Abstract

Background: Patient navigation interventions (PNIs) can provide personalized support and promote appropriate coordination or continuation of health and social care services. Online PNIs have demonstrated excellent potential for improving patient knowledge, transition readiness, self-efficacy, and use of services. However, the characteristics (ie, intervention type, mode of delivery, duration, frequency, outcomes and outcome measures, underlying theories or mechanisms of change of the intervention, and impact) of existing online PNIs to support the health and social needs of individuals with illness remain unclear.

Objective: This scoping review of the existing literature aims to identify the characteristics of existing online PNIs reported in the literature.

Methods: A scoping review based on the guidelines outlined in the Joanna Briggs Institute framework was conducted. A search for peer-reviewed literature published between 1989 and 2022 on online PNIs was conducted using MEDLINE, CINAHL, Embase, PsycInfo, and Cochrane Library databases. Two independent reviewers conducted 2 levels of screening. Data abstraction was conducted to outline key study characteristics (eg, study design, population, and intervention characteristics). The data were analyzed using descriptive statistics and qualitative content analysis.

Results: A total of 100 studies met the inclusion criteria. Our findings indicate that a variety of study designs are used to describe and evaluate online PNIs, with literature being published between 2003 and 2022 in Western countries. Of these studies, 39 (39%) studies were randomized controlled trials. In addition, we noticed an increase in reported online PNIs since 2019. The majority of studies involved White females with a diagnosis of cancer and a lack of participants aged 70 years or older was observed. Most online PNIs provide support through navigation, self-management and lifestyle changes, counseling, coaching, education, or a combination of support. Variation was noted in terms of mode of delivery, duration, and frequency. Only a small number of studies described theoretical frameworks or change mechanisms to guide intervention.

Conclusions: To our knowledge, this is the first review to comprehensively synthesize the existing literature on online PNIs, by focusing on the characteristics of interventions and studies in this area. Inconsistency in reporting the country of publication, population characteristics, duration and frequency of interventions, and a lack of the use of underlying theories and working mechanisms to inform intervention development, provide guidance for the reporting of future online PNIs.

Introduction

Background

Individuals living with chronic illness or illnesses or disability have reported increased reliance on the health care system, as well as social supports for relevant resources or services (ie, medication, equipment, therapy, and counseling), particularly emphasizing the past decade [1-4]. This poses a problem, as they also face a number of challenges when navigating the health care system. These challenges can be attributed to various factors, such as a lack of proper care coordination and continuity of health care services [5-8]. Other concerns include patients' inadequate knowledge related to their conditions or disabilities and the lack of adherence to treatment plans [2,9]. It is also specifically challenging for patients with complex health needs to find appropriate health care services as there is a lack of training in specialized care provision [10-12]. Altogether, these challenges pose a threat to the use, coordination, and continuation of health care services for patients with chronic health conditions or disabilities.

In particular, individuals struggle with coordination difficulties [13]. Literature supports this finding, with a relationship between self-reported care coordination difficulties and the level of patient engagement and chronic illness complexity being observed [13,14]. It is critical to address this gap by providing navigation services for these patients with multiple and complex chronic conditions as a lack of proper coordination and continuation of services can lead to negative outcomes related to one's health and well-being, including one's ability to integrate and participate within the community [5-8,13,15].

Patient navigation commonly involves the use of one-to-one interactions between navigators and patients or their family members and caregivers to promote recommended health care use behaviors from patients' screening, to diagnosis, to resolution [10,16-19]. Patient navigation can be provided in the form of a professional, lay, or peer (with training) navigator [20].

Current literature has identified patient navigation interventions (PNIs) as an effective care approach for populations with chronic illness or disabilities in relation to managing their care through assistance with navigating the health care system [1,10,13,16,21-27]. In a systematic review, McBrien et al [27] assessed the impact of patient navigation on patients living with chronic diseases such as cancer, diabetes, HIV or AIDS, cardiovascular disease, chronic kidney disease, and dementia. The authors found that of the included 67 randomized controlled trials (RCTs), 44 trials indicated that patient navigation improved primary outcomes, specifically those related to the patients' care or health care navigation process [27]. A meta-analysis of RCTs involving various patient populations revealed that compared to usual care, patient navigation more than doubled the likelihood of patients' health screening rates and attendance at care events [25]. Similar findings were reported in a scoping review by Kokorelias et al [10] that summarized the literature on patient navigation for adults with chronic conditions, whereby patient navigation increased a patient's overall satisfaction with their care and improved access to care, education, and adherence to medication and treatment completion. Likewise, in the context of cancer care, reviews of patient navigation have concluded that PNI programs were found to be cost-effective approaches to care when considering factors such as life expectancy, incremental cost-effectiveness ratios, and quality-adjusted life-years [28,29], thus further supporting the benefit and need for patient navigation. While informative, these reviews focused on PNIs in general and were not specific to online PNIs.

One example of patient navigation is peer navigation, which involves trained peer navigators who have lived experiences of health conditions or disabilities that they can use to provide personalized support to patients with different needs [19,23,30-33]. Personalized support in patient or peer navigation may involve the following types of support: educational or informational (sharing of advice, personal experiences, first-hand knowledge, resources, and factual information), psychosocial (provision of emotional and social support using empathy, validation, mentorship, motivation, feedback, and reflection), and instrumental (assistance with administrative activities, accessing and navigating services or resources, advocacy) [19,23,30-33].

Consistent with the theoretical underpinnings of the Social Cognitive Theory [34], the provision of such personalized support in patient navigation can promote patients' perceived self-efficacy, appropriate health care use behaviors, and related outcomes (ie, community integration, quality of life, and well-being). For instance, Cabassa et al [35] systematic review identified peer-based navigation interventions to be among the most promising interventions for improving the health outcomes of individuals with serious mental illnesses. Peer navigators with lived experience improved health outcomes by facilitating linkages between individuals seeking care and health care services [10,36-39].

One area of development that warrants further exploration is online PNIs for a breadth of chronic conditions in the adult population. Research has shown that online-based PNIs have a great potential for improved health outcomes (eg, increased patient knowledge, transition readiness, self-efficacy, and appropriate use of health care services) in various patient populations. Casillas et al [40] conducted a three-arm RCT to test the efficacy of both a peer navigation intervention and an intervention involving the use of mobile technology (ie, SMS text messaging) in promoting cancer survivorship care in adolescents and young adults. Compared to standard care, these online interventions demonstrated the following statistically significant benefits: online peer navigation improved

participants' self-efficacy in survivorship care, SMS text messaging improved survivorship-focused knowledge, and both interventions improved participants' attitudes in seeking survivorship care [40]. Specifically, the SMS text messaging group exhibited higher levels of survivorship care knowledge compared to the control group (P<.05), while the peer navigation group showed increased survivorship care self-efficacy compared to the control group (P<.05). Both intervention groups demonstrated more positive attitudes toward seeking survivor-focused care compared to the control group (SMS text messaging group: P<.05; peer navigation group: P<.05) [40]. Considering the initial efficacy observed in both interventions, each has the potential to be used in the future to educate and empower adolescent and young adult cancer survivors in accessing necessary survivorship care [40]. Online support has also been deemed a more flexible and sustainable care model when offered to individuals with intellectual disabilities, especially during the COVID-19 pandemic [41]. Moreover, online patient navigation can better reach rural, remote, and other underserved communities.

Objective

Despite the demonstrated benefits of online patient navigation for various patient populations, the extent of the literature specifically focused on online PNIs across a range of chronic conditions or disabilities is uncharted. Therefore, the purpose of this scoping review is to comprehensively search databases and summarize data from peer-reviewed publications to address the following research question: What is known from the existing literature about the key characteristics (ie, intervention type, mode of delivery, duration, frequency, outcomes and outcome measures, underlying theories or mechanisms of change of the intervention, and impact) of online PNIs used across a range of chronic conditions or disabilities?

Methods

Research Design and Methodological Framework

A scoping review methodology was used given the broad nature of the research objective and question, and the lack of previous comprehensive reviews conducted in this area. A scoping review, also known as a scoping study, serves as a form of knowledge synthesis designed to explore research questions and map key concepts, types of evidence, and research gaps related to a defined area or field. This approach involves systematic searching, selection, and synthesis of existing knowledge [42] (page 28). Thus, a scoping review was deemed suitable to help identify key concepts and evidence related to online PNIs for adults with chronic conditions or disabilities. This scoping review was guided by the framework proposed by the Joanna Briggs Institute (JBI) Manual for Evidence [43-45]. The JBI framework was selected as it was developed based on previously reported methodological frameworks by Arksey and O'Malley [46] and Levac et al [47]. This refined framework provides additional guidance and clarity on the steps involved in the collection, analysis, and dissemination of research findings [43-45]. Specifically, the JBI framework focuses on aspects of the research process that have not been addressed as extensively in previous frameworks. The methods and the findings are reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews; Multimedia Appendix 1) to further enhance the reporting of findings, as consistent with the JBI methodology [43-45,48]. A protocol was not published prior to the completion of this scoping review.

Inclusion and Exclusion Criteria

All empirical study designs (eg, experimental, quasi-experimental, observational, qualitative studies, not review methodologies) reported in peer-reviewed, full text (eg, no conference abstracts) were included to increase the scope of the literature found. To address the identified gaps in the current literature on online PNIs, only peer-reviewed studies involving trained navigators and PNIs delivered using an online format, and software or application-based PNIs both with or without allocated trained navigator support were included. Our review encompasses a broad spectrum of online PNIs including those featuring hybrid formats. These interventions incorporate both online elements and face-to-face or other non–internet-related components, ensuring a comprehensive assessment of diverse intervention modalities and their characteristics. Participants in these studies had to be adults (aged 18 years and older) with chronic conditions or disabilities as recognized by the Public Health Agency of Canada (PHAC) [49], the Canadian Chronic Disease Surveillance System, and the World Health Organization. These conditions based on their PHAC categorization could include exclusively physical or mental health–based conditions, or both. Examples of common chronic diseases and conditions, as defined by the PHAC, the Canadian Chronic Disease Surveillance System, and the World Health Organization, include cardiovascular disease (eg, heart failure, hypertension, and stroke), chronic respiratory disease (eg, asthma and chronic obstructive pulmonary disease), diabetes mellitus (types combined, but not gestational diabetes), mental illnesses (alcohol or drug-induced disorders, mood and anxiety disorders, and schizophrenia), musculoskeletal disorders (eg, arthritis and osteoporosis), and neurological conditions (eg, dementia, epilepsy, multiple sclerosis, and Parkinson) [49-51]. Additionally, studies with participants living with HIV and AIDS were also included [52]. Only studies published between 1989 and 2022 and available in full text in English were included due to feasibility considerations (ie, members of the research team could only read in English) and resource constraints. The Report to the Nation on Cancer in the Poor that began work in the area of patient navigation began in 1989 [21]. Exclusion criteria included PNIs that were delivered in alternate formats (eg, face-to-face, telephone, and mail).

Data Collection and Management

Comprehensive literature search strategies based on the inclusion and exclusion criteria of this scoping review were developed in collaboration with an experienced librarian (LP). The search strategies were further informed by the Participants/Concept/Context framework as recommended in the JBI methodology. The search strategy included medical subject headings and text words related to adults with chronic conditions or disabilities and online PNIs (Multimedia Appendix 2). The search strategy was first developed, tested, and refined

in MEDLINE (OVID interface) prior to being used in other databases. The following databases were searched using the finalized MEDLINE strategy: CINAHL (EBSCO interface), Embase (OVID interface), PsycInfo (OVID interface), and Cochrane Central Register Controlled Trials (Cochrane Library). The use of multiple health care–related databases helped broaden the scope of the comprehensive literature search. Data yielded from the comprehensive literature search strategies were stored and screened using the online Covidence software program (SaaS Enterprise) [53,54]. These data were screened at 2 levels (ie, level 1 and level 2 screening). Study titles and abstracts were screened first, followed by the screening of full-text studies. Screening at both levels was conducted by 2 independent reviewers (MM and SRS) to ensure accuracy in the included results. Discrepancies were addressed through consensus between the reviewers and the senior author (KMK). Reference lists of all included studies were reviewed to determine any studies that may have been missed from the database search. Gray literature was not included.

Data Extraction and Analysis

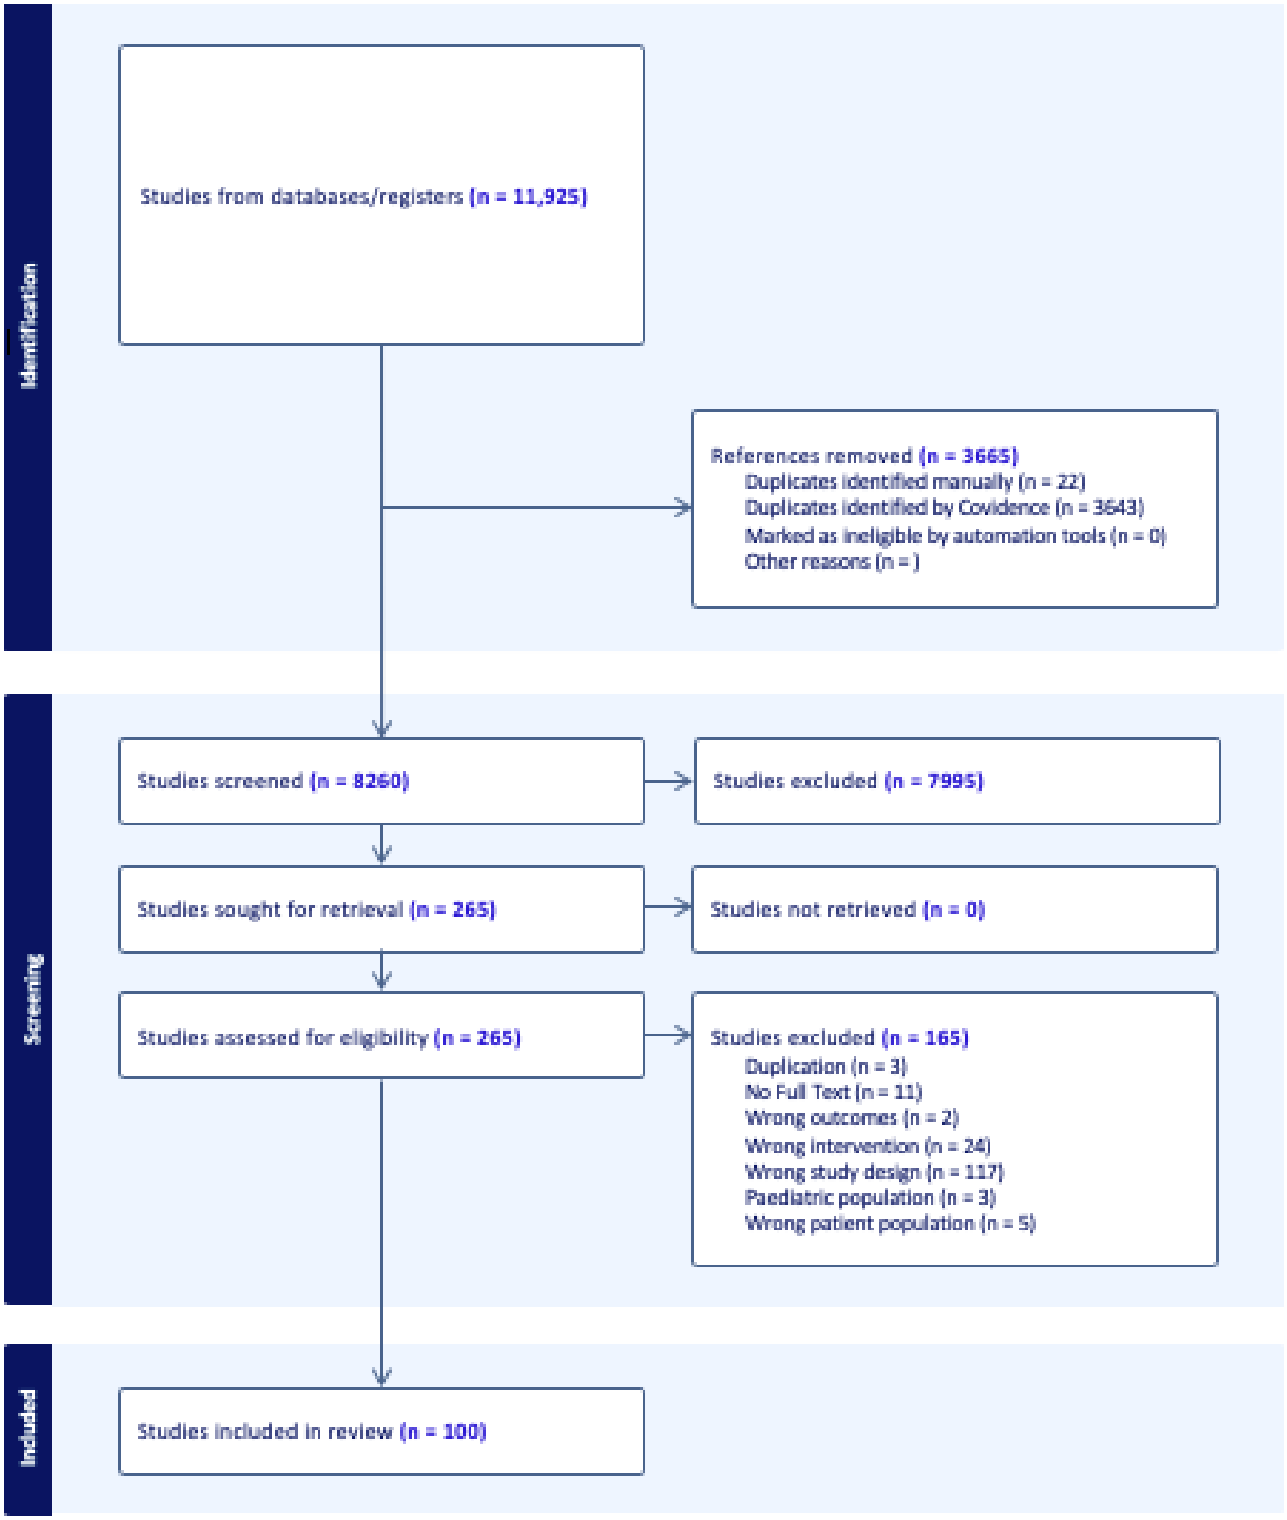
Data extraction was carried out by extracting key information or data from the included studies. A data extraction form, developed by the authors, was used to chart and record this information to ensure easy referencing and tracking of each study to ensure clarity. The form was first piloted on the first 5 included studies by all members of the research team. The extraction template was further informed by the Template for Intervention Description and Replication (TIDieR) checklist and guide, which is a framework that aims to promote replicability and implementation of interventions through the consistent reporting of key intervention characteristics [55]. The following data were extracted from the full-text studies: study characteristics (ie, title, author or authors, publication year, publication country, study purpose or objective or objectives, and study design), participant population characteristics (ie, sample size, race or ethnicity, condition or disability, age, and sex), and key characteristics of the intervention (ie, name, type, description, setting, duration, frequency, mode of delivery, underlying theories, behavior change techniques or working mechanisms, context, outcome measures used, and quantitative and qualitative outcomes). In line with scoping review methodologies, we did not evaluate the quality of included studies [56]. Data were extracted by 2 independent reviewers (MM and SRS) and any disagreements were resolved through consensus. Following data extraction, the following information was specifically summarized using descriptive statistics [57] and directed content analysis [58] to provide an accurate overview of the published literature on the key characteristics of online PNIs in adults with chronic conditions or disabilities. The research team reviewed the coded data to create a set of categories that capture the key themes, concepts, and variables relevant to the research question. This involved both inductive categories (emerging from the data) and deductive categories (informed by the TIDieR framework). The authors then began coding the selected studies according to this scheme, using Excel (Microsoft Corp) to facilitate this process. The Excel document was then reviewed by all members of the research team to identify patterns and trends. The team met over a series of meetings to determine key interpretations of the results.

Results

Overview

The PRISMA-ScR flowchart displayed in Figure 1 shows an overview of our comprehensive literature search, which yielded 11,925 studies.

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flowchart.



Study Characteristics

The publication dates ranged from 2003 to 2022, with some years yielding no publications. The greatest number (n=20, 20%) were published in 2019 with 19 (19%) studies published in 2020. As for the publication country, all studies were published in Western countries. A total of 48 (48%) studies were conducted and published in the United States, followed by 23 (23%) studies from Canada, and 19 (19%) studies from the United Kingdom. There was a variation of study designs observed in the review. The most common study design included RCTs (n=39, 39%). The included studies focused on the development, implementation, and testing of online PNIs. Of the studies included, 82 (82%) studies specified their sample size. There was a significant range in the overall participant sample size (including intervention and control arm or arms), observed from 9 to 14,584 participants, with the median being 97 (IQR 342) participants. When comparing the sample sizes

of the intervention and control arms, 24 studies had an approximately equal division, while 21 studies did not. In addition, 55 studies did not specify the sample size of the intervention or control groups. Multimedia Appendix 3 outlines the study characteristics.

Population Characteristics

Among the included full-text studies, the majority (n=79, 79%) of the studies' participants had conditions or disabilities that would be classified exclusively as physical health-based conditions according to the PHAC (including cancer, heart disease, diabetes, and stroke), while only 11% (n=11) of the studies represented participants with solely mental health-based conditions (eg, mood disorders, substance use and addictions, and eating disorders). A total of 10% (n=10) of the studies represented participants who had both physical and mental health–based conditions. One study represented participants who had post–COVID-19 condition. In terms of the participants' age, 55% (n=55) of the studies provided this information. Across the studies that reported age (regardless of study design), the mean age range (with SD) of the participants included in the studies' intervention arms (ie, those who participated in online PNI) was between 19.84 (SD 1.61) and 69.6 (SD 9.1) years. When comparing the age of the participants in the intervention and control arms, 37% (n=37) of the studies had similarly aged participants (ie, 20-70 years of age). With regards to the sex of participants, 20 (20%) studies included only female participants while only 4 (4%) studies included only male participants. A total of 19 (19%) studies had an approximately equal distribution of females and males, and 14 (14%) studies did not specify the sex of the participants or inconsistently reported this information. In terms of the racial or ethnic representation of participants in studies, more than half (n=54, 54%) of the studies did not specify this information. Among those that did, in 20 (20%) studies, the majority of the participants were White, followed by the following racial groups: Black, African, or African-American (16 studies), Hispanic or Latinx (5 studies), and Asian or Asian American (4 studies; terminology as used by the original authors of the included studies). Only one study focused on the Indigenous population (in Australia).

Intervention Characteristics

Types of Intervention

Among the 100 included studies, the most common intervention type was a combination (n=61, 61%), which included a mix of peer, patient, and other navigation types including coaching, digital navigation (including mobile, eHealth, or telehealth-based interventions, or software application-based interventions), and self-management. Within the "other" category, intervention types included a mixture or combination of peer, patient, and other navigation intervention types, as well as the exclusive implementation of interventions such as coaching, counseling, health promotion, digital navigation, self-monitoring, or self-management. A total of 32 (32%) studies were exclusively patient navigation-based, and 7 (7%) studies were exclusively peer navigation-based. Other studies did not clearly specify the intervention type (ie, who the intervention was led by or what it involved).

Several studies explored diverse online PNIs for cancer-related support and care. While the interventions varied across studies, commonalities and differences emerged. One study introduced a virtual navigation tool providing comprehensive cancer information accessible 24/7, emphasizing its value in validating information and controlling exposure, while another used nurse navigators sending scripted messages, resulting in improved quality of life and symptom burden among participants [59]. A similar modality was used by other studies that used peer navigation and SMS text messaging interventions for educating cancer survivors on late effects and survivorship care, leading to improved survivorship knowledge, attitudes, and self-efficacy [40]. On the contrary, some scholars focused on self-monitoring and physical activity, noting enthusiasm and continued use among participants [60,61].

In the context of multimorbidity, the studies featured various adaptations and design elements tailored for both physical and mental health conditions and examined technology use for patients with multiple chronic conditions, focusing on communication tools, tracking medical information, and decision-making support, intending to address self-management challenges and health care navigation issues [62]. Allen et al [63] developed an internet-based health coaching intervention targeting chronic pain, depression, and mobility difficulties, emphasizing patient-clinician communication improvement and patient empowerment through goal-setting and constructive communication tools. On the other hand, some interventions focused on peer visitation, support groups, and educational materials, enhancing recovery expectations and satisfaction [64,65]. Thus, both chronic conditions, like cancer and multiple chronic conditions, used strategies such as technology integration for communication, support, and information dissemination, tailored interventions addressing specific conditions and associated challenges, peer support networks fostering engagement and optimism, and empowerment strategies encouraging collaborative patient-clinician communication, goal-setting, and self-efficacy. Multimedia Appendix 4 outlines the intervention characteristics.

Duration and Frequency

Of the included studies, the duration and frequency of interventions were varied. Of the 100 included studies, 55 (55%) studies specified a duration and only 17 (17%) studies specified a frequency of the intervention. Other studies included a variable duration or frequency that was tailored to the needs of individual patients. Of the 55 (55%) studies that specified duration, 7 (7%) studies were offered for a year. A total of 41 (41%) studies were offered for 1 month up to 11 months, 3 studies were offered weekly (eg, one time per week), and 4 (4%) studies were held on a daily basis. In addition, of the total studies included, 14 studies had a variable duration, 24 (24%) studies did not specify, and there were 7 (7%) studies where the duration was not applicable (eg, proof of concept, usability, and beta-testing). In terms of frequency, of the 17 (17%) studies that specified frequency for interventions, 3 (3%) studies were month-based, 10 (10%) studies were week-based, and 4 studies required day-to-day engagement from participants. Of the total studies included, 46 (46%) online PNIs had variable frequency, 30 (30%) did not specify frequency, and there were 7 (7%) studies

that reported interventions where the frequency was not applicable as the interventions only occurred once.

Mode of Delivery

Of the included studies, 56 (56%) of the 100 studies reported using an online mode of asynchronous or synchronous delivery for interventions, without any other components. A total of 13 (13%) studies used a format that was hybrid, with both online and offline intervention formats. In total, 22 (22%) studies included SMS text messaging as the main component of intervention delivery, of which 14 (14%) studies had SMS text messaging mixed with other intervention formats such as the use of telephone calls, educational videos, websites, and online support groups. Finally, 9 (9%) of the 100 studies used a mixed format including intervention components such as software programs and applications, telephone calls, in-person interactions, email, automated phone lines, and other online-based intervention formats.

Underlying Theories

In total, 78 (78%) studies did not specify the use of any underlying theories, models, and frameworks, that were used to guide the PNIs. Of the 22 (22%) studies that did specify an existing theory, a total of 21 different theories were identified. Four studies indicated that the intervention was based on more than one theory. Social cognitive theory followed by the self-determination theory, self-efficacy theory, behavior change theory, and community empowerment were the most common theories used. The most common working mechanism among these was a combination (n=20, 20%) of various mechanisms, which included coaching, education, peer support, navigation, self-management, and cognitive behavioral therapy among others. Self-management (n=19, 19%) and navigation (n=19, 19%) followed as other commonly identified mechanisms.

Outcome Measures

Multiple outcome measures were used in these studies; however, the most commonly used outcome measures included: the Short Form-36 survey questionnaire to measure participants' health-related quality of life, the Patient Health Questionnaire-9 to measure participants' psychological outcomes, and the Health Education Impact Questionnaire to measure participants' knowledge and self-management related outcomes. Additional standardized and nonstandardized outcome measures were used to report on common intervention outcomes such as the interventions' feasibility, acceptability, efficacy, effectiveness, uptake, use, and retention, and participants' clinical symptoms or outcomes (physical, mental, emotional or psychosocial), lifestyle or behavioral changes, quality of life, user experience or satisfaction, adherence, knowledge, attitudes, and self-efficacy.

Outcomes and Impact of Online PNIs

Out of the 76 (76%) studies that reported quantitative findings (including RCTs and non-RCTs), 46 (60.5%) studies demonstrated significant improvements. Improvements were commonly demonstrated in the following outcomes: appointment adherence, intervention retention, knowledge, self-monitoring of symptoms, and physical and mental health symptoms. Of the 23 (23%) studies that reported qualitative findings, 8 (35%) studies identified specific themes and subthemes [62,66-72]. The included qualitative studies spoke of themes that described usability or user experience, as well as participants' experience with the PNI as it related to self-management, education, knowledge, navigation, engagement, encouragement or support, and feedback.

Discussion

Principal Findings

This scoping review aimed to investigate the key characteristics of reported online PNIs to inform future intervention development and research evaluation. A total of 100 peer-reviewed studies were included. Overall, online PNIs are highly variable with various modalities for delivery, durations, frequencies, and contexts of support provided. Few studies reported participants' sex, diagnoses, age, and race or ethnicity. Moreover, most of the literature was published in Western countries, resulting in a lack of data from non-Western countries, as well as PNIs that reflect the needs of individuals from non-Western countries. Despite this, we were able to ascertain through the results of 20 RCTs (the highest level of evidence) [73] that in general, online PNIs improve outcomes of patients' self-management, knowledge, clinical symptoms (physical or mental health–based), and use and navigation of health care services.

The majority of the online PNIs were designed for physical health-based conditions (including cancer, heart disease, diabetes, and stroke), while few studies focused solely on mental health–based conditions. Our investigation revealed a notable scarcity of online PNIs specifically targeting multimorbidity of physical and mental health conditions (n=10), signifying a considerable gap in available interventions addressing the complex needs of individuals with multiple chronic conditions. This paucity carries significant implications, indicating an unmet need within the digital health landscape, that is needed to ensure comprehensive care for those navigating multifaceted health challenges. Participants in the RCTs ranged from 20 to 70 years of age. As with other reviews of digital health interventions to support the coordination of care [74,75], our review noted a lack of inclusion of particular groups of older adults (ie, 70 years and older), despite this group representing a large proportion of individuals living with chronic conditions [76] who could benefit from online health interventions [75,77]. Moreover, our review found a lack of literature exploring the impact of online PNIs on Indigenous populations and non-White populations such as Black, Asian, and Hispanic individuals, making it difficult to ascertain their unique needs to inform further online PNIs. As such, future research on online PNIs is encouraged to explore the interaction of racial and cultural factors of different groups to improve service delivery [78].

Our review highlights how future online PNIs can better support various patient populations. Only one study cited in our review noted the racial preferences of participants in which Black patients preferred the services of a Black (virtual) provider [79]. Ethnic minorities and other underserved populations often face unique barriers to accessing health services that patient navigation is able to assist with overcoming [10,80,81]. Social

and environmental factors, such as finances, health literacy, and availability of health services, influence health access [82-84]. To overcome these barriers, it is necessary to create efficient processes for referring communities affected by social and environmental factors to suitable resources, ensuring that their needs are adequately met [85,86]. Culturally appropriate patient navigation can assist with learning about the unique information needs and barriers that face particular communities and facilitate an appropriate referral and support process to services [10,87]. While online PNIs can help overcome traditional barriers to seeking support, such as transportation [88], it is important to consider that shifting to online PNIs may also increase risks to access and equity as a result of digital inequity (ie, gaps in use and participation in the use of technology) [89]. Future research efforts on online PNIs should also consider the individual needs of target populations (eg, access and geographical location, income, and digital literacy), as well as the significance of an individual-based versus group-based mode of delivery of online PNIs.

We also noted the lack of consistent reporting of intervention characteristics. For example, the duration and frequency of interventions were not reported consistently or were variable among the included studies in our review. Moreover, multiple studies did not specify the exact frequency of their intervention. Similar trends were observed in a previous review on web-based peer support interventions where the authors reported "a lack of consistency" and variation regarding the reporting of intervention characteristics such as duration and frequency [75]. The reporting of intervention doses associated with improved outcomes is important to guide other jurisdictions looking to implement or build upon existing interventions [90]. Frameworks, such as the TIDieR, have been posited as helpful for guiding researchers in reporting a full description of complex interventions [55] such as PNIs. The TIDieR can help guide the reporting of future online PNIs to ensure transparency and improve the quality of patient navigation research. Relying solely on reported intervention characteristics, however, can imply a limitation of the personalization of interventions (ie, inflexibility in the duration and frequency tailored to participant needs). While this can be a great guide for replicating the interventions, and further testing and implementation, patients with chronic illness may require individualized approaches to care [91]. Further research is needed to understand how the duration, frequency, and support provided within existing online PNIs may evolve across the illness and care trajectory of patients. Moreover, the TIDieR is only beneficial for reproducibility in the setting specified by the original individual study and therefore cannot guide researchers to implement the intervention in different contexts or settings [90]. Researchers should then reply on implementation frameworks, such as the PRACTical planning for Implementation and Scale-up guide to provide practical direction on implementing online PNIs into new sessions [92].

Despite a substantial portion (78%) of the studies not explicitly delineating underlying theories or frameworks, the 22% of studies that did highlight a diverse array of theoretical foundations (ie, Social Cognitive Theory emerged prominently, followed by self-determination theory, self-efficacy theory, behavior change theory, and community empowerment among others). This diversity underscores the need for a more comprehensive and structured integration of theoretical frameworks within the design and implementation of online PNIs. Integration of frameworks within online PNIs can help researchers understand the underlying mechanisms driving these interventions and will help to establish standardized evaluation metrics. Moving forward, comprehensive research could delve into exploring the efficacy and synergies of combining multiple theories to inform the design and implementation of online PNIs effectively. Furthermore, investigating how specific mechanisms within these theories (eg, coaching, education, and peer support) contribute to PNI outcomes can enrich our understanding and potentially optimize intervention strategies. This calls for a systematic and comparative analysis to discern the differential impact of diverse theoretical orientations on the effectiveness, sustainability, and scalability of PNIs across various health contexts and participant demographics.

Digital health interventions often incorporate elements akin to navigation programs including patient education, remote monitoring, and personalized feedback. These features aim to empower patients in self-management and facilitate communication with health care providers. In contrast, navigation programs traditionally focus on guiding patients through complex health care systems, providing support in appointment scheduling, access to resources, and continuity of care. However, as digital health evolves, distinctions between these approaches can blur. Many digital health solutions now integrate navigation functionalities such as decision support tools and care coordination platforms. This integration raises questions about the delineation between virtual care and navigation programs, particularly regarding their roles in improving health outcomes and patient experience across different chronic diseases. Moving forward, future research should explore synergies between digital health interventions and navigation programs to optimize their combined impact on chronic disease management. This includes examining the effectiveness of integrated approaches in enhancing patient adherence, reducing health care disparities, and improving the overall quality of care.

Finally, we found that online PNIs are an accessible and user-friendly option for navigational support to patients. Similar trends were observed in other studies involving peer and professional navigators [10,19,20,36,93-101]. Similarly, positive and statistically significant outcomes were also reported in another scoping review on web-based peer support, where the authors found that interventions in 4 of their 6 included RCTs improved the health navigation, emotional self-management, self-efficacy, social participation, and attitudes of adults with chronic conditions [75]. Overall, these findings demonstrate how online PNIs could play a crucial role in improving health use and navigation among adults with chronic conditions and disabilities. Additionally, a common theme that was reported by patients, specifically among the qualitative findings of studies from our review was that online PNIs provided more accessibility, engagement, and encouragement to participants navigating their health. Gaining insight on what would construe the ideal patient navigator and ideal patient navigator program

for patients with chronic health conditions is still in its infancy [102,103], and as such conducting more qualitative research with diverse patient populations would be valuable in refining and co-designing novel online PNIs and navigator roles.

Limitations

Although a systematic, comprehensive review was conducted to identify key characteristics of online PNIs, the authors acknowledge that this scoping review has some limitations. First, search results were limited to publications in English studies published after 1989, and while the broad search strategy made it unlikely that potentially eligible publications were missed as a result, we may have created a bias toward studies from English-speaking countries, which might have contributed to the majority of data coming from Western countries. We also excluded gray literature. The majority of the data extraction was not completed in duplicate, which may have affected the reliability of the extracted data. Incomplete reporting on study characteristics by original study authors also made it challenging to comment on additional participant characteristics (eg, socioeconomic status, education level, and digital literacy) that would have provided valuable information.

Conclusions

This review has mapped the existing literature on online PNIs, and in doing so, has identified several gaps that should be addressed in future research and intervention development efforts. Although many positive outcomes were reported for online PNIs, a lack of variation in included study samples, as well as a lack of consistency in reporting, was observed in the reporting of TIDieR intervention characteristics including the following: the publication country of studies, population characteristics such participants' age, sex, and racial or ethnic background, duration and frequency of interventions, and the use of underlying theories and working mechanisms to inform intervention development. Future research and development efforts should consider using theories and models, expanding inclusion criteria, and reporting key intervention characteristics more consistently.

Abstract

Background: Modern approaches such as patient-centered care ask health care providers (eg, nurses, physicians, and dietitians) to activate and include patients to participate in their health care. Mobile health (mHealth) is integral in this endeavor to be more patient centric. However, structural and regulatory barriers have hindered its adoption. Existing mHealth apps often fail to activate and engage patients sufficiently. Moreover, such systems seldom integrate well with health care providers' workflow.

Objective: This study investigated how patient-provider communication behaviors change when introducing patient-generated data into patient-provider communication.

Methods: We adopted the design science approach to design PatientHub, an integrated digital health system that engages patients and providers in patient-centered care for weight management. PatientHub was developed in 4 iterations and was evaluated in a 3-week field study with 27 patients and 6 physicians. We analyzed 54 video recordings of PatientHub-supported consultations and interviews with patients and physicians.

Results: PatientHub introduces patient-generated data into patient-provider communication. We observed 3 emerging behaviors when introducing patient-generated data into consultations. We named these behaviors *emotion labeling*, *expectation decelerating*, and *decision ping-pong*. Our findings show how these behaviors enhance patient-provider communication and facilitate patient-centered care. Introducing patient-generated data leads to behaviors that make consultations more personal, actionable, trustworthy, and equal.

Conclusions: The results of this study indicate that patient-generated data facilitate patient-centered care by activating and engaging patients and providers. We propose 3 design principles for patient-centered communication. Patient-centered communication informs the design of future mHealth systems and offers insights into the inner workings of mHealth-supported patient-provider communication in chronic care.

Introduction

Background

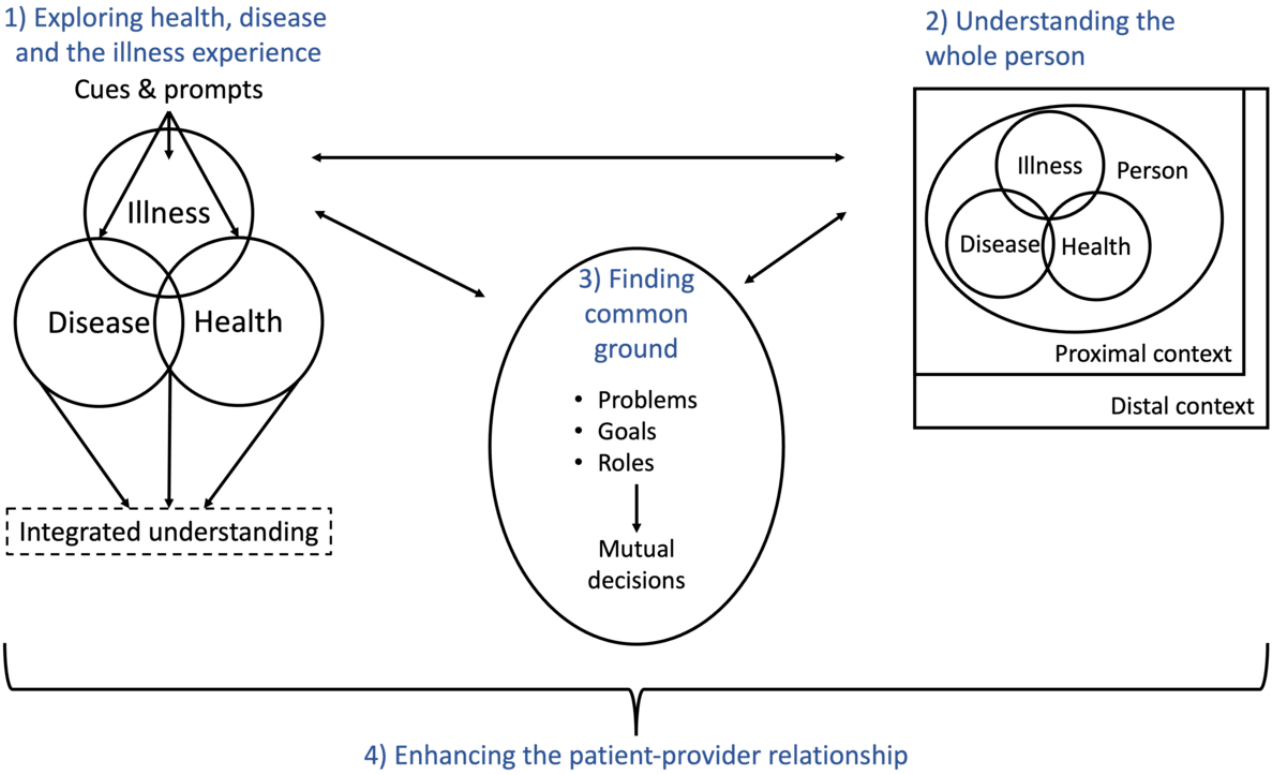
The quality of the patient-provider relationship is strongly linked to patients' increased adherence and better health outcomes [1-3]. Patient-provider communication requires exchanging accurate and relevant information to better understand patients and their preferences and context [4,5]. However, provider instructions are complex and not communicated adequately to patients [3,6] as health care providers often lack the time or communication training [7]. In turn, patients have difficulties recalling crucial information (eg, their adherence to taking medication regularly), impeding providers' ability to quickly assess their medical condition and derive actions [8,9]. Therefore, adherence and health outcomes are often subpar—especially in people with chronic conditions [6,10,11]. Due to its centrality, improving patient-provider communication is a topic of continued interest in medical research.

Patient-Centered Care

Over the last decades, the understanding of good patient-provider communication has evolved. Historically, providers have possessed most of the power in patient-provider communication [12]. These power dynamics mainly occurred due to the significant knowledge difference between providers and patients [13]. The resulting paternalistic model, in which the providers made all the decisions, led to poor adherence and increased health care costs [14,15]. Newer approaches such as shared decision-making and patient-centered care ask providers to adopt more inclusive methods focusing on the collaborative nature of patient-provider communication [4,5,16-18].

Patient-centered care proposes a holistic clinical method that centers on the patients and their preferences and contexts [4,5,19]. It is defined as "respectful of and responsive to individual patient preferences, needs, and values and ensuring that patient values guide all clinical decisions" and is 1 of 6 key elements of high-quality care [16]. The clinical method of patient-centered medicine by Stewart et al [4] is among the most frequently used frameworks. It proposes a communication approach that suggests looking beyond a patient's acute problem and into their history and context (Figure 1). The framework suggests (1) *exploring health, disease, and the illness experience*; (2) *understanding the whole person*; and (3) *finding common ground* to (4) *enhance the patient-clinician relationship*. In the following paragraphs, we describe each of those dimensions.

Figure 1. Patient-centered care framework by Stewart et al [4].



Exploring health, disease, and the illness experience highlights the importance of understanding the patient's experience. People have different interpretations and unique experiences of health and illness. Someone with an asymptomatic disease may perceive themselves as healthy, whereas others feel ill without having a disease. Providers should seek to understand and support the patient's view of their situation and their experience of health and illness by listening to their concerns and feelings [4,20]

Understanding the whole person focuses on understanding the patient's proximal and distal context [4]. It enables meaningful conversations about the illness and treatment options as providers know their patients as people (eg, what is currently important to them) [20]. Younger patients might struggle more with a diagnosis than older people. A patient's relationships,

work, education, lifestyle, and culture play a significant role in their treatment.

Patients and providers work together to *find common ground* regarding the problems and priorities, the goals of the therapy, and the roles of the patient and the provider [4]. It stresses the emotional engagement with the patient and the genuinely collaborative aspect of finding common ground to arrive at mutual decisions [4].

Enhancing the patient-clinician relationship is the goal of every encounter in patient-centered medicine [4]. Health care becomes genuinely patient centered through an integrated understanding of the patient's experience, understanding them as a whole person, and mutual decisions [20]. The framework by Stewart et al [4] conceptualizes patient-provider communication to achieve patient-centered care. It proposes a mindset that places patients at the center of clinical practice.

Patient-Generated Data in Patient-Provider Communication

This shift in the mindset has attracted increasing interest in health informatics research that studies the effect of technology on patient-provider communication [21-27]. In face-to-face consultations, patient data generated on mobile health (mHealth) apps become increasingly important as they allow patients and providers to gain deeper insights into patients' routines and adherence to therapy plans. Patient-generated data are health-related data gathered or created by patients, usually through wearables and mHealth [28]. Studies in health informatics and related fields have demonstrated the potential of patient-generated data to increase patient-provider communication [22,29,30]. mHealth allows patients to generate abundant health information, such as dietary patterns, emotional conditions, or objective measures such as blood pressure [22,23,31]. These data allow for insights into the patient's health experience and journey unlike ever before [32,33].

mHealth-supported approaches have significantly improved patient-provider communication, adherence, and health outcomes in chronic care [34-36]. Studies have shown how these patient-generated data allow patients and providers to engage in collaborative sensemaking that improves decision-making [23,30,31,37]. It allows for deeper discussions about personal values [14,16] and improves patients' understanding of their condition and treatment [38]. Furthermore, introducing patient-generated data into consultations affects the role dynamics of therapeutic sessions [34]. For example, sharing clinical notes shifts power in the patient-provider relationship [36]. Other studies report how sharing patient-generated data through mHealth leads to greater disclosure and better communication in consultations, resulting in better health outcomes [30,31].

These insights have been validated for different age groups [30,39,40] and chronic conditions (eg, chronic kidney disease) [21,25,35,41]. This previous research shows the positive impact of introducing patient-generated data into consultations on adherence and health outcomes [35,36]. For example, Vitger et al [35] describe the positive impact of generating data on a smartphone app on patient activation, communication confidence, and preparedness for decision-making in patients with schizophrenia.

While existing research agrees on the vital role of patient-generated data in patient-provider communication [19,21,23], significant obstacles remain to leverage their potential. So far, structural and regulatory barriers have slowed advances [42,43]. mHealth apps seldom integrate with the provider's workflow, leading to a fragmentation of health data [44,45]. More importantly, Cozad et al [46] found that only a few mHealth apps engage and activate patients to participate in patient-centered care. Finally, most studies report on the positive effects of patient-generated data on patient-provider communication, but they often fail to investigate the communication behaviors that use patient-generated data. Accordingly, patient-provider communication remains a black box that receives patient-generated data as input and creates better communication as output (Figure 2). Little to no research focuses on the design of systems that (1) integrate patient-generated data into the provider's workflow and (2) use these data in consultations to enhance patient-provider communication. This study aimed to address this research gap by designing and evaluating an integrated digital health system that enhances the patient-provider communication.

Figure 2. The process of patient-provider communication as a black box.

Methods

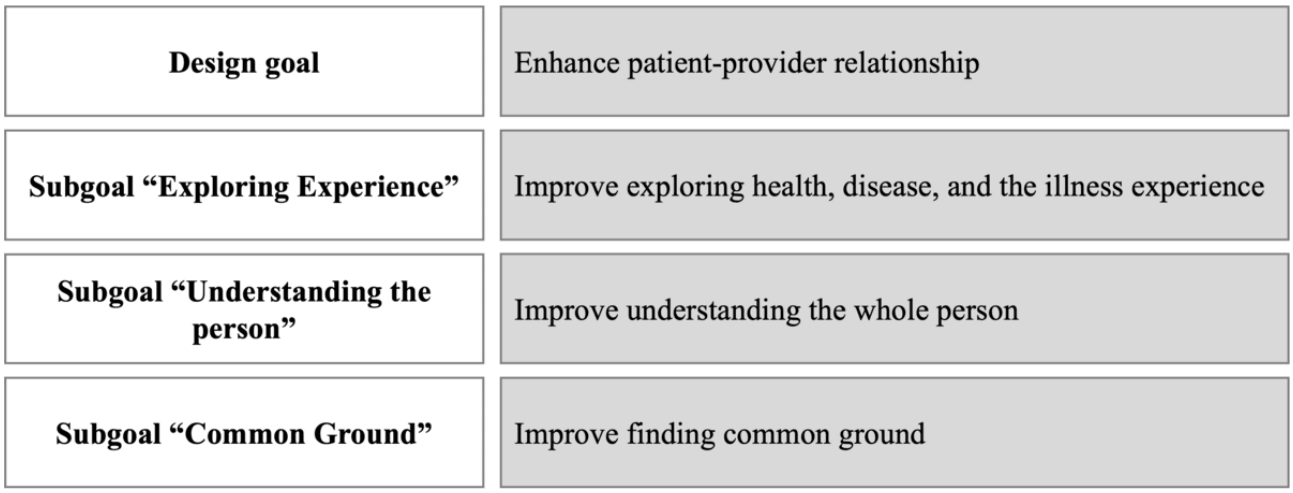
Overview

This study addressed the research gap described previously by developing PatientHub in a design science research (DSR) approach to enhance the patient-clinician relationship [47,48]. DSR is a suitable approach as it systematically solves important general problems and generates new knowledge in the form of design principles, theoretical models, approaches, and impacts of technology use [49]. DSR proposes to ground a solution's design in existing knowledge and theories, so-called kernel theories, to justify design decisions [50]. Due to these properties, design science is increasingly applied in medical informatics to study emerging technologies [48,51,52].

To address the research gap, we (1) designed PatientHub and (2) studied its impact on patient-provider communication by

adopting the patient-centered care framework proposed by Stewart et al [4] as our kernel theory. PatientHub is an integrated digital health tool that introduces patient-generated data into consultations. We build on the strong correlation between patient-generated data and improved patient-provider communication established in recent work [34-36]. While the patient-centered care framework offers a holistic foundation for improving patient-provider communication, it lacks a clear operationalization of the 3 dimensions that offer mHealth designers and health care providers guidance on implementing patient-centered care. Specifically, it is unclear how to integrate patient-generated data into the consultation process and how patients and providers use them for patient-centered care. Accordingly, we formulated a design goal and several subgoals in line with our kernel theory (Figure 3 [4]).

Figure 3. Design goal and subgoals based on the patient-centered care framework [4].



The following sections present the PatientHub design, our field study approach, and the data analysis method.

PatientHub Design

The project team designed PatientHub in 4 iterations. Our project team included a medical informatics company, a health institute specializing in chronic care, and 2 research institutions.

PatientHub's design is grounded in the patient-centered care framework [4] and leverages existing design knowledge [21-23,34,39,53]. Over the 3 preliminary iterations, we continuously evaluated and improved the design. We tested the first design iteration by applying the think-aloud method with 7 participants acting as patients [54]. After refining the design in the second iteration, a focus group of 5 domain experts from software development, medicine, and research evaluated the revised PatientHub. In the third iteration, 3 health care providers and 5 patients evaluated the design in role-plays of consultations. This paper reports on the field study evaluating the prototype with actual patients and physicians.

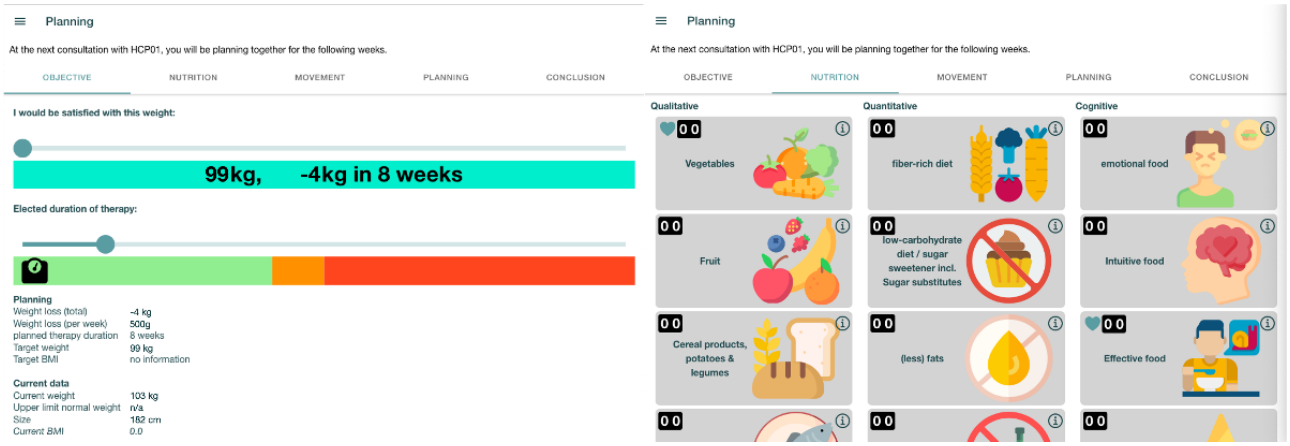
PatientHub aims to enhance patient-provider communication by integrating patient-generated data into the consultation. It consists of a patient app, where patients generate data, and a consultation app, where patient-generated data provide a foundation for discussion in the consultation. In the following section, we describe the design implementation using a scenario and screenshots of PatientHub. It represents a potential user story of PatientHub during the field study.

PatientHub Scenario

John is a patient at Laura's clinic struggling with obesity. Last week, Laura proposed that John try PatientHub to help them advance John's journey to better health. In the patient app on his smartphone, John tracked his dietary and activity habits in daily notes in a digital journal, filled out a general health questionnaire, and selected favorites for behavior change interventions as part of a 1-week preparation phase.

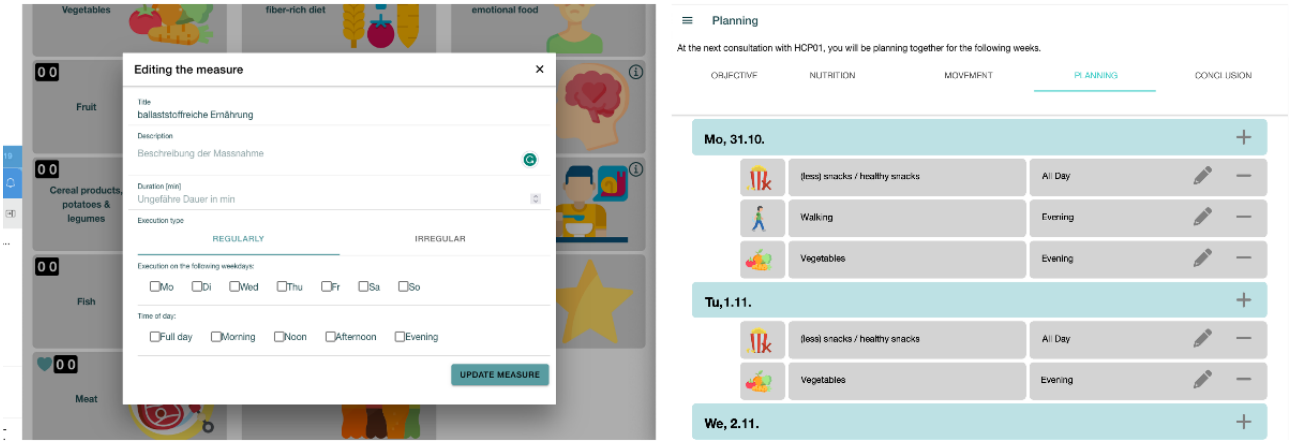
In the initial consultation, Laura and John review the journal entries, questionnaire answers, and intervention favorites in the consultation app on a tablet. The consultation app consists of 4 screens: goal setting, defining dietary and activity interventions, planning, and closing. For goal setting, John and Laura discuss target weight and therapy duration with a tablet-based visualization using sliders (Figure 4, left). As the visualization relates weight loss and duration to each other, they can discuss healthy weight loss and set realistic goals. To define dietary and activity interventions, John liked 3 interventions he would like to explore. John and Laura can discuss additional interventions from a list of obesity-friendly interventions (Figure 4, right; selected by medical professionals).

Figure 4. Goal setting (left) and dietary intervention (right) app screens.



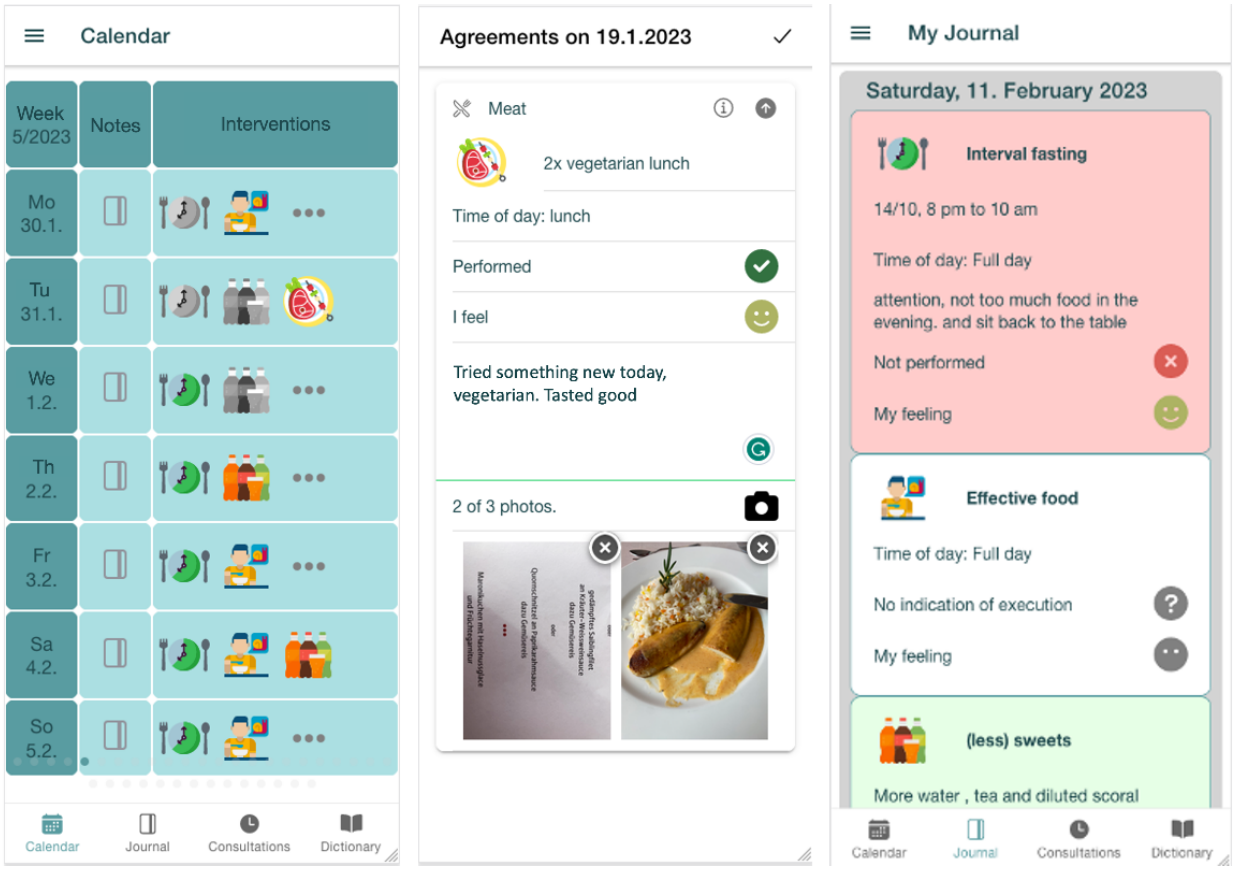
To create an intervention, they specify a name, a description (eg, 8000 steps per day), a duration (if applicable), recurrence (ie, regular or irregular), and preferred days and times (Figure 5, left). The consultation app allows them to discuss the interventions to arrive at a patient-centered therapy plan considering John's specific context. In planning, John and Laura see an overview of the interventions in calendar form (Figure 5, right). They can adjust the therapy plan if necessary (eg, move an intervention from Monday to Tuesday). Once the therapy plan is finalized, all information is automatically shared with John on the patient app.

Figure 5. Measure specification (left) and planning (right) app screens.



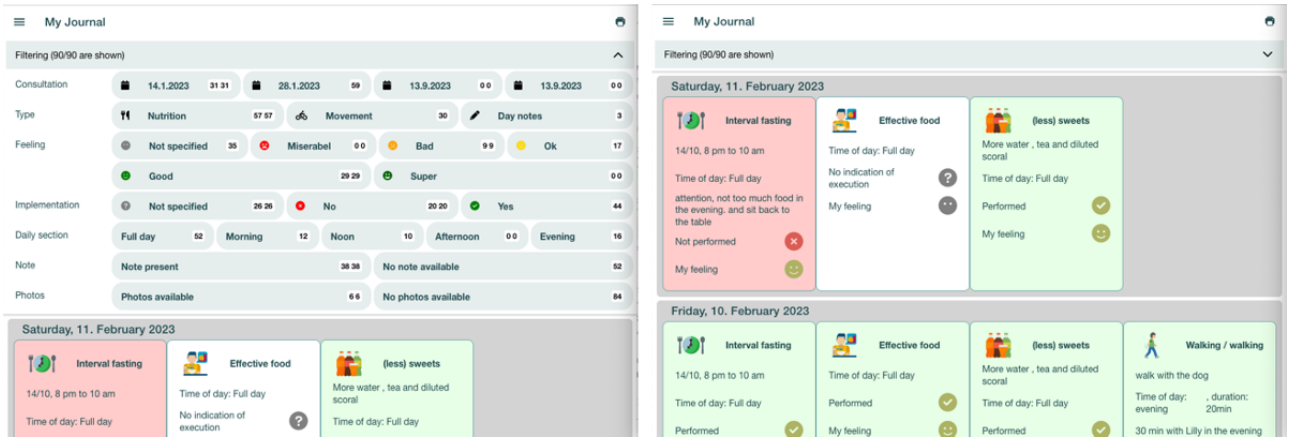
John tracks his health journey in PatientHub's journal for 2 weeks. He tracks his adherence to the therapy plan and his experience while executing it. John sees each intervention in the calendar, where open interventions are grayed out and become colored once completed (Figure 6, left). For example, John had to limit carbohydrate-dense foods today. He clicks on the gray task icon to create a task-specific entry. He marks the task as completed and sets his emotional state to medium as he missed out on dessert today. John then uploads a picture of his lunch and writes a note (Figure 6, middle). He can now review his entries in his journal (Figure 6, right). John carried out the therapy plan and kept his digital journal during the 2-week implementation phase leading up to the follow-up consultation with Laura.

Figure 6. Calendar (left), journal entry (middle), and journal overview (right) app screens.



The follow-up consultation focuses on reviewing John's journal. Laura and John apply different filters to the journal entries, such as task type (ie, diet, activity, and daily note), emotions, execution, and media type (Figure 7, left). This way, they can review interventions that were not completed or completed but not enjoyed by John (Figure 7, right). Through this discussion, they identify opportunities to improve the therapy plan and adherence. They adjust interventions as in the initial consultation by going through diet, activity, and planning before closing the consultation. Again, all data are shared across the PatientHub apps and the loop between consultations is closed. John enters a new implementation phase where he records his progress, which he will review again with Laura.

Figure 7. Filter options (left) and journal overview (right) app screens.



Data Collection

Overview

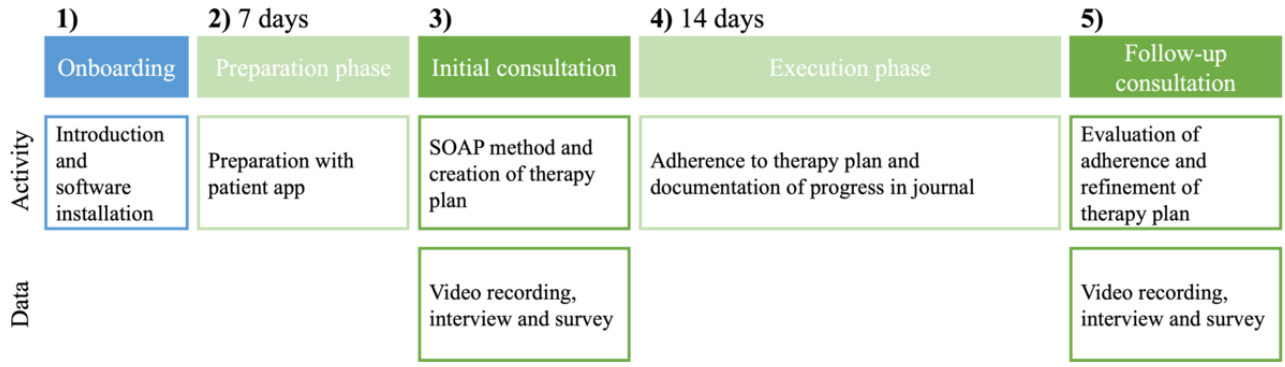
In line with the "human risk and effectiveness" strategy [55], we evaluated PatientHub in a naturalistic setting to assess its effects on patient-provider communication. For this purpose, we collected data in a 3-week field study. The data set contained video recordings of each consultation and interviews with each participant after both consultations. We analyzed 27 initial and follow-up consultations (54 recordings) to study emerging behaviors when integrating patient-generated data into the consultations. Furthermore, we analyzed interviews with all participants to study how patient-generated data enhance patient-provider communication (66 interviews in total; physicians were interviewed once per phase). In the interviews,

the participants reflected on their experiences throughout the field study. The authors and the project team developed the interview guides based on the kernel theory (ie, patient-centered care). The interview guide further included questions about the participants' experience using PatientHub and their implementation of the therapy plan. There were separate interview guides for patients and physicians and initial and follow-up consultations. English translations of the interview guides can be found in Multimedia Appendices 1-4. The interviews were held either in Swiss German or German by the lead author and experienced project members with digital health backgrounds. They were transcribed verbatim and anonymized.

The combination of video recordings and interviews provided us with a rich data set to evaluate the impact of PatientHub on patient-provider communication behaviors. Furthermore, evaluating in the field offered us valuable insights into the experience of patients and physicians when engaging with PatientHub.

The 3-week field study comprised five phases: (1) onboarding, (2) preparation phase, (3) initial consultation, (4) execution phase, and (5) follow-up consultation. Patients were asked to engage with the patient app of PatientHub during the preparation and execution phases. In the following sections, we outline the study design in detail, depicted in Figure 8.

Figure 8. Field study design. SOAP: Subjective, Objective, Assessment, Plan.



Onboarding

Patients

The study team explained the study design to the patients, including the process for the 3 weeks and the study aim, and answered any questions. All patients were interviewed and completed a survey regarding their previous experience in chronic care. The patients installed and logged into the system with help from the study team. Finally, they received instructions for the upcoming week, the so-called preparation phase.

Physicians

The physicians were introduced to the study design and goal. They received training on PatientHub before the initial consultations. While the training focused on the consultation app, we also introduced the patient app to the physicians.

Preparation Phase (Patients Only)

Patients kept a journal regarding diet and physical activity as daily notes in the patient app. They were asked to complete a general health questionnaire and select 3 favorite dietary and activity interventions.

Initial Consultation (Patients and Physicians)

The goal of the initial consultation was for the patients and physicians to create a therapy plan with dietary and activity interventions. They reviewed the patient-generated data (ie, questionnaire and journal entries). Furthermore, they discussed a desired weight loss goal and therapy duration. Finally, they created a therapy plan for the following 2 weeks. During the consultation, patients and physicians could use the consultation tool (see the aforementioned description). Physicians saw 4 to 5 patients throughout the field study, and the patient-provider matching stayed the same.

Execution Phase (Patients Only)

Over 2 weeks, patients implemented the therapy plan and generated data on their progress in the journal. Before the follow-up consultation, they filled out a shortened health questionnaire.

Follow-Up Consultation (Patients and Physicians)

The goal of the follow-up consultation was to tailor the therapy plan to the individual patients. Patients and physicians reviewed the patient's adherence to the therapy plan together. Insights from the discussion led to adjusting the therapy plan for the next execution phase. This marked the end of the field study.

Participants

The field study included 28 patients and 6 health care providers (ie, physicians in this study). Only 4% (1/28) of the patients dropped out after the initial consultation (patient 24), whereas all physicians completed the 3-week study. Before the field study, we conducted a pretest in December 2022 with 2 participants to uncover and resolve software bugs and flaws in the study design. The actual field study took place in 2 clinics in Switzerland in 2 rounds between January 2023 and April 2023 for logistic reasons. The first round was conducted in January 2023 with 18 patients and 4 physicians, and the second round started in March 2023 involving 10 patients and 2 physicians. We maintained the same study design and evaluated the same prototype.

To evaluate the effects of PatientHub on patient-provider communication in the most realistic setting, the inclusion criteria for patients were (1) age of ≥18 years, (2) a BMI of >25 kg/m^2

or specific medical indications for weight loss (eg, diabetes), (3) ability to communicate in written and verbal German, and (4) ownership of a computer and smartphone and adequate handling of both. Physicians were selected through personal contacts and had to meet the following inclusion criteria: (1) licensed physicians in Switzerland, (2) experience counseling patients with overweight, (3) ability to speak German, and (4) familiar with computers and tablets in consultations. Tables 1 and 2 present the demographic data of the participating patients and physicians, respectively.

Table 1. Demographic data of participating patients.

Participant	Sex	Age (y)	BMI (kg/m^2)	Occupation
Patient 01	Male	63	36.8	Electrician
Patient 02	Female	72	35.4	Retired
Patient 03	Female	81	34.4	Retired
Patient 04	Male	41	27.6	Lecturer
Patient 05	Female	72	29.3	Librarian
Patient 06	Male	84	30.8	Retired
Patient 07	Female	78	30.5	Retired
Patient 08	Male	62	31.9	Auditor
Patient 09	Male	81	32.5	Production manager
Patient 10	Female	37	46.3	Bank clerk
Patient 11	Male	65	25.7	Electrician
Patient 12	Female	55	41.5	Office clerk
Patient 13	Male	76	30.6	Musician
Patient 14	Female	84	35.6	Homemaker
Patient 15	Female	65	30.7	Retired
Patient 16	Male	58	36.8	Driver
Patient 17	Male	60	22.3	Teacher
Patient 18	Female	61	35.3	Chairwoman
Patient 19	Male	56	30.5	Lecturer
Patient 20	Male	57	36.6	Scientific assistant
Patient 21	Female	71	40.4	Retired
Patient 22	Female	58	37.6	Depositary
Patient 23	Male	66	31.1	Retired
Patient 25	Female	59	41.1	Office clerk
Patient 26	Male	53	27.2	Remedial teacher
Patient 27	Male	75	39.5	Office clerk
Patient 28	Female	65	26.7	Architect

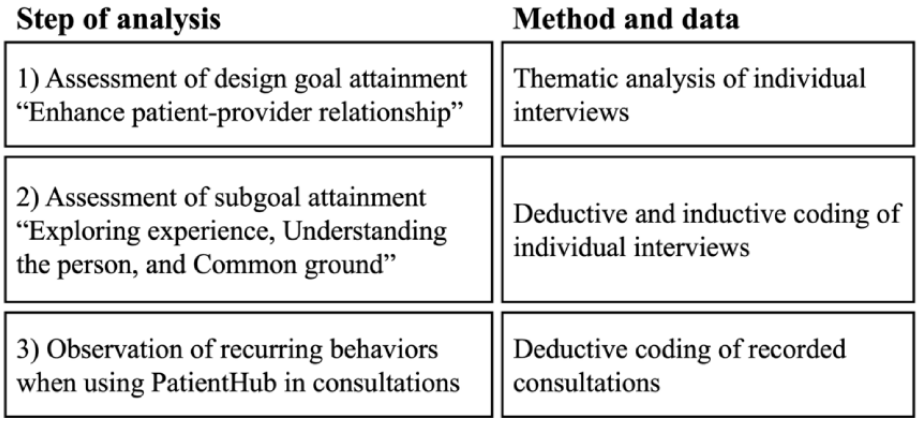
Table 2. Demographic data of physicians.

Participant	Sex	Age (y)	Workplace	Discipline
Provider 01	Female	28	Hospital	Surgery
Provider 02	Female	27	Hospital	Psychosomatics
Provider 03	Male	59	Hospital	General medicine
Provider 04	Female	58	Private clinic	General internal medicine
Provider 05	Male	52	Private clinic	General medicine
Provider 06	Female	44	Private clinic	General internal medicine

Data Analysis

The framework for evaluation in DSR proposes a continuum from formative to summative evaluation [55]. The framework offers 4 evaluation strategies, from which this study adopted the "human risk and effectiveness" strategy as the addressed problem is social and user centered [55]. Our analysis consisted of summative and formative elements as the study aimed to improve on the process under evaluation (ie, patient-provider communication). Accordingly, we applied deductive and inductive coding methods in 3 steps for the data analysis, as depicted in Figure 9.

Figure 9. Data analysis approach.



To study the effect of PatientHub on patient-provider communication, we analyzed individual interviews with patients and physicians and 54 video recordings of face-to-face initial and follow-up consultations (27 recordings each). This three-step analysis allowed us to assess (1) whether and (2) how PatientHub enhances patient-provider communication (interviews) and to (3) observe recurring behaviors when engaging with patient-generated data in consultations (video recordings). The research team consisted of a graduate student with a medical and information systems background (coding author), a PhD student in digital health (lead author), and 2 senior researchers in DSR.

First, we assessed the design goal attainment "enhance patient-provider relationship" by analyzing the interviewees' accounts regarding their perception of their relationship with the physicians (summative). After determining whether PatientHub had enhanced the patient-provider relationship, the coding author conducted a thematic analysis of the interviews [56]. This allowed us to identify the aspects that characterize high-quality patient-provider communication when using PatientHub (formative). The coding author created in vivo codes focusing on the effects on patient-provider communication attributed to patient-generated data in the consultation. The lead author conducted quality assurance by reviewing and revising the codes. In an iterative process, the lead and coding authors then grouped the codes into 4 characteristics of high-quality patient-provider communication: *personalization*, *actionability*, *trustworthiness*, and *equality*.

Second, we assessed the attainment of our subgoals "exploring experience," "understanding person," and "common ground" by applying a mixed deductive and inductive analysis [57,58]. We developed an initial coding scheme from related work on our kernel theory, patient-centered care [4,20]. We complemented the coding scheme with codes derived from the literature on patient-provider communication [22,23,38,39,59]. Again, the coding author created in vivo codes to capture emerging phenomena. She coded approximately 20% of the interviews before discussing the results with the lead author to refine the coding strategy. The coding author then finished coding all interviews. Finally, the lead author reviewed and refined the coding by discussing discrepancies with the coding author. In a workshop, the author group synthesized how PatientHub improved each dimension of patient-centered care.

Third, we deductively analyzed the video recordings regarding emerging behaviors [58]. The coding author analyzed the recordings based on the coding scheme applied and refined in the interview analysis. The coding scheme sensitized us to patient-centered behaviors enabled through PatientHub. During the coding of the videos, the coding scheme was expanded with in vivo codes to include emerging phenomena [58]. The video recordings were analyzed in 2 rounds on-site at one of the clinics (to ensure data privacy). We extracted emerging behaviors from the first coding round by drawing sequential processes. Initial drafts of these processes were discussed in a workshop including the author group and members from the project consortium. In the second coding round, we iterated on all video recordings based on the identified behaviors to refine our understanding and transcribed relevant sequences from the recordings. This step allowed us to formalize the 3 communication behaviors described in the *Results* section.

Ethical Considerations

While the ethics committee of the canton of Zurich confirmed that this study is not subject to the Swiss Human Research Act (BASEC-Nr. Req-2018-00847), we still decided to obtain written consent from all patients and physicians before the field study. The informed consent form educated participants about their rights and responsibilities, data use, and privacy measures following the World Medical Association Declaration of Helsinki [60]. The participants had the possibility to opt-out at any time during the study. The form also informed the participants' data will be gathered deidentified by assigning each participant with an identifier (ie, patient 1 to patient 28

and provider 1 to provider 6). Multimedia Appendix 5 provides the authors' positionality statement to give the readers a better understanding of the authors' backgrounds.

The participating clinics selected patients using a purposeful sampling approach [61]. The compensation for patients was CHF 50 (approximately US $60) and a raffle ticket for a restaurant voucher worth CHF 200 (US $230.15).

Results

Overview

In this section, we present our findings. First, we examine the attainment of the design goal (ie, enhance the patient-provider relationship) and discuss the 4 characteristics of high-quality patient-provider communication identified in the analysis. We then examine how patients and providers perceived patient-centered care in these consultations (ie, subgoals). Finally, we introduce 3 emerging communication behaviors when engaging with patient-generated data.

Enhancing the Patient-Provider Relationship With PatientHub

Overview

When asked about their relationship with the providers, the patients reported high satisfaction with their interaction compared than previous experiences. They often described an intimate connection that would feel significantly older than the 3 weeks of the valuation. In total, 4 central characteristics emerged from our data analysis that explain this enhanced patient-provider communication. Patients and providers commonly raised these characteristics when asked about their perception of the new approach supported by PatientHub compared with previous experiences. In the following sections, we explore each characteristic in more detail. Textbox 1 provides quotes from patients and providers for each characteristic.

Textbox 1. Characteristics of enhanced patient-provider communication with exemplary quotes.

Personalization of health care

- "She has tried to address the fact that I am not allowed to be overburdened with walking because the knees just do not work" (patient 07). Others highlighted the enriching discussions they had with the physicians "because I noticed that these are not standard answers.... He looks at you [the patient] as a human being, as an individual" (patient 25).

Actionability of interventions

- "It is simply a clean data basis. Now we're talking facts and not 'How did you perceive it?' or 'How was it for you?' but Bam! There! Suddenly, 'how many times did you go on the cross trainer?' 'how many times did you get the interval fasting done?'" (patient 04).
- "I was really happy to see the results. Because I remember the last time you said that you do so much, and you don't see any results, and now we have the result" (provider 01).

Trustworthiness of communication

- "She was prepared. So, she read my brainy entries [laughs].... So, she obviously prepared for me. She looked at the questionnaire that I filled out [during the preparation phase]. She wrote down questions about it. That really feels good" (patient 17).
- "They were unbelievably more trusting. They revealed so many, many things. So, I think it was a very different level of trust already compared to last time" (provider 05).

Equality of partners

- "I came here prepared and I already had ideas. If I had to choose favorites now [in the consultation], I would have come and I would have accepted [the physician's proposal]. Then you are externally steered" (patient 26).

Personalization of Health Care

Patient-generated data support patients and providers in personalizing health care as they facilitate in-depth discussions about the patients, their context, and their experience with their health. The data provide a solid foundation based on facts instead of gut feelings and memory. Therefore, the mutually agreed upon therapy plans consider the patient to be a person with their preferences, needs, and limitations. The physicians were understanding when proposing interventions and considered the patients' circumstances. All patients in the interviews highly appreciated this (Textbox 1).

Actionability of Interventions

Patients and providers appraised the concreteness of the discussions facilitated by the consultation tool with the intervention screens (Figure 4, right). Many patients reported previous frustrating experiences in which providers stayed abstract in their recommendations (eg, "eat less sweets"). Due to the more integrated and holistic understanding of the patients, providers and patients could concretely discuss problems and priorities, goals, and expectations regarding each other's roles. Many specifically highlighted how the patient-generated data allowed them to agree on actionable interventions. Therefore, patients perceived providers as more empathic and engaged in their health journey. For example, patient 26 "felt joy from the provider.... I think she was very motivating and also praised that I had done well." The providers proved the perception right as many were pleased with their patients' progress, such as provider 01 and patient 02 (Textbox 1).

Trustworthiness of Communication

Patients and providers believed that sharing patient-generated data requires trust in the first place and creates trustworthy communication. Patients perceived it as appreciation (Textbox 1, patient 17). The providers reciprocated this appreciation. When asked about the relationship between her and the patients after only 2 consultations, provider 05 highlighted how PatientHub created a trusting foundation that made the discussions in the consultations much more meaningful (Textbox 1, provider 05).

Approximately half (15/27, 56%) of the patients raised the topic of surveillance concerning sharing their data. However, most patients appreciated the subtle surveillance as it made the therapy plan more binding. Only 19% (5/27) of the patients felt uncomfortable sharing too much personal information. Accordingly, they only shared what they felt comfortable with in the journal.

Equality of Partners

Finally, PatientHub leads to a shift in the perceived roles of patients and providers. Many patients perceived control over the decisions made in the consultation. This perceived control leads to the feeling of cooperation between equal parties in the decision-making process. The patients felt strengthened in their position as they were the experts on their data (Textbox 1, patient 26).

The preparation allowed patient 26 to have an opinion instead of mindlessly accepting the provider's proposition. Furthermore, in the follow-up consultations, patients defended their standpoints and argued for changes to the therapy plan. For example, patient 18 demanded the reintroduction of carbohydrates into her diet due to her physically demanding job. As a result of this approach, patient 23 experienced the consultation as "an open conversation and not somehow top-down. On the same level and friendly." Many providers, too, remarked on the shift in power balance.

The Process of Patient-Centered Care

Our analysis elicited the 4 characteristics of high-quality patient-provider communication. In the following sections, we explore the process of enhancing patient-provider communication by discussing the 3 dimensions of patient-centered care (ie, subgoals)

Finding Common Ground

Overall, we observed that the consultations centered on the 3 aspects of finding common ground: problems and priorities, goals, and roles. PatientHub introduced patient-generated data into the natural consultation process through screens for goal setting, interventions, and planning. Patients and providers reported that the tool was a significant part of the consultation as it formed the starting point for exploring problems, priorities, and roles. The data also served as a reference to argue for or against a proposition, thereby shaping the individual roles. Therefore, patients and providers arrived at mutual decisions regarding all 3 aspects of finding common ground. When asked about the reasons for the positive impact of PatientHub, provider 01 answered the following:

> *You are pulling in the same direction. And are in the same reality. And that makes a much better team. And just have a more balanced, I do not want to say power balance, but a more balanced decision-making.*

However, patient-generated data did not solely support finding common ground directly. Each behavior explored the other 2 components to indirectly inform mutual decisions made in the consultations.

Exploring Health, Disease, and the Illness Experience

The general health questionnaire and journal entries allowed patients and providers to discuss the patients' unique perceptions of their health in both consultations (ie, the "exploring experience" subgoal). For example, provider 02 recognized in the journal overview (Figure 7, right) that patient 08 ate too few vegetables and drank too much alcohol, which the patient agreed with. Instead of staying abstract about the consumed amount of alcohol, they had a clear impression of the number of alcoholic beverages that the patient drank in a week. Several patients realized during the consultation that they were emotional eaters. The patient-generated data prompted the provider or patient to highlight such experiences. In addition to behaviors, they often discussed emotional aspects of the patient's experience. For example, 2 patients said that they did not like swimming because they did not want to show themselves in bathing suits. Patient 11 mentioned in the questionnaire that he feared the health problems associated with obesity. During the consultation, provider 03 could follow-up on this answer by asking why the patient was afraid. Patients and providers explored the target weight reported in the questionnaire during goal setting. Often, they discussed the origin of this specific target, such as a feeling of well-being or a historic weight they had during a significant part of their life (eg, before they became parents).

Patient-generated data had an even more profound impact during the follow-up consultation. Patients and providers could gather an integrated understanding of the patients' experience in the execution phase. The patients documented their emotions and thoughts using emojis, pictures, and text in journal entries (Figure 6). These data provided patients and providers with a rich foundation for discussions in the follow-up consultation. Instead of relying on the patients' memory and accuracy, providers had in-depth insights into the adherence and patient experience. Sometimes, patients highlighted a journal entry because they believed that it was significant for their (lack of) success in following the therapy plan. For example, patient 07 referred to the picture of an icy peer to explain her nonadherent behavior to the "walking" intervention. Most providers emphasized the benefit of recording a patient's emotional state. This way, they could inquire about negative feelings related to a specific intervention. For example, provider 01 could identify a potential correlation between patient 01's emotional state and his adherence to intermittent fasting. Together, they explored that patient 01 was under pressure at work during the execution phase. This led to him feeling tense and not sleeping well. Therefore, he was not motivated to adhere to intermittent fasting. However, they realized that the patient indeed felt better on

days when he could adhere to the intervention, as provider 01 recalled in the interview:

> *And then you could break that down nicely and say, hey, you did it. The mood was good. Look at the app. It was ALWAYS good for you to do [intermittent fasting]. And then it really came back from the patients like this: Yes, that's right.*

Understanding the Whole Person

Traditionally, consultation time is limited to a few minutes per patient. This limited time often does not allow providers to ask questions not directly associated with the presented problem. Consequently, understanding the whole person often falls victim to other, more pressing matters. However, the journal entries and the corresponding overview and filters allowed providers to understand the patient's daily life ("understanding person" subgoal). In addition, the journal entries served as the foundation to further gain a better understanding of the whole person during the consultation (Figure 7). For example, provider 03 and patient 12 discussed her consumption of vegetables, where patient 12 said the following:

> *Probably too little in proportion. Because I have to be honest, I don't like to cook..... And many times, it is so my partner works irregularly. And when we come home in the evening, something should just quickly be on the table. And I don't want to stand two hours in the kitchen when I have worked all day.*

This quote illustrates how patient-generated data prompted provider 03 to learn about patient 12's experience and her proximal context—her partner working shifts might interfere with regular habits. In general, the available information and the subsequent discussion yielded interesting insights that providers usually would not obtain, as they all said during the interviews. For example, it became evident that chocolate yogurt was a central piece of patient 18's diet. Patient 28 preferred to walk alone as he was an only child. Patients 01 and 25 had dogs, but another household member usually walked them. Patient 03 cooked for her husband and did not think he would want to eat less meat or try different grains. In addition, she drove him to therapy and, therefore, had less time for cooking.

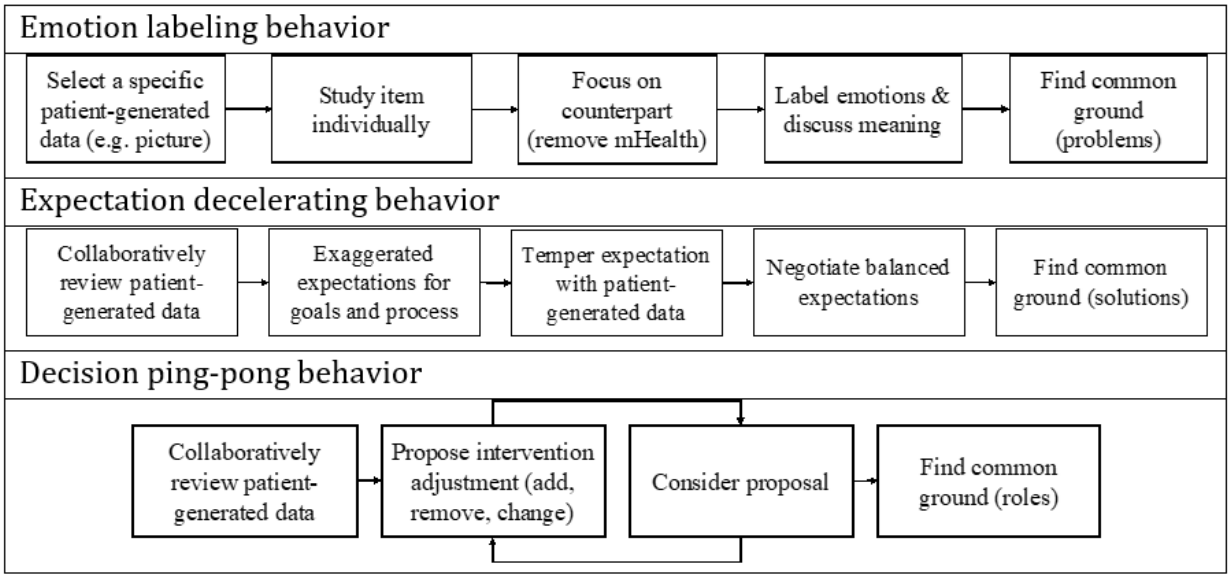
In general, patients believed that their data helped providers obtain a better understanding of them. For example, patient 16 liked that the provider had more background information before the initial consultation. Patient 10 shared this opinion as she believed that it would be impossible to obtain such a deep understanding in such a short time. The providers agreed with the patients and explicitly mentioned PatientHub's advantages to understand the whole person better. Providers 01 and 04 referred to "look beneath the patient's surface" as a significant advantage.

Emerging Patient-Provider Communication Behaviors

Overview

In the following sections, we outline 3 behaviors that we could repeatedly observe across consultations when using PatientHub. First, we describe each behavior. Then, we provide examples of the behaviors and highlight how patients and providers perceived them. Figure 10 provides visual representations of the sequential activities of the behaviors.

Figure 10. Visual representations of the 3 emerging patient-provider communication behaviors.



Emotion Labeling

This behavior is called emotion labeling as patients and providers discussed patients' experiences based on patient-generated data and attached a label to it (Figure 10). The behavior occurred at the beginning of each consultation (initial and follow-up). Patients and providers sat around the table's edge so that both had visual access to the tablet facing them. The tablet showed the journal overview with patient-generated data (Figure 7, right). The 2 variations of this behavior differed depending on the person who initiated the behavior. Providers commonly selected specific patient-generated data to start the

behavior (eg, a journal entry or a questionnaire response). Often, providers referred to pictures shared by the patients. They were picked due to the client's reported adherence or nonadherence, emotional state, or uploaded pictures. Less often, patients initiated the behavior by referring to a specific item that represented a problem or priority. The initiator pointed to the specific item and sometimes opened the journal entry. After both acknowledged the item, they moved the focus from the tablet to the other person, adjusting their seating position and turning their bodies and heads toward one another. The provider even moved the tablet out of the shared interaction space in some consultations. Then, patients and providers labeled the patients' emotions regarding the matter represented by the selected item. They discussed the item and its meaning for the patient's experience or context to arrive at a common understanding of the patient's problems and priorities.

One example of emotion labeling is patient 18, who craved chocolate yogurt. The photos and text in the journal allowed provider 04 to elicit the issue and sensibly raise the topic of the large amount of sugar in chocolate yogurt. During the discussion, they explored this craving to discover 2 reasons for it. First, chocolate yogurt was a fast and enjoyable meal after a long and stressful workday. Second, the yogurt satisfied an emotional need as it was something to look forward to. Therefore, provider 04 proposed reducing the quantity of chocolate yogurt and adding plain yogurt with fruits or jam as a low-sugar alternative. This resonated well with patient 18:

> *Ah, I'm allowed to eat chocolate yogurt (laughs). I noticed right away that she was not telling me: You're not allowed to do that anymore; from now on, there's only this and that. It's often restrictions that make things difficult. I have seen that I should lose weight over a long time, and then it doesn't have to be as radical. This way, we can mix it up.*

Patients also raised issues on their own. Patient 02 believed that one of her core problems was drinking too much alcohol, which she documented in the journal. During the interview, provider 01 explained that the journal helped her assess the quantity as unproblematic and that she would have reacted differently without the patient-generated data. They identified the guilt associated with drinking alcohol as a constant stressor.

Expectation Decelerating

Expectation decelerating (Figure 10) occurs when one party needs to reduce the momentum that the other is exhibiting. The behavior followed the emotion labeling behavior, where patients and providers mutually agreed on the patients' problems and priorities regarding weight management.

Expectation decelerating varied between the initial and follow-up consultations. In the initial consultation, the providers changed the topic to discuss target weight. They reviewed the patient's desired weight and therapy duration before the consultation. However, they first invited patients to talk about their target weight and the reason for this specific target. Upon understanding the patient's reasoning, they focused on the goal-setting screen (Figure 4, left), where the patient-generated data are prefilled (ie, target weight and therapy duration). Providers proposed an intermediate goal and explained their reasoning depending on the targeted weight loss and therapy duration. To illustrate the proposal, providers moved the weight and time slider to the proposed goal. A scale icon indicated the sustainability of the target weight and time frame on a color scale from green to red. A 500-gram weekly weight loss was considered sustainable [62]. If the chosen target was beyond this limit (ie, the scale icon was in the red area), the providers would highlight this and explore the relationship between weight and time with the patient. They simulated different scenarios to understand sustainable weight loss. In the end, they left the decision up to the patients. The exploration led to either a prolonged therapy duration or setting an intermediate goal.

In the follow-up consultation, expectation decelerating occurred after reviewing the patient's adherence using the journal entries. To conclude the emotion labeling behavior, patients or providers often proposed adding new interventions or increasing their frequency (eg, running more often). While substituting ineffective interventions usually generated mutual agreement, adding to the existing interventions was often more intensely debated. Frequently, the providers advised against a patient's request, referring to patient-generated data to highlight the continued effectiveness of the existing interventions. However, patients also had to decline similar propositions by providers. Similarly, they referred to their journal entries or insights based on these data to argue their position. The following excerpt shows a discussion regarding the therapy duration in the initial consultation between patient 06 and provider 02:

> *Provider 02: I have seen your target weight or desired weight would be 76 kg.*
>
> *Patient 06: I am also already satisfied with 77 to 78 kg.*
>
> *Provider 02: So, let's say we want to aim for 78 kg (sets target weight with slider). What is your wish when you want to reach it?*
>
> *Patient 06: Yes, that's what I am like. I want it as soon as possible. But then you gain it back again soon, right?*
>
> *Provider 02: Yes exactly. So, what does soon mean concretely? We can now play it through virtually what that means as a weekly goal. So that would be 4 kg if we say 78 kg. When do you want to have that?*
>
> *Patient 06: I don't know, I say in two months it should be possible.*
>
> *Provider 02: In two months, that would be eight weeks (Provider adjusts the slider on the tablet). That is not completely unrealistic for 4 kg, but it is relatively strict. So, if you actually don't want it to be an extra burden, an additional task, then it's too ambitious. Then I would rather put it at three months, right? (adjusts slider). Then you see, there is the scale that shows how much weight you would have to lose or how ambitious that it is. We are now well in the green zone. Concretely that would mean a little more than 300 grams decrease per week.*

Often, patients entered the consultation with overambitious goals, as they recalled themselves in the interviews. Furthermore, they were enthusiastic after the 2-week execution phase as they could follow most interventions and proposed including more interventions. Providers used patient-generated data to decelerate the patients' drive to maintain sustainable progress and prevent setbacks. While deceleration might be negatively connotated, most patients drew motivation from this behavior. For example, patient 02 mentioned that the 5 kg they decided on motivated her more than if she had tried to lose the initial 15 kg. Furthermore, patient 12 summarized the following:

> *Yes, and what really stuck with me was that he took a little bit of the pressure off. When you always have the feeling that you have to lose as much weight as possible as quickly as possible. That he then said: It's good and healthy to lose 500 grams a week. That has stayed with me very much, and has also motivated me, so that I did not think: Oh in 14 days I should be 10 kg lighter.*

Patient 16 agreed and mentioned the sliders, visualizing the relationship between weight loss and time, as essential for setting realistic goals. The providers agreed with this perception as the patient-generated data would provide a solid foundation to assess the therapy plan's effectiveness, which is usually missing in conventional consultations. Provider 06 highlighted the following:

> *Yes, I always have the feeling that I always have to make suggestions. And [with the patient-generated data] you could say, we've done a good job. We are good. We continue to do so. Done.*

Provider 02 agreed that patients usually quit because they want to achieve overly ambitious goals. With patient-generated data, they could credibly show that it is possible to lose weight with small and sustainable changes.

Decision Ping-Pong

Decision ping-pong refers to the back-and-forth process of mutual decision-making (Figure 10). It occurred when creating and adapting the therapy plan. The input for this behavior was patient-generated data created outside the consultations. During the preparation phase, patients selected favorites from a list of dietary and activity interventions and documented their daily lives in journal entries.

In the initial consultation, providers initiated the behavior by moving to the interventions screen to display the patient's favorites, marked with a "heart" icon (Figure 4, right). Providers asked the patients why they selected the specific interventions to start the decision ping-pong. Often, patients chose the interventions as they had previously engaged in an activity or started the intervention themselves only recently. Next, providers asked patients which favorites to add as an intervention. After the patients decided on an intervention, they discussed details such as frequency and duration. A back-and-forth followed to first agree on a frequency and duration (if applicable). Once agreed, patients and providers negotiated the timing of this intervention (ie, days and time of the day). While providers often proposed the frequency and duration, the patients usually initiated the discussion on timing according to their professional and private situations. This ping-pong was repeated until both were satisfied with the therapy plan. Interestingly, patients started proposing interventions themselves after some repetitions (eg, after adding 2 interventions).

In the follow-up consultation, the behavior occurred slightly differently. First, patients or providers initiated the behavior to discuss the necessity of exchanging ineffective interventions based on the journal entries crafted by the patients in the execution phase. The behavior ended if they mutually agreed not to adjust the therapy plan. If they decided to adjust, the behavior continued as in the initial consultation.

The following excerpt shows a discussion between patient 10 and provider 03 about an activity intervention:

> *Patient 10: Or aerobics would be something I would like to do.*
>
> *Provider 03: So once in the evening?*
>
> *Patient 10: Yes.*
>
> *Provider 03: Thursday is busy [with other interventions]*
>
> *Patient 10: Then, we will take Monday.*
>
> *Provider 03: Or after cleaning (both laugh).*
>
> *Patient 10: No, thank you.*
>
> *Provider 03: Monday?*
>
> *Patient 10: Yes.*
>
> *Provider 03: In the evening?*
>
> *Patient 10: Mhm.*
>
> *Provider 03: How long?*
>
> *Patient 10: Half an hour.*
>
> *Provider 03: Half an hour. I think so too. We will just put that in now.*

A total of 30% (8/27) of the patients explicitly mentioned their appreciation for the realistic goals as an outcome of this process. Patient 21 liked that the provider said that "You cannot just cancel everything overnight. Then you just stop again." After 2 weeks, patient 16 compared the results to other diet regimes he had followed in the past:

> *The whole thing is calmer and less stressful. It feels easier. It goes on for a longer time, but it is more pleasant to get through the day that way.*

The provided selection of tasks and the talk with the physician helped produce ideas that the patients usually would not have produced. Patient 04 said that he would not have chosen intermittent fasting but he did because a professional explained it. The decision ping-pong showed that it could be adapted to his situation. The process also inspired the providers as provider 05 said that he would not have all these ideas spontaneously.

Discussion

Principal Findings

Supporting patient-provider communication using patient-generated data is a growing topic of interest in health

informatics and related fields. However, the existing literature often overlooks the processes (ie, communication behaviors) when enhancing patient-provider communication using patient-generated data. More importantly, existing mHealth apps are seldom integrated into the provider's workflow and do not sufficiently engage and activate patients in patient-centered care [44-46]. Through a design science approach, we explored how to design an integrated digital health system and its impact on the communication behaviors of 27 patients and 6 providers.

Previous work has demonstrated the benefits of integrating patient-generated data into consultations [32,35,38,45,63,64]. We expand on this work by studying the effect of patient-generated data on patient-provider communication behaviors. As argued in the Introduction section, current research focuses on the input (patient-generated data) and output (enhanced patient-provider communication; Figure 2). Our analysis elicited 3 emerging behaviors that open the black box of patient-provider communication. On the basis of our theoretical foundation and empirical findings, we propose patient-centered communication in 3 design principles to operationalize the patient-centered care framework.

Facilitate Emotion Labeling to Explore Health, Disease, and the Illness Experience and Understand the Whole Person

The emotion labeling behavior highlights how the input is initially processed. Patient-generated data enable patients and providers to reflect on patients' emotions related to their health. For example, patients speak about their insecurities when engaging in physical activities in public due to being overweight. Prompted by photos, emojis, and text, patients and providers explore patients' unique experience with their health and disease ("exploring experience" subgoal). Furthermore, emotion labeling uncovers obstacles in the patients' journeys to better health. As described in the Results section, journal entries allowed patient 03 and provider 01 to uncover and discuss the reason for the patient's nonadherence. Patient-generated data allowed the patient and provider to understand the patient as a whole person and their proximal context ("understanding person" subgoal).

Existing research has shown how visualizations of health data increase health literacy in patients [38]. Our results show how patient-generated data are used to not only educate patients but also collaboratively generate new insights. We argue that patient-generated data enhance patient-provider communication by stimulating the exploration of a patient's experience and context. Providers can usually only scratch the surface of a patient's story in consultations. PatientHub introduces them to their patients' world, allowing them to dive below the surface and gain an integrated understanding. The patients themselves also profit from their data. Our results show that generating data often initiates self-reflection that fosters patients' understanding of themselves. Therefore, patient-provider communication becomes more patient centric. Patients and providers explore the patient's experience and context to find common ground regarding problems and goals.

Facilitate Expectation Decelerating to Find Common Ground on Problems and Solutions

The expectation decelerating behavior processes patient-generated data differently. Instead of beginning with a patient's experience or context, patients and providers used patient-generated data to assess problems or goals. Our results show 2 areas in which patient-generated data decelerated patients and providers: setting goals and developing therapy plans. Providers referred to these data in the former to decelerate the patients' ambitions. They suggested either more long-term planning or a more achievable intermediate goal. When developing therapy plans, patients and providers resisted the urge to add more or exchange interventions too quickly due to patient-generated data ("common ground" subgoal). As seen in the Results section, patient 01 could successfully argue his standpoint on keeping intermittent fasting in his therapy plan due to his data. The data allowed them to assess the therapy plan's effectiveness, resulting in the mutual decision not to adapt it if the effectiveness persisted. Existing research demonstrates the value of patient-generated data for problem-solving and decision-making [23,64]. While we agree with their findings, the saying "It's a marathon, not a sprint" highlights the importance of expectation decelerating. Our results show how patient-generated data are applied in consultations to resist the urge to hurry long-term behavior change. Accordingly, expectation decelerating might counteract the common pressure of a quantified self to always strive for more [65]. Quantified humans use data to continuously find inefficiencies and improve on those, often resulting in unhealthy pressure. Instead of expanding the therapy plan, patients and providers could assess the effectiveness of the current plan in the follow-up consultation. They had a reliable foundation for decision-making instead of hampering long-term success with impulsive actions. They defined achievable targets with a personalized therapy plan tailored to the patient. Therefore, patients might have more endurance in their marathon race to change their lifestyle.

Facilitate Decision Ping-Pong Between Patients and Providers to Find Common Ground on Their Roles

Decision ping-pong reflects on how patient-generated data affect the dynamics of patient-provider communication. Existing research in medicine and human-computer interaction postulates the importance of shared decision-making [4,17,21,23,53]. Our results expand on these insights by examining how patient-generated data include the patient in decision-making as an expert and how this changes the consultation dynamics ("common ground" subgoal). Many patients noticed how their position had changed in the initial consultation compared with their previous experience. We argue that introducing patient-generated data goes beyond facilitating informed decision-making. With these data, patients provide "proof" of their adherence, for example, through pictures. Moreover, they have a much deeper knowledge of PatientHub's content. It contains patient-generated data and evokes memories that might not be documented in the system. Equipped with this knowledge, patients become experts in their own domain: their health journey.

In shared decision-making, the implicit understanding is that providers assess the patient's state and offer options [17]. Existing research often sees patient-generated data as crucial information for providers to offer better health services [22,64]. Studies explore ways to design technology to make large amounts of patient-generated data consumable for providers [23]. Implicitly, this focus places the responsibility for data interpretation on the providers. However, we believe that patient-generated data could partially relieve providers from this burden. Patient-centered care emphasizes mutual decisions; therefore, patients should carry this burden with their providers.

Our results show that most patients willingly accepted such a role as they felt taken more seriously, could defend their position, and perceived having control over the decision-making process. Integrating patient-generated data into the consultation empowers patients to assume a more active role in their health care. We argue that providers must not be solely responsible as our results highlight how patients become experts in their health journey. Instead, the responsibility is shared between patients and providers according to their expertise. While providers assess the data against their medical knowledge, patients interpret the data in the context of their lives and experiences. Therefore, their communication becomes truly "respectful of and responsive to individual patient preferences, needs, and values and ensuring that patient values guide all clinical decisions" [16].

Conclusions

This study evaluated communication behaviors that emerge when introducing patient-generated data into patient-provider communication. We studied how these behaviors in patient-provider communication actualize the potential of patient-generated data to increase patient-centeredness. Our analysis uncovered 3 communication behaviors in medical consultations when using PatientHub. Furthermore, we demonstrated how enhanced patient-provider communication is necessary for patient-centered care. On the basis of our findings, we believe that this study contributes to research in 2 ways. First, we emphasize the value of patient-provider communication. The identified behaviors demonstrate how data-supported patient-provider communication creates value, not the technology and data themselves. Second, the behaviors offer actionable insights into implementing patient-centered care.

However, this study does not come without limitations. First, while we evaluated PatientHub in the most realistic setting, its applicability in the real world depends on regulatory and security frameworks. Second, the generalizability could be further increased with a larger sample size and a randomized controlled trial. Future research could also investigate how patient-generated data empower patients individually to study the changing role dynamics in medical consultations.

Abstract

Background: Information control is a promising approach for managing surgical specimens. However, there is limited research evidence on surgical near misses. This is particularly true in the closed loop of information control for each link.

Objective: A new model of surgical specimen process management is further constructed, and a safe operating room nursing practice environment is created by intercepting specimen near-miss events through information safety barriers.

Methods: In a large hospital in China, 84,289 surgical specimens collected in the conventional information specimen management mode from January to December 2021 were selected as the control group, and 99,998 surgical specimens collected in the information safety barrier control surgical specimen management mode from January to December 2022 were selected as the improvement group. The incidence of near misses, the qualified rate of pathological specimen fixation, and the average time required for specimen fixation were compared under the 2 management modes. The causes of 2 groups of near misses were analyzed and the near misses of information safety barrier control surgical specimens were studied.

Results: Under the information-based safety barrier control surgical specimen management model, the incidence of adverse events in surgical specimens was reduced, the reporting of near-miss events in surgical specimens was improved by 100%, the quality control quality management of surgical specimens was effectively improved, the pass rate of surgical pathology specimen fixation was improved, and the meantime for surgical specimen fixation was shortened, with differences considered statistically significant at $P<.05$.

Conclusions: Our research has developed a new mode of managing the surgical specimen process. This mode can prevent errors in approaching specimens by implementing information security barriers, thereby enhancing the quality of specimen management, ensuring the safety of medical procedures, and improving the quality of hospital services.

Introduction

Overview

Pathological specimens are an important basis for judging the outcome of a patient's disease [1]. Surgical specimen management involves many aspects, and errors in any part of the specimen management process may lead to serious consequences. The management of surgical pathological specimens directly affects the quality and safety of nursing management in the operating room. Therefore, how to reduce the occurrence of abnormal events has become the focus of nursing in the operating room.

A near miss is a commonly used term in clinical nursing, referring to a kind of nursing abnormal event that may damage the life, health, and safety of patients but has not yet developed to the end point [1,2]. It has similar causes and development paths with adverse events (the event caused inconvenience or harm to the patient), but the number is far greater than adverse events. At the same time, it has little harm to patients and hospitals and can give early warning before harm to patients, help the medical management system to carry out forward-looking and proactive risk assessment and prevention, which is regarded as a better learning resource and a risk management method advocated by the hospital's fine management. Studies have shown that specimen approach failure is related to a variety of factors, such as human negligence, unreasonable workflow, and communication problems [3-7]. In recent years, information management of surgical specimens has gradually become the core issue that operating room managers continue to explore.

Surgical specimen informatization refers to the digital management process of specimen information obtained during surgery. It enhances data traceability, improves management efficiency, and ensures the accuracy and security of medical information. Specimen informatization involves digitally performing specimen collection, identification, transport, and reception [8]. Surgical specimen control refers to the effective management and control of specimen collection, processing, recording, and storage during surgery. It aims to ensure the quality of surgical specimens and data integrity. Process control should be implemented at critical nodes, with risk control points established throughout the entire process. Furthermore, problems occurring at all stages should be closely monitored and supervised [9].

Study Purpose

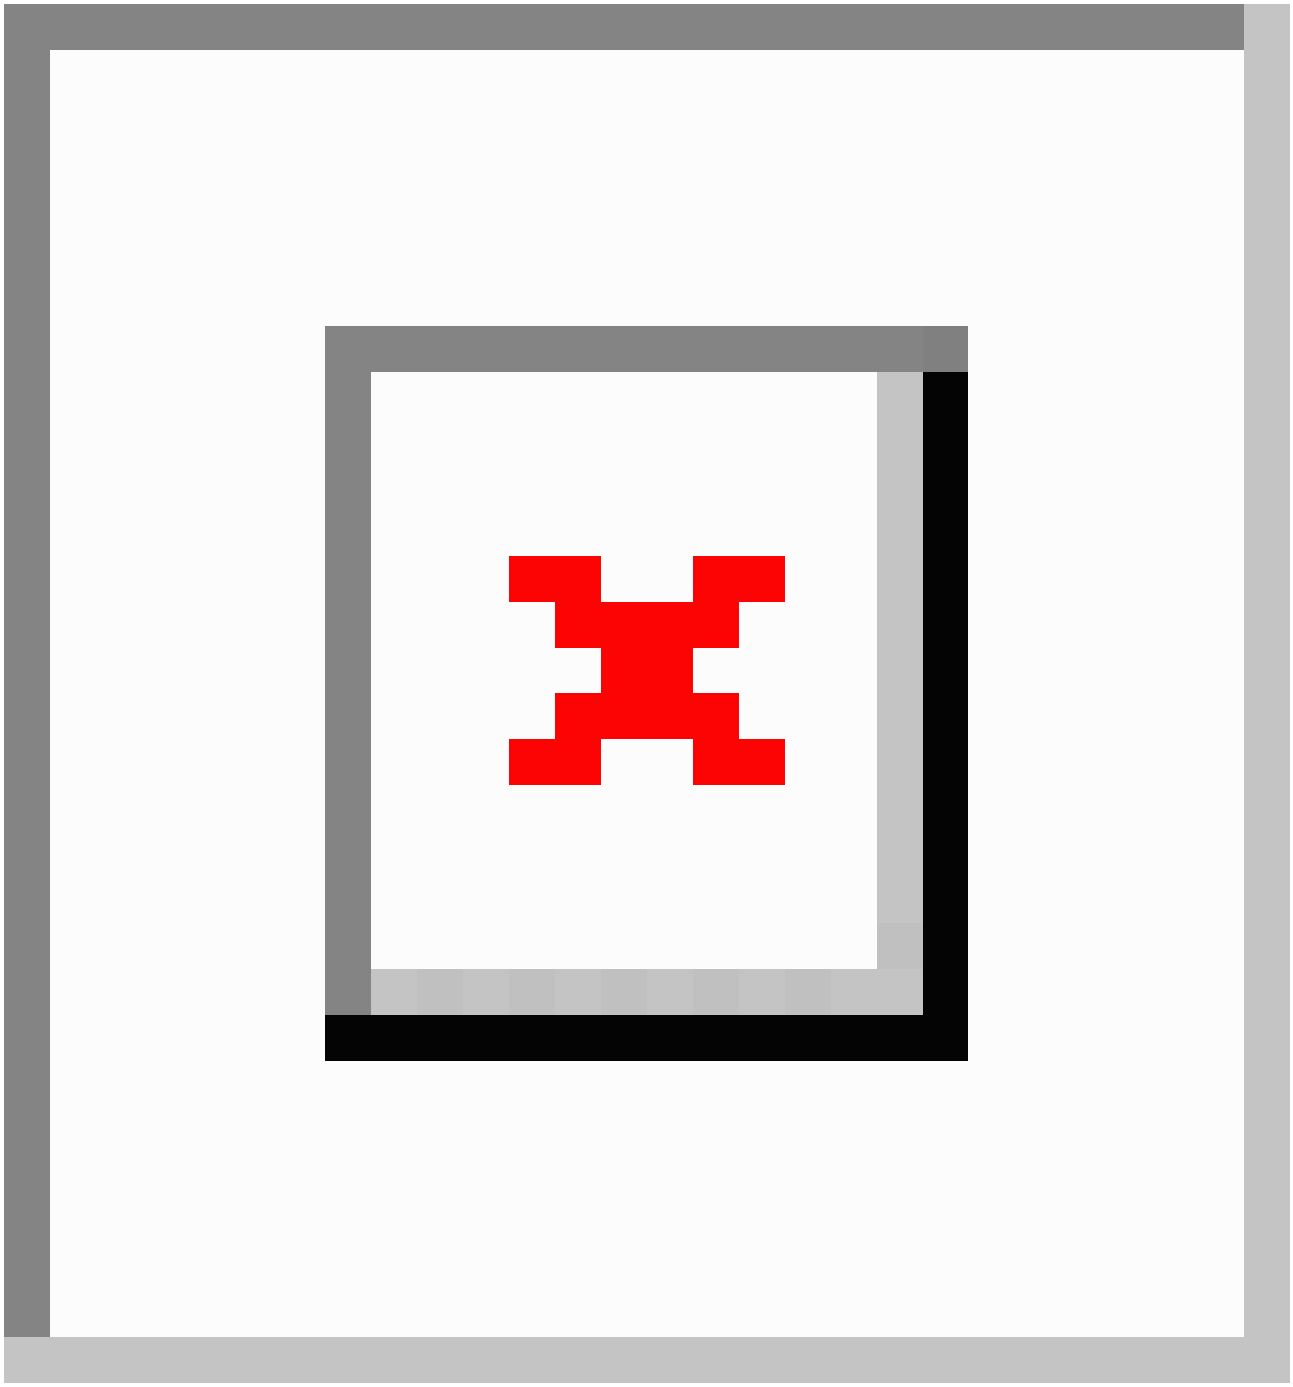
In the quality and safety of nursing care in the operating room, it has always been a hot issue to explore the application of intelligent management to the surgical specimen inspection process and safety management [10]. The purpose of this study is to further explore the effectiveness evaluation and improvement methods of information safety barriers, and fill the gap in the research field of the quality and safety impact of surgical specimens. At the same time, a new model of surgical specimen process management is further constructed and a safe operating room nursing practice environment is created by intercepting specimen approach error events through information safety barriers.

Methods

Study Design and Participants

The objects of this study were different transportation modes of surgical specimens from 2021 to 2022. The acquisition and preliminary processing of surgical specimens were carried out by standardized trained surgeons and surgical nurses. The exclusion criteria for participants in this study were (1) there was no fixed time information for labeled specimens and (2) no specimen transport time was indicated. In this research, the information transportation process management model of surgical specimens in 2021 was classified as the control group (group A) and the improved information transportation process management model of surgical specimens in 2022 was classified as the experimental group (group B). The data related to these specimens were retrospectively analyzed to explore the advantages of the new mode over the traditional mode of information transportation process management of surgical specimens (Figure 1).

Figure 1. Flowchart of pathological sample test in operating room.

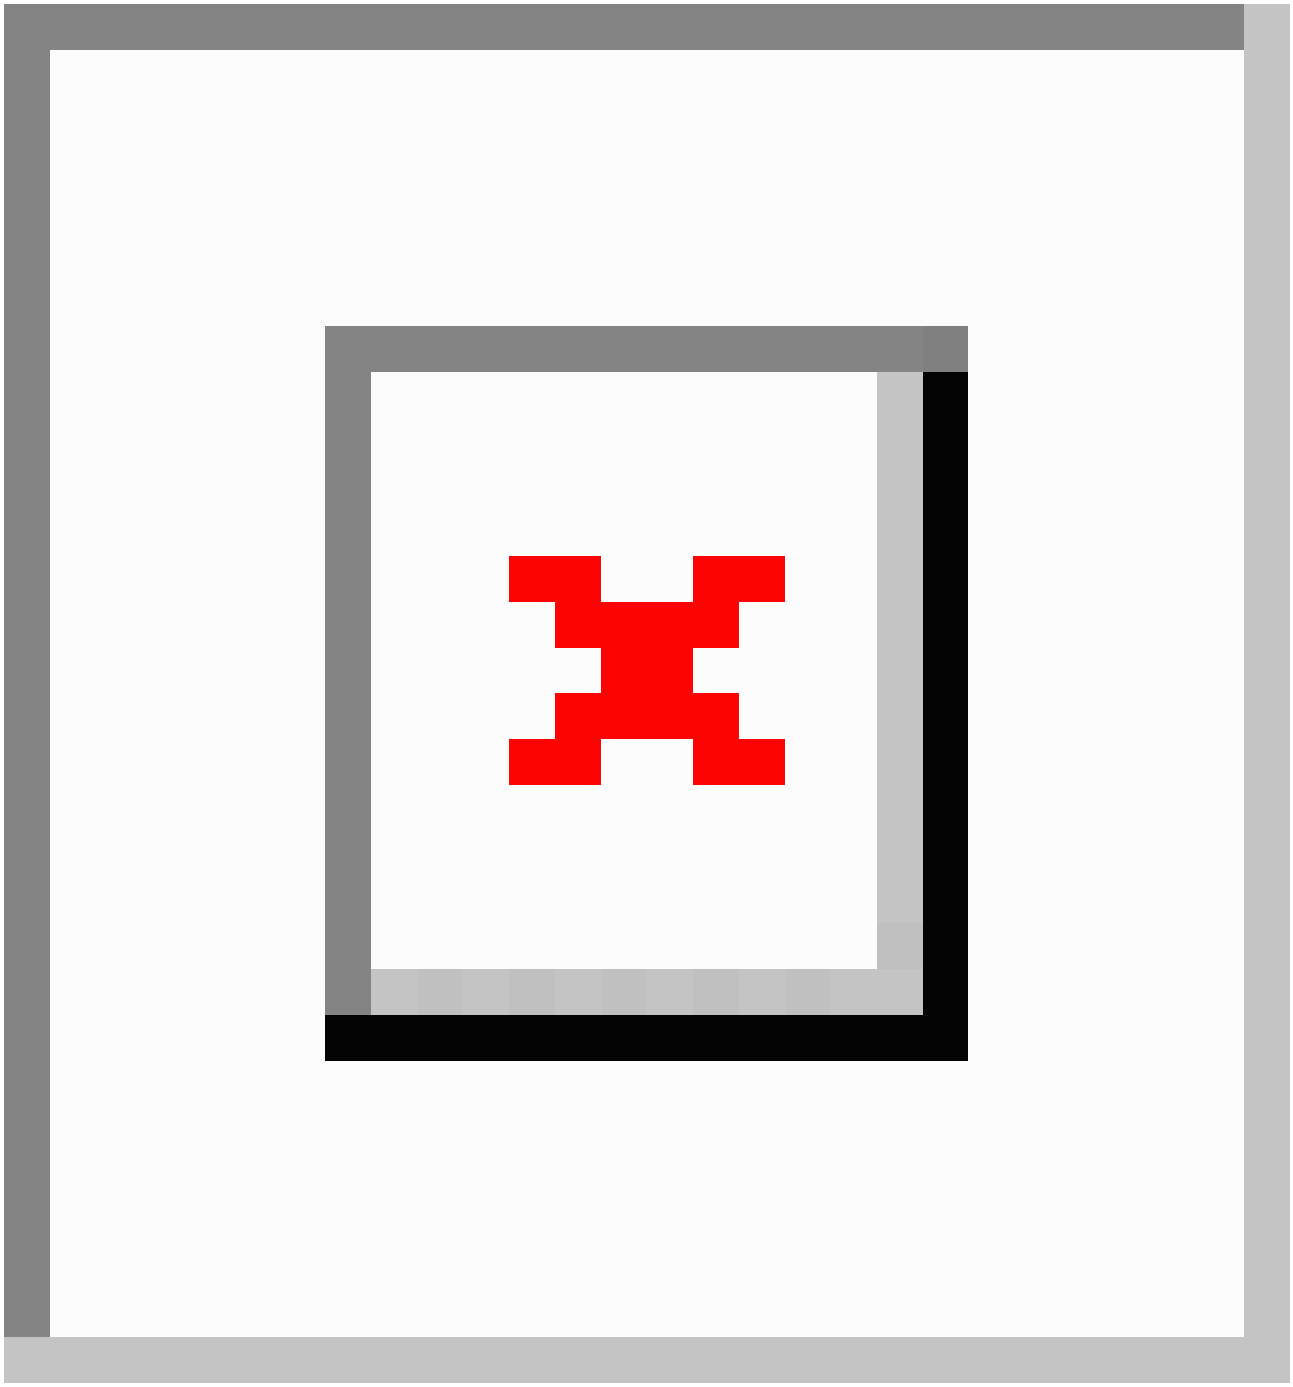


Platform Run Time

The system uses a C/S (Client/Server) structure, using PowerBuilder (version 11.5; SAP) development tools and Oracle database (Oracle Corporation) development. It follows a 3-layer technical architecture mode, with each application module functioning independently to support multiuser concurrent operations. Users access the system through the computer client. The platform consists of 4 ports, each with specific components and functions illustrated in Table S1 in Multimedia Appendix 1.

Surgical specimen process management modes are first, label—handwashing nurse, itinerate nurse, and the attending surgeon tripartite the type and name of the surgical specimen sent for examination and print the primary and secondary barcodes of specimen information. Second, transport and fixation—dedicated surgical specimen delivery personnel. Finally, reception—the pathology department staff scanned the 2D barcode of the surgical specimen, received the surgical specimen, and scanned the code for traceability in all links. All links are scanned for traceability (Figure 2).

Figure 2. Flowchart of specimen inspection in the operating room.



Procedure for Each Port Specimen

Overview

The computer operation of the nurse in the operating room is as follows. First, the itinerant nurse selects the type of surgical specimen in the operation interface of the operating room management system nurse (Figure S1A in Multimedia Appendix 2). Then the itinerant nurse prints the first-level barcode (Figure S1B in Multimedia Appendix 2) and the second-level barcode (Figure S1C in Multimedia Appendix 2) of the specimen information and pastes the second-level barcode on the specimen while checking the type and name of the specimen confirmed by the handwashing nurse, the itinerant nurse, and the surgeon. Finally, the system automatically pops up a box to select the person who submitted for testing and pushes the corresponding specimen submission method and information into the operating room (Figure S1D in Multimedia Appendix 2).

The operation of sending and storing specimens on the hospital's mobile app is as follows. First, the transport personnel used formalin for specimen fixation. Then the transport personnel scans the 2D barcode code on the surgical specimen on the hospital's mobile app (Figure S1E in Multimedia Appendix 2) and confirms it (Figure S1F in Multimedia Appendix 2). Finally, the transport personnel sent the surgical specimen to the pathology department for confirmation.

Confirmation of Receiving Surgical Specimens in the Pathology Department

The personnel of the pathology department scan the 2D code of surgical specimens at the receiving window to confirm receipt and import into the pathology reporting system (Figure S1G in Multimedia Appendix 2).

Maintenance of Basic Items of the System and Approval of Pathological Application Form Modification

The operating room management system only allows the head nurse to approve the application form modification of incorrect surgical specimens. The manager of the pathology department can modify the application form approved by the head nurse and query the history record (Figure S1H in Multimedia Appendix 2).

Testing of Platform Functions

Before launching the platform, the research and development team repeatedly simulated tests to improve platform functions, simplify operation steps, beautify the appearance of the interface, increase the output traffic of the base station, and solve problems, such as slow network speed and running lag.

Presurgical Specimen Analysis Stage

Link Control Step Diagram

The pictures below describe the control of each step in detail (Figure S2A in Multimedia Appendix 2).

Step 1

Control the error of filling in surgical specimen information. (1) Enter the operation specimen selection page and (2) select the specimen type (Figure S2B in Multimedia Appendix 2).

Step 2

Control patient identity information errors. (1) Label—surgical specimens, (2) the itinerant nurse enters the specimen's name, (3) the system bounce window 1 prompts "Please scan the wristband 2D barcode code to confirm," (4) the information is correct, and (5) the scan code is approved (Figure S2C in Multimedia Appendix 2).

Step 3

Control the error of surgical specimen information. (1) The system bounce window 2 prompts "The key information of the newly added surgical specimen site is inconsistent with the diagnostic site," (2) the system automatic bounce box to please check with the surgical doctor again "Please enter the checker's account password," (3) double-check the information, (4) itinerant nurse input the surgeon's account with the doctor's consent, and (5) the surgeon can print the pathology bar code after confirming the information is corrects (Figure S2D in Multimedia Appendix 2).

Step 4

Control the qualified rate of specimen fixation. In the fixation process of ordinary pathological specimens, the system will automatically remind the unfixed surgical specimens after 20 minutes (Figure S2E in Multimedia Appendix 2).

Step 5

Control the error of the diagnosis site of the pathology report. Selecting the automatic import and retention of surgical specimens (Figure S2F in Multimedia Appendix 2).

Step 6

Control abnormal error tracking management of surgical specimens. The status of surgical specimens in each step is distinguished by different color blocks. The full-time specimen staff and the full-time receiving staff of the pathology department check whether each surgical specimen has reached the closed-loop state. If the surgical specimen is not received more than half an hour after isolation, the system will automatically warn that the specimen has not received the prompt. In case of surgical specimen execution error, the itinerant nurse should report the cause of the failure in applying for close proximity on the pathology application sheet interface, and the specimen should be correctly executed after the examination and verification by the leader nurse. Analyze and rectify each data fetching exception problem (Figure S2G in Multimedia Appendix 2).

Primary Outcomes

The objective of this study is to compare the effectiveness of implementing information safety barriers in reducing the incidence of surgical specimen errors. These errors encompass inaccuracies in patient information registration, specimen identification and localization, as well as errors in the submission of specimens for examination. The error rate of surgical specimen' submission is equal to the number of surgical specimen submission errors divided by the total number of surgical specimen submissions divided by 100%.

Secondary Outcomes

This study aimed to compare the timeliness of fixing common pathological specimens before and after implementing the surgical specimen management mode with information security barrier control. The timeliness of fixation was assessed based on the passing rate and average fixation time of common pathological specimens. The fixed pass rate of common pathological specimens is equal to the number of fixed specimens completed within 30 minutes divided by the total number of fixed specimens multiplied by 100%. The average fixation time of common pathological specimens is equal to the total fixation time of a single common pathological specimen divided by the total fixation time of all common pathological specimens.

The reporting rate of surgical specimen near misses was compared between the 2 groups—the near miss events included wrong patient information registration, wrong specimen name and location, and wrong specimen type (such near miss events were corrected before the pathology report was issued by the pathology department, which did not cause serious consequences to patients, but there were great safety risks). The close error reporting rate of surgical specimens in the 2 groups was compared. The near error reporting rate is equal to the actual number of reported cases divided by the total number of reported close errors multiplied by 100%. The actual number of reported cases was the number of cases actually reported after the

occurrence of abnormal events by revising the information on surgical specimens through written records.

The list of all surgeons and operating room nurses was obtained through the hospital information system, and 60 surgeons and 60 operating room nurses were randomly selected by using the random number table method to investigate the satisfaction of surgeons and operating room nurses on the surgical specimen disposal process and specimen management mode, and the satisfaction evaluation was collected at the end of specimen data collection in the control group and the improved group. Satisfaction is rated on a 5-point scale from very dissatisfied to very satisfied.

Ethical Considerations

The study design and procedures conformed to the Declaration of Helsinki. This study was approved by the ethics review board of the First Affiliated Hospital of Wenzhou Medical University (KY2023-R098).

Statistical Analysis

SPSS (version 26.0; IBM Corp) statistical software was used for statistical analysis. Use cases (percentage) and (mean, SD) were used to represent counting and measuring data, respectively. The *t* test was used for comparison among measurement data groups, the chi-square test was used for counting data, and the rank sum test was used for rank data.

Results

Primary Outcomes

From January 1, 2021, to December 31, 2021, the total number of pathological specimens is 84,289, of which 55,545 are ordinary, 1096 are paraffin accelerated, and 27,648 are frozen. From January 1, 2022, to December 31, 2022, the total number of pathological specimens was 99,998, of which 62,383 were ordinary, 5744 were paraffin accelerated, and 31,871 were frozen (Table 1). Before the implementation, there were 31 errors surgical specimen in submitting surgical specimens, including 17 errors in the name and location of surgical specimens, 6 errors in the type of specimens submitted, 2 errors in the information of registered patients, and 6 errors in the left and right sides of pathology reports. After the implementation, there were 4 errors in surgical specimens, including 4 errors in the name and location of surgical specimens (Table 2). The chi-square test showed that the error rate of surgical specimens' submission was significantly lower than that before implementation and the difference was statistically significant (χ^2_1=25.9; *P*<.001).

Table . Summary table of surgical specimen types and quantities for 2021 - 2022.

Year	Paraffin specimen, n	Frozen specimen, n	Paraffin acceleration, n	Total, n
2021	55,545	27,648	1096	84,289
2022	62,383	31,871	5744	99,998

Table . Information on the occurrence of misses from 2021 - 2022.

Near miss events	Number (2021/2022), n/N	Key points of miss
Incorrect registration of patient information	2/0	Errors in electronic surgery notification checks
The specimen's name was entered in the wrong place	17/4	Communication and checking failures between medical and nursing staff
Wrong type of surgical specimen sent for examination	6/0	Roving nurse operator error
Pathology report error	6/0	Pathologist makes error in entering surgical site in pathology report

Secondary Outcomes

After the implementation of the new surgical specimen process management mode, the fixed pass rate of common pathological specimens increased to 99%, and the average fixation time was reduced to 10.221 (SD 12.552) minutes, while the differences were statistically significant (*P*<.001) with chi-square test and *t* test. At the same time, we found that only 13 of the 31 (41.9%) near-miss events in 2021 were reported, compared to all of the 4 (100%) near-miss events in 2022. We used Fisher precision probability test to measure the increase in the rate of near-miss reporting, which showed a statistically significant difference between 2021 and 2022 (*P*=.045; Table 3).

Table . Fixed qualification rate and average qualification time of common pathological specimens.

Indicators	2021	2022	Chi-square (*df*)/*t* test	*P* value
Fixed pass rate, n/N (%)	53,001/55,545 (95.5)	61,730/62,383 (98.9)	114,798.6 (1)[a]	<.001
Fixed meantime (minutes), mean (SD)	12.597 (13.032)	10.221 (12.552)	34.3 (232,657)[b]	<.001
The rate of near miss reporting, n	41.9	100	N/A[c]	.045

[a]Denotes the chi-square value.

[b]Denotes the *t* test value.

[c]N/A: not applicable.

Comparison of the satisfaction degree of doctors and nurses in relevant clinical departments with the procedure and management of surgical specimens before and after implementation. After the implementation, the satisfaction score of doctors in relevant clinical departments with the quality of pathological specimen management was 93.3% (56/60), higher than 58.3% (35/60) before the implementation, and the difference was statistically significant with rank sum test (P<.001; Table 4).

Table . Comparison of satisfaction with surgical specimen handling process and management between the 2 groups of medical staff.

Group	Great satisfaction, n	Satisfaction, n	Ordinary, n	Dissatisfaction, n	Be very dissatisfied, n	*z* score	*P* value
Doctor satisfaction						−5.133	<.001
Control group (n=60)	15	20	22	2	1		
Improvement group (n=60)	45	11	4	0	0		
Nurse satisfaction						−4.848	<.001
Control group (n=60)	14	22	20	3	1		
Improvement group (n=60)	46	10	4	0	0		

Discussion

Principal Findings and Contributions

The goal of this study is to develop a new surgical specimen operating standard and procedure that can effectively reduce the incidence of surgical specimen errors. Standardized procedures and standardized operations can simplify the work of nurses and medical teams and improve the quality of work [8]. In the traditional model mode, during the practice of the specimen identification stage, the surgeon's verbal error, nursing interruption, input error, verification and communication failure, and other links would occur [11]. Key errors in surgical specimen management will directly lead to errors in surgical specimens, resulting in incomplete or inaccurate diagnoses of patients by clinicians. This can lead to inappropriate and inaccurate treatment and care, causing temporary or permanent physical and psychological harm to patients. Therefore, we have developed a new operating standard and procedure for surgical specimens, which can effectively reduce the occurrence of surgical specimen errors, greatly improve the working efficiency of the operating room, reduce the risk of surgical specimen route errors, and ultimately greatly improve the quality of medical care and guarantee the medical safety of patients.

There were 17 errors in identifying parts of surgical specimen names in our research in 2021, mainly on the left and right sides and the upper, middle, and lower parts. And the early warning information safety barrier in our new management model can intercept the wrong specimen names. When the specimen name is inconsistent with the diagnosis site during operation, the system will automatically pop-up to remind that the interception barrier is inconsistent with the diagnosis site of the patient (left and right side and other key controls such as upper, middle, and lower). If correct, the specimen name bar code will be printed. If it is inconsistent with the diagnosis site, the system will display the red large font box "specimen name is inconsistent with the diagnosis, please check the specimen name again is correct" to play a role in checking again. In particular, errors on the right and left sides of key points can lead to a series of pathological diagnosis errors leading to very serious adverse events. The results showed that in 2022, the error rate of specimen name identification was significantly reduced to 4 cases, among which 4 cases of specimen name error were mainly caused by the failure of bilateral surgical site verification for the same incision. Meanwhile, the error rate of surgical specimens was significantly lower than that before the operation (χ^2_1=25.9, P<.001).

Theoretical and Practical Significances

In the quality and safety of nursing care in the operating room, it has always been a hot issue to explore the application of intelligent management to the surgical specimen inspection process and safety management [10]. The process of specimen inspection was improved to achieve information-based closed-loop management, and barcode technology was used to track and record the whole process of specimen inspection to form closed-loop management, so as to improve the accuracy and traceability of intraoperative pathological specimen information [9]. The traditional specimen inspection is done by scanning the 2D barcode code, but there is no information reminder function. In this paper, the link of specimen fixation is proposed. If the surgical specimen is not fixed 20 minutes after registration, the computer pop-up window will remind "Abnormal specimen submission," display the name of the corresponding operating room, itinerant nurses and patient information, and urge the itinerant nurses to submit pathological specimens for examination in time to prevent late and missed inspection of surgical specimens. Barcode technology is used to track and record the whole process of surgical specimen submission, forming closed-loop management and improving the accuracy and traceability of intraoperative pathological specimen information [12], accurately implement closed-loop management of specimens, transport personnel pays attention to the status of surgical specimens in real time, whether it has closed loop, and promptly urge itinerant and hand-washing nurses to implement the specimen inspection work in strict accordance with the surgical specimen inspection system. If the time from marking to receiving of surgical specimen exceeds half an hour, the system will show a red warning module that the specimen is not alerted to the pathology department, which can effectively reduce the incidence of surgical specimen delivery near misses. A shorter time for surgical specimen examination can reduce the difficulty of pathological diagnosis [13]. The qualified rate of fixation of common pathological specimens increased to 99%, and the differences were statistically significant (P<.001). Controlling the closed-loop management of the information of each link of surgical specimens, the number of specimens sent for surgery at each stage, and the status of specimens at each link are distinguished by different color blocks. The full-time specimen-sending personnel and the full-time receiving personnel of the pathology department checks whether each surgical specimen has reached the closed-loop state. It achieves accurate control of each link in the process of submitting surgical specimens, refines the standardized process of submitting surgical specimens, and ensures the controllability of each link, thus ensuring the correctness and simplification of the entire process of submitting surgical specimens, improving the qualification rate of handling surgical specimens, and reducing the risk of approaching errors [14].

With the high-quality development of hospitals, the informatization of operating rooms has been fully popularized and entered the era of a new paperless model [15]. It is particularly important to track and manage the surgical specimens and analyze the abnormal process. The traditional mode refers to the manual way to collect information manually, and the information filled in manually may have problems such as missing filling, wrong filling, mistransmission, and so forth. This paper uses network technology to realize information sharing and captures data through nursing managers to modify surgical specimens and near misses. In case of surgical specimen execution error, the traveling nurse should report the cause of the incident near the error on the interface of the pathology application form, and the specimen will be correctly executed after approval and verification by the head nurse. After using the new management mode, the near-miss reporting rate increased to 100% (P=.045). Meanwhile, this is also one of the ways to collect surgical specimen errors. Through information collection, we can find the causes of specimen errors and analyze and improve the key links of information. In the event of a surgical specimen near miss, the nurse on duty applied for specimen review, entered the reasons for the error, and made an application. After the review by the regulator, the correct name of the specimen can be obtained, the analysis and rectification of each data capture abnormal problem can be carried out, and scientifically use the quality tracking management tool of specimen approaching error anomaly to analyze the root cause and learn from it. It is helpful to improve the correct execution rate of surgical specimens and enhance the awareness of specimen management [2].

IT has been used to effectively improve the process of surgical specimen inspection [16], which has a sensitive and accurate perception function and effective verification, supervision, and control function, and improves work efficiency and the overall quality of specimen inspection. The satisfaction of medical staff had significantly increased to 93.3% (P<.001), and the efficiency of surgical specimen inspection was improved. The research on the prevention of surgical specimens near misses through effective information control link technology and the establishment of intelligent closed-loop management mode of pathological specimens in intelligent operating rooms is still rare, and there are no relevant reports at home and abroad. Through statistical analysis of medical satisfaction, this paper shows that the work of nurses and medical teams can be simplified and the quality of work can be improved [7,8]. The purpose of this study is to construct a new model of surgical specimen process management through the information security barrier to prevent the specimen from approaching the wrong event to create a safe operating room nursing practice environment.

Limitations

First, different personnel receive different education levels and ages, so different personnel have different ability to operate the system, so there will be deviations. Furthermore, different types of surgery may require different methods of recording and managing specimen information. There is also a Hawthorne effect in this study, which affects the results. In addition, inadequate information management systems can lead to data underreporting or inaccurate reporting, which can have serious implications for patient diagnosis and treatment. Finally, the direct relationship between the management model and patient outcomes was not discussed in our study and we will conduct this part in future studies. In conclusion, all of these issues may lead to limitations in the study.

Conclusions

We have developed a novel mode of managing the surgical specimen process. This new model effectively controls and manages the entire process, including the preanalysis stage, analysis stage, and fault analysis stage, of the information security barrier. It significantly reduces the risk of near misses associated with surgical specimens. Moreover, the new management model serves as a valuable reference for clinical decision makers and enables multiple hospitals to enhance operating room efficiency, reduce the occurrence of near misses in surgical specimens, and ultimately improve the quality of medical care while ensuring patient safety.

Abstract

Background: "Lock to Live" (L2L) is a novel web-based decision aid for helping people at risk of suicide reduce access to firearms. Researchers have demonstrated that L2L is feasible to use and acceptable to patients, but little is known about how to implement L2L during web-based mental health care and in-person contact with clinicians.

Objective: The goal of this project was to support the implementation and evaluation of L2L during routine primary care and mental health specialty web-based and in-person encounters.

Methods: The L2L implementation and evaluation took place at Kaiser Permanente Washington (KPWA)—a large, regional, nonprofit health care system. Three dimensions from the RE-AIM (Reach, Effectiveness, Adoption, Implementation, Maintenance) model—*Reach*, *Adoption*, and *Implementation*—were selected to inform and evaluate the implementation of L2L at KPWA (January 1, 2020, to December 31, 2021). Electronic health record (EHR) data were used to purposefully recruit adult patients, including firearm owners and patients reporting suicidality, to participate in semistructured interviews. Interview themes were used to facilitate L2L implementation and inform subsequent semistructured interviews with clinicians responsible for suicide risk mitigation. Audio-recorded interviews were conducted via the web, transcribed, and coded, using a rapid qualitative inquiry approach. A descriptive analysis of EHR data was performed to summarize L2L reach and adoption among patients identified at high risk of suicide.

Results: The initial implementation consisted of updates for clinicians to add a URL and QR code referencing L2L to the safety planning EHR templates. Recommendations about introducing L2L were subsequently derived from the thematic analysis of semistructured interviews with patients (n=36), which included (1) "have an open conversation," (2) "validate their situation," (3) "share what to expect," (4) "make it accessible and memorable," and (5) "walk through the tool." Clinicians' interviews (n=30) showed a strong preference to have L2L included by default in the EHR-based safety planning template (in contrast to adding it manually). During the 2-year observation period, 2739 patients reported prior-month suicide attempt planning or intent and had a documented safety plan during the study period, including 745 (27.2%) who also received L2L. Over four 6-month subperiods of the observation period, L2L adoption rates increased substantially from 2% to 29% among primary care clinicians and from <1% to 48% among mental health clinicians.

Conclusions: Understanding the value of L2L from users' perspectives was essential for facilitating implementation and increasing patient reach and clinician adoption. Incorporating L2L into the existing system-level, EHR-based safety plan template reduced the effort to use L2L and was likely the most impactful implementation strategy. As rising suicide rates galvanize the urgency of prevention, the findings from this project, including L2L implementation tools and strategies, will support efforts to promote safety for suicide prevention in health care nationwide.

KEYWORDS

suicide prevention; firearm; internet; implementation; suicide; prevention; decision aid; risk; feasible; support; evaluation; mental health; electronic health record; tool

Introduction

Firearm-related suicide accounts for approximately half of the suicide deaths in the United States annually [1]. Firearms are common in Americans' lives [2]; about one-third of Americans report owning firearms [3], and an additional 10% report living in a household with a firearm [4], with higher rates in western states [2], among veterans [5], and in rural areas [6]. Moreover, the rate of ownership of new firearms appears to have increased recently among women, Black people, and Hispanic people [7]. Suicide attempts by firearm are highly lethal; researchers estimate that 85% to 95% of individuals who attempt suicide by firearm do not survive [8,9], and people with access to firearms, particularly if firearms are kept loaded and unlocked [10,11], have increased suicide risk [12,13]. Clinicians may have opportunities to intervene with patients at risk for firearm-related suicide because about 50% of individuals who die by suicide see a clinician in the month before death, and over 80% see one in the year before death [14]. Moreover, clinician-initiated discussions about reducing access to firearms have demonstrated effectiveness for improving firearm security practices (particularly in combination with free safe storage devices) [15-17], as well as promising findings for reducing suicide attempts [18,19].

Despite its potential benefits, clinician-initiated dialogue about limiting access to firearms is an uncommon practice across many primary care and mental health specialty practices [18,20]. Common barriers include time, clinicians' unfamiliarity with firearms, and concerns about negatively impacting relationships or alienating patients [21]. "Lock to Live" (L2L) is a self-directed, anonymous, web-based decision aid that was designed to address these barriers. L2L was developed in collaboration with clinicians, firearm owners, and people who had experienced suicidal thoughts and attempts [22]. Consistent with international design standards [23,24], the L2L decision aid steps users through various considerations regarding in-home and out-of-home firearm storage options, such as types of storage, costs of storage, and background check requirements, with a goal of encouraging storage solution discussions that are consistent with the users' values and preferences [22]. Two subsequent research studies demonstrated promising results for the feasibility and acceptability of offering L2L emergency care encounters [25] and for the uptake of L2L when it was offered via secure patient portal messages after outpatient care encounters [26]. Though L2L appears to be a useful tool for supporting suicide prevention in clinical practice, little is known about how to use L2L during routine health care encounters outside of a research context.

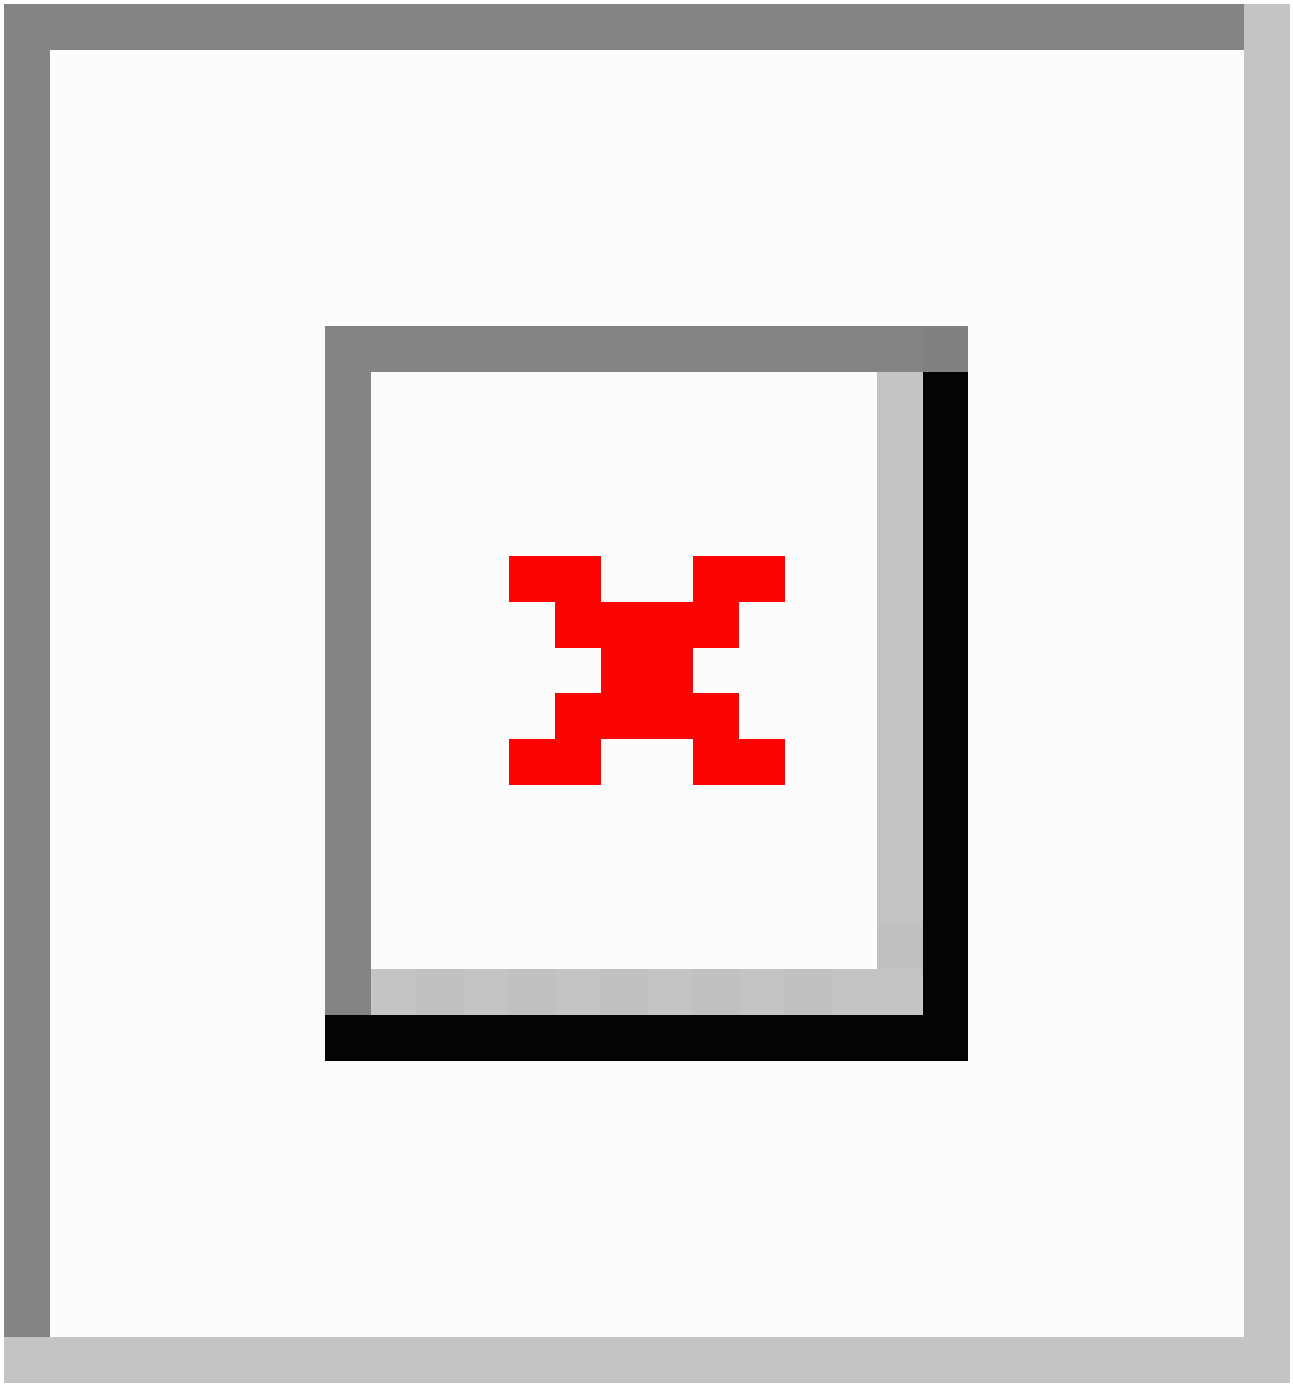
The goal of this project was to use mixed methods (qualitative and statistical evaluations) to support the implementation and evaluation of L2L during primary care and mental health specialty encounters in a large, regional health care system. Specifically, this project used semistructured interviews with clinicians and patients to support implementation, as well as statistical analyses to evaluate the reach and adoption of L2L over a 2-year period. The evaluation findings will inform considerations for implementing L2L nationwide to support suicide prevention in health care systems.

Methods

Setting

L2L implementation and evaluation took place at Kaiser Permanente Washington (KPWA)—1 of 8 regional Kaiser Permanente health care systems, which together form one of the nation's largest nonprofit health care organizations and serve 12.5 million people [27]. At the time of this evaluation, KPWA had provided comprehensive medical care to approximately 700,000 members across Washington State via employer-sponsored insurance plans, individual insurance plans, or capitated Medicaid or Medicare programs. In 2016, KPWA augmented standard clinical workflows to support the identification and engagement of patients at high risk of suicide attempts (Figure 1) [28,29]. Specifically, a system-level electronic health record (EHR) template was created to support clinician-initiated safety planning among patients who are identified as at high risk of suicide during primary care and mental health specialty encounters [28,30]. Nationally, safety planning is a widely recommended best practice [31], and KPWA had an established process for safety planning that included addressing access to lethal means but did not offer any specific resources to clinicians or patients about firearm storage options. Consistent with the goal of L2L, step 6 of this safety plan template was designed to support patients in limiting access to lethal means, such as firearms and prescription medications.

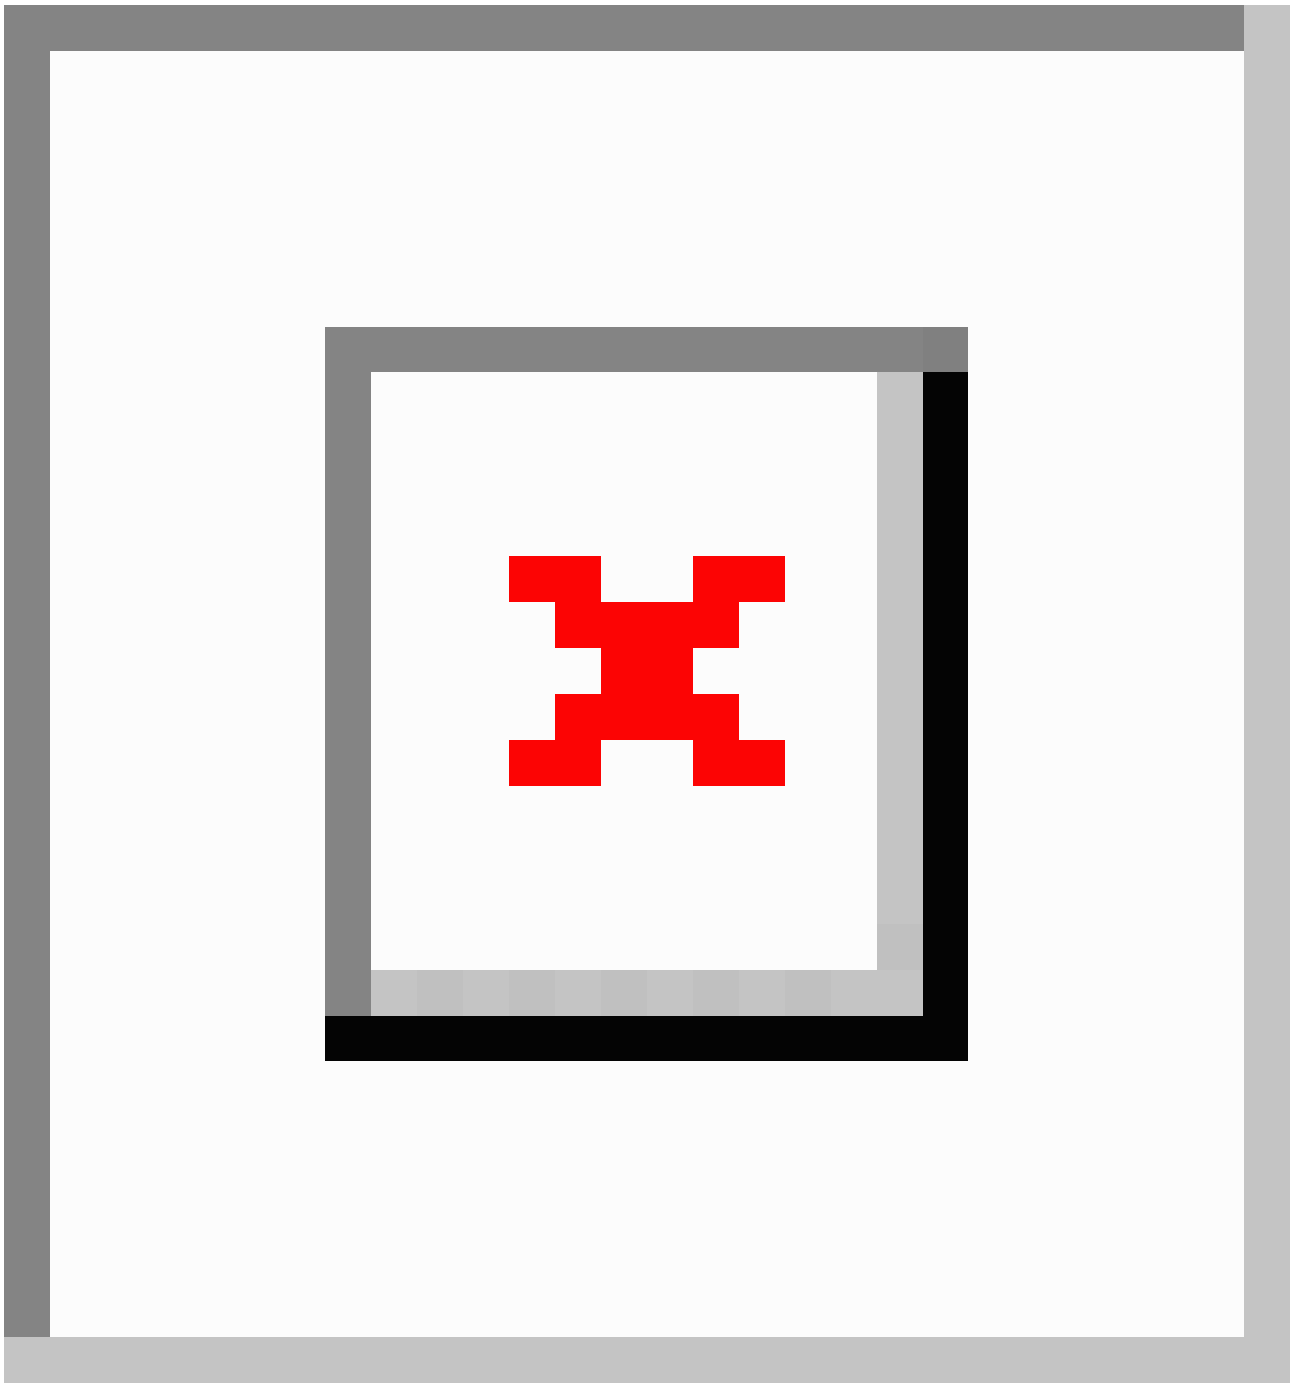
Figure 1. Clinical workflow for supporting the identification and engagement of patients at high risk of suicide during primary and mental health specialty encounters at Kaiser Permanente Washington.



Implementation and Evaluation Framework, Data Sources, and Study Design

Three dimensions from the RE-AIM (Reach, Effectiveness, Adoption, Implementation, Maintenance) model—*Reach*, *Adoption*, and *Implementation* [32,33]—were selected to both inform and evaluate the implementation of L2L at KPWA (Multimedia Appendix 1) over a 2-year observation period (January 1, 2020, to December 31, 2021). Specifically, a qualitative, team-based, formative evaluation [34] was used, involving semistructured interviews with purposefully sampled patients and clinicians to facilitate implementation tools and strategies. Descriptive statistical analyses were used to evaluate the reach of L2L among patients identified at high risk of suicide and L2L adoption over a 2-year observation period. The findings were stratified by primary care and mental health specialty service settings due to the variation in the timing of the L2L trainings across these settings (Figure 2).

Figure 2. L2L implementation tools and strategies used over four 6-month subperiods of the 2-year observation period (January 1, 2020, to December 31, 2021). Tools are shown in blue, strategies are shown in green, and capped lines indicate semistructured interviews. EHR: electronic health record; KPWA: Kaiser Permanente Washington; L2L: Lock to Live; LICSW: licensed clinical social worker.



Semistructured Qualitative Interviews

EHR data were used to purposefully recruit adult patients to participate in semistructured interviews that included questions to elicit suggestions about introducing L2L, as part of a broader interview that focused on exploring perceptions regarding and experiences with firearm access assessment [35]. An invitation letter was mailed to sampled patients (age≥18 y) who had received a standardized question about firearm access ("Do you have access to guns? Yes/No") in the prior 2 weeks on a mental health questionnaire [30]. A stratified sampling distribution was used to recruit approximately equal numbers of patients in 3 groups, including those who (1) reported firearm access, (2) reported no firearm access, and (3) did not respond (ie, left the question blank). The three sampling groups were also designed to purposefully include patients who had reported thoughts about self-harm in the prior 2 weeks via the ninth question of the 9-item Patient Health Questionnaire (PHQ-9) [36]. Interviewers attempted to reach all invitees for 2 weeks to invite them to participate in a phone interview. Following the portion of the interview guide that focused on firearm access assessment [35], interviewers described how patients reporting suicidal thoughts would soon be receiving L2L and elicited feedback about how to introduce this tool in a way that would make patients more likely to use it (Multimedia Appendix 2). This portion of the interview transcript was extracted into Excel

(Microsoft Corporation) and analyzed by using a team-based, rapid, qualitative inquiry approach [37]. This involved an iterative data analysis wherein 2 coders independently coded the L2L portion of the transcript by using a combination of deductive and inductive content analyses, with codes developed a priori from the interview guide as well as codes that emerged from the interviews [38]. This was followed by several rounds of discussions with 2 additional team members who reviewed the coded data and reconciled themes iteratively for the purpose of using the summarized themes to facilitate implementation.

Following the completion of the qualitative analysis that focused on patient-informed L2L implementation, interviewers initiated clinician recruitment activities, which were also more broadly focused on firearm access assessment. At the recommendation of care delivery leaders, interviewers outreached to the following two groups of clinicians responsible for engaging patients identified at risk of suicide in risk mitigation (ie, safety planning [39]): (1) licensed clinical social workers (LICSWs) supporting integrated mental health in primary care [28] and (2) consulting nurses (registered nurses) responsible for connecting patients (ie, those reporting suicidality after business hours via telephone) to telephone-based follow-up care. The L2L portion of the interview guide included questions informed by patient interviews (Multimedia Appendix 2) and was analyzed by using the same rapid, qualitative inquiry approach [37] that was used for patient interviews for the purpose of further facilitating L2L implementation.

Descriptive Statistical Analyses

L2L Reach and Adoption

EHR data were used to summarize L2L "reach," which was defined as the proportion of patients identified as at high risk of suicide via routine screening and assessment clinical workflows (Figure 1) and received the web-based decision aid. Specifically, we described characteristics of patients who had a documented safety plan during the 2-year observation period and characteristics of patients who had a safety plan that included a reference to L2L. Next, we described the adoption of L2L by primary care and mental health specialty clinicians over four 6-month subperiods of the observation period by calculating the proportions of patients identified at high risk of suicide (via suicide risk assessment; described in the *Measures* section) who had a documented safety plan with a reference to L2L and those who had a documented safety plan without a reference to L2L. We selected 6-month subperiods as the most helpful way to visually describe L2L adoption over time, since implementation paused during the initial COVID-19 outbreak (described in the *Implementation Timeline, Tools, and Strategies* section). We stratified by service setting due the variation in the timing of L2L trainings for these groups of clinicians.

Measures

The Columbia Suicide Severity Rating Scale (C-SSRS) was used to measure suicide risk, as per current clinical workflows. Specifically, patients reporting some level of suicide attempt planning or intent in the past month (ie, answering "yes" to C-SSRS question 3 or higher) were considered to be at "high risk" and alerted clinicians (via EHR prompts) to initiate safety planning. Distinctive phrases from standard EHR-based templates were used to detect safety plans documented in the text of clinical notes among patients identified at high risk (Multimedia Appendix 3). Sociodemographic and clinical characteristics of interest, including those known to be associated with firearm ownership and suicide risk [40,41], were measured by using the following administrative and diagnostic EHR data: age (continuous); sex (male or female); race and ethnicity (Asian, Black, Hispanic or Latinx, White, other, or unknown); insurance type (commercial, Medicare, Medicaid, or other); rurality (urban, large suburban, small suburban, or mostly rural) [42,43]; and prior year mental health, substance use, and self-harm diagnoses derived from the *International Classification of Diseases, Tenth Revision, Clinical Modification*. Reported firearm access was measured based on a positive response to the question on the mental health questionnaire [30] that was also used for qualitative interview recruitment (described in the *Semistructured Qualitative Interviews* section).

Ethical Considerations

The project team received approval from the KPWA Region Institutional Review Board (review number: 1826198) to conduct this study. Patients who agreed to participate in the phone interview provided oral consent, including permission for the interview to be audio-recorded and professionally transcribed, and they received a US $50 cash incentive for participation. During clinician recruitment activities, clinicians received up to 3 email invitations, which included a study information sheet and instructions for opting out of participation and further contact. Participating clinicians verbally consented to participation and received a US $50 gift card for participation.

Results

Implementation Timeline, Tools, and Strategies

Over the 2-year implementation period (January 1, 2020, to December 31, 2021), a team of researchers and care delivery leaders took a pragmatic approach to iteratively creating and refining L2L implementation tools and strategies for primary care and mental health specialty clinicians (Figure 2). Initially, tools included an EHR-based macro (ie, EPIC SmartPhrase [Epic Systems Corporation]) for clinicians to easily add a URL and QR code referencing L2L to safety planning templates and a 1-page quick-start guide (ie, "Huddlecard") with information on how to use the new SmartPhrase during routine clinic meetings (ie, "huddles"). In February 2020, the LICSWs who supported mental health care delivery in primary care [28] received information about L2L during a brief, web-based staff training session. Additional trainings that were planned for mental health specialty clinicians were put on hold during the widespread service disruption that subsequently occurred in response to the initial COVID-19 outbreak in March 2020. Additional tools and strategies were used, following recommendations from the care delivery leaders responsible for primary care and mental health service recovery and from the patients and clinicians who participated in semistructured qualitative interviews (detailed in the *Findings From Semistructured Qualitative Interviews* section).

Findings From Semistructured Qualitative Interviews

Of 76 patients who were purposefully sampled during 2 waves of recruitment, 36 were interviewed from November 18, 2019, to February 10, 2020 (Table 1). Five organizing themes were derived from the portion of the interview that elicited perceptions and suggestions about L2L and were used to create a handout for clinicians, with suggestions about how to introduce L2L to their patients at risk of suicide (Multimedia Appendix 4), including recommendations to (1) "have an open conversation," (2) "validate their situation," (3) "share what to expect," (4) "make it accessible and memorable," and (5) "walk through the tool" (Table 2). In addition to these recommendations, patients expressed a preference for receiving information about L2L from "trusted" and "caring" clinicians.

Table . Characteristics of patient (n=36) and clinician (n=30) semistructured interview participants.

		Patients	Clinicians
Sex, n (%)			
	Female	17 (47)	24 (80)
	Male	19 (53)	6 (20)
Age (y), mean (SD)		47.3 (17.9)	44.3 (12.1)
Age category (y), n (%)			
	19-29	8 (22)	1 (3)
	30-49	11 (31)	20 (67)
	50-64	9 (25)	6 (20)
	≥65	8 (22)	3 (10)
Race and ethnicity, n (%)			
	American Indian or Alaska Native	0 (0)	1 (3)
	Black	3 (8)	2 (7)
	Asian or Pacific Islander	3 (8)	5 (17)
	Latinx or Hispanic	1 (3)	4 (13)
	Unknown	2 (6)	0 (0)
	White	27 (75)	18 (60)
Reported firearm access[a,b], n (%)		16 (44)	N/A[c]
Reported thoughts about self-harm (prior 2 wk)[a,d], n (%)		15 (42)	N/A

[a]Patients' responses recorded on the Kaiser Permanente Washington mental health monitoring questionnaire used for criterion sampling within the 2 wk prior to the recruitment initiation.

[b]"Do you have access to guns? Yes/No."

[c]N/A: not applicable.

[d]Ninth question on the 9-item Patient Health Questionnaire: "Thoughts that you would be better off dead, or of hurting yourself."

Table . Thematic analysis of semistructured interviews with patients (n=36) and recommendations for introducing "Lock to Live" (L2L).

Themes	Illustrative quotes[a]	Recommendation
Show caring and compassion, ask permission, and respect autonomy	• "I think it's important to just take a breath, sit down with them, hold their hand, look them in the eye - 'how can I help you? Help me help you. What's going on? Tell me. What are you thinking? How are you feeling? How can I help you?' Instead of an assembly line and 'I only have a few minutes,' so they [providers] don't take the time." (Patient B029) • "I would hope the provider is very warm and caring and explains it's a safety precaution, it's for your better health and it insures you'll be safer…basically it's another part of your little toolbox to keep yourself well." (Patient A032) • "Probably compassionately, potentially generalized to begin with, to find out if the person is resistant right upfront… Maybe you could put a question, 'would you be willing to consider options for storing or access to lethal means, whether it's firearms or medication? Is it something you would be willing to discuss and look into if you were experiencing suicidal thoughts?'" (Patient A005) • "We're offering you the means to protect yourself, this is not an us decision, this is a you decision. So here is the website, the online information and we encourage you to look at it, but it's your decision….Nobody can force you to do things. So bringing it up more as like – not we're taking it [firearm] away from you, but letting you decide what to do with it." (Patient A024) • "Reassuring people that their firearm ownership will not end because they're going through a rough patch in life; their ability to have their own authority to hold onto their possessions [will not end], firearms or not." (Patient B036)	"Have an open conversation": patients were more willing to listen and try a tool if a clinician took the time to connect, showed compassion for people's unique experiences, and showed respect for autonomy.
Frame as helpful resource and normalize experiences	• "I think overall education about the topic to start out with, just to say…'this is what we have found is helpful, in these situations.' Moving more into letting people know what their resources could be. Just education to be begin with, so it's not so threatening. I think anytime somebody's in a vulnerable place emotionally, they're already possibly feeling threatened and they may not want to trust a lot of people." (Patient A005) • "I would hope it would be pretty real, like a conversation…'based on your health concerns you're showing, we've got some important information we'd like to share with you,' especially if that person has a relationship or feels responsible with the person presenting it, would stay there together and talk about it afterwards….Also statistics to help a person realize how more common this is." (Patient A011)	"Validate their situation": normalize their experience, share how common suicidal thoughts are, and be nonjudgmental in your approach; people have a variety of gun beliefs.

Themes	Illustrative quotes[a]	Recommendation
Address privacy and security	• "[The provider] would have to explain what it does, how it's going to work and how private it is - nobody can get into your part of the website anyway, your personal page, where you go. So she has to reassure them about that….I just don't feel that being online is that secure." (Patient B004) • "privacy is probably number one and an assurance that you're not being turned in….I would be concerned in our surveillance state that disclosing things to a website about my firearm use might somehow come close to violating some kind of civil right to privacy." (Patient B008) • "As long as people don't have to put in information which can be tracked, I can see lots of people using it. I mean the minute [you have to enter] your name, address, phone number, medical ID number, whatever else, people are going to go – eh." (Patient A033)	"Share what to expect": address privacy and how information is stored if patients visit the website; assure patients that L2L is anonymous.
Accessibility is key	• "You don't want to make it hard to find on a website because it doesn't take me very long. If something's really hard to find on a website, I'm out of there." (Patient B004) • "If there are hoops to jump through before you can access it, if you have to log in, go through a bunch of pages - maybe if it was right there, ready to access at any time, I'd say that'd be better." (Patient B008) • "I'd love to see it everywhere. Have little cards that could be given out, a billboard, having my doctor [send it]." (Patient A033) • "If I knew it existed, I would probably try it. advertise it." (Patient A032) • "Highlight it in your After Visit Summary too." (Patient A002)	"Make it accessible and memorable": have multiple routes for sharing the website and sending reminders (after-visit summary, message, website, pamphlet).
Demonstrate and "show, don't just tell"	• "I think when you're in a pit of despair, to go and do it on your own, some people will do that and other people will not. They need to be taken by the hand and go, 'what do you think about this?' Read it together." (Patient B036) • "I'm more keen to follow somebody who's like 'I'm offering you the opportunity to maybe do this together,' instead of 'I'm watching out for you.'" (Patient A024) • "Being shown an example would be nice, showing it off briefly. Knowing more specifically what it does or how it could be helpful as opposed to just knowing it exists." (Patient B033) • "I think showing the patient or at least offering, would you like me to show you? Not just telling somebody, because short term memory is only like 30 s or a couple minutes and then you forget about it." (Patient A002)	"Walk through the tool": most patients said that a website walk-through, rather than simply having a conversation, would be helpful to overcome the barrier of trying something new, especially if already depressed.

[a]Identifier "A": patients in the first wave of interviews; identifier "B": patients in the second wave of interviews (grammatic edits, noted in brackets, were added to clarify intended meaning).

Of 51 purposefully sampled clinicians responsible for safety planning with patients identified at high risk of suicide, 30 were interviewed from July 7, 2020, to October 8, 2020 (Table 1), including 25 LICSWs and 5 registered nurses. During the

interviews with LICSWs, only 3 had actually used L2L with a patient—9 were unfamiliar with L2L, and 12 were familiar with but had not yet used L2L. Most clinicians saw clear benefits to L2L as an option for supporting both clinicians and patients. Several clinicians expressed concern about using the tool to replace dialogue about lethal means, and most supported the idea of a walk-through, as patients had recommended. Clinicians also expressed a strong preference to have L2L information included by default in the EHR-based safety planning template, in contrast to having clinicians remember to add it (via SmartPhrase). A clinician also suggested automatically including L2L in after-visit summaries when patients reported thoughts about self-harm on the PHQ-9. The implementation team worked with clinical partners to update the system-level, EHR-based safety plan template to include L2L information and updated the Huddlecard to communicate this change (Multimedia Appendix 5). After-visit summaries were used to provide safety plans to patients who were seen via a secure, web-based patient portal, and L2L was automatically included after the template change. Several clinicians also requested follow-up trainings or refreshers about L2L. The team therefore conducted a round of brief trainings, which were presented during routine clinic huddles with mental health specialty clinicians, and created a 3-minute training video (Multimedia Appendix 6).

Findings From Descriptive Statistical Analyses

During the study period, 2739 adult patients reported some prior-month suicide attempt planning or intent via routine suicide risk assessment workflows during primary care or mental health specialty encounters and had a documented safety plan, including 745 (27.2%) who also received L2L. Overall, there were no major differences in the demographic and clinical characteristics between patients who received L2L and the broader population that was identified as at risk of suicide and had a documented safety plan (Table 3).

Table . Characteristics of patients who received "Lock to Live" (L2L; n=745) and were among patients with a documented safety plan (n=2739) during the implementation period (January 1, 2020, to December 31, 2021).

[a]Includes safety plans with L2L.

[b]At evaluation midpoint (January 1, 2021).

[c]At first encounter.

[d]Missing information for 22 patients.

[e]During implementation period.

The adoption of L2L increased substantially over the 2-year observation period (Tables 4 and 5). During this time, rates of documented safety plans among patients identified at high risk of suicide (C-SSRS score≥3) remained fairly consistent—51.2%

to 55.2% of primary care patients and 73.4% to 78.4% of mental health specialty patients had a documented safety plan. However, over four 6-month subperiods of the observation period, L2L adoption rates increased substantially from 2% to 29% among primary care clinicians and <1% to 48% among mental health clinicians, increasing primarily after L2L was integrated into the EHR-based safety planning template.

Table . Proportions of primary care patients who were identified as at high risk of suicide and had a documented safety plan during primary care encounters over the implementation period (January 1, 2020, to December 31, 2021).

Subperiods of implementation period	Patients with a documented safety plan that did not include "Lock to Live," %	Patients with a documented safety plan that did include "Lock to Live," %
Months 1-6	53.5	1.6
Months 7-12	50	4.1
Months 13-18	41.7	11.1
Months 19-24	22.2	29.1

Table . Proportions of primary care patients who were identified as at high risk of suicide and had a documented safety plan during mental health specialty encounters over the implementation period (January 1, 2020, to December 31, 2021).

Subperiods of implementation period	Patients with a documented safety plan that did not include "Lock to Live," %	Patients with a documented safety plan that did include "Lock to Live," %

Months 19-24	25.9	48.4

Discussion

This novel study used mixed methods to support the implementation and evaluation of a web-based decision aid that was designed to help patients at risk of suicide limit access to firearms. Specifically, findings from semistructured interviews with patients and clinicians were used to facilitate L2L implementation, while statistical analyses were used to describe rates of reach among patients identified at risk of suicide and increased adoption by clinicians who cared for them during the 2-year observation period.

L2L development centered users' values and preferences in the design process [22]. Similarly, the tools and strategies developed for this project used information from semistructured interviews with people who were the most likely to be impacted by L2L implementation, including firearm owners, patients experiencing suicidality, and the clinicians who care for them. Clinicians have reported a lack of experience with handling firearms and have expressed apprehension about discussing firearm safety due to concerns about damaging relationships with patients [44-46]. Likewise, patients have expressed apprehension about disclosing access to firearms due to concerns about privacy, autonomy, and firearm ownership rights [47,48]. For these reasons, patients and clinicians perceive firearm access assessment as challenging but also as valuable for supporting suicide prevention [35]. This implementation project showed that clinicians, that is, those responsible for engaging at-risk primary care and mental health patients in suicide risk mitigation, willingly adopted the use of L2L to support safety planning.

This study also has important implementation implications. Unsurprisingly, the rates of L2L adoption increased after L2L was incorporated into the existing system-level safety planning template as a default (primarily in the latter half of year 2). This finding underscores the importance of removing barriers to the adoption of web-based decision aids and making adoption "easy" [49]. In contrast, those seeking change often focus on amplifying benefits or "selling" their new idea or innovation; however, it may be equally as important or more important to focus on "friction," that is, "psychological forces that oppose and undermine change," such as inertia, effort, emotion, and reactance [50]. In the case of L2L, reducing the effort required for clinicians to remember to use L2L appeared to be the main driver of its adoption. However, the tools and strategies that were designed to communicate about the benefits of using L2L (eg, training, video, Huddlecard, and newsletter information) were likely necessary for leaders to understand L2L's value to patients and clinicians and approve the system-level change that was required to make L2L easier to use for clinicians.

This study has important clinical implications for supporting suicide prevention in health care. First, L2L supports clinicians who engage patients identified at risk of suicide in collaborative safety planning and lethal means counseling, which are evidence-based suicide risk mitigation practices that are recommended by the Zero Suicide Institute and follow the principles outlined in the National Strategy for Suicide Prevention [29,51-53]. Moreover, the recommendations from interview participants ("have an open conversation," "share what to expect," and "walk through the tool") support a motivational interviewing approach to lethal means counseling and align with the recommendations of the Veterans Health Administration [54]. Second, L2L was developed by patients with lived experiences of suicidality and firearm ownership; therefore, L2L supports cultural competency in health care as

a culturally aligned intervention [55]. Finally, this technology-based, EHR-embedded approach to addressing lethal means supports all 6 aims of health care quality that are outlined by the Institute of Medicine—*safe*, *effective*, *patient-centered*, *timely*, *efficient*, and *equitable* [56,57].

