprecision, most studies regard it as a form of noise that should be corrected or circumvented. For instance, Liu et al [23] use confidence scores and normalization techniques based on the labeling structure to estimate the correct span.

Zhu and Li [7] introduced a boundary regularization technique, redistributing a portion of the probability assigned to an annotated span to its neighboring words. This process produces a smooth transition between entity annotations and their nonentity surroundings, mitigating annotation boundary inconsistencies.

Shen et al [24] propose the NER task as a boundary-denoising diffusion process, where a model is trained to derive precise NEs from noisy spans. The authors added controlled noise to gold entity boundaries and used the imprecise data to teach a model to apply a reverse diffusion process to recover the original entity boundaries.

On the other hand, Andrade et al [8] identified that imprecise boundary annotation may not have an extensive impact in some applications. The authors evaluated the effect of various levels of imprecise boundary annotation on NER and entity linking. They identified that models are resilient to a certain amount of noise, showing a small performance drop in that range.

Methods

Data Set

We used the MedTxt-CR-JA corpus [25] in our experiments. This data set comprises 148 open-access case reports in Japanese. Textbox 1 presents an example document from the data set.

A case report is a detailed description of a patient's medical condition, containing, among other information, the temporal progression of the disease and its treatment. Its format is similar to a discharge summary and is frequently used in medical NLP, such as in MIMIC-III [26] or n2c2 shared tasks [27].

This corpus was used in previous studies [28] and contains pre-existing annotations for diseases and symptom names, drugs, anatomical parts, etc. Although we discarded these labels for our experiments, we use them as a gold standard (GS) for evaluation purposes. From now on, this set of annotations is identified as the *gold standard corpus* (GSC).

Textbox 1. Example of a case report from MedTxt-CR-JA and its English translation.

Original:

５８歳，女性．

初診の約２週間前より皮疹が出現，増悪してきたため来院した．

初診時，体幹 四肢に広範囲に浮腫性紅斑が出現し，一部では小水疱を形成していた．

手指背では関節部に一致して角化性紅斑を認め，爪囲には紅斑 紫斑を，眼周囲には軽度の紫紅色斑を認めた．

この時点ではＣＰＫ，ＬＤＨの軽度上昇，抗核抗体２０倍以外，特に異常はなく，確診に至らないため，ステロイド軟膏外用にて経過観察していたところ，３週目頃より体幹 四肢の皮疹が角化性赤色斑へと変化し，１か月目頃より上眼瞼の浮腫性紅斑が著明となり，典型疹となった．

肺癌の合併により発症１年２か月後に死亡した．

臨床経過から，初診時にみられた多形紅斑様あるいは湿疹様の皮疹を皮膚筋炎の早期皮疹と考えた

English translation:

A 58-year-old female.

The patient visited this hospital due to the appearance of a skin rash which worsened about 2 weeks before her first visit.

At the initial examination, the patient had extensive edematous erythema on her torso and extremities, with forming blisters.

Keratinized erythema was uniformly observed around the joints on the back side of the fingers, erythema and purpura were observed around the nails, and mild purplish-red spots were observed around the eyes.

At this point, there were no abnormalities other than mildly elevated CPK and LDH and 20-fold increase in antinuclear antibodies.

Consequently, follow-up with a topical steroid ointment was carried out.

However, by the third week, the skin rash on the torso and extremities changed to keratotic red plaques, and edematous erythema of the upper eyelids became prominent by approximately the first month and became a typical rash.

The patient died 1 year and 2 months after the onset of illness due to complications of lung cancer.

Based on the clinical history, the erythema multiforme or eczema-like skin rash seen at the time of the initial examination is considered to be an early-stage skin rash of dermatomyositis.

We randomly selected a subset of 100 documents from the full corpus, referred to from now on as the *data set*. To minimize the difference in difficulty between texts, we selected documents with similar lengths and quantity of GS entities. Texts are, on average, 554 characters long, roughly equivalent to 250-300 English words, containing around 10 entities per text.

Even though the set of documents for annotation may be considered small, it is worth noting that a scenario with such a small amount of data is not uncommon in the clinical setting, where strong data restrictions usually limit the amount of data available to work with [29].

Annotation Guidelines

It is common to define a set of guidelines before an annotation process to minimize the divergences between annotators and guarantee consistency.

We followed the annotation schema as defined by Yada et al [30]. To simplify the evaluation process, annotators were asked to label only positive (nonnegated) entities of the "Diseases and symptoms" category. We provided the participants with a document describing what should be annotated and some examples, as summarized in Table 1.

Table 1. Annotation guidelines.

Description	Examples[a]
What to annotate	
Reported symptoms, disease names, and clinical findings (pathology, CT[b], and other images)	• Patient visited this hospital due to the appearance of a *skin rash*.
Clinical suspicion, even if there is a slight possibility of disease occurrence	• *Epicarditis* was *suspected* and the patient was hospitalized on July 2.
The locus of a condition, such as an anatomical structure or location, body substance, or physiologic function	• Abdominal CT scan revealed *many enlarged intra-abdominal lymph nodes*.
Adjectives and other modifier words that alter the characteristics or intensity of a condition	• Patient had no subjective symptoms other than a *high fever*. • There was *spotty necrosis* in the lobules.
What should not be annotated	
Absence of symptoms or diseases. Basically, a negation of a clinical concept	• Abdominal findings were unremarkable. • The rash disappeared in about 2 months.
General discussion of a condition merely as a reference and not as a clinical finding	• There is a possibility of primary biliary cholangitis when elevated hepatobiliary enzymes are detected.
Numeric or qualitative findings of an investigation, such as laboratory test values	• The measured blood pressure was abnormal.

[a]In the examples, entities that should be annotated are marked in italics.

[b]CT: computed tomography.

Annotation Methodologies

Our goal is to evaluate whether relieving the emphasis on entity boundary improves annotation speed while maintaining the overall quality of the produced labels. Thus, we compared the *traditional* (boundary-strict) annotation method against 2 proposed boundary-free approaches: *lenient span* and *point annotation*. Figure 1 presents a comparative example of each annotation method.

Traditional Annotation

Traditional annotation requires precise annotation of each NE's exact start and end positions.

Lenient Span Annotation

Lenient span annotation introduces flexibility to the annotation boundaries. While the annotation is still composed of a span, start and end positions are not required to be exactly aligned with the NE boundaries.

Point Annotation

Unlike span-based paradigms, this method requires selecting a single point at any position within the NE span without explicitly specifying the span. It prioritizes speed and simplicity in scenarios where it is not straightforward to determine the NE span precisely. On the other hand, it may introduce ambiguity in the information captured by the annotation.

Note on LLM Annotation

While the use of generative LLMs for text annotation is gaining traction, in this work, we seek ways to aid human annotation and reduce the necessary effort as much as possible where LLMs cannot be used.

The use of LLMs still raises concerns about privacy and security issues; as due to the necessary infrastructure and computational power needed, these models are usually held in the cloud and owned by third-party companies [31]. Given the sensitive nature of clinical data, the usage of LLMs in NLP tasks on real-world data is usually constrained by the policy of medical institutions.

Thus, there is still a need for manual annotations until performant medical LLMs can be accessed through a secure private network or hosted inside hospital facilities at a reasonable cost.

Annotation Task

We asked 4 annotators with medical background and different levels of annotation experience to participate in the experiments. They produced 3 annotated corpora by labeling the documents from the data set using each evaluated methodology. We measured the time taken for each annotation session and computed agreement metrics. We then used each produced corpus to fine-tune a Bidirectional Encoder Representations From Transformers (BERT)–based [32] NER system and evaluated its performance to assess the corpora quality.

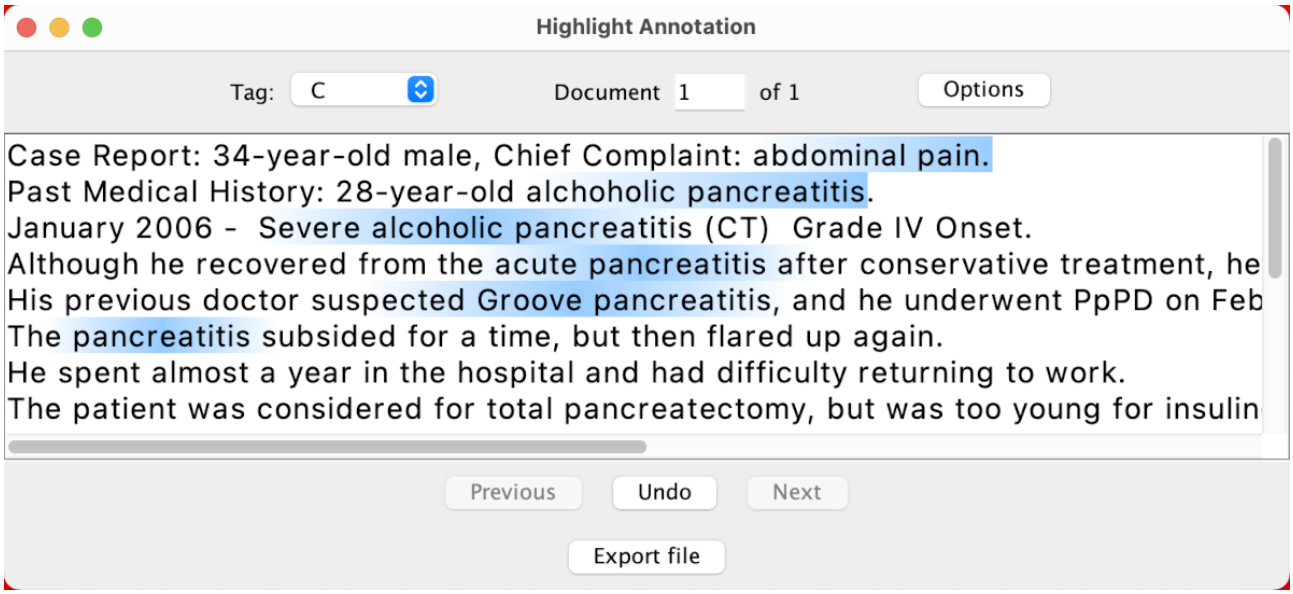
Annotation Tool Development

We developed a Java-based annotation tool to support the proposed boundary-free approaches [33]. Annotations can be presented with smoothed edges using a gradient of color to represent a *soft boundary* and encourage the annotators to be less meticulous when marking the boundaries of the concept. Figure 2 shows a screenshot of the main annotation window.

The text is displayed in its original style, keeping line breaks, spacing, and special characters. Since there is no pretokenization of the texts, annotators can select text spans with character-level precision.

The tool has the following two modes to annotate a concept: (1) *click and drag* and (2) *click-only.*

Figure 2. Screenshot of the annotation tool.



Click and Drag

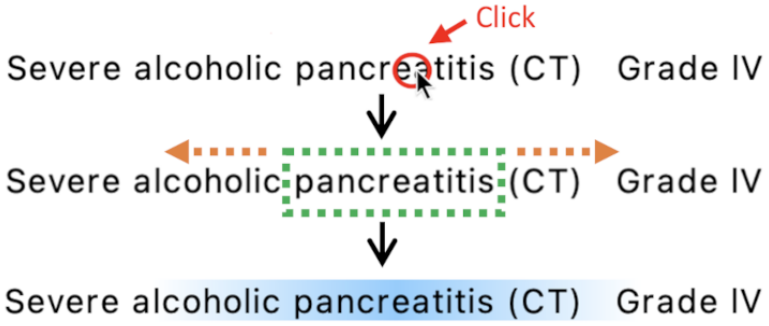
The user clicks on the location where the concept begins and drags the mouse up to where it ends. After releasing the mouse, the area becomes highlighted, representing the labeling.

Click-Only

The user clicks on an entity to label it. While the annotation is stored as a single point, the position will be expanded to a *simulated* span on the interface, representing approximately the labeled concept, as shown in Figure 3.

The annotators received instructions on how to use the tool and a video demonstrating the annotation of a document. They were also supplied with 10 test documents to familiarize themselves with the tool.

Figure 3. Example of a click-only annotation. The selected position, represented by the red circle, is expanded to the word boundaries (in green) plus a random span (orange arrows).



Labeling Workflow

To minimize the number of times each annotator would annotate the same document yet allow us to have at least 2 sets of annotations for a given methodology, we divided our data set of 100 documents into 4 splits.

For each annotation session, each participant received a file containing 2 splits and the annotation methodology that should be used (totaling 50 documents per annotator), as presented in Table 2.

Table 2. Data split for crossover experiment design.

Annotator or annotators	Documents			
	1-25	26-50	51-75	76-100
A	P[a]/T[b]	P	S[c]/T	S
B	S/T	S/T	P	P
C	S	P/T	P/T	S/T
D	P	S	S	P/T

[a]P: point annotation.

[b]T: traditional annotation.

[c]S: lenient span annotation.

We attempted to maximize the mixing between the annotator and the methodology used.

The work was executed in 3 different sessions, the first for point annotation, followed by the lenient span annotation, and lastly, the traditional annotation. During the first 2 sessions, the annotation tool was configured to show smooth edges, and annotators were instructed not to fix slightly incorrect annotations as long as the core concept was highlighted in the tool's interface.

Although the same annotator worked on the same document more than once, the traditional annotation (third) session was conducted 6 months later to avoid memory bias affecting the annotation time measurement. This time annotators were instructed to be as precise as possible when selecting the entity spans and not to refrain from undoing incorrect annotations. The annotation tool was configured beforehand to present the annotations with precise hard boundaries, as any other standard annotation software.

Across all sessions, participants were instructed to annotate the broadest expression whenever in doubt about whether some words should be included in the annotation. Each session produced 2 parallel sets of annotations for each document, unified in a single corpus for each annotation method.

We resolved all disagreements between the 2 sets automatically. We accepted all annotations made by either annotator, even if there is no matching counterpart. Whenever there is boundary disagreement, we choose the broadest span possible when combining the 2 annotations.

For *point* annotations, we grouped annotations that refer to the same NE and averaged their positions. We consider annotations as referring to the same concept when located within 6 characters of distance from each other. The distance limit was chosen based on the average Japanese word length, around 3 characters. We chose a larger value to account for multiword concepts.

Point-to-Span Estimation

Being aware that the single-position label produced by the *point* annotation method may not convey enough information about the adequate range of the NE to be extracted when training the model, we developed a *point-to-span* estimation method [34]. It can complement the annotation with span information without additional manual work.

We used a BERT model (referred to as the *expansion model*) that receives the positional annotation and attempts to predict the original NE span. Effectively, it works as a method to convert Points into Span-based annotations, as illustrated in Figure 4.

The *point-to-span* estimation model is based on the pretrained *tohoku-nlp/bert-base-japanese-char-v2* model [35], and it was fine-tuned using the training parameters presented in Table 3. Training was performed on a server with 2 NVIDIA Quadro RTX 8000 GPUs.

Figure 4. Flow of the point-to-span estimation process. BERT: Bidirectional Encoder Representations From Transformers.

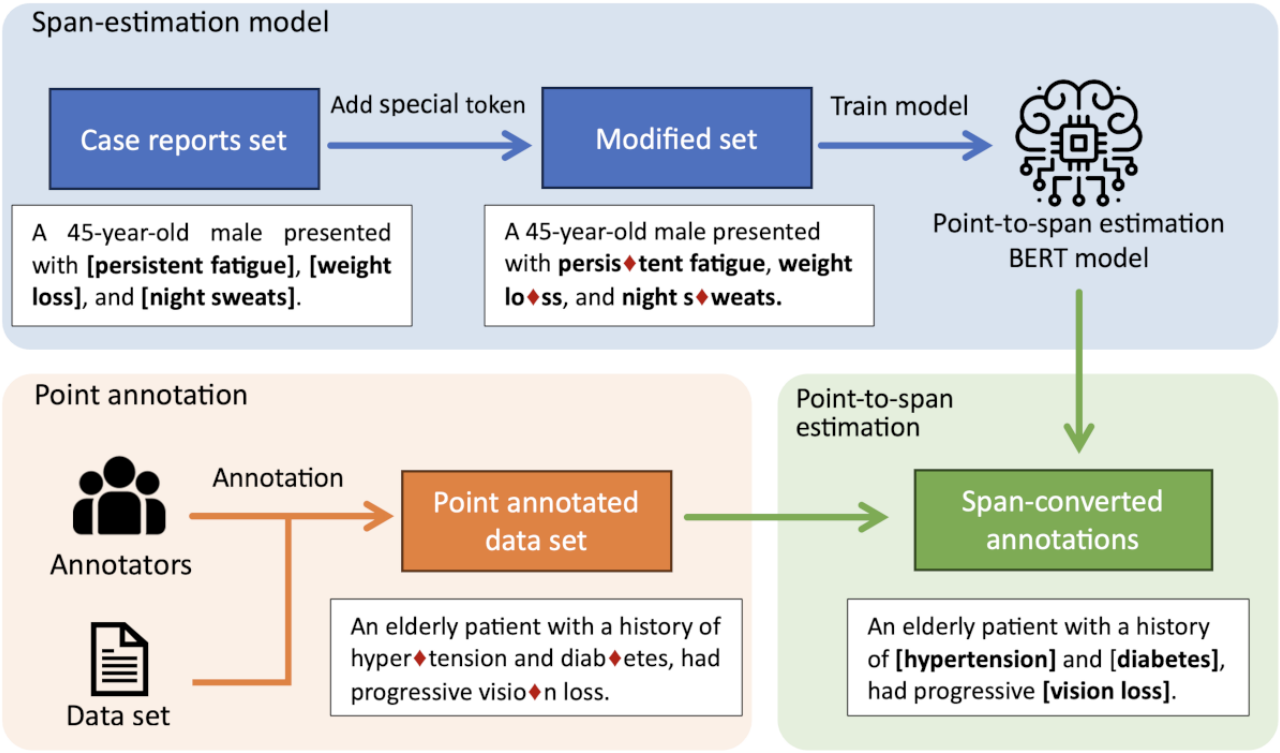


Table 3. Hyperparameters used for model training.

Parameter	Value
Max epochs	10
Training batch size	16
Learning rate	3×10^{-5}
Optimizer	AdamW
Max sentence length	512 characters
Model selection	Early stopping
Training time	Approximately 30 min

As training data, we used a large data set of Japanese medical texts with labeled diseases and symptoms consisting of 1027 synthetic medication history notes generated through crowdsourcing. In total, 10 experienced dispensing pharmacists were hired as writers to craft the corpus. Each writer was assigned 1 of 285 drug names and tasked with creating a "typical" clinical narrative.

Before being fed to the model, each annotation of the training data was replaced by an identifier token in a random location within its span based on a truncated normal distribution. A different distribution was used for each annotation, centered on the middle point, with SD being a sixth of the annotation length. Due to the randomicity of the data, we augmented the data set 10 times by re-executing the annotation replacement module and generating different valid positions for the .

The expansion model was then trained to identify this token and output the start and end positions of the concept based on the word containing the token and its surrounding context.

We evaluated the model by predicting the spans for annotations on the GSC. We preprocessed the GSC annotations using the same method to replace the annotations with . tokens. Our best model was able to achieve an F_1-score of 0.77.

We applied the expansion model to the point-annotated data set to infer spans for each annotation, producing a *point-expanded* corpus. Effectively, the combination of point annotation and expansion allows the generation of a span-annotated data set with less human effort.

Evaluation

Annotation Method Efficiency

We evaluated the annotation methods according to the following:

- Annotation quality: We assessed the percentage of GSC concepts that were correctly annotated. We consider an annotation correct when at least 1 token overlaps with the GS span.

- Annotation time: Annotators manually measured the time they took to work on the data during each session. They were instructed to start the timing after loading the texts in the annotation software.
- Interannotator agreement (IAA): We use Cohen Kappa [36], one of the most common metrics for gauging agreement between annotators. Kappa is a function of the proportion of observed and expected agreement, and it may be interpreted as the proportion of agreement corrected for chance [37].

Given that the *point* annotation methodology allows for multiple correct annotations within the NE span, we computed an additional *adjusted variant* of the metrics specifically for these annotations. In this variant, we considered annotations to agree if they were within a 3-character range of each other, reflecting the average word length in the Japanese language.

Downstream Task Performance

As one of the typical downstream tasks, we developed an NER system to benchmark each annotation approach. We again employed the pretrained *tohoku-nlp/bert-base-japanese-char-v2* model [35] and fine-tuned it using our annotated corpora.

We used the same training parameters for all models, as presented in Table 3. To minimize the variability between results, we used 5-fold cross-validation and averaged the obtained values.

We evaluated model predictions on the MedTxt-CR-JA test set, comprised of 75 documents, by the metrics of *precision*, *recall*, and *F-score*. We employ two variants of the metrics: (1) strict and (2) relaxed.

Strict metrics follow CoNLL criteria [38] and only consider predictions where the span exactly matches the ground truth. These metrics allow us to estimate how closely the model fits the GS.

Relaxed metrics [39] accept partial matches or extra tokens as long as at least 1 token of the predicted span overlaps with the GS span. This variant allows assessing the model's capability of identifying the presence of concepts of interest in the text.

Ethical Considerations

In this study, an annotation process was conducted with the help of human participants. All annotators were provided with detailed information about the purpose, methods, and potential uses of the data they produced, and their informed consent was obtained.

To ensure the privacy of all the patients related to the medical data used in this study, we selected a data set already fully anonymized.

As this research did not use personally identifiable information, it was exempt from institutional review board approval in accordance with the Ethical Guidelines for Medical and Health Research Involving Human Subjects stipulated by the Japanese national government (Chapter 1, Part 3, 1C) [40].

Results

Annotation Method Efficiency

Upon merging the data received from the annotators, we produced the final version of the annotated corpus for each one of the methodologies. Table 4 shows some statistics of the produced corpora.

There is no substantial difference between *traditional* and *lenient span* methods when comparing the average length of the produced annotation. However, both produced annotations slightly larger than the gold annotations due to the disagreement resolution approach adopted in this study.

Table 4. Statistics of the produced corpora.

Method	Total annotations	Average annotation length (character)
Gold standard	1167	6.31
Traditional	1065	7.30
Lenient span	1012	7.30
Point	1066	—[a]

[a]Not applicable.

Annotation Quality

Table 5 shows the average of GSC annotations covered by each corpus.

Although none of the methodologies captured all the ground truth concepts, the percentage of entities captured was similar for every method, with less than a 10% (73 annotations) difference between the best (lenient span) and worst (point).

As the value of missed entities is consistent for all methodologies, we attribute it to some divergence between the guidelines for annotating the GSC and the one used in this study. Differences in the interpretation may have led the annotators to skip some of the entities.

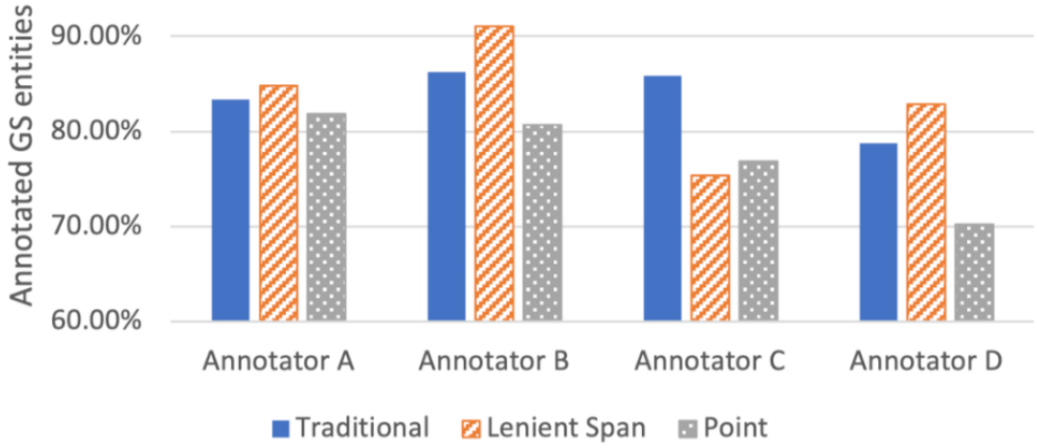
We noticed that the traditional methodology presented a more constant accuracy throughout the annotators, while the boundary-relaxed methods had more variation, especially for annotators C and D.

Figure 5 presents the accuracy of the annotations of each participant in relation to GSC on each methodology.

Table 5. Average number of correctly annotated gold standard (GS) entities per annotation method.

Method	Annotated GS entities, n (%)
Traditional	819 (83.56)
Lenient span	796 (83.65)
Point	746 (77.41)

Figure 5. Annotation accuracy per annotator. GS: gold standard.



Annotation Time

The time measurement results in Table 6 demonstrate that both boundary-free annotation techniques can provide time-saving benefits. On average, reductions of around 25% (around 28 min) and 20% (around 21 min) were observed when using *point* and *lenient span* methods, respectively, compared to the *traditional* annotation process.

Table 6. Comparison of the individual annotation time per annotation method[a].

Annotator	Traditional	Lenient span	Point
A	1:23:44	1:03:23 24%)	0:54:35 (–35%)
B	1:09:14	0:52:07 (–25%)	0:48:45 (–30%)
C	3:16:58	2:10:20 (–34%)	2:15:27 (–31%)
D	1:10:23	1:31:29 (+30%)	1:10:40 (+0%)
Average	1:45:05	1:24:20 (–20%)	1:17:22 (–26%)

[a]Times are presented in the HH:MM:SS format, with the percentage comparison to the traditional method in parenthesis.

Interannotator Agreement

As evidenced by the results presented in Table 7, the IAA measured for both boundary-free annotation methods overcame the *Traditional* methodology.

Point annotations recorded the lowest agreement due to the inherent low probability of annotators precisely pinpointing the exact same position within an NE. Despite that, it achieves the highest measured agreement using the adjusted variant of the metrics.

Table 7. Average interannotator agreement per annotation methodology.

Method	Cohen Kappa
Traditional	0.731
Lenient span	0.774
Point	0.326
Point (adjusted)	0.811

Downstream Task Performance

Table 8 presents the NER model evaluation results.

We trained a GSM using the GS data as a reference for our system's best possible performance.

The data produced in our annotation experiments probably have lower quality due to the lack of proper curation and review

sessions. Thus, when comparing the *Traditional* annotation approach against the GSM, there is a slight decrease in performance: 15% and 11% on strict and relaxed metrics, respectively. Nevertheless, the relation between precision and recall remains the same, as both models were trained on similarly boundary-strict annotations.

Table 8. Evaluation of the trained named entity recognition models.

Method	Strict			Relaxed		
	Precision	Recall	F_1-score	Precision	Recall	F_1-score
Gold standard model	0.72	0.78	0.75	0.90	0.89	0.89
Traditional	0.60	0.69	0.64	0.77	0.81	0.79
Lenient span	0.56	0.54	0.55	0.67	0.62	0.64
Point	0.00	0.00	0.00	0.60	0.45	0.51
Point (expanded)	0.34	0.35	0.35	0.73	0.71	0.72

Discussion

Principal Findings

Throughout the experiments, it was noticeable that simplifying the annotation process contributed to a more comfortable experience for the participants. We observed increased annotation speed, annotator agreement, and overall positive feedback from the annotators regarding the changes.

Although we showcase our proposal in clinical data, the annotation methodologies are both domain and language-agnostic, so they can be applied to texts of different domains and idioms.

Annotation Speed Improvements

The results in Table 6 show that simplifying the constraints under which annotators work can effectively increase the speed at which they execute the task. By virtually removing the need to decide on entity boundaries, both proposed methodologies allowed the annotation of our data set in less time than the *traditional* method.

However, while an overall decreasing trend in annotation time was observed, different annotators experienced varying degrees of time reduction. Notably, annotator C experienced a significant increase in efficiency when using these methodologies. Conversely, annotator D was quicker with the *traditional* annotation scheme. Still, his precision was lower than other annotators, as shown by the individual accuracy results presented in Figure 5.

Annotator Agreement Improvements

Meanwhile, the IAA evaluation (Table 7) revealed some interesting insights into the annotation consistency of each methodology. Both the *lenient span* and the adjusted *point* agreement overcame the *traditional* methodology by 5.88% and 10.94%, respectively.

While we believe that slightly different interpretations of what information should be annotated may have diminished *traditional* approach agreement, such a finding was still unexpected due to the higher flexibility given to the annotators when removing the need for entity boundaries. However, this improvement can be attributed to the ease with which annotators can consistently agree on the core parts of mentions (or the "main words") compared to determining the precise boundaries of entire entities. Such boundaries may or may not encompass adjectives, modifiers, etc, which often contribute to annotation disagreements.

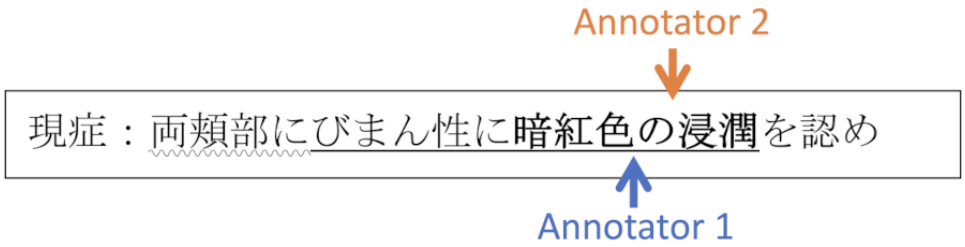
Notably, *point* annotations perceived a large difference in the agreement values measured using the default and *adjusted* variants of the IAA metrics. This is explained by the fact that, even though it is virtually impossible for annotators to select the same character in an NE for all annotations, they generally selected positions close to each other for the same NE. Such finding is evidenced by the distribution of annotation pairs based on the number of characters of difference between them, as depicted in Table 9.

Such a small distance is due to annotators' diligence in positioning the annotation close to the center of the NE's core word. As in the sentence shown in Figure 6 (which translates to "Current symptoms: Diffuse dark red infiltration is observed on both cheeks."), even though the span of the desired annotation is quite large, both annotators placed their labels near the most relevant set of words, "dark red infiltration."

Table 9. Distribution of annotation pairs based on the distance between them.

Number of characters of difference	Annotations, n (%)
0	661 (41.31)
1	640 (40.00)
2	145 (9.06)
3	52 (3.25)
4	25 (1.56)
5	15 (0.94)
6	15 (0.94)
7	14 (0.94)
8	11 (0.69)
9	15 (0.94)
≥10	7 (0.44)

Figure 6. Example of 2 distinct point annotations in a named entity with a large span (underscored). The annotations are located near the center of the core word (in bold).



Annotator's Opinions

Annotator feedback was positive especially regarding the *point* annotation, given its simplicity. The participants highlighted the easiness of the single-click selection mode, particularly due to the reduced mouse manipulation needed.

However, the participants expressed difficulty in understanding the correctness of their annotations and whether the chosen range was indeed accurate. They felt that the soft boundaries displayed by the annotation tool turned the annotations ambiguous, making them unsure whether they matched the range they intended to select.

Impacts on Model Performance

While achieving significant improvements in annotators' work quality, the additional flexibility from boundary-free methods considerably impacted model performance, particularly in strict evaluation, due to the imprecise training data, as seen in Table 8.

The *lenient span*–trained model exhibited a significant subside in its recall, which hindered strict and relaxed evaluations. We did not expect that the ambiguity in NE boundaries could affect the model's capability of locating NEs in the text.

While such performance drop may be acceptable for some applications, we believe additional annotation postprocessing methods could restore the accuracy to levels similar to the *traditional* schema.

Point-to-Span Estimation

In particular, the insights from *point* annotation experiments underscore the potential of automated methods to supplement human annotations. We believe that *point-to-span estimation* can be pivotal for improving annotation speed, but beyond that, it can be proven beneficial to aid in addressing other annotation problems.

Given the lackluster nature of the annotation task, it is not uncommon that annotators make mistakes, such as including punctuation markers or failing to label part of the NE simply for a lack of focus. The span estimation model can be a tool to "normalize" such annotations.

Furthermore, the estimation could be integrated into the actual annotation process by coupling it with our annotation tool, enabling the "click-only" annotation interface to present the predicted span directly and allowing the annotator to correct its mistakes.

However, there is potential for enhancements in the expansion model. Although expanding a point to the expected word seems to be a simple task, as we are evaluating our methods on a scriptio continua language, which makes the definition of the word boundaries not as obvious as in space-delimited languages, such as English.

Through analysis of the model's output, we have observed that the estimation model exhibited a tendency to choose spans larger than the GS entities, particularly when characters that act like

qualitative adjectives (such as “高” for high, “急性” for acute, “巨大” for huge) were connected to the concept of interest.

For instance, the model outputted “高度の肝萎縮“ (Severe liver atrophy) instead of only “肝萎縮” (Liver atrophy). Another example was the expansion of the term “巨大な脾腎シャント“ (Giant splenorenal shunt), where 巨大な (Giant) was included.

Yet, even though the model output in these examples can be regarded as “incorrect” when compared to the GSC, from a clinical point of view, it is not uncommon that some diseases are distinguished by such modifier words. For example, “急性胆嚢炎” (acute cholecystitis) and “慢性胆嚢炎 (chronic cholecystitis), which even have different International Classification of Diseases codes, K81.0 and K81.1, respectively.

Error Analysis

Figures 7 and 8 present example comparisons between all the evaluated models in 2 different sentences.

We could not identify any unusual behavior when inspecting the traditional annotation model output. Yet, we highlight that the lenient span model portrayed a tendency to overly extend the span lengths. In some cases (as shown especially in Figure 8), multiple NEs are “merged” into a single continuous extraction.

As seen in both examples, the model trained with raw point annotations could not extract NE spans, denoting that the single position annotation contains insufficient information to train the model properly.

In contrast, the model trained on expanded point annotations showcases the effectiveness of the *point-to-span* estimation method. Although strict metrics are still substantially lower than other approaches, relaxed results are comparable to the *traditional* annotation approach. The analysis of the model output evidenced that, while it could locate most concepts of interest, it struggled in correctly extracting multiword concepts.

Figure 7. Comparison of model output for the sentence “While waiting for a CT scan, patient went into cardiopulmonary arrest (CA), but could not be resuscitated and died.” Gold standard entities and model extractions are marked in bold and underscored. White space tokenization was added to the Japanese text to enhance readability for non-Japanese readers. The original text does not contain spaces.

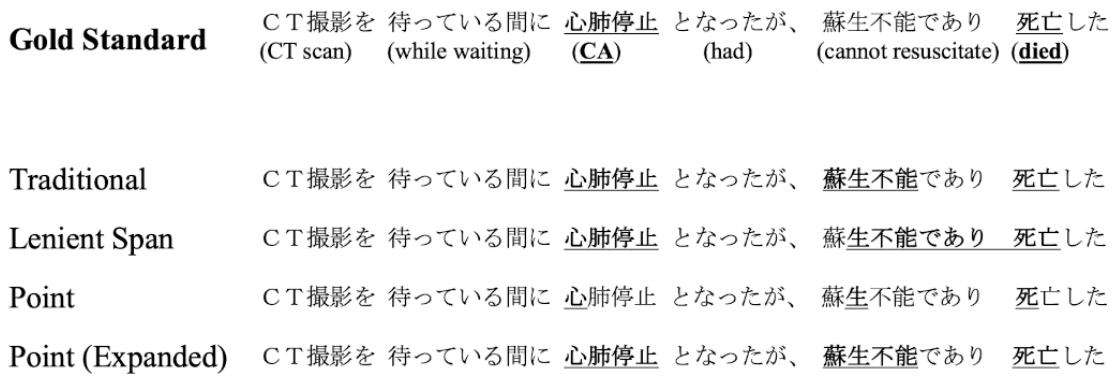


Figure 8. Comparison of model output for the sentence “History of hypertension (HTN), diabetes, hyperlipidemia (HLD), or atrial fibrillation (AFib).” Gold standard entities and model extractions are marked in bold and underscored. White space tokenization was added to the Japanese text to enhance readability for non-Japanese readers. The original text does not contain spaces.

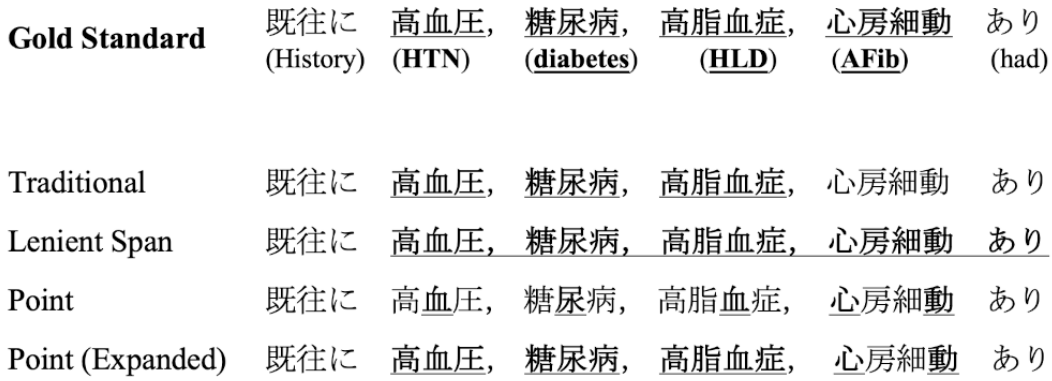

Limitations

While our research focused on exploring novel approaches to text annotation and revealed promising findings, a few concerns and limitations need further investigation. Our investigations were only conducted in the Japanese language. Though our proposal is language independent, applying our techniques in a space-delimited language, such as English, could introduce some bias. Evaluation using different languages is, thus, encouraged. Since our data set in this study has an English variant, we plan to conduct additional experiments.

We concentrated on a singular entity class, disease, and symptom names to streamline the analysis. Even though our texts contain a large number of entities, a single class annotation may not represent a real use case. Exploring our methodologies

in a multiclass scenario would enhance the robustness of our findings and conclusions.

Furthermore, we acknowledge that automated labeling techniques, such as preannotation, can affect the improvements observed in annotation time by adopting boundary-free methodologies. We chose not to incorporate these features in our annotation tool to minimize the number of variables affecting the annotation process.