There are several limitations of this project that have implications for future research. First, the implementation of L2L at KPWA occurred during the initial outbreak of a global pandemic, which impacted the original implementation plans while health care systems responded to the pandemic and rapidly shifted toward providing web-based mental health care [58]. Semistructured interviews with patients took place prior to this shift. Future research should explore optimizing mental health care delivery workflows that support web-based suicide risk identification (ie, screening and assessment) [59] and incorporating L2L in web-based care encounters via secure telehealth platforms that are designed to support patient engagement. Second, L2L recognizes and addresses firearm policies related to background checks and how these policies might influence the legality of temporary firearm transfers for addressing suicide risk, but it does not address specific state laws. Additional work to understand the legality of recommendations about firearm safety practices may be helpful for health care systems that implement L2L. Third, this project was not designed to measure the specific impact of individual implementation strategies or determine whether L2L was effective in helping patients reduce access to firearms for suicide prevention purposes. Measuring the effectiveness of this tool, which was designed to support population-based suicide prevention, would require extending the implementation of L2L to other large health care systems nationwide and conducting other analyses that are designed to measure key functions of suicide prevention practices, including risk identification, engagement in evidence-based risk mitigation and treatment, and supportive care transitions [29]. Finally, L2L is meant to support adult patients at risk of suicide reduce access to firearms and other lethal means; additional tools and strategies are required to support youth at risk of suicide. Notably, there is a similar web-based decision aid that is available for this purpose; "Lock and Protect" was designed to help parents and caregivers reduce access to lethal means for youth suicide risk mitigation [60]. Similarly, the "Safety in Dementia" web-based decision aid was developed to support caregivers in addressing firearm access among individuals with Alzheimer disease and related dementias [61]. Future research should evaluate the implementation of these tools in routine care delivery.

In conclusion, incorporating L2L into the existing system-level safety plan template reduced the effort required to use L2L and was likely the most impactful implementation strategy for increasing clinician adoption and patient reach. However, understanding the value of L2L from the users' perspectives was essential for effectively amplifying the suicide risk mitigation benefits. As rising suicide rates galvanize the urgency of prevention [62], the implementation tools and strategies developed for this project will be useful for health care systems nationwide.

Acknowledgments

This implementation evaluation was funded by Kaiser Permanente's Office of Community Health and Center for Gun Violence Research and Education, as part of its Firearm Injury Prevention Program, and the Centers for Disease Control and Prevention (R01CE003460). Abstract

Background: Despite the potential of routine health information systems in tackling persistent maternal deaths stemming from poor service quality at health facilities during and around childbirth, research has demonstrated their suboptimal performance, evident from the incomplete and inaccurate data unfit for practical use. There is a consensus that nonfinancial incentives can enhance health care providers' commitment toward achieving the desired health care quality. However, there is limited evidence regarding the effectiveness of nonfinancial incentives in improving the data quality of institutional birth services in Ethiopia.

Objective: This study aimed to evaluate the effect of performance-based nonfinancial incentives on the completeness and consistency of data in the individual medical records of women who availed institutional birth services in northwest Ethiopia.

Methods: We used a quasi-experimental design with a comparator group in the pre-post period, using a sample of 1969 women's medical records. The study was conducted in the "Wegera" and "Tach-armacheho" districts, which served as the intervention and comparator districts, respectively. The intervention comprised a multicomponent nonfinancial incentive, including smartphones, flash disks, power banks, certificates, and scholarships. Personal records of women who gave birth within 6 months before (April to September 2020) and after (February to July 2021) the intervention were included. Three distinct women's birth records were examined: the integrated card, integrated individual folder, and delivery register. The completeness of the data was determined by examining the presence of data elements, whereas the consistency check involved evaluating the agreement of data elements among women's birth records. The average treatment effect on the treated (ATET), with 95% CIs, was computed using a difference-in-differences model.

Results: In the intervention district, data completeness in women's personal records was nearly 4 times higher (ATET 3.8, 95% CI 2.2-5.5; *P*=.02), and consistency was approximately 12 times more likely (ATET 11.6, 95% CI 4.18-19; *P*=.03) than in the comparator district.

Conclusions: This study indicates that performance-based nonfinancial incentives enhance data quality in the personal records of institutional births. Health care planners can adapt these incentives to improve the data quality of comparable medical records, particularly pregnancy-related data within health care facilities. Future research is needed to assess the effectiveness of nonfinancial incentives across diverse contexts to support successful scale-up.

Introduction

Background

Maternal mortality, a pressing global health concern, is particularly prevalent in low- and middle-income countries [1-5]. The existing research attributes the persistence of maternal deaths largely to inadequate health care quality during labor, delivery, and immediate postpartum care in health facilities [6,7]. Almost every low- and middle-income country implements the Routine Health Information System (RHIS) to address this challenge [8-10]. The RHIS has gained prominence for its practical roles in improving the quality of services, including (1) facilitating evidence-based action by enabling the early detection of pregnancy-related complications, (2) serving as a repository for clients' data to ensure the continuity of pregnancy-related care, and (3) functioning as the primary data source essential for health monitoring and evaluation at all levels of the public health system [11-16]. Despite its potential, the performance of RHIS remains suboptimal, primarily because of incomplete and inaccurate data, hindering its effective use by decision makers [17-20].

In Ethiopia, the introduction of the RHIS dates back to 2008 [21,22]. Ongoing efforts are in place to enhance the data quality of the RHIS in Ethiopia through interventions such as the Performance Monitoring Team (PMT), lot quality assurance sampling (LQAS), and the Capacity Building and Mentorship Program (CBMP) [23-25]. However, despite these efforts, the quality of RHIS data still lags in Ethiopia [15,26]. This challenge is pertinent to institutional birth, as shown by some previous studies in Ethiopia. For instance, a study [27] reported a completeness rate of only 18.4%. Another study from Ethiopia found that 66% of health facilities managed to produce accurate data within an acceptable range [28]. Furthermore, comparing the data from health facilities with external sources such as the Ethiopian Demographic Health Survey reveals concerns regarding data quality in Ethiopian RHIS [26].

Incentives and Its Impact on Health Care Quality

Previous studies have shown that offering incentives for personnel responsible for data collection and management can improve data quality in the RHIS. According to some studies, incentives are essential for addressing the negative attitudes and values that undermine data quality within the RHIS, which are primary challenges to achieving desired quality of RHIS data [29].

The effectiveness of incentives in health care is grounded in theoretical and empirical evidence. Theories like the theory of planned behavior emphasize the connection between motivation and improved health care quality [30]. Some studies demonstrated that incentive-based interventions can predict up to 48% of desired health care behavior [31,32].

Despite the growing interest in using incentives in health care [32-38], determining the most effective approach remains a research priority. Incentives can be financial [39,40] or nonfinancial. Financial incentives have been extensively studied globally [33,37-39,41-43], but there is limited evidence supporting their consistent impact on health care quality [40]. Some studies have even cited the counterproductive effects of financial incentives on health care [44].

Compared to financial incentives, the impact of nonfinancial incentives on health care quality has been minimally studied [45]. Nonfinancial incentive schemes offer noncash rewards or benefits to motivate recipients using approaches that involve recognition through public profiling or reporting; career advancement opportunities; providing certificates to top performers; and ensuring improved working conditions, such as vacations, grading systems, and packaging interventions with in-kind items [46-53]. Previous studies have demonstrated the effectiveness of nonfinancial incentives in enhancing the quality of health services. For instance, nonfinancial incentive schemes in the United States, India, El Salvador, and Tanzania have been reported to enhance the performance of health care providers, including enhanced root cause data analysis of medical errors, expanded community outreach services, better maternal and child care services, and higher quality health care consultations [50,51,54,55].

Objectives

This study aimed to evaluate the effect of performance-based nonfinancial incentives (PBNI) on enhancing the quality of institutional birth data, measured by the completeness and consistency of data within women's individual medical records (IMRs).

Methods

Study Design and Period

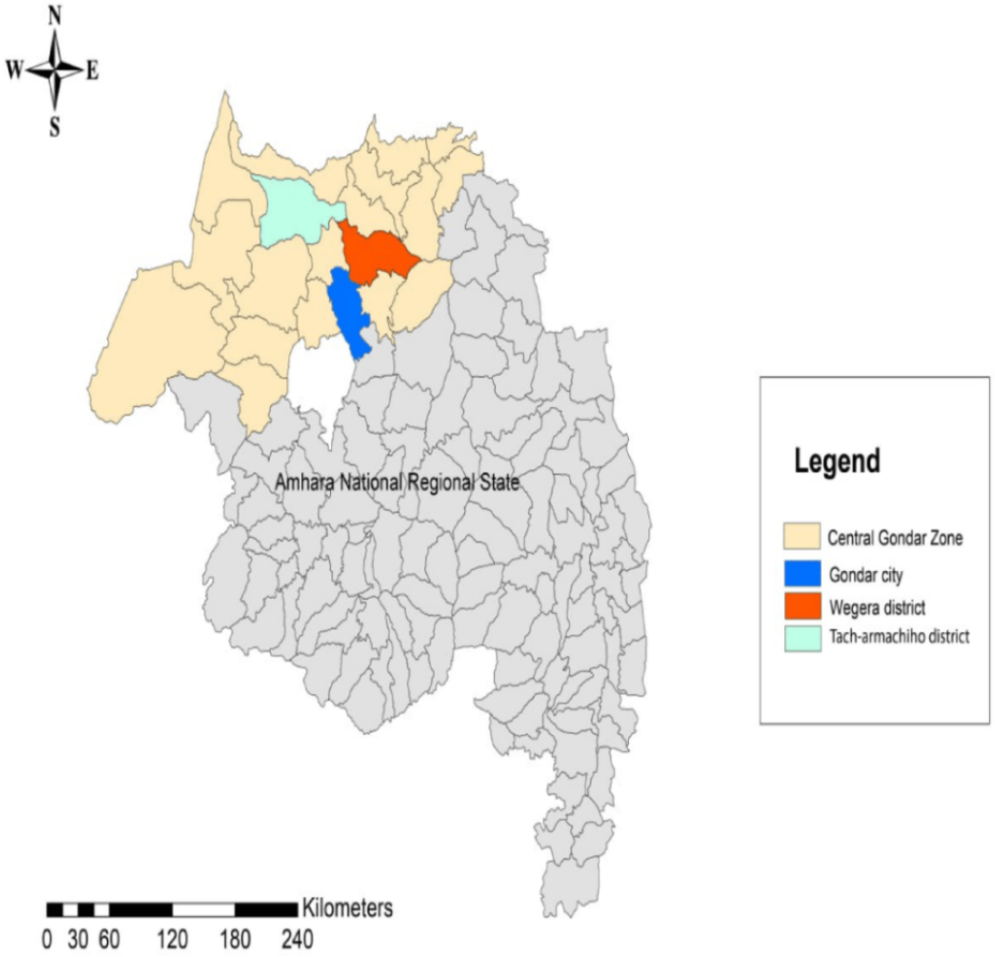
This study used a quasi-experimental design with a comparator group in the pre-post period to examine the effect of PBNI on the data quality of IMRs of institutional births. A cross-sectional survey within an institutional setting was used to review institutional birth–related medical records. The study included the IMRs of women who gave birth within 6 months before (April to September 2020) and after (February to July 2021) the intervention.

Study Setting

This study was conducted in the Amhara National Regional State, specifically in the Central Gondar Zone districts of "Wegera" and "Tach-armachiho" in northwest Ethiopia (Figure 1). According to the Ethiopian Central Statistical Agency projection, the total population in both districts was approximately 398,350 in 2021, with an estimated 93,214 women in the reproductive age group (15-49 years) [56,57].

The districts hosted 2 primary hospitals, 13 health centers, and 72 health posts. The intervention district had 678 health care providers and 215 support staff, whereas the comparator district had 202 health care providers and 141 support staff [58]. These districts were chosen for their involvement in the CBMP, a collaborative initiative between the Ethiopian Ministry of Health and the University of Gondar [24,59,60]. As part of the CBMP, the University of Gondar provides ongoing technical support, including training, supervision, and mentorship to health facilities in both districts, to enhance data quality and information use [59]. This study evaluated the effect of PBNI in the "Wegera" district, with the "Tach-armachiho" district serving as a comparator.

Figure 1. Map of the study area.



Intervention

Intervention Aim and Design

The PBNI intervention was implemented in the "Wegera" district between October 2020 and July 2021 to improve the data quality and use of the RHIS. PBNI was designed as a package with multiple nonfinancial incentive components. Incentives were offered across 3 levels: health facilities, departments, and individual health care workers. Individual health workers were offered nonfinancial incentives, including smartphones, flash disks, power banks, and scholarships. Desktop computers were offered at the department and health facility levels. Health workers, departments, and health facilities that earned nonfinancial incentives in each round were awarded certificates of recognition [61].

Target Areas for PBNI

The study included 6 (75%) out of the 8 health centers in "Wegera." The departments involved in the PBNI program include Maternal and Child Health, Outpatient Department, under-5 Outpatient Department, the Health Management Information System (HMIS), and the Medical Record Unit (MRU). Health workers who participated in the PBNI program included various experts, such as medical record personnel, health IT (HIT) personnel, health officers, midwives, nurses, and personnel involved in laboratories and pharmacies.

Awardees Selection Procedures

The selection of the best performers was conducted through 2 approaches: a subjective and an objective approach.

Subjective Approach

The subjective approach involved requesting management authorities in the intervention district to nominate the best-performing employees. The subjective approach was chosen owing to practical constraints, as the quantitative measurement of all health workers' performance was infeasible owing to limited resources. Accordingly, the number of potential

awardees was reduced to a manageable level, allowing us to concentrate on objectively evaluating the candidates.

The subjective approach was conducted in 2 phases. In the initial phase, health office department managers in the intervention district nominated 12 individuals, selecting 2 from each of the 6 participating health centers. The second phase mirrored the first phase, except that the selection process took place at the level of each health center, where the heads of each health center were tasked with nominating the best performers. With 2 nominees selected by the heads of each health center, another 12 individuals were identified. Consequently, 24 individuals were identified using a subjective approach.

Objective Approach

Previous research indicates that effective health care incentives depend on rewarding specific performance [62,63]. In this study, for the purpose of incentivizing 3 entities—health centers, departments, and individual health workers—we used a flexible approach that used objective measures to identify the best performers. For health centers, 14 quantitative performance measures, each of which was established with specific targets and points to be earned, were used (Textbox 1). The allocation of point values and performance targets took priority for the RHIS activities, as defined by the Ethiopian Ministry of Health [22].

The performance of departments and the 24 individuals selected during the subjective phases was objectively evaluated, aligning the 14 quantitative performance measures with their relevant roles and job descriptions. Further details on the performance measures used are described in prior studies [58,61,64,65].

Textbox 1. The performance indicators used to determine the awardees of nonfinancial incentives, northwest Ethiopia, 2021.

Indicators and points (total points: 90)

1. Source documents completeness rate: 10
2. Report timeliness: 5
3. Lot quality assurance sampling performance: 6
4. Data consistency among registers and reports: 12
5. Health centers established by Performance Monitoring Team: 8
6. Action plan implemented regularly: 10
7. Conducted internal supervision: 5
8. Gaps identified and prioritized by Performance Monitoring Team: 5
9. Conducted root cause analysis: 5
10. Feedback provided for case teams by health centers: 4
11. Number of feedback entries provided to health posts by health centers 5:
12. Information display status: 5
13. Report completeness: 5
14. Consistency among medical records: 5

The Awarding Processes

Initially, the team from the University of Gondar visited the health office department and health centers in the intervention district to communicate the commencement of the program. During this announcement phase, a banner illustrating the nonfinancial rewards was displayed within the compounds of the health facilities. Nonfinancial incentives were offered to the recipients through 3 ceremonial award programs that took place bimonthly. The attendees of the PBNI ceremonial award include representatives from the University of Gondar, Federal Ministry of Health, Amhara Regional Health Bureau, Central Gondar Zone, and “Wegera” District Health Office departments. These representatives comprised health experts and administrative personnel. Officials from the Federal Ministry of Health and University of Gondar rewarded the top-3 individuals, departments, and health centers. Certificates of recognition were presented to awardees during these bimonthly forums. Ceremonial events were also accompanied by presentations detailing the performance measurement and award selection procedures by the professionals from the University of Gondar.

Study Participants

Overview

The participants in this study were women who had given birth in the health centers at the study sites. The IMR sets of these individuals were examined. Thus, for each woman, there would be a set of 3 types of records: delivery register, integrated individual folder (IIF), and integrated card. These 3 sets of IMRs were combined to form a single study cohort. The 3 types of IMRs evaluated in this study, designed to record institutional birth data following the guidelines established in Ethiopia [66], are described in the following sections.

Integrated Card

The integrated card captures data on pregnant women throughout antenatal, labor, delivery, and postnatal care. It facilitates the recording of medical histories, physical examination results,

and other clinical data for both women and newborns, allowing health care providers to complete it upon birth.

Delivery Register

The delivery register is a serial-long register designed to contain a list of all women who give birth at the facility, with data abstracted from the integrated card.

Women's IIF

The IIF is designed to consolidate the entirety of a woman's personal records, including the integrated card. It ensures the convenient access to comprehensive medical data, with the front section containing personal identification data filled out during registration and the inner part featuring a summary sheet completed by service providers after each visit.

Sample Size Calculation

The required sample size for this study was calculated using StatCalc (Epi Info version 7.0; Centers for Disease Control and Prevention), incorporating assumptions to detect differences in completeness and consistency rates between the intervention and comparator groups. The assumptions included 80.3% completeness and 29.5% consistency from a prior unpublished pilot study (Taye, BK, unpublished data, September 2021), a 1:1 ratio of the intervention to the comparator group, a 5% anticipated change in the intervention group [55], 80% power, 95% CI, and a 10% nonresponse rate. Separate calculations yielded approximately 1969 participants (985 in each group) for completeness and approximately 3007 (1504 in each group) for consistency. From the 2 computed samples, we chose 1969 participants, considering the available resources for feasibility.

Inclusion and Exclusion Criteria

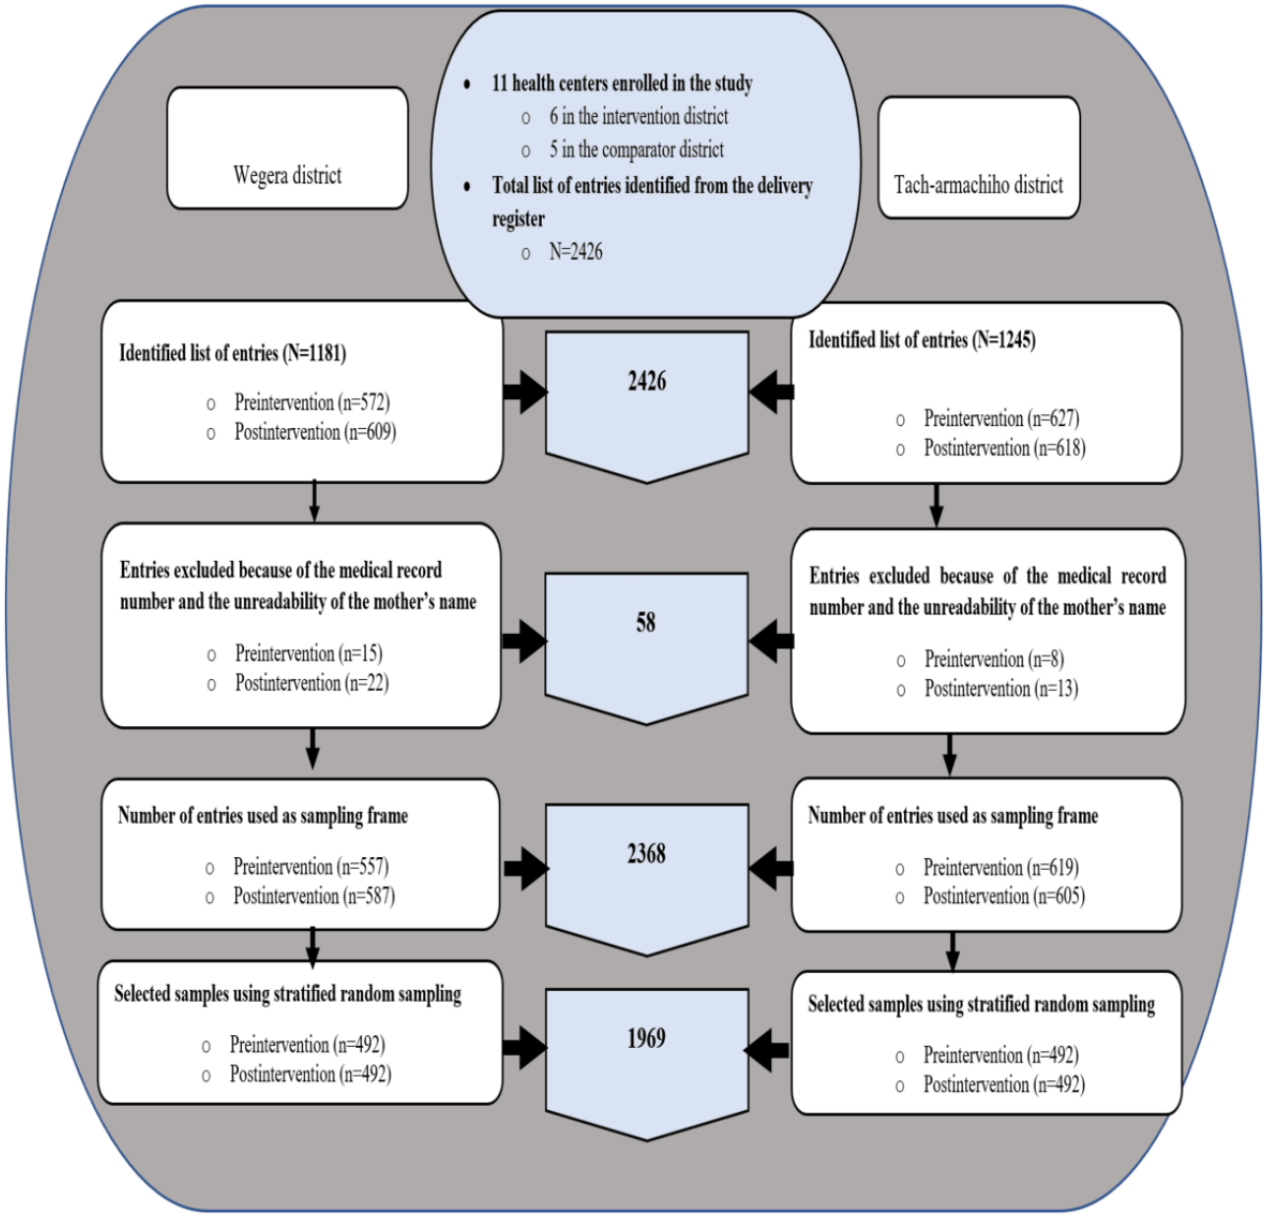
A list of women who gave birth during the study period was used as a sampling frame to select the study sample. Three distinct IMRs in combination (delivery register, IIF, and integrated card) were necessary for each participant. The inclusion criteria in this study mandated that women's "medical record numbers" (MRNs) and the mother's full name be legibly recorded on the delivery register. The readability of these 2 variables was necessary to match and retrieve women's IIF data from the MRU.

Sampling Procedure

A total of 11 health centers were included in the pre- and postintervention periods, of which 6 (55%) were in the intervention district and 5 (45%) were in the comparator district. In total, 2426 women's entries were identified from the delivery register across the baseline and end line periods.

Of the 2426 entries, we excluded 58 (2%) due to unreadability of the MRNs and the full names of the mothers, resulting in 2368 (98%) entries of women on the delivery register. The list of 2368 women in the delivery register was used as a sampling frame to select 1969 (83.1%) samples through stratified random sampling. Subsequently, the women's IIF was retrieved from the MRU (Figure 2).

Figure 2. A diagram illustrating the process of study sample selection.



Variables and Measurements

Outcome Variables

Completeness

Completeness refers to the presence of data elements in the targeted data set [67]. Within the RHIS, assessing the completeness of data elements mandates the presence of its corresponding services or medical procedures in health facilities [68]. Accordingly, this research evaluated the completeness of the 33 data elements where the guideline necessitates their recording [66]. Of the 33 data elements, 16 (48%) were from the integrated card (mother's name, gravida, para, MRN, date and time of admission, ruptured membranes, date and time of delivery, mode of delivery, placenta details, newborn's sex, newborn outcome, single or multiple births, term or preterm status, and the name and signature of providers), 7 (21%) were from the individual folder (facility name, registration date, client's sex, mother's age, date of delivery, Department-provided service, and serial number), and 10 (30%) were from the delivery register (serial number, age, address, date and time of delivery, newborn outcome, mode of delivery, maternal status, newborn's sex, and the name and signature of providers).

Consistency

According to previous research [69], consistency is a measure of data accuracy (the extent to which data elements accurately represent the true numbers), commonly assessed in RHIS through data verification (agreement of data among data sources). This research crosschecked the agreement between the data elements in the source documents to assess consistency. The delivery register served as the gold standard, allowing a comparison with 12 data elements abstracted from the IIF and integrated card, including the serial number, MRN, mother's name, delivery date and time, mode of delivery, newborn's sex, provider's name and signature, Apgar score, newborn's weight, mother's HIV test acceptance, and mother's HIV test results.

In this study, data collectors judged the completeness and consistency of data elements, and the decision adhered to the guidelines [66]. For completeness, data collectors observed the presence of data elements in personal records and declared and coded each data element as 1 for "Yes" if recorded and 0 for "No" if unrecorded. Regarding consistency, data collectors verified elements from comparable records for agreement, coding them as 1 for "Yes" if consistently recorded and 0 for "No" otherwise.

Independent Variables

The characteristics of health facilities supposed to be associated with the data quality of institutional birth were included in the analysis, drawing from pertinent literature and guidelines in the field [22,66,70-72]. These independent variables were the presence of HIT personnel, availability of data recording tools, availability of trained providers, supportive supervision from higher officials, existence of PMT, PMT per membership standard, monthly PMT meetings, monthly conducted LQAS, conducted root cause analysis (RCA) on the identified gaps, internal supervision, and availability of HMIS guidelines. Details of the measurement and data management for outcomes and independent variables have been outlined in a previous study [73].

Data Collection

In total, 11 data collectors, HIT personnel, and related health sciences graduates were recruited for the data collection. The data collectors received a 3-day training that covered the study's objectives, methodology, and ethical considerations. The principal investigator and the other 2 supervisors supervised the data collection process.

Statistical Analysis

Data were entered into the EpiData (version 3.1; Epi Data Association) and exported into Stata (version17.0; StataCorp) for analysis.

Descriptive Statistics

The frequency distribution of women's IMRs is presented based on the characteristics of the health facilities. Pearson chi-square tests were computed to assess the comparability of the data on the study participants' baseline characteristics between the intervention and comparator groups.

The completeness and consistency proportions were computed for specific data elements, with the average rates calculated for the study participants. The completeness proportion of data elements was determined by dividing the number of participants with recorded data elements by the total number of study participants. Meanwhile, the mean completeness proportion was calculated by dividing the number of data elements recorded per participant by the total expected number of data elements. Likewise, the consistency proportion of data elements was determined by dividing the number of participants with consistently recorded data elements by the total number of study participants, and the mean consistency proportion was calculated by dividing the number of data elements consistently recorded per participant by the total expected number of data elements.

Changes in completeness and consistency proportions between the study groups were compared by computing absolute differences and their corresponding 95% CIs, using a 2-sample proportion test.

Difference-in-Differences Analysis

This study used difference-in-differences (DID) to estimate the average effect of PBNI on data completeness and consistency [74,75]. The average treatment effect on the treated (ATET) was computed using the DID model. The DID model used can be described as follows:

(1)

where γ_i represents the outcome (either completeness or consistency) for each study participant. The variable 1(g = intervention) is an indicator for the study group, taking the value of "1" if the participant belongs to the intervention group and "0" otherwise. Similarly, the variable 1(t = post) is a binary indicator, taking the value of "1" for the participants sampled during the end line period and 0 otherwise. $Z_{igt}\beta$ represents the independent variables, that is, the characteristics of health facilities included in the DID model. D represents the intervention in this study (PBNI). σ represents the coefficient of average treatment effect on the intervention group (ATET), providing estimates of the average effect of the PBNI on the outcome variables, and  are the residual errors.

Ethical Considerations

Ethics clearance was obtained from the University of Gondar's Institutional Ethical Review Board (RNO: V/P/RCS/05/861-2021). As this study used medical records rather than human participants, obtaining informed consent from the participants was not feasible.

Results

Description of Women's IMRs by Health Facilities' Baseline Characteristics

In this study, 91.92% (1810/1969) of the samples met the analysis criteria for the coexistence of all 3 distinct IMRs. Of the analysis sample, 49.78% (901/1810) were sampled from the intervention district and 50.22% (909/1810) from the comparator district, whereas 49.56% (897/1810) were enrolled at baseline and 50.44% (913/1810) were enrolled at end line.

Among the baseline samples involved in the analysis, 51% (458/897) were enrolled from the intervention district and 48.9% (439/897) were from the comparator district. When comparing study participants according to baseline health facility characteristics, the distribution was identical (897/897, 100%) across the following variables: the presence of HIT personnel, the existence of PMT, the PMT established per membership standard, monthly PMT meetings in the last 6 months, and monthly LQAS in the previous 6 months.

Most of the IMRs (425/458, 92.8%) in the intervention district were from health centers where the data recording tools were fully available, compared with 12.3% (54/439) in the comparator

district (*P*<.001). In the intervention district, 69% (316/458) of the IMRs were from health centers where most providers had received training on data quality, compared with 65.6% (288/439; *P*=.28) in the comparator district. In the intervention district, 39.7% (182/458) of the IMRs were from health centers with at least 3 supportive supervision visits by higher officials, compared with 65.6% (289/439; *P*<.001) in the comparator district. Nearly one-third of the IMRs (145/458, 31.6%) in the intervention district were from health centers that conducted at least 2 internal supervisions, compared with 4.8% (21/439; *P*<.001) in the comparator district. Less than three-fourth of the IMRs (303/458, 66.2%) in the intervention district were from health facilities that conducted RCA at least 3 times, compared with 25.2% (111/439; *P*<.001) in the comparator district. In the intervention district, 92.8% (425/458) of the IMRs were from health centers with fully available HMIS guidelines, compared with 91.8% (403/439; *P*=.58) in the comparator district (Table 1).

Specific Data Elements Completeness Across Study Groups

Table 2 compares the intervention and comparator districts regarding the completeness of specific data elements across the 3 IMRs. Concerning the data elements from the integrated card, the "Name of the mother" showed 95.6% (861/901) completeness in the intervention district compared with 92.6% (842/909; *P*=.004) in the comparator district. The completeness proportion of "Gravida" was 91.7% (826/901) in the intervention district, compared with 90.4% (822/909; *P*=.18) in the comparator district. The completeness proportion of "MRN" was 92.7% (835/901) in the intervention district, compared with 84.9% (771/909; *P*<.001) in the comparator district. The completeness proportion of "Time of Admission" was 92.5% (833/901) in the intervention district, compared with 88.7% (806/909; *P*=.003) in the comparator district. The completeness proportion of "time of delivery" was 94.9% (855/901) in the intervention district, compared with 89.6% (814/909; *P*<.001) in the comparator district. The completeness proportion of "Name and signature of providers" was 90.1% (812/901) in the intervention district, compared with 86.8% (789/909; *P*=.01) in the comparator district.

In the IIF, the "date of delivery" completeness proportion was 39.3% (354/901) in the intervention district, compared with 29.4% (268/909; *P*<.001) in the comparator district. The completeness proportion of "Date of registration" was 99.8%

(900/901) in the intervention district, compared with 93.4% (849/909; *P*<.001) in the comparator district. The completeness proportion of "Department-provided service" was 37.1% (334/901) in the intervention district, compared with 29.4% (267/909; *P*<.001) in the comparator district. The completeness proportion of "Serial Number" was 35.2% (318/901) in the intervention district, compared with 31% (282/909; *P*=.03) in the comparator district.

Regarding the data elements in the delivery register, the "Serial Number" and "Age" were found to be recorded for all study participants across the intervention and comparator districts. In the intervention district, the "time of delivery" showed 92.7% (835/901) completeness, compared with the comparator district, which showed 62.6% (571/909; *P*<.001) completeness. In the intervention district, the "date of delivery" showed 99.7% (899/901) completeness, compared with the comparator district, which showed 95.3% (867/909; *P*<.001) completeness. The completeness proportion of "sex of newborn" was 99.4% (896/901) in the intervention district, compared with 99% (900/909; *P*=.14) in the comparator district. The "Name and signature of providers" completeness proportion was 78.3% (706/901) in the intervention district, compared with 80.9% (736/909; *P*=.92) in the comparator district.

Table 2. Specific data elements' completeness in individual medical records of institutional births across intervention and comparator districts, northwest Ethiopia, 2021.

Completeness	Intervention (N=901), n (%)	Comparator (N=909), n (%)	Difference[a] (95% CI)	*P* value[b]

[c]A number of times a woman has given birth to a viable child.

[d]No difference among intervention and comparator group.

Average Data Completeness Across the Pre- and Postintervention Periods

For the integrated card, the average completeness increased from 86.2% (95% CI 83.9%-88.57%) at the baseline to 96.6% (95% CI 96%-97.1%) at the end line in the intervention district; however, in the comparator district, it showed a decrease from 91.1% (95% CI 89.4%-92.7%) at the baseline to 87% (95% CI 84.2%-89.7%) at the end line.

The average completeness of the IIF increased from 58.9% (95% CI 57.6%-60.2%) at the baseline to 85.3% (95% CI 83.6%-87%) at the end line in the intervention district, whereas the comparator district showed a change from 63.5% (95% CI 61.5%-65.4%) to 68.1% (95% CI 65.6%-70.6%).

In the intervention district, the mean completeness proportion of the delivery register increased from 94.6% (95% CI 93.9%-95.2%) at the baseline to 99.3% (95% CI 99%-99.5%) at the end line. In comparison, the comparator district showed a change from 93.5% (95% CI 92.9%-94%) to 93.6% (95% CI 92.9%-94.3%).

In the intervention district, the average data completeness proportion across the 3 individual IMRs was 82.9% (95% CI 81.88%-4.1%) at the baseline, and it increased to 95% (95% CI 94.6%-95.5%) at the end line. In the comparator district, the average data completeness proportion across the 3 IMRs was 86% (95% CI 84.96%-86.97%) at the baseline but decreased to 84.97% (95% CI 83.28%-86.66%) at the end line (Multimedia Appendix 1).

Effect of PBNI on Data Completeness

In the intervention district, the "integrated card" resulted in an average 2.6 percentage-point increase in completeness compared with the comparator district (ATET 2.67, 95% CI 0.7-4.4; *P*=.04). On average, the intervention district showed a 3.8 percentage-point increase in the completeness of the delivery register compared with the comparator district (ATET 3.8, 95% CI 2.9-4.8; *P*=.01). The intervention district showed a 6.8 percentage-point increase in the average completeness of the IIFs compared with the comparator district (ATET 6.8, 95% CI 4.55-9; *P*=.02). Overall, on average, the intervention district showed a 3.8 times higher chance of complete recording of IMRs compared with the comparator district (ATET 3.8, 95% CI 2.2-5.5; *P*=.02; Table 3).

Table 3. Effect of performance-based nonfinancial incentives on the data completeness in individual medical records of institutional births, northwest Ethiopia, 2021.

Completeness	Intervention, mean (SD)	Comparator, mean (SD)	Intervention effect, ATET[a] (95% CI)[b]	*P* value
Integrated card	91.3 (18.8)	88.9 (24.9)	2.6 (0.7-4.4)	.04
Integrated individual folder	71.9 (21.1)	65.8 (24.8)	6.8 (4.6-9)	.02
Delivery register	96.8 (5.8)	93.6 (6.9)	3.8 (2.9-4.8)	.01
Overall	88.8 (11.2)	85.4 (15.3)	3.8 (2.2-5.5)	.02

[a]ATET: average treatment effect on the treated.

[b]ATET estimates adjusted for covariates (presence of health information technology personnel, availability of data recording tools, availability of trained providers, supportive supervision from higher officials, existence of the Performance Monitoring Team [PMT], PMT per membership standard, monthly PMT meeting, monthly conducted lot quality assurance sampling, conducted root cause analysis, internal supervision, and availability of Health Management Information System guidelines).

Consistency of Specific Data Elements Across Study Groups

Regarding the delivery register and IIF, the "date of delivery" showed a consistency proportion of 82.3% (742/901) in the intervention district, compared with 58.7% (534/909; *P*<.001) in the comparator district. The "Serial Number" showed a consistency proportion of 42.1% (380/901) in the intervention district, compared with 45.5% (414/909; *P*=.92) in the comparator district.

Comparing the delivery register and integrated card, the "MRN" exhibited a consistency proportion of 87% (784/901) in the intervention district, compared with 74.9% (681/909; *P*<.001) in the comparator district. The "time of delivery" showed a consistency proportion of 88.2% (795/901) in the intervention district, compared with 56.7% (516/909; *P*<.001) in the comparator district. The "Name and signature of providers" showed a consistency proportion of 89.5% (807/901) in the intervention district, compared with 77.7% (707/909; *P*<.001) in the comparator district. The "newborn weight" had a consistency proportion of 85.7% (773/901) in the intervention district, compared with 82.1% (746/909; *P*=.01) in the comparator district. The "Women's HIV test accepted" showed a consistency proportion of 39.9% (360/901) in the intervention district and 40.5% (368/909; *P*=.59) in the comparator district (Table 4).

Table 4. Consistency of specific data elements across the intervention and comparator districts, northwest Ethiopia, 2021.

Consistency	Intervention (N=901), n (%)	Comparator (N=909), n (%)	Difference[a] (95% CI)	*P* value[b]
Delivery register vs integrated individual folder				
Date of delivery	742 (82.3)	534 (58.7)	23.6 (19.55 to 27.66)	<.001
Serial number	380 (42.1)	414 (45.5)	3.36 (−7.93 to 1.2)	.92

[a]The absolute difference is calculated by subtracting the consistency proportion of the comparator group from that of the intervention group.

[b]*P* value based on 2 independent sample proportion tests.

Pre- and Postintervention Changes in Average Data Consistency

In the intervention district, the average consistency proportion increased from 71.6% (95% CI 69.6%-73.6%) to 89.2% (95% CI 88.2%-90.2%) after the intervention. In the comparator district, it increased from 68% (95% CI 66.2%-69.8%) to 70.8% (95% CI 67.9%-73.6%) post intervention. Overall, the average consistency proportion increased from 69.8% (95% CI 68.5%-71.2%) to 79.6% (95% CI 78%-81.3%) after the intervention.

Effect of PBNI on Data Consistency

On average, the intervention district showed an 11.2 percentage-point increase in the consistency of data among the delivery register and IIF compared with the comparator district (ATET 11.2; 95% CI 9.6- 12.87; *P*=.007). The intervention district showed an 11.6 percentage-point increase in the average consistency of data among the delivery register and the integrated card compared with the comparator district (ATET 11.6; 95% CI 3.1-20.1; *P*=.04). Overall, the average consistency of data among IMRs in the intervention district was 11.6 times higher than that of the comparator district (ATET 11.6; 95% CI 4.2- 19; *P*=.03; Table 5).

Table 5. Effect of performance-based nonfinancial incentives on data consistency in individual medical records of institutional births, northwest Ethiopia, 2021.

Consistency	Intervention, mean (SD)	Comparator, mean (SD)	Intervention effect, ATET[a] (95% CI)[b]	*P* value
Delivery register vs integrated individual folder	62.2 (36.4)	51.1 (45.5)	11.2 (9.6-12.8)	.007
Delivery register vs integrated card	83.5 (19.9)	72.6 (26.0)	11.6 (3.1-20.1)	.04
Overall	80.2 (19.1)	69.4 (26.1)	11.6 (4.2-19)	.03

[a]ATET: average treatment effect on the treated.

[b]ATET estimates adjusted for covariates (presence of health information technology personnel, availability of data recording tools, availability of trained providers, supportive supervision from higher officials, existence of the Performance Monitoring Team [PMT], PMT per membership standard, monthly PMT meeting, monthly conducted lot quality assurance sampling, conducted root cause analysis, internal supervision, and availability of Health Management Information System guidelines).

Discussion

Principal Findings

This study evaluated the effect of PBNI on the quality of institutional birth data in northwest Ethiopia. PBNI improved both data completeness and consistency. The intervention district showed a 12% increase in data completeness compared with the comparator district, which showed a 1% decrease. Regarding data consistency, the intervention district improved by 18%, whereas the comparator district saw a 3% improvement. Controlling for other variables in the DID analysis, women’s

IMRs from the intervention district exhibited nearly 4 times higher data completeness and approximately 12 times greater data consistency than the comparator district.

Comparison With Prior Work

This study revealed a positive effect of PBNI on the data completeness and consistency of women's IMRs for institutional births. This finding aligns with that of previous studies that demonstrate the effectiveness of nonfinancial incentives in improving different aspects of health care quality. For instance, nonfinancial incentives have been proven to enhance the quality of medical error RCA in a US study [50]. Furthermore, studies from India and El Salvador [51,54,76] have shown an increase in the equitable and quality provision of maternal and child services. Nonfinancial incentives have also been reported to enhance quality consultations, according to studies from Tanzania [55,77]. The demonstrated effectiveness across contexts suggests the adaptability of nonfinancial incentives to improve the data quality and the quality of pregnancy-related services at health care facilities. These findings are particularly relevant for resource-limited settings where poor health care quality is associated with persistent mortality rates among mothers and children [3,5,78].

In this study, PBNI induced a greater extent of change compared with that in previous studies [51,54]. This difference may be due to differences in the incentive structures among the studies. In contrast to prior research that used team-based incentives, this study provided incentives at 3 levels: health facilities, departments, and individual health workers. Notably, the similarity between previous and current studies is apparent in the use of team-based incentives, reflected in this study's provision of incentives at the departmental level. Some earlier studies support the efficacy of team-based incentives in health care, emphasizing their role in fostering collective engagement [79-84]. Despite variations in the magnitude of the effect, the findings of this study do not contradict earlier research on the effectiveness of team-based incentives. Instead, the findings assert the potential for increased effectiveness by combining team-based, individual, and facility-level incentives.

According to this study, the effect of PBNI on data quality varies across the 3 women's records (integrated card, IIF, and delivery register). For example, although the integrated card saw a 3% increase in data completeness, women's folders increased by approximately 7%. These variations may suggest that the effectiveness of PBNI varies across health workers' professions. In Ethiopia, for instance, nonprofessional health workers are largely responsible for women's folder data, whereas midwives and other professionals are responsible for recording integrated card data [66]. Previous research in India has also demonstrated that the effectiveness of nonfinancial incentives varies depending on the health workers' professions, with frontline health workers experiencing a greater performance than supervisors [54]. Another study in northwest Ethiopia found a strong correlation between health worker motivation and their professional category [85]. These findings indicate the importance of recognizing the differences in the effectiveness of incentives and tailoring interventions to specific groups of health workers. Hence, policy makers and health care managers need to consider these variations when designing incentive programs, adopting a flexible approach that accounts for diverse roles and responsibilities.

This study reinforces the existing evidence that favors nonfinancial incentives in health care over financial incentives [86-90]. Concerns about financial incentives contradicting health care providers' intrinsic motivation to deliver quality care are widespread [86,90-100]. Therefore, this study suggests the practical use of nonfinancial incentives to enhance health care quality, especially in countries such as Ethiopia with limited financial capability. Prior studies in African countries have also indicated the importance of nonfinancial incentives in improving health care quality [44,101,102].

Policy and Research Implications

This study introduces PBNI as an effective intervention to improve the quality of institutional birth data. These findings underscore the potential of PBNI to complement established interventions to enhance RHIS performance, such as supportive supervision, mentorship, training, and feedback.

As this study evaluated the effect of PBNI on institutional birth data—a core indicator of maternal health care quality—the implications extend to broader RHIS data related to maternal and child services. These findings indicate the potential of PBNI to improve the quality of health services, which can contribute to maternal and child morbidity and mortality reduction. Hence, health care planners can consider adapting PBNI to improve the quality of maternal and child health services.

This study examined the effectiveness of PBNI in the context of health workers in health centers. Future studies are essential to understand the impact of PBNI on health staff across diverse settings, including health posts and hospitals.

Strengths and Limitations of the Study

One of the strengths of this study lies in its evaluation of the effect of PBNI on data quality within women's IMR in institutional births. Unlike most previous studies on RHIS data quality, which studied health facilities as the unit of analysis, this study delved into the individual level of data quality, which is essential to understanding how PBNI influences client-level service quality. In addition, we attempted to detect the minimum effect of the PBNI, using a sufficient study sample, and compared the intervention with comparator sites, increasing the robustness of the findings. Furthermore, to establish a causal effect of PBNI, the study used DID analysis, a recognized causal analysis technique in nonrandomized studies. Nevertheless, it is essential to recognize the limitations of this study. First, the retrospective design prevented randomization in the selection of the study participants. Second, interviewer bias is possible during the completeness and consistency assessments, as data collectors judged these aspects despite training to reduce bias. Although we attempted to disentangle the effect of PBNI from other potential factors, unmeasured confounders may still exist. Moreover, the security issues in Northern Ethiopia might have disrupted the effectiveness of the PBNI, as the intervention coincided with security problems in the adjacent regions.

Conclusions

This study shows that PBNI improves institutional birth data quality, as demonstrated by enhanced completeness and consistency. The effectiveness of PBNI can be extended to enhancing comparable RHIS data in maternal and child care and improving service quality at health care facilities. Health care planners can consider PBNI to enhance the quality of maternal and child health services in health care facilities. Future studies are essential to understand the impact of PBNI in diverse health care settings.

Acknowledgments

This work was financially supported by the Doris Duke Charitable Foundation (grant 2017187). The mission of the Doris Duke Charitable Foundation is to improve the quality of people's lives through grants supporting the performing arts, environmental conservation, medical research, and child well-being and through the preservation of the cultural and environmental legacy of Doris Duke's properties. The authors would like to express their gratitude to the supervisors, data collectors, and health office departments of the Central Gondar Zone, Wegera district, and Tach-armachiho district.

Authors' Contributions

BKT conceived and designed the study, performed the data collection, analyzed and interpreted the data, and drafted the manuscript. LDG, AA, SAM, JK, MKG, and BT analyzed and interpreted the data, and contributed to writing the manuscript. All authors reviewed and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Electronic health records (EHRs) are increasingly used for epidemiologic research to advance public health practice. However, key variables are susceptible to missing data or misclassification within EHRs, including demographic information or disease status, which could affect the estimation of disease prevalence or risk factor associations.

Objective: In this paper, we applied methods from the literature on missing data and causal inference to assess whether we could mitigate information biases when estimating measures of association between potential risk factors and diabetes among a patient population of New York City young adults.

Methods: We estimated the odds ratio (OR) for diabetes by race or ethnicity and asthma status using EHR data from NYU Langone Health. Methods from the missing data and causal inference literature were then applied to assess the ability to control for misclassification of health outcomes in the EHR data. We compared EHR-based associations with associations observed from 2 national health surveys, the Behavioral Risk Factor Surveillance System (BRFSS) and the National Health and Nutrition Examination Survey, representing traditional public health surveillance systems.

Results: Observed EHR-based associations between race or ethnicity and diabetes were comparable to health survey-based estimates, but the association between asthma and diabetes was significantly overestimated (OR_{EHR} 3.01, 95% CI 2.86-3.18 vs OR_{BRFSS} 1.23, 95% CI 1.09-1.40). Missing data and causal inference methods reduced information biases in these estimates, yielding relative differences from traditional estimates below 50% ($OR_{MissingData}$ 1.79, 95% CI 1.67-1.92 and OR_{Causal} 1.42, 95% CI 1.34-1.51).

Conclusions: Findings suggest that without bias adjustment, EHR analyses may yield biased measures of association, driven in part by subgroup differences in health care use. However, applying missing data or causal inference frameworks can help control for and, importantly, characterize residual information biases in these estimates.

Introduction

Understanding patterns and risk factors of chronic disease burden is a key function of public health practice. Electronic health record (EHR) data have numerous strengths that can be leveraged for this purpose, including near real-time information on large patient populations, allowing for improved precision and timeliness when estimating patterns or trends in disease burden [1]. EHRs also contain clinically based diagnoses, laboratory results, and physical measurements [2]. Often, researchers use these clinical data to classify patients' disease status using rule-based computable phenotypes or prespecified logic-based criteria [3]. Using EHR-defined measures of disease offers promise for improving the estimation of patterns or associations compared to traditional surveillance systems (eg, health surveys), several of which have poor validity from

self-reported disease status and limited reliability for small subgroups or geographies [4].

Despite these strengths, the classification of disease status using EHR data is susceptible to information biases. Misclassification or measurement errors in key variables can bias estimates of epidemiologic associations. Within EHR data, a diagnostic suspicion bias could occur if certain patients are disproportionately screened for health outcomes compared to others (eg, those who are obese may be more likely to be screened for diabetes with A_{1c} testing) [5], and an informed presence bias could occur if, for example, patients who visit the health system more frequently are sicker or have more opportunities to receive a diagnosis than infrequent visitors [6]. These different biases can distort our understanding of patterns or risk factors for disease burden, such as by underestimating the relative burden among individuals with limited or more fragmented access to care. Notably, selection biases whereby the EHR sample is not generalizable to the target population can also affect estimates of epidemiologic associations, and misclassification itself can be framed as a selection bias issue [7]. Improving our capacity to address misclassification, framed as an information bias issue herein, is a critical step to providing valid inferences.

A variety of statistical approaches and frameworks have been developed to help address misclassification, including treating misclassification as a missing data problem, a causal inference problem, or both [8,9]. With EHR-based computable phenotypes, researchers often rely on variables that are not identifiably missing (eg, lack of diagnosis codes are assumed to mean the absence of disease). For example, pertinent evidence of the disease may be absent from a single EHR due to patients receiving care across multiple distinct health care systems, which could lead to individuals being falsely classified as disease-free [5]. Internal or external data sets can allow for the validation and correction of the computable phenotype's performance, but these data sets are often costly or resource-intensive to obtain [8,10]. Under a missing data framework, the observed health outcome can be assumed to have some level of misclassification and the true health outcome for some or all of the patients can be treated as missing [8,11]. Traditional missing data methods, such as regression calibration, multiple imputation, and inverse probability weighting (IPW), can then be used to address this misclassification [8,10-12].

Misclassification in disease status can also be conceptualized using directed acyclic graphs (DAGs), illustrating factors that affect the causal relationship between the true and observed exposure and outcome [8,13]. Researchers can use traditional epidemiologic methods to control for variables that act as confounders of the observed exposure and outcome. For example, researchers often hypothesize that the number of health care encounters affects the misclassification of EHR-defined disease status through an informed presence bias, with EHR samples further restricted to those with at least 1 encounter [6]. Prior studies have demonstrated that conditioning on the number of encounters can sometimes reduce confounding from differential misclassification but also has the potential to induce a smaller Berkson's or M-bias if the number of encounters is a common effect of the exposure and outcome, particularly when computable phenotypes are highly sensitive [14]. Nevertheless, DAGs offer a promising approach to address misclassification.

In this paper, we applied missing data and causal inference frameworks to evaluate the impact of information biases in EHR data on longstanding epidemiologic research questions about diabetes among young adults. Diabetes is a serious, chronic condition that is still relatively rare within this age group, affecting an estimated 3% of those aged 18 - 44 years [15] but is increasing in both prevalence and incidence [16-18]. We first aimed to estimate the age and sex-adjusted odds of diabetes by race or ethnicity, given established differences in diabetes prevalence across racial or ethnic groups [15,19,20]. Second, we characterized the association between asthma and diabetes, presuming a causal relationship between these chronic conditions [21]. For the target population of in-care US adults aged 18 - 44 years, we compared estimated associations using these frameworks to estimates based on probability samples from national health surveys. This work informs the broader discussion on how to address differential misclassification of disease outcomes within EHR data.

Methods

EHR Sample

The EHR sample comprises patients from NYU Langone Health, a large academic medical center with primary service areas in the New York City boroughs of Manhattan, Brooklyn, and Queens. EHR data were pulled from the Epic Clarity database for all New York City–resident patients aged 18 - 44 years who had an inpatient or outpatient encounter from 2017 to 2019.

Demographic variables of age, sex (male or female), race or ethnicity (White, Black, Latino, Asian, and other), most recent insurance status (Medicaid vs non-Medicaid), and neighborhood poverty level (<10%, 10%-<20%, 20%-<30%, and ≥30% living in poverty within resident census tract) were defined for each patient. Race or ethnicity was imputed for those with unknown race or ethnicity (19.4%, n=88,102) using the Bayesian Improved Surname Geocoding (BISG) methods through the "wru" R package (R Core Team) [22]. Neighborhood poverty level was assigned using zip code tabulation area poverty group when census tract level data were unavailable (1%). Those with an unknown or other age or sex (<1%) were excluded from all analyses.

Health care use variables of total encounters, duration within the NYU Langone Health system, presence of at least 1 routine health exam (2024 ICD-10-CM: Z00.*), presence of at least 1 diabetes-related laboratory (fasting glucose, random glucose, or A_{1c}), and presence of at least 1 encounter with an endocrinology review of systems, or inventory of signs or symptoms of diseases related to the endocrine system, were also defined. Endocrinology review of systems were identified using keyword text searches of history and physical examination notes and progress notes (Multimedia Appendix 1).

Patients were classified as having prevalent obesity, asthma, and diabetes if they had evidence supporting these chronic conditions, using all historical EHR data through 2019, and

were classified as not having each respective health outcome without such evidence. In alignment with diabetes definitions from national health surveys, EHR-defined diabetes included all diabetes types. Evidence of diabetes included at least 2 encounter diagnoses for diabetes (ICD-10-CM: E08.*, E09.*, E10.*, E11.*, and E13.*); or 1 encounter diagnosis and at least 2 elevated A_{1c} laboratory results ≥6.5%; or at least 1 antidiabetes prescription medication (not including metformin or acarbose) [23]. Evidence of asthma was defined as at least 2 encounter diagnoses for asthma (ICD-10-CM: J45*–J46*) or at least 2 prescriptions for asthma-related medications [24]. To maintain consistency across chronic disease classification methods, evidence of obesity was defined as a most recent BMI ≥30 kg/m^2, with no naïve corrections for those who were missing BMI, height, or weight measurements (19.1%, n=86,709).

EHR-Based Estimation

We estimated odds ratios (OR) for diabetes by race or ethnicity and asthma status under 4 EHR-based estimation methods that we describe herein. First, "naïve" models were estimated by fitting a logistic regression model for observed diabetes status (DM*) on the total sample (n=454,612). ORs for race or ethnicity were adjusted for age and sex and ORs for asthma were adjusted for the potential confounders of age, sex, race or ethnicity, Medicaid insurance status, obesity, and neighborhood poverty level, as informed by existing literature [25-27].

Second, "sufficiency" models were estimated among the subset of patients who we hypothesized to have sufficient data, defined as those with at least 1 encounter with an endocrinology review of systems or those who were classified as diabetic through the above definition (n=181,036). Since diabetes is a rare disease within the young adult population, we assumed that the specificity of the classification was near-perfect and all patients who were classified as diabetic had sufficient data [28]. Sensitivity analyses tested this assumption and varied the definition of sufficient data to incorporate information related to the other health outcomes (eg, having a diabetes-related laboratory, BMI measurement, and respiratory review of systems; Multimedia Appendix 1). Sufficiency models were estimated by fitting a logistic regression model for DM* using the same covariates as the naïve models.

Third, using "IPW" models, we hypothesized that missing health outcomes would be predicted by demographics (eg, differential screening by race or ethnicity), health care use (eg, informed presence bias), and neighborhood (eg, degree of continuity of care within the health system by catchment area). We estimated the probability of having sufficient data using a multilevel logistic regression model including all demographic and health care use variables and a random intercept for neighborhood defined by public use microdata areas. Stabilized IPW weights were then calculated as the inverse of the predicted probability of having sufficient data multiplied by the overall probability of having sufficient data [10]. The final models were estimated by fitting a logistic regression model for DM* on the subset of patients defined as having sufficient data (n=181,036), weighted for the stabilized IPW weights and using the same covariates as the naïve models.

Fourth, using DAG models (Multimedia Appendix 1), we hypothesized that total encounters would both be associated with differential misclassification of health outcomes through an informed presence bias and be a common effect of the health outcomes, consistent with prior research [6,14]. DAG models were estimated by fitting a logistic regression model for DM* using the total sample (n=454,612), controlling for total encounters and the covariates included in the naïve model. Further details on these models can be found in Multimedia Appendix 1.

Comparison to Survey-Based Estimation

For comparison to traditional surveillance systems, samples were obtained from 2 publicly available national health surveys, the 2019 Behavioral Risk Factor Surveillance System (BRFSS) and the pooled 2013-March 2020 National Health and Nutrition Examination Survey (NHANES). BRFSS is a cross-sectional telephone survey conducted by the Centers for Disease Control and Prevention annually on a sample of over 400,000 US adults [29]. Within BRFSS data, diabetes and asthma were defined by self-reported prior diagnosis from a medical provider, and obesity was defined by a BMI ≥30 kg/m^2 based on self-reported height and weight. Demographic variables of 5-year age group, sex (male or female), race or ethnicity (White, Black, Latino, Asian, and other), insurance status (uninsured vs insured), and income level (<US $50,000, US $50,000-<US $75,000, ≥US $75,000) were defined for each respondent. To reduce the effects of undiagnosed diabetes on misclassification of self-reported diabetes status, the BRFSS survey data were subset to those aged 18 - 44 years who were in care, as defined as those who reported having a personal health care provider.

NHANES is a cross-sectional survey involving interviews and physical examinations that is conducted by the Centers for Disease Control and Prevention annually on a sample of approximately 5000 US children and adults [30]. Within NHANES data, diabetes was defined by a self-reported prior diagnosis or elevated laboratory results (A_{1c}≥6.5% or fasting glucose≥126 mm Hg) [15,31]. Sensitivity analyses varied this definition to be based solely on self-reported prior diagnosis. Asthma was defined by self-reported prior diagnosis from a medical provider and obesity was defined by a measured BMI≥30 kg/m^2. Demographic variables of age, sex (male or female), race or ethnicity (White, Black, Latino, Asian, and other), insurance status (Medicaid vs non-Medicaid), and income level (≤130%, 130% - 350%, >350% of the federal poverty level) were defined for each respondent. NHANES data were subset to those aged 18 - 44 years.

Survey-based estimates were obtained by fitting logistic regression models for diabetes accounting for the unequal probability sample, stratification, and clustering in the complex sample designs [32,33]. Survey-based ORs for race or ethnicity were adjusted for age and sex and ORs for asthma were adjusted for age, sex, race or ethnicity, obesity, insurance status, and income level. Relative differences between EHR-based and survey-based ORs were calculated as percent differences.

Ethical Considerations

This study was approved by the NYU Langone Health Institutional Review Board (i20-01338) and Columbia University Institutional Review Board (AAAU5390) and informed consent was waived. Participants were not compensated.

Results

EHR Sample

The EHR sample comprised 454,612 patients seen within the NYU Langone Health system from 2017 to 2019 (Table 1). A total of 37.8% (n=171,968) of patients were male and 22.2% (n=100,979) had Medicaid insurance. The largest racial or ethnic group within the sample was White, with 41.8% (n=190,225) having a White race or ethnicity recorded within the EHR, and 52.1% (n=237,057) classified as White through BISG imputation. Approximately one-quarter (n=115,249) of patients had a routine medical exam and one-half (n=205,408) had a DM-related laboratory. Within the full sample, 3.1% (n=14,044) of patients were classified as having diabetes, 17.5% (n=79,580) were classified as being obese, and 4.2% (n=19,240) were classified as having asthma.

Table . Descriptive summary of the New York University patient population by data sufficiency status[a,b].

Variables	Total sample (N=454,612)	Insufficient case (n=273,576)	Sufficient case[a] (n=181,036)
Age (years), mean (SD)	32.13 (7.11)	32.02 (7.13)	32.31 (7.07)
Sex (male), n (%)	171,968 (37.8)	100,964 (36.9)	71,004 (39.2)
Medicaid insurance, n (%)	100,979 (22.2)	59,001 (21.6)	41,978 (23.2)

[a]Sufficient cases defined as those with at least 1 encounter with an endocrinology review of systems or those who were classified as diabetic through the computable phenotype of having at least 2 encounter diagnoses for diabetes, 1 encounter diagnosis and at least 2 elevated A_{1c} laboratory results ≥6.5%, or at least 1 antidiabetes prescription medication.

[b]Including all A_{1c}, random blood glucose, and fasting blood glucose laboratory results.

[c]Number of encounters.

[d]Number of years in the health system.

[e]Proportion of individuals residing in the Public Use Microdata Area (PUMA) neighborhood who are present within the electronic health record system.

A total of 39.8% (n=181,036) of the patient population were classified as having sufficient data (Table 1). Patients who were classified as sufficient had greater health care use, measured by a higher average number of total encounters, greater duration within the NYU system, and greater proportion having at least 1 BMI, routine health exam, or diabetes-related laboratory. Compared to insufficient cases, a greater proportion also had a known race or ethnicity (87.4%, n=158,172) or were classified as diabetic (7.8%, n=14,044), obese (22.5%, n=40,761), or asthmatic (7.2%, n=13,073).

Within the total naïve EHR sample, those who were classified as nondiabetic consistently had lower health care use than those who were classified as diabetic (Table 2). This pattern was disrupted in the sufficiency sample, where a greater proportion of patients who are nondiabetic had at least 1 routine medical exam (46.7%, n=77,927 vs 32.3%, n=4536 of patients who are diabetic) and almost all patients had a recorded BMI regardless

of diabetes status. Within both the naïve and sufficiency samples, a lower proportion of those classified as nondiabetic were of Black or Latino race or ethnicity and were classified as having asthma or obesity compared to those classified as diabetic.

Table . Descriptive summary of the New York University patient population by diabetes status[a,b] .

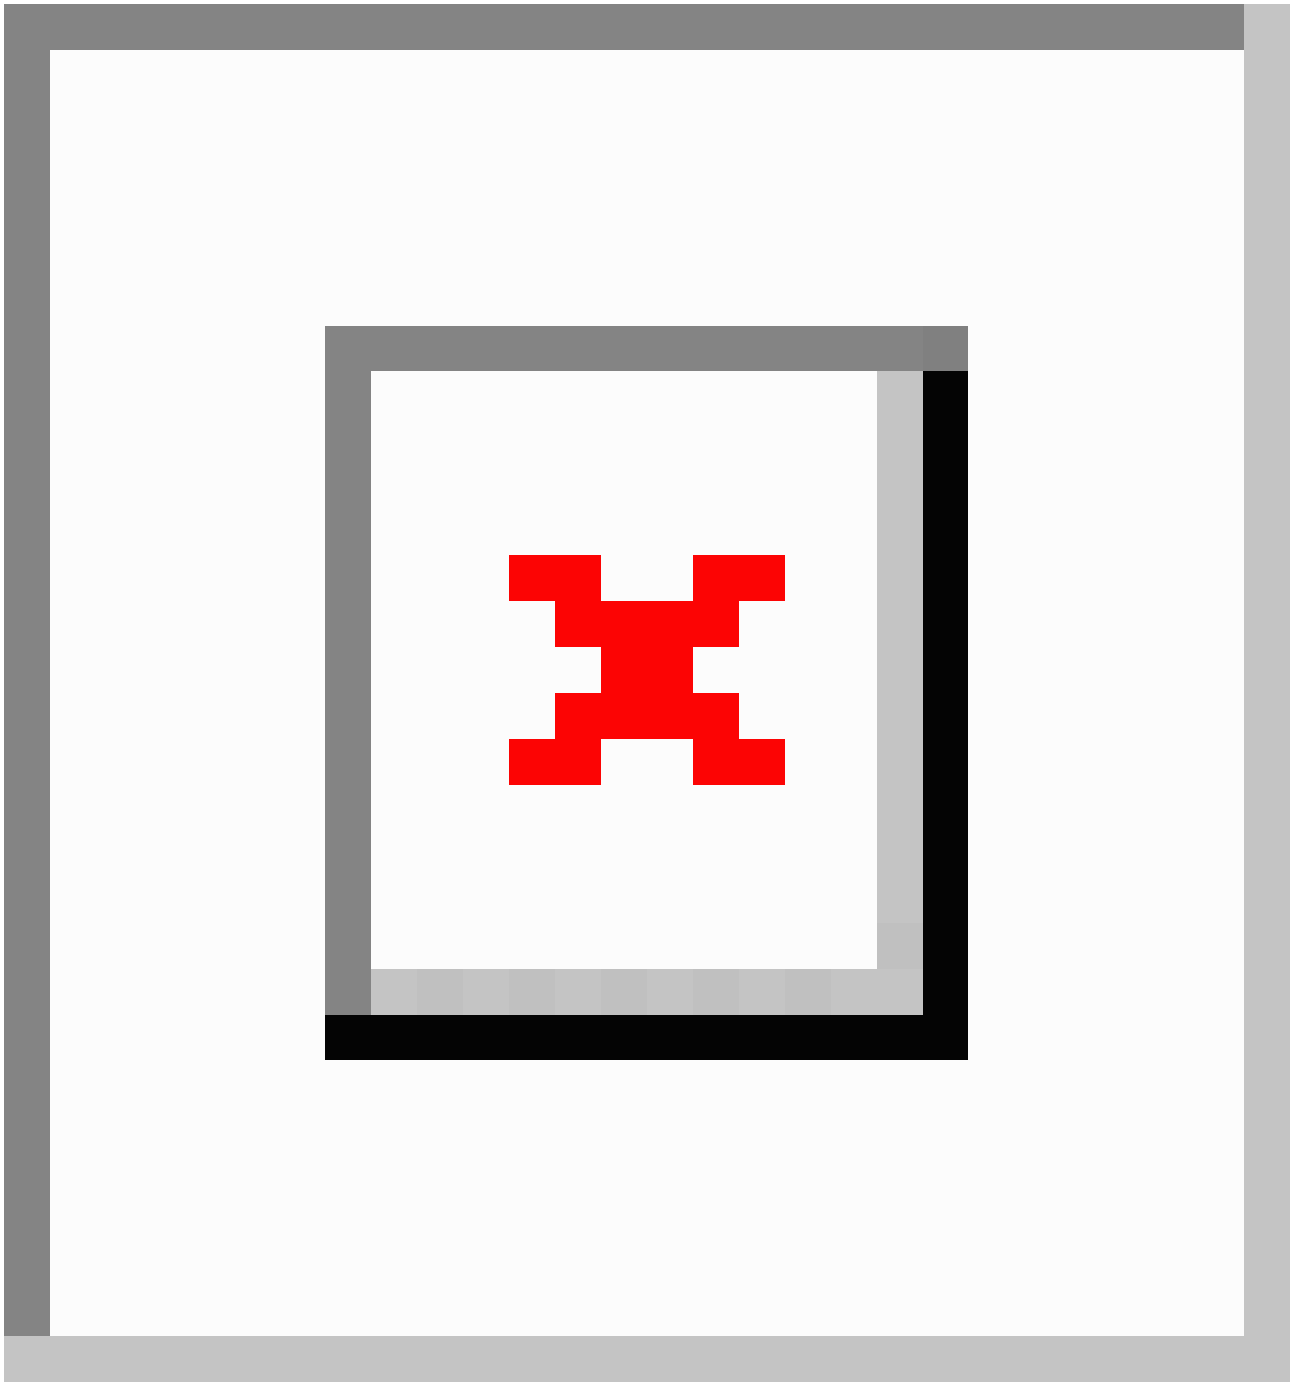
Estimated Associations With Race or Ethnicity

Estimated associations between race or ethnicity and diabetes were comparable across BRFSS and NHANES surveys (Figure 1). In both the survey and EHR-based analyses, respondents who were Black or Latino had significantly higher odds of diabetes compared to White respondents, controlling for age and sex. The naive EHR-based OR estimate for Latino patients was 26% higher than the BRFSS point estimate (OR_{Naive} 1.93, 95% CI 1.85 - 2.01 vs OR_{BRFSS} 1.53, 95% CI 1.32 - 1.77). Sufficiency, IPW, and causal methods reduced this association, with point estimates falling within the 95% CIs and relative differences below 15% compared to both health survey estimates. BRFSS and NHANES respondents who were Asian did not have significantly higher odds of diabetes compared to White respondents, and CIs were wide due to the small sample sizes of this subgroup. Within the EHR analyses, patients who were Asian had a significant 11% - 26% increased odds of diabetes.

Figure 1. Odds ratios for diabetes by race or ethnicity and asthma, EHR-based estimates versus health survey estimates. BRFSS: Behavioral Risk Factor Surveillance System; DAG: directed acyclic graph; EHR: electronic health record; IPW: inverse probability weighting; NHANES: National Health and Nutrition Examination Survey.



Estimated Associations With Asthma

In the BRFSS and NHANES analyses, having asthma was associated with an approximate 20% - 40% increased odds of diabetes after controlling for demographics and obesity (OR_{BRFSS} 1.23, 95% CI 1.09 - 1.40 and OR_{NHANES} 1.38, 95% CI 1.01 - 1.91). In the naive EHR analysis, asthma was strongly associated with diabetes, with those with asthma estimated to have 3 times the odds of diabetes as those without asthma after controlling for demographics and obesity (95% CI 2.86 - 3.18). This association was reduced in the sufficiency sample and the IPW-weighted sample, with corrected OR estimates falling within the 95% CI of the NHANES estimate and having an approximate 30% - 50% relative difference from the health survey point estimates. The association between asthma and diabetes was further reduced in the DAG model (OR 1.42, 95% CI 1.34 - 1.51), falling within the 95% CIs of both survey-based estimates and having a 3% relative difference from the NHANES point estimate and a 15% relative difference from the BRFSS point estimate (Figure 1). Sensitivity analyses varying the definition for sufficiency (Table S3 in Multimedia Appendix 1), varying the BRFSS inclusion criteria, or varying the NHANES diabetes definition produced similar patterns in these results (Table S1 in Multimedia Appendix 1).

Discussion

Principal Findings

Our analysis explored the potential impact of information biases on observed associations of diabetes risk factors within an EHR sample of young adults. We estimated naïve associations on the full patient sample and then attempted to address information biases using missing data and causal inference frameworks. Biases were apparent in the naïve association between asthma and diabetes, which was significantly higher than the health survey-based estimates used as a benchmark for the expected association. All EHR-based methods resulted in estimated associations between race or ethnicity and diabetes that were largely comparable to health survey-based estimates. Those who were observed to have diabetes had greater health care use than those who were classified as nondiabetic, which could reflect an information bias where those with a greater number of health care encounters may have been more likely to have documentation of an underlying diabetes or asthma diagnosis. Attempting to address this bias through missing data or causal frameworks reduced the estimated associations between asthma and diabetes, with the causal framework having the best performance in producing an estimate comparable to the benchmarks.

Within naïve analyses, the observed age and sex-adjusted ORs for diabetes among Latino patients appeared slightly inflated compared to health survey estimates. Using IPW, or controlling the number of health care encounters produced ORs that were closer to health survey estimates. Despite the potential to introduce collider bias, subsetting to those with sufficient data also led to estimated associations that were more similar to health survey estimates than the naïve method. Prior research has demonstrated that Latino and Black individuals may have increased screening for diabetes while Asian individuals may have decreased screening compared to White individuals [34]. These disparities in screening practices may partially explain the observed patterns within the EHR estimates. Increased likelihood of screening would produce a positive bias while decreased likelihood of screening would produce a negative bias in naïve EHR associations. The tested methods may have helped correct for this bias by controlling or restricting based on factors associated with the likelihood of diabetes screening, resulting in decreases in the Latino ORs and increases in the Asian OR relative to naïve estimates.

Consistent with prior research, the naïve association between 2 EHR-observed conditions, asthma and diabetes, was substantially positively biased relative to health survey estimates and prior studies from the literature [5,6,14,21]. Imposing data sufficiency criteria to subset to those for whom we had greater confidence in an accurate diabetes classification helped to reduce disparities in health care use by observed diabetes status. In addition, while all correction methods greatly reduced the estimated association between these 2 chronic conditions, the DAG method had the largest impact on this estimate, suggesting use was a strong confounder of the association between these observed health outcomes. Since the presence of either chronic condition may cause increased health care use, it is also possible that controlling for this variable induced a small collider bias, producing an estimate that was lower than the sufficiency or IPW estimates. However, prior research suggests that the magnitude of this collider bias would be small relative to the confounding bias imparted when not controlling for this variable [14]. All corrected EHR estimates were still higher than the health survey point estimates, suggesting that the NYU patient population may not be generalizable, that there are residual biases in these estimates, or that there are other inherent differences between EHR and survey-based estimates. For example, individuals interacting with the NYU hospital system may be sicker and more likely to have multiple chronic conditions than those who receive care at independent primary care practices and conditioning on sicker patients could potentially introduce a collider bias if presence within the hospital system was a common effect of these conditions. This selection bias was not addressed in this work and is an important avenue for future research.

Limitations

This study applied 2 bias correction frameworks to a large, diverse patient population and these findings can inform broader discussions on addressing misclassification of disease outcomes within epidemiologic studies using EHR data. However, there are limitations to these analyses. Importantly, internal or external validation samples were not available to inform computable phenotype sensitivity or specificity for these methods [8], and the sufficiency and IPW models relied on the strong assumption that sufficient cases had no misclassification in diabetes status. Sensitivity analyses were used to test this assumption, but it is possible that imposing sufficiency determinations generated a collider bias by selecting sicker individuals or those with diabetes [5], which could explain why these methods found higher odds of diabetes among those with asthma compared to the DAG method. That said, internal and external validation samples are often costly or time-intensive to obtain, so these

methods offer an imperfect, yet feasible, solution within resource-constrained environments. In addition, methods focused on addressing differential misclassification of health outcomes, but there is potential for misclassification within other covariates. The hypothesized DAG likely represents a simplified depiction of information biases within these data. In particular, a large proportion of patients had an unknown race or ethnicity, and the BISG imputation methods used may have differential performance by race or ethnicity or marital status [35]. Overall, determining the accuracy of the EHR-based estimates was challenging due to the wide CIs for survey-based estimates, but EHR-based associations had greatly improved precision due to the diversity and larger sample size of these data.

Additionally, comparisons were made to estimates from 2 health surveys, which have distinct biases that were not addressed in this analysis. The BRFSS is limited to self-reported health outcomes, which can be prone to misclassification. However, evidence suggests that self-reported diabetes status may have good validity relative to other chronic conditions [4,36,37]. Physical measurements from NHANES may improve the classification of diabetes status among those who are unaware or undiagnosed [15]. However, the smaller sample size of this survey requires multiyear pooled analyses, which can be biased by changes in screening or diagnostic criteria over time. For example, in 2015, the American Diabetes Association lowered the recommended BMI screening threshold for Asian American individuals to better account for the differential risk of diabetes at equivalent BMI levels, which could change the burden of undetected diabetes within this subgroup across time [38]. The complementary strengths of these 2 data sources may help to remedy these unaddressed biases. However, differences in the targets for inference could have contributed to the observed differences between the EHR and survey estimates. Survey estimates reflect national data, which may not be transportable to this New York City patient population. Although local versions of these health surveys are available, sample sizes were too small to produce reliable associations. Covariate definitions also varied across data sources. Importantly, individual-level income was available within the survey data but was unavailable in the EHR data. The use of neighborhood-level poverty likely resulted in residual confounding in all EHR-based ORs for asthma, which may have contributed to the positive relative differences compared to survey-based estimates.

Conclusions

EHRs offer a compelling data source for public health research; however, differential misclassification of disease status has the potential to bias the results of these studies. Methods to control for factors that affect misclassification using a causal framework, particularly when an informed presence bias can be hypothesized to strongly confound the exposure-outcome relationship, should be considered to help produce valid estimates of risk factor associations. The next steps include applying these methods to additional exposure-outcome relationships and incorporating the longitudinal nature of EHR data to assess causal relationships between chronic conditions.

Authors' Contributions

Abstract

Background: Patient-monitoring software generates a large amount of data that can be reused for clinical audits and scientific research. The Observational Health Data Sciences and Informatics (OHDSI) consortium developed the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) to standardize electronic health record data and promote large-scale observational and longitudinal research.

Objective: This study aimed to transform primary care data into the OMOP CDM format.

Methods: We extracted primary care data from electronic health records at a multidisciplinary health center in Wattrelos, France. We performed structural mapping between the design of our local primary care database and the OMOP CDM tables and fields. Local French vocabularies concepts were mapped to OHDSI standard vocabularies. To validate the implementation of primary care data into the OMOP CDM format, we applied a set of queries. A practical application was achieved through the development of a dashboard.

Results: Data from 18,395 patients were implemented into the OMOP CDM, corresponding to 592,226 consultations over a period of 20 years. A total of 18 OMOP CDM tables were implemented. A total of 17 local vocabularies were identified as being related to primary care and corresponded to patient characteristics (sex, location, year of birth, and race), units of measurement, biometric measures, laboratory test results, medical histories, and drug prescriptions. During semantic mapping, 10,221 primary care concepts were mapped to standard OHDSI concepts. Five queries were used to validate the OMOP CDM by comparing the results obtained after the completion of the transformations with the results obtained in the source software. Lastly, a prototype dashboard was developed to visualize the activity of the health center, the laboratory test results, and the drug prescription data.

Conclusions: Primary care data from a French health care facility have been implemented into the OMOP CDM format. Data concerning demographics, units, measurements, and primary care consultation steps were already available in OHDSI vocabularies. Laboratory test results and drug prescription data were mapped to available vocabularies and structured in the final model. A dashboard application provided health care professionals with feedback on their practice.

Introduction

The digitalization of health care organizations has made it possible to automatically collect and reuse data from electronic health records (EHRs) for care, administrative, and research purposes [1]. Data reuse generally relies on extracting data from source databases, formatting and normalizing it in a data warehouse [2-5]. Over the last few years, hospital-based data warehouses have started to provide comprehensive overviews of patient management during a hospital stay or on a hospital ward. However, these data warehouses do not contain data on primary care or other data not related to the hospital stay. These data cover first-line services—outpatient care provided in local practices, including general practice, community pharmacy, dental care, and optometry [6,7]. Additionally, data from all individuals covered by the French national health insurance scheme are anonymously and prospectively included in the

national claims database [8]. These data are used for reimbursement purposes and are not clinical.

The reuse of EHR data is now a major topic of interest for hospital care [9,10] and primary care [4,11]. Several research groups have retrospectively reused primary care data on patients with neuromuscular diseases [12], diabetes [4,13], dermatological diseases [14,15], lung diseases [16], cancer [17], or urinary tract infections [18] or on older adult patients [19]. Several national projects aim to collect primary care data on a routine basis. The main primary care projects are the Clinical Practice Research Datalink and The Health Improvement Network in the United Kingdom [20,21], the Veterans Administration data warehouses in the United States [22], and the Canadian Primary Care Sentinel Surveillance Network in Canada [23]. Nevertheless, the reuse of health care data (and especially primary care data) faces many challenges [9,10,24-27]. The abovementioned projects collect data from millions of patients by implementing local data models. A UK project uses a national database (BioBank) to standardize vaccination data into a common data model (CDM) format [28].

The heterogeneous structure of the data and the use of country- and facility-specific vocabularies create barriers to the implementation of multicenter studies and the sharing of data, methods, and results. Initiatives such as those proposed by the Observational Health Data Sciences and Informatics (OHDSI) consortium seek to (1) standardize data structure and vocabularies; (2) promote reproducible research and collaboration; and (3) share methods, tools, and results [29,30]. The OHDSI has notably developed the Observational Medical Outcomes Partnership (OMOP) CDM [31] and provides standard data structures and vocabularies that are independent of individual software developers and countries [32].

Hospital and claims databases have already undergone the mapping process to adopt the OMOP CDM format [33-35]. Nevertheless, primary care data, specifically general practice data, which serve as a valuable addition to hospital and claims databases, are still rarely being integrated into the OMOP CDM format.

Data standardization might facilitate the development of common tools for health care professionals, such as activity dashboards and software for managing multicenter research projects. Hence, the primary objective of this study (part of the Primary Care Data Warehouse [PriCaDa] project) was to transform primary care data into the OMOP CDM format.

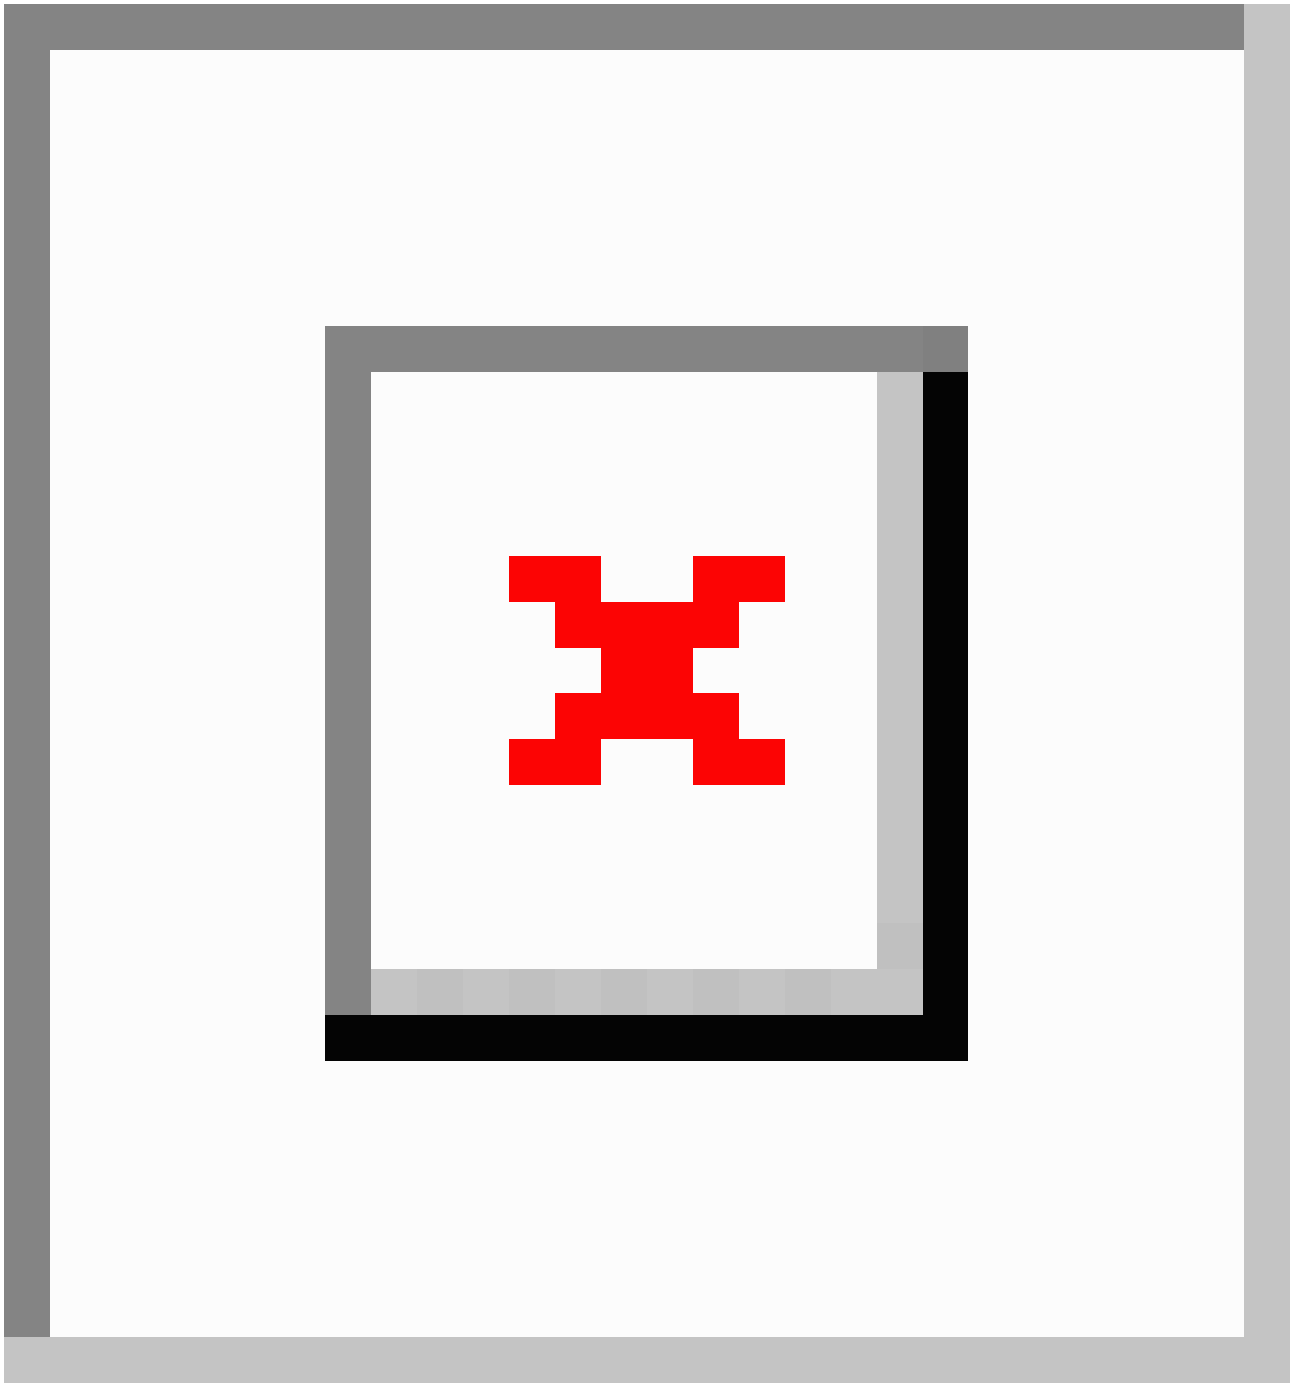
Methods

Overview

The goal of the PriCaDa project is to reuse primary care data and to provide an overview of the practices of health care professionals working in primary care (family physicians, nurses, and pharmacists).

In this study, we used primary care data from a multidisciplinary health center (MHC) located in the town of Wattrelos, France, in collaboration with the software company that produced the MHC's EHR software (Weda). Weda ranks third in terms of sales volume, boasting over 20,000 health care professionals in France as users [36]. We used an extract-transform-load (ETL) process to create a data warehouse (Figure 1), using Python and SQL scripts. The data warehouse was stored in a PostgreSQL database, using version 5.4 of the OMOP CDM [31]. The first step in the ETL process was to extract, classify, and normalize entities from the XML files. The database was then scanned and assessed with the OHDSI tool White Rabbit [37] to create a report on each raw table, attribute, and data type. The OHDSI tool Rabbit In A Hat was then used to implement the specifications of the structural mapping, which aims to associate each local table and local column to the corresponding OMOP nomenclature [38]. Then, transformation steps normalize the structure and the semantic of the data source to the OMOP CDM format. The final step is to load the data into the OMOP CDM. The development of a dashboard was proposed for a practical application.

Figure 1. Pipeline of the primary care data transformation into the OMOP CDM. CDM: Common Data Model; ETL: extract-transform-load; OMOP: Observational Medical Outcomes Partnership.



Ethical Considerations

The study was approved by the staff at the MHC in Wattrelos and the management of the Weda software house. Furthermore, the study was registered with the French National Data Protection Commission (*Commission nationale de l'informatique et des libertés*; reference 2022 - 203). In line with the French legislation on retrospective studies of anonymized data from routine clinical practice, approval by an institutional review board was not required [39]. All the data collection and analysis methods complied with relevant guidelines and regulations. Patient confidentiality was maintained at all times, and all the data were anonymized before extraction. The Weda software exports data with an identifier for each patient and consultation. This identifier is replaced during the transformations with a unique artificial ID. For this unique ID, sequences provided by the database management system (ie, PostgreSQL) were generally used to create an autoincrement primary key.

Data Extraction

Following approval by the MHC's staff, Weda exported an XML-based hierarchical structure file for each patient. A primary care consultation occurs in 4 steps. At each step, the family physician collects data on the patient's health status. In step one (arrival), the reason for consultation is recorded as free text. In step two (the interview), the physician records clinical signs and symptoms as free text. In step three (the examination),

the physician makes biometric measurements and enters the data in a structured way in the appropriate fields of the software (variables, values, and units). Step four (the outcome) includes the diagnosis (if made, as free text), any drug prescriptions (documented with the *Code Identifiant de Spécialité* [CIP; the French national drug code]), any referrals (as free text in a PDF letter), and information on vaccinations. The parts of the Weda software dedicated to these steps depend on the physician's habits; some physicians put all observations into a single field.

Furthermore, the family physician receives laboratory test results from medical laboratories and clinical reports from other specialist physicians. The test variables differ from one medical laboratory to another. For example, one laboratory might use the term "creatinine" and a specific unit, whereas another might use "create" and a different unit for the same variable. These reports were documented as free text.

Transformation Steps

Semantic Mapping

The goal of semantic mapping was to link local vocabularies to standard vocabularies that have been defined by the OHDSI community and are available in an web-based tool [32,40]. The difficulty of the mapping depends on the vocabularies available in the source data. We defined four difficulty levels: level 1 for local vocabulary items that already belonged to the standard OHDSI vocabulary; level 2 for local, nonstandard vocabulary items for which the mappings to the standard OHDSI vocabulary already existed; level 3 for local vocabulary items that did not correspond to the OHDSI vocabulary but were in a structured format (manual mapping was necessary); and level 4 for local vocabulary items that did not correspond to the OHDSI vocabulary and were in an unstructured format (free text). Natural language processing (NLP) techniques, such as fuzzy matching algorithms, SpaCy tools, and regular expressions, can be used for concept identification and information extraction. The free text (eg, reasons for consultation, symptoms, diagnosis, and clinical reports) was sometimes heterogeneous and unstructured. Indeed, a single free-text record can consolidate various types of information, including the reason for a consultation, the patient's clinical signs, and their diagnosis, all of which may vary based on the practices of the individual family physician.

For difficulty levels 2 and 3, the data were mapped manually and independently by two experts (MF and CJ). A κ score was computed as a statistical metric for assessing the degree of consensus among the annotators tasked with assigning labels to data. It gauges the degree to which the annotators' assessments align, while also considering the potential for chance agreement. The score ranges from 0 to 1 (1 for perfect agreement among annotators). A κ score below 0.4 indicates weak agreement, a κ score above 0.6 (60%) suggests moderate agreement, and a κ score exceeding 0.8 (80%) signifies strong agreement [41]. Any disagreements were settled by a third expert (PQ). This mapping provided correspondences between the local vocabulary items and standard vocabulary items. When necessary, new primary care concepts not available in the OHDSI vocabularies were loaded into the CONCEPT table. The Logical Observation Identifiers Names and Codes vocabulary was used to map laboratory test variables. The source laboratory test concepts contained the name of the laboratory test variable used by the laboratory, together with the unit. The text referencing the laboratory test variables was cleaned up by grouping equivalent source concepts. Punctuation and special characters were removed, and abbreviations or spelling differences were replaced and grouped under the full name (eg "CRP" was replaced with "C-reactive protein"). Chapter numbers or line numbers at the beginning of a line were removed. Multiple spaces were replaced by a single space, and stop words (eg, "of," "to," or "an") were removed. The Systematized Nomenclature of Medicine was used to map biometric variables, with the Unified Code for Units of Measure for units of measurement and the *International Classification of Diseases, 10th Revision* (*ICD-10*) for the patient's medical history. Drug prescriptions were recorded using CIP drug name codes. The CIP code was extracted from the Weda EHR software and mapped to the Anatomical Therapeutic Chemical (ATC) code and then the RxNorm code (ATC to RxNorm mapping is already available in the OMOP CDM).

The new concepts were integrated into the CONCEPT table with a concept identifier greater than 2,000,000,000. When a local concept is mapped, the correspondence with a standard OMOP concept is loaded into the CONCEPT_RELATIONSHIP table (resulting in a link between a local concept identifier and a OMOP standard concept identifier). As a result, the identifiers of standard concepts can be loaded into the x_concept_id column of the corresponding table for the local concept (eg, new local concepts in the MEASUREMENT table that are mapped are associated with the standard concepts loaded into the measurement_concept_id column).

Structural Mapping

The goal of structural mapping was to transform the source structure into the OMOP CDM structure. The mapping comprised two steps. In the first step, the relevant variables required for the OMOP model were selected and normalized in a table format. In the second step, the variables and table structures were transformed to match the OMOP CDM nomenclature. We observed that most of the medical histories were coded as free text, rather than nomenclature items. The DIAGNOSIS source table contained the information from the patient interview (clinical signs), the clinical examination (measurements), and the "outcome" parts of the consultation. However, this field contained data related to several types of medical information in text format. The MEASUREMENT table contained information from the "laboratory data" and "biometrics" source tables. Outliers were removed, and primary and foreign keys were identified. New artificial identifiers were created for the primary key in each table.

Data Loading and Quality Assessment

After the semantic and structural transformations, the data were loaded into the OMOP model. We used Achilles, a data quality assessment and visualization tool developed by the OHDSI community. Achilles reports the compliance of the mapping with the constraints of the OMOP CDM (the primary and foreign keys), the vocabulary (ie, the correct choice of concepts corresponding to each table), and the business rules (ie, rules

that ensure data consistency, for example, data chronology respects real life). Based on the Achilles analysis tables, the Atlas server summarizes the results of the data quality assessment in a dashboard [42]. Kahn et al [43] have developed a data quality framework for the secondary use of EHR data integrated into the Atlas quality assessment dashboard. *Conformance* describes "the compliance of the representation of data against internal or external formatting, relational, or computational definitions." *Completeness* computes "features that describe the frequencies of data attributes present in a data set without reference to data values." *Plausibility* describes "the believability or truthfulness of data values." The data quality assessment context *verification* is a strategy "for the source of expectations or comparisons of EHR data based on internal characteristics" [43].

To test the relevance and usability of primary care data in the OMOP CDM, we compared the results of several queries of the OMOP CDM with the results obtained directly from the Weda software. The queries were run by a physician (CJ) who used the software in his clinical practice. To ensure that the patient records could be checked manually, the queries were chosen to keep the resulting number of patients low. Two queries corresponded to the MHC's general activity (eg, the number of patients per family physician), two corresponded to prescription data, and a fifth query corresponded to laboratory test data.

Practical Application

Using RShiny and the *shiny*, *shinyBS*, *shinycssloaders*, *shinydashboard*, *shinyjs*, and *shinyWidgets* libraries, we implemented a dashboard to report the MHC's general activity, prescriptions, and the distribution of the laboratory test results [44].

Results

Data Extraction

The data were extracted in July 2021. The available patient profiles dated back to 1997, and data on clinical measurements, drug prescriptions, and laboratory tests were available from 2013 onward. The extracted data contained 18,395 patient files. Each patient's file contained anonymized demographic information (ie, sex, year of birth, the town or city of residence, and the country of residence), the date of the first consultation, and the name of the family physician with whom the patient was registered. It also contained the patient's medical history (documented with *ICD-10* codes or as free text), information related to the consultation, laboratory test results, and clinical reports from other physicians (also as free text).

Transformation

Semantic Mapping

In all, 17 vocabularies were mapped (Table 1).

All the new concepts were added to the CONCEPT table (n=10,221). These primary care concepts were added alongside the existing concepts in the OMOP model developed by OHDSI. The mapping between local concepts and standard concepts was integrated into the CONCEPT_RELATIONSHIP table (n=9432).

Table . The concept mapping. When a local vocabulary is not given, it means that the concept had to be created.

Feature	Local vocabulary	OMOP[a] vocabulary	Level of mapping difficulty	Concepts, n	Mapped concepts, n/N (%)	Associated records, n/N (%)
Care site	—[b]	Care site	Level 1	1	1/1 (100)	1/1 (100)
Medical histories	*ICD-10* [c]	*ICD-10*	Level 1	83	80/83 (96.4)	2252/2315 (97.3)

[a]OMOP: Observational Medical Outcomes Partnership.

[b]Not applicable.

[c] *ICD-10: International Classification of Diseases, 10th Revision.*

[d]ATC: Anatomical Therapeutic Chemical.

[e]CIP: *Code Identifiant de Spécialité* (the French national drug code).

[f]SNOMED: Systematized Nomenclature of Medicine.

[g]LOINC: Logical Observation Identifiers Names and Codes.

[h]UCUM: Unified Code for Units of Measure.

[i]23% (257,801/1,120,859) not available.

More than 80% (9100/9946, 91.5%) of the drug records and more than 90% (80/83, 96.4%) of the *ICD-10*–coded medical history records were mapped. Less than 4.9% (12/243) of the biometric measurement concepts were mapped; the latter accounted for 96.2% (172,549/179,337) of the records because a small number of concepts were used (eg, weight, height, and heart rate; Table 1). The remaining records were free-text and family physician–dependent variables. The writing style can vary and the same variable can be asked in several ways. For example, to find out whether the patient is a smoker, the family physician can input the information in the family physician–dependent variable "does my patient smoke?" "is he a smoker?" or "do you smoke?"

For level 3 mapping difficulties, drug-related concepts (coded as CIP codes) were mapped in two steps. RxNorm is the standard classification chosen by OHDSI for the OMOP model, and therefore, we had to map our local terminology (ie, CIP)

to RxNorm. First, the CIP codes were mapped to the ATC codes. Second, the ATC codes were mapped to the RxNorm codes, using the correspondences already implemented in the CONCEPT_RELATIONSHIP table.

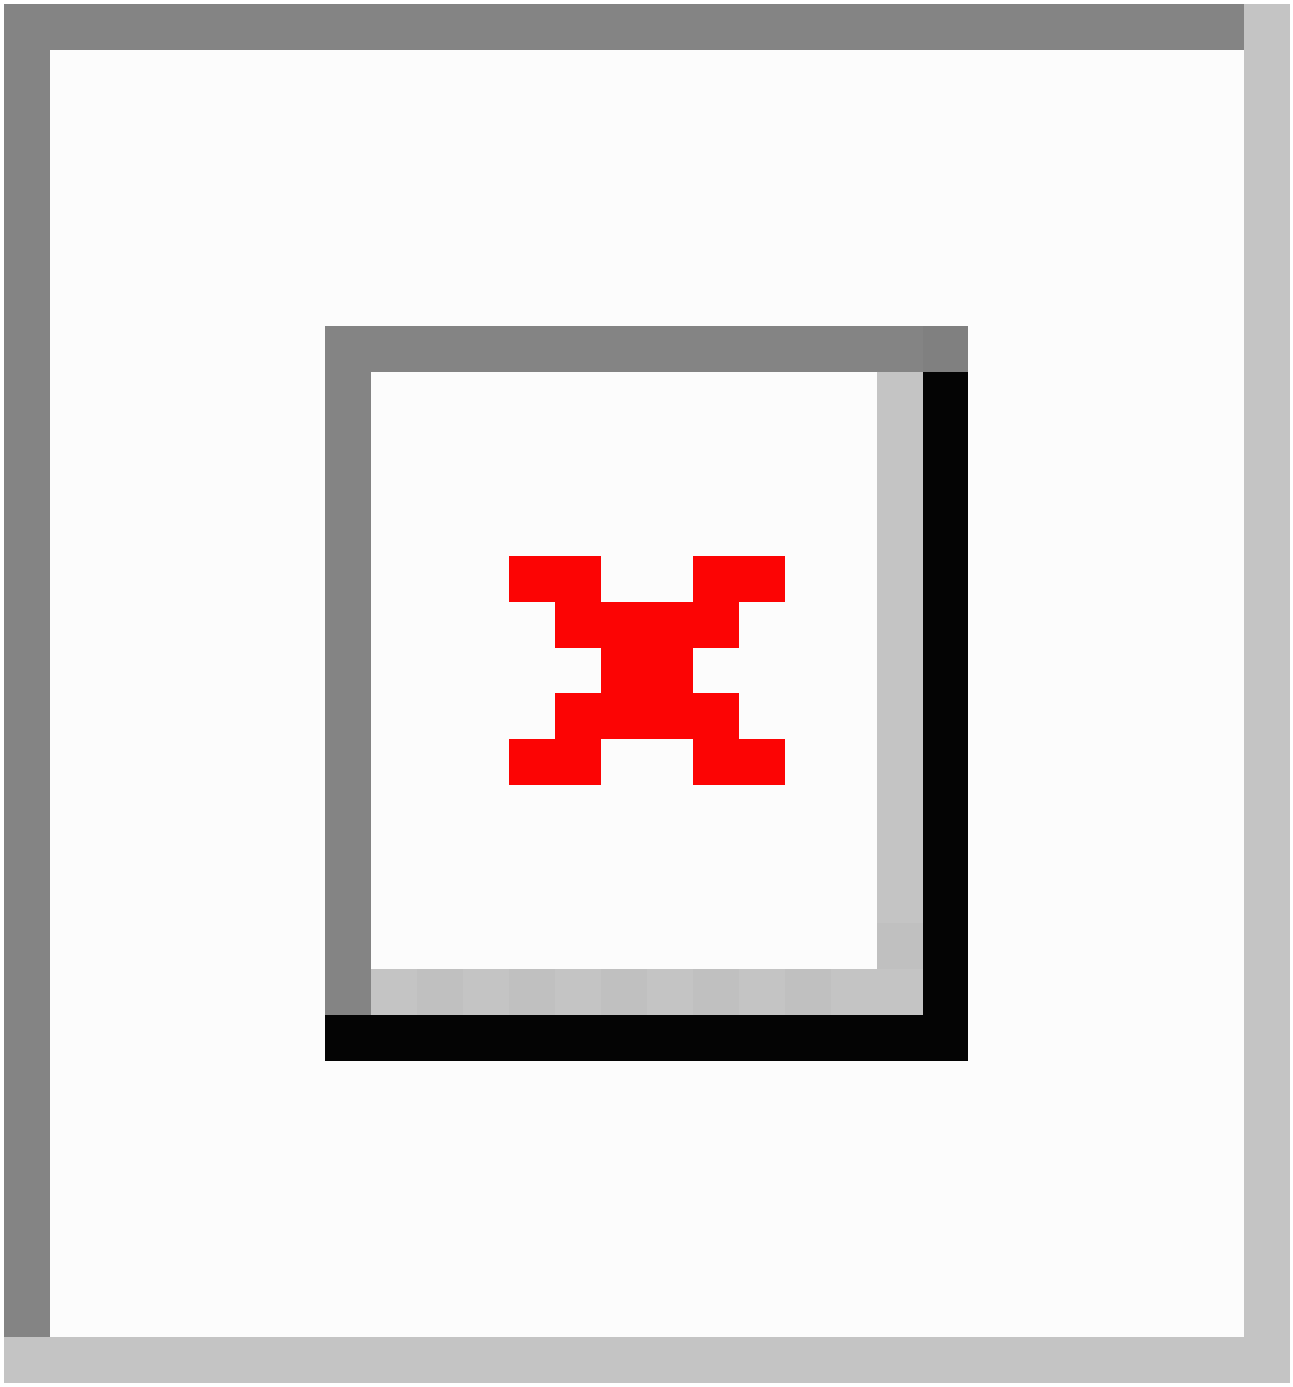
With regard to the laboratory test variables, the cleaning step reduced the number of concepts from 3003 to 2312. We restricted the mapping to the most frequently cited laboratory test concepts in the MEASUREMENT table, with the aim of covering more than 80% of the records. Disagreements over laboratory test concept mapping by experts were resolved by consensus and the involvement of a third annotator. The experts disagreed about 24.3% (37/152) of the mapped concepts, which corresponds to a κ score of 75%.

Structural Mapping

Several XML tables in the source model corresponded to tables in the OMOP CDM format (Figure 2). Information about the patient, the family physician, the profile creation date, and the health care center was stored in the PERSON, PROVIDER, OBSERVATION_PERIOD, and CARE_SITE tables, respectively. The medical history (documented with *ICD-10* codes) was stored in the OBSERVATION table. Each consultation at the health care center corresponded to a record in the VISIT_OCCURRENCE table, identified by a visit_concept_id (A*mbulatory Primary Care Clinic/Center*; concept_id=38004247). Biometric measurements were stored in the MEASUREMENT table, with a concept type corresponding to *EHR physical examination*. Laboratory test results were stored in the MEASUREMENT table, with a concept type *Lab* (concept_id=32,856). The feature measurement_source_type_id distinguishes each source table (laboratory data or biometrics measurements). Each drug prescription was stored in the DRUG_EXPOSURE table. Free-text information collected during the consultation was stored in the NOTE table with an appropriate source vocabulary concept identifier (eg, a note of clinical signs; the reason for the consultation; medical histories; the outcome of the consultation; and, in some cases, the associated diagnosis). Medical reports from a specialist physician not based in the MHC were recorded in the NOTE table (Figure 2).

All the standard concept types used to identify information in the various source tables are detailed in Multimedia Appendix 1; for example, the NOTE table contains information about the reason for the consultation, the patient's medical history, and other medical reports.

Figure 2. Structural mapping of each source variable to the OMOP CDM format. Common Data Model; OMOP: Observational Medical Outcomes Partnership.



Data Loading and Quality Assessments

Records spanning 20 years (592,226 consultations by 18,395 patients) were integrated into the OMOP CDM. The numbers of records per OMOP table before and after the ETL process and the related computing time are reported (Table 2). The CARE_SITE and DRUG_ERA tables were implemented using data transformed into the OMOP format.

The Atlas Server dashboard produced the data distributions for each table. An example of the distribution of blood potassium concentrations is shown in Multimedia Appendix 2.

The Atlas dashboard's overview tab provided a top-level summary of the total number of passes and failures by Kahn category (Figure 3). We found 28 *Conformance* failures that did not respect the specifications of the OMOP CDM. There were 21 *Completeness* failures related to potentially missing data and 23 failures related to *Plausibility* for implausible dates or measurement values. For each of these failures, the results tab (Multimedia Appendix 3) displayed one line per *verification*.

Table . The volume of each table before and after the ETL[a] process and the associated computing time.

OMOP[b] tables	Records before the ETL process, n	Records after ETL process, n	Computing time (s)	Local tables

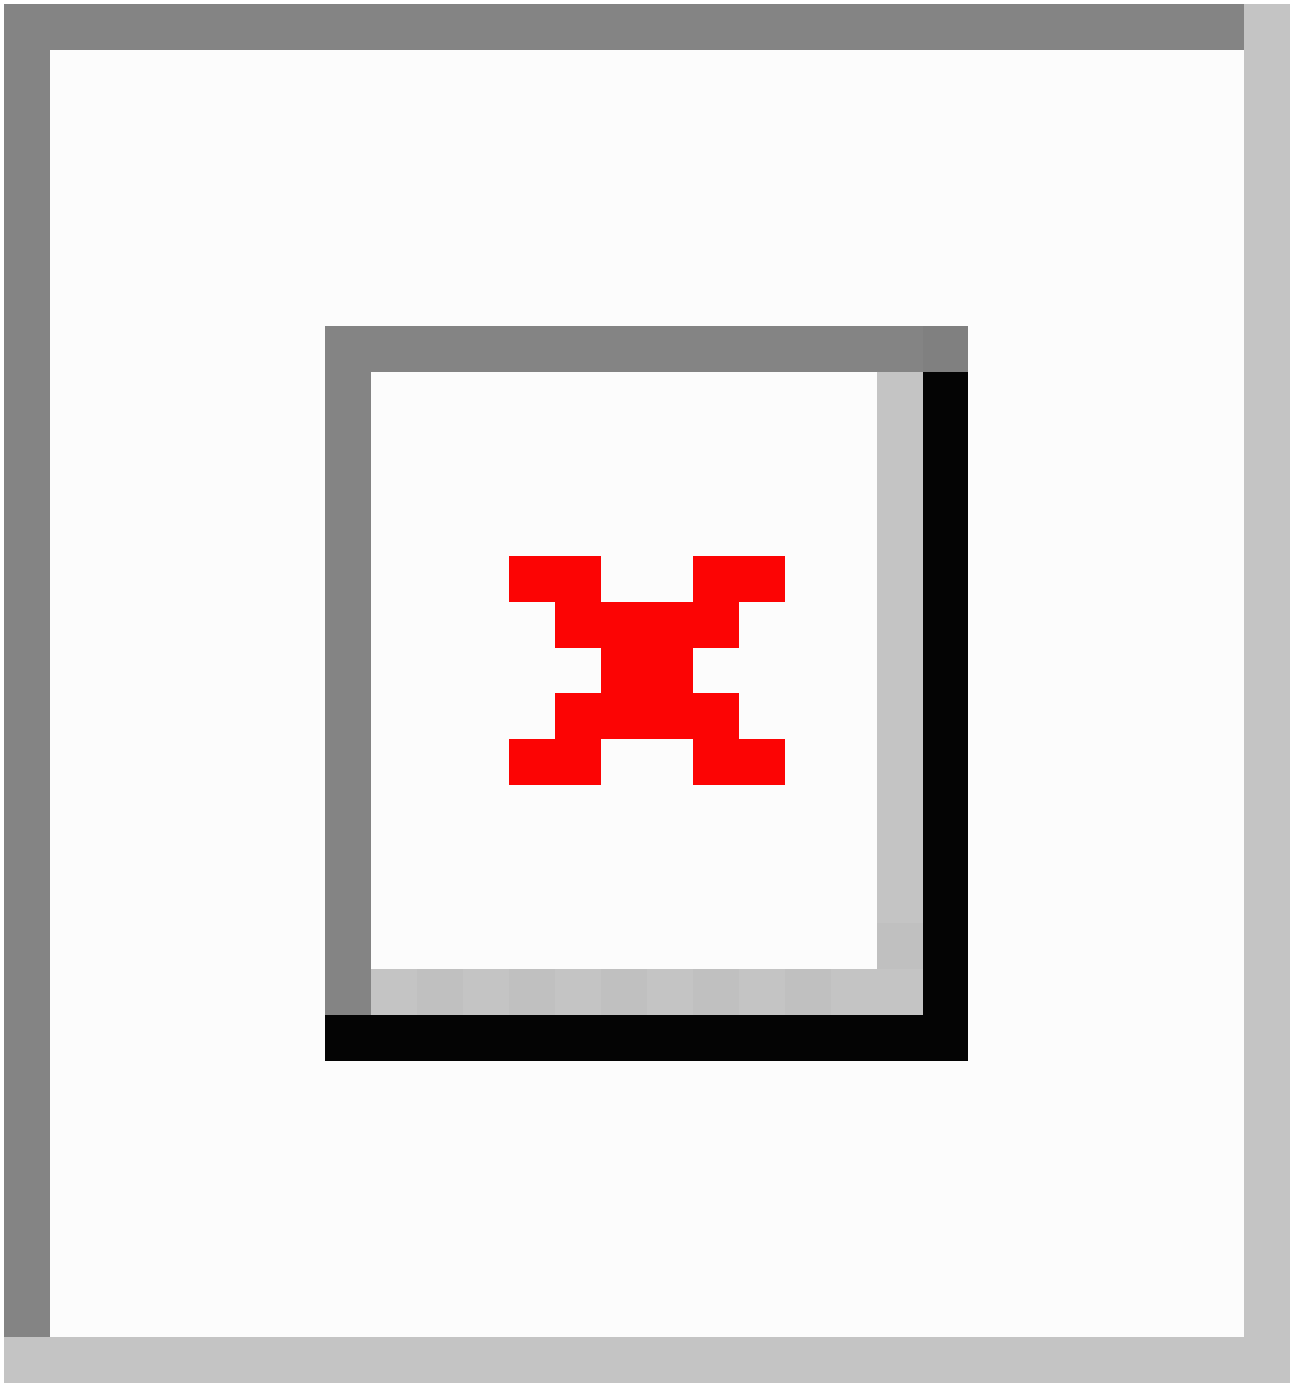
[a]ETL: extract-transform-load.

[b]OMOP: Observational Medical Outcomes Partnership.

[c]Not applicable.

[d]MHC: multidisciplinary health center.

Figure 3. The data quality assessment dashboard. NA: not available.

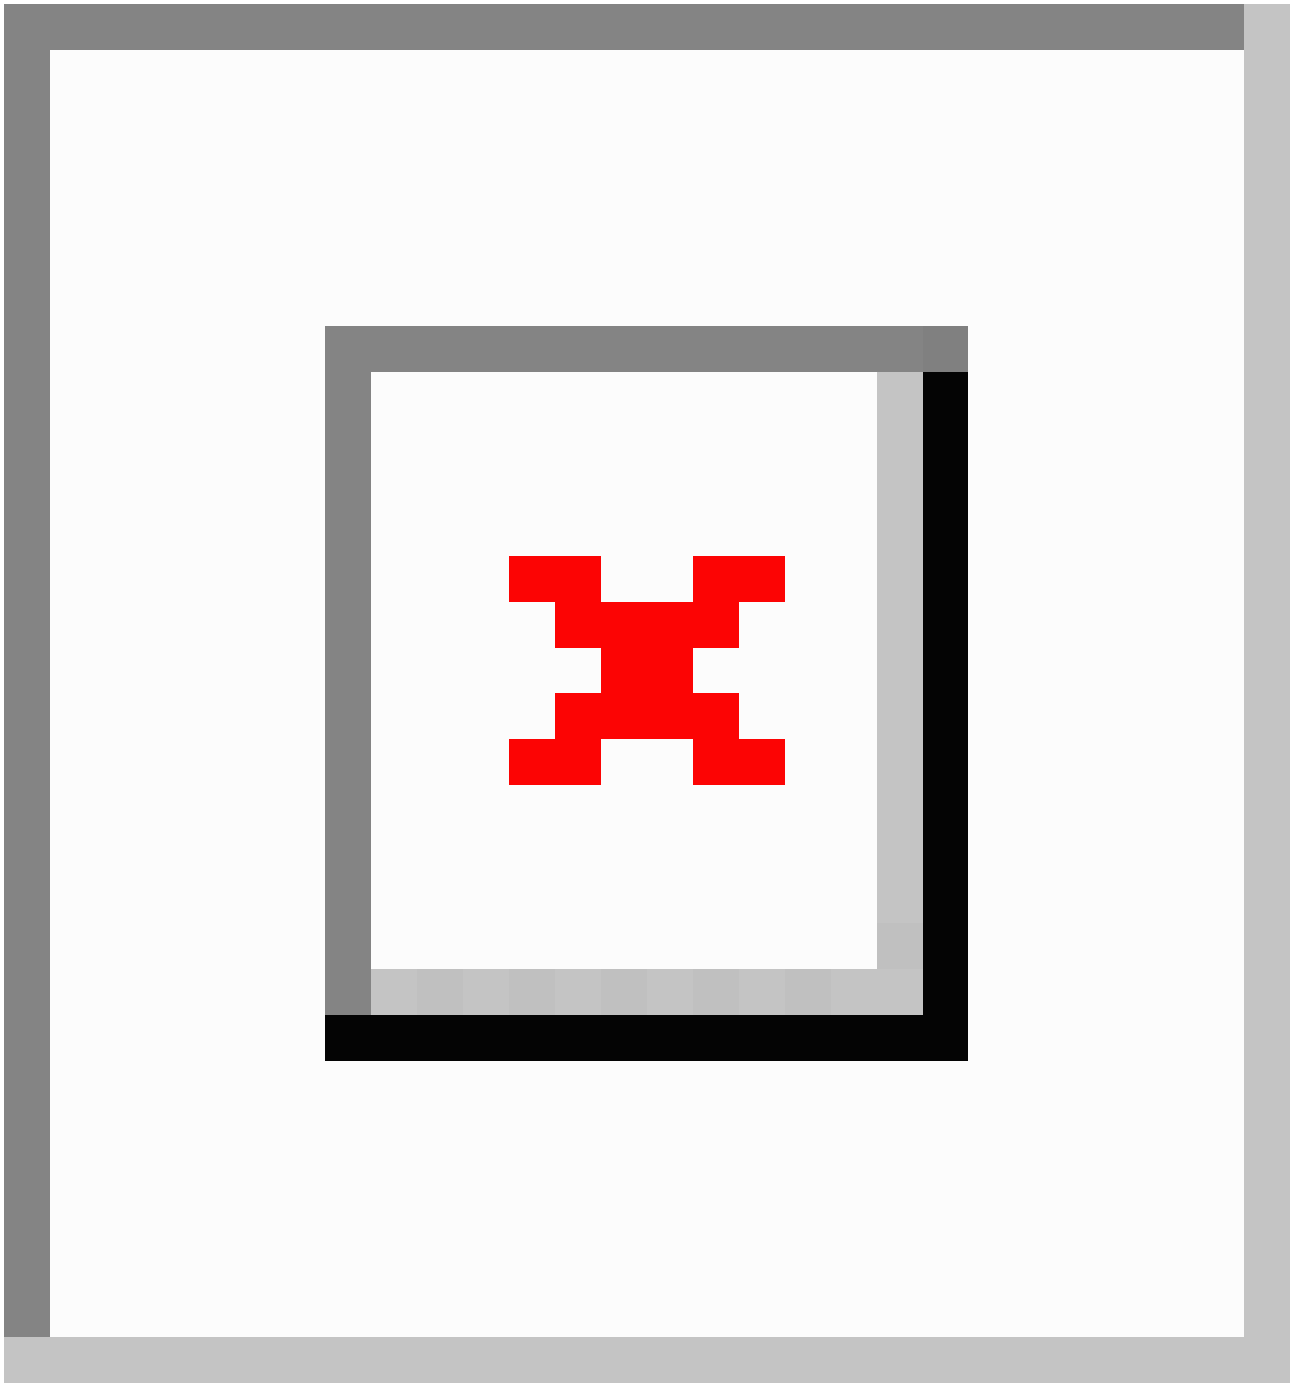


The concordance of results obtained from data quality evaluation queries between the source EHRs and the data warehouse's records proved that the process was reliable (Multimedia Appendix 4). In the event of a difference between the two (results obtained from the data warehouse in OMOP format and results from the Weda software), we had to check the patient records in the software to identify what the correct figure was. Patients whose profile had been created after 2021 had to be removed from the results produced by the Weda software because the extraction data (stored in the data warehouse) goes up to June 2021 at the latest, and queries on the software interface allow filtering for the entire year. The family physician must declare when he or she became the patient's referring family physician. This family physician declaration is dated in the Weda software. This date is not found in the data warehouse. The date of the patient's registration with the family physician was also taken into account in the queries; registrations after the extraction date were removed. Queries concerning the laboratory test results were checked manually by one of the MHC's family physicians (CJ). Some laboratory test results were saved in the "reports" part and others were saved in the "consultations" part on the software.

Practical Application

A 3-tab prototype dashboard was implemented (Figure 4). The first tab concerned the MHC's activity, the second concerned drug prescriptions, and the third concerned laboratory test results.

Figure 4. The prototype primary care dashboard. PriCaDa: Primary Care Data Warehouse.



Discussion

Principal Findings

In this study, we implemented primary care data into the OMOP CDM format from a French health care facility. Five concepts related to the consultation (reason for the consultation, diagnosis, and comments), the clinical report by another physician, some medical histories, referrals, and vaccination data in free text were stored in the NOTE table, and three structured free-text concepts were mapped to standard concepts (laboratory test results, biometrics, and measurement units). Overall, we included 592,226 consultations and 10,221 concepts over 20 years, including 9432 mappings between local concepts and standard concepts. The concept mapping was validated by three experts, including a family physician. We then used queries to validated the design of the OMOP CDM by comparing the results obtained in our data warehouse with those obtained in the source software.

The OMOP model was originally developed to answer pharmaco-epidemiologic questions by reference to hospital databases or claims databases. New types of data have since been integrated, such as those in the fields of cancer, microbiology, and anesthesia [32,33,45]. Integrating these new data types might present difficulties not foreseen in the original CDM. Integrating primary care data required the addition of 10,221 new concepts. Through the sharing of tools and methods, the OMOP model enables reproducible analyses of decentralized data [28,46].

Comparison With Previous Work

This work stands out for its integration of out-of-hospital clinical data over a long time period. In contrast to the French national health care database (*Système National des Données de Santé*), we included clinical data. Similarly, the data produced by French hospital included test results from the hospital's laboratory only. We were able to load data from outpatient treatments and out-of-hospital medical laboratories into the OMOP model; in France, these data are not documented in claims and hospital databases. We also have data on drug prescriptions and associated dosage (duration of treatment, number of refills, number of drugs per dose, and dosing period), whereas the *Système National des Données de Santé* only contains data on prescription fulfillment.

By using a CDM, we will be able to share our work with other primary care data reuse initiatives [28].

This study had a number of strengths. First, it was based on collaboration between data scientists and family physicians. Each data transformation step was approved by the MHC's family physicians. Second, working with the EHR software's developer enabled us to understand the software's structure and export format. The involvement of the software developer in the study expedited the data extraction process. This collaboration with the software developer allowed us to retrieve the data in XML format, comprehend each of the XML tags, and discern the origin of the XML information within the software. Third, our development of a dashboard gave health care professionals an overview of their practice in terms of the number of patients followed and the number of consultations carried out over a defined period.

Limitations

The first limitation is that a large proportion of the extracted primary care data had been entered as free text and required NLP methods or manual examination to be used secondarily. Moreover, the primary care EHR software provides information on drug prescriptions but not on filling or patient compliance.

The free text was difficult to map. Although the most frequent codes were mapped, further mapping and information extraction are needed. NLP methods might be able to recover the free-text information on the diagnosis established during the consultation and the symptoms mentioned.

Perspective

The next step in the project will involve sharing the ETL process with other health care facilities equipped with Weda software or other software. A qualitative study during the presentation of the dashboard to the health care professionals might improve the prototype dashboard and identify unmet needs for further development. This extension will provide us with an opportunity to conduct multicenter studies and to integrate data from other professions working in primary care (such as nurses, midwives, physiotherapists, and pharmacists).

Conclusion

We implemented primary care data from a French health care facility into the OMOP CDM format. Data concerning demographics, units, measurements, and primary care consultation steps were already available in the OHDSI vocabularies. Laboratory test results and drug prescription data were mapped with the available vocabulary and structured in the final model. However, the free text in the primary care EHR software complicates the reuse of additional clinical information such as diagnoses, symptoms, clinical reports, and reasons for consultation. A dashboard application provided health care professionals with feedback on their practice.

Acknowledgments

We thank Dr David Fraser (Biotech Communication SARL, Ploudalmézeau, France) for editorial assistance and helpful advice. The research was funded by the French government through the GIRCI Nord-Ouest program (GIRCI is a French abbreviation for "interregional groups for clinical research and innovation"; project: "REsP-IR"). The funding bodies did not participate in the design of this study; its execution, analyses, interpretation of the data; or the decision to submit the results.

Abstract

Background: The traditional clinical trial data collection process requires a clinical research coordinator who is authorized by the investigators to read from the hospital's electronic medical record. Using electronic source data opens a new path to extract patients' data from electronic health records (EHRs) and transfer them directly to an electronic data capture (EDC) system; this method is often referred to as eSource. eSource technology in a clinical trial data flow can improve data quality without compromising timeliness. At the same time, improved data collection efficiency reduces clinical trial costs.

Objective: This study aims to explore how to extract clinical trial–related data from hospital EHR systems, transform the data into a format required by the EDC system, and transfer it into sponsors' environments, and to evaluate the transferred data sets to validate the availability, completeness, and accuracy of building an eSource dataflow.

Methods: A prospective clinical trial study registered on the Drug Clinical Trial Registration and Information Disclosure Platform was selected, and the following data modules were extracted from the structured data of 4 case report forms: demographics, vital signs, local laboratory data, and concomitant medications. The extracted data was mapped and transformed, deidentified, and transferred to the sponsor's environment. Data validation was performed based on availability, completeness, and accuracy.

Results: In a secure and controlled data environment, clinical trial data was successfully transferred from a hospital EHR to the sponsor's environment with 100% transcriptional accuracy, but the availability and completeness of the data could be improved.

Conclusions: Data availability was low due to some required fields in the EDC system not being available directly in the EHR. Some data is also still in an unstructured or paper-based format. The top-level design of the eSource technology and the construction of hospital electronic data standards should help lay a foundation for a full electronic data flow from EHRs to EDC systems in the future.

(JMIR Med Inform 2024;12:e52934) doi:10.2196/52934

KEYWORDS

clinical trials; electronic source data; EHRs; electronic data capture systems; data quality; electronic health records

Introduction

Source data are the original records from clinical trials or all information recorded on certified copies, including clinical findings, observations, and records of other relevant activities necessary for the reconstruction and evaluation of the trial [1]. Electronic source data are data initially recorded in an electronic format (electronic source data or eSource) [2,3].

The traditional clinical trial data collection process requires a clinical research coordinator (CRC) who is authorized by the investigators to read from the hospital's electronic medical record and other clinical trial–related data from the hospital information system and then manually enter the patient's data into the electronic data capture (EDC) system. After data entry, the clinical research associate visits the site to perform source data verification and source data review. The drawbacks of collecting data by manual transcription are that data quality and timeliness cannot be guaranteed and that it is a waste of human and material resources. Using electronic source data opens a new path to extract patients' data from electronic health records (EHRs) and transfer it directly to EDC systems (often the method is referred to as eSource) [4]. eSource technology in a clinical trial data flow can improve data quality without

compromising timeliness [5]. At the same time, improved data collection efficiency reduces clinical trial costs [6].

eSource can be divided into two levels. The first level is to enable the hospital information system to obtain complete data sets; the second level is to allow direct data transfer to EDC systems based on the clinical trial patients' electronic data in hospitals to avoid the electronic data being transcribed manually again, which is the core purpose of eSource [7]. This project will explore the use of eSource technology to extract clinical trial data from EHRs, send it to the sponsor data environment, and discuss the issues and challenges occurring in its application process.

Methods

Ethics Approval

This study was approved by the Ethics Committee and Human Genetic Resource Administration of China (2020YW135). During the ethical review process, the most significant challenges were patients' informed consent, privacy protection, and data security. The B7461024 Informed Consent Form (Version 4) states that "interested parties may use subjects' personal information to improve the quality, design, and safety of this and other studies," and "Is my personal information likely to be used in other studies? Your coded information may be used to advance scientific research and public health in other projects conducted in future." This project is an exploration of using electronic source data technology instead of traditional manual transcription in the process of transferring data from hospital EHRs to EDC systems, which will improve the data quality of clinical trials and will improve the data flow in the future. Therefore, this project is within the scope of the informed consent form for study B7461024, which was approved by the ethics committee after clarification.

Project Information

This project was conducted from December 15, 2020, to November 19, 2021, which was before China's personal information protection law and data security law were introduced. The data for this project were obtained from an ongoing phase 2, multicenter, open-label, dual-cohort study to evaluate the efficacy and safety of Lorlatinib (pf-06463922) monotherapy in anaplastic lymphoma kinase (ALK) inhibitor–treated locally advanced or metastatic ALK-positive non–small cell lung cancer patients in China (B7461024), registered by the sponsor on the Drug Clinical Trials Registration and Disclosure Platform (CTR20181867). The data extraction involved 4 case report form (CRF) data modules: demographics, concomitant medication, local lab, and vital signs, which were collected in the following ways:

- Demographics: Originally entered directly into the hospital EHR then manually transcribed by the CRC to the sponsor's EDC system
- Local lab: Laboratory data collected by the hospital laboratory information management system (LIMS) and then manually transcribed by the CRC into the EDC system
- Vital signs: Hospital uses paper-based tracking form provided by the sponsor to record patients' vital signs and investigators transcribe the vital signs data into the hospital medical record
- Concomitant medication: Similar to vital signs, hospital uses the paper tracking form provided by the sponsor to record the adverse reactions and concomitant medication; investigator might also transfer the concomitant medication data into the hospital EHR, but there was no mandatory requirement to transfer these data into patients' medical records

All information was collected from 6 patients in a total of 29 fields (Textbox 1).

Data Process Workflow

Overview

The study chosen in our project used the traditional manual data entry method to transcribe patients' CRF data into the EDC system. This project proposes testing the acquisition of data directly from the hospital EHR, deidentification of the patients' electronic data on the hospital medical data intelligence platform, mapping and transforming the data based on the sponsor's EDC data standard, and transferring the data into the sponsor's environment. The data was transferred from the hospital to the sponsor's data environment and compared to data that was captured by traditional manual entry methods to verify the availability, completeness, and accuracy of the eSource technology.

In the network environment of this project, the technology provider accessed the hospital network through a virtual private network (VPN) and a bastion host, and processed the data of this project as a private cloud, thus ensuring the security of the hospital data.

Data Integration

The hospital information system involved in this project has reached the national standards of "Level 3 Equivalence," "Electronic Medical Record Level 5," and "Interoperability Level 4." The medical data intelligence platform in this project is deployed in a hospital intranet, isolated from external networks. Integrated data from different information systems, including the hospital information system, LIMS, picture archiving and communication system, etc, were deidentified from the platform and transferred to a third-party private cloud platform for translation and data format conversion after authorization by the hospital through a VPN.

The scope of data collection in this project was limited to patients who signed Informed Consent Form (Version 4) for study B7461024. The structured data of four CRF data modules (demographic, concomitant medications, local lab, and vital signs) were extracted from the source data in hospital systems, and data processing was completed.

Three-Layer Deidentification of Data

In this project, three layers of deidentification were performed on the electronic source data to ensure data security. The first layer of deidentification was performed before the certified copy of data was loaded to the hospital's medical data intelligence platform. The second layer of deidentification follows the Health Insurance Portability and Accountability Act (HIPAA) by deidentifying 18 data fields at the system level. A third layer of deidentification was performed when mapping and transforming third-party databases for the clinical trial data (demographics, concomitant medications, laboratory tests, and vital signs) collected for this study, as required by the project design.

Collected data did not contain any sensitive information with personal identifiers of the patients, and all deidentification processes were conducted in the internal environment of the hospital. In addition to complying with the relevant laws and regulations, we followed the requirements of Good Clinical Practice regarding patient privacy and confidentiality, and further complied with the requirements of HIPAA to deidentify the 18 basic data fields. Data fields outside the scope of HIPAA will be deidentified and processed in accordance with the TransCelerate guidelines published in April 2015 to ensure the security of patients' personal information and to eliminate the possibility of patient information leakage [8].

The general rules for the third layer of deidentification were as follows:

- Time field: A specific time point is used as the base time, and the encrypted time value is the difference between the word time and the base time
- ID field: Categorized according to the value and only shows the category
- Age field: Categorized according to the value and only shows the category
- Low-frequency field: set to null

In addition, all data flows keep audit trails throughout and are available for audit.

Data Normalization and Information Extraction

After three layers of deidentification, the data was transferred from a hospital to a third-party private cloud platform through a VPN, where translation from Chinese to English and data format conversion were implemented. The whole transfer process was performed for the data that was collected for the clinical trial of this study. Standardization of data is a crucial task during the data preparation phase. This process involves consolidating data from different systems and structures into a consistent, comprehensible, and operable format. First, a thorough examination of data from various systems is necessary. Understanding the data structure, format, and meaning of each system is essential. The second step involves establishing a data dictionary that clearly outlines the meaning, format, and possible values of each data element. Next, selecting a data standard is necessary to ensure consistency and comparability. In this study, we adopted the Health Level 7 (HL7) standard. Additionally, data cleansing and transformation are needed to meet standard requirements, including handling missing data, resolving mismatched data formats, or performing data type conversions. Extract, transform, and load tools were used to integrate data from different systems. Data security must be ensured throughout the data integration process. This includes encrypting sensitive information and strictly managing data permissions. Data verification and validation steps were then performed by professional staff on the translated data. The data from the hospital's medical data intelligence platform were then converted from JSON format to XML and Excel formats. The processed data was transferred back to the hospital via a VPN to a designated location for final adjudication before loading to the sponsor's environment.

One-Time Data Push and Quality Assessment

After the hospital received the processed data, it was then pushed by the hospital to the sponsor's secure and controlled environment (Figure 1). All data deidentification processes were conducted in the hospital's environment, and none of the data obtained by the sponsor can be traced back to patients' personal information to ensure their privacy and information security.

The data quality of this project was assessed using industry data quality assessment rules [9], which are shown in Table 1.

Figure 1. Project operation flow. EHR: electronic health record.

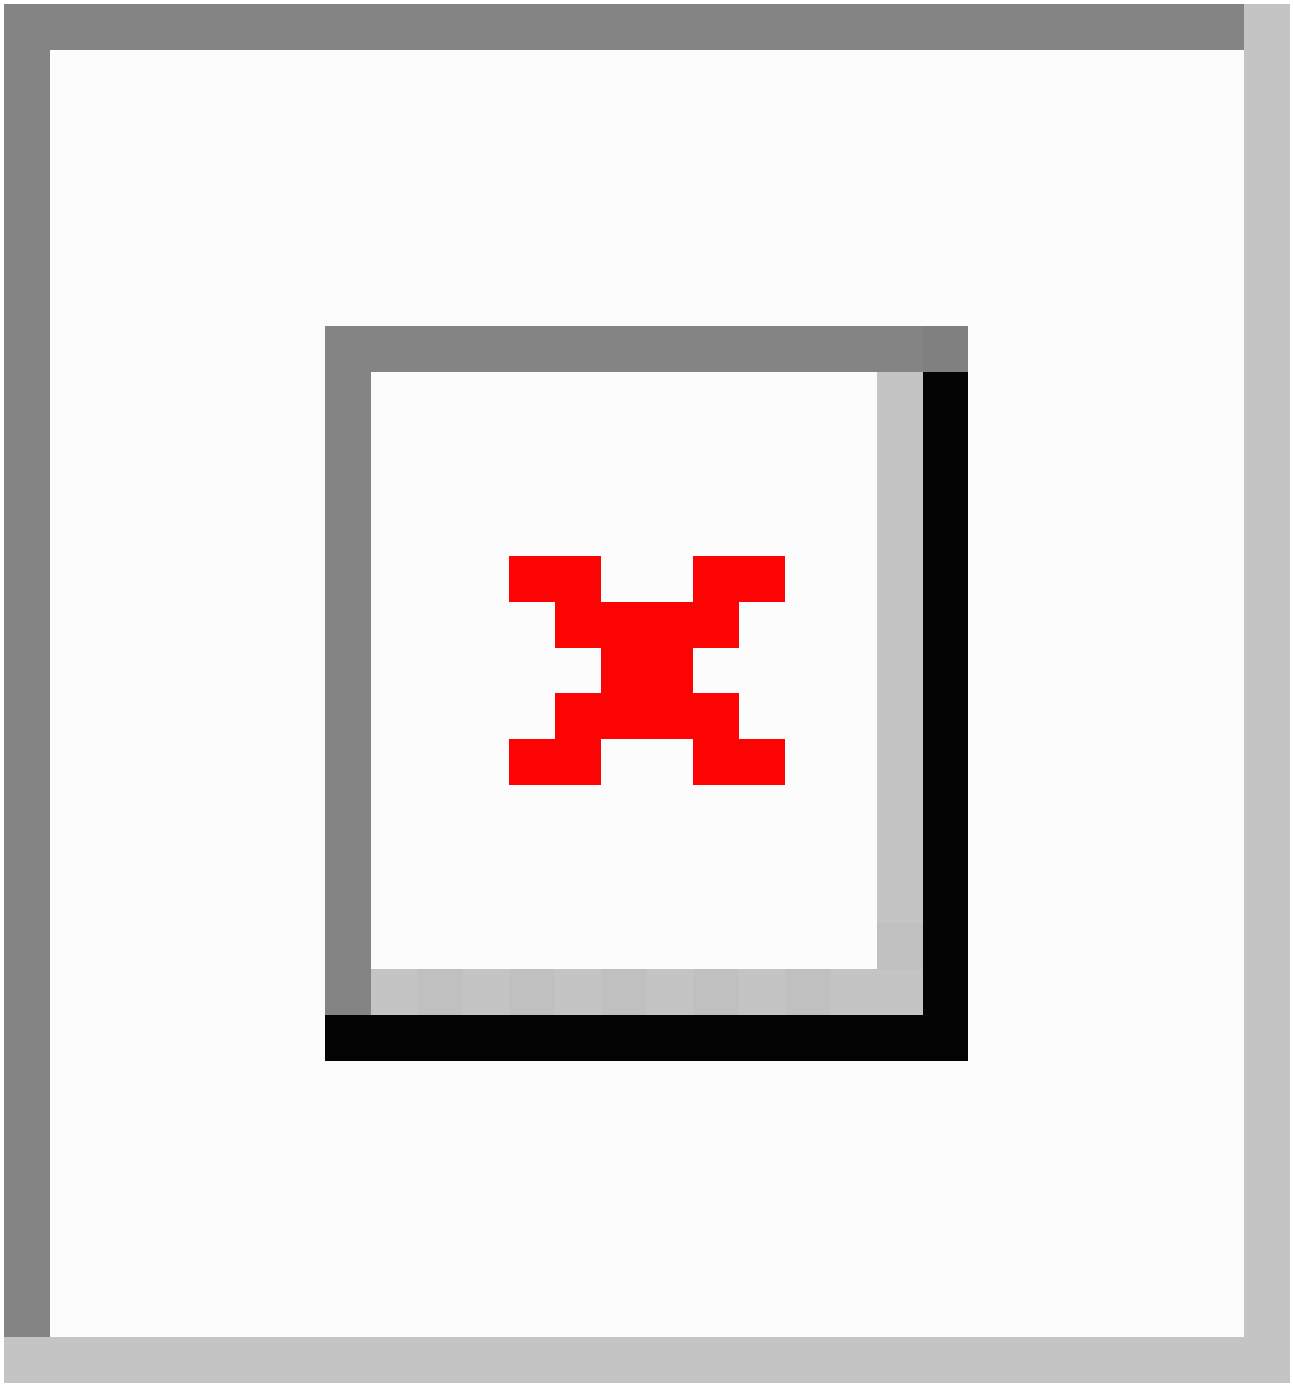

Table . Introduction of data quality assessment rules.

Data validation methods	Dimension	Method description	Cases
Data availability verification	Field dimension	The ratio of the total number of data fields in the clinical trial CRF[a] available in the hospital EHR[b] to the total number of data fields required in the electronic CRF: EHR[c]/CRF[d] × 100%	Based on the electronic CRF, 6 data fields in the demography need to be captured, and 3 of them have records in the EHR. Data availability: 3/6 × 100% = 50%
Data availability verification	Field dimension	The ratio of the total number of data fields in the clinical trial CRF (eSource) that can be transmitted electronically in the hospital's EHR to the total number of data fields required in the electronic CRF: eSource[e]/CRF[d] × 100%	Based on the electronic CRF, 6 data fields in the demography need to be captured, and 2 data fields can be captured by the eSource method. Data availability: 2/6 × 100% = 33.33%
Data completeness verification	Numerical dimension	The ratio of the total number of nonnull data (eSourceV) captured (processed and sent to the sponsor) via the eSource method to the total number of data fields requested on the electronic CRF: eSourceV[f]/CRF[d] × 100%	Based on the clinical trial design, 38 concomitant medication pages need to be collected: 7 pages were collected via eSource and 2 fields was entered per page. Data completeness: 7 × 2/(2 × 38) × 100% = 18.42%
Data accuracy verification	Numerical dimension	Matching of data field values in the hospital's EHR with data field values that can be captured by eSource (data fields that are processed and sent to the sponsor)	4 fields of demography were successfully transmitted through eSource, with 4 data points in each. After comparing with the data in the electronic data capture system, there were no mismatches for one data point. Data accuracy: 8/(2 × 4) × 100% = 100%

[c]Total number of data fields in the hospital's EHR.

[d]Total number of data fields requested in the electronic CRF.

[e]Total number of data fields captured (processed and sent to the sponsor) through the eSource method.

[f]Total number of nonempty data fields captured (processed and sent to the sponsor) through the eSource method.

Results

In this project, we collected patients' demographics, vital signs information, local laboratory data, and concomitant medication data from EHRs, successfully pushed the data directly to the designated sponsor environment, and evaluated the data quality from three perspectives including availability, completeness, and accuracy (Table 2).

- The eSource-CRF availability score, which is used to evaluate the ratio of fields in EHR that can be collected by eSource and used for CRF, was low for demographics, blood tests, and urine sample tests but higher for vital signs and concomitant medications.
- Data completeness, defined as the ratio of the total number of nonnull data captured by eSource to the total number of data fields required in the electronic CRF, was used to evaluate the ratio of nonnull data fields in the CRF that can be captured by eSource. In this study, the completeness score of the vital signs module was only 1.32%, and the concomitant medications and laboratory test modules also had poor performance in the data completeness evaluation.
- Data accuracy, defined as the compatibility between the data field values in the hospital EHR and the data field values that can be collected using eSource, was 100% for all modules.
- EHR-CRF availability, which is used to evaluate the ratio of fields in the EHR that can be used for the CRF, was 50%, 60%, and 66.67% for demographics, blood tests, and urine sample tests, respectively, in this study, and the rest of the data were 100% available.

Table . Metrics measured.

CRF[a] domain		CRF-EHR[b] data availability, n/N (%)	CRF-eSource data availability, n/N (%)	Data completeness (preliminary findings), n/N (%)	Data accuracy (preliminary findings), n/N (%)
Definition		Study CRF data elements available in hospital EHR	Study CRF data elements available in hospital EHR and able to be electronically transferred through eSource technology	Study CRF data elements available and entered into hospital EHR and transferred through eSource technology	Study CRF data elements available and entered into hospital EHR and transferred through eSource technology with expected result (eg, matches what was entered directly in form)
Demographics		3/6 (50.00)	2/6 (33.33)	12/12 (100.00)	12/12 (100.00)
Vital signs		10/10 (100.00)	9/10 (90.00)	24/1812 (1.32)[c]	20/20 (100.00)
Local lab					
	Blood biochemical tests	6/10 (60.00)	5/10 (50.00)	12,968/13,540 (95.78)[d]	7767/7767 (100.00)
	Urine sample tests	6/9 (66.67)	5/9 (55.56)	15/40 (37.56)	15/15 (100.00)
Concomitant medication		10/10 (100.00)	9/10 (90.00)	14/76 (18.42)[e]	6/6 (100.00)

[a]CRF: case report form.

[b]EHR: electronic health record.

[c]Checks were made with the relevant clinical research associates (CRAs) regarding the original data collection and CRF completion methods for the following reasons: vital signs were obtained using paper tracking forms provided by the sponsor as the original data source, and the data may not be transcribed into the hospital information system (HIS) by the researcher. Therefore, data from many visits are not available in the HIS.

[d]A total of 2708 blood biochemistry tests were involved.

[e]Concomitant medication uses tracking forms to record adverse event and ConMed (a paper source), and data may not be transcribed into the HIS. As confirmed by the CRA, the percentage of paper ConMed sources was approximately 80%.

Discussion

Although EHRs have been widely used, the degree of structure of EHR data varies substantially among different data modules. In EHRs, demographics, vital signs, local lab data, and concomitant medications are more structured than patient history or progress notes and often contain unstructured text [10]. Therefore, we selected these 4 well-structured data modules for exploration in this project.

For demographics data, among the 6 required fields (subject ID, date of birth, sex, ethnicity, race, and age), subject ID (subject code number/identifier in the trial, not the patient code number/identifier in the EHR system), ethnicity, and race were not available in the EHR, so the EHR-CRF availability score was 50%. Since this was an exploratory project, the date of birth field was also deidentified and thus could not be collected based on our deidentification rule, so the eSource-CRF availability score was 33%. In the future, the availability score can reach close to 100% by bidirectional design of the EHR and CRF under the premise of obtaining compliance for industrial-level applications.

The low availability score of local laboratory data on EHR-CRFs is due to the lack of required fields in the hospital system; “Lab ID” and “Not Done” do not exist in the LIMS, and for the “Clinically Significant” field, the meaning of laboratory test results needs to be manually interpreted by an investigator, so they cannot be transcribed directly. The availability score of eSource-CRFs was further decreased because the field “Laboratory Name and Address” is not an independent structured field in the EHR. The completeness score of urine sample test data was only 37.56% because during the actual clinical trial, especially amid the COVID-19 pandemic period, patients completed study-related laboratory tests at other sites, and those test results were collected via paper-based reports, so the complete data sets cannot be extracted from the site’s system.

To improve data availability in future applications, clinical trial–specific fields need to be added to EHR designs for those data that require an investigator’s interpretation such as “Clinically Significant,” and data transfer and mapping processes for the determination of the scope of data collection also needs to be optimized. Based on these two conditions, the completeness score can be improved to over 90%.

The availability and accuracy of vital signs data are ideal. However, since not all vital signs data collection was recorded by the electronic system during the actual study visit, many vital signs data were collected in “patient diary” and other types of paper-based documents during the study, resulting in a serious limitation in data completeness. With the development of more clinical trial–related electronic hardware and enhancements in products intelligence, more vital signs data will be directly collected by electronic systems, and the completeness of vital signs data transferred from EHR to EDC will be greatly improved in the future.

In the concomitant medication module, there was a good score for availability and accuracy because the standardization and structuring of prescriptions are well done in this hospital system. However, the patient's medication use period during hospitalization is recorded in unstructured text, so the data could not be captured for this study, resulting in a low completeness score of 18.42% for concomitant medication.

In summary, the accuracy score of eSource data in this study was high (100% for all fields). A study by Memorial Sloan Kettering Cancer Center and Yale University confirmed that the error rate of automatic transcription reduced from 6.7% to 0% compared to manual transcription [10]. However, data availability and completeness have not reached a good level. Data availability varies widely across studies, ranging from 13.4% in the Retrieving EHR Useful Data for Secondary Exploitation (REUSE) project [11] to 75% in The STARBRITE Proof-of-Concept Study [12], mainly related to the coverage and structure of the EHR.

National drug regulatory agencies (eg, US Food and Drug Administration [FDA], European Medicines Agency, Medicines and Healthcare products Regulatory Agency, and Pharmaceuticals and Medical Devices Agency) have developed guidelines to support the application of eSource to clinical trials [3,13-15]. The new Good Clinical Practice issued by the Center for Drug Evaluation in 2020 encourages investigators to use clinical trials' electronic medical records for source data documentation [1]. Despite this, we still encountered challenges, including ethical review and data security, during this study's implementation process. Without knowing the precedents, the project team decided to follow the requirements for clinical trials to control the quality of the study. There were no existing regulatory policies or national guidance on eSource in China at the time of this study. The project team provided explanations for inapplicable documents and communicated several times to ensure the approval of relevant institutional departments before finally becoming the first eSource technology study to be approved by the Ethics Committee and Human Genetic Resource Administration of China.

In the absence of regulatory guidelines, our eSource study, the first in China's International Multi-center Clinical Trial, navigated challenges in data deidentification. We adopted HIPAA and TransCelerate's guidelines [8]. Securing approval under "China International Cooperative Scientific Research Approval for Human Genetic Resources," we answered queries and achieved unprecedented recognition. For transferring data from the hospital to the sponsor's environment, we prioritized security and obtained necessary approvals. Iterative revisions ensured a robust data flow design. Challenges in mapping hospital EHR to EDC standards highlighted the need for a scalable mechanism. This study pioneers eSource tech integration in China, emphasizing the importance of seamless data mapping. In the process of executing data standardization, several challenges may arise, including inconsistent data definitions. Data from different systems may use different definitions due to the independent development of these systems, leading to varied interpretations of even identical concepts. To address this issue, establishing a unified data dictionary is crucial to ensure consensus on the definition of each data element. Different systems might also use distinct data formats such as text encodings. Preintegration format conversion is required, and extract, transform, and load tools or scripts can assist in standardizing these formats. During the integration of data from multiple systems, it is possible to discover data in one system that is not present in another. In the data standardization process, considerations must be made on how to handle missing data, which may involve interpolation, setting default values, etc. Quality issues like errors, duplicates, or inaccuracies may exist in data from different systems. Data cleansing, involving deduplication, error correction, logical validation, etc, is necessary to address these quality issues. Different systems may generate data based on diverse business rules and hospital use scenarios. In data standardization, unifying these rules requires collaboration with domain experts to ensure consistency.

Internationally, multiple research studies and publications have been released on regulations, guidelines, and validation of eSource. The FDA provided guidance on the use of electronic source data in clinical trials in 2013 that aims to address barriers to capturing electronic source data for clinical trials, including the lack of interoperability between EHRs and EDC systems. The European-wide Electronic Health Records for Clinical Research (EHR4CR) project was launched in 2011 to explore technical options for the direct capture of EHR data within 35 institutions, and the project was completed in 2016 [16]. The second phase of the project connected the EHRs to EDC systems [17] and aimed to realize the interoperability of EHRs and EDC systems. The US experience focuses more on improving and standardizing the existing EHRs to make them more uniform.

In Europe, the experience focuses on breaking down the technical barrier of interoperability between EHRs and EDC systems. In China, the current industry trends focus on the governance of existing EHR data in the hospital and the building of clinical data repository platforms [7]. Clinical data repository platforms focus on data integration and cleaning between EHRs and other systems in hospital environments and on unstructured data normalization and standardization by natural language processing and other AI technology [18]. At the national level, China is also actively promoting the digitization of medical big data and is committed to the formation of regional health care databases [19], which lays the foundation for the future implementation of eSource in China [20].

This study evaluates the practical application value of eSource in terms of availability, completeness, and accuracy. To improve availability, the structure of the CRF needs to be designed according to the information of the EHR data at the design stage of clinical trials. Even so, since EHRs are designed for the physicians to conduct daily health care activities, certain fields in clinical trials (eg, judgment of normal or abnormal values of laboratory tests and judgment of correlations of adverse events and combined medications) are still not available, and clinical trial–specific fields need to be added to EHR designs for those data that require investigators' interpretation to improve data availability. Completeness could be improved by the development of hospital digitalization that ensures patients' data is collected electronically rather than on paper. Additionally, 2708 blood test records were successfully collected from only 6 patients via eSource in this study, which indicates

that laboratory tests often contain large amounts of highly structured data that are suitable for eSource. EHR-EDC end-to-end automatic data extraction by eSource is suitable for laboratory examinations and can improve the efficiency and accuracy of data extraction significantly as well as reduce redundant manual transcriptions and labor costs. Processing unstructured or even paper-based data in eSource is still a big challenge. Using machine learning tools (eg, natural language processing tools) for autostructuring can be explored in the future. The goal is to have common data standards and better top-level design to facilitate data integrity, interoperability, data security, and patient privacy protection in eSource applications. During deidentification, we processed certain data with a specific logic to protect privacy. The accuracy assessment was performed during the deidentification step to ensure that the data was still sufficiently accurate while meeting privacy requirements. Reversible methods need to be used when performing deidentification as well as providing controlled access mechanisms to the data so that the raw data can be accessed when needed. It is worth noting that different regions and industries may have different privacy regulations and compliance requirements. When deidentifying, you need to ensure that you are compliant with the relevant regulations and understand the limitations of data use. This may require working closely with a legal team.

In the future, we can consider adding performance analysis, including an assessment of data import performance. This involves evaluating the speed and efficiency of data import to ensure it is completed within a reasonable timeframe. Additionally, analyzing data query performance is crucial in practical applications to ensure that the imported data meets the expected query performance in the application. For long-term applications involving a larger size of patients, it is advisable to consider adding analyses related to maintainability and cost-effectiveness. This includes implementing detailed logging and monitoring mechanisms to promptly identify and address potential issues. Furthermore, for the imported data, establishing a version control mechanism is essential for tracing and tracking changes in the data. Simultaneously, for overall resource use, evaluating the resources required during the data import process ensures completion within a cost-effective framework. It is also important to consider the value of imported data for clinical trial operations and related decision-making, providing a comparative analysis between cost and value.

Abstract

Background: Individuals from minoritized racial and ethnic backgrounds experience pernicious and pervasive health disparities that have emerged, in part, from clinician bias.

Objective: We used a natural language processing approach to examine whether linguistic markers in electronic health record (EHR) notes differ based on the race and ethnicity of the patient. To validate this methodological approach, we also assessed the extent to which clinicians perceive linguistic markers to be indicative of bias.

Methods: In this cross-sectional study, we extracted EHR notes for patients who were aged 18 years or older; had more than 5 years of diabetes diagnosis codes; and received care between 2006 and 2014 from family physicians, general internists, or endocrinologists practicing in an urban, academic network of clinics. The race and ethnicity of patients were defined as *White non-Hispanic*, *Black non-Hispanic*, or *Hispanic or Latino*. We hypothesized that Sentiment Analysis and Social Cognition Engine (SEANCE) components (ie, negative adjectives, positive adjectives, joy words, fear and disgust words, politics words, respect words, trust verbs, and well-being words) and mean word count would be indicators of bias if racial differences emerged. We performed linear mixed effects analyses to examine the relationship between the outcomes of interest (the SEANCE components and word count) and patient race and ethnicity, controlling for patient age. To validate this approach, we asked clinicians to indicate the extent to which they thought variation in the use of SEANCE language domains for different racial and ethnic groups was reflective of bias in EHR notes.

Results: We examined EHR notes (n=12,905) of Black non-Hispanic, White non-Hispanic, and Hispanic or Latino patients (n=1562), who were seen by 281 physicians. A total of 27 clinicians participated in the validation study. In terms of bias, participants rated negative adjectives as 8.63 (SD 2.06), fear and disgust words as 8.11 (SD 2.15), and positive adjectives as 7.93 (SD 2.46) on a scale of 1 to 10, with 10 being extremely indicative of bias. Notes for Black non-Hispanic patients contained significantly more negative adjectives (coefficient 0.07, SE 0.02) and significantly more fear and disgust words (coefficient 0.007, SE 0.002) than those for White non-Hispanic patients. The notes for Hispanic or Latino patients included significantly fewer positive adjectives (coefficient −0.02, SE 0.007), trust verbs (coefficient −0.009, SE 0.004), and joy words (coefficient −0.03, SE 0.01) than those for White non-Hispanic patients.

Conclusions: This approach may enable physicians and researchers to identify and mitigate bias in medical interactions, with the goal of reducing health disparities stemming from bias.

Introduction

Background

Language and communication play a significant, if not primary, role in social relations across different cultures [1]. Language has increasingly been recognized as a relevant form of data that describe relations and behavior [2]. One of the most intimate forms of communication between individuals occurs between clinicians and patients during clinical visits. However, these encounters may be undermined by different forms of bias directed toward patients from certain racial and ethnic minority groups [3]. Generally, *bias* refers to an evaluation, decision, perception, or action in favor of or against a person or group compared to another. Bias can be blatant, wherein it is characterized by deliberate actions (eg, racist comments) that are intentionally and overtly discriminatory [4]. Bias can also be subtle, including "actions that are ambiguous in intent to harm, difficult to detect, low in intensity, and often unintentional but are nevertheless deleterious" to targets [4]. Subtle bias by health care clinicians is linked to negative outcomes for racial and ethnic minority patients, particularly Black non-Hispanic and Hispanic or Latino patients [5].

Race and Racial Bias in Medical Interactions

Health disparities between racial and ethnic groups have historically been attributed to varying levels of socioeconomic status, as well as genetic and biological factors that were thought to predispose groups to different medical conditions. Research has emerged over the past few decades demonstrating that in fact, there is no biological basis for racial and ethnic differences. Humans share 99.9% of their genome, and the 0.1% variation cannot be explained or elucidated by race [6]. Race describes physical traits considered socially significant, and ethnicity denotes a shared cultural heritage, such as language, practices, and beliefs [7]. As such, race and ethnicity are social constructs, and since the landmark report *Unequal Treatment* in 2002 detailed the impact of racial and ethnic discrimination in patient-clinician interactions, research interest in this area has burgeoned [8]. Relative to White non-Hispanic patients, Black non-Hispanic and Hispanic or Latino patients are less likely to ''engender empathic responses from clinicians, establish rapport with clinicians, receive sufficient information, and be encouraged to participate in medical decision making" [9]. A lack of relationship building [10], reduced positive patient and clinician affect [11], decreased patient trust [12], and fewer patient questions [13] are all more likely outcomes for Black non-Hispanic and Hispanic or Latino patients compared to White non-Hispanic patients during medical interactions. Indeed, the 2018 *National Healthcare Disparities Report* revealed that, compared to White non-Hispanic patients, Black non-Hispanic patients receive inferior care on 40% of quality measures, and Hispanic or Latino patients receive worse care on 35% of quality measures, many of which indicate biased and discriminatory behaviors by clinicians [14]. For example, indicators were worse for Black non-Hispanic and Hispanic or Latino patients than White non-Hispanic patients for measures such as "physicians sometimes or never showed respect for what they had to say" and "physicians sometimes or never spent enough time with them" [14]. Black non-Hispanic and Hispanic or Latino patients are more likely to report racial and ethnic bias and discrimination during medical encounters compared to White non-Hispanic patients [15]. Yet, less is known about the manifestations and details of such experiences during the clinician-patient interaction [16] and whether racial and ethnic discrepancies in care can be observed in the content of electronic health records (EHRs). Similar to the thesis described in *Unequal Treatment*, we hypothesized that the mitigation of bias at the clinician level is needed to improve patient outcomes for diverse racial and ethnic populations and narrow the disparities gap. To address bias, researchers need to understand how to measure its existence, and clinicians need to be informed of its manifestations.

Research Contributions

Bias can have many forms—blatant, subtle, malevolent, or benevolent—all of which can be indicated by language. With increasing access to EHR documentation and advances in natural language processing, we may be better equipped to identify differences in clinician encounters with patients of diverse racial and ethnic backgrounds. This study searched for linguistic discrepancies in EHRs using a natural language processing approach followed by linear mixed effect model analyses. EHRs are digital summaries of the clinician-patient encounter and include the clinician's assessment of the interaction, as well as the patient's health history. Since the clinician is responsible for inputting information, as well as reviewing the information inputted by other care clinicians in the EHR for each patient encounter, the contents of the EHR may be particularly useful in illuminating biases that clinicians hold toward patients of different racial and ethnic backgrounds. Although several studies have indicated that clinician bias occurs, particularly in racially and ethnically discordant interactions (ie, when the patient and clinician are of different racial and ethnic backgrounds), relatively little research has examined the ways in which the clinician may be thinking about the patient and how the clinician's sentiment and cognitions are reflected in the language of the EHR [8,17]. EHRs can include many years of patient-clinician interactions, with multiple clinicians having access to them, allowing for biases to be passed on and potentially impact future medical decisions.

Our data set contained EHR notes for a large sample of White non-Hispanic, Black non-Hispanic, and Hispanic or Latino patients with diabetes in the Southern United States. The natural language processing tool, Sentiment Analysis and Social Cognition Engine (SEANCE), was applied to assess multiple linguistic markers in the EHR text [18,19]. We then explored whether 8 of the 20 SEANCE components (see Table 1) differed for patients of different races and ethnicities [20,21].

Table . Description of SEANCE[a] components.

Component label	Indices, n[b]	Key indices[c]	Language examples
Negative adjectives	18	NRC[d] negative adjectives, NRC disgust adjectives, NRC anger adjectives, GI[e] negative adjectives, and Hu-Liu[f] negative adjectives	Unkind, bad, cruel, hurtful, and intolerant
Positive adjectives	9	Hu-Liu positive adjectives, VADER[g] positive adjectives, GI positive adjectives, and Lasswell[h] positive affect adjectives	Supportive, kind, great, and nice
Joy words	8	NRC joy adjectives, NRC anticipation adjectives, and NRC surprise adjectives	Admiration, advocacy, elated, glad, liking, and pleased
Fear and disgust words	8	NRC disgust nouns, NRC negative nouns, NRC fear nouns, and NRC anger nouns	Abnormal, adverse, attack, cringe, criticize, distress, intimidate, unequal, and stigma
Politics words	7	GI politics nouns and Lasswell power nouns	Alliance, ally, authorize, civil, concession, consent, and oppose
Respect words	4	Lasswell respect nouns	Status, honor, recognition, and prestige
Trust verbs	5	NRC trust verbs, NRC joy verbs, and NRC positive verbs	Affirm, advise, confide, and cooperating
Well-being words	4	Lasswell well-being physical nouns and Lasswell well-being total nouns	Alive, ambulance, adjust, afraid, blood, clinic, and nutrition

[a]SEANCE: Sentiment Analysis and Social Cognition Engine.

[b]Indices refer to the number of dictionary lists from which the component was developed.

[c]The key indices came from the following dictionary lists: NRC Emotion Lexicon [18,22], the Harvard-IV dictionary list used by the General Inquirer [23], the Hu-Liu polarity word lists [22,23], the Valence Aware Dictionary and Sentiment Reasoner [24], the Lasswell dictionary lists [25,26], and the Geneva Affect Label Coder database [27]. For a thorough review of the SEANCE indices and corresponding dictionaries, see Crossley et al [18].

[d]NRC: NRC Emotion Lexicon.

[e]GI: General Inquirer.

[f]Hu-Liu: Hu-Liu polarity word lists.

[g]VADER: Valence Aware Dictionary and Sentiment Reasoner.

[h]Lasswell: Lasswell dictionary lists.

We hypothesized that the SEANCE components for negative adjectives, positive adjectives, joy words, fear and disgust words, politics words, respect words, trust verbs, and well-being words and the mean word count in the notes would be indicators of bias, as these concepts have been linked to bias in nonmedical contexts. Ng's [28] review of linguistic racial bias in verbiage offers the rationale for our choice of fear and disgust words, politics words, respect words, and trust verbs as indicators of bias, whereas the work of Li et al [29] examining gender differences in standardized writing assessment provides further support for our use of SEANCE as a tool for examining biases in language. We selected positive and negative adjectives, well-being words, politics words, and word count indicators as prior research demonstrates that clinicians may be less likely to establish rapport and provide appropriate medications and are more inclined to show negative attitudes and be dismissive toward Black non-Hispanic and Hispanic or Latino patients as a result of their unconscious racial and ethnic biases [30-33].

Specifically, we investigated which aspects of communication differ and whether differences are indicative of biased interactions. Any systematic variation in language can convey differential perceptions, attitudes, and expectations. For example, words such as "resistant" or "non-compliant" could reflect bias if (all else being equal) they tend to be used more to reflect people from some racial or ethnic backgrounds than others. This work aimed to elucidate for clinicians and researchers where discrepancies in communication emerge in the EHR and whether these differences are indicative of racial and ethnic bias. We also assessed the extent to which clinicians perceive linguistic markers to be indicative of bias.

Methods

Sample

This was a cross-sectional study using EHR-derived physician notation of outpatient clinical encounters. We extracted EHR encounters (n=15,460) for patients (n=1647) who were aged 18 years or older; had more than 5 years of diabetes diagnosis codes; and received care between 2006 and 2014 from family physicians, general internists, or endocrinologists practicing in an urban, academic network of clinics. We chose this disease

because of its high prevalence (11.3% in the United States) and chose to examine outpatient visits because of the relative scope of annual outpatient visits (1 billion) relative to hospital admissions (32 million) [34-36]. The demographic variables collected were patient race and ethnicity, sex, and age. The race and ethnicity of patients were defined as *White non-Hispanic*, *Black non-Hispanic*, or *Hispanic or Latino* (see Table 2 for a summary of patient demographics).

Table . Patient demographics of the final sample.

Variable		Value (n=1562)
Age (years)		
	Mean (SD)	68.74 (13.76)
	Range	20-102
	Median (IQR)	69 (61-78)
Sex, n (%)		
	Female	871 (55.74)
	Male	691 (44.26)
Race and ethnicity, n (%)		
	White non-Hispanic	682 (43.66)
	Black non-Hispanic	755 (48.34)
	Hispanic or Latino	125 (8)

SEANCE Algorithm

SEANCE is a lexical scoring algorithm that includes over 200 word vectors (also referred to as indices or features) designed to assess sentiment, cognition, and social order, which were developed from preexisting and widely used databases such as EmoLex and SenticNet [22,37]. In addition to the core indices, SEANCE allows for several customized indices, including filtering for particular parts of speech and controlling for instances of negation [18]. Since SEANCE computes such a large quantity of indices, Crossley et al [18] developed 20 components from all the indices using principal component analysis (PCA) [18]. These components are essentially clusters of related indices in SEANCE and allow users to interpret the SEANCE output at a more macro level. This process enabled them to summarize the SEANCE indices into a smaller and more interpretable set of variables. In the PCA by Crossley et al [18], they retained even the smallest components, setting a conservative cutoff point for inclusion (ie, 1% for variance explained by each component). The analyses for this research were run on a subset of 8 of the 20 *components* that Crossley et al [18] developed. We selected these 8 components a priori (see Table 1 for a description of the selected components).

We chose SEANCE instead of other natural language processing tools, such as Linguistic Inquiry and Word Count (LIWC), because it contains a larger number of core indices taken from multiple lexicons, as well as 20 components, and is based on the most recent improvements in sentiment analysis [18]. In their validation of SEANCE, Crossley et al [18] found that SEANCE components demonstrated significantly greater accuracy than LIWC indices (P<.001) for 3 of the 4 review types examined. In addition to the core indices, SEANCE allows for several customized indices, including filtering for parts of speech (also known as "parts-of-speech tagging") and controlling for instances of negation, which LIWC does not offer. We analyzed all words in the EHR (ie, *not* single parts of speech), but we controlled for negation. For example, this means that "not good" would be recognized as *not being positive* by SEANCE, as opposed to LIWC, which would see the word "good" and count it as positive.

Validation of the Sentiment Analysis Approach

To provide validation of the sentiment analysis approach used in this study, we surveyed subject-matter experts in EHR note writing (ie, physicians, physician assistants, and nurse practitioners) to garner their perspectives on the appropriateness of the linguistic components identified in our pilot study as indicators of subtle racial and ethnic bias in EHR notes. The team of researchers for this study included industrial-organizational psychologists who have expertise in bias and discrimination; however, it was also valuable to garner opinions from clinicians who are experts in EHR note writing and who understand the differences in the types of language used. To recruit participants, we used a combination of opportunistic and snowball sampling, starting with individuals within our personal networks. Through a web-based program, we asked participants to indicate the extent to which they thought the language domains (eg, negative adjectives, fear and disgust words, etc) were reflective of bias in EHR notes. Participants were told the following:

> *One type of language that could represent bias reflects the amount of NEGATIVE ADJECTIVES contained in the electronic health record. Examples of negative adjectives include "unkind," "bad," "harmful," "intolerant," and "stupid." If these kinds of words were used to describe Black or LatinX patients more than White patients, to what extent do you think this would be indicative of racial bias? Please indicate the extent of your agreement on the 1 to 10 scale below.*

The same formatting was used for each of the linguistic components, with component-specific language examples offered so participants understood the types of sentiment that each component was designed to assess.

Cross-Classified Linear Mixed Effects Models

We used the *lme4* package in R (R Foundation for Statistical Computing) to perform linear mixed effects analyses of the relationships between the outcomes of interest (SEANCE components and word count) and patient race and ethnicity, controlling for patient age. We ran an identical analysis, treating 8 different SEANCE components and the mean word count in the EHR as the dependent variables, while leaving all other variables consistent across the models. The same steps of entering fixed and random effects were applied across all cross-classified linear mixed effects models with different dependent variables (ie, negative adjectives, positive adjectives, well-being words, trust verbs, fear and disgust words, joy words, politics words, respect words, and mean word count).

We first ran a null model with only the random intercepts. We then added random effects and applied a crossed design (vs a traditional nested structure), leading us to have intercepts for physicians and patients. Then, we ran a model with the random intercepts as well as the fixed effects. As fixed effects, we entered *race and ethnicity* and *age* (without an interaction term) into the model. For all models examined, the intercept variation can be attributed primarily to different physicians rather than patients. We used a 95% CI to determine statistical significance. To be more conservative, given that we ran multiple tests, we also computed an additional set of CIs at the 99th percentile.

Ethical Considerations

We obtained ethics approval from the University of Texas Health Science Center's Committee for the Protection of Human Subjects (HSC-MS-18-0431) and the Rice University Institutional Review Board (IRB-FY2021-325). Participants consented and received a US $25 gift card after completing the survey. EHR data were deidentified prior to the analysis.

Results

Description and Justification for Cross-Classified Analyses

An initial inspection of the data revealed that 2 physicians were extreme outliers, accounting for 16.53% (2555/15,460) of the notes in our sample. To ensure that the overrepresentation of these physicians would not bias the results, we removed those notes from the data set (taking us from our initial sample of 15,460 visits with 283 physicians and 1647 patients to 12,905 visits with 281 physicians and 1562 patients; Table 2). The distribution of visits by patients indicates an average of 8.27 visits per patient with a minimum of 1, a median of 5, and a maximum of 97. Physicians see 11.72 patients on average, with a median of 2 and a maximum of 143, suggesting a skewed distribution. Despite the relatively large number of patients seen by some physicians, these physicians accounted for substantially fewer patient notes than the 2 physicians that were previously removed. Patients see 2.11 physicians on average, with a minimum of 1 and a maximum of 12; however, the distribution suggests that 6.6% (109/1647) of patients saw 5 or more physicians. Moreover, 742 (45.1%) of the 1647 patients saw 1 physician, whereas 119 (7.2%) saw 4 physicians. In our data set, patients can have multiple visits to a variety of physicians, indicating that patient visits are not nested within physicians. Further, physicians may see different patients with no consistent overlap of patients between physicians, indicating that physicians are not nested within patients. Thus, there is no clear hierarchical nesting of patients within physicians (or vice versa), which suggests that a cross-classified design is more appropriate than a traditional, hierarchical, multilevel model structure.

Cross-Classified Linear Mixed Effects Model Results

In the negative adjective component model (Table 3), the random effects of patient (σ^2=0.02) and physician (σ^2=0.12) indicated that intercept variation in use of negative adjectives is mainly a function of the physician rather than the patient. The physician random effect was over 5 times as large as the random effect for the patient; the intraclass correlation (ICC) for physicians was 0.41 and the ICC for patients was 0.07 (ICC_{total}=0.481). This pattern of results in random effects and ICC values for patients and physicians was consistent across the other 8 models. Overall, 2 of the 5 relationships (ie, the significant difference in positive adjectives for Hispanic or Latino and White non-Hispanic patient notes, and the significant difference in trust verbs for Hispanic or Latino and White non-Hispanic patient notes) that were previously significant at the 95th percentile had CIs that included zero at the 99th percentile. For 3 of the SEANCE components—well-being, politics, and respect words—and for the overall word count, there was not a statistically significant difference between the 3 races and ethnicities. In contrast, for all the other remaining SEANCE components, there was a statistically significant race and ethnicity effect for either Black non-Hispanic or Hispanic or Latino patients relative to White non-Hispanic patients. Specifically, notes for Black non-Hispanic patients contained significantly more negative adjectives and fear and disgust words than those for White non-Hispanic patients. Notes for Hispanic or Latino patients included significantly fewer positive adjectives, trust verbs, and joy words than those for White non-Hispanic patients. As such, across most of the SEANCE components, we observed favoritism of White non-Hispanic patients in terms of note content.

Table . Fixed effects model results for negative adjectives, positive adjectives, well-being words, trust verbs, joy words, politics words, respect words, fear and disgust words, and word count.

[a]Random effects are presented as estimate and SE. For the fixed effect estimates, cell entries are parameter (β) estimates, SE, and 95% CIs. White non-Hispanic was the reference group for race and ethnicity.

[b]Significant effects based on the 95% CIs.

Sentiment Analysis Validation

In all, 27 participants completed the surveys (see Multimedia Appendix 1 for the demographics of the participants). On a scale of 1 to 10, with 10 being extremely indicative of bias, participants rated negative adjectives as 8.63 (SD 2.06), fear and disgust words as 8.11 (SD 2.15), positive adjectives as 7.93 (SD 2.46), trust verbs as 7.56 (SD 2.64), and joy words as 6.81 (SD 2.47). The means and SDs for each of the components are reported in Table 4. The results of this preliminary analysis provide support for the validity of the linguistic components as indicators of bias in EHRs, as our sample of clinicians regard them as highly suggestive of bias if used differently for patients of diverse racial and ethnic backgrounds.

Table . Subject-matter expert assessment of bias based on specific linguistic markers.

Component	Score, mean (SD)[a]
Negative adjectives	8.63 (2.06)
Fear and disgust words	8.11 (2.15)
Positive adjectives	7.93 (2.46)
Joy words	6.81 (2.47)
Trust verbs	7.56 (2.64)
Politics words	7.07 (2.32)
Respect nouns	7.56 (2.55)
Well-being words	5.56 (2.55)
Mean word count	6.11 (2.19)

[a]Scale ranges from 1 (*Not at all indicative of bias*) to 10 (*Extremely indicative of bias*).

Discussion

Principal Findings

We found that the words that physicians use in EHR notes differ based on the racial and ethnic backgrounds of patients. Specifically, for Black non-Hispanic patients, notes consisted of words that convey negativity, fear, and disgust. When seeing Hispanic or Latino patients, physicians used fewer positive words and were less likely to use words that communicate trust and joy. Our findings are consistent with others who have documented that physicians communicate in the EHR differently (ie, more negatively) when caring for patients from some minority groups [9,17], which may ultimately result in adverse and inequitable health outcomes for patients. Our results also align with other papers that found that stigmatizing language is more commonly used in EHRs for minority populations [38-42]. Those papers used language guidelines [38] and experts [39] to identify stigmatizing language. We came to a similar conclusion by using established language dictionaries and contend that our approach allows for a more comprehensive assessment of language. For example, a prior paper used 15 descriptors [42]. In contrast, our approach encompasses tens of thousands of words, including multiple word lists, positive and negative sentiments, and emotions. Thus, this method does not merely capture the presence or absence of stigmatizing language, but rather offers a broader glimpse of the clinician-patient relationship. Furthermore, the validation survey confirmed that subject-matter experts perceive the types of words included in this study to be indicative of bias when used differentially for patients of diverse racial and ethnic backgrounds. Taken together, these findings indicate that the language used differs for patients based on racial and ethnic backgrounds and that those differences are suggestive of bias. As a result, our paper is the first to use this particular method to examine outpatient, diabetes notes. Since diabetes quality measures already exist, our analysis allows researchers to link bias to differences in quality in future studies [43].

EHR notes are important, although imperfect, assessments of physician attitudes toward their patients. With more and more time now being devoted to EHR documentation, physicians are increasingly burned out, which has led to the adoption of more efficient data entry strategies such as using templates, copy-pasting previous text, and inserting preset language [44,45]. Consequently, notes can be standardized, limiting our ability to assess physician attitudes and subconscious biases toward patients. Despite these caveats, notes remain the definitive and often sole account of what happened in the examination room, and based on these data, Black non-Hispanic and Hispanic or Latino patients are written about differently than White non-Hispanic patients.

The method described in this paper offers a scalable blueprint that provides clinicians with data about their interactions with patients and overcomes limitations of other traditional measures of bias. Existing measures require primary data collection through surveys, videotaped encounters, and confederate observations. Surveys assess perceptions of interactions and are prone to retrospective bias and socially desirable responding, whereas the time-consuming nature of encounters and observations lack scalability and limit the number of clinicians that can receive feedback at any given time. The relevance of alternative measures has also been questioned. For example, critics of the implicit association test have asked whether performance on the test is applicable to real-world contexts [46], which may explain why some change their behavior when confronted with their own biases, whereas others do not [5,47]. In contrast, our method uses data that are automatically and universally collected through the course of delivering care and generated by physicians in actual encounters.

Limitations

When interpreting our results, several limitations should be considered. First, due to limitations in our data, we are unable to determine which additional team members, including scribes, medical assistants, and residents, contributed to the notes. However, attending physicians are ultimately responsible for the content and have the authority and responsibility to modify language that is inconsistent with their values. Second, we lack information about physicians in this sample and do not have access to physician demographic characteristics (eg, their racial and ethnic backgrounds), although this would be an important next step. We attempted to account for this limitation by comparing language within rather than across physicians. Third, we included all language within notes, including physical exams,

medications, and past medical histories. These sections can be guided by templates or not actively entered by physicians. We retained these parts in case the language within these sections contributed to variation. An alternative approach could assess only the history of present illness, assessment, and plan sections of the note and could yield different results. Additional work is needed to determine whether differential word choices reflect attitudes and behaviors toward patients. EHR notes serve a wide range of purposes. They convey medical information to others, remind physicians of their impressions, communicate plans to patients, provide justification for billing codes, and serve as legal evidence [44]. Thus, specific phrases (eg, worsening, uncontrolled, or adherence) may be required for billing, compliance, and legal purposes and may not reflect bias toward patients. Finally, these results may not be generalizable to other conditions. Our findings may be unique to the language used for diabetes care and by clinicians who manage diabetes. Determining whether these results persist for different diseases (eg, cancer, heart disease, and acute injuries) is an important next step.

Directions for Future Research

Additional research is needed to interpret and provide context for this exploratory work. To determine whether these measures are associated with bias, subject-matter experts could label notes using known patterns of bias (eg, the ratio of collective to personal pronouns, the amount and level of abstraction of speech, and passive vs active voice) [48]. Further research is needed to understand whether biased language in notes reflects biased behaviors during encounters as well as inequitable health outcomes for some racial and ethnic minority populations. Conducting further experiments (eg, with research actors as patients in a mock medical visit) could help determine whether biased language in notes reflects manifestations of bias during encounters (eg, less eye contact, hostile language, or less time spent on education and counseling). If bias is confirmed, we need to determine whether clinicians who use differential language provide worse care and quality for minority patients. Ultimately, this tool may be used to identify and mitigate bias. Future studies should assess whether receiving feedback using this method leads to behavior change and whether changing the language used in EHR notes leads to changes in patient interactions. Although many strategies for reducing bias exist—such as affirming egalitarian goals, seeking common-group identities, perspective taking, and individuation—it is unclear which approach best complements our proposed method [5].

Conclusion

In this novel, exploratory work, we used natural language processing and found that compared to encounters with White non-Hispanic patients, physicians use language conveying more negativity, fear, and disgust in their encounters with some racial and ethnic minority patients. If confirmed in future studies, these features could be used to make clinicians aware of their biases with the goal of reducing racial and ethnic discrimination and the resulting health inequities.

Abstract

Background: The SARS-CoV-2 pandemic has demonstrated once again that rapid collaborative research is essential for the future of biomedicine. Large research networks are needed to collect, share, and reuse data and biosamples to generate collaborative evidence. However, setting up such networks is often complex and time-consuming, as common tools and policies are needed to ensure interoperability and the required flows of data and samples, especially for handling personal data and the associated data protection issues. In biomedical research, pseudonymization detaches directly identifying details from biomedical data and biosamples and connects them using secure identifiers, the so-called pseudonyms. This protects privacy by design but allows the necessary linkage and reidentification.

Objective: Although pseudonymization is used in almost every biomedical study, there are currently no pseudonymization tools that can be rapidly deployed across many institutions. Moreover, using centralized services is often not possible, for example, when data are reused and consent for this type of data processing is lacking. We present the ORCHESTRA Pseudonymization Tool (OPT), developed under the umbrella of the ORCHESTRA consortium, which faced exactly these challenges when it came to rapidly establishing a large-scale research network in the context of the rapid pandemic response in Europe.

Methods: To overcome challenges caused by the heterogeneity of IT infrastructures across institutions, the OPT was developed based on programmable runtime environments available at practically every institution: office suites. The software is highly configurable and provides many features, from subject and biosample registration to record linkage and the printing of machine-readable codes for labeling biosample tubes. Special care has been taken to ensure that the algorithms implemented are efficient so that the OPT can be used to pseudonymize large data sets, which we demonstrate through a comprehensive evaluation.

Results: The OPT is available for Microsoft Office and LibreOffice, so it can be deployed on Windows, Linux, and MacOS. It provides multiuser support and is configurable to meet the needs of different types of research projects. Within the ORCHESTRA research network, the OPT has been successfully deployed at 13 institutions in 11 countries in Europe and beyond. As of June 2023, the software manages data about more than 30,000 subjects and 15,000 biosamples. Over 10,000 labels have been printed. The results of our experimental evaluation show that the OPT offers practical response times for all major functionalities, pseudonymizing 100,000 subjects in 10 seconds using Microsoft Excel and in 54 seconds using LibreOffice.

Conclusions: Innovative solutions are needed to make the process of establishing large research networks more efficient. The OPT, which leverages the runtime environment of common office suites, can be used to rapidly deploy pseudonymization and biosample management capabilities across research networks. The tool is highly configurable and available as open-source software.

Introduction

Background

As a response to the SARS-CoV-2 pandemic, many research projects have been rapidly set up to study the virus, its impact, and possible interventions [1,2]. This accelerated the general trend toward large collaborative networks in biomedical research [3,4]. These are motivated by the need to generate sufficiently large data sets and collections of biosamples, which are essential for developing new methods of personalized medicine and generating real-world evidence [5]. However, setting up such networks usually takes quite some time, as common tools and policies are needed to achieve interoperability and enable the required flows of data and biosamples [6,7]. One area in which this challenge is frequently encountered is the handling of personal data and the related data protection issues, which can arise in all processing steps, from collection [8] to sharing [9] and even analysis and visualization [10].

Laws and regulations, such as the European Union General Data Protection Regulation (GDPR) [11] or the US Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule [12], advocate for various strategies for the protection of personal data. In general terms, the GDPR prohibits the processing of sensitive categories of personal data, including medical data, unless consent is given. However, under certain conditions, processing is also possible without consent if technical and organizational safeguards are implemented [13]. Although there is no consensus on which protection methods are best suited for use in biomedical research [14], pseudonymization (also called coding or pseudo-anonymization) [15] is a common strategy, which can also be used to deidentify data under the HIPAA Privacy Rule. Pseudonymization is an essential aspect of the GDPR, as it is mentioned in multiple articles, in particular as a data minimization measure [16]. In this privacy-by-design approach, directly identifying data about study subjects are stored separately from biomedical data and biosamples, which are needed for scientific analyses [17]. The link between the different types of data and assets is established through secure identifiers, the so-called pseudonyms [18], which enable data linkage and allow the reidentification of subjects only if strictly necessary, for example, for follow-up data collection.

Objective

Although pseudonymization is done in almost any biomedical study, there are currently no pseudonymization tools that can rapidly be rolled out across many institutions. Existing tools, such as the Generic Pseudonym Administration Service (gPAS) [19] and Mainzelliste [20], are client-server applications, requiring server components to be deployed to and integrated into the institutions' IT infrastructures. Although this can have some important advantages (see the *Limitations and Future Work* section), it is usually time-consuming, for example, due to a lack of resources or efforts required to ensure compliance with local security policies. Moreover, using central services, such as the European Unified Patient Identity Management (EUPID) [21], is often not an option, for example, when data should be reused and consent is missing for this type of processing [22].

In this paper, we present the ORCHESTRA Pseudonymization Tool (OPT) that has been developed under the umbrella of the ORCHESTRA consortium. This project faced the challenges described in the previous paragraph when quickly establishing a large-scale research network as part of Europe's rapid pandemic response [23]. Hence, the OPT has been developed with the aim of supporting (1) the registration, pseudonymization, and management of study subject identities as well as biosamples; (2) rapid rollout across research network partners; and (3) scalability and simple configurability. The objective of this paper is to describe the design and implementation of the OPT and to offer insights into its usability and scalability, as evidenced by its deployment in the ORCHESTRA research network.

Methods

Ethical Considerations

The work described in this article covers the design and implementation of a generic research tool, which did not involve research on humans or human specimens and no epidemiological research with personal data. Therefore, no approval was required according to the statutes of the Ethics Committee of the Faculty of Medicine at Charité - Universitätsmedizin Berlin. However, the individual studies which use the tool usually have to apply for ethics approval. For example, the COVID HOME study within the ORCHESTRA project was approved by the Medical Ethical Review Committee of the University Medical Center Groningen (UMCG) under vote number METc 2020/158.

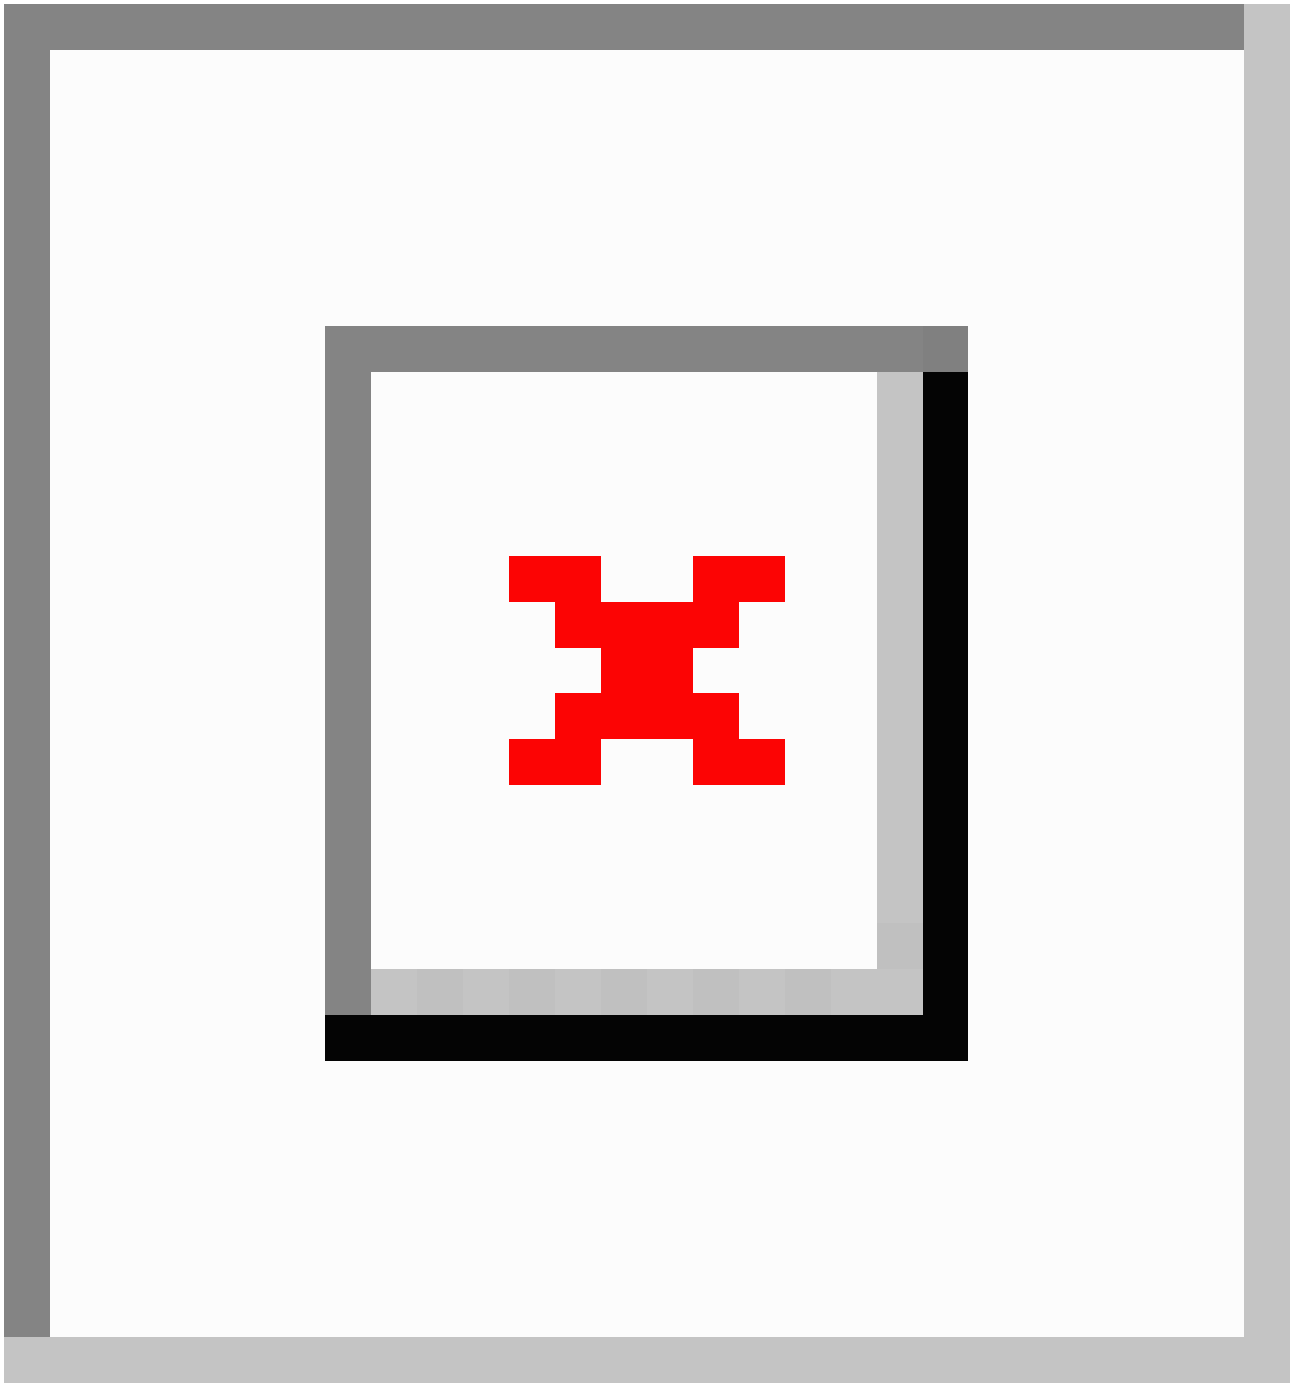
General Approach

The OPT has been designed to support general pseudonymization workflows that are needed in most biomedical research projects, as illustrated in Figure 1.

When a subject is admitted to the hospital, visits a study center, or has a follow-up visit, they are enrolled in the study. In this setting, the physicians or study nurses collect directly identifying and medical data and, according to the study protocol, the appropriate biosamples. The identifying attributes are entered into the OPT to create a unique pseudonym: the OPT Subject ID. During the follow-up visits, the study staff can use the OPT to retrieve an existing pseudonym from a subject that was already enrolled in the study. In all downstream data collection or processing, the OPT Subject ID can be used instead of identifying data so that the medical data are protected but still linked to the study subject and across visits. In addition, biosample data can also be entered into the OPT and linked to the appropriate subject to generate 1 or more additional pseudonyms: the OPT Biosample IDs. A label can then be generated for each biosample vial, containing the OPT Biosample ID, the OPT Subject ID, a DataMatrix Code, a QR code, or a barcode (containing the OPT Biosample ID) for tracking the biosample via scanners commonly used in laboratories. Study-specific information, for example, the exact information to capture for each study subject and biosample, the number and schedule of visits, and the types and schedules of biosample collections, can all be configured in the OPT. Moreover, in addition to its applicability in prospective studies, as described above, the software also supports importing existing

data about subjects and biosamples that can be used in retrospective study designs.

Figure 1. Basic concept of the OPT. IDAT: identifying data; MDAT: medical data; PID: patient ID; PSN: subject pseudonym; PSN-S: sample pseudonym; SDAT: sample data; SID: sample ID.



Implementation Details

To overcome challenges caused by the heterogeneity of IT infrastructures across different institutions and a potential lack of support by IT departments due to resource constraints, the OPT has been implemented based on programmable runtime environments that are available at practically any institution: office suites. These suites, especially the one by Microsoft, are among the most important and widely used applications around the world and still play a key role in many sectors today. The OPT is available for Microsoft Office as an Excel application and for LibreOffice as a Calc application. The application logic has been implemented in the embedded Basic scripting language using efficient algorithms for data management. Although Visual Basic for Applications is supported by Microsoft Office and LibreOffice Basic is supported by LibreOffice, they share similarities but are not fully compatible with each other. In the development process of the OPT, the Excel version serves as the primary implementation, and changes as well as additions are regularly ported to the LibreOffice version to achieve feature parity.

For generating the labels for the biosample vials, the OPT is delivered together with a single-page label printing application

that takes pseudonyms and metadata (eg, visit labels) as input and generates printable labels. Although this application is implemented using web technologies such as HTML, CSS, and JavaScript, it is delivered as files and can be executed locally without access to the internet. The label printing application works in any common web browser and can be called via the OPT. Properties of the labels to be printed can either be automatically transmitted via the URL for a single label or manually copied into the application via an input field for bulk printing of a larger number of labels. It is also possible to host the application on a web server. However, in this case, the URL function will be deactivated in the OPT to ensure that no data are sent to the server that hosts the application. It is important to note that the application still runs completely locally in the browser of the user, and no data ever leave the devices used to print labels. The pseudonyms and biosample metadata will be temporarily managed in the browser of the device.

Specific Functionalities

In addition to study subject and biosample management, the OPT also provides import and export functionalities, statistics, and a range of configuration options. In this section, we will briefly introduce each function, whereas a structured overview can be found in Multimedia Appendix 1. Regarding the subject-related functions, the OPT supports individual or bulk registration and a search function for finding pseudonyms for already registered subjects. An important feature of the software is a search function, required for any new patient or sample registration, which prevents multiple registrations of the same study participant. The search, to be performed as the first step of the registration, is linked to several data quality checks as well as a fuzzy record linkage process that prevents duplicate registrations. The bulk registration functionality enables the use of the OPT for retrospective pseudonymization of existing data sets. The search function supports wildcards and fuzzy matching across a configured set of master data attributes. Additional properties for the registered individuals can be documented to account for site-specific requirements.

Biosample-related functions are designed analogously to those for study subject management. In addition, labels can be generated and printed through the service described in the previous section.

Import and export functionalities are provided to enable the creation of backups (see the next section) and the migration from old versions of the OPT as part of update processes.

Finally, separate worksheets display statistical information about the data captured, such as the number of subjects registered or pseudonyms created for different study visits. Extensive configuration options are also available through a separate worksheet.

All functionalities of the OPT are described briefly in an integrated Quick User Guide and in detail in a comprehensive user manual [24].

Security Considerations and Features

The data collected during study subject and biosample registration, as well as the pseudonyms generated, are sensitive and a critical part of the data managed in any study. Hence, the confidentiality, integrity, and availability [25] of the data managed in the OPT must be ensured. In this context, the approach taken by the OPT clearly trades off some of the guarantees that could be provided by a client-server application against the possibility of rapid deployment and rollout. However, as described in the user manual, care has been taken to provide robust guarantees by specifying requirements on how the OPT should be deployed and used [24]. First, the OPT should not be placed on a local drive but on a network share that is integrated with the institution's Authentication and Authorization Infrastructure and, hence, provides means for controlling who is able to access the software in read or write mode and from which devices. Second, it is highly recommended that this share be backed up regularly so that data can be restored in case of problems. This should be complemented by regular, for example, daily, manual backups through the export functionality provided by the OPT and according to reminders that are displayed by the software. Finally, the office suites used as runtime environments do not provide multiuser support, and the application can only be opened by 1 user with write permission at any point in time. To enable parallel read access, the OPT comes with a script that opens a temporary read-only copy of the software. This allows, for example, laboratory technicians to use the OPT for generating biosample labels in parallel with ongoing registration processes. The measures described in this section have proven to be effective, and no problems have been encountered to date during extensive use of the software at many institutions (see the *Results* section).

Results

Overview of the Application

The graphical user interface of the OPT is divided into 10 different perspectives that provide access to the functionalities described in the previous sections. One of those sheets, the configuration sheet, is hidden from the users. All other sheets have write protection using the integrated protection functions of the spreadsheet software, except the input fields and the buttons, to ensure that data management is only performed through the specific functionalities provided by the software. A password is set by default for the write protection, which can be changed by the administrator at any time. However, it is important to keep the password safe. Figure 2 provides an overview of 4 important perspectives.

Figure 2. Perspectives of the OPT for (A) configuration, (B) registration and search, (C) data overview, and (D) statistics. OPT: ORCHESTRA Pseudonymization Tool.

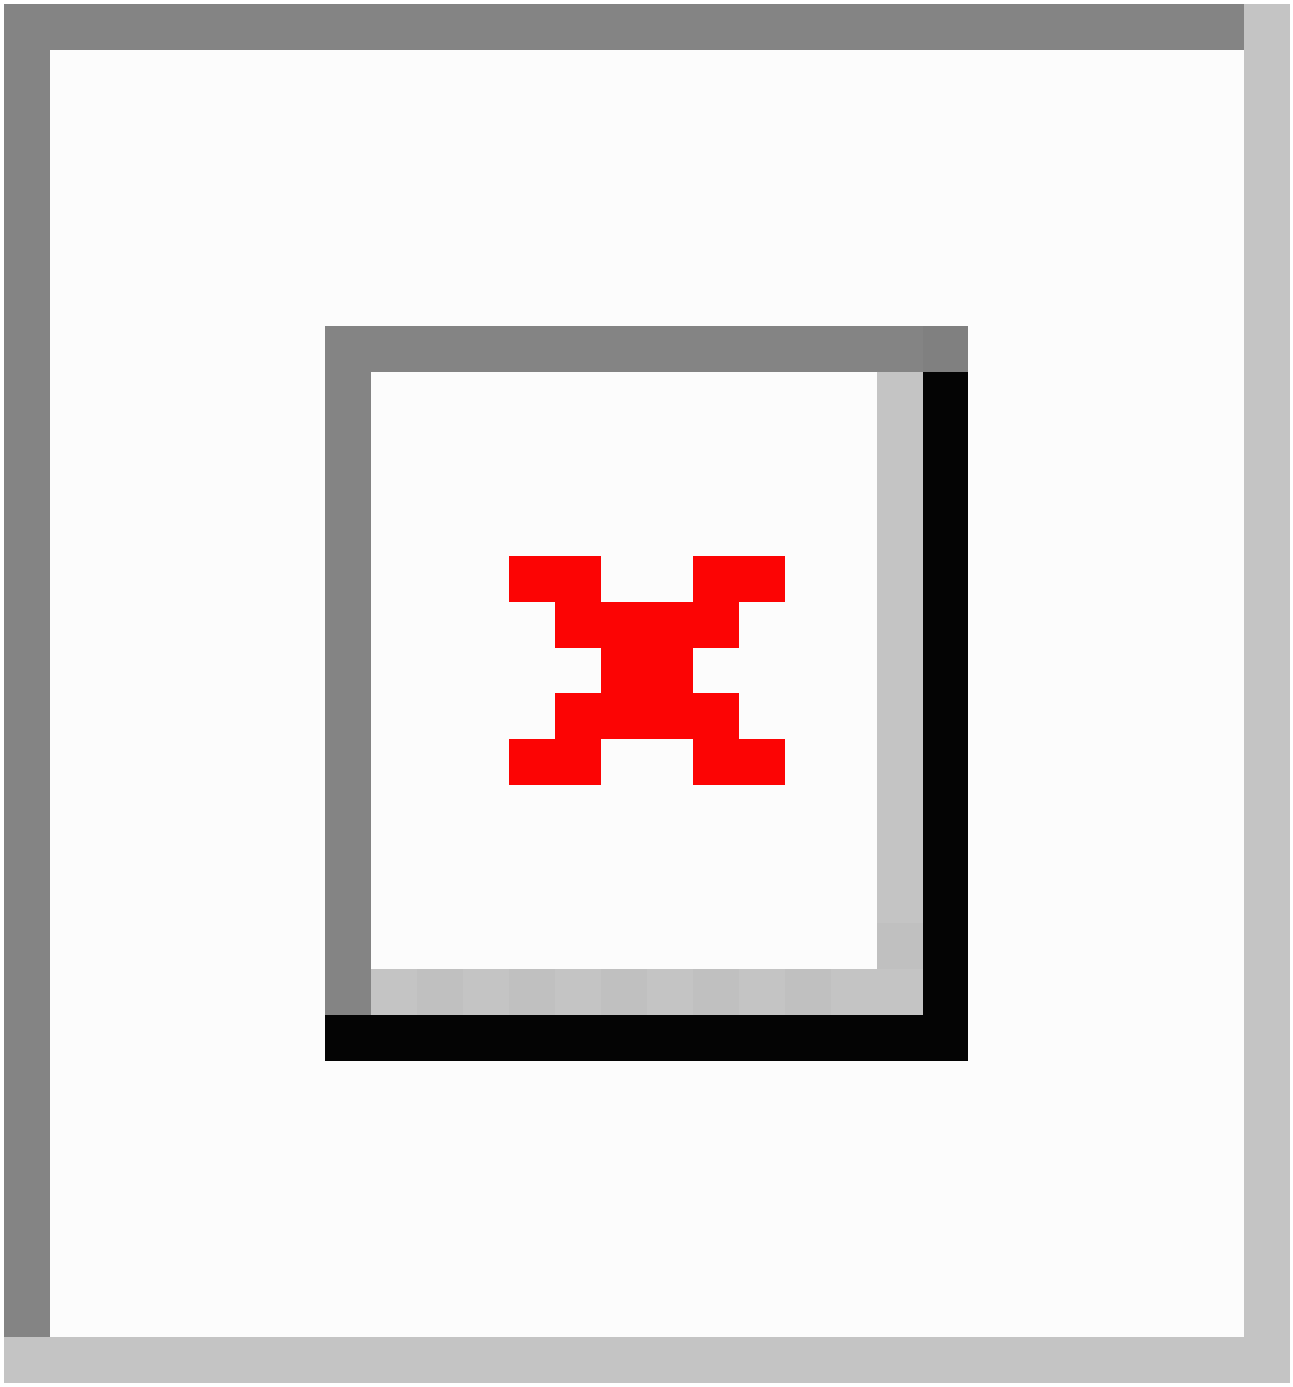


Figure 2A shows the configuration sheet, in which the specifics of the algorithm for generating pseudonyms, the study schedule, and the data fields to be documented can be specified. Figure 2B shows the interface provided for searching and registering subjects, with a search form on the left side of the sheet and a results list on the right side. All study subject data stored in the OPT are listed in the sheet shown in Figure 2C. This sheet also allows users to document any additional data that a site may require. Finally, Figure 2D shows a sheet providing statistical information on the number of subjects and biosamples registered, as well as insights into how these numbers have developed over time.

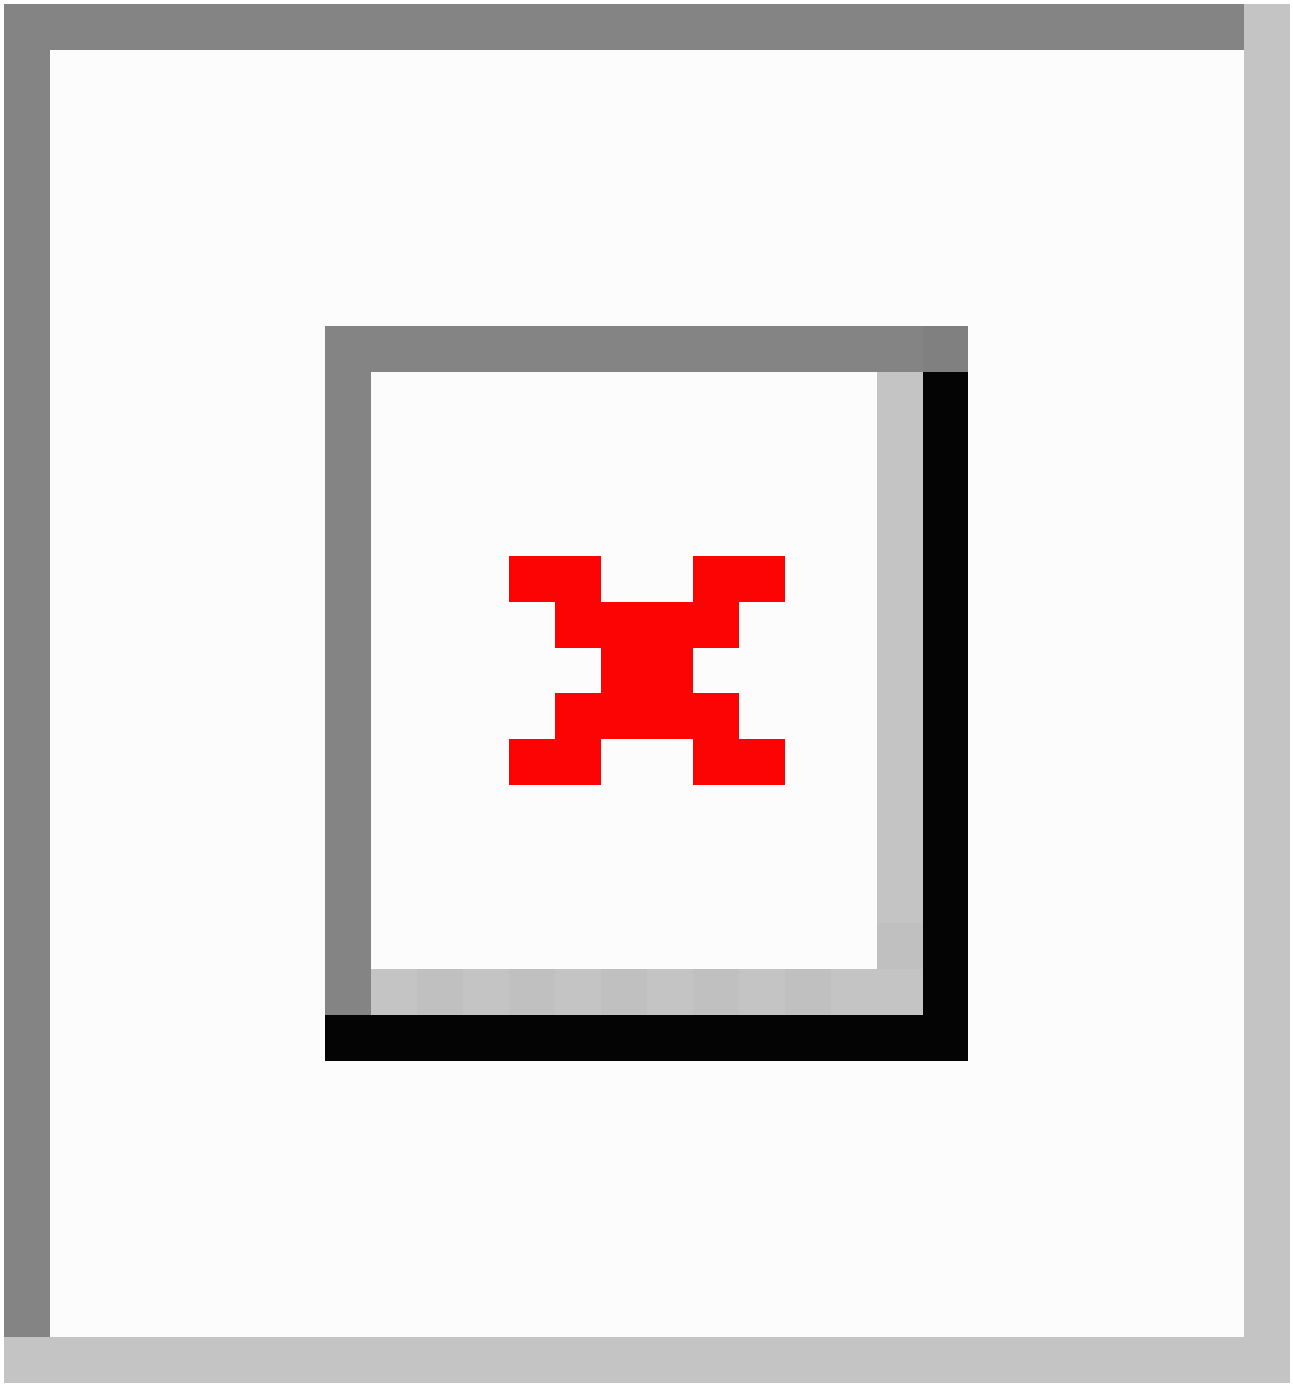
An overview of the label printing application is provided in Figure 3. As shown in the figure, the data that are to be printed on the labels are listed, and the number of rows and columns can be configured to support printing in bulk or for individual labels. The figure also shows an example of a sheet that can be printed and a detailed image of a single label. The data that are printed on those labels include the biosample and study subject IDs, the associated visit of the study schedule, and the biosample type.

Figure 3. Overview of the label printing application. OPT: ORCHESTRA Pseudonymization Tool.



Use of the OPT in the ORCHESTRA Project

ORCHESTRA is a 3-year international research project about the COVID-19 pandemic that was established in December 2020, involving 26 partners from 15 countries. The aim of ORCHESTRA is to share and analyze data from several retrospective and prospective studies to provide rigorous evidence for improving the prevention and treatment of COVID-19 and to better prepare for future pandemics [26,27].

The data management architecture in ORCHESTRA consists of 3 layers that build upon each other. The first layer is formed by "National Data Providers," which consist of the participating partners (universities, hospitals, and research networks). These provide the subject data and samples for joint analyses. On the second layer, "National Hubs" pool pseudonymized data in national instances of the Research Electronic Data Capture (REDCap) system [28]. Finally, the "ORCHESTRA Data Portal" forms the third layer, in which access to aggregated data and results is provided through a central repository.

In ORCHESTRA, the OPT was used for implementing pseudonymization at the data providers' sites. Each participating site named 1 or 2 persons responsible for technical aspects, such as setting up the required network share and installing updates, as well as several study nurses or clinicians, who would use the OPT. With these users, we performed regular training sessions and provided contact details in case of questions. As of June 2023, 19 instances of the OPT have been rolled out to 13 sites in 11 countries, including Germany, France, Italy, and Slovakia

in Europe; Congo in Africa; and Argentina in South America. A world map highlighting all the countries in which the OPT has been rolled out can be found in Multimedia Appendix 2.

On average, each instance of the OPT was used by up to 4 staff members. The OPT has been successfully rolled out, used, and maintained at large sites with committed IT departments, as well as at smaller, resource-constrained institutions. Overall, it has been in constant production use for more than 2 years. In the majority of the sites (10/13, 77%), the OPT Microsoft Excel version was used, whereas the remaining sites (3/13, 23%) used the LibreOffice release. In total, more than 10,000 study subjects and 15,000 samples have been registered in the OPT across all sites, and more than 10,000 labels have been printed. To evaluate the usability of the OPT, we conducted a survey among all active users, leveraging the widespread System Usability Scale [29] questionnaire, which includes 10 Likert-scale questions. During this survey, our system was designed to prevent multiple responses from individual participants and the submission of incomplete responses. We received 6 responses from 9 invited users, resulting in a score of 75 on a scale from 0 to 100, which adjectively translates to “good” [30].

Performance Evaluation

As mentioned, the OPT has been carefully designed to provide acceptable performance, even when large data sets are being processed or a large number of subjects or samples are being managed. In this section, we present the results of a brief performance evaluation. Our test environment consisted of an average office laptop, which was equipped with a quad-core 1.8 GHz Intel Core i7 CPU and a 64-bit Microsoft Windows 10 operating system. On top of it, Microsoft Excel 2016 (x32) and LibreOffice 7.0 (x64) were installed. Figure 4 provides an overview of the execution times of the most important functionalities of the OPT for different cohort sizes.

The numbers clearly show that the OPT works well and provides excellent performance for small or medium-sized data sets and acceptable performance for large data sets.

Figure 4. Execution times of the most important operations of the ORCHESTRA Pseudonymization Tool: (A) import, (B) registration, and (C) search.

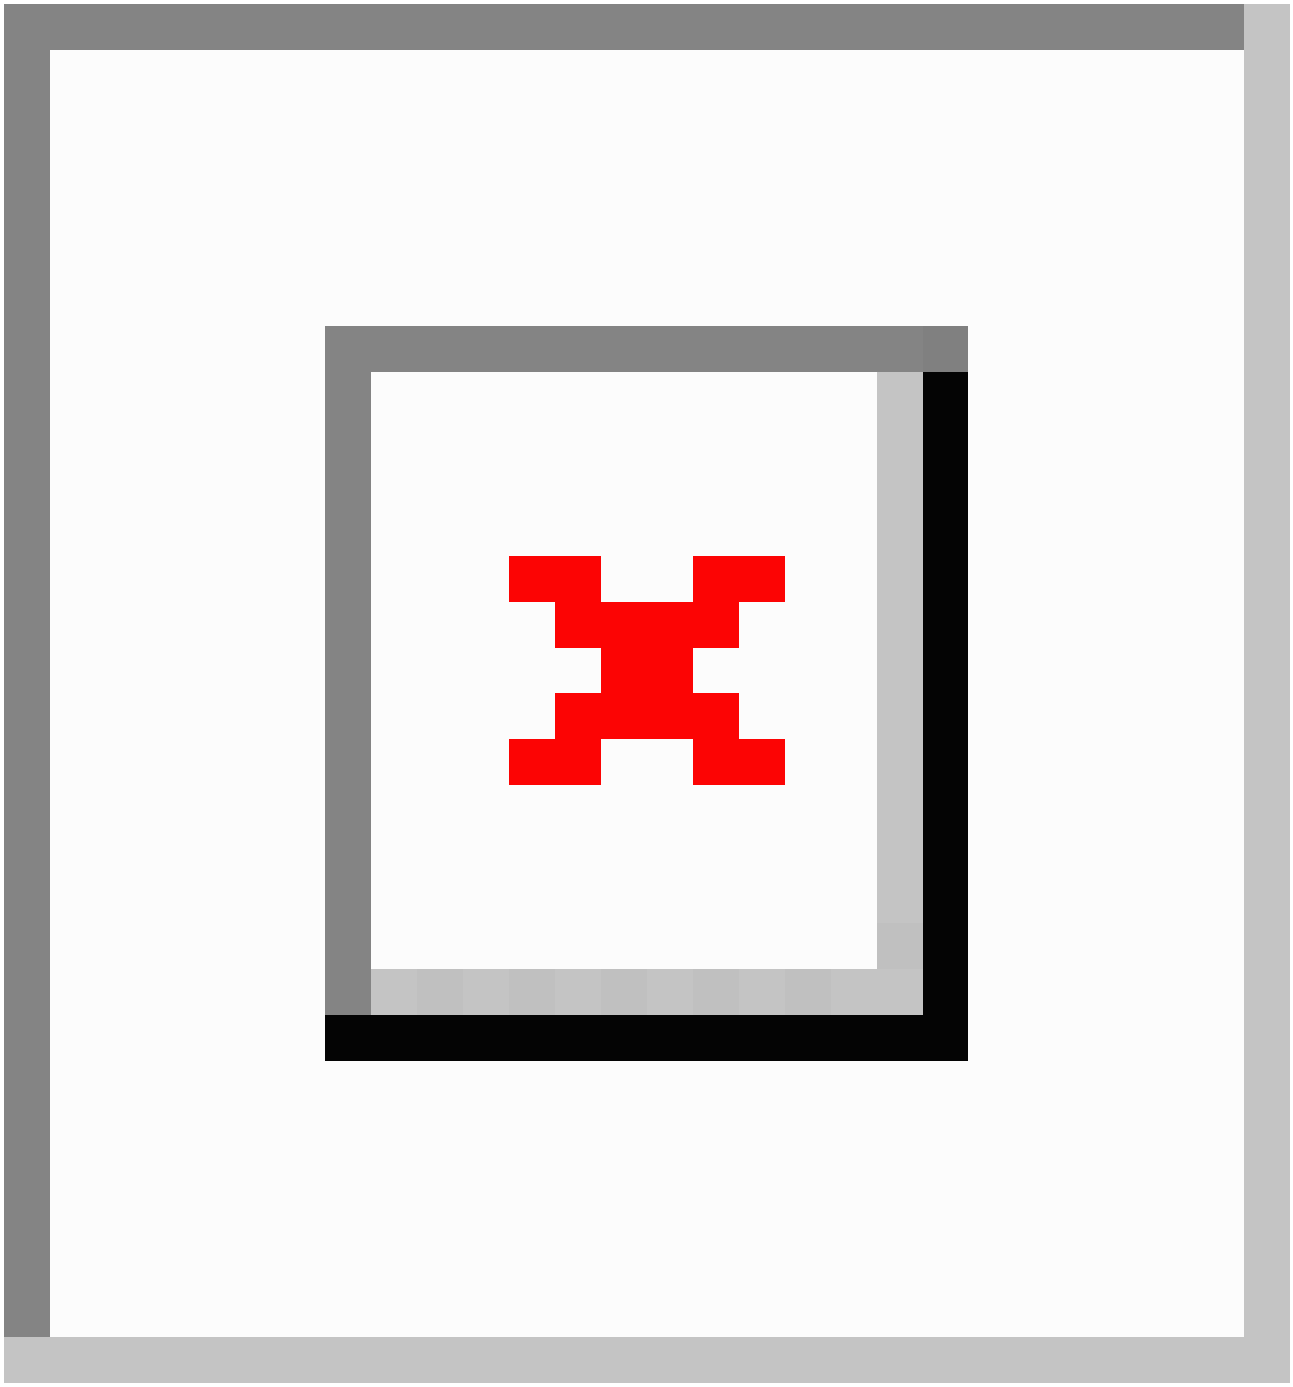


Figure 4A shows the average execution times for importing data about study subjects and samples. Data about subjects were imported into a completely empty OPT, whereas data about samples were imported into an OPT that already had the corresponding study subjects registered, so that each biosample was assigned to exactly 1 subject. For example, importing the data of 100,000 subjects took about 10 seconds in the Excel version and 54 seconds in the LibreOffice version. During the registration, the existence of the associated study subject in the OPT is checked, which makes the registration of samples slower compared to the registration of subjects. This is also noticeable in Figure 4B, which shows the average execution times for registering a single study subject or sample. As can be seen, using an OPT data set in which 100,000 entities were already registered, this took between 2 and 4 seconds in the Excel version and between 4 and 6 seconds in the LibreOffice version. Figure 4C shows the average execution times for searching for entities and obtaining their pseudonym, which is roughly twice as fast as the registration operation.

As performance is associated linearly with the number of entities already managed, subsecond response times can be expected for instances in which around 15,000 or fewer subjects or samples have been registered. This is consistent with our experiences from the deployments in the ORCHESTRA research network.

Discussion

Principal Findings

In this paper, we presented the OPT, a comprehensive, scalable, and pragmatic pseudonymization tool that can be rapidly rolled out across large research networks. To achieve this, the software has been implemented based on runtime environments that are available at practically any institution: office suites. The software supports a broad range of functionalities, from registering and pseudonymizing subject and biosample identities to search and depseudonymization functions, statistics about the data managed, as well as import and export features. We have described measures that are recommended to ensure the security of the data managed by the OPT and reported on our experiences gained after 2 years of successful operation in a large research network on COVID-19. Finally, we have also presented the results of a performance evaluation showing that the software provides excellent performance for small or medium-sized data sets and acceptable performance for large data sets. The OPT is available as open-source software [31] and can be configured to meet the needs of a wide range of biomedical research projects.

Limitations and Future Work

To achieve the design goals of the OPT, some compromises had to be made regarding data management. Compared to using client-server applications that use database management systems to store data, it is more difficult to ensure the confidentiality, integrity, and availability of the data managed with the OPT. There is also limited support for multiuser scenarios. However, we have developed and documented a set of measures that, if taken, help to still ensure a high level of data security. For this to work, it is important that users adhere to those recommendations. Therefore, all users of the OPT should familiarize themselves with the manual [24], and ideally, they should also be trained in the use and operation of the software. Despite these limitations, we strongly believe that our approach offers an innovative take on pseudonymization tools that can rapidly be rolled out across large research networks. Of course, it would be even more desirable if global standards for pseudonymization functions could be developed and agreed upon. Such global standards would ensure that solutions already existing at many research institutions are interoperable and can readily be used in joint research activities.

Comparison With Related Work

A range of pseudonymization tools has been described in the literature and are available as open-source software. However, they are either based on a client-server architecture and hence require quite some effort to be rolled out across sites, based on central services and hence not usable if consent is lacking for this type of processing, or offered as command-line utilities or programming libraries for IT experts.

Examples of client-server approaches include the work by Lablans et al [20] to provide a RESTful interface to pseudonymization services in modern web applications, which is based on a concept suggested by Pommerening et al [6] in 2006. Moreover, researchers from the University of Greifswald in Germany have designed and developed several client-server tools that can be used to manage subjects, samples, and other aspects of biomedical studies [32,33].

Examples of central services for pseudonymization include the EUPID, which was developed in 2014 by the Austrian Institute of Technology for the European Network for Cancer Research in Children and Adolescents project [21]. Another example is the Secure Privacy-preserving Identity management in Distributed Environments for Research (SPIDER) service, which was launched in May 2022 by the Joint Research Centre [34]. Both services support linking and transferring subject data across registries without revealing their identities. However, biosample data management is not possible with them. Further centralized concepts include the one described by Angelow et al [35].

Examples of command-line utilities, application programming interfaces, and programming libraries include the generic solution for record linkage of special categories of personal data developed by Fischer et al [36]; that by Preciado-Marquez et al [37]; and the PID (patient ID) generator developed by the TMF (Technologies, Methods and Infrastructure for Networked Medical Research e.V.), the German umbrella association for networked medical research [6].

Conclusion

Widely available office suites provide runtime environments that offer opportunities to rapidly roll out software components for biomedical studies across a wide range of large and resource-constrained research institutions. We have demonstrated this through the development, practical use, and evaluation of the OPT, which offers pseudonymization functionalities for study subjects and biosamples. As we believe that the software is of interest to the larger research community, it has been made available under a permissive open-source license [31].

Abstract

Background: Self-administered web-based questionnaires are widely used to collect health data from patients and clinical research participants. REDCap (Research Electronic Data Capture; Vanderbilt University) is a global, secure web application for building and managing electronic data capture. Unfortunately, stakeholder needs and preferences of electronic data collection via REDCap have rarely been studied.

Objective: This study aims to survey REDCap researchers and administrators to assess their experience with REDCap, especially their perspectives on the advantages, challenges, and suggestions for the enhancement of REDCap as a data collection tool.

Methods: We conducted a web-based survey with representatives of REDCap member organizations in the United States. The survey captured information on respondent demographics, quality of patient-reported data collected via REDCap, patient experience of data collection with REDCap, and open-ended questions focusing on the advantages, challenges, and suggestions to enhance REDCap's data collection experience. Descriptive and inferential analysis measures were used to analyze quantitative data. Thematic analysis was used to analyze open-ended responses focusing on the advantages, disadvantages, and enhancements in data collection experience.

Results: A total of 207 respondents completed the survey. Respondents strongly agreed or agreed that the data collected via REDCap are accurate (188/207, 90.8%), reliable (182/207, 87.9%), and complete (166/207, 80.2%). More than half of respondents strongly agreed or agreed that patients find REDCap easy to use (165/207, 79.7%), could successfully complete tasks without help (151/207, 72.9%), and could do so in a timely manner (163/207, 78.7%). Thematic analysis of open-ended responses yielded 8 major themes: survey development, user experience, survey distribution, survey results, training and support, technology, security, and platform features. The user experience category included more than half of the advantage codes (307/594, 51.7% of codes); meanwhile, respondents reported higher challenges in survey development (169/516, 32.8% of codes), also suggesting the highest enhancement suggestions for the category (162/439, 36.9% of codes).

Conclusions: Respondents indicated that REDCap is a valued, low-cost, secure resource for clinical research data collection. REDCap's data collection experience was generally positive among clinical research and care staff members and patients. However, with the advancements in data collection technologies and the availability of modern, intuitive, and mobile-friendly data collection interfaces, there is a critical opportunity to enhance the REDCap experience to meet the needs of researchers and patients.

Introduction

Background

Accurate and complete health outcome data directly from patients or study participants (hereon referred to as *patients*) are critical for health care and research [1-3]. Unfortunately, it can be burdensome to extract patient-reported health data that researchers or providers need [4,5]. Collecting patient-reported outcomes data is becoming increasingly important in clinical research and care [6,7]. Self-administered web-based questionnaires, which patients can complete at a clinic or at home, are becoming a conventional approach to collect data for clinical research. Web-based questionnaires have advantages of being low-cost and easy to deploy at scale. A variety of clinical research electronic data capture (EDC) tools exist to streamline remote data collection and management. These systems comply with privacy regulations, integrate with different tools (such as electronic health records [EHRs]) for efficient data collection, and reduce the effort of sharing data [8]. However, user experience, cost, and maintenance of such commercial EDC systems are often prohibitive. An understanding of user experiences and preferences regarding EDC tools is critical in assessing stakeholder needs, satisfaction, and challenges in clinical and research settings.

REDCap (Research Electronic Data Capture; Vanderbilt University) is a global, secure web application for building and managing EDC for clinical research [9,10]. Developed by Vanderbilt University, REDCap is freely available for its consortium members (ie, network of nonprofit collaborators and supporters), who have an established agreement with the university. REDCap is compliant with global privacy regulations (such as the Health Insurance Portability and Accountability Act [HIPAA] of 1996) and used by more than 2.2 million researchers in more than 140 countries [9]. REDCap allows researchers to build and conduct electronic surveys, track and manage study information, schedule visits, and manage databases that are fully customizable and at no cost [11]. REDCap is designed to support data capture for research studies, providing (1) an intuitive interface for validated data capture, (2) audit trails for tracking data manipulation and export procedures, (3) automated export procedures for seamless data downloads to common statistical packages, and (4) procedures for data integration and interoperability with external sources.

Although REDCap is widely used, user needs and preferences of EDC via REDCap have rarely been studied [12,13]. For example, 1 usability study of a REDCap-based patient-facing intervention reported that patient participants found REDCap useful and easy to use but showed concerns about wordiness and inconsistent visual design [13]. Researchers have reported frequently on the implementation, use, and interventions using REDCap [10,14-20]. Understanding the preferences and needs of REDCap administrators and researchers using REDCap to capture data could help enhance existing features and EDC processes in general. While REDCap is a robust clinical research data management system, this study solely focuses on the experience of REDCap as an EDC tool. To the best of our knowledge, such preferences have not yet been studied.

Objective

The aim of this study was to survey REDCap administrators and researchers in the United States to assess their experience with REDCap, including perspectives on advantages, challenges, and suggestions for enhancement.

Methods

Study Settings and Respondents

We conducted a web-based survey with representatives of member organizations listed as REDCap Partners on the REDCap website [21]. The roles of the listed members were unclear at the time of invitation sent via email. The email communication included information related to the study goals, voluntary participation, and a link to the REDCap survey. Respondents were compensated with a US $10 electronic gift card for completing the survey.

Ethical Considerations

This study was reviewed and approved as exempt human subjects research by the Medical University of South Carolina Institutional Review Board (Pro00082875).

Survey Design

We developed a web-based survey with multiple-choice and free-response questions (Multimedia Appendix 1) to capture the perspectives of researchers and administrators from participating REDCap consortium organizations. Our research team includes experts in biomedical informatics, behavioral sciences, mixed methods research, and user experience. The survey included 4 sections, as follows:

- *Demographics*: multiple-choice questions capturing participant role in their respective organization (Q1) and organization use of REDCap (Q2)
- *Quality of patient-reported data collected via REDCap*: Likert-scale questions capturing perspectives (ranging from 1=strongly agree to 5=strongly disagree) on the accuracy, reliability and completeness of data reported using REDCap (Q3)
- *Patient experience with REDCap*: Likert-scale question focusing on perspectives (ranging from 1=strongly agree to 5=strongly disagree) on REDCap usability, including ease of use, success rate, and completion time (Q4).
- *Data collection experience*: Free-response questions asking about the advantages (Q5), challenges (Q6), and suggestions of enhancements related to data collection, patient experience, and engagement (Q7).

Data Collection and Analysis

We collected and managed study data using REDCap EDC tools hosted at the Medical University of South Carolina [22,23]. We generated plots and univariate statistics to summarize the data (eg, frequencies, means, SDs, and percentages). We conducted 1-way ANOVA tests to determine differences in data quality and patient experience variables by participant role and REDCap use duration. For the ANOVAs, the primary role variable was restructured to include "Educators" in the "Other" category due to the low sample size (n=1). Excel (Microsoft Corp) and SPSS (version 29; IBM Corp) were used for analyses. Free-response questions were qualitatively analyzed to identify emerging themes related to REDCap data collection experience [24]. We randomly selected 15% of the responses for initial coding and codebook development. The coding unit was done by the entirety of the participant entry. Thematic analysis of all qualitative data was done over 4 iterations using MAXQDA, during which emergent themes were identified. While the research team reviewed and honed the codes and codebook, 1 team member coded and finalized thematic coding. Discrepancies were resolved through consensus. Emergent themes were organized by frequency and topic, allowing for further qualitative analysis using complex coding query to determine concurrent themes. We reported the total frequencies per code, which may not align with the number of participants. For example, 1 participant may report a code multiple times throughout their response [25]. While thematic analysis allows us to identify principle emergent themes, it also can help identify uncommon trends that may be significant but would require further investigation in follow-up research [26]. Responses from incomplete surveys with missing quantitative or qualitative responses were excluded from the analysis

Results

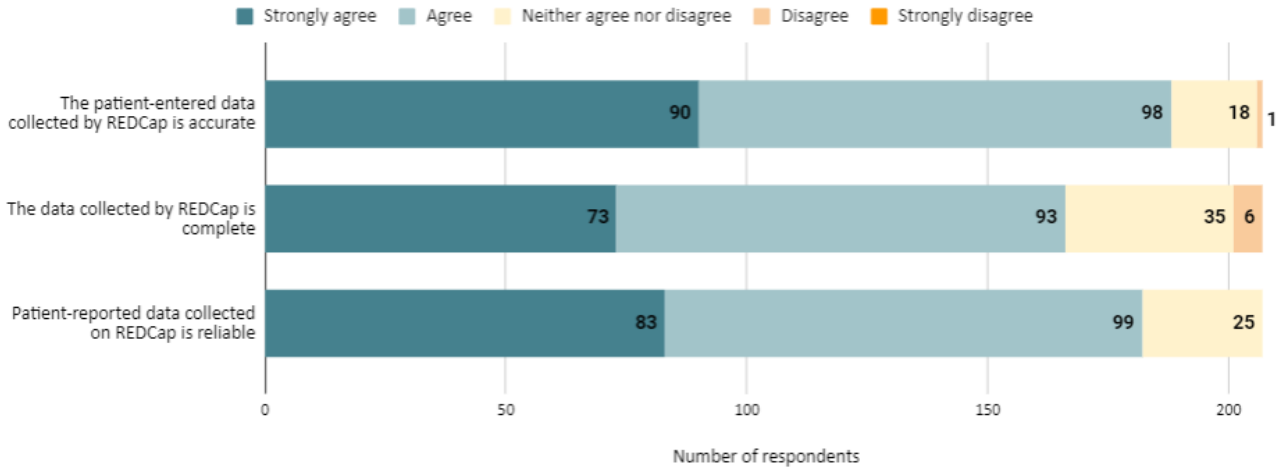
Demographics

Between October and November 2020, 3058 representatives from 1676 REDCap member organizations in the United States were invited to complete the survey. In total, 285 (9.3%) invitees started the survey, of which 207 completed the survey. Most (150/207, 72.5%) respondents were REDCap administrators, followed by researchers (25/207, 12.1%). Furthermore, 1 (0.5%) respondent was an educator and 31 (15%) respondents served in other roles, including IT directors and managers, research coordinators and managers, program managers, project managers, director of research, library directors, and data analysts. Respondents reported that their organization had used REDCap for <5 years (92/207, 44.4%), 5 to 10 years (83/207, 40.1%), or >10 years (32/207, 15.5%).

Quality of Patient-Reported Data Collected via REDCap

We asked respondents about their perspectives of the quality of the survey data, including the accuracy, reliability, and completeness of the data collected using REDCap (Figure 1). Most respondents strongly agreed or agreed that the data collected via REDCap are accurate (188/207, 90.8%), reliable (182/207, 87.9%), and complete (166/207, 80.2%). We observed no statistically significant group differences in accuracy ($F_{2,204}$=1.003; P=.37), completeness ($F_{2,204}$=0.243; P=.78), or reliability ($F_{2,204}$=0.245; P=.78) among respondent role groups. Furthermore, we observed no statistically significant group differences in accuracy ($F_{2,204}$=0.672; P=.51), completeness ($F_{2,204}$=0.045; P=.96), or reliability ($F_{2,204}$=1.712; P=.18) among REDCap use groups.

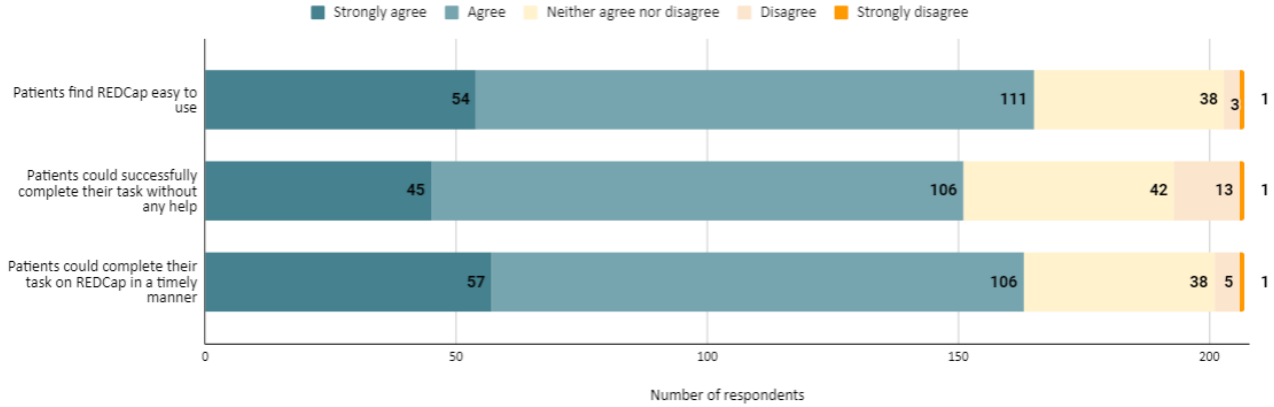
Figure 1. Quality of patient-reported data collected via REDCap (Research Electronic Data Capture).



Patient Experience With REDCap

We also asked respondents about their perspectives on patient experiences with completing surveys using REDCap. Figure 2 summarizes their responses. More than half of respondents strongly agreed or agreed that patients find REDCap easy to use (165/207, 79.7%), could successfully complete tasks without help (151/207, 72.9%), and could do so in a timely manner (163/207, 78.7%). We observed no statistically significant group differences in ease ($F_{2,204}$=2.025; P=.13), successful task completion ($F_{2,204}$=0.671; P=.51), or timely task completion ($F_{2,204}$=2.303; P=.10) among respondent role groups. Furthermore, we observed no statistically significant group differences in ease ($F_{2,204}$=0.711; P=.49), successful task completion ($F_{2,204}$=1.851; P=.16), or timely task completion ($F_{2,204}$=2.000; P=.13) among REDCap user groups.

Figure 2. Patient experience with REDCap (Research Electronic Data Capture).



REDCap Advantages, Challenges, and Enhancement Suggestions

We asked respondents about the advantages, challenges, and suggestions for future enhancements using free-response questions. The analysis yielded 8 primary codes: survey development, user experience, survey distribution, survey results, training and support, technology, security, and platform features. Within each of these themes, responses were further categorized at secondary and tertiary levels. Multimedia Appendix 2 shows the qualitative codebook with illustrative examples for each code. Table 1 shows the frequencies response classification of advantages, disadvantages, and enhancements for each code category based on respondents' responses.

Table 1. Counts and percentages of response classification of REDCap (Research Electronic Data Capture) users[a].

Code	Advantages, n (%)	Challenges, n (%)	Enhancements, n (%)
Survey development			
Design	52 (50.5)	59 (47.6)	40 (47.1)
Survey design	10 (9.7)	39 (31.5)	21 (24.7)
Response and logic	13 (12.6)	22 (17.7)	18 (21.2)

[a]Due to the coding process (eg, double coding), the total number of secondary and tertiary codes may not add up to the primary code or 100%. The percentages are calculated based on the total number of codes in secondary and tertiary categories.

Survey Development and Customization

Respondents perceived that REDCap surveys were generally easy (20 codes) and quick (2 codes) to set up, build, organize, and maintain (2 codes). One participant commented on these topics, “Easy to build surveys Easy to make questions easy to answer Easy to build branching questions.”

However, respondents also noted that incorrect setup by the study staff and limited default formatting options and flexibility could be challenging in developing and completing surveys (3 codes).

While some respondents pointed out that REDCap provides continuous releases with new features (2 codes) and various design and automation options to ask a variety of questions for

efficient data collection (8 codes), respondents frequently pointed out the value of well-designed survey instruments in gathering high-quality information and engaging patients. They reported that complex, poorly designed surveys and ambiguous instructions (39 codes) could result in poor patient experience, potentially impacting the survey response rate and quality of data gathered. Respondents provided suggestions for enhancing survey design capabilities to streamline survey design and layout for the patients (including simplifying survey formatting, survey nesting abilities, and use of embedded fields). Respondents also suggested pilot testing of surveys before sending them out to patients (3 codes) and for study teams to follow best practices and guidelines to be more informed in survey methodologies and development. For example, 1 respondent commented:

> *Study teams following best practices with survey methodology and design, which can involve keeping surveys short & sweet, choosing appropriate field types for the question at hand, phrasing questions and response options well to reduce mental burden and make it easier for patients to answer questions.*

Respondents also reported that the availability of various response types, data validation, and branching logic ensure high-quality data collection (13 codes). One respondent commented on this advantage, "The wide array of validations can help patients enter data correctly."

Another respondent noted similarly, "Data validation and branching logic make participants conform to data standards and allows researchers to obtain higher quality data."

While data validation was discussed positively, respondents more frequently noted the challenges with response and logic types (22 codes), often pointing out that the actual response and logic types available from REDCap are not conducive to good survey design. One respondent made a clear reference to this issue saying, "It all depends on who sets up the survey, but until recently it has been a challenge to create grids of disparate data entry fields."

In addition, some respondents noted that due to the logic types, patients can make critical mistakes affecting the completeness of the data:

> *...branching logic at a very question to determine if they qualify or not. Sometimes, they accidently select different value in a hurry, and the survey gets completed. It is hard for them to change the response or refill the survey without admin help.*

Respondents noted many enhancement potentials within this category, such as voice input (4 codes), superior data entry experience (5 codes), use of a more conversational approach in response types (1 code), more effective multimedia (5 codes), and gamification of survey (2 codes). While REDCap offers multimedia options, respondents often suggested that options become more interactive and effective:

> *...more visual aids in questions, and the ability to answer with images. For example, by painting the areas afflicted on an image.*

One respondent explained how multimedia may be further useful:

> *...ability to add images to response options. Especially when working with minorities (traffic lights, or smiley faces).*

In addition to the design of the surveys, respondents noted that while REDCap surveys are readily customizable (7 codes), there are far more reported challenges (17 codes) and need for enhancements (15 codes). Respondents noted customization was not possible in some cases: "Default formatting options are limited."

However, many respondents focused on the lack of multi-language support (9 codes) as the critical challenge:

> *...multi-linguistic support. This is always a challenge for any software system/platform, and REDCap is no different...*

They frequently suggested enhancements to include multi-language support (8 codes) and customizations in forms' appearance (6 codes). For example, 1 respondent mentioned, "Allow for some more customization of the overall look/feel of surveys."

With respect to challenges with survey interactions, respondents reported that REDCap capabilities at the time did not send new surveys or allow patients to complete future surveys if previous surveys were incomplete (2 codes). One respondent mentioned the following:

> *...[t]he longitudinal design functionality in REDCap requires a participant to take each form before moving to the next, but our experiment design does not require this, and sometimes people will miss sessions and need to move on to the form for the next one. But if we stack all of the forms in one event, we cannot direct people to an individual form, only to the queue.*

One participant commented on REDCap's "inability to provide staff log-in status." (1 code). Respondents requested features for internal messaging or chat between study staff (2 codes), enhancing flow and cross-linking between projects (2 codes), ability to easily add study staff members outside of the organization (1 code), and ability for patients to skip longitudinal surveys (1 code).

User Experience

Respondents perceived REDCap to be easy to use for both patients (ie, to take surveys) and the study staff (ie, to build and distribute surveys; 57 codes). One respondent commented as follows:

> *REDCap is the easiest way to survey patients, families, and staff who are not part of our study team. We would not be able to conduct these surveys without it!*

They also perceived REDCap to be user-friendly (11 codes), simple (8 codes), intuitive (3 codes), timely (2 codes), and reliable (3 codes). Although some respondents reported REDCap allows for quick data collection (7 codes), they perceived that

lengthy or poorly designed surveys (eg, too many clicks and not enough instructions) could lead to fatigue and poor participation (15 codes). While the usability perceptions were generally positive, respondents reported that the platform was not as user-friendly or outdated as other commercial data collection platforms (4 codes), unintuitive (2 codes), and clunky for study staff (4 codes). They reported that "REDCap is not the simplest tool to learn how to use" for study staff (4 codes) and patients (3 codes). Respondents suggested the need to enhance accessibility features, such as the ability to change font size, screen reader view, and text-to-voice, among others (3 codes). In total, 8 (3.9%) of 207 respondents reported that the REDCap interface was advantageous for study staff considering its consistent interface and automated features, which reduce burden.

Respondents generally reported REDCap's visual user interface as challenging to use. Although some respondents perceived the interface to be clean or simple looking (9 codes) and optimized for various devices (5 codes), other respondents perceived that REDCap's interface was not modern looking (7 codes) or appealing (5 codes). One respondent mentioned, "The web interface of our survey pages are very basic, and narrow," whereas another respondent said, "[REDCap has] Very set layout of each item, can't make it look more 'modern' like other websites are at this time."

Respondents considered REDCap as not having a configurable design (4 codes) and some noted the user interface's poor functionality (8 codes). One respondent described both issues when explaining the challenges of the user interface:

> *REDCap is simply not user friendly in any way. The data structures are often too rigid and frankly outdated in being an effective tool for data collection.*

Respondents suggested the redesign of the REDCap user interface to be consistent with modern data collection platforms (27 codes), options to change the visual appearance and formatting of the surveys (3 codes), adding progress tracking aids (such as an automatic progress bar) for patients (2 codes), and a more flexible interface (1 code).

Some respondents appreciated REDCap's mobile access (4 codes), availability of mobile apps for study staff (REDCap mobile app; 2 codes) and patients (MyCap; 6 codes) supporting offline data collection, and perceived REDCap to be easy to use on mobile devices (3 codes) and mobile friendly (5 codes). While respondents appreciated the mobile interface, they reported that the mobile experience is affected by poor and suboptimal mobile user interface and scaling on smaller screens (5 codes). One participant reported the following:

> *We design our surveys on a computer, but many of our participants use their phones. We try to check how answers scale when the screen size changes, but some phones rescale to a different aspect ratio leading to challenges.*

They also reported that although the REDCap mobile app is available for study staff, it is not ideal and is difficult for study staff to set up the app (4 codes). One respondent mentioned the following:

> *I think that the REDCap mobile app is a bit too far separated from the web version, in as much as there is no access to external modules and other important features.*

Respondents suggested a need for an enhanced mobile app and interface (21 codes), including advanced capabilities for the study staff to view study records and perform analysis (2 codes) and push notifications (2 codes). One respondent mentioned the following:

> *[They need] better workflows with mobile phones, like notifications instead of just text messages. Something like an App except not the current one which is focus on asymmetric internet access.*

Respondents also commented on patient experience with REDCap. Overall, respondents noted that REDCap makes it easier for patients to complete the surveys at their convenience (10 codes), all while increasing engagement levels (9 codes). They saw REDCap as a way to make data collection more efficient and empowered (2 codes), especially as patients did not need to register or remember usernames or passwords to use the platform (3 codes). One participant said, "[Survey] Can be done at the patient's convenience from any digital device." A common challenge reported was the patient's desire and motivation to complete the surveys, being able to use the platform, and fatigue with lengthy surveys (13 codes). Suggestions for improving patient experience included maintaining engagement using visual aids and gamification (3 codes), a patient dashboard to keep them up to date on status of longitudinal studies (1 code) and making the platform more patient friendly (1 code). One respondent commented as follows:

> *For longer surveys, having a way of maintaining engagement by making the surveys more interactive (e.g. fun feedback to participants as they progress) would be nice. Some periodic messages of encouragement like "Great job!" "Keep it up!"*

Survey Distribution and Reminders

Respondents found it advantageous that REDCap included multiple ways to invite patients, such as emails or embedded links (4 codes). REDCap surveys were easy to distribute (11 codes) and could be automated and scheduled on a timeline easily. One participant commented on this aspect, "It can send surveys to participants directly, and on a schedule when the project is longitudinal." REDCap's ability to send patients custom links was an advantage respondents liked (3 codes): "For online surveys: able [to] send individualized email links...automated email with message that has piping upon completion." One respondent pointed out that there was "no scheduling component for visits" and suggested this feature. One respondent suggested the ability to send attachments with automatic notifications.

In addition, the ability to send completion reminder emails to patients was reported to reduce the burden on clinic staff while engaging patients (7 codes). Reminders also allowed the study staff members to follow up on incomplete surveys but 1 respondent mentioned that this was challenging while respondents suggested for improvements in customizing

reminders and enhanced tracking for incomplete surveys longitudinally (3 codes):

> *If there was a more efficient way to upload and manage patient invitations, as well as identify which patients have completed the survey within previous xx months therefore a new survey invitation does not need to be sent.*

Respondents noted patients sometimes missed invitations and reminders because email service providers blocked the emails (2 codes): "We have had email providers block REDCap emails, specifically Yahoo.com email." There was also confusion about the email sender as the emails were "from" REDCap instead of the study staff (2 codes):

> *From my experience... The emails that are sent out to respondents are not user friendly. The 'From' text box comes from REDCap, not from my email address.*

In addition, this respondent noted the emails were not user-friendly, sometimes arriving with broken links going to patient's junk mail, and requiring patients create a completely new log-in to complete a survey. One respondent suggested REDCap may "make it easier to send mass emails that are individually linked with the patient's profile; create a prettier or more visually appealing interface for patients." Furthermore, integrations to link communications to personal calendars were thought to be beneficial (3 codes). Respondents wanted a way to automatically opt out patients from surveys that were being distributed over a period (2 codes). One participant stated they, "would really like to be able to set a flag for opt-out subject [s] when distributing surveys over a period of time. We currently have to remove their emails to prevent future distribution."

Respondents commented on the "Save and Return" feature (25 codes), which allows patients to leave and return using a unique code to complete the survey at a later time. Although REDCap's Save and Return feature existed, respondents noted that this feature was often difficult to use (15 codes). They reported that patients may forget or not save their return code or may not know how to return to the survey, resulting in incomplete data or delay in data collection. One respondent commented, "It is not always obvious how to 'save and return later' if that is an option or even be aware that that is an option." Respondents suggested improvements (9 codes) to send the unique save and return code via emails, with reminders and save in invitation logs such that the study staff could provide it to patients if needed. In addition, respondents suggested that improving user-friendliness and patient awareness of this feature could increase response rates and data completion. A participant noted the following:

> *If they [patients] don't complete the survey the first time they often forget their return code and lose it. It would really help if the reminder emails had the return code, of if it could be included on the survery [sic] invitation log page that would make it much easier to find and give to the patient.*

Results and Data

Respondents liked that REDCap made data exportation easy for storage and analysis purposes (8 codes). Not only was it easy to export data out of the REDCap survey tool, it also made the analysis of the data much easier for the study staff, even those with minimal statistics training. As 1 respondent put it, "[REDCap has a] good translation into a dataset [and] easy statistics for those with minimal statistical training." Respondents (4 codes) pointed out the need for improving data exports and seamless communication with third-party solutions to send and receive information:

> *Being able to send to communicate and receive information from other software programs like Clinical Conductor for Demographic information and seamless data uploads.*

Respondents perceived that it is easy to create reports and monitor patient responses on REDCap and review specific data points (5 codes). Some respondents provided suggestions to edit charts and graphics as well as being able to share user- or survey-specific data (3 codes). For example, 1 respondent mentioned the following:

> *Ability for researchers to edit/modify graphics that can be automatically displayed with reports within redcap. This would facilitate researchers' ability to use those charts."*

Another respondent mentioned, "built in tools to share summary-level data (you vs the whole study) or findings." While respondents perceived that REDCap allows capturing accurate and complete high-quality data (3 codes), 1 respondent mentioned the following:

> *As with every self-service data entry portal accuracy of self-service data entry is wildly unreliable. There is real value to having a trained rep assisting the client enter information, when possible.*

Training and Support

Respondents reported that REDCap's active online community and support allowed REDCap users (including administrators and researchers) to find information and answers on how to manage, design, and conduct surveys (8 codes): "...it has a huge user base and a great consortium full of all the information you need to begin administering [surveys]." Respondents mentioned needing REDCap or IT support for patients to complete consent forms or surveys (12 codes). Although support existed for survey designers and administrators, it did not extend to patients completing surveys. Respondents suggested REDCap needed a way to educate or support patients in completing surveys (10 codes) and obtain help via on-demand messaging to study staff members (2 codes). As 1 participant suggested, REDCap should allow patients to "Click icon and get video explaining any information on a field." Another participant asked that REDCap have the following:

> *Dedicated instrument defined support button at the top that takes participants to a page made by the study team where we can put in a zoom room link monitored by study staff, phone numbers, or some pointers on definitions/examples on the instrument.*

Respondents also suggested a need for obtaining standardized patient feedback surveys to better engage them and understand their experience (6 codes).

Although some respondents mentioned REDCap required minimal training to get started (7 codes), some respondents (especially REDCap administrators) mentioned the need for training survey designers to set up REDCap tools and surveys to design high-quality surveys (7 codes). When asked about challenges, 1 participant mentioned the following:

> *Lack of resources for support (in person- phone) and functionality. It is not always easy and takes a lot of time to build tools. Not able to use to its fullest capacity or correctly—basically training ourselves. Library or community network does not help either. Not knowing how to set up properly more complicating functions inhibits usage.*

Respondents suggested more information and mandatory training for survey builders, including better guidelines and training videos to enhance builder and patient experience (8 codes). Respondents also perceived that patients taking surveys often do not understand how to fill out surveys or certain questions (8 codes) and having expert survey designers and well-designed surveys could alleviate these concerns (1 code).

Technology

Respondents often noted challenges of access to the internet and devices (51 codes) as well as technology literacy (33 codes):

> *Patients [without] a computer, device, or smart phone may not be able to use REDCap.*

As REDCap is web based, data collection could be difficult in rural and low-resource areas due to lack of access to technology (4 codes), such as a computer or reliable internet connection. Another participant noted, "I do work in global health, so our colleagues in resource-limited settings have challenges with the internet connection."

They also noted REDCap's ability to integrate with other technologies, such as messaging tools (eg, Twilio) as well as open application programmable interface to be beneficial (11 codes). In comparison, 1 participant noted as a challenge that, "integrating the ReCap [sic] extract with Epic [EHR] data. But once the system is setup it's easy to maintain." Respondents suggested integrations with other clinical trial management systems for seamless data transfers and EHRs to conduct surveys or autopopulate patient medical information:

> *The only other thing that would be super cool is if it could blow surveys into EPIC for documentation when needed.*

Respondents also referred to the informed consent capabilities of REDCap (8 codes). Even though they noted the consent module to be advantageous to obtain remote informed consents especially after the COVID-19 pandemic (5 codes), respondents suggested more enhancements, such as a 1-step consent process (3 codes).

Security

Respondents commented positively on the security and compliance of REDCap (15 codes). They reported that HIPAA compliance and the ability to store patient data securely are important advantages of REDCap. One participant commented that "all client data can be stored in one HIPAA compliant platform."

Respondents mentioned mistrust of technology (3 codes) could make patients feel uncomfortable sharing medical information on web-based platforms. One respondent commented that surveys requiring password protection are difficult for patients. They also provided enhancement suggestions (2 codes) related to maintaining HIPAA compliance, enhancing security, and assuring patients that their health information is safe and secure with REDCap.

Platform Features

Respondents found REDCap advantageous in enabling researchers to collect and patients to provide health data remotely (23 codes):"It has made it much easier for patients to submit their questionnaires and information using an online platform," especially during and after the COVID-19 pandemic.

Respondents perceived REDCap as a comprehensive or versatile (5 codes) data collection solution noting the following: "It provides us a comprehensive tool for collecting, tracking, and managing patient data and outreach." They also noted administration and maintenance (3 codes) to be advantageous as REDCap allows "being able to maintain administrative research tasks together with the data collection." They noted REDCap's offline data collection (using REDCap mobile apps) to be challenging (3 codes) and suggested that the offline feature should be improved for better data collection experience (2 codes). In addition, respondents noted the familiarity with REDCap among researchers (2 codes) and seamlessness (1 code) for the study personnel to be advantageous.

In addition, REDCap being available for free to REDCap consortium members was sought to be beneficial (10 codes). While some respondents noted REDCap being simpler and easier than other commercial platforms and paper forms (3 codes), some also noted that REDCap's interface was not easy to use or user-friendly compared to modern data collection tools (5 codes).

No Input

Respondents did not provide inputs with respect to advantages, disadvantages, and enhancement suggestions stating lack of experience or ability to provide inputs or not using REDCap for patient data collection (81 codes). Some nonsensical or unrelated comments lacking information context or irrelevant responses were excluded from the analysis. For example, when asked about enhancement suggestions for REDCap, 1 participant responded, "To REDCap or??."

Discussion

Overview

This study aimed to identify the advantages, challenges, and future opportunities for enhancements from the perspectives of REDCap administrators and researchers. To the best of our knowledge, this is one of the early studies of user perspectives on REDCap services and features. We believe that the findings of this study will aid REDCap developers and consortium users in better understanding stakeholder needs to enhance and customize REDCap features as well as researchers in improved survey development and data collection.

Principal Findings

Respondents had overwhelmingly positive perceptions of REDCap's survey design and data collection interface. The vast majority of respondents agreed or strongly agreed that data collected via REDCap were accurate (188/207, 90.8%), reliable (182/207, 87.9%), and complete (166/207, 80.2%). They found REDCap advantageous as it is free for its consortium members, secure, and easy to use. Respondents also perceived REDCap as easy and flexible to create and customize surveys including a variety of response and validation options, which make data collection easier for survey takers. However, respondents pointed out that poor survey design—often attributed to human factors (eg, lengthy forms and lack of knowledge among study staff) or technology limitations (eg, restrictions in survey and visual formatting in REDCap)—could result in poor patient experience and, ultimately, response and completion rates. Optimal design of survey forms is critical for assuring patient comprehension of the forms and accurate data collection [27,28]. Furthermore, direct investigations of REDCap user experiences and preferences could allow better understanding of the need for study staff and patient education. In addition, further research related to user needs for survey development and optimization can lead to enhancing their experience of developing high-quality surveys. One respondent pointed out the following:

> *It [REDCap] needs a much better understanding of how users engage the questions on a form (e.g., sit and watch users and staff try to figure out acceptable data type entries!). Needs a solid revamping in how it works "out front" and to run a series of user groups—patient and staff.*

Although respondents appreciated the availability of REDCap's community support for administrators and study staff, they pointed out that REDCap has room for improvement in this realm: the tool is not simple to learn, and there is a need for more training of study staff to help develop efficient, unambiguous survey instruments that can enhance patient experience. Poorly designed surveys and questions could potentially lead to incomplete responses and inaccurate data. Respondents pointed out the need for supporting patients, especially to ensure they understand the questions and can obtain help when needed in filling out surveys. Direct help from study staff members to fill out surveys or having the ability to directly send a message to study staff could alleviate misunderstandings and errors in completing surveys. Previous research suggests that the ability to obtain clarifications about survey questions can enhance response accuracy [28]. Further research and availability of resources are necessary to guide study staff members in creating well-designed instruments. In addition, understanding the factors affecting patients' experience in completing REDCap surveys and reasons for misunderstanding and errors could also enhance the REDCap experience and health data collection processes.

Opinions on patient experience and usability were more mixed. Most respondents agreed or strongly agreed that patients found REDCap easy to use (90.4%), able to be completed without assistance (79.8%), and able to be completed in a timely manner (87.5%). These strongly positive perceptions of REDCap usability are consistent with a prior study in which 6 out of 7 participants needed no help using REDCap, achieved 71% to 100% task completion, and provided 89% positive reaction words [13]. Qualitative outcomes showed that respondents perceived REDCap made it convenient for patients to provide data remotely without having to log in or remember credentials. Although they commented that patients can complete REDCap surveys using a device of choice (such as a laptop or mobile), technology access and technology literacy appeared to be a concern. Living in rural or low-income areas also presented issues for survey access. Respondents noted low-resource areas without stable internet access meant data collection was not reliable. Lack of internet access not only meant surveys could not be accessed but also meant the data collection process could be interrupted. REDCap's MyCap and REDCap Mobile app can allow study staff and patients to complete the collection of data offline, but they were also deemed challenging due to the lack of features compared with the web interface. In a study by Doyle et al [19], the REDCap mobile interface was less favorably received by participants. Similarly, REDCap's *Save and Return* feature allows users to complete surveys at a later time, which could be helpful during poor internet access; however, respondents recommended enhancements in the feature to improve patient experience, specifically an easier way for patients to remember and retrieve the return code. One participant noted this difficulty that patients face in attempting to use the feature:

> *If they don't complete the survey the first time, they often forget their return code and lose it. It would really help if the reminder emails had the return code, or if it could be included on the survey invitation [log-in] page...*

It is imperative to better understand patient and research participant experience with REDCap in completing surveys via larger and direct studies.

This study identified opportunities to improve the usability of REDCap. Respondents suggested enhancements in the patient-facing survey user interface to be in line with present EDC tools on the market, wanting a sleeker, modern, and cleaner looking interface. A variety of EDC tools are available for health care and non–health care data collection providing modern, device-friendly, and intuitive user interfaces to promote patient engagement [29-32]. In recent years, virtual conversational agents or chatbots have emerged as intuitive and engaging mediums for data collection. Modern data collection tools allow

survey designers to develop chatbot-based interactions to collect health data mimicking human-to-human conversations. Studies have shown that individuals prefer chatbot-based conversational data collection experience in comparison to traditional web-based forms [33,34]. Visual and graphical enhancements in REDCap appearance of surveys, patient communication, and researcher interface could support modernization of REDCap-based surveys, thus providing study staff and patients with clear and effective experience of health data collection.

Respondents wanted the mobile interface updated to look more like other commercial products, such as Qualtrics or SurveyMonkey. As more individuals are using mobile devices to obtain health information, it is of great importance to enhance their experience with mobile data collection [35]. They also suggested that the mobile apps have similar features as the web-based REDCap. Other requests included REDCap to support more languages or a translation service, where surveys could be translated to patients' preferred languages. Though it has some language capabilities, including Spanish, respondents wanted more language options built into REDCap. In addition, there was concern about the literacy of patients leading to suggestions for REDCap to include tools allowing patients with various literacy levels to access surveys. Respondents suggested inclusion of voice capabilities and more multimedia and gamification features in response options, such as a picture interface where patients could locate their pain visually for researchers. Inclusion of these features could further enhance the experience among patients with higher accessibility needs and low literacy. We also noted that some respondents suggested features that were available within REDCap at the time of conducting the survey. Suggestions included availability of REDCap's mobile version, embedded fields for responses, and integrations with messaging services such as Twilio. This again points out the need for education among study staff and organizational administrators to enable the optimal and effective use of REDCap features.

Limitations

This study is not without limitations. Although we recruited over 200 respondents, the sample size is small in comparison with the existing user base. We recruited fewer researchers (25/207, 12.1%) than administrators (150/207, 72.5%) who may be more directly involved in survey design and data collection. We also did not ask for participants' training and experience with REDCap. Future studies should focus on better understanding user perspectives (especially researchers) while also considering the type and amount of REDCap training received by the user. We asked individuals' opinions that are valuable but may be subject to bias, incomplete recall, or lack of information. For example, we asked information about their institution's REDCap use, but we did not include a response option or decline responding if they did not have accurate information. We also used REDCap as the platform to conduct our survey, which may have potentially biased responses by familiarizing participants with REDCap more than necessary. Participants' free-ended responses may have been influenced by how our study was designed or how the features were used. Future, more direct studies are warranted to better understand preferences. We recruited respondents from current REDCap consortium members, who may be more likely to believe REDCap is highly usable, as they may act as REDCap champions within institutions. We may be missing critical information by not capturing the perspectives of people who are not frequent users or consortium members. Future research should capture opinions of novice or past REDCap users. We also did not ask for information about participants' institutions, REDCap versions and plug-ins used, or institutional policies and customizations. It is possible that participant feedback may be related to institutional requirements or policies. Furthermore, we asked researcher and administrator opinions on patient experience. However, we did not directly assess the patient or research participant experience. Understanding patient experience is important to study in future research. In addition, a comparison of the REDCap experience with other EDC platforms could provide a better understanding of study staff and patient needs. A recent study compared individuals' experience in completing health forms using REDCap versus a chatbot platform. The results revealed that over 69% of participants preferred a chatbot for data collection with higher usability and net promotor scores for the chatbot [33]. The chatbot provided superior engagement and interactivity and was perceived as more intuitive than a standard, web-based REDCap interface. Future studies should look into better understanding study staff and patient needs to optimize survey development and data collection experience.

Conclusions

This pilot study aimed to assess stakeholder perspectives on experience with REDCap as an electronic health data collection tool. The findings revealed researchers and administrators perceive REDCap as a valued, low-cost resource that enables them to remotely collect and report health data in a secure and easy way. They also indicated a generally positive health data collection experience by clinical research and care staff members and patients. Although, with the advancements in data collection technologies and availability of interactive and intuitive user interfaces, there is a critical opportunity to enhance the REDCap experience to meet the needs of its vast user base of researchers and patients.

Abstract

Background: Interpretability and intuitive visualization facilitate medical knowledge generation through big data. In addition, robustness to high-dimensional and missing data is a requirement for statistical approaches in the medical domain. A method tailored to the needs of physicians must meet all the abovementioned criteria.

Objective: This study aims to develop an accessible tool for visual data exploration without the need for programming knowledge, adjusting complex parameterizations, or handling missing data. We sought to use statistical analysis using the setting of disease and control cohorts familiar to clinical researchers. We aimed to guide the user by identifying and highlighting data patterns associated with disease and reveal relations between attributes within the data set.

Methods: We introduce the attribute association graph, a novel graph structure designed for visual data exploration using robust statistical metrics. The nodes capture frequencies of participant attributes in disease and control cohorts as well as deviations between groups. The edges represent conditional relations between attributes. The graph is visualized using the Neo4j (Neo4j, Inc) data platform and can be interactively explored without the need for technical knowledge. Nodes with high deviations between cohorts and edges of noticeable conditional relationship are highlighted to guide the user during the exploration. The graph is accompanied by a dashboard visualizing variable distributions. For evaluation, we applied the graph and dashboard to the Hamburg City Health Study data set, a large cohort study conducted in the city of Hamburg, Germany. All data structures can be accessed freely by researchers, physicians, and patients. In addition, we developed a user test conducted with physicians incorporating the System Usability Scale, individual questions, and user tasks.

Results: We evaluated the attribute association graph and dashboard through an exemplary data analysis of participants with a general cardiovascular disease in the Hamburg City Health Study data set. All results extracted from the graph structure and dashboard are in accordance with findings from the literature, except for unusually low cholesterol levels in participants with cardiovascular disease, which could be induced by medication. In addition, 95% CIs of Pearson correlation coefficients were calculated for all associations identified during the data analysis, confirming the results. In addition, a user test with 10 physicians assessing the usability of the proposed methods was conducted. A System Usability Scale score of 70.5% and average successful task completion of 81.4% were reported.

Conclusions: The proposed attribute association graph and dashboard enable intuitive visual data exploration. They are robust to high-dimensional as well as missing data and require no parameterization. The usability for clinicians was confirmed via a

user test, and the validity of the statistical results was confirmed by associations known from literature and standard statistical inference.

Introduction

The amount and availability of data around us are constantly increasing. Researchers are increasingly using statistical models to guide their data-driven scientific work. However, as the relationships discovered increase in complexity, the models themselves are becoming gradually less transparent. In high-stake decision fields, such as health care, data explanation and justification of decision-making are essential for the applicability and distribution of novel technologies. Here, we present new methods for extracting statistical insights from large data sources and visualizing the results based on graph structures. The methods balance complexity and comprehensive description of the results on the one hand and clarity and interpretability for clinicians and patients on the other hand.

The availability of large quantities of medical data is growing [1,2] and thus enabling machine learning methods to play an ever-increasing role in medical research [3-5]. With the undoubtedly numerous advantages of “big data” in medicine arises the problem of increasing complexity and lack of transparency for clinicians [6,7]. In this context, the call for more interpretable statistical models is gaining more attention [8,9]. In addition to the interpretability of the applied models and results, good data visualization methods are key for the knowledge communication with clinicians and patients. Many methods have been developed over the years [10-12].

For data-driven analysis, approaches originating from the mathematical field of graph theory gain an increasing amount of attention for health care applications [13]. A graph consists of nodes representing arbitrary objects and edges each connecting 2 nodes corresponding to some form of relation between them. Graph-based database technologies, such as Neo4j (Neo4j, Inc) [14], allow more efficient retrieval of large amounts of data compared to traditional relational database systems [15,16], and many software tools for interactive, graphical user interfaces are available [14,17-20].

Knowledge graphs are a form of data representation capturing large quantities of data from potentially multiple sources in a graph structure. Existing data are usually processed and jointly represented to enable accessible, often visual, exploration of condensed knowledge across different data modalities and sources. Owing to their intuitive and versatile character, knowledge graphs have many applications in the medical domain [21]. Examples are the representation of biomolecular pathways [22], research related to COVID-19 or diabetes [23,24], knowledge about dietary supplement [25], and networks of complex disease interactions [26].

Statistical analysis discovering relations between variables within a medical data set can be captured within a graph structure. In this context, Bayesian networks are of increasing interest in the medical domain [27,28]. They represent conditional dependencies as edges and the absence of an edge as probabilistic independence [29]. Using these conditional dependencies, Bayesian networks can be used for inferring neural networks [30] or diagnosis prediction [31]. However, they are sensitive to missing data during the model training process [32]. Markov models describe states, for example, events during a patient’s hospital stay, as nodes and transition probabilities between states as edges [33]. As a result, Markov models are applied for the analysis of time-dependent dynamic processes in health care [33-35]. In association rule learning, relations between variables are extracted from a data set based on different measurements of interest, for example, conditional probability [36]. This concept is applied to extract patterns from clinical databases [37] or find suitable drug treatments [38]. All 3 approaches capture variable relations across a complete data set.

In this work, we developed the attribute association graph (AAG), a new graph structure capturing statistical knowledge extracted from a data set. We aimed to combine the focus of knowledge graphs on interpretability, accessibility, and visual exploration with graph-based statistical methods. We sought to develop a novel and robust tool for statistical analysis that is intuitively usable by physicians. We tailored our approach specifically to the needs of data-driven analysis in the medical domain by incorporating disease and control cohorts and aiming for robustness to high-dimensional or not normally distributed data, small sample sizes, and missing values. The graph is visualized, and nodes and edges representing variable relations of interest are highlighted to attract the attention of the user and facilitate the data analysis. We complemented the AAG with a dashboard for further data exploration. Only mouse clicking and search bar prompting in English are required for the navigation of the graph and dashboard. We aimed to evaluate the validity of the statistical analysis represented by the graph structure and dashboard. Therefore, we conducted an exemplary data analysis based on a large epidemiological study. The results of the analysis were compared with findings from literature and standard statistical inference using CIs of Pearson correlation coefficients. In addition, we assessed the usability of the visualization for medical researchers. We conducted user tests with physicians using standardized usability tests, user tasks, open feedback questions, and a free data exploration. The generated graph structure and dashboard are freely available to clinical researchers for exploration on their own computers.

Methods

AAG Definition

Our goal is to visualize participant attributes and the statistical traits and relationships between them in a compact, interpretable, and intuitive way. As a participant attribute, we consider a singular value or semantically meaningful value group for a variable, for example, "the participant was diagnosed with hypertension" or "participant has total cholesterol level above 200 mg/dL." For the statistical analysis, we use simple metrics, which were found to be intuitive for clinicians [39]. The metrics are calculated for a disease and control group and compared to identify attributes with a large deviation. Thus, in contrast to traditional association rule mining [36], Bayesian networks [29], or Markov models [34], attributes can be selected, which appear more often in the disease group compared to the control group. As we analyze relations of singular attributes instead of associations between variables, our results are methodologically different from correlation analysis, such as chi-square tests [40] or Pearson correlation coefficients [41].

In the AAG, single attributes are captured as nodes and visualized as colored spheres of different sizes. Each node has parameters for the name of the attribute's variable, its value, and a short description including units of measurement for metric variables. In addition, we assigned labels to each node depending on the broad categories of the represented attribute, for example, *Cardiac*, *Condition*, or *Medical History*.

For metric variables, we calculated reference ranges based on their value distribution within the whole data set. We defined the reference range as all values within SD around the mean. On the basis of reference ranges, we derived 3 additional nodes for the attribute associated with values below, within, and above the reference range. The 3 nodes inherit the parameter's *name* and *description* from the original nodes. They have the value *low*, *normal*, or *high*. In addition, they contain the lower and upper bound of the reference range. All participants are assigned to 1 of the 3 nodes based on their attribute value. Thus, metric values, for example, patient laboratory results, are labeled in comparison to the whole data set and enriched with semantics.

In addition, we enriched the nodes with several statistical measurements of the described participant attribute within the data set. The resulting parameters are given in Table 1. Note that the relative attribute share accounts for the common problem of missing data [42,43] and is an upper bound to the relative total share. By measuring the difference and quotient of relative attribute shares, the distinction in attribute distribution between the 2 groups is expressed. The size and color of the node visualization capture parts of these measurements to support the data exploration with visual highlights.

Table 1. Statistical parameters for a node describing attribute *a* together with a short description and formula[a].

Parameter	Description	Formula
Absolute count	Number of group members having attribute *a*	c_i
Relative total share	Fraction of group members have attribute *a*	
Relative attribute share	Relative total share, missing value adjusted	
Relative attribute share difference	Absolute difference of relative attribute shares	
Relative attribute share quotient	Fraction of maximum and minimum relative attribute share	

[a]Parameters with subscript *d* refer to the disease group. Parameters with subscript *c* refer to the control group. Subscript *i* refers to a definition for both groups, that is, $i \in \{d,c\}$. Let g_i be the group size, and  be the number of group members having a valid value for the attribute *a*, that is, not a missing value.

We assigned a frequency label impacting the node's size based on the maximum relative attribute share. Therefore, a node's size indicates how common an attribute is within one of the groups. Let p be the maximum relative attribute share of a node. The node is assigned to 1 of the following 3 frequency label types:

- $p \geq 0.5$: labeled as *highly frequent*; the node has the largest size.
- $0.1 \leq p < 0.5$: labeled as *frequent*; the node has a medium size.
- $p < 0.1$: labeled as *infrequent*; the node has the smallest size.

In addition, we assigned a distinction label to each node from which its color is derived. The distinction label, and thus the node color, indicates how much the attribute distribution differs between groups. Here, brighter colors signal a larger distinction. We reuse the symbols in Table 1. Each node is assigned 1 of 5 colors and distinction label types:

- $\delta \geq 0.2$ or $\gamma \geq 2.0$:
  - $p_d > p_c$: labeled as *highly related*; the node is colored in red.
  - $p_d < p_c$: labeled as *highly inverse*; the node is colored in blue.
- ($\delta \geq 0.1$ or $\gamma \geq 1.5$) and $\delta < 0.2$ and $\gamma < 2.0$:
  - $p_d > p_c$: labeled as *related*; the node is colored in orange.
  - $p_d < p_c$: labeled as *inverse*; the node is colored in turquoise.
- $\delta < 0.1$ and $\gamma < 1.5$: labeled as *unrelated*; the node is colored in beige.

Combining size and color, nodes that are displayed largest and brightest represent attributes with high frequency and large distinction between groups. As all parameters calculated for an individual node depend only on data for a single variable, the computation time needed for the calculation of all nodes of the graph scales linearly with the number of variables and linear with the sample size.

In the AAG, edges point from a source node to a target node, indicating the conditional dependence of the target attribute on the source attribute. The edges are displayed as lines with arrows pointing from the source node sphere to the target node sphere. The calculated statistical parameters for the conditional dependence are presented in Table 2. Note that the relative conditional share is conceptually equivalent to confidence in association rule learning [36]. By measuring the difference and quotient of the relative conditional share and the unconditional relative attribute share of the target node, the impact of the added condition is expressed. This impact can be negative if the unconditional relative attribute share is larger than the relative conditional share. We assign a type to each edge to capture the impact of the added condition. In the visualization, the line thickness of the edge is given by its type. We reuse the symbols in Table 2. Each node is assigned to 1 of the following 3 types:

- $\delta' \geq 0.2$ or $\gamma \geq 2.0$: assigned to the *high conditional difference* type; the edge has the thickest line.
- ($\delta' \geq 0.1$ or $\gamma \geq 1.5$) and $\delta' < 0.2$ and $\gamma < 2.0$: assigned to the *medium conditional difference* type; the edge has a thinner line.
- $\delta' < 0.1$ and $\gamma < 1.5$: assigned to the *low conditional difference* type; the edge has the thinnest line.

Table 2. Statistical parameters for an edge pointing from a source node *x* to a target node y[a].

Parameter	Description	Formula
Absolute cooccurrence	Number of group members having both attributes of *x* and *y*	o_i
Relative conditional share	Fraction of group members with attribute of *x*, also having attribute of *y*	
Conditional and unconditional target share difference	Absolute increase of relative conditional share compared to relative attribute share of *y*	
Conditional and unconditional target share quotient	Quotient of relative conditional share and relative attribute share of *y*	

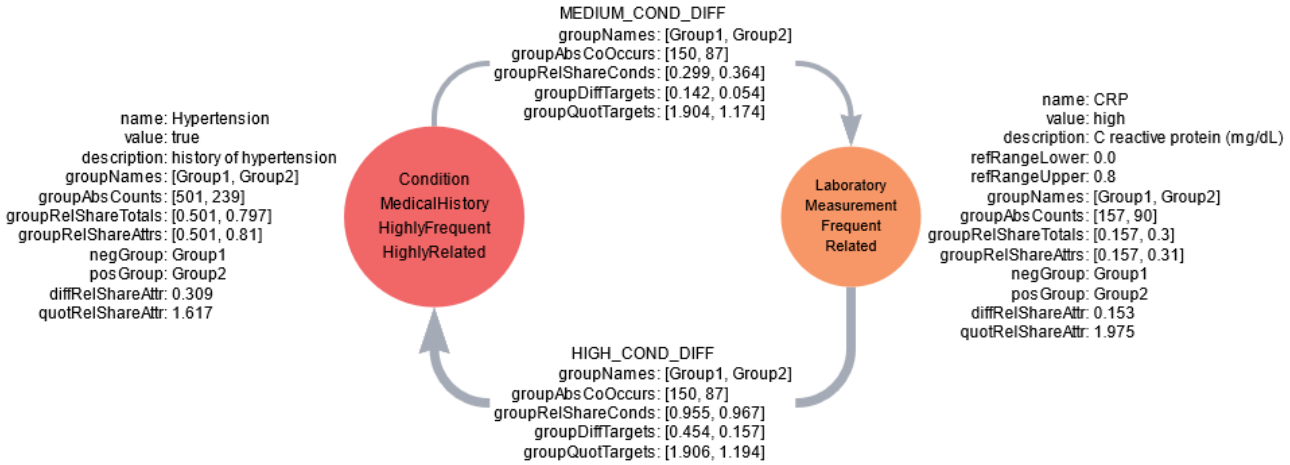
[a]Subscript *i* refers to a definition for both groups. Let be the absolute count of *x* and be the relative attribute share of *y*.

The computation time for the generation of all the AAG's edges scales quadratically with the number of variables in the data set and linear with the sample size.

In the last step, the nodes and edges are filtered by their statistical parameters to highlight the most relevant attributes and conditional dependencies. A detailed description of the filtering procedure is provided in Multimedia Appendix 1 [41,44,45]. We represented the extracted data in a graph structure using the graph data platform Neo4j [14] and the graphical user interface Neo4j Bloom (Neo4j, Inc) [19]. The graph structure can be navigated by mouse clicking and via a search bar typing prompts in English.

Figure 1 [46] shows a minimal fictional example of an AAG with 2 nodes capturing fictional data about history of hypertension and high C-reactive protein (CRP) measurements as well as their relationship in participant group 1 (control group) and 2 (disease group). We conducted a hypothetical data analysis, as we intend the AAG to be used. For CRP measurements (mg/dL), a fictional reference range of 0.0-0.8 was derived. From the difference of the relative total share and relative attribute share, we can infer existing missing values on group 2 for both attributes. In group 1, no missing values exist because relative total share and relative attribute share do not differ. Regarding the quotient of relative attribute shares, we can infer group 2's participants being almost twice as likely to show a high CRP value. Thus, a CRP measurement >0.8 mg/dL might be highly related to the condition or property of group 2 compared to participants of group 1. A history of hypertension appears approximately 30% more often in group 2, giving a 60% proportional increase. As a result, its node is labeled as highly related to the condition or property of group 2. Viewing the data of the edges, we find that almost all participants with a high CRP measurement also have a history of hypertension in both groups. Therefore, high CRP values could be an indicator for hypertension in both fictional groups. Conversely, only approximately one-third of participants with a history of hypertension also show high measurements of CRP. This pattern of conditional relationship is similar between groups and could thus be independent of the group definitions, for example, medical condition and control group.

Figure 1. An attribute association graph with 2 nodes represented as spheres and 2 edges represented as lines with arrows. The arrow indicates the target node of the edge. Node parameters are depicted next to the spheres. Labels are shown inside the spheres with one label per line. The edge's parameters are depicted on top of the edge. The heading above the edge's parameters specifies the edge type (MEDIUM_COND_DIFF for medium conditional difference, HIGH_COND_DIFF for high conditional difference). Absolute counts (groupAbsCounts), relative total shares (groupRelShareTotals), relative attribute shares (groupRelShareAttrs), difference between relative attribute shares (diffRelShareAttr), quotient between relative attribute shares (quotRelShareAttr), absolute cooccurrence (groupAbsCoOccurs), relative conditional share (groupRelShareConds), difference to target relative attribute share (groupDiffTargets), and quotient to target relative attribute share (groupQuotTargets) are depicted as lists with the score for group 1, followed by the score for group 2. Group 2 is the disease group (posGroup), and group 1 is the control group (negGroup). The color of the sphere indicates the deviation label of the node: orange (related) and red (highly related). The size of the sphere indicates the frequency label from medium (frequent) to the largest size (highly frequent). The line thickness indicates the type of edge from medium (medium conditional difference) to thickest (high conditional difference). Descriptions of all parameter names, edge types, labels as well as color, size and thickness encoding can be found in the ZFDM repository. CRP: C-reactive protein.



Dashboard

To complement the AAG, we generated a dashboard using the NeoDash (Neo4j, Inc) [17] toolkit. With the dashboard, users can investigate the average and distribution of metric variables across participant groups in more detail. In addition to the cardiovascular disease and control cohorts, the group of all participants contained in the Hamburg City Health Study (HCHS) data set was included. We developed 2 different tabs. The first tab allows for comparison of participant groups. We included the sizes of disease and control group. In addition, variable distributions can be compared between groups. For this purpose, we applied the following workflow to all metric variables and participant groups. First, we measured the variable average within the group. Second, we generated a binned distribution by rounding the measurements to multiples of 0.1, 0.5, 1, 5, 10, or 50 depending on the SD within the group. Bins containing <0.5% of the participants or <3 participants are summarized. We removed distributions without any bins fulfilling these requirements. The user can select 2 groups and variables for the distributions shown in the first tab of the dashboard. The averages of all metric variables for all 3 groups are shown in the first tab as well. To make them comparable in a figure, the averages of each variable are normalized by the maximum average of that variable. In the second tab, the user can investigate the relationship between 2 variables within a participant group. For the first variable, the generated binned distribution across the group is shown. For the second variable, we use precalculated averages of participants within a bin. The x-axis of the resulting figure shows the bin values of the first variable, and the y-axis shows the average value of the second variable for participants of that bin.

HCHS Data Set and Cohort Selection

To evaluate the AAG and dashboard, we used an exemplary data exploration workflow of a large epidemiological cohort study. We compared the results with findings from literature and standard statistical analysis. The HCHS is a single-center, prospective, observational, population-based cohort study of 45,000 randomly selected residents of the metropolitan region of Hamburg, Germany, aged between 45 and 74 years. The study design has been published [47], and the study is registered [48]. The study focuses on major chronic diseases, causes for their development, as well as factors for survival and support for life in survivorship. The study considers >6000 properties per participant. The data are raised from 18 examinations, primarily targeting major organ systems, as well as questionnaires about medical and family history, physical condition, dietary habits, lifestyle, and various other topics. The examinations will be repeated after 6 years to obtain large-scale, long-term assessments. For this analysis, the HCHS committee provided a subset of the whole HCHS data set focusing on cardiovascular and cancer diseases. The subset consists of 524 selected attributes for the first 10,000 participants enrolled in HCHS, including information about laboratory analyses; electrocardiography (ECG); magnetic resonance imaging; vascular ultrasound examinations; blood pressure measurements; cardiovascular and cancer medical history questionnaires; as well as dietary, lifestyle and sleeping habits. We selected 131 (25%) of these 524 attributes, translated their descriptions to English, assigned labels to each variable to broad variable groups, and added Systematized Nomenclature of Medicine Clinical Terms [49] or Logical Observation Identifier Names and Codes [50] codes. When no directly fitting code was found, we chose the code of a related term. A full list of all variables, descriptions, labels, vocabulary codes, and data types can be

freely accessed [46]. In some cases, the reference ranges calculated for the AAG deviated from the usual reference ranges known from the literature because of a different value distribution in the HCHS data set. In these cases, we manually adjusted the reference intervals according to the Merck Manual of Diagnosis and Therapy manual [44]. A full list of the adjusted reference ranges can be found in Table S1 in Multimedia Appendix 1. In this work, we focused on participants with a general cardiovascular condition. We included participants in this cohort who met any of the following criteria: showed any pathological cardiovascular findings during the cardiac magnetic resonance imaging examination; had a missing sinus rhythm; had a finding of atrial fibrillation or flutter in the ECG check; or reported a medical history of cardiac infarction, coronary artery disease, angina pectoris, congestive heart failure, myocarditis, or valvular endocarditis in the questionnaire. As a result, the disease cohort contained 1917 participants. In addition, we derived the control group of 8083 participants not exhibiting any of the conditions and findings.

User Tests

Study Design

We conducted a user test using a mixed methods approach to evaluate the usability of the AAG. The associated questionnaire can be found in Multimedia Appendix 2. We did not consider the proposed dashboard in the user test, as dashboards are widely used in the medical domain [11,51-53]. The usability testing consisted of 3 main parts in the following order: (1) in a 30-minute preparation phase, participants independently worked through the AAG user manual and the Neo4j Bloom overview website [19]; (2) a semistructured interview with open feedback questions and user tasks was conducted; and (3) participants completed the System Usability Scale (SUS) [54]. The SUS is a standardized and validated instrument for usability testing of systems, frequently used in this context [25,52,55,56]. The SUS comprises 10 questions rated on a 5-point Likert scale. The total score, ranging from 0 to 100, is calculated from all questions to ensure comparability. With the addition of user tasks and feedback questions tailored to the AAG, we aimed to create additional insights on the usability of the specific parts of the graph as well as observe the data exploration conducted by the users. The user tasks can be grouped into three categories: (1) reproducing the introduced labels and metric parameters; (2) using the application functionalities necessary for exploration; and (3) conducting a free exploration of 2 AAG subgraphs of the HCHS data set: first, the 10 nodes with the highest quotient of relative attribute shares related to the cardiovascular disease group; and second, the subgraph of nodes regarding laboratory measurements. The user results for tasks of categories 1 and 2 were evaluated as correct or incorrect by the authors. During the exploration of the 2 subgraphs, the users were asked to verbalize their findings, and the results were recorded and categorized by the authors. The participant answers to the open feedback questions were also broadly categorized by the authors.

Participant Recruitment

The study participants for the user tests included 10 physicians from various specialties and fields of activity. This group comprised 2 anesthetists, 2 cardiologists, 1 neurologist, 1 radiologist, 2 resident doctors in the field of child and adolescent psychiatry, 1 medical student in the final year, and 1 physician working in the public health sector. With this heterogeneous group composition, we aimed for a comprehensive usability assessment of the presented methods across the clinical field. The recruitment of participants was conducted on a voluntary basis, supported by the research team's network. It was assumed that the participants had no bias regarding the AAGs, as the methodology and visualization had not been officially released and were therefore not used by the participants at the time of the user test.

Ethical Considerations

The HCHS study was approved by the Ethics Committee of the Hamburg chamber of physicians (PV5131) and has been registered at ClinicalTrial.gov (NCT03934957).

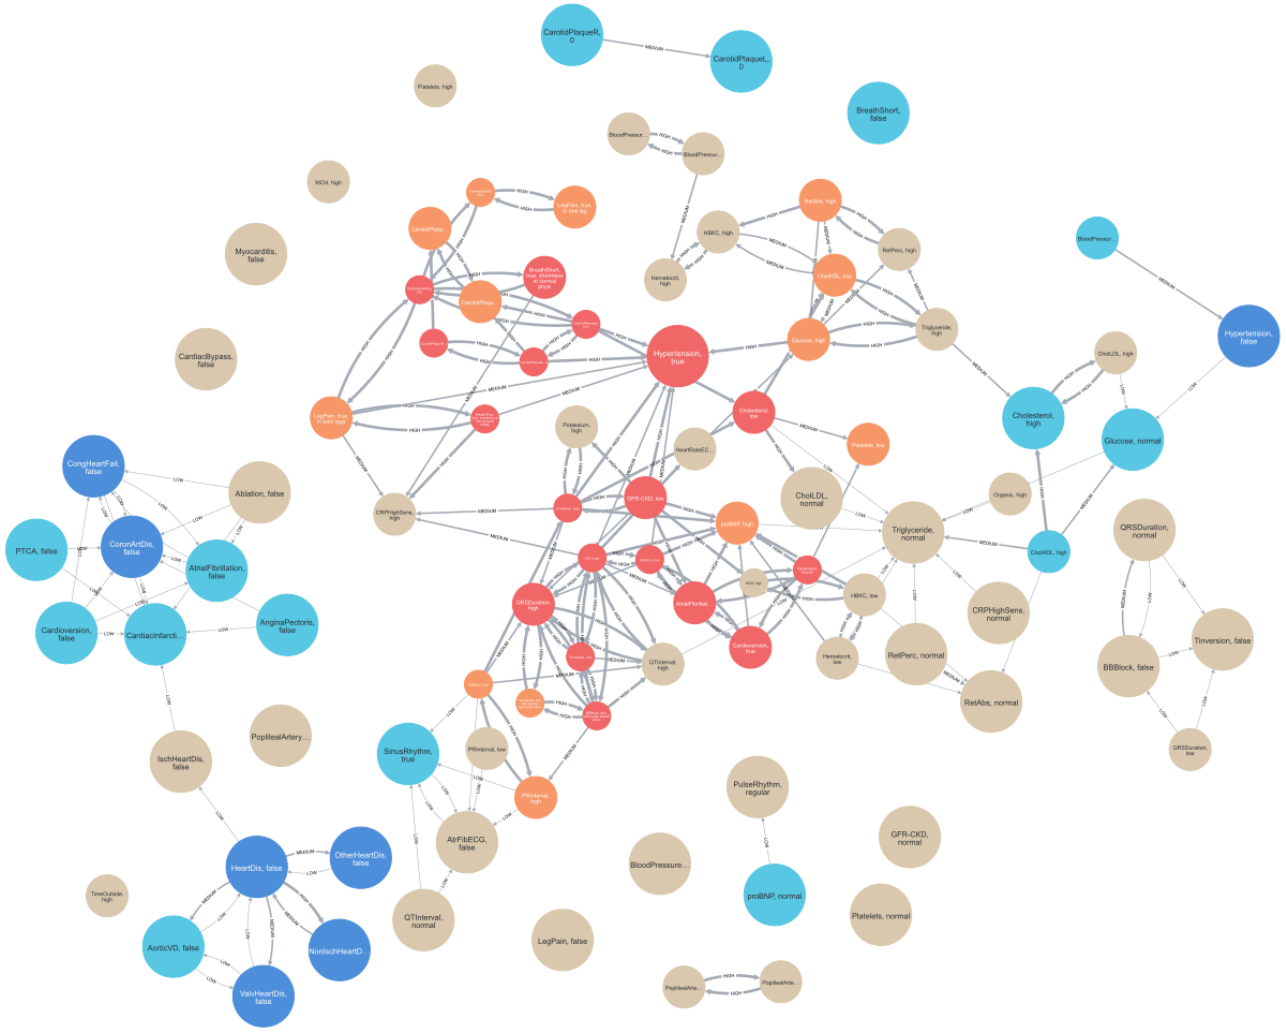
Results

Exemplary Data Analysis

We have generated the AAG for the disease and control group within the HCHS data set based on our definition of a general cardiovascular disease. In this paragraph, we give an exemplary data analysis using the graph and some aspects of the dashboard. This analysis was conducted by the authors of this work independently of the exploration of users during the usability test. The analysis is meant to showcase the usability of the graph representations and is by no means exhaustive. The Neo4j database dumps, configuration files, and user guide can be freely accessed [46]. In addition, the software tool used to generate AAGs was made publicly available [57] and will be presented in an upcoming publication. To assess the compatibility of the presented methods with standard statistical inference, we calculated Pearson correlation coefficients [41], 1-tailed CIs at the confidence level of 95% using the Fisher transformation [45], and P values for 1-tailed null hypothesis testing of statistical independence for all associations discussed in the following data analysis. The results can be found in Table S2 in Multimedia Appendix 1.

For brevity, we define the cardiovascular disease group as group A and its control group as group B. Group A contains 1917 participants, and group B contains 8083 participants. The generated AAG is shown in Figure 2 [14,46]. The nodes labeled as related or highly related form a cluster in the middle of the graph with the highest density of edges between them. Most of the inverse and highly inverse labeled nodes are primarily located on the periphery of the graph with many interconnections but few connections to the inner cluster. This observation indicates a clear distinction highlighted by the graph between the attributes based on their cooccurrence with cardiovascular disease within the HCHS data set.

Figure 2. The attribute association graph describing the cardiovascular disease cohort and control group extracted from the Hamburg City Health Study data set. Screenshot taken from the Neo4j Browser. Nodes are depicted as spheres, and edges are depicted as lines between spheres. The color of the sphere indicates the deviation label of the node: vanilla (unrelated), orange (related), red (highly related), turquoise (inverse), and blue (highly inverse). The size of the sphere indicates the frequency label from the smallest (infrequent) to the largest size (highly frequent). The line thickness indicates the type of edge from thinnest (low conditional difference) to thickest (high conditional difference). The text inside the node spheres states the variable name, followed by the value of the attribute. Data and variable descriptions can be found in the ZFDM repository. For a higher-resolution version of this figure, see Multimedia Appendix 3. Variable descriptions are found in Multimedia Appendix 4.



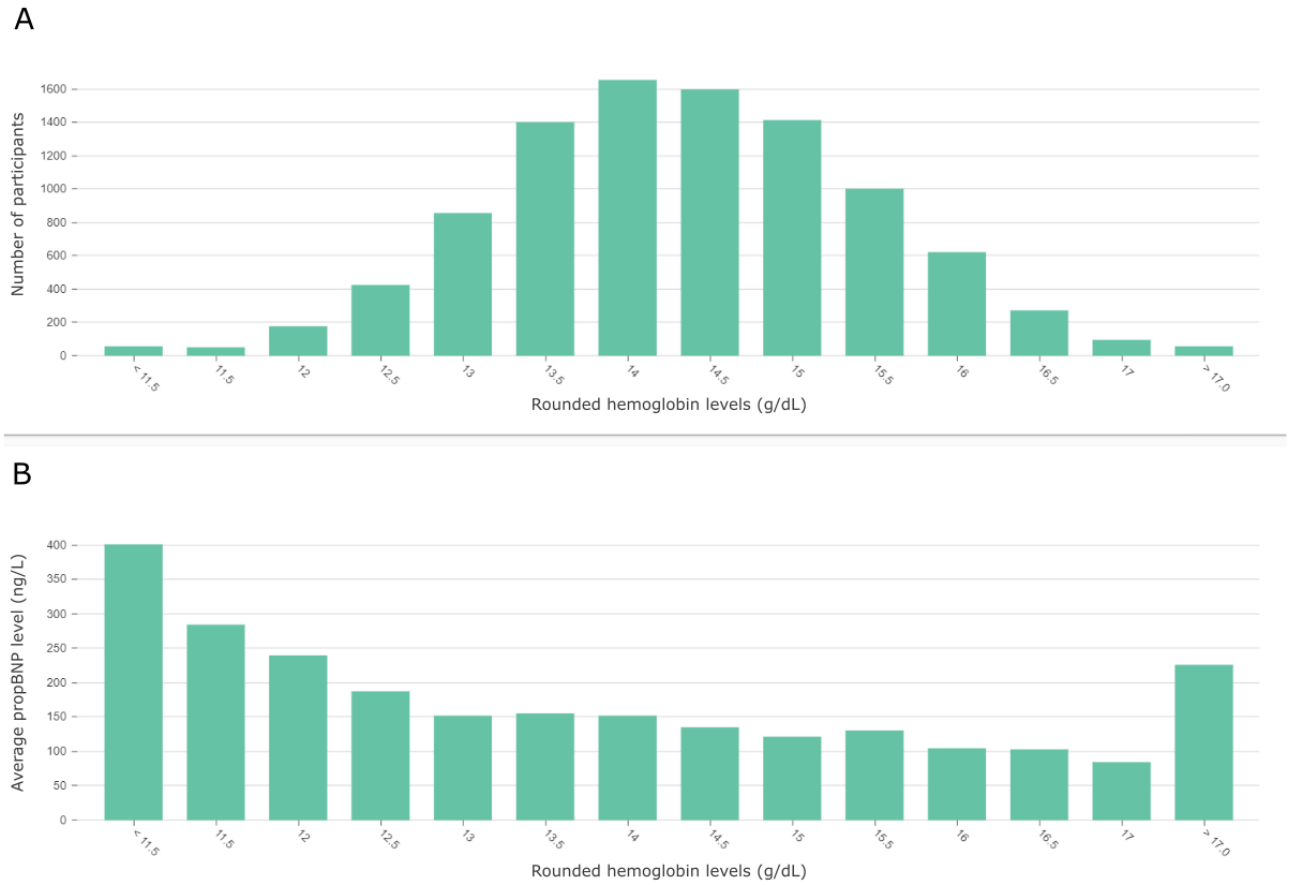
For a more detailed analysis of this AAG, we focused on the laboratory results data shown in Figure 3 [14,46]. Within the graph, 3 nodes are labeled as highly related, along with several adjacent nodes labeled as related. The nodes representing glomerular filtration rate <60 mL/min/1.73 m^2 ("GFR-CKD, low") and creatinine levels >1.2 mg/dL ("creatine, high") are identified as highly related and are interconnected. Furthermore, they are also connected to the node representing elevated potassium levels >4.15 mmol ("potassium, high") through high conditional difference relationships. The presence of a low glomerular filtration rate, high creatinine, and elevated potassium levels are all correlated with chronic kidney disease [58], which in turn is a risk factor for the development of cardiovascular conditions [58,59]. Thus, all 3 laboratory results are associated with heart disease in clinical settings [60], which coincides with the findings presented in this graph. The respective 95% CIs lie fully above 0 for creatine and potassium levels and fully below 0 for the glomerular filtration rate. The relative attribute share of the nodes for glomerular filtration rate <60 mL/min/1.73 m^2 ("GFR-CKD, low") in group A is, with 12%, more than twice as high as the relative total share. This indicates missing values for glomerular filtration rate measurements in participant with a cardiovascular condition. The related node in the center of Figure 3 ("proBNP, high") represents elevated N-terminal prohormone of B-type natriuretic peptide (proBNP) levels >125 ng/L, which were identified as a biomarker for cardiac diseases [61]. With 47%, group A has a 1.7-fold increased relative attribute share for this attribute compared to group B. The associated CI for the Pearson correlation coefficient is strictly positive. The node has 3 incoming edges of high conditional difference. Of these 3 edges, 2 describe the relationship between low glomerular filtration rate and high creatinine levels to elevated proBNP levels. Participants of group B with 1 of these properties are at least 1.6-fold more likely to show elevated proBNP levels >125 ng/L compared to general patients of group B. The same pattern can be observed in group A, which is consistent with the impact of worsening kidney function on proBNP concentration [62,63]. The CIs of the Pearson correlation coefficient of proBNP and glomerular filtration rate is strictly negative, and the CI for

creatinine and proBNP levels is fully positive. The third incoming edge is of type high conditional difference. It indicates a relationship between hemoglobin levels <13 g/dL ("HBKC, low") and elevated proBNP measurements. Although the node for low hemoglobin levels is labeled as unrelated, measurements <13 g/dL appear with a 1.4-fold increase in group B compared to group A. The associated CI is close to, but fully above, 0. Interestingly, participants of both groups with low hemoglobin levels are approximately 1.5-fold more likely to exhibit high proBNP measurements compared to general participants of their group, a phenomenon observed in other studies [64-66]. The Pearson correlation coefficient CI for proBNP and hemoglobin levels are close to, but fully below, 0. Overall, these 3 relationships confirm that while elevated proBNP levels serve as a biomarker for cardiac conditions, other factors may also contribute to its elevation.

Figure 4 was extracted from the dashboard and discloses the relationship of hemoglobin and proBNP levels across the whole data set in more detail. Average proBNP values increase for participants with hemoglobin levels <13 g/dL. Interestingly, proBNP levels also increase in participants with high hemoglobin values >17 g/dL. For further investigation, we returned to the graph and inspected the node ("HBKC, high") for high hemoglobin levels >15.5 g/dL. This threshold is exceeded by 21.5% of the participants in group A and by only 15.3% of the participants in group B. These observations align with the calculated, strictly positive CI and findings of other studies associating high hemoglobin concentrations with cardiovascular disease [67,68]. The third node ("cholesterol, low"), which is labeled as highly related, can be seen in the lower center of Figure 3. It represents total cholesterol levels <150 mg/dL, which is exhibited by 16.3% of group A and only 5.5% of group B. Conversely, total cholesterol levels >200 mg/dL are observed in 47.3% of group A and 61.2% of group B. As a result, the corresponding node ("cholesterol, high") is labeled as inversely related.

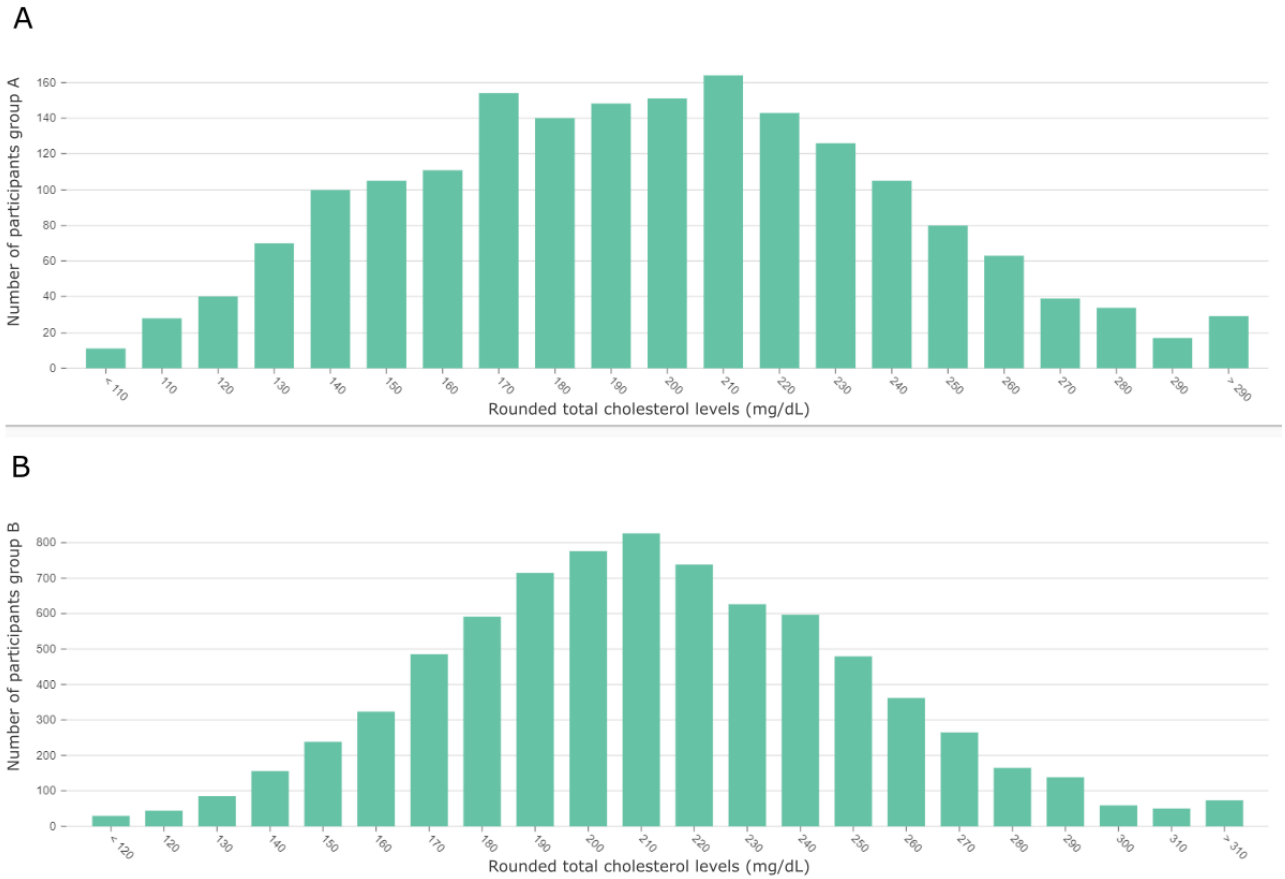
Figure 3. A subgraph of the full attribute association graph describing the cardiovascular disease cohort and control group extracted from the Hamburg City Health Study data set. Screenshot taken from the Neo4j Browser. Only nodes representing laboratory measurements and edges between them are shown. The color of the sphere indicates the deviation label of the node: vanilla (unrelated), orange (related), red (highly related), turquoise (inverse), and blue (highly inverse). The size of the sphere indicates the frequency label from the smallest (infrequent) to the largest size (highly frequent). The line thickness indicates the type of edge from thinnest (low conditional difference) to thickest (high conditional difference). The text inside the node spheres states the variable name, followed by the value of the attribute. Data and variable descriptions can be found in the ZFDM repository. CKD: chronic kidney disease; CRP: C-reactive protein; GFR: glomerular filtration rate; HBKC: hemoglobin level; HDL: high-density lipoprotein; LDL: low-density lipoprotein; proBNP: prohormone of B-type natriuretic peptide. For a higher-resolution version of this figure, see Multimedia Appendix 5. Variable descriptions are found in Multimedia Appendix 4.

Figure 4. (A) Distribution of hemoglobin levels (g/dL) across all participants of the Hamburg City Health Study data set. (B) The average N-terminal prohormone of B-type natriuretic peptide (proBNP) level (ng/L) per participant of the data set with a rounded hemoglobin level specified on the x-axis. This figure is a screenshot from the dashboard.



However, in Figure 5, we can observe that the highest number of participants in both groups exhibit a slightly elevated total cholesterol level of 210 mg/dL. Next, we inspected the 2 nodes (“CholLDL, normal” and “CholLDL, high”) for low-density lipoprotein (LDL) cholesterol levels. Measurements >130 mg/dL (“CholLDL, high”) appear with a 1.3-fold increase in group B. LDL cholesterol levels <130 mg/dL (“CholLDL, normal”) appear in 68.1% of group A and 59.7% of group B. These observations are peculiar because elevated total and LDL cholesterol are commonly recognized as important risk factors for cardiovascular diseases [69-73]. A similar pattern can be inferred from the 2 nodes (“CholHDL, low” and “CholHDL, high”) for measurements of high-density lipoprotein (HDL) cholesterol. Levels <45 mg/dL appear with a 1.7-fold increase in group A, whereas measurements >83 mg/dL showed a 1.8-fold increase in group B. This observation coincides with the widely accepted inverse association of HDL levels with cardiovascular diseases [74,75]. It is noteworthy that the nodes for high LDL and HDL cholesterol levels share an edge with the node for high total cholesterol levels. The same holds true for low HDL, normal LDL, and low total cholesterol measurements. These edges are all labeled with “high conditional difference.” The CIs for all 3 cholesterol measurements and the membership to group A are strictly negative. The CIs for total cholesterol levels and HDL as well as LDL cholesterol measurements are strictly positive, with the correlation coefficient of LDL and total cholesterol being close to 1. In summary, reduced overall cholesterol, LDL cholesterol, and HDL cholesterol levels appear more often in the cardiovascular disease group compared to the control group and are associated with each other. As stated earlier, this observation contradicts the commonly accepted association of elevated overall and LDL cholesterol with cardiovascular diseases. It could be attributed to the widely used therapy with statins [76], which mainly targets the reduction of LDL and overall cholesterol [77]. On the basis of this idea, the high conditional difference relation between elevated creatinine levels and low total cholesterol measurements found in Figure 3 and the associated strictly negative CI for the Pearson correlation coefficient could be explained by statin-associated muscle symptoms [78]. However, additional information about the medication history of the participants would be required and could be a starting point for further investigation.

Figure 5. (A) Distribution of total cholesterol levels (mg/dL) for the cardiovascular disease group (group A) and (B) its control group (group B) derived from the Hamburg City Health Study data set. This figure is a screenshot taken from the dashboard.



User Tests

The participants indicated a work experience in the current field ranging from 1 to 10 years, with an average of 5.8 years. The data exploration tools mostly used by the participants were SPSS (IBM) [79], R [80], and Microsoft Excel (Microsoft) [81]. No users mentioned any prior experience with graph-based statistical analysis tools. The results of the user test can be found in Multimedia Appendix 3.

In Figure 6, the results of the SUS questionnaire are shown and range from 62.5 to 85.0. The mean of 70.5 indicates the passing of usability criteria [82] and a rating of "good" usability [83]. In addition, physicians rated the user-friendliness on a scale from 1 (very bad) to 10 (very good), with a mean of 7.0 in accordance with the SUS results.

In Figure 7, the percentage of the 10 participants with successful completion is shown for each user task. The average score across all tasks is 81.4%, with 6 (86%) of 7 navigation tasks being correctly completed by all participants. However, only 20% (2/10) of participants queried successfully for the 10 nodes most statistically associated with the disease group by the quotient of relative attribute shares. Regarding the description tasks of category 1, all but 1 task of reproducing label and parameter meaning was completed by at least 70% (7/10) of users. An exception was task C3.2 where participants should describe the meaning of the edge parameter for the difference of relative conditional share and relative attribute share of the target node. This task was only completed correctly by 30% (3/10) of the participants. In addition, only 30% (3/10) of the participants found the parameter names for nodes understandable, and only 10% (1/10) of the participants classified the edge parameter names as clear.

During the free data exploration, all participants noticed the unusually low levels of total and LDL cholesterol in the cardiovascular disease group compared to the control group, which is also discussed during the exemplary data analysis conducted by the authors. In addition, 40% (4/10) of the participants suspected this association to be caused by medication not represented in the data set. Overall, 60% (6/10) of the participants discussed ECG signals, and 60% (6/10) of the participants discussed kidney metabolism. Moreover, 70% (7/10) of the physicians mentioned the results of their data exploration to be plausible, except for total and LDL cholesterol unprompted. Regarding the answers to the open feedback questions, 80% (8/10) of the participants mentioned the colors and sizes of nodes to be helpful, and 40% (4/10) of the participants referred to the display of attribute connections as edges becoming apparent. Moreover, 30% (3/10) of the participants mentioned the benefit of initial data exploration without the need for numerical values. As to disadvantages of the AAG, 30% (3/10) of the users mentioned the edge definitions being hard to understand, 20% (2/10) assessed the graphs to be too crowded to get a good overview, and 20% (2/10) stated that they would need more practice to use the tool efficiently.

Figure 6. The System Usability Scale (SUS) score for each of the 10 participants of the user test. In addition, the average score is represented by a horizontal dashed line in red.

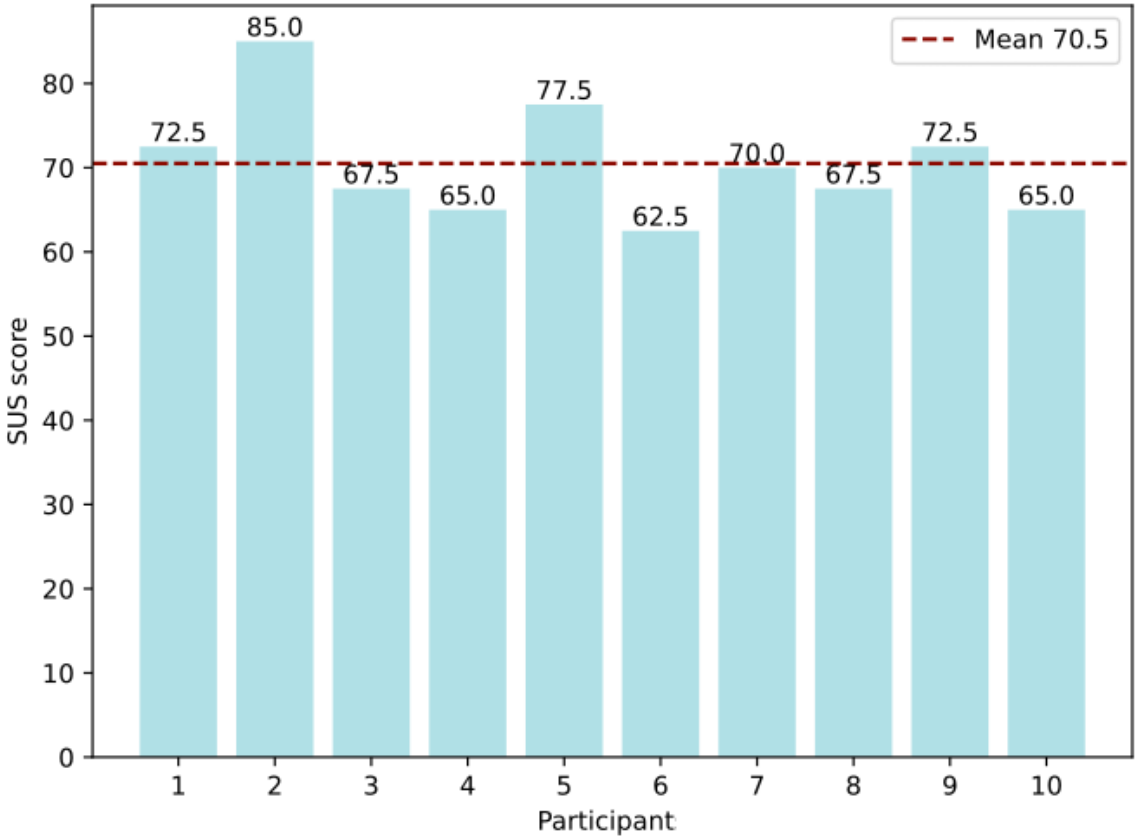


Figure 7. Correct task completion by participants during the user test in percentage. Task numbering is taken from the questionnaire. A short description of the tasks is given on the left. Bars for description and reproduction of labels and metrics (task category 1) are depicted in turquoise. Bars for graph navigation tasks (task category 2) are depicted in pink. Average percentages of correct tasks are plotted as dashed lines for description, navigation, and all tasks.

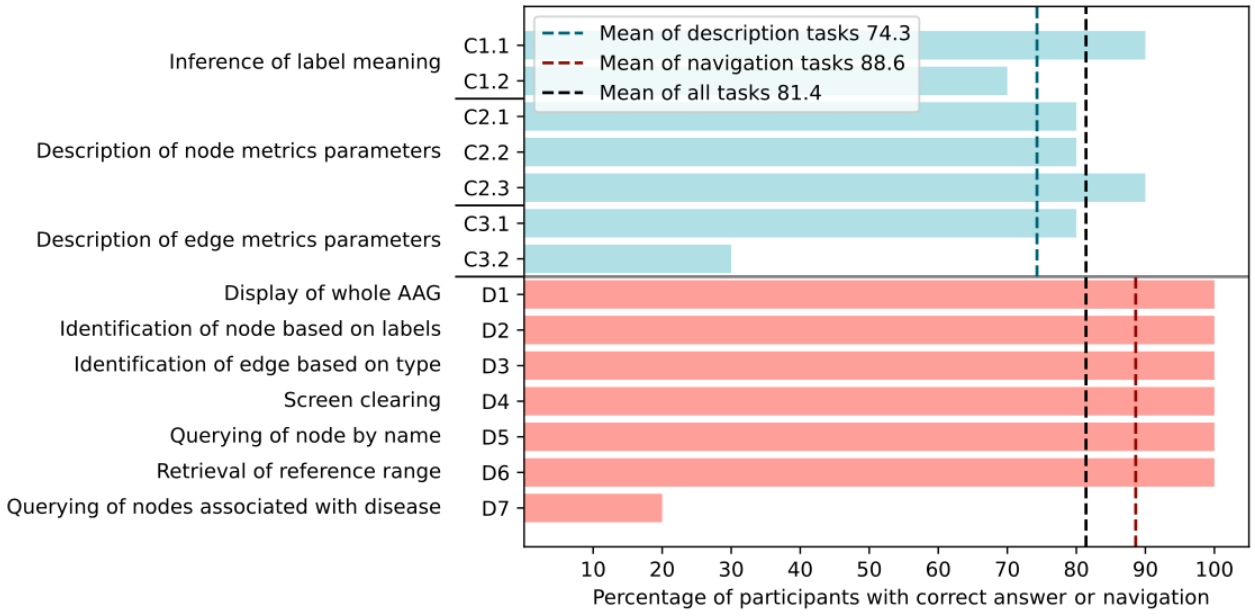

Discussion

Principal Findings

In this work, we presented the AAG for visual exploration of medical data sets using disease and control cohorts. The graph structure represents attributes as nodes and identifies as well as visually highlights attributes, which are linked to the observed disease by robust statistical metrics. Relations between attributes are captured as edges by conditional frequencies. As a result, attributes associated with the observed disease are visually clustered and clearly separated from attributes, which are associated with the control group. The graph structure detects and handles missing values without the need for data deletion.

The usability of the AAG and dashboard was assessed using an exemplary data analysis. All but 1 association of laboratory measurements and cardiovascular diseases extracted from the HCHS data set are in line with findings from the literature. The exceptions are unusually low total and LDL cholesterol levels in participants with cardiovascular disease, which might be caused by lipid-lowering therapy. All results extracted from the AAG were confirmed by standard statistical inference using null hypothesis testing and CI for the Pearson correlation coefficient. In addition, a user test with physicians was conducted using the standardized SUS questionnaire, nonstandardized open feedback questions as well as user tasks, and a free data exploration. The SUS score of 70.5% and average successful task completion of 81.4% show a general acceptance and good usability of the AAG. After the initial 30-minute preparation period, all users were able to navigate the graph and could extract medical knowledge that they considered plausible and meaningful. In addition, all participants identified the unusual lipid levels in participants of the cardiovascular disease group and some suspected medication not represented in the data set to be the cause. The encoding of statistical results by color, size, and clustering of nodes as well as thickness of edges was seen as helpful by the users. The users regarded the tool as useful for accessible hypothesis formation during the initial research phase.

Comparison With Prior Work

Other existing data-driven approaches based on graph structures focus mainly on the connection of different data sources as knowledge graphs [23,24,26] or direct clinical decision support through outcome prediction [27,31,35,38,84-86]. To our knowledge, a graph structure capturing statistical measurements of a medical data set using disease and control cohorts with a clear focus on interpretability and visualization is a novel approach. In addition, as our proposed methods consider single attributes and pairs of attributes, they are robust to high-dimensional data, which pose a problem for many other statistical models applied to the medical domain [87]. We believe that the usability of graph-based visualizations in the medical field is rarely assessed using standardized tests such as the SUS questionnaire. The only other results known to the authors reported a slightly lower SUS score of 64.4 [25].

Regarding the graph-based statistical framework, we see our work closest related to Bayesian networks [29] and association rule learning [36]. While Bayesian networks can hold strong predictive power [88], the choice of prior distribution and sensitivity to data quality can be challenging for clinicians [89]. In association rule learning, conditional relationships between attributes are partially expressed through the confidence parameter, which is quite similar to our methodology in that regard. However, we enrich the added condition with semantics by calculating difference and quotient to the unconditional relative frequencies. Finally, none of the 2 methods measure statistical differences between disease and control cohorts. We believe this to be vital in our approach for generation of insight and adoption in the medical domain.

Limitations

We intended the AAG and dashboard as a compact visualization for data exploration in the initial phase of research projects. We aimed to incorporate easily interpretable, robust metrics in the form of conditional and unconditional absolute and relative frequencies as well as their deviations between disease and control cohorts. However, because of this choice of metrics, the accuracy could be lower when used in prediction tasks compared to, for example, Bayesian networks or other nonlinear models. In addition, CIs and null hypothesis significance testing play a key role in statistical inference of medical data [90]. They are not incorporated into the methods presented here but could be a follow-up to the initial exploration using the AAG. Finally, temporal data cannot be handled with the proposed methodology in the current form, and Markov models [33] could be applied instead.

Regarding the usability of the visualization, the results of the user test indicate a need for simplification of the parameter names regarding the statistical measurements. In addition, the comparison of conditional and unconditional frequencies captured in the edges of the graph structure was not accessible enough for the users. Moreover, the prompt for retrieval of nodes most associated with one of the groups was considered too lengthy by the users. The authors will incorporate this valuable feedback in the next update iteration of the presented methods.

Conclusions

In this work, we introduced the AAG, a novel graph-based representation of statistical data combined with a dashboard. These structures can be visually explored and allow for data analysis tailored to the needs of the medical domain. The usability of the graph structure and dashboard was confirmed by user tests conducted with physicians. In addition, the validity of the incorporated statistical analysis was assessed through an exemplary data analysis of a large epidemiological study, and its compatibility with standard statistical methodology and findings from the literature was established. For the future, it might be of interest to enable clinicians in generating their own AAGs without the need for programming experience as an extension to their existing data analysis workflow. To achieve this, we developed a software package [57], which will be presented in an upcoming publication. We think that accessible data analysis and intuitive presentation for clinicians and patients is the way forward in a world of ever-growing data availability and complexity.

Acknowledgments

The authors would like to thank the Hamburg City Health Study (HCHS) committee for granting access to the HCHS cohort study data set. The authors received no specific funding for this work. In terms of overall funding for the underlying HCHS, various institutes and departments at the University Medical Center Hamburg-Eppendorf contribute with their own individual and scaled budgets. The HCHS is additionally funded by the Joachim Herz Foundation, the Leducq Foundation (grant 16 CVD 03), the euCanSHare grant agreement (grant 825903-euCanSHare H2020), and the Innovative Medicine Initiative (grant 116074). The HCHS is further supported by Deutsche Gesetzliche Unfallversicherung (DGUV), Deutsches Krebsforschungszentrum (DKFZ), Deutsches Zentrum für Herz-Kreislauf-Forschung (DZHK), Deutsche Stiftung für Herzforschung, Seefried Stiftung, Bayer, Amgen, Novartis, Schiller, Siemens, Topcon, and Unilever and by donations from the "Förderverein zur Förderung der HCHS e.V." and TePe (2014). Sponsor funding has in no way influenced the content or management of this study. RT reports research support from the German Center for Cardiovascular Research (DZHK), the Kühne Foundation, the Joachim Herz Foundation, the Swiss National Science Foundation (Grant NoP300PB_167803) and the Swiss Heart Foundation.

Data Availability

The data sets generated and analyzed during this study are available in the ZFDM repository [46]. The HCHS data set itself is not publicly available due participant data privacy. The attribute association graph (AAG) and dashboard data as Neo4j dumps, Neo4j Bloom configuration as JSON files, as well as a detailed installation and user guide as PDF file and descriptions for all variables of the Hamburg City Health Study data subset can be found in the repository [46]. Adjusted reference ranges and filter criteria for the AAGs, Pearson correlation coefficients, as well as the user test questionnaire and results can be found in Multimedia Appendices 1, 2 and 6. Code repository, Python package, and software tool to create custom AAGs [57] will be described in an upcoming publication.

Conflicts of Interest

RT reports speaker honoraria/consulting honoraria from Abbott, Amgen, Astra Zeneca, Psyros, Roche, Siemens, Singulex and Thermo Scientific BRAHMS. RT is co-founder and shareholder of the ART-EMIS Hamburg GmbH, which holds an international patent application on a computing device for estimating the probability of myocardial infarction (International Publication Numbers WO2022043229A1, TW202219980A).

Multimedia Appendix 1
Attribute association graph filter criteria, manually adjusted reference ranges, Pearson correlation coefficients, CIs at the confidence level of 95% using the Fisher transformation, and *P* values for 1-tailed null hypothesis testing of statistical independence.

Multimedia Appendix 2
User test questionnaire.
[PDF File (Adobe PDF File), 161 KB - medinform_v12i1e49865_app2.pdf]

Multimedia Appendix 3
The attribute association graph describing the cardiovascular disease cohort and control group extracted from the Hamburg City Health Study data set. Screenshot taken from the Neo4j Browser. Nodes are depicted as spheres, and edges are depicted as lines between spheres. The color of the sphere indicates the deviation label of the node: vanilla (unrelated), orange (related), red (highly related), turquoise (inverse), and blue (highly inverse). The size of the sphere indicates the frequency label from the smallest (infrequent) to the largest size (highly frequent). The line thickness indicates the type of edge from thinnest (low conditional difference) to thickest (high conditional difference). The text inside the node spheres states the variable name, followed by the value of the attribute. Data and variable descriptions can be found in the ZFDM repository.

Multimedia Appendix 4
Variable descriptions for Figures 2 and 3.
[XLSX File (Microsoft Excel File), 24 KB - medinform_v12i1e49865_app4.xlsx]

Multimedia Appendix 5
A subgraph of the full attribute association graph describing the cardiovascular disease cohort and control group extracted from the Hamburg City Health Study data set. Screenshot taken from the Neo4j Browser. Only nodes representing laboratory

measurements and edges between them are shown. The color of the sphere indicates the deviation label of the node: vanilla (unrelated), orange (related), red (highly related), turquoise (inverse), and blue (highly inverse). The size of the sphere indicates the frequency label from the smallest (infrequent) to the largest size (highly frequent). The line thickness indicates the type of edge from thinnest (low conditional difference) to thickest (high conditional difference). The text inside the node spheres states the variable name, followed by the value of the attribute. Data and variable descriptions can be found in the ZFDM repository. CKD: chronic kidney disease; CRP: C-reactive protein; GFR: glomerular filtration rate; HBKC: hemoglobin level; HDL: high-density lipoprotein; LDL: low-density lipoprotein; proBNP: prohormone of B-type natriuretic peptide.

Abstract

Background: Leveraging electronic health record (EHR) data for clinical or research purposes heavily depends on data fitness. However, there is a lack of standardized frameworks to evaluate EHR data suitability, leading to inconsistent quality in data use projects (DUPs). This research focuses on the Medical Informatics for Research and Care in University Medicine (MIRACUM) Data Integration Centers (DICs) and examines empirical practices on assessing and automating the fitness-for-purpose of clinical data in German DIC settings.

Objective: The study aims (1) to capture and discuss how MIRACUM DICs evaluate and enhance the fitness-for-purpose of observational health care data and examine the alignment with existing recommendations and (2) to identify the requirements for designing and implementing a computer-assisted solution to evaluate EHR data fitness within MIRACUM DICs.

Methods: A qualitative approach was followed using an open-ended survey across DICs of 10 German university hospitals affiliated with MIRACUM. Data were analyzed using thematic analysis following an inductive qualitative method.

Results: All 10 MIRACUM DICs participated, with 17 participants revealing various approaches to assessing data fitness, including the 4-eyes principle and data consistency checks such as cross-system data value comparison. Common practices included a DUP-related feedback loop on data fitness and using self-designed dashboards for monitoring. Most experts had a computer science background and a master's degree, suggesting strong technological proficiency but potentially lacking clinical or statistical expertise. Nine key requirements for a computer-assisted solution were identified, including flexibility, understandability, extendibility, and practicability. Participants used heterogeneous data repositories for evaluating data quality criteria and practical strategies to communicate with research and clinical teams.

Conclusions: The study identifies gaps between current practices in MIRACUM DICs and existing recommendations, offering insights into the complexities of assessing and reporting clinical data fitness. Additionally, a tripartite modular framework for fitness-for-purpose assessment was introduced to streamline the forthcoming implementation. It provides valuable input for developing and integrating an automated solution across multiple locations. This may include statistical comparisons to advanced

machine learning algorithms for operationalizing frameworks such as the 3×3 data quality assessment framework. These findings provide foundational evidence for future design and implementation studies to enhance data quality assessments for specific DUPs in observational health care settings.

Introduction

Insight Into Medical Informatics in Research and Care in University Medicine Data Integration Centers and Data Use Projects

The German Medical Informatics Initiative (MI-I) [1] was launched by the German Federal Ministry of Education and Research to enhance digital health and clinical research infrastructure advancements in Germany. This initiative comprises multiple large consortia. The Medical Informatics in Research and Care in University Medicine (MIRACUM) consortium [2] is among the MI-I consortia that focus on integrating clinical and research data to enhance patient care and facilitate data-driven medical research at German university hospitals. However, MIRACUM includes 10 university hospitals and further medical research institutions across Germany, all of which instantiate medical Data Integration Centers (DICs). The DICs are crucial in gathering, harmonizing, and integrating clinical data from various source systems, including electronic health records (EHRs), clinical imaging systems, and other health-related databases. Additionally, the DICs' efficient data pipelines support uniform and secure data storage, enabling significant privacy-preserved sharing and analysis of patient data.

Among others, a cornerstone of the MIRACUM consortium's mission is also to foster data-driven medical research and the improvement of clinical patient care through the implementation of data use projects (DUPs). The DUPs use integrated and harmonized clinical data to answer pertinent research questions, such as identifying patterns, creating predictive models, or supporting evidence-based decision-making in the clinical field. Some of the key investigation areas of focus in the MIRACUM DUPs' applications so far include personalized medicine [3-5], clinical decision support [6-10], disease monitoring and surveillance [11], drug safety and pharmacovigilance [12], population health management [11], and translational research [13]. Ensuring an appropriate level of data quality (DQ) is imperative for the successful execution of DUPs that use MIRACUM DICs' clinical data, particularly during the development and implementation of data extraction-transformation-loading [14] processes.

Evaluating the DQ Impact on Secondary Use: Emphasis on Fitness-for-Purpose

Despite the establishment of robust data integration pipelines within each of the MIRACUM DICs [2,15], improving the fitness-for-purpose of generated data requires overcoming the challenges related to DQ for specific DUP purposes. As a crucial determinant for generating credible evidence [16], high-quality data are essential for drawing sound conclusions. This ensures that a larger target group, for instance, clinicians, health care providers, or givers, may rely on research findings. Conversely, compromised DQ [17] can lead to erroneous results, harmful treatment decisions, or a loss of public trust in the scientific community. However, several studies [18-22] have presented and discussed frameworks and methodologies about how to assess and ensure the quality of EHR data. It remains crucial to gauge the fitness of clinical data to enable achieving designated medical DUP objectives. In the context of observational DIC data-driven studies, for instance, ensuring DQ is of high importance to ensure the validity of the study results, which can emerge as a paramount challenge to overcome. Weiskopf and Weng [20] and Kahn et al [22] emphasized the relevance of adhering to the recommended references, such as the 3×3 data quality assessment (DQA) framework [21], when using EHR data to pursue specific research inquiries. Nevertheless, these current approaches might not comprehensively address the subjective understanding of data fitness that may arise from the diverse backgrounds of secondary data users.

The definition of fitness-for-purpose of clinical data might emphasize greater complexity depending on the requirements of the intended data use or research question to be investigated. In certain DUP contexts, clinical data may be considered as "fit for purpose," when all eligible patients simply present complete information about specific treatments. In other DUP scenarios, a plausible correlation between these treatments and certain specific diagnostic indicators, laboratory outcomes, or caregiver-related metadata may be additionally required. Girman et al [23] proposed a definition for EHR data fitness-for-purpose, which can be summarized in two dimensions: (1) relevance and (2) reliability. The first dimension, relevance, ensures that the target data elements are available, and a sufficient number of representative patients are present for the study. The second dimension, reliability, verifies whether the data to be used are sufficiently accurate, complete, and traceable (provenance).

However, the interpretation of what constitutes "fitness," and how to assess it, can substantially vary across different professional domains. For example, a computer scientist might prioritize the algorithmic reliability of data, whereas health care providers might pay attention to the clinical relevance of the data to patient care. These differing perspectives can profoundly affect the ways of assessing data fitness, highlighting the need for more empirical investigation in this domain, especially in multidisciplinary settings such as those of the MIRACUM DICs.

Prior Works, Contemporary Overview of DQ, and Existing Research Gaps

Against the backdrop described in the previous section, a dynamic DQA tool was designed and implemented [14,24], during the earlier stages of the MIRACUM project, based on the DQA framework suggested by Kahn et al [22]. This tool allows for capturing and assessing DQA metrics, including data completeness, conformance, and plausibility checks, between data sources and target systems to validate DICs' extraction-transformation-loading processes. Additionally, it facilitates cross-location comparisons of DQ distributions. Furthermore, conducting a DQA study that included comorbidity analysis [25] enriched our initial understanding of strategies to assess the DQ for specific research purposes. However, these significant efforts have yet to comprehensively provide a workable solution for automated assistance for assessing the fitness of DIC data to complete the ongoing or upcoming DUPs.

To bridge the divide between current practices and required improvements, it is imperative to initially capture and understand the activities applied by the MIRACUM DICs to assess and report about the data fitness-for-purpose throughout the data delivery process. Therefore, Reynolds et al [26] introduced objective considerations for evaluating the data fitness-for-purpose, but the authors did not delve deeper into how the DQ checks could be performed based on the research question criteria set by the researchers in an automated way. In contrast, Cho et al [27] developed a fitness-for-purpose tool that assesses data completeness, which may be more practical than intrinsic DQA tools. The predictive data completeness, as proposed by Weiskopf et al [21], which aims to assess, for instance, the impact of missing documentation of data elements such as chronic diseases on the prediction of clinical events, was scarcely addressed. Furthermore, Raman et al [28] suggested conducting study-specific fitness-for-purpose assessment in the early stage of trials and sharing the results in a transparent manner. Nevertheless, knowing whether and how these assessments correlate with successful trials could be valuable. Despite these insights, there is a considerable benefit in exploring common practices and prerequisites for creating a universally deployable solution, spanning multiple sites and systems, and automating the assessment of data fitness-for-purpose.

This research addresses several benefits. On the one hand, it is the first qualitative empirical investigation, gathering and analyzing the experiences in the assessment of data fitness-for-purpose in German medical DICs. This offers the opportunity to gain valuable information about possible existing solutions, challenges, and observable deficits, in comparison with internationally established evidence [21,27,28]. On the other hand, this allows for the investigation of relevant practice-oriented requirements for the development of an evidence-based tool that would enable an automated holistic assessment for DIC data fitness-for-purpose.

Research Aims

In light of the aforementioned research landscape, this investigation seeks to identify and describe (1) to what extent do the MIRACUM DICs address the fitness-for-purpose of observational health care data and how do the applied approaches contrast with existing recommendations and (2) what key requirements are necessary to develop an automated system within the MIRACUM DICs for assessing the fitness-for-purpose of EHR data for research or clinical applications.

Methods

Approach Overview

In this section, we detail the methods used to address the research questions described previously. This encompasses outlining the ethical considerations, the study design, the study sample, and the procedures used to gather and qualitatively analyze the data.

Ethical Considerations

The study did not require formal ethics approval from the Ethics Committee II of the Medical Faculty Mannheim at the University of Heidelberg, as it involved anonymized data collection that complies with the requirements of the professional code for physicians and the General Data Protection Regulation. Informed consent was obtained from all participants for the participation in the survey on assessing the quality of observational data for secondary use. All data were deidentified to ensure privacy and confidentiality, with no personal information collected or published, and participants received no compensation.

Study Design

In the course of this investigation, we performed a qualitative study. Therefore, we meticulously implemented a survey across all 10 medical DICs participating in the MIRACUM consortium. Adhering to the directives outlined in the GESIS (Society of Social Science Infrastructure Institutions) survey guideline version 2.0 [29], we developed a survey instrument consisting of 6 open-ended questions (refer to Textbox 1). Such a format facilitates respondents' ability to articulate their perspectives unrestrictedly, thereby fostering the acquisition of valuable insights and preventing the proliferation of superfluous response alternatives [29]. The instrument was formatted into a questionnaire that was distributed to all participating DIC locations. An accompanying guide was additionally provided during the survey dissemination, which outlined the expected time for the survey completion, the preference for keyword-oriented responses, the intended deadline for response submission, and background information regarding the survey (Multimedia Appendix 1).

Textbox 1. Overview of the survey questionnaire.

Metadata related to the location and survey

- Location name
- Data Integration Center (DIC) data quality (DQ) officer
- Deadline
- Survey feedback completion date

Metadata related to the survey respondents

- Gender
- Educational background
- Highest degree
- Years of experience with data quality assessment (DQA)
- Years of experience with observational data fitness-for-purpose assessment

Survey questions

- Question 1: On average, how many data requests or local data use projects are handled at your site DIC per quarter?
- Question 2: Which contents are mostly in focus in your local data use projects (eg, care evaluation in transfusion medicine), and which data repositories are most frequently queried in this context (Informatics for Integrating Biology and Bedside, Observational Medical Outcomes Partnership, Fast Healthcare Interoperability Resources, etc)?
- Question 3: How are data use project–specific DQ requirements collected from the perspective of data requesters at their DIC?
- Question 4: In addition to the current Medical Informatics for Research and Care in University Medicine DQA tool, what tools or technical approaches do you use for data use project–specific DQA?
- Question 5: What measures are taken at your location to communicate with data requesting sites about the quality of provided data for the intended purpose, so that data requesters have opportunities to estimate the fitness of the data to complete the intended project?
- Question 6: What would be their expectations or requirements for a fitness-for-purpose cross-site DQ framework that you could adopt in the future to measure DQ related to their data use projects?

Sample

All medical DICs from the 10 university hospitals affiliated with the MIRACUM consortium were invited to participate in the survey. For each DIC (MIRACUM site), the responsibility of completing the survey was delegated to potential participants. The participants were specialized professionals with expertise in DQ, responsible for evaluating and enhancing the quality of observational data for secondary use within their respective DIC in the context of intern- or cross-location DUPs. While each DIC submitted a single survey response detailing their practice related to assessing data's fitness-for-purpose, they had the flexibility to involve 1 or multiple participants based on their availability during the data collection period.

Data Collection

We conducted the data collection from April 15 to June 15, 2022, using a survey questionnaire comprised of 6 open-ended questions. To streamline the survey process for all participating sites and to maintain clear documentation of the participant's responses, we used Atlassian Confluence (version 7.13.11) [30] as our documentation software.

The data collection process was initiated by extending formal invitations to the DICs through email. These invitations included a link directing to a confluence main page, which outlined the objectives of the survey and provided instructions on how to respond to the survey questions. Additionally, each participating location had access to a distinct embedded confluence-landing subpage, structured with 2 information entry areas. The first input area enabled the entry of meta-information, collecting demographic data on each participant involved in the survey. These included gender, educational background, highest degree obtained, and years of experience in DQA and fitness-for-purpose evaluation. The second area was devoted to gathering specific responses to the 6 open-ended survey questions. Upon completing the meta-information provision and responding to the survey questions, the involved participants completed the survey by submitting their site response and documenting the date of completion.

The survey specifically inquired about the quarterly frequency and current objectives driving observational DUPs within the DICs. Our inquiry was guided by the 3×3 EHR DQA guideline by Weiskopf et al [21], which illustrates the project-specific nature of data fitness evaluations for particular uses. This framework served as a preliminary theoretical basis for our study, allowing us to explore how DICs manage and align data requester expectations concerning observational DQ throughout the data lifecycle—from the initial request to the final delivery. In addition to examining the procedural aspects of DUP-related DQ management, our survey aimed to uncover the underlying mechanisms through which DICs implement and communicate the fitness-for-purpose of data within research and clinical teams. Additionally, we sought to identify the standards required

by each DIC for a scalable, automated solution to assess and report on data fitness-for-purpose in the MIRACUM DUP context.

Data Analysis

We analyzed the data using the thematic analysis (TA) method suggested by Braun and Clarke [31,32]. This approach was strategically chosen to identify and rectify any potential errors in the coding process. This methodology aligns with best practices recommended for qualitative research and is supported by precedents established in similar studies [31-33]. The TA framework offers practical and meaningful steps to deeply understand the common thoughts, experiences, or behaviors [34] among the specific cohort of participants.

Following the TA framework of Braun and Clarke [32], our analysis progressed through 6 structured stages, including data familiarization, initial codes generation, theme identification, theme review, theme definition and naming, and report writing [32,34]. First, we familiarized ourselves with the material through multiple, exhaustive readings of each location's feedback and took targeted notes. This facilitated the jotting down of early impressions. Second, we generated initial codes by manually classifying each relevant data segment. In this context, we proposed an initial coding concept (Table 1), which we created based on the vivo coding [34] (verbatim coding) method. This consisted of codes derived from the data by mainly using the language and terminology used by the study participants. This approach helped encapsulate codes reflecting the perspectives and actions expressed by the study participants. Throughout this process, there were numerous iterative discussions within the research team. Third, we used a dynamic approach to combine, compare, and analyze each of the generated code. This interpretive process enabled to inductively derive appropriate themes that have a concise and meaningful connection to the survey data. However, we ensured the themes also accurately reflected the entire data set. In the fourth step, we thoroughly reviewed these themes, ensuring that each theme has sufficient commonality, coherence, and distinctiveness to each other. In the fifth step, we assigned descriptive and accurate titles to each theme, enabling a comprehensive illustration of the key information of participants' responses. Finally, in the sixth step, we created this manuscript as part of a TA-guided qualitative data analysis process. The condensed analytical process documentation is included in Multimedia Appendix 2. The main objective of the initial coding was to ascertain the reliability and accuracy of the framework prior to its application to a larger data set, thereby enhancing the overall integrity and validity of the research findings. Furthermore, the research team collaboratively discussed and refined the initial coding to avoid overlapping with other codes. This supported the refinement of the initial coding to the final code (see Results section). This increased both the relevance and the representativeness of the inductively generated themes and codes in light of the large information corpus provided by the participating DIC locations. The final codes are presented in the *Results* section of this paper.

We migrated the aggregated data from the confluence platform into a comprehensive Microsoft Word document for in-depth analysis (Multimedia Appendices 2 and 3). The collected data from the first survey question were analyzed using the open-source software RStudio (Posit) [35]. The scripts used for this analysis are presented in Multimedia Appendix 4.

Table 1. Initial coding.

Selected preliminary codes	Illustrating examples of key terms
Clinical research purposes as primary emphasis of data use projects	Clinical research, clinical trials, and observational studies
Applying the 4-eyes principle	Mutual control and the involvement of an independent person
Using overview dashboard	Data portal, integration portal, and information dash
Check for data plausibility	Plausibility checks, data verification, and data items comparisons
System comparisons	Data quality comparison between data sources and target systems
Data consistency checks	In-depth examination of data completeness, data conformity, and data correctness (including plausibility) with regard to an intended data use
Data provenance collection	Collection and documentation about where the data came from

Results

Overview

This study involved all 10 MIRACUM DICs including 17 participants. The greatest proportion of the participants were male (11/17, 65%), had backgrounds in computer sciences (8/17, 47%), and held a master's degree (6/17, 35%). On average, the participants had 3.7 (SD 5.3) years of experience in assessing DQ and 1.3 (SD 1.5) years in evaluating data fitness-for-purpose. The study also revealed that most MIRACUM-affiliated DICs conduct 2 to 5 DUPs quarterly, with a single location handling up to 20 DUPs in the same timeframe. Additionally, the analysis identified 27 codes grouped into 6 themes.

Scope of Participants

Of the 10 MIRACUM DIC sites solicited for participation, all accepted to engage in the study. In total, 17 participants agreed to respond to the survey questionnaire. Table 2 presents the demographic characteristics of the participants and shows the distribution of their years of experience in assessing both general DQ and data fitness-for-purpose.

Table 3 shows an overview of the DUP frequencies across the MIRACUM DICs. The MIRACUM-affiliated sites have

undertaken an average of 5.8 (SD 6.5) DUPs on a quarterly basis, with a few sites executing up to 15 or 20 DUPs within the same timeframe. One DIC did not conduct any DUP.

Thematic Representation of Data

Overview

This subsection presents a thematic representation of findings derived from responses in the MIRACUM DICs. Through a comprehensive coding process, we identified 27 distinct codes, which were subsequently organized into 6 key themes. These themes approach various relevant aspects of assessing the fitness for use of EHR data within the context of DUPs. Below is an overview of the identified themes: objectives of DUPs in MIRACUM DICs, use of heterogeneous types of data repositories, strategies for gathering DUP-specific DQ criteria, methods for evaluating the data fitness-for-purpose, existing implementations and reporting mechanisms for data fitness-for-purpose, and requirements for a scalable data fitness-for-purpose assessment solution. Results are presented below, summarized and illustrated with quotes from site feedback, aligned with the COREQ (Consolidated Criteria for Reporting Qualitative Research).

Objectives of DUPs in MIRACUM DICs

Most MIRACUM sites (8/10, 80%) reported that DUPs primarily engaged in clinical research, with a focus on the analysis of clinical events, the assessment of health care quality, and the development of prediction models for clinical associations. The participating sites provided detailed accounts of their research activities.

The MIRACUM site 4 underscored, for instance, the relevance of qualifying research questions and quality assessment, including “Qualifying research questions (doctoral dissertations etc.), quality assessment, proof of qualification, where so far mostly the mirror system of ORBIS serves as data repository.”

Another participating site illustrated the type of clinical questions they address, by focusing on “Clinical research questions e.g. number and context data on splenectomies, context data on urological sepsis.” This indicates an in-depth examination of specific medical procedures and conditions, as observed at MIRACUM site 4.

A further narrative provided a broader perspective on the research activities, describing a research focus on

> *Department- and unit-specific clinical questions e.g., prediction of departmental sepsis and associations with specific treatment procedures/ICD diagnoses. Other example: patient case-based analysis of multiple clinical complications associated with specific clinical and demographic characteristics.*

This comprehensive approach at MIRACUM site 9 exemplifies the depth and complexity of the clinical research being conducted, which would aim to link various clinical and demographic factors with health outcomes. These narratives collectively describe the diverse and detailed nature of the clinical research efforts within DUPs, thereby demonstrating an important commitment to improving health care quality and developing predictive models based on extensive clinical data.

Use of Heterogeneous Types of Data Repositories

Overview

In the analysis of clinical data repositories used for DUP execution, 5 prominent repositories were identified from site feedback, revealing a diverse and dynamic landscape of data management systems. These systems range from broadly used ones such as the Clinical Data Warehouse (DWH) to specialized frameworks designed to meet specific research needs or privacy considerations. This variety reflects the differing technological

preferences across sites and underscores the complexity of DQ and data management in clinical research settings. The key repositories are as follows:

Use of Clinical DWH

The Clinical DWH emerges as the most commonly used repository for executing DUPs, as evidenced by its application in DUP-related DQA and reporting activities. In total, 3 (30%) of the 10 surveyed sites indicated that they primarily rely on the DWH for their internal research queries, quality assurance, and reporting needs. The respondents at MIRACUM site 2 and site 9 indicated that while the DWH is the primary repository for general queries, other specialized repositories, such as Informatics for Integrating Biology and Bedside (i2b2), Observational Medical Outcomes Partnership (OMOP), and Fast Healthcare Interoperability Resources (FHIR), are reserved for specific project needs, such as MI-I or MIRACUM requests. The following statements can show this:

> *Internal research queries, quality ensuring and reporting are mainly performed using the DWH. The i2b2/OMOP/FHIR repositories are mainly used for MI-I/MIRACUM specific requests.* [Survey question 2, MIRACUM site 2]

> *Most queries through the cDWH and i2b2 repo.* [Survey question 2, MIRACUM site 9]

Data Representation Model (i2b2, OMOP, and FHIR)

These models are notably prevalent, being used in 7 (70%) of the 10 sites. They are particularly suited to internal and cross-location DUP projects that require specific data handling or analysis frameworks. This pervasive use is corroborated by feedback from MIRACUM site 2, where i2b2 and OMOP are used for internal projects: "The i2b2/OMOP/FHIR repositories are mainly used for MI-I/MIRACUM specific requests." This indicates the existence of a relevant and versatile framework capable of supporting a multitude of research needs.

ORBIS System Use

At 1 (10%) surveyed site, the ORBIS system, particularly its mirror component, is exclusively used as the primary data repository. The system supports a range of academic and quality assurance activities, such as doctoral dissertations and qualification proofs, thereby emphasizing its specialized application in academic and clinical research environments. This is presented in the following statement: "Qualifying research questions (doctoral dissertations etc.), quality assessment, proof of qualification, where so far mostly the mirror system of ORBIS serves as data repository" (Survey question 2, MIRACUM site 3).

OPAL DataSHIELD Framework

In total, 2 (20%) of the 10 sites surveyed indicated a preference for the OPAL DataSHIELD framework for data storage and analysis. This preference may indicate a strategic choice for environments where data privacy and security are of paramount importance. This is evidenced by the use of DataSHIELD for analysis without direct querying of data repositories, as observed at MIRACUM site 10: "Analyzing is performed via DataSHIELD, therefore no direct query in data repositories" (Indirect i2b2).

CentraXX Repository

The local research repository CentraXX is referenced by 1 (10%) site for the purpose of storing frequently requested data items. The respondents from MIRACUM site 6 reported that "The most frequently requested data items are stored in the local research repository CentraXX" (Survey question 2). This repository's use serves to illustrate its role in facilitating rapid access to high-demand data, which could be of paramount importance for the efficient conduct of DUPs at the local level.

Strategies for Gathering DUP-Specific DQ Criteria

Overview

The analysis of data collection methods used by the DICs for the DUPs reveals a multifaceted approach aimed at enhancing the fitness of data through rigorous validation processes and strategic requester-provider interactions. In this subsection, we present the reported practices to ensure the alignment and quality of data for DUPs.

Detailed Request Submission

A noteworthy observation is that a considerable proportion of DICs (4/10, 40%) emphasize the importance of detailed and precise data requests. This approach serves as a preemptive measure to ensure that the data delivered are aligned with the needs of the requester. In the event of discrepancies between the requested and provided data, the aforementioned sites use a postprocessing step to rectify any misalignments. This process is captured by a statement from one of the survey respondents:

> *During the data request, we advise that the requested data should be described as fine-grained and exact as possible. If the data provided does not match the request, a "post-processing" process will be initiated.* [Survey question 3, MIRACUM site 1]

Participatory Discussion for Data Validation

Half of the surveyed sites (5/10, 50%) use participatory discussions between data providers and requesters as a core strategy for data validation. These discussions aim to identify and mitigate any factors that might reduce the quality of the data, such as issues with free text information or the specific documentation practices of the data-providing institution. The respondents noted that:

> *The requested data are usually discussed at least once with the requester and quality-reducing aspects are worked out together, e.g., free text information, documentation practice in the respective data-providing institution (usually the requester comes from the same institution and knows it very well).* [Survey question 3, MIRACUM site 3]

Quality Requirements Gathering

A collection of DQ requirements is conducted at a minority of the sites (1/10, 10%), with the use of a feasibility or data request form. The form is completed by both data requesters and internal data request administrators in order to gather specific DQ

requirements. The aforementioned process is described as follows:

> *Project-related data quality requirements are gathered using a Feasibility Request (FR) form completed by the data requester & internal data request administrator.* [Survey question 3, MIRACUM site 9]

However, 2 (20%) of the 10 sites did not apply any approach to gather the DUP-related DQ requirements.

Methods for Evaluating the Data Fitness-for-Purpose

Overview

In terms of applied methods to assess whether the DIC data suite is for the carrying out of various DUPs, 3 approaches were revealed.

Four-Eyes Principle

This method, which was observed at 3 (30%) of the 10 sites, places an emphasis on ensuring that the data are fit for the intended purposes through mutual control and content validation. The fundamental principle is straightforward: before any data are provided or issued. It is subjected to scrutiny by at least 2 individuals, thereby enhancing both accuracy and reliability.

The MIRACUM site 3 highlighted the development of a metadata repository–supported DQA tool, indicating that this approach is being further systematized: "Mutual control before issue/provision (4-eyes principle), an MDR-supported DQA tool is under development."

Similarly, MIRACUM site 9 provided further insight into the practical application of this principle, describing a 2-tier validation process as follows:

> *4-eyes principle: Content validation of the queries by a second data scientist (possibly also with a separate query), so that it is ensured that the query actually does what it is supposed to do. Content-related plausibility control of the results from the query through medical colleagues.*

Comparison of Data Values Distribution

This approach, used by 2 (20%) of the 10 sites, validates data by contrasting the distribution of data values from different systems. The MIRACUM site 2 provided an illustrative example of this method by comparing the hit ratios generated by independent systems: "For project-specific validation, comparison of hit ratio from different systems created by an independent person." This process not only identifies discrepancies or anomalies but also serves to reinforce the integrity of the data through independent verification.

Data Consistency Checks

The consistency checks are used by 2 (20%) of the 10 sites to verify the appropriateness of data formats, types, and variable associations. The MIRACUM site 10 exemplifies this process by using DataSHIELD to verify data formats and the number of variables prior to initiating analyses: "Verification of the data format or type, the number of variables via DataSHIELD before the analyses." This step could be of paramount importance in ensuring that the data meet the requisite standards for subsequent analytical procedures. It might serve as a foundational check that prevents the propagation of errors in data handling and analysis.

Existing Implementations and Reporting Mechanisms for Data Fitness-for-Purpose

Overview

The following measures were identified to technically implement and report fitness-for-purpose of clinical data.

Data Requester Feedback and Adjustment Process

At a majority of the study sites (6/10, 60%), the implementation of a feedback mechanism that involves data requesters is of high importance. Here, data requester feedback is systematically gathered and analyzed. In light of this input, the queries used to select data undergo adjustments and validations in accordance with the 4-eyes principle. This process is illustrated by a representative from MIRACUM site 9:

> *Then the data request administrator, who goes through the data to be delivered together with the data requester, delivers the data. In case of change requests/incorrect quality in the data, the data selection queries are adjusted and validated again via the 4-eyes principle, and documented.*

Feedback Loop and Quality Control

In 2 (20%) of the 10 surveyed sites, a continuous feedback loop is established among the data requester, data request administrator, internal data scientists, and the data transfer office. This iterative process is highly relevant for the refinement of DQ prior to final delivery. As described by MIRACUM site 9, the cycle involves a series of checks and rechecks:

> *This results in the feedback cycle: data requester => data request administrator => internal data scientists => data request administrator => data requester. Only in case of a complete match (from the data requester's perspective) the final data delivery takes place.*

Reporting Quality Using Dashboard

The use of technological tools to report on DQ was observed in 2 (20%) sites. Specifically, these sites use an overview dashboard within a self-developed data integration portal. This tool provides a streamlined and transparent view of DQ metrics, which can be essential for ongoing assessment and improvement. A representative from MIRACUM site 7 described the utility of the dashboard as follows: "Overview dashboard in the self-developed data integration portal," indicating a technology-driven approach to quality reporting.