The observed performance of the trained NER models could have been impacted by our choice of using a simple and automatic approach to solve disagreements. Although it avoids additional annotator work and simplifies the research flow, implementing adjudication or review sessions with the annotations would be preferred, as it could have provided a better annotation quality.

LLMs are prevalent in the current NLP research scenario, and their application has led to the development of systems that push state-of-the-art performance in many different tasks. In the current state of our work, we have not adopted LLMs. Still, we acknowledge that the accuracy of our methods may be improved by employing such methods in our workflow, possibly replacing the Point-to-span BERT model.

Conclusions

In this study, we investigated the effects of reducing the emphasis on entity boundary annotations while labeling NEs in a medical data set. We proposed 2 novel boundary-free annotation methodologies, *lenient span* and *point* annotation. We evaluated the impact of their application in an annotation process regarding annotation efficiency and the quality of the labeling produced.

We also publicly released our developed annotation tool [33] and point-to-span estimation model [34].

Our results demonstrate a trade-off relation between annotation efficiency and model performance. Although not surprising, it unveils the weak points of each methodology and uncovers potential adjustments that can be made to each approach. We underscore that completely disregarding boundary information may ease the annotator's work while it sacrifices performance to some extent.

We plan to evaluate the proposed methodologies in other languages in future work. We also intend to explore the impact of postprocessing techniques, such as normalization or boundary regularization, to enhance model output performance.

Abstract

Background: Large language models show promise for improving radiology workflows, but their performance on structured radiological tasks such as Reporting and Data Systems (RADS) categorization remains unexplored.

Objective: This study aims to evaluate 3 large language model chatbots—Claude-2, GPT-3.5, and GPT-4—on assigning RADS categories to radiology reports and assess the impact of different prompting strategies.

Methods: This cross-sectional study compared 3 chatbots using 30 radiology reports (10 per RADS criteria), using a 3-level prompting strategy: zero-shot, few-shot, and guideline PDF-informed prompts. The cases were grounded in Liver Imaging Reporting & Data System (LI-RADS) version 2018, Lung CT (computed tomography) Screening Reporting & Data System (Lung-RADS) version 2022, and Ovarian-Adnexal Reporting & Data System (O-RADS) magnetic resonance imaging, meticulously prepared by board-certified radiologists. Each report underwent 6 assessments. Two blinded reviewers assessed the chatbots' response at patient-level RADS categorization and overall ratings. The agreement across repetitions was assessed using Fleiss κ.

Results: Claude-2 achieved the highest accuracy in overall ratings with few-shot prompts and guideline PDFs (prompt-2), attaining 57% (17/30) average accuracy over 6 runs and 50% (15/30) accuracy with k-pass voting. Without prompt engineering, all chatbots performed poorly. The introduction of a structured exemplar prompt (prompt-1) increased the accuracy of overall ratings for all chatbots. Providing prompt-2 further improved Claude-2's performance, an enhancement not replicated by GPT-4. The interrun agreement was substantial for Claude-2 (k=0.66 for overall rating and k=0.69 for RADS categorization), fair for GPT-4 (k=0.39 for both), and fair for GPT-3.5 (k=0.21 for overall rating and k=0.39 for RADS categorization). All chatbots showed significantly higher accuracy with LI-RADS version 2018 than with Lung-RADS version 2022 and O-RADS (P<.05); with prompt-2, Claude-2 achieved the highest overall rating accuracy of 75% (45/60) in LI-RADS version 2018.

Conclusions: When equipped with structured prompts and guideline PDFs, Claude-2 demonstrated potential in assigning RADS categories to radiology cases according to established criteria such as LI-RADS version 2018. However, the current generation of chatbots lags in accurately categorizing cases based on more recent RADS criteria.

Introduction

Since ChatGPT's public release in November 2022, large language models (LLMs) have attracted great interest in medical imaging applications [1]. Research indicated that ChatGPT showed promising applications in various aspects of the medical imaging process. Even without radiology-specific pretraining, LLMs can pass board examinations [2], provide radiology decision support [3], assist in differential diagnosis [3-6], and generate impressions from findings or structured reports [7-9]. These applications not only accelerate the imaging diagnosis process and alleviate the workload of doctors but also improve the accuracy of diagnosis [10]. However, limitations exist, with 1 study showing ChatGPT-3 producing erroneous answers for a third of daily clinical questions and about 63% of provided references were not found [11]. ChatGPT's dangerous tendency to produce inaccurate responses is less frequent in GPT-4 but still limits usability in medical education and practice at present [12]. Tailoring LLMs to radiology may enhance reliability, as an appropriateness criteria context aware chatbot outperformed generic chatbots and radiologists [12].

The American College of Radiology Reporting and Data Systems (RADS) standardizes communication of imaging findings. As of August 2023, there have been 9 disease-specific systems endorsed by the American College of Radiology, referring to products from the lexicons to report templates [13]. RADS reduces terminology variability, facilitates communication between radiologists and referring physicians, allows consistent evaluations, and conveys clinical significance to improve care. However, complexity and unfamiliarity limit adoption. Consequently, endeavors should be pursued to broaden the implementation of RADS. Therefore, we conducted this study to evaluate LLM's capabilities on a focused RADS assignment task for radiology reports.

A prompt serves as a directive or instruction given to LLMs to generate a particular response. The technique of "prompt tuning" has emerged as a valuable approach to refine the performance of LLMs, particularly for specific domains or tasks [14]. By providing structured queries or exemplary responses, the output of chatbots can be tailored for accurate and relevant answers. Such prompt-tuning strategies leverage LLMs' knowledge while guiding appropriate delivery for particular challenges [14]. Given the complexity and specificity of the RADS categorization, our investigation emphasizes different prompt impacts to assess chatbot capabilities and potential performance enhancement through refined prompting tuning.

In this study, our primary objective was to meticulously evaluate the performance of 3 LLMs (GPT-3.5, GPT-4, and Claude-2) for RADS categorization using different prompt-tuning strategies. We aimed to test their accuracy and consistency in RADS categorization and shed light on the potential benefits and limitations of relying on chatbot-derived information for the categorization of specific RADS.

Methods

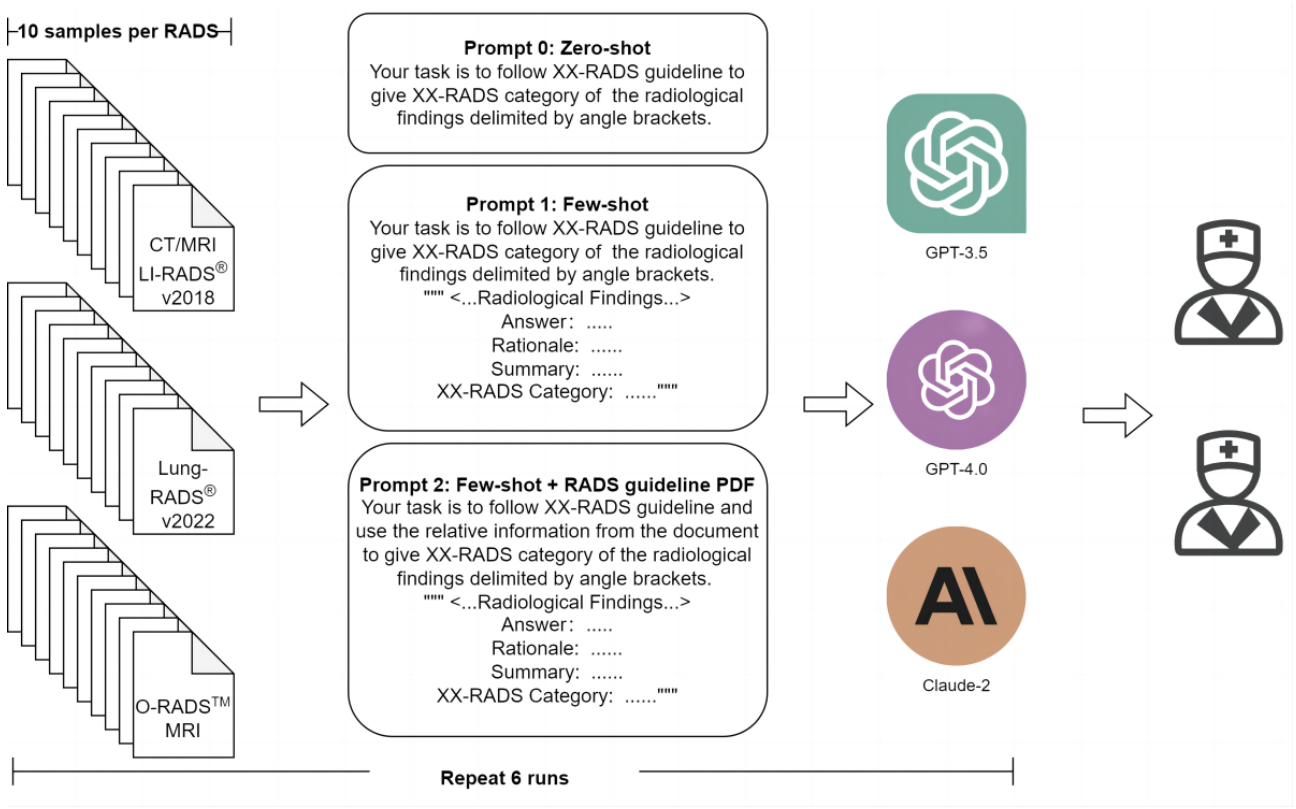
Ethical Considerations

As the study was based on radiological data that were artificially generated by radiologists and did not involve the participation of human subjects, the study was determined to be exempt from ethical review, in accordance with the regulations established by the institutional review board of Henan Provincial People's Hospital.

Study Design

The workflow of the study is shown in Figure 1. We conducted a cross-sectional analysis in September 2023 to evaluate the competency of 3 chatbots—GPT-3.5, GPT-4 (OpenAI, August 30, 2023 version) [15], and Claude-2 (Anthropic) [16]—in the task of assigning 3 RADS categorizations to radiology reports. Given the chatbot's knowledge cessation was as of September 2021, we opted for Liver Imaging Reporting & Data System (LI-RADS) version 2018 [17], Lung CT (computed tomography) Screening Reporting & Data System (Lung-RADS) version 2022 [18], and Ovarian-Adnexal Reporting & Data System (O-RADS) magnetic resonance imaging (MRI) (developed in 2022) [19] as the yardsticks to compare the responses engendered by GPT-3.5, GPT-4, and Claude-2. A total of thirty radiology reports for either CT or MRI examinations were composed for this analysis, with 10 cases representing each of the 3 RADS reporting systems. The radiology reports used for testing were generated by radiologists with more than 10 years' experience to correct the wording styles from real-life cases based on respective RADS systems. For each RADS (ie, LI-, Lung-, and O-RADS), we attempted to reflect the complexity and diversity so that the reports cover typical cases in clinical practice. Therefore, reports with 2-3 simple cases and 7-8 challenging cases were generated for 1 RADS. These include scenarios such as prior examination comparison, the presence of multiple nodules, extensive categorization under different RADS systems, and updates from the most recent LI-RADS and Lung-RADS guidelines. The characteristics of radiology reports for each RADS and the distribution of the number of the reports across the 3 RADS are shown in Multimedia Appendix 1. The objective was to evaluate the performance of chatbots on a highly structured radiology workflow task involving cancer risk categorization based on structured report inputs. The study design focused on a defined use case to illuminate the strengths and limitations of existing natural language-processing technology in this radiology subdomain.

Figure 1. Flowchart of the study design. CT: computed tomography; LI-RADS: Liver Imaging Reporting & Data System; Lung-RADS: Lung CT Screening Reporting & Data System; MRI: magnetic resonance imaging; O-RADS: Ovarian-Adnexal Reporting & Data System; RADS: Reporting and Data Systems.



Prompts

We collected and analyzed responses from GPT-3.5, GPT-4, and Claude-2 for each case. To mitigate bias, the radiological findings were presented individually via separate interactions, with corresponding responses saved for analysis. Three prompt templates were designed to elicit each RADS categorization along with explanatory rationale: Prompt-0 was a zero-shot prompt, merely introducing the RADS assignment task, such as "Your task is to follow Lung-RADS version 2022 guideline to give Lung-RADS category of the radiological findings delimited by angle brackets."

Prompt-1 was a few-shot prompt, furnishing an exemplar of RADS categorization including the reasoning, summarized impression, and final category. The following is an example:

> *Your task is to follow Lung-RADS version 2022 guideline to give Lung-RADS category of the radiological findings delimited by angle brackets. """ < …Radiological Findings… > Answer: Rationale: {…} Overall: {…} Summary: {…} Lung-RADS Category: X """*

Prompt-2 distinctly instructed chatbots to consult the PDF of corresponding RADS guidelines, compensating for these chatbots' lack of radiology-specific pretraining. For Claude-2, the PDF could be directly ingested, while GPT-4 required the use of an "Ask for PDF" plug-in to extract pertinent information [20,21].

Each case was evaluated 6 times with each chatbot across the 3 prompt levels. The representative radiological reports and prompts are shown in Multimedia Appendix 2. The links to all the prompts and guideline PDFs are shown in Multimedia Appendix 3.

Evaluation of Chatbots

Two study authors (QW and HL) independently evaluated the following for each chatbot response in a blinded manner, with any discrepancies resolved by a third senior radiologist (YW). The following were assessed for each response:

1. Patient-level RADS categorization: judged as correct, incorrect, or unsure. "Correct" denotes that the chatbot accurately identified the patient-level RADS category, irrespective of the rationale provided. "Unsure" denotes that the chatbot's response failed to provide a decisive RADS category. For example, a response articulating that "a definitive Lung-RADS category cannot be assigned" would be categorized as "unsure."
2. Overall rating: assessed as either correct or incorrect. A response is judged incorrect if any errors (Es) are identified, including the following:
   - E1: a factual extraction error that denotes the chatbots' inability to paraphrase the radiological findings accurately, consequently misinterpreting the information.
   - E2: hallucination, encompassing the fabrication of nonexistent RADS categories (E2a) and RADS criteria (E2b).
   - E3: a reasoning error, which includes the incapacity to logically interpret the imaging description (E3a) and the RADS category accurately (E3b). The subtype

errors for reasoning imaging description include the inability to reason lesion signal (E3ai), lesion size (E3aii), and enhancement (E3aiii) accurately.
- E4: an explanatory error, encompassing inaccurate elucidation of RADS category meaning (E4a) and erroneous explanation of the recommended management and follow-up corresponding to the RADS category (E4b).

If a chatbot's feedback manifested any of the aforementioned infractions, it was labeled as incorrect, with the specific type of error documented. To assess the consistency of the evaluations, a k-pass voting method was also applied. Specifically, a case was deemed accurately categorized if it met the criteria in a minimum of 4 out of the 6 runs.

Statistical Analyses

The accuracy of the patient-level RADS categorization and overall rating for each chatbot was compared using the chi-square test. The agreement across the 6 repeated runs was assessed using Fleiss κ. Agreement strength was interpreted as follows: <0 signified poor, 0-0.20 indicated slight, 0.21-0.40 represented fair, 0.41-0.60 was interpreted as moderate, 0.61-0.80 denoted substantial, and 0.81-1 was characterized as almost perfect. Statistical significance was defined as 2-sided $P<.05$. All analyses were performed using R statistical software (version 4.1.2; The R Foundation).

Results

Performance of Chatbots

The performance of chatbots is shown in Figure 2 and Tables 1 and 2, with the links to case-level details provided in Multimedia Appendix 4. For the overall rating (Table 1, average row and Figure 2A), Claude-2 with prompt-2 demonstrated significantly higher average accuracy across the 30 cases than Claude-2 with prompt-0 (odds ratio [OR] 8.16; $P<.001$). GPT-4 with prompt-2 also showed improved average accuracy compared with GPT-4 with prompt-0, but the difference was not statistically significant (OR 3.19; $P=.13$). When using the k-pass voting method (Table 1, k-pass voting row), Claude-2 with prompt-2 had significantly higher accuracy than Claude-2 with prompt-0 (OR 8.65; $P=.002$). Similarly, GPT-4 with prompt-2 was significantly more accurate than GPT-4 with prompt-0 (OR 11.98; $P=.01$). For the exact assignment of the patient-level RADS categorization (Table 2, average row and Figure 2B), Claude-2 with Prompt-2 showed significantly more average accuracy than Claude-2 with prompt-0 ($P=.04$).

Consistency of Chatbots

As shown in Table 3, among the 30 cases evaluated in 6 runs, Claude-2 with prompt-2 showed substantial agreement (*k*=0.65 for overall rating; *k*=0.74 for RADS categorization). GPT-4, when interfaced with prompt-2, demonstrated moderate agreement (*k*=0.46 for overall rating; *k*=0.41 for RADS categorization). When evaluated with prompt-1, GPT-4 presented moderate agreement (*k*=0.38 for overall rating; *k*=0.42 for RADS categorization). In contrast, Claude-2 showed substantial agreement (*k*=0.63 for overall rating; *k*=0.61 for RADS categorization), while GPT-3.5 exhibited a range from slight to fair agreement. With prompt-0, Claude-2 showed moderate agreement (*k*=0.49) for overall rating and substantial agreement for RADS categorization (*k*=0.65). GPT4 manifested slight agreement (*k*=0.19) for the overall rating and fair agreement for RADS categorization. Meanwhile, GPT-3.5 showed fair agreement (*k*=0.28) for the overall rating and moderate agreement (*k*=0.57) for RADS categorization.

Table 3. The consistency of different chatbots and prompts among 6 runs.

Subgroup Analysis

Since the knowledge base for ChatGPT was frozen as of September 2021, accounting for the knowledge limitations of LLMs developed before the latest RADS guideline updates, we compared the responses of different RADS criteria. The total accurate responses across 6 runs were computed for all prompts. Both GPT-4 and Claude-2 demonstrated superior performance in the context of LI-RADS CT/MRI version 2018 as opposed

to Lung-RADS version 2022 and O-RADS MRI (all $P<.05$; Table 4). Figure 3 delineates the performance of various chatbots across different prompts and RADS categories. For the overall rating (Figure 3A), Claude-2 exhibited a progressive trend of enhancement of overall rating accuracy from prompt-0 to prompt-1 to prompt-2, with 20.0% (12/60), 36.7% (22/60), and 75.0% (45/60) for LIRADS; 11.7% (7/60), 18.3% (11/60), and 48.3% (29/60) for Lung-RADS; and 10.0% (6/60), 20.0% (12/60), and 41.7% (25/60) for O-RADS, respectively. Notably, with prompt-2, Claude-2 achieved the highest overall rating accuracy of 75% in older systems such as LI-RADS version 2018. Conversely, GPT-4 improved with prompt-1/2 over prompt-0, but prompt-2 did not exceed prompt-1. For the RADS categorization (Figure 3B), prompt-1 and prompt-2 outperformed prompt-0 for LI-RADS, irrespective of chatbots. However, for Lung-RADS and O-RADS, prompt-0 sometimes superseded prompt-1.

Table 4. The performance of chatbots within different RADS criteria[a].

Chatbots and RADS[b]	Year of development	RADS categorization (correct/incorrect/unsure), n/n/n	*P* value	Overall rating (correct/incorrect), n/n	*P* value

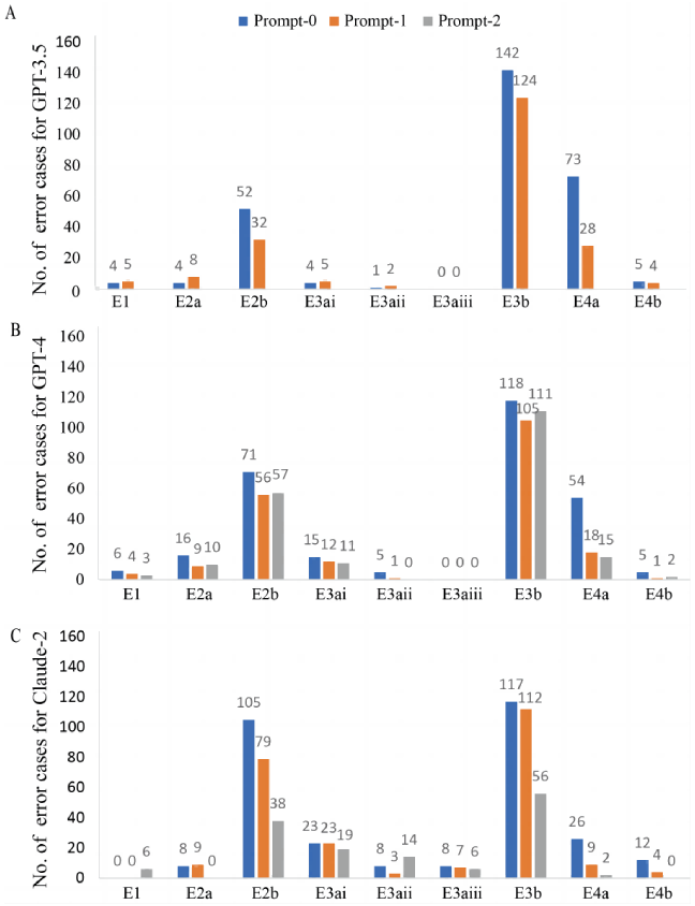
Analysis of Error Types

A total of 1440 cases were analyzed for error types, with details provided in Multimedia Appendix 4. The bar plot illustrating the distribution of errors across the 3 chatbots is shown in Figure 4. A typical example of factual extraction error (E1) occurred in response to the seventh Lung-RADS question. The statement "The 3mm solid nodule in the lateral basal segmental bronchus

is subsegmental" is inaccurate, as the lateral basal segmental bronchus represents one of the 18 defined lung segments and not a subsegment [22].

Figure 4. The number of error types for different chatbots. E1: Factual extraction error denotes the chatbots' inability to paraphrase the radiological findings accurately, consequently misinterpreting the information. E2: Hallucination, encompassing the fabrication of nonexistent Reporting and Data Systems (RADS) categories (E2a) and RADS criteria (E2b). E3: Reasoning error, which includes the incapacity to logically interpret the imaging description (E3a) and the RADS category accurately (E3b). The subtype errors for reasoning imaging description include the inability to reason lesion signal (E3ai), lesion size (E3aii), and enhancement (E3aiii) accurately. E4: Explanatory error, encompassing inaccurate elucidation of RADS category meaning (E4a) and erroneous explanation of the recommended management and follow-up corresponding to the RADS category (E4b).



Hallucination of inappropriate RADS categories (E2a) occurred more frequently with prompt-0 across all 3 chatbots. However, this error rate decreased to zero for Claude-2 when using prompt-2, a trend not seen with GPT-3.5 or GPT-4. A recurrent E2a error in LI-RADS was the obsolete category LR-5V from the 2014 version, now superseded by LR-TIV in subsequent editions [23,24]. Furthermore, hallucination of invalid RADS criteria (E2b) was more prevalent than that of E2a. For instance, the LI-RADS second question response stating "T2 marked hyperintensity is a feature commonly associated with hepatocellular carcinoma (HCC)" is inaccurate, as T2-marked hyperintensity is characteristic of hemangioma and not hepatocellular carcinoma. Despite initial higher E2b rates, Claude-2 demonstrated a substantial reduction with prompt-2 (105 to 38 instances), exceeding the decrement seen with GPT-4 (71 to 57 instances).

Regarding reasoning error, incorrect RADS category reasoning (E3b) was the most frequent error but decreased for all chatbots with prompt-1 and prompt-2 versus prompt-0. Claude-2 reduced errors by almost half with prompt-2, while the GPT-4 decrease was less pronounced. Lesion signal interpretation errors (E3ai) included misinterpreting hypointensity on diffusion-weighted imaging as "restricted diffusion," rather than facilitated diffusion. Lesion size reasoning errors (E3aii) occurred in 34 of 1440 cases, predominantly by Claude-2 (25/34, 73.5%), especially in systems such as Lung-RADS and LI-RADS where size is critical for categorization. Examples were attributing a 12-mm pulmonary nodule to the ≥6-mm but <8-mm range, or assigning a hepatic lesion measuring 2.3 cm × 1.5 cm to the 10- to 19-mm category. Reasoning enhancement errors (E3aiii) were exclusive to Claude-2 in O-RADS, where enhancement significantly impacts categorization. Misclassifying images at 40 seconds postcontrast as early or delayed enhancement exemplifies this error.

Explanatory errors (E4) including incorrect RADS category definitions (E4a) and inappropriate management recommendations (E4b) also substantially declined with prompt-1 and prompt-2. For instance, in the first Lung-RADS question response, the statement "The 4X designation indicates infectious/inflammatory etiology is suspected." is incorrect. Lung-RADS 4X means category 3 or 4 nodules with additional features or imaging findings that increase suspicion of lung cancer [18].

Discussion

Principal Findings

In this study, we evaluated the performance of 3 chatbots—GPT-3.5, GPT-4, and Claude-2—in categorizing radiological findings according to RADS criteria. Using 3 levels of prompts providing increasing structure, examples, and domain knowledge, the chatbots' accuracies and consistencies were quantified across 30 cases. The best performance was achieved by Claude-2 when provided with few-shot prompting and the RADS criteria PDFs. Interestingly, the chatbots tended to categorize better for the relatively older LI-RADS version 2018 criteria in contrast to the more recent Lung-RADS version 2022 and O-RADS guidelines published after the chatbots' training cutoff.

The incorporation of RADS, which standardizes reporting in radiology, has been a significant advancement, although the multiplicity and complexity of these systems impose a steep learning curve for radiologists [13]. Even for subspecialized radiologists at tertiary hospitals, mastering the numerous RADS guidelines poses challenges, requiring familiarity with the lexicons, regular application in daily practice, and ongoing learning to remain current with new versions. While previous studies have shown that LLMs could assist radiologists in various tasks [2-5,7,11], their performance at RADS categorization from imaging findings is untested. We therefore evaluated LLMs for focused RADS categorization of testing cases.

Without prompt engineering (prompt-0), all chatbots performed poorly. However, accuracy improved for all chatbots when provided an exemplar prompt demonstrating the desired response structure (prompt-1). This underscores the use of prompt tuning for aligning LLMs to specific domains such as radiology. Further enriching prompt-1 with the RADS guideline PDFs as a relevant knowledge source (prompt-2) considerably enhanced Claude-2's accuracy, a feat not mirrored by GPT-4. This discrepancy could stem from ChatGPT's reliance on an external plug-in to access documents, while Claude-2's architecture accommodates the direct assimilation of expansive texts, benefiting from its larger-context window and superior long document–processing capabilities.

Notably, we discerned performance disparities across RADS criteria. When queried on older established guidelines such as LI-RADS version 2018 [17], the chatbots demonstrated greater accuracy than more recent schemes such as Lung-RADS version 2022 and O-RADS [18,19,25]. Specifically, GPT-4 and Claude-2 had significantly higher total correct ratings for LI-RADS than for Lung-RADS and O-RADS (all $P<.05$). This could be attributed to their extensive exposure to the voluminous data related to the matured LI-RADS during their pretraining phase. With prompt-2, Claude-2 achieved 75% (45/60) accuracy for overall rating LI-RADS categorization. The poorer performance on newer RADS criteria highlights the need for strategies to continually align LLMs with the most up-to-date knowledge.

A deep dive into the error-type analysis revealed informative trends. Incorrect RADS category reasoning (E3b) constituted the most frequent error across chatbots, decreasing with prompt tuning. Targeted prompting also reduced critical errors such as hallucinations of RADS criteria (E2b) and categories (E2a) likely by constraining output to valid responses. During pretraining, GPT-liked LLMs predict the next word in the unlabeled data set, risking learning fallacious relationships between RADS features. For instance, Lung-RADS version 2022 lacks categories 5 and 6 [18], though some other RADS such as Breast Imaging Reporting and Data System include them [26]. Using prompt-0, chatbots erroneously hallucinated Lung-RADS categories 5 and 6. Explanatory errors (E4) including inaccurate definition of the assigned RADS category (E4a) and inappropriate management recommendations (E4b) also substantially declined with prompt tuning. For instance, when queried on the novel O-RADS criteria with prompt-0, chatbots hallucinated follow-up recommendations from other RADS criteria and responded "O-RADS category 3 refers to an indeterminate adnexal mass and warrants short-interval follow-up." Targeted prompting appears to mitigate these critical errors such as hallucination and incorrect reasoning. Careful prompt engineering is essential to properly shape LLM knowledge for radiology tasks.

Limitations

There are also several limitations in this study. First, only the LI-RADS CT/MRI and O-RADS MRI were included, excluding LI-RADS ultrasound (US) and O-RADS US guidelines, which are often practiced in an independent US department [27,28]. Second, the chatbot's performance was heavily dependent on prompt quality. We test only 3 types of prompts and further prompt strategies studies are warranted to investigate the impact of more exhaustive engineering on chatbots' accuracy. Third, GPT-4-turbo was released on November 6, 2023, representing the latest GPT-4 model with improvements in instruction following, reproducible outputs, and more [29]. Furthermore, its training data extend to April 2023 compared with September 2021 for the base GPT-4 model tested here. We are uncertain about this newest GPT-4-turbo model's performance on the RADS categorization task. Evaluating GPT-4-turbo represents an important direction for future work. Fourth, our study focused on 3 of 9 RADS [13], with a limited 10 cases for each RADS category. Although our choice ensured a blend of old and new guidelines and tried to cover all the RADS scores as much as possible, extending evaluations to all the RADS guidelines and incorporating more radiology reports from real clinical scenarios could offer deeper insights into potential limitations. Nonetheless, this initial study highlights critical considerations of prompt design and knowledge calibration required for safely applying LLMs in radiology. Fifth, evaluating the performance of the LLM in comparison with radiologists of varying expertise levels proves valuable for discerning its strengths and weaknesses in real-world applications. This comparative analysis will be undertaken in our forthcoming studies.

Conclusions

When equipped with structured prompts and guideline PDFs, Claude-2 demonstrates potential in assigning RADS categories

to radiology cases according to established criteria such as LI-RADS version 2018. However, the current generation of chatbots lags in accurately categorizing cases based on more recent RADS criteria. Our study highlights the potential of LLMs in streamlining radiological categorizations while also pinpointing the enhancements necessary for their dependable application in clinical practice for RADS categorization tasks.

Acknowledgments

This study has received funding from the National Natural Science Foundation of China (82371934 and 82001783) and Joint Fund of Henan Province Science and Technology R&D Program (225200810062). Abstract

Background: Artificial intelligence (AI) chatbots have recently gained use in medical practice by health care practitioners. Interestingly, the output of these AI chatbots was found to have varying degrees of hallucination in content and references. Such hallucinations generate doubts about their output and their implementation.

Objective: The aim of our study was to propose a reference hallucination score (RHS) to evaluate the authenticity of AI chatbots' citations.

Methods: Six AI chatbots were challenged with the same 10 medical prompts, requesting 10 references per prompt. The RHS is composed of 6 bibliographic items and the reference's relevance to prompts' keywords. RHS was calculated for each reference, prompt, and type of prompt (basic vs complex). The average RHS was calculated for each AI chatbot and compared across the different types of prompts and AI chatbots.

Results: Bard failed to generate any references. ChatGPT 3.5 and Bing generated the highest RHS (score=11), while Elicit and SciSpace generated the lowest RHS (score=1), and Perplexity generated a middle RHS (score=7). The highest degree of hallucination was observed for reference relevancy to the prompt keywords (308/500, 61.6%), while the lowest was for reference titles (169/500, 33.8%). ChatGPT and Bing had comparable RHS (β coefficient=–0.069; *P*=.32), while Perplexity had significantly lower RHS than ChatGPT (β coefficient=–0.345; *P*<.001). AI chatbots generally had significantly higher RHS when prompted with scenarios or complex format prompts (β coefficient=0.486; *P*<.001).

Conclusions: The variation in RHS underscores the necessity for a robust reference evaluation tool to improve the authenticity of AI chatbots. Further, the variations highlight the importance of verifying their output and citations. Elicit and SciSpace had negligible hallucination, while ChatGPT and Bing had critical hallucination levels. The proposed AI chatbots' RHS could contribute to ongoing efforts to enhance AI's general reliability in medical research.

KEYWORDS

artificial intelligence (AI) chatbots; reference hallucination; bibliographic verification; ChatGPT; Perplexity; SciSpace; Elicit; Bing

Introduction

Artificial intelligence (AI) evolved from the early twentieth century until Turing [1] conceptualized machine learning in the 1950s and introduced the idea of using machines to process information in order to solve problems and make decisions. Since then, scientists and others have pursued the dream of creating machines that mimic human intelligence through cognitive processes such as thinking, data processing, and planning. AI development requires foundational work in spoken language processing and information storage. Achieving these milestones involves numerous obstacles, including significant technical and financial challenges, which delay the maturation of AI [2].

A major hurdle in AI development was natural language processing, which progressed through multiple phases and culminated with the invention of bidirectional encoder representations from transformers, self-attention, and sequence-to-sequence deep learning technologies. These transformers marked a pivotal advancement in AI development, generating fluent and coherent large language models (LLMs), as they enabled the analysis of each word in an input sequence in context to its neighbors on both sides [3].

In 2018, OpenAI unveiled its first Generative Pre-trained Transformer, ChatGPT, enhancing its utility and potential applications in various human activities, including health care and medical research sectors. Initially, ChatGPT stored data in its database without access to continually updated human literature. It later evolved to employ internet access. Subsequently, other AI chatbots specializing in health care and medical research were introduced. The implementation of AI chatbots in health care is optimistically viewed as a means to improve health care systems, medical education, and patient outcomes [4-6]. They are also viewed as potentially valuable tools in medical research and manuscript writing due to their capabilities in organization, data processing, text generation, and summarization [7,8].

Since the public launch of ChatGPT at the end of 2022, the medical literature surrounding AI has expanded tremendously [9]. Most studies have addressed its potential contributions to medical research and health care practices. However, a critical analysis of the literature reveals that a minority of AI chatbot users realized early that these LLMs do not voluntarily cite credible references to authenticate their information [10-12]. Even when ChatGPT and other AI chatbots were challenged to authenticate their outputs with references [13,14], they generated multiple citations with detailed bibliographic data that seemed perfectly authentic, but most were actually fabricated, contained at least one falsified citation data, or were completely erroneous when verified through medical literature resources [13-16].

These fictitious citations raised major concerns about the AI chatbots' algorithms and methodology of natural language processing, especially regarding references, their bibliographic data credibility, and authenticity. Such erroneous outputs were described in the literature as AI hallucinations or fabrications. The mechanism of these fabrications remains unclear, though some AI developers have identified this faulty output and described it as a misalignment between user expectations and AI chatbot capabilities related to machine learning training issues without proposing definite explanation for that phenomenon or a methodology to assess its references' hallucination degree or impact on AI platform output [17]. Another possible explanation for reference hallucinations is an encoding/decoding transformer glitch or the way AI chatbots handle bibliographic data as text amenable to manipulation. Some investigators assessed the AI-generated medical information, including the ability to verify references and its publication date, but did not pay attention specifically to certain identifiers of references that help to verify their authenticity [18].

Investigating the sources of these hallucinations and taking serious steps to fix the contributing factors to this phenomenon is an urgent need in the current stage to implement AI technology in health care practice and medical research with high credibility. The first step is to identify the degree of these hallucinations, especially in relation to references and their bibliographic data across different AI chatbots.

Utilization of AI-generated medical information is becoming a routine tool for physicians and trainees in medical education and even for diagnosis and management. Therefore, the verification of references for this information is extremely important to avoid adopting or utilizing erroneous unverified information and might be disastrous if used in medical management. Therefore, we proposed to construct a reference evaluation tool that can be universally applied to assess AI chatbot–generated references, which would be a helpful tool for assessing the output, its credibility, and its ability to be implemented into practice. This study aims to introduce this tool as Reference Hallucination Score (RHS) and to demonstrate its application in evaluating and comparing the outputs of 6 AI chatbots, stratify their citation output according to the RHS, and assess the variables that are associated with RHS. This initiative is the first to specifically address the gap in evaluating AI referencing hallucinations, thereby offering a unique approach that fills a critical gap in enhancing the reliability of AI-generated references, improving trust in AI outputs within medical research, and guiding the development of more robust and reliable AI models.

Methods

Medical Prompts

We challenged 6 AI chatbots with 10 medical prompts addressing various medical topics. The selected AI chatbots were ChatGPT 3.5, Bard, Perplexity, Bing, Elicit, and SciSpace [19-24]. We chose them because these are the most widely used AI chatbots in the literature and medical research and because of their ease of access by users. Using the focus group technique, we structured 10 medical prompts with the best possible textual format and clarity to be understood by the AI chatbots. Each of the 2 prompts addressed a similar medical topic: the first in a basic format and the second in a complex or scenario-based format. The prompts are provided in Multimedia Appendix 1. The 5 general topics for the medical prompts were glucose control in gestational diabetes, triggering factors in older adults

with asthma, septic shock in infants with severe combined immunodeficiency, arthritis in patients with sickle cell disease, and substance abuse in patients with personality disorders.

All the prompts were formulated according to the following format: (1) begin by searching PubMed for papers related to the topic; (2) review the search results and select 10 relevant and recent papers; (3) ensure that all information is accurate and up-to-date; (4) format the list of papers in a clear and organized manner, using a consistent style for each entry; (5) include any additional information or notes that may be relevant or helpful for readers; and (6) double-check the accuracy and completeness of the list before publishing or submitting it. The same 10 prompts were applied to each of the 6 AI chatbots. Each prompt requested the AI chatbots to compile a list of 10 references. Each prompt listed 7 items for every reference: reference title, journal name, authors, DOI (digital object identifier), publication date, paper web link, and the reference's relevance to the keyword prompts.

RHS Development

Using the Delphi technique, we proposed the RHS. Score development went through a robust and meticulous methodology as follows:

Literature Review

We commenced with an exhaustive review of existing literature to identify unique identifiers for reference scoring. This step was vital for understanding the current landscape and ensuring that our tool addresses the new gap in the field.

Expert Consultation Using the Delphi Technique

Our approach utilized the Delphi technique—a systematic, multistep process involving rounds of anonymous feedback from experts to reach a consensus. We detail the implementation of this technique as follows.

1. Initial survey of senior librarians: We consulted 2 senior librarians to gather insights on the proposed bibliographic identifiers, seeking their expert suggestions for improvements.
2. Expanded survey of the senior physicians: We further extended our consultation to 12 senior physicians and 11 junior physicians, most of whom are academicians, to assess the relevance and importance of the suggested bibliographic identifiers and to collect additional suggestions.
3. Consensus building among authors: The final step involved synthesizing the feedback received and reaching a consensus among the authors, based on the mean results from the surveyed academics, to finalize the bibliographic identifiers for the hallucination score.

The RHS is an AI chatbot scoring system to evaluate paper references generated by the AI chatbot based on the hallucination severity. The RHS is calculated based on the total score according to the presence of hallucination in any of the 7 parameters (Table 1). The parameters are 4 reference items or identifiers given a score of 2 if they encountered any error in the reference title, journal name, authors' names, or DOI, as the authors judged it as a major degree of hallucination. A score of 1 was given to any error in any of the other 3 identifiers, that is, reference publication date, reference web link, or reference relevance to the keyword prompts, as they were judged as minor degrees of hallucination. The maximum RHS is 11, indicating the maximum degree of reference hallucination, and the minimum RHS is 0, denoting no reference hallucination. To achieve the best outcome from the proposed RHS, the prompts submitted to the AI chatbot should include clear instructions to include all 7 referencing items. The authenticity of the citations' items is evaluated by comparing AI chatbot responses to PubMed and Google Scholar responses. If the AI chatbot could not produce any reference to a specific prompt, the AI chatbot was given a score "N" for that prompt and was scored as failing to generate a result.

Table 1. Reference hallucination score (total score=11).

Reference identifier	Item hallucination score
Erroneous date of publication[a]	1
Erroneous web link of the paper[b]	1
Erroneous citation relevance[c]	1
Erroneous title of the paper[d]	2
Erroneous digital object identifier[e]	2
Erroneous authors' names[f]	2
Erroneous name of the journal[g]	2

[a]The publication date is missing or inaccurate.

[b]The link to the paper is missing or directs to a different paper or an error page.

[c]The keyword prompts are not in the title, abstract, or reference keywords.

[d]The title provided by the artificial intelligence platform is misspelled, incomplete, or nonexistent.

[e]Digital object identifier is missing, inaccurate, nonexistent, or directs to a different paper.

[f]Any author's name is missing, misspelled, or nonexistent.

[g]The journal's name is missing, misspelled, did not publish the paper, or does not exist.

Testing AI Chatbots

Our methodology of judging the hallucinations depended on using a systematic verification process based on PubMed and Google Scholar to ensure legitimacy, accuracy, and transparency. Each reference was initially verified using PubMed by searching for its DOI. If the DOI was inconclusive or unavailable, we leveraged a combination of the paper's title, author names, and other vital details to ascertain its existence and accuracy within the PubMed database. In case of failure to reach the reference through PubMed, Google Scholar was the second step for verification using DOI, the paper's title, authors, and other pertinent details to ensure the reference authenticity.

Each reference's total hallucination score was calculated according to the RHS methodology. Then, the mean RHS of the produced references of each prompt was calculated. This was applied to the 6 AI chatbots. The chatbots' RHS items were compared across the studied chatbots according to hallucination, correct results, and failure to generate results. The median RHS of the complex prompts was compared with basic prompts, and finally, the median RHS of each AI chatbot was compared across all the studied chatbots. Linear regression was used to assess the independent association between mean RHS and other predictors, namely, the studied chatbot, prompt type, and prompt iteration.

Statistical Analysis

The mean (SD) values were used to describe continuous variables. The median (IQR) values were used to describe continuous variables with statistical evidence of skewness. The frequencies and percentages were used to describe categorically measured variables. The Kolmogorov-Smirnov statistical test and histograms were used to assess the statistical normality assumption of the metric variables. The categorical Cronbach α test was used to assess the internal consistency for the reliability of the 7 parameters of the RHS. The nonparametric Kruskal-Wallis analysis of variance test was used to compare the RHS item results across the studied chatbots and to compare the median RHS for statistically significant differences. The Mann-Whitney *U* nonparametric test compared the chatbots' median RHS for statistically significant differences between basic and advanced prompts. The multivariable generalized linear models with gamma regression analysis assessed significant differences in the mean RHS by regressing it against the AI chatbot, prompt complexity, and prompt iterations. The association between the mean RHS and tested predictor independent variables was expressed as an exponentiated β coefficient (risk rate) with its associated 95% CI. The SPSS statistical computing software (IBM Corp) was used for the statistical data analysis, and the α significance level was considered at .05.

Ethical Considerations

This paper did not involve research on living creatures; therefore, no institutional review board approval was required.

Results

A total of 10 prompts were entered into each AI chatbot. Half inquired about the basic medical topics, and the other half about clinical scenarios or complex medical topics. Each prompt requested 10 references related to the prompt topic with their reference data according to our research methodology. Bard was the only AI chatbot that failed to produce any response to all the 10 applied medical prompts. Bard's response to our prompts was, "I'm a language model and don't have the capacity to understand and respond." The AI chatbots failed to generate any reference response for 35 (7%) of the 500 references. The highest hallucination/erroneous output was for the reference relevancy to the prompt content (308/500, 61.6%), followed by publication date (237/500, 47.4%), authors' names (228/500, 45.6%), DOI (227/500, 45.4%), and reference web link (187/500, 37.4%). Regarding the reference title and journal name, the AI chatbots' output had hallucination results of 33.8% (169/500) and 37.6% (188/500), respectively.

Figure S1 in Multimedia Appendix 1 shows each AI chatbot's reference results (correct and hallucinating or erroneous results). SciSpace and Elicit had the highest correct reference identifiers' results, with 629 and 597, respectively. ChatGPT had the highest hallucination results at 592. Bing had the highest rate of failure to generate results at 210. The Kruskal-Wallis nonparametric test showed that the AI chatbots differed significantly with respect to their total hallucination results (χ^2_4=205.9; *P*<.001), correct results (χ^2_4=305.0; *P*<.001), and failure to generate results (χ^2_4=104.3; *P*<.001). The Bonferroni-adjusted post hoc pairwise comparison test was used to compare the chatbots. SciSpace and Elicit did not differ significantly with respect to their hallucination or correct results (*P*>.99). Both had significantly fewer hallucinations and higher correct results compared to the other chatbots (*P*<.001). ChatGPT had the highest rate of hallucination results. Bing and ChatGPT had no significant difference in their correct results (*P*>.99). Bing and Perplexity had no significant difference in their hallucination results (*P*>.99) and were significantly superior to ChatGPT. Perplexity was superior to both regarding its correct results (Bing, *P*=.002; ChatGPT, *P*=.004). Bing had the highest rate of failing to generate results compared to the rest (*P*<.001), followed by Perplexity.

Table 2 displays the detailed results of the studied AI chatbots' reference characteristics. The Kruskal-Wallis nonparametric test showed that the AI chatbots differed significantly in their results. SciSpace and Elicit generated the lowest number of hallucination results regarding title, journal name, authors' names, DOI, and reference web links compared to all the other AI chatbots (*P*<.001). However, Elicit and Perplexity showed no significant difference in hallucinating the publication date results, and both hallucinated more than SciSpace.

Table 2. Artificial intelligence chatbot hallucinating/erroneous reference identifiers' results.

Reference identifier	ChatGPT	Perplexity	SciSpace	Elicit	Bing	Chi-square *(df)*	*P* value
Title	82	41	0	0	46	231.4 (4)	<.001
Digit Object Identifier	89	73	8	4	53	261.26 (4)	<.001
Journal name	83	56	0	0	49	249.4 (4)	<.001
Authors' names	89	74	0	0	65	341.1 (4)	<.001
Publication date	88	48	0	40	61	199.9 (4)	<.001
Reference web link	84	49	3	1	50	231.4 (4)	<.001
Reference relevance to topic prompt	77	63	60	58	50	10.77 (4)	.03

Perplexity, Bing, and ChatGPT had no significant difference regarding their hallucination results for DOI, authors' names, reference web links, and reference titles. Perplexity and Bing hallucinated significantly lesser than ChatGPT regarding the journal name. Perplexity hallucinated slightly lesser than ChatGPT regarding reference title. Bing had significantly fewer hallucination results for references' irrelevancy to the prompt medical topic than ChatGPT (*P*=.045). The remaining AI chatbots, including Bing, did not show a significant difference (*P*>.05).

Table 3 shows AI chatbots' RHS with the descriptive analysis of the median (IQR) for each studied AI chatbot. Kruskal-Wallis analysis showed that chatbots differed significantly with respect to their overall measured hallucination scores (χ^2_4=277.7; *P*<.001). ChatGPT and Bing had the highest median RHS but did not differ significantly (*P*>.99). SciSpace and Elicit had the lowest median RHS (*P*<.001) and did not differ significantly (*P*>.99). Perplexity and Bing did not vary significantly with respect to their median total RHS (*P*=.19). On the other hand, Perplexity had a considerably lower median total RHS than ChatGPT (*P*=.003). For the prompt complexity, the median RHS did not differ significantly for each of the studied AI chatbots (*P*>.05).

Table 3. Reference hallucination scores with bivariate analysis of the artificial intelligence chatbots.

Chatbot	Hallucination score, median (IQR)[a]			*z* test statistic *(df)*	*P* value
	Total RHS[a]	Basic prompts RHS	Advanced prompts RHS		
ChatGPT	11 (1)	11 (1)	11 (0.25)	1.25 (100)	.21
Perplexity	7 (5)	7 (8.25)	8 (5)	0.837 (95)	.40
SciSpace	1 (1)	1 (1)	1 (1)	0.942 (100)	.35
Elicit	1 (2)	1 (2)	1 (2)	0.207 (100)	.84
Bing	11 (6)	11 (6)	11 (5)	0.207 (70)	.84

[a]RHS: reference hallucination score.

Table 4 shows the multivariable generalized linear models with γ regression of the mean total hallucination score based on the chatbot, prompt complexity level, and prompt type. ChatGPT and Bing had the highest mean total hallucination scores and did not differ significantly (*P*=.32). SciSpace had the lowest mean total hallucination score compared to ChatGPT (β coefficient=–1.748; *P*<.001). Elicit had the second lowest total mean hallucination score compared to ChatGPT (β coefficient=–1.63; *P*<.001). Perplexity had the third lowest score compared to ChatGPT (β coefficient=–0.345; *P*<.001).

Table 4. Multivariable generalized linear mixed regression analysis of the artificial intelligence chatbots' total hallucination score[a].

	β coefficient (95% CI)	*P* value
Intercept	2.142 (1.997 to 2.288)	<.001
Chatbot vs Bing	–0.069 (–0.206 to 0.067)	.32
Chatbot vs Elicit	–1.630 (–1.769 to –1.492)	<.001
Chatbot vs SciSpace	–1.748 (–1.880 to –1.617)	<.001
Chatbot vs Perplexity	–0.345 (–0.510 to –0.181)	<.001
Prompt complexity vs advanced level	0.486 (0.326 to 0.645)	<.001
Prompt number	0.018 (–0.006 to 0.041)	.10
Interaction effect: prompt number vs prompt complexity	–0.077 (–0.108 to –0.046)	<.001

[a]Dependent outcome variable: reference hallucination score+1; probability distribution = gamma link function with log shape.

The level of prompt complexity also significantly affected the hallucination score when compared across all the AI chatbots. The advanced prompts' mean total hallucination score was significantly higher than the basic prompts' mean total hallucination score (β coefficient=0.486; *P*<.001). The prompt topic did not correlate significantly with the AI chatbots' mean hallucination score (*P*=.14). However, the interaction term between the prompt medical topic and prompt complexity was found to be statistically significant (β coefficient=–0.077; *P*<.001), indicating that some topics, when presented to the chatbots in a complex scenario, resulted in significantly lower mean total hallucinations compared to the basic presentation of the same topic (*P*<.001). The mean hallucination score based on prompt topic and prompt complexity did not significantly interact with any specific AI chatbots studied.

Discussion

Principal Findings

Our findings showed variations in the RHS across different AI chatbots, ranging from almost null for SciSpace and Elicit to a critically high degree of hallucination for ChatGPT [25]. Among the bibliographic items we studied, the publication date (237/500, 47.4%) showed erroneous or hallucinating results, while the reference title (169/500, 33.8%) showed the least hallucinating or erroneous results. Reference relevancy to the prompt topic was the most common source of hallucination, ranging from 50 erroneous results in case of Bing chatbot up to 77 erroneous results in case of ChatGPT. Bard failed to generate any references for all the studied 10 prompts.

The scientific community uses a transparent, reproducible, and accessible archiving system for its large, evolving research data. For example, FAIR (Findability, Accessibility, Interoperability, and Reuse) guidelines ensure that reference data are archived in a findable, accessible, interoperable, and reusable format to facilitate its citation, maintain researchers' credibility, and ensure data integrity and nonrepudiation [26]. Citation is a vital step for information verification and authentication. AI chatbots that have gained recent widespread use still lack a transparent and robust system for verifying citations and their information sources. Additionally, AI chatbots encounter a hallucination/fabrication phenomenon recognized early in their use in health care. Hallucinations have been encountered in various domains, including the content itself and the cited references, including their bibliographic identifiers [12,27-29]. However, it is worth noting that this obstacle is improving gradually, especially by introducing research, dedicated medical chatbots, and upgrading existing ones [16,30].

A possible explanation for AI chatbots' referencing hallucination is the methodology LLMs use to handle citations. LLMs may deal with citations and their bibliographic identifiers as text, making them vulnerable to paraphrasing and other linguistic manipulations and perhaps as a watermark so that the output that is generated by AI could be identified versus that produced by humans to reduce AI misuse [29,31,32]. Buholayka et al [33] reported that ChatGPT is trained to give uninterrupted flow of conversation even at the cost of giving hallucinating results. Another possible mechanism related to AI chatbots' natural language processing methodology involves encoding and decoding defects during prompt processing, generating errors, and fabricating results [34]. Additional factors might include insufficient training data for the LLM [17,35,36], context misinterpretation, lack of external validation, and overreliance on pattern recognition, all of which could contribute to variable degrees of hallucination, depending on the specific LLM and prompt structure.

Ye et al [37] constructed a systematic approach to AI chatbot hallucination by introducing a unique classification of hallucinations across diverse text generation actions, thereby furnishing theoretical insights, identification techniques, and enhancement strategies. Their methodology consists of 3 domains: (1) comprehensive classification for hallucinations manifested in text-generation tasks, (2) theoretical examinations of hallucinations in LLMs and amelioration, and (3) several research trajectories that hold promise for future exploration. Dhuliawala et al [38] suggested another model to potentially reduce hallucination by the chain-of-verification method. Their 4-step process consists of the chatbot drafting its initial response, formulating verification questions to scrutinize the draft, addressing these questions independently to prevent bias, and finally, generating a thoroughly verified response. Further research needs to be performed to see which model and which LLM receives a better hallucination score with time.

Our findings align with those of Hua et al [25] who evaluated hallucinations in AI-generated ophthalmic scientific abstracts

and references. The uniqueness of our pioneering work is the introduction of a novel RHS to assess AI chatbots. RHS is based on 6 important reference items that make each reference unique and easily trackable for citation, in addition to a seventh item related to the relevance of the reference to the topic prompt [26]. The score was constructed based on any reference's most usable and unique items, with differential weights according to their uniqueness and importance in tracking and identifying any reference.

Variations in hallucination degrees among the different bibliographic items highlight the variations among AI chatbots in handling and identifying references. Having a critically high hallucination rate of the cited reference's relevance to the prompted topic stresses the possibility that AI chatbots identify certain keywords in the prompt and try to search for relevant references but, most of the time, fail to identify the correct and relevant keywords, or as described by a recent OpenAI company statement, they do not align properly with user intentions, leading to the citation of relatively irrelevant sources [17]. Further, hallucinating the paper title and DOI is risky in terms of inability to access the reference. Other identifier hallucinations such as journal name or authors may not greatly block the access to the cited reference.

According to our study, ChatGPT 3.5 had the highest total hallucination score, with the most hallucinations in all aspects of bibliographic items. This echoes other observations. Walters and Wilder [16] described many hallucinations in ChatGPT's bibliographic citations. Their study used ChatGPT 3.5 and ChatGPT 4 to generate literature reviews. They analyzed 636 bibliographic citations across 84 papers, finding a significant number of fabricated citations (55% for GPT 3.5, 18% for GPT 4) and errors in the nonfabricated ones (43% for GPT 3.5 and 24% for GPT 4). Despite GPT 4 showing notable enhancement and insights over GPT 3.5, fabricated references persist [39]. Bing's total hallucination score did not differ significantly from that of ChatGPT as they both had critically high scores. SciSpace and Elicit had comparable individual rates of hallucination regarding the different bibliographic items, although SciSpace had the lowest total number of hallucinations, followed by Elicit. When considering the different studied reference items, ChatGPT, Bing, and Perplexity had comparable hallucinating results apart from the journal name, where Bing and Perplexity hallucinated lesser than ChatGPT. Perplexity stood in the middle, as its overall hallucination score was worse than SciSpace and Elicit on one side and better than ChatGPT and Bing on the other. Our observations align with those of others who investigated AI platforms for writing and research objectives, as they found that Elicit and SciSpace are far more dedicated to searching for scientific papers and summarizing references [40]. This observation stresses scholars' urge to vigilantly examine reference accuracy for any LLM-generated citations, especially if they are not dedicated to research purposes [12].

An interesting observation from our study is the failure of some chatbots to generate the prompted citations, as ChatGPT, Bing, and Perplexity had comparable individual hallucination reference results apart from journal names, where Bing and Perplexity hallucinated lesser than ChatGPT. Bing had a significantly higher rate of failure than ChatGPT, even though it performed comparably in all aspects. Such performance by Bing has been observed in another study that prompted ChatGPT, Bard, and Bing for multiple choice question generation, where Bing had a significant rate of generation failure compared to the other two [41].

Prompt structure and complexity had an interesting association with hallucination score, as complex or clinical scenarios triggered significantly more hallucinations across AI chatbots but not for certain ones. This was also observed when challenging ChatGPT versions 3.5 and 4 with orthopedic questions matched with images, as they both performed far better with simple text multiple choice questions than those with images [42]. On the other hand, when prompted in a complex or scenario format, specific medical topics caused lesser hallucination than when prompted in a basic format. This observation might be explained by the transformer's methodology and their differential performance with different text structures.

Bard performance might point to serious glitches in its text recognition or transformer performance in medical research, at least in certain topics or in the ones used in our study. Previous work has shown serious fabrications encountered in Bard similar to ChatGPT [43]. Overall, our observations extend other findings that AI chatbots provided citations with varying degrees of inaccuracy or hallucination, necessitating users to independently verify the information obtained from these language models [43]. As such, hallucinations put the whole AI chatbot data output under significant question, especially in implementing and applying AI aid into clinical practice [44,45].

Our study incorporates a meticulous design by constructing a novel scoring system to assess AI chatbots' hallucination in relation to references and their reference items with differential weights based on their importance. The multifaceted verification approach that we adopted is a robust method to ascertain the authenticity and relevance of the references generated, providing a replicable model for future studies. That score has proven to differentiate the performance of 5 common chatbots skeptically. The invention of a hallucination score will be a vital step toward systematically evaluating and improving the referencing capabilities of AI chatbots and LLMs. It will also triage AI chatbots' hallucinations, which is a critical step in verifying the authenticity of their content.

Study Limitations

Our study has potential limitations. The methodology used to construct the RHS is novel and is liable for future improvements. The RHS included a limited number of bibliographic parameters, which we believed, based on our consensus and expert colleagues of academics, are the most important and unique reference identifiers. However, other researchers might perceive additional variables or identifiers as crucial. The prompt structure that we used was after extensive trials to reach the prompt structure that produces AI-generated references and their identifiers accurately as much as possible. Still, the prompt design is liable for limitation, as LLM output depends hugely on the prompt structure fed to them. Prompt structure might explain partly the failure of Bard Chatbot to generate any

references, as it might need a special design of prompting. However, we do not believe that the prompt strategy was a major limitation, as it succeeded in generating outputs in almost all the other studied AI chatbots. Additionally, the medical prompts utilized might have a limited scientific scope, which may not cover the full spectrum of medical topics and scenarios that LLMs might encounter in real-world applications. Yet, proposed prompts to assess AI chatbots' referencing hallucination require future refinement, especially with the introduction of new AI chatbots and specifically those that are specialized in the medical field.

Regarding the verification process of the references' identifiers, even though we utilized multiple web-based steps utilizing PubMed and Google Scholar, this might still be suboptimal because although we relied heavily on existing databases and search engines, those engines might have their own set of limitations in indexing or recognizing all published literature, and future researchers might propose more universal agreed-on methodology in that regard. We selected only 6 chatbots for assessment; this might not provide a fair and comprehensive understanding of the hallucination problems encountered across the myriad of AI chatbots that are increasingly becoming available and more specialized. The potential biases in selecting AI chatbots and medical prompts, along with the verification process used, might impact the study results by not fully representing the breadth of AI capabilities and challenges. These limitations should be addressed in future research by expanding the number of chatbots studied, diversifying the medical prompts and their structure addressing medical basic knowledge, diagnosis, and management, in order to strengthen the generalizability of the findings. Finally, the verification processes need to be refined. Our proposed RHS needs future sharpening and application to different and future AI chatbots, especially medical ones, to test its generalizability and sensitivity to assess reference hallucination. Adding more bibliographic parameters might enhance its sensitivity. Furthermore, refining the definition of erroneous citations could potentially improve RHS performance and applicability, particularly in relation to the relevance of the references to the prompted topic.

Conclusion

Our novel RHS tool encompasses a methodology for delineating referencing inaccuracies, crucially in medical domains. It has shown variations across the analyzed AI chatbots. We evaluated the performance of 6 common AI chatbots. Elicit and SciSpace had the least hallucination, with almost none, while ChatGPT and Bing had a critical degree of hallucination. This emphasizes the pressing need for enhanced evaluation mechanisms of AI chatbots' output, particularly the cited references, and highlights the need to verify their output and apply it skeptically, all in order to grade AI chatbots' credibility in terms of their contribution in health care and medical research areas. Additionally, our work establishes a foundation for ensuing research aimed at augmenting the reliability of AI chatbots in academic and clinical landscapes. Improving the LLM mechanism of reference recognition and handling is an important necessity and needs maturation and improvement of the algorithms. Training in user prompt strategy is another trajectory to address to achieve the best performance of these chatbots and improve chatbot-user alignment. Future improvement of RHS or developing new versions will improve AI chatbot assessment and categorization and potentially help AI engineers to evaluate their work. The significance of RHS and its potential impact on improving the reliability of AI-generated references cannot be overstated. The key takeaways highlight the broader implications for the use of AI in medical research, emphasizing the necessity for rigorous evaluations to enhance trust and reliability in AI outputs.

Abstract

Background: A wealth of clinically relevant information is only obtainable within unstructured clinical narratives, leading to great interest in clinical natural language processing (NLP). While a multitude of approaches to NLP exist, current algorithm development approaches have limitations that can slow the development process. These limitations are exacerbated when the task is emergent, as is the case currently for NLP extraction of signs and symptoms of COVID-19 and postacute sequelae of SARS-CoV-2 infection (PASC).

Objective: This study aims to highlight the current limitations of existing NLP algorithm development approaches that are exacerbated by NLP tasks surrounding emergent clinical concepts and to illustrate our approach to addressing these issues through the use case of developing an NLP system for the signs and symptoms of COVID-19 and PASC.

Methods: We used 2 preexisting studies on PASC as a baseline to determine a set of concepts that should be extracted by NLP. This concept list was then used in conjunction with the Unified Medical Language System to autonomously generate an expanded lexicon to weakly annotate a training set, which was then reviewed by a human expert to generate a fine-tuned NLP algorithm. The annotations from a fully human-annotated test set were then compared with NLP results from the fine-tuned algorithm. The NLP algorithm was then deployed to 10 additional sites that were also running our NLP infrastructure. Of these 10 sites, 5 were used to conduct a federated evaluation of the NLP algorithm.

Results: An NLP algorithm consisting of 12,234 unique normalized text strings corresponding to 2366 unique concepts was developed to extract COVID-19 or PASC signs and symptoms. An unweighted mean dictionary coverage of 77.8% was found for the 5 sites.

Conclusions: The evolutionary and time-critical nature of the PASC NLP task significantly complicates existing approaches to NLP algorithm development. In this work, we present a hybrid approach using the Open Health Natural Language Processing Toolkit aimed at addressing these needs with a dictionary-based weak labeling step that minimizes the need for additional expert annotation while still preserving the fine-tuning capabilities of expert involvement.

Introduction

The advent of the electronic health record (EHR) and the wealth of longitudinal clinical data contained therein have afforded tremendous opportunities for both clinical research and digital health applications. Fundamental to the feasibility of both of these applications is the availability of clinical information, which, despite the plethora of raw data available in the EHR, can be nontrivial to extract in a computationally accessible format. This is particularly the case for information only accessible within unstructured data, such as clinical narratives, due to the intrinsic nature of human language. The same information can be expressed in many different ways, making the task of algorithmic extraction and standardization for computational semantic interpretation very challenging. Concurrently, however, as much as 80% of clinically relevant information has been found to only be accessible in unstructured form [1]. The need for computationally accessible information extracted from unstructured data has been particularly highlighted with recent research efforts surrounding the ongoing COVID-19 pandemic, particularly with respect to its postacute sequelae (PASC) [2-5]. PASC is defined as ongoing, relapsing, or new symptoms or other health effects occurring after the acute phase of the SARS-CoV-2 infection (ie, present 4 or more weeks after the acute infection). A substantial portion of the information of interest relevant to PASC, for instance, signs and symptoms, is often recorded only within narrative text and is not otherwise found within structured EHR data [6].

One proposed solution to computational extraction of the information within unstructured text is natural language processing (NLP). While a multitude of approaches to clinical NLP currently exist, several existing limitations in these approaches that slow down the development process are magnified by the ongoing and evolving nature of the PASC task. In previous work, we introduced the Open Health Natural Language Processing (OHNLP) Toolkit (OHNLPTK), an NLP framework aiming to provide NLP capabilities at scale in a standards-compliant and consensus-driven manner. In this work, we will highlight current limitations in NLP algorithm development approaches and illustrate our approach to addressing these issues by using PASC as an NLP algorithm development use case for the OHNLPTK.

NLP-Based Clinical Information Extraction

Fundamentally, many of the current applications for clinical NLP lie in information extraction [7]: specifically, the identification of the presence of certain clinical concepts within a clinical narrative, determination of whether it applies to the patient to which the clinical document in question pertains (eg, identification of positive or negative, subject, and other clinically relevant contextual information), and normalization such that named entities sharing the same semantic meaning but with differing lexical forms are mapped to a consistent, codified, computationally accessible definition.

In the following subsections, we will briefly discuss existing approaches to each of these tasks as well as several resources

that can be used to augment each of these tasks as relating to PASC.

Clinical Named Entity Recognition

Identification of clinical concept mentions within unstructured text is a named entity recognition (NER) task. Broadly, approaches to this problem can be subdivided into 3 subcategories: symbolic [8-12], statistical (including deep neural) [13-17], and some hybrid of the 2 [18-21], alluding to the approach used to identify the boundaries of the entities within the text itself. Symbolic approaches are typically either expert-driven, where symbolic rule sets are handcrafted by clinical domain experts, or dictionary-based, where various clinical ontologies are mined for lexical variants for matching purposes. Statistical systems bypass such knowledge engineering efforts by training a machine learning system to label concept mentions given a collection of annotated text documents with concept mentions manually annotated by domain experts.

Each of these approaches has its own benefits. Due to their nature of being handcrafted by domain experts, expert-driven approaches can achieve extremely high performance and can be easily fine-tuned to meet application-specific needs and correct any observed errors. Conversely, expert-driven systems tend to be limited in scope to specific concepts due to their need for expert knowledge engineering, which can be expensive both temporally and financially. While this is sufficient for many applications, such an approach is only suitable if sufficient resources are present for the domain experts and the set of concepts that are needed is known. Dictionary-based symbolic systems aim to address this issue. The solution to the domain expertise problem has been through the use of general clinical ontologies and similar vocabulary resources, such as the National Library of Medicine's Unified Medical Language System (UMLS), either as a basis to construct general dictionaries that cover concepts from a much greater breadth of the clinical domain, although without the manual curation that is afforded to expert-driven systems, or to derive a larger set of lexical variants for a specific set of concepts without the need to engage domain expertise. While these systems tend to not perform as well as expertly curated rule-based systems, generally high performance has been shown to be achievable. For statistical systems, the creation of a high-quality annotated corpus is also an expensive and laborious process. The situation becomes more complicated in cases of multisite collaboration as clinical narratives may contain patient identifier information, making data sharing challenging, and at the same time, the local site may not have the necessary resources for creating annotated corpora. Additionally, they are difficult to fine-tune as there is very little control short of additional annotation and training data manipulation to correct any errors. Models used for statistical approaches include conditional random fields [14,21-23], hidden Markov models [24-26], Bidirectional Encoder Representations from Transformers (BERT) (after finetuning specifically to accomplish the NER task) and BERT-like models (which are particularly prevalent in, but not exclusive to, multilingual use cases) [13,15,27-30], and other neural methods such as recurrent neural networks and convolutional neural networks [17,31-34].

Contextual Feature Detection for Clinical Named Entities

Unlike in the general domain, certain contextual features pose a great impact on the relevance and meaning of extracted concepts in the clinical domain. Of particular note is a concept's assertion (asserted vs possible vs hypothetical), negation, temporality, and whether or not it relates to the patient (as opposed to, eg, a family member), as all of these drastically change the relevance of the concept for downstream applications.

Much like for NER, both symbolic and statistical approaches exist for context detection, with many of the same benefits and drawbacks for each. Among the symbolic systems [35-38], the ConText algorithm proposed by Chapman et al [39] is a symbolic system that is widely adopted among clinical NLP implementations. Various statistical approaches have also been proposed, ranging from traditional statistical machine learning methods such as linear kernel support vector machines [40-42] to deep neural methods [43-45]. There is no clear evidence that statistical approaches outperform the widely adopted ConText algorithm [42].

Concept Normalization Approaches and Available Resources

Identification of named entities and whether they apply to the patient is only part of the problem for clinical information extraction tasks: to be computationally accessible, these named entities must first be mapped to some known coding system such that named entities with differing lexical variations but with the same semantic meaning are grouped in some computationally accessible manner; that is, a computationally accessible thesaurus for the extracted named entities must be constructed.

There are several approaches to this concept normalization (also often referred to as entity linking) problem. One of the side benefits of symbolic NER methods is that they will often have this normalization built in, whether as part of the construction process by domain experts for expert-based systems or due to the nature of their lexical variants being derived from structured ontologies that themselves often act as pseudothesauri, as is the case for the UMLS for dictionary-based systems [10,11,21].

The same is not always true for NER approaches based on statistical methods: while some systems, particularly those trained to extract a specific set of clinical concepts, do incorporate normalization by the very nature of their training approach, other systems trained to perform general named entity recognition do not incorporate such an element. A secondary step must then be taken to perform such a normalization, oftentimes again leveraging ontologies by doing similarity matches against ontology entries [21]. Despite this, it is worthwhile to note that normalization performance is typically inferior to that of symbolic approaches.

Irrespective of the approach, a common theme in clinical NLP is that the extracted named entities are typically mapped to some ontology for later ease of computational access, particularly the UMLS due to its breadth of source vocabularies.

PASC and the Emergent Phenotyping Workflow Problem

It is worthwhile to note that NLP-derived data often serves as supplemental information, in that it is used to supply information that, while needed for a particular use case, cannot be found in structured data. This is especially true for phenotyping and similar cohort identification tasks such as clinical trial recruitment, which often have specific inclusion and exclusion criteria that draw from information elements in both structured and unstructured data.

When the inclusion or exclusion criteria and features of interest pertain to emergent entities of interest, however, as was the case with COVID-19, existing approaches to constructing NLP algorithms break down. Statistical methods for NER require data to train, which may not yet exist in sufficiently large volumes due to the fact that the entities of interest themselves are emergent. Additionally, it is worthwhile to note that in certain circumstances surrounding emergent clinical entities, drastic changes to clinical workflow and, by extension, the contents of the documentation itself can occur, as was the case with COVID-19.

Symbolic methods, however, may not necessarily fare better. Ontology-derived dictionary-based approaches can fail in these circumstances due to the fact that ontologies and similar resources used may not yet be updated to contain these emergent entities (or may not yet have new or updated names to refer to existing entities as the terminology used changes over time), and their slow update frequency (biyearly, in the case of the UMLS) results in them being unsuitable for dealing with emergent needs. Expert-driven systems, on the other hand, fare better due to their relative ease of fine-tuning, but the limitations faced by expert-based NER still apply, rendering a purely expert-driven solution infeasible for many use cases.

It is important to note that these problems do not only occur with the introduction of emergent diseases, as was the case with the COVID-19 and PASC studies; rather, attempts to construct NLP systems to address these use cases magnify existing limitations that typically only slow down the development process.

Irrespective of whether these limitations merely slow down or completely hinder NLP development for a particular use case, such limitations are undesirable given the increasing demand for NLP to fulfill a variety of information needs. It thus becomes evident that an approach capable of prototyping and developing NLP systems in a more rapid manner is needed that can combine the fine-grained control and rapid prototyping ability of expert-driven systems with the general applicability afforded by dictionary systems. It is this need that motivates the work presented here.

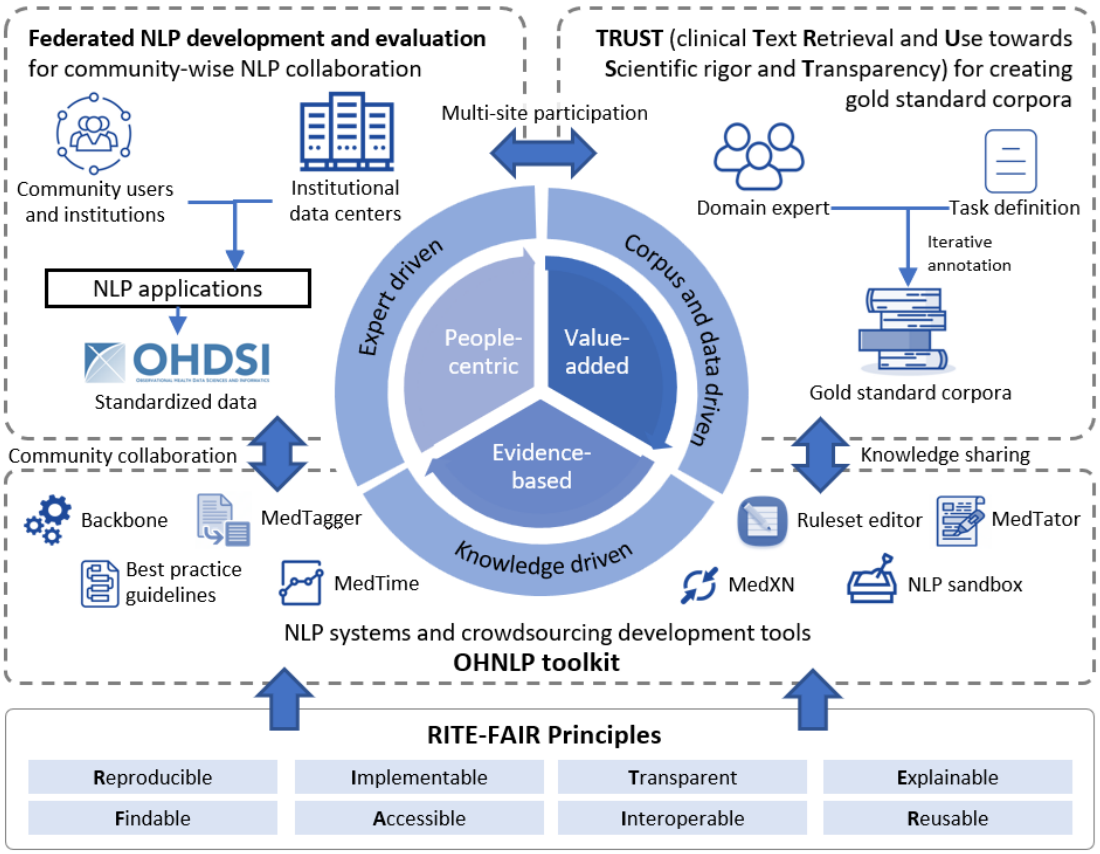
Usage of NLP for PASC-Related Tasks

With regard to NLP usage in the context of PASC, rather than a focus on NLP algorithm development, NLP has primarily been used indirectly for other tasks within the PASC context. For instance, Bhavnani et al [46] extracted 20 signs or symptoms defined by the CDC as being PASC-related from clinical narratives to identify symptom-based phenotypes for patients with PASC, while Zhu et al [47] fine-tuned various BERT-based models to classify documents pertaining to patients with PASC signs or symptoms. More applicable to this work is work primarily focused on identifying what specific NLP-derived signs or symptoms are appropriate for inclusion in a PASC signs or symptoms extraction task. For instance, Wang et al [48] used MTerms [49] to mine existing UMLS concepts from clinical narratives associated with COVID-19 positivity to build a lexicon of 355 long COVID-19 symptoms. We use their developed lexicon as one of the bases for further development in this study.

Clinical NLP to Empower Clinical Research and Translation

We developed the OHNLPTK as part of previous work to enable the rapid development and dissemination of NLP algorithms for empowering clinical research and translation [50]. We follow the RITE-FAIR (reproducible, implementable, transparent, explainable-findable, accessible, interoperable, and reusable) principles [51] to ensure scientific rigor and fairness for resources developed, demonstrated, and disseminated for clinical NLP for health. We have released the OHNLPTK to encourage collaboration across the clinical NLP community to address real-world data problems. The toolkit consists of the following components: (1) a federated NLP deployment framework for privacy-preserving clinical NLP enabled by clinical common data models, (2) a clinical text retrieval and use process toward scientific rigor and transparent (TRUST) process, and (3) an open science collaboration toward real-world clinical NLP (Figure 1).