Requirements for a Scalable Solution for the Data Fitness-for-Purpose Assessment

Table 4 summarizes the requirements gathered during the survey including some exemplifying quotes. The MIRACUM DICs emphasized diverse key attributes for the development of a data fitness-for-purpose assessment tool. These include flexibility, understandability, practicability, and extendibility in terms of usability. From a technical perspective, there was a preference

for dashboard implementation, system comparison features, data consistency checks, and ensuring uniformity in the FHIR profiles. Additionally, the consideration of data provenance was mentioned as an important feature in assessing fitness-for-purpose.

Table 4. Summary of requirements for implementing a data fitness-for-purpose assessment tool.

Requirement dimension and key attributes	DICs[a] (n=10), n (%)	Illustrating quotes
Usability		
Flexibility	1 (10)	"Flexible organization of the DQ system" [Survey question 6, MIRACUM[b] site 1].
Understandability	2 (20)	"Understandability for the clinician and data scientist/statistician Fitness-for-use dashboard" [Survey question 6, MIRACUM site 2].
Practicability	1 (10)	"Generally enough that it can be used in every DIZ and for every request. It should be pragmatic and easy to understand, so that it can always be used as a basic tool and its benefits are seen equally by all parties (data provider, data supplier, data requester)" [Survey question 6, MIRACUM site 3].
Extendibility	1 (10)	"In the short term, it is limited to the essentials to be able to use it and gain experience. In the long term, it may even be possible to modularize it and thus use it only in parts" [Survey question 6, MIRACUM site 3].
Technical and functionalities		
Dashboard implementation	3 (30)	"Implementation of a dashboard" [Survey question 6, MIRACUM site 1].
System comparison	3 (30)	"Complete non-interactive integration of the DQ process as an operation within the data pipelines for complete monitoring of the mapping of source and target systems with automatic machine-readable report generation (no PDF)" [Survey question 6, MIRACUM site 7].
Data consistency checks	3 (30)	"Mapping and automation of DQ checks based on the specific data quality metrics • Data completeness: are there enough patients at the DIZ site to carry out the planned projects • Data plausibility: formulation & automation of general-transferable plausibility checks (e.g., no readmission after a death, ...) that could affect the outcomes of most DRs • Data conformity: uniform mapping and verification of conformity of ICD, OPS, LOINC codes, and adequate reporting in the systematics" [Survey question 6, MIRACUM site 9].
FHIR[c] profiles uniformity	3 (30)	"Uniform FHIR profiles across MIRACUM partners" [Survey question 6, MIRACUM site 10].
Data provenance collection	1 (10)	"Structured Provenance Documentation: • where did the data come from, • what processing steps were performed on the data up to the time of data delivery, • Are there changes to the data that may represent a potential impact on the planned data use project?" [Survey question 6, MIRACUM site 9].

Discussion

Principal Findings

Overview

This investigation examined the practices surrounding the fitness-for-purpose of observational health care data within MIRACUM DICs. It revealed both strengths and areas needing improvement in current approaches compared to established evidence. It also highlighted the active engagement of MIRACUM DICs in assessing data suitability for clinical research, using a diverse array of data repository infrastructures. However, the findings also underscored an important variation in methods for DQA and a general lack of standardization, suggesting the need for a more harmonized approach to enhance the accuracy and reliability of clinical data for specific secondary use purposes. Practical requirements were identified to support future implementation studies toward automating the observed processes.

Addressing Fitness-for-Purpose of Observational Health Care Data

Our study set out to examine the extent to which MIRACUM DICs address the fitness-for-purpose of observational health care data and the ways in which these approaches differ from

existing benchmarks. On the one hand, the demographic data suggest that the majority of participating MIRACUM DIC DQ experts have a computer science background and the prevalent academic qualification was a master's degree. This is indicative of the technological proficiency of the participants about data handling and engineering, but the participants may lack specific clinical or statistical expertise. This could be required for accurately assessing the suitability of clinical data for secondary use purposes. On the other hand, it is apparent that the MIRACUM DICs are actively engaged in fitness-for-purpose assessment of data, particularly for clinical research questions ranging from clinical event investigations to complex prediction models. This reflects the substantial amount of evidence [3,5,8,9,12] achieved since the inception of the German MI-I, implying a potential of fitness-for-purpose in DIC data, which should be further investigated based on the DIC data–driven research question. Interestingly, various repositories are used, including Clinical DWH, i2b2, OMOP, FHIR, ORBIS system, and OPAL DataSHIELD framework, indicating the use of diversified data infrastructure. However, there is a lack of harmonization and standardization in terms of strategies for assessing the suitability of DIC data with methods including the 4-eyes principle, system comparisons, and data consistency checks.

Compared to existing evidence, carrying out data consistency checks by the DICs nuancedly aligns with the recommendations of Kahn et al [22]. This process helps the MIRACUM sites in using the existing MIRACUM DQA tool to determine whether the integrated DIC data across the source and target databases [14,24] adhere to specified standards (conformance), whether certain data elements or values are sufficient (completeness), or if they are accurately reported (plausibility). In contrast, implementing the items from the 3×3 DQA guideline proposed by Weiskopf et al [21] was barely observable. This approach recommends specific DUPs by using particular methods (eg, rate of data regularity as proposed by Sperrin et al [36]) to assess DQ. For instance, this involves examining whether information regarding patients, data variables, and timeframe are completely, correctly, and currently integrated. This enables the research or clinical team to transparently determine the fitness-for-purpose of the data delivered by DICs. Automating such a process would enhance the integration of much more evidence, ensuring DQ for executing DUPs within the MIRACUM DICs. Therefore, the investigation of Razzaghi et al [37] could be seen as an initial roadmap toward a technical implementation. This describes a framework operationalizing such a fitness-for-purpose assessment process, with a particular focus on assessing clinical diagnosis or care. Furthermore, this should be evaluated in a closed association with DQ principles (outlier detection, plausibility, etc), as reported in various existing recommendations [20-22,38].

Key Requirements for Automating the Assessment Process

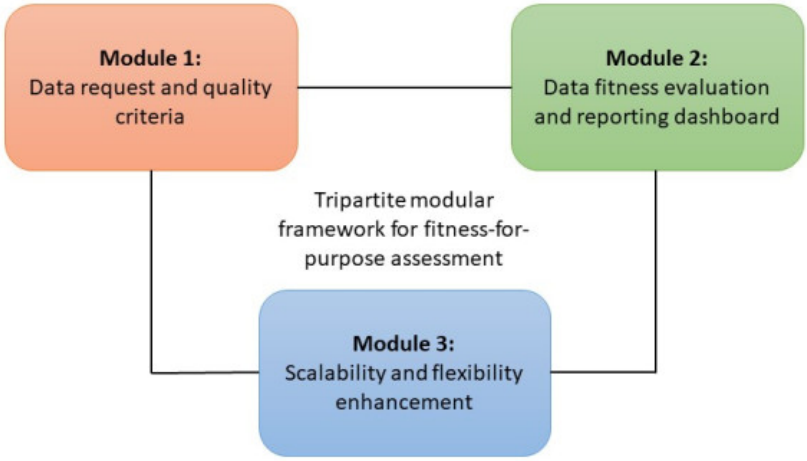
Our second research question focused on identifying the essential requirements for automating the assessment of fitness-for-purpose of EHR data within MIRACUM DICs. The TA revealed that from the perspective of the MIRACUM DICs, a scalable system for assessing the suitability of clinical data should be flexible, easily understandable, practicable, and modularizable (able to be extended in modules). However, the DICs expressed a need for user-friendly dashboards, facilitating an automated performance of system comparisons, data consistency checks, and data provenance collection in DUPs. These practice-oriented expectations adhere to the definition of fitness-for-purpose proposed by Girman et al [23], which considers assessing the availability of relevant data and the data provenance as key points for capturing fitness-for-purpose. A prior study by Gierend et al [15] explored the current status of provenance collection, which may present straightforward support in implementing this approach at the MIRACUM DIC level. However, the heterogeneity in the used data repositories at the DICs revealed that any automated solution would need to be repository agnostic or interoperable with multiple type of databases. In addition, the strategies for gathering of DUP-specific DQ criteria included consistent data description by requesters and participatory discussion between data providers and requesters. This suggests that an automated solution would require incorporating a flexible but stringent set of DQ criteria or functions, such as suggested by Weiskopf et al [20,21], Razzaghi et al [37], or Schmidt et al [38], that can be adjusted based on dynamic inputs. Finally, common approaches for assessing the fitness-for-purpose included the 4-eyes principle, comparison of data value distribution, and data consistency checks. These DQ verification processes suggest the need to incorporate robust DQA mechanisms into automation. These mechanisms could potentially use machine learning or rule-guided algorithms similar to the machine learning–supported DQA framework developed by Mark et al [39]. By considering these diverse aspects, we can consistently streamline the assessment of the fitness-for-purpose of clinical data, benefiting both research and clinical applications.

Derivation of a Roadmap Framework for Fitness-for-Purpose Assessment

Overview

Based on the findings discussed earlier, a guiding framework for an automated solution for assessing the fitness-for-purpose of EHR at the MIRACUM DICs was elaborated and structured into 3 modules (Figure 1). These modules have been designed to be pragmatically implementable and closely aligned with the survey insights to facilitate a smooth transition into practical application.

Figure 1. Tripartite modular framework for fitness-for-purpose assessment.



Data Request and Quality Criteria Module

This module should centralize and streamline the data requests and collection of DUP-specific DQ criteria. This module should include a user interface for data requesters to input their data requirements (eg, study fit criteria) and fitness-for-purpose criteria (eg, based on DQ rules from the 3×3 framework [21]).

Data Fitness and Reporting Dashboard Module

This module incorporates mechanisms for data fitness assessment reflecting the need for evaluating the data fitness for specific DUPs. It should use the fitness-for-purpose criteria collected from module 1 to perform data accuracy evaluation, alongside functionalities for comparing data values across different systems (eg, i2b2, OMOP, and FHIR). Furthermore, this module should feature a decision-supporting dashboard for visualizing these assessments by providing an overview of the data's fitness-for-purpose, which may facilitate structured documentation of DQ assurance tasks into the data management plans of DUPs.

Scalability and Flexibility Enhancement Module

This module is dedicated to the technical aspects of items from modules 1 and 2, addressing the requirements for a scalable solution, including the implementation of a user interface and dashboard, system comparison features, data consistency and provenance checks, and uniformity in FHIR profiles. Moreover, it should be implemented under consideration of usability requirements expressed by the DICs.

Each module was elaborated to address specific aspects identified in the survey to ensure a comprehensive and user-friendly solution for the automated DQ or fitness-for-purpose tool. This approach should not only facilitate the implementation process but also improve the efficiency and effectiveness of DQ and fitness-for-purpose checks across all MIRACUM DICs.

Strengths and Limitations

The strengths of this investigation lie in its comprehensive data collection and analysis. Using established approaches, such as the TA-based framework of Braun and Clarke [31,32], we provided a holistic view of the current state of the assessment of fitness-for-purpose observational EHR data at the MIRACUM DICs. Given the importance of reflexivity in qualitative research, as discussed by Braun and Clarke [32], we acknowledge our theoretical stance toward a constructivist approach, where knowledge is viewed as a construct rather than discovery. This perspective informed our analysis to interpret the data through a lens that considers both the factual and the contextual dimensions conveyed by the participants. As such, our survey questions, detailed in Textbox 1, were crafted not only to gather empirical information but also to probe deeper into the implications and the perceived effectiveness of DQ practices. Furthermore, the comprehensive examination of all MIRACUM DICs, illustrated diversified ways of conducting secondary use of EHR data and fitness-for-purpose assessments, highlighting additional proficiency.

However, our study also presents some limitations. The study cohort was restricted to the MIRACUM consortium. Expanding the research to include other MI-I consortia and DICs not affiliated with the MI-I project would enhance the sample's representativeness and the generalizability of the earned findings.

Implications for Future Research and Practice

To ensure that DIC data are suitable for research and clinical applications, it is crucial for MIRACUM DICs to align their DQA processes with established best practices and recommendations. Future research should aim to investigate the correlation adhering to the recommendations with the successful conduction of DUPs by evaluating whether clinical research questions (eg, cross-location analysis of comorbidities [25]) were more consistently addressable. For research practice, there is an accentuated need to develop automated and scalable solutions to assess the fitness-for-purpose of EHR DIC data, and our study provides the foundational insights to drive this technological advancement. Importantly, the solution could be based on the proposed tripartite modular framework. This could ease the integration into existing infrastructures of MIRACUM and eventually MI-I DICs, taking into account the key requirements identified by this investigation.

Conclusions

While the MIRACUM DICs focus on assessing the quality of clinical data for DUP conduction, there is a relevant variation

in the used methods and requirements to automate these processes. With the increasing volume and complexity of health data, having a standardized and scalable solution to automate the assessment of fitness-for-purpose is essential to maintain the integrity of research and clinical practice. Follow-up investigations should be directed toward building systems guided by evidence-based practices that should be customized to the specific needs and circumstances of MIRACUM and MI-I DICs.

Acknowledgments

This research was funded in part by the German Federal Ministry of Education and Research through the Medical Informatics in Research and Care in University Medicine consortium (grants 01ZZ1801E and 01ZZ1801A). For the publication fee, we acknowledge financial support from Heidelberg University. This work was performed in (partial) fulfillment of the requirements for obtaining the degree “Dr sc hum” of the Medical Faculty Mannheim of the University of Heidelberg (GKW).

Data Availability

The qualitative data collected and analyzed during this study are available in Multimedia Appendices 2 and 3. Furthermore, the R-based script used to plot the data use project execution frequency is available as well in Multimedia Appendix 4.

Authors' Contributions

GKW developed the research concept and methodology, collected and analyzed data, generated and reviewed themes and codes, visualized data, programmed in R, wrote the original draft, and reviewed and edited the manuscript. PM contributed to the methodology, reviewed themes and codes, and edited and reviewed the manuscript. SAS collected data and also edited and reviewed the manuscript. FS edited and reviewed the manuscript, provided supervision, and secured funding. TG contributed to the conceptualization and methodology of the study, edited and reviewed the manuscript, provided supervision, managed the project, and acquired funding. All authors reviewed the final manuscript.

Abstract

Background: The bidirectional encoder representations from transformers (BERT) model has attracted considerable attention in clinical applications, such as patient classification and disease prediction. However, current studies have typically progressed to application development without a thorough assessment of the model's comprehension of clinical context. Furthermore, limited comparative studies have been conducted on BERT models using medical documents from non–English-speaking countries. Therefore, the applicability of BERT models trained on English clinical notes to non-English contexts is yet to be confirmed. To address these gaps in literature, this study focused on identifying the most effective BERT model for non-English clinical notes.

Objective: In this study, we evaluated the contextual understanding abilities of various BERT models applied to mixed Korean and English clinical notes. The objective of this study was to identify the BERT model that excels in understanding the context of such documents.

Methods: Using data from 164,460 patients in a South Korean tertiary hospital, we pretrained BERT-base, BERT for Biomedical Text Mining (BioBERT), Korean BERT (KoBERT), and Multilingual BERT (M-BERT) to improve their contextual comprehension capabilities and subsequently compared their performances in 7 fine-tuning tasks.

Results: The model performance varied based on the task and token usage. First, BERT-base and BioBERT excelled in tasks using classification ([CLS]) token embeddings, such as document classification. BioBERT achieved the highest F_1-score of 89.32. Both BERT-base and BioBERT demonstrated their effectiveness in document pattern recognition, even with limited Korean tokens in the dictionary. Second, M-BERT exhibited a superior performance in reading comprehension tasks, achieving an F_1-score of 93.77. Better results were obtained when fewer words were replaced with unknown ([UNK]) tokens. Third, M-BERT excelled in the knowledge inference task in which correct disease names were inferred from 63 candidate disease names in a document with disease names replaced with [MASK] tokens. M-BERT achieved the highest hit@10 score of 95.41.

Conclusions: This study highlighted the effectiveness of various BERT models in a multilingual clinical domain. The findings can be used as a reference in clinical and language-based applications.

Introduction

Since 2015, deep learning is increasingly being used in clinical natural language processing (NLP) [1]. Large language models (LLMs) based on deep learning technology are widely used in numerous clinical NLP domains [2]. Because contextual comprehension is critical for the overall performances of NLP models, studies have focused on the development of models

that excel in conveying contextual information. Conventional approaches of NLP involve crafting word-to-word sequence models such as the hidden Markov model and using limited datasets annotated with labels such as disease and medication names [3-5]. However, studies are increasingly focusing on fine-tuning LLMs that have been pretrained on massive unlabeled biomedical literature sources, such as Medical Information Mart for Intensive Care (MIMIC-III) [6] and PubMed [7,8]. This shift in the NLP research direction has substantially elevated the contextual understanding capabilities of models and inspired studies on clinical NLP that focus on LLM utilization. For example, studies on automated summarization [9-11] have effectively extracted critical phrases from diverse sources, including biomedical papers and patient records. In addition, studies on entity extraction [12-15] have identified major entities such as disease names and drug names. However, these studies have focused exclusively on English-language corpora.

In the multilingual clinical domain, we proposed a set of contextual understanding conditions, with a comprehensive suite of clinical NLP evaluations specifically for these conditions. The proposed approach involves comparatively assessing bidirectional encoder representations from transformers (BERT) models [16] to provide guidelines for selecting the most suitable BERT model for a particular condition.

We proposed 2 hypotheses to examine 4 BERT models. First, we assumed that within the multilingual clinical domain, a language model capable of comprehending multiple languages would achieve superior performance. Second, models with the capacity to comprehend medical contexts would demonstrate superior efficacies. We selected BERT-base [16], Korean BERT (KoBERT) [17], Multilingual BERT (M-BERT) [18], and BERT for Biomedical Text Mining (BioBERT) [7] for the study. We pretrained these models on visit records on 160,000 patients. Subsequently, we introduced a series of comprehensive downstream tasks to learn the conditions required for these models to achieve effective contextual understanding. We assumed that an effective language model thrives in contextual comprehension under the following conditions:

- The model can determine whether the provided documents pertain to the same patient (tasks 1 and 2).
- The model is proficient in identifying the department associated with a given document (task 3).
- The model can discern the descriptions within medical records for the conditions of different patients (tasks 4 and 5).
- The model can ascertain the connection among sentences (task 6).
- The model can competently deduce disease names based on existing knowledge (task 7).

The rationale of the proposed conditions is the widespread adoption of BERT models in the medical domain for various applications.

BERT has been applied in medical natural language inference research to assess the relationship between 2 sequences (premise and hypothesis) with entailment, contradiction, or neutrality labels. Percha et al [19] used a fine-tuned BERT to locate clinical notes relevant to query sentences. Romanov and Shivade [20] created the MedNLI clinical dataset for natural language inference. They used several models and methodologies, such as bag-of-words, InferSent, and enhanced sequential inference models, to confirm the efficacy and validity of their datasets. Boukkour et al [21] introduced an alternative approach to BERT tokenization, proposing a convolutional neural network–based character-based tokenizer as a replacement for WordPiece Tokenizer, which is used to pretrain BERT, to improve BERT performance on the MedNLI dataset. Kanakarajan et al [22] pretrained the ELECTRA model, which is named “efficiently learning an encoder that classifies token replacements accurately,” [23] using abstracts from PubMed, and evaluated its performance on the MedNLI dataset.

BERT was applied to categorize clinical notes. Rasmy et al [24] introduced Med-BERT, which pretrained BERT using electronic health record data to classify diabetes and pancreatic cancer datasets. This model exceeded gated recurrent units by 2 - 4 in terms of area under the receiver operating characteristic score. Zhang and Jankowski [25] proposed average pooling transformer layers handling token-, sentence-, and document-level embeddings for classifying *International Classification of Diseases* codes. Their model outperformed the BERT-base model by 11 points.

For the reading comprehension task, BERT can be used to determine the answer span within a given text. Pampari et al [26] proposed the electronic medical record question answering (emrQA) dataset to determine the answer span to a question in a clinical context. Yue et al [27] compared the performances of BERT-base, BioBERT, and ClinicalBERT [8] on the emrQA dataset and additional test datasets to address the problems of the emrQA dataset. Rawat et al [28] used 30 logical forms to express questions in semistructured texts and identified the correct responses in the emrQA dataset. They entered clinical notes and questions and used multitask training to simultaneously predict the logical structure of the question and the text span of the answer in a clinical note. Savery et al [29] introduced the MEDIQA-AnS dataset, which contains questions and corresponding answers regarding the health care concerns of patients. The correct answers to these questions, which contain valuable information about the patients, are used as summaries.

BERT can be used to extract information from clinical notes. Yang et al [15] used the 2010 i2b2 [30], 2012 i2b2 [31], and 2018 national NLP clinical challenges (n2c2) [32] datasets to compare the information extraction performances of BERT models, namely, BERT-base, ELECTRA, A Lite BERT (ALBERT) [33], and Robustly Optimized BERT Pretraining Approach (RoBERTa) [34]. The test results revealed that RoBERTa outperformed the other models. Richie et al [35] used Clinical BERT [8] to extract the social determinants of patient health, namely, employment, living tobacco, alcohol, drug use, and their attributes, from the n2c2 2022 Track 2 dataset [36]; for instance, texts such as “works” and “unemployed” were extracted for detailing employment information.

Although studies have extensively examined BERT versatility, they have focused only on English corpora. To address this limitation, we comprehensively analyzed the efficacies of BERT models in various tasks involving medical documents in both Korean and English.

The rest of the manuscript is organized as follows. The *Methods* section outlines the diverse tests used for BERT analysis and their application procedures. The *Results* section presents a summary of the outcomes of each test. The *Discussion* section outlines the distinctive characteristics of each BERT model and presents a thorough analysis for understanding the reasons for these characteristics. Finally, the *Conclusion* section summarizes the study and emphasizes its significance.

The aim of this study was to identify the BERT models that perform optimally in the bilingual (Korean and English) clinical domain. To achieve this objective, we designed 7 tasks, evaluated the performance of 4 BERT variants (BERT-base, BioBERT, KoBERT, and M-BERT) across these tasks, and assessed their relative significance.

Methods

Dataset

We obtained outpatient records from 8 departments, namely, endocrinology, respiratory, cardiovascular, gastroenterology, rheumatology, nephrology, allergy medicine, and infectious medicine departments, at Seoul National University Hospital in South Korea. We collected the records of 164,460 outpatients between 2010 and 2019. The dataset comprised 2,453,934 documents, with 412,499,140 tokens generated after tokenization using white space. The distribution of tokens and documents for various departments was as follows: endocrinology (tokens: 91,352,271; docs: 496,938), respiratory (tokens: 31,556,578; docs: 195,048), cardiovascular (tokens: 114,978,554; docs: 696,061), gastroenterology (tokens: 57,755,571; docs: 416,062), rheumatology (tokens: 24,857,675; docs: 204,600), nephrology (tokens: 70,865,514; docs: 322,629), allergy medicine (tokens: 17,024,481; docs: 92,041), and infectious medicine departments (tokens: 4,108,496; docs: 30,555). Table 1 provides statistical data for the corpus. Table 2 presents the clinical note of a patient experiencing rheumatoid arthritis.

Table . Statistical data of clinical notes in Seoul National University Hospital between 2010 and 2019.

Department	Tokens, n	Documents, n
Endocrinology	91,352,271	496,938
Respiratory	31,556,578	195,048
Cardiovascular	114,978,554	696,061
Gastroenterology	57,755,571	416,062
Rheumatology	24,857,675	204,600
Nephrology	70,865,514	322,629
Allergy medicine	17,024,481	92,041
Infectious medicine	4,108,496	30,555
Sum	412,499,140	2,453,934

Table . The example of a clinical note that was used for training bidirectional encoder representations from transformers models (for better understanding, an English translation has been added).

[f]WNL: within normal limits.

[g]CRP: C-reactive protein.

Ethical Considerations

We obtained approval to use the original data collection for research purposes from the institutional review board (IRB) at Seoul National University Hospital (IRB no. C-2108-008-1242). According to the institution's IRB policy, the data cannot be publicly disclosed due to patient privacy concerns. Instead, we provide an overview of the data in Table 2.

BERT Models

The BERT-base model is a precursor in pretrained transformer encoders [37]. Vast open-domain data sources, including Wikipedia and BooksCorpus, are used to train the model [38]. The model is primarily focused on English text. The configuration of this dataset facilitates the expression of contextual representations of English sequences.

The BioBERT model is an evolution of BERT and is pretrained on PubMed data and enriched with biomedical entities, rendering BioBERT proficient in comprehending terminologies such as disease and drug names. In this study, we used the latest iteration of BioBERT, that is, BioBERT version 1.1.

The SKT Corporation in South Korea devised the KoBERT model to enhance the comprehension and processing of the Korean language. Data from Korean Wikipedia and news articles were used to pretrain the model.

The M-BERT model was obtained from a richly varied corpus of 104 languages, enabling a contextual representation that spans both English and Korean sequences.

Pretraining

To enhance the bilingual clinical contextual understanding capabilities of BERT models, we conducted additional pretraining using an extensive dataset comprising 159,460 out of 164,460 outpatient records from Seoul National University Hospital, employing masked language modeling. The data were preprocessed meticulously using this strategy. WordPiece Tokenizer was used by BERT-base, BioBERT, and M-BERT; SentencePiece Tokenizer [39] was used by KoBERT. All tokenizers were case-sensitive. Subsequently, random tokens within the input sequence were replaced with [MASK] tokens. This process was reiterated 10 times to yield the data required for pretraining. The pretraining task of the model involved reinstating the [MASK] token to its original token, drawing on the data crafted through this preprocessing procedure.

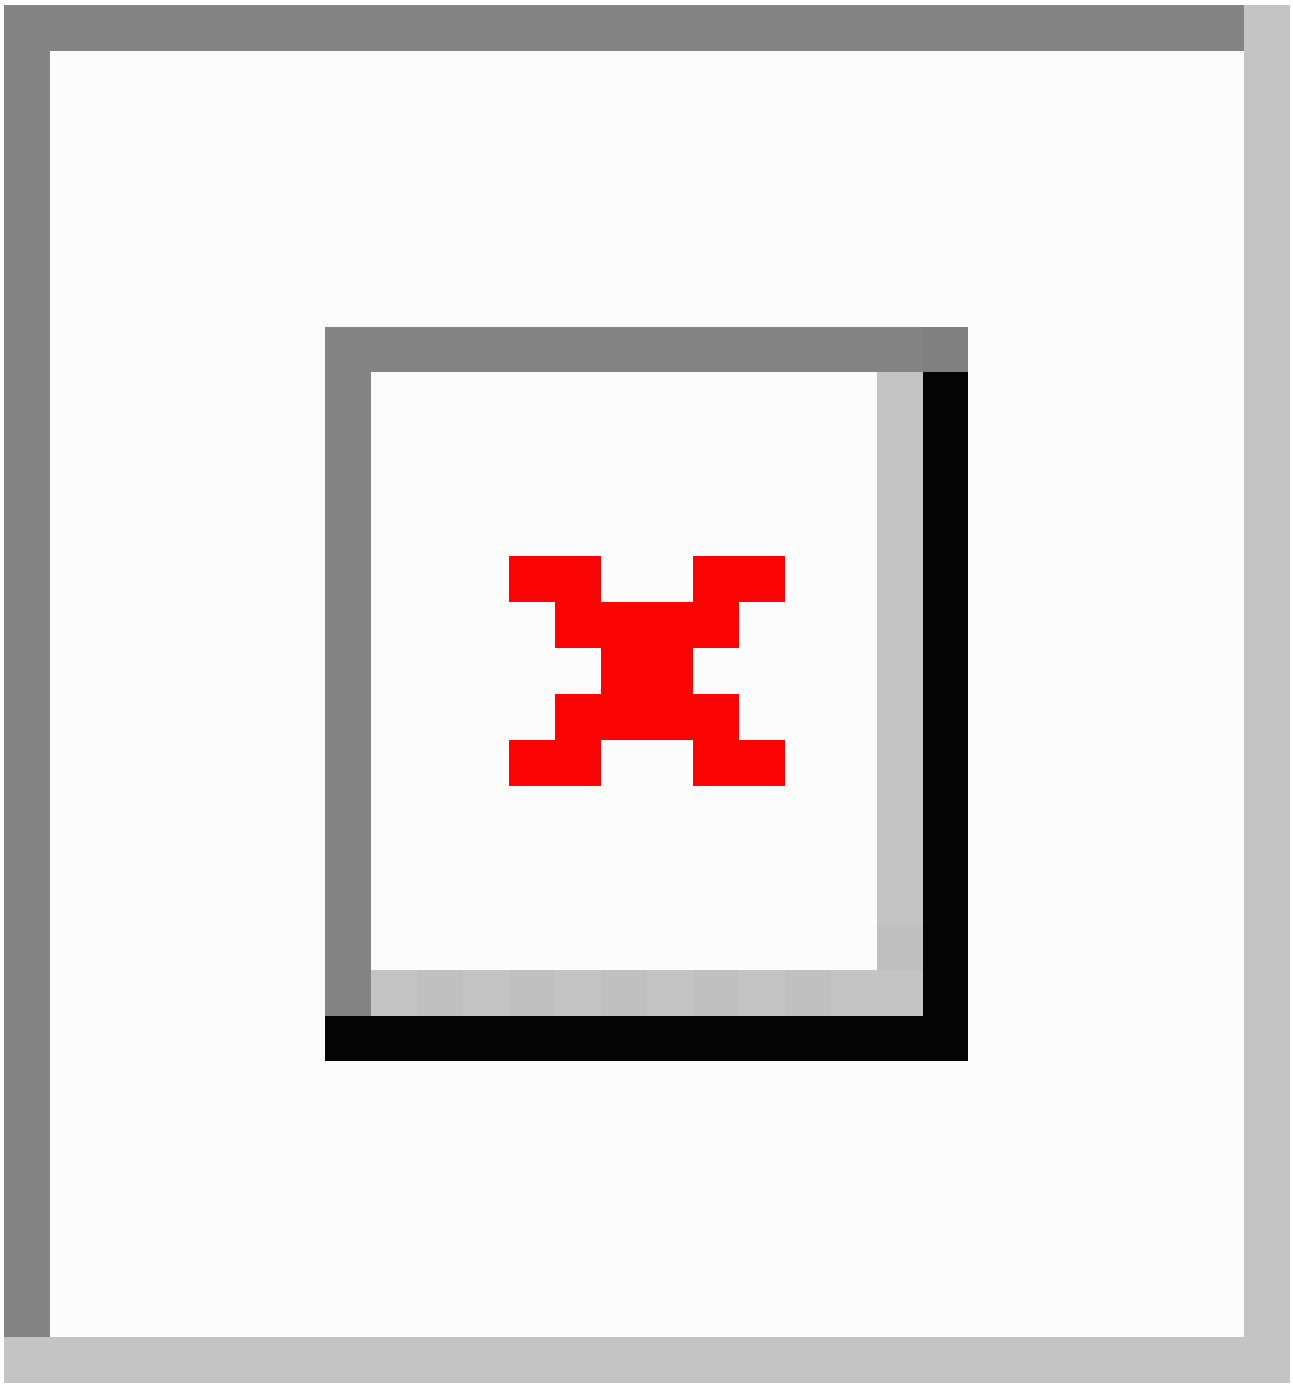
Multifaceted Clinical NLP Tasks

The evaluation framework encompassed 5 characteristics. Each characteristic was examined through 7 distinct downstream tasks that were designed to assess the clinical contextual comprehension capabilities of various BERT models.

Homogeneity Determination

As seen in Figure 1, we used 2 single outpatient records per input sequence to determine document homogeneity. Each model performed binary classification, discerning whether the records corresponded to those of the same patient (task 1). We extended this examination to the section level, tasking each model with predicting homogeneity based on a smaller segment of a page (task 2). In task 2, the objective was to determine whether 2 sequences originated from the same patient record, with 1 sequence containing an assessment section and the other section containing a randomized section.

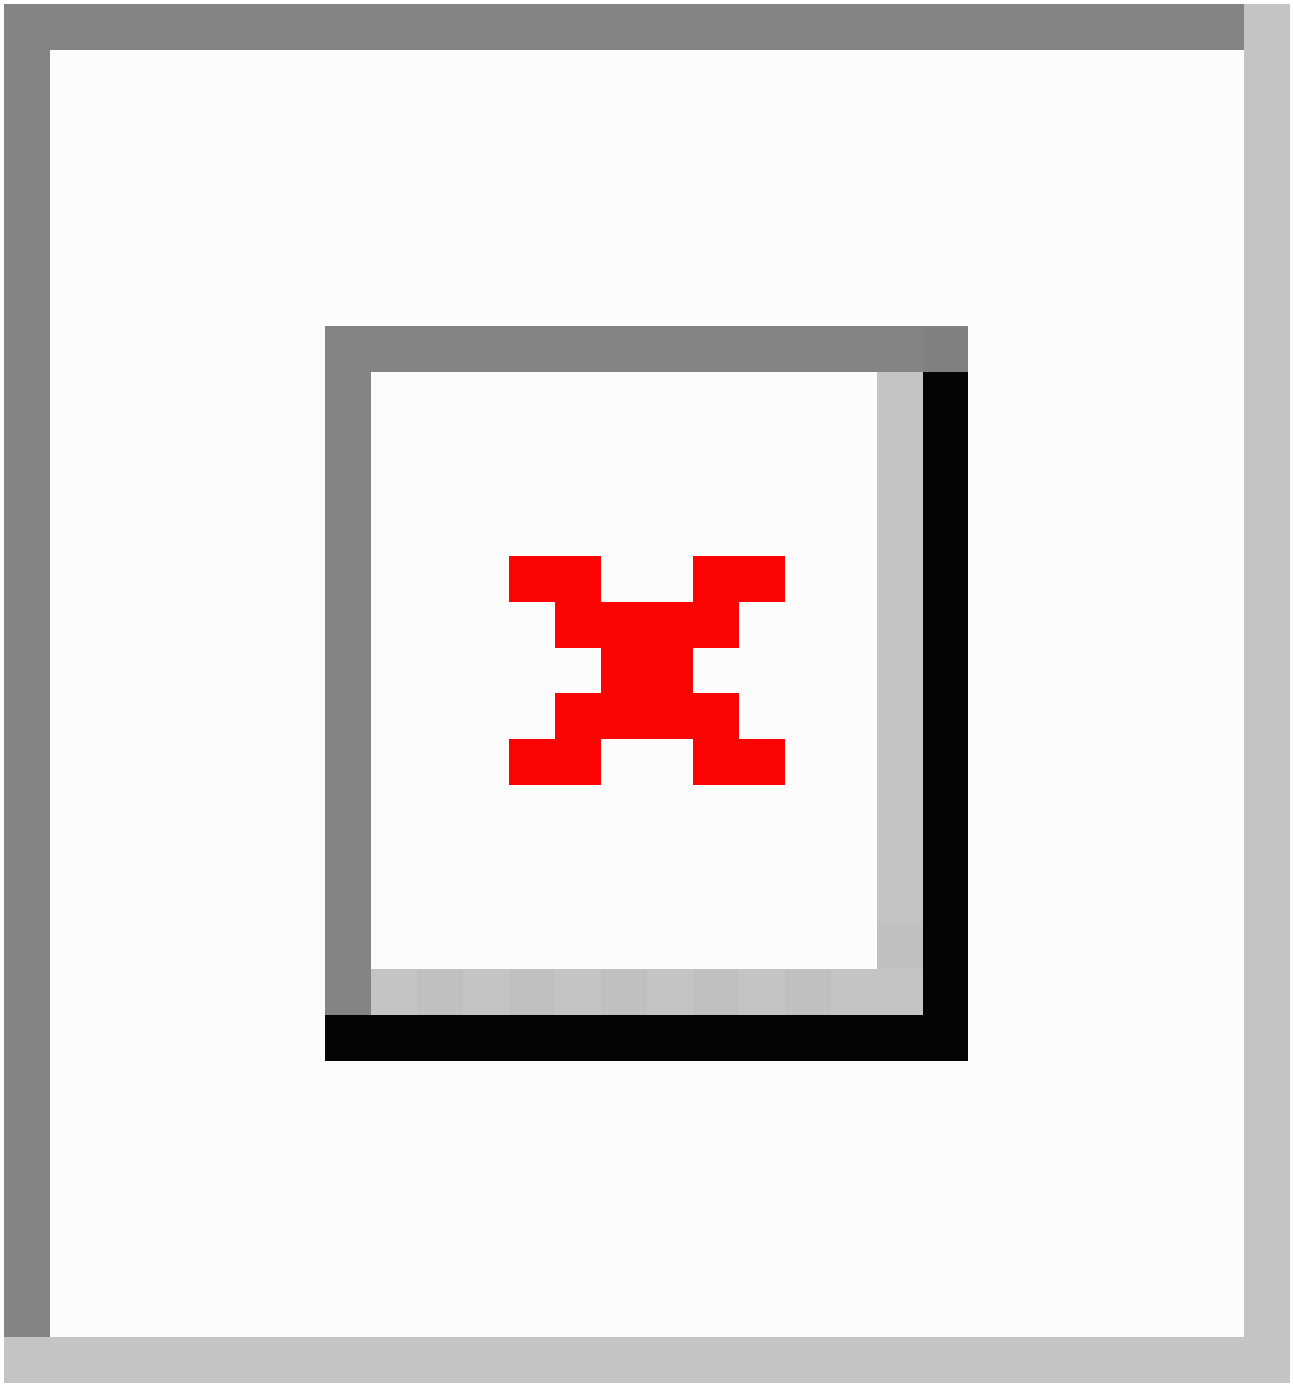
Figure 1. Document homogeneousness test (tasks 1 and 2). BERT: bidirectional encoder representations from transformers; CLS: classification.



Document Representativeness

As seen in Figure 2, to assess document representativeness, we devised a task that focused on department identification by using individual visit records (task 3).

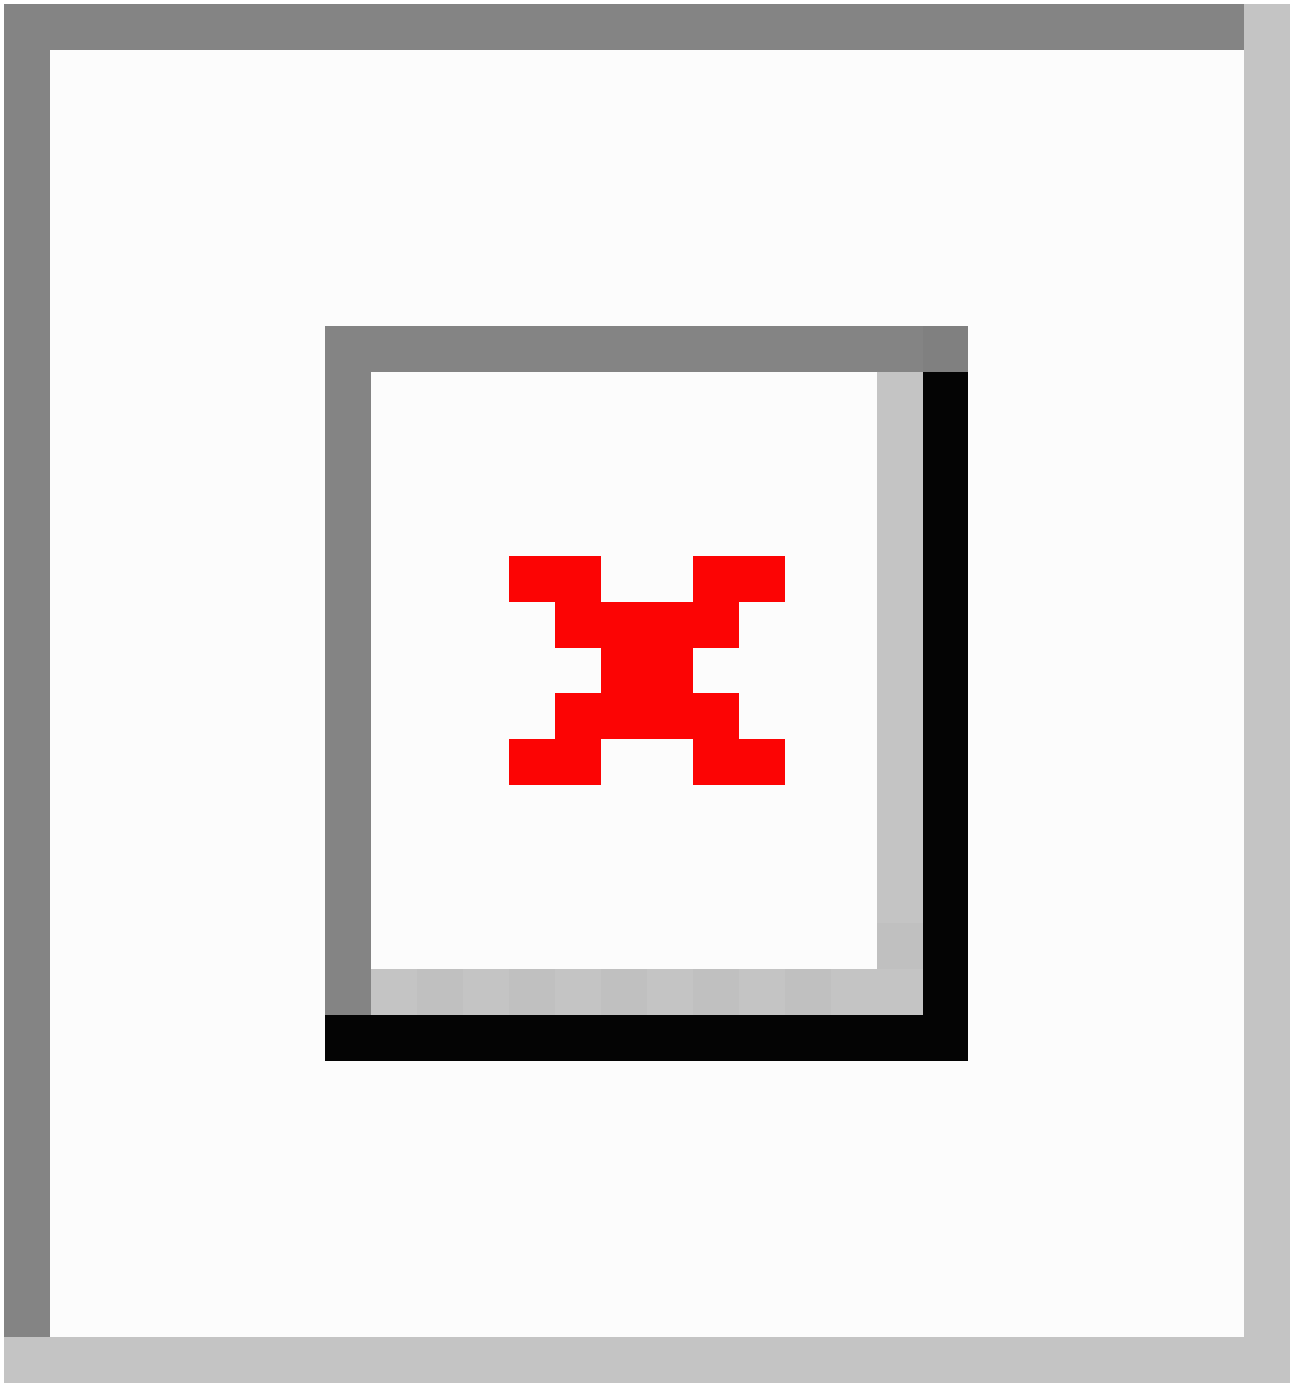
Figure 2. Document representativeness test: classifying documents (task 3). BERT: bidirectional encoder representations from transformers; CLS: classification; SEP: separator.



Reading Comprehension Test

The reading comprehension test (Figure 3) test extracted summarized content from a visit record. We focused on extracting the assessment section from the Subjective, Objective, Assessment, Plan (SOAP) or the history, physical examination, laboratory, assessment, and plan sections. The experiments encompassed 2 setups, namely, 1 setup with section-shuffled documents (task 4) and 1 setup with maintained section-order documents (task 5).

Figure 3. Reading comprehension test: identifying the department associated with a given document (with section shuffling: task 4; w/o section shuffling: task 5). BERT: bidirectional encoder representations from transformers; CLS: classification; SEP: separator; w/o: without.

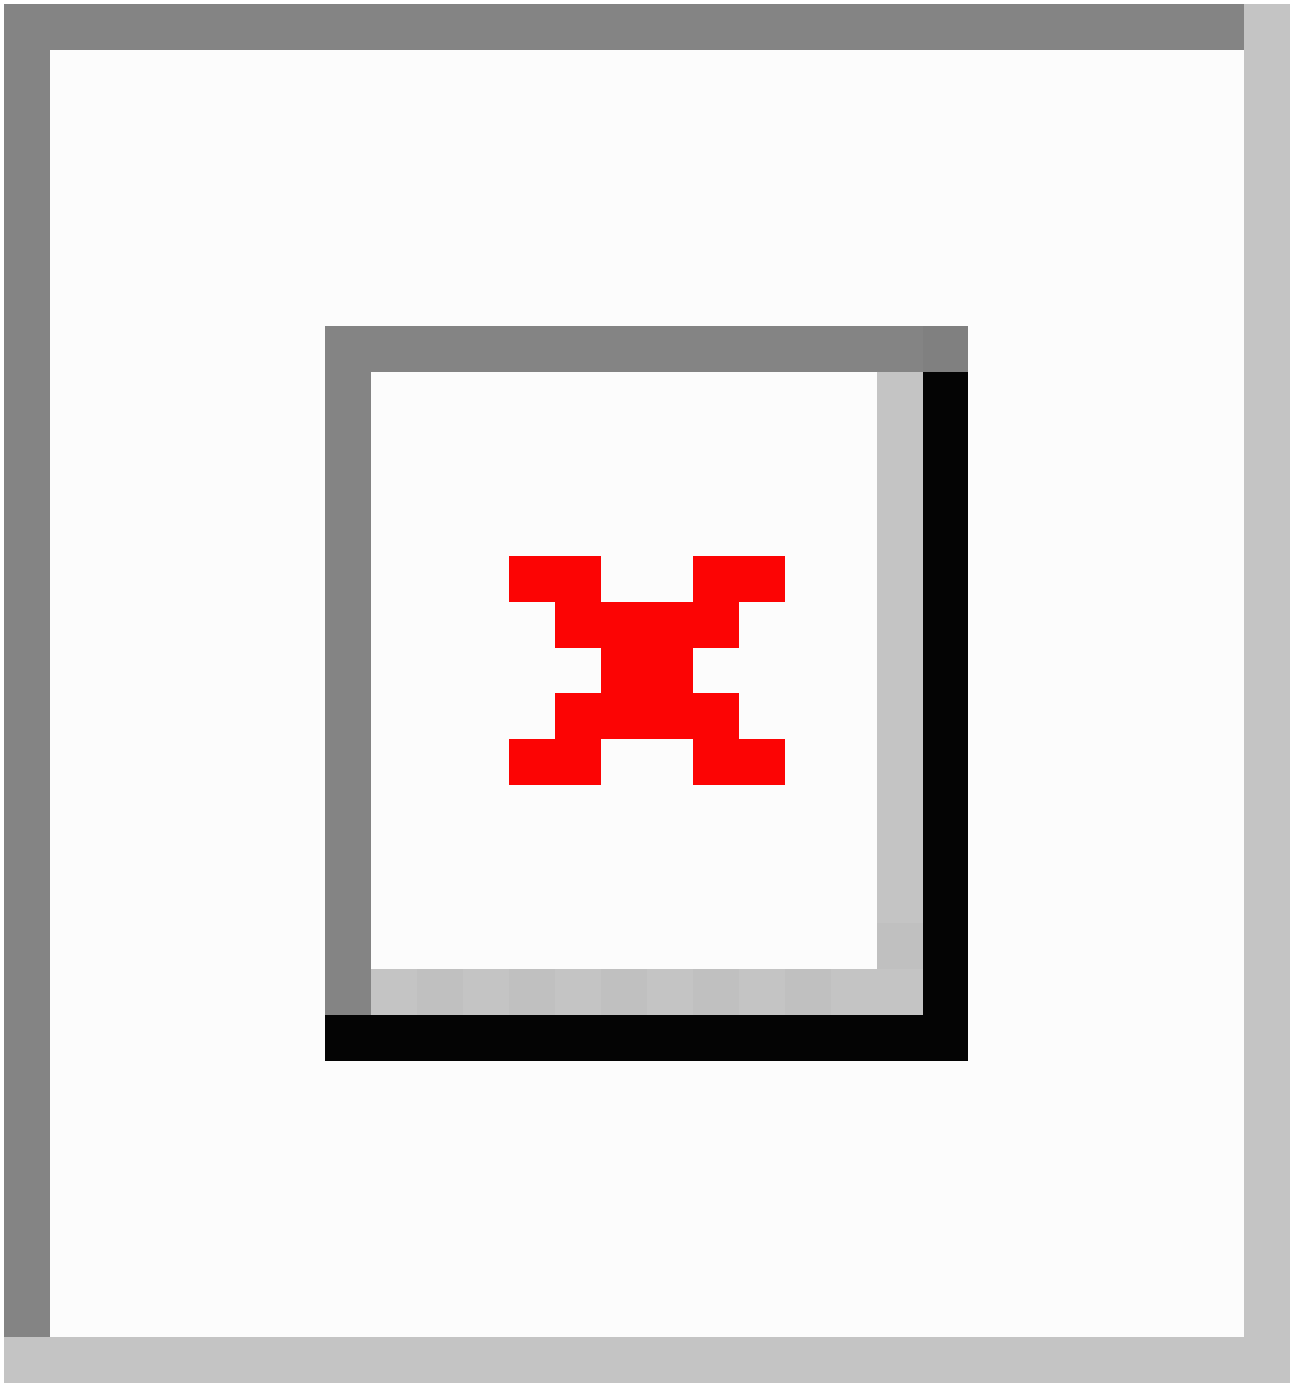


Contextual Connections

As seen in Figure 4, we introduced a task that required the model to differentiate the most recent visit record from a set of 4 candidate documents when given a query document representing the oldest visit record (task 6). The limitation of BERT models regarding the amount of the input length they can handle necessitates a workaround because simultaneously inputting both the query document and 4 candidate documents is not feasible. To address this problem, we adopted a 2-step approach. First, each individual document was independently inputted into BERT to acquire document embeddings. Subsequently, these document embeddings, forming a pair comprising the query document and the kth candidate document embeddings, were introduced into a feedforward neural network (FFNN) [40]. For example, if the query and document embedding pair for the most recent visit were inputted into the FFNN, the model was trained to output a prediction value of 1; this value was assigned based on our assumptions. We postulated that the query document, which corresponded to the earliest visit among the 5 documents, and the last document, which denoted the most recent visit, encompassed the most distinct narrative. Consequently, we measured the cosine distances between these 2 embeddings and directed the model to output a prediction value of 1, which indicated the greatest distance in terms of cosine similarity. By contrast, if the query and nonanswer

document embedding pairs were presented to the FFNN, the model was trained to output a prediction value of zero.

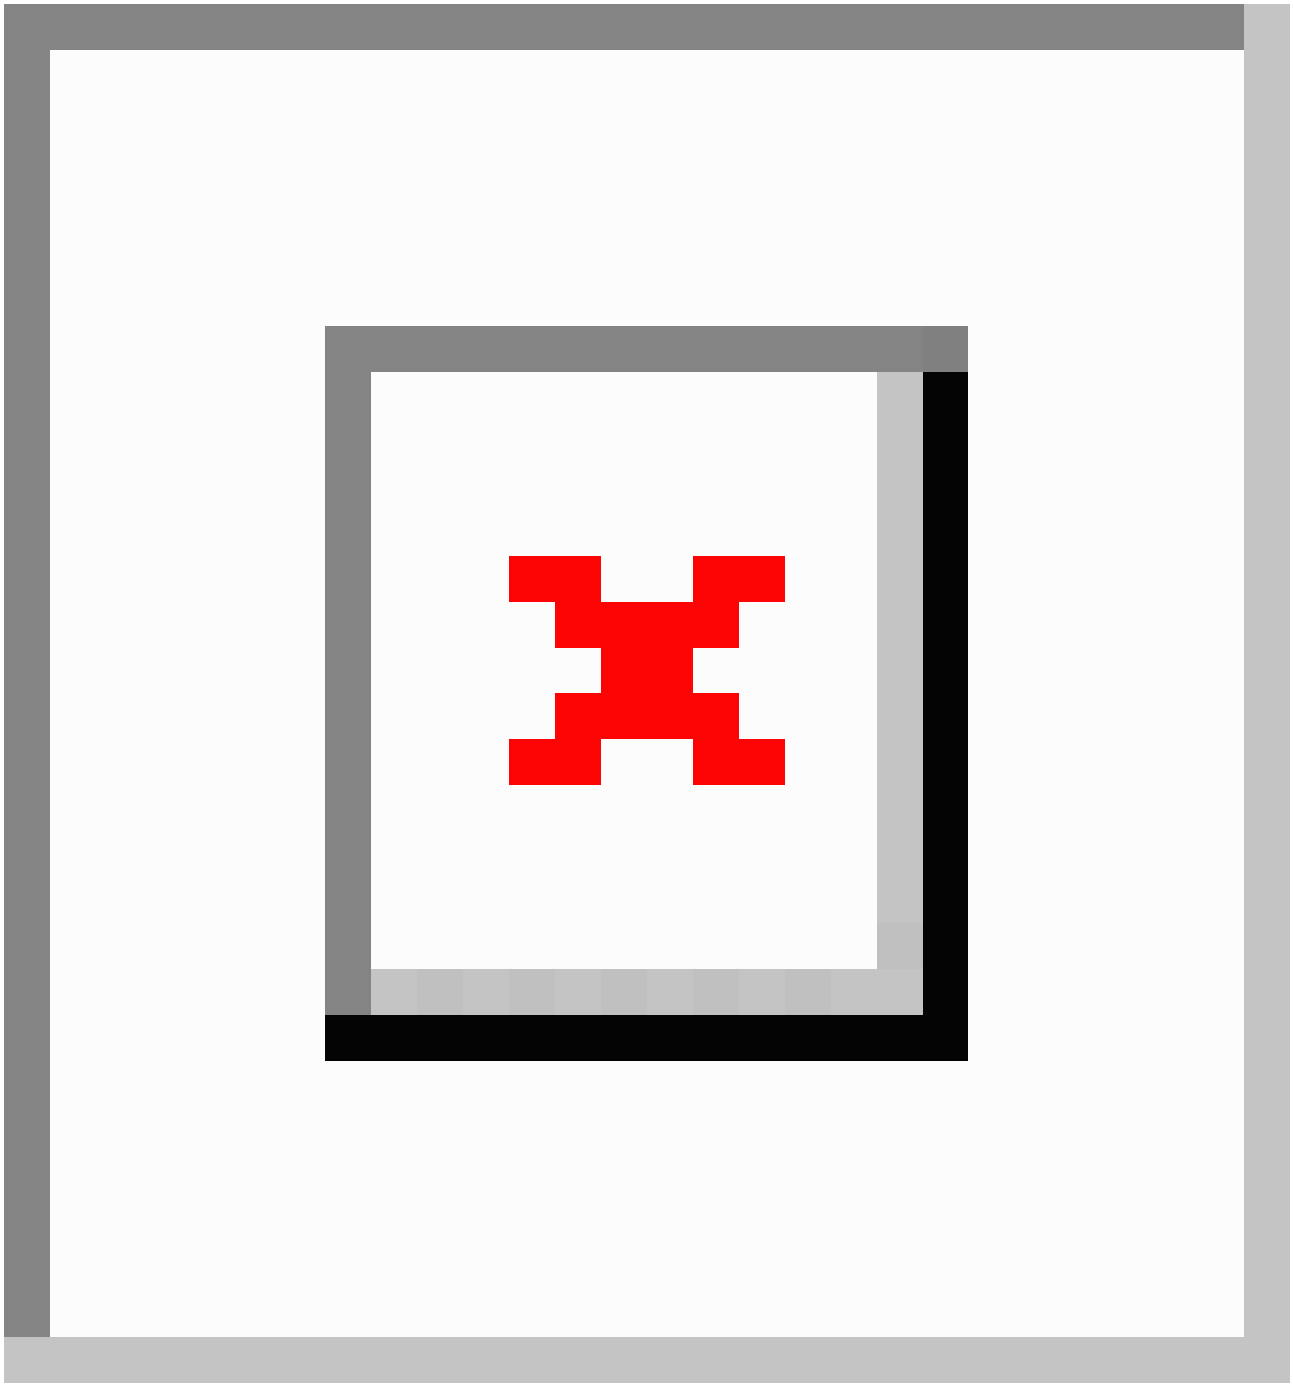
Figure 4. Document connectivity test: finding the last visited document (task 6). BERT: bidirectional encoder representations from transformers.



Knowledge Reasoning

The knowledge reasoning characteristic (Figure 5) evaluated the capacity of a model to deduce entities from masked text (task 7). Each model was tasked with deducing disease names from masked visit records in which the disease names had been replaced with [MASK] tokens. We used MetaMap [41] to create a dataset by identifying diagnostic names. Each model, when presented with the [MASK] token and context, selected the correct disease name from 63 disease names. A comprehensive list of the entities is shown in Table S1 in Multimedia Appendix 1.

Figure 5. Knowledge reasoning test: finding the disease name (task 7). BERT: bidirectional encoder representations from transformers; CLS: classification; SEP: separator.



Experimental Settings

We trained and evaluated 4 types of publicly available BERT models through the following process. We used records of 159,460 patients out of 164,460 patients for pretraining. In the pretraining procedure, 15% of random tokens from the 159,460 patient records were masked. Among them, 80% of the masked tokens were replaced with [MASK] tokens, 10% were replaced with random tokens, and the remaining 10% retained their original tokens. We trained the BERT models to restore [MASK] tokens to their original tokens.

After pretraining, the 4 BERT models were fine-tuned for tasks 1 - 7. For fine-tuning, we used 5000 patient records that were not used in pretraining. We assigned 4000 patients to the training set and 1000 patients to the test set and then created training and evaluation data specific for each task. In each task, the 4 pretrained BERT models were trained using the training set and evaluated on the test set.

In the pretraining step, 4 NVIDIA 3090 graphics processing units (GPUs) were used in parallel for 3 epochs. After pretraining, all the models were fine-tuned using a 1080ti GPU except for task 6, in which 3090 GPU were used, because this task required more calculation procedures and memory. The detailed hyperparameter settings are described in Table S2 in Multimedia Appendix 1. The detailed experimental settings and analysis code used in this study are available on GitHub [42].

Results

Results of Tasks 1-3

In tasks 1 - 3, BERT-base and BioBERT exhibited the best scores; Tables 3 and 4 present the corresponding results.

Table . Results of various BERT[a] models in tasks 1 and 2.

Model	Task 1: Determination of whether 2 documents are from the same patients			Task 2: Determination of whether 2 sections are from the same patients		
	Precision	Recall	F_1-score	Precision	Recall	F_1-score
BERT-base	84.44	94.19	89.05	89.28	87.60	88.43
BioBERT[b]	83.36	96.21	89.32	92.92	82.73	87.53
KoBERT[c]	83.95	74.05	78.69	90.68	75.78	82.56
M-BERT[d]	83.22	94.02	88.29	83.56	93.38	88.19

[a]BERT: bidirectional encoder representations from transformers.

[b]BioBERT: BERT for Biomedical Text Mining.

[c]KoBERT: Korean BERT.

[d]M-BERT: Multilingual BERT

Table . Results of various BERT[a] models in task 3.

Model	Task 3: Identification of the department associated with a given document accuracy
BERT-base	96.75
BioBERT[b]	97.44
KoBERT[c]	95.38
M-BERT[d]	96.06

[a]BERT: bidirectional encoder representations from transformers.

[b]BioBERT: BERT for Biomedical Text Mining.

[c]KoBERT: Korean BERT.

[d]M-BERT: Multilingual BERT.

In the homogeneity test conducted on document-level inputs (task 1), BioBERT achieved the highest F_1-score, whereas in the test conducted on the section-level inputs (task 2), BERT-base achieved the highest F_1-score. Comparing the scores under tasks 1 and 2 revealed that BioBERT exhibited a more substantial drop in performance than those of other models. By contrast, KoBERT consistently demonstrated a diminished performance compared with that exhibited by other BERT models. In the document representativeness test, which entailed the selection of a single department from a set of 8 department candidates, BioBERT exhibited superior performance in terms of accuracy, which was the evaluation metric.

Results of Tasks 4-7

In tasks 4 - 7, M-BERT achieved the best scores (Tables 5 and 6).

Table . Results of various BERT[a] models in tasks 4 and 5.

Model	Task 4: Finding the assessment section with inputs that are section-shuffled			Task 5: Finding the assessment section with inputs that are not section-shuffled		
	Precision	Recall	F_1-score	Precision	Recall	F_1-score
BERT-base	71.03	61.74	60.83	74.59	59.14	56.69
BioBERT[b]	72.16	56.31	51.64	74.71	55.99	51.17
KoBERT[c]	76.57	77.41	76.88	92.61	93.88	93.15
M-BERT[d]	93.15	94.61	93.77	96.52	96.37	96.44

[b]BioBERT: BERT for Biomedical Text Mining.

[c]KoBERT: Korean BERT.

[d]M-BERT: Multilingual BERT.

In the reading comprehension tests (tasks 4 and 5), the performances of the models were evaluated in terms of the F_1-score, which was calculated by measuring the proportion of tokens within the predicted interval that correctly overlapped with the actual interval. M-BERT achieved the highest performance in reading comprehension tests. In addition, the models exhibited the largest performance differences in these tests. In the context connectivity test (task 6), M-BERT exhibited the highest performance with an F_1-score of 64.75, whereas all the other models achieved a score lower than 60 (BERT-base: 59.78; BioBERT: 58.39; KoBERT: 25.62; and M-BERT: 64.75). In the knowledge-reasoning test (task 7), the M-BERT model exhibited the best performance. The primary objective of this test was to accurately prognosticate 63 potential candidate diagnoses, as extracted from clinical documents, in which the diagnosis name was substituted with [MASK]. In our assessment, we used hit@k (where k=1, 3, or 10). For instance, in task 7, BERT computes probabilities for 63 diseases based on a provided context. In this context, hit@k is a true positive if k diseases with the highest probability encompass the correct disease. The final evaluation score is then determined by dividing the number of true positives by the total number of sequences under assessment.

Discussion

Suitability of BERT-Base and BioBERT for English [CLS] Embedding (Tasks 1-3)

In tasks 1 - 3, the BERT classification ([CLS]) embedding was the input for the FFNN. The [CLS] token, positioned at the far-left side of the input sequence, is a classification token. The embedding of this token is commonly used as a feature for classification tasks, indicating the model's comprehension of segment-level or document-level context. In tasks 1 and 2, homogeneity was assessed at the document and section levels, respectively, and BioBERT and BERT-base demonstrated the highest performances, respectively. In task 3, BioBERT achieved the highest score. Based on these observations, we inferred that BERT-base and BioBERT would be suitable for tasks involving [CLS] embedding.

Generally, a model's ability to understand context diminishes as the number of tokens absent from its dictionary increases. Unknown ([UNK]) tokens represent tokens absent from the model's dictionary, and the presence of these tokens correlates with lower model performance. The higher the frequency of [UNK] tokens, the greater the challenge for the model to accurately comprehend the context. Notably, despite the limited inclusion of Korean tokens, these models excelled in tasks 1 - 3 (Table S4 in Multimedia Appendix 1). BERT-base and

BioBERT, which were pretrained on English sentence patterns, exhibited improved performances because of the prevalence of English sentences in outpatient visit records, which typically detailed their diseases.

Influence of Multilingual Capabilities in Reading Comprehension Tasks on Outcomes (Tasks 4 and 5)

In tasks 4 and 5, the reading comprehension ability of the model was assessed by determining the scope of the assessment section. Among models, M-BERT demonstrated the highest performance, whereas BERT-base and BioBERT exhibited the lowest test scores. The presence of extensive multilingual capabilities in the reading comprehension tests was the predominant factor influencing these outcomes.

To comprehend why BERT-base and BioBERT exhibit markedly inferior performance compared with M-BERT in tasks 4 and 5, understanding the composition of the BERT model dictionaries and the function of the [UNK] token is crucial. In BERT models, a dedicated tokenizer is used to segment text into tokens. These tokens are retained if present in the model's dictionary; otherwise, the tokens are substituted with [UNK] tokens, representing unknown entities. Consequently, a higher prevalence of [UNK] tokens indicates a diminished ability of the model to comprehend the semantic nuances of the sequence. In tasks 4 and 5, where each token's semantic relevance determines its association with an assessment section, models with inadequate knowledge of individual tokens exhibit poor performance. The dictionaries of BERT-base and BioBERT contain minimal Korean characters, resulting in the majority of Korean tokens being replaced with [UNK] tokens. By contrast, M-BERT encompasses a comprehensive range of Korean characters in its dictionary. Therefore, BERT-base and BioBERT exhibit notably inferior performance in tasks 4 and 5 compared with M-BERT.

Relationship Between Multilingual Capability and Task Complexity (Task 7)

Task 7, which was focused at evaluating the aptitude of a model for knowledge inference, was more complex than other tasks. Notably, M-BERT outperformed the other models in task 7, securing hit@1, hit@3, and hit@10 scores of 61.12, 81.64, and 95.41, respectively. These results highlighted the pivotal role of the dictionary in knowledge inference. Furthermore, when processing documents in multiple languages, M-BERT outperformed BERT-base, which had been exclusively trained in a single language.

For task 6, the test results were poor. An analysis indicated that BERT models did not excel in this task because of the prevalence of outpatient medical records in the copy-and-paste format (Table S6 in Multimedia Appendix 1). Consequently, the significance of task 6 in this study was low.

Contributions to the Clinical Text Processing and Medical Fields

Importance of Multilingual Models

The experiment highlights the significance of using multilingual language models in processing bilingual clinical notes. The findings demonstrated that using a model capable of handling 2 languages yields superior performance compared with relying solely on a single language model. This insight is particularly relevant for countries such as Korea and Japan, where clinical documentation typically involves a mixture of languages.

Base for Model Selection

Furthermore, this study provides empirical evidence for choosing a proper BERT model, a factor not substantiated in existing NLP research. For instance, in previous studies, such as that conducted by Kim and Lee [43], M-BERT was used for tasks such as extracting disease names, symptoms, and body parts from Korean text without providing explicit justification. The experimental results satisfied this gap by showcasing the superiority of M-BERT in understanding bilingual clinical text and supporting appropriate BERT selection in future studies.

Limitations and Future Works

Limited Scope of Clinical Notes

This analysis primarily focused on outpatient visit records. Future studies should encompass a broad range of clinical notes, including surgical notes, hospitalization records, and discharge summaries. Comparing and validating the performance of BERT models across various types of clinical documentation provides a comprehensive understanding of their effectiveness.

Single-Institution Data

This study exclusively used data from Seoul National University Hospital, which can limit the generalizability of the findings. Clinical notes can vary considerably in style and content across various health care institutions. Therefore, future studies should involve data from multiple hospitals to validate BERT model performance in various clinical settings.

More Tasks Should Be Verified

The BERT model requires further validation in bilingual clinical text. Oh et al [44] conducted a study to recognize protected health information in the publicly available i2b2 2014 dataset. However, we could not perform this task because manual labeled annotations are required to extract non-English entities in bilingual clinical notes. In future studies, various tasks using bilingual clinical notes should be proposed.

Conclusions

In this study, we comprehensively compared 4 BERT models, encompassing text in both English and Korean, within the multilingual clinical domain. We pretrained these models with approximately 160,000 patient records and evaluated their performances for 7 diverse downstream tasks. The experimental findings are summarized as follows.

First, the BERT-base and BioBERT models excelled in document classification tasks using [CLS] tokens. These results highlighted their superiority over M-BERT in tasks involving simple pattern recognition in word sequences. Second, the significance of having a comprehensive dictionary was evident in the reading comprehension task in which comprehensive token usage was required. The exceptional performance of M-BERT, which encompassed a broad range of Korean and English tokens, clearly confirmed the importance of the dictionary. Third, multilingual proficiency was pivotal for tasks

that demanded complex reasoning. Both M-BERT and BioBERT excelled in task 7, which focused on diagnosing a multitude of candidates, and notably, M-BERT consistently outperformed BioBERT.

Our findings highlighted the suitability of BioBERT and BERT-base for tasks that relied on sequence patterns in multilingual clinical domains. In addition, M-BERT, which had an expansive dictionary and aptitude for leveraging Korean and English clinical contexts, was highly suitable for tasks involving textual content comprehension. The experimental results of the BERT models in mixed-language clinical documents provide valuable insights for future medical NLP research and appropriate BERT model selection for different types of tasks.

Acknowledgments

This study was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (no. NRF-2021R1I1A4A01042182).

Data Availability

The datasets generated and/or analyzed during the current study are not publicly available due to patient privacy concerns. Patient records contain personal information, and, as such, Seoul National University's institutional review board does not permit public disclosure of the data.

Authors' Contributions

KK, SP, JM, and SP conceptualized the paper, developed the methodology, and prepared the original draft of the manuscript. KK contributed to software implementation and validated the findings. JYK and EYL curated the data, conducted investigations, and contributed to data analysis and interpretation. JE, KJ, YEP, EK, and JL contributed to methodology development, conducted formal analysis, and provided insights throughout the research process. JC supervised the study, managed the project administration, and contributed to reviewing and editing the manuscript.

Abstract

Background: The application of machine learning in health care often necessitates the use of hierarchical codes such as the International Classification of Diseases (ICD) and Anatomical Therapeutic Chemical (ATC) systems. These codes classify diseases and medications, respectively, thereby forming extensive data dimensions. Unsupervised feature selection tackles the "curse of dimensionality" and helps to improve the accuracy and performance of supervised learning models by reducing the number of irrelevant or redundant features and avoiding overfitting. Techniques for unsupervised feature selection, such as filter, wrapper, and embedded methods, are implemented to select the most important features with the most intrinsic information. However, they face challenges due to the sheer volume of ICD and ATC codes and the hierarchical structures of these systems.

Objective: The objective of this study was to compare several unsupervised feature selection methods for ICD and ATC code databases of patients with coronary artery disease in different aspects of performance and complexity and select the best set of features representing these patients.

Methods: We compared several unsupervised feature selection methods for 2 ICD and 1 ATC code databases of 51,506 patients with coronary artery disease in Alberta, Canada. Specifically, we used the Laplacian score, unsupervised feature selection for multicluster data, autoencoder-inspired unsupervised feature selection, principal feature analysis, and concrete autoencoders with and without ICD or ATC tree weight adjustment to select the 100 best features from over 9000 ICD and 2000 ATC codes. We assessed the selected features based on their ability to reconstruct the initial feature space and predict 90-day mortality following discharge. We also compared the complexity of the selected features by mean code level in the ICD or ATC tree and the interpretability of the features in the mortality prediction task using Shapley analysis.

Results: In feature space reconstruction and mortality prediction, the concrete autoencoder–based methods outperformed other techniques. Particularly, a weight-adjusted concrete autoencoder variant demonstrated improved reconstruction accuracy and significant predictive performance enhancement, confirmed by DeLong and McNemar tests (P<.05). Concrete autoencoders preferred more general codes, and they consistently reconstructed all features accurately. Additionally, features selected by weight-adjusted concrete autoencoders yielded higher Shapley values in mortality prediction than most alternatives.

Conclusions: This study scrutinized 5 feature selection methods in ICD and ATC code data sets in an unsupervised context. Our findings underscore the superiority of the concrete autoencoder method in selecting salient features that represent the entire data set, offering a potential asset for subsequent machine learning research. We also present a novel weight adjustment approach for the concrete autoencoders specifically tailored for ICD and ATC code data sets to enhance the generalizability and interpretability of the selected features.

Introduction

Machine learning is increasingly being used in health care to analyze patient data and provide insights on improving health outcomes and the quality of care [1]. With the rise of electronic health data (EHD) and entering a large amount of data per patient in hospitals, there are big opportunities to train machine learning models for a variety of applications, such as the prediction or diagnosis of diseases, outcome prediction, and treatment planning [1,2]. EHD are a valuable source of information on a patient, containing details on their demographics, hospital visits, medical diagnoses, physiological measurements, and treatments received [3]. However, despite the opportunities offered by these large data sets, there are challenges in terms of data quality, privacy, and the complexity of medical conditions [1]. In terms of machine learning, EHD can include many irrelevant and redundant features, where their direct use can lead to the "curse of dimensionality" as the high dimensionality of the data can make it more difficult to extract meaningful patterns and relationships [4]. Therefore, it is important to apply appropriate techniques for dimensionality reduction and feature engineering to address this challenge and improve the effectiveness of predictive models built from EHD.

Feature selection is one of the critical aspects of machine learning. It involves selecting a subset of relevant features that are the most useful for predicting a target variable. In the case of medical data, these features could include patient demographics, medical history, laboratory test results, and diagnosis codes [3]. Feature selection is essential because it can help improve the accuracy and performance of machine learning models by reducing the number of irrelevant or redundant features and avoiding overfitting [4]. Unsupervised feature selection is a type of feature selection method that is used when there is no target variable available to guide the selection of features. Unlike supervised feature selection, which chooses features that better predict a certain target variable, unsupervised feature selection methods rely on the intrinsic structure of the data to identify the most important features. This behavior helps the selected features to be unbiased and perform well when there are no labeled data. It can also reduce the risk of overfitting to a certain target variable and ensure robustness to new target variables [5]. This is an important advantage in health care, where collecting labeled data is usually difficult and the same data are often used to predict multiple target variables.

Generally, there are 3 main categories of feature selection methods: filter, wrapper, and embedded methods. Filter methods use statistical tests such as variance to rank individual features within a data set and select the features that maximize the desired criteria. However, they usually lack the ability to consider the interactions between features [6]. Wrapper methods, on the other hand, select features that optimize an objective function for a clustering algorithm. Therefore, these methods are generally specific to particular clustering algorithms and may not be suitable for use with other algorithms. Wrapper methods can detect potential relationships between features, but this often results in increased computational complexity [5]. Embedded methods also take into account feature relationships but generally do so more efficiently by incorporating feature selection into the learning phase of another algorithm. Lasso regularization is one of the well-known embedded methods that can be applied to a variety of machine learning models [6].

The *International Classification of Diseases, Tenth Revision* (*ICD-10*) is a method of classifying diseases that was created by the World Health Organization and is used internationally [7]. It categorizes diseases based on their underlying cause, characteristics, symptoms, and location in the body and uses codes to represent each disease. The *ICD-10* system organizes thousands of codes in a hierarchical structure that includes chapters, sections, categories, and expansion codes. Within this structure, section codes and their corresponding chapter codes can be thought of as child-parent relationships, with each *ICD-10* code serving as a node in the classification system. The same relationship applies to categories and sections, as well as expansion codes and categories. The high number of codes in this system is one of the major challenges of using them in machine learning applications [8]. It is worth noting that Canada has added or changed some codes in the lower levels according to their health care system requirements (*ICD-10, Canada* [*ICD-10-CA*]) [9].

Similar to International Classification of Diseases (ICD) codes, the Anatomical Therapeutic Chemical (ATC) classification system, developed by the World Health Organization Collaborating Centre for Drug Statistics Methodology, is an international tool for the active and systematic categorization of active pharmaceutical ingredients [10]. ATC codes are also structured hierarchically and are assigned based on the organ or system they impact, as well as their therapeutic, pharmacological, and chemical properties. This hierarchical system comprises 5 distinct levels, with the lower levels providing detailed information about the pharmacological subgroup and chemical substance, and the highest level representing the anatomical main group. As in the *ICD-10*, the ATC's hierarchy introduces child-parent relationships at each level.

In this research, we used 3 administrative databases comprising *ICD-10* and ATC codes pertaining to patients with coronary artery disease (CAD). These databases, relevant to acute care, ambulatory care, and pharmacy facilities, were used to select the most insightful codes characterizing this cohort.

Methods

Data Set and Preprocessing

The Alberta Provincial Project for Outcome Assessment in Coronary Heart Disease (APPROACH) registry [11] is one of the most comprehensive data repositories of CAD management in the world, matching unique disease phenotypes with rich clinical information and relevant outcomes for patients in Alberta, Canada, who have undergone diagnostic cardiac catheterization or revascularization procedures. Our cohort's patients were selected from the APPROACH registry. These patients underwent diagnostic angiography between January 2009 and March 2019 at 1 of the following 3 hospitals in Alberta: Foothills Medical Centre, University of Alberta Hospital, and Royal Alexandra Hospital. We excluded patients

with ST elevation myocardial infarction from the study to focus on nonemergency CAD.

Discharge Abstract Database (DAD), National Ambulatory Care Reporting System (NACRS), and Pharmaceutical Information Network (PIN) data for the abovementioned patients were extracted from Alberta provincial health records. The DAD contains summary hospitalization information from all acute care facilities in Alberta. The NACRS includes all visits to ambulatory care facilities (ie, emergency department, urgent care, and day surgery visits) in the province as well as some nonabstracted data from other specialty clinics. The PIN is based on a system that collects all prescription medicine dispensations from pharmacies all over Alberta.

In the DAD and NACRS, for each patient, we aggregated all *ICD-10-CA* codes of hospital admissions or physician visits every 3 months following the first admission date (all codes in that period are treated as 1 record's codes). This helps us to make sure that chronic diseases are captured more comprehensively in fewer records and reduce the effect of noisy records. We did a similar procedure for ATC codes in the PIN data set and aggregated the codes every 6 months, since most medications prescription refills did not extend beyond 6 months. We one-hot encoded the *ICD-10-CA* and ATC codes and their parent nodes for each record. For example, if the *ICD-10-CA* code "I251" was present, "I25," "I20-I25," and "Chapter IX" were also encoded in the one-hot table. Similarly, if the ATC code "C07AB02" was present, "C07AB," "C07A," "C07," and "C" were also encoded. We show the number of all unique *ICD-10-CA* or ATC codes in the data set with N_{All}.

To validate the performance of the selected features in a real clinical problem, we pulled the mortality data of the patients enrolled in the cohort from the Vital Statistics Database and matched them with the aggregated records to determine 90-day mortality following the end of the last procedure.

Feature Selection

The following unsupervised algorithms were used for feature selection:

- Concrete autoencoder (CAE) [6]: In this method, continuous relaxation of discrete random (concrete) variables [12] and the Gumbel-Softmax reparameterization trick are used to construct a special layer in the neural network to transform discrete random variables into continuous ones, which allows for efficient computation and optimization using gradient-based methods. The reparameterization trick allows the use of a softmax function in this layer, which is differentiable, unlike the argmax function. This characteristic is useful for designing an autoencoder, in which features are selected in the concrete layer (as the encoder) through the softmax operation and a common neural network (as the decoder) is used to reconstruct the main feature space out of the selected features. During the training, a temperature parameter can be gradually decreased, allowing the concrete selector layer to try different features in the initial epochs and behave more similar to an argmax function in the last epochs to keep the best features. After training, we can use an argmax function on the weights to find the features passed to the neurons of the encoder layer. One of the major problems of this method is that it may converge to a solution where some duplicate features are selected in some neurons (ie, fewer than the desired number of features are selected).
- Autoencoder-inspired unsupervised feature selection (AEFS) [13]: This method combines autoencoder and group lasso tasks by applying an $L_{1,2}$ regularization on the weights of the autoencoder. The autoencoder in this method tries to map the inputs to a latent space and then reconstruct the inputs from that space. The $L_{1,2}$ regularization will optimize the weights (change them toward 0) to select a smaller number of features. The neural network structure of the autoencoder will enable the model to incorporate both linear and nonlinear behavior of the data in the results. After training this neural network, the features with higher weight values in the first layer can be selected as the most informative features. The authors claimed that this algorithm showed promising results in computer vision tasks.
- Principal feature analysis (PFA) [14]: This method selects features based on principal component analysis (PCA). The most important features are selected by applying a *k*-means clustering algorithm to the components of PCA and finding the features dominating each cluster (closest to the mean of the cluster). This algorithm is primarily designed for computer vision.
- Unsupervised feature selection for multicluster data (MCFS) [15]: This approach prioritizes the preservation of the multicluster structure of data. The algorithm involves constructing a nearest neighbor graph of the features, solving a sparse eigen-problem to find top eigenvectors with regard to the smallest eigenvalues. Then, an L_1-regularized least squares problem is optimized to find the linear weights between the features and the eigenvectors. This allows us to define the MCFS score as the maximum weight of each feature across different clusters and select the highest scores as the best features.
- Laplacian score (LS) [16]: The LS algorithm uses the nearest neighbor graph to capture the local structure of the data in the affinity matrix. For each feature, its adjusted variation is calculated by removing the feature's mean, normalized by a degree matrix, which itself is derived from the sum of similarities in the affinity matrix. The Laplacian matrix, essential for this calculation, is formed by subtracting the affinity matrix from the degree matrix. The significance of each feature is then assessed by the LS, which is the ratio of the feature's ability to preserve local information (captured by its adjusted variation's alignment with the Laplacian matrix) to its overall variance (measured by its alignment with the degree matrix). The lower the LS, the more relevant the feature for representing the intrinsic geometry of the data set.

We applied the LS, AEFS, PFA, MCFS, and CAE algorithms to a 67% training data set (split based on patients) of one-hot encoded features to select the best 100 features (N_{Best}=100) with the following specifications (we chose N_{Best} based on preliminary experimentations).

For the AEFS method, we used a single hidden-layer autoencoder and optimized the loss function as described in Han et al [13], with α=0.001 as the trade-off parameter of the reconstruction loss and the regularization term and β=0.1 as the penalty parameter for the weight decay regularization. The choice of these parameters was based on preliminary experimentations on a small set of data and exploring α and β of {0.001, 0.1, 1, 1000}.

For the PFA method, we used incremental PCA instead of the normal PCA in the original paper [14], with a batch size of $2N_{All}$ due to the high computational cost. We decomposed the data to NAll2 components and then applied *k*-means clustering to find N_{Best} clusters. We also tried { NAll5,NAll3,NAll2 } as the number of components of the PCA in the preliminary experiments.

To use the LS and MCFS methods for feature selection, we used the Euclidean distances between features to construct a nearest neighbor graph G based on the 5 nearest neighbors. For the LS method, we set the weights of the connected nodes of G to 1, assuming a large *t* in the LS formulation. Then, we computed the LS for each feature and selected the top features with higher scores. Due to the high computational resources required for the LS and MCFS methods, we did not explore different parameters and used the same settings suggested by the implementation codes of these algorithms.

As the structure of the loss function allows us to prioritize some target variables, the CAE method was applied in 2 different ways—with and without adjusting weights for features. The reason for adjusting the weights is that since there are many correlated features in the *ICD-10-CA* and ATC code data sets, the model may choose one of them randomly [3]. Therefore, we applied the function in equation 1 as the class weights of the features to the loss function of the model:

(1)WF=11+dF

where W_F is the weight for feature *F* and *d*(*F*) is the depth of feature *F* as a node of the *ICD-10-CA* or ATC tree. This weight adjustment will force the model to give more importance to the features at the top of the tree and to generalize more in clinical settings. In the rest of the paper, this variant of the CAE model will be referred to as the CAE with weight adjustment (CAEWW) and the regular CAE model will be referred to as the CAE with no weight adjustment (CAENW).

We defined N_{Best} neurons in the concrete selector layer and used a learning rate of 0.001, a batch size of 64, and 1000 epochs. We also controlled the learning of the concrete selector layer by the temperature parameter that started from 20 and decreased to 0.01 exponentially (this annealing strategy was suggested by Abid et al [6] for better convergence). The decoder of the CAE was a feed-forward neural network with 2 hidden layers with 64 neurons and used a sigmoid activation function for the output layer and a leaky rectified linear unit activation function for the other layers. The learning rate, number of neurons, and the layers were determined based on preliminary experiments for the fastest convergence of the autoencoder.

Evaluation of Selected Features: Reconstruction of Initial Feature Space

To evaluate the effectiveness of the selected features, we trained a simple feed-forward neural network model using the chosen features to reconstruct the original feature space for each data set separately. The neural network consisted of 2 hidden layers, each with 64 neurons, and used leaky rectified linear unit activation functions, with a 10% dropout rate, in the hidden layers and a sigmoid activation function in the output layer. We trained the model using the same training set used in the feature selection step and evaluated its performance on the remaining 33% test set using binary cross entropy. We also calculated the accuracy of each feature selection method to determine which method produced the most accurate results. One of the challenges in comparing models with a large number of targets is that the accuracy values are inflated, because most of the targets are heavily imbalanced (ie, most of them were 0s) and the models were able to predict them easily. To circumvent this issue, we used a 2-tailed *t* test analysis and compared the accuracy values of the classes with the accuracy of a baseline model that simply outputs the mode of the training data for each class regardless of the input.

Evaluation of Selected Features: Prediction of 90-Day Mortality

To demonstrate the utility of using unsupervised feature selection methods in a supervised setting, we conducted a case study where we used the selected features from each method to predict 90-day mortality following the end of the last procedure for each data set separately. Since our data sets were highly imbalanced, with only ~6%, ~2%, and ~1% of the aggregated records for the DAD, NACRS, and PIN data set, respectively, leading to 90-day mortality, we upsampled the minority class using random sampling to balance the training sets. We then trained extreme gradient boosting (XGBoost) models using the training sets with 5-fold cross-validation to tune the hyperparameters for each model. We used the best models to predict the binary outcome variables on the test sets and measured their performances. XGBoost was selected for its efficiency with sparse data, which was crucial for our data sets. XGBoost's regularization features help prevent overfitting [17]. Additionally, its ability to provide interpretable models through tree-based Shapley values aligns with our objective to not only predict mortality but also understand the contributing factors [18]. XGBoost's scalability on multiple processors and speed (for both training [17] and Shapley analysis [18]) are also beneficial for processing large volumes of data and complex model tuning. After training the mortality prediction models for each method and data set, we calculated tree-based Shapley values corresponding to the features. This allowed us to rank the importance of each feature and explain their roles in predicting mortality.

We have made the implementation code for the methods discussed available at our GitHub repository [19].

Ethical Considerations

This study received ethics approval from the Conjoint Health Research Ethics Board at the University of Calgary

(REB20-1879). Informed consent was waived due to the retrospective nature of the data and the large number of patients involved, making it impractical to seek consent from each patient. All data were deidentified. No compensation was provided to the participants as the study did not involve direct participant interaction.

Results

Data Set Description

Table 1 summarizes the characteristics of the patients in the cohort at the time of their initial catheterization. The total numbers of patients with at least 1 record in the respective data sets, as well as the time ranges for each data set, are provided in Table 2. The aggregation procedure described in the *Methods* section reduced the number of records to the values listed in the "Aggregated Records" row, and the table also includes the total number of codes (unique *ICD-10-CA* or ATC codes and their parent codes) in a data set, along with the average number of codes per record. Multimedia Appendix 1 illustrates the percentages of the 20 most common *ICD-10-CA* and ATC codes within each processed data set. Within the data set, there were 9942 cases corresponding to a 90-day mortality, resulting in a 20% mortality rate in the cohort. The final aggregated data for each data set were split into 67% for the training sets and 33% for the test sets at the patient level.

Table . Key characteristics of the patients with CAD[a] enrolled in the cohort.

Variable		Overall (N=51,506)
Total population, n (%)		51,506 (100)
Sex, n (%)		
	Female	12,875 (25)
	Male	38,631 (75)
Age (years), mean (SD)		66.09 (11.41)
BMI (kg/m ^{2}), mean (SD)		29.51 (7.45)
	Missing data, n (%)	8449 (16.4)
CAD type, n (%)		
	Non-ST elevation myocardial infarction	24,119 (46.83)
	Unstable angina	10,671 (20.72)
	Stable angina	9832 (19.09)
	Missing data	6884.0 (13.37)
Canadian Cardiovascular Society angina grade, n (%)		
	II (slight limit)	4688 (9.1)
	IVb	7513 (14.59)
	IVa (hospitalized with acute coronary syndrome)	21,117 (41)
	III (marked limit)	2581 (5.01)
	IVc	1627 (3.16)
	I (strenuous)	1309 (2.54)
	Atypical	698 (1.36)
	Other or missing data	11,973 (23.25)
Diabetes, n (%)		
	No diabetes	37,544 (72.89)
	Type II	12,067 (23.43)
	Type I	806 (1.56)
	Other	1089 (2.11)

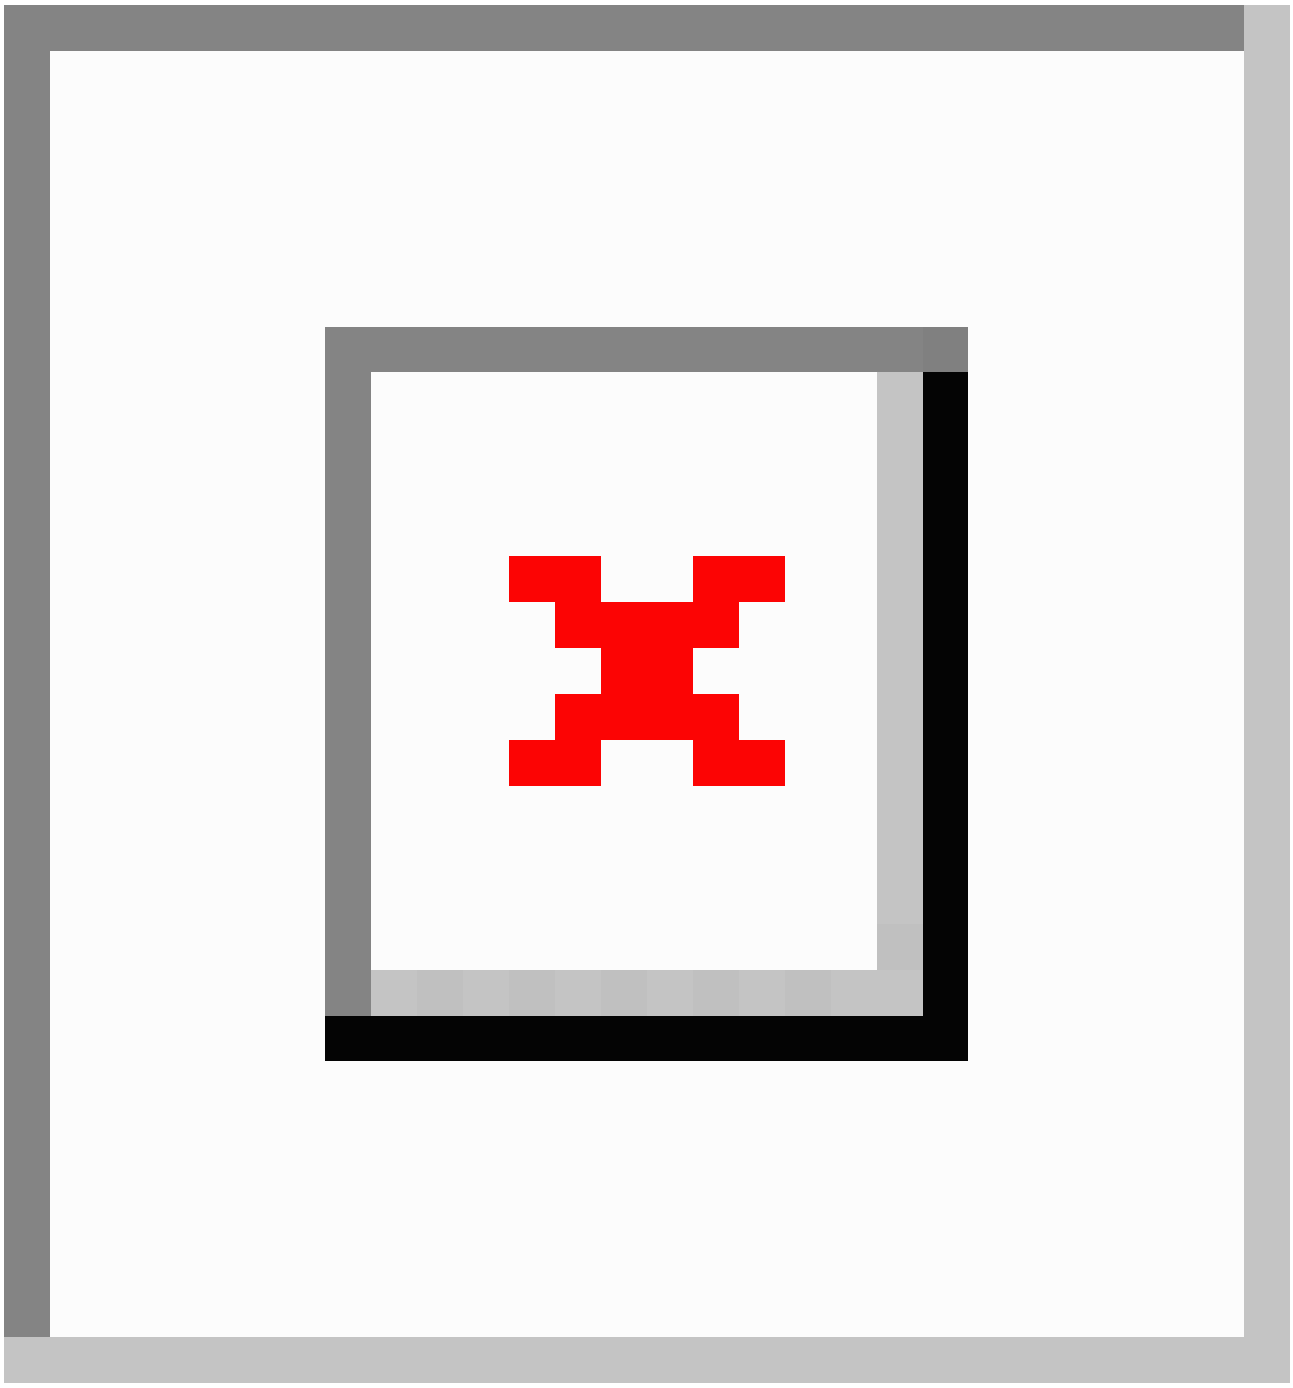
Both tables indicate that the CAE methods generally selected superior features compared to the other algorithms. Adjusting the weights within the CAE improved the performance of feature space reconstruction slightly. In terms of predicting 90-day mortality, the CAE methods again performed better than the other methods, as evidenced by the AUC-ROC. This superior performance was statistically significant in most instances (P<.05), according to the DeLong test for AUC-ROC. Furthermore, the McNemar test revealed a significant difference between the overall performance of the mortality prediction models trained on the features of the CAEWW method and those based on the other methods (P<.05). The P values of the McNemar and DeLong tests can be found in Table S2 of Multimedia Appendix 2.

Figure 1 shows the log-scale histograms of the original feature space reconstruction accuracy in each *ICD-10-CA* or ATC code for different feature selection methods. It shows that CAEWW and CAENW were the best methods in terms of reconstructing the majority of the features with high accuracy. The other methods, despite having high average accuracy, performed poorly in reconstructing some of the features.

Figure 1. Log-scale histograms of the initial feature space reconstruction accuracy in each International Classification of Diseases (ICD) code for different feature selection methods and different data sets: (A) concrete autoencoder with weight adjustment (CAEWW), (B) concrete autoencoder with no weight adjustment (CAENW), (C) autoencoder-inspired unsupervised feature selection (AEFS), (D) unsupervised feature selection for multicluster data (MCFS), (E) principal feature analysis (PFA), and (F) Laplacian score (LS). DAD: Discharge Abstract Database; NACRS: National Ambulatory Care Reporting System; PIN: Pharmaceutical Information Network.



Characteristics of the Selected Features

We also calculated the average depths of the codes selected by each method and compared them (using 2-tailed *t* test analysis) against the CAEWW method that is intended to select more general codes (ie, smaller depths). The CAEWW method selected codes with average depths of 1.38, 1.42, and 1.99 for the DAD, NACRS, and PIN data sets, respectively. Although CAEWW's code depths were significantly lower than the depths of the codes selected by the other methods (all $P<.05$), there was no significant difference between the CAEWW and CAENW methods (with average depths of 1.48, 1.45, 2.03; all $P>.05$). The *P* values can be found in Table S3 of Multimedia Appendix 2. Figure 2 illustrates the difference in average code depth among the different methods.

We used the average of the mean absolute Shapley values from each mortality prediction model as an index for the importance of the features selected by each method. To compare the CAEWW method with the other methods across the 3 different data sets, we conducted a 2-tailed *t* test analysis. The CAEWW method did not show any significant difference from the

CAENW methods across all data sets (all $P>.05$). However, the CAEWW method did yield significantly higher mean absolute Shapley values compared to the other methods (AEFS and PFA; all $P<.001$). The AEFS and PFA methods had the lowest Shapley values compared to all the other methods, indicating that they selected lower-quality features for this task. The P values are available in Table S4 in Multimedia Appendix 2. Figure 3 illustrates the aforementioned differences in mean absolute Shapley values. Figure 4 shows the Shapley plots of the 20 most important features selected by the CAEWW method across different data sets. The corresponding Shapley plots for the other methods can be found in Multimedia Appendix 3 (Figures S1-S5). Additionally, Multimedia Appendix 4 (Tables S1-S18) includes all chosen features, detailed descriptions, and the average absolute Shapley values across all data sets and methods.

Figure 2. Average depths of the selected codes by each method in the *ICD-10-CA* or ATC tree. Methods with average depths significantly ($P<.05$) larger than the CAEWW method in their corresponding data set are marked with asterisks (*). AEFS: autoencoder-inspired unsupervised feature selection; ATC: Anatomical Therapeutic Chemical CAENW: concrete autoencoder with no weight adjustment; CAEWW: concrete autoencoder with weight adjustment; DAD: Discharge Abstract Database; *ICD-10-CA*: *International Classification of Diseases, Tenth Revision, Canada*; LS: Laplacian score; MCFS: unsupervised feature selection for multicluster data; NACRS: National Ambulatory Care Reporting System; PFA: principal feature analysis; PIN: Pharmaceutical Information Network.

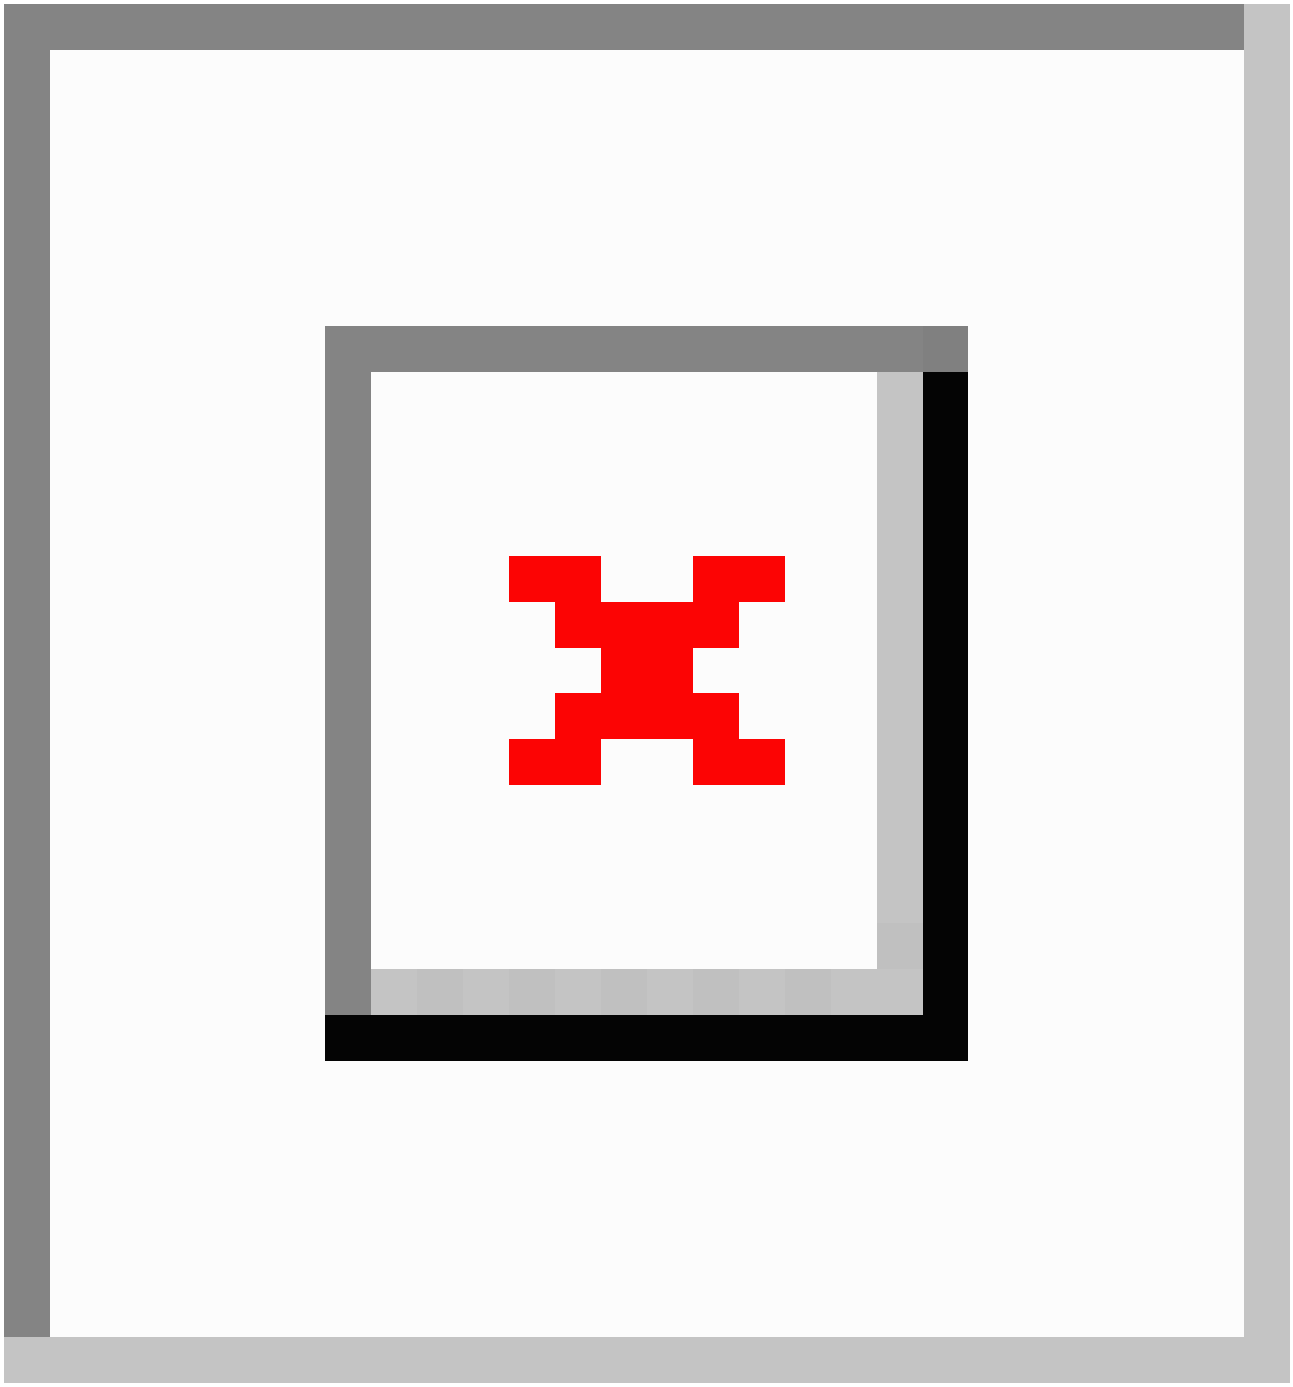


Figure 3. Average of mean absolute Shapley values of features in each mortality prediction model. Methods with average values significantly (P<.05) smaller than the CAEWW method in their corresponding data set are marked with asterisks (*). Figure 4. SHAP values of the features selected by the CAEWW method across different data sets (20 most important features): (A) Discharge Abstract Database (DAD), (B) National Ambulatory Care Reporting System (NACRS), and (C) Pharmaceutical Information Network (PIN). CAEWW: concrete autoencoder with weight adjustment; SHAP: Shapley additive explanations.

Discussion

Principal Findings

The high dimensionality of the ICD and ATC code databases necessitates the use of dimensionality reduction techniques to feed the data into machine learning models. Due to interpretability concerns in the health domain, selecting from original features, rather than transforming them into new features, is an essential step in reducing dimensionality. In this study, we demonstrated that the CAE methods performed the best in selecting the most informative ICD and ATC codes in an unsupervised setting. Using a clinical outcome as a case study, we also demonstrated that ICD and ATC code features selected by the CAE methods were able to predict the outcome variable with better accuracy than the other methods in the study, even though they were derived from an unsupervised setting in the absence of the target variable. This indicates that the selected features can be considered unbiased toward a specific target variable and explain the phenomenon appropriately. We also showed that the AEFS and PFA methods did not select high-quality features in our data set and were not suitable for both tasks of reconstructing the feature space and predicting 90-day mortality. The LS and MCFS methods, however, showed better performance in both tasks (slightly lower than the CAE methods). Furthermore, the features selected

by the CAE methods (especially CAEWW) were generally higher-level codes (ie, lower depth in the hierarchical structure), which helps the study to find generalized solutions.

It is worth mentioning that our methodology code is publicly shared, allowing other researchers to use the desired methods for selecting the most informative features within cohorts with large ICD, ATC, or other hierarchical-coded health databases [19].

Computational Cost

The MCFS, PFA, and LS methods had multiple special matrix operations that made them computationally expensive. Considering our large-scale, high-dimensional data set, these algorithms were not possible to run on a personal computer and we had to optimize the operations for an advanced computing cluster with 40 Intel Xeon Gold 6342 2.80 GHz CPUs and 2048 GB RAM. The MCFS and LS feature selection experiments had some shared operations and together took over 2 days to complete. The PFA method also needed less than a day for the entire feature selection experiments. The AEFS and CAE methods, however, had the advantage of using GPUs and optimized deep learning libraries for training the neural networks and were faster. Each of these algorithms took less than 4 hours on an Nvidia A100 80 GB GPU.

Selected Features

The Shapely analysis of the 20 most important features selected in each data set using the CAEWW method for predicting mortality revealed the multidimensional capabilities of this method in identifying relevant information. In the DAD and NACRS data sets, it selected disease codes relevant to mortality among patients with CAD. In both data sets, diseases related to cardiovascular conditions, hypertensive and circulatory disorders, metabolic disorders, renal failures [21], and cancer [22] were selected, which are important factors in the outcomes of patients with CAD. Furthermore, DAD-based features included accidents, arthropathies, and hospitalization-specific conditions, whereas the NACRS data set resulted in falls [23]; digestive disorders [24]; and codes related to the rehabilitations, management, or complexity of the diseases. In the PIN data set, direct interventions for CAD and related risk factors were mainly selected, including high-ceiling diuretics, statins, ace inhibitors, angiotensin II receptor blockers (plain and combinations), direct factor Xa inhibitors, vasodilators, antianemic preparations, antithrombotic agents, and other lipid-modifying agents, addressing heart failure, cholesterol management, blood pressure control, anticoagulation, anemia, and blood flow. Also, drugs related to accompanying diseases or conditions with CAD were selected: gastrointestinal issues (pantoprazole and general drugs for acid-related disorders [25,26] and drugs for constipation [27]), pain management (opioids, other analgesics, and antipyretics) [28], inflammatory conditions and immune responses (anti-inflammatory and antirheumatic products and corticosteroids for systemic use) [29,30], mental and behavioral health (antipsychotics) [31], respiratory conditions (adrenergic inhalants [32]), and urological issues [33].

Previous studies typically selected codes as machine learning model features based on expert opinions, the presence of high-level codes (eg, categories or chapters), or a combination of both [34,35]. To the best of our knowledge, only 1 study [3] attempted to offer a sophisticated feature selection method using tree-lasso regularization for ICD code data sets, but it was in a supervised setting that required an outcome variable. Our study provides a general tool for health researchers to select the most informative ICD and ATC codes without biasing the study toward a specific outcome variable. We also introduced a unique target weight adjustment function to the CAE model to guide the model to select higher levels of the ICD table compared to the model without adjustment.

Limitations and Future Work

One of the limitations of this study was the incapability of the CAE method to select an exact number of desired features. Since the neurons in the concrete selector layer work independently, there is a possibility of selecting duplicate features. Therefore, the number of final selected features can be fewer than the desired number. Although it indicates that the decoder model is still capable of reconstructing the initial feature space with a smaller number of features, some researchers may prefer to have an exact number of features they desire for their models. One previous study [36] has used a special regularization term in the training step to enforce the model not to select duplicate features. This method can be investigated for the ICD and ATC codes in the future.

The aggregation of codes should be viewed as a trade-off in this study. We needed to select a reasonable aggregation period that covers both long-term and short-term diseases. A shorter period could skew the results by including multiple correlated records from the same patient. Conversely, longer periods could weigh short-term diseases equally with long-term ones, and the codes of the patients with fewer records (eg, recent patients in the cohort) would have a lower chance of selection.

Another limitation was that we only used 3 data sets of a specific disease cohort to choose the features. Therefore, the selected features in this study may not generalize to other patient cohorts or diseases. Furthermore, we selected the 100 best features, but other data sets or patient cohorts may require a different number of features. Future studies may investigate the impact of the number of features on the results. Moreover, our hyperparameter analysis was conducted within a constrained scope due to limited computational resources. Future studies could further explore the impact of a broader range of hyperparameter values. We anticipate that the CAEs hold potential for this area due to their flexible neural network structure and optimized algorithms. A similar limitation also applies to the mortality prediction case study, where we only trained XGBoost and did not explore other model types.

Conclusions

In this study, we investigated 5 different methods for selecting the best features in ICD and ATC code data sets in an unsupervised setting. We demonstrated that the CAE method can select better features representing the whole data set that can be useful in further machine learning studies. We also introduced weight adjustment of the CAE method for ICD and ATC code data sets that can be useful in the generalizability

and interpretability of the models, given that it prioritizes selecting high-level definitions of diseases.

The CAEWW method outperformed all other methods in reconstructing the initial feature space across all data sets. We validated the selected features through a supervised learning task, predicting 90-day mortality after discharge using 3 distinct data sets. Features selected via the CAEWW method demonstrated significantly improved performance on this task, as evidenced by the DeLong and McNemar tests. Given the advantages of the CAE method, we recommend its use in the feature selection phase of EHD analysis with ICD or ATC codes.

Acknowledgments

This study was supported by the Libin Cardiovascular Institute PhD Graduate Scholarship, the Alberta Innovates Graduate Scholarship, and a Project Grant from the Canadian Institutes of Health Research (PJT 178027).

Authors' Contributions

PG led the conceptualization of the study, designed the research methodology, executed the study, performed the data analysis, and drafted the original manuscript. JL provided the data set essential for the research, contributed to study supervision, and critically reviewed and revised the manuscript. Both authors read and approved the final manuscript.

Conflicts of Interest

JL is the chief technology officer, a co-founder, and a major shareholder of Symbiotic AI, Inc. The authors have no further conflicts of interest to declare.

Abstract

Background: Predicting hypoglycemia while maintaining a low false alarm rate is a challenge for the wide adoption of continuous glucose monitoring (CGM) devices in diabetes management. One small study suggested that a deep learning model based on the long short-term memory (LSTM) network had better performance in hypoglycemia prediction than traditional machine learning algorithms in European patients with type 1 diabetes. However, given that many well-recognized deep learning models perform poorly outside the training setting, it remains unclear whether the LSTM model could be generalized to different populations or patients with other diabetes subtypes.

Objective: The aim of this study was to validate LSTM hypoglycemia prediction models in more diverse populations and across a wide spectrum of patients with different subtypes of diabetes.

Methods: We assembled two large data sets of patients with type 1 and type 2 diabetes. The primary data set including CGM data from 192 Chinese patients with diabetes was used to develop the LSTM, support vector machine (SVM), and random forest (RF) models for hypoglycemia prediction with a prediction horizon of 30 minutes. Hypoglycemia was categorized into mild (glucose=54-70 mg/dL) and severe (glucose<54 mg/dL) levels. The validation data set of 427 patients of European-American ancestry in the United States was used to validate the models and examine their generalizations. The predictive performance of the models was evaluated according to the sensitivity, specificity, and area under the receiver operating characteristic curve (AUC).

Results: For the difficult-to-predict mild hypoglycemia events, the LSTM model consistently achieved AUC values greater than 97% in the primary data set, with a less than 3% AUC reduction in the validation data set, indicating that the model was robust and generalizable across populations. AUC values above 93% were also achieved when the LSTM model was applied to both type 1 and type 2 diabetes in the validation data set, further strengthening the generalizability of the model. Under different satisfactory levels of sensitivity for mild and severe hypoglycemia prediction, the LSTM model achieved higher specificity than the SVM and RF models, thereby reducing false alarms.

Conclusions: Our results demonstrate that the LSTM model is robust for hypoglycemia prediction and is generalizable across populations or diabetes subtypes. Given its additional advantage of false-alarm reduction, the LSTM model is a strong candidate to be widely implemented in future CGM devices for hypoglycemia prediction.

Introduction

Diabetes is a serious long-term disease with considerable influence on global health [1]. Type 1 diabetes mellitus (T1DM) is a disease in which the pancreas produces little or no insulin [2], whereas insulin resistance and insufficient insulin are the primary contributors to the development of type 2 diabetes mellitus (T2DM) [3]. Although the pathogenic mechanisms of

T1DM and T2DM are different, glucose-lowering treatments such as insulin administration are the common leading cause of hypoglycemia events in patients with both diabetes subtypes [4]. Severe hypoglycemia is a frequent phenomenon in patients with T1DM, with an annual prevalence of 30%-40% [5]. Although the risk of severe hypoglycemia in patients with T2DM is relatively lower, 46%-58% of these patients were reported to have experienced mild hypoglycemia symptoms over a 6-month period [6]. Patients experiencing frequent hypoglycemia events have 1.5-6.0 times increased risks of cardiovascular events and mortality than those without such events [7]. Patients with T2DM from Southeast Asia appear to have an elevated risk of hypoglycemia, as these patients are more often treated with a premixed insulin formulation, are younger, and have a lower BMI than those of their counterparts from Western countries [8-11]. Given that demographic and clinical factors such as ethnic group, diabetes subtype, and BMI are all important components of the complex risk profile of hypoglycemia, accurate risk prediction and prevention of hypoglycemia across populations and diabetes types remain significant challenges in diabetes management.

Recently, continuous glucose monitoring (CGM) has demonstrated good potential to predict hypoglycemia. For patients who wear insulin pumps or those who require multiple daily insulin injections, hypoglycemia prediction based on CGM data could provide a timely warning of impending hypoglycemia for the individual to take immediate action and increase their glucose levels. CGM devices are designed to produce time-series data by recording interstitial glucose concentrations within a relatively short interval of 5-15 minutes over a few days. Therefore, it is possible to leverage the early glucose readings to predict hypoglycemia events over the short-to-medium time horizon. Time-series forecast algorithms such as autoregressive and moving-average algorithms were first adopted to utilize the short-term temporal features of CGM data to predict hypoglycemia [12-15]. A small study including 17 patients with T1DM showed that these CGM-based algorithms achieved 86% sensitivity but only 58% specificity in hypoglycemia prediction [16]. Similar results from studies implementing these time-series forecast algorithms indicated that the low specificity might frequently generate false alarms, leading to discontinuation of CGM use in hypoglycemia prevention [17,18].

To improve the sensitivity and particularly the specificity of hypoglycemia prediction, both traditional machine learning algorithms such as support vector machine (SVM) and random forest (RF) models, along with deep learning models such as the convolutional neural network and long short-term memory network (LSTM) have been used to leverage more temporal features of CGM data [19-25]. When the features, including the mean of glucose and range of time in hyperglycemia, based on CGM data collected over the previous 6 hours were fed into the RF model, hypoglycemia prediction achieved a sensitivity of 93% and a specificity of 91% in a study of 112 patients with T1DM [26]. More recently, when an LSTM deep learning model was implemented on CGM data for hypoglycemia prediction, it achieved a sensitivity of 97% with remarkably few false alarms (0.9 false alarms per week) on a test data set including 10 patients with T1DM, thereby illuminating a path toward the widespread clinical adoption of CGM in hypoglycemia prediction [27].

However, a well-known challenge in implementing predictive models is their generalization [28]. The predictive performance of models could be substantially reduced when used in a setting that is not well-represented by the training data set [29,30]. This is particularly relevant in the case of hypoglycemia prediction, as the previously developed models for this purpose were mostly trained on a small data set of patients with T1DM from Western populations. In addition, the lack of a common test data set rendered the comparison of predictive performances between models unreliable. With recent improvements in measurement accuracy, CGM devices have also gained momentum and have begun to be adopted more widely for the management of T2DM, including in developing countries. Therefore, the established hypoglycemia prediction models should be validated in more diverse populations and over a wide spectrum of patients with different types of diabetes.

We hypothesized that the promising LSTM model for hypoglycemia prediction from CGM data could maintain good predictive performance in different settings for different populations. In this study, we assembled two large CGM data sets from China and the United States, both including patients with T1DM and patients with T2DM. We developed the LSTM model on the Chinese data set and then examined the model performance in the data set from European-Americans in the United States. Apart from exploring the model's generalization ability for T1DM and T2DM separately, we also compared the predictive performance of the LSTM model with that of SVM and RF models to further indicate its translational potential.

Methods

Ethical Considerations

The study protocol was approved by the ethics committees of Kunshan Hospital Affiliated to Jiangsu University (2023-03-014-H01-K01) and the study was performed in accordance with the principles of the Declaration of Helsinki. Written informed consent was obtained from each participant before taking the measurements. The data analyzed were anonymized. All participants volunteered to participate in the project with no compensation provided.

Data Collection

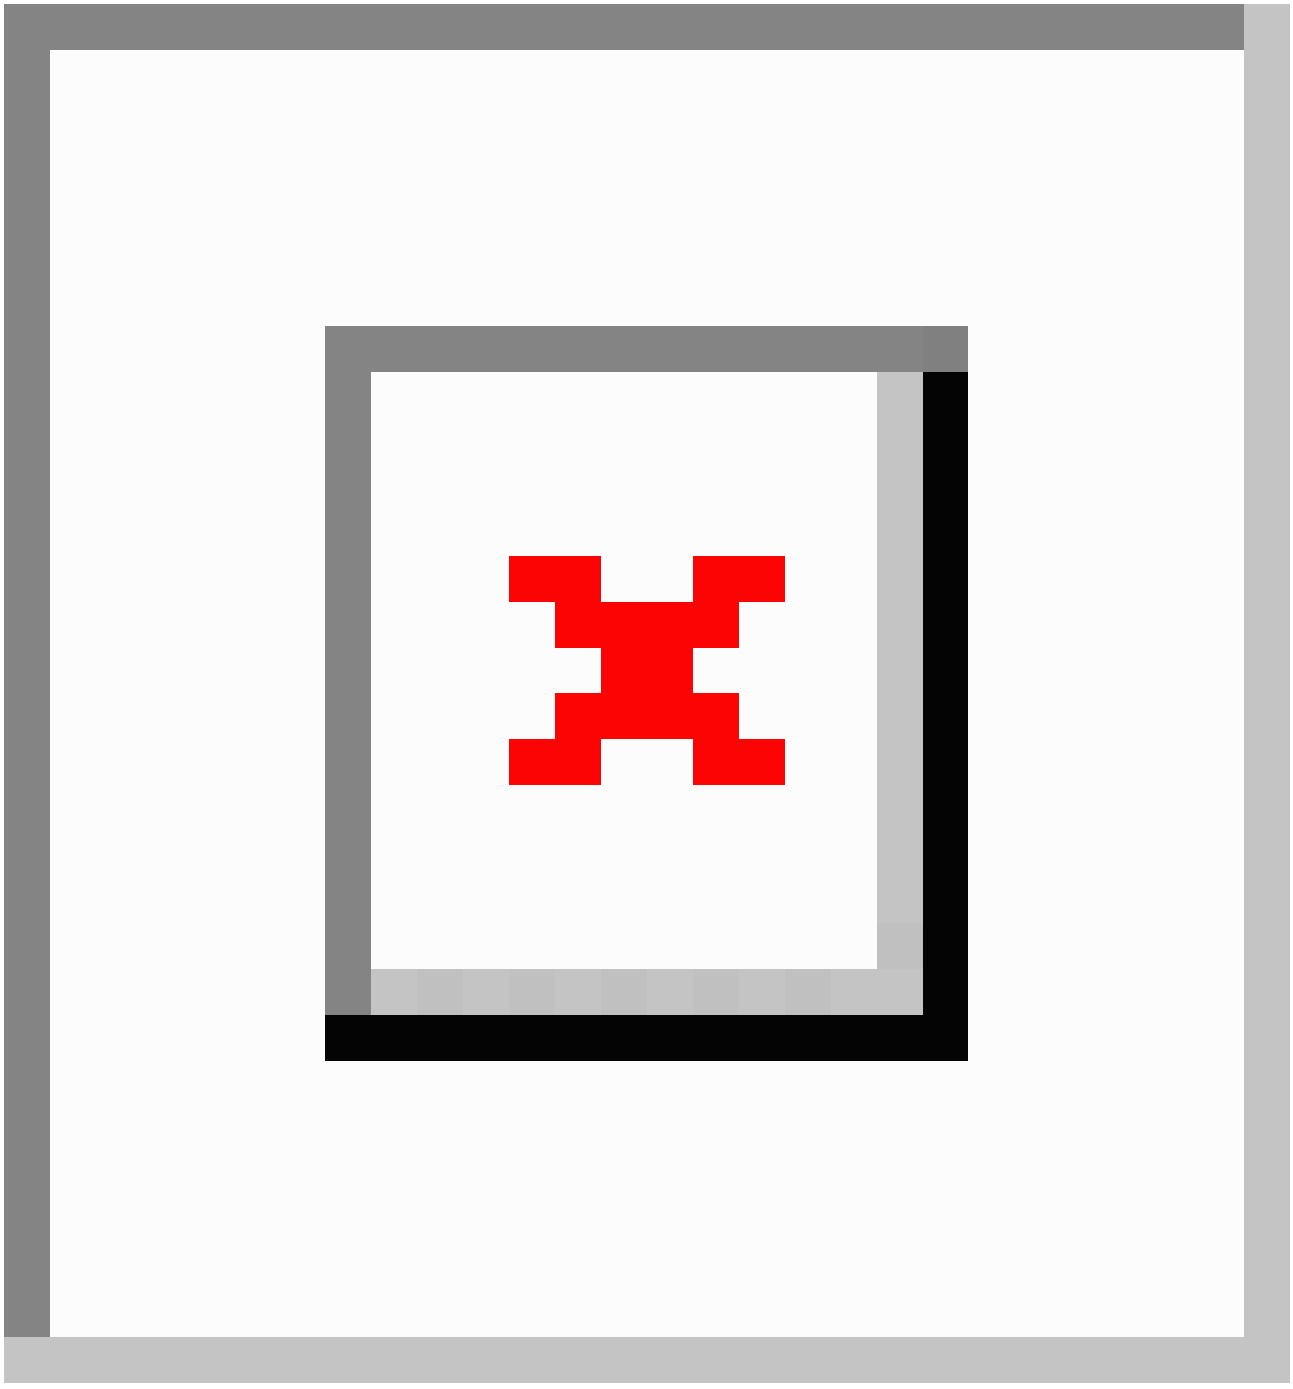
We collected a primary data set comprising 1578 days of CGM data collected from 264 Chinese people with diabetes to develop a deep learning model for hypoglycemia prediction. The individuals' glucose levels were monitored using the Medtronic MiniMed CGM device, which requires calibration according to self-monitored blood glucose levels. This CGM device can record glucose levels every 5 minutes over 3 days.

The mean absolute relative difference (MARD) was used to evaluate the quality of the CGM data. The MARD represents the average of the absolute error between all CGM values and matched reference values. A small MARD indicates that the CGM readings are close to the reference glucose value, whereas a larger MARD percentage indicates greater discrepancies between the CGM and reference glucose values. Each individual

had at least 5 self-monitoring of blood glucose (SMBG) measurements. As reference glucose values, the SMBG was used to calculate the MARD of CGM data. The data for 72 participants were filtered out because their MARD was higher than 15%, leaving data for 192 participants with 808 days of CGM data for analysis.

To examine whether the deep learning model trained and developed with data from the Chinese population could be generalized to a different population, we assembled a large validation data set that mainly comprised data from individuals of European-American ancestry. The validation data set shared by the A1c-Derived Average Glucose study group includes 507 participants and 7299 days of CGM data, also collected with Medtronic MiniMed devices [31]. After filtering out individuals without diabetes, 427 patients with either T1DM or T2DM were included to validate the model. This validation data set was split into two groups: the T1DM group of 268 participants with 3932 days of CGM data and the T2DM group of 159 participants with 2259 days of CGM data. Figure 1 provides the flowchart of exclusion criteria for the primary data set and validation data set.

Figure 1. Flowchart of exclusion criteria for the primary data set and validation data set. MARD: mean absolute relative difference.



Outcome

The glucose values reported by CGM devices were classified into three categories: nonhypoglycemic level (glucose>70 mg/dL), mild hypoglycemic level (glucose=54-70 mg/dL), and severe hypoglycemic level (glucose<54 mg/dL) according to the international consensus on CGM utility [32].

Data Preprocessing

The primary data set consisting of 192 patients was randomly split into three disjoint data sets, namely the training data set, development data set, and test data set, at a 7:1.5:1.5 ratio. The training data set was used to train the model, whereas the development data set was used to select the hyperparameters in the training process. The test data set was used to evaluate the performance of the developed model.

The CGM sensor may fail to detect a valid glucose level, resulting in the CGM device missing glucose values continuously. To preserve as much of the CGM data as possible, we divided an individual's CGM data into different segments at the time points of missing data rather than discarding all of the CGM data. A segment was removed if it was shorter than 6 hours (72 data points). We set each glucose value reported by the CGM device as a predictive target if there were sufficient data prior to the target time at which the predictive target was located. The data used to predict the hypoglycemic level of the predictive target were retrieved from a 6-hour time window spanning from −390 minutes to −30 minutes of the target time. After preprocessing the primary data set, the training, development, and test data sets included 100,879, 21,895, and 21,324 samples generated from 134, 29, and 29 participants, respectively. Similarly, the T1DM group and T2DM group from the validation data set contained 712,018 and 405,224 samples generated from 268 and 159 participants, respectively.

Model Development

We used the common bidirectional LSTM model containing both forward and backward layers to capture the long-range temporal features in the time-series CGM data and to combine these features with context factors [33]. Each LSTM layer consists of 128 memory cells [34]. We chose a set of context factors, including gender, age, diabetes type, and hemoglobin A_{1c} value, to capture the background risk of hypoglycemia and enhance the model's predictive performance [26]. Therefore, each input data sample included 72 points of CGM data collected during 6 hours and the context factors. The output was the probability of the target glucose value being at the nonhypoglycemic level, mild hypoglycemic level, and severe hypoglycemic level.

We trained the LSTM model to predict the categories of a CGM value within 30 minutes on the prediction horizon. The training process would be terminated if the accuracy failed to increase for 10 consecutive epochs. We used root mean square propagation [35] as the optimizer and set the mini batch size to 64. The LSTM model was developed using the Python package Keras [36]. We also developed models to implement the SVM and RF algorithms for comparison. The SVM model was developed using the radial basis function as the kernel function, which was also used in previous studies of hypoglycemia prediction [37]. The RF model included 100 trees and was developed with the Scikit-learn Python package [38] under default parameters. The input to the SVM and RF models was the same as that used for the LSTM model.

Model Evaluation

Sensitivity, specificity, and the area under the receiver operating characteristic curve (AUC) were used to evaluate model performance. The label for each sample was the category of a single CGM data point. Sensitivity and specificity indicate the proportion of the labels of CGM data points that were correctly predicted. The DeLong method was used to measure the 95% CIs for the AUC values [39]. All methods of evaluation were developed using Python and the pROC R package [40].

Results

Characteristics of the Data Set

Table 1 summarizes the characteristics of the primary data set and the validation data set. As expected, the average age of patients with T1DM was lower than that of the patients with T2DM in both data sets (Wilcoxon rank sum test, $P<.001$).

Table . Characteristics of the primary data set and validation data set.

Variables		Primary data set		Validation data set	
		Type 2 diabetes (n=175)	Type 1 diabetes (n=17)	Type 2 diabetes (n=159)	Type 1 diabetes (n=268)
Age (years), mean (SD)		53.30 (11.78)	40.59 (13.02)	55.64 (9.32)	43.06 (12.85)
Women, n (%)		51 (29.14)	11 (64.71)	81 (50.94)	140 (52.24)
Predictive targets, n					
	Nonhypoglycemia	129,609	12,029	396,415	660,111
	Mild hypoglycemia	1350	336	5985	28,287
	Severe hypoglycemia	608	166	2824	23,620
Hemoglobin A_{1c} (%), mean (SD)		7.69 (1.71)	8.46 (2.22)	7.01 (1.24)	7.51 (1.30)

Model Performance on the Primary Test Data Set

Using the primary data set from 192 individuals, the three models of LSTM, SVM, and RF were trained and we then evaluated their performance based on the AUC. At the mild hypoglycemic level, the LSTM model achieved an AUC of 97.22% (95% CI 96.78%-97.66%), which was significantly higher than the AUC of 94.33% (95% CI 93.13%-95.53%) and 94.81% (95% CI 93.72%-95.91%) achieved by the SVM and RF models, respectively (both $P<.001$). At the severe hypoglycemic level, the LSTM model achieved an AUC of 99.64% (95% CI 99.53%-99.76%), which was significantly higher than the AUC of 98.30% (95% CI 98.00%-98.60%) and 97.88% (95% CI 96.93%-98.83%) achieved by the SVM and RF models, respectively (both $P<.001$). These results demonstrated that the LSTM model could outperform the SVM and RF models in predicting hypoglycemia.

Model Generalization on the Validation Data Set

We then utilized the validation data set from 427 European-Americans to evaluate the generalization of the LSTM model developed from our primary data set of 192 Chinese individuals. The LSTM model achieved an AUC of 94.61% (95% CI 94.51%-94.71%) for mild hypoglycemia, which was significantly higher than the AUC of 92.59% (95% CI 92.48%-92.71%) and 91.43% (95% CI 91.28%-91.58%) achieved by the SVM and RF models, respectively (both $P<.001$). The LSTM model achieved an AUC of 96.40% (95% CI 96.25%-96.55%) for severe hypoglycemia, which was significantly higher than the AUC of 95.27% (95% CI 95.15%-95.39%) and 95.17% (95% CI 95.01%-95.32%) achieved by SVM and RF models, respectively (both $P<.001$). Although AUC values of the LSTM model decreased by approximately 3% in the validation data set compared to those from the primary test data set, the overall AUC was still higher than 94%, indicating that the LSTM model could accurately predict hypoglycemia in a different population.

Next, the generalizability of the LSTM model to various disease subtypes was evaluated in the subgroups of T1DM and T2DM from the validation data set. For T1DM, the LSTM model achieved an AUC of 93.49% (95% CI 93.38%-93.61%) at the mild hypoglycemia level, which was significantly higher than the AUC of 90.92% (95% CI 90.78%-91.06%) and 89.74% (95% CI 89.57%-89.92%) achieved by the SVM and RF models, respectively (both $P<.001$). In addition, the LSTM model achieved an AUC of 95.89% (95% CI 95.73%-96.05%) at the severe hypoglycemia level, which was significantly higher than the AUC of 94.06% (95% CI 93.91%-94.21%) and 94.53% (95% CI 94.37%-94.70%) achieved by the SVM and RF models, respectively (both $P<.001$).

For T2DM, the LSTM model achieved an AUC of 96.83% (95% CI 96.66%-97.01%) at the mild hypoglycemia level, which was significantly higher than the AUC of 95.72% (95% CI 95.51%-95.93%) and 94.08% (95% CI 93.73%-94.43%) achieved by the SVM and RF models, respectively (both $P<.001$). In addition, the LSTM model achieved an AUC of 97.65% (95% CI 97.27%-98.04%) at the severe hypoglycemia level, which was significantly higher than the AUC of 96.02% (95% CI 95.70%-96.34%) and 95.71% (95% CI 95.23%-96.19%) achieved by the SVM and RF models, respectively (both $P<.001$).

The AUCs of the LSTM model were consistently higher than those from the SVM and RF models in both the T1DM and T2DM data sets. Taken together, these results demonstrated that the LSTM model could be generalized to different diabetes subtypes without significant loss of predictive performance.

Comparison of the False Alarm Rate

Finally, we examined whether the LSTM model could achieve a low false alarm rate (ie, high specificity) under satisfactory sensitivity. According to previous studies of hypoglycemia prediction, we set the model parameters to fix the satisfactory sensitivity level at 90% and 95% for mild and severe hypoglycemia prediction, respectively [21,26,37]. As shown in Table 2, while maintaining a sensitivity of 90% for mild hypoglycemia, which is difficult to predict, the LSTM model could achieve a specificity of 88.43%, which was higher than the specificity obtained from the SVM and RF models. For severe hypoglycemia, when a higher satisfactory sensitivity rate of 95% was set, the LSTM model achieved a specificity of 87.34%, which was higher than that obtained from the SVM model. Moreover, the RF model could not achieve a sensitivity of 95% for the severe hypoglycemic level. Taken together, these results demonstrated that the LSTM model could maintain a lower false alarm rate than the SVM and RF models in clinically practical settings.

Table . Specificity and sensitivity of the three models on the validation data set.

	Mild hypoglycemic level		Severe hypoglycemic level	
	Specificity (%)	Sensitivity (%)	Specificity (%)	Sensitivity (%)
LSTM[a]	88.43	90.00	87.34	95.00
SVM[b]	82.57	90.00	80.67	95.00
RF[c]	82.65	90.00	Not determined	Not achieved

[a]LSTM: long short-term memory.

[b]SVM: support vector machine.

[c]RF: random forest.

Discussion

Principal Findings

In this study, we assembled two large CGM data sets from China and the United States to develop and validate an LSTM deep learning model for hypoglycemia prediction. The LSTM model could maintain good predictive performance when applied to data sets from a different ethnic population or any common subtype of diabetes. The LSTM model could also predict both mild and severe hypoglycemia with higher accuracy than the traditional SVM and RF models. While targeting clinically meaningful high sensitivity, the LSTM model could achieve high specificity, thereby reducing the rate of false alarms.

Compared with the models tested without external validation in most previous studies of hypoglycemia prediction, we developed an LSTM model and validated the model in a data set from a different population to examine its generalizability [27]. There are considerable differences in dietary structure and clinical practice between China and the United States, which are among the many factors that might affect the risk of hypoglycemia. Previous studies demonstrated that clinical models trained in one population could result in an AUC reduction as great as 15% when applied to a distinct population [41-43]. However, the LSTM model derived from our Chinese training data set maintained high prediction performance (AUC>93%) with only a minor loss of 3% in the US data set, indicating good generalizability of the model. As CGM devices are becoming more widely adopted, the generalizability of the LSTM model could be further improved by training the model with data from multiple populations or can be fine-tuned for the target population using a transfer-learning approach [44].

We also examined the generalizability of the LSTM model on another dimension of diabetes pathogenicity. Given the different pathogenic mechanisms between T1DM and T2DM, hypoglycemia occurring in different diabetes subtypes would be expected to be preceded by various patterns of glucose fluctuation, which could be leveraged by the LSTM model for prediction. Therefore, the model was expected to lose predictive performance when the training and validation data sets had different proportions of diabetes subtypes. Indeed, we observed a higher AUC value for T2DM than for T1DM in the validation data set, which was likely due to the fact that our training data set primarily consisted of individuals with T2DM. However, for either subtype of diabetes, the LSTM model consistently maintained an AUC value above 93%, indicating the good generalizability of the model. With the increasing popularity of CGM usage in the management of all subtypes of diabetes, the LSTM model could be further improved by using larger training data sets with a wider representation of the various diabetes subtypes.

Achieving high sensitivity has been the main focus of previous models for hypoglycemia prediction, as severe hypoglycemia requires immediate external intervention [15,32]. With the sacrifice of high specificity, false alarms became an obstacle for the safe and widespread use of CGM devices [45-47]. False-alarm fatigue could lead to users ignoring the true alarms of hypoglycemia and contribute to the discontinuation of CGM use [45]. Moreover, glucose control could be compromised, as CGM users may frequently take action to elevate their glucose level when a false alarm is generated [46]. Therefore, it is imperative to balance the false alarm rate with sufficient sensitivity of the prediction. In this study, we demonstrated that the LSTM model would generate fewer false alarms than the traditional machine learning models under satisfactory sensitivity rates of 90% and 95% for mild and severe hypoglycemia, respectively. Therefore, the balanced hypoglycemia prediction performance from the LSTM model demonstrated that it has potential to promote the use of CGM in a variety of clinical settings.

One reason for the better predictive performance of the LSTM model than the SVM and RF models might be that the LSTM algorithm is more suitable for analyzing sequential data. CGM data are a type of sequential data that are generated in time order. The LSTM algorithm consists of memory cells that learn the sequential nature of observations within CGM data [48]. The input of one memory cell is the glucose value taken at one time point and then the LSTM takes all of the glucose values as inputs sequentially. Every memory cell retains the relevant information and discards irrelevant information for the predictive task, and then the relevant information in one cell is delivered to the next cell [49-53]. With this sequential structure, LSTM networks incorporate CGM data from the past to accurately make predictions of hypoglycemia risk in the near future.

Limitations

There are several limitations of this study. Although we tested the generalizability of the LSTM model using two data sets from China and the United States, further validation might still be required for application of the model in other countries. Similarly, as only T1DM and T2DM were included in our data sets, the model should be tested with wider and more representative training data sets to validate its utility on other minority subtypes of diabetes. Moreover, data from only one CGM device manufacturer were available for this study. Thus, it is unknown whether the model would perform equally well with data collected from other devices such as factory-calibrated CGM or noninvasive CGM devices. However, given that all of the devices were strictly calibrated by finger-stick glucose values, the fluctuation patterns and temporal dependence of CGM data, which are key factors for the LSTM prediction task, should be largely captured by any certified CGM device. Moreover, the performance of the LSTM model for hypoglycemia prediction will need to be further validated in a CGM data set without missing data.

Conclusions

We developed an accurate LSTM model for mild and severe hypoglycemia prediction using a large data set of 619 patients with diabetes from China and the United States. The model could be robustly generalized to different populations or any common subtype of diabetes. Moreover, while maintaining satisfactory levels of sensitivity, the model could also achieve high specificity, indicating its potential to mitigate the hypoglycemia false-alarm fatigue that is frequently observed in clinical practice. Taken together, we demonstrated that the

LSTM model is a strong candidate algorithm to be further tested and implemented for the wider clinical adoption of CGM.

Abstract

Background: Acute kidney injury (AKI) is a marker of clinical deterioration and renal toxicity. While there are many studies offering prediction models for the early detection of AKI, those predicting AKI occurrence using distributed research network (DRN)–based time series data are rare.

Objective: In this study, we aimed to detect the early occurrence of AKI by applying an interpretable long short-term memory (LSTM)–based model to hospital electronic health record (EHR)–based time series data in patients who took nephrotoxic drugs using a DRN.

Methods: We conducted a multi-institutional retrospective cohort study of data from 6 hospitals using a DRN. For each institution, a patient-based data set was constructed using 5 drugs for AKI, and an interpretable multivariable LSTM (IMV-LSTM) model was used for training. This study used propensity score matching to mitigate differences in demographics and clinical characteristics. Additionally, the temporal attention values of the AKI prediction model's contribution variables were demonstrated for each institution and drug, with differences in highly important feature distributions between the case and control data confirmed using 1-way ANOVA.

Results: This study analyzed 8643 and 31,012 patients with and without AKI, respectively, across 6 hospitals. When analyzing the distribution of AKI onset, vancomycin showed an earlier onset (median 12, IQR 5-25 days), and acyclovir was the slowest compared to the other drugs (median 23, IQR 10-41 days). Our temporal deep learning model for AKI prediction performed well for most drugs. Acyclovir had the highest average area under the receiver operating characteristic curve score per drug (0.94), followed by acetaminophen (0.93), vancomycin (0.92), naproxen (0.90), and celecoxib (0.89). Based on the temporal attention values of the variables in the AKI prediction model, verified lymphocytes and calcvancomycin ium had the highest attention, whereas lymphocytes, albumin, and hemoglobin tended to decrease over time, and urine pH and prothrombin time tended to increase.

Conclusions: Early surveillance of AKI outbreaks can be achieved by applying an IMV-LSTM based on time series data through an EHR-based DRN. This approach can help identify risk factors and enable early detection of adverse drug reactions when prescribing drugs that cause renal toxicity before AKI occurs.

Introduction

Acute kidney injury (AKI) is associated with a mortality rate of 40% - 70% in hospitalized patients who develop AKI and causes significant kidney damage even after recovery, leading to dialysis, longer hospital stays, and increased costs of care [1-4]. Early detection of AKI increases the likelihood of AKI prevention, associated morbidity, and costs [5]. As no specific treatment can reverse AKI and the recognition of patients at risk of AKI before diagnosis contributes to better clinical outcomes than treatment after AKI occurs [6], early detection of AKI is essential for prompt therapeutic intervention.

Several studies have attempted to predict AKI occurrence. With the increasing availability of clinical databases, they developed models to predict the occurrence of AKI using electronic health records (EHRs) [7-18]. Although these studies used EHRs, the number of patients in the patient population was small because they focused on specific patients, such as surgical patients, patients with sepsis, and older adults. There have also been a number of studies using artificial intelligence (AI) models to predict AKI. Although attempts have been made to predict the occurrence of AKI early, few models have provided clear rationales and explanations [19-21]. Therefore, time series data analysis is required for AKI prediction models to reflect the temporal information between variables [22]. Time series analysis for AKI is necessary because the length of time each patient stays in a hospital or intensive care unit can differ from person to person, and the frequency of measurements can vary from values that are measured continuously (eg, blood pressure) to laboratory values that are measured on an as-needed basis. Recently, an interpretable multivariable long short-term memory (IMV-LSTM) method for considering time series data has been published [23]; however, little research has been conducted on this method.

To address these issues, this study aimed to apply and validate a multicenter-based explainable time series AI model for predicting the occurrence of AKI caused by specific nephrotoxic drugs in 6 hospitals in South Korea by using a large clinical database with a common data model (CDM) through a distributed research network (DRN).

Methods

Ethical Considerations

This study was approved by the institutional review committees of Severance Hospital (SH; 4-2021-1209), Gangnam Severance Hospital (GSH; 3-2021-0005), Konyang University Hospital (KYUH; 2021-10-003-001), Ajou University Hospital (AJUH; AJIRB-MED-MDB-21 - 676), Seoul National University Cancer Hospital (SNUH; E-2207-151-1342), and the National Cancer Center (NCC; 2022-0184). All retrospective data were anonymized and appropriate measures were taken to protect participant information.

Study Design

This retrospective observational cohort study analyzed the EHRs from 6 hospitals in South Korea between 1994 and 2021 to predict AKI. The EHRs were converted to OMOP-CDM (Observational Medical Outcomes Partnership Common Data Model) version 5.3.1. The 6 hospitals were SH, GSH, KYUH, AJUH, SNUH, and the NCC. An overall diagram of the cohort composition is provided in Figure 1.

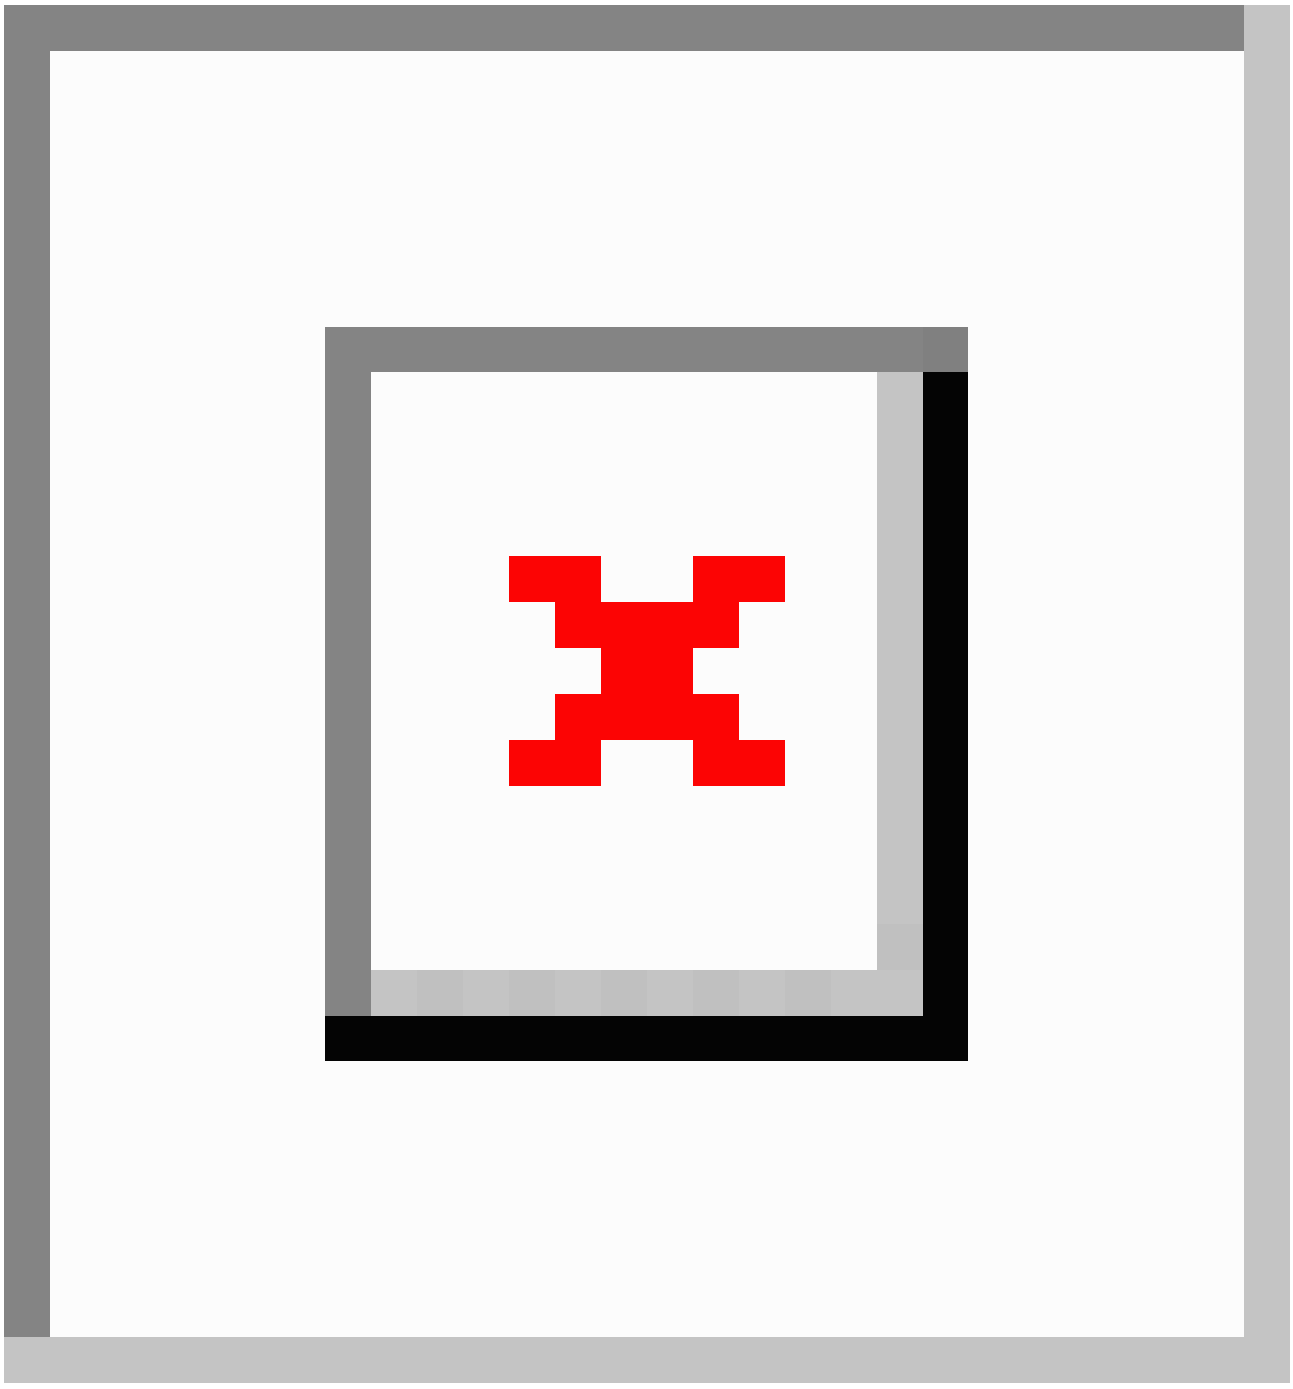
In our cohorts, we adopted criteria based on serum creatinine (SCr) to define AKI according to the Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guidelines and the previously defined AKI classification stages mapped in the “injury” category [24-26]. The criterion is an increase in the SCr level to 2 times the baseline value. As an alternative to the baseline SCr levels, we defined the upper limit of normal (ULN) value of SCr as 1.2 mg/dl [27].

The targeted drugs were selected from 5 medications associated with a high risk of AKI according to the US Food and Drug Administration (FDA) and previous studies: acetaminophen; vancomycin; 2 nonsteroidal anti-inflammatory drugs (NSAIDs), naproxen and celecoxib; and 1 antiviral drug, acyclovir [21,22].

The inclusion criteria were as follows: (1) the target drugs were administered, (2) the patient had a visit record of at least 30 days prior to the observation period, and (3) the patient underwent at least 2 SCr tests during the preobservation period (0 - 60 days before the study). The exclusion criteria were as follows: (1) the patient had at least 1 SCr test outside the ULN value in the preobservation period. Participants were divided into case and control cohorts based on whether they met previously defined AKI criteria for 60 days after taking the first medicine. The observation period refers to the time range before and after the initial medication intake for each patient within the cohort. The cohort definitions were created using ATLAS, a web-based tool (Observational Health Data Sciences and Informatics), and are available as JSON files on GitHub [28].

To adjust for differences between cases and controls to reduce the effect of confounding variables, we used propensity score matching (PSM). Covariates included were age, sex, and SCr value at baseline. We normalized the covariates by applying standard scaling to ensure consistent dimensions across variables. A propensity score for each patient was generated by logistic regression. Patients were matched in a 1:3 ratio using a K-nearest neighbor (K-NN) algorithm using the Python *scikit-learn* library.

AJUH: Ajou University Hospital; GSH: Gangnam Severance Hospital; IMV-LSTM: interpretable multivariable long short-term memory; KYUH: Konyang University Hospital; NCC: National Cancer Center; OMOP: Observational Medical Outcomes Partnership; SH: Severance Hospital; SNUH: Seoul National University Cancer Hospital; ULN, upper limit of normal.



Candidate Predictors for Time Series

Candidate predictors were extracted from several key domains within the CDM containing per-patient observational data using structured query language tools in Python. Age and sex were used in the *person* domain, clinical laboratory tests in the *measurement* domain, medications in the *drug exposure* domain, diagnostic records in the *condition occurrence* domain, and surgical/procedure records in the *procedure occurrence* domain. Lab tests were treated as continuous variables, while other medications, conditions, and procedures were treated as binary variables. Statistical methods were used to select the variables. To identify predictors, we tested the statistical significance of the difference between the enrollment time of the cohort and the onset date of AKI using a 2-tailed paired *t* test and the McNemar test for continuous and dichotomous variables, respectively. To create a time series table, the candidate variables were pivoted into columns and dates were placed into rows. Missing values were handled in the following ways: forward fill for laboratory tests and diagnoses and zero fill for medications and treatments. The window size for predictions used 4-week sequence data and was processed by shifting the data of the prediction cycle by 2 weeks.

AKI Prediction Modeling

LSTM models based on recurrence have been designed to process time series data [29]. Attention-based LSTM models were initially proposed for learning words and the relationships between words in natural language processing [30,31] and later evolved into a key component of deep learning, becoming one of the methods used to provide interpretations, including importance scores for predicted outcomes.

As an advanced LSTM model, we used the IMV-LSTM module for the learning model, which is a multivariate LSTM neural network for the prediction and interpretation of multivariate time series [23]. This model improves on the LSTM-attention model, which can predict variable importance using multivariate inputs to configure variable-wise hidden states and mix both temporal and variable levels of attention for improved interpretability. The model was trained for 200 epochs with a batch size of 64 and a learning rate of 1e-3. An Adam optimizer was used with early stopping after 20 epochs. The data set was divided into training, test, and validation sets at a 6:2:2 ratio. Prediction performance was evaluated using the area under the receiver operating characteristic curve (AUROC) value. Additionally, we used the accuracy, precision, F_1-score, and area under the precision-recall curve (AUPRC) to ensure robustness for unbalanced data.

In this study, AKI prediction models were created for each hospital and drug. Each model had a different selection of candidate variables. To interpret the predictors in each model, variable- and temporal-wise attention scores were extracted from all trained models. These scores were then aggregated by calculating the overall temporal attention score, which was obtained by taking the weighted average of the temporal attention value over the attention value for each predictor variable. The resulting scores were plotted as heat maps for interpretation.

Statistical Analysis

We used statistical packages based on Python and R (R Project for Statistical Computing) for the statistical analysis. First, to compare the AKI and non-AKI groups, we calculated significance using the χ^2 test for categorical variables and an independent-sample 2-tailed *t* test for continuous variables. Second, to identify differences in the pattern of AKI occurrence between cohorts and drugs, a histogram was plotted for patients in each cohort from the date of cohort entry (the first day of administration of the target drug) to the date of AKI occurrence. Differences between drugs were analyzed using an independent-sample2-tailed *t* test. Third, we compared the distribution of the aggregated temporal attention scores with the actual trained data with box plots of the data for 4 weeks at 1-week intervals. A repeated ANOVA test was performed to identify temporal differences.

Results

Demographic and Clinical Characteristics

The demographics of the 31,012 patients without AKI and the 8643 patients with AKI across the 6 hospitals after PSM are shown in Table 1.

Table . Demonstration and clinical characteristics of patients with and without AKI across 6 hospitals after propensity score matching. The *P* values were obtained by conducting a 2-sample *t* test to compare the means for cases and controls.

[a]SH: Severance Hospital.

[b]GSH: Gangnam Severance Hospital.

[c]KYUH: Konyang University Hospital.

[d]AJUH: Ajou University Hospital.

[e]SNUH: Seoul National University Cancer Hospital.

[f]NCC: National Cancer Center.

By hospital, the cohort consisted of 14,046 patients from SH, 2180 from GSH, 2493 from KYUH, 4331 from AJUH, 13,174 from SNUH, and 4431 from NCC after matching the propensity scores. Propensity matching was performed using age, sex, and SCr levels at baseline. As for the changes in covariates, the difference in mean age decreased from 6.39 (60.65 – 54.26) to 0.44 (60.65 – 60.21) years, the difference in male ratio decreased from 16.49% (63.17% – 46.68%) to 7.02% (63.17% – 56.15%), and the difference in SCr at baseline decreased from 0.14 mg/dL (0.71 – 0.58 mg/dL) to 0.03 mg/dL (0.71 – 0.67 mg/dL) (Table S2 in Multimedia Appendix 1). There were still statistically significant differences in PSM age (60.66, SD 15.86 vs 60.22, SD 15.94 years; *P*=.03), gender (63.17% vs 56.15% male; *P*<.001), and SCr at baseline (0.71, SD 0.61 vs 0.68, SD 0.41 mg/dL; *P*<.001). Patients who developed AKI had more severe neoplasms (ie, active cancers; 70.6% vs 44.26%; *P*<.001) and chronic liver disease (15.83% vs 6.55%; *P*<.001). Moreover, the analysis revealed the following differences: sepsis (6.5% vs 1.94%; *P*<.001), diabetes mellitus (19.43% vs 14.57%; *P*<.001), hypertension (27.81% vs 23.5%; *P*<.001), anemia (9.81% vs 4.8%; *P*<.001), and heart failure (4.79% vs 3.07%; *P*<.001). There was no significant difference between hypotension (0.24% vs 0.21%; *P*=.56), potassium (4.11, SD 0.57 vs 4.11, SD 0.51 mmol/L; *P*=.48), or renal artery stenosis (0.07% vs 0.03%; *P*=.13). Hypoalbuminemia, obesity, peripheral vascular disease, renal artery stenosis, liver dysfunction, and prior kidney surgery had low incidence rates (<2%).

Distribution of Adverse Drug Events

To analyze the differences in drug patterns at the time of AKI occurrence, we assessed the pattern for each drug. The median number of days for the occurrence of AKI among the drug and cohort patients in the entire hospital was 17 (IQR 7-33 days). Vancomycin appeared after a median period of 12 days, followed by naproxen (18 days), acetaminophen (19 days), celecoxib (22 days), and acyclovir (23 days). When comparing the IQR values, celecoxib (10 - 41 days) and Acyclovir (10 - 41 days) showed a relatively broad distribution, whereas acetaminophen (9 - 34 days) and naproxen (8 - 34 days) were distributed over 25 days. Vancomycin (5 - 25 days) exhibited the narrowest distribution. Celecoxib and acyclovir tended to be relatively distributed compared to acetaminophen, vancomycin, and naproxen. We compared the onset times of all drug pairs and hospital pairs to check the similarity in AKI occurrence (Figure 2). The patterns between specific drugs was similar for celecoxib and acyclovir (*P*=.88) and for acetaminophen and naproxen (*P*=.57). The patterns between hospitals were similar for SH and AJUH (*P*=.98), SH and GSH (*P*=.36), GSH and AJUH (*P*=.42), GSH and NCC (*P*=.24), and SNUH and NCC (*P*=.26).

Figure 2. (**A**) Comparison of acute kidney injury (AKI) onset time between drugs and (**B**) AKI onset time between hospitals. The *P* values were obtained by conducting independent 2-tailed *t* tests between each aggregated pair. AKI Prediction Model Performance

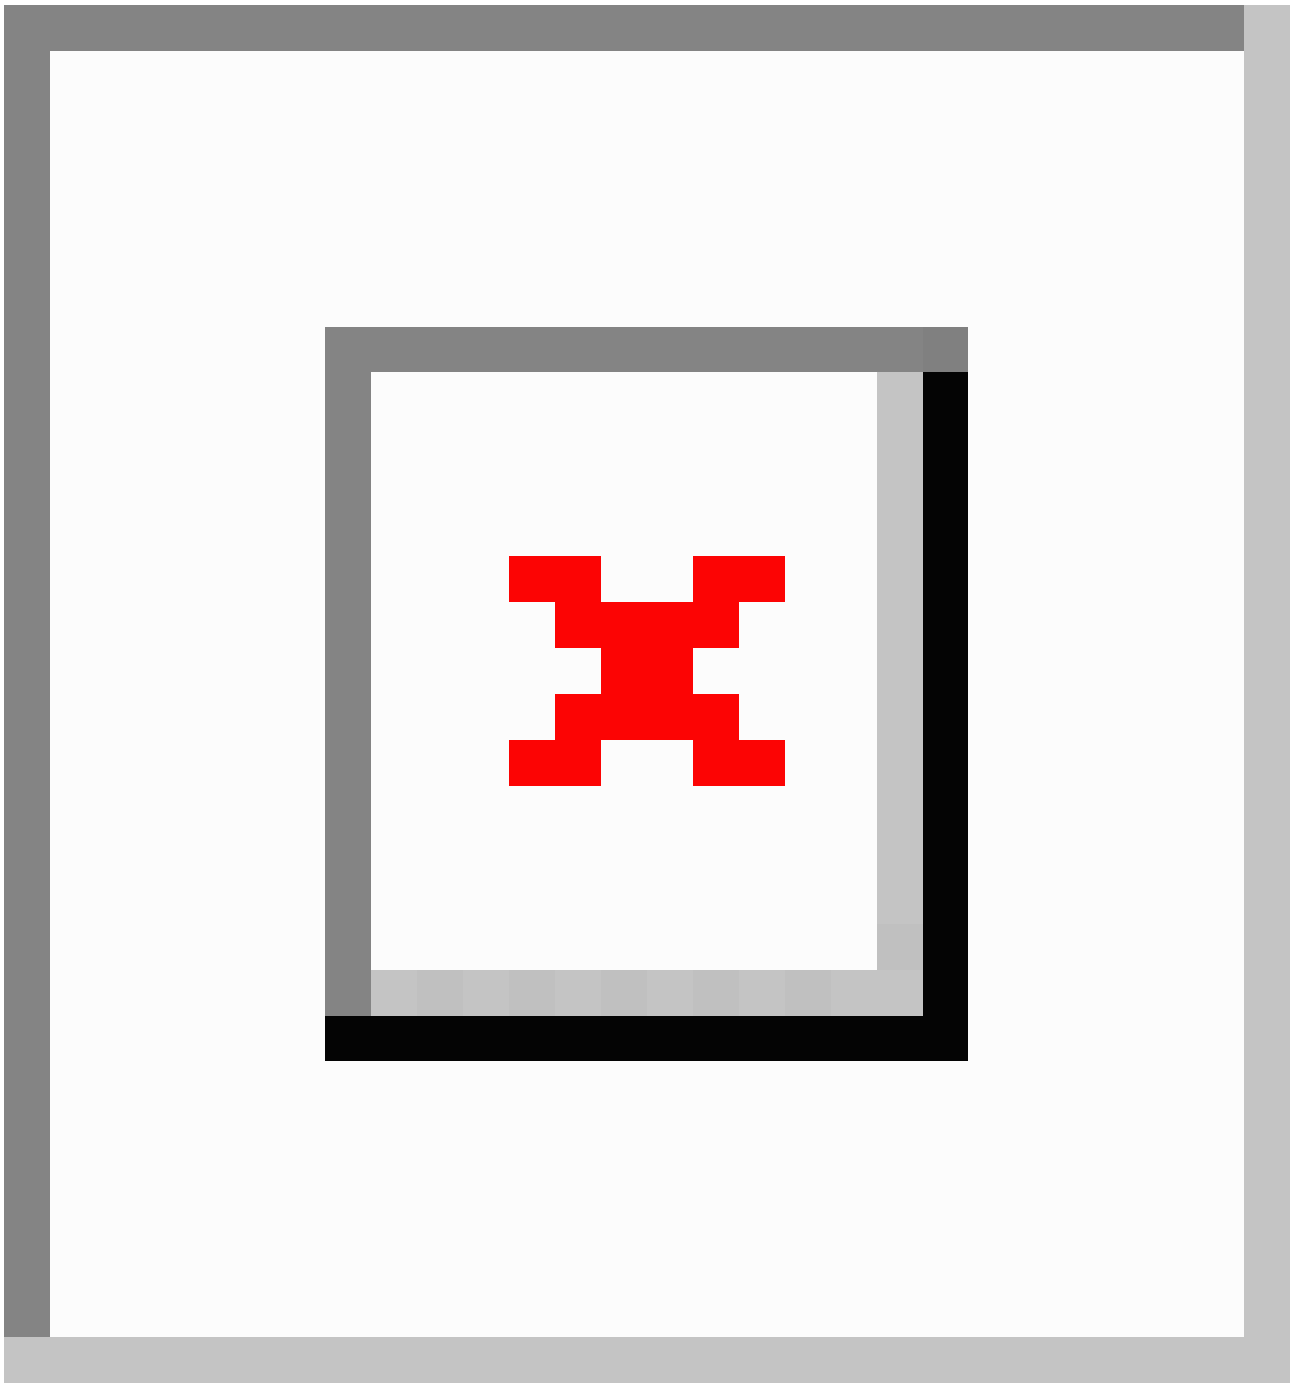
The AUROC for each drug and hospital to evaluate the AKI predictive model, based on respective test sets (internal validation) is shown in Figure 3. A total of 26 trained models achieved a high AUROC value, of 0.92 on average, with each verification data set. In addition, among the averages of the drugs, acyclovir had the highest average AUROC score of 0.94, followed by acetaminophen (0.93), vancomycin (0.92), naproxen (0.90), and celecoxib (0.89). The highest AUROC value (0.97) was observed for the model of SH's celecoxib and acyclovir, SNUH's vancomycin, and KYUH's acyclovir prescription patients.

Multimedia Appendix 2 presents data on the precision, accuracy, F_1-score, and AUPRC of each predictive model. Overall, the average accuracy of the AKI prediction models was 0.88, whereas the average AUPRC and F_1-scores were both 0.78. The acyclovir prescription model achieved the highest accuracy score (0.91), followed by vancomycin (0.90), acetaminophen (0.89), naproxen (0.89), and celecoxib (0.86). Individually, the acyclovir SH model showed the best performance, with an AUPRC of 0.92 and an accuracy of 0.91.

The square brackets indicate the 95% CI. AJUH: Ajou University Hospital; GSH: Gangnam Severance Hospital; KYUH: Konyang University Hospital; NCC: National Cancer Center; SH: Severance Hospital; SNUH: Seoul National University Cancer Hospital.



Temporal Feature Importance of the AKI Prediction Model

To interpret the AKI prediction model, we demonstrated the temporal attention values of each contributing variable in the 4 weeks prior to AKI onset, which were weighted aggregates from the model for each drug and hospital, as shown in Figure 4A. The temporal change pattern of the actual data corresponding to each variable in the 4 weeks prior to AKI onset is shown in Figure 4B. We also confirmed the difference in the distribution of highly important features between the case and control data using a 1-way ANOVA. The attention scores for all variables across all hospitals are detailed in Multimedia Appendix 3

The last week of lymphocytes (attention score at −1 week: 0.41) and the second week of calcium (attention score at −3 weeks: 0.41) showed the highest attention scores, followed by albumin (attention score at −1 week: 0.37; attention score at −4 weeks: 0.37), hemoglobin (attention score at −4 weeks: 0.37), and cholesterol (attention score at −4 weeks: 0.37). In Figure 5, the distribution of data by variable between the 2 groups was confirmed using actual data. There was a difference in data distribution between the case and control groups from the beginning. The values of lymphocytes, albumin, and hemoglobin in the case group decreased over time, while urine pH and prothrombin time in the case group tended to increase over time.

Figure 4. (**A**) Temporal attention score of important features of acute kidney injury (AKI) prediction model and (**B**) distribution of data over time (*P* values: repeated measures ANOVA). The figure shows the change over a 4-week period prior to the AKI event.

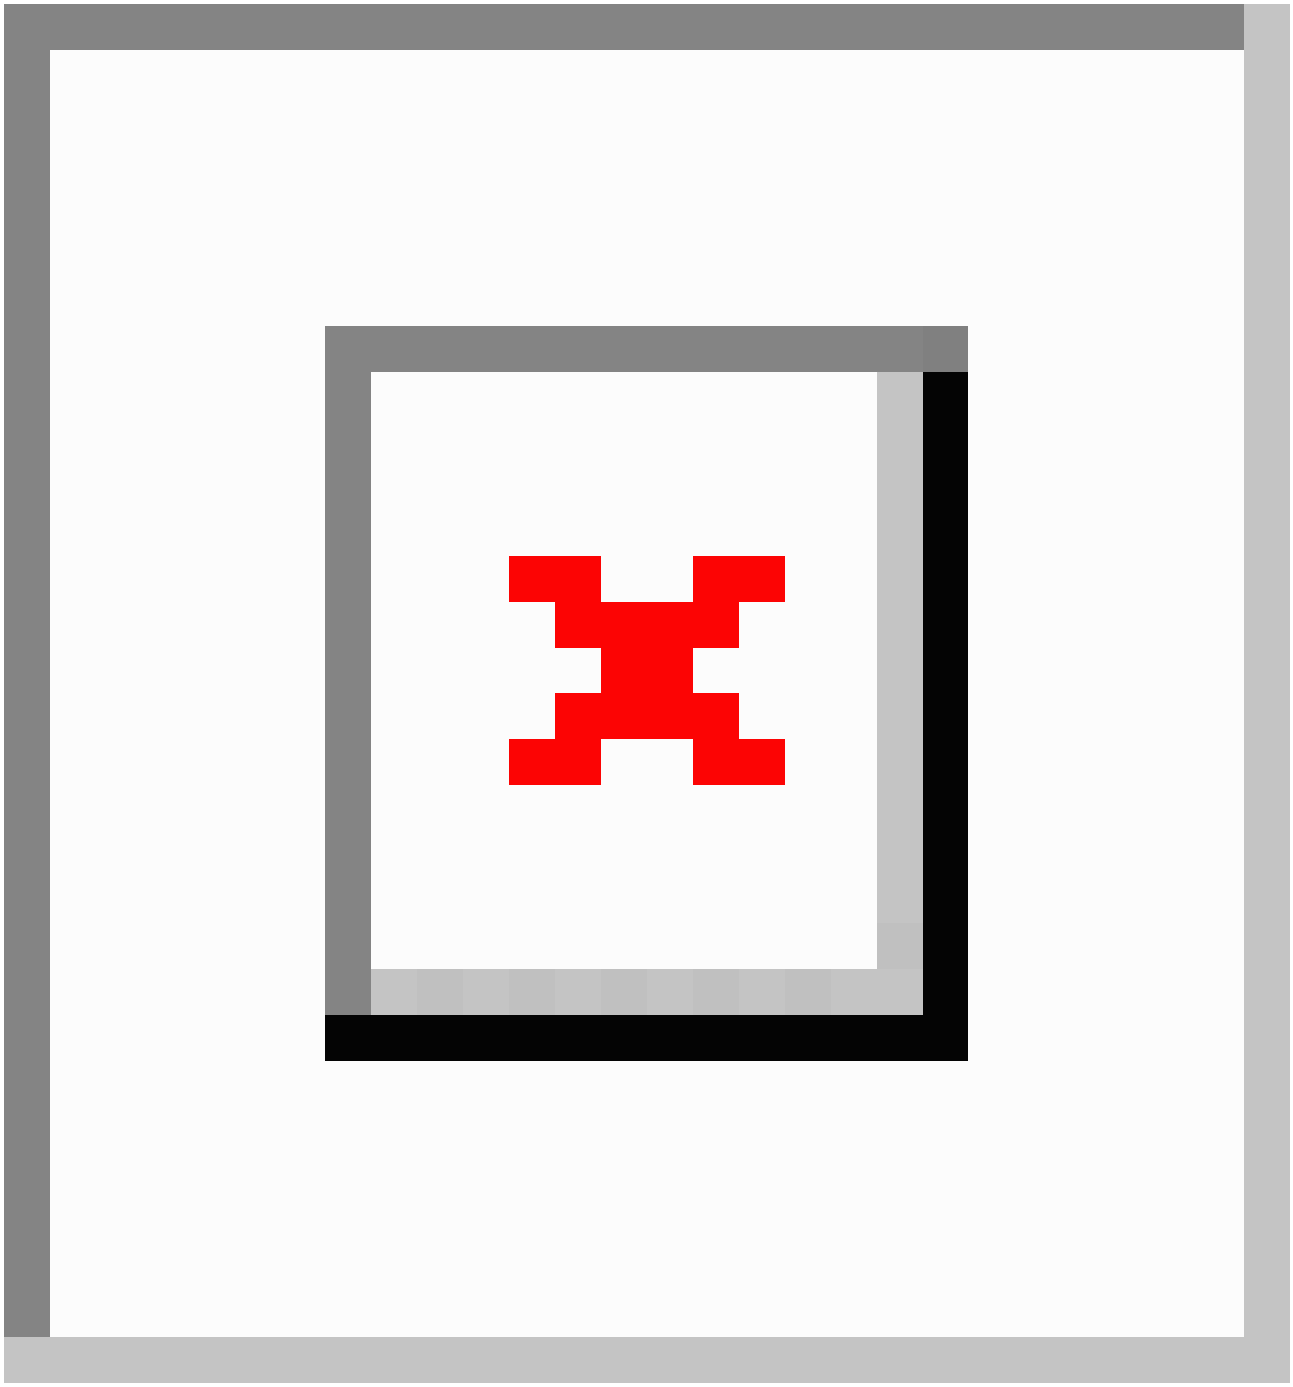


Figure 5. Acute kidney injury (AKI) onset time after drug administration at various medical centers. The red lines shows the median value. AJUH's naproxen and GSH's acyclovir cases were excluded as the number of AKI case groups was less than 20. AJUH: Ajou University Hospital; GSH: Gangnam Severance Hospital; KYUH: Konyang University Hospital; NCC: National Cancer Center; SH: Severance Hospital; SNUH: Seoul National University Cancer Hospital.