Figure 1. An overview of the Open Health Natural Language Processing ecosystem. FAIR: findable, accessible, interoperable, and explainable; NLP: natural language processing; OHNLP: Open Health Natural Language Processing; RITE: reproducible, implementable, transparent, and explainable.

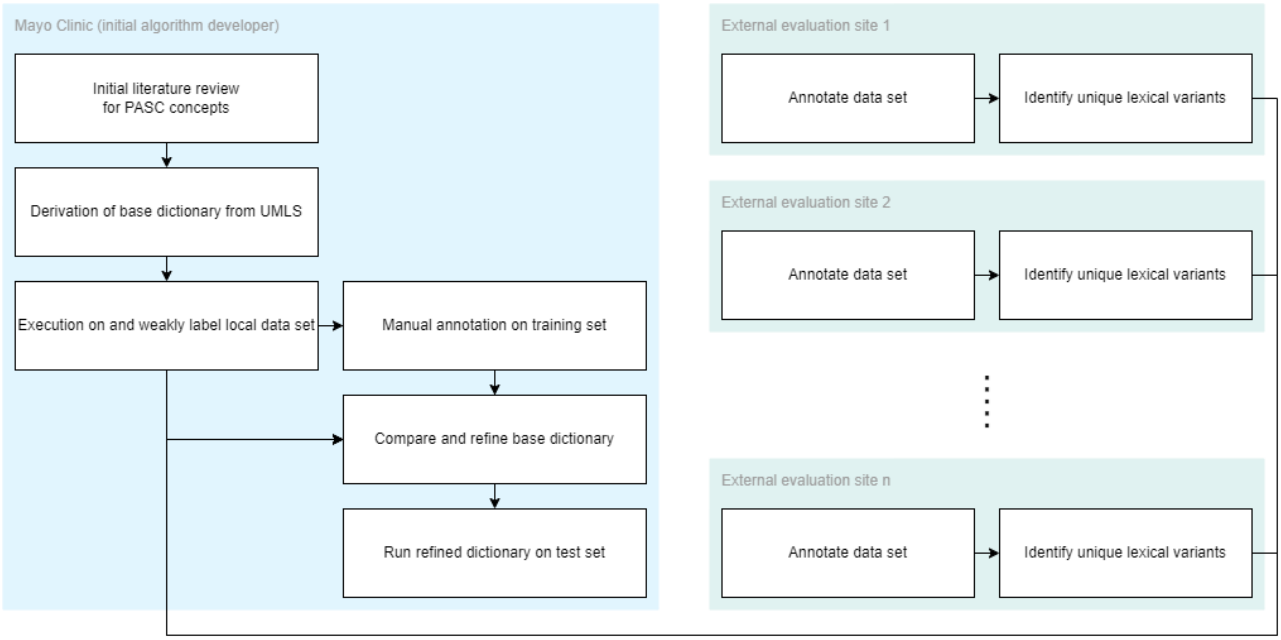


Methods

Overview

In this study, we report on the use of the OHNLPTK to rapidly develop and prototype an NLP system using a case study on PASC signs and symptoms based on PASC resources available in 2 studies. In the ensuing subsections, we will detail each of the steps associated with the creation and evaluation of the final NLP algorithm. For an overview of the entire process, please refer to Figure 2.

Figure 2. An overview of dictionary construction and federated refinement workflows. PASC: postacute sequelae of SARS CoV-2 infection; UMLS: Unified Medical Language System.



PASC Resources

As PASC has been recognized nationally, some useful language resources have been developed. Deer et al [52] identified 303 articles published before April 29, 2021, curated 59 relevant manuscripts that described clinical manifestations in 81 cohorts of individuals 3 weeks or more following acute COVID-19, and mapped 287 unique clinical findings to Human Phenotype Ontology (HPO) terms. Wang et al [48] identified 355 long COVID-19 symptoms corresponding to 1520 UMLS concepts, which in turn resulted in 16,466 synonyms identified from 328,879 clinical notes of 26,117 COVID-19 positive patients from their postacute infection period (days 51-110 from the first positive COVID-19 test).

Dictionary Construction

An initial phenotype definition consisting of textual descriptions, *International Classification of Diseases*, and HPO codes corresponding to clinical entities of interest to PASC was obtained from the aforementioned PASC resources. These entities, where possible, were cross-referenced against the UMLS 2021AB version to obtain an algorithmically derived base dictionary for further refinement. Entities that could not be cross-referenced for enhancement were noted for manual annotation in our second step.

Dictionary Enhancement and Rule Creation

We collected 128 clinical notes from the post–COVID-19 care clinic at Mayo Clinic and split them into a training set (98 notes) and a testing set (30 notes). For the training set, the algorithmically derived base dictionary was run on the document set to generate a weakly labeled data set that was then loaded into the MedTator web annotation tool [53] for manual review and dictionary refinement. Deficiencies (ie, mentions and concepts that were not identified or contained within the algorithmically defined base dictionary) were identified by domain expert review on the training set. Identified missed lexical variants were then manually linked to an appropriate concept ID and added to the base dictionary. Additionally, any concepts missed during base dictionary generation (ie, a clinical concept that was identified as PASC-relevant in the training set but was not part of those concepts identified in the 2 PASC resources used as a baseline) were manually added. To capture complex contextual information, additional rules were created. For example, for "learning difficulty," a rule was created to combine a set of terms meaning difficulty with learning, that is, "(%reDIFFICULTY) to (learn, retain, and gain) new information." The testing set was manually annotated by a single human annotator blindly using the NLP system.

Concept Normalization

Due to the fact that the base dictionary was derived from a structured metathesaurus, the UMLS concept normalizations to UMLS concept unique identifiers (CUIs) were already present. To be compatible with standardization and cross-compatibility, we opted to further map the UMLS CUIs to associated Observational Health Data Sciences and Informatics (OHDSI) Athena concept IDs [54], which are used as part of the OHDSI Observational Medical Outcomes Partnership (OMOP) common data model. This was done algorithmically using text string matching for concept names, followed by manual linking when an exact text match could not be found. For PASC terms that could not be mapped, we manually reviewed and aligned them with the closest Athena concept identifiers, if available, or mapped them to the HPO identifiers. Concept IDs that could not be mapped to either an Athena concept ID or an HPO identifier (due to emergent entities not being yet present in the source vocabularies) were encoded with custom IDs, and these IDs were recorded for later updates once associated ontologies were updated.

Lift Analysis and Local Evaluation

Dictionary coverage was compared before and after refinement to evaluate the effect of our weakly supervised refinement approach, specifically with respect to the number of relevant mentions missed by an ontology-based dictionary-only approach.

Beyond being used in the multisite evaluation phase described later in this study, Mayo Clinic's 30-note testing set was also separately compared against the results from the refined NLP algorithm for in-depth evaluation of NLP and manual annotation mismatches.

Multisite Evaluation

The resulting NLP algorithm was distributed to 5 sites (University of Minnesota, University of Kentucky, University of Michigan, Stony Brook Medicine, and Columbia University) for evaluation to evaluate the federated evaluation component of the OHNLPTK. Each site manually annotated 10 notes for long COVID-19 signs or symptoms using 2 annotators with an independent adjudicator for disagreements. The resulting text annotations (medical concepts that do not contain PHI) were then returned to the Mayo Clinic for dictionary coverage analysis through comparison against the NLP algorithm.

Ethical Considerations

Human subject ethics review and informed consent were handled through the individual institution review boards of participating institutions, which gave final approval for this research on the participating patient cohort. The N3C data transfer to National Center for Advancing Translational Sciences is performed under a Johns Hopkins University Reliance Protocol (IRB00249128) or individual site agreements with the National Institutes of Health. All data transmitted to the coordinating site was either manually deidentified or did not contain PII by definition before transmission. No specific compensation was provided to participants as part of this research.

Results

Dictionary Construction, Lift Analysis, and Local Evaluation

The final dictionary created from previous PASC resources consists of 12,145 unique text strings, mapped to 2343 HPO or OMOP concept identifiers. Within the Mayo Clinic training or development set, the baseline system detected 8090 PASC concept mentions. After manual verification, we identified that 338 PASC concept mentions were missed, rendering the total number of annotated mentions within the training set to be 8428. The final refined dictionary includes 12,234 unique text strings,

mapped to 2366 HPO or OMOP concept identifiers (ie, 23 additional concepts and 89 additional text strings were added). A total of 4 PASC concepts present in the UMLS were captured that could be mapped to neither the OMOP vocabulary nor the HPO (eg, teeth chatter and unrefreshed sleep).

For the local evaluation portion of this study, only the PASC sign and symptom sections of the 30 Mayo Clinic test set notes were compared. In the following report of the results, to facilitate reader understanding, we will use the traditional true positive, false positive, or false negative terminology common to NLP evaluations, despite them not being fully applicable due to varying definitions of what is a true positive depending on what the resulting NLP artifacts are being used for or how PASC-related should be defined for the use case (eg, is it PASC-related if the patient had severe COVID-19 in the past or only if it is explicitly written out as "...consequent to previous COVID-19 infection?"). For more details on this, please refer to the "Discussion" section "On Gaps in the NLP Clinical Information Extraction Subtask." A total of 1560 annotations were produced by the NLP algorithm, while manual annotation produced 1067 annotations. Of these, 1061 (236 unique text strings ignoring capitalization) would be considered true positives in a traditional NLP evaluation, 489 (445 unique text strings ignoring capitalization) false positives, and 6 (4 unique text strings ignoring capitalization) false negatives. It is important, however, to note that due to certain features of this task, a traditional NLP evaluation is not necessarily fully accurate. For instance, among a substantial portion of the "false positives," the NLP algorithm made accurate extraction of a sign or symptom that is PASC-related, but human annotation did not occur as the sign or symptom is preexisting and not resulting due to acute COVID-19 infection. For example, the patient has a previous medical history of some of those signs or symptoms, like a headache or migraine, before COVID-19. Similarly, false negatives may not necessarily be attributed to issues with the NLP algorithm. For instance, of the 4 unique text strings composing the false negatives (sexsomnia, taste or smell changes, burning mouth, and sensitivities to noise and light), one (sexsomnia) was not recorded as a PASC-related concept in either of the source articles from which the NLP concepts to extract were defined, but was suggested to be PASC-related within the textual narrative itself and was therefore annotated as such by the human annotator. The other 3 were either caused by a span mismatch or were lexical variants that were neither in the ontologies used to generate the baseline dictionary nor in the training set for manual expert refinement.

Multisite Evaluation

In Table 1, we present the results from manual annotation after adjudication as well as the dictionary coverage for these annotations.

Table 1. Dictionary coverage statistics.

Results	Site 1	Site 2	Site 3	Site 4	Site 5
Number of annotations, n	126	23	171	118	73
Number in dictionary, n	77	20	138	84	65
Coverage ratio, n/n (%)	77/126 (61.1)	20/23 (87)	138/171 (80.7)	84/118 (71.2)	65/73 (89)

In Table 2, we present an analysis of the annotations not covered by the NLP algorithm. Here, we define a new concept as an annotation that was not included as a concept in the original dictionary or rule set, a new variant as an annotation that is an additional lexical variant of a concept existing in the original dictionary or rule set, and an annotation error as an annotation that falls outside of our task definition: for example, COVID-19 or long COVID-19 is not a sign or symptom of COVID-19 or PASC. For a detailed listing of missed terms, please refer to Multimedia Appendix 1.

Table 2. Statistics of annotations not covered by dictionary.

Results	Site 1	Site 2	Site 3	Site 4	Site 5
Number of annotations not covered by natural language processing, n	49	3	33	34	8
New concept, n/n (%)	23/49 (46.9)	2/3 (66.7)	9/33 (27.3)	4/34 (11.8)	1/8 (12.5)

Discussion

Overview

The COVID-19 pandemic and the associated PASC problem highlighted the importance of having a framework for NLP development that is sufficiently flexible to both provide general concept detection capabilities without requiring extensive domain expertise to craft rule sets or annotate extensive data sets, but also with sufficient flexibility for fine-tuning and addition of concepts that are not present in the base ontologies from which the dictionaries are derived. Additionally, it has highlighted the need for such an NLP development process to be agile in iteration, as the rapidly changing concepts and definitions associated with these emergent concepts are inherently incompatible with the relatively slow process associated with traditional NLP or information extraction (IE) algorithm development (as by the time the algorithm is developed, the definition will have changed). Here, we have presented an approach to NLP algorithm development that

allows us to achieve reasonable results on limited data sets with a rapid turnaround time (the entire process was accomplished over a month) by leveraging federated algorithm development and common infrastructure. The resulting NLP algorithm has been published as part of the open-sourced MedTagger NLP framework [9] and is being executed at 10 academic medical centers as part of their NLP data submissions to the National COVID-19 Cohort Collaborative (N3C) data set [55]. In this section, we will first discuss several gaps in the current NLP development process that were suspected and the degree to which the OHNLPTK was able to address them, and, finally, we will discuss several of this study's limitations and key takeaways.

On Gaps in the NLP Development Process

Our execution of the PASC use case using the OHNLPTK confirmed many of the suspected gaps in the current NLP ecosystem pertaining to emergent diseases.

First, the potential coverage gap of a purely ontology-derived dictionary-based approach to NLP is highlighted: of the 8428 PASC-related concept mentions within our corpus, the baseline ontology-derived dictionary only identified 8090 mentions, missing 338. These 338 mentions span 167 concepts, highlighting the need for secondary expert-based refinement.

Additionally, this case study highlighted the infeasibility of a purely expert-based approach: there were 1018 unique lexical variants covering PASC-related clinical concepts within our training corpus after dictionary-based weak labeling and expert enhancement. Based on this lexicon size, an expert-based approach to implementing an acceptable NLP system would either be prohibitively expensive resource-wise (by horizontally scaling through adding additional experts) or unreasonably time-consuming, to the point of rendering the approach completely infeasible depending on the study's time constraints.

While it is difficult to draw conclusions about the viability of statistical approaches based solely on what was done in this case study, it is worthwhile to note that of the 8428 PASC mentions in our training corpus, the vast majority were weakly labeled through dictionary lookups, while the remainder were manually derived through an expert review. It is very likely that the manual effort required to fully annotate the train data set for a fully supervised approach would have been prohibitively expensive for many studies, given these statistics. Additionally, as these 8428 PASC mentions are split in turn across many concepts, there are very few unique mentions or lexical examples per concept. By extension, there is an insufficient number of examples to support training high-performing models for all concepts, and annotation of further training data would be required. In fact, this data problem is further exacerbated.

It is thus evident that a hybrid approach that integrates each of the three approaches of statistical, symbolic expert-driven, and symbolic dictionary-based would be ideal. Based on the results of the execution of our PASC use case, we believe that we have demonstrated that expert refinement of a rule set on top of a data set already weakly labeled by an ontology-derived dictionary is one such viable hybrid approach.

With our use case demonstration, we also show that the OHNLPTK can be leveraged to execute an NLP development process following this approach. An initial dictionary derived from the UMLS can be directly loaded into deployed instances of the OHNLPTK without any additional software modification. Weakly labeled NLP output can be directly piped to OHNLPTK's MedTator component for expert review, and additional finetuning is autonomously translated into refinement rules that can, in turn, be executed on top of the base dictionary.

On Gaps in the NLP Clinical Information Extraction Subtask

In this case study, we have strictly focused on clinical information extraction, which has thus far been the core focus for a significant portion of clinical NLP applications. It is important, however, to note that even with a clinical information extraction algorithm, the output may not be wholly applicable and/or useful to the use case. There were multiple instances where our NLP system correctly extracted mentions of some PASC-related terms that were marked as false negatives upon comparison against the gold standard.

Upon further investigation, we discovered that the NLP system correctly identified mentions of the entities in question, but they were not annotated by the annotator as they were not specific to PASC. For instance, while headaches are a valid symptom that is associated with PASC, they may also occur independently due to unrelated reasons. While human annotators have the capability to make this distinction, our NLP system cannot currently make such a distinction and simply naively extracts all valid mentions. Strictly speaking, from the perspective of the NLP-based named entity recognition and linkage subtask (ie, "identify mentions of headaches, and annotate them as such"), the algorithm output is correct. Conversely, however, for real-world use cases such as the PASC investigation use case presented here, not making such a distinction has a significant impact on the practical usability of the NLP artifacts produced. While such contextual differentiation would fall under a different subtask and is not strictly information extraction, the ability to perform this differentiation is crucial for many use cases and is an existing gap in current clinical NLP offerings. We aim to further explore approaches to this differentiation task as part of our future work.

On Federated Evaluation and Associated Benefits

Before federated evaluation can be done, a common working definition or annotation guideline must be defined. The addition of other data and sites, however, also introduces its own complexity, specifically with respect to the aforementioned issue of how to define a concept mentioned as being "PASC-related," on which sites had a very broad spectrum of definitions. We concluded as a group that differentiating whether a mention of, for example, a headache is PASC-related ought to be considered a separate task from the clinical information extraction task and that such filtering, if needed, would be done as a separate, post-IE step.

We opted to evaluate the dictionary-based NLP system using dictionary coverage as opposed to a more traditional precision, recall, and F_1-score. This was done because we wished to

evaluate the ability of a generic NLP algorithm to meet the needs of multiple institutions in a cost-effective manner. Due to the recency and evolutionary nature of long COVID-19, it follows that each site's definition (or at least those of the participating annotators) of "PASC or long COVID-19" may differ, thus rendering it difficult to construct a gold standard with a consistent set of concepts. Instead, by allowing individual sites to determine what constitutes a long COVID-19 for their needs, we can evaluate the coverage—that is, to what extent said need is met by the NLP algorithm.

While the initial Mayo-developed NLP system performs reasonably well across the participating sites that returned evaluation results, not all information needs are met in terms of dictionary coverage. We note that site 1 only had 61.1% (77/126) dictionary coverage; of those annotations not covered, 46.9% (23/49) were new concepts. Manual review indicated some of these new concepts were lung-related (pneumothorax, hydropneumothorax, and ground glass attenuation), which suggests site 1's PASC-related symptoms are slightly different than other sites. A total of 9 of these new concepts (9/23, 39.1%) were the result of a very detailed note (32,000 characters in length) of a complex PASC case where other poor-health and pain-related concepts (gallstones and cholelithiasis) were intermixed with chest pain, lung pain, and difficulty breathing. For all sites, more than a third of the missing annotations were categorized as missing lexical variations of included concepts that did not appear within either the autonomously generated ontology-sourced dictionary or the Mayo documentation set used for dictionary refinement.

Such results illustrate the importance of multisite NLP development, particularly in the latter case, which is one of the pitfalls that would be commonly found in traditional NLP tasks. Our results therefore fundamentally demonstrate the advantage of the high degree of portability resulting from a common NLP infrastructure when discussing generalizable NLP solutions. As gaps in data coverage are assessed across a variety of health care institutions, NLP algorithm refinement is vastly simplified, thus granting greater confidence in the wide-range generalizability of the final solution. Similarly, the addition of these additional sites with their own respective annotators also helps mitigate potential bias associated with single-site or single-annotator definitions of the PASC sign or symptom extraction task.

Beyond the issue of what clinical concepts to include is another issue less addressed in this study: a definition of what sorts of data to include. This is a challenge exacerbated by the fact that, much like how emergent diseases will constantly have an evolving associated concept set, the way they are documented (and their extent) is also constantly changing and subject to high levels of disagreement. This phenomenon can be seen in the wildly different annotated concept counts within the evaluation sites despite sharing the same concept set to annotate: certain sites only considered a specific section of a clinical note explicitly dedicated to documented PASC complications to be appropriate as input data, while others used the entire clinical note for any patient that had visited their long COVID-19 clinic. This wide variance in data inclusion definition further supports the need for federated development and evaluation efforts as outlined in this study to further expose the developed algorithm to this wide variety of data types. Furthermore, the fact that the condition is emergent inherently limits data set sizes; at the time this study was conducted, long COVID-19 clinics were still a relatively novel concept in their initial stages of implementation. A key benefit of such a federated evaluation and iterative refinement process would be to help mitigate the limited amount of data available inherently associated with an emergent condition by spreading out the data set to multiple sources and making it available for the development of a wider variety of documentation types.

Limitations

Several limitations exist in this study. First, we compared dictionary coverage as an evaluation, rather than doing a traditional NLP system evaluation. This is primarily due to the lack of a fully annotated gold standard to evaluate against, driven primarily by the ongoing evolutionary nature of the pandemic, causing associated documentation to continuously change. This renders a truly scientifically rigorous gold standard difficult to construct, as annotation guidelines must be constantly updated and there will be very little consensus due to a lack of clear clinical guidelines. Instead, we note that this limitation highlights the need for iterative development, which further emphasizes the need for an agile NLP development, evaluation, and refinement process such as the one we present here.

Additionally, one of the emphases of the OHNLP consortium is the organization of multi-institutional, federated evaluation for NLP algorithm development, enabled by a common NLP system deployment (the OHNLPTK). As such, we are currently in the process of disseminating the algorithm presented here to multiple member sites, who will all conduct a formal evaluation of this algorithm.

Finally, it was previously noted that in order to codify and normalize concepts that do not yet exist in controlled ontologies, we introduced our own coding scheme for several concepts. It is important for standardization's sake, however, to loop back to the original ontologies used and have these concepts incorporated into these source ontologies. This process is ongoing as of the writing of this article.

Conclusion

The PASC NLP problem has highlighted many of the limitations present with current NLP development approaches. The evolutionary and time-critical nature of the PASC NLP task exacerbates many of these limitations, which previously only presented a slowdown of the development process, into limitations that cause many approaches to be outright infeasible. The need for agile and iterative NLP development is thus made evident. Fundamentally, this can be observed as an amalgamation of wanting the benefits of expert-driven systems while minimizing the time and resource expenditure of expert involvement. Here we have presented a hybrid approach that we believe presents such benefits, with a dictionary-based weak labeling step minimizing the need for additional expert annotation while still preserving the fine-tuning capabilities of expert involvement.

Acknowledgments

The research reported in this publication was supported by the National Center for Advancing Translational Sciences (NCATS) of the National Institutes of Health (U01TR002062: AW, LW, HH, SF, SL, HL, KN, and NPP; UL1TR002240: DAH; UL1TR001998: DRH and RK; UL1TR002489: PJL, PIK, and ERP; UL1TR003015: MZ; and UL1TR003098: CGC). This effort was also supported through the National COVID-19 Cohort Collaborative (N3C) and is part of the NIH (National Institutes of Health) Researching COVID to Enhance Recovery (RECOVER) initiative, which seeks to understand, treat, and prevent the postacute sequelae of SARS-CoV-2 infection (PASC). For more information on N3C, refer to [56]. For more information on RECOVER, refer to [57]. N3C efforts were possible because of the patients whose information is included within the data from participating organizations [58] and the organizations and scientists [59] who have contributed to the ongoing development of this community resource [60]. Similarly, we would like to thank the National Community Engagement Group (NCEG), all patients, caregivers, and community representatives, and all the participants enrolled in the RECOVER Initiative. In particular, we gratefully acknowledge Teresa Akintonwa for serving as a patient representative for this manuscript. N3C and RECOVER efforts were funded by the NIH under NCATS (U24TR002306) and the National Heart, Lung, and Blood Institute (OT2HL161847: RZ, KN, NPP, JH, SR, VL, RAM, MS, CE, FMK, MAH, CGC, AEW, and RAM). Portions of the data generated from analyses described in this publication are made accessible through the NCATS N3C data enclave at [61] under the N3C attribution and publication policy (v1.2-2020-08-25b). Provisioning of such data is supported by NCATS (U24TR002306). The N3C data transfer to NCATS is performed under a Johns Hopkins University Reliance Protocol (IRB00249128) or individual site agreements with NIH. The N3C data enclave is managed under the authority of the NIH; information can be found at [62].

Authors' Contributions

Authorship has been determined according to the International Committee of Medical Journal Editors (ICMJE) recommendations. AW, LW, HH, SF, SL, and HL were responsible for study design, initial pipeline or natural language processing (NLP) algorithm development, initial single-site evaluation, extramural (non-Mayo site) Open Health Natural Language Processing Toolkit or NLP algorithm deployment support, and project coordination among extramural sites. DAH, DRH, RK, RZ, KN, NPP, JH, SR, VL, RAM, MS, CE, FMK, MBP, JD, LL, GSDH, RTM, AEW, PJL, PIK, ERP, MZ, RDP, NG, MAH, and CGC were responsible for NLP algorithm deployment, pipeline execution, feedback for iterative pipeline or implementation development, and experimental procedures. DAH, DRH, RK, RZ, KN, NPP, JH, SR, VL, RAM, MS, CE, and FMK were responsible for federated evaluation efforts. All authors reviewed and contributed expertise to the manuscript.

Conflicts of Interest

MBP, JD, LL, and GS-DH are affiliated with TriNetX LLC. All other authors have no conflicts of interest to declare.

Abstract

Background: Natural language processing (NLP) techniques can be used to analyze large amounts of electronic health record texts, which encompasses various types of patient information such as quality of life, effectiveness of treatments, and adverse drug event (ADE) signals. As different aspects of a patient's status are stored in different types of documents, we propose an NLP system capable of processing 6 types of documents: physician progress notes, discharge summaries, radiology reports, radioisotope reports, nursing records, and pharmacist progress notes.

Objective: This study aimed to investigate the system's performance in detecting ADEs by evaluating the results from multitype texts. The main objective is to detect adverse events accurately using an NLP system.

Methods: We used data written in Japanese from 2289 patients with breast cancer, including medication data, physician progress notes, discharge summaries, radiology reports, radioisotope reports, nursing records, and pharmacist progress notes. Our system performs 3 processes: named entity recognition, normalization of symptoms, and aggregation of multiple types of documents from multiple patients. Among all patients with breast cancer, 103 and 112 with peripheral neuropathy (PN) received paclitaxel or docetaxel, respectively. We evaluate the utility of using multiple types of documents by correlation coefficient and regression analysis to compare their performance with each single type of document. All evaluations of detection rates with our system are performed 30 days after drug administration.

Results: Our system underestimates by 13.3 percentage points (74.0%−60.7%), as the incidence of paclitaxel-induced PN was 60.7%, compared with 74.0% in the previous research based on manual extraction. The Pearson correlation coefficient between the manual extraction and system results was 0.87 Although the pharmacist progress notes had the highest detection rate among each type of document, the rate did not match the performance using all documents. The estimated median duration of PN with paclitaxel was 92 days, whereas the previously reported median duration of PN with paclitaxel was 727 days. The number of events detected in each document was highest in the physician's progress notes, followed by the pharmacist's and nursing records.

Conclusions: Considering the inherent cost that requires constant monitoring of the patient's condition, such as the treatment of PN, our system has a significant advantage in that it can immediately estimate the treatment duration without fine-tuning a new NLP model. Leveraging multitype documents is better than using single-type documents to improve detection performance. Although the onset time estimation was relatively accurate, the duration might have been influenced by the length of the data follow-up period. The results suggest that our method using various types of data can detect more ADEs from clinical documents.

Introduction

Processing large amounts of data using artificial intelligence can help to rapidly obtain a comprehensive understanding of the patient status, which can potentially streamline medical studies focusing on patient stratification, drug safety, and adverse drug event (ADE) detection. Particularly, information on ADEs must be collected prospectively, which is expensive and time-consuming. Even when data are collected retrospectively from electronic health records containing information on various modalities, it is challenging to comprehensively survey the medical details of a large number of patients.

Fortunately, natural language processing (NLP) methods can be used to aid such tasks. Recent advances in NLP have enabled the automatic extraction of contextual information from text. Bidirectional Encoder Representations from Transformers (BERT), a transformer-based model released in 2019, has achieved high accuracy in many NLP tasks [1]. Particularly, using diverse medical records for training machine learning models on multiple aspects of patient information can improve their prediction accuracy in the medical domain, leading to the development of specialized models such as ClinicalBERT and BioBERT [2-5].

The ADE detection systems that use such models have been applied to actual texts in existing research [6-10]. Several studies have also used NLP in retrospective observational studies, similar to the approach used in this study [11,12]. McKenzie et al [11] conducted a retrospective analysis of pneumonia using electronic health records; however, they used rule-based NLP methods for 2 types of documents, clinical notes and radiology reports written by physicians, thus leaving room for further investigation into performance.

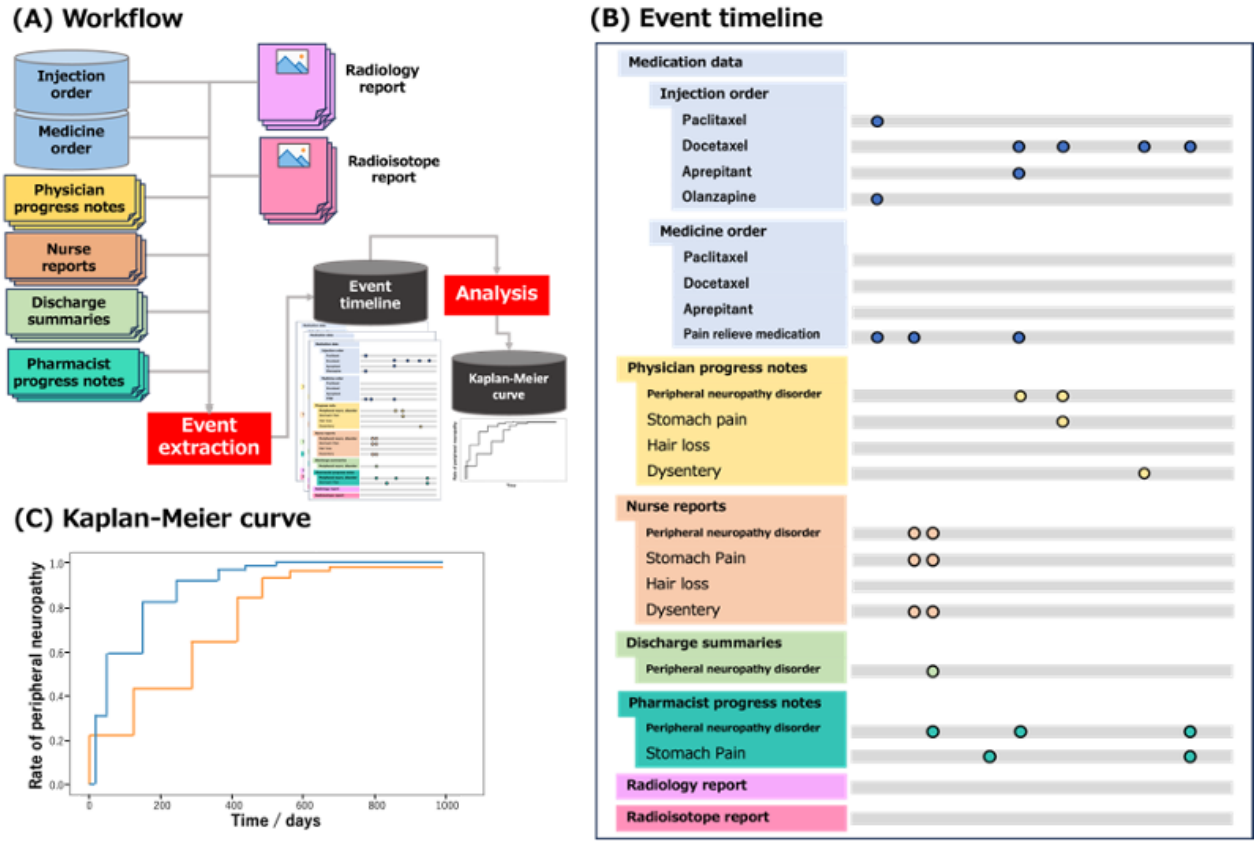
In addition to physicians' records, medical institutions have a wide variety of documents from multiple co-medical personnel, including nursing records, pharmacists' progress notes, and medication orders. Using multiple types of medical documents on retrospective studies requires a comprehensive and robust data analysis because of the expected decrease in missing event detection. While such an analysis is difficult when performed manually due to time requirements and human resource constraints, an NLP-based approach should be more efficient and effective.

A common method for information extraction using NLP is to treat it as a text classification task specific to each document type. However, document-specific text fine-tuning requires that each model be fine-tuned individually for each specific document type, which does not fully demonstrate the strength of automated processing. Fine-tuning a model requires labeled data, and since such data are unlikely to be available beforehand, it requires manual annotation by health care professionals. Even if annotated data are available, privacy concerns and data security restrictions imposed by medical institutions usually make access to them rather difficult. Furthermore, as the transmission of such data over the internet is usually not allowed, the usage of the cloud computational power becomes unfeasible.

For such reasons, fine-tuning models for each individual document type becomes impractical. Therefore, in this study, we used a named entity recognition (NER) model for medical documents, which does not require fine-tuning for each document type. The NER model can be easily used for information extraction without fine-tuning with the target documents since it is already fine-tuned with medical documents to detect symptoms.

In this study, we examined the usefulness of analyzing various medical Japanese documents, including medical records written by physicians and co-medical professionals, to capture the onset and duration of ADEs. Figure 1 shows the basic idea of our approach. Our medical NLP method aims to comprehensively analyze ADE-relevant information contained in medical documents, including nursing records, pharmacist progress notes, and other medical texts, in addition to physicians' records. Our method identified more ADEs from various document types compared to a single type, resulting in a performance similar to that of the typical manual analysis.

Figure 1. Data flow of the proposed system. (A) shows the events from multiple types of documents are extracted. An event timeline (B) is created from each clinical data using the natural language processing method, and then the curve (C) is created based on the aggregated results. The dots in the event timeline indicate the timing at which the description of drug administration or symptom onset is recorded. Based on (B), patients who received the target drug (a taxane drug in this study) are selected, and the Kaplan-Meier curve (C) is generated.



Methods

Overview

Our study uses a retrospective observational approach based on NLP, which enables the handling of a large amount of data. The NLP techniques used were NER and normalization, which extract symptoms from documents and transform them into their standardized forms. We evaluated our method by obtaining the Kaplan-Meier curves based on symptoms that were normalized to peripheral neuropathy (PN). In addition, we also evaluated the duration of PN.

Materials

This study used data from all patients diagnosed with breast cancer (N=2289) treated at the Kyoto University Hospital between 2019 and 2021. The patient data consisted of 2 types of medication orders (structured data) and 6 types of texts written in Japanese (unstructured data). We apply NLP methods to extract information from such unstructured data. Unstructured data require an NLP method to extract information, such as ADEs. Table 1 lists the number of all breast cancer patient orders and text data records included in each document.

Table 1. Amount of order data and text data. The unit of record is per drug for order data and per timing recorded by physicians or co-medicals for text data.

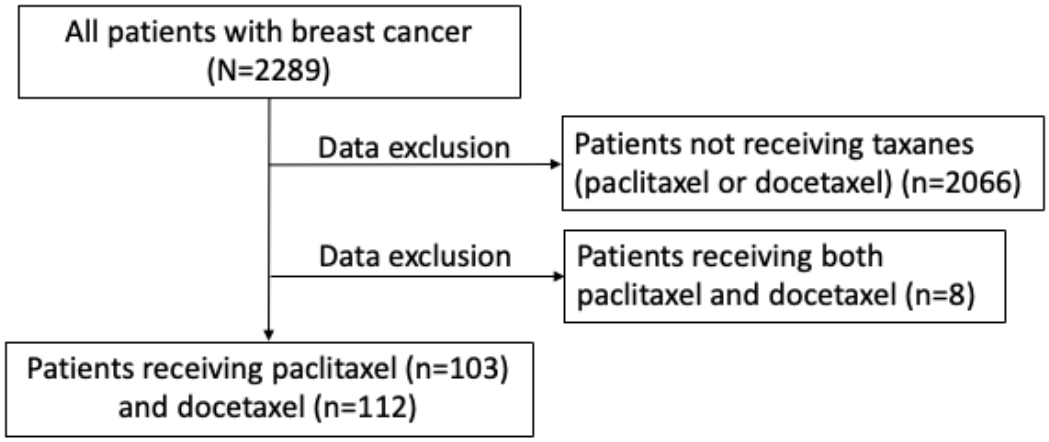
Data type	Records, n
Order data	
Injection order	44,896
Medicine order	63,077
Text data	
Physician progress notes	159,736
Nursing records	40,385
Discharge summaries	23,073
Radiology reports	5663
Radioisotope reports	1147
Pharmacist progress notes	29,148

Inclusion and Exclusion Criteria

The aim of this study was to leverage the strengths of NLP to automatically analyze a large number of documents and evaluate the usefulness of the proposed method. We selected PN as our disease for evaluation, as it satisfies the following conditions: (1) side effects are long-lasting, which means that monitoring many documents is required, and (2) information on the onset of the symptom is not normally included in structural databases.

We selected taxane drugs, such as paclitaxel and docetaxel for the evaluation, as they frequently cause PN. As shown in Figure 2, patients receiving either type of taxane drugs were included in the analysis, whereas those receiving both paclitaxel and docetaxel were excluded. Patients selected according to these criteria were then analyzed for the development of PN as an outcome.

Figure 2. Flowchart describing the procedure for selecting patient data according to criteria.