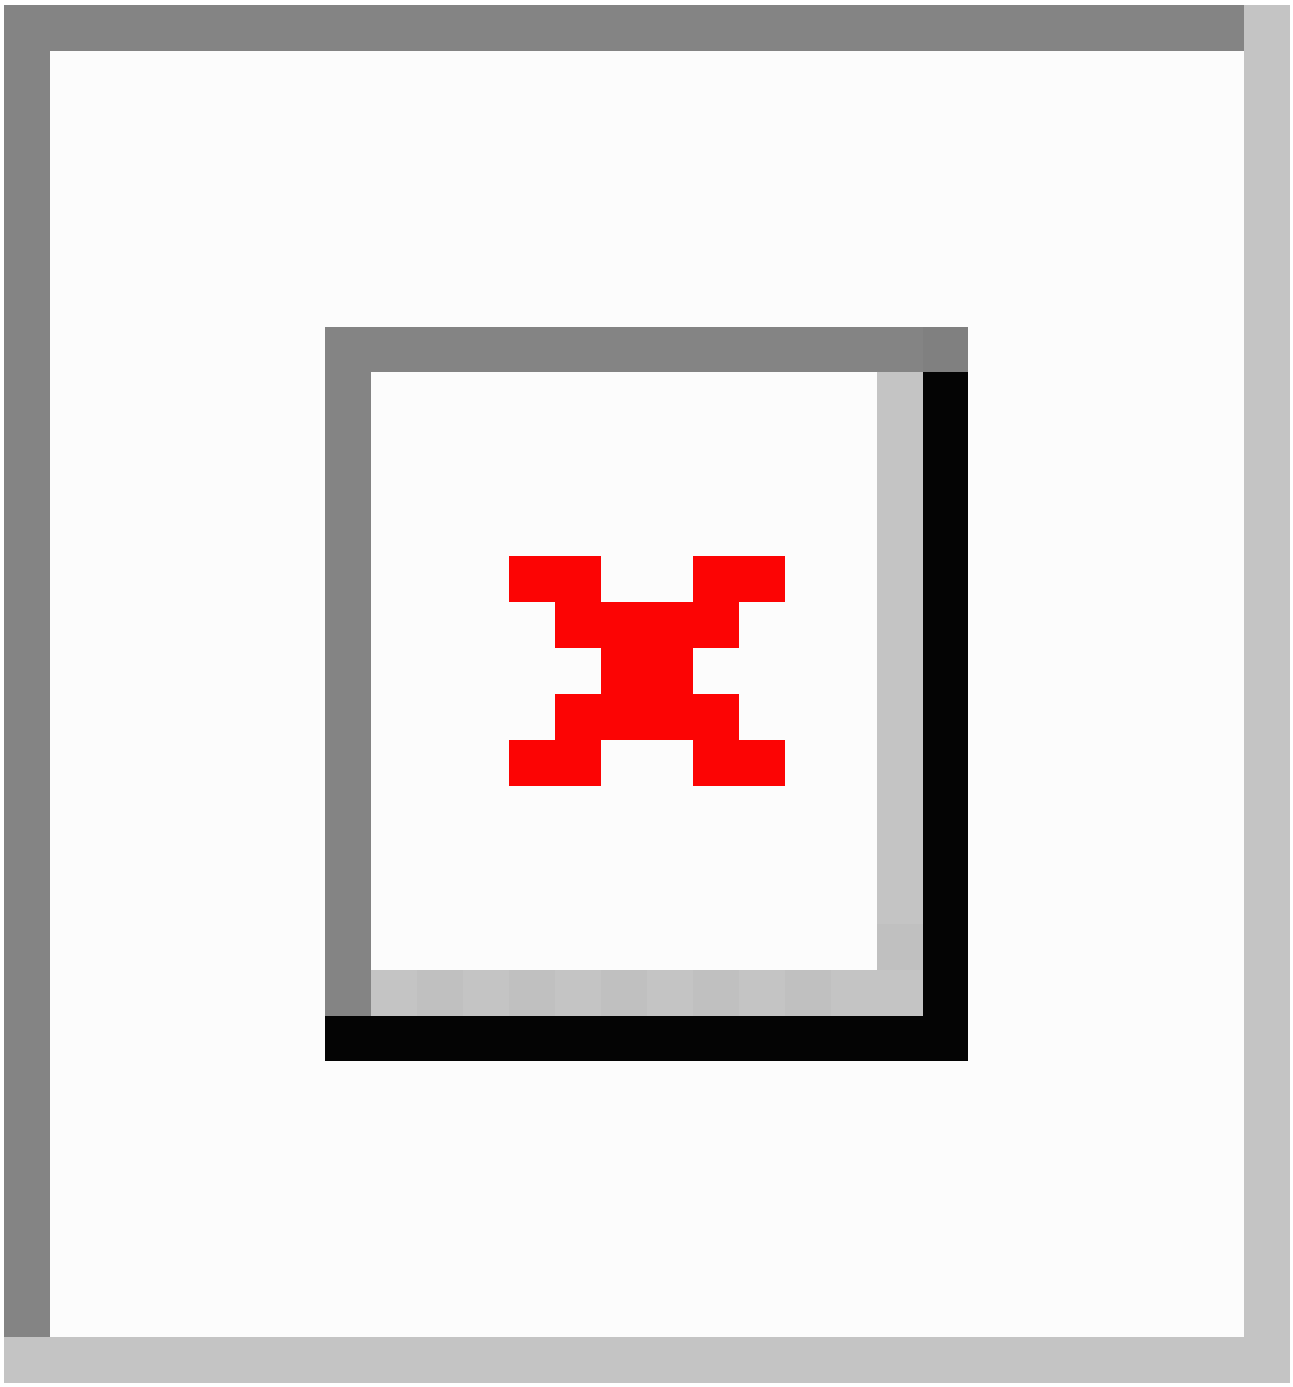

Discussion

Principal Findings

In this study, we developed time series–based IMV-LSTM models to predict AKI in patients taking specific nephrotoxic drugs using CDM-based DRNs in a 6-hospital EHR-based system. The principal findings are as follows: first, this study provides an interpretation of the temporal importance of variables for predicting AKI, and the models also achieved high performance, with an average AUC of 0.92%. Second, our study is a scalable multicenter study using a DRN, which can contribute to understanding drug-induced AKI. To the best of our knowledge, this is the first study to build an AKI prediction model by applying a time series–based IMV-LSTM model to a CDM using EHR data from 6 hospitals.

We established a retrospective cohort of patients who took nephrotoxicity-inducing drugs at 6 hospitals. With respect to demographic characteristics, we observed variations in the overall patient count and prevalence of comorbidities when comparing individuals with AKI and without AKI across different hospitals. Nevertheless, the majority of patients who developed AKI at most hospitals were older than 60 years and

had a high prevalence of comorbidities, including cancer (n=6001, 69.43%), hypertension (n=2404, 27.81%), diabetes (n=1679, 19.43%), and chronic liver disease (n=1231, 14.24%), which is consistent with findings reported in previous studies [32-35].

The pattern of each drug's association with AKI (Figure 5) showed that the median number of days for AKI onset when using nephrotoxic drugs was 17 (IQR 7-33) days. The onset occurred earliest with vancomycin (12, IQR 5-25 days) and latest with acyclovir (23, IQR 10-41 days). In previous studies [36,37], the time to onset of vancomycin-induced AKI showed a similar pattern to our results. We also found differences in the AKI onset between different classes within the same NSAID, and the multicenter AKI cohort showed similarities between hospitals. The finding of similar patterns in the AKI onset in the multicenter cohort supports the reliability of the AKI cohort and increases the explanatory power of AKI prediction models.

AKI is common among inpatients [38,39]. Previous models predicted AKI in the intensive care unit (ICU) and in surgical patients during hospital admission. For example, Zimmerman et al [40] predicted the occurrence of AKI in ICU inpatients (AUC 0.783), and Tseng et al [41] developed a predictive score for the development of AKI after cardiac surgery (AUC 0.839). Hsu et al [42] developed a risk score function for community-acquired AKI for inpatients (AUC 0.818). Koyner et al [10] developed a model to predict AKI in hospitalized patients (AUC 0.90). Despite this progress, few studies have applied time series deep learning to provide a temporal interpretation of drug-induced AKI, and our model stands out because it can predict nephrotoxic drug–induced AKI in a diverse hospital population.

This study achieved improved performance compared to previous AKI studies using recurrent neural networks (RNNs) [21,43-45]. Our model improves performance up to an AUC of 0.97 and an overall average of 0.92, which outperforms previous studies showing AKI prediction with RNN-based methods by Kim et al [43] in hospitalized patients (AUC 0.927), Rank et al [45] in cardiac surgery patients (AUC 0.893), and Xu et al [44] in inpatients (AUC 0.908). These results show promise for our model as a tool to predict AKI and facilitate early intervention and mitigation strategies for patients.

This study also provides additional interpretations regarding the temporal importance of features for AKI prediction. Some studies have reported information on interpretability or provided information about the interpretability of variables at the feature importance level [46]. However, our results show the importance of variables and the temporal importance of variables in the development of AKI. In this study, we highlight the vital role of temporal patterns of various indicators, such as lymphocytes, calcium, albumin, hemoglobin, and cholesterol, in predicting disease states, particularly the onset of AKI. The temporal pattern of lymphocytes increased gradually, peaking 1 week before AKI onset. The use of lymphocyte and neutrophil counts as predictive factors for AKI is consistent with other studies [47,48]. Calcium shows a pattern of peaking 3 weeks before AKI onset, and Prior studies showed an association between impacted calcium metabolism and AKI [49,50]. Albumin shows the highest pattern 1 and 4 weeks before onset, and low serum albumin levels (hypoalbuminemia) are a predictor of AKI [48,51,52]. Hemoglobin shows a pattern with a peak 4 weeks before onset, and previous studies have shown that the risk of AKI increases stepwise with a further decrease in hemoglobin concentration [53]. Temporal variations in variables based on reported laboratory data for the early detection of AKI emphasize the importance of monitoring and early intervention in populations.

In addition, this retrospective study can be followed by a subsequent study to validate the practicality of the AKI prediction model in clinical practice by applying it to a prediction system in a hospital EHR.

Limitations

This study has several limitations. First, because we used the CDM, it does not reflect the full range of clinical data. For example, we could not include admission records, which would have revealed a patient's condition. However, the use of CDM data allowed for a multicenter study that could be easily extended to other institutions that have converted to the CDM. Second, this was a retrospective study and could not address the underlying causes of AKI. Therefore, prospective studies are needed for validation with actual clinical data. Third, as with all retrospective studies, there may be unintentional patient selection bias and unaccounted-for confounders. However, to compensate for these limitations, we tried to equalize the distribution of patient characteristics through PSM. We also used a limited follow-up period to minimize the impact of these factors.

Conclusions

This study demonstrates the high performance of the IMV-LSTM method for AKI prediction using hospital EHR-based time series data. Our model can provide real-time assessment of AKI occurrence and individualized risk factors for AKI using time series data. We also demonstrated the robustness of our model through multicenter validation using a CDM through a DRN of 6 hospitals in South Korea, which also proves that scalability to other institutions that are converted to the CDM is possible. This may provide an objective quantitative tool for identifying patients at risk of developing AKI.

Acknowledgments

This study was supported by a grant from the Korea Institute of Drug Safety and Risk Management in 2021. This work was supported by the Bio-Industrial Technology Development Program (20014841) funded by the Ministry of Trade, Industry & Energy (Korea). We would like to thank the Medical Informatics Collaborative Unit members of Yonsei University College of Medicine for their assistance in data analysis.

Abstract

Background: Early identification of impending in-hospital cardiac arrest (IHCA) improves clinical outcomes but remains elusive for practicing clinicians.

Objective: We aimed to develop a multimodal machine learning algorithm based on ensemble techniques to predict the occurrence of IHCA.

Methods: Our model was developed by the Multiparameter Intelligent Monitoring of Intensive Care (MIMIC)–IV database and validated in the Electronic Intensive Care Unit Collaborative Research Database (eICU-CRD). Baseline features consisting of patient demographics, presenting illness, and comorbidities were collected to train a random forest model. Next, vital signs were extracted to train a long short-term memory model. A support vector machine algorithm then stacked the results to form the final prediction model.

Results: Of 23,909 patients in the MIMIC-IV database and 10,049 patients in the eICU-CRD database, 452 and 85 patients, respectively, had IHCA. At 13 hours in advance of an IHCA event, our algorithm had already demonstrated an area under the receiver operating characteristic curve of 0.85 (95% CI 0.815 - 0.885) in the MIMIC-IV database. External validation with the eICU-CRD and National Taiwan University Hospital databases also presented satisfactory results, showing area under the receiver operating characteristic curve values of 0.81 (95% CI 0.763-0.851) and 0.945 (95% CI 0.934-0.956), respectively.

Conclusions: Using only vital signs and information available in the electronic medical record, our model demonstrates it is possible to detect a trajectory of clinical deterioration up to 13 hours in advance. This predictive tool, which has undergone external validation, could forewarn and help clinicians identify patients in need of assessment to improve their overall prognosis.

KEYWORDS

cardiac arrest; machine learning; intensive care; mortality; medical emergency team; early warning scores

Introduction

The prognosis of in-hospital cardiac arrest (IHCA) is poor as it represents the culmination of heterogeneous multi-organ dysfunction, with few treatments [1]. IHCA has an incidence of 9 to 10 per 1000 admissions and a mortality rate of 80% - 100% [2]. Therefore, clinical guidelines emphasize the urgent need for early identification of patients at risk for IHCA [3]. Early warning scores were developed to facilitate early identification of impending clinical deterioration and trigger

rapid interventions [4]. However, many traditional early warning scores are limited by considerable variation in discrimination in different populations and are often not sufficiently sensitive [5].

Recent research indicates that the implementation of the electronic Cardiac Arrest Risk Triage (eCART) score has significantly decreased the incidence of IHCA at UChicago Medicine [6]. However, the inclusion of laboratory data in eCART substantially diminishes the practicality and immediacy of this scoring system. Moreover, other studies have reported that calculating the Modified Early Warning Score (MEWS) 0.5 hours before a cardiac arrest can significantly increase the survival-to-discharge rate in patients experiencing IHCA [7]. Nonetheless, a 0.5-hour lead time is often insufficient for a prompt reaction during a patient's rapid deterioration. Given the continuously generated real-time information, such as vital signs, a time-varying model could be constructed for more timely and early identification of IHCA.

The aim of our study was to develop a recurrent neural network–based model using the electronic health records (EHRs) of a single tertiary medical center to predict incident IHCA. We hypothesized that variations in physiological parameters, evaluated in the context of known comorbidities, could help to predict incident cardiac arrest. We also aimed to validate the model in an independent cohort and compare it to a previous scoring system.

Methods

Ethics Approval

Given the retrospective study design, the Research Ethics Committee of the National Taiwan University Hospital (NTUH) approved this study (project approval 202206108RINB) and waived the requirement for obtaining informed consent.

Data Source

Predictive models were developed using the Multiparameter Intelligent Monitoring of Intensive Care (MIMIC)–IV v0.4 database and were externally validated using the Electronic Intensive Care Unit Collaborative Research Database (eICU-CRD) v2.0 [8,9]. Pre-existing institutional review board approval was waived given the deidentified nature of this public data set (Massachusetts Institute of Technology: 0403000206; Beth Israel Deaconess Medical Center: 2001-P-001699/14) [8]. One author who completed the Collaborative Institutional Training Initiative examination (certificate 57186438 for author HJJ) obtained access to the database and performed the data extraction. To assess the performance of our model in practical applications, we collected clinical data from the electronic medical records of the NTUH, spanning from 2008 to 2018. To decrease patient heterogeneity and feature variability, we applied the same inclusion criteria and data processing workflow to the 3 databases. We extracted data on patients older than 20 years who were hospitalized in intensive care units (ICUs) for at least 24 hours. Patients were excluded if they were encoded with a deceased status but without an IHCA labeling defined as below. We employed 5-fold cross-validation in our training cohort, randomly dividing the data set into 5 equally sized subsets. Four of these folds (80% of the MIMIC-IV cohort) were used for training, while the remaining fold (20% of the MIMIC-IV cohort) was reserved for internal validation. Performance metrics were recorded for each iteration, resulting in five distinct performance scores. These scores were then averaged to derive a singular more robust performance estimate for the model. Finally, external validation was performed on the entire eICU-CRD cohort.

Disease Outcome Ascertainment

In the MIMIC-IV cohort, patients were marked with IHCA if they were either labeled with a time-stamped database-specific procedure code (22,5466 cardiac arrest) or diagnosed with the *International Classification of Diseases, Ninth Revision* (*ICD-9*), Procedure Coding System (PCS) code 9960 (cardiopulmonary resuscitation, not otherwise specified). Although the MIMIC-IV database contained both *ICD-9* and *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*) codes, we did not convert *ICD-9*-PCS code 9960 to the *ICD-10*-PCS code, as the most approximately equivalent indicated code 5A1.2012 (performance of cardiac output, single, manual) represented variable definitions. For the eICU-CRD cohort, patients were classified with IHCA if they either presented with a time-stamped database-specific procedure note indicating cardiopulmonary resuscitation or were administered epinephrine, either as a bolus of 1 mg/10 ml or an infusion rate of 30 mg/250 ml at 100 ml/hr, with an associated administration time. In both the MIMIC-IV and eICU-CRD cohorts, the control group was defined as patients who were not labeled as having experienced an IHCA or being deceased, and the reference time was set as the ICU discharge time. For IHCA patients with multiple labelings, we only selected the time of the first label as the reference time. The data collection method in the NTUH database involves identifying patients with specific *ICD* codes (*ICD-9* 427.5; *ICD-10* T46.2, 145.8, 146.9). Patients who have been diagnosed with the aforementioned codes followed by the initiation of cardiopulmonary resuscitation or bolus epinephrine injection will be classified as patients who experienced IHCA.

Data Curation and Features Extraction

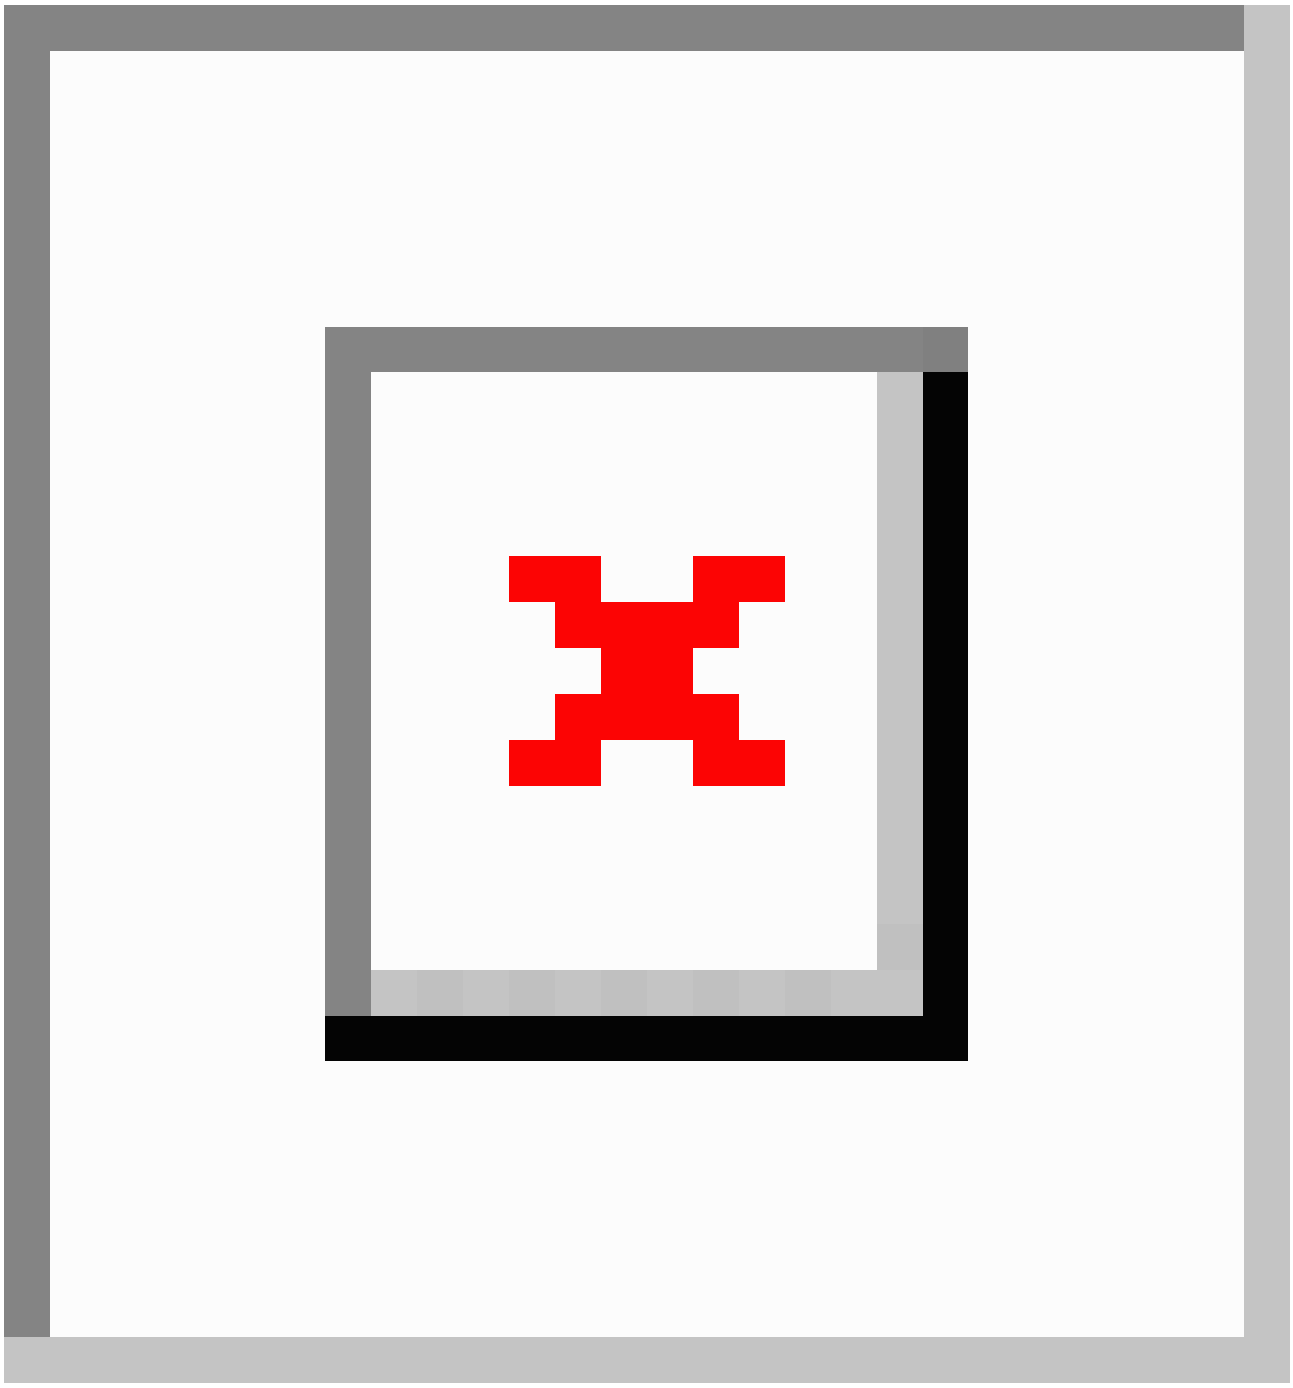
Two types of features were extracted: time-independent baseline features and time-varying physiologic readings from bedside monitors. Baseline features, which are variables registered at the time of admission, consisted of three types: (1) demographic information such as gender, age, ethnicity, type of ICU admission, and BMI; (2) chronic comorbidities, as identified by combined comorbidity score and Elixhauser Comorbidity Index [10,11]; (3) presenting illness, as identified by *ICD* codes for acute cardiac disease, respiratory insufficiency, sepsis, and potential reversible causes of cardiac arrest, popularly known as the *H*'s (hyperkalemia, hypokalemia, hypothermia, hypoxemia, hypovolemia, hydrogen ion, eg, acidosis) and *T*'s (spontaneous tension pneumothorax, thrombosis, cardiac tamponade) by resuscitation guidelines [12]. Physiologic readings, which consisted of 6 vital signs: heart rate (HR), respiratory rate, O_2 saturation (SpO_2), systolic blood pressure (sBP), diastolic blood pressure, and mean arterial pressure, were extracted on an hourly basis. For all patients, vital signs in the 24 hours prior to the reference time were recorded. To balance

model utility with adequate accuracy, we only investigated the risk of cardiac arrest starting from 13 hours prior to the event. To overcome the time series' irregularity, specific rules were applied to combine multiple vital signs in the same hour (Multimedia Appendix 1). The remaining missing values in vital signs were filled with the last observation carried forward method. To eliminate the misguidance of our imbalanced data set, we tested the two following remedies: synthetic minority oversampling technique (SMOTE) and near miss algorithm [13,14]. We employed SMOTE in the following training with a nearest neighbor interpolation of 1 as it yielded a better performance compared to the near miss algorithm (Figure S1 in Multimedia Appendix 1). After applying SMOTE, the numbers of IHCA patients and control patients were equal, signifying data balance.

Model Development

Our predictive model was encoded in three layers (Figure 1). First, random forest (RF) was responsible for classifying the baseline features [15]. For hyperparameter optimization, the number of estimators was set to 5, the maximum depth was set to 20, and Gini impurity was used to determine the split. Nodes are expanded until all leaves contain fewer than 2 samples [16]. Second, recurrent neural network with the long short-term memory (LSTM) architecture stored the vital signs trajectories in an hourly pattern [17]. There were 3 hidden layers and 8 cells each, with a tangent and a sigmoid activation function. The learning rate was set to 0.001, and a dropout rate of 0.4 was applied for regularization [18]. The Adam algorithm was adapted for optimizing network weights [19]. Last, the support vector machine (SVM) with a radial basis function kernel integrates the RF and LSTM models to generate the final prediction. The SVM predicts the identical target outcome by learning the relationship between the predictions from two base models (RF and LSTM) and the target outcomes in the training set [20]. All the models were implemented in Python 3.8.3 (Python Software Foundation) with TensorFlow 2.1.0, pandas 1.1.2, scikit-learn 0.24.2, and NumPy 1.19.1 libraries.

Figure 1. Illustration of the modeling framework. Each patient's data from the electronic health record were used as input for our model. Four preprocessing steps are carried out on the vital signs to obtain fixed-interval data. All features go through SMOTE to overcome data imbalance and are split into training and testing groups. Baseline features are inputted to random forest, and vital signs are inputted into LSTM for prediction. Support vector machine then integrates both models. AUROC: area under the receiver operating characteristic curve; LSTM: long short-term memory; SHAP: Shapley Additive Explanations.



Evaluation Strategy

To identify the perfect algorithm, the following machine learning (ML) techniques were evaluated in terms of prediction performance. First, based on the baseline data's time independency and binary structure, logistic regression (LR), *k*-nearest neighbor (KNN), extreme gradient boosting (XGBoost) tree, and SVM were compared with RF for model fitness. In the LR model, we applied an L2 penalty with a stopping tolerance set at 1e-4, and the model underwent a maximum of 100 iterations. For the KNN algorithm, we set the parameter K to 2, utilizing Euclidean distance as the chosen metric. In the XGBoost model, the number of estimators was configured to 5 with a maximum depth of 5 and a learning rate of 0.1. Hyperparameter optimization was carried out through a grid search. In the SVM, we used a radial basis function with an L2 penalty, setting the regularization parameter to 1. The SVM model was executed with a stopping tolerance of 1e-3, and no limit was imposed on the maximum number of iterations. For the time-dependent vital signs trajectories, the incorporation of memory gates in LSTM indicates its superiority in handling long sequence data. Thus, no other model comparison was made.

To compare different stacking techniques, LR was also implemented for comparison with SVM. Last, as we aim to use neural networks to accommodate our feature's complexity, we connected this 3-layer model by engaging a deep neural network in baseline data prediction and final stacking. The hyperparameters of the deep neural network were set at an epoch of 30, batch size of 24, and the Adam algorithm as optimizer. Model performance was assessed based on discrimination and calibration using the internal validation cohort, as quantified by the area under the receiver operating characteristic curve (AUROC) with mean values and 95% CIs [21]. Sensitivity and specificity metrics are presented by two binary classifications, including a predefined threshold of 0.5 and an optimal cutoff determined by the Youden index [22]. We used the Brier score to assess accuracy and visualized calibration curves across deciles based on observed and expected cardiac arrest numbers [23].

Model Interpretation

The importance of baseline features in the RF model was ranked based on "gain," the cumulative improvement in accuracy of the nodes attributed to a specific feature. To focus more on the local impact of each vital sign at the patient level, we employed the Shapley Additive Explanations (SHAP) method to explain how our LSTM model makes predictions during a specific timepoint [24].

Comparison With Previous Prediction Score

The Cardiac Arrest Risk Triage (CART), a commonly used cardiac arrest prediction model, was calculated to put the prediction results in perspective with prior studies [25]. A previously described "early warning score efficiency curve" was created to compare CART and our prediction model [26]. By plotting the percentage of detected events within 13 hours followed by the observations above the predefined threshold, a 0.5 probability in our model, and a score of 20 in the CART model, we could demonstrate the changes of cumulative incidence as the event time approached. Due to the large number of missing data for temperature and neurological status in our development cohort, we were unable to compare our risk prediction tool against the MEWS or Acute Physiology and Chronic Health Evaluation.

Results

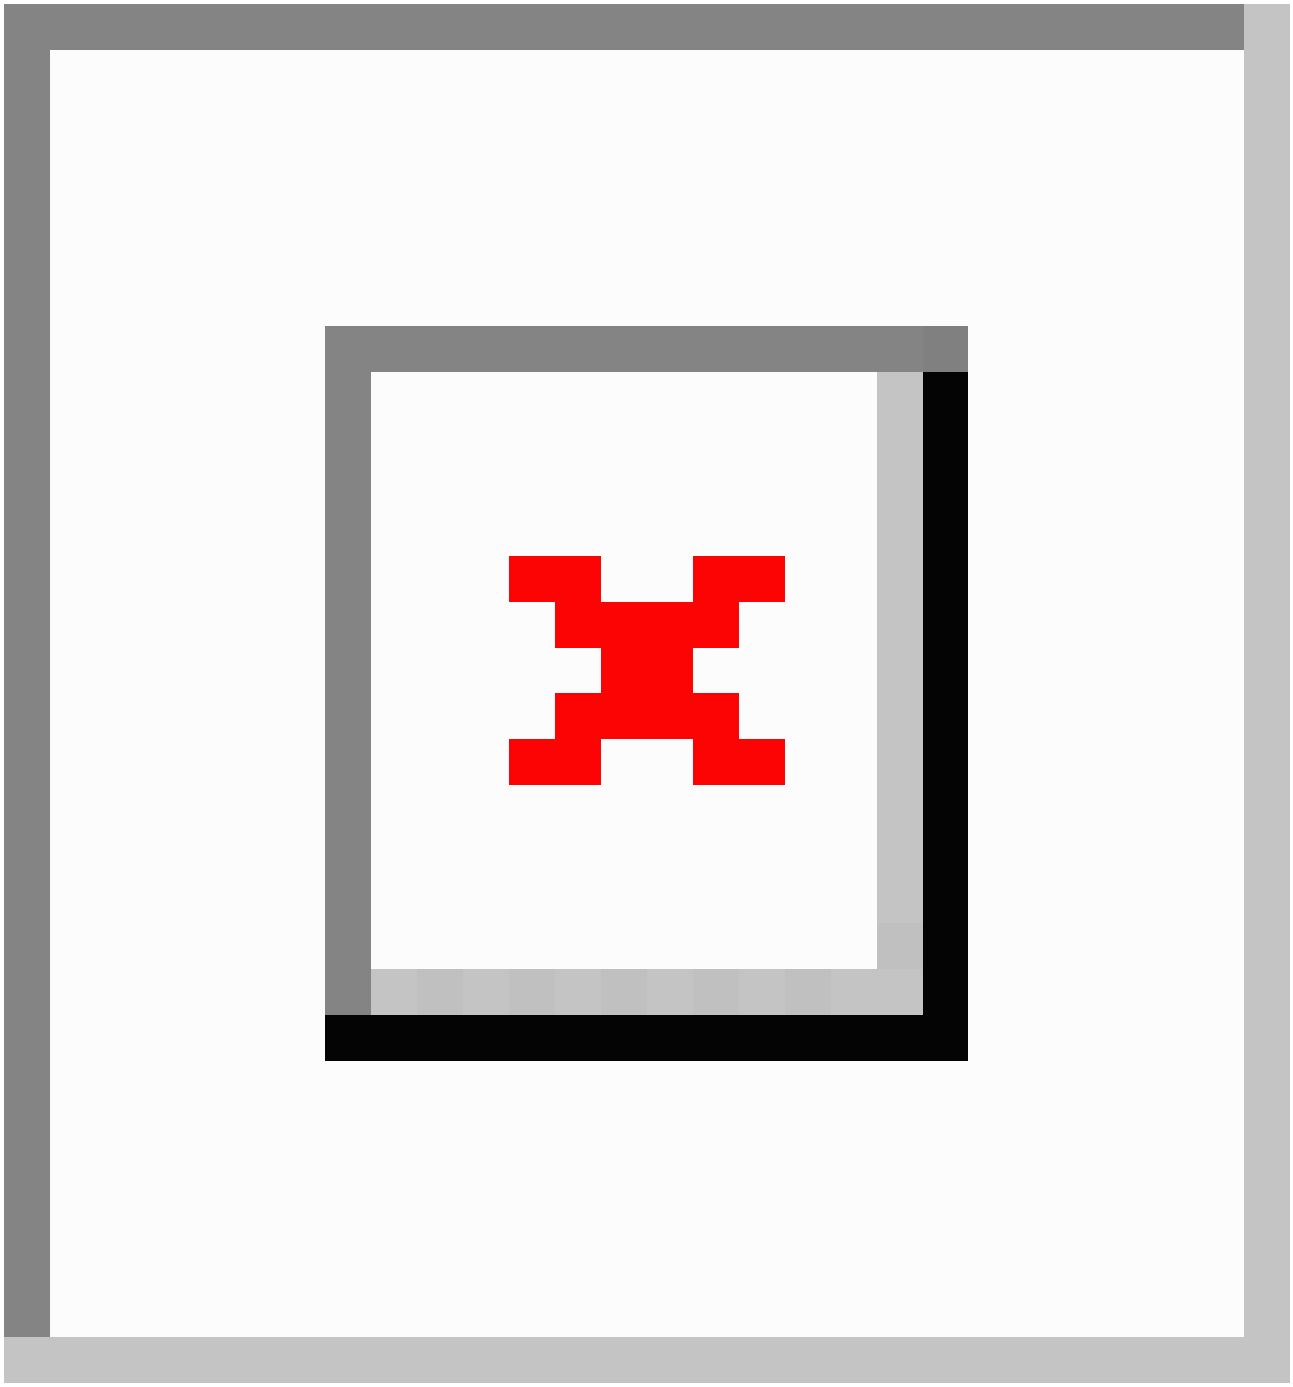
Patient Characteristics

A total of 34,633 patients in the MIMIC-IV database and 79,643 patients in the eICU-CRD database were included in our analysis. After processing the vital signs data, a total of 452 IHCA patients and 23,457 control patients from MIMIC-IV were used for model development, whereas 85 IHCA patients and 9964 control patients from eICU-CRD were used for external validation. Table S1 in Multimedia Appendix 1 shows the baseline characteristics of the IHCA group and the control group for the two cohorts. IHCA patients were significantly older (P<.001) and scored higher on combined comorbidity scores and the Elixhauser Comorbidity Index. In terms of presenting illness, myocardial infarction, pneumonia, respiratory failure, and the 5 *H*'s and 5 *T*'s were more prevalent in IHCA patients than among control patients.

Prediction From Time-Independent Data

Patient demographics, comorbidities, and presenting illness were first classified by RF. Figure 2 demonstrates the discrimination of the RF model (AUROC 0.80, 95% CI 0.779 - 0.844; sensitivity 0.71; specificity 0.78; F_1-score 0.79. The top five important features listed by RF include the presence of respiratory failure or acidosis, comorbid uncomplicated hypertension, comorbid fluid and electrolyte disorder, and initial ICU being the cardiac ICU.

Figure 2. Prediction from baseline features. (A) AUROC for evaluating the discriminatory ability of random forest on baseline features. (B) Feature importance derived from the random forest model. AUROC: area under the receiver operating characteristic curve.



Modeling of Time-Dependent Data

The trajectories of six vital signs were modeled with respect to time. Figure S2 A in Multimedia Appendix 1 illustrates that in the MIMIC-IV cohort, the control group exhibited a constant value of all six vital signs throughout the 24-hour collecting period. However, the vital signs of the IHCA patients were characterized by progressive deterioration in the last several hours. Of note, throughout the 24-hour monitoring period, patients who developed cardiac arrest exhibited, on average, a 12-mmHg lower sBP, 1.5% lower SpO_2, and a 9-bpm higher resting HR compared to the control group. However, the exact timing of the start of deterioration could not be clearly marked on the plot. A similar vital signs trajectory was seen in the eICU-CRD cohort (Figure S2 B in Multimedia Appendix 1).

Prediction From Time-Dependent Data

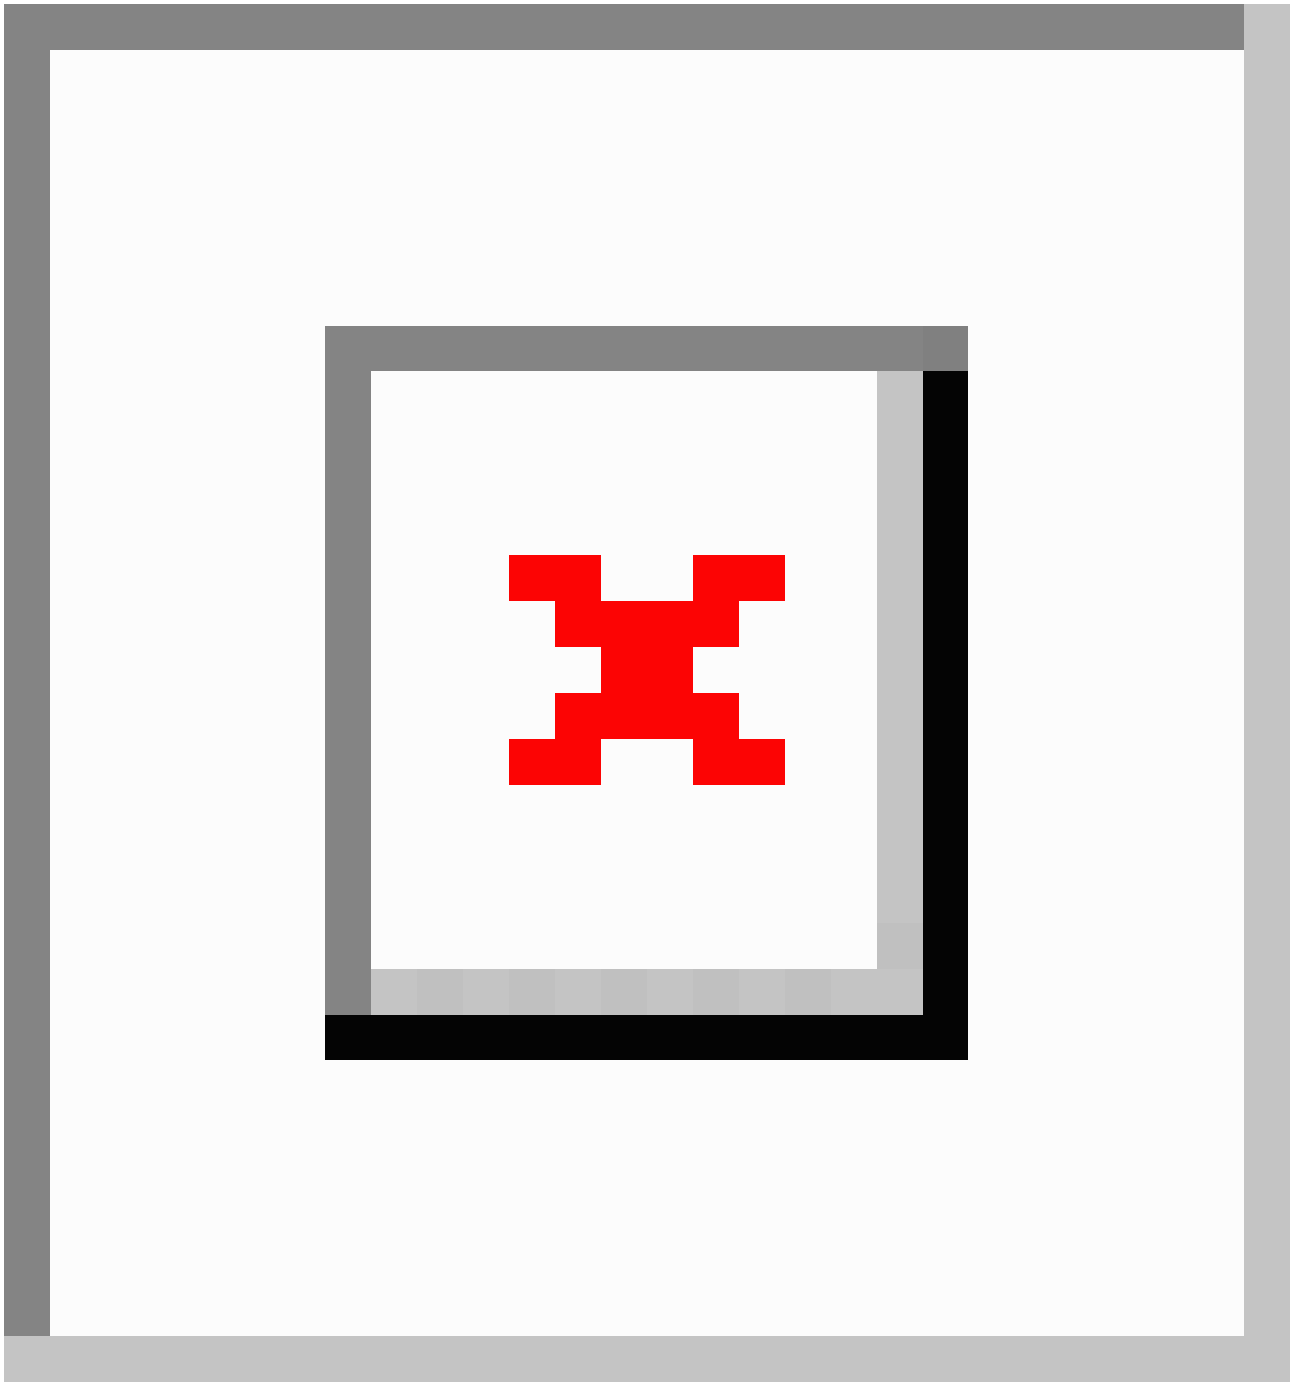
The hourly AUROC values for predicting cardiac arrest are presented in Figure S3 in Multimedia Appendix 1, which shows the results after SMOTE and cross-validation. A steady rise in AUROC was observed in the hours leading up to cardiac arrest with a sharp increase in the preceding 3 hours.

Performance of the SVM-Based Stacking Model

In the final step of model construction, we stacked the LSTM model with the RF model and combined both predictions from baseline features and vital signs. AUROCs of the stacked model

exhibited consistently better predictions compared with the baseline and vital signs–only model, with the highest AUROC of 0.91 (95% CI 0.874 - 0.935), sensitivity of 0.80, specificity of 0.86, and F_1-score of 0.85 1 hour prior to the event. Further evaluation of the stacked model presented an increase in sensitivity, specificity, negative predictive value, and F_1-score by the reduction of the time interval (Figure 3). However, the calibration plot showed a risk of overestimation and a steadily low Brier score throughout the 13 hours of prediction time (Figure S4 in Multimedia Appendix 1). Additionally, in Figure S5 in Multimedia Appendix 1, we compared the model performance using different cutoffs. We found that the optimal cutoff defined by the Youden index (at 13 hours: 0.29; at 12 hours: 0.25; at 11 hours: 0.38; at 10 hours: 0.25; at 9 hours: 0.28; at 8 hours: 0.26; at 7 hours: 0.28; at 6 hours: 0.30; at 5 hours: 0.26; at 4 hours: 0.38; at 3 hours: 0.30; at 2 hours: 0.34; at 1 hour: 0.35) presented with a better sensitivity compared with the predefined 0.5 cutoff; the largest difference was 14% at 12 hours prior to the event.

Figure 3. Performance of the stacked model in the Multiparameter Intelligent Monitoring of Intensive Care (MIMIC)–IV database. AUROCs (95% CIs) of the long short-term memory (LSTM) model with vital signs as input (orange plot), RF model with baseline features as input (gray plot), and stacked model after integration of RF and LSTM (blue plot) are shown. The three models' exact AUROCs, sensitivity, specificity, NPV, and F_1-score of the stacked model are listed in the table. AUROC: area under the receiver operating characteristic curve; NPV: negative predictive value; RF: random forest.



External Validation

We performed external validation of the stacked model in the eICU-CRD database. The results showed the best performance at 1 hour prior to IHCA with an AUROC of 0.89 (95% CI 0.849 - 0.920), sensitivity of 0.79, specificity of 0.83, and an F_1-score of 0.81. These findings align closely with the AUROC obtained from the MIMIC-IV data set (Figure 4). To further validate our model in an actual clinical scenario, we identified 1935 IHCA patients and 3692 control patients from the ICU of the NTUH. Additionally, our model demonstrated high prediction sensitivity and an AUROC of 0.945 when predicting IHCA 1 hour prior to its occurrence (Figure 5).

Figure 4. Performance of the stacked model in the Electronic Intensive Care Unit Collaborative Research Database (eICU-CRD). External validation of the stacked model is performed on the eICU-CRD. AUROC (95% CI) is plotted in a blue line; sensitivity is plotted in a gray line. AUROC: area under the receiver operating characteristic curve.

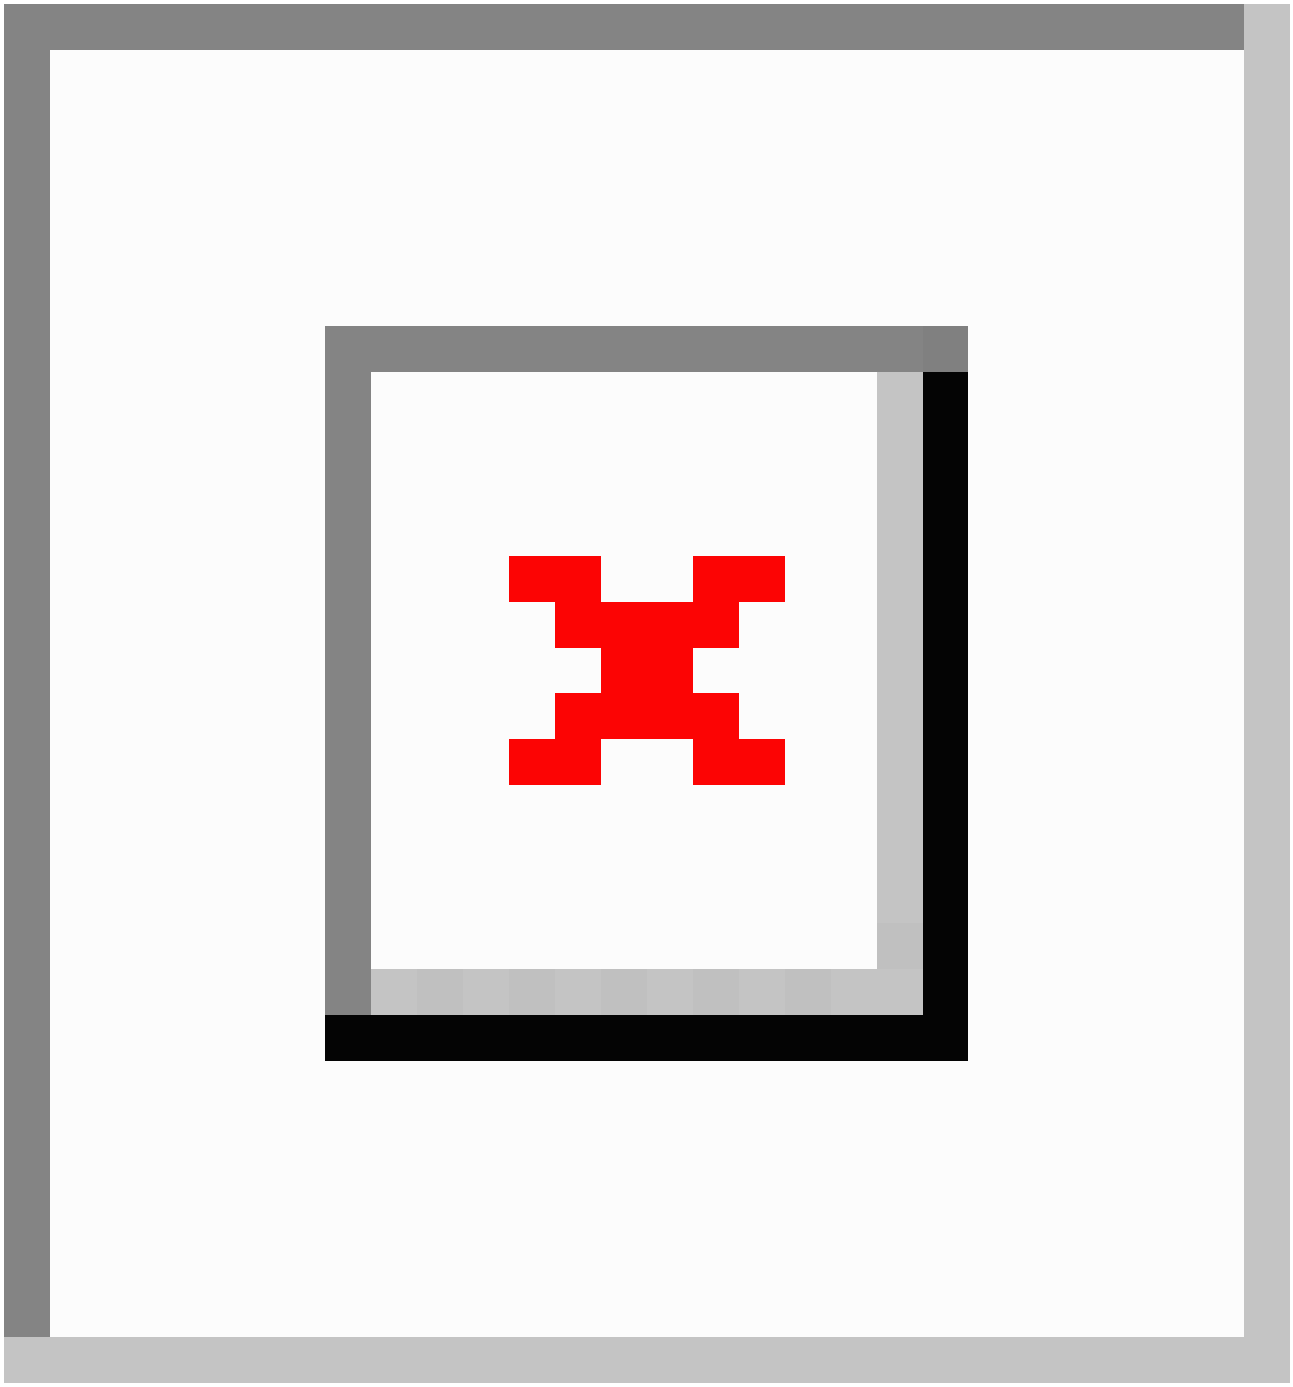


Figure 5. Performance of the stacked model in the clinical scenario. External validation of the stacked model is performed using data from 1935 in-hospital cardiac arrest patients and 3692 control patients collected from the National Taiwan University Hospital. AUROC is plotted in a blue line; sensitivity is plotted in a gray line. AUROC: area under the receiver operating characteristic curve.

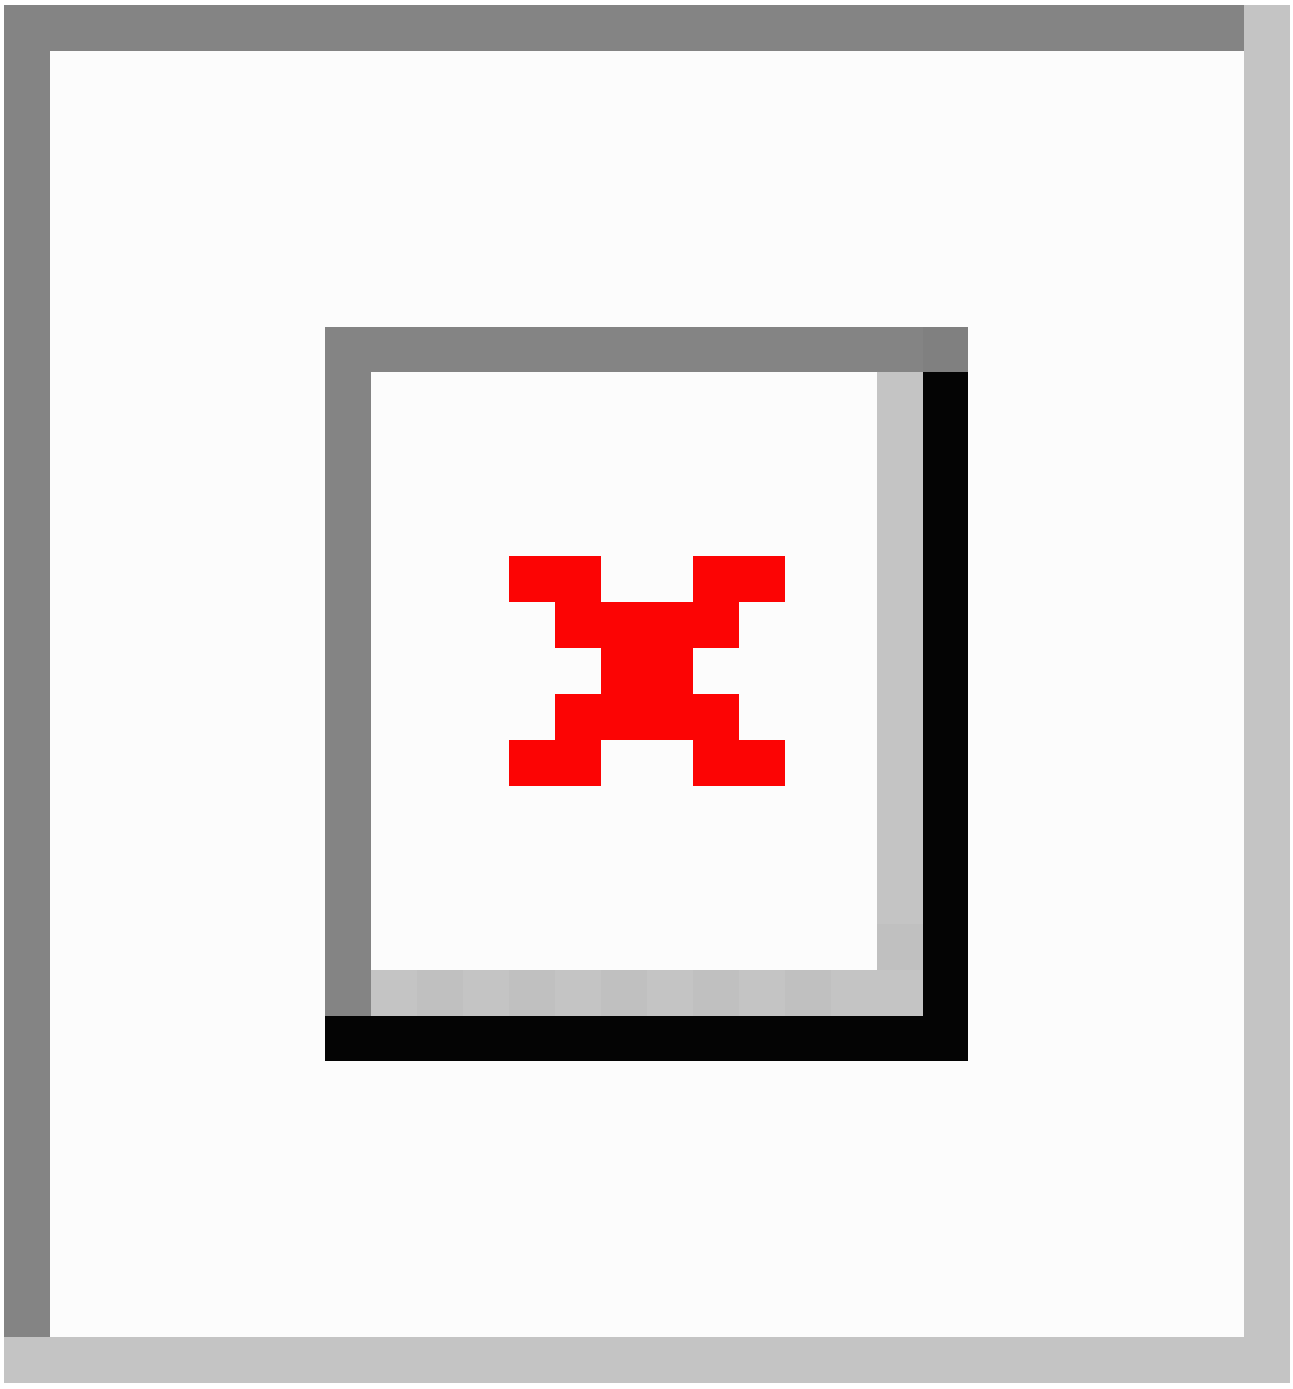

Local Interpretation of the LSTM Model

We adopted the SHAP method to enable model explanation from an individual patient's perspective. In each box, SHAP values for specific vital signs are assigned, with positive SHAP values in red indicating a risk factor and negative SHAP values in blue indicating a protective factor. Figure S6 A in Multimedia Appendix 1 represents a patient from the MIMIC-IV database experiencing IHCA at 0 hours. As IHCA approaches, an increase in sBP from its average contributes to an elevated risk, with the most significant effect occurring 6 hours prior to IHCA. However, at 1 hour before IHCA, the most significant risk becomes a decrease in sBP from its average. Figure S6 B in Multimedia Appendix 1 illustrates another IHCA patient from the eICU-CRD database. In contrast to Figure S6 A in Multimedia Appendix 1, the most prominent feature at 1 hour prior to IHCA is a decrease in HR and SpO_2 from its baseline value. These figures showcase diverse presentations leading to IHCA in various patients, providing a valuable guideline for medical staff to identify the specific organ failure responsible for IHCA. The significance lies in enabling a swift response, incorporating timely interventions such as intubation for saturation drop and the administration of inotropic agents for decreased sBP. This approach ensures that medical staff will

not delay necessary treatments while determining the cause of IHCA.

Performance Compared With Different ML and Deep Learning Algorithms

Conventional statistics and supervised ML algorithms were compared to predict IHCA using only baseline features. RF demonstrated superior performance in terms of AUROC compared with XGBoost, LR, KNN, and SVM (Figure S7 in Multimedia Appendix 1). SVM also presented preferable results during the stacking operation compared with LR throughout the 13-hour prediction period. AUROCs at 1 hour prior to the incidence of IHCA were 0.91 versus 0.80 (Figure S8 in Multimedia Appendix 1). Finally, using a neural network to connect baseline, vital signs, and stacking predictions did not reveal an improving outcome (Figure S9 in Multimedia Appendix 1). After comparing several algorithms and combinations, RF, LSTM, and SVM predictions still yielded the most satisfactory results.

Detection Efficacy Compared to Previous Prediction Score

We compared the performance of our proposed model to that of the CART score. Overall, our model demonstrated better AUROC throughout the prediction period (Figure S10 in Multimedia Appendix 1). As illustrated in Figure S11 in Multimedia Appendix 1, it is evident that at 12 hours prior to cardiac arrest, our model was able to detect over 70% of patients at risk for IHCA, compared to the CART score that did not surpass a 65% detection rate even 1 hour prior to IHCA.

Discussion

Principal Findings

In this retrospective study of 34,633 patients in the MIMIC-IV database, we constructed a high-performance multimodal model (AUROC 0.91, 95% CI 0.874 - 0.935) that can predict IHCA up to 13 hours in advance using EHRs and high-resolution time series physiological readings. As the time of cardiac arrest approached, our model yielded a steady increase in the detection rate, finally reaching 89% 1 hour prior to the event. We also illustrated the impact of each vital sign on the prediction of cardiac arrest associated with individual patients through the use of SHAP values. Furthermore, we demonstrated the advantage of this ML algorithm over the CART score, which was derived using traditional regression models.

Comparison to Prior Work

As a ubiquitous activity in the hospital, several studies have demonstrated the importance of vital signs measurement in determining a patient's disease course [27]. Diastolic blood pressure, respiratory rate, and maximum HR have all been found to be significant and independent predictors of cardiac arrest [28]. However, maintaining a minimal model with only vital signs or adding lab data as predictors at the cost of decreasing model adaptability remains a dilemma [29,30]. The lactic acid level is the most representative laboratory biomarker in circulatory failure but had a high rate of missingness in the MIMIC-IV database (16,317/23,909, 68.2%). This motivated us to abandon utilizing lab results and assess if a nimbler model could be constructed with vital signs trends alone, overlaying the easily obtainable *ICD* codes and patient demographics as baseline features. Unsurprisingly, a significant increase in AUROC was discovered by adding demographics and comorbidities to the vital signs–only model. Furthermore, an SVM-based stacked model can address the predictive capabilities of underlying conditions and dynamic changes during disease deterioration. Stacking proves advantageous by compensating for the weaknesses of both models, with RF potentially struggling with highly correlated data and LSTM excelling in handling timely intricate information.

Distinct Advantages of Our Approach

The reason for not establishing an end-to-end neural network throughout the prediction stood out, as supervised ML algorithms retained the ability to determine the importance of each predictor and have better model explainability. Moreover, in the ensemble technique, stacking excels over both boosting and bagging due to its versatility in integrating diverse data domains and combining various types of models. Late fusion at the model level is also preferred over other fusion methods for mitigating feature discrepancies and enabling independent model training between the time-independent baseline and time-dependent vital signs. Additionally, the outperformance of SVM over LR in the stacking operation could be attributed to better data handling using the nonlinear kernel function. To evaluate the external validity of our model, we tested it on two distinct data sets—the eICU-CRD and NTUH databases—both representing patient groups with diverse ethnicities and disease backgrounds. Over a 10-year duration, we identified 1935 (34.3%) IHCA cases in NTUH. In contrast to prior IHCA prediction studies, such as Kwon et al's [31] 2.3% (n=1233) over 7 years, Chae et al's [32] 1.3% (n=1154) over 4 years, and Ding et al's [33] 23.09% over 5 years (n=1796), our clinical database demonstrated a higher IHCA incidence yet fewer cases [31-33]. This disparity is attributed to our ICU-focused validation database, in contrast to earlier studies that encompassed all patients who were hospitalized. Consequently, our approach ensures heightened data precision and a more nuanced understanding of patient dynamics through continuous monitoring within this critically ill cohort. Nevertheless, our high prediction quality in both independent databases ensures the credibility of our model across various demographic groups and subpopulations. The consistent performance across these data sets not only minimizes the possibility of overfitting but also validates the generalizability of our predictions.

Limitations of Our Methodology

Our study had limitations because we used data collected from one medical center. First, due to the nature of EHRs, we were unable to determine the reason for the multi-scale gaps and different frequencies of each input. Second, we did not include clinical interventions, body temperature, and mental status in our model. Clinical interventions may change the disease course or even terminate the deterioration process. Nevertheless, the complexity of the treatment record and the high frequency of missing values in temperature and mental status compelled us to omit these valuable predictors. Third, our identification of

IHCA relied on time-labeled database-specific procedure codes, *ICD* procedure codes, or administration of epinephrine in resuscitation dosages. In real-time clinical scenarios, delays in data entry may occur as documentation is considered secondary to patient care. Additionally, the accuracy of these codes is often operator dependent and may vary across different ICU policies. To minimize recording biases, we manually reviewed all IHCA vital signs data and only included reasonable measurements, ensuring that the identified IHCA timepoints correlated with the worst patient vital signs.

Conclusion

We built a multimodal ML model based on time serial vital signs and three types of baseline features, which were all easily accessible in the ICU. Our model showed high accuracy in detecting clinical deterioration leading to the development of IHCA up to 13 hours in advance in both the internal and external validation cohorts. A model like this could be integrated into a hospital's EHR system to identify high-risk patients and provide clinical decision support.

Abstract

Background: The phenomenon of patients missing booked appointments without canceling them—known as Did Not Show (DNS), Did Not Attend (DNA), or Failed To Attend (FTA)—has a detrimental effect on patients' health and results in massive health care resource wastage.

Objective: Our objective was to develop machine learning (ML) models and evaluate their performance in predicting the likelihood of DNS for hospital outpatient appointments at the MidCentral District Health Board (MDHB) in New Zealand.

Methods: We sourced 5 years of MDHB outpatient records (a total of 1,080,566 outpatient visits) to build the ML prediction models. We developed 3 ML models using logistic regression, random forest, and Extreme Gradient Boosting (XGBoost). Subsequently, 10-fold cross-validation and hyperparameter tuning were deployed to minimize model bias and boost the algorithms' prediction strength. All models were evaluated against accuracy, sensitivity, specificity, and area under the receiver operating characteristic (AUROC) curve metrics.

Results: Based on 5 years of MDHB data, the best prediction classifier was XGBoost, with an area under the curve (AUC) of 0.92, sensitivity of 0.83, and specificity of 0.85. The patients' DNS history, age, ethnicity, and appointment lead time significantly contributed to DNS prediction. An ML system trained on a large data set can produce useful levels of DNS prediction.

Conclusions: This research is one of the very first published studies that use ML technologies to assist with DNS management in New Zealand. It is a proof of concept and could be used to benchmark DNS predictions for the MDHB and other district health boards. We encourage conducting additional qualitative research to investigate the root cause of DNS issues and potential solutions. Addressing DNS using better strategies potentially can result in better utilization of health care resources and improve health equity.

Introduction

Adding to the existing pressures on the health care system [1,2], further substantial disruptions are caused when patients fail to attend their prescheduled appointments [3]. This is defined as Did Not Show (DNS), which is a scheduled but not utilized clinical appointment that patients failed to attend without canceling or rescheduling. This phenomenon is also known as Did Not Attend (DNA) or Failed To Attend (FTA). Causes include the patient forgetting about their appointment, miscommunication [4], logistical difficulties, appointment scheduling conflicts, and family/work commitments [3,5].

DNS can adversely affect patients' well-being, cause them and the system financial stress, and disturb health care operations and systems. Globally, DNS has an overall rate of 23%, with a wide geographical variation (13.2% in Oceania, 19.3% in

Europe, 23.5% in North America, 27.8% in Asia, and 43% in South America [6]). DNS is expensive for health systems; for example, estimated annual losses amounting to £790 million (over US $1 billion) were found in the United Kingdom [7] and $564 million in the United States [8]. It affects both primary and secondary health care [9], although secondary care losses are higher.

Patients mostly fail to comply with their clinical appointments when symptoms become less severe or unnoticeable [10,11], which might deteriorate underlying syndromes [12,13]. Patients are more likely to demand immediate medical attention when contracting serious health issues or require acute and emergency care if they miss scheduled health care appointments [12,14-16].

Eliminating DNS is hard to achieve, and its adverse effects necessitate methods and approaches for managing DNS such as sending digital reminders by text, phone, and email [17,18]. These approaches have not been very effective, as they are time-consuming and costly, and the health care system still faces DNS issues. Overbooking [3,19], open access [20], and DNS penalty approaches have also been used to enhance clinical slot utilization but can cause longer waiting times for patients and overtime for clinical staff [21].

Inspired by the success of artificial intelligence (AI) in different sectors, including health care [22,23], we considered the application of AI for DNS management via predicting the probability of DNS appointments [13,19,24,25]. AI and its subset techniques, such as machine learning (ML), are powerful for extracting cognitive insights from massive amounts of data [26,27].

The predicted DNS probabilities proved to be successful in providing the required information for DNS management [25] and supporting health care managers in making informed decisions for prioritizing patients and delivering clinical assistance. This enables health care providers to reschedule and reuse limited clinical resources for urgent cases while also expanding access to health care services for patients from diverse backgrounds, thereby promoting health care equity.

Therefore, clinical capabilities and medical resources can be used more effectively and efficiently, decreasing patients' wait times, increasing their satisfaction, and enhancing health productivity.

Most studies concerned with predicting DNS have mainly comprised small data sets or specific groups of people to develop models for DNS learning and prediction; however, DNS tends to be varied across populations. For example, longer distances to a medical facility increase DNS [8], but this finding was contradicted in another study [28]. Likewise, patients with chronic illnesses adhere to their scheduled appointments [13], while other studies [29] have shown that patients with more severe diseases have a higher DNS rate. Even within a single medical organization, DNS factors vary across different clinics [14]. These examples highlight the inconsistent nature of DNS predictors, showcasing the complexity of predicting tasks in this domain. Such variations pose challenges in creating a universal formula or model to effectively address DNS prediction issues on a global scale.

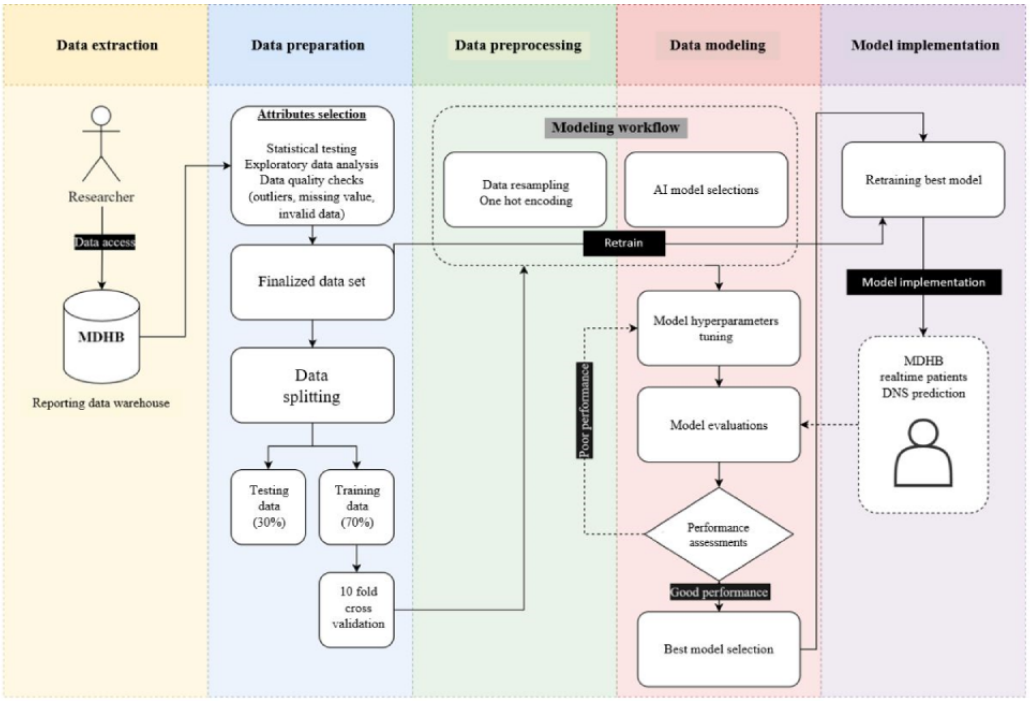
Considering the very limited DNS research in New Zealand and the complexity of developing a general DNS predictive model, we concentrated on the DNS issue in the MidCentral District Health Board (MDHB) hospital as a proof of concept. MDHB is located in the center of the North Island, New Zealand, covering a land area of over 8912 km^2 and with a population of over 191,100 people. In this region, about 18% of people are aged 65 years or older, with over 20% being Māori, and a higher proportion than the national average resides in more deprived areas [30]. These demographic factors could lead to inequity in access to health care services. To support MDHB in addressing health equity and providing additional support for patients, this study aimed to develop ML models and compare their performance in predicting the probabilities of future DNS appointments at MDHB. This study utilized a data set spanning 5 years of collected data.

Methods

Overview

Our research was organized into the following phases (Figure 1)**.** The initial phase involved *data extraction*, defining the data set to be used, and outlining the data extraction process. The *data preparation* phase involved conducting exploratory data analysis (EDA) to profile data and exclude irrelevant observations from the research. Subsequently, the data set was split into 2 parts—70% (454,831 records) for training and 30% (194,927 records) for testing. To avoid data linkage, the training and testing data sets were not mixed during the ML modeling phase. Moreover, the training set underwent a 10-fold cross-validation strategy to prevent bias as much as possible and fully utilize its limited training information. Next, the *data preprocessing* phase involved cleaning and transforming the cross-validation sets, ensuring that the training set was ready for the data modeling stage. A 10-fold cross-validation resampling strategy was applied to further optimize the utilization of the 70% training data. In the *data modeling* phase, we used 3 ML algorithms and tuned their hyperparameters to identify the best performance among the algorithms. Finally, in the *model evaluation* phase, various evaluation metrics were employed to determine the best-performing ML model for DNS prediction.

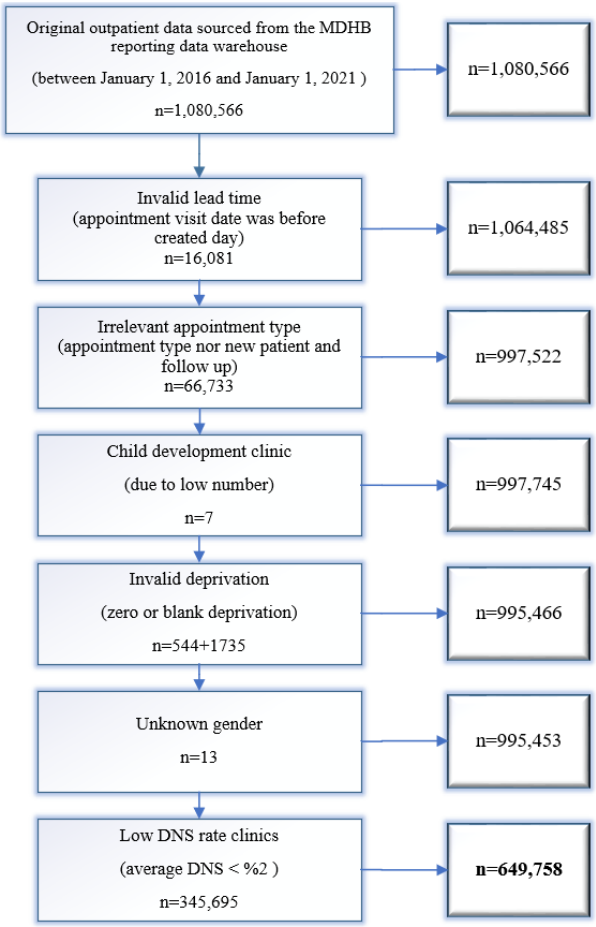
Figure 1. Research flow and procedure. AI: artificial intelligence; MDHB: MidCentral District Health Board.



Data Access and Extraction

Our data were sourced from MDHB reporting SQL farm and contained only outpatient visits with no link to other data sets. This significantly mitigated risks related to patient reidentification. Data deidentification and encryption were applied before data access, and New Zealand National Health Index numbers were encrypted to protect patients' privacy. We acquired 1,080,566 outpatient visit records from 38 clinics between January 1, 2016, and December 31, 2020, satisfying the research requirements with almost 57,000 DNS incidents (5% of the entire data set). The steps of data exclusion are presented in Figure 2. Because not many missing records were identified in the data sets, those with missed values were directly excluded.

Figure 2. Research data exclusion. DNS: Did Not Show; MDHB: MidCentral District Health Board.



Ethical Considerations

This study received ethics approval from the Auckland University of Technology (AUT; 20/303) and MDHB (2020.008.003), following which data access to the MDHB reporting data warehouse was granted.

Data Preparation

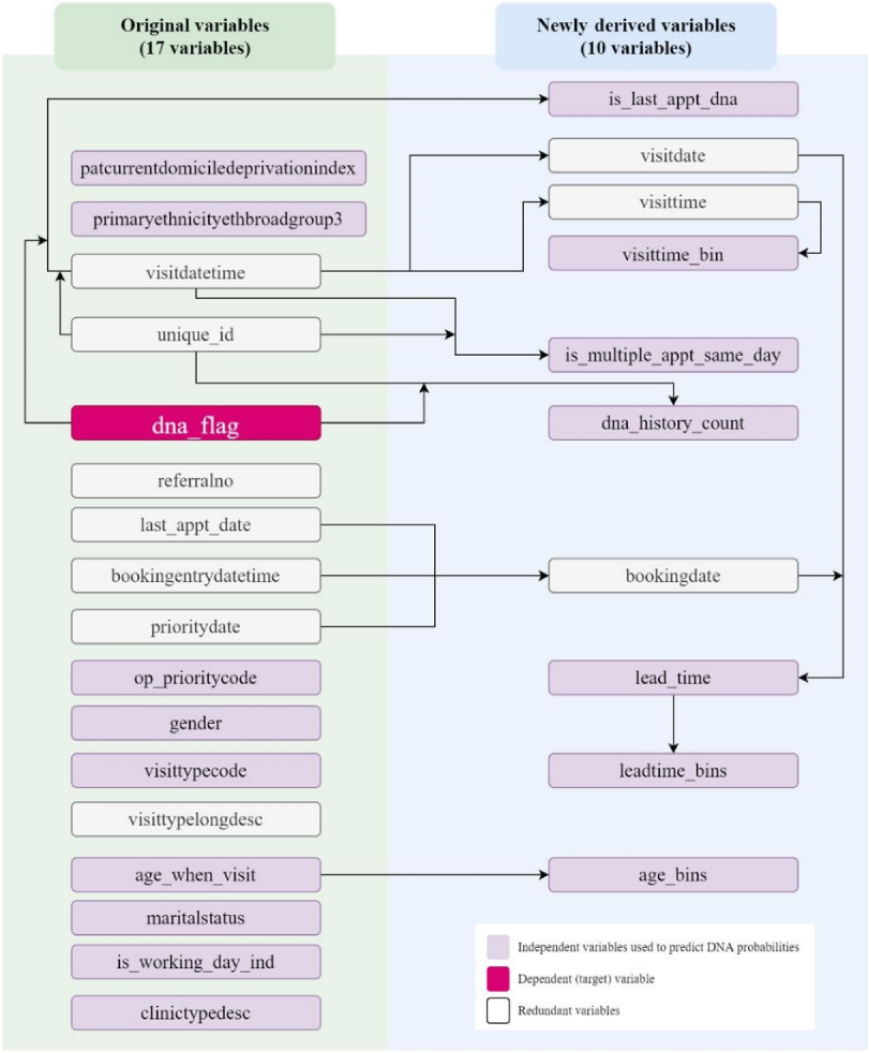
Phase Description

In this phase, understanding the data was important to adequately prepare them for the experiments. The data preparation process included data transformation and derivation (Figure 3). Following suggestions from the literature, new research variables were derived and introduced because some valuable DNS predictors were absent in the MDHB data set. For example, no direct information was available on the patients' DNS history [21,31], appointment lead time [31,32], or latest appointment DNS outcome [13]. The lead time was calculated by comparing the difference in days between the appointment creation date and the visit date. Appointments with longer lead times were expected to have greater DNA probability than those with shorter lead times [29].

Therefore, to better understand patient behavior and DNS patterns, we derived 10 new variables on top of the original variables (Figure 3). These attributes were introduced to support us in understanding when patients were more likely to miss their appointments in general and to identify regular nonadherent patients.

Initially, we extracted a data set with 17 columns and over 1 million records (Multimedia Appendix 1). Informed by the literature review [14,29,31-33], we derived and introduced another 10 variables on top of the original data and increased the data columns to 27. Among all the variables, 16 (59%) were used for ML modeling, and the redundant ones were excluded. The *dna_flag* attribute was the dependent (target) variable. Figure 3 demonstrates the original variables in addition to 10 newly derived ones.

Figure 3. Variable transformation and derivation visualization.



Cardinality Reduction

We conducted a cardinality reduction analysis to reduce variable categories with low frequency and small samples. The data set mostly included categorical variables, with numeric variables being rare. Each categorical level is called a cardinality, which means how many distinct values are in a column. In our data set, some categorical variables had fewer levels, such as patient gender—M (male), F (female), and U (unknown)—while others had hundreds of variations, such as suburbs or diagnosis codes.

Developing ML models often involves numerous categorical attributes, necessitating examination of the variables' cardinality, as most ML algorithms are distance-based and require converting categorical variables to numeric values. Categorical variables with high cardinality levels will derive massive new columns and expand the data set. This expansion increases model complexity, elevates computational costs, and decreases model generalization, which makes handling the data set challenging [34]. Therefore, we investigated the cardinality of our research variables and deployed a reduction strategy accordingly.

Cardinality reduction analysis was conducted to reduce the number of categories within variables with low frequency and small sample sizes. Following suggestions from the literature, new research variables were also derived and introduced, including patients' prior DNS history [14,16,21] and the appointment lead time [14,16,29,32].

Statistical Test

The chi-square test was used for analyzing homogeneity among different groups within variables [35] and for testing the independence between categorical variables [36]. The chi-square statistics (χ^2) and their *P* values were calculated to investigate whether different levels of a variable contributed differently to DNS events.

The confidence level (α=.05) was adopted as the *P* value threshold in the chi-square test. A *P* value less than .05 provided enough confidence to reject the null (H_0) hypothesis and accept the alternative hypothesis (H_A). The tested categorical variable was associated with DNS events [36]. Hence, we may consider using it for future prediction.

After the data preparation process, 16 variables were selected to predict the target *dna_flag*. Among them, 12 modeling predictors were nominal variables, including binary variables (Multimedia Appendix 2). We, therefore, conducted the chi-square (χ^2) statistical test to investigate the relationship

between those predictors and DNS events (Table 1). The chi-square was calculated using the following equation, where O and E are observed and expected values [36,37]:

After preparing the data set and before developing the ML models, an EDA was conducted to gain a deeper understanding of the research data landscape. EDA is a fundamental data analysis required before hypothesis and modeling formulation [38]. Its findings can be used to verify misleading models at a later stage [38] and reveal unexpected patterns [39]. The EDA helped uncover patients' DNS patterns through data aggregation and data visualization analysis. Finally, the EDA findings were validated against the ML model outcomes to verify their accuracy.

Table 1. Chi-square test on categorical variables.

Categorical variables	Chi-square statistic	Chi-square *P* value

Data Preprocessing

Due to the high number of categorical variables in our data set, the one-hot encoding technique was used in the preprocessing phase. Because distance-based algorithms can only deal with numerical values, in the cardinality reduction section, we used the one-hot encoding method to convert our categorical variables to numbers. After the conversion, different variables were introduced to our training data set, also known as indicator variables. For example, the variable gender derived 3 variables, *gender_male*, *gender_female*, and *gender_unknown*. Each of those variables can have a value of either 1 or 0.

As the predictive performance of classifiers is highly impacted by the selection of the hyperparameters [40], we conducted hyperparameter tuning to optimize our algorithms' learning process. We further optimized this process using the Grid Search method to boost the performance of our chosen models. Table 2 outlines specific details regarding the hyperparameters utilized.

Table 2. Hyperparameter tuning of the data modeling.

Models and hyperparameters	R package	Range	Purpose
Logistic regression			
penalty	Glmnet	1e-10- 1	Total amount of regularization used to prevent overfit and underfit
Random forest			
Trees	Ranger	300- 1000	Number of trees in the forest
Min_n	Ranger	3-10	Minimum amount of data to further split a node
Mtry	Ranger	3-5	Maximum number of features that will be randomly sampled to split a node
XGBoost[a]			
Trees	XGBoost	300-1000	Number of trees in the forest
Min_n	XGBoost	3-10	Minimum amount of data to further split a node
mtry	XGBoost	3-10	Maximum number of features that will be randomly sampled to split a node
tree_depth	XGBoost	3-12	Maximum depth of the tree

[a]XGBoost: Extreme Gradient Boosting.

Data Modeling

Addressing the imbalanced data set posed the main data modeling challenge. The annual DNS rate for MDHB was around 5%, which means 95% of the appointments were attended visits. This imbalance significantly affected the accuracy of our ML model in predicting attended cases. To tackle this issue, various internal and external strategies exist [41,42]. In this study, we employed an external approach that involved utilizing standard algorithms intended for a balanced data set but applying resampling techniques to the trained data set to reduce the negative impact caused by the unequal class. Our focus was on the resampling strategy, known for its effectiveness in handling imbalanced classification issues and its portability [42].

The resampling strategy involved 2 methods: (1) oversampling, where the size of the minority class is increased randomly to approach the majority class in a class-imbalance data set [43,44]; and (2) undersampling, where the size of the majority class decreases randomly to align with the minority class [43,44]. This strategy falls under both the oversampling and undersampling categories. Given the lack of definitive guidance on the effectiveness of these methods [42-44], we adopted both and compared their results.

Since we dealt with a binary classification prediction problem, supervised and classification algorithms were selected. Algorithms with good interpretability were also considered to explain which predictive variables influence DNS prediction more significantly. In a study concerning variable importance, tree-based models, such as random forest (RF) and gradient-boosted decision trees, were shown to inherently possess features that measure variable importance [45].

For the imbalanced data set, we used ensembling methods due to their proven advantages [46,47]. The following algorithms were chosen for developing DNS prediction models: logistic regression (LR), RF, and Extreme Gradient Boosting (XGBoost).

LR was chosen because it is a suitable analysis method across multiple fields for managing binary classification [48]. Our research concerned a supervised classification problem to predict whether a future outpatient appointment will become a DNS visit. With the response variable (*dna_flag*) offering dichotomous outcomes—either yes (1) or no (0)—LR stood as a fitting choice due to its proficiency in predicting binary outcomes and its established effectiveness in prior studies [7,13,33,49]. Tree-based ensembling algorithms were also chosen for their proven ability to deal with imbalanced data sets and model explainability [46,47]. RF can effectively handle combining random resampling strategies in imbalanced prediction. Tree-ensembling methods have more advanced prediction ability than a single model because they integrate prediction strength from several base learners [50].

Model Implementation and Evaluation

We used 10-fold cross-validation for model selection and bias reduction. The hyperparameters were tuned to boost each classifier's performance. We followed suggestions from the literature suggestions to use sensitivity, specificity, and the area under the receiver operating characteristic (AUROC) curve to quantify the models' prediction strength for the imbalance problem prediction.

During this phase, we used the testing data to validate the best predictive model chosen based on the model evaluation criteria. For this study, data before 2021 were used in the data modeling process. We coordinated with MDHB to access outpatient appointments from 2021 for model validation. Specifically, we used both weekly and monthly data for prediction, comparing these with actual appointment outcomes to validate the model. The benefit of using a new data set for validation was to assess model bias and goodness of fit outside the research environment. Positive performance and high prediction accuracy would

indicate potential real-life implementation of our research model after further investigation.

Results

Our study only included new patients and follow-up appointments. Therefore, we analyzed DNS costs limited to new patient and follow-up outpatient services over the last 5 years. The MDHB provided us with costing information for 34 different departments, and we calculated the DNS cost for each department (Table 3). In 2020, there were 2812 new patient DNS visits and 6240 follow-up DNA visits causing a loss of at least $2.9 million (US $1.8 million) at MDHB. More information regarding this calculation is provided in Multimedia Appendix 3 [51].

Each department was assigned a corresponding outpatient appointment price for a new patient and follow-up outpatient appointment services. We aggregated the total DNS occurrences of new patients and follow-up appointments, multiplying corresponding unit prices to quantify their financial impact. For instance, in 2020, there were 301 new patients and 745 follow-up patients who missed their scheduled bookings, which caused a revenue loss of $300,442 (US $190,000) in the orthopedics department.

Although the initial research expected to address the DNS issue for all outpatient clinics and patients at the MDHB, due to the broad scope of the DNS, we concentrated on clinics with a higher percentage of DNS and narrowed down the research scope to prioritize workloads. To successfully build a model for our focused patient groups, we eliminated as many irrelevant data points as possible. Then, data used for the model training were more fit for purpose for the high-needs population.

The modeling data set was created using 649,758 records and 17 columns (Figures 1 and 3). We developed ML models based on LR, RF, and XGBoost algorithms, with hundreds of hyperparameter combinations in our data modeling. To evaluate the models' prediction performance, accuracy, sensitivity, specificity, AUROC curves, and cost (computation time) were calculated (Table 4). The aim was to identify the best model and hyperparameters that resulted in optimal sensitivity and AUROC performances. Model prediction accuracy is critical; however, it was not a primary concern in this research as we dealt with an imbalanced data set [52].

Table 4 presents a summary comparison of the models' performance. As shown in the table, the LR-based model was the fastest and RF the slowest in terms of computation time. LR had the lowest AUROC scores (ie, the low DNS events prediction accuracy), while RF and XGBoost had a similar area under the curve (AUC) performance (around 0.92).

The undersampling strategy significantly improved our models' sensitivity. Sensitivity was chosen over accuracy because we were dealing with an imbalanced data set [52]. Sensitivity quantified the models' ability to correctly predict positive (DNS) cases that help detect high-risk DNS patients. RF and XGBoost had a very close sensitivity of 0.82. However, considering the computation cost factor, XGBoost had the lowest modeling time. XGBoost with undersampling was our best ML model for the DNS prediction. Its ROC curve is illustrated in Figure 4.

A further investigation was also performed to identify the top predicting factors for each model (Multimedia Appendix 4). The purpose of calculating variable significance scores was not to plug them into a calculation formula but to showcase which variables were more relatively critical in calculating the risk of DNS. Variable importance is critical to AI model development, as variables do not contribute evenly to the final prediction. Therefore, we focused on the most influential predictors and excluded irrelevant ones by scoring the variables' prediction contributions [53]. Variable importance is a measurement quantifying the relationship between an independent variable and the dependent [46].

The results shown in Multimedia Appendix 4 matched the chi-square statistical test results (Table 1). The leading factors were determined and selected using the variable (feature) importance. It was evident that the *dna_history_count* variable was the most influential predictor following *is_last_appt_dna*, *age_when_visit*, and *lead_time*. Additionally, *ethnicity* played an important role in constructing the XGBoost model for the DNS prediction.

We also aggregated outpatient appointment data and ranked the observed DNS rate of all outpatient clinics (Multimedia Appendix 5). We carried out this analysis to initiate an understanding of how disease type might influence the DNS rate.

Table 3. DNS[a] costs in 2020 at the MDHB[b] hospital[c].

Clinics	NP[d] DNS count	NP DNS price	Total NP DNS cost	FU[e] DNS count	FU DNS price	Total FU cost	Total DNS cost

Discussion

Principal Findings

Our results are comparable to similar previously published analyses [9], although the AUC for XGBoost was slightly higher in our case. This may be due to the data selection and local characteristics. We initially built a generic DNS prediction model for all outpatient clinics at MDHB. However, in light of the literature and DNS complexity, the project scope was narrowed down to clinics with higher DNS rates. As discussed previously in this paper, we excluded irrelevant and missed data, invalid lead time appointments, and clinics with very low DNS rates. This approach improved the ML models' performance and made sense from an operational perspective. The developed models provided insights useful for understanding the contributing factors for DNS. We found that patient DNS history, appointment characteristics, work commitments, and socioeconomic status substantially contributed to DNS events.

Patient DNS History

Understanding patients' DNS history was crucial for predicting future DNS patterns (Table 5) and developing the ML models. This also aligned with the chi-square test results (Table 1), which ranked the *dna_history_count* and *is_last_appt_dna* variables as the most important factors. Total DNS counts and the latest appointment's DNS outcome are pivotal for calculating

the probabilities of future DNS occurrences. These factors are consistent with the findings in the literature [14-16,21,32,54].

Managing DNS involves identifying patients with low adherence to scheduled visits for additional attention. Centralizing and managing DNS history can provide a comprehensive view, preventing data silos or gaps. Centralized monitoring can enhance the visibility of recurring DNS incidents and proactively alert clinicians of potential DNS cases. Our models account for changes in DNS behavior. To reduce the prediction bias, we screen for the most recent appointment DNS outcome (*is_last_appt_dna*).

Table 5. Top prediction variables in the developed ML[a] models.

[a]XGBoost: Extreme Gradient Boosting.

Appointment Characteristics

Certain appointments expected more nonadherence, with distinct predictors related to appointment characteristics such as "working day" and "high lead time." Longer lead times correlated with increased DNS probability, while appointments on working days were more prone to DNS than nonworking days. These findings align with reports from [33,54,55] and emphasize the significant impact of appointment lead time on DNS prediction, as also indicated in [8,14,16,32,33,54]. This underscores how appointment characteristics directly affect DNS outcomes immediately after scheduling. Therefore, incorporating ML-predicted DNS risk estimations during appointment scheduling could automatically flag higher DNS probability for proactive management.

Furthermore, our analysis of the *op_priorityc*ode variable (Multimedia Appendix 1) indicated that, in general, patients with more serious health conditions were more likely to attend their appointments. This observation is reflected in Multimedia Appendix 5, which compares the DNS rates of different clinics with the overall average DNS rate of 0.053% (depicted red line). For example, patients visiting the audiology clinic had a potential DNS rate of 19.1% compared to a 0.9% DNS rate for the radiation oncology clinic. Our analysis of the *op_priorityc*ode variable was based on categorical data types reflecting appointment urgency and not based on a detailed analysis of each patient's diagnosis.

Work Commitments

Our findings suggest that patients struggled to adhere to appointments on working days or during working hours. Younger adults, particularly those between 20 and 30 years of age, had higher DNS rates due to work commitments, while older adults aged 65 years and above rarely missed their visits.

Furthermore, the XGBoost-based model highlighted that being single was an indicator of DNS visits (Figure 4). This could relate to time constraints among young professionals, a finding consistent with other studies [8,28,33,56]. For this group, a targeted reminder system could be developed to concentrate on appointments with higher DNA probability compared to the

DNS risk threshold. Consequently, the population-based reminding system could help optimize resource allocation, including staff efforts and costs.

Socioeconomic Status

We explored the deprivation index and clustered patient populations by using their ethnicity (Multimedia Appendix 6). Our findings indicated a strong association between European and Māori ethnicities and DNS outcomes, ranked among the top 5 predicting factors (Multimedia Appendix 4). Māori and Pacific populations had the highest DNS rates, in line with other research findings [56], while the European ethnicity had the lowest DNS rates. Māori and Pacific populations tended to reside in areas characterized by higher deprivation rates, whereas the percentage of other ethnicities living in higher deprivation regions decreased when the deprivation index increased.

In New Zealand, Māori and Pacific ethnical groups required increased health care attention [57] to ensure equity in the health care system. As indicated in Table 6, a larger proportion of these ethnic groups are situated in suburbs and areas with higher deprivation indexes (such as 8, 9, and 10) [58]. The higher deprivation index was also a strong indicator of socioeconomic deprivation geographically [58]. According to the New Zealand Index of Deprivation, neighborhoods with higher deprivation were more likely to experience adverse living conditions such as damp, cold, and crowded housing.

Moreover, regions with higher deprivation exhibit higher rates of unemployment, increased dependence on benefits, and more single-parent families [58]. Consequently, these living conditions and income disparities made patients living in these regions more susceptible to illness, while also encountering more barriers and obstacles in addressing their medical needs.

At MDHB, dedicated working groups were established to support Māori and Pacific patients in attending their scheduled hospital appointments. Our research reiterates the importance and necessity of those working groups, acknowledging the value of their work. Moreover, our model can support them further by providing tangible DNS probability scores to prioritize patients who require additional attention and support.

Table 6. Percentage of population residing at each deprivation level [58].

Deprivation level	Māori, n (%)	Pacific, n (%)	European, n (%)	Asian, n (%)	Other, n (%)
1	3113 (7)	293 (1)	37,314 (86)	2077 (5)	835 (2)

10	31,998 (35)	6283 (7)	52,064 (56)	1610 (2)	521 (1)

Operational and Managerial Implications

The total DNS loss incurred by the MDHB hospital was around $2.9 million (US $1.8 million) in 2020. Notably, we observed that clinics with less life-threatening diseases (diabetes, audiology, and dental) had higher DNS rates. Considering our use of MDHB data, we expect to identify similar patterns in other district health boards for which the same DNS predicting factors can be applied for DNS management.

While the primary objective of our research was to calculate DNS risk for promoting health equity, we believe that leveraging DNS prediction can aid in managing limited health care resources more efficiently. By quantifying the DNS probability for future appointments on a scale from 0.00 to 1, clinicians or hospital operation managers can develop more personalized health care services for their patients. This leads to enhancing equity in accessing health care services for a wider population.

The predictions derived can support MDHB managers in designing, planning, and implementing more informed DNS management strategies. For example, a DNS appointments threshold (eg, 0.7) can be set, and all appointments with predicted odds greater than 0.7 can be selected, releasing 70% of resources and allocating some (or all) to the remaining 30% of patients with a higher DNS risk. Potentially, these released resources can subsidize interventions to support attendance. Without DNS prediction, the hospital cannot decide where to focus on solving the DNS problem and must invest money uniformly for every patient, leading to equality rather than equity in health care service access. Equality is not fit for purpose, especially considering the high attendance rate of 95% over the past 5 years, indicating that most patients attend appointments without additional support. However, for more optimum use of health care resources, other policies and guidance for appointment scheduling should be considered [59].

Potential Interventions to Reduce DNS

DNS Suggests Life Hardships

When patients miss medical appointments, it is a critical indicator suggesting they may be experiencing hardships in their lives [15,54,60]. Considering that a higher DNS rate correlates with a higher deprivation index, we can assume that

people residing in these areas may face greater transportation limitations. Moreover, people with severe mental health or addiction issues may not be able to independently visit their doctors [15]. These vulnerable groups require additional and ongoing appointment assistance. Unfortunately, they have been historically disadvantaged and marginalized by the current health care system [61].

The DNS prediction model we developed can help health care practitioners identify patients at higher risk of DNS. Targeted DNS improvement solutions can be designed based on predicted DNS probability, patient demography, and clinical history. This type of application can leverage the DNS prediction model to help identify and deliver patient-centric medical services to patients requiring additional help. Some examples are discussed in the subsequent sections.

Expanding Integrated Health Care Networks

For patients not facing life-threatening illnesses or requiring long-term health management (such as patients with diabetes), expanding services closer to patients might help meet their needs. MDHB could consider deploying clinicians to outsourced sites to supervise practitioners or attend to patients directly. Moreover, increasing collaborations with primary health care networks, promoting nurse-led services, and contracting private specialists can also be viable options for decreasing DNS rates. Developing a one-stop medical hub with multidisciplinary clinics for patients with lower clinical risk could encourage attendance and reduce DNS visits [19]. This is consistent with the New Zealand Ministry's latest health care system reform strategies, which aim to uplift health care equity [61]. The reform emphasizes the establishment of more locality networks in the community, resonating well with our research findings.

After-Hour Appointment Slots

To support young adults who are occupied by daily work, it might be favorable to increase more after-hour service slots in clinics when possible. If more appointment slots can be organized before or after working hours, working professionals may have more chances to adhere to their clinical appointments. Piloting more weekend clinics can also be a choice to meet younger generations' needs. In consonance with our suggestion, the recent New Zealand health care reform also promoted more affordable after-hours services [61]. Additionally, offering transportation assistance and improved wraparound well-being support for patients with a high-risk score could increase attendance. At-home patient visits could also be offered and delivered to patients facing severe transport limitations.

Limitations

Despite the success of our DNS prediction model, we need to acknowledge that it has some limitations. First, our model was trained on 5-year period data from MDHB. The single data source prevented us from exploring other critical dimensions such as household data or beneficiary data. We believe adding those data points would improve the prediction model and discover more patients' DNS patterns.

Furthermore, we pairwise compared the attribute *dna_flag* with other DNS predictor factors. However, future research should consider investigating and analyzing the association between variables and adding further variables to the conditioning set. This expanded analysis would offer deeper insights into patients' DNS behaviors.

Conclusions

To the best of our knowledge, this study represents one of the first attempts in New Zealand to develop ML prediction models supporting DNS management. We successfully developed and tested ML models to predict probabilities of outpatient appointments' DNS. Our selected model had an AUROC of 0.92 and a sensitivity performance of 0.82.

Acknowledgments

The authors would like to thank the New Zealand MidCentral District Health Board (MDHB) for their support of this study. We appreciate the advice, help, and support from the MDHB data analytics team, Dr Richard Fong, and Mr Rahul Alate. Without their contribution, this study would not have been possible.

Abstract

Background: Patients with cancer starting systemic treatment programs, such as chemotherapy, often develop depression. A prediction model may assist physicians and health care workers in the early identification of these vulnerable patients.

Objective: This study aimed to develop a prediction model for depression risk within the first month of cancer treatment.

Methods: We included 16,159 patients diagnosed with cancer starting chemo- or radiotherapy treatment between 2008 and 2021. Machine learning models (eg, least absolute shrinkage and selection operator [LASSO] logistic regression) and natural language processing models (Bidirectional Encoder Representations from Transformers [BERT]) were used to develop multimodal prediction models using both electronic health record data and unstructured text (patient emails and clinician notes). Model performance was assessed in an independent test set (n=5387, 33%) using area under the receiver operating characteristic curve (AUROC), calibration curves, and decision curve analysis to assess initial clinical impact use.

Results: Among 16,159 patients, 437 (2.7%) received a depression diagnosis within the first month of treatment. The LASSO logistic regression models based on the structured data (AUROC 0.74, 95% CI 0.71-0.78) and structured data with email classification scores (AUROC 0.74, 95% CI 0.71-0.78) had the best discriminative performance. The BERT models based on clinician notes and structured data with email classification scores had AUROCs around 0.71. The logistic regression model based on email classification scores alone performed poorly (AUROC 0.54, 95% CI 0.52-0.56), and the model based solely on clinician notes had the worst performance (AUROC 0.50, 95% CI 0.49-0.52). Calibration was good for the logistic regression models, whereas the BERT models produced overly extreme risk estimates even after recalibration. There was a small range of decision thresholds for which the best-performing model showed promising clinical effectiveness use. The risks were underestimated for female and Black patients.

Conclusions: The results demonstrated the potential and limitations of machine learning and multimodal models for predicting depression risk in patients with cancer. Future research is needed to further validate these models, refine the outcome label and predictors related to mental health, and address biases across subgroups.

Introduction

Background

Depression in patients with cancer occurs frequently around diagnosis and treatment and has been negatively associated with a patient's prognosis, quality of life, and treatment adherence [1-5]. Despite affecting up to 20% of patients with cancer and far exceeding the prevalence in the general population (8.4% in the United States [6]), depression is underdiagnosed and often untreated [1,3,7-9]. Constrained clinician time and a strong focus on anticancer treatment may contribute to the insufficient identification of patients at risk for depression [10-13]. Early detection of depression in patients with cancer may enable timely mental health support to augment the anticancer treatment.

Clinical decision support tools with artificial intelligence (AI) technologies could synthesize the abundance of data collected during treatment to help clinicians identify which patients may need specific attention and steer additional mental health resources to those at high risk. A recent review [14] of AI models developed for depression risk in primary care [15], elderly care [16,17], and social media posts [18-20] highlights how AI tools have the potential for early identification of mental health issues. However, oncology-specific applications are rare, and those that do exist are developed on selected small samples that may not generalize to clinical care settings [21,22]. This leaves a gap in oncological care for mental health.

Objective

We aimed to develop a prediction model for early identification of patients at risk for depression within the first month of chemo- or radiotherapy treatment. We assessed the relevance of different data modalities for predictive performance in a retrospective cohort study.

Methods

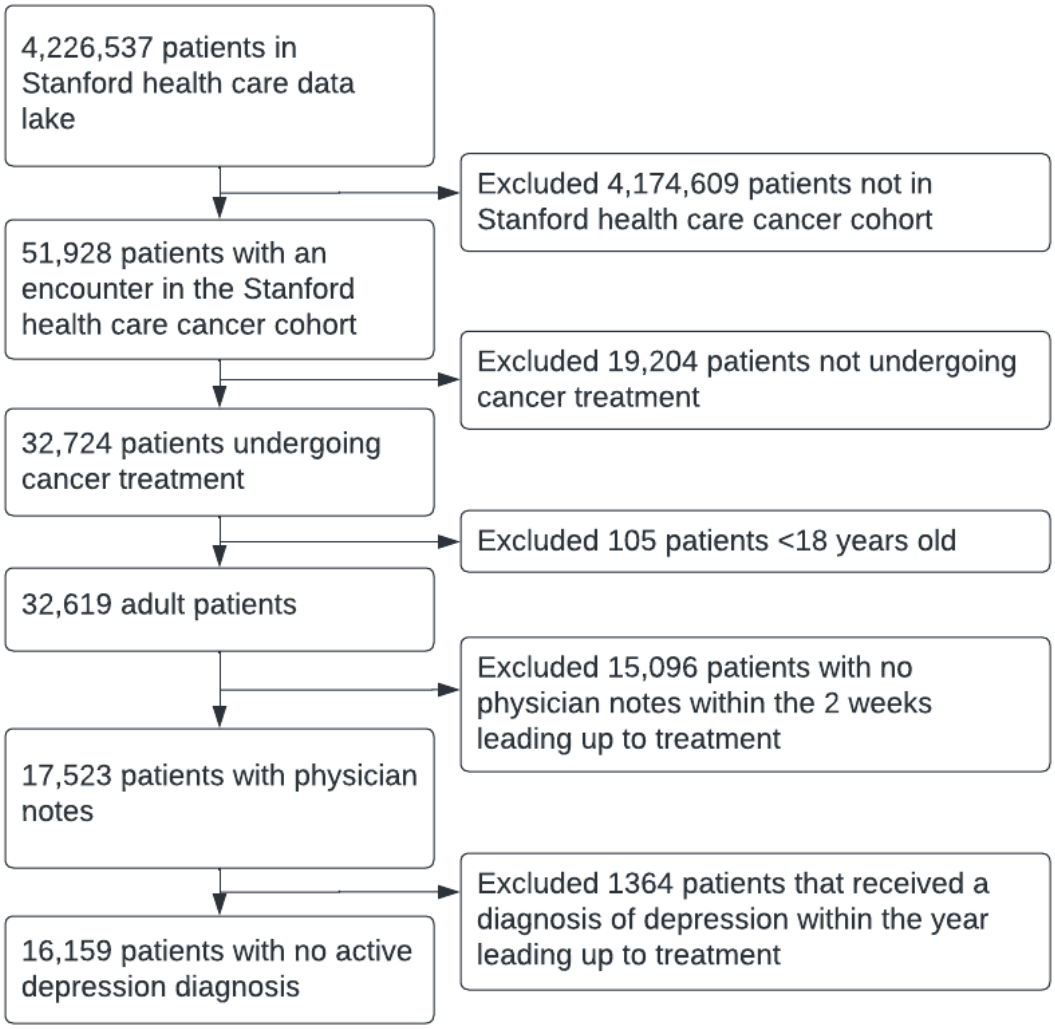
Data Source and Patient Population

This retrospective observational study used data from the integration of 3 health care organizations: an academic medical center (AMC), a primary and specialty care alliance (PSC), and a community medical center (CMC). These organizations offer a wide spectrum of specialized and advanced health care services for complex medical conditions, operating in over 600 clinics. The PSC, established in 2011, comprises more than 70 primary and specialty clinics throughout the California Bay Area. The CMC provides a range of inpatient and outpatient services in the Tri-Valley region of East Bay and was acquired by the AMC in 2015. Following the merger and acquisition, all health care settings adopted the same Epic-based electronic health record (EHR; Epic Systems Corporation) system. Patients for the study were identified from a clinical data warehouse that consolidated patient data from the AMC, PSC, and CMC from 2008 to 2021 [23]. The EHR system was initiated in 2005, and by 2008, the data had reached a state of robustness and high quality. The study concluded in 2021 to ensure that all patients who visited the clinic during the extended period were comprehensively captured.

As an integral component of the EHR system, the MyHealth portal and web interface are seamlessly incorporated into the EHR. This integration includes a patient portal, enabling patients to engage with their health care teams through secure email communication. Patient-generated emails were systematically gathered from the MyHealth patient portal. These email exchanges feature structured subject lines, with patients selecting from a predefined set of categories such as "Non-Urgent Medical Question," "Prescription Question," "Visit Follow-Up Question," "Test Results Question," "Update My Health Information," "Scheduling Question," and "Ordered Test Question." The email body allows for free-text input but is limited to 1000 characters. Importantly, all incoming emails are meticulously triaged to the appropriate members of the patient's health care team, including clerical, scheduling, clinical, or other team members, who take the necessary actions or provide responses as needed [24].

Adult patients receiving chemo- or radiotherapy treatment were included in the cohort. Given the data-intensive nature of the techniques used [25], our objective was to encompass all eligible patients throughout the entire available period at the time of our analysis. The start of cancer treatment was defined as the first patient encounter that registered chemotherapy (including targeted and immunotherapy) or radiotherapy ("chemotherapy" and "clinical procedure codes" in Multimedia Appendix 1). We excluded patients who did not receive cancer treatment (eg, patients seen for a second opinion only), were younger than 18 years, and had no clinician notes within the 2 weeks leading up to the treatment (Figure 1). We also excluded patients with a depression diagnosis within the year leading up to treatment as we aimed to focus on individuals who are at risk of developing depression during or after their treatment (Figure 1). It was assumed that these patients were already receiving treatment for their depression or at least had additional support offered to them.

Figure 1. Flowchart of cohort selection.



Ethical Considerations

This study was approved by the Stanford institutional review board (#47644). Informed consent was waived for this retrospective study for access to personally identifiable health information as it would not be reasonable, feasible, or practical. The data are housed in the Stanford Nero Computing Platform, which is a highly secure, fully integrated internal research data platform meeting all security standards for high risk and protected health information data. The security is managed and monitored, and the platform is updated and adapted to meet regulatory changes.

Predictive Outcome

Depression was defined in consultation with oncologist coauthors (DWB and MR) as a depression diagnosis via the *International Classification of Diseases* (ICD)-9 and ICD-10 codes obtained from EHR data ("ICD depression codes" in Multimedia Appendix 1). This end point was chosen as it was the most conservative and has been shown to correlate reasonably well with clinical opinion [26]. Depression risk was predicted within 1 month of cancer treatment. This time window was chosen as depression prevalence is highest during diagnosis and the acute phase of cancer treatment [27].

Structured Data Predictors

The following variables were obtained from structured EHR fields: sex (male and female), age, insurance status (private, Medicare, Medicaid, and other or not identified), cancer stage (I, II, III, IV, and missing), hospitalized in the previous month (yes or no), 1 or more emergency department visits in the previous month (yes or no), the Charlson comorbidity score [28], and the number of emails sent in the month prior to treatment (none, 1-3, 4, or more) based on a previous study [24]. Insurance status was recoded into 4 comprehensive categories (private, Medicare, Medicaid, and other or not identified). Cancer stage was also recoded to contain the 4 main stages (I, II, III, IV, and missing). Whether or not patients sent emails at night in the previous month was also included as insomnia and depression are intimately related [29]. Binary variables were added indicating whether a patient had previously received a depression diagnosis; depressant medication; or a referral to a psychiatrist, psychologist, or social worker. Finally, race and ethnicity (Hispanic, non-Hispanic Asian, non-Hispanic Black, and non-Hispanic White) was included in one of the sensitivity analyses (see below). The ethnicities "Latino" and "Hispanic" were merged into 1 category (Hispanic). The categorical predictors were converted into dummy variables.

Descriptive statistics were reported in terms of percentages for categorical variables and the mean and SD for continuous variables. We analyzed the cancer and insurance information that was closest to, but preceding, the patient's start of treatment. We stratified descriptive statistics according to outcome (depression diagnosis or not) and messaging behavior (active email communicator in the past month or not).

Unstructured Text Predictors

Unstructured text included patient emails with the subject "Non-Urgent Medical Question" sent through a secure patient portal and clinician notes [24].

A Bidirectional Representations from Transformers (BERT) model was trained on a subset of manually labeled emails to classify each email as being "concerning for depression" or not (see the Multimedia Appendix 2 [30-33] for further details on the annotation strategy and model development). Automatically sent emails; copies of previously sent emails; and emails containing questionnaires, appointment requests, and medication refill requests were removed from the set of patient emails. Emails with less than 30 words were removed from the data set. Each email in the final data set was truncated to a maximum token length of 512. This BERT model assigned each patient email a classification score ranging from 0 (not concerning for depression at all) to 1 (most concerning for depression). These email classification scores were summarized at the patient level by calculating the minimum email classification score in the previous month, the maximum score in the previous month, and the mean score in the previous month. These email classification features were then included as structured data in the subsequent model developments.

Clinician notes that were shorter than 100 words or longer than 5000 were removed as these contained erroneous entries or long copies of previous notes, respectively. Notes with mentions of clinical trials, duplicates, and empty notes were also removed. We merged the most recent clinical notes (at most 3) created within the 2 weeks before the start of treatment. The merged notes were decomposed into chunks of at most 25 sequences (to avoid computational issues), each sequence consisting of 256 tokens.

Model Development

For all models, data were randomly split into the same two-thirds for the train set and one-third for the test set. A total of 6 models were trained to assess the value of multimodal data for this use case.

First, a machine learning (ML) model was developed based on the structured EHR data (model 1), email classification scores (model 2), and the combination of the 2 (model 3). The following ML algorithms were compared for these models: least absolute shrinkage and selection operator (LASSO) logistic regression, a decision tree, random forest, gradient boosting decision trees, *k*-nearest neighbor, and naive Bayes.

LASSO logistic regression is a regularized regression approach, providing both variable selection and shrinkage of regression coefficients. A decision tree is a nonparametric algorithm consisting of a hierarchical tree structure. A random forest combines the predictions of many independently built decision trees into 1 prediction. Gradient boosting decision trees essentially optimize random forest estimation by gradient boosting. The *k*-nearest neighbor algorithm is also nonparametric and uses proximity to previously seen data points to make predictions. Finally, naive Bayes is a generative algorithm that models the distribution of its predictors to make predictions.

The hyperparameters of these models (see Tables S1-S3 in Multimedia Appendix 2) were optimized using Bayesian optimization and 5×10-fold cross-validation. The final ML models were trained on all training data with optimized hyperparameters. The best-performing ML algorithms were the basis for extension with unstructured data.

We trained BERT models based on the clinician notes (model 4), the structured EHR data in combination with the clinician notes (model 5), and the structured EHR data in combination with the email classification scores and the clinician notes (model 6). BERT models are deep learning language models that learn contextual relations between words in a text. Models 5 and 6 made use of a modality-specific deep learning architecture to combine the different data modalities in the modeling process (see Multimedia Appendix 2 for more details) [34]. We used a pretrained DistilBERT model [32] as it required less computation than BERT or ClinicalBERT models [33]. The hyperparameters were tuned on 80% and validated on 20% of the training data. The model parameters of the best-performing epoch on the validation data were chosen for further analyses. Probability estimates were recalibrated via isotonic regression for all models [35].

Statistical Analysis

Model discrimination was quantified by the area under the receiver operating characteristic curve (AUROC), sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) on the test data. Calibration was assessed through calibration plots, with a calibration intercept and slope as summary performance measures [36]. CIs were obtained via bootstrapping (based on 1000 iterations).

As an initial assessment of clinical usefulness, we performed a decision curve analysis for all 6 models plotting net benefit (NB) across a range of decision probability thresholds [37,38]. NB is defined as the number of true-positive classifications penalized for false-positive classifications [39]. The models have the potential to improve clinical decision-making when they have higher NB than 2 baseline strategies: label all as high risk for developing depression and label none as high risk for developing depression.

Sensitivity Analysis

Sensitivity analyses were performed on the best-performing model to evaluate the impact of modeling choices on model outcomes. Additional models considered different prediction windows (45 days, 2 months, 3 months, and 6 months after the start of cancer treatment). Moreover, patients dying within these prediction windows are a potential competing risk for patients at risk for depression. We therefore removed these patients from the train and test data and repeated the analyses. Variants of outcome definitions such as predicting a prescription of

antidepressant medication and a referral to a psychiatrist, psychologist, or social worker within 1 month of cancer treatment ("antidepressant medication" and "mental health referral" in Multimedia Appendix 1) were considered. These definitions were chosen as they might indicate a patient experiencing depression without being officially diagnosed. We also trained a model on the combined outcome of either receiving a depression diagnosis, antidepressant medication prescription, or referral to a psychiatrist, psychologist, or social worker.

Fairness Analysis and Including Race and Ethnicity

To identify potential fairness issues for specific demographic groups, AUROC, calibration slope, and intercept were compared across sex and race and ethnicity groups [40]. In addition, race and ethnicity was added as a confounder to assess its effect on subgroup model performance.

Software, Data, and Reporting

All analyses were performed in Python 3.9.7 (Python Software Foundation). Code is available in a git repository [41]. We followed the MINIMAR reporting guidelines (see Multimedia Appendix 2) [42].

Results

Descriptive Statistics

A total of 16,159 patients starting cancer treatment between 2008 and 2021 were included in the analyses, of whom 437 (2.7%) received a diagnosis of depression within 1 month of cancer treatment (Table 1 and Figure 1). The 437 patients receiving a depression diagnosis within 1 month of treatment were, on average, younger, more likely to be female, more likely to be non-Hispanic White, and less likely to be non-Hispanic Asian (Table 1). Moreover, patients with a depression diagnosis made more emergency department visits (Table 1). They were also more likely to have received a previous depression diagnosis more than a year before the start of treatment, a prescription for antidepressant medication, and a mental health referral.

Patients who sent emails (4816/16,159, 29.8%) were more likely to be non-Hispanic White or Asian and be privately insured (Table S4 in Multimedia Appendix 2). On average, they were less likely to be hospitalized but made more emergency department visits 1 month prior to treatment and had a higher Charlson comorbidity score; they were also more likely to have previously received a depression diagnosis, antidepressant medication, and a mental health referral.

Table 1. Descriptive statistics of the cancer cohort.

Descriptive statistics	All (N=16,159)	No depression diagnosis within 1 month after onset of treatment (n=15,722, 97.3%)	Depression diagnosis within 1 month after onset of treatment (n=437, 2.7%)

History of mental health referral	2707 (16.8)	2563 (16.3)[a]	144 (33)[a]

[a]This was tested at the 5% significance level.

Performance Statistics

The best-performing ML models were based on LASSO logistic regression (Table 2; Tables S1 and S3 in Multimedia Appendix 2). The model based on structured data alone had an AUROC of 0.74 (95% CI 0.71-0.78). The combination of structured data with email classification scores also had an AUROC of 0.74 (95% CI 0.71-0.78), while a model based solely on email classification scores had an AUROC of 0.54 (95% CI 0.52-0.56). At a high level of sensitivity (0.9 at a decision threshold of 1%; Table 3), the PPV of the best-performing model based on structured data was low (0.04; Table 3). At higher decision thresholds (3% and 10%; Table 3), the PPV was increased to 0.07 and 0.17, respectively, but this came at a cost of sensitivity (0.63 and 0.19).

The BERT model based on the clinician notes performed worst and had an AUROC of 0.50 (95% CI 0.49-0.52; Table 2). Combining structured EHR data with clinician notes did improve AUROC performance (0.71, 95% CI 0.68-0.75; Table 2) and so did adding email classification scores (0.70, 95% CI 0.67-0.73; Table 2).

Calibration was acceptable for all ML models. The BERT-based models tended to produce overly extreme risk estimates even after recalibration.

The decision curve analysis showed a small range of decision thresholds for which the best-performing model (LASSO logistic regression based on structured data) had higher NB than the treat all or treat no one strategies (Figure 2). At a decision threshold of 3%, the model with structured EHR data had a NB of 0.01. This represents a net increase of 1 true positive patient at risk for depression per 100 patients without increasing any false positives (at the start of treatment). At a threshold of 10%, the model had a NB of only 0.002, so 2 net true positives per 1000 patients.

Table 2. Discrimination and calibration for predicting depression risk within 1 month after the onset of treatment (test data).

Type of data	AUROC[a] (95% CI)	Calibration intercept (95% CI)	Calibration slope (95% CI)
Structured EHR[b] data	0.74 (0.71 to 0.78)	0.07 (–0.09 to 0.24)	0.93 (0.77 to 1.09)
Patient emails	0.54 (0.52 to 0.56)	–0.02 (–0.18 to 0.14)	1.0 (0.52 to 1.48)
Structured EHR data and patient emails	0.74 (0.71 to 0.78)	0.07 (–0.09 to 0.24)	0.91 (0.76 to 1.07)
Clinician notes	0.5 (0.49 to 0.52)	–0.05 (–0.21 to 0.11)	0.94 (–1.32 to 3.2)
Structured EHR data and clinician notes	0.71 (0.68 to 0.75)	–0.09 (–0.25 to 0.07)	1.92 (1.57 to 2.28)
Structured EHR data, clinician notes, and patient emails	0.7 (0.67 to 0.73)	–0.16 (–0.32 to –0.0)	2.46 (1.98 to 2.93)

Sensitivity Analysis

The models predicting depression risk within 45 days (AUROC 0.73, 95% CI 0.69-0.76), 2 months (AUROC 0.73, 95% CI 0.70-0.76), 3 months (AUROC 0.73, 95% CI 0.71-0.76), and 6 months (AUROC 0.72, 95% CI 0.70-0.74) of cancer treatment obtained similar discrimination and calibration compared to the base model predicting depression risk within 1 month (LASSO logistic regression; Table S5 in Multimedia Appendix 2). In the test data, a total of 24 (0.4%) patients died within 1 month after starting treatment. Omitting patients dying within the time frames of interest (1 month-6 months) had no impact on model performance (Table S6 in Multimedia Appendix 2). The model trained to predict depression medication (LASSO logistic regression) also obtained similar discrimination (0.75, 95% CI 0.73-0.78; Table S7 in Multimedia Appendix 2) and calibration compared to the base model predicting depression risk via depression diagnosis. The model trained to predict a referral to a psychiatrist, psychologist, or social worker obtained a lower AUROC of 0.62 (95% CI 0.60-0.64; Table S7 in Multimedia Appendix 2) and comparable calibration.

Fairness Analysis and Including Race and Ethnicity

The fairness analysis showed that model discrimination was similar for male patients (AUROC 0.73, 95% CI 0.67-0.80; Table S8 in Multimedia Appendix 2) and female patients (AUROC 0.74, 95% CI 0.70-0.78; Table S8 in Multimedia Appendix 2). The calibration plot showed that depression risk was underestimated for female patients and overestimated for male patients (Figure S1 in Multimedia Appendix 2). Discrimination was best for the non-Hispanic Black patients (AUROC 0.92, 95% CI 0.84-0.99; Table S8 in Multimedia Appendix 2), with respect to the non-Hispanic White patients (AUROC 0.74, 95% CI 0.69-0.78; Table S8 in Multimedia Appendix 2) and the non-Hispanic Asian patients (AUROC 0.75, 95% CI 0.63-0.87; Table S8 in Multimedia Appendix 2), and it was worst for Hispanic patients (AUROC 0.71, 95% CI 0.62-0.80; Table S8 in Multimedia Appendix 2). Predictions were underestimated for the non-Hispanic Black patients and overestimated for the non-Hispanic Asian patients (Figure S1 in Multimedia Appendix 2). Adding race and ethnicity as a feature to the best-performing model did not improve model discrimination or calibration (AUROC 0.74, 95% CI 0.71-0.78 vs 0.74, 95% CI 0.70-0.77; Table S9 in Multimedia Appendix 2).

Discussion

Principal Findings

This study developed a prediction model to identify patients with cancer at risk for depression within 1 month of chemo- or radiotherapy treatment. We used data from a large comprehensive cancer center with over 16,000 patients. The best-performing models (LASSO logistic regression with structured data with or without patient email classification scores) had reasonable AUROC and calibration. The LASSO logistic regression model with structured data demonstrates a small improvement in NB over the baseline strategy of labeling no one as at risk for depression. Multimodal BERT models (trained on structured data and unstructured text) did not perform better than the best-performing ML model trained solely on structured data.

To date, depression in patients with cancer is underdiagnosed, and studies show that patients with depression are up to 3 times more likely to be noncompliant with medical treatment recommendations [3,43,44]. Treatment adherence is a high priority, given the evidence demonstrating statistically significant associations between treatment nonadherence and patient outcomes, including cancer progression, low-value health care use, and worse survival [45-48]. Therefore, an AI model—which flags patients at risk for depression with minimal clinical input and workflow disruption—is needed at the point of care to prompt clinicians to intervene early and improve patient well-being and anticancer outcomes.

This model may be used in preparation for clinical consultations to more efficiently use the limited time allotted to oncologist-patient interaction to facilitate any needed additional mental health support. By harnessing a combination of structured EHR data and unstructured text data from patient emails and clinician notes, the tool can offer a comprehensive assessment of a patient's depression risk and help synthesize this information at point of care for the provider. With the ability to establish personalized risk assessments, determine clinical use thresholds, and address potential biases in risk assessment, a clinical decision support tool developed from this work has the potential to significantly enhance the quality of care and mental health outcomes for these vulnerable patients. As the study recognizes the need for ongoing validation, refinement, and bias mitigation, it underscores the dynamic and adaptable nature of this tool in improving cancer care and treatment adherence. This tool can be a valuable addition to the health care system, ultimately improving mental health outcomes and treatment adherence for these vulnerable patients.

The created model has good performance, although our label (receiving a depression diagnosis) depends heavily upon the accurate recognition of depression by the care team. The model's clinical usefulness depends on the acceptability of the test trade-off. The best-performing model had a high false-positive rate at high levels of sensitivity, and the decision curve analysis showed a test trade-off of 100 assessments for 1 additional true positive patient at a decision threshold of 3%. If these assessments can be done nearly for free (eg, a quick check during a patient visit) and if we already miss all future depressions, then this small improvement may be welcome, although this warrants further validation and testing in the clinical environment. The high false-positive rate and small NB of the best-performing model are likely affected by the moderate discrimination and low event rate [49]. In future developments, the NB may be increased by focusing on improving the labeling of the outcome variable. In addition, richer input data not available to us at the time of analysis could improve model discrimination, like information on lifestyle habits, self-reported mental health assessments, and clinical and pathological factors.

As depression presents differently across sex, race, and ethnicity [50-52], algorithmic fairness forms an important concern when predicting depression risk. We found discrepant model calibration across race, ethnicity, and sex even when controlling

for race, ethnicity, and sex in the model. These results align with previous findings that showed poor calibration for minority groups [53,54] and stress the importance of algorithmic fairness assessment in the depression domain. The differences in calibration may be caused by different (recorded) depression rates among groups. This could result in a disproportionate number of missed patients in need of additional mental health resources in specific groups. For example, female and non-Hispanic Black patients might consistently receive a lower predicted risk score than their actual risk. A next step could be to apply bias mitigation techniques for in- or postprocessing during model development, like threshold selection and recalibration within specific groups [55]. Moreover, more diverse data may be collected to adequately capture the differences in symptomatology between different groups. For example, we may include appetite disturbances that are reported more by women and comorbid alcohol and substance abuse that are reported more by men [50].

We also found discrepant model discrimination across race and ethnicity, with the highest AUROC for the non-Hispanic Black group. These findings diverge from the literature, where the AUROC of the minority groups is usually lower compared to the majority group [56]. However, caution is needed when interpreting this finding, due to the very low number of positive cases in this group (less than 20). More data should be collected to better investigate these differences.

The models based solely on text information (patient emails and clinician notes) performed on par with a random coin toss. This implies that the signal-to-noise ratio in this type of data may be too low to be of prognostic value for this specific use case. This might be particularly true for patient emails, where the frequency of the emails varied widely between patients. However, it is important to note that unstructured text, such as patient emails and clinician notes, can potentially provide valuable information that is not captured in structured data. Therefore, multimodal models that incorporate both structured and unstructured data have the potential to improve clinical predictions. Increasing and regularizing the frequency of digital contact between patient and clinician may aid future research on multimodal models in this field, for example, through digital systems for monitoring patient-reported outcomes [57,58]. Digital communication with the aid of chat robots such as ChatGPT [59] provides further direction to better capture patients' mental health status. This finding also implies that structured data contains strong predictors for depression risk, for example, a history of depression or mental illness, which is well established in the literature and should be considered for future model developments [60-62].

Limitations

This study had limitations. First, we used the ICD codes for depression diagnosis as indicators of depression risk. This provided a clear and detectable label for our outcome event in the EHR. However, not all patients experiencing depression will receive a coded depression diagnosis with a related ICD code as underdiagnosis is a common problem [3,9]. It is possible that depression may have been diagnosed elsewhere and not recorded in our EHR, that depressive symptoms may have existed and not been recorded or ignored by the oncology-focused clinicians, or that the patient did not express their depressive symptoms to their oncology-focused clinician. In addition, some inconsistencies persisted between the ICD-9 and ICD-10 codes, with the ICD-10 codes including depression associated with bipolar disorder. This may have compromised the accuracy of our predictive models in this exploratory study and should be considered for future research.

Moreover, changing the outcome of interest to either antidepressant medication or a referral to a psychiatrist, psychologist, or social worker did not change the accuracy of the predictive models. An explanation might be that patients with depression are often treated with antidepressants by primary care doctors. For antidepressant medication, it is important to note that there may have been overascertainment as this medication is also used to treat more severe and chronic forms of anxiety. This should be considered when interpreting our results and warrants further study.

Second, the modeling approach was focused on a point-of-care solution, meaning we used clinically meaningful end points (eg, 1 month after starting cancer treatment) and used a diverse patient population. Although this provides the potential for broad application across multiple cancer types, the diversity in cancer types and cancer stages might have introduced noise and impacted model performance.

Third, we used cut-off values for clinician notes that were too short or too long to keep the modeling computationally feasible. This may have led to information loss. Future research may investigate ways of retaining this information when preprocessing texts. Finally, we used data from a single integrated health system for model development, albeit comprised of 3 sites (academic hospital, community hospital, and community practice network). As the cultural background of patients and some data are specific to this health system, our results may not generalize to other populations. Further validation on data sets with different demographics and examination of the mechanisms driving potential biases are needed.

Conclusions

This study demonstrated the potential and limitations of using structured and unstructured text data for predicting depression risk in patients with cancer using a variety of ML and multimodal models. After further validation and mitigating biases across subgroups, these models have the potential to improve patient outcomes by alerting clinicians of the possible need to escalate support among this vulnerable patient population. Future studies might improve the prediction of depression risk in patients with cancer by refining the outcome label, expanding the predictors related to mental health, and devoting part of the digital patient communication to mental health aspects.

Acknowledgments

We like to thank Max Schuessler, Vaibhavi Shah, and Angelo Capodici for their help with the annotations of patient emails. Our special thanks go to Dr David Spiegel for reviewing this article for psychiatric relevance and accuracy. This work was funded by the Leids Universiteits Fonds/Slingelands Fonds, the Prins Bernhard Cultuurfonds or Crone-Haver Droeze Fonds, and Fonds Dr Catharine van Tussenbroek. These funders played no role in study design, data collection, analysis, and interpretation of data, or writing the manuscript.

Data Availability

The data sets generated and analyzed during this study are not publicly available due to the protected nature of the patient data. Requests to access these data sets should be directed to boussard@stanford.edu.

Authors' Contributions

AdH, MvB, and THB were responsible for the conceptualization and design of the study. AdH performed the data extraction. AdH and CF performed the data analysis. MR and DB provided clinical advice and recommendations on usability and clinical relevance. AdH drafted the original manuscript. All authors had full access to all the data, critically analyzed, reviewed, contributed, and approved the final manuscript.

Conflicts of Interest

DB reports institutional research funding from BeyondSpring, leadership roles or stock ownership in Artelo and Madora, and personal fees from G1 Therapeutics, Bristol Myers Squibb, Merck & Co Inc, and Eli Lilly and Company all outside the submitted work. THB is a board member and stockholder of Athelo Health, a stockholder at Verantos, Inc, and a consultant for Grai-Matter outside the submitted work. The other authors declare no competing interests.

Abstract

Background: Infants born at extremely preterm gestational ages are typically admitted to the neonatal intensive care unit (NICU) after initial resuscitation. The subsequent hospital course can be highly variable, and despite counseling aided by available risk calculators, there are significant challenges with shared decision-making regarding life support and transition to end-of-life care. Improving predictive models can help providers and families navigate these unique challenges.

Objective: Machine learning methods have previously demonstrated added predictive value for determining intensive care unit outcomes, and their use allows consideration of a greater number of factors that potentially influence newborn outcomes, such as maternal characteristics. Machine learning–based models were analyzed for their ability to predict the survival of extremely preterm neonates at initial admission.

Methods: Maternal and newborn information was extracted from the health records of infants born between 23 and 29 weeks of gestation in the Medical Information Mart for Intensive Care III (MIMIC-III) critical care database. Applicable machine learning models predicting survival during the initial NICU admission were developed and compared. The same type of model was also examined using only features that would be available prepartum for the purpose of survival prediction prior to an anticipated preterm birth. Features most correlated with the predicted outcome were determined when possible for each model.

Results: Of included patients, 37 of 459 (8.1%) expired. The resulting random forest model showed higher predictive performance than the frequently used Score for Neonatal Acute Physiology With Perinatal Extension II (SNAPPE-II) NICU model when considering extremely preterm infants of very low birth weight. Several other machine learning models were found to have good performance but did not show a statistically significant difference from previously available models in this study. Feature importance varied by model, and those of greater importance included gestational age; birth weight; initial oxygenation level; elements of the APGAR (appearance, pulse, grimace, activity, and respiration) score; and amount of blood pressure support. Important prepartum features also included maternal age, steroid administration, and the presence of pregnancy complications.

Conclusions: Machine learning methods have the potential to provide robust prediction of survival in the context of extremely preterm births and allow for consideration of additional factors such as maternal clinical and socioeconomic information. Evaluation of larger, more diverse data sets may provide additional clarity on comparative performance.

Introduction

Preterm birth has long been a leading cause of infant mortality, with the lowest gestational age births associated with the highest rates of mortality [1]. In 2019, 59,506 infants were born at 31 weeks or less in the United States, and the infant mortality rate in this cohort was 18% [2]. When a patient is expected to deliver an extremely preterm infant, counseling on possible outcomes, methods of resuscitation, and anticipated course in the neonatal intensive care unit (NICU) ideally begins prior to birth. Many providers have used the National Institute of Child Health and Human Development (NICHD) risk calculator to initiate this discussion on the chances of infant mortality and severe morbidity after birth. The calculator is based on a logistic regression model using 5 prepartum factors (gestational age, estimated weight, sex, antenatal steroids, and multiple birth), derived from the preterm birth data of a network of US hospitals. With advances in NICU care and more knowledge about long-term outcomes, the calculator was updated in 2020 and maintains a similar performance (mean 0.744, SD 0.005) [3,4]. After initial resuscitation, several scoring systems are also available to predict mortality after a neonate arrives in the NICU [5-7]. However, they are less predictive with extremely low birth weight infants, as evidenced by the Score for Neonatal Acute Physiology With Perinatal Extension II (SNAPPE-II) survival model having a mean performance of 0.78 (SD 0.01) for infants weighing less than 1500 g at birth versus 0.91 (SD 0.01) overall. On review of several models, Clinical Risk Index for Babies (CRIB) had the highest performance in predicting very low birth weight neonate survival, with a mean of 0.88 (SD 0.02), although the CRIB and SNAPPE models were developed with data from geographically separate populations (Europe vs North America) [8].

Despite counseling supported by available risk calculators, decisions surrounding the continuation of life support and redirection to end-of-life care remain extremely difficult in the context of birth at the periviable preterm gestational ages because the postnatal course can be highly variable [9-11]. In addition, perceptions regarding the clinical situation can differ among providers and family members, and consideration of clinical and social context may be helpful [12,13].

Numerous machine learning models have been tested to improve the prediction of adult intensive care unit outcomes. The Medical Information Mart for Intensive Care III (MIMIC-III) database, which contains electronic health record (EHR) information of critical care patients at the Beth Israel Deaconess Medical Center from 2001 to 2012, has often been a source of data used in their development and testing [14-17]. Using the NICU data from MIMIC-III, this study builds and compares different types of machine learning algorithms that predict neonatal mortality and examines the value of incorporating features representing both structured and unstructured clinical elements for extremely preterm infants.

Methods

Ethical Considerations

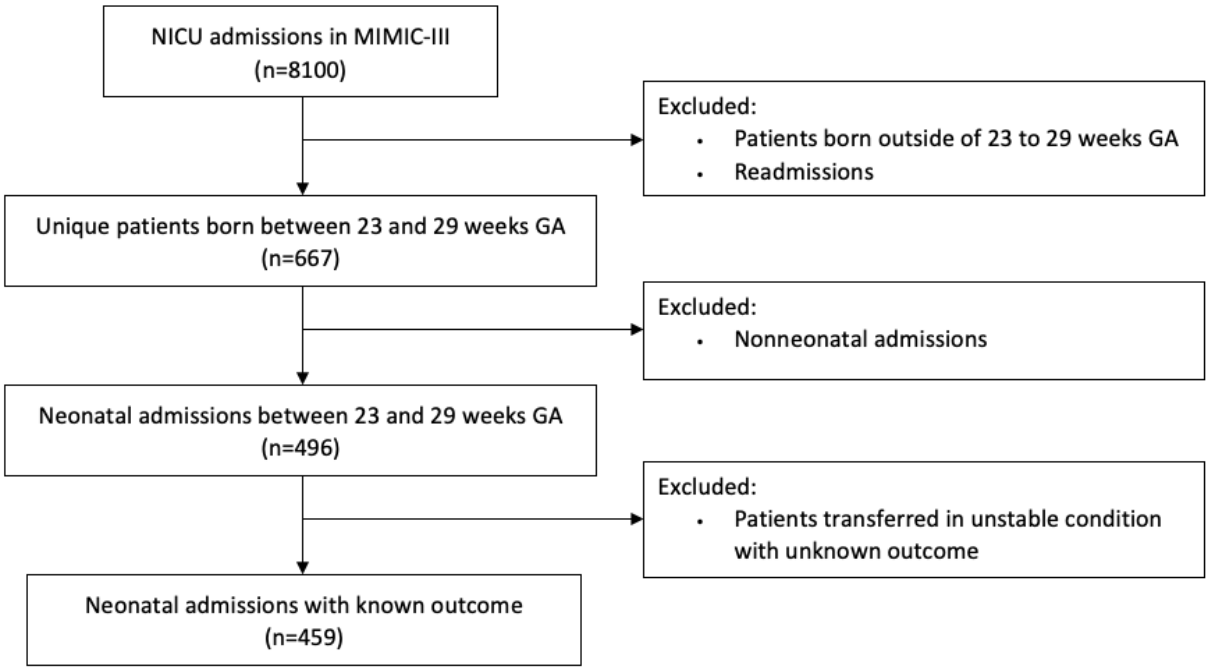
The institutional review board of the University at Buffalo determined the study (ID STUDY00003721) to be exempt as a secondary analysis of a publicly available data set. A data use agreement was obtained for the MIMIC-III database, which contains deidentified protected health information freely available for secondary analysis. The primary data collection for MIMIC-III was originally approved by the institutional review boards of Beth Israel Deaconess Medical Center and Massachusetts Institute of Technology with a waiver of individual patient consent, and no compensation was provided at that time.

Data Selection

Records of extremely preterm neonates admitted to the NICU in the MIMIC-III database were extracted using PostgreSQL (The PostgreSQL Global Development Group). A query was performed for admissions with *ICD-9* (*International Classification of Diseases, Ninth Revision*) codes corresponding to extremely preterm delivery less than 30 weeks as well as very low birth weight. From the resulting records, those of neonates born outside of 23 to 29 weeks were excluded, as well as duplicate records and readmissions. Some records corresponded to nonneonatal admissions, for example, where an infant had a prior history of preterm birth, and they were excluded. When the remaining records were reviewed, it was found that some neonates were transferred outside of the hospital for surgery and had an unknown outcome. These records were also excluded (Figure 1).

From the 459 neonatal admission records that were selected, the patients' demographics, vital signs, laboratory results, medications, procedures, and clinical text were queried from the database and reviewed. Of the available information, relevant elements were extracted based on factors found to be pertinent in previous scoring systems and expert knowledge. By manually curating the clinical text, including completed admission and discharge notes, we were able to incorporate features found only in unstructured form, including maternal clinical comorbidities and pregnancy complications. For this study, consideration of neonatal assessment and treatment was limited to data found initially at the time of NICU admission. The nonnumerical elements were encoded. Data that varied by clinical severity were encoded in that order, and the remaining categorical data underwent binary encoding. Median imputation was used to complete missing data.

Figure 1. Flowchart of selection criteria. GA: gestational age; MIMIC-III: Medical Information Mart for Intensive Care III; NICU: neonatal intensive care unit.



Ultimately, 83 features that could be used in machine learning algorithms were generated, of which approximately half represented maternal clinical and demographic information, with the remaining features representing infant findings at the time of admission (Multimedia Appendix 1).

Model Analysis

Several machine learning classification algorithms were implemented using Python 3.8 scikit-learn 1.2, and the resulting models were tested for their efficacy in predicting mortality. The same algorithms were also examined considering only prepartum features, assuming birth weight would be an estimated weight, to produce models that could be of assistance for clinicians counseling patients prior to an extremely preterm birth.

The performance of each model was endeavored to be optimized. To ensure that feature value range did not drive performance, standard scaling as well as min-max scaling were applied to quantitative features and used for models that were dependent upon distance calculations (eg, logistic regression, neural network, and support vector machine [SVM]). The final reported models used standard scaling due to improved performance over min-max scaling. Scaling was not performed for models invariant to monotonic transformations, such as random forest [18]. For the decision tree–based models, the hyperparameters of number of trees and maximum depth were adjusted. Number of trees began at 50 estimators and was increased by 50 until performance plateaued, which was at 250 trees with a maximum depth of 6 for the random forest method and 350 trees with a maximum depth of 5 for AdaBoost. The k value in the k-nearest neighbor algorithm was adjusted from the default value of 3 up to 20 (approximating the square root of the number of samples), and performance peaked at 4 in the final model. Because of the expected relatively small and imbalanced class sizes (8.1% in the minority class), a held-out test set was not used, and 10-fold stratified cross-validation with an 80:20 training and testing ratio was performed to ensure similar ratios across folds [19]. Mean performance metrics for F_1-score, area under the receiver operating characteristic (AUROC), and average precision are reported, as well as log loss and Brier score, where a smaller value is ideal when considering imbalanced classification.

Features most correlated with the predicted outcome were determined for the higher-performing methods. For the logistic regression model, coefficients most positively and negatively associated with mortality could be determined. For the remaining machine learning models, the most influential features were either directly queried using an available scikit-learn method or through the calculation of feature permutation importance.

Results

Of the included neonatal patients, 37 of 459 (8.1%) expired during the admission period after birth. The average length of stay for infants who survived after initial admission was 62.5 (SD 37.3) days. The average gestational age of the neonates at birth was 27 (SD 1.67) weeks, and 236 (51.4%) were male versus 223 (48.6%) female. Birth weights ranged from 365 to 2165 g, with the average birth weight being 1016 (SD 278) g, and 441 neonates were considered to have a very low birth weight (<1500 g). The average maternal age was 31.4 (SD 6.02) years. In terms of race and ethnicity, the majority of the included infants were in a category considered to be White (n=278, 60.1%), followed by Black (n=69, 15%), unknown (n=42, 9.2%), other (n=25, 5.4%), Hispanic (n=25, 5.4%), Asian (n=16, 3.5%), and Native American (n=4, 0.9%; Table 1).

Logistic regression, Naïve Bayes, k-nearest neighbor, SVM, random forest, AdaBoost, and neural network classifiers were compared for efficacy in predicting mortality (Figure 2 and Table 2). Standard scaling transformation improved performance only for the logistic regression, SVM, and neural network methods. The random forest model had the highest predictive

performance when considering overall AUROC (mean 0.91, SD 0.07), F_1-score (0.67), and Brier score (0.06). The AdaBoost model had the next highest AUROC (mean 0.88, SD 0.10); however, the F_1-score (0.45) was low due to poor precision. On the other hand, the neural network model yielded the top F_1-score (0.67) and Brier score (0.05) despite having a lower AUROC (mean 0.84, SD 0.16). SVM was overall next best performing model (mean 0.86, SD 0.13; F_1-score 0.62; Brier score 0.06), followed by logistic regression (mean 0.82, SD 0.16; F_1-score 0.61; Brier score 0.08). The Naïve Bayes (mean 0.74, SD 0.22; F_1-score 0.40; Brier score 0.25) and k-nearest neighbor (mean 0.64, SD 0.13; F_1-score 0.34; Brier score 0.07) methods were the worst performing.

Figure 2. Receiver operating characteristic curves for the highest-performing models in Table 2. A: Logistic regression; B: SVM (support vector machine); C: Random forest; D: AdaBoost; E: Neural networks, F: Naïve Bayes; AUROC: area under the receiver operating characteristic; FP: false positive; TP: true positive.

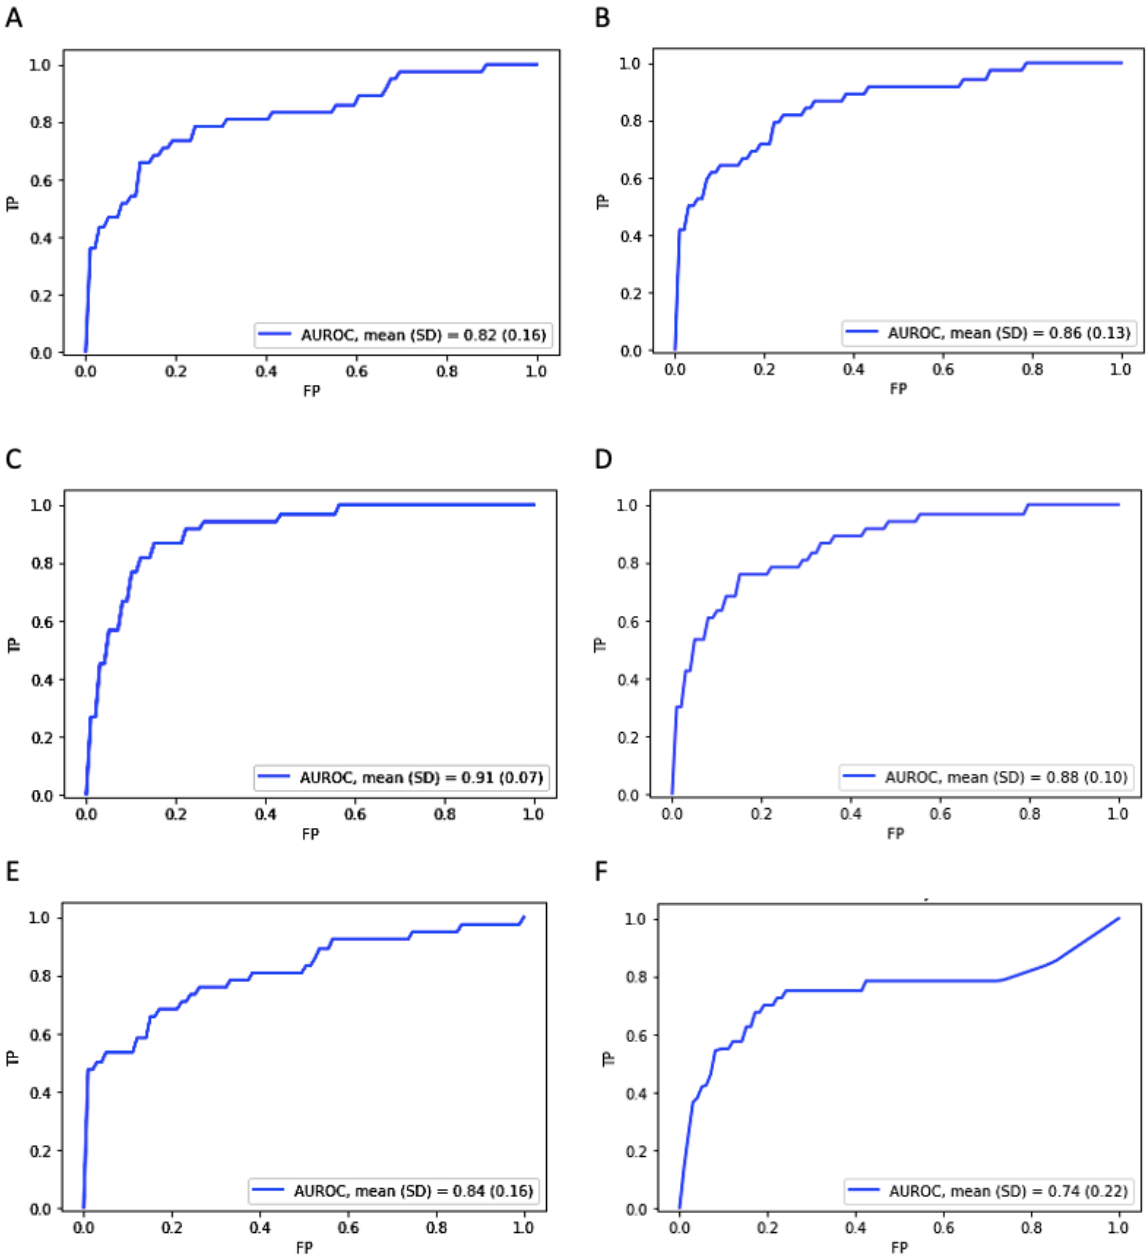

Table 2. AUROC[a], average precision, F1-score, log loss, and Brier scores for 10-fold stratified cross-validation predicting mortality using initial neonatal intensive care unit admission features (lower log loss and Brier scores are ideal when considering imbalanced classification).

Method	AUROC, mean (SD)	Precision, mean (SD)	F_1-score	Log loss score	Brier score
Logistic regression	0.82 (0.16)	0.55 (0.25)	0.61	0.35	0.08
SVM[b]	0.86 (0.13)	0.61 (0.24)	0.62	0.20	0.06
Random forest	0.91 (0.07)	0.61 (0.22)	0.67	0.19	0.06
AdaBoost	0.88 (0.10)	0.55 (0.25)	0.45	0.80	0.07
Neural network	0.84 (0.16)	0.65 (0.24)	0.67	0.30	0.05
Naïve Bayes	0.74 (0.22)	0.39 (0.17)	0.40	3.90	0.25
K-nearest neighbor	0.64 (0.13)	0.24 (0.16)	0.34	1.74	0.07

[a]AUROC: area under the receiver operating characteristic.

[b]SVM: support vector machine.

On post hoc chi-square analysis of the categorical variables, the factors that most influenced the outcome were insurance status, initial breathing assessment of the infant, and presence of a serious fetal anomaly (Table 3). When examining Pearson correlation of continuous variables, higher levels of ventilation and blood pressure support as well as higher arterial blood gas base deficit were properties mildly to moderately correlated with mortality. Larger gestational age, birth weight, and higher APGAR (appearance, pulse, grimace, activity, and respiration) scores at birth negatively correlated with mortality to a similar degree (Table 4).

Similar features were most strongly associated with outcome in the machine learning–based models, although they varied in importance (Table 5). For example, in the random forest model, gestational age, birth weight, and initial oxygen level were of higher importance, whereas in the neural network model, initial blood pressure support and activity level were the most influential features.

Evaluation of classifiers using only prepartum features, assuming birth weight as the estimated weight, also yielded the highest performance measures with the random forest method (Table 6). The random forest features that were consistently of highest importance included gestational age, weight, and maternal age (Table 7).

Table 3. Chi-square: categorical features significantly associated with outcome.

Feature	Description	Chi-square (*df*)
un_ins	Uninsured	22.8 (1)
breathing1	Initial breathing assessment	21.4 (2)
anomaly	Serious fetal anomaly	20.8 (1)
airway1	Initial type of airway or ventilation	17.1 (4)

[b]SVM: support vector machine.

Several of the important features found in the top-performing models were among those manually curated in unstructured form, including the presence of maternal hypertensive disease and diabetes, uncertain pregnancy dating (uncertain), fetal anomaly (anomaly), and twin-twin transfusion syndrome.

Discussion

Principal Findings

There is a potential for existing risk calculators to be outperformed by tree-based machine learning algorithms, as indicated by the higher performance of our random forest model versus SNAPPE-II in the context of extremely premature or very low birth weight infants (in fact AUROC increased to mean 0.92, SD 0.05 when only the neonates <1500 g were considered in the random forest model to directly compare to SNAPPE-II). Performance difference compared with CRIB is inconclusive, however. In terms of estimating neonatal mortality prior to preterm birth, although the point estimates of several of the machine learning algorithms using additional features extracted from the EHR were higher than that of the NICHD calculator, overlapping CIs preclude any conclusion about significant differences in performance.

Comparison to Prior Work

Examination of prior work further points to the importance of using data available from the EHR, including unstructured health data. For example, the relatively high-performing CRIB score includes the presence of fetal malformation as a variable. Saria et al [20] incorporated signal processing of short-term time series data from neonatal vital sign sensors to produce a model classifying infants at high risk for severe morbidity or mortality. To maintain accuracy over time, Meadow et al [11] proposed a longitudinal NICU survival model combining adverse events, imaging report information, and caretaker intuition. Hamilton et al [21] more recently applied tree-based machine learning in the context of preterm birth to determine clusters of pregnancy characteristics that were at the highest risk for severe neonatal morbidity or mortality.

Strengths and Limitations

This study is limited by a small data set with data from a single institution, which in turn limits the ability to establish statistical significance in performance differences and the variety of machine learning methods that can be examined. Because of the retrospective nature of the study, there is less control over the format of the data and the amount of missing data. Although a single-institution data set is usually considered a limitation, Rysavy et al [4] emphasized that extremely preterm neonatal outcomes are significantly influenced by the hospital of birth and suggested maintaining ongoing and updated prediction models from outcomes within hospital systems. Using machine learning would be ideal for this task, allowing for consideration of a number of features retrievable from the EHR with a high tolerance for missing or outlier data as the volume of data increases. Tree-based machine learning algorithms may be additionally advantageous due to their ability to iteratively combine numerous weakly predictive features into stronger predictors.

Knowledge of the most influential features, which was possible to visualize in the majority of the presented models, provides transparency. Understanding which factors contribute most to the prediction of outcomes in a model can help clinical providers derive greater intuition regarding how applicable the model is to a particular patient.

The inclusion of maternal information and pregnancy characteristics found in unstructured form in the MIMIC-III database allowed for consideration of factors beyond the numerical neonatal data. Some of these additional variables, such as the presence of fetal anomalies or twin-twin transfusion syndrome, were found to be of high importance in several top-performing models, especially in those used in the prepartum period prior to an anticipated extremely preterm delivery. This illustrates that machine learning–based models could potentially be helpful for continuity of care, starting in the prepartum timeframe with ongoing predictive ability after birth. Maternal demographic information had an influence on mortality prediction in some of the higher-performing models but not others. Although demographic data can provide additional knowledge of social context, unintended bias can also be introduced into the resulting model [22].

Future Directions

Future work anticipates further evaluation of these methods on larger, more diverse data sets to determine if there is a significant and reproducible performance advantage. Expanding the study to include additional data would also allow the evaluation of more powerful machine learning methods such as deep learning methods. Eventually, the maintenance of a more representative and up-to-date cohort for training could potentially be accomplished via collaborative or federated learning techniques across institutions [22,23]. To address the possibility of algorithmic bias, further work could include a comparison of prediction results using models with and without protected demographic features and a calculation of the level of discrimination that could result. Assessment of more data from underrepresented groups may also aid in producing increasingly accurate and less discriminatory models [24,25].

In this study, unstructured information was manually extracted from admission and discharge notes in the MIMIC-III database and allowed for consideration of additional relevant features in our models. This suggests that the use of natural language processing to better understand clinical context may further improve the prediction of outcomes of extremely preterm births. As automated natural language processing of clinical notes becomes more mature and prevalent, the use of these features gleaned from unstructured EHR data will be increasingly applicable [26].

Additional potential future directions include integrating with or adding functionalities found in other intensive care unit models, such as time series modeling, and predicting outcomes other than mortality, such as the development of comorbidities, discharge location, length of stay, and likelihood of readmission.

Conclusions

This study examined machine learning models produced from the MIMIC-III NICU data set and their predictive ability in the

clinically challenging situation of extremely preterm birth. The tree-based random forest model was found to have higher performance than the SNAPPE-II model when predicting the survival of extremely preterm infants of very low birth weight. Several other models, including those using only features that would be known prepartum, also appeared to have good predictive performance but failed to show a statistically significant difference from prior models. Features of highest importance in these models were explored and included traditional variables, such as gestational age and birth weight, but also information that may be found in unstructured form in the EHR. Evaluation of these and even more advanced machine learning methods on larger data sets may offer further clarity about performance differences, and natural language processing techniques would allow for greater use of unstructured clinical information.

Abstract

Background: Medical image analysis, particularly in the context of visual question answering (VQA) and image captioning, is crucial for accurate diagnosis and educational purposes.

Objective: Our study aims to introduce BioMedBLIP models, fine-tuned for VQA tasks using specialized medical data sets such as Radiology Objects in Context and Medical Information Mart for Intensive Care-Chest X-ray, and evaluate their performance in comparison to the state of the art (SOTA) original Bootstrapping Language-Image Pretraining (BLIP) model.

Methods: We present 9 versions of BioMedBLIP across 3 downstream tasks in various data sets. The models are trained on a varying number of epochs. The findings indicate the strong overall performance of our models. We proposed BioMedBLIP for the VQA generation model, VQA classification model, and BioMedBLIP image caption model. We conducted pretraining in BLIP using medical data sets, producing an adapted BLIP model tailored for medical applications.

Results: In VQA generation tasks, BioMedBLIP models outperformed the SOTA on the Semantically-Labeled Knowledge-Enhanced (SLAKE) data set, VQA in Radiology (VQA-RAD), and Image Cross-Language Evaluation Forum data sets. In VQA classification, our models consistently surpassed the SOTA on the SLAKE data set. Our models also showed competitive performance on the VQA-RAD and PathVQA data sets. Similarly, in image captioning tasks, our model beat the SOTA, suggesting the importance of pretraining with medical data sets. Overall, in 20 different data sets and task combinations, our BioMedBLIP excelled in 15 (75%) out of 20 tasks. BioMedBLIP represents a new SOTA in 15 (75%) out of 20 tasks, and our responses were rated higher in all 20 tasks (P<.005) in comparison to SOTA models.

Conclusions: Our BioMedBLIP models show promising performance and suggest that incorporating medical knowledge through pretraining with domain-specific medical data sets helps models achieve higher performance. Our models thus demonstrate their potential to advance medical image analysis, impacting diagnosis, medical education, and research. However, data quality, task-specific variability, computational resources, and ethical considerations should be carefully addressed. In conclusion, our models represent a contribution toward the synergy of artificial intelligence and medicine. We have made BioMedBLIP freely available, which will help in further advancing research in multimodal medical tasks.

Introduction

Background

In recent decades, the fields of data analysis, machine learning, and deep learning have undergone remarkable advancements, with profound implications for various professional domains [1,2]. One of the most promising frontiers for these advancements is medical science, where data-driven models have the potential to bring about significant breakthroughs [3,4]. Medical data predominantly exist in the form of images and textual reports, encompassing x-ray images, medical records, and more. To harness the full potential of these data sources, a visual language model capable of extracting insights from both images and text becomes paramount. Visual language models, which are at the core of this research, represent a fusion of computer vision and natural language processing (NLP). These models possess the capability to understand and generate text-based descriptions for visual content, making them invaluable in contexts where both images and text are essential for comprehensive analysis.

This study explored and adapted visual language models specifically for medical data sets, building upon the foundation laid by existing models. The primary objective was to enhance the performance of these models when confronted with medical data, such as the Radiology Objects in Context (ROCO) [5] and Medical Information Mart for Intensive Care-Chest X-ray (MIMIC-CXR) [6] data sets. This was achieved through a comprehensive process of pretraining on medical data sets and rigorous fine-tuning, with the ultimate goal of determining the optimal model configurations and parameters. This study thus facilitates advancements in health care, contributing to more accurate diagnoses; streamlined medical reporting; and, ultimately, improved patient care. We have made BioMedBLIP models freely available, facilitating the progress of research in diverse medical applications involving multiple modalities [7].

Related Work

In the domain of visual language models and their applications within the medical field, several notable studies and advancements have paved the way for this research project. These works solve different problems within health care analytics and have played critical roles in shaping this study's foundation.

Within the medical domain, image captioning has emerged as a valuable tool that enables health care professionals and researchers to enhance their diagnostic and reporting processes. Image captioning technology allows for the automatic generation of textual descriptions for medical images, such as x-rays, magnetic resonance imaging (MRI) scans, and computed tomography (CT) scans. This capability brings about several significant benefits. First, it aids clinicians in the diagnostic process by providing detailed descriptions of medical images, helping medical professionals to quickly and accurately identify abnormalities or pathologies in the images, thus improving the efficiency and accuracy of diagnoses. Second, image captions serve as a means of clear and standardized communication among health care professionals, reducing the potential for misinterpretation when multiple experts are involved in the diagnostic process. Third, image captions make medical images more accessible to a broader audience, including patients, promoting health literacy and patient engagement. Moreover, in a clinical setting, image captions expedite the process of creating medical reports, improving the overall quality of patient records. They also play a valuable role in medical education and training, aiding in the learning and teaching of medical imaging and diagnostics. Pavlopoulos et al [8] proposed that biomedical image captioning can significantly expedite clinicians' diagnostic processes and presented a comprehensive survey covering various aspects of medical image captioning, including data sets and evaluation measures. Furthermore, the task of the automatic generation of medical image reports, introduced by Jing et al [9], aimed to streamline the reporting process for physicians, enhancing both efficiency and accuracy. To address this, Jing et al [9] used a hierarchical Long Short-Term Memory model, which was tested on 2 publicly available data sets, Indiana University X-Ray [10] and Pathology Education Informational Resource (PEIR)-Gross [9].

This connection between image captioning and medical report generation underscores the practical utility of visual language models in improving health care processes. In addition to these advancements, the field of medical visual question answering (VQA) has gained increasing relevance. Medical VQA tasks involve developing models capable of answering questions related to medical images and bridging the gap between textual queries and visual data. Lin et al [11] introduced various medical data sets and proposed methods to enhance model performance in medical VQA tasks. We used various data sets presented by Lin et al [11] in our experiments. Furthermore, Li et al [12] emphasized the significance of pretraining models on general images to capture meaningful representations of medical data, thus laying the groundwork for our approach. This insight served as our motivation to explore an approach of pretraining models on domain-specific medical data sets, with the aim of achieving enhanced performance for medical VQA (MedVQA) tasks. Notably, Li et al [12] encountered a limitation in their work, as they did not pretrain models using medical data sets. Their decision was influenced by computational resource constraints, and they believed that domain-specific pretraining would be the key to improving model performance in MedVQA tasks. To address this gap in the research landscape, we took the initiative to pretrain our model using medical data sets, thereby bridging the gap between general and medical image understanding.

Transformer models have become instrumental in a diverse array of applications in various vision and language (V+L) tasks, including medical VQA. The Transformer, proposed by Vaswani et al [13], represents a departure from traditional recurrent or convolutional neural networks. Its architecture replaces recurrent layers with a multihead self-attention encoder and decoder

structure. Compared to traditional recurrent neural network models, the Transformer significantly reduces training time, making it a scalable solution capable of handling a wide range of inputs and applicable to diverse V+L tasks, including the analysis of medical images.

Several prominent transformer-based models have had a significant impact on the landscape of NLP and multimodal tasks. One of the most influential models is Bidirectional Encoder Representations From Transformers (BERT). Proposed by Devlin et al [14], BERT has demonstrated its efficacy in a wide variety of NLP tasks. This is achieved through a pretraining phase where 15% of input sequences are masked. These masked tokens can be replaced with random words, original words, or MASK tokens. Subsequently, the transformer auto-encodes these tokens, and fine-tuning is applied to adapt the pretrained model to downstream tasks. The generalization capabilities of BERT are remarkable, making it adept at handling a wide array of semantic tasks. This is due in part to its bidirectional training, which allows the model to learn contextual information from both the left and right sides of a given word.

BERT's versatility allows it to be tailored for various applications, and one domain where it has shown great promise is the biomedical field. In the biomedical domain, text data often exhibit complex language patterns and domain-specific terminology. Lee et al [15] recognized the need for a model that could adapt to these linguistic intricacies and introduced BioBERT, a BERT-based model fine-tuned on biomedical text. BioBERT effectively addresses the word distribution shift from general data to biomedical data, making it a valuable tool for tasks such as biomedical text mining. The BioBERT model's workflow involves transferring weights from BERT, which is pretrained on general domain data, to BioBERT. Subsequently, BioBERT is pretrained on biomedical domain data, followed by fine-tuning and evaluation of various downstream tasks. This adaptation enhances BioBERT's performance in domain-specific tasks, such as biomedical text classification and named entity recognition.

The success of BERT and its adaptations has paved the way for exploring their application in multimodal tasks, where both text and image data are involved. For instance, VisualBERT, proposed by Li et al [16], was inspired by BERT and designed to capture rich semantics in V+L tasks. It uses a stack of Transformer layers and integrates pretrained object proposal systems for image feature extraction. In the training process, VisualBERT uses self-supervised learning with masked word tokens and performs image caption classification tasks with true and false captions. This approach enables the model to capture intricate relationships between text and image content, making it highly suitable for multimodal tasks where textual descriptions are needed for visual content.

Learning Cross-Modality Encoder Representations from Transformers (LXMERT), another notable model, builds upon the success of BERT and its variants [17]. Tan and Bansal [17] recognized the importance of interpreting the semantic meaning of both images and text while exploring the relationships between V+L. LXMERT's encoders, based on the Transformer architecture, are pretrained on large volumes of image-text pairs. The pretraining process, inspired by BERT, includes techniques such as adding random masks. Interestingly, LXMERT's pretraining approach has been found to outperform data augmentation, a common practice used to increase the amount of training data. Consequently, LXMERT is well suited for tasks that involve understanding and generating textual descriptions for visual content, such as image captioning and VQA.

As the field of V+L tasks continues to evolve, so do the transformer-based models designed to tackle them. The Vision Transformer (ViT), introduced by Dosovitskiy et al [18], represents an innovation to address the challenges of applying the Transformer architecture directly to computer vision tasks. ViT operates by dividing an image into 16×16 patches and processing them with position embeddings using a standard Transformer encoder. This approach has shown promise, but it demands substantial computational resources and extensive training data. Notably, ViT32 ViT was used by Eslami et al [19] as part of fine-tuned versions of Contrastive Language-Image Pretraining (CLIP), comparing the performance of different models in the medical domain.

Similarly, Universal Image-Text Representation (UNITER), proposed by Chen et al [20], takes inspiration from the BERT model. The UNITER model has demonstrated strong performance in various V+L tasks. The architecture of UNITER uses the Transformer as its core, with the image and text embedder working in tandem to encode image and text features into a common embedding space. This approach enables the generation of contextual embeddings, facilitating a better understanding of the relationships of V+L. These transformer-based models collectively represent a spectrum of approaches and adaptations within the broader field of V+L tasks.

The landscape of transformer-based models, ranging from BERT to ViT, demonstrates their adaptability and effectiveness in various domains, including NLP and multimodal tasks. CLIP, introduced by Radford et al [21], represents a significant step forward in the multimodal domain. CLIP was designed to connect images and text through a shared embedding space, enabling it to understand the relationship between the 2 modalities. By pretraining on a massive data set containing images and their associated textual descriptions, CLIP can align images with natural language descriptions, making it a versatile tool for a wide range of tasks. This novel approach has significant implications for the medical field, where visual data, such as medical images, often require textual descriptions for comprehensive analysis and interpretation.

Building upon the success of CLIP, PubMedCLIP emerged as a tailored solution for MedVQA. Eslami et al [19] recognized the need for a model specifically adapted to the medical domain and developed PubMedCLIP, a fine-tuned version of CLIP trained on a data set of medical image-text pairs from PubMed articles. This adaptation enables PubMedCLIP to better understand the nuances of medical images and text, resulting in improved performance on MedVQA tasks.

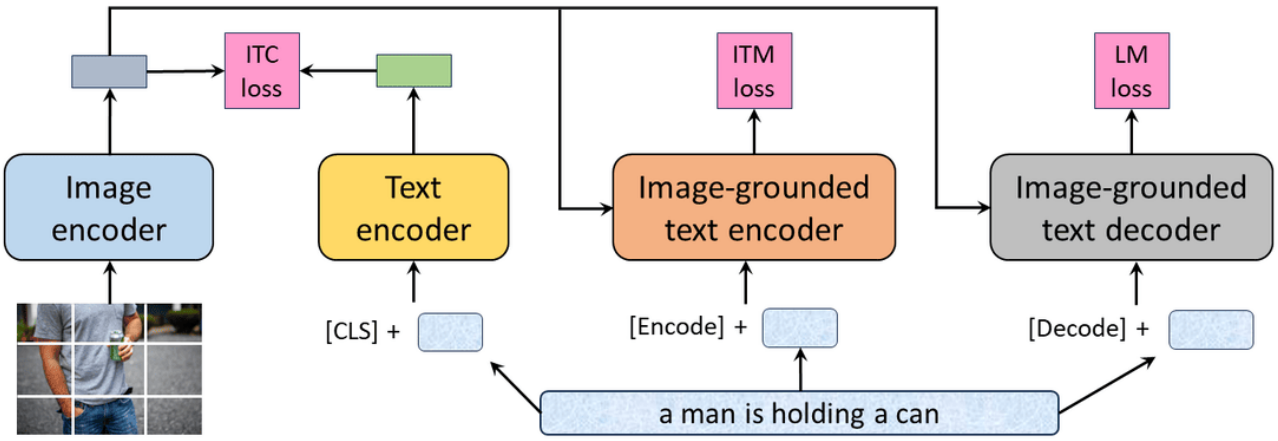
One of the recent works fusing medical imaging and text data is MedBLIP [22]. MedBLIP uses a trainable 3D vision encoder,

MedQFormer, which connects medical images with language models. However, MedBLIP could not significantly improve VQA performance and classification accuracy. For the experimental evaluation of MedBLIP, authors only used MRI scans and text, which will limit the use of MedBLIP in the case of other modalities, such as positron emission tomography, CT, and x-ray images.

Despite performing well in vision-language tasks, CLIP suffers from a number of limitations. Firstly, it is primarily focused on vision-language understanding tasks, such as image retrieval and VQA. This means that it is not well suited for generation tasks, such as image captioning. Secondly, CLIP is trained on a large data set of image-text pairs collected from the web. However, these data are often noisy and contain incorrect or misleading captions. This can lead to CLIP making mistakes when performing tasks that require an accurate understanding of the relationship between images and text.

To address these limitations, Li et al [23] proposed Bootstrapping Language-Image Pretraining (BLIP), a vision-language pretraining framework. BLIP, as shown in Figure 1, is a unified model that can be used for both understanding and generation tasks. This is achieved by incorporating a captioning module into the model, which allows BLIP to generate captions for images. In addition, BLIP addresses the issue of noisy web data by bootstrapping the captions. This means that a captioner generates synthetic captions and a filter removes the noisy ones. This results in a cleaner data set that can be used to train a more robust model. As a result of these improvements, BLIP has been shown to achieve state-of-the-art (SOTA) results on a wide range of vision-language tasks, including image retrieval, VQA, image captioning, and visual grounding. In addition, BLIP is more efficient to train and can be fine-tuned for downstream tasks with lesser data. Finally, BLIP is more interpretable than CLIP, as the captioning module allows users to understand how the model is reasoning about images.

Figure 1. Pretraining architecture of Bootstrapping Language-Image Pretraining (BLIP). CLS: classification; ITC: image-text contrastive; ITM: image-text matching; LM: language modeling.



Capitalizing on the strengths of BLIP, we propose BioMedBLIP by pretraining and fine-tuning the model with a medical data set to achieve SOTA results on medical vision-language tasks. Specifically, BLIP's unified approach to vision-language understanding and generation makes it well suited for tasks such as medical image classification, medical image retrieval, and medical image captioning. In addition, BLIP's ability to handle noisy data makes it well suited for training on medical data sets, which can often be noisy and contain incomplete or inaccurate information. We evaluated our pretrained model using various standard task-specific performance metrics.

Methods

In this section, we describe our pretraining process along with training strategies and resources used.

BioMedBLIP

Overview

BLIP, initially pretrained on general image data sets, possesses knowledge rooted in general image understanding. However, medical images exhibit distinct characteristics that differentiate them from general images. Many medical images are gray scale, such as x-rays and MRI scans, which results in a significant divergence between the general image domain and the medical image domain. To bridge this gap, we conducted the pretraining of BLIP using medical data sets, producing an adapted BLIP model tailored for medical applications.

As shown in Figure 1, BLIP is organized into 4 key modules.

- Visual transformer block (image encoder): the first module serves as an image encoder, using a visual transformer to extract features from medical images.
- BERT-based text encoder: the second module is a text encoder based on BERT. It processes textual data, ensuring a comprehensive understanding of medical texts.
- Cross-attention and binary classification: the third module shares parameters with the text encoder, facilitating joint image-text embeddings through cross-attention. It uses a binary classifier to confirm the pairing of images and text.
- Text decoder: the final module is a text decoder, which shares some components with the preceding encoders, such as feed-forward and cross-attention layers. However, it maintains its own causal self-attention layers. The text

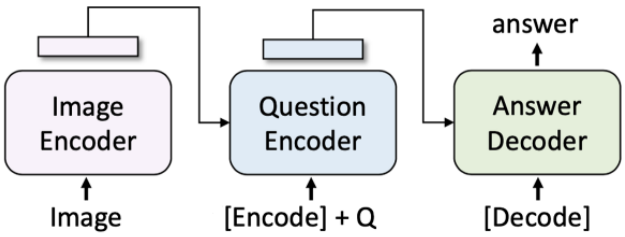
decoder generates text auto-regressively, and cross-entropy loss is applied during this process.

For BLIP, we explored various pretraining approaches. Initially, we attempted to pretrain BLIP from scratch. Subsequently, we pretrained BLIP from a provided checkpoint using the ROCO and MIMIC data sets. Further experimentation involved extending the checkpoint with the inclusion of the ROCO data set onto the MIMIC data set. To apply BLIP to downstream tasks, we followed the BLIP framework's process to refactor the model's modules and assembled an adapted model tailored for specific tasks.

BioMedBLIP VQA Generation Model

For VQA tasks, we adopted the structure provided by BLIP, as depicted in Figure 2. VQA tasks require the model to generate textual answers based on given images and question pairs. The process involves encoding the image to create image embeddings, producing image-question joint embeddings with the help of the question encoder, and using the answer decoder to generate the final answer.

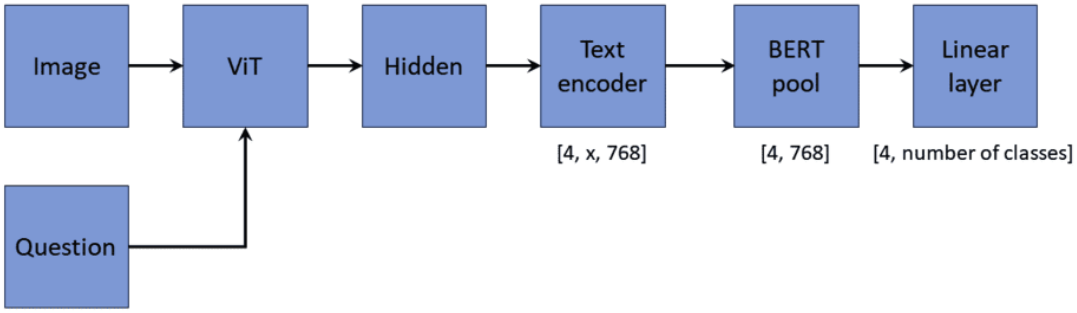
Figure 2. BioMedBLIP visual question answering generation model.



Modified BLIP Classification Model

The modified BLIP classification model, illustrated in Figure 3, shares similarities with the generation model. It generates joint image-text embeddings using the image encoder and text encoder. However, instead of using the answer decoder, a pooling layer is introduced to reduce the vector dimension. Subsequently, a linear classification layer is applied to produce multiple classification results.

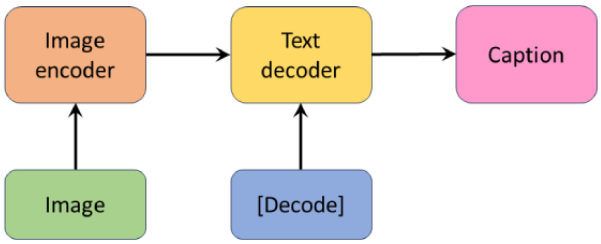
Figure 3. BioMedBLIP classification model. ViT: Vision Transformer.



BioMedBLIP Image Caption Model

The image caption model, presented in Figure 4, is composed of the image encoder and text decoder, following BLIP's implementation. Unlike VQA tasks, the image captioning task involves generating text based solely on images. Therefore, the text encoder is omitted, and the text decoder takes image embeddings provided by the image encoder and the *[Decode]* token as input to produce image captions.

Figure 4. BioMedBLIP image caption model.



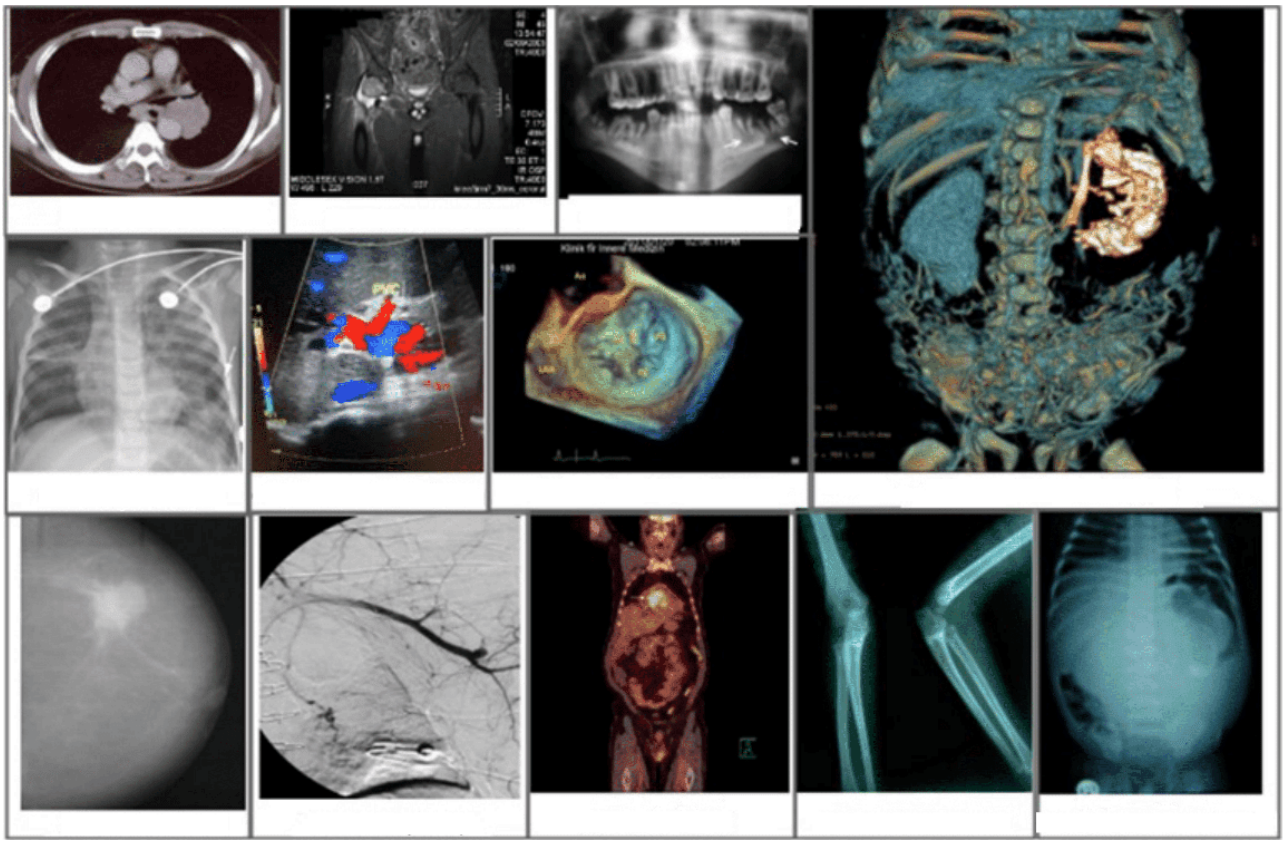
Data Sets

Our research leverages a diverse range of medical data sets, encompassing a variety of visual and textual medical data sources. These data sets serve as the foundation for pretraining and fine-tuning our visual language model.

ROCO Data Set

The ROCO data set [5] plays a pivotal role in pretraining BioMedBLIP. It encompasses over 81,000 radiology images representing multiple medical imaging modalities, including CT, ultrasound, x-ray, fluoroscopy, positron emission tomography, mammography, MRI, and angiography [5]. Our approach involved consolidating the training, validation, and test data into a single comprehensive JSON file, enabling the pretraining of BioMedBLIP. Notably, the captions in the ROCO data set were sourced from peer-reviewed scientific biomedical literature and downloaded from a GitHub link [24]. Some examples are shown in Figure 5.

Figure 5. Some images in the Radiology Objects in Context data set.



MIMIC-CXR Data Set

The MIMIC-CXR data set is a large data set that consists of 377,110 chest x-rays corresponding to 227,827 imaging studies [6]. Some examples of chest x-rays from this data set are shown in Figure 6. In our context, we used this data set for BioMedBLIP's pretraining. It is worth noting that each medical study extracted from the hospital's electronic health record system can be related to multiple chest x-rays. Our efforts focused on filtering the chest x-rays, retaining those with anteroposterior and posteroanterior positions, and ensuring that each medical report had a single associated chest x-ray. After preprocessing, we obtained 218,139 image-caption pairs, which were instrumental in pretraining BioMedBLIP. The medical studies are XML files, and we extracted the "Findings" and "Impressions" sections as the caption for medical images.

Figure 6. Chest x-rays in the Medical Information Mart for Intensive Care-Chest X-ray data set.

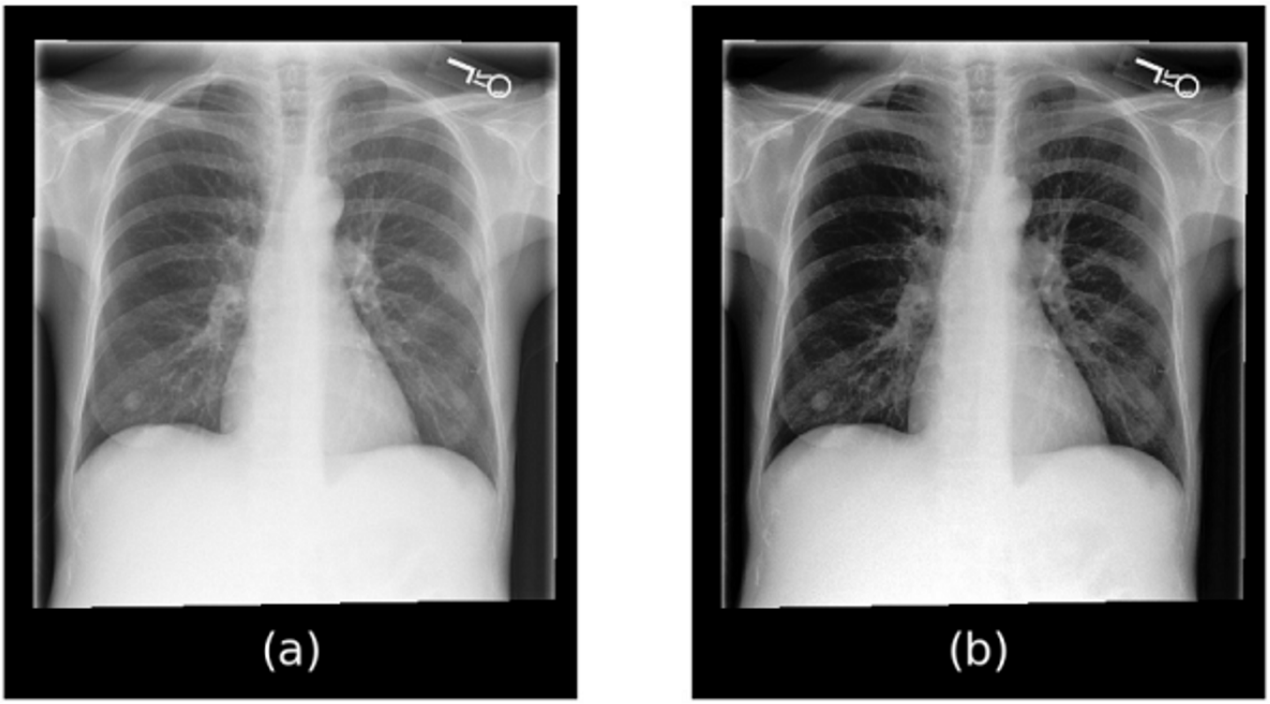


Image Cross-Language Evaluation Forum 2019 Data Set

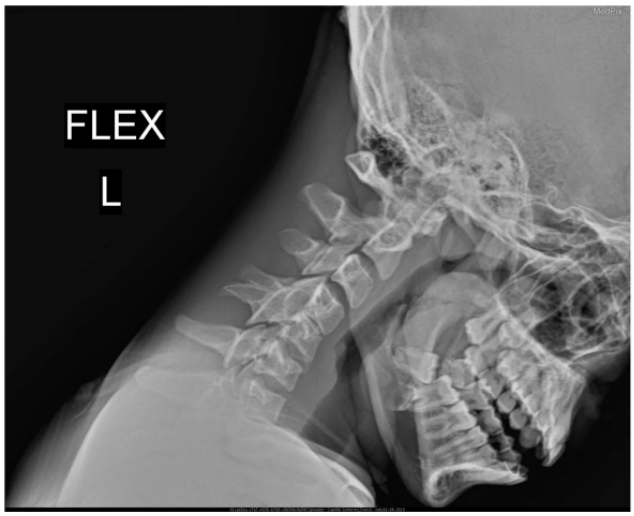
The Image Cross-Language Evaluation Forum (ImageCLEF) 2019 data set [25,26], provided by the ImageCLEF organization for evaluation, served as a critical component in our work. This data set comes in 3 parts: training, validation, and testing sets. No preprocessing was performed on the data set, and it was leveraged for our VQA generation task. It contains 12,792; 2000; and 500 image-caption pairs for the training, validation, and testing sets, respectively. An example of a radiology image in the ImageCLEF data set is shown in Figure 7.

Figure 7. A radiology image from the Image Cross-Language Evaluation Forum 2019 data set.



Semantically-Labeled Knowledge-Enhanced Data Set

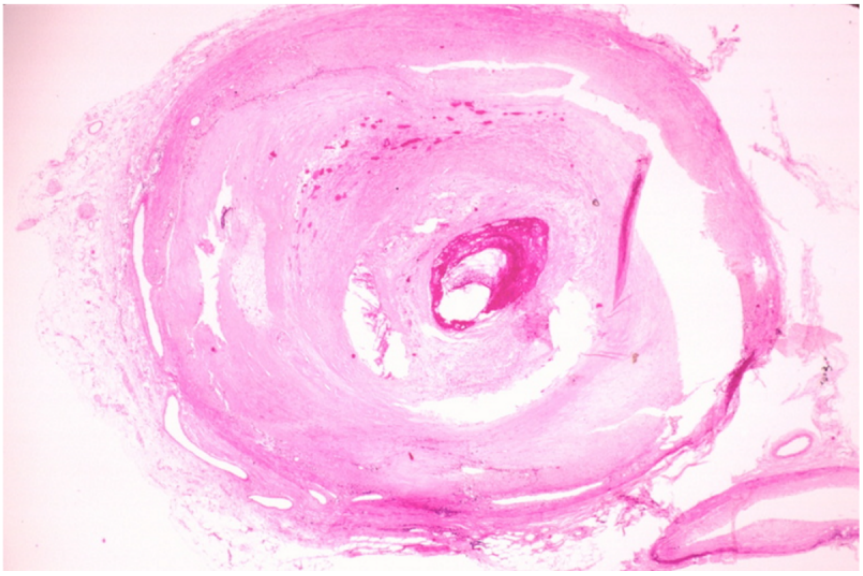
The Semantically-Labeled Knowledge-Enhanced (SLAKE) data set [27] was designed for medical VQA tasks [28]. We used this data set for VQA generation and VQA classification tasks. The SLAKE data set has both Chinese question-answer pairs and English question-answer pairs. Our data set preparation included filtering to retain only English question-answer pairs. After filtering, the SLAKE data set consisted of 4919, 1053, and 1061 image-caption pairs for the training, validation, and testing sets, respectively. Notably, the SLAKE data set features 2 different answer types, open and close, allowing us to assess model performance for open-ended and close-ended questions. An example of a radiology image from the SLAKE data set is shown in Figure 8.

Figure 8. A radiology image from the Semantically-Labeled Knowledge-Enhanced data set.

PathVQA Data Set

The PathVQA data set is a VQA data set for "AI pathologist" development [29]. It contains numerous pathology images together with questions and corresponding answers. All image-question-answer triplets are manually checked to ensure correctness. In our setting, we obtained a data set with 32,795 image-question-answer pairs after initial preprocessing. We further categorized questions into open-ended and close-ended questions using our own splitting, yielding 20,968; 5241; and 6552 image-question-answer pairs for the training, validation, and testing sets, respectively. All these images in the validation and testing sets were picked randomly. An example of a pathology image from the PathVQA data set is shown in Figure 9. We used this data set to perform the VQA generation and VQA classification tasks in our project.

Figure 9. A pathology image from the PathVQA data set.



VQA-RAD Data Set

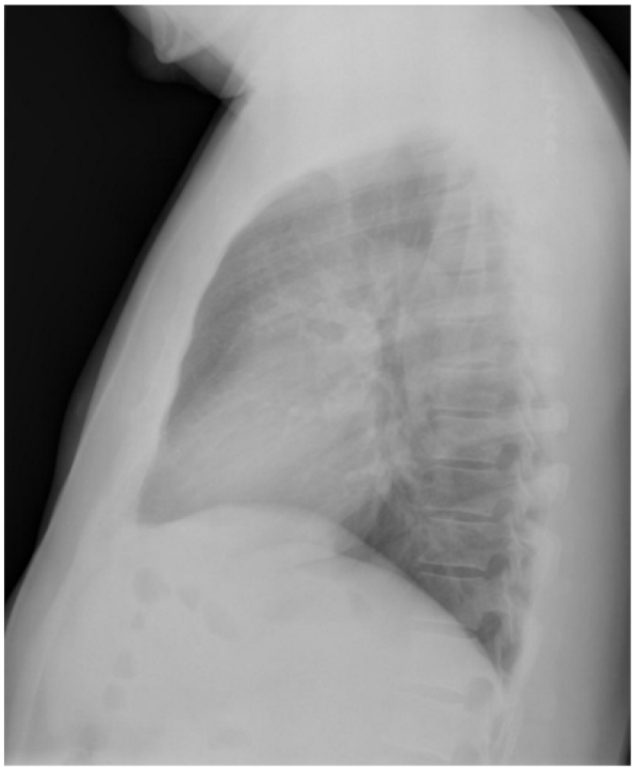
VQA-RAD is the first data set that was manually constructed. During the data collection process, clinicians asked natural questions about radiology images. Meanwhile, their reference answers would be provided [30]. It has radiology images together with question-answer pairs. We used the original data [31] splitting and did not perform any data preprocessing on this data set. It contains 2452, 614, and 452 image-question-answer pairs for the training, validation, and testing sets, respectively. An example of a radiology image from the VQA-RAD data set is shown in Figure 10. We used the VQA-RAD data set to implement the VQA generation and VQA classification tasks.

Figure 10. A radiology image from the Visual Question Answering in Radiology data set.

Open-I Data Set

The Open-I data set [32] is a compilation of chest x-ray images collected from open-source literature and biomedical image collections. Our focus was specifically on the chest x-ray images within this data set. We downloaded the data set from the official Open-I website, which comprises 2 parts: images and medical reports. The medical reports were stored as XML files, with the "Finding" and "Impression" sections extracted as captions for the images. Our downloaded version contained 2452, 614, and 452 image-caption pairs for the training, validation, and testing sets, respectively. An example of a radiology image from the Open-I data set is shown in Figure 11.

Figure 11. A radiology image from the Open-I data set.

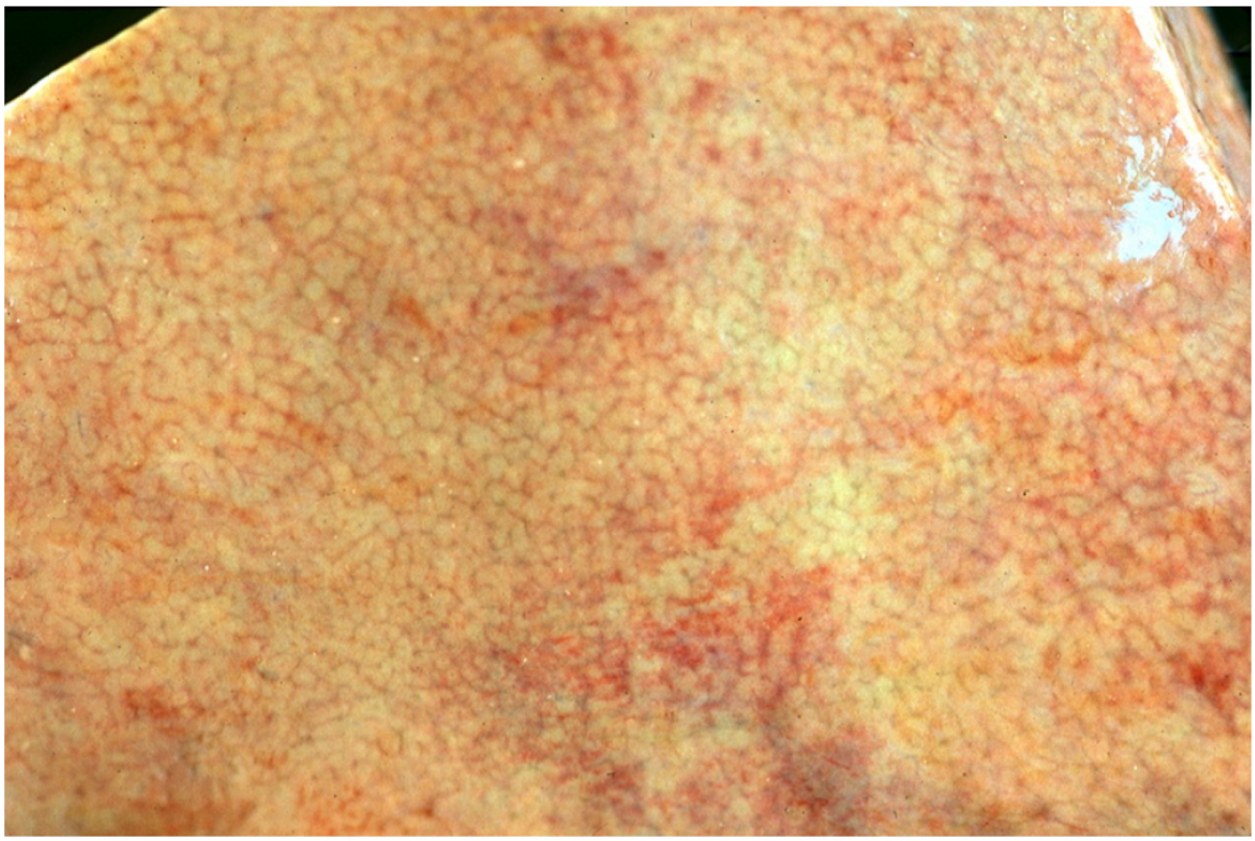


PEIR-Gross Data Set

The PEIR-Gross data set originated from the PEIR and contains 7442 image-caption pairs across 21 subcategories [9]. Our data set preparation involved splitting it into training and testing sets. We also generated a validation set by randomly selecting 10% of the training data. After preprocessing, we had 6029, 669, and 745 image-caption pairs for the training, validation, and testing sets, respectively. An example of a medical image from the

PEIR-Gross data set is shown in Figure 12. This data set was used for image captioning tasks.

Figure 12. A medical image from Pathology Education Informational Resource-Gross data set.



Implementation

Overview

In addition to the original BLIP base model checkpoint obtained from the original BLIP GitHub repository [33], we also meticulously pretrained a series of checkpoints on various medical data sets. These checkpoints serve as critical resources that we are making available for the broader research community and our clients. Here, we provide a comprehensive list of these checkpoints:

- Original BLIP base model checkpoint (ViT-Base): this checkpoint represents the foundational BLIP model pretrained on the LAION115M data set.
- Pretraining on combined-MED checkpoints: these checkpoints were derived from pretraining on a comprehensive data set combining SLAKE, Open-I, ImageCLEF, and PathVQA data sets from scratch, with versions available for both 20 and 50 epochs.
- Pretraining on SLAKE checkpoint: this checkpoint is the result of pretraining on the SLAKE data set from scratch, spanning 20 epochs.
- Pretraining on ROCO checkpoint: pretrained on the ROCO data set from scratch, this checkpoint encapsulates knowledge gained over 10 epochs.
- Pretraining on MIMIC-CXR checkpoint: for up to 10 epochs, this checkpoint embodies the insights obtained from pretraining on the MIMIC-CXR data set from scratch.
- Pretraining on ROCO from the BLIP original checkpoint: this checkpoint extends the pretraining on the ROCO data set from the existing BLIP checkpoint up to 50 epochs.
- Pretraining on MIMIC-CXR from the BLIP original checkpoint: similar to the ROCO extension, this checkpoint involves the pretraining on the MIMIC-CXR data set from the original BLIP checkpoint and spans up to 50 epochs.
- Pretraining on ROCO and MIMIC-CXR from the BLIP original checkpoint: this checkpoint represents an amalgamation of knowledge acquired from both ROCO and MIMIC-CXR data sets, building upon the original BLIP checkpoint and extending to 50 epochs.

Pretraining Details

To undertake the pretraining of the BLIP model, our approach involved several key steps. Initially, we used the ROCO data set for the pretraining of the BLIP original checkpoint, resulting in the creation of the BioMedBLIP-ROCO models. These models were uniquely identified by the number of epochs they were pretrained for, with “BioMedBLIP-ROCO-10,” for instance, signifying the original BLIP checkpoint pretrained on the ROCO data set for 10 epochs. This choice was informed by the fact that the original BLIP checkpoint had been trained on millions of standard images and, therefore, already possessed the fundamental knowledge required for a visual language model. Our attempt to pretrain BLIP from scratch yielded unsatisfactory performance. Subsequently, we embarked on pretraining the original BLIP checkpoint with the MIMIC-CXR data set to produce the BLIP-MIMIC models. Finally, we took

the BLIP-MIMIC checkpoints and further pretrained them using the ROCO data set, resulting in the creation of the BioMedBLIP-ROCO and MIMIC models. In this study, we retained checkpoints representing 10, 20, and 50 epochs for each of these models.

To optimize the pretraining process, we conducted a series of experiments aimed at identifying the most suitable hyperparameters. The selected hyperparameters for the pretraining process were as follows: initial learning rate: $3e^{-5}$; warmup learning rate: $1e^{-6}$; warmup steps: 3000; and optimizer: AdamW.

Fine-Tuning Details

The fine-tuning phase involved an extensive process encompassing various BLIP checkpoints and data sets, which included the BLIP original base model checkpoint, BioMedBLIP-ROCO-10, BioMedBLIP-ROCO-20, BioMedBLIP-ROCO-50, BioMedBLIP-MIMIC-10, BioMedBLIP-MIMIC-20, BioMedBLIP-MIMIC-50, BioMedBLIP-ROCO&MIMIC-10, BioMedBLIP-ROCO&MIMIC-20, and BioMedBLIP-ROCO&MIMIC-50. These checkpoints were fine-tuned on a selection of data sets, namely, ImageCLEF, SLAKE, VQA-RAD, PathVQA, Open-I (Indiana University X-RAY), and PEIR-Gross.

For the fine-tuning process, we adhered to the common practice of splitting the data sets into training, validation, and test sets. Typically, the training set constitutes 80% of the total data set, while the test set encompasses the remaining 20%. In certain cases, the data set authors had already performed the necessary data set splits, and we made no further modifications to these sets. In addition, we created an answer list to facilitate the evaluation of predicted VQA generation sentences, VQA classification labels, and image captions.

As part of our methodology, we used a YAML configuration file, which proved essential for adapting to different running environments. Through a series of meticulously designed experiments, we optimized the hyperparameters for each checkpoint's fine-tuning process. These hyperparameters included train batch size, test batch size, learning rates, and the number of epochs. Importantly, the optimal hyperparameters varied for each checkpoint when applied to different data sets, ensuring the fine-tuning process was meticulously tailored for each specific scenario.

Resources

This study relied on a combination of hardware and software resources to execute efficiently. We used 3 primary platforms for code execution: Google Colab (Google Inc), Google Cloud Platform (Google Inc), and the University of Sydney's Artemis HPC supercomputer. Google Colab we used had an Intel(R) Xeon(R) central processing unit (CPU) running at 2.30 GHz, an Nvidia Tesla P100-PCIE-16GB (Nvidia Corp) graphics processing unit (GPU), and 12.8 GB of RAM. The version of the Google Cloud platform we used had 4 CPU cores, a Tesla A100-PCIE-40GB GPU, and 26 GB of RAM. On the Artemis HPC platform [34], we had access to an impressive array of resources, including 7636 CPU cores, 45 TB of RAM, 108 NVIDIA V100 GPUs, 378 TB of storage, and 56 Gbps FDR InfiniBand networking. For our pretraining tasks, we specifically used 4 CPU cores, Tesla V100-PCIE GPUs, and 48 GB of RAM. Our code is available on HuggingFace [7].

Ethical Considerations

In our study, ethical considerations were meticulously observed to ensure compliance with relevant regulations and standards. We did not require ethics approval for this research because the data sets used, including ROCO, MIMIC-CXR, SLAKE, PathVQA, VQA-RAD, ImageCLEF, Open-I, and PEIR-Gross, are publicly available. These data sets have been previously collected, anonymized, and made accessible for research purposes by their respective organizations and custodians. No user data or human data were collected directly by us for this study. We strictly adhered to data use policies specified by the data providers, ensuring that all data handling was performed in accordance with ethical guidelines. In addition, the data sets used did not contain personally identifiable information, and appropriate measures were taken to maintain data privacy and security throughout the research process. Using publicly available data, we ensured that our research complied with institutional and local policies regarding the use of medical data for research purposes.

Results

Overview

In this section, we describe our evaluation metrics along with the results and findings. The purpose of our experimentation was to evaluate how adding domain-specific information helps in improving the performance of downstream tasks in the biomedical domain. For this reason, we have compared the results of our models with the original BLIP model.

Evaluation Metrics

In this subsection, we provide a detailed overview of the specific evaluation metrics used to assess the performance of our model across various downstream tasks.

- VQA generation: for VQA generation, we used exact match (EM) as the metric. EM assesses the model's performance by treating predictions that precisely match the ground truth as correct answers. It is particularly relevant for evaluating generative tasks.
- VQA classification metrics: for VQA classification, we used accuracy. Accuracy is a fundamental metric for classification tasks, quantifying the proportion of correctly classified instances.
- Report generation or image captioning metrics: Bilingual Evaluation Understudy (BLEU) is a metric that assesses the similarity between the generated answer and the reference answer, considering n-grams. BLEU-1, in particular, focuses on 1-grams.

VQA Generation Results

Overview

For the VQA eneration task, we used the SLAKE, VQA-RAD, PathVQA, and ImageCLEF data sets to check the performance of our models BLIP-Original, BioMedBLIP-ROCO, and BioMedBLIP-MIMIC&ROCO. These models were designed to generate answers for visual questions and underwent different pretraining strategies. Tables 1 and 2 present a comparison of BioMedBLIP models with the SOTA model.

Table 1. Comparison of BioMedBLIP models versus the SOTA[a] on VQA[b] generation tasks (part 1).

Data set	Original BLIP[c] (SOTA; accuracy)	BioMedBLIP models (accuracy)			
		ROCO[d]-10	ROCO-20	ROCO-30	MIMIC[e]-10
SLAKE[f]-Overall	77.95	80.87	80.11	80.21	78.51
SLAKE-Open	73.80	75.81	74.57	75.04	73.80
SLAKE-Close	87.26	88.70	88.70	89.42	85.82
VQA-RAD[g]-Overall	34.37	35.70	*37.03* [h]	35.03	26.16
VQA-RAD-Open	39.66	43.02	*46.37*	43.02	26.82

Results on the SLAKE Data Set

For the overall SLAKE data set, the BioMedBLIP MIMIC&ROCO-10 model exhibited the highest EM accuracy, reaching an impressive 82%, outperforming the BLIP original model and other variants. The results in SLAKE-Open highlighted the superiority of the BioMedBLIP MIMIC&ROCO-50 model, which achieved the best performance with an EM accuracy of 76.59%. Finally, in the SLAKE-Close category, the BioMedBLIP MIMIC&ROCO-10 model stood out with an impressive accuracy of 90.87%, demonstrating its strong performance in generating answers that match ground truth answers exactly.

Results on the VQA-RAD Data Set

The original BLIP (SOTA) model, serving as the baseline, achieved an EM score of 34.37 in the "VQA-RAD-Overall" category. However, it was surpassed by our BioMedBLIP model, specifically "ROCO-20," which demonstrated exceptional performance with an EM score of 37.03, indicating its effectiveness in generating accurate answers to visual questions. This trend continued in the "VQA-RAD-Open" data set, where BioMedBLIP-ROCO-20 outperformed the baseline with an EM score of 46.37, highlighting its strong performance in open-ended VQA tasks. Notably, the close-ended category also saw success for the BioMedBLIP models, with "MIMIC&ROCO-10" and "MIMIC&ROCO-50" achieving the top EM score of 32.35.

Results on the PathVQA Data Set

In the evaluation of VQA generation tasks on the PathVQA data set, the original BLIP (SOTA) model exhibited an EM score of 66.64, setting a high standard. Among the BioMedBLIP models, "ROCO-20" emerged as the top performer in the PathVQA-Overall and PathVQA-Open categories, achieving scores of 64.65 and 40.79, respectively. Particularly noteworthy is "MIMIC&ROCO-10," which achieved a competitive EM score of 61.74 in the PathVQA-Overall task. In the PathVQA-Close category, "BioMedBLIP-ROCO-20" stood out with an EM score of 88.57, surpassing the original BLIP (SOTA) model. The BioMedBLIP models "MIMIC&ROCO-10" and "MIMIC&ROCO-50" also displayed a strong performance. These results emphasize the effectiveness of different pretraining strategies and the potential for improved performance in VQA generation tasks using the PathVQA data set with BioMedBLIP.

Results on the ImageCLEF Data Set

The SOTA original BLIP model achieved an EM score of 48.20. In contrast, the BioMedBLIP models, which were pretrained with different data sets and epochs, demonstrated notable improvements. Notably, the BioMedBLIP model pretrained with ROCO (10 epochs) emerged as the top performer with an impressive EM score of 58.27, surpassing the SOTA model. This suggests that the use of the ROCO data set for pretraining significantly enhances the ability of the model to generate precise answers to visual questions on the ImageCLEF data set. Other variants of the BioMedBLIP model, pretrained with different data sets and epochs, also exhibited varying degrees of success in this task.

VQA Classification Results

Overview

For the VQA classification task, we used the SLAKE, VQA-RAD, and PathVQA data sets to check the performance

of our models BLIP-Original, BioMedBLIP-ROCO, and BioMedBLIP-MIMIC-CXR. These models were designed to generate answers for visual questions and underwent different pretraining strategies. Tables 3 and 4 present a comparison of the BioMedBLIP models with the SOTA models.

Table 3. Comparison of BioMedBLIP models versus the SOTA[a] on VQA[b] classification tasks (part 1).

Data set	Original BLIP[c] (SOTA; accuracy)	BioMedBLIP models (accuracy)

Results on the SLAKE Data Set

In the context of VQA classification tasks using the SLAKE data set, the evaluation results are presented in terms of accuracy, allowing for a comprehensive comparison between the original BLIP model and several BioMedBLIP variants, each pretrained with specific data sets and epochs. The BioMedBLIP models demonstrated their potential for significant improvements over the original BLIP model. In the "SLAKE-Overall" data set category, BioMedBLIP models pretrained with the ROCO data set consistently outperformed the original BLIP model, with ROCO-10 achieving an accuracy of 81.06. Furthermore, BioMedBLIP models pretrained with the MIMIC-CXR data set, particularly MIMIC-20, showcased strong performance. For the SLAKE open-ended data set subtask, the model pretrained with both MIMIC-CXR and ROCO for 20 epochs achieved an accuracy of 77.90, surpassing the original BLIP model. For the SLAKE close-ended data set, the ROCO-20 variant of BioMedBLIP stood out with an accuracy of 85.10, clearly surpassing the original BLIP model's performance. These results emphasize the significance of data set choice and pretraining duration, with BioMedBLIP models showcasing their potential for improved accuracy in classifying visual questions within the SLAKE data set.

Results on the VQA-RAD Data Set

In the VQA-RAD-Overall data set, encompassing both open-ended and closed-ended questions, none of the BioMedBLIP models outperformed the original BLIP model, highlighting the challenges in achieving superior accuracy in a mixed question type. However, in the VQA-RAD open-ended data set, all the BioMedBLIP models excelled, surpassing the original BLIP model's accuracy and showcasing their effectiveness in open-ended question answering. Four variants of BioMedBLIP models, namely, MIMIC-10, MIMIC-20, MIMIC-50, and MIMIC&ROCO-10, had the highest score of 28.49. For the VQA-RAD close-ended data set, the BioMedBLIP models did not surpass the original BLIP model, with the best performers being ROCO-10 and ROCO-30. This shows that further research is warranted on strategies to improve the performance on the close-ended VQA-RAD data set.

Results on the PathVQA Data Set

On the PathVQA-Overall data set, the original BLIP model achieved an accuracy of 60.09, while the BioMedBLIP models demonstrated varied performance. Notably, the model pretrained with both MIMIC-CXR and ROCO data sets for 50 epochs emerged as the top performer, achieving an accuracy of 61.13. This dual pretraining approach showed significant promise in enhancing classification accuracy. For the PathVQA-Open data set, the original BLIP model achieved the highest accuracy of 37.21, with BioMedBLIP models pretrained on ROCO and MIMIC-CXR data yielding slightly lower results. The highest performance among BioMedBLIP models came from the model pretrained with both data sets for 50 epochs, reaching an accuracy of 34.09, which is very close to the original BLIP model's accuracy. In contrast, the original BLIP model excelled on the PathVQA-Close data set, achieving an impressive accuracy of 85.15. Nevertheless, the BioMedBLIP model pretrained with both MIMIC-CXR and ROCO for 50 epochs outperformed the original BLIP model, achieving an accuracy of 86.29.

These results collectively indicate that the choice of pretraining strategy and the duration of training significantly influence the classification accuracy of BioMedBLIP models on the various VQA classification data sets, with the combined data set pretraining demonstrating notable advantages in certain contexts.

Image Captioning Task Results

We used the PEIR-Gross data set for the image captioning task to check the performance of our BioMedBLIP models. For the image captioning task, BLIP-original had a BLEU-1 score of 24.8. Similarly, when using the ROCO data set for training, the BioMedBLIP models had scores of 24.4, 24.6, and 25.1 for 10, 20, and 30 epochs respectively. Furthermore, when the MIMIC data set was used, the BLEU-1 score of 23.1, 23.9, and 24.1 was achieved by BioMedBLIP models when trained for 10, 20, and 50 epochs respectively. Additionally, when the training data combined MIMIC and ROCO, the BLEU-1 score of 23.9, 24.3, and 24.2 was achieved for 10, 20, and 30 epochs respectively by BioMedBLIP models. In terms of BLEU-1 scores, higher values are indicative of better performance. The results show that the BioMedBLIP-ROCO-50 model surpassed the original BLIP model in the image captioning task with a BLEU-1 score of 25.1 (over 1.2% improvement from the score of the original BLIP model), demonstrating that our approach has the potential to enhance the model's capabilities for generating captions. In contrast, all other models, including various pretraining strategies and epochs, exhibited slightly lower BLEU-1 scores. While some models may have exhibited minor variations in performance, it is essential to emphasize that, overall, our results were quite consistent. This consistency indicates that our pretraining strategies and fine-tuning approaches are robust and capable of producing reliable outcomes.

Discussion

Principal Findings

In the presented VQA generation, VQA classification, and report generation tasks, we aimed to assess the performance of our BioMedBLIP models against the SOTA original BLIP model using diverse medical image data sets and pretraining strategies. The findings indicate that our BioMedBLIP models, pretrained with specialized medical data sets, exhibit substantial improvements in generating answers for visual questions, as well as in classifying images and questions, depending on the specific data set and pretraining strategy used.

In this section, it is important to emphasize the general trends and insights that can be drawn from these results:

- Data set specificity: the choice of pretraining data sets, such as ROCO and MIMIC-CXR, significantly impacts model performance in both VQA generation and VQA classification tasks. Specialized medical data sets have proven to be valuable for enhancing model capabilities in medical image analysis and question answering.
- Pretraining duration: longer pretraining durations, as evidenced by models such as MIMIC&ROCO-50, have

shown their potential to improve classification accuracy in specific categories of questions, demonstrating the importance of considering pretraining strategies tailored to the task.
- Diverse performance: our models exhibit varying levels of success across different data sets and task categories. This underscores the need for flexibility in selecting pretraining strategies, depending on the specific goals and data sets of a given application.
- Image captioning: our approach, particularly the one followed for BioMedBLIP-ROCO-50, demonstrates improvements in generating captions for medical images, showcasing the model's capacity to excel in both VQA and image captioning tasks.
- Selection of epoch numbers: in our experiments, we observed that the BioMedBLIP models converge at varying numbers of epochs, depending on the data set and the specific downstream tasks involved. This variability is typical in deep learning, where a model's loss decreases up to a certain point and then may increase, indicating that longer training periods do not necessarily yield better performance.

These results underscore the potential of our BioMedBLIP models to excel in a wide range of medical image analysis and question answering tasks, with their performance varying depending on the specific data set and task at hand. BioMedBLIP was tested using 20 different data sets and task combinations. Our method excelled in 15 (75%) out of 20 tasks. BioMedBLIP represents a new SOTA in 15 (75%) out of 20 tasks, and our responses were rated higher in all 20 tasks (P<.005) in comparison to SOTA models. Regression analyses showed that our model's VQA generation has a statistically significant predictor (P<.002) on the SLAKE, PathVQA, and ImageCLEF data sets. In contrast, our model's VQA classification has a relatively lower predictor (P<.003) on the SLAKE, PathVQA, and VQA-RAD data sets in accordance with the regression analyses.

VQA Generation

For the SLAKE data set, our model, pretrained on a combination of general domain data sets and medical domain data sets (MIMIC-CXR and ROCO), consistently outperformed other models across various SLAKE data sets, including open-ended, close-ended, and aggregated types. In contrast to the study by Li et al [12], our results affirm the benefits of pretraining on both general and medical data sets, addressing limitations in their work. This underscores the advantage of a domain-specific model for specialized downstream tasks. Notably, our observations align with the findings of Eslami et al [35], indicating that a pretrained ViT, such as our BLIP model, possesses a comprehensive understanding of image content and long-range dependencies, essential for interpreting the SLAKE data set. Surprisingly, in the VQA-RAD data set, the model pretrained solely on the ROCO data set (for 20 epochs) excelled in open-ended and aggregated tasks, while the MIMIC-CXR and ROCO model performed better in the close-ended task. Contrary to expectations, the model pretrained on general domain data sets and ROCO outperformed the model pretrained on larger domain-specific data sets for PathVQA and ImageCLEF. We attribute this to the superior preprocessing of the ROCO data set, incorporating red bounding boxes that aid in learning crucial image regions. Moreover, our 50-epoch pretraining might not suffice for larger data sets, suggesting the need for further exploration with extended training. Overall, our models demonstrated superior performance on the medical data sets compared to the original BLIP model, emphasizing the efficacy of our approach in medical image analysis.

VQA Classification

In the exploration of VQA classification tasks, diverse models underwent experimentation and fine-tuning across data sets such as SLAKE, PathVQA, and VQA-RAD, encompassing open-ended, close-ended, and aggregated question types. Notably, the SLAKE data set consistently emerged as the data set where BioMedBLIP models consistently exhibited superior performance. Tables 3 and 4 highlight that, in the majority of cases, the BioMedBLIP models performed better than the original BLIP model.

Furthermore, our experiments delved into the impact of different epoch settings on model performance. An intriguing observation emerged, indicating that the relationship between a model's performance and the number of epochs is not consistently positive. This suggests the critical importance of judiciously selecting epoch configurations during the construction of visual language models for medical data sets, challenging the notion that more epochs always lead to improved accuracy.

Image Captioning

In the context of the image captioning task, our findings, while not entirely satisfactory, reveal promising aspects, particularly with the BLIP-ROCO 50 model. This variant surpasses the original BLIP model in BLEU measurements, hinting at potential improvements in using the BLIP model for image captioning. However, the overall performance of the modified models hovers around 23% to 25%, suggesting that the BLIP model may not be inherently well suited for image captioning tasks.

Further Insights

The development and application of our BioMedBLIP models have far-reaching implications across the health care and educational sectors. First and foremost, our models can significantly contribute to improving medical diagnosis and decision support systems. By enhancing the capacity to analyze medical images and answer visual questions, they have the potential to facilitate more accurate and timely health care interventions, ultimately benefiting patient outcomes. In medical education and training, our models can serve as valuable tools for students and professionals alike. Automated question answering capabilities can bridge knowledge gaps and improve learning outcomes in a field that demands continuous learning. Moreover, the automation of image analysis and question answering tasks has the potential to reduce the workload on medical professionals, allowing them to allocate more time to complex aspects of patient care. In terms of research, our models can expedite medical investigations by streamlining the analysis of extensive data sets, potentially leading to groundbreaking discoveries and advancements in the field. Finally, on a global

scale, the availability of advanced artificial intelligence models such as ours can improve medical services in underserved regions where access to specialized medical expertise is limited, thereby contributing to more equitable health care delivery. However, these opportunities are accompanied by ethical and societal responsibilities. Ensuring patient privacy, addressing biases in the data, and maintaining transparency in the development and deployment of artificial intelligence models are pivotal steps to maximize their positive impact while mitigating potential risks and pitfalls in the medical field and beyond.

Our BioMedBLIP models, while showing promise in medical image analysis, come with inherent limitations. First, their performance is heavily contingent on the quality and diversity of the training data. Limitations in data availability, such as smaller or less representative medical data sets, can hinder the model's ability to generalize to real-world scenarios and may introduce biases. Second, the variability in model performance across different data sets and task categories poses a challenge. Achieving optimal results often demands the fine-tuning of pretraining strategies for specific tasks, which may not always be straightforward in practical applications. While choosing the models appropriate for real-world applications, there are various considerations to be made. In our work, we have presented widely used metrics to evaluate model's performance. Different downstream tasks might have different metrics that are used for evaluation. In this case, comparison on the grounds of the most relevant metrics should be made. Moreover, the computational demands for pretraining models, especially in the context of medical tasks, can be substantial, potentially limiting the accessibility of our approach to settings with limited computational resources. We recommend training models for different epochs before selecting them for real-world applications. This is because for different data sets and tasks, the models tend to show convergence at different numbers of epochs. Finally, ethical and privacy concerns are paramount in the use of medical image data. Striving to ensure strict compliance with data protection regulations and maintaining patient privacy and data security are imperative in any real-world implementation.

Conclusions

In conclusion, our development and evaluation of BioMedBLIP models for medical image analysis tasks reveal both promise and practical considerations. These models have shown substantial potential in enhancing the interpretation of medical images and responding to visual questions in a health care context. The choice of pretraining data sets, including ROCO and MIMIC-CXR, plays a pivotal role in model performance, underscoring the importance of specialized medical data for training. Furthermore, a longer duration of pretraining, exemplified by the MIMIC&ROCO-50 model, has demonstrated the potential to elevate classification accuracy in specific question categories. However, our findings highlight the variability in performance across different data sets and tasks, necessitating a flexible approach to pretraining strategies. Moreover, our models have promising implications across health care and education. They can bolster medical diagnosis, decision support systems, and research efforts while also streamlining medical education and reducing the workload on health care professionals. The global accessibility of these models can bring specialized medical expertise to underserved regions.

Authors' Contributions

UN designed and conducted the experiments. UN, ST, and AM provided technical insights and analyzed the results. UN, ST, and AM jointly wrote the first draft and revised it. AM supervised the project. All authors approved the final version of this manuscript.

Abstract

Background: Hereditary angioedema (HAE), a rare genetic disease, induces acute attacks of swelling in various regions of the body. Its prevalence is estimated to be 1 in 50,000 people, with no reported bias among different ethnic groups. However, considering the estimated prevalence, the number of patients in Japan diagnosed with HAE remains approximately 1 in 250,000, which means that only 20% of potential HAE cases are identified.

Objective: This study aimed to develop an artificial intelligence (AI) model that can detect patients with suspected HAE using medical history data (medical claims, prescriptions, and electronic medical records [EMRs]) in the United States. We also aimed to validate the detection performance of the model for HAE cases using the Japanese dataset.

Methods: The HAE patient and control groups were identified using the US claims and EMR datasets. We analyzed the characteristics of the diagnostic history of patients with HAE and developed an AI model to predict the probability of HAE based on a generalized linear model and bootstrap method. The model was then applied to the EMR data of the Kyoto University Hospital to verify its applicability to the Japanese dataset.

Results: Precision and sensitivity were measured to validate the model performance. Using the comprehensive US dataset, the precision score was 2% in the initial model development step. Our model can screen out suspected patients, where 1 in 50 of these patients have HAE. In addition, in the validation step with Japanese EMR data, the precision score was 23.6%, which exceeded our expectations. We achieved a sensitivity score of 61.5% for the US dataset and 37.6% for the validation exercise using data from a single Japanese hospital. Overall, our model could predict patients with typical HAE symptoms.

Conclusions: This study indicates that our AI model can detect HAE in patients with typical symptoms and is effective in Japanese data. However, further prospective clinical studies are required to investigate whether this model can be used to diagnose HAE.

Introduction

The rare genetic disease hereditary angioedema (HAE) induces acute attacks of swelling in various regions of the body, including the face, hands, arms, legs, abdomen, genitals, buttocks, and throat. Gastrointestinal disturbances such as abdominal pain, nausea, and vomiting are frequently associated with edema. Laryngeal edema is rare, even though more than half of the patients with HAE encounter this life-threatening condition [1]. Its global prevalence is estimated to be 1 in 50,000 people, with no reported bias among different ethnic groups [2]. In Japan, about 1 in 250,000 people are diagnosed with HAE, which suggests that only 20% of potential HAE cases are identified [3], suggesting that many patients with HAE remain undiagnosed in Japan. Furthermore, in Japan, the mean duration from the first symptoms to diagnosis is 15.6 years [4], which is longer than that in Europe and the United States [5,6]. Early detection of undiagnosed patients is critical for effective treatment of HAE.

To overcome this situation in Japan, the Diagnostic Consortium to Advance the Ecosystem for Hereditary Angioedema (DISCOVERY) was established in 2021 [7]; it aimed to identify patients with undiagnosed HAE and provide them with appropriate treatment as early as possible.

In this study, we aimed to develop an artificial intelligence (AI) model that can detect suspected patients with HAE using medical history data (claims and electronic medical records [EMRs]) in the United States. We then sought to validate the model's performance in detecting HAE cases. In addition, we conducted a pilot study at Kyoto University Hospital (KUHP) using the EMR data to verify the model's applicability to medical data obtained from the Japanese population. The main objective of this study was to verify whether this model could identify patients with a history of HAE or related diseases.

Methods

Overview

First, we developed an AI model using medical history data from the United States as a reference. Thereafter, we applied the model to medical history data from Japan and verified its efficacy using a Japanese dataset. Note that we used a large dataset of patients from the United States as input for the model, considering that HAE is a rare disease.

Initial Model Development with US Dataset

Data Selection

The Merative MarketScan Explorys Claims-EMR Data Set (formerly IBM Watson Health) [8] was used to obtain patient-level linked claims and EMR data for US patients. The diagnoses and prescription histories of patients with edema or digestive symptoms from January 2012 to January 2021 were identified from the dataset and were used to build our model. Data from a total of 4,283,815 patients were used in the study.

To identify the diagnosis history of patients, the *International Classification of Diseases* (*ICD*) [9] code (ninth and 10th edition) available in this dataset was used. However, the *ICD* code for HAE (D84.1) represents "defects in the complement system," which is also applicable to other similar diseases. Therefore, we used the prescription history of drugs administered only for HAE (Table 1) to distinguish patients with HAE. We categorized the patients with a prescription history of these drugs as the "HAE group," representing patients presumed to have HAE.

Table 1. US Food and Drug Administration–approved medications used only for hereditary angioedema (as of January 2022).

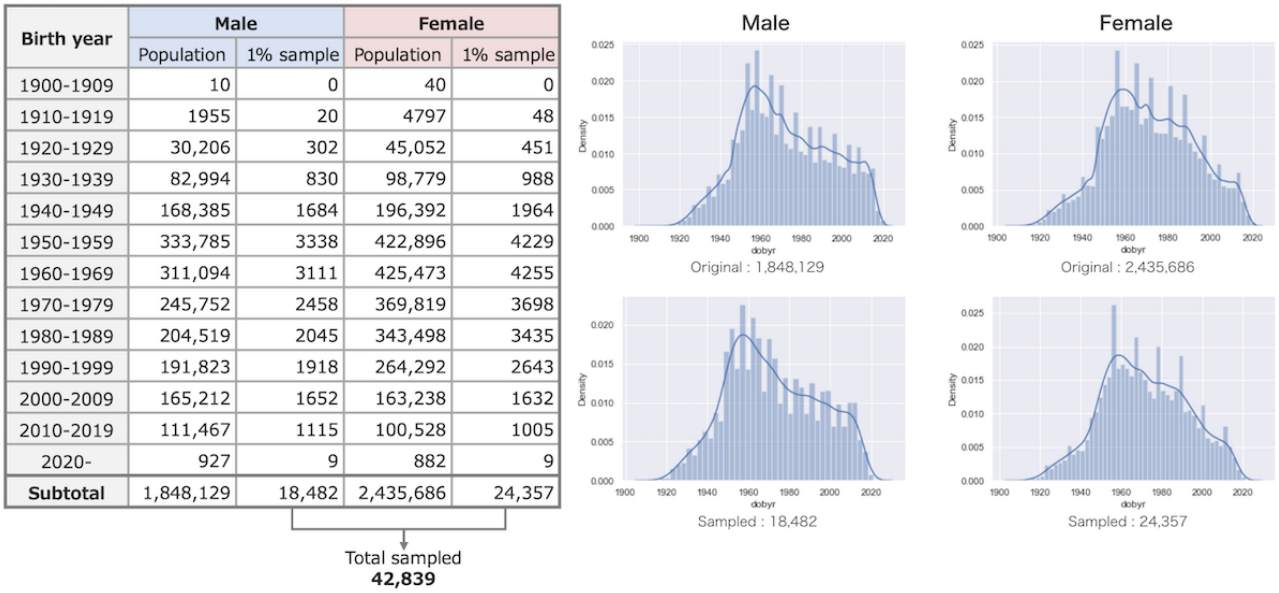
[a]NDC: National Drug Code.

To maintain the demographic characteristics of the original data, the control group was randomly sampled from 1% of the remaining patients, with a fixed ratio of age groups and male-to-female ratio (Figure 1). Note that this was crucial to reduce the data volume to operate the model using limited computation resources (2 central processing units and 16 GB of memory). This was done considering the potential use of the model in various medical institutions in the future.

Figure 1. Comparison of the distribution of the 1% sampled data set with that of the population. dobyr: date of birth year.



Birth year	Male		Female	
	Population	1% sample	Population	1% sample
1900-1909	10	0	40	0
1910-1919	1955	20	4797	48
1920-1929	30,206	302	45,052	451
1930-1939	82,994	830	98,779	988

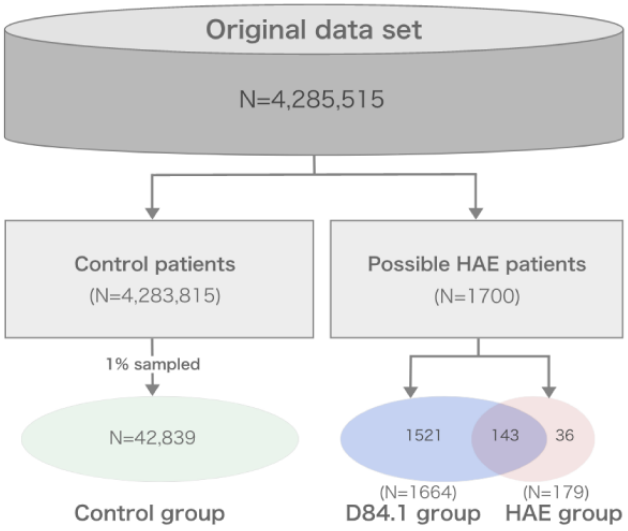
2000-2009	165,212	1652	163,238	1632
2010-2019	111,467	1115	100,528	1005
2020-	927	9	882	9
Subtotal	1,848,129	18,482	2,435,686	24,357

Finally, 3 groups were included for model development and validation (Figure 2): the HAE group with 179 patients, D84.1 (including individuals that likely have HAE but do not have a prescription history of HAE-specific treatments) with 1521 patients, and the control group with 42,839 patients.

Figure 2. Flowchart depicting the different patient groups created using the US data set; HAE: hereditary angioedema.



To develop the model, the *ICD* code was used to create features that described the diagnostic history of patients. As this dataset contained both *ICD-9* and *ICD-10* codes throughout the data period, we standardized the 2 *ICD* types. We assigned codes representing the same disease items from both *ICD-9* and *ICD-10* codes under a single ID.

Model Development

Feature Selection

We counted the number of types of *ICD* codes diagnosed in both the HAE and D84.1 groups, as these 2 groups should have similar features. Furthermore, the differences in *ICD* code types between the groups were required to create a model that can identify patients with HAE. We examined rank correlations between the 2 groups and found it to be approximately 0.08, which suggested that the 2 groups had different characteristics. We then examined specific *ICD* codes that were significantly ranked differently between the two groups and identified 25 such *ICD* codes, which were then used as the primary features in developing the model.

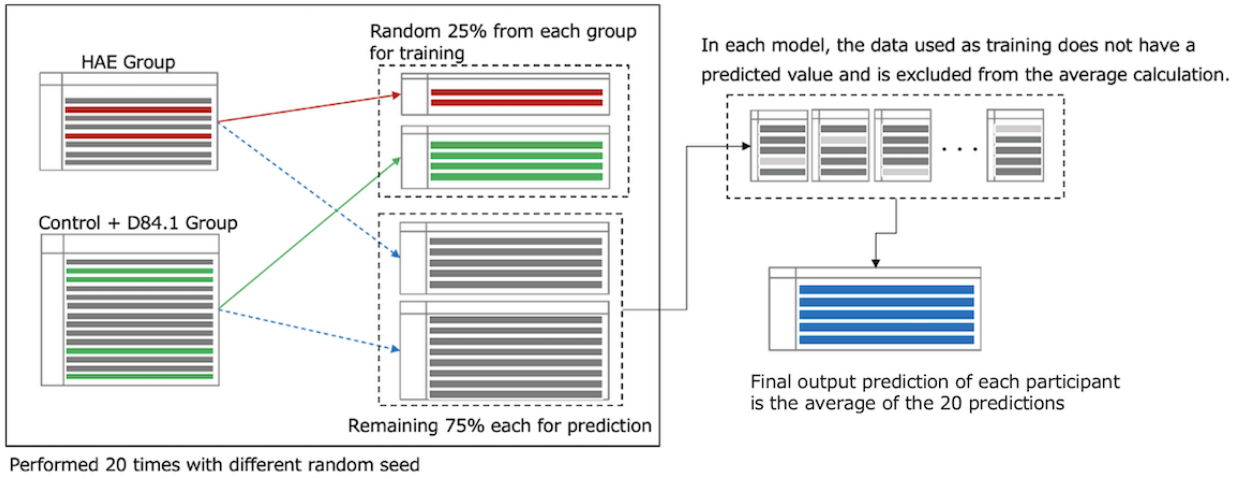
We also examined *ICD* codes that were diagnosed several times over a period of 1 year. This is important as patients with HAE tend to have repeated occurrences of swelling in various regions of the body [1], which can lead to the diagnosis of stomachaches and edemas. We counted the number of patients who had been diagnosed with stomachaches or edemas between 2 and 4 times per year and found a substantial difference between both groups. Considering that the medical record entry may overlap multiple times when changing the record types, we conducted the removal of duplicates based on the date and *ICD* code for each patient. Thereafter, we labeled a group of *ICD* codes related to abdominal pain or edemas and counted the number of times they were assigned in a 1-year span window for each patient based on this dataset. From this exploratory analysis, we included instances where individuals experienced four or more incidences of stomachaches and 3 or more incidences of edema per year as part of the main features of our model. The table of the explanatory variables is provided in Multimedia Appendix 1.

Model Building

The number of patients in the HAE group was extremely small compared with that in the control + D84.1 groups; thus, to avoid overfitting, we used bootstrap sampling [10,11] to create the model. A generalized linear model [12] with regularization terms [13,14] was adopted. We used $\log\left(\frac{p}{1-p}\right)$ for the link function to create a logistic model that would indicate the likelihood of the patient belonging to the HAE group. We chose logistic regression for evaluation as it allows for regression with regularization and is relatively easy to use for evaluating and interpreting feature importance by checking the coefficients. The estimation of the partial regression coefficients was calculated by the maximum likelihood method, which estimates parameters (known as maximum likelihood estimates) that maximize the likelihood of the given observed values. The regularization parameter λ was set to 1 to ensure that it was Lasso regularization.

We used 25% of the data from the HAE group and another 25% from the control + D84.1 groups to train the model, which was then used to predict the remaining 75% of each group. This modeling process was performed 20 times with different random seeds. The average predicted value was calculated as the final output for all the patients. In each trial, the sample used as training data did not have a predicted value and was excluded from the average value calculation (Figure 3). Upon applying the regularization using Lasso regression, the number of substantial features was sorted out during each calculation by mathematically adjusting the coefficients of some variables to 0. The number of sorted features varied with an average of 10; notably, different features were selected every time.

Figure 3. Training data extraction and prediction calculation of the constructed model. HAE: hereditary angioedema.



Evaluation Method and Threshold Setting

After obtaining the final value for each participant, we performed Welch *t* test on the 2 distributions to confirm that the 2 groups had different means. Subsequently, we defined the threshold value that yielded the most balanced classification accuracy using the receiver operating characteristic (ROC) curve. ROC curves help visualize the entire scenario of trade-offs between sensitivity and precision across a set of cutoff points. The volumes of the HAE and control + D84.1 groups were not equal; therefore, it was important to check the balance between sensitivity and precision rather than the accuracy itself.

Model Application to Japanese EMR Data

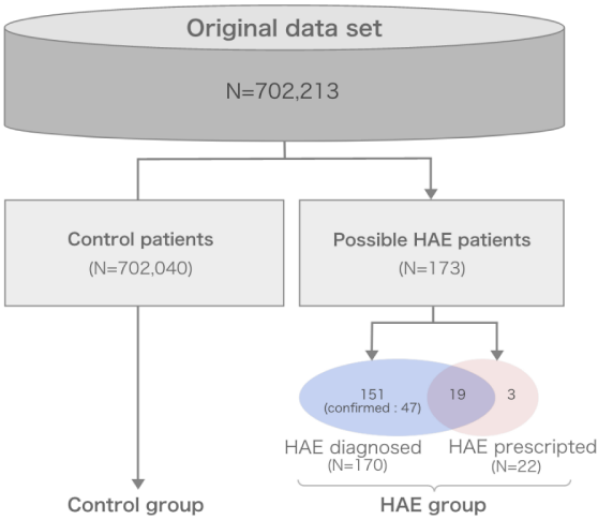
Data Extraction and Model Application

For the validation step using Japanese data, data were extracted from a data warehouse (DWH), which collects medical data from the EMR of the KUHP. Patient IDs in the DWH are pseudonymized. The medical data were obtained for a total of 702,213 patients, among which 22 had a history of HAE, 47 had a confirmed diagnosis of HAE, and 123 had a suspected diagnosis of HAE. The data for model validation included those associated with patients from all these groups (patients using drugs for HAE, patients with confirmed HAE, and patients suspected to have HAE). This was done because physicians may have suspected HAE for some patients if their symptoms were similar to those of patients with the condition. Therefore, these 3 types of patients were considered as the patients with HAE in the study (HAE group; Figure 4).

To adapt the model to Japanese data, we used the standard disease name codes widely used in Japan, as defined by the Medical Information System Development Center (MEDIS-DC) [15], instead of the *ICD* code. Although the *ICD* code is the basic classification code for diagnosis, the standard disease name codes have more subdivisions compared with the *ICD* code, and hence, they can provide a more precise clinical diagnosis. We converted the *ICD* codes using the standard disease name code master for *ICD-10* [16].

Patient data extracted from the DWH were transferred to the Google Cloud Platform server (a virtual private cloud environment) hosted at KUHP. The AI model and statistical programs were stored in a container and sent to the server. We then accessed the server through a virtual private network, which could only be accessed by the authors of this study. The model was applied to all patient data on this server.

Figure 4. Flowchart depicting the different patient groups obtained from the KUHP data set. HAE: hereditary angioedema.



Ethical Considerations

This study was approved by the Ethics Committee of the Kyoto University Hospital (approval number R3750). In this study, we used pseudonymized information that had already been processed, thus individual informed consent was not required. The pseudonymized medical data is made available for academic research in accordance with KUHP's privacy policy. Information regarding each study is publicly disclosed on the institution's website, where patients are informed of their right to opt out along with the opt-out procedure.

Results

Evaluation of the Initial Model

Welch *t* test indicated that the 2 patient groups did not have the same mean values, as suggested by the *P* value of 2.2e-16. Furthermore, the area under the ROC curve was 86.4%, which was obtained when only the HAE group was set as true and all the other groups as false. The best accuracy threshold of this ROC curve was calculated as 39%, with an accuracy of 99.6%. This is because the volume of the control + D84.1 group was larger than that of the HAE group. The true-positive (sensitivity) of this threshold was only 10.6%, with a precision of 54.3%.

As we aimed to identify patients likely to have HAE, we searched for a different threshold that could improve the sensitivity while keeping the precision at an acceptable level. Considering the fact that the prediction of the HAE group had  and , 0.075-0.125 could be a good threshold candidate. We confirmed the sensitivity and precision for the thresholds of 0.075, 0.1, and 0.125 to determine the most balanced threshold, as shown in Table 2.

Table 2. Cross-tabulation was calculated at 3 different threshold values using all data groups for a detailed evaluation of different scaled precisions and group sensitivities.

	Control group		D84.1 group	D84.1 and HAE[a]	HAE group (not D84.1)	Score (%)			
	100% scale converged	1% scale				1% scale precision	100% scale precision	Sensitivity 1[b]	Sensitivity 2[c]
Suspection statistic (threshold=0.1)									
Not suspected, n	4,279,500	42,795	1312	55	30	27.1	2.0	61.5	52.5
Suspected, n	4400	44	209	88	6	—[d]	—	—	—
Suspection statistic (threshold=0.075)

Suspected, n	3300	33	178	81	3	—	—	—	—

[a]HAE: hereditary angioedema.

[b]Excluding "not D84.1" patients.

[c]Including "not D84.1" patients.

[d]Not applicable.

The threshold value of 0.1 had a sensitivity of 52.5% and precision of 27.1%, indicating that 1 out of 2 known HAE group participants can be correctly detected, and 1 out of 4 detected participants should correctly belong to the HAE group. If we exclude the HAE group participants who were not diagnosed with D84.1, the sensitivity was 61.5%. This result was calculated based on 1% of the sample size of the original control group; thus, by multiplying the number of all participants from the control group by 100, we obtained a 100% scale precision of 2%. This was 2 times better than the 1% precision goal set at the beginning of the study. This means that based on this model, 1 out of 50 suspected patients is highly likely to have HAE. Considering that HAE prevalence is estimated to be 1 in 50,000 people, we can expect to find undiagnosed patients with HAE quickly and efficiently using this model output.

From a conservative standpoint, the threshold value of 0.1 seems optimal. However, to identify more potential patients with HAE, it might be better to apply the 0.075 threshold, which has a sensitivity of 55.3% and a precision of 23.9%. If we recalculate the 100% scale precision in the same manner as described above, we obtain 1.6%. This means we can still achieve our goal of 1% precision while improving the sensitivity.

In addition, we need to consider the fact that the ratio of suspected patients in the US dataset can be calculated to be approximately 0.09% with a 0.1 threshold and 0.15% with a threshold of 0.075. If this model is to be used on a much smaller volume dataset compared with the US dataset, there is an approximately 2 times higher risk of obtaining zero suspected patients with a 0.1 threshold than with the 0.075 threshold.

Application of the Model to Japanese EMR Data

To verify the performance of this model using Japanese data, it was applied to patient data obtained from KUHP, and the output of potential patients with HAE was obtained based on the selected threshold. The diagnostic histories of these patients were stored at a single university hospital. Compared with the dataset used to build the original model, the variation and coverage of the entire diagnostic history were assumed to be relatively low. Therefore, we adopted a threshold value of 0.075 in this validation study to aggressively identify patients with HAE. We considered the HAE group (Figure 4) as the correct data for this validation.

As shown in Table 3, 65 of 173 patients with HAE were detected using this model, indicating a sensitivity of 37.6%.

Table 3. Cross-tabulation with precision and sensitivity scores of Kyoto University Hospital results.

	Control group	HAE[a] group			Score (threshold=0.075)	
		Prescripted	Prescripted and diagnosed	Diagnosed	Precision (%)	Sensitivity (%)
Suspection statistic (threshold=0.075)					3.2	31.8
Not suspected	701,829	2	13	93		
Suspected	211	1	6	58		

[a]HAE: hereditary angioedema.

Some patients in the HAE group did not have a diagnostic history specific to HAE (eg, abdominal pain, swelling, or edema) within the KUHP data. Their common symptoms might have been treated by their primary doctors or clinics and not at this university hospital. Furthermore, because HAE is a hereditary disorder, some patients may have been diagnosed through family testing. These factors appear to lead to a lower sensitivity score for the Japanese dataset than that for the US data.

The precision score was 23.6%, which is more than 14 times higher than that of the initial model. As mentioned in the Introduction section, only 20% of patients in Japan are diagnosed with HAE, which means that 80% of patients with HAE are undiagnosed. Therefore, the 211 patients from the control group who were suspected to have HAE in our model may be undiagnosed patients with HAE.

Discussion

Principal Findings

In this study, we developed an AI model for screening patients with HAE and validated its performance using 2 methods.

First, a large patient dataset was selected to build a model containing patient-level linked claims and EMR data from the United States. The advantage of this dataset is that it contains a long-term prescription and diagnostic history across multiple medical institutes. The diagnostic characteristics of patients with HAE were determined by analyzing the dataset. Based on these characteristics, we constructed a generalized linear model with regularization terms. At a threshold of 0.1, the sensitivity score was 52.5% and the precision score was 27.1% if patients with possible HAE were included in the correct answer group. When these were excluded from the correct answers, the sensitivity score was 61.5%.

We then applied this model to Japanese EMR data. This validation was conducted at a single university hospital using DWH data. Generally, patients often visit local hospitals and rarely visit university hospitals if they present with common symptoms. Considering this situation, data obtained from a single university may have some difficulty with model performance. Although the sensitivity score was lower than that of the US dataset (37.6%), the precision score reached 23.6% with a threshold value of 0.075. This implies that our model has a high possibility of identifying patients with undiagnosed HAE in Japan.

Limitations

Our study had several limitations. Generally, because HAE is a rare disease, patient group data (correct answer data in machine learning) are quite small. In addition, the variance in each patient's features was larger than that in common diseases. We also suggest possible limitations and countermeasures.

Family History

In our basic analysis of the HAE group, we found that some patients in the HAE group had a lower diagnostic history than others. We suspected that these patients had been diagnosed with HAE based on their family histories. Because our model uses the diagnostic history to calculate the probability, these cases are potentially difficult to detect.

US Patient Data Consists of Data From Multiple Hospitals

Our model may rely on the fact that US patient data consists of data from multiple hospitals. Collecting data from multiple hospitals will allow tracking of the records of a single patient across these hospitals and provide a more detailed medical history. For validation in the Japanese dataset, we could only use data from a single university hospital, which may be one of the reasons for the low sensitivity.

Potential Patients With HAE Might Be Included in the Control + D84.1 Groups

Since the HAE diagnosis rate was low, it is likely that there were more patients with HAE in the control + D84.1 groups. In our approach, we assigned the HAE group a prescription history of HAE drugs to keep the model conservative.

Possible Difference in Diagnostic Tendency Between the United States and Japan

If there are differences in how doctors make diagnostics between countries, we may need to customize the model or threshold to adapt it to Japan and other countries.

Comparison With Previous Work

Few previous studies have focused on screening patients for rare diseases based on diagnostic histories such as medical claims. Nonetheless, some studies have focused on a few rare diseases. For example, a previous study used AI models based on diagnostic history to identify patients with Pompe disease [17]. In this study, 104 patients were flagged by the model to have the disease, but only 19 were determined by specialists to have a high likelihood of having Pompe disease, rendering a precision score of 18.27% [17]. In comparison, our model recorded a precision of 23.6%. Screening for rare diseases is extremely difficult compared with other common diseases, for which abundant data exist; however, our results indicate that AI models can show high performance for screening rare diseases.

Conclusions and Future Directions

Considering the prevalence of HAE (1/50,000), the screening performance of this model was 1,000 times greater than that achieved through random searching using US data. Owing to their prevalence and recognition rates, identifying undiagnosed patients with rare diseases is an arduous task. This study suggests that patient screening for HAE may become significantly more efficient if this AI model is used. This approach is particularly valuable for the diagnosis and treatment of rare diseases.

In addition, during the validation phase using the Japanese data, the model was effective at a single university hospital. Although only the diagnosis codes recorded in the EMR were available, the model could detect patients with typical symptoms of HAE. The performance of the model can likely be improved further if this model is applied to the data from city hospitals or medical claims, which contain diagnostic histories of patients in multiple medical institutions. This can provide more comprehensive information on the symptoms and diagnostic histories of each patient.

In this study, only patients with a diagnostic history of HAE within the dataset were defined as correct answers. By providing a diagnosis rate, these data may include patients with undetected HAE. The model performance cannot be strictly calculated in such situations. Therefore, further studies are needed to determine whether patients with undiagnosed HAE should be included in the predicted group. This is because identifying undiagnosed patients with HAE is a critical issue, especially in Japan; we will implement a prospective clinical study using our AI model.

The constructed model may help researchers, physicians, and other health care professionals identify undiagnosed HAE cases. Eventually, if this strategy can identify undiagnosed patients and provide them with proper treatment, their quality of life will likely be improved.

Abstract

Background: Acute kidney injury (AKI) is a common adverse outcome following nephrectomy. The progression from AKI to acute kidney disease (AKD) and subsequently to chronic kidney disease (CKD) remains a concern; yet, the predictive mechanisms for these transitions are not fully understood. Interpretable machine learning (ML) models offer insights into how clinical features influence long-term renal function outcomes after nephrectomy, providing a more precise framework for identifying patients at risk and supporting improved clinical decision-making processes.

Objective: This study aimed to (1) evaluate postnephrectomy rates of AKI, AKD, and CKD, analyzing long-term renal outcomes along different trajectories; (2) interpret AKD and CKD models using Shapley Additive Explanations values and Local Interpretable Model-Agnostic Explanations algorithm; and (3) develop a web-based tool for estimating AKD or CKD risk after nephrectomy.

Methods: We conducted a retrospective cohort study involving patients who underwent nephrectomy between July 2012 and June 2019. Patient data were randomly split into training, validation, and test sets, maintaining a ratio of 76.5:8.5:15. Eight ML algorithms were used to construct predictive models for postoperative AKD and CKD. The performance of the best-performing models was assessed using various metrics. We used various Shapley Additive Explanations plots and Local Interpretable Model-Agnostic Explanations bar plots to interpret the model and generated directed acyclic graphs to explore the potential causal relationships between features. Additionally, we developed a web-based prediction tool using the top 10 features for AKD prediction and the top 5 features for CKD prediction.

Results: The study cohort comprised 1559 patients. Incidence rates for AKI, AKD, and CKD were 21.7% (n=330), 15.3% (n=238), and 10.6% (n=165), respectively. Among the evaluated ML models, the Light Gradient-Boosting Machine (LightGBM) model demonstrated superior performance, with an area under the receiver operating characteristic curve of 0.97 for AKD prediction and 0.96 for CKD prediction. Performance metrics and plots highlighted the model's competence in discrimination, calibration, and clinical applicability. Operative duration, hemoglobin, blood loss, urine protein, and hematocrit were identified as the top 5 features associated with predicted AKD. Baseline estimated glomerular filtration rate, pathology, trajectories of renal function, age, and total bilirubin were the top 5 features associated with predicted CKD. Additionally, we developed a web application using the LightGBM model to estimate AKD and CKD risks.

Conclusions: An interpretable ML model effectively elucidated its decision-making process in identifying patients at risk of AKD and CKD following nephrectomy by enumerating critical features. The web-based calculator, found on the LightGBM model, can assist in formulating more personalized and evidence-based clinical strategies.

KEYWORDS

nephrectomy; acute kidney injury; acute kidney disease; chronic kidney disease; machine learning

Introduction

Renal tumors rank as the second most prevalent neoplasms in urology, succeeding bladder cancer, and their annual incidence is on the rise [1,2]. Nephrectomy remains the preferred therapeutic modality for localized renal tumors [3], and patients who are eligible for nephrectomy generally favor longer life span [4]. Nevertheless, a decline in kidney function frequently ensues following nephrectomy. It has been proven that the nephron reduction stemming from radical nephrectomy (RN) or partial nephrectomy (PN) can result in postoperative acute kidney injury (AKI), subsequently heightening the risk of chronic kidney disease (CKD) and mortality [5,6]. Therefore, it is crucial to discern the predicted risk factors associated with renal function decline and precisely forecast postoperative renal impairment, enabling timely intervention.

AKI and CKD are not 2 separate clinical syndromes but often manifest as a continuum of disease [7]. The 16th Acute Disease Quality Initiative meeting has defined acute kidney disease (AKD) as the occurrence of acute or subacute damage or loss of kidney function for a duration of 7 to 90 days after the onset of an AKI-initiating event [8]. Within the AKD time frame, interventions like patient education, medication adjustments, and regular follow-up can be initiated, potentially leading to disease reversal [9]. According to AKD definition, renal recovery is classified into 3 primary groups: transient AKI, subacute AKD, and persistent AKI [8].

Recent, noteworthy strides in machine learning (ML) have given rise to remarkable breakthroughs, encompassing fields like autonomous driving, recommending products, and surpassing human expertise in intricate games such as chess [10-12]. These advancements have increasingly impacted the health care domain, particularly in clinical decision support systems, aiding in clinical decision-making, forecasting disease progression, and enhancing the distribution of medical resources [13,14]. ML offers significant advantages in clinical decision-making by analyzing large datasets, facilitating high-throughput and real-time predictions, and identifying complex patterns. However, considering the challenges related to decision-making transparency, individual patient variability, and ethical concerns, ML should be considered a complementary tool to enhance physicians' diagnostic capabilities rather than substituting their expertise. One of the prominent challenges faced by ML in the health care domain is the enigma referred to as the "black-box phenomenon," indicating the deficiency in interpretability experienced by both patients and health care providers [15,16]. The absence of interpretability in predictive models can erode trust in these models, particularly in health care, where numerous decisions directly involve matters of life and death. Recent advancements, however, have introduced algorithms that effectively extract crucial variables and elucidate model decisions [17].

Currently, there is limited research on the risk prediction of AKD following nephrectomy, and the impact of postnephrectomy AKD on CKD remains unclear. Additionally, there is a lack of interpretable ML models and web-based prediction tools for both AKD and CKD. Therefore, this study aimed to achieve the following objectives: (1) assess the postoperative occurrence rates of AKI, AKD, and CKD in patients who underwent nephrectomy; (2) contrast the long-term renal prognosis across AKI recover, subacute AKD, and patients with AKD and AKI; (3) formulate risk prediction models for both AKD and CKD through the use of diverse ML algorithms; (4) determine the optimal models, evaluate their predictive efficacy, and explain via Shapley Additive Explanations (SHAP) values and Local Interpretable Model-Agnostic Explanations (LIME) algorithms; (5) use directed acyclic graphs (DAGs) to explore potential associations and causal pathways between features; and (6) devise an easily accessible web-based prediction tool tailored to estimating the likelihood of AKD and CKD after nephrectomy. We hypothesized that patients with acute or subacute renal impairment are more susceptible to CKD progression compared to those with normal renal function. Furthermore, we expected significant differences in the development of CKD among patients recovering from AKI, those with subacute AKD, and those experiencing AKD with AKI.

Methods

Study Design

We conducted a retrospective review of medical records for 2637 patients who underwent nephrectomy between July 2012 and June 2019. Ultimately, the study included 1559 eligible patients. The patient data were sourced from a prominent tertiary hospital known for its comprehensive services and ranked among the top 60 nationwide in terms of overall performance. Patients were followed up for a duration ranging from 3.0 to 62.8 months until December 2019, with the primary focus being on the development of CKD as a long-term outcome. The patient data were randomly stratified into training, validation, and test sets, using Python's stratified random sampling method, maintaining a ratio of 76.5:8.5:15. Internal validation was performed through 10-fold cross-validation, involving the partitioning of the training and validation sets into 10 subsets. A majority of 9 of these subsets were used for model training, and the remaining 1 was dedicated to model evaluation. The exclusion criteria for this study encompassed the following characteristics: (1) patients younger than 18 years of age or with

hospitalization duration <24 hours, (2) patients with inadequate serum creatinine (Scr) monitoring interval, (3) patients with anatomical kidney malformations, (4) patients undergoing renal cyst unroofing or donor nephrectomies, (5) patients with pre-existing CKD or undergoing dialysis prior to nephrectomy, and (6) patients lacking essential features such as Scr.

Ethical Considerations

This study received approval from the Ethics Committee of the Affiliated Hospital of Qingdao University (approval QDFY WZ 2018-9-13). Informed consent was waived due to the retrospective nature of the data and the large number of patients involved, making it impractical to seek consent from each patient. All data were deidentified. No compensation was provided to the participants as the study did not involve direct participant interaction.

Data Collection

Clinical and demographic data were extracted through the application of natural language processing and parsing methods on structured information within the electronic health record. Preoperative complete blood counts, coagulation markers, blood chemistry analyses, urine tests, and echocardiography were performed within 3 days of admission. Comorbidities were defined based on the *International Statistical Classification of Diseases, Tenth Revision*. Comprehensive data on concomitant medications were meticulously collected, with particular attention to instances where these medications were administered prior to the occurrence of kidney injury. The surgical details encompass the surgical approach (laparotomy, laparoscopy, and da Vinci surgery), procedure type (RN and PN), duration of the surgery, pathological findings, maximum excision diameter, and blood loss.

Outcome Definitions

The primary outcome of our study was postoperative AKI. The secondary outcomes were AKD and CKD. AKI was defined as an increase in Scr to ≥0.3 mg/dL within 48 hours or ≥1.5 times the baseline value within 7 days, following the 2012 Kidney Disease Improving Global Outcomes guideline [18]. According to the 2017 Acute Disease Quality Initiative, AKD was defined as persistent renal damage or renal dysfunction for a duration of 7 to 90 days after exposure to an AKI initiating event [8]. CKD was defined as abnormalities of kidney structure or function for at least 3 months [19]. Based on the diagnostic criteria for AKI and AKD, patients exhibited three distinct trajectories of renal function following kidney injury: (1) AKI recover, if Scr returned to baseline value within 7 days (AKI without AKD); (2) AKD with AKI, if stage 1 or greater AKI persisted for ≥7 days after an AKI initiating event (continuous AKI progressing to AKD); and (3) subacute AKD, if Scr levels increased slowly but lasted more than 7 days (AKD without AKI). The final classification consisted of four categories: (1) no kidney disease (NKD), (2) AKI recover, (3) AKD with AKI, and (4) subacute AKD.

Baseline Scr was defined as the most recent Scr level measured before nephrectomy. The diagnosis time of AKI, AKD, and CKD was established when patients first met the respective diagnostic criteria. All patients underwent at least 3 Scr tests, including 2 during hospitalization and 1 at the first follow-up. If elevated Scr levels did not return to baseline, additional tests were conducted once a week during hospitalization or at the next follow-up. The estimated glomerular filtration rate (eGFR) was calculated by using the Chronic Kidney Disease Epidemiology Collaboration creatinine formula [20].

Model Development and Interpretation

The Light Gradient-Boosting Machine (LightGBM) algorithm was used to construct predictive models. LightGBM, a tree-based gradient-boosting framework, adeptly manages high-dimensional and extensive datasets [21]. By integrating gradient-based 1-side sampling and exclusive feature bundling, LightGBM effectively mitigates overfitting and notably outperforms the computational speed and memory use of Extreme Gradient-Boosting and stochastic gradient-boosting techniques [22]. In our comparative analysis, we trained various ML models, including LightGBM, Gradient-Boosting Machine, k-nearest neighbors, multilayer perceptron, logistic regression (LR), naive Bayes, random forest (RF), and support vector machine, using the same dataset and applying consistent imputation and scaling techniques. We initially used the default hyperparameters of each ML algorithm to establish our models. Subsequently, we conducted manual parameter tuning by grid search to optimize the performance. The process of parameter optimization was facilitated through 10-fold cross-validation, aiding in the identification of the most suitable hyperparameter configurations [23].

For discerning significant features that influenced the algorithm and ensuring the appropriateness of the optimal model, we used SHAP and LIME to interpret the model from both global and instance-based perspectives. SHAP values, rooted in the Shapley value from coalitional game theory, quantify the influence of each feature variable on the target outcome, elucidating the derivation of a sample's predicted result [24]. LIME uses local surrogate models for explaining individual predictions. Its core method perturbs an input instance to generate interpretable samples, upon which a linear model approximates the complex model's decision-making process near the instance [25]. The SHAP summary plots exhibit the relative significance of individual features in predictions, along with their corresponding positive or negative impact directions. The SHAP interaction plots reveal the interactions among multiple features and illustrate how their combined influence impacts model predictions. We separately used the top 10 features from the AKD and CKD models and created SHAP dependence plots through pairwise combinations to elucidate the influence of individual features on the model's predictions and the correlations among them. Additionally, we highlighted features with significant correlations in Figure S5 in Multimedia Appendix 1. The SHAP force plots and LIME bar plots were used to clarify individualized forecasts, demonstrating each feature's contribution to the prediction of individual samples. Finally, we used AKD and CKD as outcomes and applied the PC algorithm to construct DAGs, facilitating the exploration of potential associations and causal pathways among the top 20 features [26,27].

Web-Based Prediction Tool

A web-based calculator for predicting AKD and CKD among those patients was developed using the "Streamlit" application in terms of the optimal model. Streamlit, an open-source Python framework, aids developers in swiftly constructing web-based and responsive applications [28]. To improve the user-friendliness of the web calculator, this study implemented 2 panels: one for inputting model parameters and acquiring AKD or CKD probabilities and another for providing a model introduction.

Statistical Analysis

Features with a missing proportion exceeding 15% (n=234) are removed, while those with missing proportions less than 15% (n=234) are imputed using an RF model. Using LR to calculate the required sample size with CKD as the outcome, we determined that a minimum of 1171 patients is necessary to attain a statistical power of 90% for detecting an effect size of 0.10 at a 2-side α=.05. Categorical features were presented using frequencies and percentages, while continuous features were presented as mean (SD) or median (IQR). Comparative analyses were performed to assess patient characteristics between individuals with and without CKD as well as among various trajectories of renal function postkidney injury. Quantile-quantile plots were generated to visually inspect the distribution patterns of continuous features. The independent 2-tailed *t* test was used for normally distributed continuous features, the Mann-Whitney *U* test for nonnormally distributed continuous features, and the Pearson chi-square test for categorical features. We used a weight rebalancing technique to adjust the weights of both the majority and minority classes in the training dataset [29]. The validation dataset underwent balancing, whereas the test datasets remained unaltered to assess model performance with representative data. The scikit-learn Python library (Python Software Foundation) includes a built-in parameter called "class weight" or "weights" for LR, RF, LightGBM, support vector machine, and k-nearest neighbors. For AKD, the class weight was set to 3.3; and for non-AKD cases, it was set to 0.6. Similarly, the class weight for CKD was set to 10.0; and for non-CKD cases, it was set to 0.5. In the case of the naive Bayes classifier, we established a prior probability of .50 for each class to achieve group balance, and we adjusted class weights in the multilayer perceptron classifier by modifying the loss function's weights. The area under the receiver operating characteristic curve (AUROC) was used for optimal model selection. The model underwent evaluation through graphical techniques, encompassing the receiver operating characteristic curve and decision curve analysis, in addition to quantitative metrics such as AUROC, average precision, precision, recall, accuracy, F_1-score, Brier score loss, and Matthew correlation coefficient. A *P* value of less than .05 was considered as significant (2-tailed). Python programming language (version 3.9.13 and integrated development environment Visual Studio Code 1.81.1) was applied to our analysis.

Results

Study Cohort

The entire study process is illustrated in Figure 1. Among the participants, 1131 (72.6%) underwent RN, and 1152 (73.9%) underwent laparotomy. The incidence rates of AKI, AKD, and CKD were 21.7% (330/1559), 15.3% (238/1559), and 10.6% (165/1559), respectively. In total, there were 451 (28.9%) patients who developed acute or subacute kidney dysfunction (AKI or AKD criterion), with 117 (7.5%) meeting both AKI and AKD criteria, 121 (7.8%) developed subacute AKD, and 213 (13.7%) experienced recovery from AKI. The quantile-quantile plots show that features including blood loss, Scr, and operative duration exhibit skewed distributions, potentially due to the distinct condition of nephrectomy patients (Figure S1 in Multimedia Appendix 1). Increased CKD rates were observed in older patients (mean age 69, SD 9.6 vs mean age 58, SD 12.3 years), male patients (n=118, 12.9% vs n=47, 7.3% in female patients), those who underwent RN (n=143, 12.6% vs n=22, 5.1% in PN), AKD with AKI (n=42, 35.9% vs n=32, 26.4% in subacute AKD, n=24, 11.3% in AKI recovery, and n=67, 6% in NKD), and individuals with 1 or more chronic complications such as hypertension, diabetes mellitus, and coronary heart disease. The demographic and clinical characteristics of the patient cohort, both within different groups and as a whole, are detailed in Table 1 and Table S1 in Multimedia Appendix 2.

Figure 1. Flow diagram of patients' enrollment. AKD: acute kidney disease; AKI: acute kidney injury; CKD: chronic kidney disease; ML: machine learning; Scr: serum creatinine.

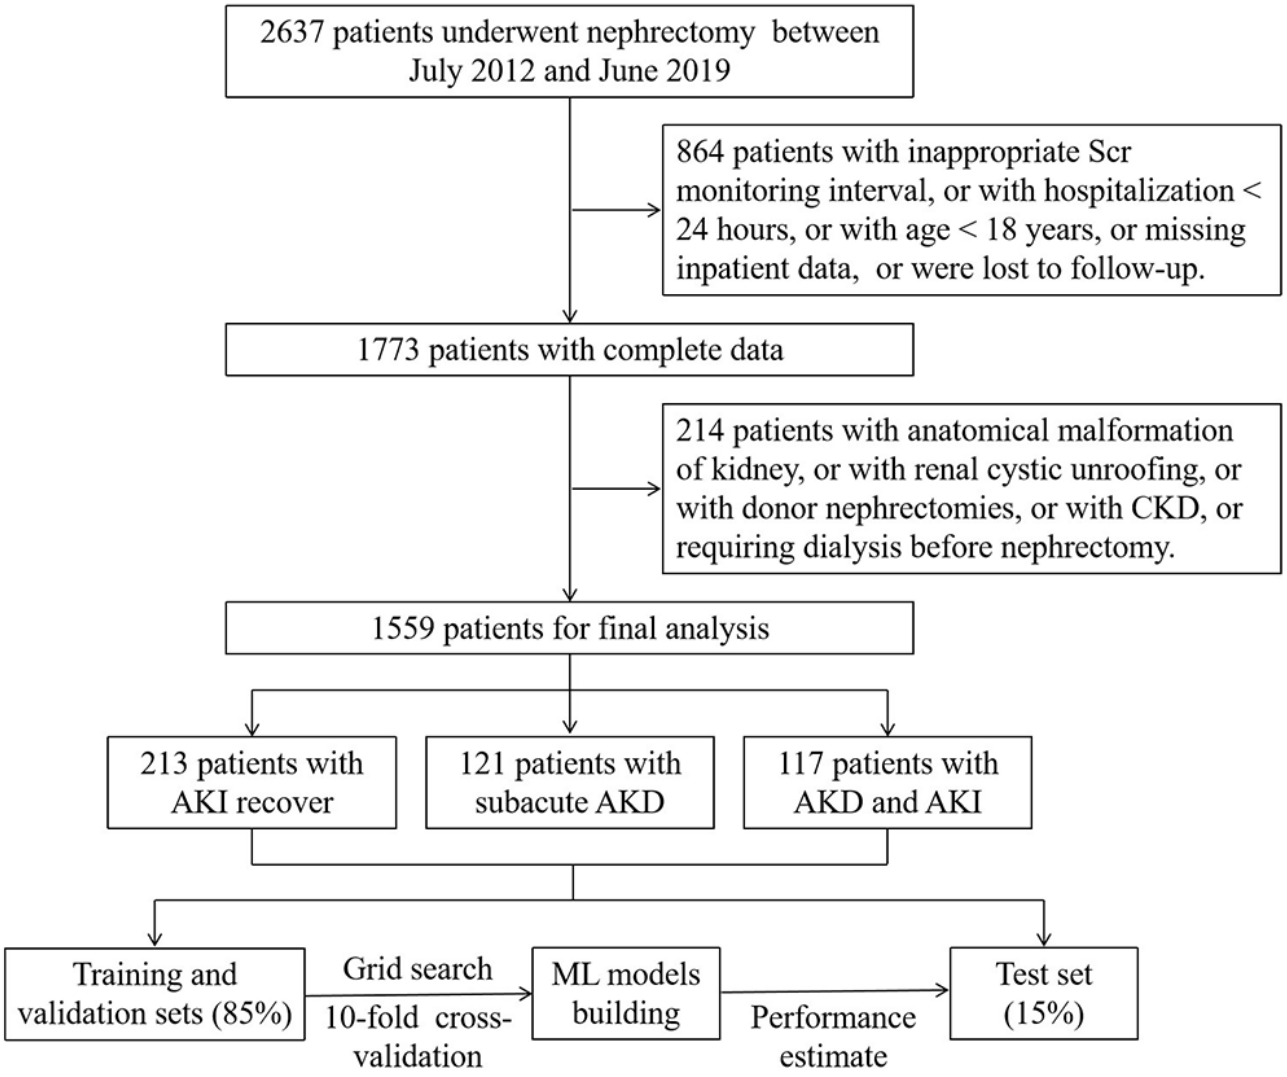

Table 1. Baseline characteristics of patients with and without CKD[a].

Features	Total (N=1559)	CKD-free (n=1394)	CKD (n=165)	*P* value
Age (years), mean (SD)	59.1 (12.5)	58 (12.3)	68.5 (9.6)	<.001
Male, n (%)	914 (58.6)	796 (57.1)	118 (71.5)	<.001

[c]ACEI or ARB: angiotensin-converting enzyme inhibitor or angiotensin receptor blocker.

[d]AKI: acute kidney injury.

[e]AKD: acute kidney disease.

Model Performance

A comprehensive set of over 90 features was served as features for both AKD and CKD and were integrated into the ML models. Among the assessed ML models, the LightGBM model demonstrated superior performance (Figure S2 in Multimedia Appendix 1 and Tables S2 and S3 in Multimedia Appendix 2). In the test set, LightGBM achieved the highest AUROC of 0.97 for AKD and 0.96 for CKD prediction. The F_1-scores, 0.75 for AKD and 0.70 for CKD, indicate a balanced trade-off between precision and recall. Additionally, Brier score loss was maintained at 0.05 for both AKD and CKD predictions, demonstrating the model's impressive calibration. To create a user-friendly web-based calculator, we simplified the model by reducing the number of input features. The inclusion of the top 10 and top 5 features for the AKD and CKD models, respectively, negligibly affected the LightGBM model's AUROC (achieving 0.94 vs 0.97 for AKD prediction and 0.94 vs 0.96 for CKD prediction, as detailed in Figure S2 in Multimedia Appendix 1 and Table 2). Notably, it outperformed all other ML algorithms in terms of AUROC (Tables S4 and S5 in Multimedia Appendix 2), while maintaining an optimal balance between precision, recall, and error rates (both false positives and negatives). Subsequently, we used the LightGBM model for result interpretation and the development of a web-based calculator. Comprehensive insights into performance metrics and visualizations are provided in Figures S2 and S3 in Multimedia Appendix 1, Table 2, and Tables S2-S5 in Multimedia Appendix 2.

Model Interpretation

The SHAP summary plots of the LightGBM models are depicted in Figure 2. Operative duration, hemoglobin (Hb), blood loss, urine protein, and hematocrit were the top 5 features associated with predicted AKD. Baseline eGFR, pathology, trajectories of renal function, age, and total bilirubin were the top 5 features associated with predicted CKD. The SHAP interaction plots visually elucidate the interplays among the top 10 features in both the AKD and CKD models (Figure S4 in Multimedia Appendix 1). The SHAP dependence plots offer detailed insights into the correlations among the top 10 features, as depicted in Figures S6 and S7 in Multimedia Appendix 1, with representative examples showcased in Figure S5 in Multimedia Appendix 1. For instance, the influence of AKI grade on the probability of AKD varies across Hb levels. Among patients with lower Hb levels, higher AKI grades are associated with a significant increase in the risk of AKD. Conversely, this correlation is less pronounced in patients with higher Hb levels. For patients presenting with a baseline eGFR below 80, postoperative complications, such as AKD with AKI, subacute AKD, or AKI recover, markedly elevate the risk of developing CKD. This observation underscores the significance of encompassing factors like trajectories of renal function within a comprehensive clinical framework, particularly one that integrates a patient's eGFR.

Sample individualized predictions with their explanations are shown in Figure 3. The AKD and CKD models, respectively, present the top 10 and top 5 features. We selected 4 random samples from the test set and analyzed them using both the SHAP and LIME algorithms. For example, Figure 3D presents an individualized explanation for a case where the actual and predicted outcomes are both CKD. The notably high predicted probability for CKD (P=.97) primarily stemmed from several incremental factors, including a low baseline eGFR level (39.36 mL/min/1.73 m^2), postoperative complications of AKD with AKI, clear cell pathology, and a history of antibiotic use, despite a normal white blood cell level (3.94×10^9/L). The SHAP force plot revealed minor deviations in the top 5 features for predicting this patient, highlighting the greater significance of γ-glutamyl transferase over albumin-globulin (AG) ratio.

DAG is a type of causal diagram comprising nodes representing features and arrows representing causal relationships between the features. Since the importance of features does not necessarily reflect causality, we designated only AKD and CKD as end points (nodes with only inward-pointing arrows) in the DAGs, without designating source nodes (nodes with only outward-pointing arrows). Given that analyzing all features (over 90) would lead to an excessively complex causal structure, we limited the analysis to the top 20 features for AKD and CKD. During the investigation of AKD as the outcome, we observed direct links from features such as AKI grade, operative duration, systolic blood pressure, Hb, antibiotic, baseline eGFR, urine protein, and hematocrit to AKD, indicating potential direct causality (Figure S8 in Multimedia Appendix 1). All these features, except for antibiotics, are among the top 10 features for AKD prediction. We discovered that the trajectories of renal function, pathology, and baseline eGFR exhibit potential direct causal relationships with CKD, and they also rank among the top 5 features in the CKD model (Figure S9 in Multimedia Appendix 1). Age did not exert a direct effect on CKD but influenced it indirectly through its impact on pathology and baseline eGFR. Despite AG and procedure being within the top 10 features for CKD, our analysis did not reveal a causal link to CKD, suggesting that while there was a correlation between AG or procedure and CKD, they were causally independent.

Figure 2. SHAP summary plots of the top 10 features in the Light Gradient Boosting Machine model for (A and B) AKD and (C and D) CKD prediction. (A) The ranking of feature importance within the AKD prediction model. Features with higher mean absolute SHAP values signify increased predictive influence. (B) Each dot represents the SHAP value of a specific feature for an individual, with red and blue indicating high and low feature values, respectively. On the x-axis, a positive or negative SHAP value signifies that the feature positively or negatively influenced the AKD prediction for the individual. (C) The ranking of feature importance within the CKD prediction model. (D) The distribution of the impacts of the top 10 features on the CKD model output. AG: albumin-globulin; AKD: acute kidney disease; AKI: acute kidney injury; ALB: albumin; CKD: chronic kidney disease; eGFR: estimated glomerular filtration rate; GGT: γ-glutamyl transferase; Hb: hemoglobin; Hct: hematocrit; MPV: mean platelet volume; SBP: systolic blood pressure; SHAP: Shapley Additive Explanations; TBIL: total bilirubin; WBC: white blood cell.

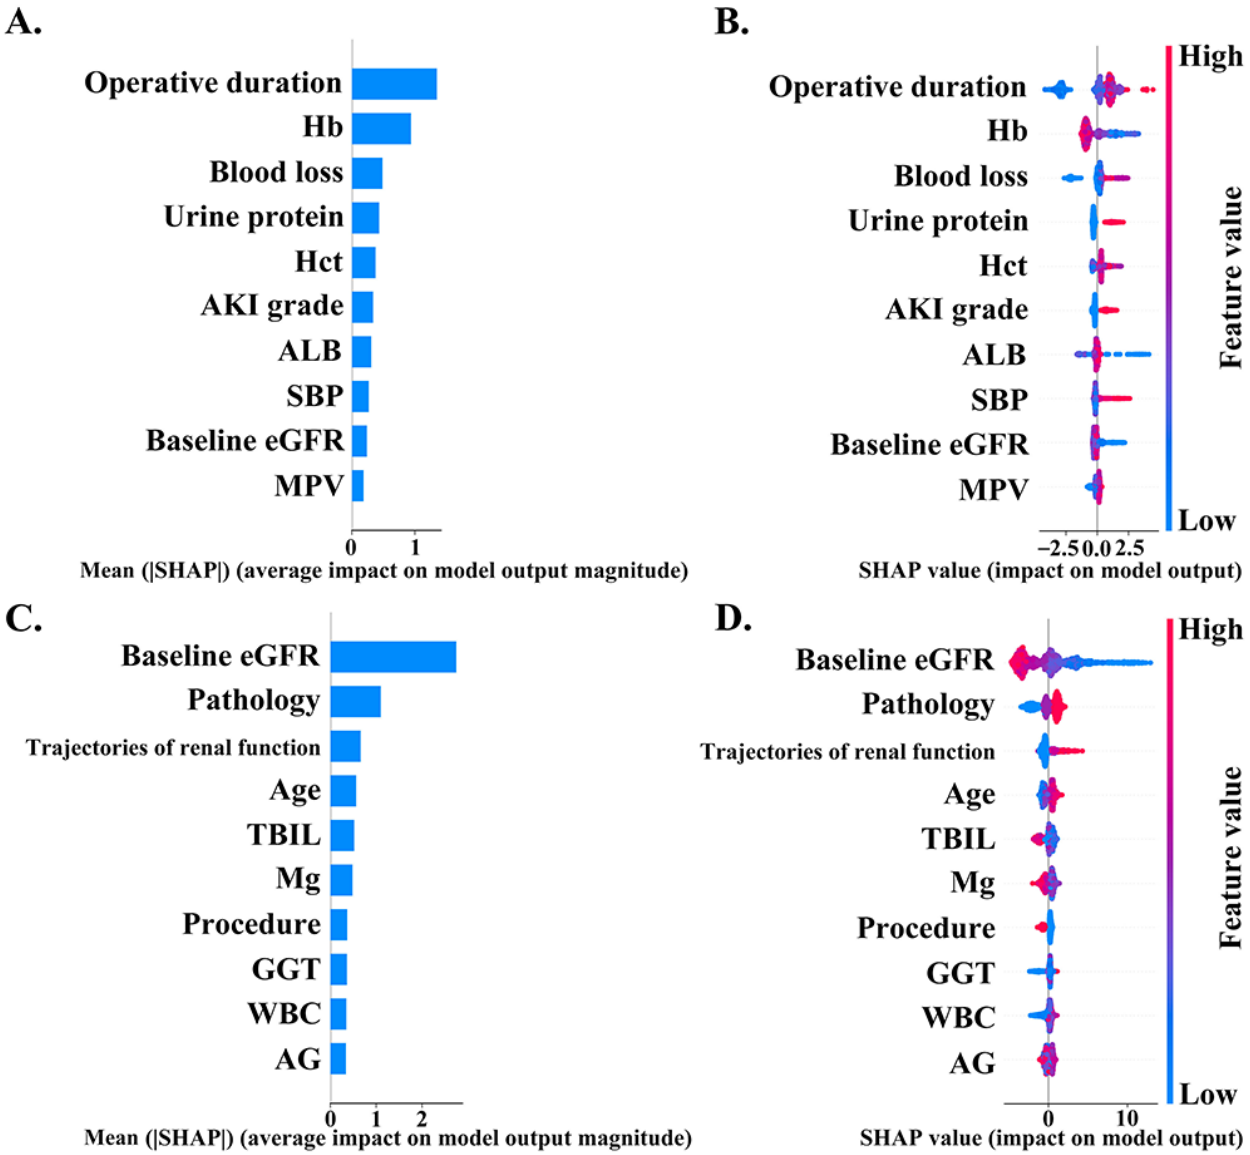

Figure 3. SHAP force plots and LIME bar plots for explaining individual predictions for (A and B) AKD and (C and D) CKD. (A) The SHAP force plot (upper section) and the LIME bar plot (lower section) are used to illustrate a case where both actual and predicted outcomes indicate AKD-free status. The SHAP force plot outlines the top 10 features for the prediction, where red feature values positively impact the AKD outcome, while blue values have a negative impact. The importance of each feature is reflected by the length of its corresponding arrow, with longer arrows highlighting more significant influences. In the LIME bar plot, the left section shows an 87% predicted probability of the patient being AKD-free. The central section lists the top 10 features for predicting AKD-free or AKD status, with the length of each bar indicating its importance. Blue bars indicate positive influences, whereas yellow bars signify negative impacts. The right panel presents the specific values at which these top 10 features have the most substantial impact on the AKD-free or AKD prediction. (B) The SHAP force plot and the LIME bar plot, emphasizing the top 10 features, depict a case where both actual and predicted outcomes align with AKD status. (C) The SHAP force plot and the LIME bar plot, emphasizing the top 5 features, depict a case where both actual and predicted outcomes align with CKD-free status. (D) The SHAP force plot and the LIME bar plot, emphasizing the top 5 features, depict a case where both actual and predicted outcomes align with CKD status. AG: albumin-globulin; AKD: acute kidney disease; AKI: acute kidney injury; ALB: albumin; CKD: chronic kidney disease; EF: ejection fraction; eGFR: estimated glomerular filtration rate; FIB: fibrinogen; FLD: fatty liver disease; GGT: γ-glutamyl transferase; Hb: hemoglobin; Hct: hematocrit; LDLC: low-density lipoprotein cholesterol; LIME: Local Interpretable Model-Agnostic Explanations; MPV: mean platelet volume; NKD: no kidney disease; NSAID: nonsteroidal anti-inflammatory drug; PCT: procalcitonin; PN: partial nephrectomy; PTA: prothrombin activity; SHAP: Shapley Additive Explanations; TBIL: total bilirubin; WBC: white blood cell.

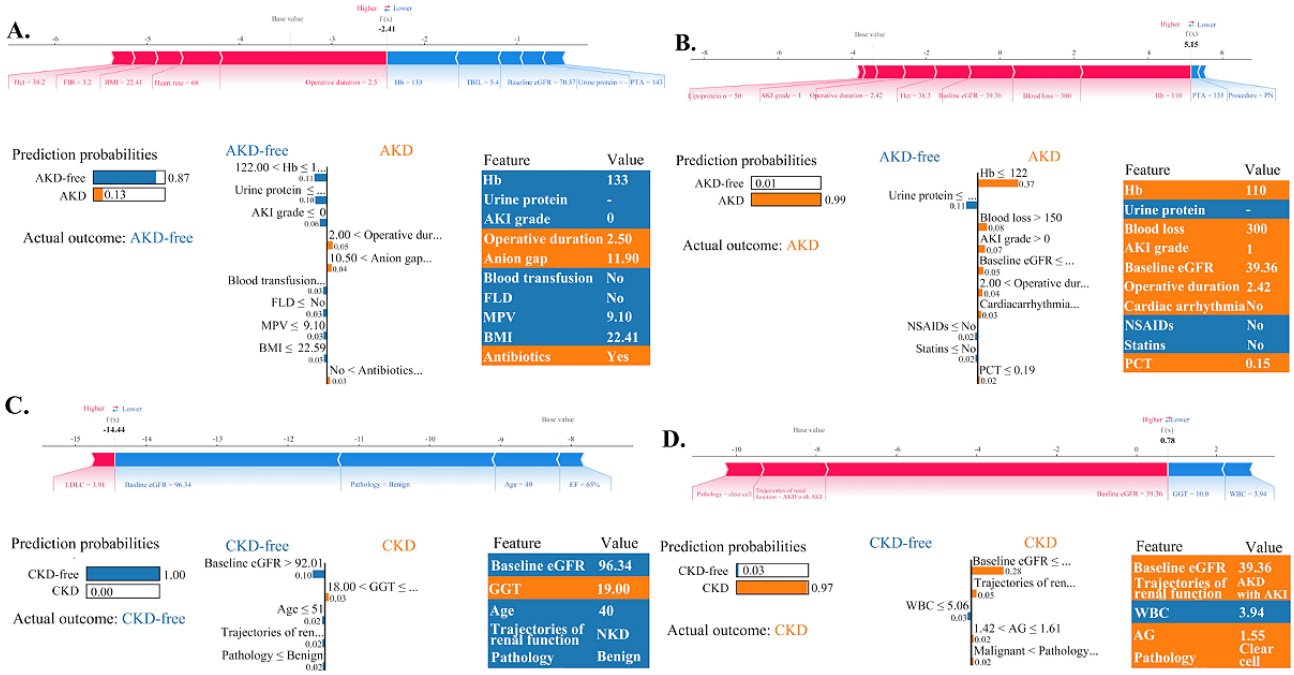

Web-Based Calculator

Since the LightGBM model proved to be the most effective in our study, we developed a web-based calculator using the "Streamlit" application to predict both AKD and CKD with this model. Restricting the LightGBM model to only the top 10 and top 5 features did not diminish predictive performance for the AKD and CKD models (AUROC: 0.94 vs 0.97 in AKD prediction and 0.94 vs 0.96 in CKD prediction). For ease of use, we constructed a web-based calculator using the top 10 and top 5 features to predict AKD and CKD, respectively. You can access this calculator at Streamlit [30].

Discussion

Principal Findings

Our exploration into the use of ML techniques to predict and elucidate outcomes in patients undergoing nephrectomy was instigated by an amplified emphasis on the long-term renal functional prognosis, the accessibility of intricate data within the electronic health record system, and the maturation of interpretable predictive models. Among patients who underwent nephrectomy, 28.9% (n=451) developed AKI or AKD. Specifically, 7.5% (n=117) of patients developed AKD in conjunction with AKI, 13.7% (n=213) experienced recovery from AKI, and 7.8% (n=121) developed subacute AKD. The incidence rate of CKD was 10.6% (n=165). We formulated a diverse array of ML models with a focus on AKD and CKD prognosis. Among these models, LightGBM exhibited the most robust predictive prowess, achieving an AUROC of 0.97 for AKD prediction and 0.96 for CKD prediction. Our research used SHAP values and the LIME algorithm to interpret the decision-making process from both global and instance-based perspectives. Additionally, we used DAG to further visualize the potential causal relationships between features and outcomes. In consideration of clinical applicability, we further developed a web application that uses the final prediction model to estimate AKD and CKD risks.

Comparison to Prior Work and Implications

Assessment of renal injury risk following nephrectomy has predominantly concentrated on AKI and CKD, with limited attention to the recovery of renal function within 7-90 days post-AKI and its enduring consequences [5,31-33]. Our prior research has unveiled discernible distinctions in the predicted risk factors between AKI and AKD. Specifically, AKD is associated with a notably elevated risk of de novo CKD

development when contrasted with AKI [34]. This study encompassed all patients who were hospitalized, with no specific subgroup analysis conducted for those undergoing nephrectomy. Hu et al [35] initially developed a predictive model for postnephrectomy AKD, using an LR model to assess predicted risk factors associated with renal injury within 3 months following nephrectomy. Nevertheless, this study did not differentiate between AKI recover, subacute AKD, and AKD with AKI. Furthermore, it did not investigate the long-term outcomes for patients experiencing these distinct renal function trajectories. In our study, we found a significant association between trajectories of renal function and the onset and progression of CKD. Specifically, the coexistence of AKD with AKI led to a CKD incidence rate of 35.9% (n=42), nearly 1.5 times higher than that observed in patients with subacute AKD (AKD without AKI). Meanwhile, the CKD incidence rate was 11.3% (n=24) for individuals who had recovered from AKI and 6% (n=67) for those with normal kidney function. Among patients with kidney injury, nearly one-third experienced subacute AKD, which did not meet the criteria for either AKI or CKD diagnosis. These individuals are frequently overlooked in the early stages due to the modest changes in renal function they exhibit; however, their risk of developing CKD is significantly elevated when compared to both patients with NKD and those who have recovered from AKI. As such, the presence of AKD serves as a critical link between AKI and CKD, aiding in the assessment of declining renal function and prognosis.

Currently, LR is the most widely used model for predicting kidney injury risk in patients undergoing nephrectomy, with limited application of ML algorithms [36,37]. Lee et al [38] used various ML algorithms to formulate a risk prediction model for AKI after nephrectomy, identifying that the LightGBM model outperforms others in terms of predictive accuracy. Compared to LR, LightGBM demonstrates enhanced speed, more efficient memory use, and superior parallel processing capabilities, which allow it to more effectively manage nonlinear relationships, large datasets, and high-dimensional data [39]. Our study has undertaken a thorough evaluation of the predictive abilities of several ML models, with LightGBM emerging as the most effective in forecasting high-risk AKD and CKD cases, alongside precisely pinpointing individual predicted risk factors. Early alerts assist in promptly notifying clinicians to undertake vigilant monitoring of patients at high risk. Addressing manageable predicted risk factors early, such as Hb, systolic blood pressure, and total bilirubin, presents a considerable opportunity to lower the occurrence of AKD and CKD, thereby enhancing patient outcomes.

Given our emphasis on interpretability, our methodology entails a thorough interpretation of the entire predictive algorithm, exploring the potential causal relationships between major features. First, we generate global-level diagrams that elucidate the contributions of each feature to the model's output along with interactions among key features. Features denoting acute injury, such as surgical factors and AKI grade, exert a significant influence on AKD. Baseline eGFR and trajectories of renal function constitute pivotal features affecting CKD. Features such as advanced age or clear cell carcinoma may be associated with an elevated CKD risk. While these attributes are generally nonmodifiable, augmenting the frequency of follow-up visits for individuals with these characteristics can effectively facilitate the early detection of renal function deterioration. Second, this study delineates the decision-making process for each patient. The examples depicted in Figure 3 elucidate the predominant feature compositions among patients exhibiting diverse predicted probabilities of AKD or CKD. Using SHAP force plots and LIME plots amplifies the individualization and transparency of the decision-making process, thereby alleviating the black-box issue inherent in the model's prediction process. Finally, DAGs were used to delve deeper into the potential causal relationships between features and outcomes. It was found that most of the top 10 features identified by SHAP values have the potential to directly or indirectly influence the occurrence of AKD or CKD.

For the sake of enhancing user convenience, we have developed web-based prediction tools for both AKD and CKD. Users can effortlessly input the values of their chosen features to calculate the probabilities of AKD and CKD following nephrectomy. Our research marks a pioneering effort in constructing web-based prediction tools for postnephrectomy AKD and CKD, which can assist clinicians in identifying high-risk individuals and risk factors. Given the clinical feasibility and straightforward accessibility of features derived from routine medical records, our models are eminently suitable for seamless integration into daily clinical practice.

Limitations and Future Directions

The study exhibits several limitations. First, the web-based prediction tool is crafted to assist clinicians in discerning individuals with elevated risk of AKD and CKD rather than serving as a replacement for clinical diagnosis. Due to the retrospective nature of data collection, it is crucial to undertake additional validation using an independent population to ensure robust predictive validity across diverse usage scenarios. Second, the collection of urine output data is subjective, and a significant number of values are missing. Consequently, this study refrained from using urine output as a diagnostic criterion for AKI. Third, our study lacks time-variant monitored values among its features. Moving forward, we intend to collect longitudinally monitored data from patients undergoing nephrectomy to enable dynamic prediction of AKD and CKD before their clinical identification. Finally, DAGs visually represent the potential causal relationships between features and outcomes. This underscores the need to further explore and quantify the causal mechanisms in future work.

Conclusions

This study has developed prediction models that accurately estimate the risk of AKD and CKD following nephrectomy. These models provide interpretability from both global and instance-based perspectives. We recommend the use of the AKD criterion in clinical practice due to its superior accuracy in predicting prognosis, particularly the development of CKD.

Abstract

Background: Prostate cancer is the second leading cause of death among American men. If detected and treated at an early stage, prostate cancer is often curable. However, an advanced stage such as metastatic castration-resistant prostate cancer (mCRPC) has a high risk of mortality. Multiple treatment options exist, the most common included docetaxel, abiraterone, and enzalutamide. Docetaxel is a cytotoxic chemotherapy, whereas abiraterone and enzalutamide are androgen receptor pathway inhibitors (ARPI). ARPIs are preferred over docetaxel due to lower toxicity. No study has used machine learning with patients' demographics, test results, and comorbidities to identify heterogeneous treatment rules that might improve the survival duration of patients with mCRPC.

Objective: This study aimed to measure patient-level heterogeneity in the association of medication prescribed with overall survival duration (in the form of follow-up days) and arrive at a set of medication prescription rules using patient demographics, test results, and comorbidities.

Methods: We excluded patients with mCRPC who were on docetaxel, cabaxitaxel, mitoxantrone, and sipuleucel-T either before or after the prescription of an ARPI. We included only the African American and white populations. In total, 2886 identified veterans treated for mCRPC who were prescribed either abiraterone or enzalutamide as the first line of treatment from 2014 to 2017, with follow-up until 2020, were analyzed. We used causal survival forests for analysis. The unit level of analysis was the patient. The primary outcome of this study was follow-up days indicating survival duration while on the first-line medication. After estimating the treatment effect, a prescription policy tree was constructed.

Results: For 2886 veterans, enzalutamide is associated with an average of 59.94 (95% CI 35.60-84.28) more days of survival than abiraterone. The increase in overall survival duration for the 2 drugs varied across patient demographics, test results, and comorbidities. Two data-driven subgroups of patients were identified by ranking them on their augmented inverse-propensity weighted (AIPW) scores. The average AIPW scores for the 2 subgroups were 19.36 (95% CI –16.93 to 55.65) and 100.68 (95% CI 62.46-138.89). Based on visualization and *t* test, the AIPW score for low and high subgroups was significant (*P*=.003), thereby supporting heterogeneity. The analysis resulted in a set of prescription rules for the 2 ARPIs based on a few covariates available to the physicians at the time of prescription.

Conclusions: This study of 2886 veterans showed evidence of heterogeneity and that survival days may be improved for certain patients with mCRPC based on the medication prescribed. Findings suggest that prescription rules based on the patient characteristics, laboratory test results, and comorbidities available to the physician at the time of prescription could improve survival by providing personalized treatment decisions.

prostate cancer; metastatic castration resistant prostate cancer; causal survival forest; machine learning; heterogeneity; prescription policy tree; oncology; pharmacology

Introduction

Prostate cancer is the second leading cause of cancer death among men in the United States and the most common cancer affecting men of African descent [1]. While early-stage prostate cancer is curable, around 10% to 50% of cases progress to metastatic castrate-resistant prostate cancer (mCRPC) within 3 years of diagnosis, which is fatal [2]. Multiple therapies exist for treating mCRPC, including androgen-receptor pathway inhibitors (ARPIs) and cytotoxic chemotherapy, such as docetaxel. ARPIs, such as enzalutamide or abiraterone, target the androgen receptor signaling pathways and are administered orally [3]. Enzalutamide is administered at 160 mg orally once daily [4]. In comparison, abiraterone acetate is administered while fasting at a dose of 1000 mg orally with coadministration of the steroid prednisone [3]. Recent prescription trends show that ARPIs are preferred for their tolerable safety profiles and improving survival [5,6]. Prescribing ARPIs instead of docetaxel might also be beneficial for African American men, though the precise mechanisms are yet known [7].

Abiraterone and enzalutamide have different mechanisms of action. Abiraterone requires coadministration of prednisone because it inhibits androgen biosynthesis, leading to mineralocorticoid excess. In contrast, enzalutamide inhibits the androgen receptor by blocking hormone signaling and does not require steroid coadministration. These differences result in varying patient outcomes and survival based on patient demographics, test results, and comorbidities [8]. Clinical trials often do not encompass the full spectrum of patient comorbidities [9]. In the absence of clear clinical evidence favoring one ARPI over the other, retrospective observational data and data analytics techniques can help determine the most suitable drug for individual patients [10].

The methods used to study outcomes using ARPIs included associative and predictive modeling. Association studies identified a few comorbidities, such as cardiovascular diseases and diabetes, as significant predictors of survival in patients with mCRPC and comorbid diseases [10]. In addition, studies of hospitalizations during ARPI treatment showed an increased risk of heart failure, atrial fibrillation, and acute kidney injury with abiraterone [11]. Enzalutamide was found to be better than abiraterone for survival as well [10,12].

Machine learning predictive models effectively predicted survival outcomes and time to treatment discontinuation using tree-based approaches while incorporating laboratory test results such as hemoglobin and albumin and comorbidities such as hypertension and diabetes [13-15]. Multiomic features combined with treatment lines predicted the response types “good, poor, and ambiguous” following ARPI treatment [16]. However, these studies did not identify patient-specific differences in outcomes (heterogeneous treatment effects in subgroups of patients), address selection bias in treatment, or prescribe specific ARPIs based on patient demographics, laboratory test results, and comorbidities.

The main objective of this study was to evaluate patient-level heterogeneity in the association between prescribed medication and overall survival duration in the form of follow-up days and subsequently to identify a set of prescription rules based on patient-specific factors. We used a causal survival forest to measure heterogeneous treatment effects among patients with mCRPC, focusing on the survival duration. Based on these findings, we developed a set of treatment rules, or a policy tree, to prescribe abiraterone and enzalutamide tailored to individual patient factors such as demographics, test results, and comorbidities.

Methods

Dataset and Its Description

The data used for analysis were from the United States Department of Veterans Affairs (VA) centers (compassing VA hospitals and clinics) stored in the Corporate Data Warehouse. A total of 3675 veterans from Corporate Data Warehouse were identified as patients with mCRPC, excluding those with missing values and including only the African American and White populations. We excluded patients with mCRPC who received docetaxel, cabazitaxel, mitoxantrone, or sipuleucel-T before or after starting abiraterone or enzalutamide. This exclusion resulted in a dataset of 2890 veterans who began treatment with abiraterone or enzalutamide between 2014 and 2017. In addition, 4 patients were excluded because they switched to different second-line treatments on the same day. Thus, the final analysis included 2886 patients. The study follow-up concluded in 2020.

Patient Demographics, Test Results, and Comorbidities

In total, 20 covariates’ age, creatinine clearance test result category, albumin result category, bilirubin result category, hemoglobin result category, race, prostate-specific antigen (PSA) test, BMI category, diabetes, hypertension, kidney disease, osteoporosis, fall, fatigue, abnormal gait, peripheral neuropathy, Parkinson’s disease, vision, orchiectomy procedure, and cardiovascular diseases (CVDs) were used. The laboratory values were calculated before treatment and were closest to the start of the first-line treatment. Covariates, such as CVD and diabetes, have been previously used to study the survival of veterans with mCRPC in univariate studies [10]. Other covariates such as abnormal gait, peripheral neuropathy (a common side effect of cancer treatment), and vision are included to capture existing comorbidities better. CVD was calculated based on Charlson and Elixhauser indices for myocardial infarction, heart failure, cardiac arrhythmia, valvular disease, complicated hypertension, peripheral vascular disease, and cerebrovascular disease based on *ICD* (*International Classification of Diseases*) codes [10]. Other comorbidity-related

covariates were based on the standard VA-Frailty health deficits based on diagnosis codes. We used proxies for comorbidities not available in our dataset but have been studied in the past, such as alkaline phosphate level. For example, kidney disease is a proxy for alkaline phosphate levels [17].

Outcome

The primary outcome of our study was overall survival duration, measured in follow-up days from the initiation of first-line treatment with an ARPI (abiraterone or enzalutamide). For a subset of patients with mCRPC (1163 out of 2886) who received the other ARPI drug as second-line treatment following the first-line therapy, we considered follow-up days to the initiation of the second-line treatment as survival duration. This approach assumed survival up to that point without accounting for follow-up days post-second-line treatment, aiming to mitigate treatment switching bias between therapies [18]. In addition, our data were limited to laboratory results and comorbidities recorded on the day of first-line treatment initiation.

Statistical Analysis

We used causal survival forests with 20 covariates to estimate heterogeneous treatment effects in follow-up days [19]. Causal forests and causal survival forests are similar to random forests and random survival forests, respectively, with the primary difference being their data splitting criteria [20]. In a random survival forest, data splitting minimizes differences in prediction errors in follow-up days within each group, considering censoring. In contrast, a causal survival forest splits data to maximize heterogeneity, that is, the difference in the estimated follow-up days between the treated and untreated groups, accounting for censoring. The advantage of using a causal survival forest lies in its robustness to censoring, unlike a causal forest [19]. In addition, compared with a random survival forest, a causal survival forest offers a more comprehensive assessment of heterogeneity. It can outperform linear regression models by measuring heterogeneous treatment effects conditional on a nonlinear function of many covariates, accounting for higher-order interactions [21].

Each observation in the dataset corresponds to a single patient with mCRPC and includes the patient's covariate data, follow-up days (the outcome), treatment assignment (1 for enzalutamide, 0 for abiraterone), and death (event). Survival duration was analyzed based on either abiraterone or enzalutamide treatment without an untreated control group. Consequently, the dataset does not allow for the determination of the individual treatment effects of each drug.

As this is a retrospective observational study, we must account for the nonrandomization of treatment assignment and use the augmented inverse-propensity weighting (AIPW) estimator, a doubly robust method. To do this, the true treatment assignment was fitted as a function of the observed covariates. The predicted value from this model provides a propensity score, that is, an estimate of the probability of treatment assignment conditioned on a set of covariates for each patient. Then, 2 models that estimate the outcome (follow-up) were fitted, one using enzalutamide and the other using abiraterone. Each outcome was then weighted by the estimated propensity score, which yields the weighted average of the two outcome models [22].

We used a causal survival forest for our analysis [19]. To ensure that the assumptions of finite horizon, ignorability, overlap, ignorable censoring, and positivity are satisfied so that the treatment effect of the drugs is identified when using causal survival forests, we made the following analytical choices. The parameter horizon, referring to restricted mean survival time, was set to a threshold so that the estimated censoring probabilities are not below 0.2, satisfying the finite horizon and positivity assumption. We started with a horizon of 2000 days (approximately close to the maximum follow-up days) and decremented by 100 to 1000.

For ignorability, we applied balanced diagnostics by checking the weighted absolute standardized mean difference (ASMD) of variables between patients treated with enzalutamide and patients treated with abiraterone. A number close to 0 indicates that the propensity scores are well-calibrated. We examined the propensity score distribution for both groups to test for overlap and checked if they clustered at 0 or 1.

The honesty fraction was set to 0.7, meaning 70% of the subsample was used for splitting and 30% for populating the leaf nodes. However, for ranking the observations based on covariates and coming up with subgroups, the model must not be fit using the observations being compared. We used 10-fold cross-fitting for this reason. The conditional average treatment effects (CATE) models were fit for 9 folds, and the "unseen" observations in the left-out fold were ranked based on their predictions and split along the median into 2 groups. The same process was repeated 10 times, with each fold serving as a left-out fold once.

We set the number of trees to 15,000. We generated the policy tree after calculating the AIPW scores. A policy tree is a set of treatment rules, that is, rule-based policies, in the form of a decision tree that physicians can use to prescribe abiraterone and enzalutamide. The policy tree was generated using 70% of the training data, and the policy's value was determined using the 30% test data. The policy value is defined as the average difference in follow-up days obtained if the patients with mCRPC are administered enzalutamide or abiraterone. R (version 4.4.1; The R Foundation) with packages *grf* and *policytree* were used for analyses.

Results

We used a causal survival forest to estimate the heterogeneity in the treatment effect on survival for the 20 covariates (refer to Table 1 for the descriptive statistics and description for all patients including based on enzalutamide and abiraterone).

Table 1. Descriptive statistics of metastatic castration-resistant prostate cancer US veterans with androgen receptor pathway inhibitors treatment initiated 2014-2017 (Total sample N=2886; abiraterone n=1649; enzalutamide n=1237).

[a]PSA: prostate-specific antigen.

We found the horizon value of 1000 to be the most suitable, with the censoring probability estimates not going below 0.2, satisfying the positivity assumption. The weighted ASMD of covariates, along with their interactions, for the abiraterone and enzalutamide-treated groups is close to zero, satisfying the balance between the 2 groups (Figure 1). Thus, the propensity score estimates from causal survival forests were well-calibrated. The plot of the estimated propensity scores showed that the scores did not cluster at zero or one and were unimodal, exhibiting overlap (Figure 2).

Figure 1. Absolute standardized mean differences of covariates and their interactions between abiraterone and enzalutamide-treated groups. The covariates closeness to zero after adjusting for selection bias (the orange dots) indicates the balance between the 2 groups.

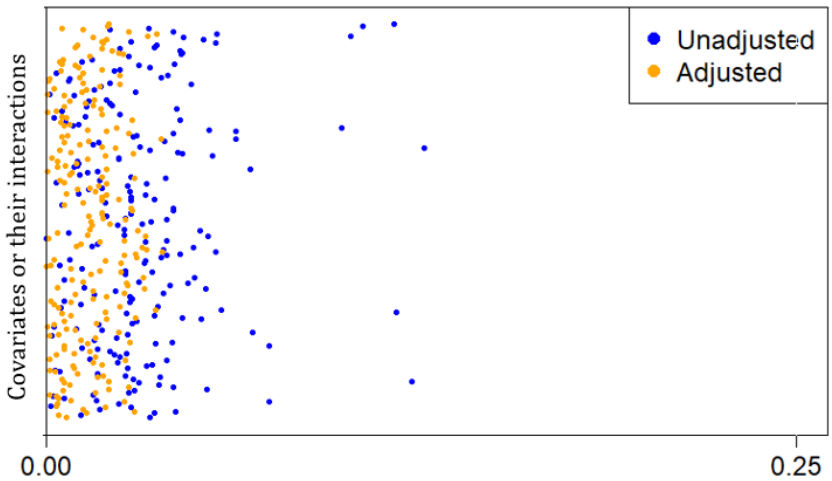

Figure 2. Estimated propensity scores from causal survival forest for metastatic castration-resistant prostate cancer US veterans with androgen receptor pathway inhibitors treatment initiated 2014-2017. The scores do not cluster at 0 or 1, indicating overlap.

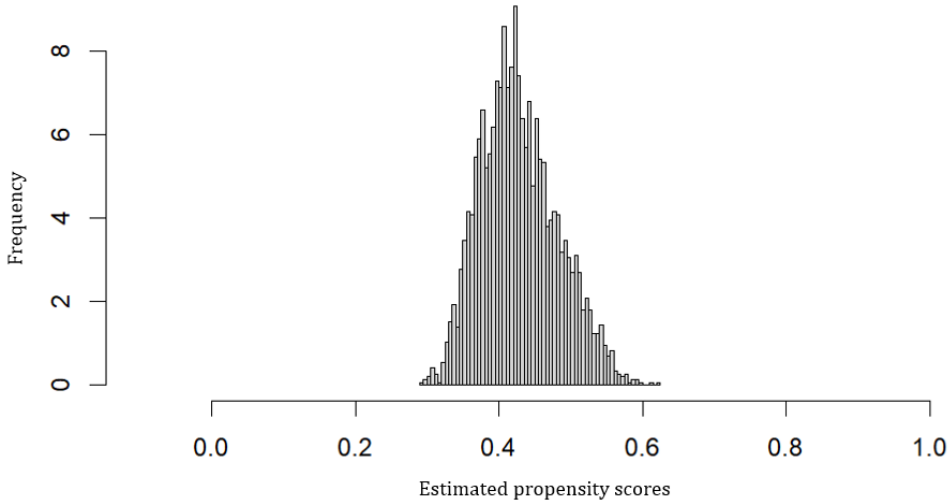
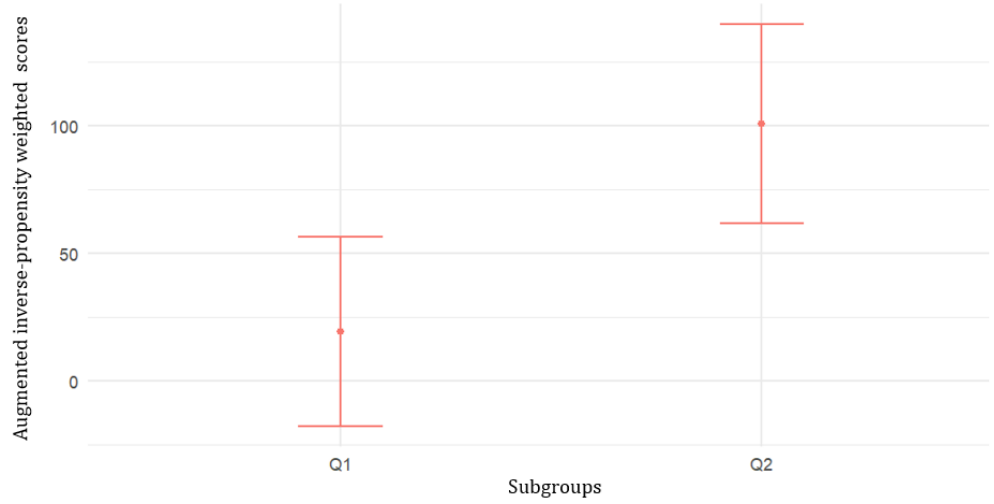


For the 2886 veterans, enzalutamide is associated with an average of 59.94 (95% CI 35.6-84.28) more days of survival than abiraterone. The CATE scores computed from the causal survival forest were used to rank and split the observations into 2 subgroups, above and below the median [23]. The average AIPW scores for the 2 subgroups were 19.36 (95% CI -16.93 to 55.65) and 100.68 (95% CI 62.46-138.89). Based on visualization (Figure 3) and *t* test, the difference between the AIPW scores for low and high subgroups was significant (*P*=.003), thereby supporting heterogeneity.

Figure 3. Augmented inverse-propensity weighted scores (mean and 95% CI) for the 2 subgroups above and below the median for all metastatic castration-resistant prostate cancer US veterans with androgen receptor pathway inhibitors treatment initiated 2014-2017.



The heatmap in Figure 4 shows the average value of each covariate within each subgroup (refer to Table 2 for descriptive statistics for the 2 subgroups). The subgroups are ordered from lowest to highest difference in treatment effects; Q2, the second subgroup, has a higher treatment effect than Q1. The color in the heatmap of each covariate is the normalized distance of the average of the covariate in the subgroup from the average of the covariate in the full data. The covariates of the heatmap are arranged in descending order of variation, comparing the variance of the covariate in a subgroup with its variance in the sample. The top 5 covariates contributing to the highest variation were peripheral neuropathy, bilirubin category, osteoporosis, PSA test result, and Parkinson's disease.

Figure 4. Average covariate values for the 2 subgroups above and below the median augmented inverse-propensity weighted score for all metastatic castration-resistant prostate cancer US veterans with androgen receptor pathway inhibitors treatment initiated 2014-2017.

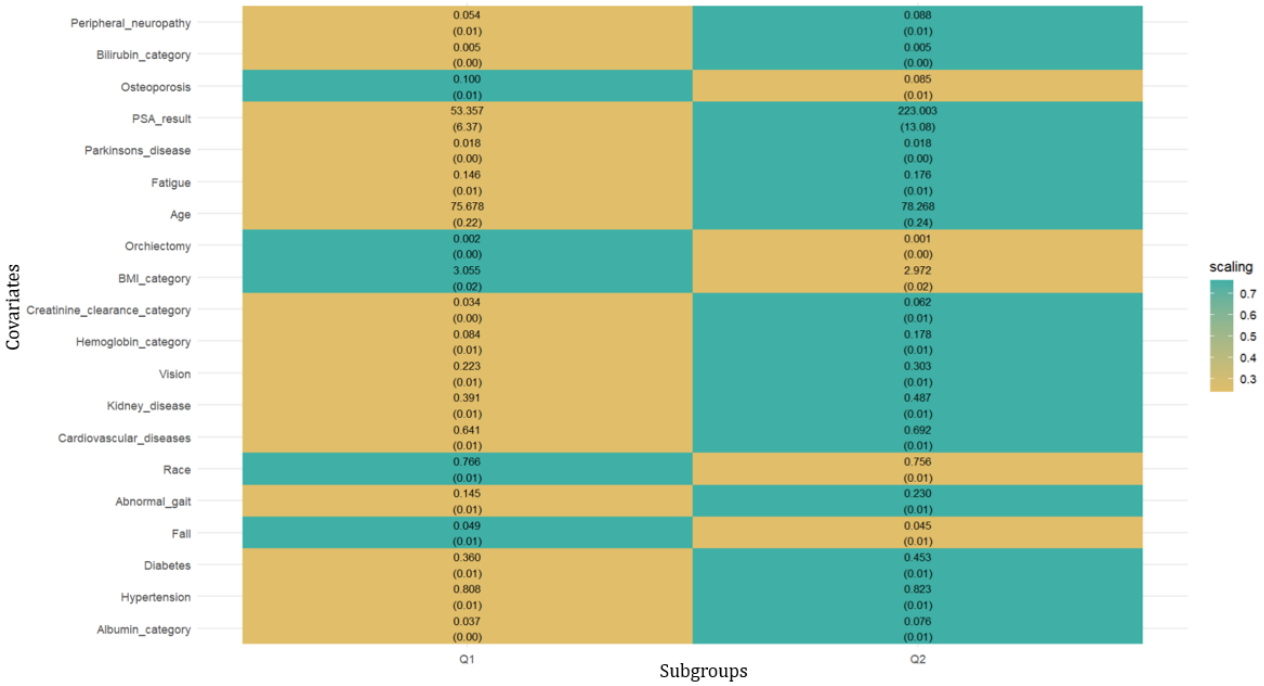


Table 2. Descriptive statistics for the subgroup of US veterans with metastatic castration-resistant prostate cancer below and above the median conditional average treatment effects (Total Sample N=2886).

[a]CATE: conditional average treatment effects.

[b]PSA: prostate-specific antigen.

We estimated the AIPW scores for treatment effects, in terms of follow-up days, for each individual if abiraterone and enzalutamide were administered. Next, we generated prescription policy trees for various depth levels. We used 70% of the data for training to generate the prescription policy tree. To arrive at the value (survival duration) that the policy bestows on a patient, we used the estimated AIPW scores for an individual if administered either abiraterone or enzalutamide based on the predictions from the prescription policy tree. We found significance in the prescription policy tree with a depth of 3. We used a minimum node size of 4. For depth 3 (Figure 5), the average number of follow-up days obtained by administering enzalutamide and abiraterone based on the generated prescription policy tree was 56.38 (95% CI 8.89 to 103.87).

Figure 5. Androgen receptor pathway inhibitors prescription policy tree estimated for US veterans with metastatic castration-resistant prostate cancer.

Discussion

Principal Findings and Comparison With Previous Work

In this study, we applied a causal survival forest to assess the heterogeneous treatment effects of the mCRPC medications enzalutamide and abiraterone on overall survival. We found that, on average, for 2886 veterans, 59.94 (95% CI 35.60-84.28) more days of survival than abiraterone. The value of our policy is 56.38 (95% CI 8.89-103.87), which is not statistically different from 59.94. This means that the simple, transparent treatment rules using the policy tree method to prescribe abiraterone and enzalutamide can achieve a policy value similar to the conditional average treatment effect. Schoen et al [10] used an adjusted hazard model and found that age, BMI, and PSA level were positively associated with mortality. Our policy tree elicited the decision checks for age, PSA level, and BMI to make prescription decisions on which of the 2 medications is likely to prolong survival.

Interestingly, even though in univariate analyses in previous studies, the median treatment duration was longer in patients with hypertension or diabetes, the policy tree did not choose both hypertension and diabetes and did not contribute to the highest variation between the 2 subgroups. In previous work, increased hemoglobin A_{1c}, a marker of diabetes severity, was associated with more prolonged survival in veterans prescribed enzalutamide compared with abiraterone [24]. Instead, our policy tree chose peripheral neuropathy. However, peripheral neuropathy is a complication of diabetes (in addition to being a predictor of severe diabetes, it could be caused by factors such as injury and exposure to toxins and is also a common side effect of cancer treatment) [7,25]. Vision loss can be a complication of diabetes and is associated with increased hospitalizations [26], impaired cognition [27], and higher mortality [28]. To delay diabetic neuropathy, apart from good glycemic control, it has also been found beneficial to control blood pressure [29]. All these could have contributed to choosing peripheral neuropathy instead of diabetes and hypertension by our policy tree.

In addition, our policy tree incorporated osteoporosis, which was also one of the top covariates contributing to the variation between the 2 subgroups. Previous studies show an increased risk of falls and fractures among patients with mCRPC taking ARPIs [30,31]. Osteoporosis and abnormal gait may identify impaired functional status or increased frailty, which is associated with survival outcomes in mCRPC [9]. Osteoporosis is a hidden nonmotor symptom of Parkinsons' disease, which contributed to variation in subgroups and was chosen by the policy tree [32]. Bilirubin levels could contribute to osteoporosis, which is also shown as one of the top variations among the two subgroups [33]. Our policy tree chose race, and existing studies have demonstrated that abiraterone has improved survival when given as the first line of treatment for the African American population [34]. Together, these results show that our policy tree could elicit a variety of comorbidities and suggest therapy.

In addition to identifying the covariates, selecting treatments for patients with mCPRC using the generated policy tree considering their demographics, laboratory measures, and comorbidities may help mitigate complications and prolong overall survival. As no generic version of enzalutamide is available in the US, the drug remains expensive. Therefore, from a cost perspective, it is prudent to administer enzalutamide only to patients most likely to benefit from it in terms of survival duration.

Limitations and Future Studies

One of the limitations of this study is that the data are only for US veterans, so that the generalization of the prescription rules to the other populations is not advised. Another limitation is that we excluded patients with mCRPC who had docetaxel, cabaxitaxel, mitoxantrone, and sipuleucel-T before or after prescribing abiraterone or enzalutamide. This was performed to identify patients with higher comorbid disease burdens with fewer therapeutic options. However, other treatments are prescribed for patients with mCRPC. A third limitation of this study was the lack of data on time-varying covariates. Even though causal survival forest is robust to censoring, it will be interesting to include time-varying covariates in the future and to check for differences in the generated policy tree. The fourth limitation of this study was that we used only 70% of the training data to generate a policy tree, because the causal survival forest used cross-fitting and honesty approaches. Furthermore, we estimated the overall benefit of the policy tree (ie, the average difference in the follow-up days obtained if the patients with mCRPC are administered enzalutamide or abiraterone by adhering to the policy tree) in this study without considering the benefits to subgroups of patients based on race or other demographics. Future research should estimate the benefit of such policy trees to see if they are equally beneficial to various subgroups of demographics. Similarly, this study used only mCRPC patient data. Future studies should develop treatment selection for earlier stages of prostate cancer, such as the metastatic hormone-sensitive stage.

Conclusions

We used a machine learning-based survival approach, that is, causal survival forest model, to estimate the variations in the survival of patients with mCRPC who were administered either enzalutamide or abiraterone. Our estimation revealed that patients with mCRPC who were administered enzalutamide had longer survival than patients who were administered abiraterone. We were able to use a data-driven approach to identify heterogeneity and subgroups of patients. We then created policy trees to aid physicians administer personalized treatment, that is, abiraterone versus enzalutamide, based on patient characteristics, including demographics, laboratory values, and comorbidities, to improve survival duration.

Acknowledgments

This study was supported by the Department of Defense Physician Research Award (W81XWH-22-1-0602) to MWS and the Igor Tulchinsky, Robert Taubman, and Richard Sandler – Prostate Cancer Foundation Valor Young Investigator Award. The funders had no role in the design, conceptualization, preparation, review, approval, or decision to submit the manuscript for publication. DG was previously affiliated with the School of Medicine at Saint Louis University during the initial submission or revision. DG completed the subsequent work and revision (including rerunning analysis) at her current affiliation with the Richard A Chaifetz School of Business at Saint Louis University.

Data Availability

Scientific community members can request the dataset by e-mailing MWS at martin.schoen@va.gov. It will be shared upon request and execution of an agreement of use. The investigator should state the reason for requesting the data and analysis plans.

Authors' Contributions

All authors had full access to the study’s data. MWS takes responsibility for the integrity of data. DG, NM, and MWS contributed to concept, design, analysis or interpretation of data, writing of manuscript, critical manuscript review, and approval.

Conflicts of Interest

MWS reports honoraria from Pfizer for a lecture on Real-World Data and consulting for ConcertAI. DG and NM do not have any conflicts of interest.

Abstract

Background: Low back pain (LBP) presents with diverse manifestations, necessitating personalized treatment approaches that recognize various phenotypes within the same diagnosis, which could be achieved through precision medicine. Although prediction strategies have been explored, including those employing artificial intelligence (AI), they still lack scalability and real-time capabilities. Digital care programs (DCPs) facilitate seamless data collection through the Internet of Things and cloud storage, creating an ideal environment for developing and implementing an AI predictive tool to assist clinicians in dynamically optimizing treatment.

Objective: This study aims to develop an AI tool that continuously assists physical therapists in predicting an individual's potential for achieving clinically significant pain relief by the end of the program. A secondary aim was to identify predictors of pain nonresponse to guide treatment adjustments.

Methods: Data collected actively (eg, demographic and clinical information) and passively in real-time (eg, range of motion, exercise performance, and socioeconomic data from public data sources) from 6125 patients enrolled in a remote digital musculoskeletal intervention program were stored in the cloud. Two machine learning techniques, recurrent neural networks (RNNs) and light gradient boosting machine (LightGBM), continuously analyzed session updates up to session 7 to predict the likelihood of achieving significant pain relief at the program end. Model performance was assessed using the area under the receiver operating characteristic curve (ROC-AUC), precision-recall curves, specificity, and sensitivity. Model explainability was assessed using SHapley Additive exPlanations values.

Results: At each session, the model provided a prediction about the potential of being a pain responder, with performance improving over time (P<.001). By session 7, the RNN achieved an ROC-AUC of 0.70 (95% CI 0.65-0.71), and the LightGBM achieved an ROC-AUC of 0.71 (95% CI 0.67-0.72). Both models demonstrated high specificity in scenarios prioritizing high precision. The key predictive features were pain-associated domains, exercise performance, motivation, and compliance, informing continuous treatment adjustments to maximize response rates.

Conclusions: This study underscores the potential of an AI predictive tool within a DCP to enhance the management of LBP, supporting physical therapists in redirecting care pathways early and throughout the treatment course. This approach is particularly important for addressing the heterogeneous phenotypes observed in LBP.

Introduction

Low back pain (LBP), the leading cause of disability worldwide [1], has a complex and multifaceted etiology [2,3], resulting in varied phenotypes even among individuals with the same diagnosis. Precision medicine supports tailored interventions to address this heterogeneity, with data-driven strategies playing a crucial role [4,5]. These strategies range from simple, pragmatic rules-based methods [6-8] (eg, STARTback, Orebro) to more sophisticated machine learning (ML) tools trained on large data sets [9-11]. In the context of LBP management, ML models have been developed to assist with screening [12-14], assess the probability of a patient transitioning from acute to chronic cases [8,15-18], predict surgical outcomes [19,20], and forecast clinical recovery prognosis [6,7,9-11,21]. Although promising, these models lack sustained, dynamic real-time patient data collection, relying heavily on patient-reported outcome measures (PROMs) and other information that is not easily scalable. This reliance, in turn, limits the ability to deliver real-time predictions throughout treatment or hinders large-scale implementation in real-world settings [9,10].

The emergence of digital care programs (DCPs) as an effective alternative for delivering LBP care [22-24] has facilitated the seamless, automatic collection of abundant data from various sources. This diverse and comprehensive patient data set, which includes passively collected real-time updates of multiple variables via the Internet of Things devices (eg, wearables) enriched with population data, enables the capture of more complex patterns, providing a more accurate representation of patients. These extensive volumes of data can be used to predict outcomes and optimize treatments, with the resulting outcomes feeding back into predictive tools in a virtuous cycle.

Previously, we demonstrated the efficacy of a remote DCP for LBP management [22], which combines exercise, education, and cognitive behavioral therapy under physical therapist (PT) supervision. In this study, we leverage all stored data (both passively and actively collected from patient and public sources) in the cloud portal, actively monitored by the assigned PT, to develop a predictive tool that can assist in optimizing treatment. This study aims to develop an artificial intelligence (AI) tool to assist PTs in predicting an individual's potential to achieve clinically significant pain relief by the end of the program. Such predictions could enable timely adjustments to the program, increasing the likelihood of success and, in turn, providing data to further refine the tool's recommendations. As a secondary aim, we sought to identify the predictors of pain nonresponse, as these factors indicate the need for greater attention from PTs. Thus, the overall objective of the study is to develop ML models to predict the likelihood that a patient will achieve clinically significant pain relief by the end of the program, with ongoing updated predictions after each completed session.

Methods

Study Design

This secondary analysis utilized data from 2 prospective studies evaluating clinical and engagement-related outcomes in patients with musculoskeletal (MSK) conditions. Data were collected from June 2020 to July 2023. This prognostic study adhered to the TRIPOD-AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis-AI) reporting guidelines (Table S1 in Multimedia Appendix 1).

Ethical Considerations

All research was conducted in accordance with the relevant guidelines and regulations set forth by the Declaration of Helsinki. This study received prospective approval from the New England institutional review board (120190313) and Advarra institutional review board (Pro00063337) and was registered on ClinicalTrials.gov (NCT04092946 and NCT05417685) on September 17, 2019, and June 14, 2022, respectively.

All participants provided electronic informed consent to participate in the study, with a waiver of documentation of consent approved by the New England and Advarra institutional review boards.

All collected data underwent a rigorous anonymization process to safeguard the privacy of the individuals involved in the research. The data collection and analysis methods complied with relevant guidelines and regulations. Participants were not offered any form of compensation.

Population

Beneficiaries of employer health plans from all US states applying to Sword Health's DCPs were included. The inclusion criteria were as follows: acute or chronic LBP, an average Numerical Pain Rating Scale (NPRS) score of ≥4/10, and at least one NPRS reassessment during the intervention. The exclusion criteria were as follows: (1) health conditions (eg, cardiac or respiratory) that are incompatible with at least 20 minutes of light-to-moderate exercise; (2) cancer-related back pain or current cancer treatment for a non-MSK condition; and (3) serious neurological signs or symptoms, including bowel or bladder dysfunction. All participants provided informed consent.

Intervention

The DCP consisted of exercise, education, and cognitive behavioral therapy for up to 12 weeks, with a default recommendation of 3 sessions per week, as described elsewhere [22], after enrolling through a dedicated website. Patients completed a baseline condition form that included information on their demographic and clinical characteristics and selected their PT based on their preferences. Subsequently, an onboarding video call was conducted in which the PTs gathered additional medical history and established goals through shared decision-making. Each patient received a Food and Drug Administration–listed class II medical device, which included a mobile app on a dedicated tablet (containing the program) combined with motion tracking, as well as a cloud-based portal that enabled asynchronous remote monitoring and treatment prescription by the PT. A tailored educational program and cognitive behavioral therapy were also provided [25-27]. Bidirectional communication with the PT was facilitated through a secure chat feature on the smartphone app and video calls.

Outcome

Considering the overarching intervention goal of promoting improvements in pain levels in daily living, pain response was selected as the primary outcome. Pain was assessed using the 11-point NPRS with a 7-day recall period during sessions 9, 18, or 27.

Pain response, defined as at least a 30% reduction in the NPRS by the end of the program, aligns with clinical recommendations from the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) [28]. This definition is supported by a consensus meeting that interpreted the clinical significance of treatment outcomes in clinical trials for chronic pain treatments. Additionally, we included the criterion of concluding the program with an NPRS score equal to or below 3 points (the threshold for mild pain) [29] to account for patients who started with lower pain levels and ended the program with acceptable pain levels. The widespread use of this binary outcome, along with its practicality in real-world settings, supported its inclusion.

Predictors: Variables Used for Model Development

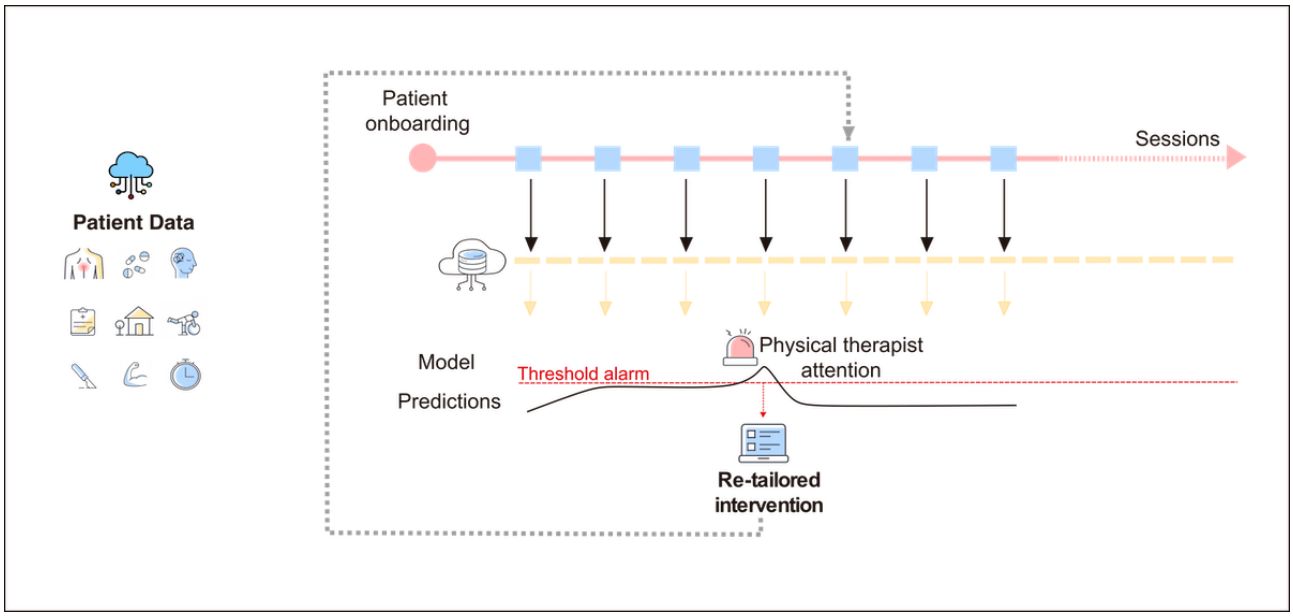
The variables used for model development were selected based on existing literature and their clinical relevance to MSK pain. A detailed description of the variable domains and their acceptable ranges can be found in Table 1. The data set variables included (1) demographic characteristics (eg, race and ethnicity, social deprivation index) [30]; (2) baseline clinical presentations (eg, acuity, disability, mental health, productivity, fear-avoidance beliefs, presence of red flags); (3) time series of mean active range of motion (ROM) throughout all repetitions of each exercise during each session; (4) session-related usability (eg, movement errors, number of exercises, sets and repetitions, the time between sessions, session duration); and (5) self-reported fatigue and pain experienced during exercises, measured on a 0-10 scale (Figure 1).

Table 1. Features domains included in the study.

Domain and subdomains	Description
Demographic	
Individual characteristics	Comprises information about gender, age, race/ethnicity, body mass index, education level, among others
Geographical location	Urban or rural location and time zone
Work characteristics	Employment status and job type
Socioeconomic	
Social deprivation	Assessed by the Social Deprivation Index (score range 0-100) [30]; socially deprived individuals were those with an index ranging from 60 to 100
Productivity	
Participation—work	Assessed by the overall work productivity (score range 0-100), presenteeism (score range 0-100), and absenteeism (score range 0-100) subscales from the Work Productivity Impairment Questionnaire for general health
Participation—social	Assessed by the non-work–related activities impairment subscale from the Work Productivity Impairment Questionnaire for general health (score range 0-100), and scores of items 8 (range 0-5), 9 (range 0-5), and 10 (range 0-5) of the Oswestry Disability Index
Clinical	
Condition	Includes musculoskeletal condition diagnosis, anatomical pain region, presence of leg symptoms (numbness or tingling), past surgery, among others
Acuity	Acute (<12 weeks) or chronic (persistent or recurring pain for ≥12 weeks)
Pain	Pain intensity assessed by the Numerical Pain Rating Scale (score range 0-10)
Functionality	Assessed by the Oswestry Disability Index (score range 0-100) considering the total score and the individual scores of items 2-7
Mental health	Assessed by the 7-item General Anxiety Disorder Scale (score range 0-21) and the 9-item Patient Health Questionnaire (score range 0-27), considering the total score and the individual score for each item; features considering moderate and severe depression or anxiety were calculated using the thresholds described in Spitzer et al [31] and Kroenke et al [32]
Fear-avoidance	Assessed by the Fear-Avoidance Beliefs Questionnaire for Physical Activity (score range 0-24), considering the total score and the individual score for each item
Surgery intent	Assessed by the question “On a scale of 0 to 100, where 0 is not at all and 100 is extremely interested, how interested are you in undergoing shoulder surgery in the next 12 months?” (score range 0-100)
Medication consumption	Considers nonopioid analgesic and opioid consumption (yes or no)
Red flags	Presence/absence of at least one red flag identified during onboard screening, which was cleared before entering the study by a physician (yes or no) [33]
Prescription	
Support level	Includes support-level perception assessed by physical therapist interactions during the intervention
Exercise Performance	
Biomechanics	Active range of motion collected by motion trackers
Exercise accuracy	Correct and wrong repeats; performance in all prescribed exercises (total correct repeats by total repeats); average stars (0-5)
Exercise-induced pain acute response	Pain felt during exercise sessions (assessed by the question “How did you feel during your session: my pain during today’s session?” (score range 0-10)
Exercise-induced fatigue intensity	Self-reported fatigue in response to the question “How did you feel during your session: My fatigue during today’s session?” (score range 0-10)
Exercise adherence	Session duration time spent on sessions (minutes) and time interval between sessions (days)
Motivation and Compliance	

Domain and subdomains	Description
Motivation	Patient's individual goals with the intervention and session commitment (through the question "How many 20-minute sessions can you commit to per week?"), among others
Enrollment aspects	The time span from enrollment to (1) onboarding and (2) session 1
Days of the week	Days of the week the patient performed the exercise session

Figure 1. Machine Learning (ML) tool development within the digital care program. All patient data collected both passively and actively regarding demographic and clinical characteristics, range of motion, and session usability, as well as collected from public sources (eg, social deprivation index) are continuously stored from onboarding to the program end, enabling the creation of a data repository within the physical therapists (PTs) cloud portal. At the end of each session, data are processed through an ML model to predict an individual's potential to achieve clinically significant pain relief at the program end. In the case of the high probability of an unfavorable outcome, an alarm is set in the PT portal for further examination and re-tailoring of the intervention.



All data were automatically stored in the cloud portal. Demographic and clinical characteristics were collected through an onboarding form using validated PROMs. ROM and session usability were passively collected, while fatigue and pain experienced during exercise sessions were recorded at the end of each session.

Sample Size

Given that there is no established method to calculate sample sizes for prognostic models using ML, we followed the recommended guideline for standard model development, which suggests obtaining 10-20 events per predictor parameter. As we estimated including up to 300 predictor variables in the models, a sample size range of 3000 to 6000 was calculated.

Missing Data and Data Preparation

The overall missingness was 18.45% (324,385/1,757,875; see Table S2 in Multimedia Appendix 1), comprising the following: 17.07% (300,117/1,757,875) missing completely at random, where the missing data points were attributed to system settings; 0.29% (5169/1,757,875) missing at random, where the missingness could be explained by other variables (eg, specific protocol prescriptions that did not include one of the studied exercises); and 1.09% (19,099/1,757,875) missing not at random, where the reasons for the missing data were related to unobserved factors. Categorical variable imputation was performed by creating a new category labeled "not available," followed by dummy encoding. Continuous variables were imputed using multiple imputations by chained equations or by assigning a value outside the distribution (eg, –1), depending on the nature of the missingness. Multiple imputations can provide unbiased estimations for data that are missing completely at random and at random. As the rate of missingness for not-at-random data is very small, we used multiple imputation techniques to handle the missing data overall. The cleaned data set included 6125 patients and contained a number of variables ranging from 235 at session 1 to 275 at session 7.

Analytical Methods

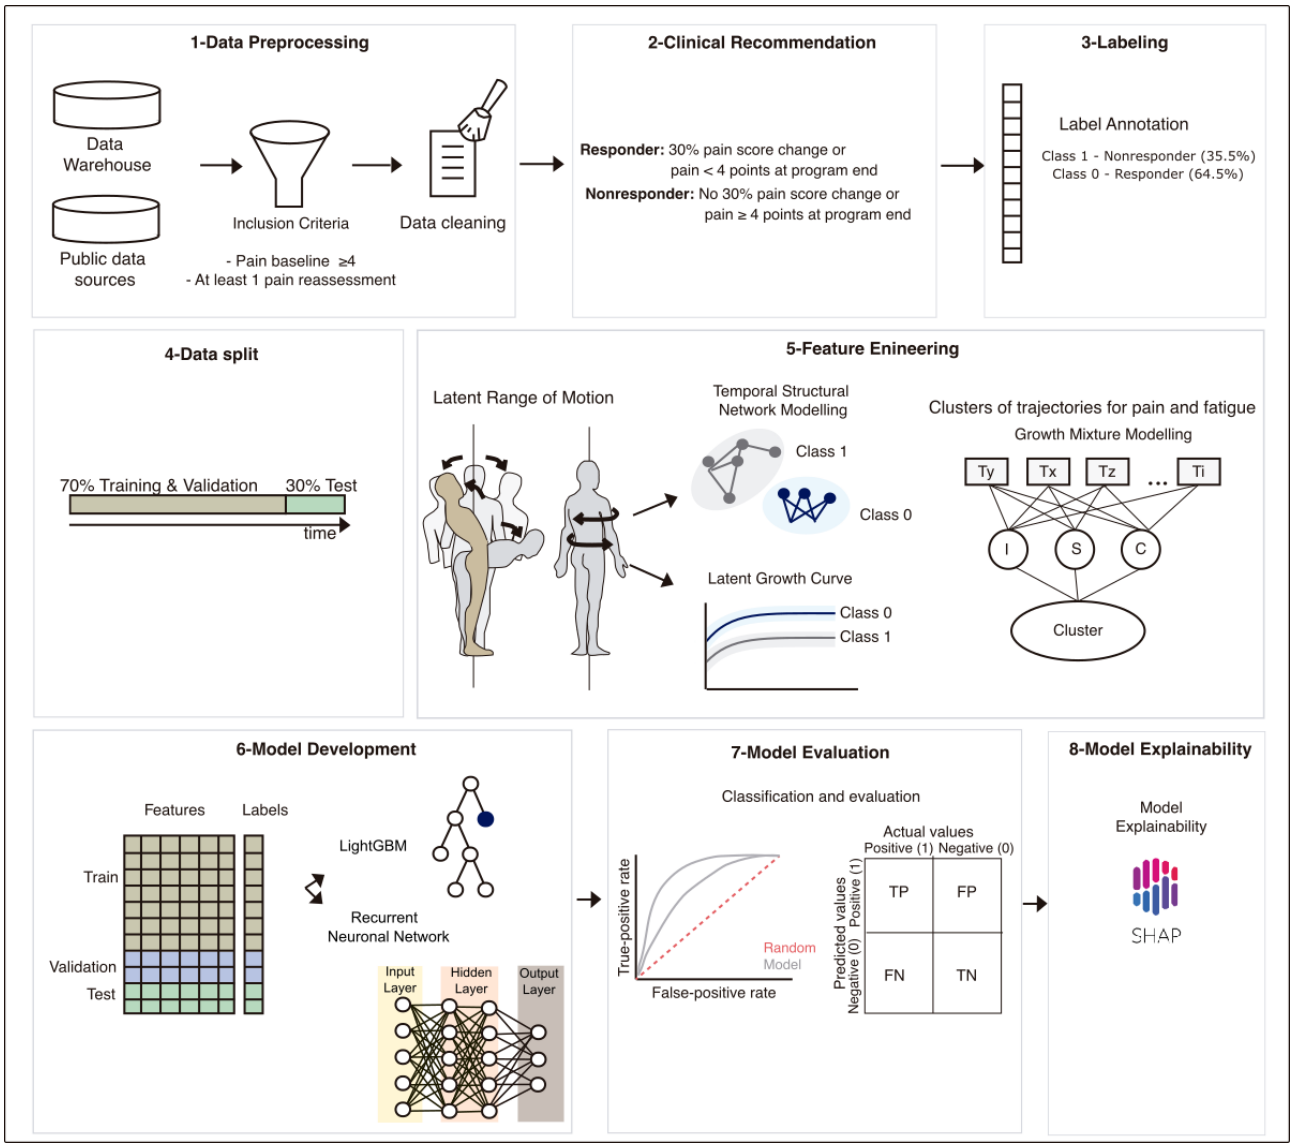
Feature Engineering

Feature engineering was utilized to capture meaningful patterns and insights from multiple variables over time, creating new features that represent the underlying relationships and dynamics within the data (as detailed in Figure S1 in Multimedia Appendix 1). A minimum of 4 sessions was required to conduct a longitudinal analysis.

ROM data from 4 exercises were encoded into a unified composite value that illustrates the longitudinal progression of trunk motion [34], utilizing both latent growth curve analysis (LGCA) [35,36] and temporal structural network modeling (Figure 2) [37]. While the former captures ROM patterns over

time to estimate individual trajectories among the 2 classes (pain nonresponders and pain responders), the latter illustrates how improvements in one exercise may be correlated with improvements in other exercises. Among a diverse array of prescribed exercises (N=117), only those that incorporated trunk motion—extension, flexion, rotation, and side bending—were included [34]. This subset was chosen due to its frequent prescription among patients and its superior performance in model comparisons, as determined by likelihood-ratio tests.

Figure 2. Model development pipeline. Data from patients with low back pain (LBP) who underwent the digital intervention were collected from the data warehouse within a specific time frame. Inclusion criteria: average pain level equal to or greater than 4 on the Numerical Pain Rating Scale (NPRS) at baseline considering a 7-day recall period; and at least one pain reassessment during the intervention. Patient data were preprocessed for the tool. Patients who did not experience a pain (NPRS) reduction of at least 30% or reported pain level higher or equal to 4 at the program end were categorized as nonresponders (labeled as "1" in the data set). Considering the overarching intervention goal of promoting improvement in pain levels, a flag was triggered when patients were likely to be nonresponders to assist PTs' clinical judgment; a split of 70/30 was performed on the data set followed by feature engineering: range of motion (ROM) was computed through temporal structural network modeling and latent growth curves, whereas pain and fatigue experienced during exercises (reported at the end of each exercise session), exercise accuracy, and time between sessions were computed using growth mixture modeling to depict changes over time. Model development consisted of a tree-based binary classifier and a recurrent neural network that were optimized using the receiver operating characteristic (ROC)-area under the curve (AUC) as the target metric. Precision-recall curves were used as evaluation metrics, and model explainability was assessed using SHAP (Shapley Additive Explanations) values. FN: false negative; FP: false positive; LightGBM: light gradient boosting machine; TN: true negative; TP: true positive.



Thus, we first constructed the LGCA and temporal structural network model for both responders and nonresponders (P<.001) to estimate an intercept, slope, curve, and latent ROM, as well as individual covariance matrices for each patient (see Equations S1-S3 in Multimedia Appendix 1). The proximity of an individual covariance matrix to the expected covariance matrices from responders and nonresponders was assessed using the chi-square measure, which was then incorporated as a feature.

Mixture clustering was used to create new features, using the probabilities of belonging to different clusters to leverage the underlying characteristics of those clusters in making predictions, following a mixture of experts approach. A growth

mixture model [38] was applied to cluster longitudinal trajectories of pain and fatigue profiles during exercise, as well as the performance of the exercises and the time spent in sessions. The intent was to capture subpopulations with a high probability of sharing similar patterns (eg, high, moderate, slight, or no improvement). The Bayesian information criterion indicated that 5 clusters provided the optimal fit for the data (see Figure S2 in Multimedia Appendix 1). The individual probability of a patient being assigned to each trajectory class was calculated using likelihood ratios (see Equation S4 in Multimedia Appendix 1), yielding 5 probabilities per participant for each variable at each session.

For the early sessions (ie, sessions 1-3), longitudinal models could not be calculated due to the requirement of at least four time points. Therefore, the raw values or their deltas between sessions were calculated for the outcomes mentioned in this section.

Labeling

Pain responders (as defined in the "Outcome" subsection) were labeled as 0, while nonresponders were labeled as 1. This labeling serves as a flag to assist PTs during monitoring and clinical decision-making, thereby representing a binary classification scheme (see Figure 2). Depending on the discharge time point (which occurred no later than the 30th treatment session), the corresponding latest survey (9th, 18th, or 27th) was used to create the labels.

Model Pipeline

Two different approaches were used to predict pain response from session 1 to session 7: a tree-based model and a recurrent neural network (RNN) model.

For the tree-based model, a light gradient boosting machine (LightGBM) was utilized, with hyperparameter optimization performed using the Optuna library [39]. This involved 50 trials per algorithm, using the area under the receiver operating characteristic curve (ROC-AUC) as the evaluation metric. LightGBM was trained with 5-fold cross-validation on the training data from each session. As these models are not sequence models, features from previous sessions were concatenated as sessions progressed, allowing models in later sessions to access features from historical sessions. An AUC of 0.5 indicates a random predictor, while an AUC of 1 signifies a perfect predictor. For each fold in the cross-validation, the synthetic minority oversampling technique (SMOTE) was applied to oversample the training data for both classes, reaching 5000 samples per class, as the absence of SMOTE negatively affected model performance. Using the hyperparameters that yielded the best validation performance, a final model was fitted on the entire training set.

An RNN model applied across the 7 sessions can be viewed as a time series (using the PyTorch Python library [40]; Python Foundation). Similar to the tree-based method, the Optuna library was utilized for hyperparameter optimization. However, unlike the tree-based setup, SMOTE was not applied due to its unsuitability for sequential data. RNN models were trained using binary cross-entropy loss and early stopping, with a patience of 10 epochs, utilizing the validation ROC-AUC as the early stopping metric. Using the hyperparameters that yielded the best validation performance, a final model was fitted on the entire training set. This final model was trained with a fixed number of epochs, defined as the average number of early stopping epochs across the cross-validation folds.

The performances of both models were assessed on the test set by calculating the ROC-AUC, precision-recall AUC, F_1-score (at a 0.5 threshold), sensitivity, specificity, and negative predictive value (Figure 2).

Model Explainability

Shapley Additive Explanations (SHAP) was applied on the best model to assess model explainability by investigating feature importance [41] (the Python SHAP library [41] for tree-based and the Python timeshare library [42] for RNN models; Figure 2). Positive SHAP values indicate higher prediction scores, meaning a higher probability of nonresponse. To understand the overall impact of different domains, SHAP values for each feature were cumulatively aggregated within their respective domains for each session. As LightGBM models were trained with an increasing number of features over time, SHAP values were normalized per session to examine the relationship between SHAP values and feature values throughout the intervention. Patient SHAP values were visualized using SHAP dependence plots, utilizing a base value of 0.028 and a contribution threshold of 0.05.

Recursive feature elimination, which involved removing features with low SHAP values after hyperparameter optimization, progressively deteriorated model performance.

Fairness

Demographic and clinical characteristics identified as statistically different between the training and test sets were subjected to subgroup analysis to assess potential bias, including factors such as gender, social deprivation index, age, acuity, and pain levels.

Model Output

The model output classified patients as responders or nonresponders, based on the previously defined outcome, and was contingent on the applied threshold (eg, 0.95).

Train and Test Sets

A data split was conducted in which 70% (4313/6125) of the patients were randomly assigned for training the model, while the remaining 30% (1812/6125) were reserved for testing.

Statistical Analysis

Demographic and clinical presentations at baseline were analyzed using means and proportions. The minimum and maximum ROC-AUC values were calculated by bootstrapping the training and test sets separately (1000 bootstrapped sets). Model comparisons involved ROC-AUCs calculated using the DeLong algorithm [43]. Feature engineering models were developed using R (version 4.2.2; R Foundation for Statistical Computing; packages: lavaan, mlVAR, xgboost, mice, and tidySEM). All other analyses were conducted using Python (version 3.9.7; package: TreeSHAP). The level of significance was set at $P<.05$, considering 2-sided hypothesis tests.

Results

Study Population

A total of 6125 patients met the inclusion criteria (see the flowchart of the study cohort in Figure S3 in Multimedia Appendix 1). Among them, 2172 (35.46%) were classified as nonresponders, while 3953 (64.54%) were responders. The analysis encompassed various domains and subdomains, including demographic, socioeconomic, productivity, clinical, prescription, exercise performance, and motivation/compliance data, up to session 7 (see further details in Table 1). Baseline demographic and clinical characteristics for the overall cohort, as well as stratified by training and test data sets, are presented in Table 2. The overall cohort primarily consisted of women (3445/6125, 56.24%), patients aged 41-60 years (3488/6125, 56.95%), fully employed individuals (5119/6125, 83.58%), and college graduates (4037/6125, 65.91%). Additionally, 2335 (38.12%) individuals were classified as obese, 1931 (31.53%) identified as racial or ethnic minorities (ie, Asian, Black, Hispanic, and other), and 1585 (25.88%) came from socially deprived backgrounds.

Table 2. Baseline demographics and clinical data.

Demographics	Overall cohort (n=6125)	Train data set (n=4313)	Test data set (n=1812)	*P* value

[a]Denotes 7 missing values.

[b]Denotes 22 missing values (higher quantiles indicate higher social deprivation).

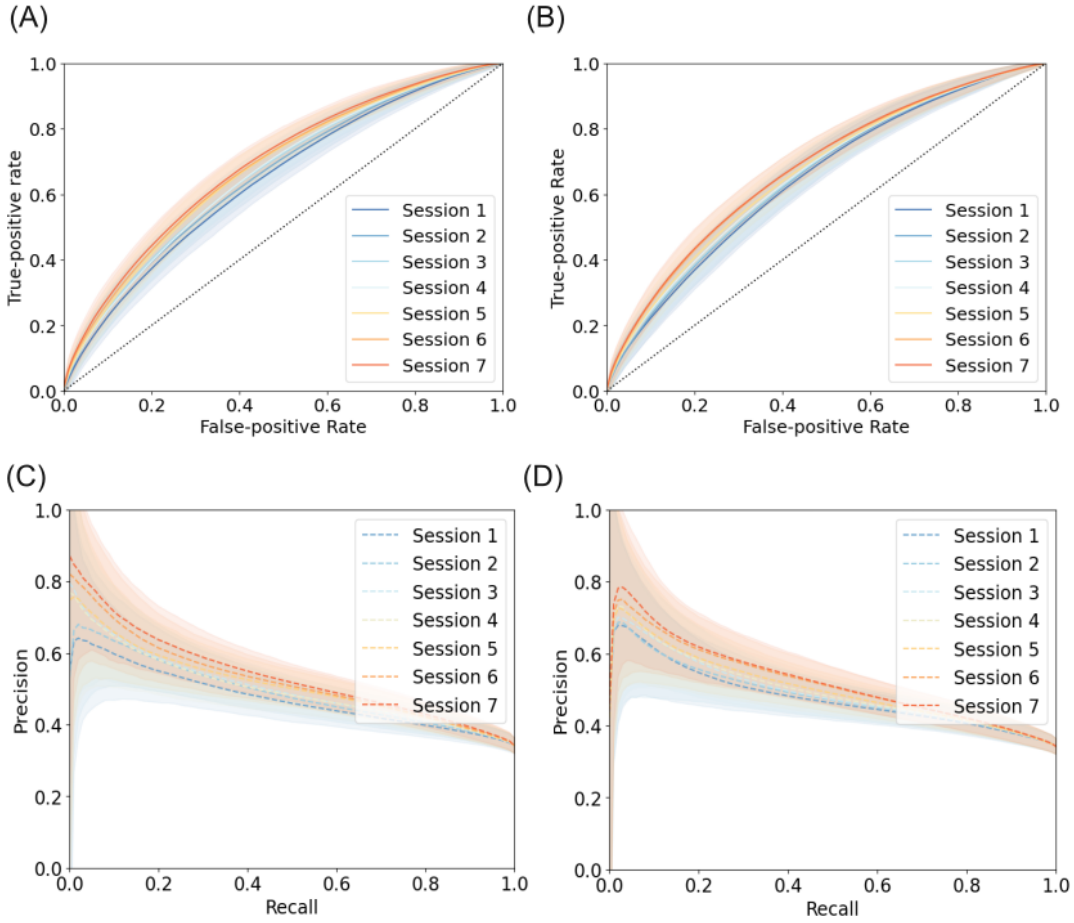
Overall, the cohort reported moderate pain, with an NPRS score of 5.7 out of 10.0 (SD 1.4), and a disability score on the Oswestry Disability Index (ODI) [44] of 23.1 (SD 12.7) at baseline. This was primarily associated with chronic pain, defined as pain lasting 3 months or longer (4957/6125, 80.93%). Severe pain (NPRS: 8-10) was predominantly reported by patients with acute LBP (168/1168, 14.38% vs 519/4957, 10.47%, in chronic cases, *P*<.001). High fear-avoidance beliefs (Fear-Avoidance Beliefs Questionnaire score ≥15 [45]) were reported by 1391 of the 6125 (22.71%) patients of the cohort, while 2144 (35.0%) and 1590 (25.96%) patients reported at least mild anxiety (7-item General Anxiety Disorder Scale [GAD-7] score ≥5 [31]) or depression (9-item Patient Health Questionnaire [PHQ-9] score ≥5 [32]), respectively. A large majority (4900/6125, 80.0%) reported impairment in daily activities (Work Productivity and Activity Impairment Questionnaire for General Health [WPAI]—activity score >0), while 3296 of the 6125 (53.81%) patients reported either presenteeism or absenteeism (WPAI overall score >0). Clinical outcomes were similar across both the training and test data sets, with the exception of the ODI, which was statistically higher in the test data set (22.6, SD 12.5 vs 24.4, SD 13.2), although this difference was not clinically meaningful [46].

Model Development

The LGCA revealed a significantly different latent representation of trunk motion over time for responders and nonresponders (*P*<.001; Figure S4 in Multimedia Appendix 1). Similarly, the temporal structural network model showed 2 significantly different temporal correlation patterns of trunk motion for responders and nonresponders (*P*<.001; Figure S5 in Multimedia Appendix 1).

The best models from both methodologies (LightGBM and RNN), following hyperparameter optimization, resulted in similar ROC-AUC scores in the test set across all time points (*P*=.98, .52, .69, .81, .38, .68, and .22, respectively, for sessions 1-7; Figure 3A and B). Model performance improved over time for both models (*P*<.001 for both, DeLong algorithm), with predictions at session 7 reaching an ROC-AUC of 0.70 (95% CI 0.65-0.71, based on bootstrap resampling; Table S3 in Multimedia Appendix 1) for RNN and 0.71 (95% CI 0.67-0.72) for LightGBM, compared with 0.66 (95% CI 0.61-0.68) and 0.67 (95% CI 0.61-0.67) obtained in session 1. These results corresponded to a precision-recall AUC at session 7 of 0.56 (LightGBM: 95% CI 0.49-0.58; RNN 95% CI 0.48-0.57; Figure 3C and D) and a weighted F_1-score of 0.68 (95% CI 0.64-0.69) for both models.