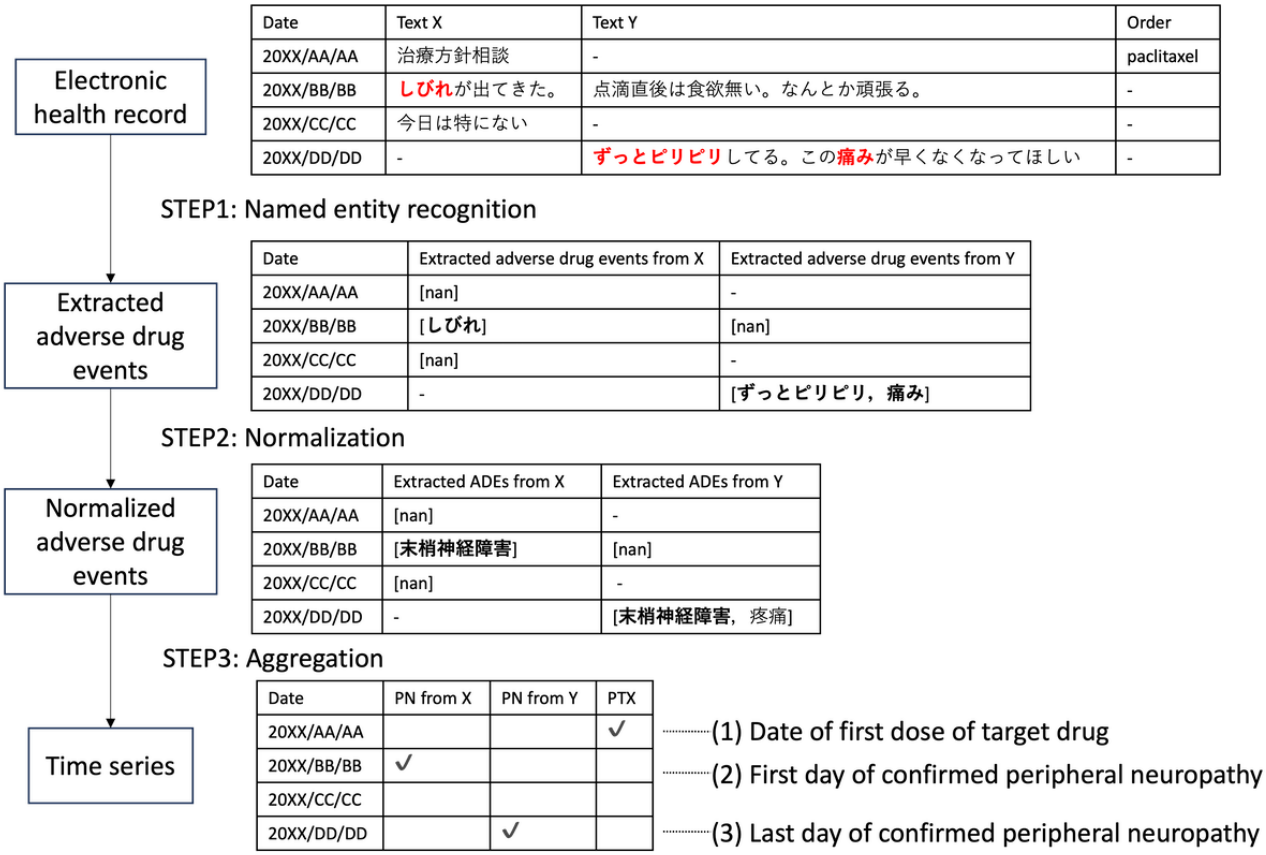


Patients who received both drugs were excluded to prevent them from introducing noise in the analysis of PN onset and duration. Administering a different taxane drug during monitoring sessions, which had not been given previously, could have adversely affected the study results.

Comparison With the Kaplan-Meier Curves

Using information extracted from multitype texts by applying our NLP method, we measured the number of days until the onset of PN after the administration of taxane drugs. As shown in Figure 3, our system is composed of 3 steps: entity recognition, normalization, and aggregation. We compared these results with those reported manually in a previous report [13].

Figure 3. Workflow of our natural language processing system, which is composed of named entity recognition, normalization, and aggregation. Text X and Text Y are examples of 2 types of documents respectively, for example, physician progress notes and pharmacist progress notes.



Named Entity Recognition

The data required for this study, which included the dates on which the symptoms occurred (obtained from text data) and drugs that were administered (obtained from medication orders), were obtained as follows: to obtain symptom data, we applied NER, an NLP method that recognizes and extracts mentions of named entities in text. We used this method to identify symptoms related to PN. We adopted MedNER-CR-JA, which is a BERT-based NER model trained using Japanese case reports [14]. Since BERT can only process a maximum of 512 tokens at a time, sentences were separated by line breaks. Only the symptoms with positive factuality, as extracted by the model, were used in the analysis.

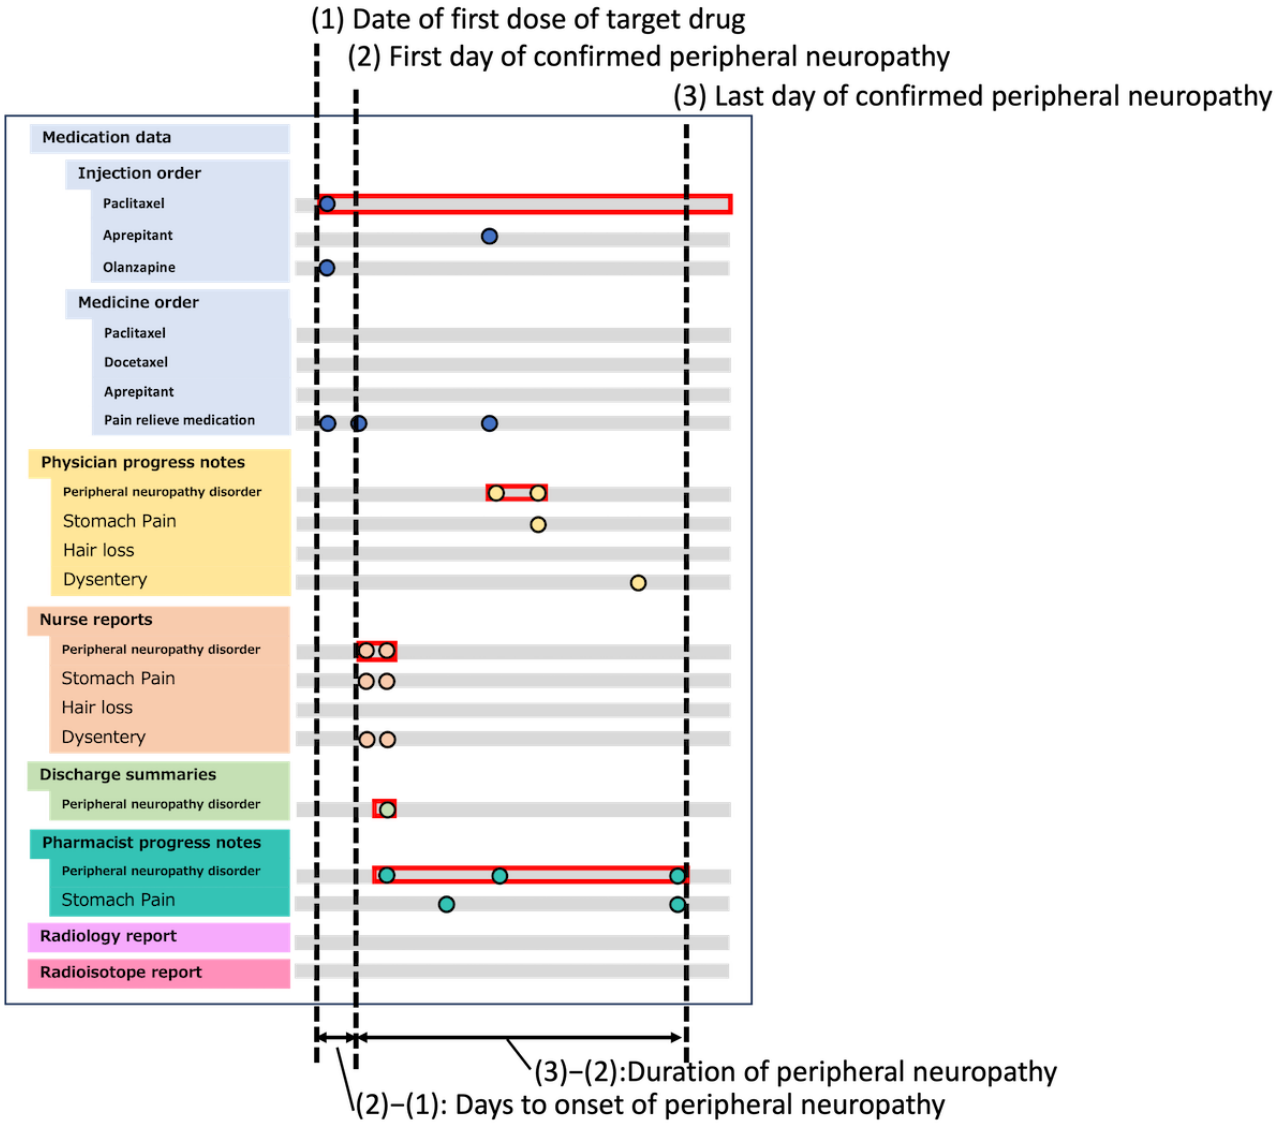
Normalization

The extracted entities are normalized by Levenshtein distance matching using a disease name dictionary (MedDic-CANCER-ADE-JA) [15]. This dictionary contains surface forms and normalized forms with respect to the side effects of anticancer drugs. We select the dictionary surface form that has the lowest Levenshtein distance in relation to the extracted term and then convert it to the related normalized form [16]. The code for this step including NER can be accessed through GitHub [17].

Aggregation

We focused on the expression normalized to PN and conducted the analysis among the converted terms. Specifically, the onset date of PN was defined as the first date on which the expression was normalized to PN in any type of document. The cumulative percentage of patients who developed PN was calculated along the time series. As shown in Figure 4, the onset date was the number of days since the first dose of paclitaxel or docetaxel. We defined the period of residual PN as the period up to the date on which the expression normalized to PN was last identified. The onset date and residual duration for each patient were summed to obtain a Kaplan-Meier plot of onset timing or residual duration, respectively. The onset date and residual duration of each patient were aggregated to obtain a Kaplan-Meier plot of onset timing or residual duration, respectively.

Figure 4. Event timeline from multiple types of data and calculation of the number of days of peripheral neuropathy onset and duration.



We propose that this definition would be more robust if the system analyzed various types of documents reviewed by multiple medical personnel. Increasing the diversity of documents analyzed reduces the risk of overlooking symptoms.

Evaluation

The cumulative percentage of the patients' PN is displayed using the event date on which PN was first identified.

We compared the results produced by our NLP system (Paclitaxel_NLP) with previous results obtained by manual extraction (Paclitaxel_MAN) based on the percentage of PN at 30 days. The detection rate was evaluated by subtracting the percentage of detections achieved by our system from the percentage of detections obtained through manual extraction [13]. We focused on the incidence of PN at 30 days since most patients generally develop the disease after 30 days [13].

In addition, the Pearson correlation coefficient was calculated for the 2 types of paclitaxel results from our system and manual results up to 101 days, the maximum duration in the previous report.

In addition, multiple regression analysis was performed to analyze the results calculated using all records and the results from each record to evaluate which explanatory variables had a greater impact.

Ethical Considerations

This study, which was evaluated and approved by the ethics committee of Kyoto University Graduate School and Faculty of Medicine, Japan (R3723-2), was performed in compliance with the Declaration of Helsinki.

Results

Preliminary Result

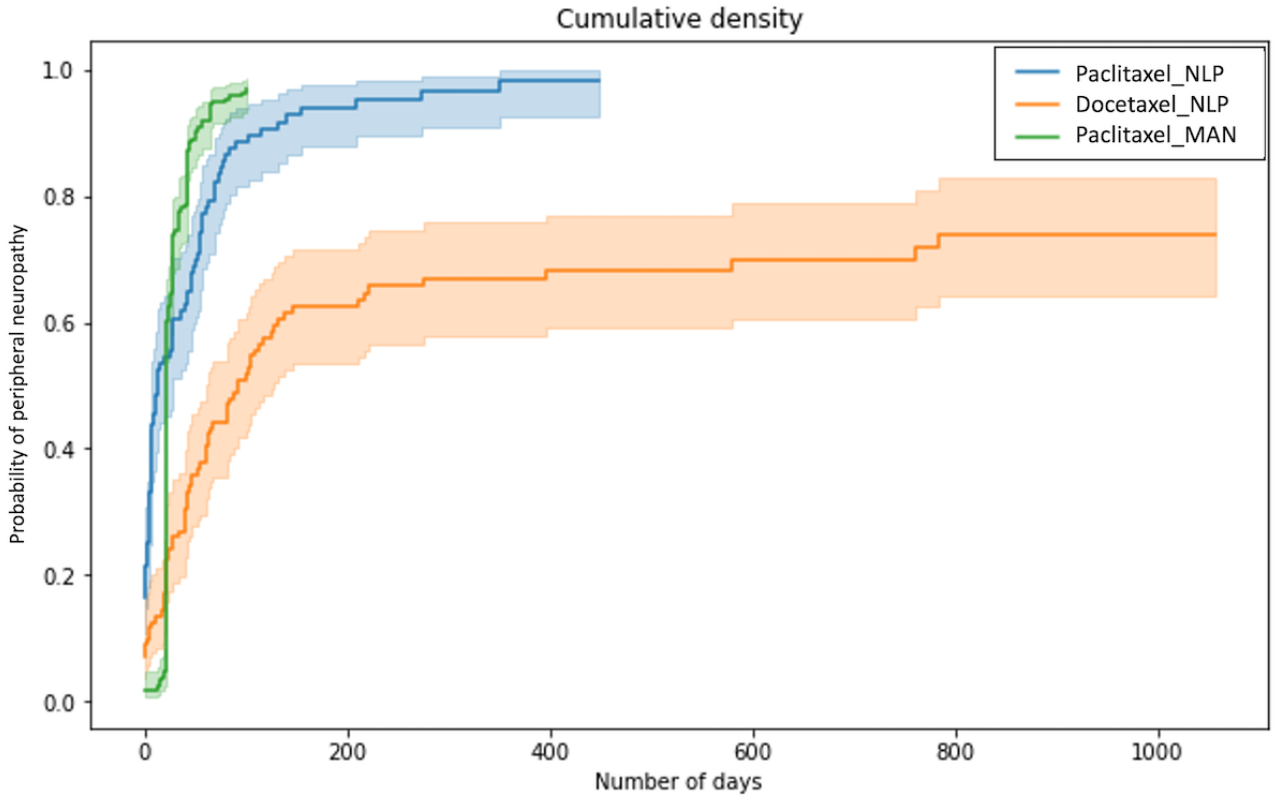
As shown in Figure 2, among the 2289 patients from the data set, 215 were selected (paclitaxel, n=103; docetaxel, n=112). A total of 2066 patients who did not receive paclitaxel nor docetaxel and 8 patients who received both paclitaxel and docetaxel were excluded. The median age of the participants was 59 years (range 33-78) for the paclitaxel-treated patients and 52 (25-73) years for the docetaxel-treated patients, which

is not significantly different from the median age of 53 (range 22-70) years in previous reports. The mean and maximum follow-up periods were, respectively, 380.3 and 1264 days for paclitaxel-treated patients and 545.1 and 1080 days for docetaxel-treated patients.

A total of 7428 symptom expressions were extracted (paclitaxel=3732 and docetaxel=3696), of which 5057 (paclitaxel=2804 and docetaxel=2253) were positive for symptom factuality and 879 (paclitaxel=569 and docetaxel=310) were PN-related.

Figure 5 shows the Kaplan-Meier curves of the results obtained by our system and the previous results obtained using a manual method. Of the 103 patients who received paclitaxel (n=103), 97 had confirmed PN; from the 112 patients who received docetaxel (n=112), 76 had confirmed PN.

Figure 5. Kaplan-Meier curves of the results obtained by our system (Paclitaxel_NLP and Docetaxel_NLP) and the previous results obtained using a manual method (Paclitaxel_MAN). The solid line indicates the proportion of patients who developed peripheral neuropathy among those who received paclitaxel or docetaxel. Filled areas indicate 95% CIs.



Comparison With the Kaplan-Meier Curves

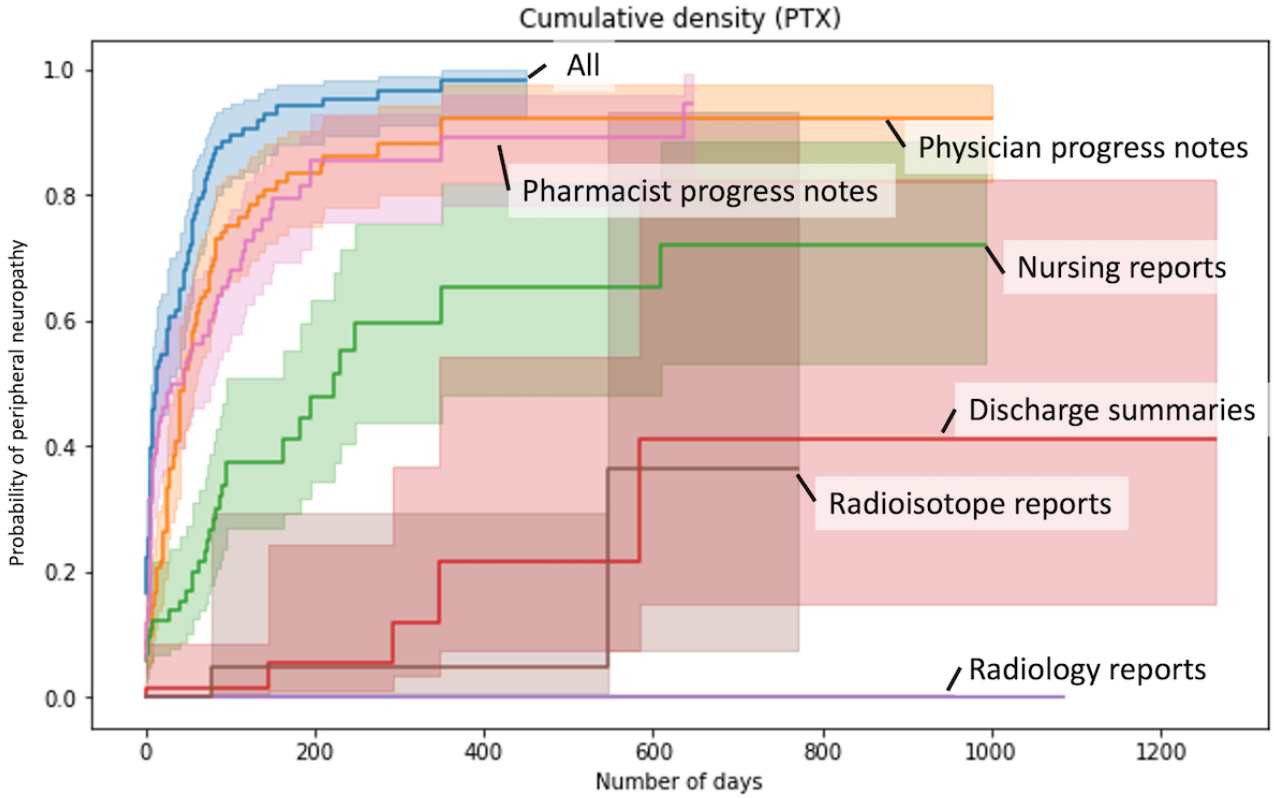
The incidence of PN caused by paclitaxel was 60.7% at 30 days, and as the previous research reported incidence was 74% at 30 days, and the detection gap was 13.3 points (74.0%-60.7%) [13]. The percentages represent the proportions of patients who were determined to have developed PN from documents.

The result does not entirely reflect the actual onset of the disease; however, the system detected PN in almost all patients over 1 year, which seems accurate enough. The correlation coefficient between the results obtained by our system (Paclitaxel_NLP) and those obtained manually (Paclitaxel_MAN) was 0.87, with a P value of 1.72×10^{-32} (<.05), indicating a high correlation.

Figure 6 shows the comparison between the results from per document type and all document types. The percentages of PN identified in each document type, in descending order, were physician progress notes, pharmacist progress notes, nursing records, discharge summaries, radioisotope reports, and radiology reports.

In order to assess which documents influenced the results calculated from all documents, multiple regression analyses were performed. The results from all documents were used as predictor variables, and the results from each document as explanatory variables. The respective regression coefficients and SD (shown in parentheses) were 0.70 (0.04) for pharmacist progress notes, 0.35 (0.03) for physician progress notes, 0.32 (0.09) for nursing records, 1.39 (1.67) for discharge summaries, 1.64×10^{-16} (1.64×10^{-16}) for radiology reports, and –0.53 (0.21) for radioisotope reports. The results suggest the importance of physician progress notes, pharmacist progress notes, and nursing reports among the document types.

Figure 6. Comparison between the results from each document type and all document types.



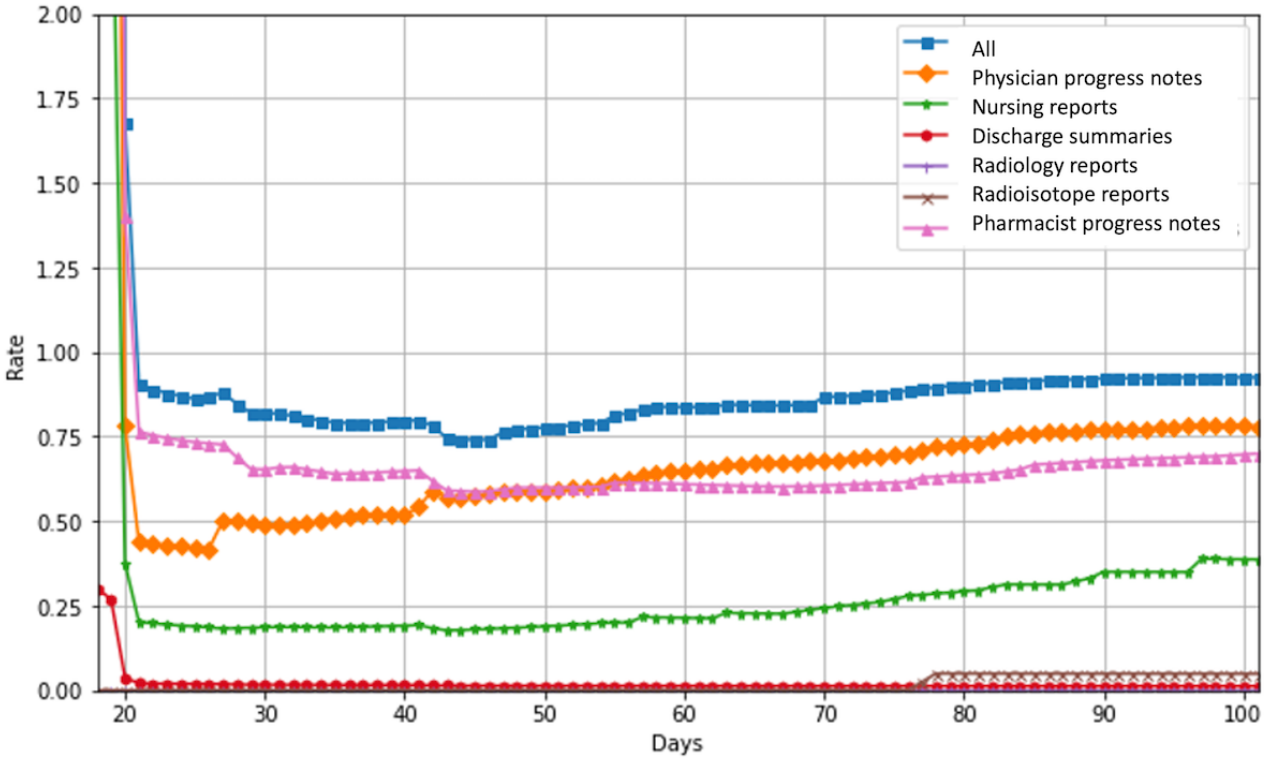
When all records were used, the system was able to detect the onset of all PNs that could be detected at 350 days. On the other hand, the same results could not be obtained, even after 600 days, when each type of documents was used independently.

The results from the pharmacist records were similar to those from all types of documents in the initial period but remained almost constant after 200 days, with few new cases of PN detected. Nursing records, which contain many records of patient care, were expected to be effective in detecting adverse drug reactions such as PN, but the detection rate was less than half that of physician and pharmacist records. The detection rate for discharge summaries, radiology reports, and radioisotope reports was very low (less than half), suggesting that these types of documents are less useful for the target diseases and target drugs in this study.

Figure 7 shows the detection rate of patients with PN in each document compared with the manual results. At 30 days, the detection rate compared with manual was 65.3% for pharmacist progress notes, 49.1% for physician progress notes, 18.6% for nursing records, 1.6% for discharge summaries, 0% for radioisotope reports, and 0% for radiology reports. The detection rates of all records were lower than the combined detection rate of all records (82.0%). This suggests that the use of multiple types of documents is effective.

In the early stage of the observation period, automatic extraction tended to overdetect PN. This is likely due to the incorrect detection of expressions related to side effect descriptions, which will be discussed in the error analysis section. The detection rate decreases in the middle of the period and slowly increases in the latter half. In the first half of the observation period, pharmacist progress notes showed the highest performance in detecting the results from a single type of documents, while physician progress notes showed the highest performance in the second half of the observation period. It is interesting to note that different document types tend to have different detection rates depending on the time of observation.

Figure 7. Rates of patients with peripheral neuropathy detected in each document compared with manual results.



Discussion

Principal Findings

In contrast to the rapid increase in the number of patients developing PN 20 days after beginning treatment in a previous report, our system detected PN at an earlier treatment stage [15].

Our method can extract symptoms from text, determine factuality, and chronologically monitor the patient's symptoms. Therefore, as long as the target symptoms are described in the text, the same method can be applied to any symptom and all drugs other than taxanes, making it a versatile and scalable method. Although there is still room for improvement in accuracy, the analysis can be automated to reduce research costs, particularly in observational studies, where large amounts of text need to be analyzed.

Error Analysis

The detection rate by our system may be affected by false negatives, suggesting that the model overlooks expressions that are difficult to detect, such as onomatopoeic expressions, as we will discuss in this section.

A detailed analysis categorized 3 types of errors, as shown in Table 2, namely, errors in symptom extraction, factuality determination, and normalization. Among these, errors in factuality determination and errors in normalization were found to increase the likelihood of outputting false positives. An example of errors in factuality determination is that explanations such as "this medicine has a risk of PN" can be misinterpreted as PN. Normalization errors included instances of normalizing expressions not limited to PN, such as "numbness" in "Numbness + in upper extremities due to cervical stenosis" to PN. All 3 types of errors were identified as false negatives. As a symptom extraction error, it was confirmed that the onomatopoeic "tingling (ビリビリ, biribiri)" was not extracted. The NER model is not effective at recognizing more informal expressions, such as onomatopoeias, probably because the model is fine-tuned using case reports, which are relatively formal sentences. As for errors in factuality determination, "tingling (ぴりぴり, piripiri)" was not extracted in "Even a rest does not stop tingling sensation in my hands." Although this text implies the positive factuality of the symptoms, the presence of negation in the sentence may have interfered with the model's determination of factuality. Note that this expression is onomatopoeic and translated into the same word in English. However, this is a different expression in Japanese, and the symptoms were properly extracted. Other expressions such as "There is a risk of paralysis (麻痺のリスクあり)" and "Explained side effects of eribulin…PN… (エリブリンの副作用...末梢神経障害...について説明)" were also incorrectly extracted. This is because such expressions are rarely used in case reports.

Table 2. Types of errors in the detection of peripheral neuropathy. Original Japanese texts are in parentheses. Italicized text is the expression extracted by named entity recognition.

Types of errors and examples	Prediction outcome
Errors in extracting symptoms	
Have a tingling sensation in my limbs. （手足がぴりぴりする）	False negative
Errors of factuality determination	
Explained side effects of eribulin: decreased blood counts, risk of infection, *PN*, fatigue, decreased appetite, etc. （エリブリンの副作用：血球減少、感染のリスク、末梢神経障害、倦怠感、食欲低下等について説明）	False positive
Owing to fractured thoracic vertebrae, there is a risk of paralysis during rehabilitation （リハビリは胸椎が骨折で麻痺のリスクあり）	False positive
Even a rest does not stop tingling sensation in my hands.（手のびりびりは休んでもマシにはなりません。）	False negative
Errors of normalization	
Numbness + in upper extremities due to cervical stenosis. （頚椎狭窄で上肢にしびれ＋）	False positive
Cellulitis of the right upper extremity （右上肢蜂窩織炎）	False positive
No abnormal changes of note in blood sampling results（特記すべき異常変化を採血結果に認めない）	False positive
Bilateral supraclavicular lymph nodes, mediastinal lymph nodes, and para-aortic lymph node metastases are considered to be affected, *decreased accumulation* （両側鎖骨上リンパ節、縦隔リンパ節、傍大動脈リンパ節転移は効果ありと考えられる集積低下）	False positive
After wearing a supporter, edema got better, but *pain and numbness* appeared. （サポーターをしたら、浮腫は良くなったが、逆に痛み しびれが出てきた。）	False negative

As a normalization error, the expression such as “pain and numbness” in the sentence “After wearing a supporter, edema got better, but pain and numbness appeared.” was normalized incorrectly because the model extracted not only numbness but also pain and numbness as a coherent expression, and any surface terms in the dictionary did not match sufficiently in this case. False positives in normalization are influenced by the surface form of the dictionary used. “Abnormal change (異常変化)” is matched to “sensory abnormality (感覚異常)” in the dictionary, and “hypoaccumulation (集積低下)” is matched to “hypoalgesia (痛覚低下).”Adjustment of the Levenshtein distance threshold may yield better results.

The false positive result suggests an early overdetection of PN in the automatic detection system, while the false negative result is associated with a decrease in the detection rate in the middle of the graph. As shown in Figure 7, for false negatives, our method of using multiple types of documents compensates for the lower detection rate compared with the use of a single document.

The impact of the error on clinical outcomes is that a false negative in the extracting symptoms and factuality determination represents a significant clinical risk because it means that an adverse drug reaction was missed. However, our method of using multiple types of documents reduces this risk compared with using only 1 type of document because the multiple types of documents complement each other and reduce false negatives. In the case of a false positive, the risk of adverse drug reactions is overestimated, and the patient may not be able to choose an appropriate treatment if the adverse drug reaction is a factor in the drug selection decision. In addition, the same phenomenon may occur in the case of normalization errors. The linking of different symptoms may also lead to incorrect conclusions about adverse drug reactions because the symptoms that occur cannot be accurately captured. For example, an unrelated symptom may be detected as a risk, resulting in unnecessary investigations.

Documents Containing Adverse Drug Event Information

Table 3 shows a breakdown of the number of documents and patients with PN detected in each document. Since large counts of PN detection are seen in nursing records, pharmacist progress notes, and physician progress notes, we assert that analyzing multiple types of documents, such as nursing records and pharmacist progress notes, is as important as physician progress notes. It can be inferred from these results that combining multiple types of medical documents not only enables the detection of more patient events, but also reduces the number of missed events per patient.

Table 3. Counts in each document type.

Document type	Documents, n			Patients, n		
	Total	Paclitaxel	Docetaxel	Total	Paclitaxel	Docetaxel
Physician progress notes	373	246	127	146	85	61
Nursing records	189	117	72	80	49	31
Discharge summaries	24	10	14	22	9	13
Radiology reports	0	0	0	0	0	0
Radioisotope reports	2	2	0	2	2	0
Pharmacist progress notes	291	194	97	137	81	56

Duration of Adverse Drug Event

Duration of PN was calculated as the period from the date of onset to the date of the last PN detection. The median number of days of PN onset by paclitaxel was 12 days, the median number of days of last confirmed onset was 126 days from the start of administration, and the median duration was 92 days. The median number of days of PN onset by docetaxel was 45.5 days, the mean number of last observed days was 135.5 days from the start of administration, and the median duration was 64.0 days. The median duration of PN with paclitaxel reported previously was 727 days, and the results are likely to significantly underestimate the duration because of the nature of the follow-up period of the analyzed data in this study, which was approximately 1000 days at most [13].

Limitations

The results obtained with our method are dependent on the accuracy of the NER model used. Although our model achieved the best performance in a shared task, there is still room for improvement, with an F_1-score of 62.9% for the extraction performance of the relevant tags in this task [18]. This model was fine-tuned based on case reports; however, we expect that fine-tuning using annotated data from the same type of documents as those used in this study, such as nursing records and progress notes, will improve the results. In addition, dictionary matching using the Levenshtein distance is performed for normalization. The normalization may have introduced false positives and false negatives.

The onset of PN was defined as the date when PN was first identified in the text. Therefore, if a PN that occurred in the past is mentioned in the text, it is possible that the onset of PN is assessed late. Similarly, the end of the PN disease period was defined as the date on which PN was last identified. The maximum follow-up period of the studies used in this study was approximately 1000 days, which may be an underestimate of the residual duration of PN.

This method focuses on the presence or absence of PN and does not quantitatively evaluate the common terminology criteria for adverse events grade. Although this model determines only the factuality of the symptoms, a more detailed analysis can be conducted by creating a model that determines the grade.

Conclusions

We proposed a system to detect PN by using NLP methods to allow the analysis of multityped documents automatically and concurrently. Analyses were performed on breast cancer patients receiving paclitaxel and docetaxel. As a result, many PN events were extracted from the nursing records and pharmacists' progress notes as well as physicians' progress notes. This approach is reasonable when considering the multiple types of records used in this study since leveraging multitype documents is better than single-type documents to improve detection performance. Based on the timing of the onset, our system underestimates by 13.3 percentage points.

We also examined persistent PN using a similar approach. Compared with the manual results, it was suggested that the duration of PN was underestimated; however, this may be due to the large difference in the follow-up periods.

Although the accuracy of the system requires further investigation, we believe that our NLP system has great potential to provide an immediate estimate of the persistence of ADEs, which traditionally requires continuous investigation and incurs high costs.

Abstract

Background: Named entity recognition (NER) models are essential for extracting structured information from unstructured medical texts by identifying entities such as diseases, treatments, and conditions, enhancing clinical decision-making and research. Innovations in machine learning, particularly those involving Bidirectional Encoder Representations From Transformers (BERT)–based deep learning and large language models, have significantly advanced NER capabilities. However, their performance varies across medical datasets due to the complexity and diversity of medical terminology. Previous studies have often focused on overall performance, neglecting specific challenges in medical contexts and the impact of macrofactors like lexical composition on prediction accuracy. These gaps hinder the development of optimized NER models for medical applications.

Objective: This study aims to meticulously evaluate the performance of various NER models in the context of medical text analysis, focusing on how complex medical terminology affects entity recognition accuracy. Additionally, we explored the influence of macrofactors on model performance, seeking to provide insights for refining NER models and enhancing their reliability for medical applications.

Methods: This study comprehensively evaluated 7 NER models—hidden Markov models, conditional random fields, BERT for Biomedical Text Mining, Big Transformer Models for Efficient Long-Sequence Attention, Decoding-enhanced BERT with Disentangled Attention, Robustly Optimized BERT Pretraining Approach, and Gemma—across 3 medical datasets: Revised Joint Workshop on Natural Language Processing in Biomedicine and its Applications (JNLPBA), BioCreative V CDR, and Anatomical Entity Mention (AnatEM). The evaluation focused on prediction accuracy, resource use (eg, central processing unit and graphics processing unit use), and the impact of fine-tuning hyperparameters. The macrofactors affecting model performance were also screened using the multilevel factor elimination algorithm.

Results: The fine-tuned BERT for Biomedical Text Mining, with balanced resource use, generally achieved the highest prediction accuracy across the Revised JNLPBA and AnatEM datasets, with microaverage (AVG_MICRO) scores of 0.932 and 0.8494, respectively, highlighting its superior proficiency in identifying medical entities. Gemma, fine-tuned using the low-rank adaptation technique, achieved the highest accuracy on the BioCreative V CDR dataset with an AVG_MICRO score of 0.9962 but exhibited variability across the other datasets (AVG_MICRO scores of 0.9088 on the Revised JNLPBA and 0.8029 on AnatEM), indicating a need for further optimization. In addition, our analysis revealed that 2 macrofactors, entity phrase length and the number of entity words in each entity phrase, significantly influenced model performance.

Conclusions: This study highlights the essential role of NER models in medical informatics, emphasizing the imperative for model optimization via precise data targeting and fine-tuning. The insights from this study will notably improve clinical decision-making and facilitate the creation of more sophisticated and effective medical NER models.

Introduction

Background

The importance of robust named entity recognition (NER) models in medical informatics has become increasingly evident; these models systematically extract structured information from unstructured textual data such as clinical notes and research articles. This capability is crucial for processing large volumes of clinical data, facilitating early disease detection and supporting personalized medicine. NER models transform complex medical data into usable information, significantly enhancing clinical decision-making and medical research [1-3]. The performance of these models directly impacts the quality of information retrieval and data analysis as medical texts often contain complex and diverse terminologies. Precision in identifying and categorizing entities such as diseases, treatments, anatomical structures, and medications is foundational to many health care applications, making NER an indispensable tool in advancing medical informatics [4].

The critical role of NER in electronic health records further illustrates its importance. NER models automatically extract essential patient information, such as symptoms and medical conditions, that is crucial for differential diagnosis and ensuring that clinicians have rapid access to critical patient history. Errors in entity classification or omission can lead to severe consequences, including misdiagnosis or inappropriate treatment, highlighting the need for highly accurate NER models. Moreover, NER facilitates medical research by enabling efficient data mining from extensive medical literature, aiding the organization and retrieval of information on various medical entities. This capability is essential in drug discovery and identifying disease biomarkers, where systematic analysis and synthesis of large amounts of text are required. For instance, in pharmacovigilance, NER models identify adverse drug reactions from clinical notes and reports, contributing to drug safety monitoring and public health initiatives [5,6].

However, the application of NER in medical informatics presents unique challenges. The complexity and specificity of medical language, including synonyms, acronyms, and context-specific meanings, necessitate the continuous refinement of NER models. Recent studies have revealed significant variability in the effectiveness of NER models across different medical datasets, potentially limiting their real-world applicability. Despite these challenges, there have been promising advancements. For example, the BBC-Radical model, which integrates Bidirectional Encoder Representations From Transformers (BERT) with Bidirectional Long Short-term Memory, and conditional random field (CRF), has demonstrated high precision, recall, and F_1-scores in extracting adverse drug reaction–related information from Chinese adverse drug event records [7]. This example illustrates the potential of combining advanced embedding techniques with traditional machine learning methods to enhance NER performance in specific contexts. These findings underscore the critical need for domain-specific adaptations and the integration of a more advanced linguistic and contextual understanding into these models. Such enhancements are essential for improving the prediction accuracy and applicability of NER models across diverse medical contexts.

Given these complexities and the need for continuous improvement, understanding the factors influencing model performance is crucial. Optimizing these models for specific tasks can significantly enhance their efficiency and accuracy. In medical informatics, this optimization is vital as the quality of data analysis directly impacts clinical decision-making. Researchers can make targeted improvements by identifying key elements of model design or aspects of training data that significantly affect performance, such as better handling of rare or complex medical terms. This knowledge assists in developing new models and refining existing ones to meet the specific needs of health care applications, thereby improving the precision of data extraction and analysis. Such improvements are crucial for the reliability of clinical information systems, reducing the risk of misdiagnosis or inappropriate treatment. Ultimately, these advancements support more accurate and informed clinical decision-making [8].

To achieve these improvements, it is essential to thoroughly evaluate the performance of various NER models across different contexts. First, this study identified 3 categories of NER models: statistical machine learning models, deep learning natural language processing (NLP) models based on BERT architecture, and large language models (LLMs). We selected these categories based on their unique strengths and potential to address specific challenges in medical NER.

Statistical machine learning models, such as hidden Markov models (HMMs) and CRF, were chosen for this study due to their established methodologies and effectiveness in sequence prediction tasks. These models leverage probabilistic approaches to capture the sequential nature of language data. However, they often struggle with the complexities of medical terminologies without extensive feature engineering. This limitation necessitates continuous refinement and adaptation to effectively handle medical texts' intricate and specialized language [9].

Deep learning NLP models, especially those based on the BERT architecture, represent a significant advancement in NER capabilities. Variants of the BERT model, such as BioBERT, Robustly Optimized BERT Pretraining Approach (RoBERTa), Big Transformer Models for Efficient Long-Sequence Attention (BigBird), and Decoding-enhanced BERT with Disentangled Attention (DeBERTa), have demonstrated exceptional performance in capturing the intricate context of medical language. We selected these specific variants for this study because they can leverage deep contextual embeddings and undergo large-scale pretraining on medical corpora, enabling them to handle the complexities of medical terminologies effectively. For instance, a model using RoBERTa with whole-word masking and convolutional neural networks achieved high F_1-scores in Chinese clinical NER tasks,

indicating its effectiveness in processing complex medical terminologies within electronic medical records [10]. This success is primarily due to their ability to leverage deep contextual embeddings and undergo large-scale pretraining on medical corpora. These models are highly effective in identifying entities across diverse medical datasets, although they require substantial computational resources and meticulous fine-tuning for optimal performance. The introduction of BERT-based NER model variants marks a significant breakthrough in medical informatics, notably enhancing medical data analysis [11]. By leveraging advanced feature extraction techniques from masked language models such as embeddings from language models and the transformer architecture, these models set new standards for precise analysis of diverse medical datasets [12]. Specifically, RoBERTa incorporates enriched training data and refined masking patterns [13], whereas BigBird addresses previous models' scalability and comprehension challenges by efficiently processing extended sequences [14]. DeBERTa's innovative attention mechanisms further enhance these capabilities [15]. BioBERT, with its specialized pretraining on extensive medical texts, exemplifies the efficacy of domain-specific adaptations, achieving unparalleled precision in recognizing medical entities [16]. This strategic focus on contextual nuances and specialized terminology significantly improves the quality of patient care decisions.

LLMs, such as those based on the generative pretrained transformer architecture, have shown significant promise in NLP, particularly in understanding complex language structures. However, as the studies by Tian et al [17], Zhao et al [18], and Hu et al [19] have highlighted, their application in medical NER presents challenges, including limited prediction efficiency, extended runtimes, and substantial hardware requirements. These challenges are compounded by the complexity and specificity of medical terminology, often resulting in suboptimal accuracy with standard medical datasets such as BioCreative V CDR (BC5CDR), Joint Workshop on Natural Language Processing in Biomedicine and its Applications (JNLPBA), and NCBI (National Center for Biotechnology Information Disease Corpus). The general optimization strategies of LLMs do not align well with the specialized needs of NER tasks in medical informatics [17-19]. Despite these challenges, we selected Gemma, a fine-tuned version adapted explicitly for medical NER tasks, for this study [20]. Gemma was chosen over other open-source LLMs such as Large Language Model Meta AI 3 [21] or Open Pretrained Transformer [22] due to its advanced capabilities in contextual understanding and efficiency in processing specialized vocabulary. Its fine-tuning process specifically targets medical terminologies, making it more adept at handling the nuances of medical language. In addition, Gemma's tailored adaptations include specific optimizations that align with the unique challenges of medical datasets, allowing it to achieve higher accuracy and reliability in recognizing entities within complex medical texts [23]. The proven effectiveness of fine-tuned models such as Gemma, as demonstrated by systems such as the Medical Named Entity Recognition–Japanese developed for analyzing pharmaceutical care records in Japanese, further underscores its suitability for medical NER tasks [24].

Building on this classification, we integrated various NER models, including HMM, CRF, RoBERTa, BigBird, DeBERTa, BioBERT, and Gemma. Following this integration, evaluating these models comprehensively to enhance their accuracy and durability is essential. Recent studies by Freund et al [25], Ahmad et al [26], and others highlight a shift toward more comprehensive evaluation metrics tailored to the specific needs of medical informatics. This shift facilitates the development of advanced NER applications, significantly improving patient care by enhancing clinical data management. This marks a substantial advancement in the integration of technology and health care. However, the evaluations' primary focus has been assessing the predictive capabilities of NER models using metrics such as precision, recall, and F_1-score. Research by Yoon et al [27], Yu et al [28], and Yadav and Bethard [29] has used these metrics to evaluate these capabilities. The study by Erdmann et al [30] also compared various NER tools for literary text corpora with human annotators using the same metrics, highlighting the importance of such evaluations in the digital humanities. Furthermore, the work by Usha et al [31] and Nagaraj et al [32], which includes advanced techniques such as confusion matrices and receiver operating characteristic and precision-recall curves, offers a more nuanced understanding of classification accuracy and errors in NER models. As the studies by Ozcelik and Toraman [33] and Akhtyamova [34] explored, error analysis is critical for understanding performance nuances, especially in identifying and categorizing short- and long-term entities. This comprehensive evaluation approach underscores the complexities and challenges in developing accurate and efficient NER models for medical informatics [33,34].

The aforementioned studies predominantly used standard metrics such as precision, recall, receiver operating characteristic curve, and F_1-score to evaluate model performance. However, these metrics fall short in capturing performance variations across different medical NER datasets and conducting a detailed analysis of how dataset characteristics affect model performance. Moreover, although these metrics are easy to compute, their interpretation proves challenging. This difficulty mainly arises from the metrics' failure to explain the broader reasons behind model outcomes as they often depend on processing microvector features that are not intuitively understandable. Consequently, researchers focused on enhancing medical NER datasets through NER models encounter significant hurdles in devising effective optimization strategies. In response, some researchers have shifted to customizing macrofactors for evaluating explanatory NER models. For example, Fu et al [35] developed an evaluation framework that outlines 8 distinct factor types to analyze their correlation with the models' F_1-score rankings. Zhou et al [36] proposed an ant colony optimization algorithm based on parameter adaptation. They designed a new dynamic parameter adjustment mechanism to adaptively adjust the pheromone importance factor. This algorithm is also suitable for selection of macrofactors. By adaptively changing the macrofactors, the algorithm can determine which macrofactors affect the prediction accuracy of the NER model [36]. Yao et al [37] also enhanced this domain with their groundbreaking a scale-adaptive mathematical morphology spectrum entropy algorithm, which

adjusts the scale of structural elements to measure macrofactors' impact on model prediction accuracy. These advancements have led to increasingly sophisticated NER model evaluations, resulting in more precise and resilient models.

Objectives

Given this context, the purpose of this study was to systematically evaluate the comprehensive performance of various NER models in the medical field focusing on both general medical texts and specific medical entity types. In addition, this study aimed to explore key macrofactors affecting model prediction performance. To achieve these goals, we used a comprehensive evaluation approach combining traditional and innovative techniques to enhance the accuracy and reliability of NER in medical informatics. This approach included analyzing hardware performance indicators such as training duration, central processing unit (CPU), and graphics processing unit (GPU) use and assessing the precision of models such as HMM, CRF, RoBERTa, BigBird, DeBERTa, BioBERT, and Gemma across different medical entity types. Furthermore, we proposed the multilevel factor elimination (MFE) algorithm, which integrates linear and machine learning strategies to filter multilayer factors and evaluate their impact on prediction accuracy. Through this comprehensive evaluation, we aimed to provide targeted recommendations for researchers, ultimately leading to the development of more accurate and reliable NER models for broader applications in the medical field.

Methods

Overview

This section outlines 2 methods: *training and evaluating medical NER models* and *further assisted evaluation*. The first method evaluates the prediction accuracy of the statistical machine learning models (HMM and CRF), the deep learning NLP models based on BERT architecture (BioBERT, BigBird, DeBERTa, and RoBERTa), and the Gemma LLM across different medical entity types, as well as overall model effectiveness. The second method further assesses the prediction accuracy of merged entity types within these models' postclassification and examines the macrofactors' influence on model performance.

Training and Evaluating Medical NER Models

Overview

This method involved training, validating, and testing NER models using hyperparameter tuning techniques. For models such as RoBERTa, BioBERT, BigBird, and DeBERTa, we used the Adaptive Moment Estimation (ADAM) optimizer for hyperparameter tuning. These strategies were applied using datasets such as the Revised JNLPBA, focusing on optimizing parameters such as learning rates, batch sizes, and other model-specific settings to enhance prediction accuracy. In addition, Gemma was fine-tuned using low-rank adaptation (LoRA) to improve its predictive performance. In contrast, models such as HMM and CRF were not subjected to hyperparameter tuning. This decision was based on the inherent simplicity of these models, which are less sensitive to hyperparameter variations than more complex deep learning models. Consequently, fine-tuning HMM and CRF would likely yield marginal improvements that did not justify the additional computational resources and time investment.

Dataset Selection

In total, 3 medical NER datasets were used to evaluate the prediction accuracy of models across different medical contexts (Table 1). These datasets use the "beginning, inside, outside" sequence annotation method (Figure 1); among them, the Revised JNLPBA dataset, provided by Huang et al [38], was selected because it retains the original semantic annotation type while addressing known vulnerabilities from the original JNLPBA dataset. It features 5 entity types (DNA, RNA, protein, cell line, and cell type), offering a focused scope on biological entities. The BC5CDR dataset, officially released by Li et al [39], was chosen for its 2 distinct entity types—disease and chemical—which present unique challenges due to their complex and overlapping terminology. Finally, the Anatomical Entity Mention (AnatEM) dataset [40], focusing on anatomical entities in medical fields, was used due to its broad range of 12 different entity types, providing a wide spectrum of medical terms. This diversity in entity numbers and types—most of which are distinct across the datasets—strengthens the evaluation by exposing the models to varied linguistic challenges, thereby reducing the randomness and contingency of the experimental results and enhancing the overall credibility of the experiment.

Table 1. Descriptive statistics of the medical named entity recognition datasets.

Dataset	Medical entity type	Entity types, n	Annotations, n
Revised JNLPBA[a]	DNA, RNA, protein, cell line, and cell type	5	52,785
BC5CDR[b]	Disease and chemical	2	38,596
AnatEM[c]	Organism subdivision, anatomical system, organ, multi-tissue structure, tissue, cell, developing anatomical structure, cellular component, organism substance, immaterial anatomical entity, pathological formation, and cancer	12	11,562

Training and Testing of the Deep Learning NLP Models With BERT Architecture

Overview

This section discusses achieving optimal prediction accuracy through meticulous hyperparameter tuning during the model training phase. We trained models such as RoBERTa, BigBird, DeBERTa, and BioBERT on datasets divided into training, validation, and test sets sourced from the Revised JNLPBA, BC5CDR, and AnatEM collections. The ADAM optimizer was used to fine-tune key hyperparameters, including learning rate, batch size, epochs, and dropout rate. This optimizer adjusts the learning rate for each parameter based on estimates of lower-order moments of the gradients, enabling faster convergence by adapting to the characteristics of the data and gradients. This adaptive adjustment enhances convergence speed and overall model performance, aiming to identify the optimal hyperparameter combination that maximizes performance on the validation set [41,42].

The models' prediction accuracy on the test set was evaluated primarily using F_1-scores for specific entity types and overall performance metrics. The F_1-scores, calculated as the harmonic mean of precision and recall, were chosen as the primary evaluation metric because they provide a balanced assessment of model performance in detecting relevant entities. This balance is crucial in medical NER, where precision measures the proportion of correctly identified entities and recall measures the proportion of actual entities correctly identified. In medical information extraction, where false positives and negatives can have significant implications, the F_1-score's ability to balance these metrics is essential. Missing important medical terms can lead to incomplete patient records or misunderstandings in medical literature, whereas false positives can introduce erroneous information into clinical decision-making processes. Thus, the F_1-score is particularly suitable and reliable for evaluating model performance in medical NER tasks, where accuracy and reliability are paramount [43].

While the ADAM optimizer dynamically adjusted learning rates during model training to improve convergence, cross-validation was used separately to evaluate and optimize hyperparameters. Cross-validation, a robust method for model validation that involves dividing the dataset into multiple subsets for validation, ensures that the chosen hyperparameters generalize well to unseen data. This distinction underscores the complementary roles of the optimizer in training and cross-validation in validating and tuning the model's hyperparameters. The selection and tuning of hyperparameters were guided by cross-validation. In this context, hyperparameter optimization aims to identify a global or satisfactory local optimum that maximizes medical NER model performance by adjusting several key hyperparameters, described in the following sections.

Learning Rate Adaptation Strategy

We used a dynamic learning rate adjustment strategy to enhance the model's efficiency in converging to an optimal local minimum—testing rates of 0.0001 and 0.00001. This approach is similar to the findings of Wu and Liu [44] on the benefits of adaptive learning rates in NLP applications.

Batch Size Considerations

Guided by research on neural network training dynamics and computational constraints [44], we selected batch sizes of 10 and 50. This allowed for more frequent model updates and a finer approach to convergence.

Epoch Configuration

The number of training epochs was set based on the dataset's complexity and initial performance metrics [45] with values of 1, 5, and 10. This adaptive approach minimized the risk of overfitting while ensuring the duration of practical training.

Dropout for Regularization

To prevent overfitting, we applied dropout rates of 0.1, 0.2, and 0.5 as informed by interim validation performance [46]. This regularization technique enhanced generalization across unseen medical texts, ensuring model reliability.

Training and Testing of the Gemma LLM

In this section, the Gemma 7B model was fine-tuned using the LoRA technique to optimize its performance on medical NER tasks. The LoRA approach was selected for its ability to efficiently adapt LLMs to specific tasks while reducing computational and memory overhead. This method involves freezing the pretrained model weights and introducing trainable low-rank decomposition matrices in each layer of the transformer architecture, significantly decreasing the number of trainable parameters and GPU memory requirements [47].

The fine-tuning process was conducted using a carefully structured setup. The Gemma 7B model was trained using datasets such as the Revised JNLPBA, BC5CDR, and AnatEM with a token cutoff length of 512 and a maximum of 20,000 samples. Preprocessing_num_workers was set to 16, and a mixture of depths was converted to facilitate diverse learning dynamics. The output configuration included saving checkpoints every 1000 steps and logging progress every 200 steps, ensuring thorough monitoring of the training process.

Training parameters included a per-device batch size of 8, a gradient accumulation step of 1, and a learning rate of 0.0001, managed by a cosine learning rate scheduler with a warm-up ratio of 0.1. The training spanned 3 epochs, using mixed precision with bfloat16 for efficiency. A weight decay of 0.01 was applied to prevent overfitting. A 10% validation split was used for evaluation, with assessments conducted every 200 steps using a batch size of 4 per device.

LoRA-specific settings included a dropout rate of 0.05 and a rank of 128 for the low-rank matrices applied across all model layers. This configuration enabled significant reductions in trainable parameters and GPU memory use. The LoRA technique allowed the Gemma 7B model to be fine-tuned effectively for complex NER tasks in the medical domain without compromising performance. These adjustments provided a scalable approach for adapting large-scale language models to specialized tasks with efficient computational resources.

Finally, the F_1-score was used to evaluate the prediction accuracy of each entity type under the Gemma 7B model. To further demonstrate the effectiveness of the fine-tuning process, metrics such as the microaverage (AVG_MICRO) and macroaverage (AVG_MACRO) were leveraged to compare the performance of the fine-tuned model against a baseline without fine-tuning.

Training and Testing of the Statistical Machine Learning Models

This section used HMM and CRF for medical NER tasks using the Revised JNLPBA, BC5CDR, and AnatEM datasets. Unlike deep learning methods and LLMs, these statistical models did not require hyperparameter tuning. HMMs were trained by estimating transition and emission probabilities, whereas CRFs used feature functions to capture relationships between labels and features in the data. The prediction accuracy for each entity type was also evaluated using the F_1-score.

Evaluative Metrics and Model Assessment

After the training, cross-validation, and testing phases, we used F_1-score metrics across various hyperparameter combinations to evaluate the model's prediction accuracy for different entity types. These F_1-scores were aggregated into AVG_MICRO and AVG_MACRO as leveraged metrics to assess the model's prediction accuracy under different hyperparameter configurations. The AVG_MICRO metric provides a comprehensive measure of overall model performance, capturing precision and recall across the dataset. The AVG_MACRO metric highlights the model's ability to handle varying entity distributions, including rare entities. This dual-metric approach ensures a balanced evaluation, preventing biases toward more common entities and maintaining consistent performance across diverse entity types [42].

To enhance our evaluation framework, we assessed training time efficiency and computational resource use, including CPU and GPU use. These additional metrics provide insights into each model's operational demands and feasibility, allowing us to evaluate their prediction accuracy and practicality for real-world applications.

Further Assisted Evaluation

Overview

This method further evaluated the relationship between medical data and NER models, focusing on categorical relaxation to reduce entity classification complexity and improve prediction accuracy. We detailed the process of merging similar entity types into broader categories and evaluated the impact on model performance through a comprehensive analysis of macrofactors such as sentence length (sLen) and entity density (eDen). These methods were applied across several datasets, such as Revised JNLPBA, BC5CDR, and AnatEM, to systematically assess NER models.

Academic Revision on Categorical Relaxation

Categorical relaxation in NER classification, particularly within the medical domain, entails merging similar medical entity types to diminish ambiguity and enhance the classification performance of NER models. This technique simplifies the classification landscape and bolsters the models' capacity to generalize from training data to unseen clinical examples. In this study, we implemented categorical relaxation by consolidating specific medical entity types, such as merging different DNA or RNA names. This method was guided by empirical evidence suggesting that merging reduces misclassifications and boosts prediction accuracy, particularly in diagnosing conditions and recommending treatments.

In the Revised JNLPBA dataset, we adopted a merging strategy based on the principles described by Tsai et al [48]. Biologically related categories such as DNA, RNA, and proteins were consolidated into a single "macromolecule" category. Similarly, entities categorized as cell lines and cell types were combined into a single "cell" entity category.

In the AnatEM dataset, we reclassified 12 entity types into 4 broader categories relevant to human health following the classification guidelines from Pyysalo and Ananiadou [40]. This reorganization is predicated on the premise that broader categories more effectively capture essential information and reduce the noise caused by particular and infrequently occurring entities.

Following categorical relaxation, we comprehensively evaluated the RoBERTa, BigBird, DeBERTa, and BioBERT models. This assessment compared the prediction accuracy of these models on the newly consolidated entity types. The objective was to determine the effects of entity type consolidation on model performance, particularly whether simplifying categories enhanced prediction accuracy across different model architectures. This method simplifies entity classification and capitalizes on the inherent similarities among entity types to improve model training and evaluation. By reducing the granularity of entity types, we posited that the models would achieve higher accuracy and more effectively address the complexities of medical texts. The specific outcomes of this categorical relaxation are detailed in Table 2.

Table 2. Merged entity types.

Dataset and medical entity type	Merged entity type
Revised JNLPBA[a]	
DNA, RNA, and protein	Macromolecule
Cell line and cell type	Cell
BC5CDR[b]	
Disease	Disease
Chemical	Chemical
AnatEM[c]	
Organism subdivision, anatomical system, organ, multi-tissue structure, tissue, cell, developing anatomical structure, and cellular component	Anatomical structure
Organism substance	Organism substance
Immaterial anatomical entity	Immaterial anatomical entity
Pathological formation and cancer	Pathological formation

Constructing and Evaluating NER Macrofactor Datasets

Macrofactor Metrics Definition

Entity macrofactor metrics were defined in an entity (entity phrase fragment) or on the entire dataset, and dataset's different attributes were described. On the basis of the 8 factor types defined by Fu et al [35], we categorized these into 6 macrofactor metrics. This categorization was derived from a detailed examination of the characteristics of 3 medical datasets, including the length of medical terminology and other relevant factors. This allowed us to distill the most pertinent metrics for our study, which included *sLen*, entity phrase length *(eLen)*, *eDen*, number of entity words in each entity phrase (*eNum*), total entity word count in each entity type *(tEWC)*, and entity label consistency *(elCon)* (Textbox 1)

Textbox 1. Definitions of macrofactor metrics.

- *sLen*: this metric refers to the string length of the sentence containing the entity phrase. It quantifies the contextual space in which entities appear. Notably, extreme values are excluded to prevent distortion in average calculations.
- *eLen*: this metric quantifies the string length of each entity phrase, which can comprise one or more entity words. Similar to *sLen*, extreme values are excluded to yield a more precise average *eLen*for each entity type.
- *eDen*: this metric is calculated as the ratio of *eLen* to *sLen*; this metric quantifies how dense entities are populated within the text.
- *eNum*: for datasets such as Revised JNLPBA labeled with the "beginning, inside, outside" sequence, this metric counts the entity words in a phrase, adjusting for labeling specifics such as combining "B-Entity label" and "I-Entity label" into a single count to avoid underrepresentation in the data.
- *tEWC*: this metric quantifies the cumulative number of entity words within each specific entity type across datasets such as the Revised JNLPBA, BC5CDR, and AnatEM.
- *elCon*: this metric evaluates the consistency of entity-type assignments to medical terms across various contexts, which is essential in datasets such as the Revised JNLPBA dataset, where terms can possess multiple semantic interpretations. For instance, "lymphocyte" may be categorized as "B-cell_type" in discussions about receptor counts and as "I-cell_type" in contexts involving blood samples. To calculate*elCon*, each term from the dataset is cataloged along with its associated entity types. For example, "lymphocyte" would be documented with both "B-cell_type" and "I-cell_type." A weight ω is assigned to each term based on the inverse number of its entity types (ω=1/number of entity types), indicating that terms linked to fewer entity types tend to demonstrate higher prediction accuracy. Terms associated with a single entity type are assigned a weight of 1, whereas those with 2 types are given a weight of 0.5. We calculate the average weight using the following formula—average weight value  —excluding extreme values to avoid data skew.

The New Macrofactor Dataset Creation

To construct the macrofactor datasets, we computed metrics such as *sLen*, *eLen*, *eNum*, *eDen*, and *elCon* for each entity word within each entity type across the Revised JNLPBA, BC5CDR, and AnatEM datasets. These metrics quantify specific linguistic and structural attributes of the datasets. In addition, we included *tEWC* as a separate column to represent the total count of entity words for every kind across the datasets, quantifying the overall entity word volume. Figure 2 shows the systematic computation of these metrics except *tEWC* to augment the macrofactor datasets.

Due to the supervised nature of these datasets, labels were assigned based on the F_1-scores achieved by the top-performing models within 3 distinct categories: statistical machine learning models (HMM and CRF), deep learning NLP models based on BERT architecture (RoBERTa, BigBird, DeBERTa, and BioBERT), and LLMs (Gemma). The model with the highest AVG_MICRO and AVG_MACRO scores was identified for each model category. The F_1-scores for each entity type, as achieved by these best-performing models, were then used as labels for the datasets. This method ensures that the labels accurately reflect the prediction accuracy for each entity type. Consequently, 9 unique macrofactor datasets were generated, each representing a combination of the computed metrics and the derived labels. Figure 3A illustrates the use of these F_1-scores as labels, whereas Figure 3B provides an example of how the dataset structure was revised based on these macrofactors.

Figure 2. Sentence length (sLen), entity phrase length (eLen), number of entity words in each entity phrase (eNum), entity density (eDen), and entity label consistency (elCon) values of an entity word.

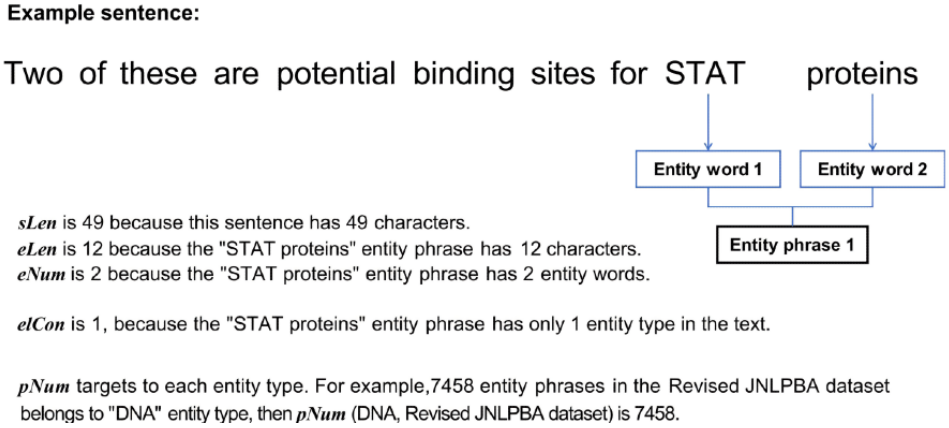

Figure 3. An example of 2 parts illustrating different components of each macrofactor dataset. Panel (A) displays the labels used in the datasets, whereas panel (B) presents a visualization of the macrofactor metrics—sentence length, entity phrase length, number of entity words in each entity phrase, entity density, and entity label consistency—using the radial tree layout algorithm. This visualization offers a structured view of the interrelationships among these metrics. AVG_MACRO: macroaverage; AVG_MICRO: microaverage.

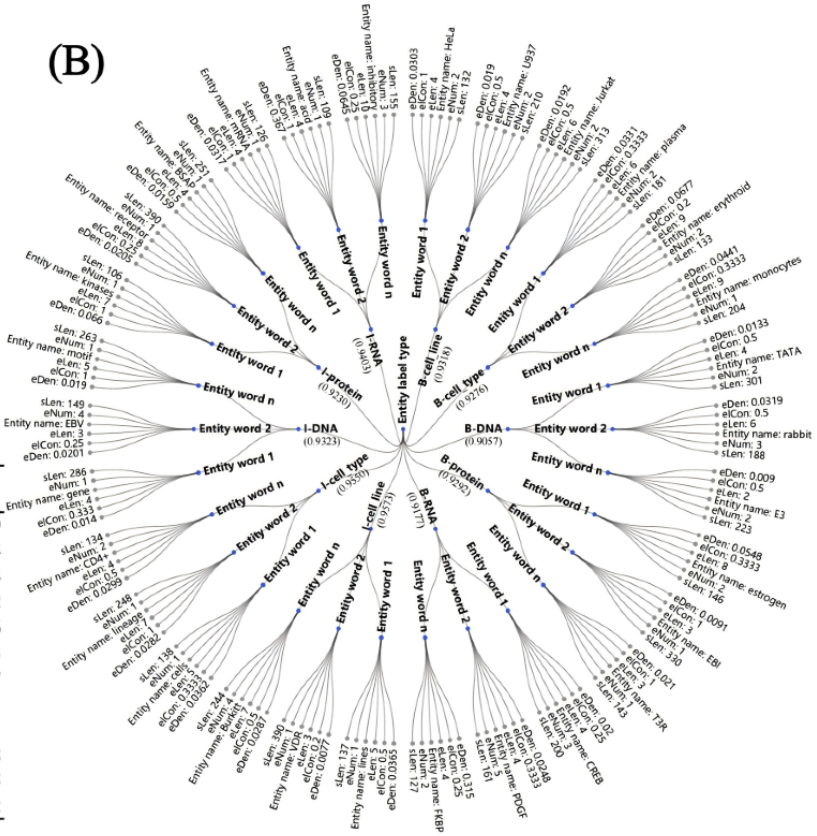
(A)

	Level	F1-Score
0	B-cell_type	0.926899
1	I-cell_type	0.952954
2	B-protein	0.926224
3	I-protein	0.914452
4	B-RNA	0.936306
5	I-DNA	0.930413
6	B-cell_line	0.940837
7	I-cell_line	0.963761
8	B-DNA	0.916821
9	I-RNA	0.944578
	AVG_MACR	0.935325
	AVG_MICR	0.928272



Preliminary Macrofactor Evaluation

Our preliminary analysis adopted a comprehensive method to assess the interactions between prediction accuracy for various entity types (eg, disease, DNA, and RNA) and 6 macrofactors. Initially, we extracted prediction accuracy data for each entity type from these NER models (HMM, CRF, RoBERTa, BigBird, DeBERTa, BioBERT, and Gemma), and we calculated the average values for macrofactor metrics such as *sLen*, *eLen*, *eNum*, *eDen*, *elCon*, and *tEWC*. We then explored the impact of each metric on the prediction accuracy for each entity type. We considered trend analysis to provide deeper insights into the relationships between these metrics and accuracy levels. In addition, the visualization of multimodel predictive trends offered a comprehensive view of model robustness across different entity types.

In-Depth Macrofactor Selection

Overview

Our subsequent research focused on identifying which macrofactors significantly impacted the models' prediction accuracy. We developed an MFE algorithm and conducted macrofactor selection. MFE is an improved algorithm based on recursive feature elimination [49] divided into 3 layers.

First Layer: Factor Ranking and Selection

The MFE algorithm inputs the calculated values for *sLen*, *eLen*, *eNum*, *eDen*,*tEWC*, and *elCon* for each entity word.

Linear correlation analysis is performed for each factor using the following function. The correlation coefficient (r) is a statistical measure used to quantify the strength and direction of the relationship between 2 variables. x_i represents individual macrofactor measurements, is the mean of all macrofactor measurements, y_i represents individual model performance measurements, and is the mean of all model performance measurements. This calculation quantifies the relationship between each macrofactor and the model's prediction accuracy.

Using a method similar to the Pearson correlation method [50], factors are ranked by their correlation scores, and the top 4 are retained for further analysis. This step ensures that only the factors with the highest potential impact are advanced, thereby efficiently streamlining the feature space.

Second Layer: Random Forest Evaluation

A random forest model performs multiple training iterations using the selected macrofactors from the first layer.

After each training session, cross-validation is used to evaluate model performance. The macrofactor with the lowest feature importance score, indicating minimal contribution to prediction accuracy, is systematically excluded from subsequent analyses. This iterative refinement process prioritizes factors that consistently enhance model accuracy [51].

Third Layer: Regression Model Optimization

The refined set of macrofactors is integrated into a regression model.

The least impactful macrofactors are sequentially eliminated based on the influence of their coefficients on the model, which is calculated as follows:

$$\text{Coefficient influence} = \beta \quad \textbf{(2)}$$

β is the coefficient related to the macrofactors; the model is retrained after each removal, continuing until no further improvement in performance is detected. This final step ensures that only the most impactful factors are retained, optimizing the model's efficiency and effectiveness.

Ethical Considerations

Ethics approval was obtained from the Institute of Medical Information and Library, Chinese Academy of Medical Sciences and Peking Union Medical College (ethics approval code: IMICAMS/01/22/HREC). After obtaining ethics approval, the Institute of Medical Information and Library, Chinese Academy of Medical Sciences and Peking Union Medical College, wrote an official ethics approval statement.

All medical NER datasets used in this paper are public datasets; no personal or sensitive information was collected, and the datasets complied with local institutional guidelines and legislation. It was unnecessary to obtain written or verbal informed consent from the participants. The experimental protocols and datasets in this study were approved by the Institute of Medical Information and Library, Chinese Academy of Medical Sciences and Peking Union Medical College. All methods were performed according to the relevant guidelines and regulations.

Results

Model Prediction Results

The predicted outcomes of the NER models following extensive training, testing, and hyperparameter optimization are detailed in Table 3. The statistical machine learning models, HMM and CRF, exhibited moderate performance. HMM showed relatively lower scores across all datasets, with AVG_MICRO scores of 0.7265, 0.825, and 0.6112 for the Revised JNLPBA, BC5CDR, and AnatEM datasets, respectively. Similarly, its AVG_MACRO was also lower, indicating limited effectiveness in capturing diverse entity types. On the other hand, the CRF model performed better than HMM, achieving higher AVG_MICRO scores of 0.8476, 0.9019, and 0.743 for the same datasets, respectively. The corresponding AVG_MACRO for CRF was also higher, reflecting its better overall accuracy and balance in entity recognition.

In contrast, the BERT-based deep learning models (BioBERT, RoBERTa, BigBird, and DeBERTa) consistently demonstrated a strong performance across multiple datasets. Notably, BioBERT achieved the highest results on the Revised JNLPBA and AnatEM datasets, with an AVG_MICRO of 0.932 and an AVG_MACRO of 0.9298 on the Revised JNLPBA dataset and an AVG_MICRO of 0.8494 and an AVG_MACRO of 0.6975 on the AnatEM dataset. However, on the BC5CDR dataset, these models performed slightly worse, with AVG_MICRO and AVG_MACRO values generally below 0.8726 and 0.858, respectively. This indicated that, while BERT-based models

exhibited robust performance in specific contexts, their generalization capabilities varied depending on the dataset characteristics.

The Gemma model demonstrated a strong performance on the BC5CDR dataset, achieving the highest AVG_MICRO of 0.9962 and an AVG_MACRO of 0.981. However, its results were less pronounced on the Revised JNLPBA and AnatEM datasets compared to BioBERT and other models.

Table 3. Model prediction accuracy comparison.

Model	Revised JNLPBA[a] dataset		BC5CDR[b] dataset		AnatEM[c] dataset	
	AVG_MICRO[d]	AVG_MACRO[e]	AVG_MICRO	AVG_MACRO	AVG_MICRO	AVG_MACRO

In addition, Figures 4 and 5 highlight the F_1-scores for each entity type achieved by the best-performing models in each category: statistical machine learning models (represented by CRF), deep learning NLP models based on BERT architecture (represented by BioBERT), and the Gemma LLM.

The performance of the CRF, BioBERT, and Gemma models on the Revised JNLPBA dataset showed distinct differences across various entity types. BioBERT consistently outperformed CRF and Gemma across most entity types. For instance, in the "B-DNA" entity type, BioBERT attained the highest score of 0.9057 compared to CRF's 0.7733 and Gemma's 0.8883. Gemma also demonstrated a high performance in several entity types, such as "B-protein" (0.9368) and "I-DNA" (0.9503). Nonetheless, it showed variability in other entity types, such as "B-RNA" (0.7925), where BioBERT achieved a significantly higher score (0.9177). While showing promising results in entity types such as "I-cell_line" (0.8911), the CRF model generally performed lower than BioBERT and Gemma. Notably, CRF's performance in the "I-RNA" entity type (0.7655) was significantly lower than that of both BioBERT (0.9403) and Gemma (0.8652).

In the BC5CDR dataset, Gemma consistently outperformed CRF and BioBERT across most entity types. For instance, in the "B-Disease" entity type, Gemma achieved an F_1-score of 0.9806, significantly higher than that of CRF (0.8993) and BioBERT (0.8615). Similarly, in the "I-Disease" entity type, Gemma attained the highest score of 0.9688 compared to CRF's 0.8497 and BioBERT's 0.7990. Gemma also demonstrated exceptional performance in the "B-Chemical" entity type (0.9926), surpassing CRF (0.9429) and BioBERT (0.9310). The "I-Chemical" entity type showed similar trends, with Gemma achieving an F_1-score of 0.9650, higher than that of CRF (0.8611) and BioBERT (0.8405). The CRF model exhibited moderate performance, achieving lower F_1-scores than Gemma but often outperforming BioBERT, particularly in the "B-Disease" and "B-Chemical" entity types.

In the AnatEM dataset, BioBERT consistently outperformed CRF and Gemma across most entity types. For instance, in the "B-Cell" entity type, BioBERT achieved an F_1-score of 0.9053, higher than that of both CRF (0.7879) and Gemma (0.8972). Similarly, in the "I-Cell" entity type, BioBERT attained the highest score of 0.9139 compared to CRF's 0.81 and Gemma's 0.8907. Gemma, while showing high performance in specific entity types such as "B-Cancer" (0.9259) and "I-Cancer" (0.9132), demonstrated more variability across different entity types. For example, Gemma's performance in the "I-Organ" entity type was lower (0.5714) than BioBERT's (0.6780). Although the CRF model showed promising results in specific entity types such as "B-Cancer" (0.844), it generally performed lower than BioBERT and Gemma. Mainly, CRF's performance in types such as "I-Organ" (0.2917) and "I-Developing_anatomical_structure" (0.00) was significantly lower than that of both BioBERT and Gemma.

Fine-Tuning Results of the BERT-Based Models

On the basis of the observations from Figures 6 and 7, the fine-tuning of models based on BERT architecture (BioBERT, BigBird, DeBERTa, and RoBERTa) across the Revised JNLPBA, BC5CDR, and AnatEM datasets demonstrated that a learning rate of 0.0001 consistently yielded the best prediction accuracy. However, the optimal configurations for batch size, epochs, and dropout rate varied significantly among the models and datasets.