Figure 3. Model performance on the test data set. Test receiver operating characteristic curve (ROC) for both (A) light gradient boosting machine (LightGBM) and (B) recurrent neural network (RNN) across the 7 sessions. True positive rate (true positives over true positives and false negatives); false positive rate (false positives over false positives and true negatives); dashed line denotes an area under the curve (AUC) of 0.5 corresponding to a random predictor; precision-recall curve for (C) LightGBM and (D) RNN models across the 7 sessions. Precision denotes true positives over true positives and false positives; recall denotes true positives over true positives and false negatives; shaded areas denote the 95% CIs.



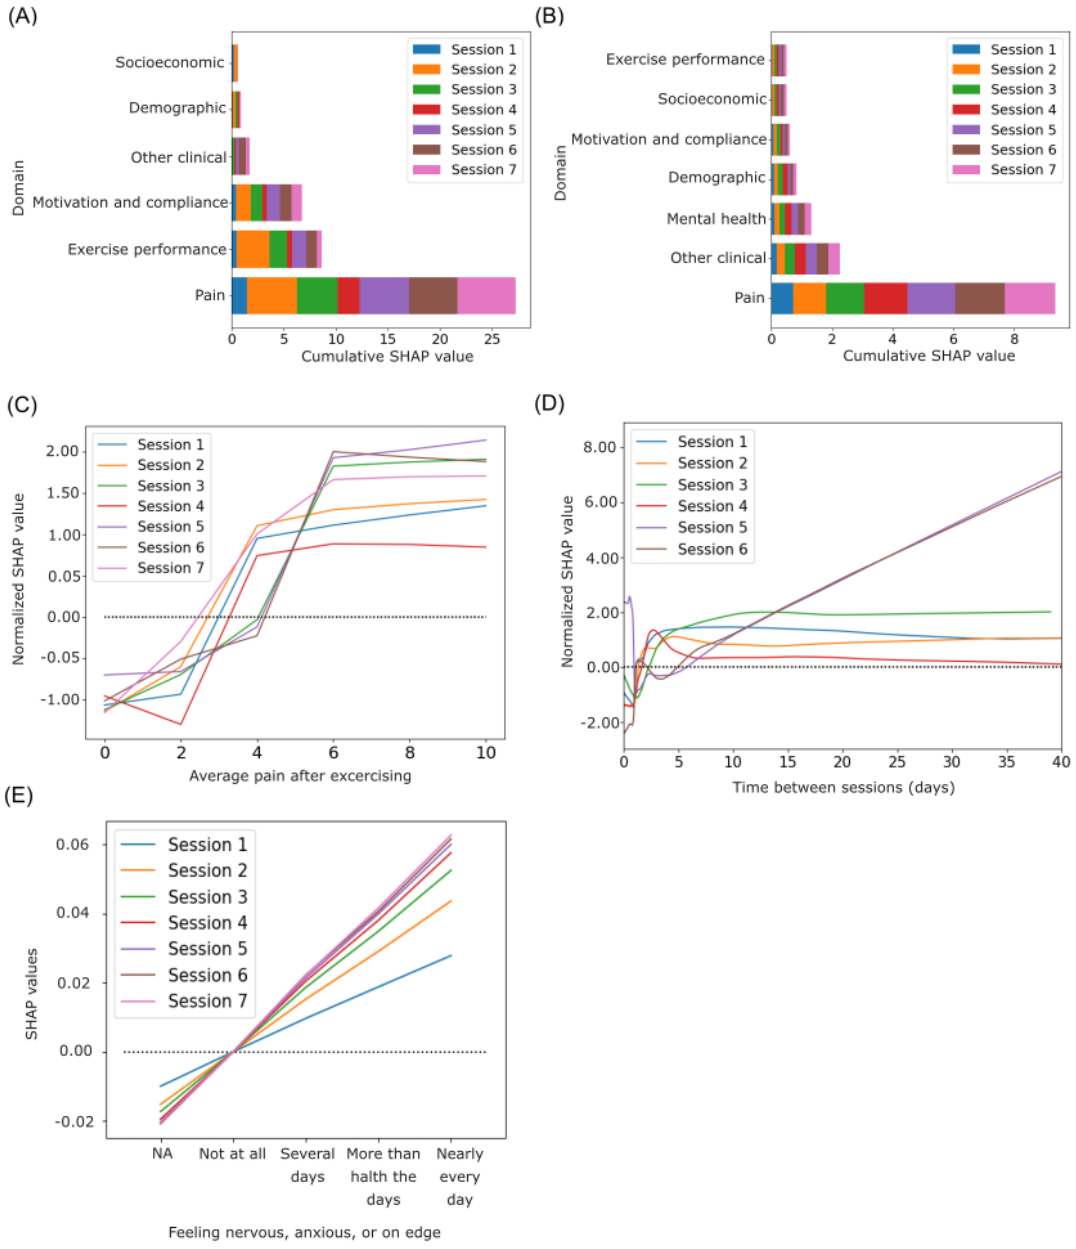
For the models described, considering a precision of 70%, the LightGBM achieved a specificity of 0.97 (95% CI 0.95-0.98), a sensitivity of 0.13 (95% CI 0.02-0.25), and a negative predictive value of 0.68 (95% CI 0.68-0.68). Similarly, the RNN achieved a specificity of 0.97 (95% CI 0.94-0.97), a sensitivity of 0.12 (95% CI 0.00-0.24), and a negative predictive value of 0.68 (95% CI 0.65-0.71).

Predictive Factors in Digital Care

Considering the best models, we analyzed the top 20 outcome predictors at each session based on absolute mean SHAP values [41]. Figure 4 depicts cumulative values of features aggregated by domains over time for the LightGBM (Figure 4A) and RNN (Figure 4B). Detailed feature stratification for both models is available in Figures S6 and S7 in Multimedia Appendix 1, respectively.

Although both models incorporated features from comparable domains, the importance of each feature varied depending on the model. The flagged domains included pain-associated metrics, exercise performance, and motivation and compliance data, which utilized real-time passive data collection.

Figure 4. Model explainability. Cumulative Shapley Additive Explanations (SHAP) values per domain considering the top 20 features at each session for both (A) light gradient boosting machine (LightGBM) and (B) recurrent neural network (RNN). SHAP values depicting the relationship between the outcome (ie, pain response) and the feature of interest: (C) average pain felt during exercising, (D) time between sessions (days), and (E) feeling nervous, anxious, or on edge (7-item General Anxiety Disorder Scale [GAD-7] scale). As LightGBM models differ in the number of features across time, and because we are interested in qualitative comparisons, SHAP values were normalized at each session by dividing by the SD of SHAP values.



Although the pain domain was highly predictive for both models (Figures 4A and B), LightGBM placed greater emphasis on exercise performance, motivation, and compliance data than the RNN. Within the exercise performance domain, the most informative features included time spent exercising, exercise accuracy, and the execution of specific exercises related to trunk motion. Notably, lower training time or poorer performance in particular sessions was associated with an increased likelihood of nonresponse (Figure S8A in Multimedia Appendix 1). Low motivation and compliance, specifically characterized by low exercise consistency—evaluated by longer intervals between sessions (>3 days, Figure 4D)—was associated with a higher likelihood of being a nonresponder. This observation was consistent across other variables reflecting motivation toward compliance, such as the time between registration and program start, as well as the reasons preventing patients from completing the program.

The RNN was more reliant on the temporal patterns of mental health and other clinical variables (eg, medication intake, intent to undergo surgery) for its predictions. The presence of mental distress was associated with a higher likelihood of being a nonresponder across all sessions, as exemplified by the item "Feeling nervous, anxious, or on edge" from the GAD-7 scale (Figure 4E). Even though LightGBM did not rank mental health features among the top 20 predictors, higher GAD-7 and PHQ-9 scores were correlated with poorer outcomes, particularly in the later sessions (eg, Figure S8B in Multimedia Appendix 1). Additionally, other clinical features, such as prescribed

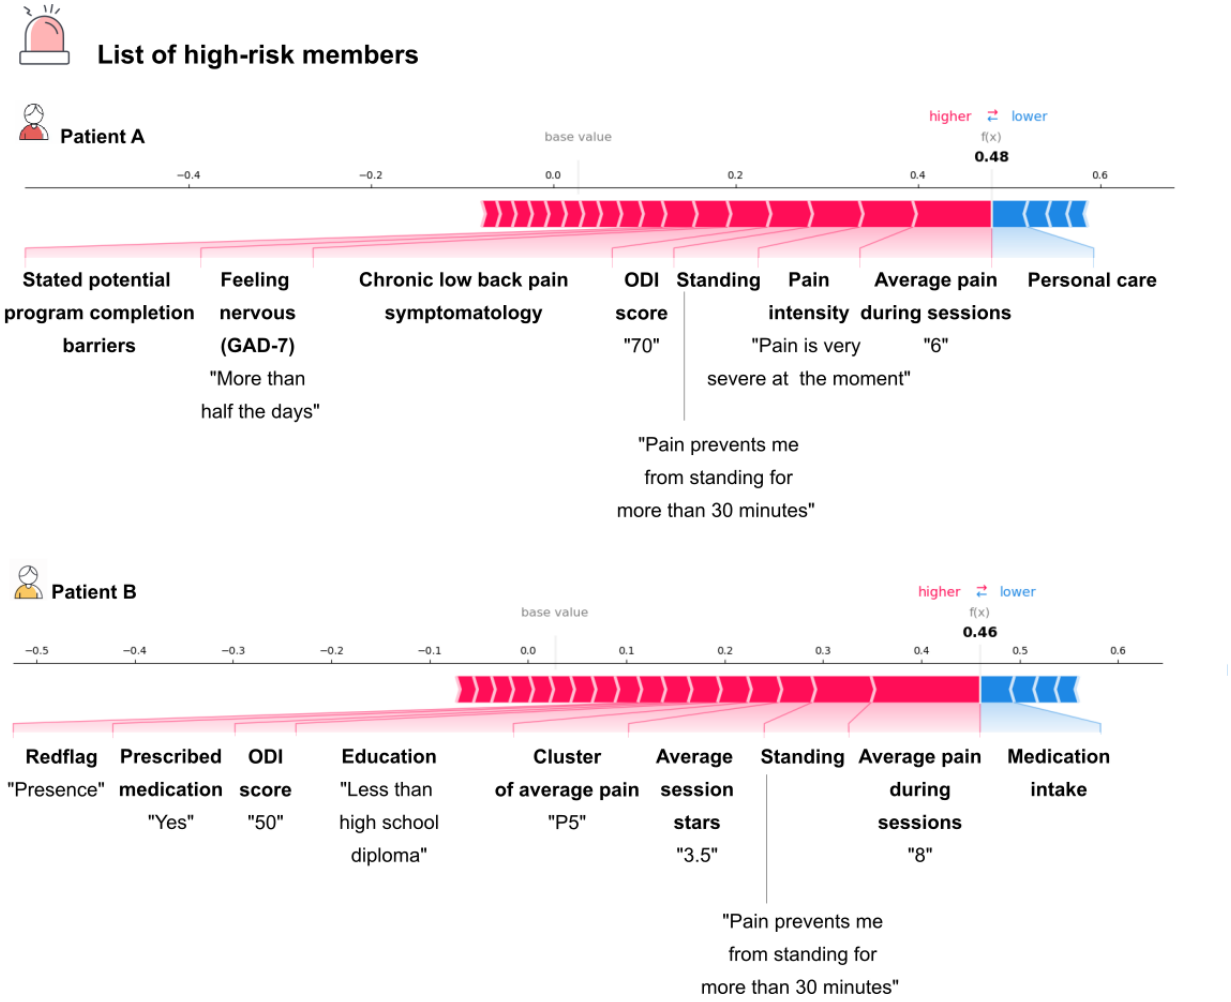
medication, were associated with a lower probability of being a responder.

Both models utilized features related to individual characteristics, including demographics and socioeconomic status. Subgroup analyses evaluating potential imbalances between the training and test sets indicated that similar results could be obtained regardless of demographic or clinical characteristics (Table S4 in Multimedia Appendix 1). Overall, women and individuals from more socially deprived areas, particularly those from regions with higher unemployment rates, had a worse prognosis compared with their counterparts (Figure S8C and S8D in Multimedia Appendix 1).

Model Applicability

Figure 5 illustrates an example of the output from the tool provided on the PT portal for 2 patients during session 4. This output includes the model's prediction of nonresponders (ie, true positives, with an RNN precision of 70% on the test set) and the key drivers behind this classification. For patient A, the classification is primarily influenced by high pain reported during exercise in session 4 (NPRS = 6 out of 10), baseline characteristics indicating severe clinical presentation (such as high ODI and mental distress), and self-reported potential barriers to motivation. Patient B also reported high pain during exercise in session 4 (NPRS = 8 out of 10) and exhibited low exercise performance for that session (3.5 out of 5 stars). Additionally, patient B indicated prescribed medication intake (eg, opioids) and the presence of at least one clinical red flag, despite being cleared by a physician to participate in the program. With an ODI score of 50 and low educational attainment, this information is subsequently analyzed by the PT, allowing for necessary refinements to the intervention. This may involve adjusting exercise intensity or type or prioritizing specific components of the DCP, such as education and cognitive behavioral therapy. These adjustments will subsequently impact future model predictions in a dynamic closed-loop optimization that contributes to the refinement of the tool.

Figure 5. Example of the integration of the model in the physical therapist portal. Example of model explainability for 2 patients, A and B, classified as high-risk nonresponders (recurrent neural network [RNN] precision 70%) at session 4. In the physical therapist portal, each patient's health record includes the prediction of the tool along with the variables that sustained the model's classification, providing insights into the specific factors affecting the patient's prognosis. The most influential factors contributing to a nonresponder prediction are highlighted in red, with factors positioned toward higher "base values" (ie, to the right) indicating a stronger impact. For example in the case of patient A, the pain felt during exercise and the baseline pain are the most influential for the model output. After analyzing the case, the physical therapist reevaluates the patient's program and the potential need for further support. Those adjustments will be subsequently fed into the tool reinforcing the dynamic optimization close loop. GAD-7: 7-item General Anxiety Disorder Scale; ODI: Oswestry Disability Index.



Discussion

Principal Findings

This study leveraged passively and automatically collected patient data from a digital MSK intervention to develop a predictive tool that assists PTs in optimizing treatment. These models utilize continuously updated data from each enrolled patient to identify early those who are less likely to achieve a clinically meaningful reduction in pain. Model performance significantly increased over time, achieving an ROC-AUC of 0.70 (95% CI 0.65-0.71, from bootstrap resampling) for the RNN and 0.71 (95% CI 0.67-0.72) for the LightGBM at session 7. These models identified features from domains related to pain, exercise performance, motivation, and compliance as the most predictive of outcomes. This information can inform PTs for continuous treatment adjustments to maximize response rates. This predictive tool operates through a dynamic loop, and when applied in clinical practice, it continuously enhances treatment refinement and improves tool performance over time.

Comparison Prior Work

Previous ML models designed to support LBP management without real-time data collection have reported performances (ROC-AUCs) ranging from 0.49 to 0.71 [6,7,9,10,21], with 1 model achieving a higher AUC of 0.84, but only near the end of treatment [11]. Additionally, the currently used STarT Back prediction tool has reported AUCs of 0.63 and 0.60-0.62 when predicting pain intensity at 12 weeks and 1 year, respectively [6,7]. The wide range of reported model performances reflects not only the challenges associated with each proposed objective but also the level of uncertainty that these tools generate. In this study, both models' performances significantly improved over time, achieving an AUC of 0.70-0.71 at session 7 using real-world data. This AUC suggests that pain response at an early stage of the intervention is partially explained by the variables used. However, as treatment progresses, it is plausible that model performance will continue to improve toward the end. As an example, Brennan et al [11] demonstrated a 1.3 times increase in model performance when using PROMs collected at session 3 to predict outcomes at session 6. Our study aimed to be less reliant on PROMs and more focused on a scalable solution capable of improving over time [47,48]. While specificity and sensitivity depend on the threshold applied, the results presented here align with those previously reported [6,7,9-11,21]. The choice of threshold to balance precision and recall must align with the clinical setting's needs, taking into account the costs and implications of false positives and false negatives.

In addition to real-time predictions, these models may offer timely insights that enable PTs to determine the need for referring patients to specialized care (eg, escalation to psychologists) through shared decision-making with the patient. Both models identified similar feature domains, including pain-associated metrics, exercise performance, motivation, and compliance, thereby surpassing the predictive value of individual demographic prognostic factors. These domains cannot be captured solely through PROMs, further emphasizing the relevance of such models in managing LBP.

To predict the pain that patients experience during daily activities, the model incorporates pain levels reported during exercise, alongside baseline clinical presentations (including the NPRS, the "pain intensity" item from the ODI, and acuity)—features previously established as poor prognostic indicators [49-51]. This underscores the importance of pain experienced during exercise as a predictor of outcomes. Specifically, exercising with pain levels exceeding 4 out of 10 has been shown to predict negative outcomes [52], suggesting that these patients may benefit from adjustments to their exercise prescriptions. The use of analgesic medications, such as opioids, has also been linked to a poorer prognosis, as noted in previous studies [53-55].

Aside from pain, both models prioritized motivation, compliance, and exercise performance data for predictions. Regarding motivation, indicators such as self-reported resistance to commit to the intervention, delayed program initiation, and extended intervals between sessions (>3 days) were associated with a lower likelihood of response, reinforcing previous findings [56]. In the exercise performance domain, the models emphasized exercise execution data, including the time dedicated to sessions, performance scores, and the number of incorrect exercises, with lower scores linked to worse outcomes. Challenges associated with compliance frequently contribute to increased frustration and decreased adherence to treatment [57,58] and have been previously described as risk factors for poor outcomes [5,59]. Co-occurring with low adherence rates, anxiety and depression were associated with a lower likelihood of response in one of the models (RNN). This finding is unsurprising, considering the well-established negative feedback loop between mental health and MSK pain [60,61].

Although the demographic and socioeconomic profiles of patients are relevant, they may be of lower importance than the previously mentioned domains. Certain groups, such as women and the unemployed, may encounter systemic barriers that hinder their ability to achieve pain relief.

In summary, implementing this tool would enhance care coordination and patient management by identifying individuals at higher risk for poor pain outcomes. This, in turn, can streamline workflows, fostering informed decision-making and tailored treatment programs. The continuous stream of data generated by patients enables refined predictions at each interaction, allowing PTs to make timely adjustments to the program. These adjustments could then be fed back into the system to further enhance its recommendations. To assess potential biases, the subgroup analyses conducted in this study focused on demographic characteristics and socioeconomic factors, indicating a low risk of bias. However, further evaluation of algorithmic bias will be necessary once the model is fully operational and deployed in real-world settings. Continuous monitoring will be essential to ensure that the model does not disproportionately impact specific populations or reinforce existing health disparities.

While there may be concerns among PTs regarding the "black box" nature of AI, model explainability will be crucial in overcoming this barrier. Before full implementation, training for PTs (or clinicians) is essential to ensure they understand and

can effectively use the tool, thereby mitigating fears and preventing erroneous use of AI. Nevertheless, the design of this AI tool ensures that final clinical decisions remain with the PT, preserving human judgment and critical reasoning. This approach can foster trust in the system and promote the safe integration of AI into clinical workflows.

Future research on the development of this predictive tool should concentrate on clinically validating the closed feedback loop. Additionally, optimizing the performance of the AI tool may be further enhanced by incorporating supplementary data sources, such as real-life context data variables obtainable from smartwatches (eg, pedometry and sleep quality) and clinical context information (eg, presence of specific comorbidities and clinical records). This could reveal additional data patterns and, consequently, contribute to improved model accuracy. With the nearly exponential increase in data, it is plausible that RNNs or other deep sequence models will continue to enhance their performance and eventually surpass LightGBM, given their natural ability to handle sequential data [47,48]. Additionally, the integration of continuous volumes of data may expand the model's predictive capabilities to assess long-term outcomes. In particular, for LBP, predicting long-term outcomes will help determine which types of interventions lead to more sustained recovery with functional improvement, and reduce the likelihood of relapse or chronicity over time.

Finally, as the AI model relies on protected health information, implementing robust safeguards and establishing data stewardship protocols are essential to maintain confidentiality, integrity, and security.

Other future considerations include exploring the application of such tools to other MSK conditions.

Strengths and Limitations

This study has important strengths. First is the novelty of exploring how data collected from a DCP can be applied in an ML model to continuously predict patient outcomes and foster personalized care. Second, this cohort's demographic and clinical characteristics mirror that of the US population reporting LBP [62,63], with the percentage of nonresponders for pain being consistent with previous studies evaluating in-person and digital LBP management [11,22,64,65]. Finally, the nature of the data that are automatically and passively collected, which are less reliant on PROMs, makes it easy to obtain and less burdensome for both patients and clinicians. However, this study also has limitations that warrant noting: (1) Although the cohort was large and decentralized, we cannot dismiss the possibility of overfitting; additionally, as the population focuses on beneficiaries of health plans, this may limit generalizability to populations not covered by health insurance. Therefore, extended testing on new cohorts is critical for the external validation of the AI tool. Such validation would provide a more accurate assessment of the model's performance, ensuring that its effectiveness and robustness are maintained across different populations that may enroll in the program. Additionally, it could help identify areas in need of improvement. Furthermore, external validation studies should be followed by real-world applications to evaluate the usefulness of the deployed model in clinical settings; (2) despite being highly used and recommended by clinical guidelines, transforming the pain outcome into a binary classification may obscure subtle variations in patient responses. This simplification could lead to misclassification of patients who are close to the threshold. Future approaches could consider modeling the outcome as a continuous variable. Additionally, developing a composite score that reflects improvements across multiple core outcome domains—including Patient Global Impression of Change and Activities of daily living functionality—could better capture the multifactorial nature of LBP and provide a more comprehensive assessment of patient improvement in a single metric; (3) we used an extensive number of features that capture critical domains in the rehabilitation realm; however, other potential features, such as measures of self-efficacy and indicators depicting transitional states between clusters of trajectories, which could hold high predictive power, were not included. Incorporating these features in future designs could enhance the model's predictive accuracy; (4) finally, the early stage of this tool's development hampers the ability to assess its impact on clinical outcomes. Future steps should focus on implementing and evaluating the tool's dynamic loop to better understand its effectiveness and feasibility, as well as to ascertain its net benefits.

Conclusions

This study underscores the potential of a predictive tool leveraging ML models to enhance the management of LBP in a digital setting, redirecting care pathways early on and throughout the treatment course, thereby fostering personalized care. The application of such a strategy is particularly important for managing a heterogeneous population with diverse phenotypes across different cultural contexts.

(JMIR Med Inform 2024;12:e57654) doi:10.2196/57654

In “A Novel Convolutional Neural Network for the Diagnosis and Classification of Rosacea: Usability Study” (JMIR Med Inform 2021;9(3):e23415) the authors made one addition.

An “Acknowledgments” section has been added that reads as follows:

> *This work was supported by The Educational Science and Planning Project of Hunan Province (XTK20BGD008).*

The correction will appear in the online version of the paper on the JMIR Publications website on March 8, 2024, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Submitted 26.02.24; this is a non–peer-reviewed article;accepted 27.02.24; published 08.03.24.

Abstract

In light of rapid technological advancements, the health care sector is undergoing significant transformation with the continuous emergence of novel digital solutions. Consequently, regulatory frameworks must continuously adapt to ensure their main goal to protect patients. In 2017, the new Medical Device Regulation (EU) 2017/745 (MDR) came into force, bringing more complex requirements for development, launch, and postmarket surveillance. However, the updated regulation considerably impacts the manufacturers, especially small- and medium-sized enterprises, and consequently, the accessibility of medical devices in the European Union market, as many manufacturers decide to either discontinue their products, postpone the launch of new innovative solutions, or leave the European Union market in favor of other regions such as the United States. This could lead to reduced health care quality and slower industry innovation efforts. Effective policy calibration and collaborative efforts are essential to mitigate these effects and promote ongoing advancements in health care technologies in the European Union market. This paper is a narrative review with the objective of exploring hindering factors to software as a medical device development, launch, and marketing brought by the new regulation. It exclusively focuses on the factors that engender obstacles. Related regulations, directives, and proposals were discussed for comparison and further analysis.

(JMIR Med Inform 2024;12:e58080) doi:10.2196/58080

Introduction

Technology has significantly reshaped how we engage with a multitude of products and services, spanning from finance and travel to health care. This progression has introduced a myriad of digital solutions into the market, designed to facilitate the diagnosis, monitoring, and treatment of diverse medical conditions, ultimately enhancing the quality of life of patients. As per MedTech Europe data, there were more than 500,000 medical technologies available in 2023 [1]. Consequently, the role of regulatory measures becomes paramount in safeguarding patient well-being. Nevertheless, regulatory frameworks must adeptly mirror technological advancements to remain pertinent and efficacious, particularly considering the transformative potential of software within the health care domain. Consequently, in the past decades, the novel concept of software as a medical device (SAMD) has been introduced [2].

Historically, Europe has served as the preferred pathway for obtaining medical device approvals. In 2010, Stanford University professor Josh Makower (Makower et al [3]) published survey results of over 200 medical technology companies titled “FDA Impact on US Medical Technology Innovation.” The survey distinctly indicated the predilection for the European Union market over its US counterpart, owing to the expeditious and cost-effective nature of the European Union regulatory process. The European Union regulatory process was noted as significantly more predictable, reasonable, and transparent; 75% of respondents rated their regulatory experience in the European Union as excellent or very good, in stark contrast to the mere 16% who bestowed similar evaluations upon the Food and Drug Administration (FDA). The author aligns with this perspective because Directive 93/42/EEC (hereinafter Medical Device Directive 93/42/EEC [MDD]) had general requirements with fewer regulatory responsibilities.

However, a certain degree of skepticism has arisen concerning the adequacy of the European Union regulation in ensuring patient safety [4]. This concern was addressed by a study conducted in 2016 by Thomas J Hwang (Hwang et al [5]) from Harvard University. The study entailed a cohort analysis, comparing safety issue rates and trial outcome reporting for medical devices approved within the European Union and the United States. The authors concluded that the medical devices approved first in the European Union were associated with an elevated risk and experienced more recalls.

Furthermore, the medical device industry in the past decades has experienced various scandals, casting doubts on the efficacy of the regulatory framework in achieving its overarching goal to ensure patient safety. Foremost among these is the Poly Implant Prothèse (PIP) scandal, an incident that has been prominently cited as a poignant illustration of regulatory deficiencies that can impede the fulfillment of their primary objectives [6].

Also, the MDD, being introduced in 1993, exhibited a notable misalignment with the latest technological advancements and was not sufficient to comprehensively cover SAMD development and launch. The European Union policy makers recognized the shortcomings, namely, outdated regulation, insufficient oversight leading to safety issues, and imprecise requirements, resulting in an "uneven level of protection of the patients, users, and public health," consequently requiring an improved regulatory framework [7]. Therefore, in 2017, the new Medical Device Regulation (EU) 2017/745 (MDR) came into force, replacing the previous MDD as well as the active implantable medical devices Directive 90/385/EEC (however, the latter is not in the scope of this paper) [8]. As per Recital 1, the new MDR is believed to solve emerging problems as well as to provide transparency and strengthen market surveillance and overall quality of medical devices, benefiting the patient. Undoubtedly, the new regulation clarifies rules for SAMD that were not clearly defined under the MDD. Furthermore, the new regulatory framework applies to all the manufacturers equally, ensuring the same high standards, irrespective of their geographic location. Such standardization and clarification of requirements eliminate disparities that have existed under the MDD, where the interpretation of regulations had varied between different member states, notified bodies (NBs), and manufacturers. However, it is too early to judge if the new regulation has achieved its main goals; as of now, no quantifiable data or research exist to demonstrate if device safety has improved or if the European Union is experiencing fewer product recalls.

Methods

The paper is a narrative literature review, and it seeks to provide a comprehensive summary of the problems, given the absence of a comparable analysis. A search in Scopus and PubMed databases was performed in November 2022 for articles written in English and published since 2017, the year when the MDR was adopted. The search included two strings: (1) ("medical" AND "device" AND "regulation") in the title, abstract, and keywords; and (2) ("medical" AND "device" AND "regulation") in the title. The specific term "software" was intentionally omitted from the search parameters, as its infrequent occurrence in titles, abstracts, or keywords would substantially limit the available pool of literature. Furthermore, it is important to acknowledge that papers can encompass analysis of the MDR in a broader context, yet not explicitly focused on SAMD, and can provide valuable insights, analysis, and conclusions for the research. First, non-English and duplicate articles were excluded, and the remaining articles were evaluated by reviewing their titles and abstracts. Then the articles were fully read, and only papers exploring and analyzing the impact of the MDR were included in the analysis. The initial search returned 341 items in total, out of which 307 items were excluded after screening due to their irrelevance. Thus, 34 papers were deemed applicable for this review.

The paper begins with a concise general overview of the impact of the MDR, exploring market data on innovations and communications from major organizations. It is followed by the main section of the paper (*The Challenges of the MDR*), presenting the analysis of the hindering factors that have been identified in academic literature. These factors were then grouped into thematic dimensions and explored in more detail, including their potential impact on the industry. The *Conclusion* section summarizes the main findings from the literature and discussions in the previous sections and suggests directions for future improvements.

The Overall Impact of the MDR

The MDR introduces more detailed requirements for all medical devices in terms of development, quality assurance, and clinical evaluation, as well as postmarket surveillance. However, the novel framework has sparked discussions on how these changes impact innovation. A survey conducted by Climedo Health revealed that 81% of the respondents consider the MDR challenging [9]. As per Stern [10], industry regulation often results in delayed or reduced firm entry into markets due to the increased time and costs, eventually reducing incentives to innovate. Thus, while the regulation is introduced to improve patient safety, the slower innovation could paradoxically result in a reduction of patient safety, since the improvements and novel devices might take longer to enter the market. So, the question remains: how to improve regulation without hindering innovation?

The regulatory framework holds particular importance for the pioneer innovators. Manufacturers who develop a first-of-its-kind product experience several disadvantages, such as the lack of specific guidance, the absence of clinical data, and little knowledge that can result in a longer development and approval process as well as additional costs. Stern [10] notes that the first entrant experiences approximately 34% longer regulatory approval process than the first follow-on entrant, also because the regulatory bodies then can release guidance materials that the later entrants can benefit from. This also means increased costs for the first entrants, although they can potentially gain the largest market share.

The industry has already brought considerable attention to the ramifications and challenges associated with the MDR on

multiple occasions. In an open letter dated April 15, 2019, the CEO of MedTech Europe, Serge Bernasconi, pointed out the lack of NBs and the unpreparedness of the regulatory system that could result in a shortage of medical devices [11]. The latest appeal was at the end of 2022 when many medical technology CEOs addressed the need for changes or else "Europe faces a scenario where a high number of existing medical devices, upon which patients, hospitals and other health institutions rely, will fail to be recertified on time and therefore risk permanently disappearing from the market. At the same time, the certification of new and improved products is also delayed, resulting in delayed patient access to the benefits of innovation" [12]. The medical associations conglomerate, The Standing Committee of European Doctors, in its letter to the President of the European Commission, Ursula von der Leyen, is being more dramatic, stating that "in some countries, up to 75% of medical devices are at risk of becoming unavailable," and that the "situation is unacceptable from the point of view of patient safety and quality of care" [13]. The emerging issue is already noticed as the manufacturers exit the European Union market due to various reasons, including increased costs and certification time, which eventually impact the patients as the devices become unavailable [14]. The expression of concern was duly acknowledged and subsequently addressed by Commissioner Stella Kyriakides at the Employment, Social Policy, Health and Consumers Affairs (EPSCO) Council in December 2022, who proposed to extend the transition period [15], and the extension was adopted with Regulation 2023/607, Article 1, by the European Parliament and the Council [16]. But would the extension, which applies only to the existing medical devices, solve all the problems?

Due to the complexity of the MDR, there are various implications for SAMD development. Therefore, the author conducted research exploring currently identified hampering factors. The paper serves as a comprehensive resource for manufacturers to proactively configure their organizational infrastructure and allocate resources in advance. In addition, it is beneficial for health care policy makers in their endeavors to assess and ameliorate industrial policies and practices. This paper will also be beneficial to the government bodies and policy makers who are responsible for the medical technology industry, as it underscores the barriers impeding the evolution of the digital health sector and can contribute to developing tools to foster and maintain innovation.

The Challenges of the MDR

In the following sections, the hindering factors are grouped into 8 dimensions and are further described and analyzed. Each of the factors has received varying attention in the literature, and their impact on a manufacturer can overlap; however, each one of them can be addressed separately. Table 1 presents an overview of the dimensions and a shortlist of the hindering factors included in each dimension.

Table 1. Hindering factors listed and consolidated into dimensions.

Dimensions	Consolidated factors	References
More complex requirements leading to delays	• More time is needed for development • More financial resources are needed, thus new products will take longer to make available in the market • Slowing industry innovation • Delays also for recertification	[17-28]
More requirements for clinical evaluation	• More manufacturers will need to conduct or repeat clinical trials • Harder to prove technical equivalence • Most small and medium-sized enterprises lack the financial resources to conduct trials	[17,19,21,22,25,26,29-34]
Increased expenses	• Regulatory changes bring additional costs to being compliant • Certification and recertification processes are costly • Postmarket surveillance seeks more resources	[17-19,24-26,30-41]
Classification issues	• Uncertainty if the product is a medical device • Classifying correctly • Up-classification, which means more complex requirements for development and launch	[17,22,29,32,36,39,42-46]
Limited availability of NBs[a]	• The small number of NBs • The capacity of existing NBs • Interdependence between manufacturers and NBs • Poor communication between stakeholders	[21,22,24,26,27,31,33,34,38,39,43,47,48]
Lack of knowledge	• Market entry depends on regulatory knowledge • Additional costs to acquire competences • Lack of knowledge of the European Databank on Medical Devices	[30,31,33,36,37,41]
Lack of guidance	• Lack of guidance materials for specific matters • Uncertainty about the processes as harmonized standards are not published • No provisions for orphan devices	[20,27,28,31,33,40,46,47]
Constraints on software updates	• Complicated process to change or add new features • Limited possibility of software customization	[17,26,34,36]

[a]NB: notified body.

More Complex Requirements Leading to Delays

One of the main challenges for all manufacturers is the complex requirements to develop and market a medical device. While the requirements are updated to ensure patient safety, numerous manufacturers may encounter challenges in meeting these requirements. This can lead to several outcomes. For example, first, the new products will take longer to be deployed [17-21], thus slowing the innovation in health care [22-24]. According to MedTech Europe data, the time to certify a medical device under MDR has now doubled to 13-18 months [49]. Second, delays in certification or recertification procedures could potentially result in a reduction of the available product range [18] and the discontinuation of certain products [25,26]. Third, new product launches could potentially be deferred or even canceled, as the emphasis shifts toward the maintenance of existing medical devices [27]. Fourth, some manufacturers might choose to continue supplying their medical devices while opting to withdraw from the European Union market [28].

Given that one of the plausible outcomes is a delayed launch or even the eventual discontinuation of a medical device, there arises a potential jeopardy to the fundamental objective of the MDR, which is to safeguard patient safety [26], since the devices will no longer be available.

More Requirements for Clinical Evaluation

Another troublesome issue for the manufacturers is the increased need to conduct clinical evaluations [17,19,21,22,29]. Although it derives from the general complexity of the requirements explored in the previous section, this matter is specific and critical for the development thus separated.

For lower-risk medical devices, the manufacturer can provide clinical evaluation without conducting its own clinical trial, yet the device must be proven to be equivalent to the compared device. In those cases, the manufacturer can use other clinical investigations and studies and papers published in peer-reviewed sources. While there are no data available on how many devices are approved based on equivalence in Europe, the data in the United States suggest that it is the majority: 99% of the devices approved between 2015 and 2020 used the 510(k) pathway (the mean number of premarket approvals was 38, compared with a mean of 2982 510(k)s annually) [50].

However, clinical evaluation without conducting own clinical trial is not an option if the developed medical device is innovative, meaning there are no equivalent devices, even if the device in question has low risk. According to the MDR, the equivalence shall be demonstrated in 3 dimensions, namely, technical, clinical, and biological (the latter does not apply to a SAMD).

Technical equivalence means "the device is of similar design; is used under similar conditions of use; has similar specifications and properties including physicochemical properties such as intensity of energy, tensile strength, viscosity, surface characteristics, wavelength, and software algorithms; uses similar deployment methods, where relevant; has similar principles of operation and critical performance requirements" (MDR, Annex XIV Part A, Article 3). The new additional requirement, which is also the most concerning aspect of a SAMD, is to compare software algorithms. While Medical Device Coordination Group 2020-5 [51] suggests the comparison needs to be done only in terms of functionality and clinical performance, not the code itself, algorithms are not public and are the essence (and the unique selling point) of software. Thus, the actual functionality cannot be thoroughly compared, especially if it is an artificial intelligence (AI) and machine learning (ML)–based solution. In the meantime, for implantable and higher-risk devices (Class III), the equivalence can be claimed only if the manufacturer has a contract in place that allows full access to the technical documentation of the equivalent device on an ongoing basis (MDR Article 61(5)). This requirement is almost impossible to fulfill in a competitive market [27].

According to Kearney and McDermott's [31] research about challenges with clinical evaluation, manufacturers also frequently have issues related to obtaining and understanding the level of clinical data required by the MDR, being reluctant to the more stringent requirements. However, the most common challenge here is the lack of skills and knowledge for preparing the clinical evaluation, which has led to an increase in outsourcing the knowledge (and consequently, increasing the costs).

An apparent consequence of the increased need for clinical trials is increased research and development costs [22,30,32], which also complicates the development process [33] and increases the maintenance costs [34]. In addition, it is no secret that most small- and medium-sized enterprises (SMEs) lack the financial resources to conduct large clinical trials [26].

Consequently, manufacturers are already deciding to exit the European Union market or at least postpone the launch of innovative products [31].

Increased Expenses

While most of the identified implications result in increased expenses, it is important to single it out and explore its impact on the development and launch of SAMDs. Also, increased costs were highlighted in the Climedo Health survey [9], where 70% of the respondents named it as their greatest challenge, 44% of respondents projected that the MDR will incur additional costs of 5% of their annual turnover, while the same number of respondents plan cost increase by 1% to 5% of their annual turnover.

The regulatory improvements will clearly bring more development process costs [17,31] as well as conformity assessment, certification, and recertification costs [25,26,32-38]. It will also require changes in organizational structure and a need to acquire new competencies, including bringing more talent on board [18,24,30,32,33,39] and seeking additional funding, which is challenging, especially for SMEs.

The new regulatory updates also establish more requirements for the postmarket surveillance process, which brings more costs [32,40]. In addition, the new unique device identification (UDI) system requires adaptation of the existing information systems, also resulting in cost increase [41].

The increased expenses, if not covered by additional investments, can eventually lead to price increases, which means decreased availability of medical devices [17,19,32,39], or in worst-case scenarios it can lead to an exit from the European Union market [32,35]. Some SMEs might need to seek other exit solutions, such as merging with large companies to keep the products running [17,32,33], resulting in less competition and few dominant companies in the market.

Classification Issues

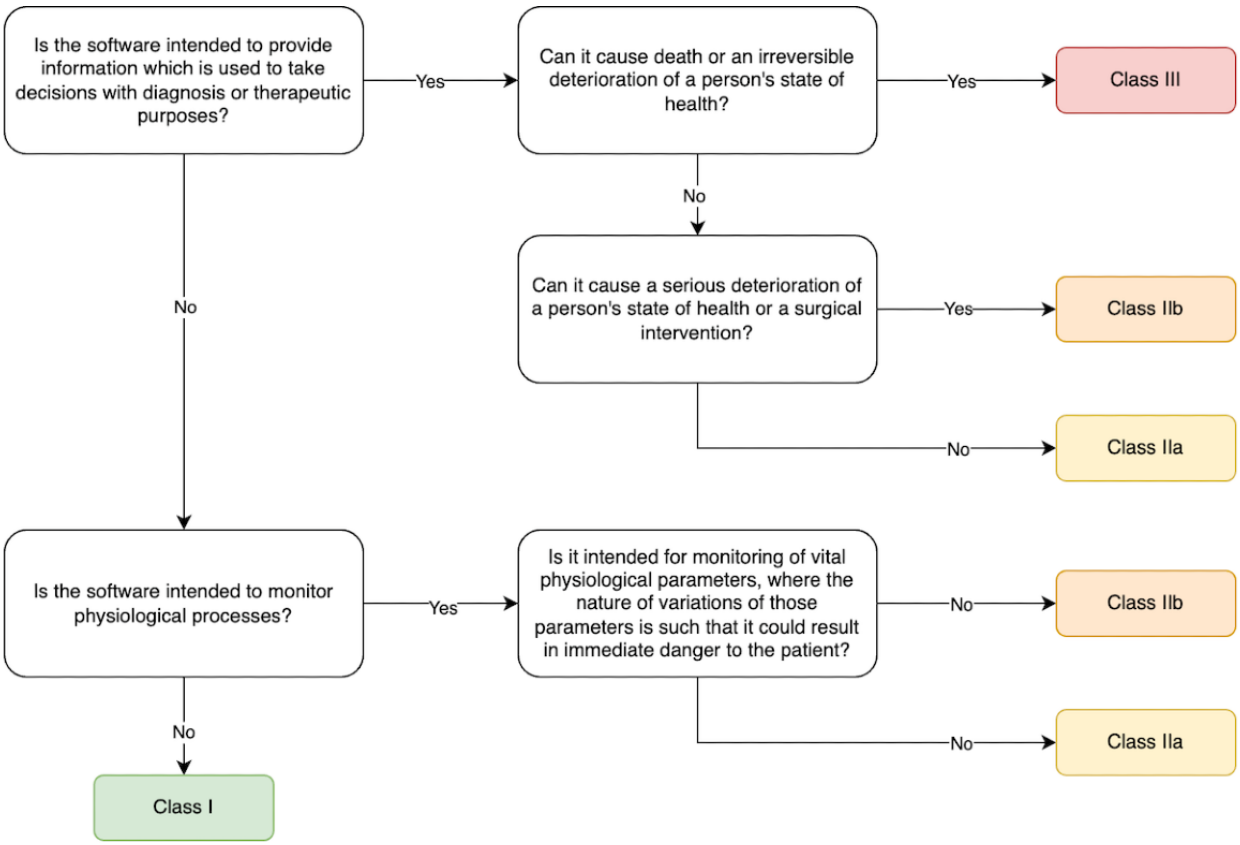
Before specifying the device class, the manufacturer must define if the developed product is a medical device: software with a medical purpose acting to benefit individual patients. Then the next step is to choose the right class according to the risk level.

In comparison to the previous directive (MDD), the MDR separates a rule for SAMDs (Rule 11, Annex VIII, Chapter III, 6.3.; Figure 1).

Yet the classification process has its struggles, such as (1) uncertainty if the developed product is a medical device at all [32,36], thus if it falls within the scope of MDR; (2) choosing the correct class [32,36,42,43]; and (3) for most SAMDs, the new MDR means up-classification [29,32,39,44,45].

The first 2 issues can be addressed with a rigorous regulation study and consultations. This is a one-time issue not impacting the manufacturers in the long term.

Figure 1. Software as a medical device classification flow.



However, considering the complexity of the regulatory requirements, SMEs might opt to position their products as health and wellness devices. This strategic approach could allow them to avoid rigorous regulatory scrutiny and lessen the challenges to launch and market their products [46]. In this context, the manufacturer's envisaged intended use of the device plays the role, rather than its actual use. This perspective is supported by the Court of Justice of the European Union with its decision on Brain Products, wherein it was established that if a product is not intended to be used for medical purposes, Conformité Européenne certification is not required [52]. Yet, the intentional falling out of the regulatory scope means the uncertain quality of the digital health tool, as well as it potentially carrying safety risks to human health, which was the initial cause of the regulatory changes. This concern is important, particularly in light of the increasing reliance of individuals on digital health technologies [46].

The third factor, up-classification, can become troublesome, as most SAMDs will be classified in at least the IIa risk class, and software in the lowest risk class I will remain as an exception [45]. This up-classification entails more complex requirements and certification processes and will result in more time needed for development and subsequent delays in obtaining market access [17,22]. Some manufacturers might choose to eliminate or limit some of the device features to keep the device in a lower-risk class [32], and this might in turn limit the availability of innovative solutions.

The complex requirements as an impediment are explored earlier in this paper.

Limited Availability of NBs

An NB is an organization that is authorized to perform conformity assessments in accordance with the MDR. Annex VII sets out general, organizational, resource, and other requirements to be met by the NBs, thus the process of establishing an NB can be lengthy and resource-intensive as well.

Consequently, the limited availability of NBs is one of the hindering factors identified, and it has two dimensions: (1) the absolute number of NBs [22,23,25,28,34,39,43,47,48] and (2) the capacity of existing NBs [33,38,43].

As of May 2024, according to the European Commission database, there are 46 authorized NBs to perform assessments following the MDR [53]. Germany and Italy have the highest concentration of NBs, with each country hosting 10. The Netherlands follows with 4 NBs. Finland, Czechia, Turkey, Poland, France, and Sweden each host 2 NBs. Meanwhile, Belgium, Croatia, Hungary, Ireland, Norway, Slovakia, Slovenia, Spain, Cyprus, and Denmark each have 1 NB.

Although the MDR entered into force in 2017, seven years have not been enough to establish a sufficient number of bodies. It is worth pointing out that not all European countries host an NB. For example, Switzerland is the second largest medical technology employer in Europe per capita, or fifth largest in absolute number of people employed [1]; however, it does not host a single NB. Ireland, which has the largest number of people directly employed in the medical technology industry per 10,000 inhabitants, hosts 1 NB. Similarly, France, which is fourth in Europe with the highest direct employment in terms

of absolute number of people employed, hosts only 2 NBs. While the international environment does not limit the applicants based on location, and manufacturers can freely choose an NB in any other country, Peter et al [34] suggested that the lack of NBs and poor communication between the manufacturers and NBs can lead to lost market opportunities. However, the authors do not mention any particular or potential examples.

The capacity of existing bodies is also being explored. Because of the low number of NBs and the increased need to acquire a certification, this can result in delays and shortages of medical devices or some manufacturers even leaving the European Union market [48]. The increased time for the certification process has been already mentioned in this paper earlier: according to MedTech Europe data, the time to certify a medical device under MDR has now doubled to 13-18 months. As per the preliminary results of the NBs survey led by Gesundheit Österreich GmbH (Austrian National Public Health Institute) with Areté and Civic Consulting [54], in March 2023, in 86% of cases, the time to acquire the certificates was more than 13 months.

Another factor identified is the interdependence of the NBs with the manufacturers [26], as the NBs would want to ensure their turnover and eventually profit, thus prioritizing the clients who would bring the largest revenue. This argument is especially troublesome for SMEs, as large companies might have the leverage to be certified first, thus leading to delays for SMEs [39]. As per the MedTech Europe report conducted in April 2022, at least 15% and up to 30% of SMEs have no access to an MDR-designated NB [49]. In addition, poor communication between the NBs and manufacturers can lead to potential setbacks during the certification process [31].

Interestingly, Fink and Akra [55] delve into an aspect concerning the regulatory frameworks in the European Union compared with the United States. While this does not pertain specifically to the Regulation, it remains a noteworthy consideration in a broader context. The distinction lies in the centralized approval process in the United States, where the FDA singularly holds authority, and the decentralized process in the European Union, involving multiple NBs. The authors mention the potential risk of different interpretations of requirements stemming from the decentralized nature of the European Union regulatory system.

Lack of Knowledge

Stern [10] in her paper titled “Innovation under Regulatory Uncertainty: Evidence from Medical Technology” separates 2 factors: technological uncertainty and uncertainty about application content and format. Thus, it is worth exploring both factors separately. (1) Technological uncertainty means the lack of knowledge and understanding of how the innovative product in question works and how it is used in the human body, as well as how the regulator will understand the mechanisms behind it; and (2) the uncertainty about application content and format is related to a lack of guidance for the product assessment phase (including the evaluation of clinical trials and the information needed to submit), and this factor is explored in the next section.

This paper revealed that the lack of knowledge can be an obstacle to entering the market, especially for start-ups [33], and it can be associated with legal risks as well [36]. There is a need to acquire more competencies [31,37], which results in additional costs [30]. Manufacturers need to improve their knowledge and skills to perform postmarket surveillance [33], and better understand the European Databank on Medical Devices system [41].

Lack of Guidance

Chatterji [56] finds evidence that nontechnical knowledge, such as understanding regulation and marketing knowledge, is of greater importance than technical knowledge. Thus, this impediment should draw the attention of the manufacturers and stakeholders.

The MDR consists of 123 articles and 17 annexes on 175 pages. In comparison, the MDD had 23 articles and 12 annexes on 60 pages. While this suggests that the new regulation shall bring clear requirements and explanations, the actual situation is on the contrary. The Climedo Health survey shows that 59% of the respondents name the lack of clarity as one of their greatest challenges [9]. The unclarity is evident in clinical evaluation [28,31], postmarket surveillance processes [46] and activities [33], or the lack of guidance in general [27,40]. Gilbert et al [20] also specify that there is a need for smarter regulation, particularly for the highest-risk (III) class devices.

Melvin [47] draws attention to the fact that the MDR has no provisions for orphan devices that are intended for rare life-threatening or chronically debilitating conditions. Since the market for these devices is small, it may become economically unfeasible for manufacturers to continue supplying them, potentially leading to their exit from the European Union market.

A significant shortcoming of the MDR is the lack of detailed requirements and guidance for AI solutions, which can become a barrier to their clinical adoption [20]. AI solutions experience rapid growth, including in health care, and the lack of regulation can lead to uncertainty for development as well as compliance. While there is the AI Act that also covers the health care industry, the manufacturers today do not have guidance, which leaves room for their interpretation.

The importance of regulatory guidance and its impact on medical devices is proved by Stern [10], showing an average decrease in regulatory approval times of 2.8 to 6.6 months when comparing innovative firstcomers with their followers.

Constraints on Software Updates

Opposite to a common hardware medical device, software can be updated regularly. It can vary from a minor update, such as a new data field or color change, to a significant update, such as a brand new feature, delivering a new type of content, or improving the AI algorithm.

This is a considerable difference if we explore the maintenance of a medical device throughout its lifecycle. The MDR now requires an NB’s involvement, namely, if a manufacturer has “any plan for substantial changes to the quality management system, or the device-range covered” (Annex IX, Chapter I, 2.4), or if technical documentation is being changed and “such changes could affect the safety and performance of the device or the conditions prescribed for use of the device” (Annex IX, Chapter II, 4.10). Thus, this requirement to involve the NB if

the manufacturer plans updates in the device is considered an impediment [17,26,34], which brings constraints on changing the software or adding new features, as well as limits software customization [36].

Nevertheless, the MDR does not specify what changes should be communicated with the NB, which eventually allows the manufacturer's interpretation to some degree. However, the Medical Device Coordination Group has provided a guidance document on significant changes regarding the transitional provision under Article 120 [57] to better understand which changes are considered "significant." It gives the explanation that minor software changes would be adding a new language or fixing bugs. Yet, changes in algorithms shall be considered as a major change, thus requiring the involvement of the NB, and this is burdensome for all AI solutions as the algorithms can change regularly. Furthermore, adding a new therapeutic feature (even if it is only enriching the content base) is considered a significant update, requiring the involvement of the NB.

Conclusions

This paper is scoped to the impact of the new MDR on the development and launch of SAMDs and does not explore its effect on patient safety. Future research should seek to investigate the benefits and impact of the MDR on increasing patient safety and if the regulatory changes have had the desired effect.

The identified hindering factors of the MDR were consolidated into eight dimensions: (1) more complex requirements leading to delays, (2) more requirements for clinical trials, (3) an increase in expenses, (4) classification issues, (5) limited availability of NBs, (6) lack of knowledge, (7) lack of guidance, and (8) constraints on software updates. Each of the factors has received varying attention, yet any single one can have a critical impact on a manufacturer, thus each company shall evaluate its strengths and weaknesses to sufficiently prepare for development.

The results show that the new regulation heavily impacts the European Union medical device industry, which can lead to either price increases or shortage of medical devices, as well as stifling innovation, which can eventually even harm the patients. Some manufacturers might evaluate the costs and potential revenue and decide to discontinue the devices. Some small start-ups may find themselves compelled to shut down their operations, while other enterprises might opt to exit the European Union market or engage in mergers with more sizable corporations. This trend is supported by Kearney and McDermott's [31] research showing the first signs of manufacturers either leaving the European Union market or seeking approval for devices in the United States first.

The fact that Europe has lost its appeal is supported by the Boston Consulting Group and University of California, Los Angeles Biodesign report [58], which shows that 89% of surveyed companies consider prioritizing the United States over the European Union. While the registration of digital technologies is quite uncertain for both United States and European Union markets, still 32% of the respondents considered the US pathway rather predictable, which is more than double that of the European Union pathway (15%) [58]. The market changes are alarming for the European Union; thus, the problems must be addressed at the European Union level. Policy makers should reconsider if all the current regulation requirements bring actual value and ensure patient safety rather than build unnecessary burdens to launch innovative digital solutions. Although the transition period for the existing medical devices has been extended, it gives time for the existing medical devices to fulfill the requirements, yet it does not address the issues with complexity, and hence further actions must be taken.

In the meantime, the growing development and approbation of digital health tools, including AI solutions, currently require a more targeted regulatory framework as we see the lack of guidance and knowledge in the domain. The MDR and respective guidelines exhibit limitations in addressing the complexities inherent to most pioneering technologies, thereby AI and ML–based solution manufacturers have room for interpretation of the applicable regulation. To address the regulatory gaps for AI and ML–driven solutions, in March 2024, the European Commission passed the AI Act [59], which will now lessen the legal uncertainties. This legislation covers various domains, and also applies to health care and medical AI, thereby ensuring more robust regulatory oversight within this landscape. Henceforth, manufacturers of AI and ML–driven solutions will be required to ensure compliance with both the MDR and the AI Act. Although the adoption of the act is commendable, in reality, it has introduced new compatibility challenges. For instance, there is uncertainty surrounding the process of providing clinical evidence for certification under the MDR. It appears that AI medical devices will be required to have Conformité Européenne certification before undergoing testing, potentially creating an infinite loop of unmet requirements, or forcing the manufacturers to conduct trials outside the European Union. Therefore, this seeks further discussions and implementation guidelines from the European Commission to help the manufacturers in their compliance journey.

Last but not the least, each European Union member state that aspires to foster the advancement of the digital health sector is encouraged to consider both monetary and nonmonetary assistance to SMEs. Such support mechanisms hold the potential to facilitate a seamless introduction of cutting-edge innovations to the marketplace. While financial assistance might be subject to budgetary constraints, nonfinancial support can be equally pronounced. This encompasses diverse facets, such as the establishment of digital health hubs to facilitate the exchange of knowledge and experience, endeavors aimed at attracting skilled personnel, and the active promotion of educational initiatives.

Abstract

Background: Pseudonymization has become a best practice to securely manage the identities of patients and study participants in medical research projects and data sharing initiatives. This method offers the advantage of not requiring the direct identification of data to support various research processes while still allowing for advanced processing activities, such as data linkage. Often, pseudonymization and related functionalities are bundled in specific technical and organization units known as trusted third parties (TTPs). However, pseudonymization can significantly increase the complexity of data management and research workflows, necessitating adequate tool support. Common tasks of TTPs include supporting the secure registration and pseudonymization of patient and sample identities as well as managing consent.

Objective: Despite the challenges involved, little has been published about successful architectures and functional tools for implementing TTPs in large university hospitals. The aim of this paper is to fill this research gap by describing the software architecture and tool set developed and deployed as part of a TTP established at Charité – Universitätsmedizin Berlin.

Methods: The infrastructure for the TTP was designed to provide a modular structure while keeping maintenance requirements low. Basic functionalities were realized with the free MOSAIC tools. However, supporting common study processes requires implementing workflows that span different basic services, such as patient registration, followed by pseudonym generation and concluded by consent collection. To achieve this, an integration layer was developed to provide a unified Representational state transfer (REST) application programming interface (API) as a basis for more complex workflows. Based on this API, a unified graphical user interface was also implemented, providing an integrated view of information objects and workflows supported by the TTP. The API was implemented using Java and Spring Boot, while the graphical user interface was implemented in PHP and Laravel. Both services use a shared Keycloak instance as a unified management system for roles and rights.

Results: By the end of 2022, the TTP has already supported more than 10 research projects since its launch in December 2019. Within these projects, more than 3000 identities were stored, more than 30,000 pseudonyms were generated, and more than 1500 consent forms were submitted. In total, more than 150 people regularly work with the software platform. By implementing the integration layer and the unified user interface, together with comprehensive roles and rights management, the effort for operating the TTP could be significantly reduced, as personnel of the supported research projects can use many functionalities independently.

Conclusions: With the architecture and components described, we created a user-friendly and compliant environment for supporting research projects. We believe that the insights into the design and implementation of our TTP can help other institutions to efficiently and effectively set up corresponding structures.

Introduction

Background

Medical research relies on the effective collection, management, and analysis of biomedical data [1]. However, the complexity of associated data flows is increasing constantly due to the rising importance of data-driven approaches from the areas of data science and artificial intelligence [2,3]. These typically require data to be reused and shared to generate the necessary large data sets, for example in neuroscience [4]. At the same time, relevant data are often highly sensitive and require protection against unauthorized use and disclosure [5]. In alignment with this need, various laws, regulations, guidelines, and best practices suggest pseudonymization as a central data protection mechanism, especially in biomedical research [6]. Pseudonymization refers to a process in which data that directly identifies individuals (henceforth denoted as identifying data), such as names and addresses, are stored separately from data and biosamples needed for scientific analyses, and research assets are identified using protected identifiers, known as pseudonyms [7]. This protects the identity of patients or study participants while still allowing the implementation of complex research workflows, for example, data linkage. It is frequently suggested to bundle pseudonymization with other functionalities relevant to data protection and compliance, such as consent management, and that those should be carried out by particularly trusted units, knwon as trusted third parties (TTPs). One example of a concept recommending TTPs is the Guideline for Data Protection in Medical Research Projects by Technology, Methods, and Infrastructure for Networked Medical Research (TMF), the German umbrella organization for networked medical research [8].

Although the general functionalities required by medical research projects may be similar, the way they are combined into workflows often differs significantly. The reason is that due to varying study schedules and (data) modalities, studies often have different requirements concerning the necessary number and types of pseudonyms as well as the research assets that have to be registered. The timing of consent collection can also vary, for example, if reconsenting is required. Another factor that can contribute to heterogeneity is the need for integration of or linkage with data from external systems or institutions. As a result, studies often develop study- or project-specific solutions to fulfill specific registration, pseudonymization, linkage, and consenting requirements [9]. Some open tools, such as Enterprise Identifier Cross-Referencing (E-PIX) [10], Generic Pseudonym Administration Service (gPAS) [11], Generic Informed Consent Service (gICS) [12], or Mainzelliste [13], have been developed and are in widespread use; however, they are usually not integrated with each other, making the implementation of more complex workflows involving different TTP operations challenging and potentially lead to systematic limitations (explained further in the *Discussion* section). Although research exists on the components mentioned above, the literature lacks insights into the design of more comprehensive architectures that support complex research workflows that are actually in production use [14,15].

Objectives

This paper presents the design of a comprehensive architecture for a TTP that aims to support a wide range of different research projects and studies using a unified system. As a first step, we present requirements elicited for this structure and then describe the implementation of a corresponding solution that reuses existing open components. These components are extended with a common application programming interface (API) and a common graphical user interface (GUI). We then present insights into our experiences with piloting this structure and describe our plans for future developments.

Methods

Requirements

TTPs typically offer a range of core functionalities based on their role in supporting research projects and clinical studies with data protection services. Three key functionalities provided are as follows: (1) identity management, through which patients and study participants are registered and their identities are managed across different systems using record linkage; (2) pseudonym management, which provides and manages pseudonyms for different research contexts and is thus critical for data protection compliance; and (3) consent management, to obtain and manage patient and participant consent for various research activities. Further components are usually included to make these core functionalities accessible. An API is necessary for the systematic retrieval of information, the implementation of complex workflows, and integration with further health care and research systems. Moreover, a well-designed GUI is necessary to enable TTP staff and study personnel to perform common tasks efficiently. An audit trail is required to ensure transparency and traceability. Furthermore, data import and export functions are necessary for transferring data from legacy systems and archiving in study-specific contexts. Finally, platform independence is an important nonfunctional requirement to support wide adoption.

A common set of tools providing these core functionalities and features (Table 1) are E-PIX [10], gPAS [11], and gICS [12], which are provided as free web-based software by the MOSAIC project from the University of Greifswald (explained in the following section). They are successfully used in a range of research projects and infrastructures [16]. Table 1 illustrates which of the above-mentioned core requirements are fulfilled by which of the MOSAIC tools.

Table . Core functional requirements and MOSAIC tools that fulfill them.

Core functional requirements		Tools		
		E-PIX[a]	gPAS[b]	gICS[c]
Basic services				
	Identity management	✓	—[d]	—
	Pseudonym management	—	✓	—
	Consent management	—	—	✓
Additional features

	Graphical user interface	✓	✓	✓
	Audit trail	✓	—	✓
	Data import and export	✓	✓	✓

[a]E-PIX: Enterprise Identifier Cross-Referencing.

[b]gPAS: Generic Pseudonym Administration Service.

[c]gICS: Generic Informed Consent Service.

[d]Not applicable.

Although the MOSAIC tools provide the basic functionalities needed, we elicited additional requirements from our extensive experience with supporting research projects. An overview is provided in Table 2. A detailed discussion is available in the section *Comparison With Prior Work*.

Table . Additional functional requirements and core services for which they are relevant.

Additional functional requirements		Identity management	Pseudonym management	Consent management
Programmatic interfaces and workflows				
	Modern REST[a] application programming interface	✓	✓	✓
	Information exchange with other systems (eg, for ingesting consents documented in the EHR[b] system)	✓	✓	✓
	Cross-system workflows (eg, creation of a primary identifier, combined with the creation of all necessary pseudonyms based on the domain tree and preparation of a consent document)	✓	✓	✓
User interfaces and services				
	Integrated user interface across all services	✓	✓	✓
	Common authentication and authorization framework with single-sign-on and associated rights and roles with the ability to connect to institutional directory services	✓	✓	✓
	Sending status messages to users in case of relevant events (eg, when a new patient has been registered)	✓	✓	✓
Specific features				
	Visualization of pseudonyms as QR codes	—[c]	✓	—
	Automated versioning when storing consent updates	—	—	✓
	Kiosk mode for consent documentation	—	—	✓

[a]REST: representational state transfer.

[b]EHR: electronic health record.

[c]Not applicable.

Programmatic Interfaces and Workflows

Representational state transfer (REST) services have become a de facto standard for modern applications over the last couple of years, as they are stateless, lean, and based on open web standards. Hence, we considered a REST API to be an important requirement for all 3 areas—identity management, pseudonym management, and consent management. Together with other common technologies, such asJavaScript Object Notation, this makes the services offered by the TTP accessible to other systems and processes. It also fosters effective information exchange with other systems, for example, to automatically generate primary identifiers and pseudonyms in case a patient is registered in the electronic health record (EHR) system. Moreover, a common API across all services also enables cross-service workflows, which we consider particularly important. An example of this is the automatic creation of pseudonyms linked to the primary identifier when registering a patient or study participant.

User Interfaces and Services

We considered an integrated user interface (UI) together with a shared authentication and authorization mechanism to be central for our TTP infrastructure. Important functionalities that the UI needs to support include depseudonymization, patient and participant registration, consent management and configuration, as well as administration. A tighter integration of the different components also facilitates sending status messages to users in case actions are required on their side.

Specific Features

We further identified requirements in regard to specific management functionalities. For example, representing pseudonyms as QR codes is important for seamless workflows

across different media; this includes printing the codes on accompanying documents or biospecimen tubes and then reading them using QR code readers. This is particularly important for biospecimen management. Moreover, we identified a need for versioning of managed consent documents. In the event of updates to consents, for example, due to wrong information on the consent form, versioning of the various consents in the system is important for traceability. This also requires the system to be able to assign consents or withdrawals to other participants (eg, if a wrong identifier has been used when originally collecting the form). In addition, a kiosk mode that locks the user into the application is needed for the secure collection of consents from patients using tablets.

Nonfunctional Requirements

The most important nonfunctional requirements are as follows: (1) scalability, particularly when executing cross-service operations, and (2) documentation of administration functions.

Building Blocks

In this section, we will describe basic building blocks of the developed application stack.

MOSAIC Tools

As mentioned previously, the application has been developed around the MOSAIC tools [17] as core components. Although these tools do not fulfill all our requirements, they provide a solid basis for implementing the core functionalities. The MOSAIC tools have been positively evaluated by the data protection authority of Mecklenburg-Vorpommern in Germany [18] and have been successfully used in several research projects, for example, the BeLOVE (Berlin Longterm Observation of Vascular Events) [19,20] and NAKO (German National Cohort) studies [21].

The MOSAIC suite consists of 3 tools [22]: E-PIX provides a master patient index following the Integrating the Healthcare Enterprise (IHE) profiles, Patient Identifier Cross-Reference (PIX), and Patient Demographics Query [23,24]; gPAS provides associated pseudonymization functionalities; and gICS supports integrated consent management. More specifically, E-PIX enables the central management of directly identifying master data and supports probabilistic record linkage. The resolution of potential matches between identifying data is supported through the UI. gPAS supports the generation and management of pseudonyms on top of the identities managed by E-PIX using different pseudonym domains that can refer to different systems, locations, or contexts. Finally, gICS supports digitally managing informed consent and supports different consent templates and associated use policies.

Following our requirements, we implemented an authentication and authorization model as well as programmatic interfaces and graphical UIs around E-PIX, gPAS, and gICS to enable integrated workflows across all 3 tools and to improve their interfaces.

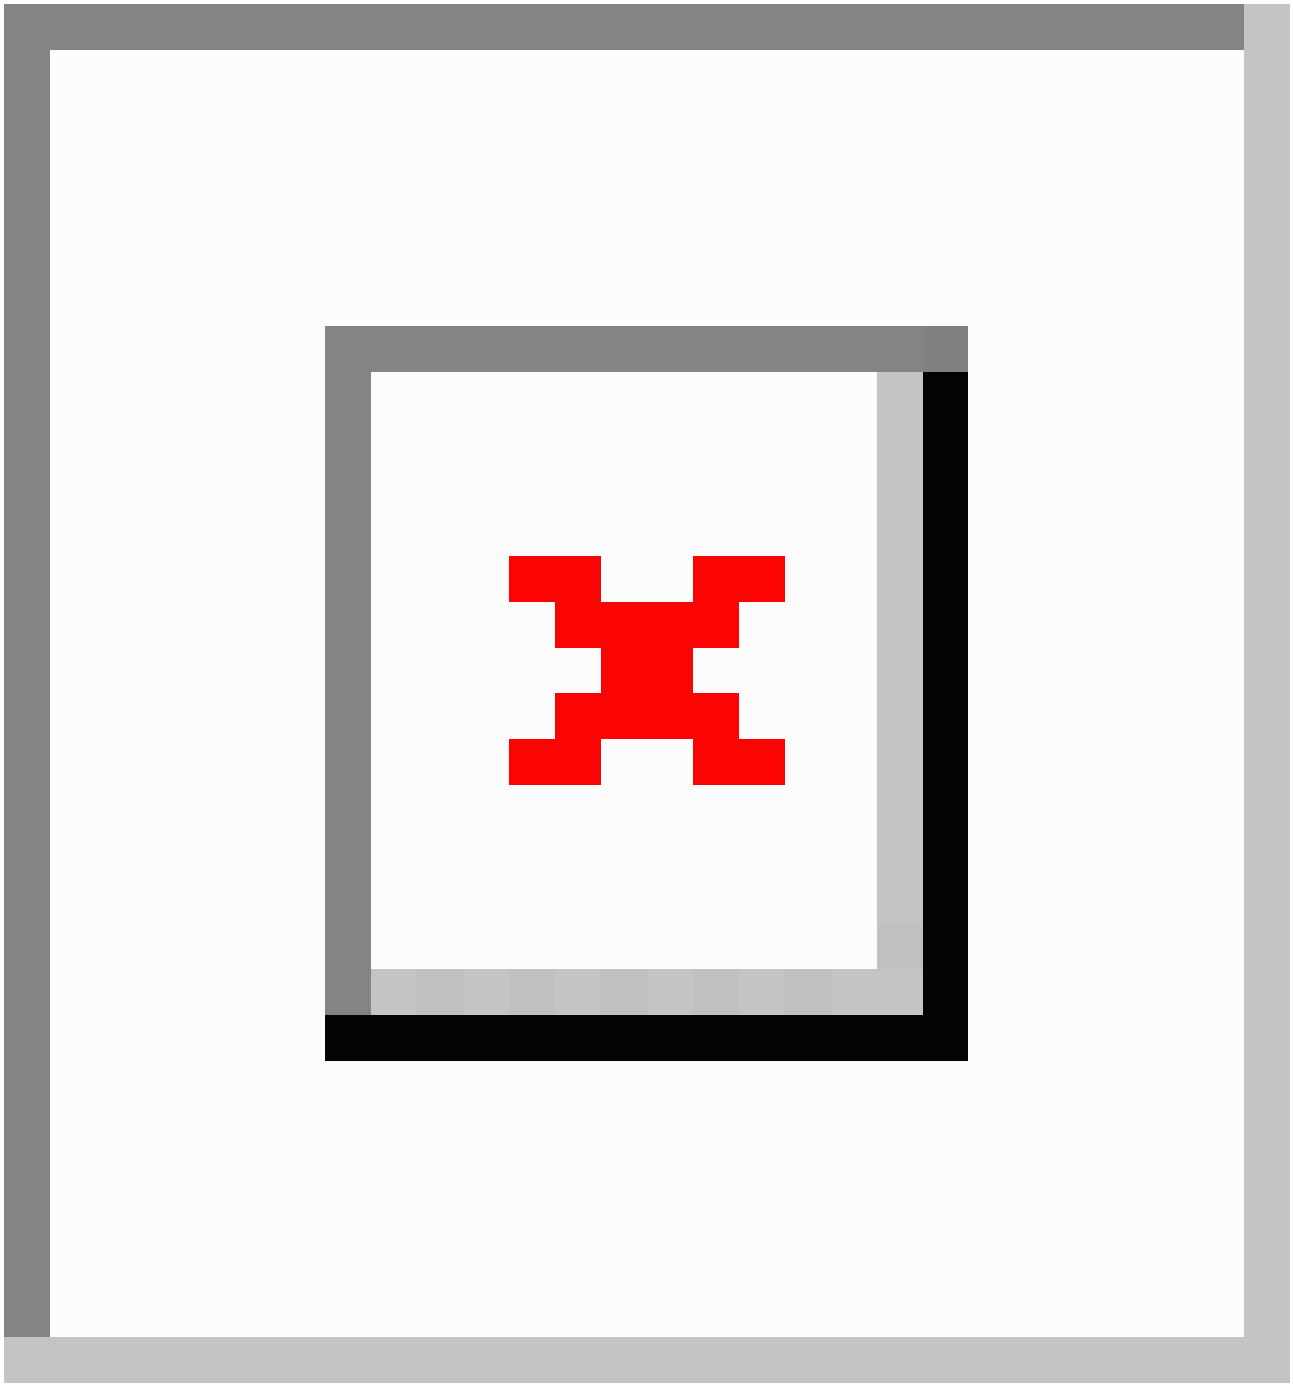
Authorization and Authentication

We designed a simple, yet flexible 3-stage authorization model, which combines permissions for basic object access with permissions regarding the domain of the object to be accessed (with create, read, write, or delete permissions) by a machine or human user of the infrastructure. An overview is provided in Figure 1.

A domain defines the scope of the data managed by the TTP (eg, a research process, a study, a project, or an institute). Multiple domains can be created within a project (eg, to store pseudonyms used in specific subprojects or contexts). Additionally, in gPAS, a domain can have parent and child domains. This results in a tree structure that can be used to tailor permissions to different scopes within individual projects [25].

On the implementation side, we mapped this model to OpenID Connect (OIDC), which is based on OAuth 2.0 [26]. The JavaScript Object Notation Web Token generated in this process contains role names as attributes, which are platform independent and can also be processed on mobile devices. This is important for the additional UIs that we had to develop. As an identity and access management solution, we chose Keycloak, which is in widespread use, has a native administration interface, and is published as open-source software under the Apache License 2.0. Importantly, it can also be connected to a range of directory services usually maintained by hospitals for account and permission management.

Figure 1. Stages of the functional authorization model.



Programmatic Interface

We decided to implement a REST API to extend the programmatic interfaces of E-PIX, gPAS, and gICS and support cross-tool workflows. Due to its stateless nature, this design enables the management and sharing of data across different systems, combined workflows, and calls by external components. One important application of the unified REST API is to combine participant registration with automatic consent checking in gICS, indexing the participant in E-PIX, and generating pseudonyms in gPAS. Furthermore, the REST API can easily be integrated with the developed authentication and authorization model as well as logging and audit trail functionalities. Existing interfaces of MOSAIC tools can also be integrated with the permission model by wrapping them behind REST interfaces.

Graphical Interfaces

Web Interface

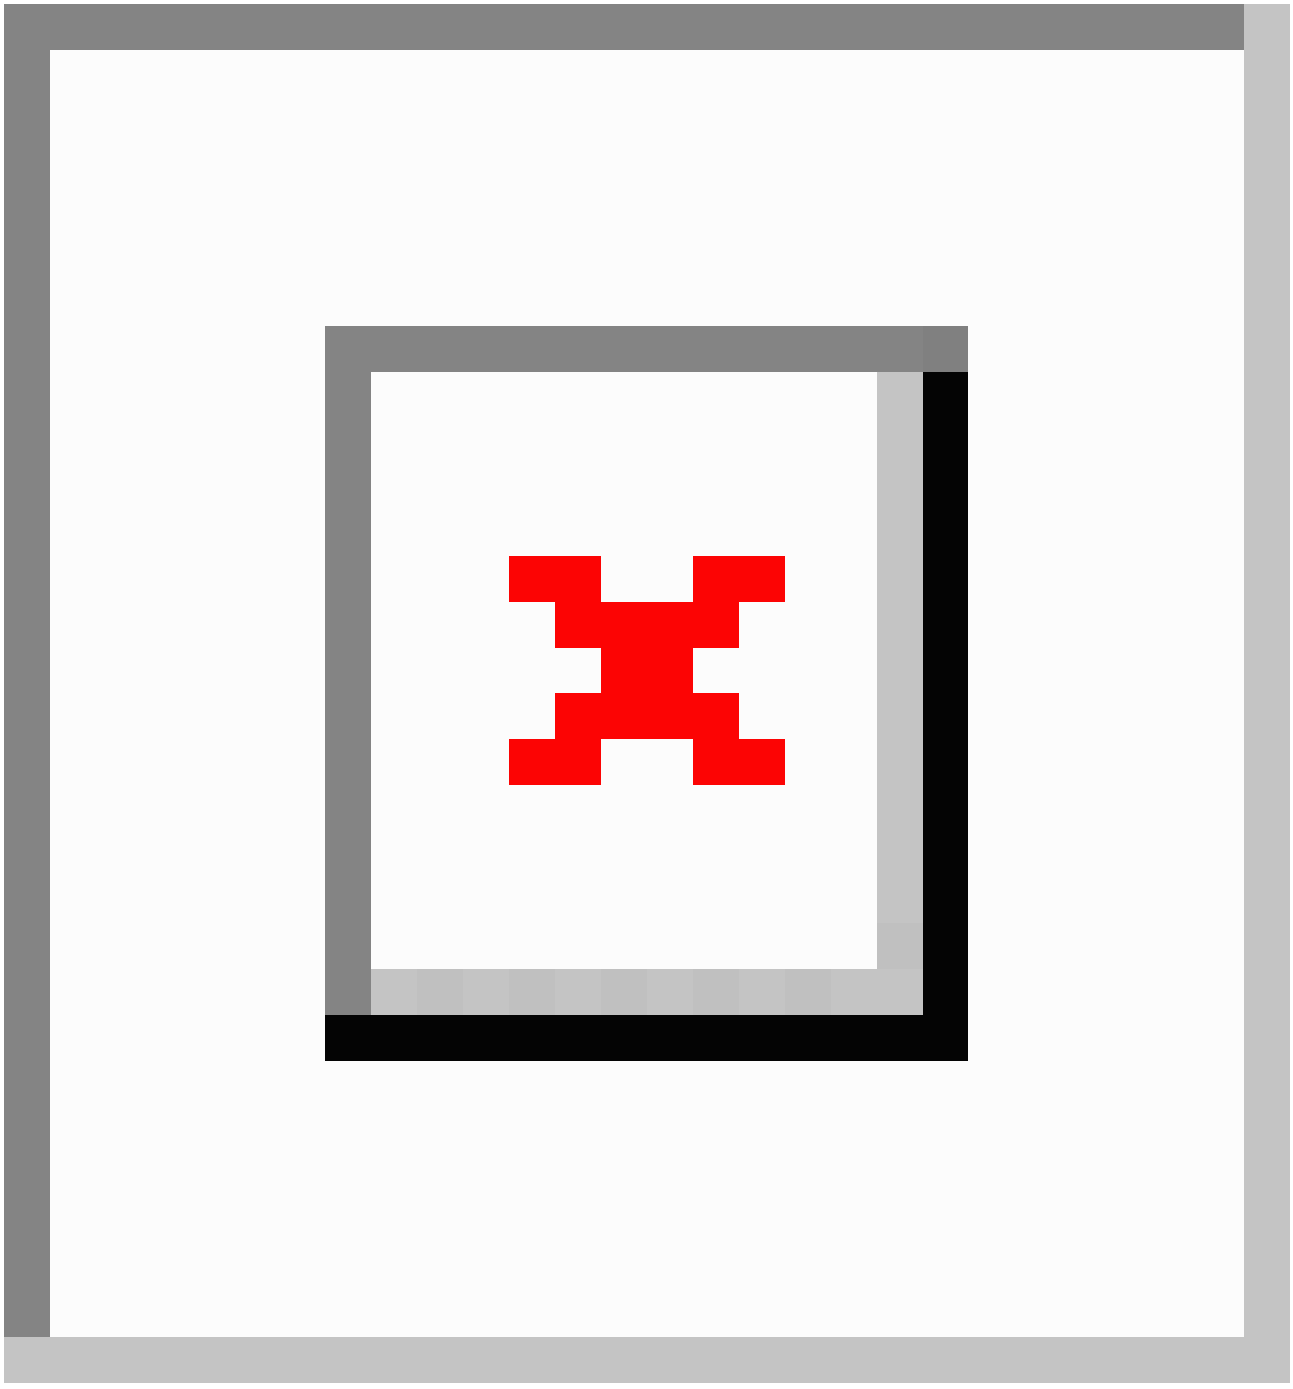
Based on the integrated programmatic API that supports all services, we have also implemented an integrated GUI, which allows accessing all TTP services in a unified manner. Analogously to the programmatic API, the UIs are integrated with the described authentication and authorization model. Users can log into the platform with their account from the connected directory service, which is abstracted way using OIDC with Keycloak. The token generated at log-in contains all assigned permissions, which are used in the UI and sent as a bearer token

with each request to the REST services. A strict content-security-policy workflow blocks the execution of foreign scripts outside the origin domain, thus increasing the level of security. Actions such as participant administration, depseudonymization, or consent administration can be performed through wizards. Users can request essential documents, such as copies of consent, directly from the web application.

Mobile App

The final building block is provided by a mobile app that serves as a direct channel from the TTP services to the participants. The most important application is collecting consent and handling withdrawals. A typical deployment consists of installing the appl on a tablet, which is then configured by study personnel and handed over to the participants (Figure 2).

Figure 2. Workflow of actions in the app.



The study personnel can log into the app using the same log-in data as for the TTP web interface. After the project staff member enters a participant identification code and selects either a consent or a withdrawal form, the selected participant fills out the form. To prevent participants from accessing unauthorized information, the app will be started in kiosk mode. The identification code is either a temporary pseudonym or an already existing pseudonym for the participant, providing direct linkage to the research project managed by the TTP. In the latter case, the app automatically opens the associated consent template. After filling out the form, the participants can enter their name and place of residence, and then, they can put their

signature in a designated field. Afterwards, the staff member provides their signature, confirming that the form has been completed with them as the assigned project staff member.

Supported Pseudonym Algorithms

In our system, generated random numbers are used as pseudonyms. The length is configurable, with a minimum of 6 digits, and is chosen based on the number of pseudonyms that are needed for the respective project. Additionally, we use the Damm algorithm to detect single-digit errors and all adjacent transposition errors with a simple checksum [27]. Moreover, pseudonyms are combined with study- and context-specific prefixes. For example, the pseudonym "BLV-US-123456" could represent an ultrasound ("US") measurement for a study participant in a study called BeLOVE ("BLV"). Finally, our system can also import and manage existing pseudonyms. As those are usually generated using different algorithms and often do not contain a checksum, we mark them as "external" within the system.

Ethical Considerations

This paper covers the design and implementation of a generic research service, which requires no ethics committee approval according to local policies. However, the individual studies that use the service have to apply for ethics approval. For example, the BeLOVE study, which is described as a case study in this paper, was approved by Charité's ethics committee (vote number EA1/066/17).

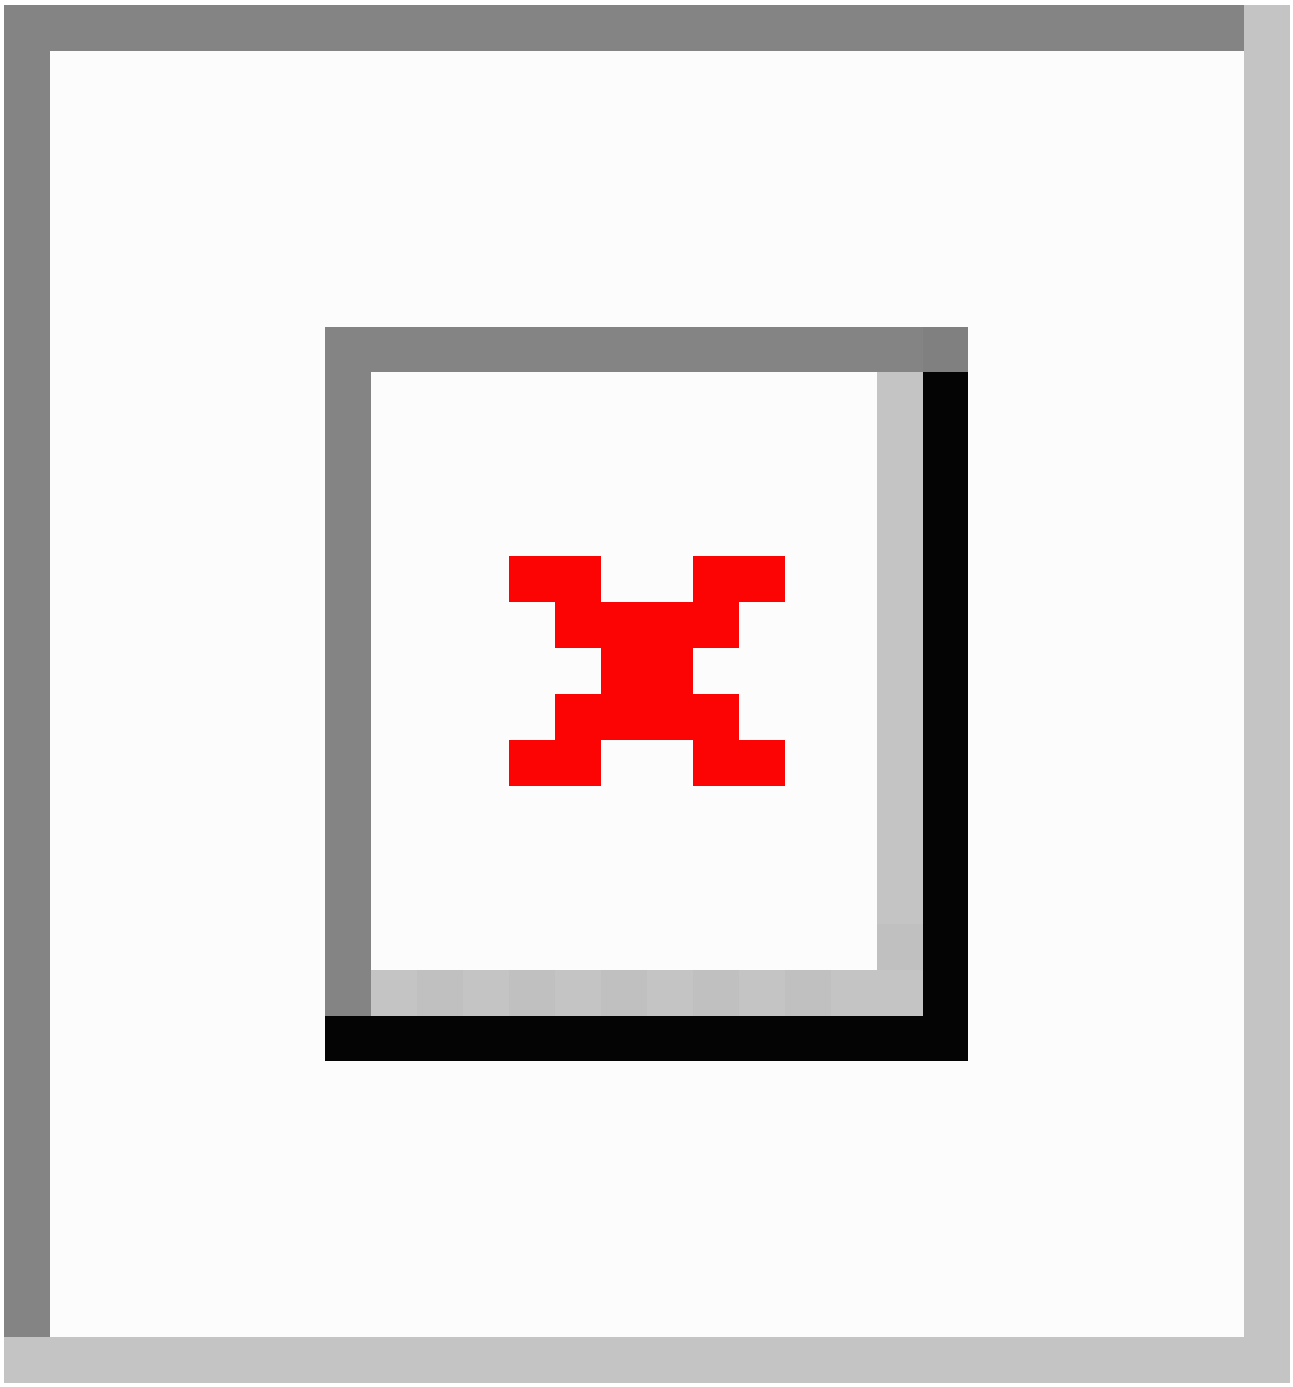
Results

In this section, we will first describe the general architecture of our solution, then cover important implementation details, and finally report on real-world experiences with the platform.

Architecture

The overall architecture is divided into the API, which wraps around the MOSAIC tools, the graphical interfaces oriented toward users, as well as the access and identity management component (Figure 3 presents more details).

Figure 3. Architecture overview, including wrapped MOSAIC stack (core components); systems maintained by the trusted third party (TTP; graphical components as well as access and identity components); systems queried by the TTP (electronic health record [EHR] system and directory services); and systems from which the TTP is queried (Research Electronic Data Capture [REDCap]). E-PIX: Enterprise Identifier Cross-Referencing; gICS: Generic Informed Consent Service; gPAS: Generic Pseudonym Administration Service.



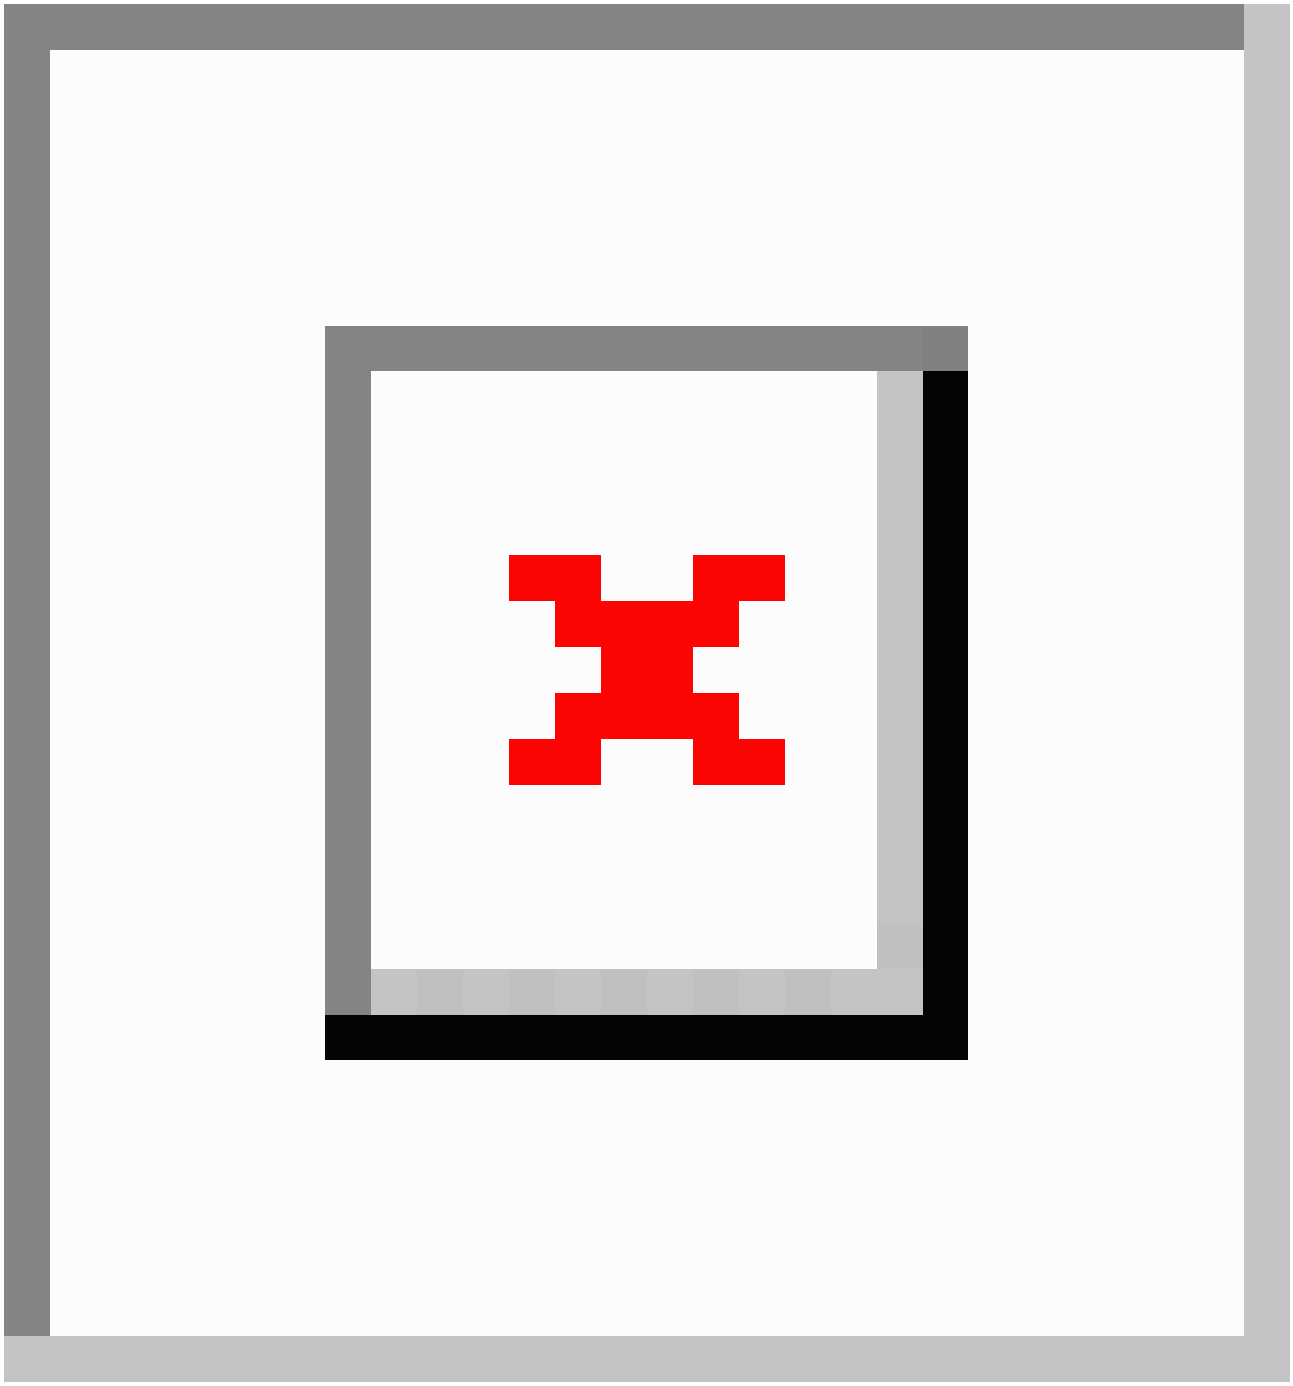
As illustrated, the core components are provided with an interface to the EHR system to support the pseudonymization of patient identities for direct reuse in the respective research context. Other systems that can access the TTP services via the REST API are, for example, electronic data capture systems, such as Research Electronic Data Capture (REDCap), or biobank information systems. All components of the respective interfaces are containerized with Docker [28] and deployed on a Docker swarm [29]. By using OIDC based on OAuth 2.0 as the standard, we were able to integrate other systems via existing packages (eg, Spring-Boot-Security) and allow other applications to access the systems. When modeling the interfaces, we ensured that anything that could be done graphically could also be done programmatically. This keeps the platform open and supports other information systems with the integration of TTP services.

Implementation

The REST API was implemented using Java 13 with the Spring Boot framework [30] by focusing on stable packages, including Spring Security for OIDC, and relying on an established framework. The resulting platform is robust, maintainable, extensible, and flexible. We have implemented 35 generic interfaces so far, most of which are Create-Read-Update-Delete (CRUD) interfaces for the key information objects Domain,

Participant, Identifier, Pseudonym, Consent, and Consent Template (Figure 4), as well as additional directory and search functions for pseudonyms and consents.

Figure 4. Key information objects and their relationships.



The web-based interface (Figures 5 and 6) is implemented using the PHP-based lightweight enterprise web framework Laravel [31]. Laravel uses a Model-View-Controller pattern [32], has a template engine named Blade, and supports agile development processes. By integrating the open-source framework Bootstrap, we were able to implement a responsive front end that could be displayed in browsers on multiple types of devices. The web application directly interfaces with the REST API and does not manage any participant data in a separate database.

Figure 5. Screenshots of the user interface: editing consent information.

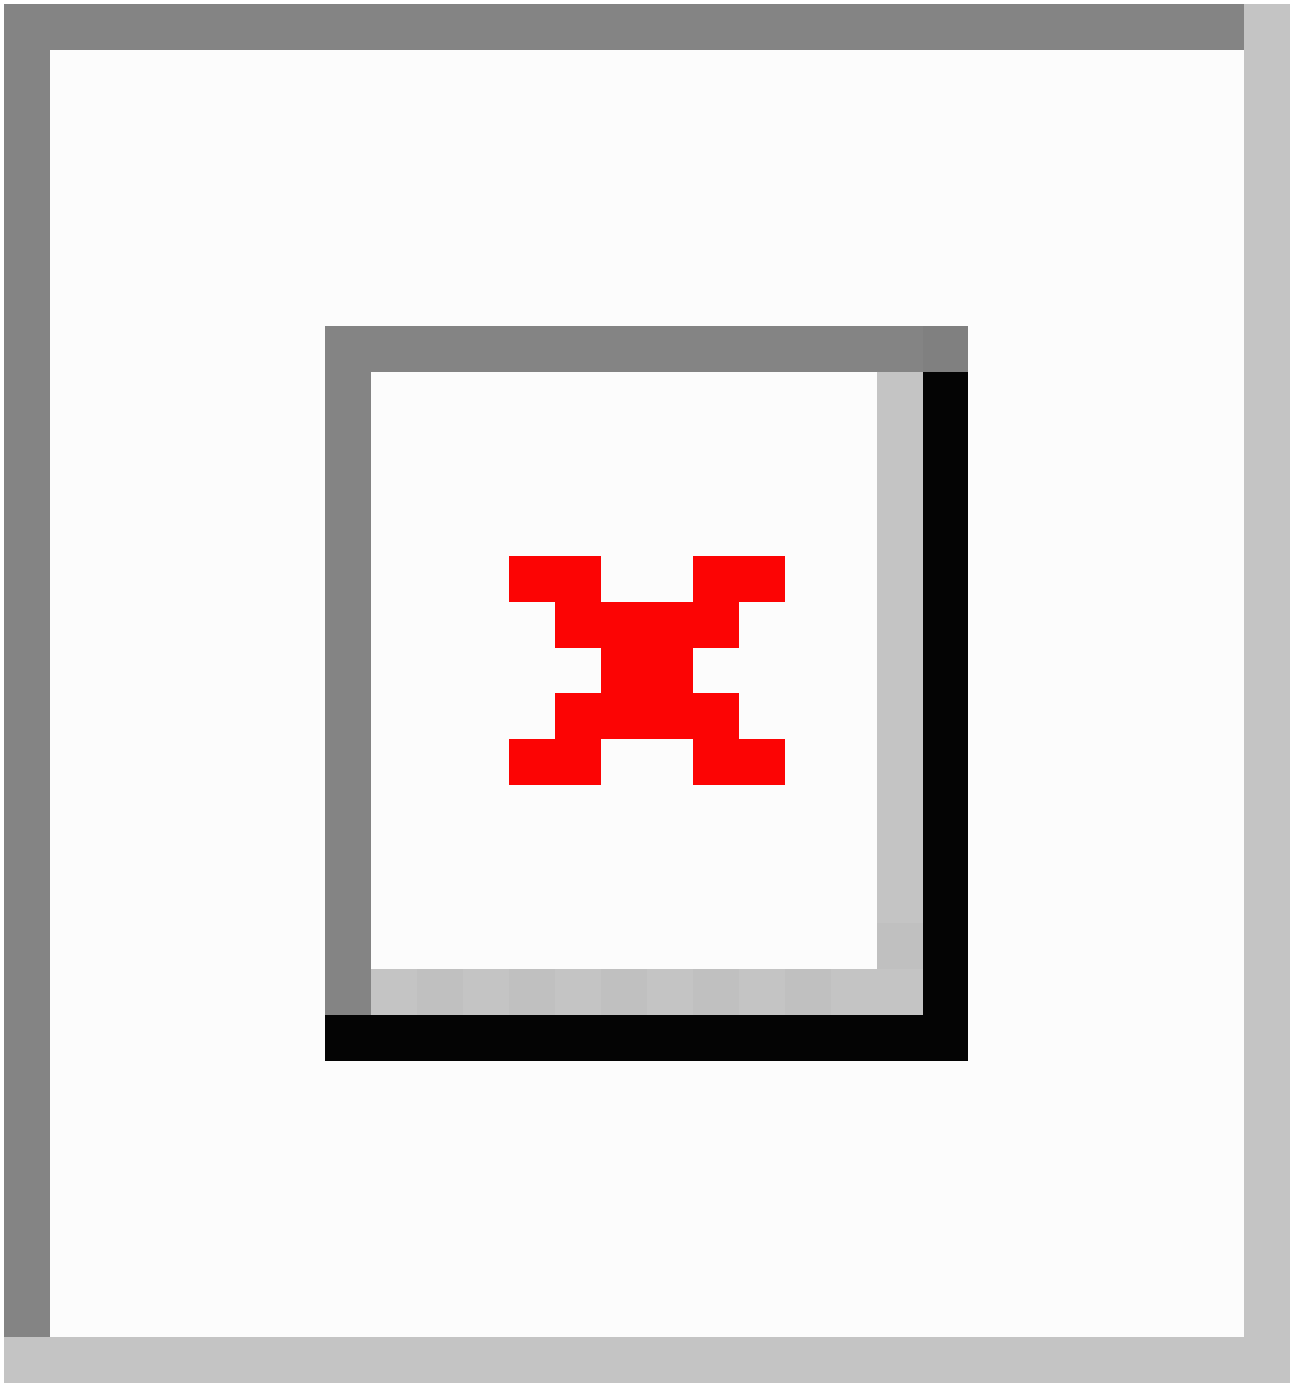


Figure 6. Screenshot of the user interface: overview of consent status.

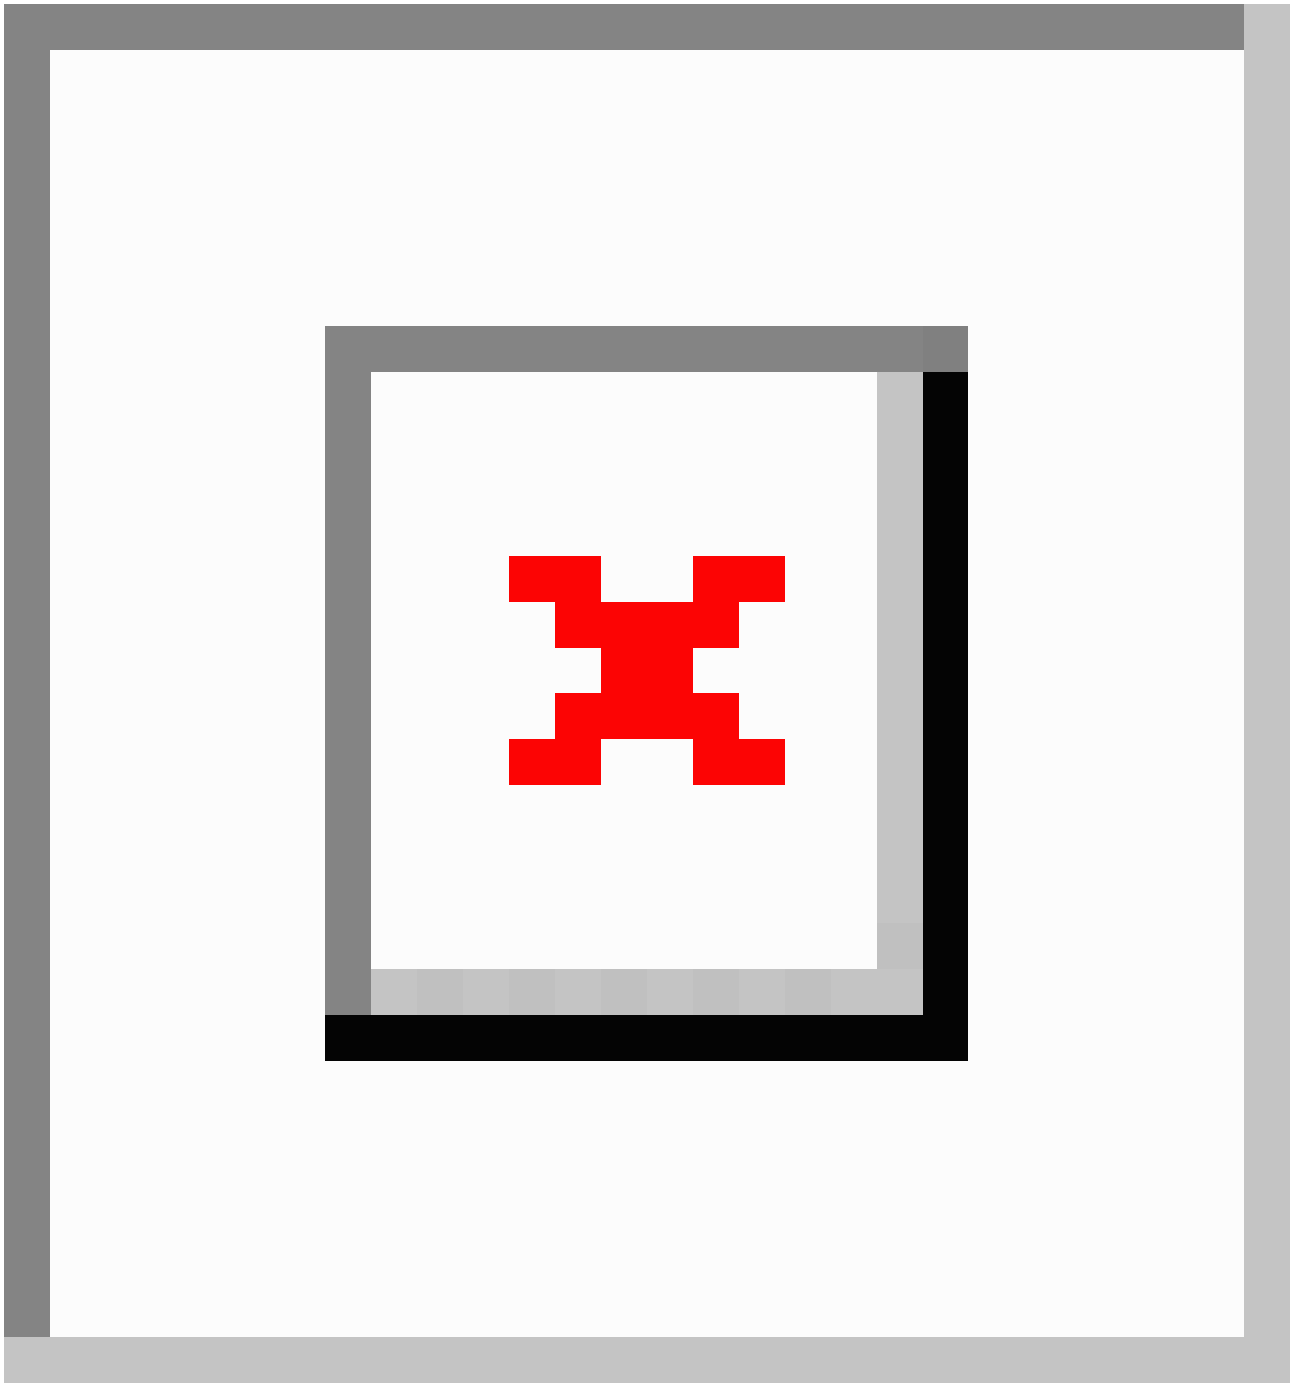

The app front end (see Figures 7-9) was developed in React Native [33] and then significantly extended to work on tablets integrated into our mobile device management. The application does not permanently store any data on the device, and processing is carried out exclusively via React Native state management.

Figure 7. Screenshot of the consent app: entering or scanning an ID.

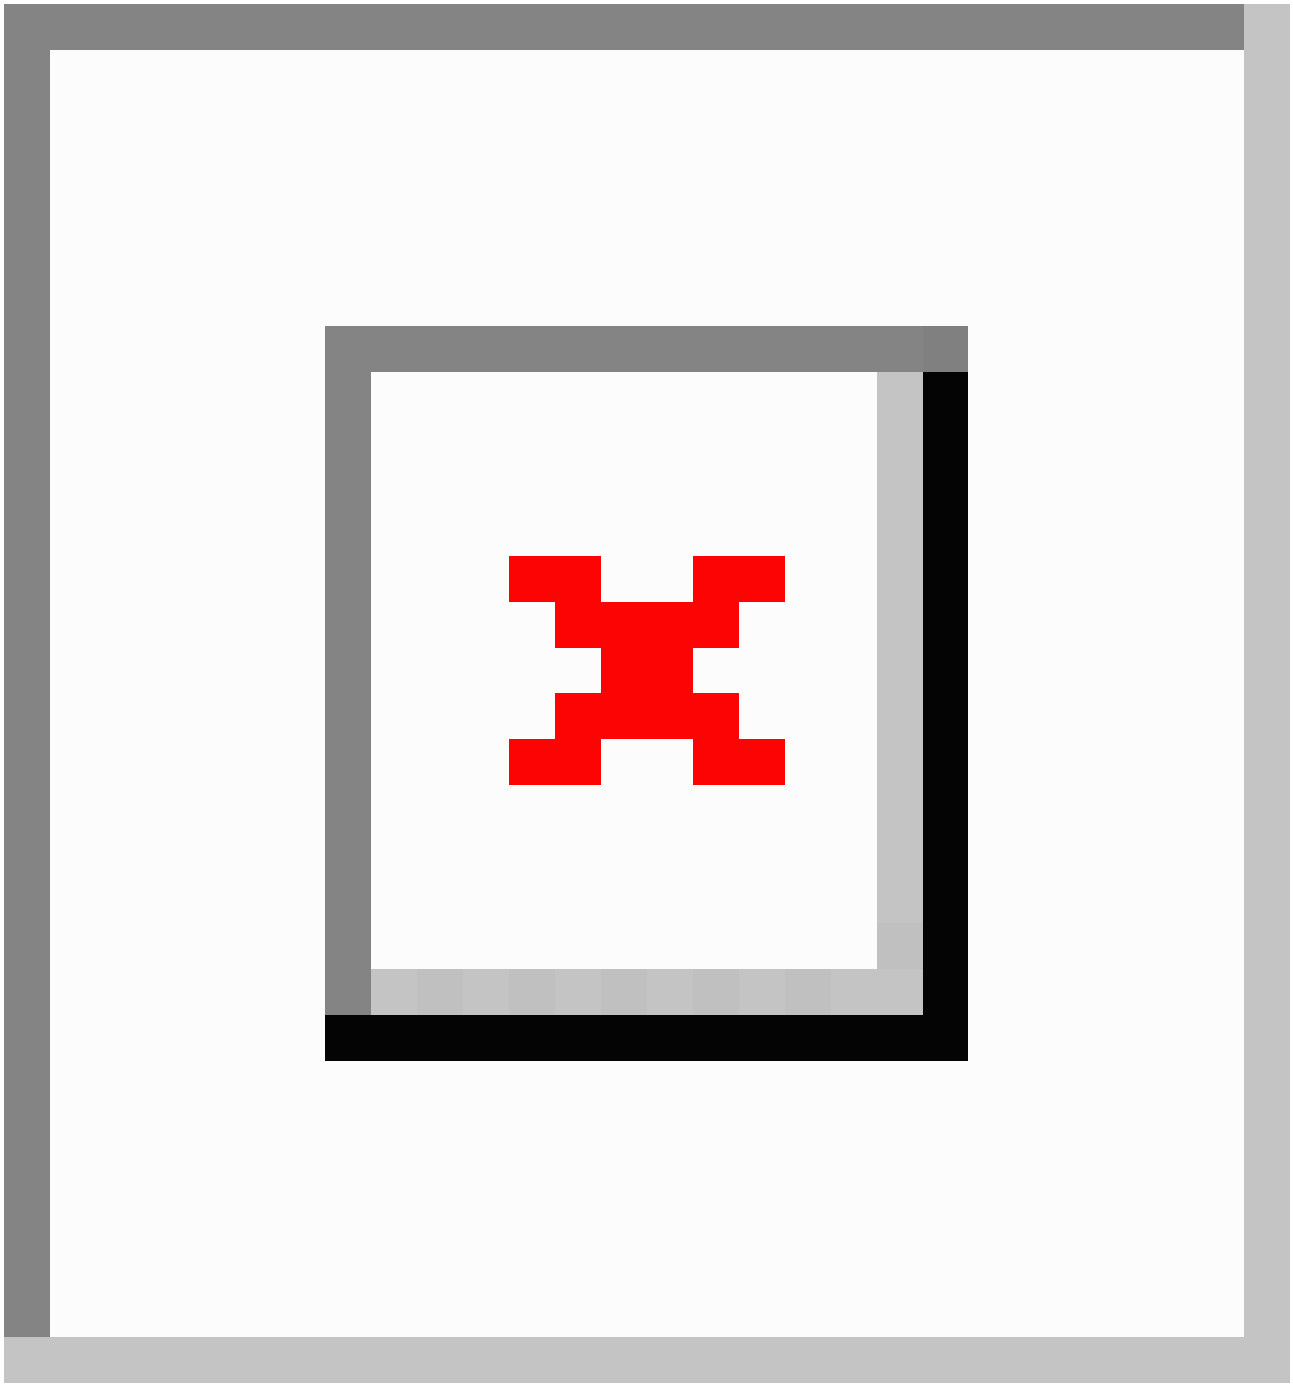

Figure 8. Screenshot of the consent app: filling out consent forms.

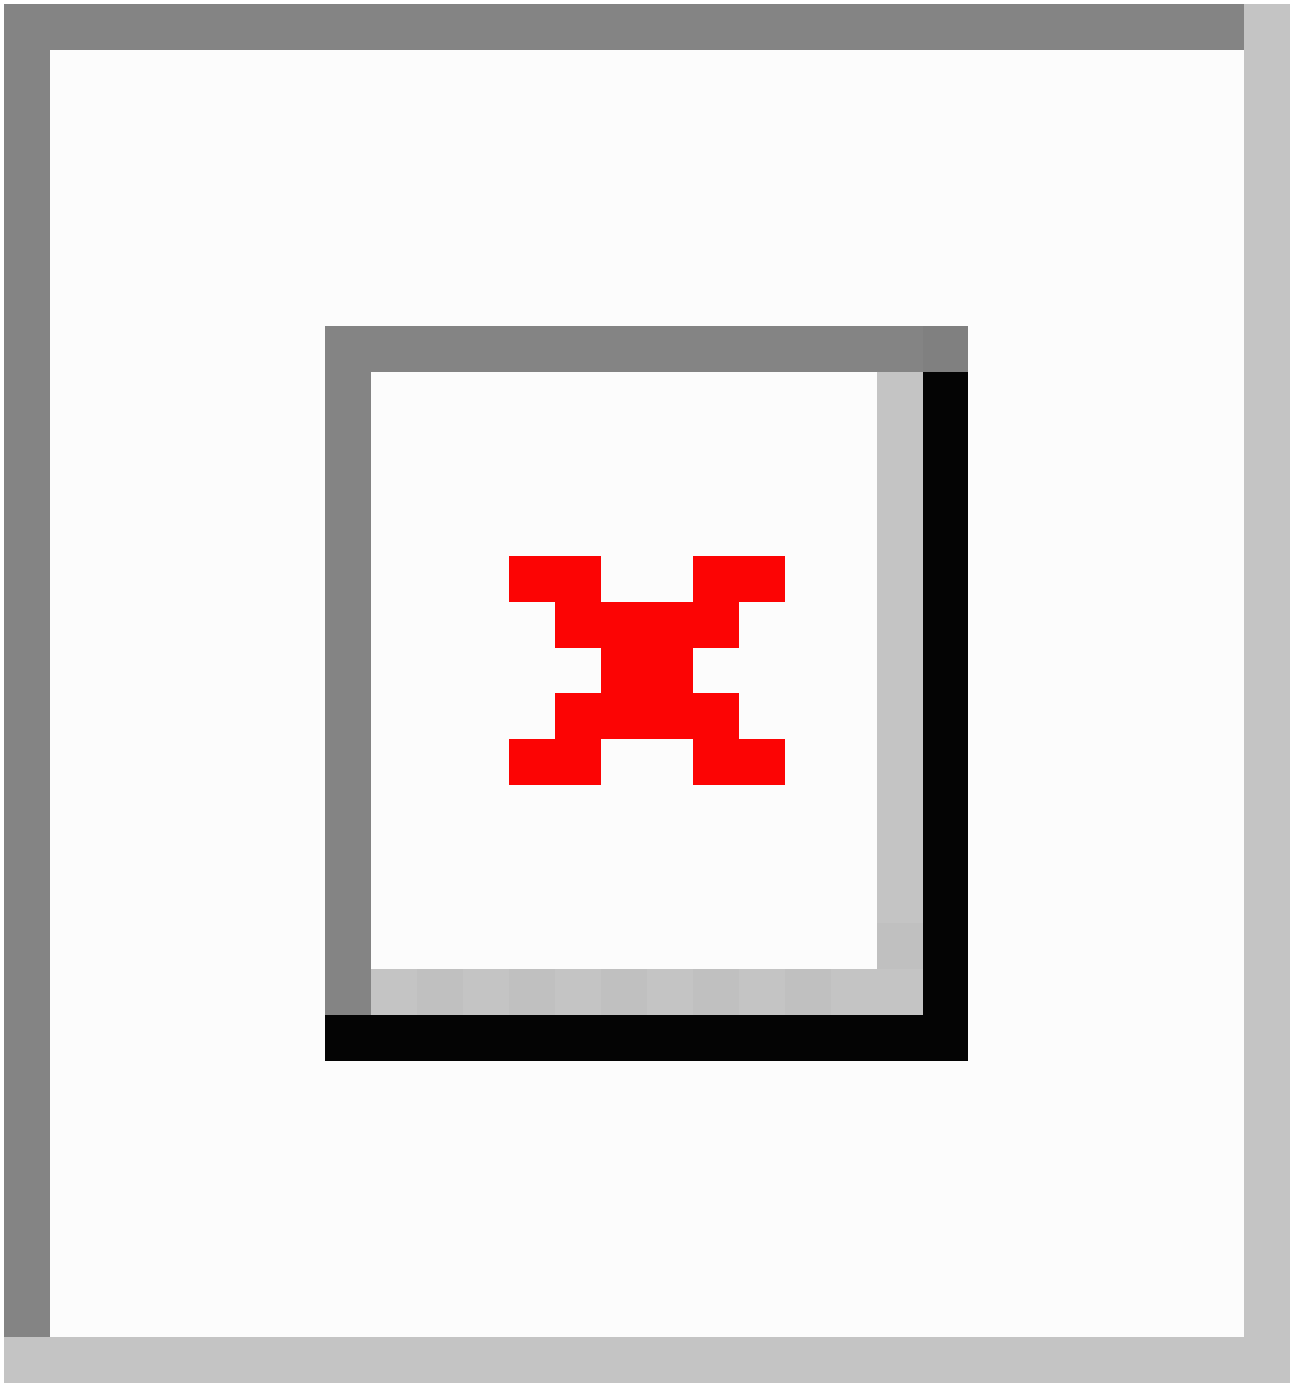

Figure 9. Screenshot of the consent app: sign and submit.

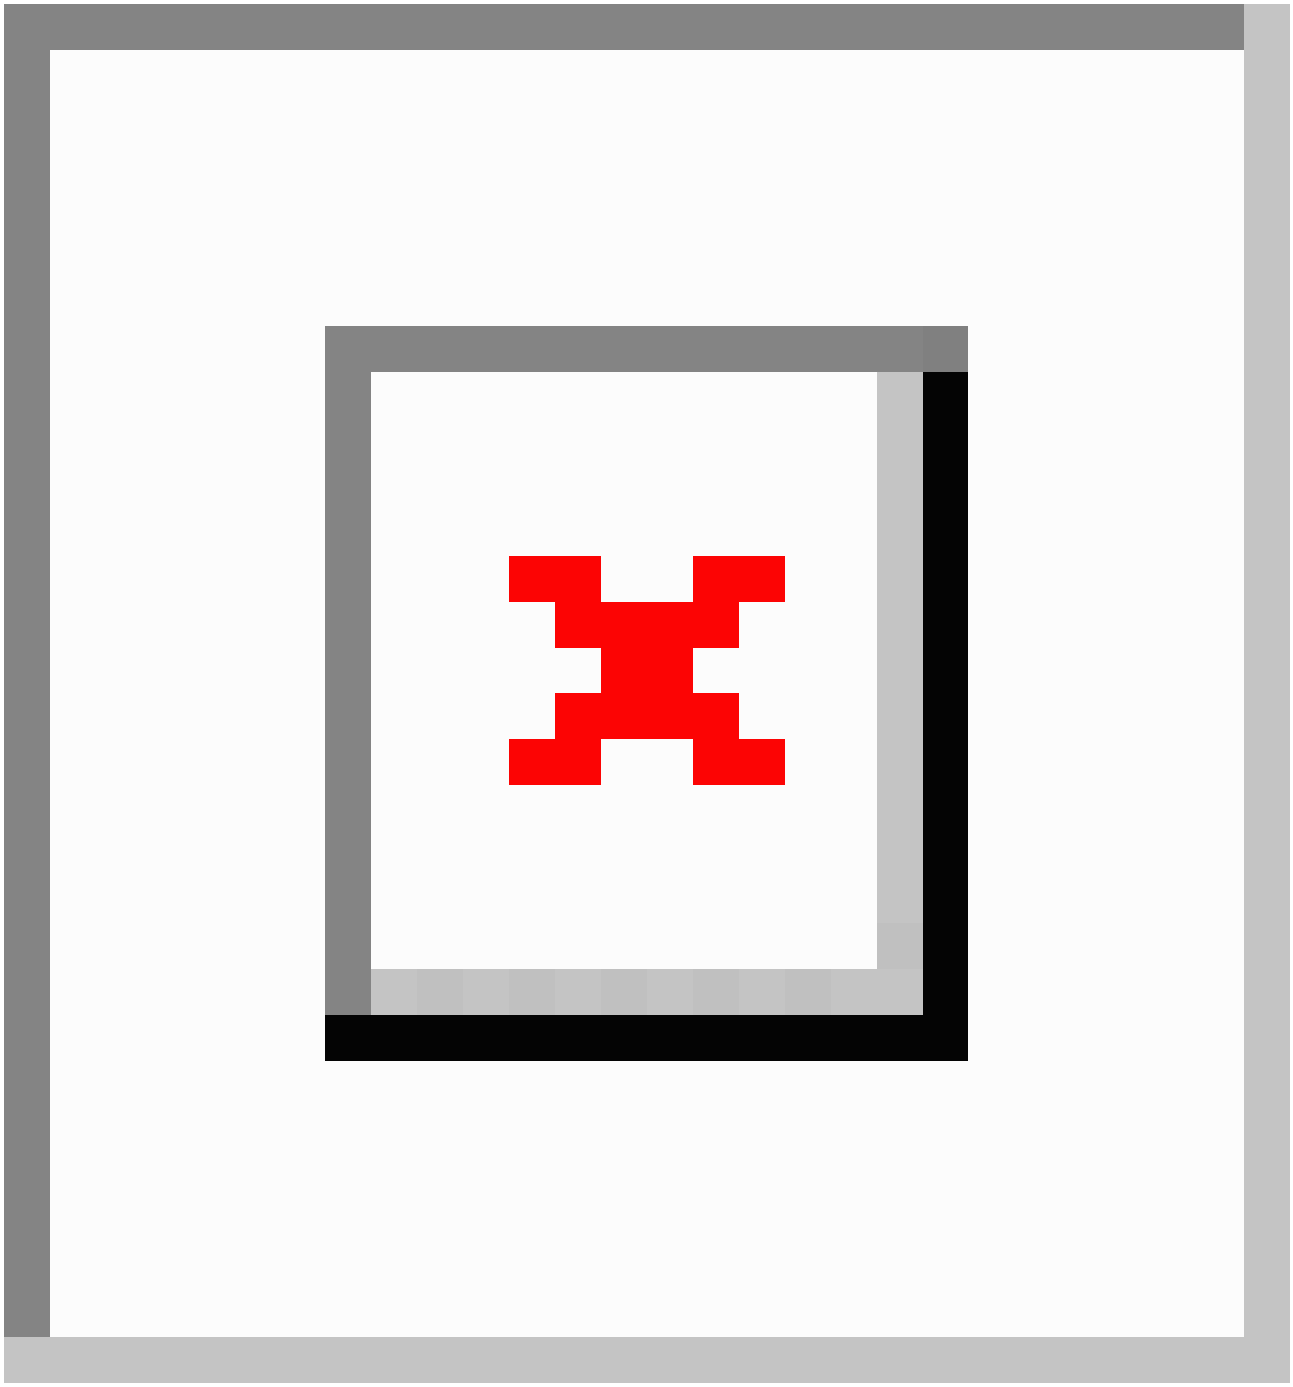

Core Functionalities for Research Projects

As a result of our development efforts, the TTP software stack provides a wide range of functionalities that research projects need. Table 3 provides an overview of frequently used common features.

Table . Essential functionalities provided to research projects.

Component	Process	Description
API[a]	Obtaining a temporary pseudonym	Automated creation of participant placeholders that can be used in third-party systems and later linked to the study identity
App	Electronic consent management	Viewing, completing, saving, and printing an electronic consent template of the respective project under a pseudonym
Web UI[b]	Participant registration	Master data and contact details can be entered manually or imported from the EHR[c] system
Web UI	Participant overview	Provides an overview of the participants and pseudonyms associated with a specific project
API	Integration with other systems	Interface for pseudonymization, depseudonymization, and linkage for third-party systems
Web UI	Depseudonymization	Resolve pseudonym to participant master data
Web UI	Retrieval of usage permissions based on consent information	Retrieve electronic representation of usage permissions from consents associated with a specific patient or participant pseudonym
Web UI	Update participant information	Use pseudonyms to update participant information

[a]API: application programming interface.

[b]UI: user interface.

[c]EHR: electronic health record.

On the API level, these features include integration with other systems to manage pseudonymization, depseudonymization, and data linkage. The app specializes in electronic consent management, specifically viewing, completing, and saving of consent templates. The web-based UI permits registration of participant details; provides an overview of participants, consents, and pseudonyms; supports depseudonymization as well as the retrieval of use permissions based on consent information. CRUD operations for major participant properties and printing consents are also supported.

Experiences in Real-World Operational Settings

The TTP has already supported more than 10 research projects since it was launched in December 2019. As of December 2022, our TTP system manages data of 3610 registered participants with 384,813 pseudonyms and 1762 consent documents. The pseudonyms fall into 2 categories: 40,867 pseudonyms have been assigned to individual participants managed by the TTP and 343,946 pseudonyms to other identifiers (eg, health insurance numbers that are managed by the TTP as part of its support for data linkage). On average, the TTP manages about 11 pseudonyms for each individual participant. As many as 153 research personnel actively engage with the software on a daily basis. Backups of our databases are created every night. These backups are stored for 90 days along with all log files.

As a case study, we will describe how the TTP services are being used by the large-scale BeLOVE study [20], which is carried out as a cooperation between several sites and departments at Charité. BeLOVE uses all services provided, from patient as well as participant registration and consent management, to pseudonym generation for the various diagnostics and phenotyping activities performed during hospitalizations or study visits (about 12 pseudonyms per participant). Compared to the initial planning of the study, which required 2 study staff for the administrative tasks, these staff requirements were in the meantime reduced to zero due to the functionality of our TTP and the associated secure outsourcing of tasks to all study staff. The use of central TTP services has also significantly reduced the efforts required for coordinating BeLOVE and its substudies with the data protection and information security officers. Within Charité's internal data integration platform, consistent pseudonyms and API access to mapping rules are frequently used to link data collected about BeLOVE participants with routine health care data collected during inpatient and outpatient encounters for various types of analyses. Secondary pseudonyms have already been generated for 10 projects in which the data have been analyzed or shared with others.

Discussion

Principal Results

In this paper, we have presented a software stack to support a TTP with its core tasks at a large German academic medical center. Our architecture extends existing systems for key functionalities, identity management, pseudonymization, and consent management with a fine-grained authentication and authorization model, a modern REST API, two types of UIs, and connections to third-party systems. These extensions were necessary to support cross-service workflows on the programmatic as well as the user level and to meet further functional and nonfunctional requirements. Our application is built using various open-source enterprise frameworks and standards (eg, OIDC) to ensure sustainability and integration

with important institutional services (eg, our user directory and leading master patient index). Our experiences with supporting a wide range of research projects with TTP services over a longer period have shown that our approach works and provides functionalities that are generic enough to support a wide range of applications.

Comparison With Prior Work

Our architecture and implementation are based on the MOASIC tools [16], which we have extended with additional components to overcome functional and nonfunctional shortcomings. Most importantly, the publicly available basic versions of the MOSAIC tools are not suitable for handling more complex and flexible workflows with fine-grained authorization. For example, supporting cross-service workflows, like registering a patient, generating pseudonyms, and preparing a consent form as an integrated operation, cannot be implemented without an additional dispatcher component that is currently not publicly available. We solved this by implementing a cross-service REST API. Although the MOSAIC tools already come with an API, it is provided individually for each service and is based on the Simple Object Access Protocol [34], which originates from the IHE web service standards [35] and is complex and slow, requiring managing server-side state. Analogously to an API, the MOSAIC tools also offer GUIs. However, they are provided individually for each service and hence do not enable users to seamlessly perform operations that require interactions with multiple core services. For this reason, we developed a cross-service UI that is based on our API. Additionally, we added functionalities for generating QR codes, versioning consent documents, and starting the system in kiosk mode. Finally, our extensions also improve the system's scalability when executing cross-service operations, such as querying for links between pseudonyms and identifiers, which can be slow when using the MOSAIC tools [36]. We also added comprehensive documentation of administration functions, which is not fully available for the current open-source versions without registration with the vendor [37].

Prior work on TTP-related services usually focused on individual components or algorithms that could support TTP operations, deployments in specific research projects, or high-level architecture overviews.

One well-known example is the one-way hash approach employed by Vanderbilt University Medical Center as part of the ingest process into their deidentified layer within a research data warehouse [38]. Pommering et al [39] describe strategies for how pseudonymization could be used in different contexts, for example, in the secondary use of EHR data or in medical research networks and biobanks. They introduced two models that support repeated depseudonymization as well as one-time use [40]. The former model was later integrated into a concept for sharing large data sets in medical research networks and biobanks [39].

Building on this, Lo Iacono [41] investigated a cryptographic approach for generating consistent pseudonyms in multicentric studies but without describing a specific implementation within a concrete project. Dangl et al [42] describe concepts and requirements for TTP services for a specific biobank of a clinical research group. Heinze et al [43] developed two services based on IHE profiles that have been implemented into the Heidelberg Personal Electronic Health Record. One service is used to capture patient consent, while the other provides a GUI to manage consents. Further components (eg, for pseudonym or identity management) were not described in detail.

Lablans et al [13] introduce the Mainzeliste, which supports managing patient identities and pseudonyms through a web-based front end. Bialke et al [10] introduce the MOSAIC tools, which we also use in our work, as a set of tools supporting central data management for studies or research networks. They also introduce the "dispatcher" as an additional component for building complex workflows [22], which is, as we described above, unfortunately not publicly available.

Aamot et al [44] compare different strategies for depseudonymization in which, among others, the strategy of Pommering et al [39] is compared with alternative approaches. Based on this comparison, they develop a pseudonymization approach using deterministic one-way mappings based on cryptographic protocols. Lautenschläger et al [45] implement and describe a generic and tightly coupled architecture and component for pseudonymization that has been used in several research projects. On the application side, Bahls et al [14] describe a TTP architecture using the MOSAIC tools for the Routine Anonymized Data for Advanced Health Services Research project. Hampf et al [17] benchmark parts of the MOSAIC tools and conclude that it would take several days to register 2 million patients with the hardware setup utilized.

Limitations and Future Work

As the most recent versions of the MOSAIC tools are not distributed as open-source software in a public repository [37], it was not possible for us to make changes to the core tools used. Instead, workarounds had to be implemented at the API or UI level, which is not ideal from an architecture perspective. Moreover, our TTP platform is currently focused on providing intra-institutional services only. In future work, we plan to extend our platform with external interfaces, enabling the TTP to act as a central trustee for multicentric projects. We also aim to implement additional programmatic interfaces following international interoperability standards, in particular, Health Level 7 Fast Healthcare Interoperability Resources [46] and enable study personnel to directly manage the permissions of associated staff. Finally, we plan to introduce a unified pool of consent policy keys to harmonize the permission information that can be queried from our system to enable automated downstream processing that considers consent information.

Conclusions

Scalable and comprehensive TTP services are central to modern data-driven medical research. However, community-based comprehensive platforms that can be used to implement such services are still lacking. We believe that our description of key requirements as well as the insights provided into our flexible architecture that combines core tools with user- and application-oriented workflows and interfaces, including third-party applications, can help other institutions setting up comparable services.

Acknowledgments

The authors would like to thank the BeLOVE (Berlin Longterm Observation of Vascular Events) study team, who have contributed to the improvement of the entire system with their constant feedback. This work was, in part, supported by the German Federal Ministry of Education and Research under grant agreement number 16DTM215 (THS-MED).

Conflicts of Interest

Abstract

Background: To circumvent regulatory barriers that limit medical data exchange due to personal information security concerns, we use homomorphic encryption (HE) technology, enabling computation on encrypted data and enhancing privacy.

Objective: This study explores whether using HE to integrate encrypted multi-institutional data enhances predictive power in research, focusing on the integration feasibility across institutions and determining the optimal size of hospital data sets for improved prediction models.

Methods: We used data from 341,007 individuals aged 18 years and older who underwent noncardiac surgeries across 3 medical institutions. The study focused on predicting in-hospital mortality within 30 days postoperatively, using secure logistic regression based on HE as the prediction model. We compared the predictive performance of this model using plaintext data from a single institution against a model using encrypted data from multiple institutions.

Results: The predictive model using encrypted data from all 3 institutions exhibited the best performance based on area under the receiver operating characteristic curve (0.941); the model combining Asan Medical Center (AMC) and Seoul National University Hospital (SNUH) data exhibited the best predictive performance based on area under the precision-recall curve (0.132). Both Ewha Womans University Medical Center and SNUH demonstrated improvement in predictive power for their own institutions upon their respective data's addition to the AMC data.

Conclusions: Prediction models using multi-institutional data sets processed with HE outperformed those using single-institution data sets, especially when our model adaptation approach was applied, which was further validated on a smaller host hospital with a limited data set.

KEYWORDS

machine learning; privacy; in-hospital mortality; homomorphic encryption; multi-institutional system

Introduction

The demand for combining widespread data from various hospitals to create a larger data set for research from medical researchers is ongoing. However, exchanging or sharing medical data among hospitals is highly challenging because of various regulations and restrictions [1]. Sharing medical data with other institutions is limited owing to concerns over personal data

breach. In other words, most medical data are exclusively accessible to each institution, but data access is mutually exclusive, blocking access from other institutions. Owing to strict data protection policies and privacy regulations, various legal and regulatory barriers to transferring patient-level heterogeneous data among institutions exist. However, as predictive studies using large data have been actively conducted in precision medicine recently, demands to compile multi-institutional data and develop widely applicable models in more diverse clinical environments are increasing. Efforts have been invested to address these challenges using emerging privacy-enhancing technologies (PETs), including homomorphic encryption (HE)—a form of encryption that permits calculations directly on encrypted data, ensuring the security of both input and output of a numerical model [2-5]. It has been demonstrated to be effective in specific "privacy-preserving data sharing and analytics" contexts, for tasks such as delegated computation (wherein data are processed by a third party without revealing its content) or generating summary statistics without exposing individual raw data [6,7]. However, owing to HE's inherent computational constraints, several HE applications have primarily focused on computationally simpler tasks, such as computing summary statistics. Nevertheless, recent advancements in HE technology have evolved to a stage wherein the development or training of predictive models—particularly with large data sets in multi-institutional studies—has become achievable.

Recent advancements in privacy-preserving techniques in medical data analysis have significantly influenced the field, particularly through the use of HE. Several studies have explored the application of HE for privacy-preserving logistic regression and collaborative learning. For example, Kim et al [8] demonstrated the feasibility of training logistic regression models on homomorphically encrypted data, while Bos et al [9] applied HE to enable secure genome-wide association studies. Furthermore, the scalability of HE-based logistic regression has been demonstrated by Crawford et al [10], who successfully trained 30,000 models on encrypted data.

Our study distinguishes itself from previous works by applying HE to enable secure multi-institutional learning for postoperative mortality prediction using real-world clinical data. In addition, we propose a method called "model adaptation" strategy that allows smaller institutions to leverage encrypted data from larger institutions, improving their predictive models' performance without compromising patient privacy. By focusing on developing a predictive model through multi-institutional collaboration and emphasizing the practical applicability of our approach, our study pushes the boundaries of privacy-preserving medical data analysis and offers tangible solutions for enhancing predictive modeling in a secure, collaborative manner.

This study, aiming to verify the feasibility of securely developing a predictive model with multi-institutional data sets, focused on protecting each institution's data set using HE technology. Furthermore, we sought to determine whether the predictive performance can be improved by merging various multi-institutional data sets to project the 30-day postoperative mortality rate. Additionally, we showcased the application of our proposed "model adaptation" strategy. By supplementing and learning from a small amount of data based on an HE-encrypted large-scale data set from external institutions, institutions can construct a predictive model applicable within their clinical setting.

Methods

Ethical Considerations

This study was approved by the Institutional Review Board (IRB) of the Asan Medical Center (AMC) (IRB No. 2021-0186) and Ewha Womans University Medical Center (EUMC) (IRB No. 2020-11-017). The requirement of obtaining written informed consent was waived owing to the retrospective study design. We used the publicly available INSPIRE data set provided by the Seoul National University Hospital (SNUH). The composition, release, and usage of the INSPIRE data set were separately approved by the SNUH's IRB (H-2210-078-1368).

Inclusion and Exclusion Criteria

We retrospectively analyzed data collected from 341,007 patients aged 18 years and older who underwent noncardiac surgeries at 3 independent institutions. The data collection period for SNUH patients who underwent noncardiac surgeries was adjusted to January 2011 to December 2020, resulting in the inclusion of 46,956 patients. Moreover, we obtained data from 162,184 patients who underwent surgeries between January 2017 and April 2021 at the AMC. The apparent disparity in the number of patients between these institutions primarily stems from the mapping of our data set with the pre-existing public database, VitalDB. Additionally, our data set included 131,867 patients who underwent surgeries between January 2001 and December 2019 at the EUMC. Patients who had undergone cardiac procedures, organ transplantations, and neurosurgical operations, as well as those with an indeterminable final clinical outcome because of insufficient follow-up within the study timeframe, were excluded. Our analysis only incorporated the first surgical procedure post-admission for patients who had undergone several surgeries within the study period.

Data Collection and Variable Selection

Data encompassing patient demographics, preoperative laboratory evaluations, details of the surgery, and postoperative clinical outcomes were culled from the electronic medical record system of each respective hospital. Variables for the model were selected in the same manner as in the previous study [11]. Features that consistently ranked high across all hospitals were considered potential candidates for subsequent analyses. The study disregarded variables exhibiting substantial disparities among hospitals, a high incidence of missing values, and susceptibility to subjective measurement and execution by medical personnel. Through these processes, the following 19 variables that served as features for our investigation were selected: (1) demographic data (age, sex, and BMI); (2) preoperative laboratory results (white blood cells, hemoglobin, platelets, sodium, potassium, blood urea nitrogen, creatinine, albumin, aspartate transaminase, alanine transaminase, glucose, prothrombin time, and activated partial thromboplastin clotting time); (3) surgery type (general, otolaryngological, urological,

orthopedic, gynecological, and plastic); (4) anesthesia type (general, neuroaxial, monitored anesthesia care, and regional); and (5) status of emergency surgery.

During the modeling process with encrypted data, we strictly adhered to the principle of complete ignorance of the data's content. This approach, integral to our study design, is not merely a precaution; rather, it is essential for ensuring our analysis' objectivity and reliability. By consciously avoiding any knowledge of the data's nature, we aimed to minimize potential biases from prior data set familiarity, thus bolstering our findings' integrity and validity, particularly in encrypted data scenarios.

Data Preprocessing

All continuous variables underwent scaling using the StandardScaler function from the scikit-learn library, while categorical variables were incorporated into the model using one-hot encoding. We assumed that standardization for each feature had been implemented at every hospital before encryption, using their respective means and standard deviations.

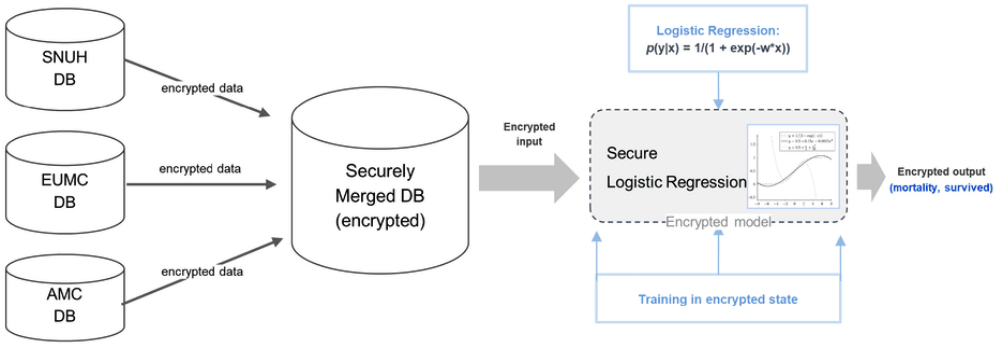
Model Outcomes

The primary outcome of interest in the study was in-hospital mortality within 30 days postoperatively. Data on in-hospital mortality were procured as binary information, derived from the final mortality date in the electronic medical record within 30 days postoperatively ("1" representing mortality and "0" indicating survival, with a threshold of 0.5).

Model Building

For modeling, secure logistic regression was used to compare the models' predictive performance (Figure 1) [8]. Complete data sets of each hospital were partitioned into training, validation, and testing data sets using a 6:2:2 distribution to develop all the models. The Nesterov Accelerated Gradient optimizer was applied to build trained models with a learning rate of 0.01 and batch size of 64 [12]. Binary cross-entropy served as the loss function for the model [13], with parameters being optimized to reduce each model's loss of function to the minimum. To address the imbalance in clinical data and more robustly assess the generalized performance of each model, we use the bootstrap sampling technique [14], which involved repeated processes of resampling training data, creating a new model, and evaluating that model. Thereafter, the model's performance was quantified as the mean performance of separate models developed with the bootstrap approach. Overfitting issues can be mitigated by averaging their results, thus increasing the model's generalizability. Consequently, the bootstrap method can significantly diminish the developed models' overfitting. To validate the predictive performance, the model was evaluated using the test set of the chosen hospital and data gathered from the amalgamations of other hospitals. For a fair comparison, we used the plaintext version of logistic regression for unencrypted data using NumPy from scratch [15], based on a stochastic approach, as opposed to using scikit-learn.

Figure 1. Schematic diagram of external validation of each hospital model. AMC: Asan Medical Center; EUMC: Ewha Womans University Medical Center; DB: database; SNUH: Seoul National University Hospital.



Model Adaptation

We proposed a methodology for "model adaptation," substantiated by the validation results for a host hospital. In the scenario, the host hospital was a small institution that may have not had an extensive data set of its own. The institution aimed to use an external data set, provided by a larger donor hospital, as a foundational training set. We assumed that the donor hospital provided its data set to the recipient hospital in an encrypted state. Moreover, we gradually increased the size of the host hospital's data set when training the predictive model to ascertain the volume at which the utilization of its data—when adapting the donated data set as a foundational training set—became effective. The approach was applied to the comprehensive AMC data set, which acted as a donor hospital, on postoperative 30-day mortality; that is, we initiated our study with all the AMC data set and progressively incorporated an increasing proportion of the EUMC and SNUH data sets. EUMC is assumed to be the AMC data's recipient. The AMC provides its own data in an encrypted state to augment the EUMC data set. Thereafter, the encrypted merged data set is used to train a logistic regression model, and inferences are made based on the EUMC's plaintext data. Over the course of this study, the EUMC data set's volume was incrementally increased by steps of 1000, 2000, 3000, and 4000, resulting in the sizes of 0, 1000, 3000, 6000, 10,000, 15,000, and 20,000. The adaptation process was applied with each increase in data size and integrated with the AMC data set, followed by training of the model and a thorough examination of the ensuing performance metrics—the receiver operating characteristic (AUROC) and area under the precision-recall curve (AUPRC). Moreover, we applied the same experimental process to the SNUH data set, using all the AMC data and gradually increasing the former's proportion.

Model Validation

Secure logistic regression with L2 regularization (called ridge regression) was developed using all the possible combinations of multicenter datasets with all input variables. The predictive performances were compared by assessing both the areas under the AUROC and AUPRC; the comparison was performed both numerically and statistically. Furthermore, AUROC and AUPRC were compared using the DeLong test [16].

Statistical Analysis and Modeling Tools

Continuous variables were expressed as mean (SD), while categorical variables were expressed as count and percentage. Continuous and categorical variables were compared among the 3 institutions using one-way ANOVA and chi-squared test, respectively. Variables with 2-tailed *P* values <.05 were considered to hold statistical significance.

We comparatively analyzed feature importance for each institution's data—as represented by the Shapley additive explanations (SHAP) values within logistic regression models—to investigate potential heterogeneity in data distributions across the 3 hospitals under consideration. Feature importance was evaluated using a logistic regression model and performed on plaintext data at each hospital without using HE. Statistical analyses were performed using Python 3.8.16 [17]. The DeLong test was performed using R 4.2.2 [18]. Secure logistic regression was conducted using scikit-learn 1.2.0 [19] and HEaaN.stat 0.2.0 [20].

Results

Study Population Characteristics

The average age of surgical patients at EUMC was the lowest, compared to the other 2 institutions, at 48.5 years (Table 1). Emergency surgeries occurred most frequently at the SNUH, with a rate of 7.4% (Table 1). Postoperative mortality within 30 days was relatively rare across all hospitals, with rates ranging from 0.2% to 0.4% (Table 1). Specifically, the rates were 0.3% at SNUH, 0.2% at AMC, and 0.2% at EUMC. The data characteristics of each hospital are shown in Table 1. When examining the SHA*P* values across all hospitals, we observed significant variation in data distributions, suggesting inherent biases within each hospital's data set, as presented in Figure S4 in Multimedia Appendix 1. Figure S5 in Multimedia Appendix 1 presents the relative odds ratios of the predictor variables affecting the outcome variable in the logistic regression models trained based on each hospital's data set. These odds ratios offer insights into each predictor variable's effect on the likelihood of the outcome and help interpret associations' magnitude and direction. Evidently, the distribution of the odds ratios of the predictor variables affecting the outcome variable differs among institutions. In the EUMC data set, only the age and general surgery department variables are statistically significant. In contrast, the significance of these and other variables varies across institutions, as demonstrated by the diverse distribution of odds ratios affecting the outcome variable depicted in Figure S2 in Multimedia Appendix 1.

Data Preprocessing: Missing Value Characteristics and Standardization

Herein, the average rates of missing values were 0.00% to 7.63% for various features (Table S4 in Multimedia Appendix 1). This discrepancy—particularly in EUMC data for BMI, type of anesthesia, and preoperative glucose—may reflect distinct characteristics inherent to the databases of each hospital (refer to Figure S2 in Multimedia Appendix 1). There was a substantial correlation (absolute correlation value of 0.7 or greater) between variables that were part of collective testing procedures, such as laboratory tests. Conversely, the correlation between other variables was relatively weak, with absolute correlation values below 0.7 (Figure S1 in Multimedia Appendix 1). Variables with a higher incidence of missing values, such as BMI and type of anesthesia at EUMC, did not exhibit significant correlations with the missing values in other variables (absolute correlation value <0.7). The analysis did not reveal any consistent pattern in the occurrence of missing values across the hospitals, implying a random nature of missing data for individual patients at each facility (Figure S2 in Multimedia Appendix 1). Considering this randomness and the low intervariable correlation of missing values, we opted to impute the missing data using the respective variables' median values.

Model Performance

Table 2 presents the validation results of the bootstrapping performance of the secure logistic regression model using various single- and multicenter combinations. Typically, the AMC and EUMC models that already had abundant data delivered superior performance when externally validated using data from other institutions. However, regarding the AMC data set's internal validation, the merged model using the entire data set demonstrated the highest performance, as indicated by AUROC of 0.941. Similarly, the AUPRC signified peak performance in the AMC data set's internal validation when the model merged with the AMC and SNU data sets, reaching 0.132. Figure S3 in Multimedia Appendix 1 provides a comparative visualization of AUROC and AUPRC. Table S3 in Multimedia Appendix 1 presents *P* values, indicative of statistical significance via the DeLong test, when comparing the predictive performance of the plaintext single-institution model and encrypted multi-institution model based on AUROC and AUPRC. Small *P* values signify a statistically significant difference in the 2 models' predictive performance.

Table 2. Validation results of single and merged secure logistic regression models for postoperative 30-day mortality on AMC, EUMC, and SNUH test data sets.

Train	Test		
	AMC[a] (n=32,437)	SNUH[b] (n=9392)	EUMC[c] (n=26,373)

[f]AUPRC: area under the precision-recall curve.

For unencrypted data, we used a plaintext version of the logistic regression model, developed from scratch using NumPy and featuring an architecture identical to that of the HE-based logistic regression model. Further, we evaluated the discrepancies between the results computed in ciphertext and subsequently decrypted, compared to those calculated directly in plaintext. The mean absolute difference was 2.02×10^{-5}, indicating a marginal difference. The minimum absolute difference was remarkably low at 6.56×10^{-10}, while the maximum absolute difference reached 7.71×10^{-4}. This observation suggests that the outcomes—irrespective of whether they are computed in plaintext or ciphertext—demonstrate an almost indistinguishable difference.

Model Adaptation Results

We investigated the scenario of model adaptation wherein we gradually incorporated the data set from another institute. Using the EUMC data set, starting with an AUROC of 0.930, there was an initial temporary decline to 0.906 when the first 1000 records from the EUMC data set were incorporated into the complete AMC data set (Figure 2, Table S2A in Multimedia Appendix 1). As more EUMC records were progressively added, a significant improvement in AUROC was observed, eventually reaching 0.954 (Figure 2, Table S2A in Multimedia Appendix 1). Similarly, the AUPRC initially decreased from 0.09 to 0.075 with the addition of the initial 1000 EUMC data to the total AMC data (Figure 2, Table S2A in Multimedia Appendix 1). However, as we continued introducing more EUMC data, the AUPRC began increasing (Figure 2, Table S2A in Multimedia Appendix 1). Upon the inclusion of 30,000 EUMC records, the AUPRC ascended to 0.11 (Figure 2, Table S2A in Multimedia Appendix 1). Using the SNUH data set, we began with an AUROC of 0.916. The increase was less pronounced than that observed with the EUMC data set (Figure 3, Table S2B in Multimedia Appendix 1). However, as we progressively included segments of the SNUH data set, the AUROC exhibited a moderate trend of progressive improvement, eventually reaching 0.926 (Figure 3, Table S2B in Multimedia Appendix 1). A decrease in the AUPRC from 0.151 to 0.131 was observed

when the first 1000 SNUH data were added to the AMC data set (Figure 3, Table S2B in Multimedia Appendix 1). As more SNUH data were added, the AUPRC gradually increased, improving to approximately 0.149, compared to the AMC single-institution model's performance, once 30,000 data points were included (Figure 3, Table S2B in Multimedia Appendix 1).

Discussion

Overview of Multi-Institutional Model Performance and Implications

This study demonstrated the potential of overcoming limitations associated with single-institution models, such as reduced external predictive power and data overfitting, through secure multi-institutional data integration using HE technology. Our approach effectively adapts predictive models to specific hospital environments, indicating a substantial improvement in model performance across different data sets. The results suggest that small- and medium-sized hospitals with limited data can enhance the predictive performance of their AI models by adopting data from larger hospitals and conducting additional combined learning using HE technology. The significance of this study lies in its practical application and validation of HE technology using real-world, multi-institutional clinical data, laying the groundwork for its potential applicability to various forms of multi-institutional clinical data in future research.

Advantages and Challenges of Multicenter Studies

The transition from single-center to multicenter studies generates large data sets ("big data"), enhancing the robustness and generalizability of research findings. These larger and more diverse data sets increase the accuracy and applicability of the results. However, multicenter studies introduce challenges such as secure and legal data sharing, inherent incompatibility

between data security and research efficacy, and potential biases from selective participant inclusion [21]. To address these issues, researchers are exploring innovative PETs like HE, federated learning, and multiparty computation, which enable secure data analyses while preserving patient confidentiality.

Federated Learning and Comparison to HE

Federated learning has been proposed as a security solution in multi-institutional data environments, as it only shares each local model's weights or parameters. The strength of federated learning—a more decentralized approach than ours—is that no patient-level data are transferred to third parties with or without encryption. However, even with aggregate-level data, such as weights of a model, patient-level information can potentially be inferred [22-25].

In this multicenter study, we used cutting-edge HE to protect personal information leakage and data security. Additionally, HE enables operations and predictive modeling on encrypted data, providing an ultimate solution that can completely resolve issues related to personal information leakage and data security. Furthermore, HE provides the maximum (strongest) security when used appropriately, such as in outsourced computation, wherein HE secures data breaches in computation. In medical fields, HE has been applied to numerous cases for fulfilling privacy requirements [26]. Previous computational inefficiency of HE may have limited its application in computation-intensive steps, such as in developing a prediction model; however, recent advancements have led the technology to be used in practice. The present multicenter study demonstrated that a prediction model can be developed completely without a data breach risk in training using HE.

Limitations and Future Directions

While HE technology allowed secure data integration, it introduced several challenges. Notably, encrypting data led to a marked increase in data size compared to plaintext, intensifying data storage requirements. Additionally, the encrypted model necessitated longer training time. Furthermore, in multi-institutional contexts, such as health care data sharing, key management in multiparty HE becomes a complex, practical challenge. These factors—expanded data size, prolonged training periods, and intricacies of key management—are essential considerations in the effective deployment and ongoing development of secure logistic regression models within encrypted data frameworks.

The study also highlighted limitations in predictive performance when models trained on diverse data sets were applied to individual hospitals. In some data sets, the merged data model's predictive performance fell short of the single-institution data model. This discrepancy indicates a complex interplay between data heterogeneity and model performance, suggesting that predictive performance may not always be enhanced through data augmentation alone, as evidenced in this study. A prediction model may lose prediction power in some institutions when trained using data from institutions with disparate data distributions. Consequently, when implementing a trained model on individual hospital data, we occasionally observed a deviation from our initial expectation that a model trained on the merged set would invariably outperform others.

Another limitation of the study was the reliance on retrospectively collected data, featuring varying extraction periods across institutions. The effects of temporal changes, including advancements in medical technology, were not fully adjusted for, potentially reducing the results' discernibility.

To address these limitations, future research should explore methods for data integration that adjust for heterogeneity. This can be achieved by prospectively collecting data from multiple institutions and conducting comparative studies on predictive performance using HE technology. Such methodologies would help to mitigate the impact of varying data extraction periods and temporal changes in medical technology. Additionally, the use of advanced statistical methods to better account for data heterogeneity might be explored as a promising avenue for further research. These studies would undoubtedly offer invaluable insights into potential strategies for enhancing predictive performance in multi-institutional settings while preserving data privacy and security.

Conclusions

In conclusion, this study demonstrated the practicality of using HE technology to combine data from real-world multi-institutional sources and develop predictive models for in-hospital mortality within 30 days postoperatively. Additionally, we showcased the implementation of privacy-preserving artificial intelligence prediction models. The findings highlight the potential for both practical applications and protection of personal information in the realm of predictive modeling. HE technology should be applied to diverse forms of multi-institutional clinical data in future endeavors to replicate, validate, and extend this study's findings.

Acknowledgments

The work was supported by the National IT Industry Promotion Agency (NIPA) grant funded by the Korean government (MSIT; A0122-23-1194, development of adoption and application technologies of AI solutions specialized in sensitive medical data protection). The research was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute, funded by the Ministry of Health and Welfare, Republic of Korea (grant HR20C0026). Moreover, the study was supported by a grant (2022IF0020, 2023IP0132) from the Asan Institute for Life Sciences, Asan Medical Center, Seoul, Korea. We would like to thank everyone who participated in the study. Specifically, we would like to express our gratitude to Professor Hyung Chul Lee from the Department of Anaesthesia and Pain Medicine at Seoul National University Hospital (SNUH). His assistance in granting us access to the INSPIRE open data set from SNUH for our research was invaluable.

Data Availability

The data set used in the study is not publicly available. However, it can be provided upon reasonable request to the corresponding authors. For the SNUH data set, we used the deidentified open data set, INSPIRE, which was compiled and made publicly available by SNUH. The construction and release of the INSPIRE data set were separately approved by the institutional review board of SNUH (H-2210-078-1368). The codes that support the findings of the study are available for download on GitHub [27].

Authors' Contributions

Abstract

Background: In recent years, the implementation of artificial intelligence (AI) in health care is progressively transforming medical fields, with the use of clinical decision support systems (CDSSs) as a notable application. Laboratory tests are vital for accurate diagnoses, but their increasing reliance presents challenges. The need for effective strategies for managing laboratory test interpretation is evident from the millions of monthly searches on test results' significance. As the potential role of CDSSs in laboratory diagnostics gains significance, however, more research is needed to explore this area.

Objective: The primary objective of our study was to assess the accuracy and safety of LabTest Checker (LTC), a CDSS designed to support medical diagnoses by analyzing both laboratory test results and patients' medical histories.

Methods: This cohort study embraced a prospective data collection approach. A total of 101 patients aged ≥18 years, in stable condition, and requiring comprehensive diagnosis were enrolled. A panel of blood laboratory tests was conducted for each participant. Participants used LTC for test result interpretation. The accuracy and safety of the tool were assessed by comparing AI-generated suggestions to experienced doctor (consultant) recommendations, which are considered the gold standard.

Results: The system achieved a 74.3% accuracy and 100% sensitivity for emergency safety and 92.3% sensitivity for urgent cases. It potentially reduced unnecessary medical visits by 41.6% (42/101) and achieved an 82.9% accuracy in identifying underlying pathologies.

Conclusions: This study underscores the transformative potential of AI-based CDSSs in laboratory diagnostics, contributing to enhanced patient care, efficient health care systems, and improved medical outcomes. LTC's performance evaluation highlights the advancements in AI's role in laboratory medicine.

Trial Registration: ClinicalTrials.gov NCT05813938; https://clinicaltrials.gov/study/NCT05813938

Introduction

In recent times, the implementation of artificial intelligence (AI) within diverse medical domains has garnered significant attention and practical application [1]. AI-driven technology has sparked a transformative wave in health care, introducing inventive solutions to enhance patient care, diagnosis, and decision-making processes [2]. A notable instance of AI's application is evident in the emergence of clinical decision support systems (CDSSs), direct tools designed to streamline health care decision-making [3].

Laboratory tests are essential in modern health care, providing valuable insight into a patient's health status and improving the accuracy of diagnosing medical conditions. The interpretation of laboratory test results is a complex process requiring medical expertise and knowledge. However, the mounting reliance on laboratory testing poses a formidable challenge for health care systems, particularly in regions where tests are often administered without direct medical oversight, as seen in Poland [4].

The significance of this challenge is highlighted by the substantial volume of inquiries related to laboratory test result interpretation, which include identifying potential causes or implications of certain findings and seeking guidance on the next steps or actions based on the test results. Data indicate that, in Poland alone, there are approximately 7 million monthly searches concerning the significance of laboratory test results. On a larger scale, within the European Union, this number escalates to around 82 million monthly searches based on data from SENUTO and Google AdWords [5]. These cases emphasize the need for effective strategies to manage laboratory test interpretation in modern health care settings.

Given the widespread use of laboratory diagnostics, which includes a wide range of tests that analyze blood, urine, tissues, and other bodily fluids to diagnose and monitor diseases, assess organ function, and guide treatment decisions, there is a growing interest in exploring the potential of CDSSs within this realm. The inherent complexities tied to test result interpretation underscore this interest. While the efficacy and safety of CDSSs have been demonstrated in various medical contexts, such as symptom assessment tools [6,7], the integration of CDSSs into laboratory diagnostics remains underexplored.

Several studies have assessed the effectiveness and safety of AI-driven symptom checkers, tools designed to aid patients in self-diagnosing symptoms and making informed health care choices [8-10]. These tools use algorithms and databases to generate potential diagnoses based on user inputs.

A notable study conducted by Semigran et al [11] scrutinized the diagnostic precision of 23 distinct symptom checkers, comparing their outcomes against physician diagnoses. The investigation disclosed that symptom checkers achieved accurate diagnoses in 34% of instances, while physicians achieved 58% accuracy. Despite relatively lower accuracy, the study underscored the potential of symptom checkers in offering reasonable differential diagnoses and supporting patient decision-making.

A more recent study by Hennemann et al [12] evaluated the performance of an app-based symptom checker within the realm of mental disorders. Results revealed that the studied symptom checker demonstrated moderate-to-good accuracy in suggesting conditions for mental disorders concerning formal diagnosis, albeit with variations across disorder categories and interrater reliability. The symptom checker's primary condition suggestion corresponded with interview-based diagnoses in 51% (25/49) of cases, with at least 1 of the initial 5 condition suggestions aligning in 69% (34/49) of cases across the patient cohort. Accuracy fluctuated across disorder categories, ranging from 82% precision for somatoform and related disorders, 65% for affective disorders, to 53% for anxiety disorders. The study concluded that symptom checkers hold promise as supplementary screening tools in the diagnostic process. Still, their diagnostic efficacy requires assessment in more extensive samples and comparison with alternative diagnostic methods.

This paper addresses the status of AI-based technologies in health care, specifically focusing on implementing CDSSs in direct-to-patient tools. After emphasizing the importance of laboratory diagnostics in contemporary health care and the challenges tied to test result interpretation, we examine the existing but limited literature concerning CDSSs' role in laboratory diagnostics, underscoring the need for further research and advancement in this domain. The objective of this study is to evaluate the performance of a novel CDSS named LabTest Checker (LTC) in a cohort of adult patients requiring laboratory testing. The main question it aims to answer pertains to the accuracy and safety of LTC.

Methods

Description of LTC Technology

LTC is an intricate medical software designed to provide assistance in the preliminary medical diagnosis process through the analysis of laboratory test results and comprehensive medical history. By leveraging advanced white-box machine learning algorithms and data analytics, LTC empowers patients and health care practitioners to derive insightful conclusions and make informed decisions. The AI models were trained on a comprehensive dataset encompassing clinical data from electronic health records, public repositories, documented case studies, and expert medical knowledge. LTC seamlessly integrates with existing electronic health record systems, automatically importing patients' latest laboratory results. This triggers a dynamic medical questionnaire presented on a user-friendly tablet interface, typically completed within 90 - 120 seconds, which delves into the patient's medical history, symptoms, and pertinent risk factors. Through this methodical scrutiny and correlation of pivotal data, LTC effectively evaluates an individual's health status and detects potential medical issues, empowering patients and health care providers to establish more accurate diagnoses and improve patient care and outcomes.

Study Setting and Population

The study was conducted at the Emergency Department (ED) of Andrzej Mielecki Public Clinical Hospital in Katowice, Poland, with 8 specialized departments and a total bed capacity of 351. This cohort study embraced a prospective data collection approach. A total of 101 self-referred patients aged ≥18 years, in stable condition, but requiring comprehensive diagnosis were enrolled between December 22, 2022, and March 31, 2023. Comprehensive diagnosis refers to cases where diagnosis based solely on subjective evaluation and physical examination is unattainable, necessitating in-depth assessment through laboratory tests. Inclusion criteria encompassed (1) age ≥18 years and (2) requirement of in-depth laboratory test investigation. The only exclusion criteria was pregnancy. Trained research staff identified and invited eligible patients to participate following an initial medical evaluation to assess eligibility based on the predefined inclusion and exclusion criteria (further details are available on ClinicalTrials.gov [13]). The study achieved a high response rate of 84.9% (101/119), indicating strong participant willingness.

Study Design

This prospective cohort study involved 101 patients, all requiring comprehensive diagnosis beyond subjective evaluation and physical examination. A panel of blood laboratory tests

exceeding the routine diagnostic work-up at the ED, including a lipid profile, erythrocyte sedimentation rate, high-sensitivity C-reactive protein, creatinine, urea, iron, liver enzymes (alanine transaminase, aspartate transferase, and gamma-glutamyl transferase), sodium, potassium, glucose, uric acid, thyroid-stimulating hormone, and complete blood count, was conducted for each participant. LTC was used to interpret these results, and its performance was compared to that of an internal medicine specialist (JC), who reviewed the urgency categorizations assigned by ED physicians and the AI-generated suggestions without prior knowledge of the LTC results. It is important to clarify that JC did not directly assess patients in the ED. Instead, attending physicians in the ED assigned the initial urgency category for each patient based on their clinical judgment. JC then reviewed these urgency classifications assigned by the ED physicians, alongside the assessments generated by the model under study. This 2-pronged approach aimed to ensure the accuracy of the urgency categorizations and provide an additional layer of validation.

Patients presenting at the ED underwent laboratory tests and provided health-related information under a doctor's supervision. This encompassed biometric details, medical history, medications, substances used, family history, symptoms, and prior test results. Based on these data and test outcomes, AI algorithms suggested underlying pathology and diagnostic-therapeutic guidance.

Accuracy and safety were assessed by comparing AI-generated suggestions to experienced doctor (consultant) recommendations, which are considered the gold standard. The consultant, blinded to the LTC results, categorized the urgency of physician interaction for each test (emergency, urgency, routine, and self-care; Table 1). Following this assessment, the LTC results were disclosed to the consultant to evaluate if adhering to LTC recommendations could avoid needless medical visits and whether LTC correctly identified the underlying causes of any abnormal results.

Table . Diagnostic and therapeutic recommendations generated by LabTest Checker (LTC) and specialist recommendations were categorized to assess LTC's precision. Sensitivity for the emergency category was computed as the ratio of LTC's correct emergency identifications to the physician's emergency identifications: *A / (A + B + C + D)*. Similarly, sensitivity for the urgency category was calculated as *F / (E + F + G + H)*. Triage accuracy was calculated as *(A + F + L + R) / total number of patients in the study*. Triage safety as calculated as *(A + E + F + J + K + L + N + O + P + R) / total number of patients in the study*.

Urgency category of contact with doctor, assigned by the consultant	Urgency category of contact with doctor, assigned by LTC			
	Emergency	Urgency	Routine	Self-care
Emergency	A	B	C	D
Urgency	E	F	G	H
Routine	J	K	L	M
Self-care	N	O	P	R

Owing to the technology's design, certain variables were excluded from determining pathology identification accuracy: (1) interpretations labeled as urgent or requiring immediate contact with a doctor were omitted to ensure patient safety and prioritize triage in emergencies, and (2) interpretations categorized as "end of diagnostic - no need for doctor contact" were omitted when results were valid or deviations were insignificant and did not signify pathology.

Ethical Considerations

The study protocol was registered on ClinicalTrials.gov (NCT05813938), and ethical approval was granted by the Bioethics Committee of the Medical University of Silesia (approval code: PCN/CBN/0052/KB1/115/I/22; approval date: November 8, 2022). All patients provided written informed consent before undergoing screening for study eligibility. To ensure privacy and confidentiality, all data collected during the study were anonymized and deidentified before analysis. Participants received no compensation for their involvement in the study. The study involved noninvasive procedures, and the primary intervention was the use of LTC to interpret laboratory test results. Participants were informed that they could seek clarification or assistance from medical professionals while using LTC.

Statistics

A power analysis was performed to determine the statistical power of this study, considering a total sample size of 101 participants in a single group of patients, which was predetermined in the study design. The power analysis was conducted using the G*Power software (version 3.1.9.7; Heinrich-Heine-Universität Düsseldorf). The power analysis was based on a 1-tailed test with an α level of .05. The effect size was calculated at 0.36. Using these parameters and the total sample size of 101, the power analysis indicated that the study would have moderate statistical power to detect a significant effect size within a single group of patients. The estimated power achieved with the given sample size was 0.82, indicating that the study had a reasonable likelihood of detecting meaningful differences within the group.

Outcome measures were prespecified and calculated with 95% CIs. The Wilson score method was used to produce CIs for sensitivity to emergency, sensitivity to urgency, accuracy of triage, safety of triage, and reduction of unnecessary visits. Calculations were performed using the statistical software package *Statistica* (version 13.0 PL; TIBCO Software Inc). Analytic data are presented as point estimates and 95% CIs, with a *P* value <.05 being considered significant.

Results

In the context of this study, the triage accuracy in the 101-patient cohort was 74.3%, with a safety sensitivity of 100% for identifying emergency cases and a sensitivity of 92.3% for detecting urgent cases. The implementation of the system led to a noteworthy 41.6% (42/101) reduction in unnecessary medical visits, and its accuracy in identifying the underlying pathology was 82.9%.

The system classified patients based on urgency: 9 patients required immediate contact; 41 needed urgent contact; 50 warranted routine contact; and 1 did not necessitate doctor contact, falling into the self-care category. Analysis by the consultant revealed disparities in urgency category assignments for 26 patients. Notably, the technology overestimated urgency for 25 patients, including cases where the consultant recommended urgent contact, but the technology indicated immediate or scheduled contact. However, the technology inaccurately assessed the urgency for 1 patient, failing to align with the specialist's urgent contact suggestion, instead proposing scheduled contact. These findings collectively underscore the triage system's effective urgency categorization while also pinpointing areas for enhancement to improve precision, diminish disparities, and prevent false negatives. These findings are detailed in Table 2.

Table . Classification outcomes of diagnostic-therapeutic recommendations proposed by LabTest Checker (LTC) and those provided by the consultant.

Urgency category of contact with doctor, assigned by the consultant	Urgency category of contact with doctor, assigned by LTC			
	Emergency, n	Urgency, n	Routine, n	Self-care, n
Emergency	7	0	0	0
Urgency	1	24	1	0
Routine	1	15	43	0
Self-care	0	2	6	1

Discussion

Principal Findings

The promising results obtained from the evaluation of LTC show the potential of AI-driven tools in assisting patients and medical professionals in navigating the complexities of laboratory test result interpretation. An accuracy rate of 74.3% demonstrates LTC's capability to furnish dependable medical recommendations grounded in blood test results, a development that holds promise for enhancing operational efficiency in the medical domain. Particularly noteworthy is LTC's impressive safety sensitivity of 100% for identifying emergency cases and a high sensitivity of 92.3% for detecting urgent cases. These results imply the system's adeptness in identifying critical scenarios, aligning with its intended role of providing secure and precise medical counsel.

Comparison to Prior Work and Broader Implications

The clinical implications of our findings extend beyond acute care settings. LTC has the potential to revolutionize health care delivery across various domains, including outpatient clinics, preventive care, and direct-to-consumer health management.

In outpatient settings, LTC could streamline triage processes by providing rapid, accurate assessments of laboratory results, allowing health care providers to prioritize patients more effectively and potentially reducing the burden on overstretched health care systems. Additionally, integrating LTC into preventive care programs could empower individuals to monitor their health proactively, fostering early detection and intervention for potential health issues.

The potential impact of LTC on the direct-to-consumer health landscape is equally promising. By providing individuals with accessible and easily understandable interpretations of their laboratory results, LTC could facilitate informed decision-making, leading to earlier detection and more effective management of health conditions. This shift toward proactive health care could encourage individuals to take greater ownership of their well-being.

While the potential of AI-driven CDSSs such as LTC is evident, it is important to acknowledge the nascent nature of this field. One such study by Gräf et al [14] compared physician and AI-based symptom checker diagnostic accuracy, where the AI achieved a diagnostic accuracy of 70%. Furthermore, a systematic review of 10 studies revealed consistently low diagnostic accuracy (range 19% - 37.9%), while triage accuracy (range 48.8% - 90.1%) was relatively higher but displayed variability among different symptom checkers [9]. Our study attempted to adhere to established reporting guidelines for machine learning models [15], but more robust research is necessary to fully understand the capabilities and limitations of AI-powered CDSSs in diverse health care settings.

Strengths and Limitations

While the study yielded promising results, several inherent limitations should be acknowledged when assessing the accuracy and safety of LTC. First, the sample size was relatively small, comprising only 101 participants. Although efforts were taken to ensure analytical strength, a larger and more diverse sample would enhance the generalizability of findings to the broader population. Furthermore, the study allowed participants to seek guidance from medical professionals when faced with uncertainties while filling out the questionnaire, which might not mirror real-world use where such guidance might not be readily accessible. While this provision was aimed at optimizing data quality, it could have potentially introduced an artificial

element, warranting caution when considering the practical implications of the technology's recommendations.

Unexpected results during the experiments included occasional discrepancies between LTC and consultant assessments, indicating potential areas for model improvement. These discrepancies could stem from complex interactions between predictor variables that were not fully captured by the model, suggesting the need for further refinement of the AI algorithms.

These limitations underscore the necessity for future research involving more representative samples and real-world use scenarios to validate the robustness and effectiveness of emerging CDSS technologies. By exploring the intersection of AI and laboratory diagnostics, we aim to lay the groundwork for future progress and foster a deeper comprehension of AI-based CDSSs' potential in reshaping laboratory medicine.

Conclusions

In conclusion, our study demonstrates the transformative potential of integrating AI into laboratory diagnostics through the LTC software. The high accuracy and safety sensitivity achieved underscore the ability of AI-driven CDSSs to identify medical conditions and provide tailored recommendations, enhancing health care decision-making.

As AI continues to evolve within health care, this study validates the promise of AI in medical diagnostics and highlights the need for continued research to refine and expand such tools. By fostering collaboration between AI experts and laboratory medicine specialists, we can unlock the full potential of AI-powered CDSSs, paving the way for a more efficient, personalized, and patient-centered approach to health care.

The results presented here offer a compelling glimpse into a future where AI-driven tools play a pivotal role in optimizing patient care and revolutionizing laboratory diagnostics.

Abstract

Background: Triage is the process of accurately assessing patients' symptoms and providing them with proper clinical treatment in the emergency department (ED). While many countries have developed their triage process to stratify patients' clinical severity and thus distribute medical resources, there are still some limitations of the current triage process. Since the triage level is mainly identified by experienced nurses based on a mix of subjective and objective criteria, mis-triage often occurs in the ED. It can not only cause adverse effects on patients, but also impose an undue burden on the health care delivery system.

Objective: Our study aimed to design a prediction system based on triage information, including demographics, vital signs, and chief complaints. The proposed system can not only handle heterogeneous data, including tabular data and free-text data, but also provide interpretability for better acceptance by the ED staff in the hospital.

Methods: In this study, we proposed a system comprising 3 subsystems, with each of them handling a single task, including triage level prediction, hospitalization prediction, and length of stay prediction. We used a large amount of retrospective data to pretrain the model, and then, we fine-tuned the model on a prospective data set with a golden label. The proposed deep learning framework was built with TabNet and MacBERT (Chinese version of bidirectional encoder representations from transformers [BERT]).

Results: The performance of our proposed model was evaluated on data collected from the National Taiwan University Hospital (901 patients were included). The model achieved promising results on the collected data set, with accuracy values of 63%, 82%, and 71% for triage level prediction, hospitalization prediction, and length of stay prediction, respectively.

Conclusions: Our system improved the prediction of 3 different medical outcomes when compared with other machine learning methods. With the pretrained vital sign encoder and repretrained mask language modeling MacBERT encoder, our multimodality model can provide a deeper insight into the characteristics of electronic health records. Additionally, by providing interpretability, we believe that the proposed system can assist nursing staff and physicians in taking appropriate medical decisions.

Introduction

Background

Emergency services are an essential aspect of the health care system in hospitals, and the demand for these services has increased exponentially in recent years. For instance, due to a rising number of elderly patients, a high volume of low-acuity patients waiting for the emergency department (ED), and limited access to medical resources in the community, it may take a long time for patients to receive medical treatment in the ED. Additionally, the situation has worsened with the shortage of experienced health care providers. In the ED, this can cause many severe clinical outcomes, such as delayed diagnosis, longer patient wait times, and increased mortality rates. Moreover, the patient and the standard health care operation procedure may be disturbed. Therefore, prioritizing ED visits and maintaining the regular operation of the health care system are essential.