BioBERT achieved an AVG_MICRO of 0.932 on the Revised JNLPBA dataset with a batch size of 50, a dropout rate of 0.5, and 5 epochs. On the BC5CDR dataset, it reached an AVG_MICRO of 0.8726 with a lower dropout rate of 0.1, a batch size of 10, and 10 epochs, whereas on the AnatEM dataset, an AVG_MICRO of 0.8494 was obtained with a dropout rate of 0.1, a batch size of 50, and 5 epochs.

BigBird consistently performed best with a batch size of 50 and 10 epochs, achieving an AVG_MICRO of 0.9277 on the Revised JNLPBA dataset. It also showed a strong performance on the BC5CDR and AnatEM datasets, with AVG_MICRO scores of 0.8461 and 0.8147, respectively.

Figure 6. Fine-tuning results of Bidirectional Encoder Representations from Transformers (BioBERT) and Big Transformer Models for Efficient Long-Sequence Attention (BigBird)—microaverage (AVG_MICRO) scores across datasets. (A) The figure shows AVG_MICRO scores for BioBERT across datasets. (B) The figure shows AVG_MICRO scores for BigBird across datasets. AVG_MICRO is used as the sole leveraged metric because both the AVG_MICRO and macroaverage metrics exhibit similar trends, generally increasing or decreasing. This similarity indicates that using AVG_MICRO alone is sufficient to understand the overall performance of the models, making the results more straightforward and focused. AnatEM: Anatomical Entity Mention; BC5CDR: BioCreative V CDR; BERT: Bidirectional Encoder Representations From Transformers; JNLPBA: Joint Workshop on Natural Language Processing in Biomedicine and its Applications.

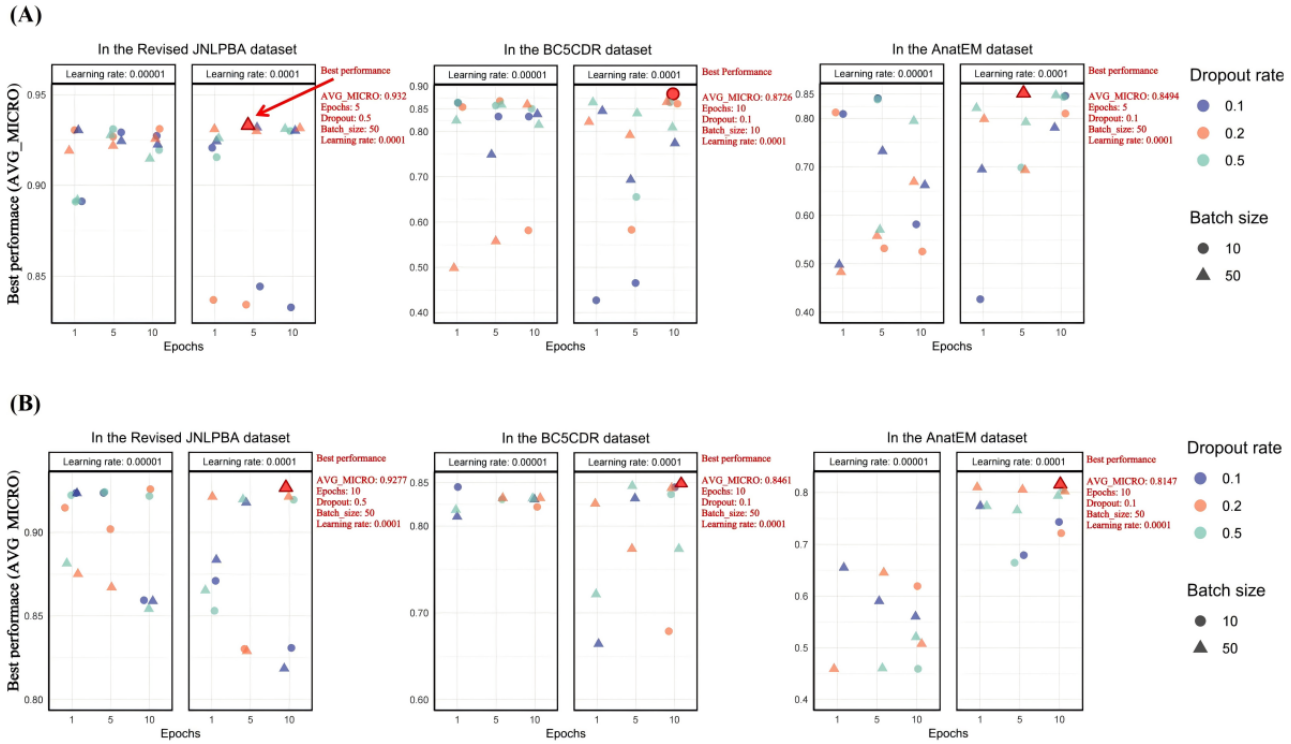

Figure 7. Fine-tuning results of the Decoding-enhanced Bidirectional Encoder Representations from Transformers (BERT) with Disentangled Attention (DeBERTa) and Robustly Optimized BERT Pretraining Approach (RoBERTa) models—microaverage (AVG_MICRO) scores across datasets. (A) The figure shows AVG_MICRO scores for DeBERTa across datasets. (B) The figure shows AVG_MICRO scores for RoBERTa across datasets. AnatEM: Anatomical Entity Mention; BC5CDR: BioCreative V CDR; JNLPBA: Joint Workshop on Natural Language Processing in Biomedicine and its Applications.

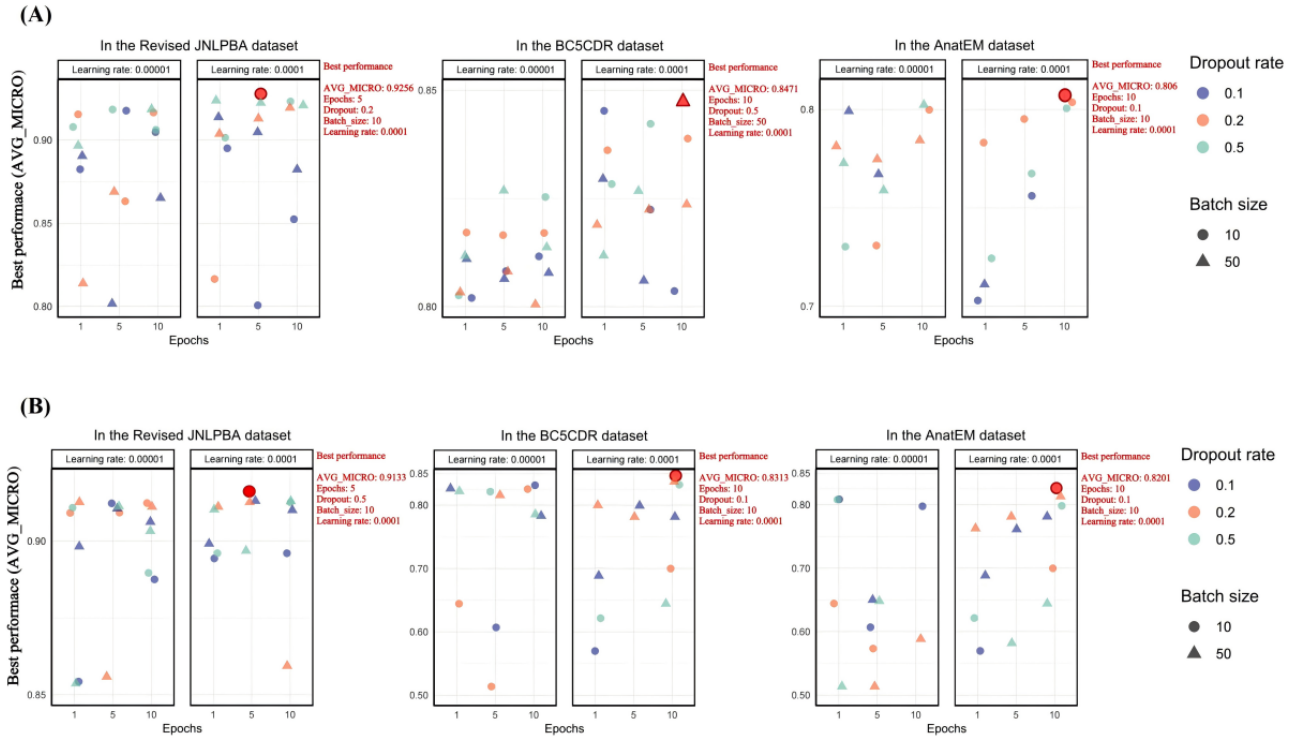

DeBERTa recorded an AVG_MICRO of 0.9256 on the Revised JNLPBA dataset with a batch size of 10, a dropout rate of 0.2, and 5 epochs. On the BC5CDR dataset, it achieved an AVG_MICRO of 0.8471 with a higher dropout rate of 0.5, a batch size of 50, and 10 epochs. For the AnatEM dataset, an AVG_MICRO of 0.806 was achieved with a dropout rate of 0.1, a batch size of 10, and 10 epochs.

RoBERTa demonstrated optimal performance across the 3 datasets using a batch size of 10. On the Revised JNLPBA dataset, RoBERTa achieved an AVG_MICRO of 0.9313 with a dropout rate of 0.5 and 5 epochs. On the BC5CDR dataset, it obtained an AVG_MICRO of 0.8313 with a dropout rate of 0.1 and 10 epochs. Similarly, on the AnatEM dataset, RoBERTa achieved an AVG_MICRO of 0.8201 with a dropout rate of 0.1 and 10 epochs.

These results underscore the critical role of hyperparameter tuning as each model and dataset required specific configurations to achieve optimal performance. While a consistent learning rate of 0.0001 was effective across all models, batch size, epoch, and dropout rate variations were necessary to adapt to the specific characteristics of different datasets and model architectures.

Fine-Tuning Results of the Gemma Model

Table 4 shows significant improvements in the Gemma model's performance metrics after fine-tuning using the LoRA technique across various datasets. The AVG_MICRO metric increased by 0.0245 for the Revised JNLPBA dataset, by 0.0111 for the BC5CDR dataset, and by 0.0083 for the AnatEM dataset. Similarly, the AVG_MACRO metric increased by 0.0173 for the Revised JNLPBA dataset, decreased by 0.0027 for the BC5CDR dataset, and increased by 0.0192 for the AnatEM dataset.

Table 4. Comparison of prediction accuracy (as microaverage [AVG_MICRO] and macroaverage [AVG_MACRO] metrics) for the Gemma model before and after fine-tuning on different datasets.

Model, dataset, and leveraged metrics	Before fine-tuning	After fine-tuning
Revised JNLPBA[a]		
AVG_MICRO	0.8843	0.9088
AVG_MACRO	0.8125	0.8298
BC5CDR[b]		
AVG_MICRO	0.9851	0.9962
AVG_MACRO	0.9837	0.9810
AnatEM[c]		
AVG_MICRO	0.7946	0.8029
AVG_MACRO	0.6304	0.6496

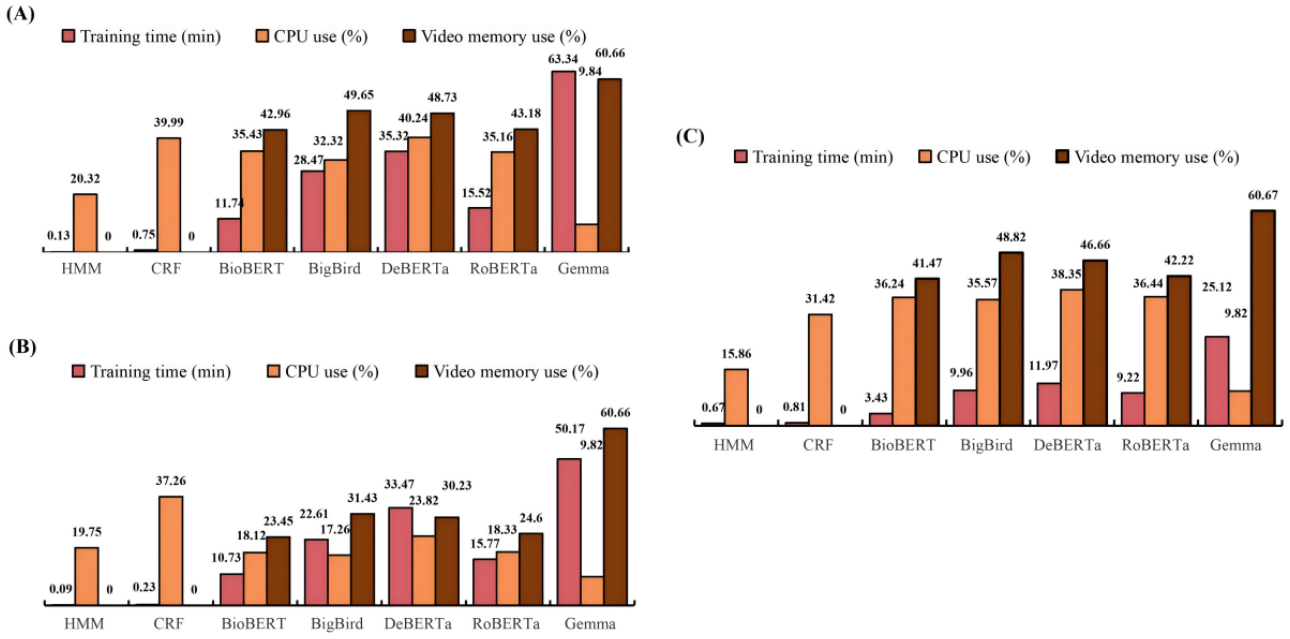
[c]AnatEM: Anatomical Entity Mention.

Model Resource Use Results

Overview

In evaluating prediction accuracy among the HMM, CRF, RoBERTa, BigBird, DeBERTa, BioBERT, and Gemma models, we documented their training time, CPU use, and GPU memory consumption performance, as shown in Figure 8.

Figure 8. Training time and central processing unit (CPU) and graphics processing unit (GPU) uses of the models. (A) The figure shows the resource use results on the Revised Joint Workshop on Natural Language Processing in Biomedicine and its Applications (JNLPBA) dataset. (B) The figure shows the resource use results on the BioCreative V CDR (BC5CDR) dataset. (C) The figure shows the resource use results on the Anatomical Entity Mention (AnatEM) dataset. BERT: Bidirectional Encoder Representations from Transformers; BioBERT: Bidirectional Encoder Representations from Transformers for Biomedical Text Mining; CRF: conditional random fields; DeBERTa: Decoding-enhanced BERT with Disentangled Attention; HMM: hidden Markov model; RoBERTa: Robustly Optimized BERT Pretraining Approach; BigBird: Big Transformer Models for Efficient Long-Sequence Attention.



Training Time

Gemma consistently required the most extended training times across all datasets, reaching a peak of 63.34 minutes in the Revised JNLPBA dataset. In stark contrast, HMM was notably more efficient, completing training in only 0.13 minutes in the same dataset and a mere 0.09 minutes in the BC5CDR dataset.

CPU Use

DeBERTa recorded the highest CPU use—40.24% and 38.35% in the Revised JNLPBA and AnatEM datasets, respectively. In the BC5CDR dataset, CRF had the highest CPU use at 37.26%. In contrast, Gemma demonstrated minimal CPU requirements, with use rates consistently at approximately 10% across all 3 datasets.

GPU Memory Consumption

Gemma had the highest GPU use, with rates consistently at approximately 61% across all 3 datasets. In contrast, the HMM and CRF traditional machine learning models recorded zero GPU use. This is because these models primarily rely on the CPU for their computations and do not leverage the parallel processing capabilities of GPUs, which are designed to accelerate deep learning tasks. Among the BERT-based models, BioBERT exhibited the lowest GPU use, consuming 42.96% and 41.47% in the Revised JNLPBA and AnatEM datasets, respectively, and only 23.45% in the BC5CDR dataset. This lower GPU consumption indicates that BioBERT, while still using GPU resources, does so more efficiently than Gemma, potentially due to its optimized architecture and more efficient use of GPU memory for processing.

Overall

Gemma required significant resources and was characterized by the highest GPU use across all datasets and the most extended training times. This computational intensity may enhance accuracy but comes at the cost of increased operational resources. In contrast, BioBERT demonstrated high prediction accuracy and lower resource consumption among the deep learning models, indicating its efficiency and suitability for environments with strict resource constraints.

Entity Type Prediction Accuracy Results

On the basis of the data presented in Figure 9, we identified specific strengths in different models using a categorical relaxation method to merge entity types. Gemma achieved the highest prediction accuracy in the “chemical,” “disease,” “pathological formation,” and “immaterial anatomical entity” types, whereas BioBERT excelled in the “organism substance” entity type. DeBERTa performed best in the “macromolecule” and “anatomical structure” entity types, demonstrating its strengths. In addition, BigBird showed a superior performance in the “cell” type.

Figure 9. Relationship between the models' prediction accuracy and merged entity types. Macrofactor Trends Impacting Model Prediction Accuracy

The results of this section primarily involve the trend relationships between the prediction accuracy of 7 NER models and 6 macrofactor metrics, focusing on the average values of these metrics across various datasets.

In the AnatEM dataset, as depicted in Figure 10, there was a distinct correlation—entity types that yielded higher prediction accuracies corresponded to increased values in *sLen*, *eLen*, *eNum*, *eDen*, and *tEWC*. This pattern indicates that the model's ability to accurately predict entities is enhanced with the rising complexity and volume of data associated with those entity types. Conversely, an inverse relationship was observed with *elCon*, which decreased as the other metrics increased. For instance, BioBERT recorded a high prediction accuracy of 90.96% in the "cell" entity type. This outstanding performance correlated with the highest metrics observed in the dataset—*sLen* peaked at 216.78, *eLen* peaked at 8.32, *eNum* peaked at 1.94, and *eDen* peaked at 0.03838. Then, the "cell" entity type's *tEWC* was notably high at 2436, demonstrating the BioBERT's ability to process extensive textual data effectively. However, *elCon* was significantly lower at 0.4642. This indicates that, although this model is adept at managing complex and voluminous data, it does not consistently ensure accurate entity labeling, suggesting a trend in which higher accuracy and complexity metrics do not correspond with label consistency.

Figure 10. Relationship between macrofactors and model prediction accuracy in the Anatomical Entity Mention (AnatEM) dataset. BERT: Bidirectional Encoder Representations from Transformers; BigBird: Big Transformer Models for Efficient Long-Sequence Attention; BioBERT: Bidirectional Encoder Representations from Transformers for Biomedical Text Mining; CRF: conditional random fields; DeBERTa: Decoding-enhanced BERT with Disentangled Attention; eDen: entity density; elCon: entity label consistency; eLen: entity phrase length; eNum: number of entity words in each entity phrase; HMM: hidden Markov model; RoBERTa: Robustly Optimized BERT Pretraining Approach; sLen: sentence length; tEWC: total entity word count in each entity type.

	Immaterial_anatomical_entity	Organism_subdivision	Developing_anatomical_structure	Anatomical_system	Pathological_formation	Tissue	Multi-tissue_structure	Organ	Organism_substance	Cellular_component	Cancer	Cell
HMM	27.68	38.41	18.18	54.09	43.03	55.94	58.37	50.89	65.14	63.19	79.20	72.49
CRF	28.49	24.8	14.59	36.96	45.24	63.68	64.09	48.51	63.66	60.52	83.28	79.89
BigBird	26.74	27.41	38.36	43.30	59.97	63.53	70.93	56.56	72.78	71.79	88.22	87.58
RoBERTa	36.55	20.21	34.29	65.28	56.77	57.66	67.10	65.65	76.91	69.93	88.56	87.66
DeBERTa	28.92	52.65	60.84	67.13	66.05	67.75	69.48	69.06	73.59	86.93	89.97	88.16
BioBERT	35.67	53.03	66.38	51.75	66.89	68.34	75.12	75.75	79.59	83.02	90.50	90.96
Gemma	37.69	50.66	46.56	63.39	68.26	67.95	76.41	68.16	75.64	75.97	91.96	89.40

The Revised JNLPBA dataset substantiated these observations, as shown in Figure 11. The "cell_type" entity type generally yielded a higher accuracy among the 7 models, showing elevated values for *sLen*, *eLen*, *eNum*, and *eDen*, with average values recorded at 187.12 (SD 10.52), 7.76 (SD 1.24), 1.91 (SD 0.32), and 0.0372 (SD 0.005), respectively. This indicated that the models achieved high accuracy and effectively handled denser entity distributions. Moreover, there seemed to be a negative correlation between higher values of *elCon* and *tEWC* and these accuracies. In addition, a comparable trend emerged in the BC5CDR dataset, where the "chemical" entity type yielded the highest accuracy across the RoBERTa, DeBERTa, and BioBERT models, aligning with the highest measurements of *sLen*, *eLen*, *eNum*, *eDen*, and *tEWC*, coupled with the lowest value of *elCon*.

Macrofactor Selection Results

Examining Tables 5-7, the results from the MFE algorithm reveal the importance of different macrofactors across various models and datasets. In the CRF model, *eNum* was identified as the most influential macrofactor for prediction accuracy in the Revised JNLPBA and AnatEM datasets. In contrast, *eLen* was found to be more influential in the BC5CDR dataset. This finding indicates that the *eNum* and *eLen* play varying roles depending on the dataset's characteristics. The Gemma model exhibited results similar to those of the CRF model, with *eNum* significantly impacting prediction accuracy for the Revised JNLPBA and AnatEM datasets. At the same time, *eLen* significantly influenced prediction accuracy for the BC5CDR dataset.

In the BioBERT model, *eNum* consistently emerged as the most critical macrofactor across all datasets (Revised JNLPBA, BC5CDR, and AnatEM); despite varying macrofactor combinations in the initial 2 layers, *eNum* was consistently chosen for the final layer. This indicates that, among the 6 macrofactors, *eNum* significantly influences BioBERT's prediction accuracy.

Discussion

Principal Findings

This study comprehensively evaluated various NER models in medical informatics, focusing on prediction accuracy, resource use, and the impact of macrofactors and hyperparameters. The primary findings indicate that BERT-based models (BioBERT, RoBERTa, BigBird, and DeBERTa) exhibited generally higher accuracy than traditional statistical models (HMM and CRF). These BERT-based models, fine-tuned using the ADAM optimizer with a consistent learning rate of 0.0001, demonstrated outstanding performance. Among them, BioBERT excelled due to its specialized pretraining on extensive medical literature. The Gemma LLM, fine-tuned using the LoRA technique, achieved the highest accuracy on the BC5CDR dataset but showed variability across the other datasets, highlighting the need for further optimization. Macrofactors such as "entity phrase length (*eLen*)" and "the number of entity words in each entity phrase (*eNum*)" significantly influenced model performance, with the MFE algorithm effectively filtering these macrofactors. Computational resource use revealed that, while Gemma required substantial resources, BioBERT was a balanced NER model with high prediction accuracy and lower computational demands, making it suitable for resource-constrained environments. These findings underscore the importance of continuous refinement and dataset-specific optimization to advance NER capabilities in medical informatics.

Evaluation of Predictive Performance Across NER Models

Evaluating various NER models on medical datasets provides significant insights into their strengths and limitations, highlighting the complexity of accurately identifying and categorizing medical entities. The performance disparity among statistical machine learning models, deep learning models based on BERT architecture, and the Gemma LLM is evident, with the latter 2 consistently demonstrating superior accuracy and robustness.

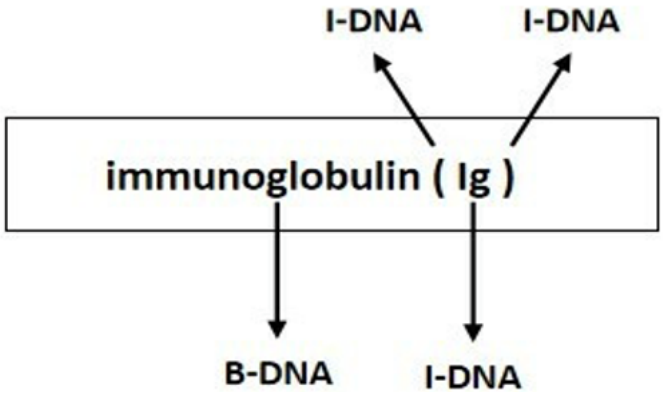
Statistical machine learning models such as HMM and CRF exhibited a moderate performance in medical NER tasks. The HMM's relatively lower scores across all datasets, with AVG_MICRO scores of 0.7265, 0.825, and 0.6112 for the Revised JNLPBA, BC5CDR, and AnatEM datasets, respectively, reflected its limited capacity to capture the nuanced patterns inherent in medical texts. While CRF outperformed HMM with higher AVG_MICRO scores of 0.8476, 0.9019, and 0.743 for the same datasets, respectively, it still fell short compared to the deep learning models. This indicates inherent limitations in CRF's feature engineering and sequence modeling capabilities, which are less adept at handling the complexity and variability of medical entities.

In contrast, the BERT-based models (BioBERT, RoBERTa, BigBird, and DeBERTa) consistently demonstrated a strong performance across multiple datasets. BioBERT's superior performance on the Revised JNLPBA and AnatEM datasets, with AVG_MICRO scores of 0.932 and 0.8494 and AVG_MACRO scores of 0.9298 and 0.6975, respectively, can be attributed to its specialized pretraining on large-scale medical literature. This pretraining allows BioBERT to capture domain-specific nuances, enhancing its ability to recognize and classify complex medical entities accurately. In the Revised JNLPBA dataset, BioBERT achieved the highest F_1-scores in categories such as "B-DNA" (0.9057) and "I-cell_type" (0.9550), showcasing its robust generalization capabilities. However, the slightly lower performance of these models on the BC5CDR dataset, where AVG_MICRO and AVG_MACRO scores were generally below 0.8726 and 0.858, respectively, suggests potential overfitting or sensitivity to the specific characteristics of this dataset. This variability underscores the necessity for further fine-tuning and incorporating additional domain-specific knowledge to improve the models' generalization capabilities across diverse datasets.

The Gemma LLM demonstrated exceptional performance on the BC5CDR dataset, achieving the highest AVG_MICRO score of 0.9962 and an AVG_MACRO score of 0.981. In specific entity types within this dataset, Gemma attained F_1-scores of 0.9806 in "B-Disease" and 0.9926 in "B-Chemical," indicating its strong capability to recognize these entities. This suggests that Gemma's architecture and training regimen are particularly well suited for this dataset, which contains only 2 entity types (disease and chemical). The narrow focus of the BC5CDR dataset may have allowed Gemma to optimize its performance more effectively than on more complex datasets with diverse entity types. However, Gemma's less pronounced results on the Revised JNLPBA and AnatEM datasets, with AVG_MICRO scores of 0.9088 and 0.8029 and AVG_MACRO scores of 0.8298 and 0.6496, respectively, indicate that, while it excels in binary entity recognition, it may require further adjustments to handle more complex, multi-entity datasets effectively. In the Revised JNLPBA dataset, for instance, Gemma showed a high performance in categories such as "B-protein" (0.9368) and "I-DNA" (0.9503) but struggled in "B-RNA" (0.7925) compared to BioBERT's 0.9177, highlighting areas for potential improvement.

Furthermore, we found significant variability in prediction accuracy across different entity types for models such as BioBERT, Gemma, and CRF, as evidenced by contrasting F_1-scores for entities like 'B-Developing_anatomical_structure' and 'I-Immaterial_anatomical_entity.' This inconsistency, illustrated in Figures 4 and 5, is primarily attributed to 2 interrelated factors: uneven data distribution and the complexities inherent in medical terminologies. First, uneven data distribution and noise in datasets such as the Revised JNLPBA, BC5CDR, and AnatEM impeded the models' ability to fully understand and accurately predict underrepresented entity types, affecting their overall performance. For example, the "protein" and "cell_type" entities in the Revised JNLPBA dataset are significantly more abundant (5256 and 2070 entity words, respectively) compared to "cell_line" and "RNA" (404 and 161 entity words, respectively). Second, multiple entity types for a single entity word complicate prediction. For instance, in the Revised JNLPBA dataset, certain symbols function as entity words within entity phrases. As depicted in Figure 12, the parentheses in the entity phrase "immunoglobulin (Ig)" from the training set are categorized as the "I-DNA" entity type. However, when predicting the entity types of parentheses in the test set, the models occasionally misclassify them as "I-DNA" even though they do not belong to this entity type in some contexts. Specifically, the phrase "(PCBA)" in the test set is not recognized as an entity phrase. However, the models may erroneously assign the parentheses to the "I-DNA" entity type, leading to prediction errors.

Figure 12. Entity type division.



These findings underscore the importance of selecting and optimizing models based on the specific characteristics of the datasets to which they are applied. The consistent performance of the deep learning models, particularly those based on BERT architecture, and the promising results from LLMs such as Gemma highlight the potential for advanced NER models to improve medical entity recognition significantly. However, achieving optimal results across diverse medical contexts will require continuous refinement and adaptation of these models to the unique nuances of each dataset.

Impact of Hyperparameters and Optimizer on the Fine-Tuning of the BERT-Based Models

The fine-tuning results of the BERT-based models (BioBERT, BigBird, DeBERTa, and RoBERTa) across the Revised JNLPBA, BC5CDR, and AnatEM datasets reveal the significant role of hyperparameter tuning and the effectiveness of the ADAM optimizer in achieving optimal prediction accuracy in medical NER tasks.

The consistent use of the ADAM optimizer with a learning rate of 0.0001 across all models demonstrated its efficacy in fine-tuning BERT-based architectures. The ADAM optimizer's adaptive learning rate mechanism, which adjusts based on the first and second moments of the gradients, ensures efficient and effective convergence. This balance is crucial for fine-tuning complex models such as BERT and its variants as it mitigates the risk of overshooting the optimal point or converging too slowly. The success of this learning rate underscores the importance of selecting a rate that balances convergence speed and accuracy.

Beyond the learning rate, hyperparameters such as batch size, epochs, and dropout rate were critical in determining model performance. Optimal configurations for these parameters varied significantly across models and datasets, emphasizing the need for dataset-specific and model-specific tuning. For instance, BioBERT achieved an AVG_MICRO of 0.932 on the Revised JNLPBA dataset with a batch size of 50, a dropout rate of 0.5,

and 5 epochs. In contrast, a smaller batch size of 10 was necessary for optimal prediction accuracy on the BC5CDR dataset. This variation illustrates how dataset characteristics heavily influence batch size selection; larger batch sizes can improve computational efficiency by leveraging the parallel processing capabilities of GPUs, whereas smaller batch sizes may allow for more frequent updates and better convergence.

The number of epochs required to achieve optimal prediction accuracy also showed variability, indicating the need for tailored training durations based on dataset complexity. BioBERT needed 5 epochs for the Revised JNLPBA dataset but 10 epochs for the BC5CDR dataset, suggesting that more training iterations are essential for specific datasets to fully capture their complexity and variability. Different datasets may demand varied training durations to achieve optimal performance.

The dropout rate, a critical parameter to prevent overfitting, exhibited significant variation across models and datasets. BioBERT, BigBird, and RoBERTa demonstrated better prediction accuracy with a lower dropout rate of 0.1 on the BC5CDR dataset, whereas a higher dropout rate of 0.5 was optimal for the Revised JNLPBA dataset. This variation underscores the differing overfitting risks and regularization needs across datasets. Higher dropout rates can prevent overfitting in more straightforward datasets but may hinder performance in more complex datasets requiring nuanced learning.

These findings emphasize the critical role of hyperparameter tuning in fine-tuning BERT-based models. While the ADAM optimizer with a learning rate of 0.0001 proved adequate, batch size, epochs, and dropout rate required careful adjustment to the specific characteristics of each dataset and model architecture. This variability highlights the necessity of a tailored approach in hyperparameter optimization to achieve optimal prediction accuracy. The consistent performance of deep learning models based on BERT architecture underscores their potential for significantly improving medical NER tasks. However, achieving optimal results across diverse medical contexts will require continuous refinement and adaptation of these models to the unique nuances of each dataset.

Impact of Hyperparameters and Optimizers on the Fine-Tuning of the Gemma Model

The fine-tuning of the Gemma model using the LoRA technique led to significant improvements in its performance metrics across various medical NER tasks, as shown in Table 4. The consistent increases in AVG_MICRO metrics across 3 datasets demonstrate the effectiveness of LoRA in enhancing model accuracy. Although the AVG_MACRO metric declined in one dataset, it still improved in the other two, reaffirming LoRA's overall positive impact on model performance.

LoRA involves freezing the pretrained model weights and introducing trainable low-rank decomposition matrices in each transformer layer, significantly reducing the number of trainable parameters and GPU memory requirements. By optimizing these low-rank matrices, LoRA adapts the model to specific tasks without the computational burden of retraining the entire model. This technique focuses on adjusting the weights of hyperparameters rather than changing their values, allowing for more precise and efficient fine-tuning. The learning rate, managed using a cosine learning rate scheduler with a warm-up ratio of 0.1, ensures stable and efficient convergence. The consistent use of a learning rate of 0.0001 across various datasets demonstrated its effectiveness in balancing convergence speed and accuracy.

Hyperparameters such as batch size, epochs, and dropout rate were critical in determining model performance. Although their values remained constant during the LoRA fine-tuning process, the adjustments made by LoRA allowed the model to adapt effectively to the specific characteristics of each dataset. For instance, the Revised JNLPBA dataset benefited from a larger batch size and fewer epochs. In comparison, the BC5CDR dataset required a smaller batch size and more epochs to capture its complexities adequately. This variability underscores the importance of dataset-specific configurations in hyperparameter tuning to maximize model performance.

The dropout rate, crucial for preventing overfitting, also showed a significant impact depending on the dataset's structure. For example, the Revised JNLPBA dataset, with its more straightforward structure, benefited from its original higher dropout rate, providing more robust regularization. Conversely, the BC5CDR and AnatEM datasets, with their more complex structures, yielded a better performance with their original lower dropout rates, allowing the model to retain more information during training. This finding highlights the necessity of understanding the specific regularization needs of each dataset to optimize model performance effectively.

The consistent improvement in AVG_MICRO and AVG_MACRO metrics demonstrates the enhanced generalization capability of the Gemma model after fine-tuning. These improvements are particularly significant for medical NER tasks, where precise entity recognition is critical for extracting meaningful information from complex texts. The results suggest that LoRA enables Gemma to capture nuanced patterns within the datasets more effectively, leading to better prediction accuracy and balanced performance across different entity types. Furthermore, the fine-tuning of the Gemma model using the LoRA technique highlights the critical role of weight adjustment in hyperparameter tuning and advanced optimization strategies in improving model performance. The significant improvements observed emphasize the potential of LoRA in efficiently adapting large-scale models to specialized tasks, making them more practical for deployment in various medical contexts.

Evaluation of Resource Use Across NER Models

Gemma consistently required the most extended training times across all datasets, peaking at 63.34 minutes in the Revised JNLPBA dataset. This extended training duration reflects Gemma's complex architecture, including numerous layers and parameters. The model's intricate design requires significant processing power and time to adjust its parameters accurately through extensive training iterations.

Regarding CPU use, DeBERTa recorded the highest use in the Revised JNLPBA and AnatEM datasets, with use rates of

40.24% and 38.35%, respectively. DeBERTa's high CPU use indicates its sophisticated architecture, which includes enhanced attention mechanisms and deeper layers compared to other models. These features demand substantial computational resources, leading to increased CPU consumption. The model's reliance on complex attention mechanisms to capture fine-grained dependencies within the text likely contributes to its higher computational intensity, impacting its efficiency in resource-constrained environments.

In the BC5CDR dataset, CRF exhibited the highest CPU use, reaching 37.26%. This high CPU use can be attributed to the intensive computations required for feature extraction and sequence labeling in a dataset with relatively more straightforward entity types. While less complex than the deep learning models, the CRF model still requires significant CPU resources for processing and optimizing the conditional dependencies between the labels, especially when the dataset has clear, well-defined entity types that increase the computational workload.

In contrast, Gemma demonstrated minimal CPU requirements, maintaining use rates of approximately 10% across all datasets. This low CPU use suggests that Gemma offloads most of its computational workload to the GPU, leveraging its parallel processing capabilities to handle the model's complex computations more efficiently. Gemma's architecture is designed to exploit GPU parallelism, which allows for faster processing of large batches of data, thereby reducing the strain on the CPU. Thus, Gemma had the highest GPU use, consistently at approximately 61% across all datasets. This high GPU use underscores Gemma's dependency on GPU resources to manage its computationally intensive tasks. The model's architecture, characterized by numerous layers and a high parameter count, requires substantial GPU resources for the parallel processing needed during training and inference. The reliance on GPUs is due to their ability to handle multiple operations simultaneously, which is essential for deep learning models with large-scale parameters and complex computations.

BioBERT demonstrated the lowest GPU use among the BERT-based models, consuming 42.96% and 41.47% on the Revised JNLPBA and AnatEM datasets, respectively, and only 23.45% on the BC5CDR dataset. BioBERT's lower GPU consumption can be attributed to its optimized architecture and efficient memory management, allowing it to balance computational demands with performance effectively. BioBERT's design leverages GPU resources efficiently, ensuring that it can achieve high accuracy without excessively taxing computational resources.

Overall, Gemma's significant resource requirements, evidenced by the fact that it had the highest GPU use and longest training times, highlight that its enhanced accuracy comes at a substantial cost in operational resources. The model's advanced architecture necessitates extensive computational power to manage the large-scale parallel processing required for its numerous parameters and layers. This makes Gemma suitable for environments in which accuracy and abundant resources are paramount. In contrast, BioBERT's combination of high prediction accuracy and lower resource consumption underscores its efficiency and suitability for environments with strict resource constraints. BioBERT's ability to balance performance with resource use makes it versatile for various medical NER applications. These findings emphasize the importance of selecting NER models based on the deployment environment's specific resource availability and operational constraints. Future research should focus on optimizing the computational efficiency of NER models without compromising their performance, ensuring that they can be effectively deployed across various medical contexts.

Variability in Prediction Accuracy Across Entity Types in NER Models

Gemma demonstrated a superior performance in the entity categories of "chemical," "disease," "pathological formation," and "immaterial anatomical entity," likely due to its advanced design in feature extraction and semantic representation. Gemma uses optimized embedding techniques and attention mechanisms specifically tailored to manage the complexities inherent in these categories. For example, Gemma may use molecular property–based embedding representations in chemical entity recognition, enabling it to capture critical features of chemical substances. Gemma integrates rich medical ontologies and knowledge graphs in the context of diseases and pathological formations, enhancing its understanding of medical terminology and complex pathological descriptions. In addition, Gemma's attention mechanisms focus on critical segments of the text, improving performance in recognizing immaterial anatomical entities.

BioBERT's outstanding performance in the "organism substance" entity category can be attributed to its extensive pretraining in medical literature, particularly that covering organism substances. On the basis of the BERT bidirectional transformer architecture, BioBERT captures long-range dependencies in complex medical texts. The intricate language and contextual information in organism substance literature are effectively parsed by BioBERT's architecture, leading to superior performance in this category. However, BioBERT's performance in the "chemical" category was not as strong as Gemma's, possibly because its pretraining data focus more on organism-related content than on chemical substances' specific features.

DeBERTa's superior performance in the "macromolecule" and "anatomical structure" entity categories was due to its innovative attention mechanisms and position encoding methods. Macromolecules and anatomical structures often exhibit high complexity and a hierarchical nature. DeBERTa's disentangled attention mechanism allows for a fine-grained capture of internal relationships and hierarchical information within these complex structures. Its enhanced position encoding method effectively represents these complex medical entities, leading to an outstanding performance in these categories.

BigBird's excellent performance in the "cell" entity category reflects its ability to handle long texts. Texts in cell biology are typically very detailed and information dense. BigBird's architecture allows for more oversized context windows, enabling effective processing and analysis of these extensive texts. BigBird maintains efficiency and accuracy through its

sparse attention mechanism, resulting in significant advantages in precisely classifying cell types.

This analysis reveals the necessity for a refined approach to improving medical NER models, emphasizing that, while extensive dataset training can improve the overall accuracy, architectural adjustments and targeted training are essential to mitigate disparities in model performance across diverse entity types. Therefore, enhancing the accuracy and robustness of NER models involves increasing the variety and volume of training data and optimizing model architectures to address the specific challenges posed by less represented or more intricate entity types.

Influence of Macrofactors on Prediction Accuracy in Medical NER

In analyzing how macrofactor metrics influence prediction accuracy across various medical entity types within 7 NER models, we observed significant nuances that reflect the complexity of modeling in medical NER tasks. Notably, entities characterized by higher values in *sLen*, *eLen*, *eNum*, and *eDen* generally yielded better prediction accuracy. This correlation suggests that entities with more extensive and detailed textual representations tend to be predicted more accurately, highlighting the models' capacity to handle intricate data structures effectively. However, a notable exception arises with *elCon*, which inversely correlated with these metrics, indicating a potential trade-off between detailed data processing and consistent label accuracy.

This phenomenon is further complicated by the varying impact of the *tEWC* on prediction accuracy across different datasets. For example, in the Revised JNLPBA dataset, lower *tEWC* values were associated with higher accuracies, suggesting that models perform better with more concise entity representations. In contrast, other datasets showed that higher *tEWC* values, indicative of richer contextual data, enhanced model performance. This inconsistency underscores the complex influence of data characteristics on model effectiveness and suggests that the optimal balance of data quantity and quality varies significantly across datasets. Therefore, tailored model training and data preparation strategies are essential to optimize prediction accuracy according to the unique characteristics of each dataset.

These observations necessitate a strategic approach to model training and data preparation that considers the unique demands of each dataset. While handling more extensive datasets can lead to better entity recognition in some contexts, balancing this with the need for precision and consistency in entity labeling is crucial. As NER technologies evolve, it becomes imperative to refine model architectures and training methodologies to ensure that models can manage the dual challenges of complexity and volume without sacrificing accuracy.

Refining Macrofactor Sensitivity to Improve NER Model Precision

Using the MFE algorithm for hierarchical macrofactor screening, *eNum* or *eLen* in each entity phrase had the most significant impact on the prediction accuracy of NER models. Unlike broader textual metrics such as *sLen* that provide general context, *eNum* directly measures the complexity of entities, whereas *eLen* captures the length of entity phrases. These factors significantly influence how models process and interpret dense information. A higher *eNum* generally indicates semantically rich entities that are potentially more challenging to analyze. At the same time, a higher *eLen* suggests that entity phrases contain more detailed and extended descriptions requiring careful parsing.

The consistent selection of *eNum* or *eLen* in the final layer of the screening process across various datasets underscores their pivotal role in enhancing the precision of entity recognition. The impact of *eNum* on model accuracy suggests that entities with a higher density of words require sophisticated model capabilities to discern and categorize detailed information accurately. Similarly, entities with longer phrases (*eLen*) present a challenge as they involve more complex syntactic and semantic structures that must be interpreted correctly.

Therefore, refining models' ability to analyze entities with higher *eNum* or longer *eLen* values could be a strategic approach to advancing NER technologies, particularly in domains such as medicine, where precise and reliable entity recognition is crucial. Enhancing how models manage and use the detailed information encapsulated in *eNum* and *eLen* will improve the robustness and effectiveness of medical NER models, ensuring that they meet the complex demands of varied and extensive datasets.

Conclusions

Medical NER is a crucial component of medical informatics, essential for identifying and categorizing named entities within unstructured medical text data. A proficient NER model significantly enhances various downstream applications, such as medical text classification, question answering, and information retrieval. Developing a high-performance NER model requires a meticulous approach that includes selecting relevant macrofactors, designing the model's architecture, and curating specialized training data tailored to medical contexts.

Our evaluation method for NER models extends beyond general metrics such as accuracy, recall, and F_1-score by incorporating an extensive analysis of macrofactors relevant to medical entities. This comprehensive approach enables a multidimensional evaluation of the models, providing insights into how different entity types, attributes, and contextual factors influence performance. For example, our findings indicate that, while "disease" frequently occurs in medical texts and requires high accuracy, entities such as "Immaterial_anatomical_entity" may not require the same precision. This discrepancy highlights the need for targeted optimization strategies for different entity types, which is crucial for advancing medical NER models.

In addition, our study explored the characteristics of entities to improve the creation of high-quality medical NER datasets and documents. This focus enhances the NER models' ability to identify entities accurately and addresses the specific needs of medical texts. While our analysis extensively covered macrofactors and their impact, it did not delve into misclassifications of entity labels or the fine-grained interactions between entity words. These areas could further refine our

understanding of model accuracy. Moreover, examining hardware performance illuminates these models' internal efficiency and resource use, which is crucial for their deployment in real-world scenarios.

In conclusion, evaluating medical NER models is essential for developing effective and precise NLP applications in health care. It gives medical researchers the insights to select and refine NER models suited to various medical scenarios, ultimately improving these systems' accuracy, robustness, and reliability. This foundational work sets the stage for future research that could explore the intricate relationships within NER systems, further enhancing the capabilities of medical informatics.

Abstract

Background: Proper analysis and interpretation of health care data can significantly improve patient outcomes by enhancing services and revealing the impacts of new technologies and treatments. Understanding the substantial impact of temporal shifts in these data is crucial. For example, COVID-19 vaccination initially lowered the mean age of at-risk patients and later changed the characteristics of those who died. This highlights the importance of understanding these shifts for assessing factors that affect patient outcomes.

Objective: This study aims to propose detection, initial characterization, and semantic characterization (DIS), a new methodology for analyzing changes in health outcomes and variables over time while discovering contextual changes for outcomes in large volumes of data.

Methods: The DIS methodology involves 3 steps: detection, initial characterization, and semantic characterization. Detection uses metrics such as Jensen-Shannon divergence to identify significant data drifts. Initial characterization offers a global analysis of changes in data distribution and predictive feature significance over time. Semantic characterization uses natural language processing–inspired techniques to understand the local context of these changes, helping identify factors driving changes in patient outcomes. By integrating the outcomes from these 3 steps, our results can identify specific factors (eg, interventions and modifications in health care practices) that drive changes in patient outcomes. DIS was applied to the Brazilian COVID-19 Registry and the Medical Information Mart for Intensive Care, version IV (MIMIC-IV) data sets.

Results: Our approach allowed us to (1) identify drifts effectively, especially using metrics such as the Jensen-Shannon divergence, and (2) uncover reasons for the decline in overall mortality in both the COVID-19 and MIMIC-IV data sets, as well as changes in the cooccurrence between different diseases and this particular outcome. Factors such as vaccination during the COVID-19 pandemic and reduced iatrogenic events and cancer-related deaths in MIMIC-IV were highlighted. The methodology also pinpointed shifts in patient demographics and disease patterns, providing insights into the evolving health care landscape during the study period.

Conclusions: We developed a novel methodology combining machine learning and natural language processing techniques to detect, characterize, and understand temporal shifts in health care data. This understanding can enhance predictive algorithms, improve patient outcomes, and optimize health care resource allocation, ultimately improving the effectiveness of machine learning predictive algorithms applied to health care data. Our methodology can be applied to a variety of scenarios beyond those discussed in this paper.

Introduction

Overview

Health care data are a critical resource that can be used to improve patient outcomes and the financial performance of health care institutions [1,2]. By analyzing patient data, health care providers can gain insights into patients' health status, identify trends, and make informed decisions about treatment plans. Properly collected, managed, treated, and interpreted health care data can help providers improve operational efficiency and reduce costs, thereby improving financial results [3].

One of the primary ways health care data can be used to enhance medical decisions and potentially improve patient outcomes is through predictive analysis. This technique uses historical data to identify patterns and predict future outcomes, thereby enabling the recognition of high-risk patients, the simulation of different therapeutic approaches, and the personalization of patient care. However, relying on historical data has its caveats, as the predictive capacity of different variables is not fixed over time. Ignoring these aspects of temporal data may lead to prediction errors and learning instabilities. These variations in performance are part of what is known as temporal data shifts [4-7].

A temporal data shift refers to a change in the statistical properties of a data set over time, which can degrade model accuracy. In health care, this may occur due to various reasons, including changes in data collection practices, software updates or replacements, changes in patient behavior or lifestyle habits,

and the introduction of new therapeutic technologies. These temporal events may lead to inconsistencies and discrepancies in the data, which may affect both the accuracy and reliability of the data and models trained on them. The impacts can be significant [4,7], as they can lead to incorrect diagnoses, inappropriate treatment plans, and poor patient outcome predictions. This highlights the importance of managing, characterizing, and mitigating these temporal effects [8].

We are particularly interested in how temporal data drifts can be used to analyze the effectiveness of new patient treatment options. Changes in predictive capacity can provide insights into the impact of new treatments on patient outcomes. For instance, by comparing data collected before and after introducing a new treatment, we can identify any shifts that may indicate improved patient outcomes. If the data drift analysis indicates a positive impact of the new treatment, health care providers may choose to continue to monitor the data to ensure that the positive effects are sustained while maintaining the use of the new therapeutic option [9].

A notable example of a condition that experienced an important data drift over time is the HIV infection. In the 1980s, HIV infection was a strong predictor of early death. However, it has now become more of a chronic condition, such as diabetes mellitus or systemic hypertension. In the same manner, advancements in breast cancer treatment have significantly increased survivorship over the years [10].

Similarly, several infectious diseases, such as poliomyelitis or measles, have been nearly eradicated in most parts of the world, making them unlikely hypotheses for new diagnoses [11,12]. In the case of COVID-19, vaccination has dramatically changed the profile of hospitalizations and deaths [4,13], initially decreasing the mean age of patients at risk and creating a clear distinction between the periods before and after vaccination.

Our Main Contribution: The Detection, Initial Characterization, and Semantic Characterization Methodology

Building upon the idea of analyzing data drifts to obtain insights into how and whether new technologies or treatments have impacted patient outcomes, this paper proposes a novel, 3-step health care temporal analysis methodology, called detection, initial characterization, and semantic characterization (DIS). The proposed DIS methodology is summarized in Figure 1. It consists of three main steps, (1) detection, (2) initial characterization, and (3) semantic characterization, which are described in the following sections.

In summary, we exploited various drift detection metrics in the detection step to identify any significant instances of data drift. Some of the metrics we explored in this step include Jensen-Shannon divergence [14], autoencoder reconstruction error [15], and centroid distances [16]. If changes were detected, we proceeded to the initial characterization step, where we obtained a global (data set–level) descriptive analysis of what changed and how the discriminative and predictive power of each feature and the distribution of labels evolved over time.

Additionally, we introduced the concept of temporal granularity in the data drift domain, which holds particular significance in health care data drifts and influences the instantiation of our third and final step. High temporal granularity is observed when a data set allows the visualization of numerous events over time for individual patients, with a clear understanding of the chronological order among these events. Conversely, low temporal granularity is observed when each patient is considered a singular event in time, lacking clarity regarding the precedence or sequence of different attributes.

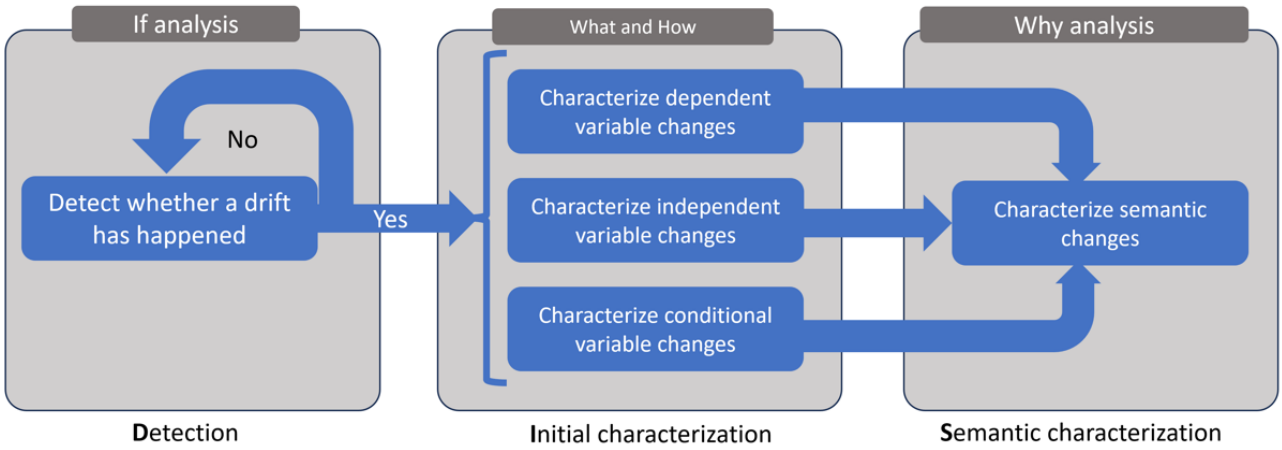
Finally, guided by these principles, we proceeded to the third, semantic characterization step, which exploits concepts popularized in the natural language processing (NLP) domain to provide a localized (instance-level) perspective of why certain shifts occurred. To achieve this, we exploited vector embeddings derived from health care events, such as sequences of the *International Classification of Diseases (ICD)* codes, vital data measurements, and consumption items. Each of these semantic units (*ICD* codes, measurements, consumed items, etc) was treated as an "event" or, in NLP terminology, a "token." By using NLP-inspired techniques to create semantic embeddings for these entities, we aimed to uncover insights into the changing context and its impact on the outcomes of interest over time.

Before delving into the details of each step in our methodology, it is crucial to emphasize that our DIS approach differs significantly from common practices. While conventional methods usually involve an ad hoc combination of techniques for data collection, qualitative data processing and extraction, and data analysis, our DIS methodology offers a planned and structured procedure, as illustrated in Figure 1. This procedure delineates the required steps to understand data drift in health care data. As we will demonstrate and discuss, these steps can be tailored to various case studies by applying different techniques depending on specific data characteristics. We also offer guidance for selecting one particular approach for a given scenario. Furthermore, we discuss how the results of each step can inform the execution of the following ones and how the combined results of all steps can support our understanding of the drift.

More broadly, to the best of our knowledge, this is the first study to examine data drifts in health care from a technology incorporation standpoint. Rather than solely focusing on enhancing the robustness of machine learning (ML) models, we delved into the underlying factors driving temporal shifts in patient outcomes. Our aim was to study the impact of emerging technologies such as new drugs, patient care policies, or vaccines. In the following sections, we detail the steps of our DIS methodology and illustrate its application in 2 case studies with distinct characteristics in terms of temporal data shifts: the Brazilian COVID-19 Registry data set [17] and the Medical Information Mart for Intensive Care, version IV (MIMIC-IV) data set [18]. By doing so, we illustrate how DIS can obtain insights into the reasons behind some real-life data drifts, as well as their potential impacts, both positive and negative, from a health care perspective.

The main contributions of this paper are summarized in Textbox 1.

Figure 1. Overview of the detection, initial characterization, and semantic characterization (DIS) methodology.



Textbox 1. Main contributions of our study.

Contributions

1. The proposal of a new data drift characterization and analysis methodology, detection, initial characterization, and semantic characterization (DIS), that is flexible enough to work on different scenarios. DIS encapsulates and cohesively organizes a sequence of necessary steps for data drift analysis.
2. A new semantic analysis step based on natural language processing embeddings for temporal understanding, which focuses on comprehending the context of relevant outcomes by examining changes in their embedding vectors over time. By incorporating such semantic techniques, DIS provides deeper insights into the reasons behind temporal changes, especially when combined with domain-specific knowledge. This approach allows for a more nuanced analysis of data evolution over time, capturing complex patterns and relationships that may not be apparent with traditional methods such as cluster analysis.
3. The application of the DIS methodology to 2 different case studies with very different temporal granularity profiles illustrates the possibility of conducting insightful analyses using the methodology. We also offer guidelines to aid practitioners in making informed decisions about which methods to use in each step of our methodology, based on particular characteristics of the data. This demonstrates the generalizability and applicability of DIS across different scenarios.

Methods

A Detailed Description of the DIS Methodology

Detection Step

In step 1 (detection), the main focus is on assessing whether the data have relevant temporal variations. Monitoring and detecting such data drifts are crucial for upholding the accuracy and reliability of ML models and for identifying beneficial and detrimental changes in health care caused by interventions, such as the introduction of new treatments or drugs. From the perspective of a health care service or company, this step identifies whether changes are occurring, potentially prompting further investigations that could enhance service efficiency over time.

For the *detection step*, we recommend splitting the data into temporal chunks and then comparing the data distributions in consecutive chunks. A drift is detected whenever the distributions of distinct chunks exhibit significant differences. Various metrics to compare empirical distributions are available in the literature. These metrics have different characteristics and underlying principles, which may lead to relevant differences in their effectiveness in detecting temporal data drifts. In this work, we considered the following metrics: centroid cosine distance [16], Jensen-Shannon divergence [14], autoencoder reconstruction error [15], classifier error (in separating 2-time chunks) [19], and principal component analysis (PCA) reconstruction error [20] metrics.

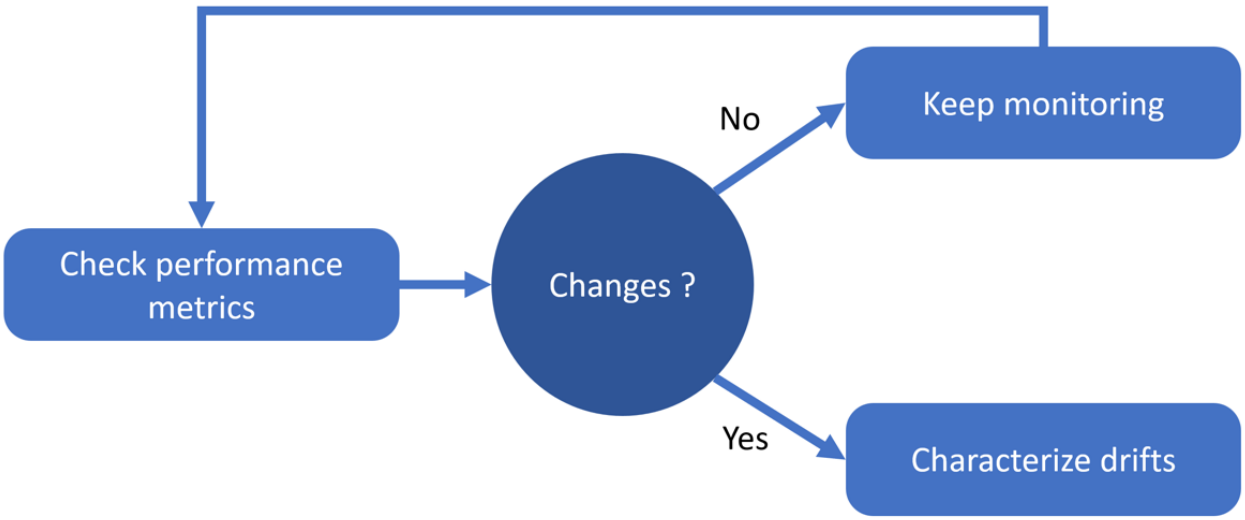
The centroid cosine distance metric assesses changes in the central points of data clusters over time and is sensitive to numeric outliers, particularly in heavy-tailed distributions where extremes can be multiple orders of magnitude larger than typical values. The PCA reconstruction error captures variations in data structure by quantifying the difference between original and reconstructed data. Similarly, autoencoder reconstruction error focuses on reconstruction accuracy. Both metrics measure the “novelty” of a data point and are sensitive to numerical outliers. By contrast, the classifier error evaluates a model’s ability to distinguish past from future data, providing insights into how drift affects predictive capabilities. Finally, the Jensen-Shannon divergence quantifies distributional changes, offering a broader perspective on underlying data distribution shifts over time. While reconstruction errors and centroids excel at detecting local outliers and structural changes, the Jensen-Shannon divergence and classifier error provide a more comprehensive view of distributional shifts, making them valuable for modeling the impact of temporal drifts on data distributions.

As an example, our prior analysis of the Brazilian COVID-19 Registry [17] revealed a data drift that significantly impacted the death prediction task, suggesting that vaccination had a pivotal role in the profiles of hospitalized and deceased patients

during the COVID-19 pandemic [4]. Although this is an interesting finding, the previous study did not present a proper structure to detect, monitor, and interpret such drifts generically, nor did it propose mechanisms to detect semantic information associated with specific outcomes.

The drift caused by vaccination can be initially hypothesized by comparing the data distributions of consecutive chunks (eg, near future vs recent past) using a classification approach. This involves monitoring the prediction model's performance over time using metrics such as accuracy, precision, and recall. Alternatively, the distribution of different features over time can be tracked using metrics such as Jensen-Shannon divergence or autoencoder reconstruction errors. If the model's performance drops (or changes) significantly over time or if the differences between the metrics exceed a certain threshold, it may indicate a data drift. A summary of this monitoring loop is illustrated in Figure 2.

Figure 2. The temporal drift monitoring loop. We usually observe temporal shifts as important variations in model effectiveness over time.



Initial Characterization Step

Once a drift has been detected, we proceed to step 2 (initial characterization), where we begin to understand, from a global perspective (all data), *how* the data have changed (Table 1 [21]). This stage focuses on developing a general (global) comprehension of the *whats* and *hows* contributing to the changes observed in the data collection. Specifically, we are interested in characterizing variations in both *dependent* $P(y)$ and independent $P(x)$ variables, as well as the conditional probability of the dependent variables given the independent variables $P(y|x)$. To reach these goals, we examine how $P(y)$ has changed by plotting its frequency over time; the same is valid for $P(x)$. For $P(y|x)$, we can explore different complementary techniques that can help understand the drifts globally. We can analyze how the different correlation metrics between the top independent variables and the dependent variable change over time, for instance, with Pearson [22] or Spearman [23] correlations, or analyze the feature importance of tree-based learners or entropy-based measures such as information gain or chi-square over time [24]. Another possibility is to exploit explainability metrics based on game theory, such as Shapley additive explanations values [25].

"Sudden drift" describes a situation where changes are abrupt and usually caused by a single event, such as a change in data collection practices, where an attribute stops being collected. "Incremental drift" describes gradual and directional changes in a data distribution, such as the observed increase in the populations with overweight and obesity over the past years. "Gradual drift" is similar but does not imply directional changes. Instead, it encompasses other gradual changes, such as the slow change in the hospital admission profile over many years. Finally, "reoccurring drift" refers to a drift pattern that repeats over time, such as the seasonal increase in emergency services admitting patients with influenza during predictable seasons of the year.

This type of analysis facilitates understanding how the relationship between predictive variables and the outcome of interest has evolved from a global perspective. Additionally, it is helpful to check the rate of change for each selected outcome by using similarity metrics and comparing the different groups of patients over time. At this stage, it is feasible to answer valuable research and business questions. For instance, we may observe a decreased likelihood of the "death" outcome in a given population, such as patients with COVID-19 or patients with breast cancer. We may also spot changes in the profiles of the patients who had adverse outcomes. Following these initial insights, the subsequent task is to understand *why* such changes happened, the goal of *step 3*.

Table 1. Drift types concerning the passing of time, according to Moreno-Torres et al [21][a].

Data drift type	Description
Sudden drift	Abrupt and unexpected changes in the data
Incremental drift	Gradual and continuous changes over time
Gradual drift	Slow and steady changes in the data distribution
Reoccurring drift	Periodic or repetitive shifts in the data

Semantic Characterization Step

In step 3, the main focus is to learn *why* the changes we observed in step 2 happened. This step integrates fundamental research and business value into our methodology and is heavily dependent on the temporal granularity of the data under evaluation. To the best of our knowledge, this is the first study to examine data drifts in health care from a technology incorporation standpoint. For instance, as mentioned earlier, we may have already learned, as a result of step 1, that a given disease or condition, such as COVID-19, had a decreased lethality over a specific time period. Given this information, what will add value to health care services is the discovery of which repeatable interventions within this time frame can be consistently beneficial.

We begin step 3 by proposing a novel NLP-inspired technique based on token embedding techniques, such as Word2Vec [26], to detect local or individual changes in outcome contexts over time. We opt for NLP-inspired techniques because they effectively model and comprehend "semantics" and "contexts." In this context, we treat each patient as a "document" and any temporally discrete health care event or information, such as disease codes or items used during a hospital stay, as a "token" (ie, the equivalent of a "word" or a "subword" in NLP). For instance, the underlying premise is that a patient's semantics can be understood by examining their diseases and consumption history. On the basis of on this representation, we characterize which entities or outcome groups have undergone the most significant changes regarding their defining characteristics in comparison to a baseline or initial time chunk. This assessment assumes a setting where we have an outcome y and the task of predicting this outcome using independent variables X. This characterization can be achieved by comparing the distance of each class's centroid to a reference centroid, where a "centroid" represents the arithmetic mean of each patient's features.

The procedure to compute each of these *centroids* is explained in Multimedia Appendix 1. In this figure, we show a simplified view of 2 groups of patients in 2D and how the centroids are calculated to be at the spatial "center" of the groups by averaging their attributes. We can compare different centroids using either a cosine distance or a cosine similarity (equation 1). This type of analysis can guide our research toward a specific hypothesis, filtering down to the pattern changes in specific outcomes, such as death or the need for mechanical ventilation during a hospital stay.

(1)

In equation 1, the cosine distance is simply 1 –cosine similarity.

The centroid of each class in the first (time) chunk will be analyzed over time, providing insights into which outcomes (eg, death vs nondeath or hospitalization vs nonhospitalization) underwent the most significant changes. From this observation, we can focus our analysis on the interest group. This approach, which will be further illustrated in our experiments, allows us to compute semantic distances among patients, between patients and outcomes, and among different outcomes.

To apply step 3 to a data set, we need to remember that health care data come in different temporal and semantic granularities. For instance, data sets such as the Brazilian COVID-19 Registry (details presented in the DIS Instantiation for the Brazilian COVID-19 Registry Data Set section) treat each patient as a single data point, characterized by atomic temporal granularity, where temporal effects are observed only at a populational level. In data sets with such low temporal granularity, it is as if all events happened simultaneously at the patient level, and we know only the relationship between those events and the patients. In these cases, modeling the relationships between entities and their resulting semantic vectors may require techniques such as graph vectorization.

On the other extreme, data sets with high temporal granularity, such as MIMIC-IV (details presented in the DIS Instantiation for the MIMIC-IV Data Set section), present patients existing within their own timelines, as well as at the populational level. Furthermore, MIMIC-IV has different levels of semantic detail, such as sequential disease codes that could be aggregated into broader groups based on their chapters (eg, both "prostate cancer" and "breast cancer" could be grouped under the "neoplasms" disease code chapter).

In both cases, we would first refer to step 2 to identify suitable candidates for the NLP-inspired modeling. In the case of MIMIC-IV, as demonstrated later, the data show a gradual and trending shift over time, with in-hospital mortality consistently decreasing over the years. Given this pattern and the granularity available in these data, we create sequences of discrete information tokens to elucidate the observed variations for each patient, such as ordinal disease codes or chapters, if a more compact set of possible semantic units is desired.

Finally, we can append "artificial tokens" at the appropriate positions on each patient's sequence, such as a "death" token at the end of the sequences of deceased patients or an "ICU" token when the patient is transferred to the intensive care unit (ICU), if applicable. With these sequences, we can obtain semantic vectors representing diseases, patients, or outcomes. Following this process on discrete temporal chunks, such as

years or months, we obtain distinct outcome tokens for each temporal chunk (eg, "death 2020" and "death 2021," effectively separating the same outcome over 2 years). With this, it is possible to compare the tokens, examining their relative distance and semantic similarity to each other and other tokens. This allows the identification of what has become more or less similar to the analyzed outcome over time.

Next, we will illustrate the application of our methodology to the 2 aforementioned case studies, with different temporal granularities. The 2 cases are very different in terms of their temporal granularity, volume, and nature of data, demonstrating the generalization capability of DIS.

DIS Instantiation

We illustrate the application of DIS to analyze temporal shifts by using the MIMIC-IV [18] and the Brazilian COVID-19 Registry data sets [17].

The MIMIC-IV data set is a comprehensive, open-access, and deidentified in-hospital patient record containing sequential diagnosis data; consumption items; vital data records; unstructured eHealth data (text data); and clinical notes for approximately 40,000 ICU patients from 2008 to 2019, designed for research in health care and medical science [18]. In this data set, age is reported in age groups, which is a requirement for deidentification.

The Brazilian COVID-19 Registry is a multicenter retrospective cohort of 10,897 patients with a confirmed diagnosis of COVID-19 admitted between March 2020 and December 2021 from 41 different Brazilian hospitals. For the purpose of the present analysis, variables collected at hospital presentation and at patient discharge were used. The data set consists of >200 features, including known comorbidities, patient's age and sex, laboratory tests (such as complete blood count, C-reactive protein, and arterial blood gas analysis), vital signs at hospital presentation (ie, arterial blood pressure, respiratory rate, and heart rate), and clinical outcomes [17].

As mentioned earlier, we chose these 2 case studies, as they illustrate scenarios where the available data have very different temporal granularity characteristics, meaning the patient's timeline can be reconstructed from the data at either a local (individual) or a populational level.

Ethical Considerations

This study was approved by the Ethics and Research Committee of the Federal University of Minas Gerais (CAAE 70801523.7.1001.5149).

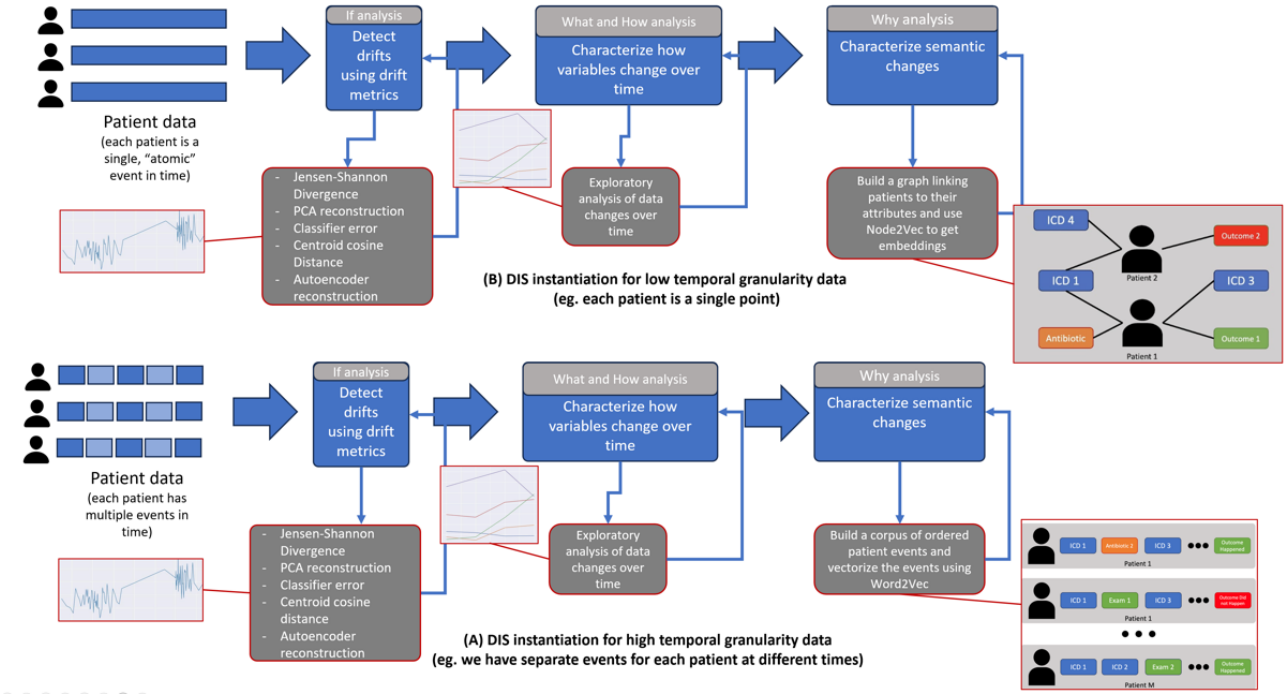
Results

Overview

The MIMIC-IV data set comprised 299,712 patients (median age 48, IQR 29-65 years), while the Brazilian COVID-19 Registry data set comprised 10,898 patients (median age 60, IQR 48-71 years).

Figure 3 illustrates how the DIS methodology is instantiated concerning the data's temporal granularity for each scenario. As explained, DIS consists of 3 steps (detection, initial characterization, and semantic characterization). The temporal granularity of the available data affects specifically the last step (semantic characterization). The figure also shows that several methods can be applied for the detection step. In our experiments, we tested and compared 5 different methods regarding their capability of accurately identifying temporal drifts in the detection step. In the second step, different exploratory techniques that measure the relationship between the dependent $P(y)$ and independent $P(x)$ variables over time can be used. We exploited multiple alternative techniques, such as feature importance and Pearson correlation. Finally, in the last step, our aim was to generate semantic embeddings for outcomes and other health care events over time and to derive insights from comparing these embeddings. We tested two different alternatives for producing such insights: (1) using our semantic embedding modeling and (2) using traditional clustering techniques over the untreated (original) data without the semantic treatment. The goal of using these 2 techniques was to illustrate insights that can be obtained with the semantic layer, which would be difficult to obtain otherwise.

Figure 3. Overview of the instantiation of the detection, initial characterization, and semantic characterization (DIS) methodology to 2 scenarios with different temporal granularities. ICD: International Classification of Diseases; PCA: principal component analysis.



DIS Instantiation for the MIMIC-IV Data Set

A notable characteristic of this data set is its high temporal granularity, enabling the tracking of time progression within each individual's hospital stay. High temporal granularity means we know the sequence of health care events at the individual level. This facilitates obtaining invaluable insights into the relationships between such events, much like it helps us learn about the semantics of words in NLP. It has been consistently shown that the order of precedence between words and how often they appear with other words are representative of those words' semantics [26]. We claim that the order of precedence and cooccurrence between health care events can also contain the "semantics" of those events. A distributed representation built from these relationships could cluster similar health care events, such as the representation of different types of diabetes or hypertension and their associated complications, in close proximity in the space. Although all dates in the data set are anonymized for privacy reasons, we can track each individual's sequence of events using the provided masking of dates. This date masking is consistent in a manner that allows for time tracking during each patient's hospital stay, and it contains a special attribute that allows for the association of patients with the yearly interval during which they were hospitalized. These yearly interval data allow us to compare how patients in each year group behaved as a group, meaning we can also measure temporal effects at the populational level. The period covered by these data set ranges from 2008 to 2019.

In other words, the data set offers temporal granularity at both the population and individual levels. However, breaking this data set into arbitrary temporal chunks is challenging because the dates are masked. Despite this, the data set contains a nonmasked anchor year group that assigns each patient to an actual year interval during which they were hospitalized. Multimedia Appendix 2 explains how this variable works. Essentially, a random time delta is fixed for each patient and added to all relevant dates, effectively masking them while preserving the relative time intervals for that patient. Consequently, direct comparison of dates between 2 different patients is not feasible, except for their "anchor_year_group" variables. For instance, a patient hospitalized in 2015 may have (through the added random time delta) dates that appear later than those of a patient hospitalized in 2020. We can only directly compare dates within the context of each patient. The real year interval during which each patient was hospitalized is preserved in their "anchor_year_group" variable, which we use in all chunking for this data set henceforth.

DIS: Detection Step (MIMIC-IV)

As described, the temporal chunks in MIMIC-IV were given by the "anchor_year_group" variable. We used this variable to separate patients into the 4 groups provided within the data set. We then used alternative drift detection approaches, namely Jensen-Shannon divergence, autoencoder reconstruction error, PCA reconstruction error, centroid distances, and classifier prediction error in separating time chunks plot for this data set considering in-hospital ICD diagnosis. The Jensen-Shannon divergence formula is shown in equation 2, where *KL* is the Kullback-Leibler (KL) divergence [27], and *P* and *Q* are the 2 variables being compared.

We started step 1 of DIS with the *drift detection* substep. As previously described, the temporal chunks in MIMIC-IV were identified through the "anchor_year_group" variable. We used this variable to separate patients into the 4 groups provided within the data set. Figure 4 shows the Jensen-Shannon divergence plot for this data set considering in-hospital *ICD*