Triage is the process of accurately assessing patients' symptoms and providing them with proper clinical treatment in the ED. Patients are assigned different priorities depending on their vital signs and chief complaints, and the judgment description from the nursing staff [1]. Many countries have developed their triage process to stratify the clinical severity of patients and thus distribute medical resources. For instance, the US Emergency Severity Index (ESI), Canadian Triage and Acuity Scale (CTAS) [2], and Taiwan Triage Acuity Scale (TTAS) are designed to improve the triage prioritizing process [3-5]. In terms of personnel, hospitals employ dedicated nurses who have been certified by the authorities to undertake the triage process. It is also essential to maintain the quality of education, training, and evaluation of those professionals, which is more difficult nowadays with the increase in the complexity of emergency care and the increase in the number of patients visiting the ED nationwide [6]. Although many standardized scales have been adopted to improve the process, there are still some limitations of the current triage system [7-9]. Among these issues, the lack of capability to prioritize patients and assign patients to appropriate triage levels is the most serious problem. According to records collected in Taiwan from 2009 to 2015, 167,598 out of 268,716 (nearly 60%) visits in the ED were assigned to level 3 in the triage process. In addition, 5-level triage mainly relies on an experienced nurse's diagnosis that is based on a mix of subjective and objective criteria. Any human judgement errors or even inaccurate measurements that occur during the triage assessment can severely affect the outcome.

Related Work

Contextualized Word Embedding

A word vector is an attempt to mathematically capture the syntactic and semantic features of a word and represent its meaning simultaneously. Computers calculate how often words appear next to each other by going through a large corpus. For instance, with GloVe [10] or word2vector [11], the word can be projected into a high-dimensional vector for further tasks.

Although these traditional word embedding methods are easy to understand and simple to implement, some limitations still need to be addressed. For example, after applying word vectors, it would be tough to train systems equipped with the softmax function owing to a large number of categories. On the other hand, the GloVe word embedding involves a numeric representation of a word regardless of where the word occurs in the sentence and the different meanings the word may have. Hence, several language models have been proposed to address these limitations, including embeddings from language models (ELMo) [12], bidirectional encoder representations from transformers (BERT) [13], and generative pretrained transformer (GPT) [14]. These celebrated language models generate general contextualized sentence embeddings by using a large scale of unlabeled corpora.

Among these famous models, BERT is the most popular model commonly used in solving natural language processing (NLP) tasks. BERT is a language model trained bidirectionally, which means that as compared to single-direction language models, it can provide a more profound sense of language context and flow. Moreover, instead of predicting the next word in the sentence, BERT also uses a novel method called "mask language modeling" (MLM). This novel algorithm randomly masks the words and then predicts them. BERT relies on the transformer architecture; however, since BERT aims to generate a language representation model, it only uses the transformer encoder by stacking them up. Later, with the help of MLM and "next sentence prediction" (NSP), BERT can achieve significant performance on lots of NLP downstream tasks by further fine-tuning on specific domains.

Deep Learning for Tabular Data

In statistics, tabular data refer to data organized in a table. Within the table, the rows and columns represent observations and attributes for those observations, respectively. Although many domains like vision, NLP, and speech enjoy the benefit of deep learning models, tabular data using deep learning methods remain questionable. On the other hand, when it comes to handling tabular data, the traditional machine learning method dominates most of the benchmarks and is commonly used in competitions, such as Kaggle, around the world. The conventional machine learning methods include methods based on decision tree (DT) such as extreme gradient boosting (XGBoost) [15], category boosting (CatBoost) [16], and light gradient boosting machine (LightBGM) [17]. The strength of these DT-based methods is that their output is easy to understand and available to provide interpretability without requiring any statistical knowledge. However, there are still some limitations of DT-based methods. Among these limitations, the most serious is that DT-based methods do not allow efficient learning with image or text encoders. Hence, many experts turn to deep learning methods instead of DT-based methods. Deep learning models enable end-to-end learning for tabular data and have many benefits at the same time. First, they can achieve better performance in a bigger data set. Second, they can alleviate the need for feature engineering. Finally, they encode multiple data types efficiently, like images along with tabular data.

However, the shortcoming of most deep learning methods is that they cannot provide interpretability. Fortunately, researchers have been aware of the problem in recent years, and several

deep learning models with interpretability have been proposed, such as TabNet [18], neural oblivious decision ensembles (NODE) [19], and TabTransformer [20].

Current Work in the Triage System

Although current triage systems, such as the ESI and TTAS, follow clear guidelines to assign patient acuity, it implicitly leaves room for clinician interpretation. Hence, the diagnosis still depends heavily on the judgment and experience of individual nursing staff. Several studies have shown that cognitive biases can influence clinical judgments [6]. In written case scenarios at multiple EDs, the average accuracies of nurses were 56.2%, 59.2%, and 59.6% in Taiwan, Brazil, and Switzerland, respectively [21]. In view of this, some studies [6,21,22] have turned to the use of artificial intelligence (AI) systems to assist with decision-making in triage. They also demonstrate the system's effectiveness with higher accuracy from the assisted means.

Numerous studies have attempted to use traditional machine learning methods in their approaches. Choi et al [6] used 3 types of conventional machine learning methods, including logistic regression, random forest, and XGBoost, to predict the Korea Triage Acuity Scale (KTAS) level. They used patients' chief complaints as categorical features, meaning that they assigned a key code to each symptom. Their best model using random forest achieved precision, recall, and area under the receiver operating characteristic curve values of 0.737, 0.730, and 0.917, respectively. Liu et al [22] used CatBoost as their model; however, the study focused on distinguishing the mis-triage of patients in levels 3 and 4 since they believed that the under-triage of critically ill patients could be life-threatening. Their model was able to reduce the life-threatening mis-triage rate from 1.2% to 0.9% prospectively. Ivanov et al [21] carried out a series of experiments to demonstrate the effectiveness of their novel idea "clinical natural language processing (C-NLP)." To cope with free-text data, C-NLP uses sentence tokenization, word tokenization, and part-of-speech tagging to extract the meaning behind free-text data. Their best model included C-NLP and XGBoost, and it was able to achieve an accuracy of 75.7%, which is 26.9% higher than the average nurse's accuracy.

The previously mentioned studies [6,21,22] achieved great performance in dealing with triage-level problems; however, these methods still have some limitations. Our proposed model aims to address these limitations and alleviate them. Multimedia Appendix 1 presents comparisons between earlier work and our study in different aspects.

Goal of This Study

Although the studies mentioned in the previous section successfully demonstrated that AI improved the triage system for predicting triage level, they unfortunately had some serious drawbacks. In this study, we attempted to overcome these drawbacks while developing an appropriate prediction system based on triage information, including demographics, vital signs, and chief complaints. We propose a system that can handle the collected heterogeneous data, including tabular data and free-text data. The proposed system is capable of providing precise suggestions for ED staff in hospitals, and it has interpretability for better acceptance by users. Moreover, it is applicable to real-world situations.

Methods

System Overview

In this study, we have proposed a system comprising 3 subsystems, with each of them handling 1 task. As shown in Figure 1, these tasks include triage level prediction, hospitalization prediction, and length of stay prediction, which are important outcomes in the ED of a hospital. Since these subsystems are developed in a similar training process, we will first introduce the conceptual level of the typical training process of each model in each subsystem and then provide further information. Finally, we will show the detailed design of each model in each subsystem.

Our study focuses on establishing an effective and precise AI system to predict the criticality of patients waiting in the ED of hospitals. By leveraging a model trained on a data set where data labels include different scales, we look forward to developing a robust model that can provide more information to the physician and nursing staff. Moreover, to assist them in making precise medical decisions, our proposed system offers multiple prediction outcomes, including triage-level classification, hospitalization estimation, and length of stay.

The system flowchart is shown in Figure 2. The system can be divided into 3 stages: pretraining stage, fine-tuning stage, and testing stage. Additionally, 2 data sets were used in our study. One was the National Taiwan University Hospital (NTUH) retrospective data set, and the other was the NTUH prospective data set collected from May 26, 2020, till February 21, 2022. These 2 data sets will be elaborated in the following sections.

In the pretraining stage, a large amount of retrospective data were used to pretrain the encoders to learn the basic information of the medical data. In addition, the pretrained encoders were transferred to the second stage. In the fine-tuning stage, we used prospective data with golden labels to fine-tune the pretrained encoder. Therefore, when the diagnosis outcomes from the physician are treated as the ground truth label, the model is more applicable to real-world situations. Finally, in the testing stage, we implemented our system in the hospital and assessed the effectiveness of the system.

Ethical Considerations

This study has been approved by the NTUH Institutional Review Board (201606072RINA, 201911054RINA, 202108090RINC).

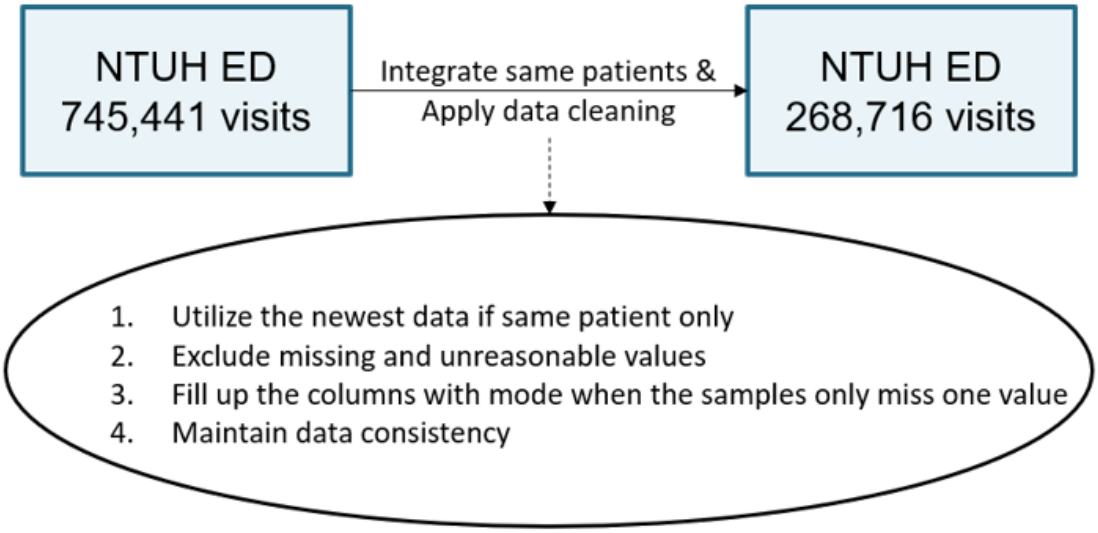
Data Preparation

NTUH Retrospective Data Set

The NTUH is a tertiary academic medical center that has almost 2400 beds and 100,000 emergency room visits per year. After receiving approval from the NTUH Institutional Review Board, we obtained the NTUH retrospective data set, which contained a total of 745,441 electronic health records (EHRs) of patients who visited the ED from the years 2009 to 2015. Since triage is the starting point of care for the ED, it is essential to ensure consistent and precise estimation of patients. The records were evaluated by dedicated personnel who were certified by the Taiwan Union of Nurses Association (TUNA), following a standard protocol.

As shown in Figure 2, in the first stage, we used the NTUH retrospective data set to pretrain our model. However, in the NTUH retrospective data set, we needed to unify the uncleaned data (Multimedia Appendix 2) initially as the members of the nursing staff have their own ways to record the estimation. We included all patients aged 20 years or older who attended the ED and excluded patients whose EHR data contained missing or unreasonable values. Unreasonable data had unreasonable values, which may have resulted from typing errors. For instance, the diastolic pressure and systolic pressure may be typed in reverse, or a nurse may accidentally omit a digit when entering values on the computer. In such a scenario, even though we may be able to infer the original intended values by examining individual data, we cannot consider this a correct sample for use. After data cleaning and merging, only 268,716 patients were enrolled in our program (Figure 3).

Figure 3. Preprocessing of the National Taiwan University Hospital (NTUH) retrospective data set. ED: emergency department.



NTUH Prospective Data Set

Each patient who visits the ED will have a PDF document form generated (triage examination and evaluation record). These records are kept for the physician to make a diagnosis. The records comprise 2 types of information. The first is structural data, including patient demographics, triage information, and vital signs, and the second is textual data, including chief complaints, historical medical information, and drug allergy.

In general, it is impossible to directly use the aforementioned records to train the model, and thus, data preprocessing is needed to extract the data from the records. We used the PDFMiner library in Python code to extract the information from the document forms as "structural data" and applied a transformation function to generate "textual data."

The information extracted from the forms and records can be divided into 2 groups: target prediction and patient feature. Detailed explanations of the patient features are provided in Table 1. On the other hand, the target ground truth contains 3 different tasks. The first task is triage level prediction, which is a 4-class classification problem, where the physician's suggestion is considered (golden standard label that is obtained from the physician by observing the process of patient diagnosis) instead of the traditional triage level. A lower level indicates that the patient more urgently requires immediate attention. The second task is hospitalization prediction, which is a 2-class classification problem, where "0" represents that the patient needs to be discharged by the hospital and "1" represents that the patient needs to be admitted. The last task is length of stay, which is a 3-class classification problem, where "0" represents that the patient will stay in the ED for less than 6 hours, "1" represents that the patient will stay in the ED for 6 to 24 hours, and "2" represents that the patient will stay in the ED for more than 24 hours.

Table 1. Detailed explanation of structural variables.

Variable	Explanation
Demographics	
Age	Patient age
Sex	Patient gender
Triage information	
Session	Patient arrival time
Return in 24 hours	Number of times the patient revisited the ED[a] in 24 hours
Clinic visit mode	Patient arrival mode
Work related	Whether the patient visited the ED because of a work accident
On the way to work	Whether the patient was on the way to work before visiting the ED
Vital sign information	
Systolic pressure	Systolic blood pressure
Diastolic pressure	Diastolic blood pressure
Pulse	Pulse
Oxygen	Oxygen saturation
Respiration	Respiration
Body temperature	Body temperature
Acute change	Any acute changes before entering the ED
Fever	Whether the patient has fever
Pain index	Self-evaluated pain score
GCS-E	Glasgow Coma Scale score of the patient (eye opening)
GCS-V	Glasgow Coma Scale score of the patient (verbal response)
GCS-M	Glasgow Coma Scale score of the patient (motor response)
Major disease	Whether the patient has an IC[b] card for severe illness
Admission count	The number of times the patient went to the hospital in 1 year
Judgement code	The judgement code for describing the patient's condition
Textual data	
Chief complaint	The patient's description of the symptoms
Judgment description	The record that describes the patient's symptoms written by the nursing staff

[b]IC: integrated circuit.

Data Augmentation

After analyzing our prospective data set, we observed an imbalanced data distribution. As machine learning algorithms tend to increase accuracy by reducing errors, most of them are biased toward the majority class and tend to ignore the minority class. For instance, 758 out of 901 (84.1%) ED patients were discharged from the hospital in our prospective data set, and the system could achieve 85% accuracy if it kept on predicting discharge. However, we did not want the system to only indicate discharge. Therefore, to avoid the above situation, we used the "synthetic minority oversampling technique" (SMOTE) to generate some synthesized data to ensure that the system could learn the different patterns between each class. In our study, the iteration of the SMOTE algorithm started by selecting 1 minority sample and finding its top 5 nearest neighbors. These 5 neighbors were chosen to generate new synthesized data by the interpolation method. Finally, the iteration was repeated several times until we obtained the minority class where the number was the same as that of the majority class. However, as the synthesized data may be too diverse, some of the data can have negative influences on the model. Therefore, we used the Tomek Links algorithm to remove some ambiguous data that may hurt model performance by pairing samples and removing the pairs with different labels. An example of the augmentation process is shown in Multimedia Appendix 3. In the original data set, we can observe that only 143 patients are admitted. After applying the SMOTE algorithm on our data set, the number of admitted patients increases to 758. We then use the Tomek Links algorithm to remove some samples that are regarded as

ambiguous samples by the algorithm. Finally, in this example, a total of 1294 patients are included in our new augmented prospective data set.

As for text data, since the SMOTE algorithm cannot generate text, we set up a mapping relation to add the text feature for each synthesized sample. First, we created a number of lists, each of which stores the chief complaints from data samples sharing the same class label. After these lists and the synthesized data were ready, for each synthesized sample, we randomly selected 1 chief complaint from the list according to its label and added it as a text feature of the synthesized sample.

Pretraining of the Vital Sign Encoder

The TabNet architecture is composed of feature transformers and attentive transformers. In TabNet's design, the mask from the attentive transformer can select the most vital feature from several features, eliminating noise caused by irrelevant features. Furthermore, the mask can be calculated to provide some interpretable information about the feature's importance. Therefore, considering the objective of this study, our work takes advantage of the encoder-decoder architecture of TabNet, which is inspired by Arik [18], and we adopted this architecture to construct our vital sign encoder (Figure 4).

Before training on the prospective data set, the vital sign encoder was pretrained on retrospective data by unsupervised learning to learn some basic information about such structural data. Structural features of demographics, triage information, and vital sign information (Table 1) were used in this step.

Figure 5 shows the process used for pretraining our vital sign encoder. In triage level prediction and length of stay prediction, since we did not have a triage golden label and length of stay label for pretraining the vital sign encoder, we used only unsupervised learning. On the other hand, both unsupervised learning and supervised learning were used for hospitalization prediction. The reason why we used the unsupervised learning algorithm is that the model can discover hidden data patterns without human intervention by analyzing and clustering the unlabeled information.

Figure 4. Vital sign encoder architecture (adapted from TabNet). FC: fully connected networks; ReLU: rectified linear unit.

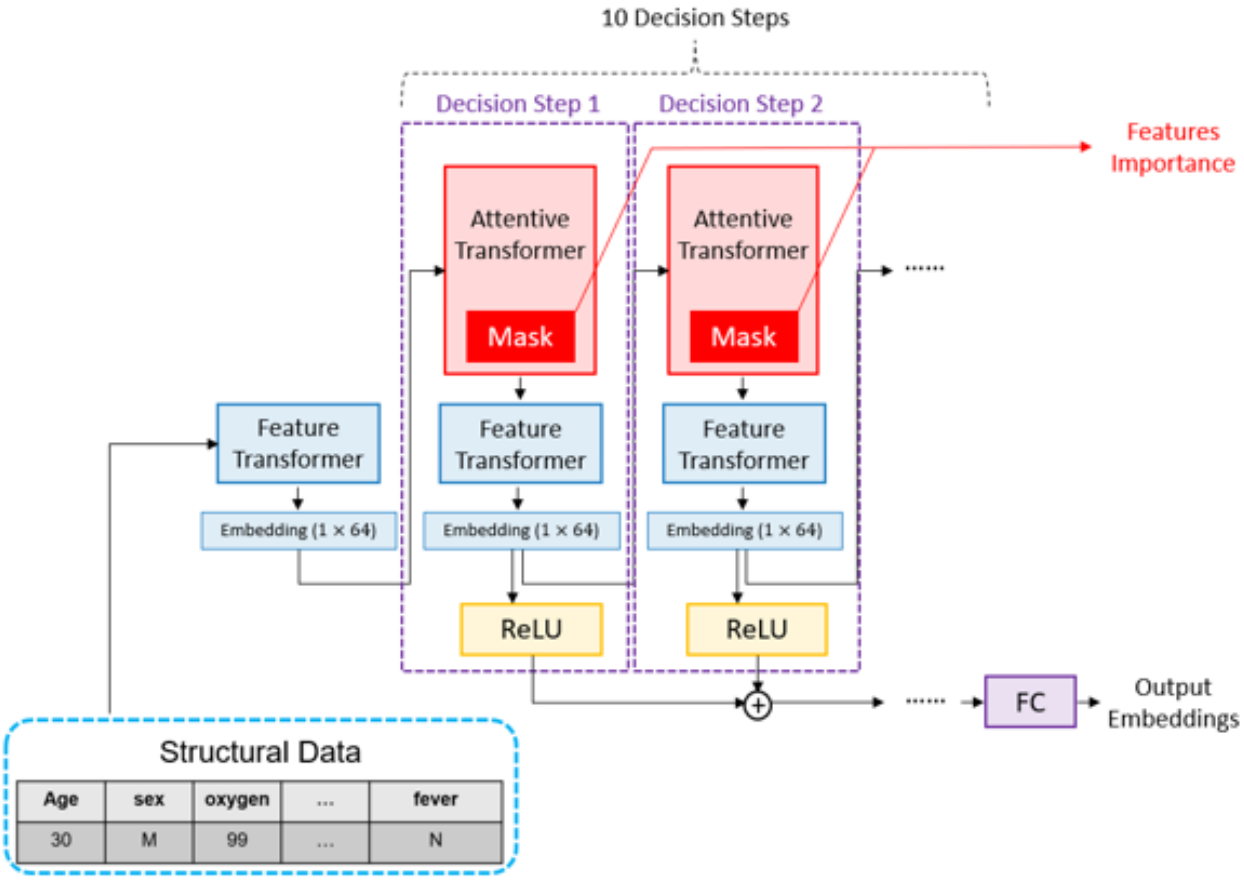

Figure 5. The flow of pretraining the vital sign encoder.

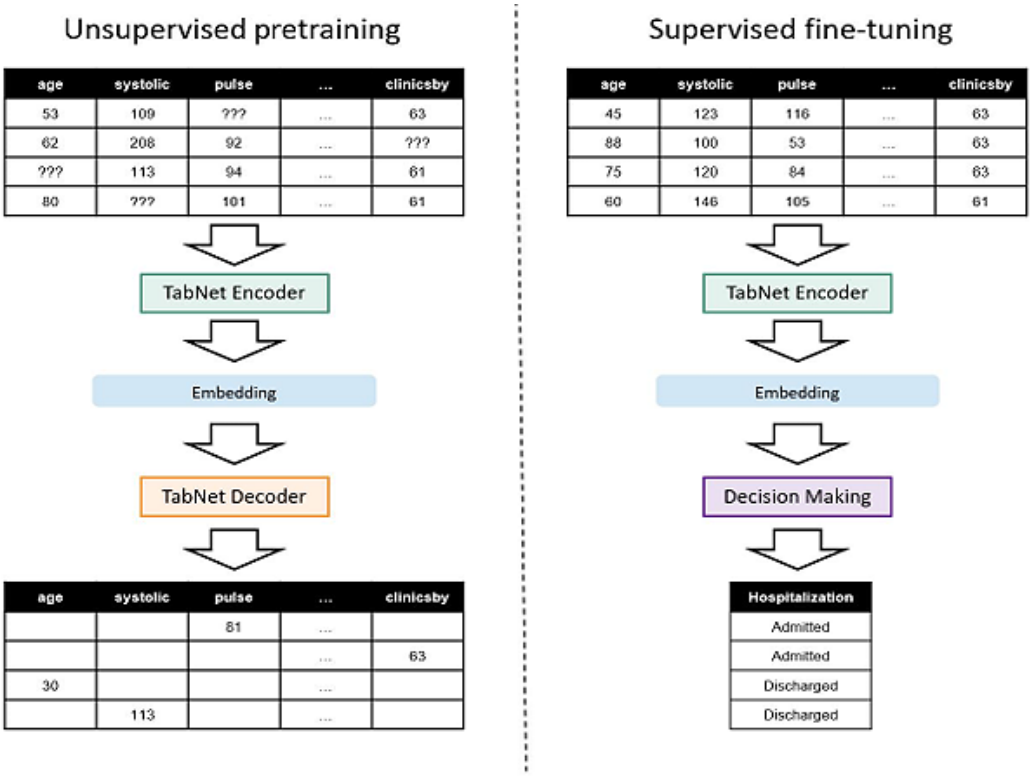


In our study, we used the encoder-decoder architecture. We masked some of the input features in our data and then reconstructed the masked features. The reconstruction loss during unsupervised learning is described as follows:

where B denotes the batch size, D denotes the dimension of features (number of features), S is a binary mask sparse matrix with size B×D for masking some of the features, and $f_{B\times D}$ and  are matrices of features with size B×D representing the ground truth feature values and the predicted outputs, respectively [18].

The purpose of Equation 1 is to calculate the distance between the ground truth feature and the predicted feature. In each iteration, the binary mask $S_{b,j}$ is sampled independently from Bernoulli distribution, and the mask can only have a value of 0 or 1. During this process involving the masked value and its reconstruction, models are believed to learn implicit relationships between features.

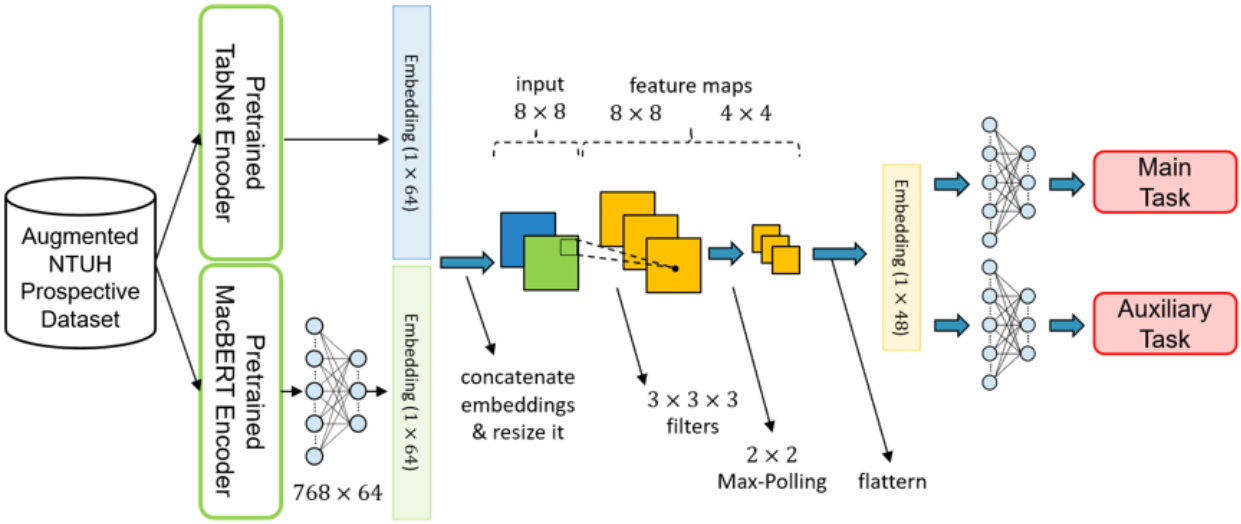
Pretraining of the MacBERT Encoder

BERT is a well-known language model that can be used to transform a word into a representation and understand the meaning behind the sentence. In addition, it performs consistently better than other language models (eg, ELMo [12] and GPT [14]) and also performs well in many different tasks. However, although the BERT model can be easily fine-tuned with an additional output layer to achieve outstanding performance, the pretraining process of the model is designed for general purposes. In this study, to better understand our medical data, we repretrained MacBERT (Chinese version of BERT) by applying MLM again. We extracted the text information from the NTUH prospective data set and then used the information to accomplish further training of MLM. All the settings of the training process followed the original set in MacBERT. By further training with MLM, the fine-tuned MacBERT could enrich its knowledge in specific domains.

Overall Model Architecture

The typical model architecture of each subsystem is shown in Figure 6. After the pretrained encoders are ready, the encoder weights are copied to the fine-tuning stage encoders. The typical model architecture can be divided into 4 main parts: input, encoders, classifiers, and output. First, in the input part, there are 2 data types, namely, structural data and free-text data. Since the prospective data set has only a limited amount of data, we sent it to the augmentation algorithm to obtain synthesized data and added them to the original data set. Second, the structural data and the free-text data are sent to the pretrained TabNet encoder and the pretrained MacBERT encoder, respectively. Afterward, to obtain a comprehensive representation of the data, 2 embeddings coming out from the pretrained TabNet encoder and pretrained MacBERT encoder are concatenated together. Third, the concatenated embeddings are passed through classifiers for output prediction.

Figure 6. Typical model architecture in the fine-tuning stage. MacBERT: Chinese version of bidirectional encoder representations from transformers; NTUH: National Taiwan University Hospital.



Input

We used the augmented NTUH prospective data set in the fine-tuning stage. The data set contains 2 data types. The first is structural data, including patient demographics, triage information, and vital sign information. The second is free-text data, including patient chief complaints, nursing staff judgment descriptions, and transformed information from the structural data (Multimedia Appendix 4). However, since MacBERT is a Chinese BERT model, which is trained on simplified Chinese, we translated our text data from traditional Chinese to simplified Chinese to achieve better performance.

Encoders

As shown in Figure 6, since there were 2 types of data to be processed, we used the TabNet encoder and MacBERT encoder to extract feature information from structural data and free-text data, respectively. We then transformed these information pieces into high-dimensional embeddings for further training.

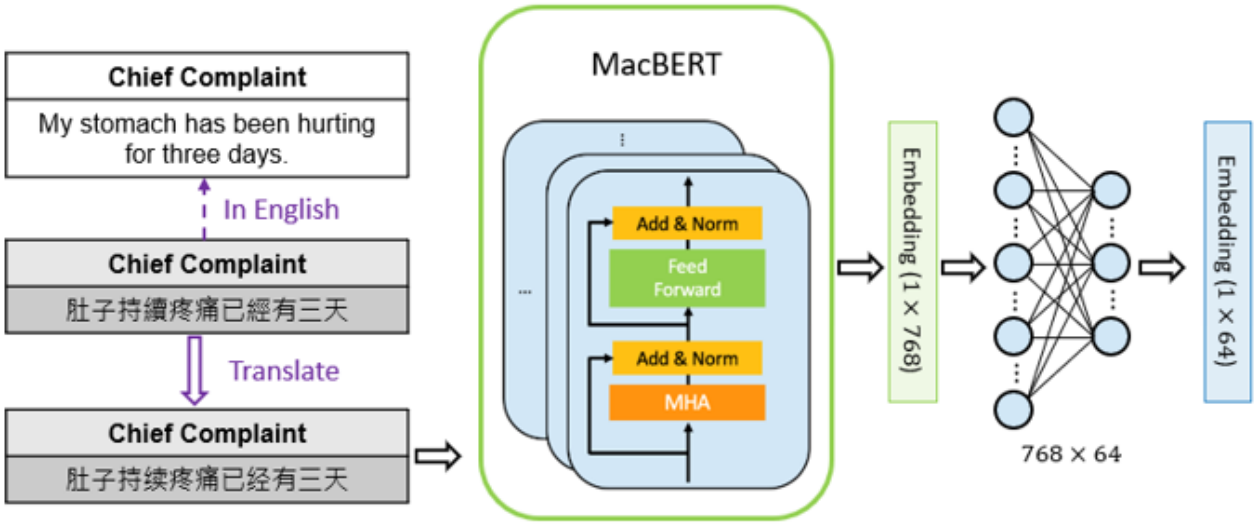
Pretrained Vital Sign Encoder

We used the pretrained TabNet encoder as our vital sign encoder. In the pretraining stage, we obtained some basic information of these medical data from the NTUH retrospective data set. As a result, to achieve better starting, the pretrained weights were directly deployed into our vital sign encoder. We stacked up 10 decision steps to build our vital sign encoder, and the dimensions of both the input and output were set to 64. A 1×64 vector was the final context vector.

Pretrained Language Model Encoder

As chief complaints are manually recorded by nurses and most of them are written in traditional Chinese, it is better to find a language model that has been trained on a Chinese corpus and can handle Chinese text well. MacBERT is an improved BERT model with novel MLM as a correction pretraining task, which mitigates the discrepancy between pretraining and fine-tuning. Moreover, it has been trained on simplified Chinese corpora, which is more suitable for our work. As a result, we decided to adopt MacBERT from Hugging Face as the chief complaint text encoder in our proposed model, instead of the original BERT model. On the other hand, we observed that the text in our data set might contain different languages, including English and Chinese. Therefore, to make MacBERT applicable to our case, we translated the text into a uniform language, namely, simplified Chinese, before sending it into MacBERT. However, since we wanted the contributions from the vital sign encoder and the MacBERT encoder to be comparable, a fully connected layer was placed after the output vector from MacBERT to decrease the vector dimension from 1×768 to 1×64. The entire process explaining how we handled the text data is shown in Figure 7.

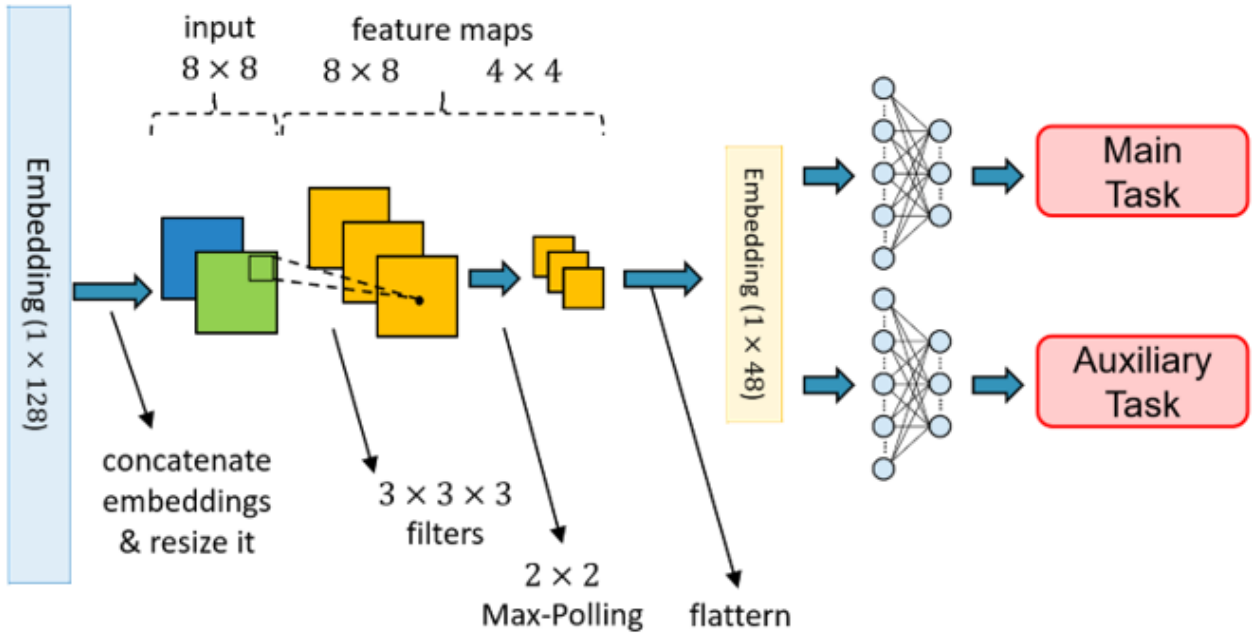
Figure 7. The entire process of handling text data. MacBERT: Chinese version of bidirectional encoder representations from transformers.



Classifiers

All the inputs were encoded into high-dimensional embeddings by the encoders mentioned in the previous stage. It is believed that both embeddings have different facets of information; therefore, instead of adding these vectors together, we concatenated these 2 vectors to obtain richer patient information before sending them into the classifiers. Moreover, in our study, we adopted the multi-task learning architecture to learn shared representation and avoid overfitting problems. As a result, there were 2 classifiers for predicting different targets, where each classifier had a 1-layer convolutional neural network and a 2-layer multi-layer perceptron. The details of the process are shown in Figure 8.

Figure 8. Components of the classifiers.



Output

In contrast to most single-output machine learning methods, our proposed model has a multi-task model architecture. Multi-task learning is a type of machine learning method by which the multi-output outcome can be learned simultaneously in a shared model. In addition to the data efficiency advantages, such an approach can reduce overfitting by leveraging auxiliary information and allowing fast learning. Since target prediction loss will update the encoders, the encoders can avoid being overfitted and learn more general knowledge. As there were 3 medical outcomes in our system, we designed 3 models with slight differences to handle different tasks. The details of these 3 models are shown in Figures 9 to 11.

Figure 9. The model architecture of triage level prediction. FL: focal loss; MacBERT: Chinese version of bidirectional encoder representations from transformers; NTUH: National Taiwan University Hospital.

$$Loss_{total} = FL_{triage} + 0.5 \times FL_{hos} + 10^{-3} \times Loss_{sparse}$$

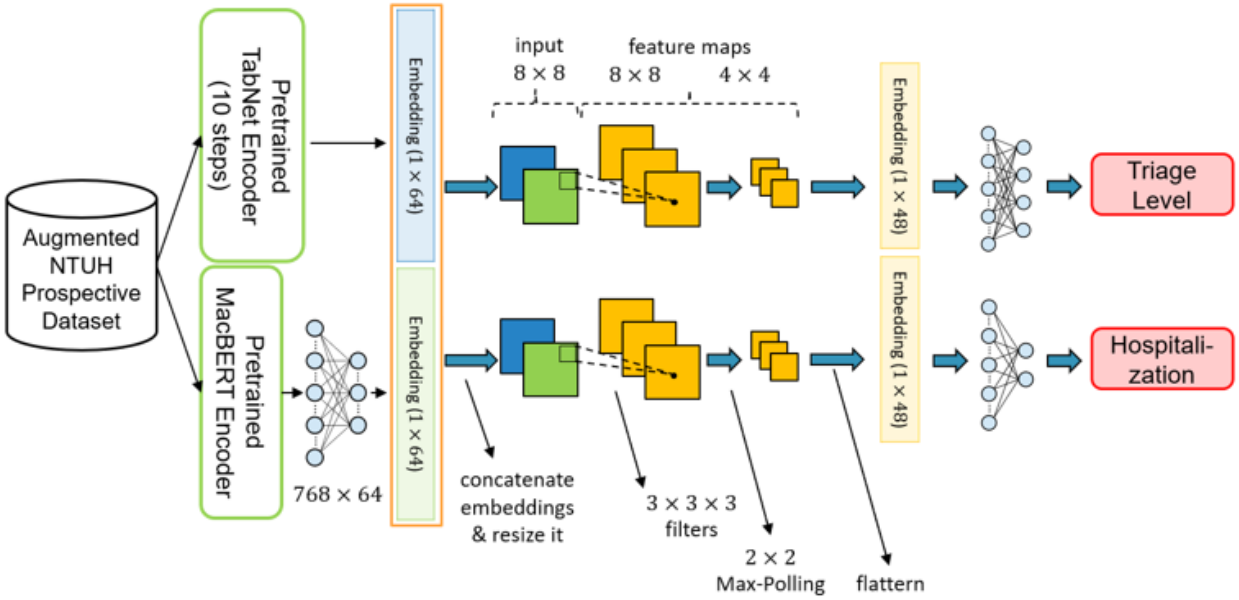


Figure 10. The model architecture of hospitalization prediction. FL: focal loss; MacBERT: Chinese version of bidirectional encoder representations from transformers; NTUH: National Taiwan University Hospital.

$$Loss_{total} = FL_{hos} + 0.3 \times FL_{triage} + 10^{-3} \times Loss_{sparse}$$

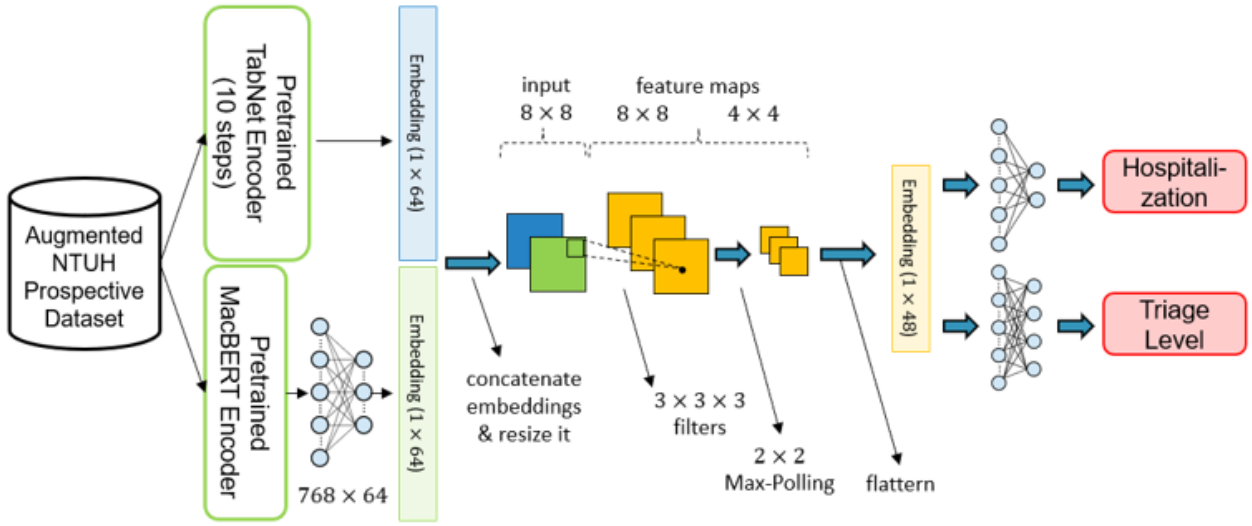

Figure 11. The model architecture of length of stay (LoS) prediction. FL: focal loss; MacBERT: Chinese version of bidirectional encoder representations from transformers; NTUH: National Taiwan University Hospital.

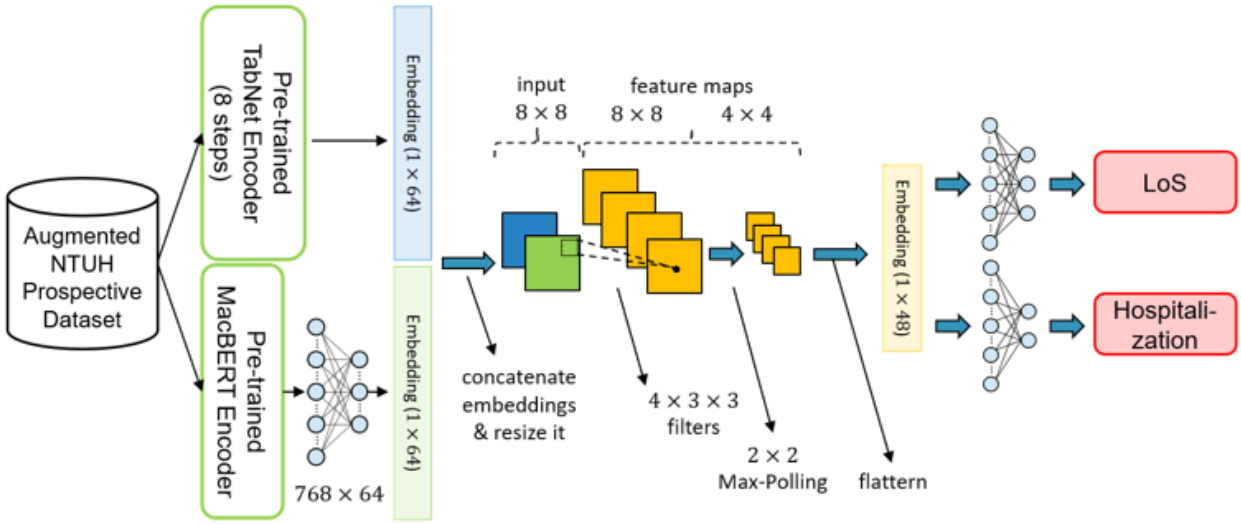
$$Loss_{total} = FL_{LoS} + 0.3 \times FL_{hos} + 10^{-3} \times Loss_{sparse}$$



Loss Function

Total loss combines focal loss and sparse entropy loss as follows:

where λ_1 is a hyperparameter for determining the learning direction of the model via controlling the balance between the main task and related task, and λ_{sparse} is a hyperparameter for controlling the sparsity of the TabNet encoder, where a greater parameter is associated with a greater effect of the tabular data on the entire model, and the TabNet encoder tends to select 1 feature in 1 decision step.

In order to assess the performance of the model, the focal loss function was utilized by comparing the ground truth label with the probability distributions over network predictions, which has been shown as follows:

where $\hat{y}$ is the model prediction, y is the ground truth value, superscript i refers to sample i, y_k is 0 or 1 (indicating whether a class label is the correct classification among K classes),  denotes the confidence score of class k, and γ is a hyperparameter that is set to 2 in our study.

TabNet uses sparse entropy loss (first proposed in [23]) to provide a favorable inductive bias for data sets where most features are redundant. The sparse entropy loss can not only help the model to select salient features from all attributes of the sample, but also fasten the training process. The equation is as follows:

where N_{steps} denotes how many decision steps are stacked up in the model, B is the batch size, D is the total number of features, M represents the mask, $M_{b,j}$ [i] refers to the mask at the i^{th} step with batch sample b and feature j, and ε is a small number to maintain numerical stability.

Results

Experimental Setup

A series of experiments were conducted to validate the effectiveness of our design. The details of our system environment are presented below. We conducted our experiments on the Ubuntu 20.04 operating system with PyTorch 1.7.1 and Python 3.9.7, and all training procedures were performed on a computer with a Nvidia RTX 3090 graphics card, an Intel Core i7-1070K processor, and 32 GB of RAM.

Training Settings

The Adam optimizer with an initial learning rate of 0.01 was used in our experiments, and it was adjusted by the "ReduceLROnPlateau" scheduler with the patient value set as 15. Meanwhile, if the loss did not improve for 50 epochs, an early stop action was taken.

All experiments were carefully conducted in the following steps: (1) The data set was divided into 3 parts (training set, validation set, and testing set in the ratio of 8:1:1); (2) The training set was used to generate synthesized data to make up the gap between classes, and the synthesized data were added into the original training data set; (3) Our design was evaluated by taking the average test performance for 10 trials, as the division of the data set might have varied effects on the experiment results.

Evaluation Metrics

Since our data set was obviously imbalanced, the accuracy performance cannot represent the effectiveness of our system. As a result, in our experiment, the evaluation metrics included

precision, recall, and F1-score. Precision measures the rate of ground truth classes that are predicted correctly. Recall measures the portion of each class of our prediction that is actually that class. Finally, F1-score represents the harmonic mean between precision and recall. Their formulas are as follows:

where TP, TN, FP, and FN denote true positive, true negative, false positive, and false negative, respectively.

Data Characteristics

Our study included 2 data sets. One data set was the NTUH retrospective data set, which contains a collection of the past EHRs of 268,716 visits from 2009 to 2015, and the other data set was the NTUH prospective data set, which contains data collected with patient consent in the NTUH ED from May 26, 2020, to February 21, 2022, and includes 901 ED patient records after removal of unreasonable and missing data. Table 2 summarizes the data characteristics of vital sign information in these 2 data sets. Despite similar average values across all fields in the 2 data sets, on performing statistical tests using *P*-values, we found that there was a significant difference between the 2 data sets. However, we believe that using data with the same data collection background but different distributions can still effectively improve the robustness and generalization ability of the model. By pretraining on diverse data, the model can learn more general representations, leading to improvements in the final predictions.

On the other hand, the distributions for different tasks are shown in Multimedia Appendix 5. It is worth mentioning that the distribution gap of the triage level between the retrospective data set and prospective data set was greater than the distribution gaps for hospitalization and length of stay. This is because hospitalization and length of stay are based on facts, and in contrast to the triage level in the retrospective data set, the triage level in the prospective data set comes from physician diagnosis. As it is believed that the doctor's triage level can assign patient acuity more accurately, we used it as our golden label for predicting the triage level. Another reason for the distribution gap could be the difficulty in collecting data from more severe patients.

Table 2. Patient characteristics in the National Taiwan University Hospital retrospective and prospective data sets.

Variable	NTUH[a] retrospective data set	NTUH prospective data set
Age (years), mean (SD)	49.1 (19.98)	52.4 (18.98)
Sex, n (%)		
Female	141,783 (52.8)	450 (50.1)
Male	126,933 (47.2)	450 (49.9)
Arrival time, n (%)		
7 AM to 3 PM	10,2256 (42.8)	518 (57.4)
3 PM to 11 PM	11,4970 (38.0)	289 (32.1)
11 PM to 7 AM	5,1490 (19.2)	94 (10.5)
Systolic blood pressure (mmHg), mean (SD)	136.3 (26.79)	132.4 (24.78)
Diastolic blood pressure (mmHg), mean (SD)	80.8 (15.22)	79.8 (13.91)
Pulse (beats/min), mean (SD)	88.8 (18.74)	89.5 (18.74)
Oxygen saturation (%), mean (SD)	97.0 (3.09)	97.7 (1.69)
Respiration (breaths/min), mean (SD)	18.2 (2.16)	18.8 (2.04)
Body temperature (°C), mean (SD)	37.0 (0.82)	36.7 (0.65)
Pain index (scale), n		
0	134,292	357
1-3	9,554	368
4-6	60,526	140
7-10	64,344	36

[a]NTUH: National Taiwan University Hospital.

Experimental Results

We compared our model's performance regarding triage level, hospitalization, and length of stay against the performance of other machine learning methods. As the data of only 901 ED visits were finally included in our study, it was a challenge to obtain a robust model with great capability to identify critical patients.

Unlike other work on triage level prediction, since we endeavored to fix the bias of traditional rule-based system triage, such as the ESI and TTAS, we used the diagnosis results provided by the physician as our golden label. As shown in Table 3, it is worth noting that our triage model achieved a nearly 30% improvement in 4 metrics, including accuracy, precision, recall, and F1-score, when compared to the results obtained from other models. These outstanding results show the promising potential of our proposed model.

As shown in Table 4, we can observe that our hospitalization model achieved the highest performance in 3 metrics, including precision, recall, and F1-score. Although the support vector machine (SVM) model achieved an accuracy of 91.2%, it may tend to predict the majority (discharge) owing to the low precision and recall values. From the previous discussion, it can be seen that our model is the most discriminative model.

Additionally, our proposed model outperformed other models. Although the study design and data set in our study are different from those in other studies, it is worth indicating that with the help of retrospective data pretraining, the model can learn more than with only the use of prospective data. Our proposed model achieved promising results, with 3%-6% improvement in accuracy (Table 5).

As shown in Table 6, although most of the models achieved an accuracy of higher than 70%, their performances on other metrics revealed that these models tend to predict the majority class. Nevertheless, except for accuracy, our length of stay model outperformed other machine learning methods in the other 3 metrics, indicating the capability of our length of stay model for discrimination.

Table 3. Performance comparison between our model and other machine learning methods in the “triage level” task.

Method	Accuracy	Precision	Recall	F1-score
TabNet [18]	0.425	0.436	0.410	0.423
NODE[a] [19]	0.472	0.324	0.328	0.324
Random forest [24]	0.354	0.506	0.300	0.376
XGBoost[b] [15]	0.351	0.394	0.308	0.345
SVM[c] [25]	0.340	0.581	0.268	0.367

Ablation Studies

Effectiveness of Multimodality

Experiments were conducted to demonstrate the superior performance of our proposed model. Since our model comprised the TabNet encoder and the language model encoder, we designed an experiment to show that the performance of a model leveraging both vital sign information and text information is better than that of a model using only 1 information modality. Table 7 shows that the proposed model achieved the best performance when both modalities were used. The results suggest that both structural and text data contribute to model prediction. The greater performance of the model using only tabular data than that using only text data could be attributed to the advantage of pretraining, as the vital sign encoder was pretrained with a large volume of retrospective data.

Table 7. The effectiveness of different modalities in the "triage level" task.

Methods	Accuracy	Precision	Recall	F1-score
Only tabular data	0.575	0.613	0.568	0.589
Only text data	0.439	0.119	0.250	0.162
Our method (tabular data + text data)	0.633[a]	0.686[a]	0.633[a]	0.658[a]

[a]Highest value.

Effectiveness of Multitask Training and Data Augmentation

Multitask learning experiments confirmed that the approach does offer advantages like improving data efficiency, reducing overfitting through shared representations, and allowing fast learning by leveraging auxiliary information. However, in order to obtain a more robust feature extractor, in a general setting, the targets in the multitask learning model should be related. As a result, in the experiments, we selected triage level prediction and hospitalization as our 2 outputs. It is believed that a patient assigned to level 1 or 2 should have a higher probability of admission to the hospital after being discharged from the ED. Moreover, since data distribution in triage labels is unbalanced, we attempted to narrow the distribution gap by using the method of data augmentation. Table 8 shows that both multitask learning and augmentation contributed to better performance.

Table 8. The effectiveness of different architectures in the "triage level" task.

Methods	Accuracy	Precision	Recall	F1-score
Multitask	0.500	0.369	0.500	0.425
Single task + augmentation	0.583	0.600	0.582	0.591
Single task	0.458	0.506	0.455	0.479
Our method (multitask + augmentation[a])	0.633[b]	0.686[b]	0.633[b]	0.658[b]

[a]The method of data augmentation used in our proposed model is described in the "Data Augmentation" subsection.

[b]Highest value.

Effectiveness of Different Language Models

Experiments were conducted to evaluate the performance between different language models (Table 9). In our original data set, the chief complaint was written in traditional Chinese. However, no language model has been trained on traditional Chinese. Hence, to solve this problem, we first translated the text features into different languages before sending them to the respective language models. The results showed that the model using MacBERT as the language encoder was better than models using other approaches.

Table 9. The effectiveness of different language models in the "triage level" task.

Methods	Data language	Accuracy	Precision	Recall	F1-score
Multilingual BERT[a]	Simplified Chinese	0.500	0.369	0.500	0.425
Multilingual BERT	English	0.583	0.600	0.582	0.591
BERT	English	0.458	0.506	0.455	0.479
Our method (MacBERT[b])	Simplified Chinese	0.633[c]	0.686[c]	0.633[c]	0.658[c]

[a]BERT: bidirectional encoder representations from transformers.

[b]MacBERT: Chinese version of BERT.

[c]Highest value.

Effectiveness of Different Fusion Methods

Experiments were conducted to demonstrate the superior performance of our proposed model. As our model directly concatenated the decreased embedding from the language model and the embedding from the vital sign encoder, we designed an experiment to show that it is necessary to make contributions for the text data and structural data to be comparable, and direct concatenation fusion can preserve more information than addition fusion. In Table 10, the first experiment involves the model adding 2 embeddings (text and vital sign embeddings) together with a learnable scale value to balance the gap between the text and vital sign embeddings, and the second experiment involves directly using the embedding from the language model instead of passing another fully connected network to decrease its dimension. The results suggest that making 2 embeddings to be comparable and using a direct concatenation fusion method can contribute to better performance.

Table 10. The effectiveness of different fusion methods in the "triage level" task.

Methods	Accuracy	Precision	Recall	F1-score
Experiment 1 (addition fusion)	0.548	0.580	0.547	0.563
Experiment 2 (no concatenation fusion)	0.583	0.634	0.583	0.607
Our method	0.633[a]	0.686[a]	0.633[a]	0.658[a]

[a]Highest value.

Interpretability

Although machine learning models can provide remarkably good prediction results, models need to provide explanations of the results that humans can understand easily. In our proposed model, for structural features, the attentive transformer from TabNet generated the mask to mask out different features in each decision step and observed how these features affect the model performance. As a final step, the attentive transformer calculated the importance of features by adding up the mask values of each step. On the other hand, BertViz [29] is an interactive tool that can visualize attention in transformer language models such as BERT. By acquiring attention scores from transformer layers in language models, BertViz can point out important words that contribute to the predicted result.

Multimedia Appendix 6 provides an inference example from the field test, and Multimedia Appendix 7 provides the prediction results of the inference sample for hospitalization. In this example, the patient shows acute change during the triage process, extremely high systolic and diastolic blood pressure, and an unusual Glasgow Coma Scale (GCS) score. As shown

in Multimedia Appendix 7 our system recommended admission of the inferenced patient, and the patient was actually admitted to the hospital. Our system not only successfully provided the correct suggestion to the nursing staff, but also indicated that acute change, systolic blood pressure, diastolic blood pressure, GCS-E, and GCS-M have important effects on the prediction result. As for text analysis, we used the concept from BertViz to extract attention scores for each token from the language model and visualize these attention scores. Although the language model had a hierarchy of linguistic signals from phrase to semantic features, it is believed that the deeper layer of the language model holds more information of the whole sentence [30]. Hence, we extracted the attention score from the ninth layer of the language model for further visualization (Multimedia Appendix 8).

System Application

Triage aims to prioritize patients in the ED and ration care toward those patients who need immediate care. However, recently, owing to the rising number of elderly patients and the high volume of low-acuity ED visits under waiting, patients tend to wait for very long to see the physician. This situation can cause several severe clinical outcomes such as increased mortality rates.

With the advancement in technology and popular application of computers nowadays, we wonder whether machine learning methods can help to mitigate the overcrowding problem in the ED. Therefore, we developed a triage system based on our proposed model and adopted it in the NTUH ED to provide stable and reasonable clinical AI suggestions to nursing staff. For application in the real world, we should take the running time of the system into account. The entire running time of each part is shown in Multimedia Appendix 9. The system takes no more than 10 seconds to make clinical predictions.

Before the system is officially launched, we planned a field test to ensure that the system can achieve promising performance in the real world. Finally, we included almost 6500 ED patients in our analysis from September 30, 2022, to December 30, 2022. The distributions of hospitalization and length of stay between these patients were quite different as compared to the NTUH prospective data set (Multimedia Appendix 10 and Multimedia Appendix 11). Especially for length of stay, patients who stayed in the ED for over 24 hours were much less in this data set than in both NTUH data sets (Multimedia Appendix 11). Moreover, since our golden triage level depended on the physician's diagnosis, it was challenging to label all patients in the field test; however, we evaluated our system in another way, which will be discussed later. The distribution gap between both NTUH data sets and the field test is presented in Multimedia Appendix 12.

As shown in Multimedia Appendix 13 and Multimedia Appendix 14, there was a slight performance gap between the experiments on the earlier mentioned data sets and the real-world data. However, from the results of the confusion matrix, it can be seen that in the case of "patients actually discharged," 2085 out of 2539 (82.1%) discharged patients were accurately predicted and were recommended to be discharged by the system. On the other hand, in the case of "patients actually admitted," 194 out of 316 (61.4%) patients were accurately predicted and were recommended to stay in the hospital.

As mentioned previously, for length of stay, there was a large distribution gap between our field test data set and the NTUH prospective data set. Multimedia Appendix 15 and Multimedia Appendix 16 show that the system cannot perform as good as it does in local experiments. However, from the results of the confusion matrix, we can observe that the system has a better capability of discriminating patients who stay for less than 6 hours, and the system tends to underestimate patients who stay in the ED for 6 to 24 hours.

Finally, Multimedia Appendix 17 and Multimedia Appendix 18 show that although the newly collected data did not have the golden triage level labels provided by the doctors, the distribution of the triage level indicated that the model predicted a fairly even distribution, while the system triage still mainly predicted level 3.

Discussion

Limitations

Although our proposed model showed good preliminary results compared to the results of other machine learning methods, it still has a long way to go. For instance, despite our model's ability to incorporate various language models, it may not perform well for languages where specific language models are not available in the training data set. Second, as we need to translate the text into a uniform language initially and the sentence in the data is not always complete, a better translator and some postprocessing techniques are needed to alleviate the problems. Additionally, as retrospective data lack a label in triage level prediction, expansion of the data set for training the model should help the model to learn a wider range of patterns and should enhance model performance. Moreover, since our proposed model can allow efficient learning of image or text encoders in the presence of multimodality along with tabular data, further work can add images or speech information into our model to help it achieve better performance.

Conclusion

Emergency services are an essential aspect of the health care system in hospitals, and the demand for these services has increased exponentially in recent years. Although Taiwan has established a standard process of assigning patients to different emergency levels, there is insufficient capacity to ensure precise assignment. Most patients are over-triaged or under-triaged, which can waste limited medical resources or have severe consequences such as patient mortality.

In this study, we aimed to design a deep learning prediction system that can prioritize patients and assign patients to appropriate triage levels. To obtain rich information from patients, our proposed model not only uses vital sign information, but also leverages text information.

Our system included a well-pretrained vital sign encoder and a repretrained MacBERT encoder. Additionally, by using the multitask learning and data augmentation method, we successfully obtained promising results for triage level

prediction, hospitalization prediction, and length of stay prediction. For triage level prediction, there were nearly 30% improvements in 4 metrics compared with other machine learning methods, including accuracy, precision, recall, and F1-score. Different modalities and model architectures have also been studied for ablation effectiveness. Moreover, our proposed model also provides clinicians with interpretability to understand the reasons behind the model predictions.

In conclusion, our system improved the prediction of 3 different medical outcomes when compared with other machine learning methods. With the pretrained vital sign encoder and repretrained MLM MacBERT encoder, our multimodality model can provide a deeper insight into the characteristics of EHRs. Additionally, by providing interpretability, we believe that the proposed system can assist nursing staff and physicians in taking appropriate medical decisions.

Abstract

Background: The World Health Organization (WHO) reported that cardiovascular diseases (CVDs) are the leading cause of death worldwide. CVDs are chronic, with complex progression patterns involving episodes of comorbidities and multimorbidities. When dealing with chronic diseases, physicians often adopt a “watchful waiting” strategy, and actions are postponed until information is available. Population-level transition probabilities and progression patterns can be revealed by applying time-variant stochastic modeling methods to longitudinal patient data from cohort studies. Inputs from CVD practitioners indicate that tools to generate and visualize cohort transition patterns have many impactful clinical applications. The resultant computational model can be embedded in digital decision support tools for clinicians. However, to date, no study has attempted to accomplish this for CVDs.

Objective: This study aims to apply advanced stochastic modeling methods to uncover the transition probabilities and progression patterns from longitudinal episodic data of patient cohorts with CVD and thereafter use the computational model to build a digital clinical cohort analytics artifact demonstrating the actionability of such models.

Methods: Our data were sourced from 9 epidemiological cohort studies by the National Heart Lung and Blood Institute and comprised chronological records of 1274 patients associated with 4839 CVD episodes across 16 years. We then used the continuous-time Markov chain method to develop our model, which offers a robust approach to time-variant transitions between disease states in chronic diseases.

Results: Our study presents time-variant transition probabilities of CVD state changes, revealing patterns of CVD progression against time. We found that the transition from myocardial infarction (MI) to stroke has the fastest transition rate (mean transition time 3, SD 0 days, because only 1 patient had a MI-to-stroke transition in the dataset), and the transition from MI to angina is the slowest (mean transition time 1457, SD 1449 days). Congestive heart failure is the most probable first episode (371/840, 44.2%), followed by stroke (216/840, 25.7%). The resultant artifact is actionable as it can act as an eHealth cohort analytics tool, helping physicians gain insights into treatment and intervention strategies. Through expert panel interviews and surveys, we found 9 application use cases of our model.

Conclusions: Past research does not provide actionable cohort-level decision support tools based on a comprehensive, 10-state, continuous-time Markov chain model to unveil complex CVD progression patterns from real-world patient data and support clinical decision-making. This paper aims to address this crucial limitation. Our stochastic model–embedded artifact can help clinicians in efficient disease monitoring and intervention decisions, guided by objective data-driven insights from real patient

data. Furthermore, the proposed model can unveil progression patterns of any chronic disease of interest by inputting only 3 data elements: a synthetic patient identifier, episode name, and episode time in days from a baseline date.

Introduction

Chronic conditions are defined as conditions that last for 1 year or more, require continuous medical care, or limit the ability to perform daily activities. They pose significant health challenges and financial burdens in the United States and worldwide [1,2]. In the United States, 6 in 10 adults have at least 1 chronic condition, and 4 in 10 have 2 or more [1]. Worldwide, nearly one-third of adults worldwide have with multiple chronic conditions [2].

Among these chronic conditions, cardiovascular diseases (CVDs), defined by the World Health Organization (WHO) as a group of disorders of the heart and blood vessels, are a significant public health concern worldwide. The WHO reported that CVDs are the leading cause of death worldwide, with an estimated 17.9 million deaths from CVDs in 2019, accounting for 32% of all deaths worldwide [3]. The American Heart Association also reported that in 2020, there were 928,713 CVD-related deaths in the United States, making it the leading cause of death in the United States [4].

CVDs are characteristically chronic, with a pattern of progression through many stages and episodic instances over time. Moreover, they are often associated with various comorbidities such as congestive heart failure (CHF), myocardial infarctions (MI), coronary heart disease, angina, stroke, and other complications [4]. For managing complex chronic conditions such as CVDs with long progression cycles, a detailed understanding of the progression pattern of disease states over time is essential [5,6]. This knowledge not only facilitates clinical decision-making but also enables hospitals to allocate their resources better [5]. Such models developed using representative population data can enable physicians to compare a patient's progress with the patterns in the base population model to evaluate whether an intervention strategy reduces the transition probabilities between states of interest [7].

When dealing with chronic diseases, physicians often adopt a "watchful waiting" strategy and actions are postponed until information from an evolving clinical scenario is available [8]. However, data-driven clinical decision support tools with the ability to generate transition probabilities and progression paths can allow the development of effective intervention strategies at a cohort level, leading to better treatment outcomes. For this purpose, researchers have proposed and developed various quantitative disease progression models based on mathematical functions to understand the progression patterns of complex chronic diseases [6]. Quantitative disease progression models can be applied to track and describe the changes in disease progression over time and enable physicians to continually monitor and tailor treatment strategies and interventions [5,6]. Such models have significantly contributed to managing chronic progressive diseases such as Parkinson disease [5] and can be a critical precursor to policy development in cancer control [9]. Work on quantitative disease progression modeling has been found addressing various conditions such as Alzheimer disease and glaucoma [10,11], chronic kidney disease [12], abdominal aortic aneurysm [13], multiple sclerosis [14], and cardiovascular disorders, such as hypertrophic cardiomyopathy [15].

Among these quantitative disease progression models, stochastic models such as Markov models are widely applied to analyze disease processes [16-18]. Soper et al [19], for example, studied the dynamic progression of COVID-19 during the course of hospitalization using a continuous-time hidden Markov model. A Markov process can be constructed as a discrete-time Markov Chain (DTMC) model when the observations of the events are captured at a fixed recurring interval of time. However, DTMC's approach to time quantification may not be suitable for diseases requiring frequent monitoring over short periods and observation over extended spans ranging from years to decades [20]. In contrast, events can be modeled as a continuous-time Markov chain (CTMC) when the recurring periods of observations are not fixed. CTMC models offer a realistic approach, supporting state transitions at any instant in a continuous time scale [21,22]. This motivated our study to adopt CTMC as the stochastic modeling method to unveil time-variant progression patterns of CVDs. There are other stochastic modeling approaches in the disease domain. We have provided a comparative analysis of the CTMC approach with 5 other approaches in Multimedia Appendix 1.

To better understand the extent of work in CTMC applications in disease progression modeling, we conducted a literature search (period: 2000-2023) and analyzed the studies that applied CTMC—an advanced stochastic modeling method—to model disease progression. The details of the paper search process and the results are described in Multimedia Appendix 2. We found only 7 papers that used the CTMC approach to model progressions of various diseases. The diseases studied in these papers are chronic or complex, requiring long-term observation and management, such as fibrosis, myelodysplastic syndromes, diabetic foot complications, Alzheimer disease, and chronic kidney disease. Each of these papers addresses a gap in understanding disease progression. For example, Meyer et al [23] aim to estimate progression time in fibrosis stages; Nicora et al [24] used simulation to generate longitudinal event data from cross-sectional patient data and build a CTMC model to

arrive at the transition probabilities representing various stages of myelodysplastic syndrome progression. Begun et al [25] note the lack of knowledge about diabetic foot progression dynamics.

This analysis indicates that although researchers clearly recognize the need and clinical benefits of time-variant stochastic models to understand the progression of chronic diseases, only a few papers have applied the CTMC approach to model disease progression, and notably, none applied CTMC to CVDs. Most of these papers are limited in scope, focused on the disease progression encompassing a limited number of states of a single disease, and do not provide any framework for application to other chronic diseases. Furthermore, within the scope of CVDs, to the best of our knowledge, there is no paper providing actionable cohort-level analytical tools based on a comprehensive, 10-state, CTMC model to unveil complex progression patterns from real-world patient data and support clinical decision-making. Thus, our paper aims to address this crucial limitation in extant health informatics literature. Specifically, our proposed CTMC model aims not only to offer tools for clinicians to make informed intervention and treatment decisions for patients with CVDs, based on objective data-driven insights from real patient data, but also be adaptable for studying the progression of other chronic and complex diseases that require monitoring over time.

Novelties and contributions of this paper include the following:

- Application of advanced stochastic modeling, CTMC, to real-life patient cohort data can uncover new knowledge about CVD progression patterns and transition probabilities.
- Physicians can potentially use the digital data visualization system as an eHealth cohort analytics tool in CVD management, and we have found 9 impactful application use cases externally validated by a panel of 7 cardiologists.
- The proposed model can unveil progression patterns of any chronic disease of interest by inputting only 3 data elements: a synthetic patient identifier, episode name, and episode time in days from a baseline date. This would allow future researchers to generate and study disease progression patterns for other chronic diseases.
- The CVD transition probabilities can help health care administrators calculate the anticipated patient mix at different CVD states for a future planning period. This can facilitate predictive resource planning, improved patient care, and cost savings.
- Results are reproducible and extendable as the data, code, and development framework are shared with the audience via a web-based repository.

Methods

Data

The data applied in this research were from a multicenter cohort study implemented by the National Heart Lung and Blood Institute (NHLBI), collected from 9 epidemiological studies (Sleep Heart Health Study) on heart and respiratory diseases comprising 5804 patient records and 4839 CVD episodes associated with 1274 patients [26]. These longitudinal data were collected in 3 cycles across 16 years, with the first collection in 1995 and 2 subsequent collections between 1995 and 2003. CVD events, including death, were tracked until 2011. The inclusion criteria of the cohort members were aged 40 years or older, with no history of sleep apnea treatment, no tracheostomy, and no current oxygen therapy.

Table 1 provides a snapshot of occurrences of various CVD episodes or states for 2 patients (patients IDs 200453 and 201195) randomly selected from the NHLBI data used in this research. CVD “states” in our model represent specific CVD events or episodes in the patient’s history. For this reason, in our model, we define CVD states as “episodic” states or events.

It is noteworthy in the above table that multiple CVD events occurred on the same day. These are examples of comorbidity and multimorbidity in real life for patients with CVD. In the Markov process, 1 patient can be only in 1 state at a time. Hence, for the same patient, every instance of comorbidity and multimorbidity event occurring simultaneously is defined as a single Markov state. Many patients can be in any of these Markov states for a patient population with CVD, but 1 patient can only be in 1 state at any given time. Based on this Markov principle and the time of occurrence of patients’ CVD episodes in our dataset, we began with 14 unique CVD Markov states as found in our data. However, 4 states were dropped as their occurrences were negligible compared to the others. This led us to a final set of 10 unique CVD states for further development of our model. The details of the record counts in the dataset for all 14 states are presented in Multimedia Appendix 3.

Table 1. Snapshot of cardiovascular disease episodes of 2 patients from the National Heart Lung and Blood Institute dataset.

Patient ID and episode name	Episode time (days from baseline)
200453	
Myocardial infarction	572
Congestive heart failure	2064
Congestive heart failure	2562
Myocardial infarction	2562
Congestive heart failure	2593
201195	
Congestive heart failure	1343
Congestive heart failure	1426
Angina	3086
Congestive heart failure	3086
Myocardial infarction	3086
Congestive heart failure	3143
Congestive heart failure	3183

Modeling Assumptions and Approximations

The modeling assumptions and approximations can be generalized into 2 categories—Markovian assumptions and CVD data–related assumptions. They are addressed in detail below.

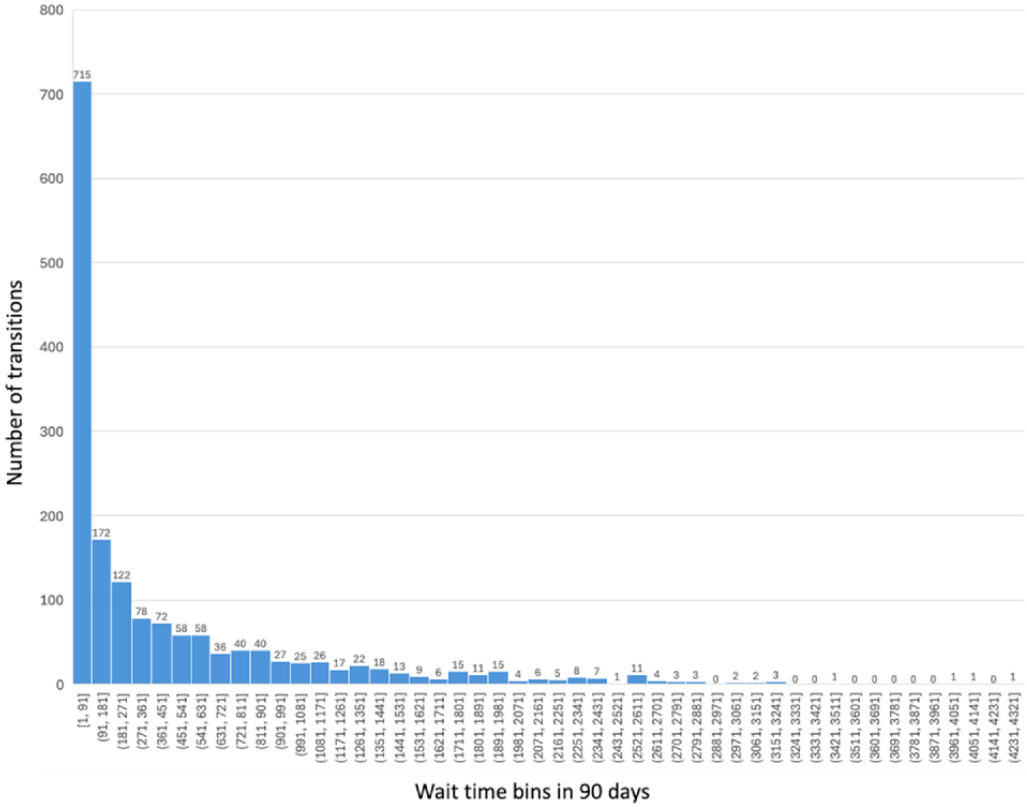
1. Finite number of Markovian states: There is a limited or finite number of possible states. States are collectively exhaustive and mutually exclusive. In CVDs, the same patient cannot be in 2 Markov states simultaneously. In our dataset of actual patients with CVD, we have found multimorbidity situations where a patient can have multiple events simultaneously. To comply with this Markovian rule, we have deliberately treated such multimorbidity events as single and unique Markov states (eg, simultaneous occurrences of angina and MI is defined as a separate unique state designated as “ANMI”).
2. Memory-less property of Markovian states: Markov states do not retain the memory of previous cycles or information from previous states leading to the future state. For example, in our model, we assume that all patients in the MI state, at the same time, have the same probability of transitioning to the angina state, irrespective of their previous history or path of reaching the previous MI state.
3. No immediate transition to the same state: Our dataset has patient instances where a patient reported the same CVD episode (eg, stroke) occurring consecutively with a time gap. In such cases, we preprocessed the data to combine them into 1 continuous state, as due to the nature of CVDs, it might not be accurate to assume that the patient had a complete remission during the interim period. For example, if a patient reported a stroke episode in day number 100 and reported a consecutive stroke again in day number 110, we assume that the patient was in the stroke state for the interim period of 10 days as well. In other words, the patient was continuously in the stroke state from 100th day to 110th day and this is counted as a single continuous disease state with longer wait time during the data preprocessing. However, if after a stroke the patient had an angina episode had a stroke again, our model state diagram would show a return to a stroke state again after the angina episode.
4. Exponential distribution approximation of wait times: Several studies and reviews support the use of exponential distribution approximations in time-to-event modeling for CVDs. For example, Sullivan [27] highlights that the exponential distribution is a common choice for modeling the time to cardiovascular events. In the application of the CTMC process in disease progression modeling for CVDs, holding time or wait time in a given state is approximated to be exponentially distributed.

Stochastic Modeling Theoretical Underpinnings

A stochastic process is a collection of random variables indexed by a variable *t*, usually representing time. A Markov Chain or Markov process is a stochastic model representing time-dependent cyclic processes. The primary advantage of a Markov process is the ability to describe, in a mathematically convenient form, the time-dependent transitions between health states [28].

As discussed in the previous section, in a disease progression process, the random time variable *t*—“wait time” or “hold time”—is known to follow an exponential distribution. As a validation, we computed our dataset’s “wait time” frequency distribution and found it to have an approximate exponential frequency distribution pattern (Figure 1), although literature indicates that it is not strictly followed in the medical field, but necessary for modeling disease progressions successfully [29].

Figure 1. Wait time–frequency distribution in the research data set.



Operational Behavior of CTMC

The operational behavior of a process modeled after CTMC can be described in the following steps, where a patient:

1. Stays X_i units of time in state i, where X_i is the random variable with an exponential distribution. The unit of time was measured in days in our study.
2. Jumps to a random next state j in a single step with probability $P(i,j)$
3. The behavior repeats across subsequent jumps.

Mathematically, CTMC can be defined by a tuple of 2 matrices: [S, R], where S is a matrix of s number of countable CTMC states and R is a transition rate matrix of ($s \times s$) size. The value of R(i,j) equals the rate at which a patient moves from state i to state j in 1 step. This R matrix is also known as the generator matrix (denoted by Q in later sections), which we will explain in the following subsection.

Generator Matrix—Q

The generator matrix, a fundamental matrix in CTMC calculations, is known by many names, such as infinitesimal generator matrix, transition rate matrix, intensity matrix, Q-matrix, etc. The generator matrix represents the rate (eg, number of transitions per day) at which transitions happen between states in 1 step. We denote it as Q-matrix with its elements as $q_{i,j}$, where

For diagonal matrix elements, $q(i,i)$ is the negative sum of the rest of the row so that the row sum of each row is equal to zero. There are several methods of calculating the generator matrix. For this study, we applied the Maximum Likelihood Estimator method, which Metzner et al [30] discussed in their paper named "Generator Estimation of Markov Jump Processes." In this method, for each state i of a finite number of states s, the generator matrix is computed as follows:

1. Calculate: $n_{i,j}$ = total number of transitions between state i to j for $i \neq j$
2. Calculate: $r_{i,j}$ = total wait time or hold time at state i before transitioning to j for $i \neq j$
3. Calculate: 
4. Place the negative of the row sum of nondiagonal positions as the diagonal entry so that the row sum of each row is zero. An infinitesimal generator matrix generates a continuous-time Markov process if and only if all off-diagonal entries are nonnegative and the sum over each row equals zero [30].

For example, if the current disease state is MI, as per our data, there are 31 cases ($n_{i,j}$) where patients have transitioned from MI to CHF state in 1 step. During the hold time or wait time computations, we found that these patients, involving 31 MI-CHF transitions, waited a total of 16,633 days ($r_{i,j}$) in the MI state before jumping to the CHF state. From these data points, $q_{i,j}$ (i=MI and j=CHF) can be calculated as 31 ÷ 16,633, which is 0.001864. This Q-matrix value is used to calculate the CTMC transition probability from MI to CHF at time t in the next step of the process.

CTMC Transition Probabilities

Transition probabilities from state *i* to *j* after waiting time *t* at state *i* are obtained by using the generator matrix, *Q*, computed earlier as $P_{i,j}(t)=e^{Qt}$, where the exponent of *e* is calculated by multiplying each element of *Q* matrix (or $q_{i,j}$) by the value of time *t*. Continuing the computation example from the previous section, if a patient is at a current state MI for 90 days, the probability of the patient transitioning to state CHF at the current time (*t*=90 days) can be calculated using the above exponential function. The calculated transition probability value from the $P_{i,j}(90)$ matrix (*i*=MI and *j*=CHF) will be 4.53% (Table 2).

Table 2. Continuous-time Markov chain (CTMC) transition probability matrix from state *i* to state *j* at a time of 90 days.

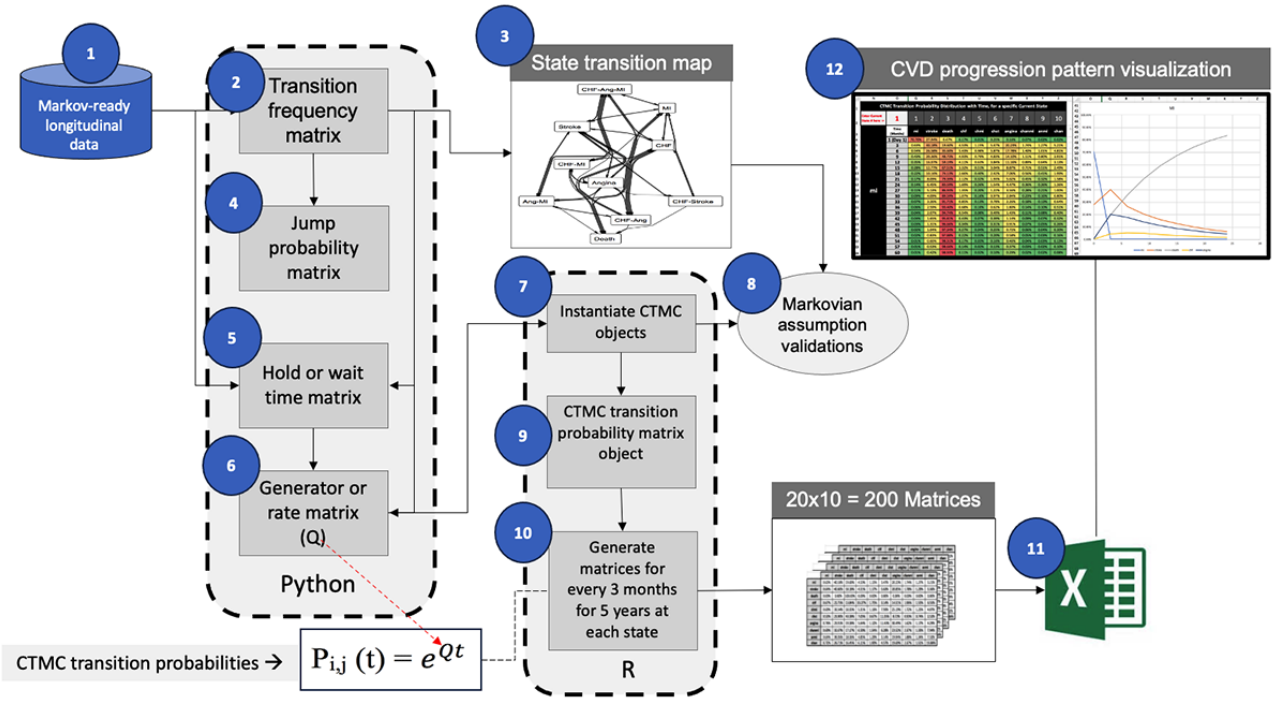
Model Development Technical Process

At this point, we want to highlight that, unlike the machine learning approach where the event probabilities are derived by training machine learning algorithms with historical data (supervised training), our approach uses a Markov Model, CTMC, which is a mathematical stochastic method to determine event probabilities and does not involve any sorts of training mechanism. Figure 2 illustrates our method used to generate a CTMC-based disease progression model for the CVDs. We have used all publicly available, open-source software tools and libraries for server-side module development (Python, Python Software Foundation, and R, R Foundation) and the widely used Microsoft Excel for front-end visualization artifacts. The *Results* section discusses further details.

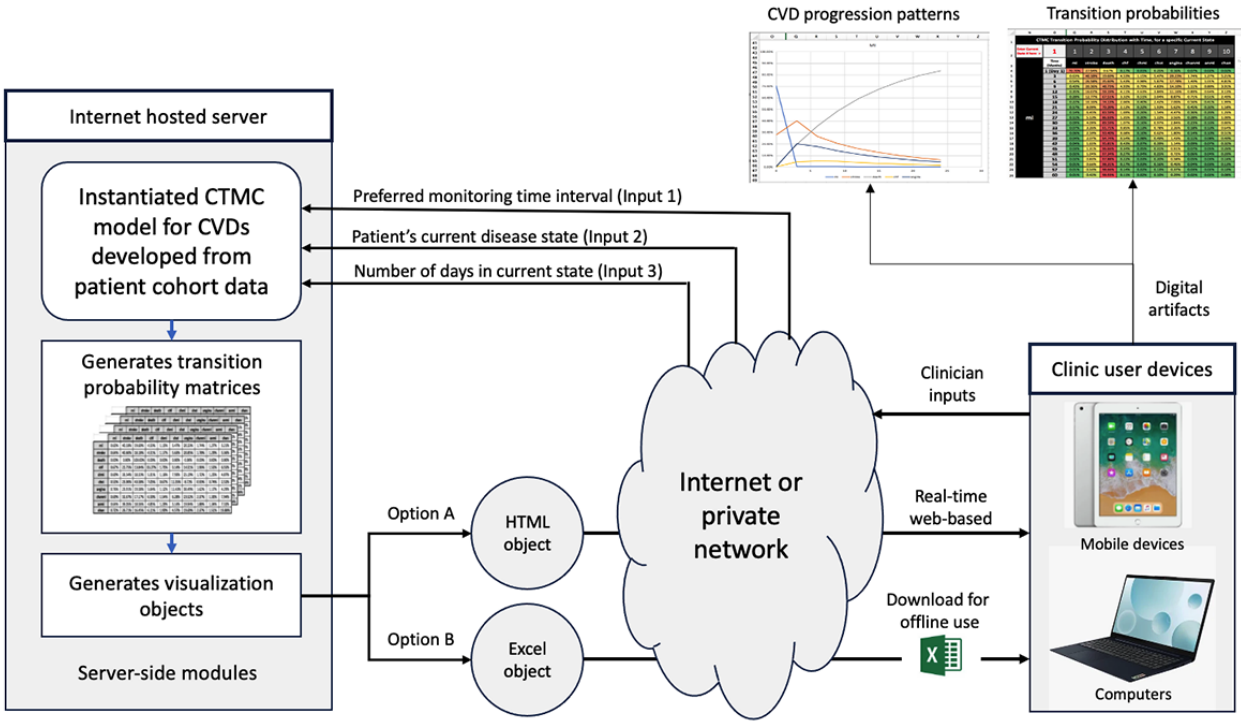
Figure 2. Development process for disease progression pattern generation and digital visualization. the circled numbers indicate the sequence of development steps and outputs. CTMC: continuous-time Markov chain; CVD: cardiovascular disease.



Deployment and User Interaction

Our developed system can be deployed as an eHealth solution for CVD clinics. In Figure 3, we present the high-level architecture of the proposed deployment configuration. Our proposed deployment design provides end users with the flexibility to use the system in real-time with an active internet or network connection using browsers, as well as the option of downloading the outputs as Excel artifacts and using them offline. We have provided the data, code, and Excel artifact (option B) via the web-based Mendeley repository [31] for reproducibility and reusability.

Figure 3. Proposed architecture for deployment of our system as an internet-based eHealth application for CVD clinicians with configurable monitoring time intervals. The architecture allows for synchronous web-based use (option A) as well as offline use via prior Excel (Microsoft Corp) artifact download (option B). CTMC: continuous-time Markov chain; CVD: cardiovascular disease.



Ethical Considerations

As discussed in this paper, cohort-level disease progression analytic tools are useful in many strategic clinical decisions. However, these are data-driven methods. Hence, ethical considerations applicable for data-driven clinical decision-making systems are important. Such considerations might include, but are not limited to, ensuring accuracy, bias-removal, fairness and equity, patient autonomy and consent, transparency and accountability, and privacy and data protection.

A Data Access and Use Agreement (the "DAUA") is executed between The Brigham and Women's Hospital, Inc., through its Division of Sleep and Circadian Disorders ("BWH") and Arin Brahma ("Data User") to facilitate access to and use of the de-identified sleep study and related covariate data originating from past NHLBI-funded research studies (the "Data"), by third-party researchers to conduct sleep research in accordance with NHLBI and BWH policies, procedures, and to the extent permitted by its Institutional Review Board (IRB) and institutional policies. The Data agreement can be made available by the authors upon request when deemed appropriate. The author has also received approval for the use of the Data for Cardiovascular Disease (CVD) research from the Institutional Review Board of Claremont Graduate University, CA, USA (Protocol ID is 3351; 01/11/2019).

Results

The results comprise the computational outputs from the method described in the previous section. They include the CVD Markov state model, various probability matrices, and the progression pattern visualization results. These are explained in detail below.

CVD Progression State Model

We generated the Markov state transition graph (see Figure 4) based on the jump frequency matrix (Table 3) information. The direction of the arrows indicates the direction of disease transition, and the thickness indicates the proportion of the patients transitioning between the states.

Figure 4 visually illustrates the chronic nature of CVDs involving various morbidity, comorbidity, and multimorbidity states. It can be observed that the state death only has incoming arrows. This property makes death an "absorbing state" in a Markov model.

Figure 4. Markov state diagram (generated from jump frequency matrix). Ang: angina; CHF: congestive heart failure; MI: myocardial infarction.

CVD State Jump Probabilities

The jump probability matrix is computed from the jump frequency matrix in Table 3 and displayed in Table 4. This matrix provides the probability of a patient jumping from state *i* to state *j*, without accounting for the effect of wait time or hold time at the current state on the transition probability. The cells with a transition probability of 0% indicate that no patient transitioned between those states.

CVD Continuous Time Transition Probabilities

Transition probabilities from state i to j after waiting time t at state i are obtained by using the generator matrix (Q) computed earlier as $P_{i,j}(t)=e^{Qt}$, where the exponent of e is calculated by multiplying each element of Q matrix (or $q_{i,j}$) by the value of time t. The generator matrix (Q) essentially represents the transition rates concerning time (eg, number of transitions per day) and is calculated before this step using the jump frequency and transition wait times.

If a patient is at a current state MI for 90 days, the probability of the patient transitioning to state CHF at the current time (t=90 days) can be calculated using the above exponential function. The calculated transition probability value from the $P_{i,j}(90)$ matrix (i=MI and j=CHF) will be 4.53% (Table 2).

This is the final set of matrices of the CTMC model that leads to the digital data visualization of the temporal progression pattern of CVDs. In CTMC, the transition probability from state i to state j depends on the current value of time, as the transition probability changes depending on how long a patient is at the initial state i. For every such value of t (time), a different CTMC transition probability matrix exists for all state i to state j transitions.

CVD Progression Pattern (Including Digital Data Visualization)

The CTMC transition probability matrix described above captures the transition probabilities at a specific recurring time interval scale of 3 months (90 days), as we assumed that, in general, CVD practitioners would review their patients' progress every 3 months. However, the model allows the generation of the above matrix in any granularity (continuous) time scale, such as by days, weeks, or months. Our model autogenerated the CTMC probability matrices for every current state at a 3-month incremental progression scale for 5 years. This led to twenty 10-states by 10-states transition probability matrices. We developed a data aggregation and visualization method that automatically combines and organizes the probabilities from 20 matrices for each disease on a 5-year running time scale. This transformation presents each interstate transition probability matrix (Figures 5 and 6 left) in a "heat map" style with a value-based color scale (green is lowest, yellow is medium, and red is severe). Furthermore, this also automatically generates a time series trend graph (Figures 5 and 6 right) of transition probabilities that reveal the disease progression patterns graphically over 5 years when the current disease state of a patient is inputted by a clinician through the digital interface. Using this system, a CVD practitioner can visualize the temporal pattern and various "what if" scenarios to assist in decision-making regarding treatment or intervention strategies. For example, a CVD practitioner might be interested in knowing: if a patient had MI 3 months back (means current time t=3 months), what would be the probability of the patient transitioning to stroke or angina? From the following CTMC matrix generated for t=3 months, or 90 days by our model (Table 2), one can observe that if the current state of the patient is MI (rows), the probability of having a stroke is 40.18% (highest) and angina 20.23% (next highest). Hence, the CVD practitioner might recommend treatment or lifestyle interventions so that the risk of stroke or angina can be reduced.

Analysis of CVD Progression Pattern

We explain our observations using an illustrative example (Figure 5—left and right), where the current CVD state of a hypothetical patient (representing population CVD progression pattern) is MI at *t*=1 (day 1 of month 1), the probability of staying in that state drops rapidly with time. In contrast, the probability of stroke, death, and CHF keeps increasing. Among these states, the probability of stroke starts with a higher probability of 28% at *t*=month 1. Continuing the analysis from Figure 5, the probability of death and angina starts at near zero but increases at a higher rate. At *t*=month 3, the probability of stroke, angina, death, and CHF peak at 40%, 20%, 20%, and 5%, respectively. At this point, if the patient transitions to stroke (40%), there is a 36% probability of death at *t*=month 6, compared to an 18% probability of angina and a 6% probability of CHF. If the patient escapes death and continues to be in the stroke state, then the probability of death crosses the 50% mark at *t*=month 9, and the death probability increases rapidly from then onwards. In 21 months, the death probability crosses the 80% mark, signifying a high probability of mortality.

Although the above findings meet the core objectives of this study, we performed further analysis of the dataset, which contributed additional interesting findings on CVD patterns. We use only 4 states—CHF, stroke, MI, and angina—for this analysis as they collectively account for 88.2% (231/262) of all CVD-related deaths (101/262, 38.6%; 74/262, 28.2%; 44/262, 16.8%; and 12/262, 4.6%, respectively). The details of this analysis are presented in Multimedia Appendix 4, and a summary of the key findings from this analysis is presented.

1. Transition rates and mean transition times: The fastest transition rate is from MI to stroke (mean transition time 3, SD 0 days, because only 1 patient had myocardial infarction to stroke transition in the dataset), and the slowest is from MI to angina (mean transition time 1457, SD 1449 days).

2. First CVD episodes: CHF is the most probable first episode (371/840, 44.2%), followed by stroke (216/840, 25.7%), angina (140/840, 16.7%), and MI (113/840, 13.5%).
3. Most dominant CVD episodes immediately after an episode: CHF is the most dominant episode after an occurrence of angina, whereas after CHF, stroke, and MI, death is the most dominant episode.

Model Validation

As practiced commonly in validating empirical models, such as machine learning predictive models, one would ideally hold some testing data out to compare to a model built on training data. Fitzpatrick [31], in his paper "Issues in Reproducible Simulation Research," states that the problem context of probabilistic models can often make this type of testing difficult. He discussed this aspect of stochastic model validations and laid a guideline for researchers working with such models. In the paper, Fitzpatrick refers to a multistage validation model from North and Macal [32] that includes validation of requirements, data, face, process, theory, and output. We used this model for internal evaluations during our model development cycles, as described in detail in Multimedia Appendix 5.

Model Artifacts, Reproducibility, and Generalizability

One of the significant outputs of this research is the CTMC model embedded visualization artifact that CVD clinicians can use as a cohort-level decision-support tool for several applications and use cases as described in detail in Multimedia Appendix 6. The user interface of this 10-state model artifact has an input field (pointed out by the text "Enter Current State# here " in Figures 5 and 6), where a clinician can be informed of the transition probability values and graphical progression patterns by entering the current CVD state of a cohort under investigation. This Excel artifact is self-contained, ready to use, and can be operated by having just the Microsoft Excel application on any computer. The artifact can be downloaded from the code repository [29].

Multimedia Appendix 7 provides more detailed information and instructions for future researchers interested in reusing these research methods, codes, and outputs to investigate the progression patterns of other chronic diseases or CVDs from different population datasets.

Discussion

Principal Findings

This research applies a well-established stochastic modeling—CTMC models on real-life patient cohort data to uncover previously unknown knowledge about CVD transition probabilities and complex progression patterns. The choice of CTMC overcame DTMC's limitations on time quantification for disease progression modeling. There are other types of Markov models applied for stochastic modeling in the disease domain. The choice of appropriate modeling method is often driven by the model's application goals (eg, patient-specific decisions vs cohort-level decisions). We have provided a detailed comparison of our choice of CTMC with 6 other methods in Multimedia Appendix 1. For complex chronic diseases such as CVDs, the availability of population-level transition probability matrices of all 10 disease states and respective progression patterns close a crucial gap in the literature and opens the door for future research on the disease progression of CVDs.

We find that the transition from MI to stroke has the fastest transition rate (mean transition time 3, SD 0 days, because only 1 patient had myocardial infarction to stroke transition in the dataset), and MI to angina is the slowest (mean transition time 1457, SD 1449 days). CHF is the most probable first episode (371/840, 44.2%), followed by stroke (216/840, 25.7%). This result reflects the epidemiological characteristics of our study cohort. However, if a dataset from a different cohort is inputted in our model, the patterns might differ.

External Validations of Clinical Applications and Usefulness

The research also has many practical implications. We organized an expert panel of 7 practicing cardiologists and conducted a combination of presentations, open-ended interviews, and structured web-based surveys to validate the applications and usefulness of our model. We have discussed the methods, results, and analysis of this external validation process in detail in Multimedia Appendix 6. Here, we are presenting 9 clinical applications and use cases that were evident from the interviews and survey.

1. This tool can help cardiologic clinics understand the effectiveness of their intervention strategies related to quality metrics, such as blood pressure thresholds for interventions.
2. Comparing the clinic-level transition rates with population-level rates built into this tool, clinics can identify a specific cohort that has significantly higher rates for certain transitions (eg, angina-to-death) and then back-identify the patients for analysis of variables leading to such outcomes.
3. Clinics can use the transition probabilities generated by this tool based on their patient cohort data to compute the patient state mix for a future period. This can allow predictive resource planning, improved patient care, and cost savings.
4. This system can be populated with CVD episode data of various clinic cohorts and subcohorts and their patterns (frequency, transition rates, probabilities, etc) can be compared. This can reveal the trend differences concerning various cohort control features such as demographics, education, nutrition profile, treatment alternatives, etc.
5. Such intercohort benchmarking can delineate best practices concerning cost-effectiveness, manpower economy, and fund allocations (eg, Affordable Care Act incentives) when the candidate cohorts are selected from disparate clinics.
6. The utility can be further extended to understand epidemiological trends of different geographical and population segments, leading to valuable inputs for the health care policymakers and administrators enabling them to target specific regions based on pattern differences.
7. This tool can also help comparison of CVD characteristics at a national level, for example, some countries might have more stroke compared to others having more CHF. This

can lead to necessary preventive measures and national health policies.

8. It can help identify temporal changes in CVD trends in patients because of shifts in major treatment paradigms (eg, prestatin vs statin period pattern changes)
9. This tool can be potentially integrated with clinic electronic health record systems to continually monitor temporal pattern shifts over time and send out automated notifications and reports based on preset quality metrics thresholds.

Study of Impact of Various Risk and Control Factors on Epidemiological Trends

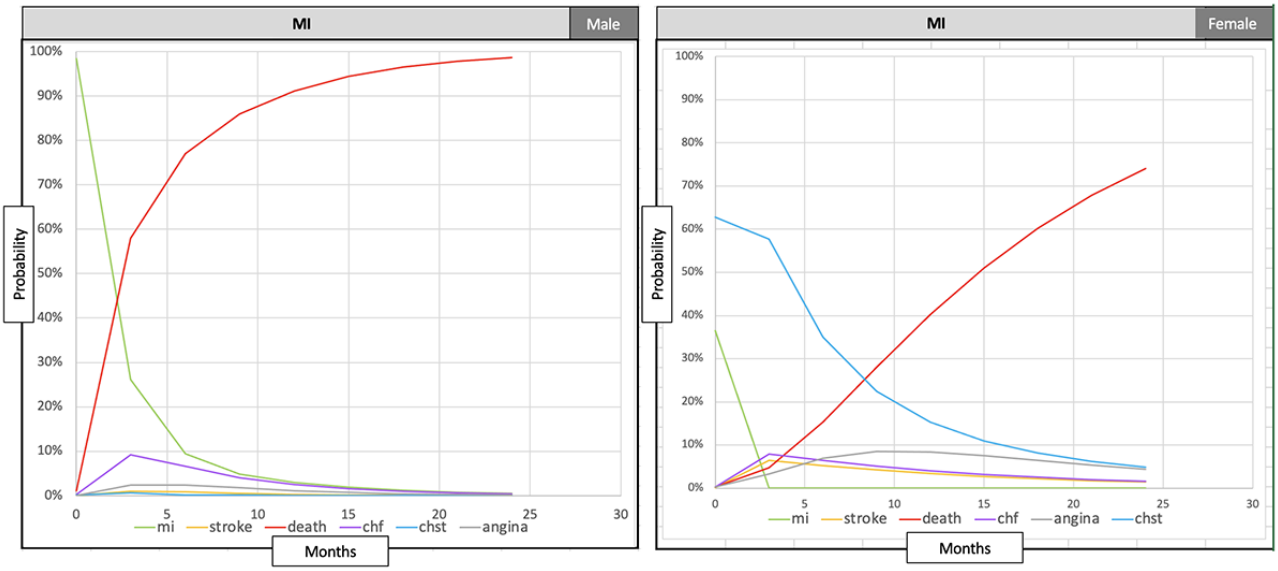
The clinical applications suggested by the expert panel point to the tool's general ability to reveal epidemiological trend differences across various subcategories within a given cohort or across different cohorts. Such subcategories might include various population risk factor groups (age, gender, smoking behavior, education levels, etc), geographical attributes (urban, rural, coastal, inland, state, country, etc), treatment policies (quality metrics), interventions (medication or procedures), and so on.

To demonstrate this key capability of our tool, we chose a population risk factor—"gender"—as an example and used the tool to visualize the CVD progression trend differences between male and female patients from our research cohort. To accomplish this, we partitioned the input dataset based on the "gender" subcategory. The data partitioning based on "gender" resulted in 278 male patients involved in 471 CVD episodes and 355 female patients involved in 592 CVD episodes. We then applied our research tool to generate 2 separate outputs corresponding to each of the genders. The visualization of the results (Figure 7) reveals distinct and interesting differences in the progression patterns between male and female patients within the cohort. In the following paragraph, we briefly outline some of the significant trend differences revealed between male and female patients when the current CVD state is "MI."

First, we observe that the transition rate to state "death" (in red color) is significantly slower for the female patients compared to the male patients. The progression curve for females is noticeably flatter compared to their male counterparts. Thus, the female patients take almost 15 months to cross the probability threshold of 50%, whereas the male patients cross that threshold in just about 2.5 months. Another key observable difference is revealed in the progression pattern of the multimorbidity state "CHST" (congestive heart failure and stroke in blue color). The graph shows that female patients have more than a 50% probability of transitioning to "CHST" immediately following their current "MI" state over the next 4 months. In contrast, male patients have negligible probabilities of transitioning to "CHST" following the current "MI" state. Also, the probabilities of transitioning out of the current "MI" state (in green color) to any other state have distinctly different patterns between the male and female patient groups. Such trend comparisons between subgroups or different cohorts might trigger further study and analysis by the clinicians leading to improved treatment strategies, quality metrics, or interventions.

In the *Deployment and User Interaction* section, we have also provided a proposed deployment architecture that will allow health care providers to implement the solution as an eHealth application over the internet. Furthermore, our cohort-level clinical decision support system can be used for other chronic diseases to unveil their progression patterns, requiring only 3 data elements as inputs: a synthetic patient identifier, disease episode name, and episode time in days from a baseline date. This approach can encourage and facilitate further studies on disease progression patterns of other chronic diseases, not limited to CVDs by future researchers.

Figure 7. CVD transition probability pattern differences between male and female patients when the patients' current state is "MI." CHF: congestive heart failure; CHST: congestive heart failure and stroke; CTMC: continuous-time Markov chain; MI: myocardial infarction.



Limitations

Our study has a few limitations. As per the Markovian assumptions, the process's behavior after any cycle is solely based on its state within that cycle, indicating that it does not retain the memory of previous cycles. This assumption about the memory-less state is tenuous in medicine since a patient's

history may give the physician important information about their condition in the present and future. Hence, this is an approximation in our model. It is noted from the literature that although the Markovian assumption is necessary to model prognosis with a finite number of states, it is not followed strictly in medical problems [33]. Next, the data used for this research comprised CVD episode records of 1274 patients. The generalizability of this model will significantly improve with a larger number of diverse patients with CVD data. The CTMC approach has its limitations as well for patient-specific decision support applications. Since a patient is likely to be associated with a specific medical history, medication, interventions, demographic risk factors, etc, each of the Markov states must be unique for all such combinations. This makes the design and computation of the CTMC model very complex, less interpretable, and computationally heavy. Other Markov methods such as the Markov decision process can model patient-specific sequential treatment decision-making processes more efficiently. These limitations also lead to future opportunities for research. Since the framework and the tool developed in this research are disease agnostic, reproducibility-tested, and the reproducible package has been publicly shared, future researchers can use this tool to populate with episodic data of any chronic disease of interest and apply them to similar clinical use cases and applications. Additionally, to improve the generalizability of its application for CVDs, data from various other cohorts can be modeled and validated by simply reusing our model with new datasets.

Conclusion

Stochastic disease progression models developed from fully observed real patient cohort data to compare a patient's CVD progression with a population pattern can provide better intervention-based decision-making capabilities to physicians. However, such models do not currently exist. This research uses CTMC methods to develop a disease progression model from the population data of 1274 patients associated with 4839 CVD episodes across 16 years. This study unveiled distinct CVD progression patterns and characteristics from the fully observed longitudinal data of patient cohorts. The results are actionable with the code and data framework shared with the audience. The model also serves as an eHealth decision support tool with digital visualization of progression patterns and opens the door for many practical applications, including proactive resource planning at hospitals. Our study results are reproducible and extendable to other chronic diseases. Despite certain limitations, this research contributes significantly to the literature and possible practical clinical applications.

Acknowledgments

We would like to thank Luanda Grazette, MD, Vishal Gupta, MD, George Ponce, MD, Jayanta Datta, MD, Wesam Alhejily, MD, Shilanjan Roy, MD, Satyajit Bose, MD, and Michael Neely, MD for providing us with valuable insights and feedback on application use cases and usefulness of our model. We also thank graduate research assistant Sebastian Van Hemert for his contributions to the literature search, testing the model's reproducibility, and developing code documentation for reproducibility.

Data Availability

The master dataset was obtained from a publicly available source—Sleep Heart Health Study by the National Heart Lung and Blood Institute (NHLBI) [26]. The preprocessed version of the dataset used for the continuous-time Markov chain (CTMC) model development is available at the publicly accessible web-based Mendeley repository [29].

Abstract

Background: Data element repositories facilitate high-quality medical data sharing by standardizing data and enhancing semantic interoperability. However, the application of repositories is confined to specific projects and institutions.

Objective: This study aims to explore potential issues and promote broader application of data element repositories within the medical field by evaluating and analyzing typical repositories.

Methods: Following the inclusion of 5 data element repositories through a literature review, a novel analysis framework consisting of 7 dimensions and 36 secondary indicators was constructed and used for evaluation and analysis.

Results: The study's results delineate the unique characteristics of different repositories and uncover specific issues in their construction. These issues include the absence of data reuse protocols and insufficient information regarding the application scenarios and efficacy of data elements. The repositories fully comply with only 45% (9/20) of the subprinciples for Findable and Reusable in the FAIR principle, while achieving a 90% (19/20 subprinciples) compliance rate for Accessible and 67% (10/15 subprinciples) for Interoperable.

Conclusions: The recommendations proposed in this study address the issues to improve the construction and application of repositories, offering valuable insights to data managers, computer experts, and other pertinent stakeholders.

KEYWORDS

data element repository; FAIR; ISO/IEC 11179; metadata; semantic interoperability

Introduction

Background

The sharing of medical data can enhance the efficiency of medical research, bolster transparency within the field of medicine, and respond to the stringent demands for research reproducibility and data openness [1]. Nonetheless, medical data present challenges due to their high complexity in semantics and heterogeneity, and they lack standards and uniform specifications at the level of fields and value domains. For instance, the numeric value "18" could represent the age at which a patient started smoking in one study, while in another, it might signify the total number of years a person has been smoking. This issue of semantic ambiguity in the data renders it challenging for other researchers to comprehend and use the information. It impedes the integration, comparison, and joint analysis of different data sets [2], thereby obstructing data sharing.

Metadata, essentially data about data, offers a solution to address such issues. Metadata can describe data, providing researchers with a comprehensive overview to aid understanding and application. Furthermore, it supports more precise retrieval and traceability. When data are accurately associated with metadata (such as "18" being linked to an individual's total years of

smoking), its semantics become much more straightforward. Metadata has already found applications in various fields, including molecular biology [3,4] and clinical medicine [5,6]. Guidelines for data management and sharing, such as the FAIR (Findable, Accessible, Interoperable, and Reusable) principles, also provide specifications for metadata to ensure that data are Findable, Accessible, Interoperable, and Reusable [7]. However, researchers often find that creating and annotating metadata are time-consuming and prone to errors [8]. This makes it challenging to ensure metadata quality and increases metadata heterogeneity across research. Hence, using standardized metadata for data collection to achieve semantic consistency from the inception of the data life cycle is essential to maximize semantic interoperability across multiple data sources.

Data elements (DEs) are vital components of metadata, representing indivisible data units within a given context. The underlying framework of DEs can furnish rich metadata information, including unique identifiers, definitions, and value domains, among other attributes. The DE repository represents a platform structured in accordance with a standardized framework dedicated to the construction, storage, administration, and dissemination of DEs. Within this repository, DEs adhere to rigorous standardization, with their conceptual aspects, value ranges, and related attributes systematically linked to controlled vocabularies and other terminological systems. A DE repository facilitates the unified management and maintenance of internal metadata, ensuring semantic consistency and reducing the cost associated with redundant design efforts for project-specific metadata. By fostering the reuse and sharing of standardized DEs, barriers to data integration are diminished, thus propelling applications such as cross-institutional and cross-study meta-analyses in the realm of medical data [9]. This, in turn, unlocks the value of medical data.

Currently, the prevailing international standards for DEs and repository construction are set by the ISO/IEC (International Organization for Standardization/International Electrotechnical Commission) 11179 standard. The ISO/IEC 11179 standard establishes a conceptual model for DEs and their repositories, while also providing regulations for activities such as DE registration and management. Many DE repositories have been constructed in the medical field based on the ISO/IEC 11179 standard. However, the broader application of DE repositories has not yet been achieved, often limited to specific projects or internal use within particular institutions [10]. As the central platform for storing, managing, and sharing DEs and metadata, the degree of completeness in its construction directly influences the practical usage of DEs. Current research tends to focus more on the specific technical aspects and standards for constructing DE repositories. Simultaneously, there is a discernible deficiency in evaluating and analyzing typical repositories in the medical domain.

Literature Review

Medical DE

Data elements, defined and standardized by the ISO/IEC 11179 standard, constitute the minors units for collecting, processing, and disseminating data [11]. The definition of DEs should ideally encompass 3 aspects—research questions, data acquisition, and data storage—to reflect the life cycle of a repository best [12]. DEs play a pivotal role in standardizing clinical data collection, enhancing data quality, facilitating secondary analysis and applications [13,14], and serving as a base for systems based on artificial intelligence (AI) [15].

Currently, the development of Des primarily relies on multidomain expert consensus and collaboration, often achieved through iterative Delphi methods for discussion, identification, and refinement of relevant DEs [16]. This approach ensures the professionalism of DEs within specific domains but demands considerable time and personnel involvement. National Institute of Neurological Disorders and Stroke (NINDS) categorizes the development of common data elements (CDEs) into 4 phases: discovery, internal validation, external validation, and distribution [17]. Numerous domains or projects have undergone multiple iterations of DE development, such as Stroke V2.0 CDE [18]. More granular domain-specific DEs have been developed or reached consensus, spanning therapeutic methods [19], examinations [20], and others. With the continuous expansion of DEs, Kim et al [21] proposed a comprehensive representation of real-world clinical semantics by defining semantic relationships and constraints between DEs.

The application and evaluation of DEs have indeed garnered considerable attention. For instance, Fitzgerald et al [22] analyzed the seizure burden using clinical data in childhood epilepsies collected from CDE-based forms within the electronic medical record. Evaluation studies encompass DE quality [23] and the effectiveness of data collection. Chen et al [24] assessed the data collection effectiveness of DEs in real-world scenarios, while Ryan et al [25] separately evaluated data capture rates for DEs in in-person and virtual visits scenarios.

Recently, several studies have sought to advance the application of AI technologies throughout the life cycle of DEs. Natural language processing can assist in extracting specific DEs from clinical documents [26-28]. Renner et al [29] explored the use of artificial neural networks to semiautomatically map DE models to the BRIDG model, thereby reducing the burden of manual mapping by experts. In addition, DEs play a role in collecting high-quality data to aid in training machine learning algorithms, further expanding their applications in the health information domain [30]. Littlefield et al [31], based on data collected through DEs, compared the performance of major machine learning algorithms with traditional statistical methods.

DE Repository

DE repositories serve as platforms for storing and managing DEs, facilitating standardization, and promoting the integration and sharing of medical data through both top-down and bottom-up approaches [32]. The bottom-up approach relies on users creating and maintaining their DEs. Hegselmann et al [33] have expanded upon this model by extracting real-world DEs from medical documents and standardizing them, thereby promoting the reusability of DEs. The DE repository can standardize metadata across various studies and institutions, facilitating data integration. Mallya et al [34] coordinated variables in 4 research endeavors through the effective usage of the DE repository.

Another crucial function of the DE repository is to ensure internal semantic consistency, thereby enhancing the semantic interoperability of DEs. One perspective suggests that the maintenance and updating of terms should be separated from the repository's operational tasks [35]. Schladetzky et al [36] developed the Mettertron system to enhance the linkage between the DE repository and the terminology system, simplifying terminology maintenance services. Meanwhile, mapping the repository model to the Web Ontology Language (OWL) ontology model can expand its semantic applications. Yuan and Li [37] constructed a semantic relation metamodel for the repository and defined mapping rules to the ontology model.

Recent research has also been conducted on data quality assessment based on the DE repository. For instance, Juárez et al [38] attempted to validate local data repositories by the central DE repository of networks, thereby providing a comparative method for assessing data quality across different sites. Kapsner et al [39] centralized the maintenance of data quality checks by associating data quality assessment tools with DE definitions in the DE repository.

Related Works

Current research lacks a comprehensive evaluation and analysis of multiple typical medical DE repositories. Ulrich et al [40] referenced information about specific metadata repositories in evaluating the application of the metadata exchange language QL4MDR. Hegselmann et al [33] also provided a brief overview of repository practices based on the ISO/IEC 11179 standard in his study on Pragmatic MDR. Nonetheless, both studies stopped short of providing a detailed evaluation or analysis and did not endeavor to suggest an analytical framework or standard.

Sasse et al [41] conducted a literature review on semantic annotation services for biomedical metadata. Through the review, they identified 10 supporting tools and conducted a detailed comparison based on 7 criteria. While their comparative dimensions are unidimensional and more aligned with tools rather than repositories, the variables in their semantic services provide a reference for the semantic dimensions in constructing the analytical framework for this study.

Stoehr et al [42] assessed the portal usability of the CoMetaR repository. They divided the web page into different modules and used the Think Aloud method along with a usability scale, conducting a combined quantitative and qualitative evaluation. While their method of module-based usability assessment provides insights for constructing usability evaluation dimensions in this study, it is worth noting that their focus is on optimizing the web page's interaction and does not compare it with the web pages of other repositories. Reichenpfader et al [43] similarly assessed the usability of the Portal of Medical Data Models (MDM-Portal) repository by analyzing the users' experience with the web page through various tests. The dimensions they analyzed also provide insights for the usability evaluation in this study.

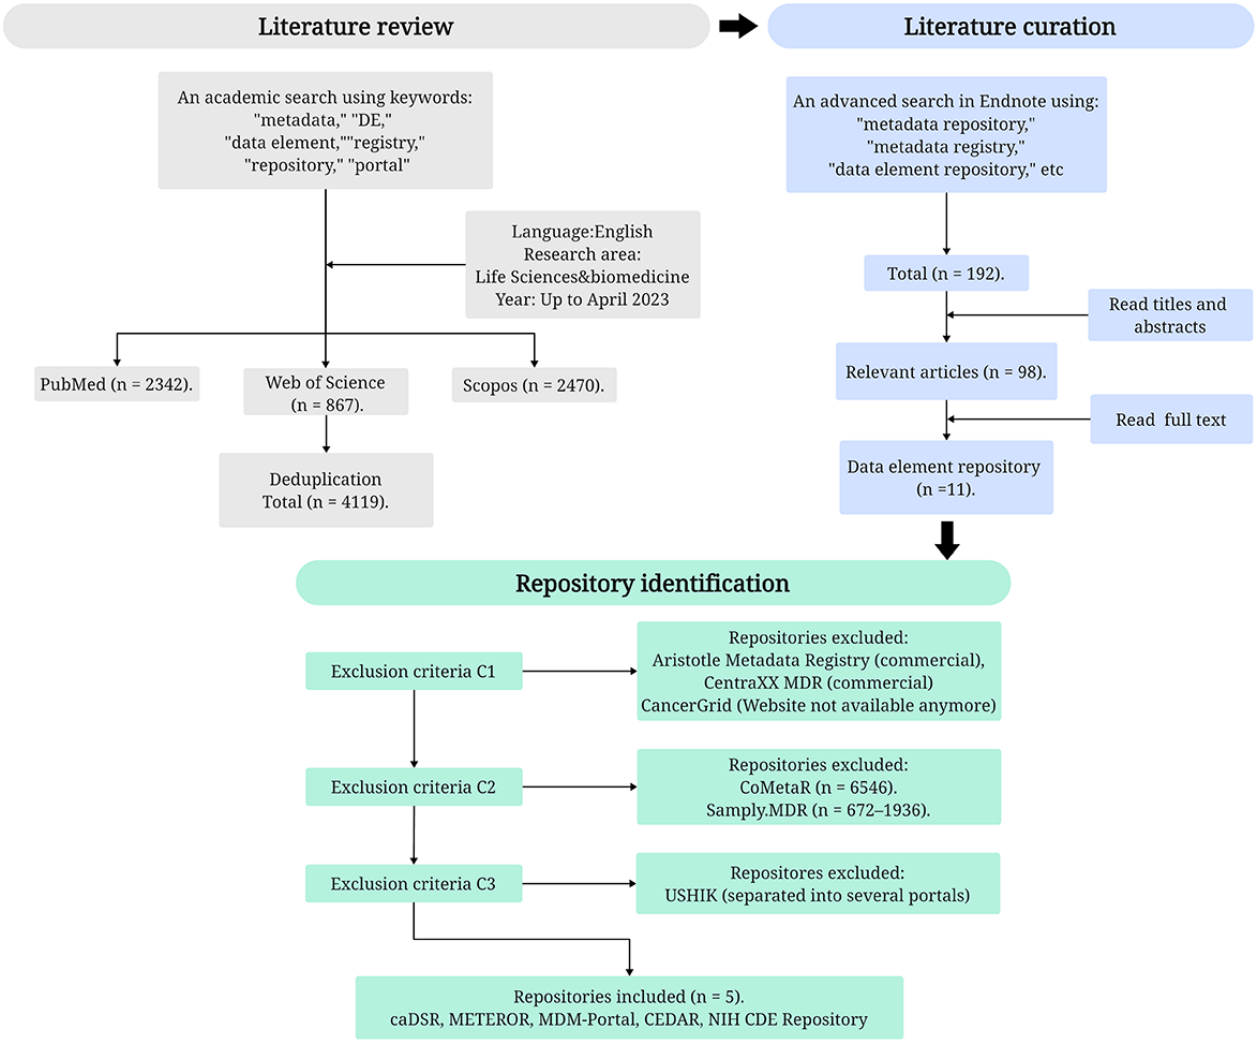
Objectives

The primary objective of this study is to explore potential issues and promote the broader application of DE repositories within the medical field by evaluating and analyzing typical repositories. Furthermore, we also endeavor to address the gap in the existing literature concerning the lack of evaluation of DE repositories, offering an overview of the typical DE repository construction in the medical field.

Methods

The method used in this study for screening medical DE repositories involves three distinct steps: (1) literature review, (2) literature curation, and (3) repositories identification (Figure 1).

Figure 1. Flowchart of screening the data element repository for this study through literature review. The upper left gray part is the first step: searching literature from various databases. The upper right blue part is the second step: obtaining the data element repository through further screening and reading of literature. The green part below is the third step: obtaining the data element repository for this study according to the 3 inclusion and exclusion criteria: C1, C2, and C3. caDSR: Cancer Data Standards Registry and Repository; CDE: Common Data Element; CEDAR: Center for Expanded Data Annotation and Retrieval; DE: Data Element; MDM-Portal: Portal of Medical Data Model; METEOR: Metadata Online Registry; NIH: National Institutes of Health.



Literature Review

This study conducted literature searches on PubMed, Web of Science, and Scopus. The searches were performed using a combination of keywords such as “metadata,” “data element,” and “DE,” combined with “repository,” “registry,” “platform,” and “portal.” The language was restricted to English, and the research area was focused on life sciences or biomedicine. Up to April 2023, a total of 4119 papers were retrieved.

Repository Curation

The retrieved literature was imported into Endnote, and an advanced search was conducted explicitly targeting titles or abstracts containing terms such as “metadata repository,” “metadata registry,” and “data element repository.” After this secondary screening, a total of 192 papers were obtained. After reviewing the titles and abstracts of these papers, 98 papers related to DE repositories were identified and subsequently read in full. In the end, 11 DE repositories (shown in Table 1) within the medical field were gathered. The information and data related to DE repositories were primarily collected from three sources: (1) the portals of various repositories, (2) relevant literature, and (3) project archives up to April 2023.

Table 1. Eleven data elements repositories retrieved from literature (repository URLs in references).

Data element repositories	Country
Samply.MDR [44]	Germany
MDM.Portal [45]	Germany
CoMetaR [46]	Germany
CentraXX MDR [47]	Germany
CancerGrid (2005-2010) [48]	United Kingdom
METEOR (METeOR) [49]	Australia
Aristotle Metadata Registry [50]	Australia
caDSR [51]	United States
USUIK [52]	United States
NIH CDE Repository [53]	United States
CEDAR [54]	United States

Repository Identification

To facilitate a more effective comparison, we established inclusion and exclusion criteria for screening the 11 repositories. The specific inclusion and exclusion criteria and the process are as follows:

1. C1: DE repositories should be open-access public platforms, meeting noncommercial or managed by nonprofit organizations (such as universities or research institutions).
2. C2: The repository's metadata or DE resources should comprise more than 20,000 records.
3. C3: We required the repository to have a well-established, independent portal to support access.

Five DE repositories were ultimately included (Table 2): Cancer Data Standards Registry and Repository (caDSR) [55], NIH (National Institutes of Health) CDE Repository, MDM-Portal [2], Metadata online registry (METEOR), and Center for Expanded Data Annotation and Retrieval (CEDAR) [56].

Table 2. Basic information of the 5 data element repositories included in this study.

Repositories	Country	First release year	Hosted by
caDSR[a]	America	2003	National Cancer Institute
NIH[b] CDE[c] Repository	America	2015	National Library of Medicine
METEOR[d]	Australia	2022	Australian Institute of Health and Welfare
MDM[e]	Germany	2012	Heidelberg University Hospital
CEDAR[f]	America	2014	Stanford University

[a]caDSR: Cancer Data Standards Registry and Repository.

[b]NIH: National Institutes of Health.

[c]CDE: Common Data Element.

[d]METEOR: Metadata Online Registry.

[e]MDM: Medical Data Model.

[f]CEDAR: Center for Expanded Data Annotation and Retrieval.

Analysis Framework

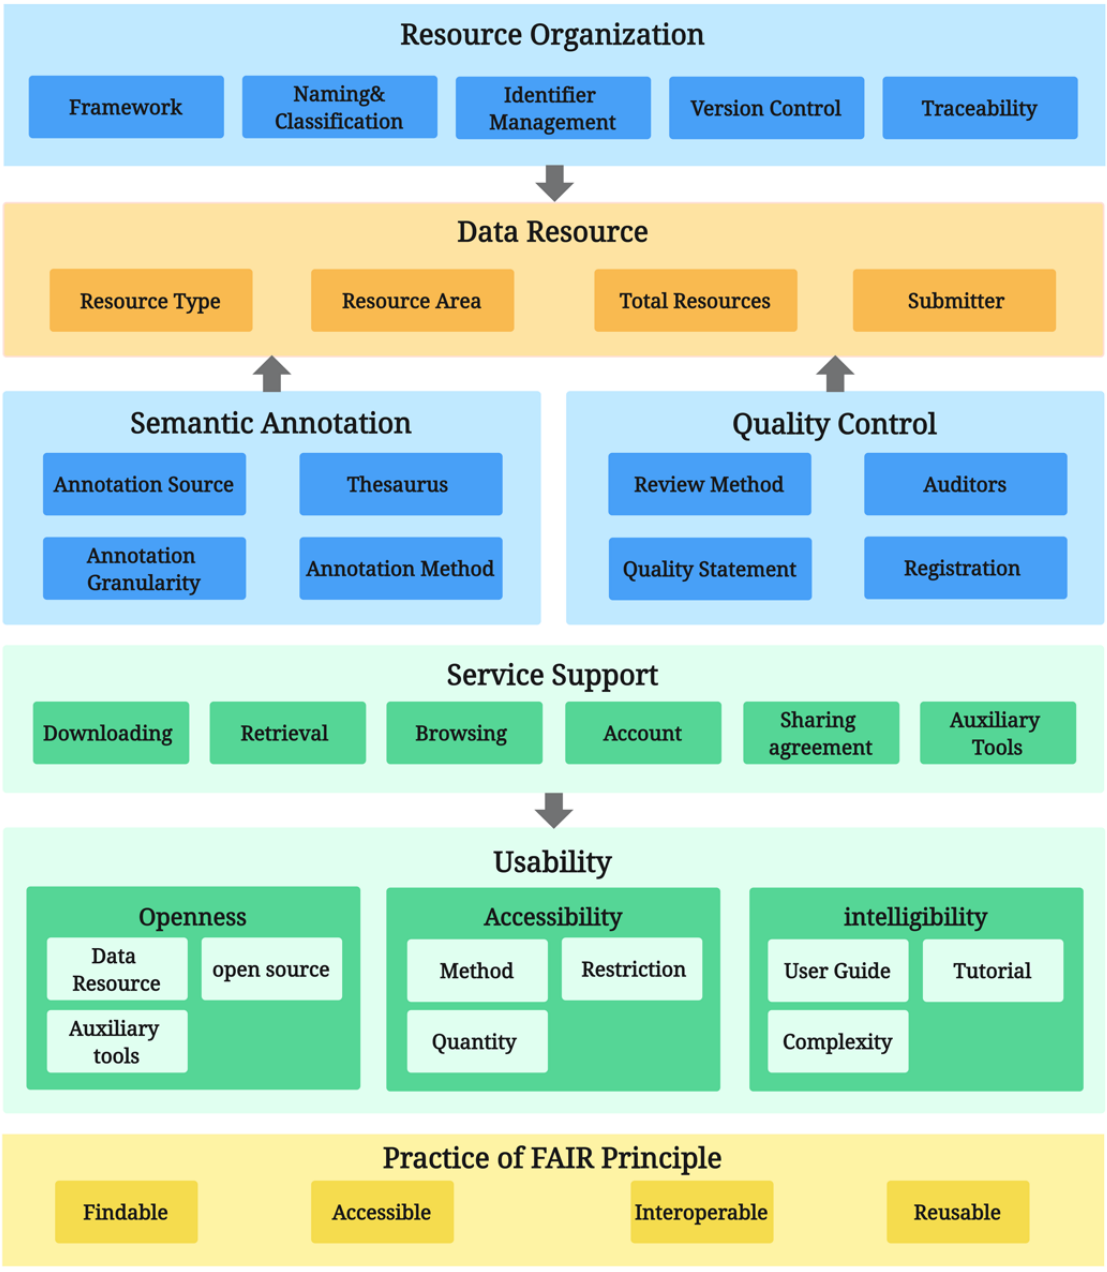
We aimed to comprehensively analyze the repositories, encompassing multiple dimensions, including technology, management, and services. To achieve this, we developed a comprehensive analysis framework consisting of 7 dimensions and 36 secondary indicators (Figure 1). The 7 dimensions include the following:

1. *Data resources*: providing an overview of the repository's data resources, including data volume, data types, data sources, coverage, and domains.
2. *Resource organization*: focusing on how metadata or DE resources are effectively organized and managed throughout their life cycle, including underlying frameworks, traceability, and version control.
3. *Quality control*: analyzing how the platform ensures the quality of stored data.
4. *Semantic annotation*: assessing how the repository achieves internal semantic consistency to enhance semantic interoperability.
5. *Service support*: examining the services offered to users by the repository, including basic services, such as retrieval and download, and advanced features such as analysis tools.

6. *Usability*: evaluating the platform's openness, accessibility, and intelligibility, including the availability of support documents and training materials.
7. *Practice of FAIR principles*: finally, analyzing the repository's adherence to the FAIR principles as a supplementary assessment.

Data resources and services dimensions are primarily determined by repository and portal characteristics, while resource organization, quality control, and semantics leverage insights from relevant literature and the ISO/IEC 11179 standard. Practice of FAIR adheres to the FAIR principle and its 15 subprinciples. Furthermore, 4 experts in data management, data warehousing construction, and data standardization participated in consultations to refine the analysis framework. Their input informed the division, naming, and selection of secondary indicators for the dimensions. The analysis framework was further refined based on expert suggestions primarily through (1) revising the name of Semantic Annotations and Service Support dimensions; (2) dividing the Usability dimension into 3 distinct modules: openness, accessibility, and intelligibility; and (3) adding more granular secondary indicators, such as source link and historical versions encoding, to enhance the depth of analysis (Figure 2). For a detailed description of the indicators included in this analytical framework, see Multimedia Appendix 1.

Figure 2. The analysis framework constructed in this study. The 7 light-colored parts represent the 7 analysis dimensions, and the dark rectangle in the middle is the specific indicator of each dimension. FAIR: Findable, Accessible, Interoperable, and Reusable.



Results

Data Resource

A comparison of the data resources of the 5 repositories was conducted (Table 3). The data resources of all 5 repositories are comprehensive, but each has its emphasis on specific subdomains. For example, caDSR focuses on cancer-related DEs, METEOR emphasizes health and welfare, while others encompass DEs from various biomedical research domains. The types of resources in the repositories include elements and forms. However, the names for DEs are not yet standardized across the repositories and may consist of terms such as CDE, DE, and Field, among others. Resources in caDSR, METEOR, and NIH CDE Repository are sourced from government and institutional research projects and are released through a top-down approach. In contrast, the other platforms rely on contributions from individual users, following a bottom-up data source model. The latter category tends to have a larger volume of resources, with MDM, for instance, cataloging the most extensive collection of DEs, totaling up to 500,000 elements and more than 20,000 forms.

Table 3. Analysis results of the 5 data element repositories in the data resource dimension.

Repositories	Area	Type	Total amount	Submitter
caDSR[a]	Cancer research, etc	DEs[b]	71,743 DEs	NIH[c] research institutes and programs
NIH CDE[d] Repository	Biomedical field	DEs and forms[e]	20,970 DEs; 1704 forms	NIH research institutes and programs
METEOR[f]	Health and welfare	DEs	21,180 DEs	Australian health department or research institution
MDM[g]	Clinical trials, special diseases, etc	DEs and forms	500,000 DEs; 24,810 forms	Individual user or project submissions
CEDAR[h]	Biomedical field	DEs and forms	120,829 DEs; 2000 forms	Individual user or project submissions

[a]caDSR: Cancer Data Standards Registry and Repository.

[b]DEs: Data Elements.

[c]NIH: National Institutes of Health.

[d]CDE: Common Data Elements.

[e]Forms: forms composed of data elements (eg, case report forms, questionnaires).

[f]METEOR: Metadata Online Registry.

[g]MDM: Medical Data Model.

[h]CEDAR: Center for Expanded Data Annotation and Retrieval.

Resource Organization

Regarding repository frameworks, all repositories except for MDM are constructed based on the ISO/IEC 11179 standard (Table 4). The DEs in these repositories are built upon the conceptual model of DEs and value domains outlined in the ISO/IEC 11179 standard. METEOR has extended this framework by introducing a top-level category called “data set specification” (DSS). This category is used to group specific DEs. For example, the “Diabetes (Clinical) DSS” in METEOR contains DEs related to standardized data collection for patients with diabetes. In MDM, which uses a custom DE framework, the attributes of DEs are relatively concise. They typically include only the DE description, data type, concept, and value domain information.

All repositories have assigned unique identifiers to their resources, although the granularity of the assignment varies. In the case of MDM, the smallest unit assigned an internal identifier is a form, and unique identifiers are not provided for individual DEs. On the other hand, other repositories assign unique identifiers at the level of individual DEs. Furthermore, the encoding of unique identifiers is standardized only within caDSR and METEOR. Simultaneously, some other repositories have inconsistent encoding methods for resources at the same hierarchical level, or they directly reference the source identifiers.

Regarding external provenance, most platforms can provide basic provenance information for DEs, such as the data submitter or the source institution. Among them, MDM provides the most detailed information, including the owner or institution of the DE, source links, and partial contact information. Regarding internal referencing and provenance, METEOR demonstrates the most comprehensive practice. It can support granularity to value domains, object classes, and properties. DEs in METEOR are listed with links to the attributes they reference and from which elements they are derived. Corresponding attributes such as value domains and object classes also provide links to all DEs that reference them. This allows for bidirectional provenance between elements and attributes.

Table 4. Analysis results of the 5 data element repositories in the resource organization dimension, with further explanation of identifiers, traceability, and version control indicators.

Repositories	Framework	Naming specification	Classification scheme	Identifier		Traceability				Version control	
				Name	Encoding	Submitter/source information	Source link	Source identifier	Internal citation link	Historical versions accessible	Version encoding

The version number formats for DEs in most repositories lack uniformity; in some cases, no version numbers are provided. In addition, some repositories do not allow access to historical versions of DEs, making them inaccessible for viewing. MDM has better version control practices in place. Historical versions of DEs are accessible and come with a standardized version number format. The version number includes a detailed editing data and information about the editor (eg, “4/6/22-Smith”). This allows users to navigate and browse historical versions using the version number as a reference.

Quality Control

DE quality control is primarily achieved through the audit process during registration. Currently, the audit process relies mainly on manual review, and it is evident shown in Table 5 that all 3 top-down repositories have established governance committees to conduct quality control audits. The audit process includes reviewing the basic attributes of elements (such as concepts and value domains), mapping or references between elements and controlled vocabularies, and the domain-specific expertise of elements. This audit process helps ensure the quality and authority of the published DEs, ensuring that their structural attributes are correct and appropriately specialized within their respective domains. However, it can be resource-intensive and time-consuming, requiring the involvement of experts. The bottom-up repositories MDM, on the other hand, cannot implement this process in the same way. Instead, it relies on repository administrators to conduct quality control audits. While this method can ensure only the basic structural integrity of data elements, its higher review efficiency makes it more suitable for bottom-up repositories handling large volumes of data element submissions.

A complete and well-defined registration workflow is a crucial part of quality control of DEs. MDM and CEDAR have not provided an entire registration process, while other repositories offer information on the registration workflow for DEs within the platform. They also assign identifiers for different registration statuses. METEOR and caDSR have more comprehensive registration statuses, with a finer-grained classification. In addition, only the NIH CDE Repository provides quality identifiers for DEs and includes only 1-level identifier (NIH-Endorsed). Other repositories do not appear to have detailed quality scoring or rating information. Only the NIH CDE Repository provides quality indicators for DEs, including a single-level indicator (NIH-Endorsed). Conversely, MDM relies on users to rate DEs, and other repositories do not seem to have detailed quality ratings or grading content.

Table 5. Analysis results of the 5 data element repositories in the quality control dimension, demonstrating the actions of each data element repository in data element quality control.

Repositories	Review method	Auditors	Quality mark	Registration			
				Registration workflow	Status identifier	Status type	Quality control records/documents
caDSR[a]	Manual review	Committee experts	No	Yes	Full life cycle	10	No
NIH[b] CDE[c] Repository	Manual review	Committee experts	NIH-Endorsed CDE	Yes	Full life cycle	2	No
METEOR[d]	Manual review	committee experts	No	Yes	Full life cycle	9	Yes
MDM[e]	Manual review	Portal administrator	No	N/A[f]	No	N/A	Partially provided
CEDAR[g]	N/A	N/A	No	N/A	No	N/A	No

Semantic Annotation

The repositories achieve semantic annotation by standardizing the mapping of DEs to terminology systems, ensuring internal semantic consistency (Table 6). The primary terminology systems used by these repositories include Unified Medical Language System (UMLS), Logical Observation Identifiers Names and Codes (LOINC), and Systematized Nomenclature of Medicine—Clinical Terms (SNOMED CT), with others such as National Cancer Institute Thesaurus (NCIT) and National Center for Biomedical Ontology (NCBO) also being used. METEOR has developed its internal glossary and achieves semantic annotation through metadata items called “Glossary Items (GIs).” GIs share the same DE framework as other elements but store the definition of a term. Other DEs can achieve semantic annotation by referencing the corresponding GI associated with a specific term. Creating and referencing internal glossaries effectively harnesses the advantages of the ISO/IEC 11179 DE framework. GIs essentially facilitate clustering according to the DE framework, including object class, property, value domain, and more. DEs belonging to the same object class can be associated with the terminology item by referencing it. For instance, by querying the GI item “person,” you can observe all DEs that reference this term as their object class. This clustering enhances the interrelatedness of DEs at the conceptual level. However, the shortcomings of internal glossaries are also evident. If DEs need to be used across institutions, there is a need for remapping terminology, or semantic inconsistencies may persist. Regarding semantic interoperability, internal glossaries are less effective referencing internationally recognized terminology repositories.

Table 6. Analysis results of the 5 data element repositories in the semantic annotation dimension, presenting the measures taken by each data element repository to semantically standardize data elements.

Repositories	Annotation source	Mapping vocabulary	Granularity	Annotation method	Annotation content
caDSR[a]	Controlled vocabulary	NCIT[b]	DE[c] concept and permissible value	Manual mapping	Terms and links
NIH[d] CDE[e] Repository	Controlled vocabulary	NCIT, UMLS[f], etc	DE concept and permissible value	Manual mapping	Terms and coding
METEOR[g]	Self-built vocabulary	Self-built vocabulary	DE concept	Manual mapping	Terms and links
MDM[h]	Controlled vocabulary	UMLS, LOINC,[i] and SNOMED CT[j]	DE concept and description	Automatic mapping	Terms and coding
CEDAR[k]	Controlled vocabulary	NCBO[l]	DE concept and permissible value	Manual mapping	Terms and links

Service Support

A robust retrieval system can enhance the discoverability of data resources within repositories. Each of the 5 repositories possesses unique search capabilities, for instance, caDSR and NIH CDE Repository allow users to search by the names of NIH-affiliated institutions (Table 7). METEOR and MDM allow users to construct search queries using Boolean operators and keywords. Furthermore, these platforms also differ in their secondary filtering criteria, with caDSR and METEOR supporting additional filters such as submitting organization, registration status, and registering organization, among others.

The repositories offer personalized services to users, including features such as personal favorites in NIH CDE Repository and METEOR, enabling users to collect elements of interest and record and browse their own created or edited metadata. In CEDAR, DEs are organized in a folder structure, facilitating the categorization and management of metadata.

With regard to data element download and export services, all repositories except CEDAR offer support for multiple export formats. MDM supports export in 18 formats, including Comma Separated Values (CSVs) and Operational Data Model (ODM), but it is limited to exporting data by form and allows only 50 downloads per week. METEOR provides Word and PDF export formats with lower levels of structure, which can impact interoperability. caDSR and NIH CDE Repository allow DEs and forms to be exported in various structured document formats such as EXCEL, XML, and JSON, providing a relatively comprehensive download service. On the other hand, CEDAR offers only JSON source code for elements without direct download capabilities. Although it has a REST API interface, it may not be as convenient for nonbatch exports.

All 4 platforms except CEDAR provide web-based metadata comparison tools, but they differ in the dimensions they support for comparison. MDM and METEOR can perform horizontal comparisons for all information of 2 DEs, while caDSR supports comparisons for multiple DEs. NIH CDE Repository offers vertical comparisons, allowing users to compare DEs with their historical versions. In addition to the comparison tools, MDM also provides a rich set of auxiliary tools, including ODMedit (for creating ODM format DEs and forms) [57], CDEGenerator (for visualizing concept frequencies in forms) [58], OpenEDC (for web-based data collection using forms), and more. MDM offers a more significant number of tools and functionality than other repositories.

Table 7. Analysis results of the 5 data element repositories in the service dimension, mainly presenting the various services provided by each data element repository on its portal website to help users better use the repository and data elements.

Repositories	Features of retrieval	Results secondary screening	Register account	Account service	Sharing agreement	Download service	Download granularity	Export format	Comparison tool	Other tools
caDSR[a]	Abbreviation of the institute's name, identifier, etc	Registration status, submitter, etc	N/A[b]	N/A	N/A	Unlimited downloads, batch download	DE and form	EXCEL, XML, and JSON	Compare 2 or more DEs[c]	Form creation
NIH[d] CDE[e] Repository	Abbreviation of the institute name, identifier, etc	Data type, submitter, etc	UTS[f] account	Personal favorites, browsing history, etc	N/A	Unlimited downloads, batch download	DE and form	EXCEL, XML, JSON	Compare different versions of DE	Not support
METEOR	Keywords, identifier, Boolean operators, etc	Registration organization, data type, etc	Internal account	Personal favorites and settings, browsing history, etc	N/A	Unlimited downloads, batch download	DE	Word, PDF	Compare 2 DEs	DE creation
MDM[g]	Keywords, Boolean operators, wild card character, etc	Keywords, research field	Internal account	Personal favorites, browsing history, etc	Four version CC 4.0 licenses	50 forms per week	Form	CSV, EXCEL, SQL, and other 18 formats	Compare 2 or more DEs	Web-based date capture, visualization, visual analysis tools, etc
CEDAR[h]	Keywords, terminology, etc	Data type, version, etc	Internal account	API[i] keys, personal folder	N/A	Not support	Not support	JSON code	Not support	DE and form creation

[i]API: Application Programming Interface.

Usability

We analyze the usability of the repositories from 3 perspectives: openness, accessibility, and intelligibility. Openness focuses on the extent to which the repository's resources and services are available for browsing and use. Among the 5 repositories in the study, access is typically restricted by requiring user accounts. Regarding data resources, caDSR, METEOR, and MDM provide unrestricted browsing access, including both forms and DEs. However, the NIH CDE Repository restricts viewing some semantic annotation content. Regarding services, MDM and CEDAR restrict auxiliary tools to logged-in users, including web-based creation and submission of DEs, among other features. In contrast, the DE creation and registration tools in the other 3 top-down repositories are not open to regular users. CEDAR requires registration for access to all services and resources, but it provides source code and technical documentation on GitHub. In summary, caDSR and METEOR exhibit the highest level of openness regarding resources and tools (Table 8).

Accessibility considers the types of accessible resources, the methods of accessibility, and the extent to which resources are accessible. There are primarily 2 ways to access repository resources: web downloads and application programming interface (API) interfaces. CEDAR does not provide web downloads and offers only JSON source code and an API interface. MDM requires user login for downloading forms and performing batch downloads, with a limit of 50 forms per week. In contrast, caDSR and NIH CDE Repository allow free downloads and batch exports of DEs without the need for login, making them relatively more accessible regarding resource availability.

Intelligibility focuses on the availability of supplementary information provided by the repositories and the complexity of constructing DEs. First, all 5 repositories offer user guide

documents on their portals, which introduce basic information and operations. In addition, CEDAR and caDSR have Archive and Wiki web pages to provide further information and support. The repositories also pay attention to teaching concepts related to DEs. Since not all users have a computer-related background, all 4 platforms except MDM provide introductions or tutorials on metadata, DEs, and the ISO/IEC 11179 standard.

In addition, most repositories lack descriptions and visual representations of their data resources' coverage areas and quantities. On its portal page, MDM provides visualizations of its DEs categorized by proportion, which can help users understand the resources within the repository. Compared with the complexity of DEs across the 5 platforms, MDM benefits from its self-built framework, resulting in relatively more straightforward and more concise DEs with better comprehensibility. In contrast, other platforms build their DEs based on the ISO/IEC 11179 standard and often expand or subdivide the framework, increasing the amount of information and complexity, which can affect comprehensibility.

Table 8. Analysis results of the 5 data element repositories in the usability dimension, mainly focusing on openness, accessibility, and usability, and comprehensively evaluating the usability of each data element repository.

Repositories	Openness					Accessibility				Intelligibility		
	Open access	Restriction	Create and submit	Open source	Auxiliary tool	Method	Limitation	Batch download	Quantity limitation	User guide	DE tutorial	DE complexity
caDSR[a]	DEs[b]	No	No	No	Yes	Download and API[c]	No	Yes	No	Document	Yes	High
NIH[d] CDE[e] Repository	DEs and forms	Partial DEs	No	No	Yes	Download and API	No	Yes	No	Documents	Yes	High
METEOR[f]	DEs	No	No	No	Yes	Download	No	Require log-in	No	Document	Yes	Middle
MDM[g]	DEs and forms	No	Yes	No	Partially require log-in	Download	No	Require log-in	50 forms per week	Video	No	Low
CEDAR[h]	DEs and forms	All resources	Yes	Yes	Require log-in	JSON code and API	Require log-in	No	No	Video and document	Yes	Middle

Practice of FAIR Principles

Finally, this study supplemented the analysis by evaluating the extent to which the 5 repositories comply with the FAIR principles. The level of compliance was categorized into 4 groups: complies completely, complies entirely, fails to comply, and unclear. The detailed content of each principle in FAIR can be found in Multimedia Appendix 2.

In Figure 3, a horizontal tally was conducted, with each of the 4 subprinciples of FAIR considered separately. The proportions of different levels of compliance to the subprinciples were calculated individually. For instance, considering the findable subprinciple, which comprises 4 principles (F1-F4), there are 20 cells. The proportions of "complies completely," "complies partly," "fails to comply," and "unclear" were then calculated for these 20 cells. The same process was applied to the remaining 3 subprinciples. Based on this step, Figure 4A was generated, depicting the overall adherence of repositories to each subprinciple. Figure 4B, calculated using the same method on a column basis, illustrates each repository's implementation of the FAIR principles.

Figure 3. Visualization of FAIR (Findable, Accessible, Interoperable, and Reusable) practices in 5 repositories, with practices divided into 4 levels: complies completely, complies partly, fails to comply, and unclear. Detailed subprinciples of FAIR are shown in Multimedia Appendix 2. caDSR: Cancer Data Standards Registry and Repository; CDE: Common Data Element; CEDAR: Center for Expanded Data Annotation and Retrieval; MDM: medical data model; METEOR: metadata online registry; NIH: National Institutes of Health.

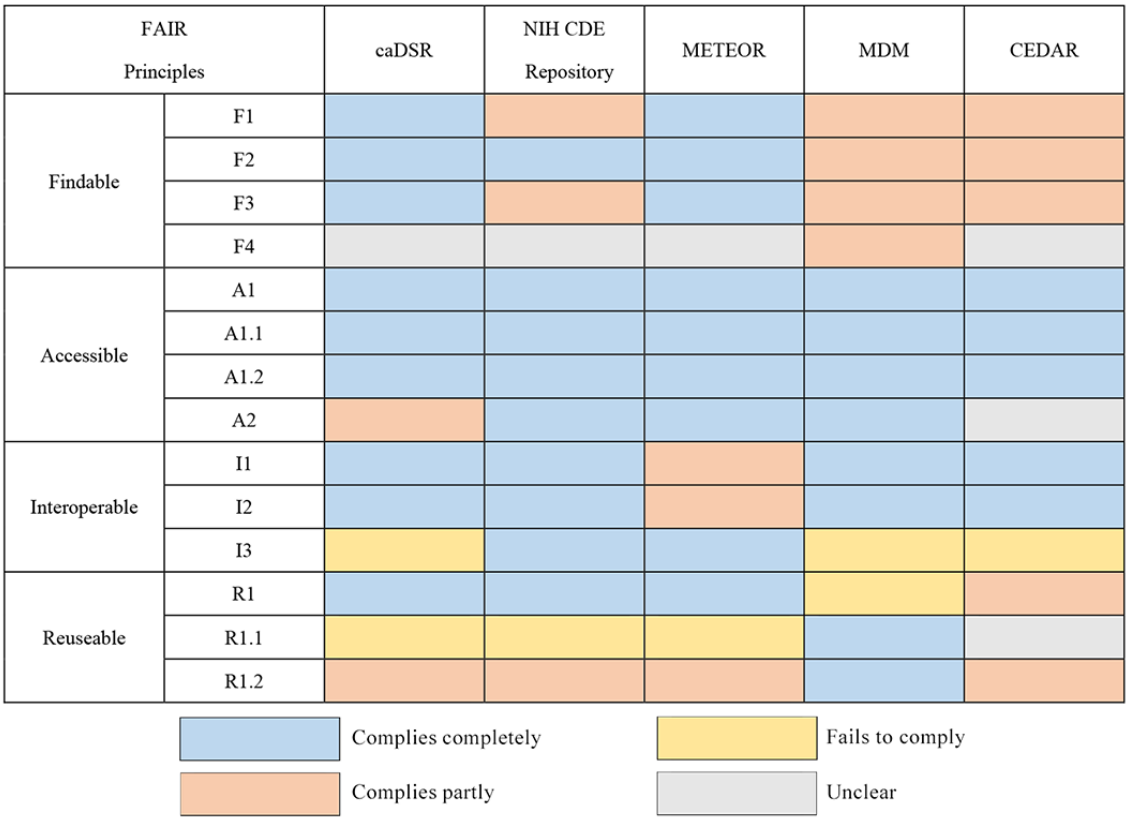

Figure 4. Statistics on the practice of FAIR (Findable, Accessible, Interoperable, and Reusable) principles based on Figure 3. (A) The figure starts from the perspective of FAIR principles and horizontally counts the practice of the 4 subprinciples in Figure 3. (B) The figure starts from the perspective of data element repositories and vertically counts the practice of FAIR principles in each repository in Figure 3. caDSR: Cancer Data Standards Registry and Repository; CDE: Common Data Element; CEDAR: Center for Expanded Data Annotation and Retrieval; MDM: medical data model; METEOR: metadata online registry; NIH: National Institutes of Health.

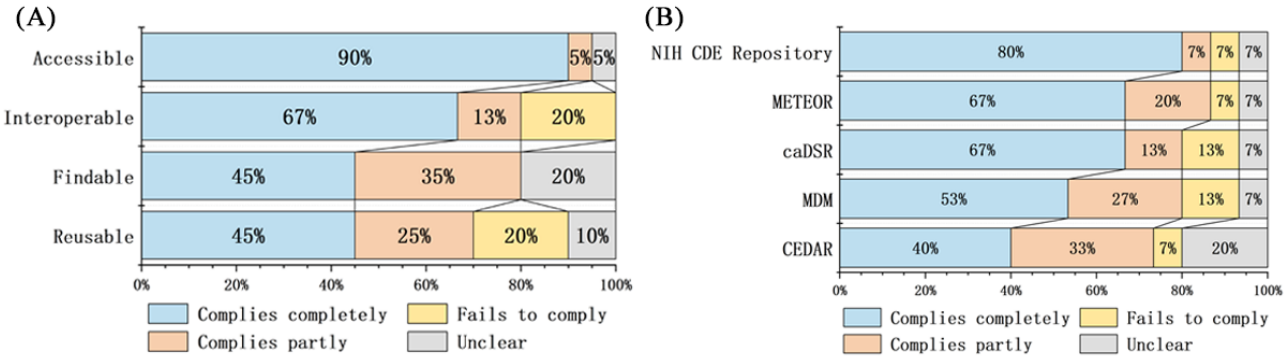

In comparison, among the 5 repositories, the NIH CDE Repository demonstrates the highest level of compliance with the FAIR principles, while CEDAR falls behind the other 4 platforms. When examining the 4 subprinciples of FAIR, overall, Accessibility is relatively well practiced and at the same time, Findability and Reusability have lower percentages of full compliance, indicating subpar adherence to these principles' aspects.

In the "Findable" principle, F4 "(Meta)data are registered or indexed in a searchable resource" is crucial for ensuring the discoverability of data resources on the web. Most of the 5 repositories analyzed in this study did not fully practice this aspect, impacting their web-based resources' discoverability. Only MDM has been registered in the international academic domain of registry and indexing for repositories, such as re3data and FAIR sharing.

In terms of the "Specific (meta)data are referred to by their identifier" subprinciple of interoperability, 3 repositories did not fully comply. This is mainly due to a lack of rich cross-referencing between DEs. METEOR had the best compliance with this subprinciple, as it provides comprehensive reference information for DEs on their detail pages.

Regarding the practice of "Reusability," the issues with the repositories primarily focus on data usage licenses and source information. Most repositories lack clear data usage licenses, which hinders data sharing. In addition, source information is often limited, with most repositories providing only submitter and time stamp information. Details about how the data were created and whether they had been previously published are typically not provided, impacting reusability.

Discussion

Principal Findings

The results of the analysis provide us with an overview of 5 DE repositories. The 2 approaches in repositories, namely, the top-down and bottom-up approaches, bring about differences and distinct characteristics regarding resources, semantics, and quality control. The community-driven, bottom-up approach where users submit resources, as seen in MDM and CEDAR, results in a richer pool of resources. This implies that repositories of this type need to implement more automation in various activities, including automated verification and terminology mapping. On the other hand, the top-down approach is the opposite of community-driven models. It relies on collaboration among experts from various domains. Expert committees are involved in designing, creating, and reviewing DEs in all 3 repositories following this approach. DEs following this approach have higher quality and authority, with a finer granularity in semantic annotations. However, consideration should still be given to their applicability outside the specific institution or research context. For example, DEs provided by repositories such as caDSR and NIH CDE Repository may be tailored to particular NIH-affiliated institutions and research scenarios. Conversely, community-driven DEs have a broader source base, potentially better reflecting real-world research situations. Their cross-study applicability might be more extensive.

Balancing the complexity and usability of DEs and repository metamodels is crucial. The data model structures built upon the ISO/IEC 11179 standard can be complex, and clinical researchers may not easily understand their underlying frameworks. It is essential to strike a balance to ensure that the repository remains user-friendly and accessible to its intended audience. Simplifying the framework, however, can complicate the organization of the repository. This may reduce the available information, which can negatively impact activities such as DE deduplication, establishing relationships, and hinder the development of advanced applications such as intelligent recommendations. While the self-built model of MDM is simple and user-friendly, it can organize resources only at the level of forms, lacking granularity down to the level of individual DEs. In contrast, repositories such as caDSR, built on the ISO/IEC 11179 standard, require more investment in learning and usage, but they offer more comprehensive and detailed management and organization capabilities.

Standardize Data Sharing

Promoting data sharing does not necessarily mean unrestricted sharing. DE sharing also requires clear agreements and statements. Among the 5 repositories in this study, only MDM provides 4 different versions of the CC-4.0 license as options for form resources, which offers clarity in licensing for these resources. The other 4 repositories have not provided such information on their platforms, and their affiliated institutions' data policies regarding the applicability to resources within these repositories are also somewhat unclear. Overall, these repositories seem to focus less on data sharing and reuse.

In the rapidly evolving landscape of open science, many mature examples of data-sharing strategies can serve as valuable references [59,60]. DEs are a form of data, and designing their sharing strategies can benefit from looking at the practices of other data-sharing platforms. We recommend that repositories clearly define protocols for sharing and reusing DEs in their portals. Furthermore, they should offer granularity down to the level of individual DEs, allowing resource submitters to choose specific sharing agreements. This approach can prevent unrestricted sharing and ensure greater control over DE access and usage.

The Interconnected Ecosystem of Repositories

While DE repositories facilitate the integration of DEs across institutions and projects, the gaps between DE repositories should not become new barriers to integration. In this study, the 5 repositories analyzed do not support direct sharing and exchange of resources among each other. Instead, resources must be exported and then recreated in the target repository. However, the exported formats may not be highly structured, and there is no support for importing these files for quick creation in another repository.

Despite most repositories being built based on the ISO/IEC 11179 standard, there is still a lack of interoperability and data exchange between these repositories. These limitations suggest establishing a comprehensive interconnected ecosystem for DE repositories. Both top-down and bottom-up approaches can complement each other in achieving this goal, thereby avoiding redundant construction and facilitating domain-specific developments. This can ultimately lead to more efficient and collaborative medical research efforts.

To build the interconnected ecosystem of repositories, our recommendations are as follows:

- Choose standardized repository frameworks (such as the ISO/IEC 11179 standard) and terminology systems (eg, UMLS) to avoid the need for secondary mapping of underlying frameworks or semantics.
- Enhance the export of DEs to provide more structured documents, such as CSV and JSON.
- Develop DE creation features that offer rapid import services, supporting content creation from structured documents.
- Consider developing a unified interface, like QL4MDR [40].

Enrich Information About DEs

A significant portion of DEs in DE repositories remains at the level of satisfying basic framework information. That is, they provide fundamental semantic information but lack application-oriented details. This includes contextual

information such as applicable scenarios, background details, and application outcomes. In this scenario, DEs are isolated fragments scattered throughout the repository, providing users minimal application support. Users are left uncertain whether a DE adheres to a particular standard or belongs to a specific data set, making it challenging to select accurate DEs and organize them into the required format. The repository also falls short in delivering advanced services such as intelligent recommendations.

Therefore, this study suggests that DE repositories should enrich the application information of DEs to support their practical use. We categorize application information into two aspects: (1) Application scenarios and background details: specifying the scenarios for which DEs are applicable, whether generic or specialized, and the standards or data sets from which they originate. Such contextual information can assist the repository in better associating and organizing relevant DEs. (2) Performance-related information: this can include statistics on the number of applications of a DE and user ratings, feedback, and other relevant details.

Furthermore, we recommend that the repositories consider using ontology resources to provide standardized terminology. Mature ontology repositories and tool kits, such as NCBO BioPortal [61] and Ontology Lookup Service [62], offer a wealth of ontology resources and support the download and localization of various ontology resources or their invocation through APIs. By using methods such as precise matching and semantic similarity calculation, DEs can be mapped to ontology terms, thereby standardizing DE concepts, value domains, and so on. This can provide specific term annotations for DEs and further enrich the available information.

Focus on Sensitive Data Protection

The existing repository contains DEs that collect sensitive information such as ID numbers, addresses, and phone numbers. However, these elements lack specific classification or identification to indicate that these DEs are used to collect sensitive data and may need to be deidentified or deleted. While the repository does not contain original research data, this remains a crucial issue for subsequent DE usage. We propose that the repository should align with the Health Insurance Portability and Accountability Act [63] or other relevant regulations and map the repository's DEs with the protected personal health information. The repository should create classifications and identifiers for privacy-related DEs. This will serve as a reminder to users about the sensitivity of such data and promote standardized usage practices.

Addressing the balance between FAIR data-sharing principles and privacy protection, we emphasize that FAIR promotes secure, compliant, and interoperable data sharing, not unrestricted dissemination. It advocates for data classification and the application of tailored sharing environments. Privacy data can be deidentified or directly removed during the aggregation phase. In subsequent sharing and reuse processes, while adhering to FAIR principles, we should establish a secure usage environment and sharing guidelines for the data. This includes data classification and grading, implementing differential sharing protocols, and using privacy-enhancing technologies such as privacy computing and federated learning to control data accessibility. This approach ensures effective data sharing and reuse under the FAIR principles while upholding privacy protection.

Implications

Theoretical Implications

In contrast to existing research that mainly concentrates developing specific technical aspects of DE repository construction, this study compares 5 typical DE repositories within the medical field and systematically evaluates and analyzes them. Furthermore, this study introduces a novel analysis framework consisting of 7 dimensions and 36 secondary indicators, based on the ISO/IEC 11179 standard and integrated with the FAIR principles. While this study focuses on the analysis of 5 DE repositories, we are confident that the proposed framework holds broad applicability to a wide range of repositories in the medical field. First, the 5 repositories included in this study have good representativeness, and their functions basically cover small repositories such as samply.MDR and CoMetaR. Therefore, the dimensions and indicators constructed by referring to these repositories can better cover general DE repositories and have more detailed content to be mined. Second, the ISO/IEC 11179 standard is an internationally used standard for the construction of DE repositories, and the FAIR principle is also a widely recognized data management and sharing guideline. Therefore, the dimensions and indicators constructed based on these 2 documents also have good applicability. Finally, in the process of constructing the analysis framework, we invited experts in data management and standardization to discuss and suggest the analysis framework. Simultaneously, the ISO/IEC 11179 standard provides specific definitions for the concept model of DEs and standardizes related management activities. Integrating of these 2 components in the analytical framework serves as the foundation for potential future research endeavors, allowing for further refinement of relevant standards and theories related to DE repositories.

Practical Implications

The practical significance of this study lies in its potential to drive the construction of DE repositories, facilitating a more robust implementation of the FAIR principles during the construction and management processes. This, in turn, contributes to a more substantial role in the data-driven advancement of medicine. For DE repository administrators, this study's findings assist them in understanding the repository's strengths and limitations, offering the necessary information for further improvements to the repository.

In addition, the integrated information on DE repositories from this research may hold practical implications for individuals involved in medical informatics research. For clinical research data managers, this information can assist them in gaining a better understanding of DE repositories. They can use this knowledge to make informed choices regarding suitable repositories and reuse DEs, reducing redundant design work in the clinical research process. For computer experts developing medical information systems, this research encompasses resource organization and management information from

multiple repositories, along with service design offered by web apps. This can reference the top-level structure of DE repositories within their respective institutes.

Conclusions and Limitations

Medical DEs enhance data quality, foster data reuse, and maximize the value of data in the era of health big data. They also form the foundational basis for AI-based medical systems. This study, using a constructed multidimensional analytical framework, evaluates and analyzes the current state of construction of typical medical DE repositories. It summarizes the characteristics of different repositories and provides recommendations based on identified issues. This study's findings can promote the broader application of DE repositories, ensuring that DEs and repositories better serve clinical and medical research needs. Furthermore, this research can have applications in medical knowledge organization, and semantic representation, thus contributing to the development of AI technologies in medicine.

This study also has some limitations and areas for future improvement. First, the study had limited inclusion of databases, focusing solely on comprehensive, noncommercial DE repositories, all in the English language. Smaller or domain-specific repositories may have been overlooked. Furthermore, the data primarily came from repository websites and literature, with little attention given to other sources such as social media accounts. This approach might have missed some of the latest updates or changes. Therefore, future research will consider expanding the scope to include more repositories for analysis, relaxing constraints related to quantity and language. In addition, efforts will be made to enhance the generality of the analysis framework and develop a practical model for DE repositories.

Abstract

Background: A large language model is a type of artificial intelligence (AI) model that opens up great possibilities for health care practice, research, and education, although scholars have emphasized the need to proactively address the issue of unvalidated and inaccurate information regarding its use. One of the best-known large language models is ChatGPT (OpenAI). It is believed to be of great help to medical research, as it facilitates more efficient data set analysis, code generation, and literature review, allowing researchers to focus on experimental design as well as drug discovery and development.

Objective: This study aims to explore the potential of ChatGPT as a real-time literature search tool for systematic reviews and clinical decision support systems, to enhance their efficiency and accuracy in health care settings.

Methods: The search results of a published systematic review by human experts on the treatment of Peyronie disease were selected as a benchmark, and the literature search formula of the study was applied to ChatGPT and Microsoft Bing AI as a comparison to human researchers. Peyronie disease typically presents with discomfort, curvature, or deformity of the penis in association with palpable plaques and erectile dysfunction. To evaluate the quality of individual studies derived from AI answers, we created a structured rating system based on bibliographic information related to the publications. We classified its answers into 4 grades if the title existed: A, B, C, and F. No grade was given for a fake title or no answer.

Results: From ChatGPT, 7 (0.5%) out of 1287 identified studies were directly relevant, whereas Bing AI resulted in 19 (40%) relevant studies out of 48, compared to the human benchmark of 24 studies. In the qualitative evaluation, ChatGPT had 7 grade A, 18 grade B, 167 grade C, and 211 grade F studies, and Bing AI had 19 grade A and 28 grade C studies.

Conclusions: This is the first study to compare AI and conventional human systematic review methods as a real-time literature collection tool for evidence-based medicine. The results suggest that the use of ChatGPT as a tool for real-time evidence generation is not yet accurate and feasible. Therefore, researchers should be cautious about using such AI. The limitations of this study using the generative pre-trained transformer model are that the search for research topics was not diverse and that it did not prevent the hallucination of generative AI. However, this study will serve as a standard for future studies by providing an index to verify the reliability and consistency of generative AI from a user's point of view. If the reliability and consistency of AI literature search services are verified, then the use of these technologies will help medical research greatly.

Introduction

The global artificial intelligence (AI) health care market size was estimated to be at US $15.1 billion in 2022 and is expected to surpass approximately US $187.95 billion by 2030, growing at an annualized rate of 37% during the forecast period from 2022 to 2030 [1]. In particular, innovative applications of medical AI are expected to increase in response to medical demand, which will explode in 2030 [2,3].

A large language model (LLM) is a type of AI model that opens up great possibilities for health care practice, research, and education, although scholars have emphasized the need to proactively address the issue of unvalidated and inaccurate information regarding its use [4,5]. One of the best-known LLMs is ChatGPT (OpenAI). It was launched in November 2022. Similar to other LLMs, ChatGPT is trained on huge text data sets in numerous languages, allowing it to respond to text input with humanlike responses [4]. Developed by the San Francisco–based AI research laboratory OpenAI, ChatGPT is based on a generative pre-trained transformer (GPT) architecture. It is considered an advanced form of a chatbot, an umbrella term for a program that uses a text-based interface to understand and generate responses. The key difference between a chatbot and ChatGPT is that a chatbot is usually programmed with a limited number of responses, whereas ChatGPT can produce personalized responses according to the conversation [4,6].

Sallam's [5] systematic review (SR) sought to identify the benefits and current concerns regarding ChatGPT. That review advises that health care research could benefit from ChatGPT, since it could be used to facilitate more efficient data set analysis, code generation, and literature reviews, thus allowing researchers to concentrate on experimental design as well as drug discovery and development. The author also suggests that ChatGPT could be used to improve research equity and versatility in addition to its ability to improve scientific writing. Health care practice could also benefit from ChatGPT in multiple ways, including enabling improved health literacy and delivery of more personalized medical care, improved documentation, workflow streamlining, and cost savings. Health care education could also use ChatGPT to provide more personalized learning with a particular focus on problem-solving and critical thinking skills [5]. However, the same review also lays out the current concerns, including copyright issues, incorrect citations, and increased risk of plagiarism, as well as inaccurate content, risk of excessive information leading to an infodemic on a particular topic, and cybersecurity issues [5].

A key question regarding the use of ChatGPT is if it can use evidence to identify premedical content. Evidence-based medicine (EBM) provides the highest level of evidence in medical treatment by integrating clinician experience, patient value, and best-available scientific information to guide decision-making on clinical management [7]. The principle of EBM means that the most appropriate treatment plan for patients should be devised based on the latest empirical research evidence. However, the scientific information identified by ChatGPT is not yet validated in terms of safety or accuracy according to Sallam [5], who further suggests that neither doctors nor patients should rely on it at this stage. In contrast, another study by Zhou et al [8] found that answers provided by ChatGPT were generally based on the latest verified scientific evidence, that is, the advice given followed high-quality treatment protocols and adhered to guidelines from experts.

In medicine, a clinical decision support system (CDSS) uses real-time evidence to support clinical decision-making. This is a fundamental tool in EBM, which uses SRs based on a systematic, scientific search of a particular subject. If ChatGPT becomes a CDSS, it is fundamental to determine whether it is capable of performing a systematic search based on real-time generation of evidence in the medical field. Therefore, this study will be the first to determine whether ChatGPT can search papers for an SR. In particular, this study aims to present a standard for medical research using generative AI search technology in the future by providing indicators for the reliability and consistency of generative AI searches from a user's perspective.

Methods

Ethical Considerations

As per 45 CFR §46.102(f), the activities performed herein were considered exempt from institutional review board approval due to the data being publicly available. Informed consent was not obtained, since this study used previously published deidentified information that was available to the general public. This study used publicly available data from PubMed, Embase, and Cochrane Library and did not include human participant research.

Setting the Benchmark

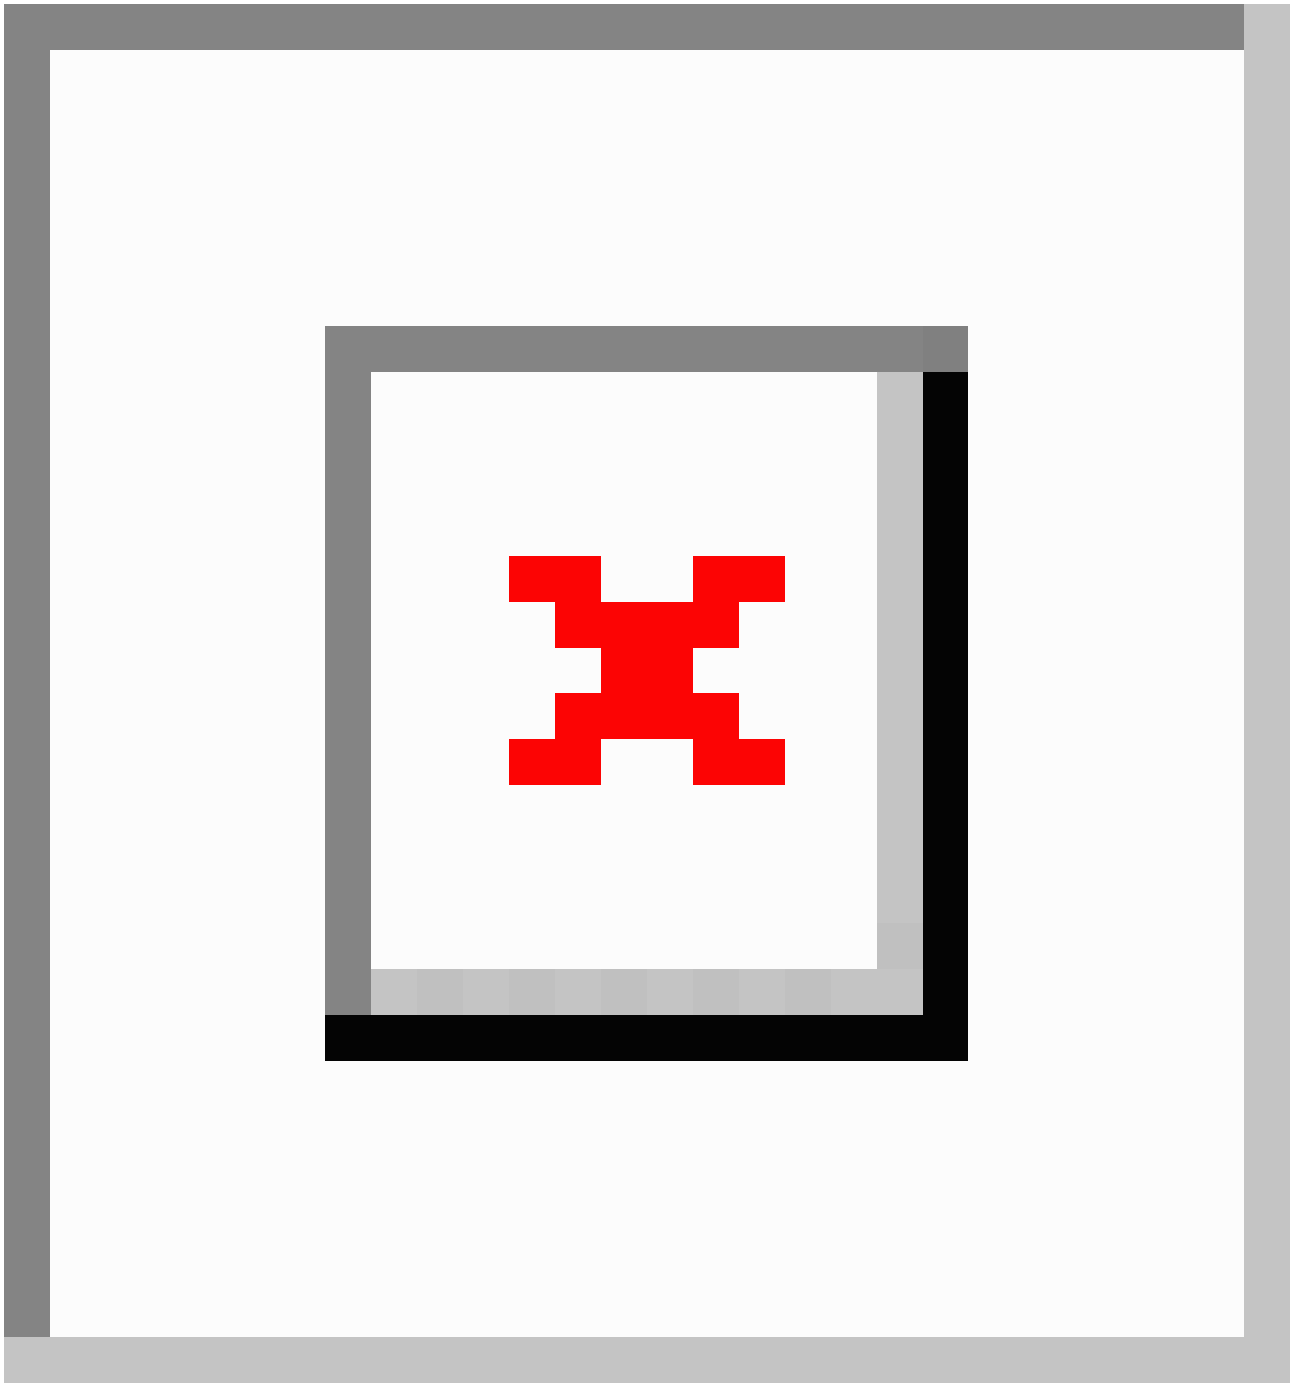
To determine whether ChatGPT, currently the most representative LLM, is capable of systematic searches, we set an SR that was performed by human experts as a benchmark and checked how many studies were finally included in the benchmark were presented by ChatGPT. We chose Lee et al [9] as the benchmark for the following reasons. First, Lee et al [9] performed an SR and meta-analysis about the medical treatment for Peyronie disease (PD) with human experts. PD typically presents with discomfort, curvature, or deformity of the penis in association with palpable plaques and erectile dysfunction [10]. Second, it was easy to compare the results of ChatGPT and the benchmark, because we had full information about the interim process and results of the study. Third, a sufficient amount of studies has been published about the medical treatment for PD, but there is still no consensus answer. So, we expected to assess the sole ability of ChatGPT as a systematic search tool with sufficient data while avoiding any possible pretrained bias. Lastly, with the topic of Lee et al [9], we could build questions that start broad and become more specific and add some conditions that could test ChatGPT's comprehension about scientific research. For example, questions could not only be built broadly by asking about "medical treatment for Peyronie's disease" but also specifically by asking about "oral therapy for Peyronie's disease" or "colchicine for Peyronie's disease." Because Lee et al [9] only contained randomized controlled trials (RCTs), we could add a condition

to the questions to restrict the study type to RCTs, which could be useful to assess the comprehension of ChatGPT.

Systematic Search Formula of Benchmark

Lee et al [9] used the following search query in PubMed and Cochrane Library: *("penile induration"[MeSH Terms] OR "Peyronie's disease"[Title/Abstract]) AND "male"[MeSH Terms] AND "randomized controlled trial"[Publication Type]*, and the following query in Embase: *('Peyronie disease'/exp OR 'Peyronie's diseas':ab,ti) AND 'male'/exp AND 'randomized controlled trial'/de*. After the systematic search, a total of 217 records were identified. Studies were excluded for the following reasons: not RCTs, not perfectly fit to the topic, not enough sample size or outcome, and not written in English. Finally, 24 RCTs were included in the SR, with only 1 RCT published in 2022 (Figure 1) [9]. The characteristics of all studies included in Lee et al [9] are summarized in Section S1 in Multimedia Appendix 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for Lee et al [9]. RCT: randomized controlled trial.



Methodology of Systematic Search for ChatGPT

Based on the search formula used in Lee et al [9], a simple mandatory prompt in the form of a question was created, starting with comprehensive questions and gradually asking more specific questions (Textbox 1). For example, questions could be built as "Could you show RCTs of colchicine for Peyronie's disease in PubMed?" with the treatment and database changed

under the same format. In addition to mandatory questions, we added questions about treatment additionally provided by ChatGPT during the conversation. Considering the possibility that ChatGPT might respond differently depending on the interaction, we arranged questions into 2 logical flows, focusing on database and treatment, respectively (Figure 2 and Figure S1 in Multimedia Appendix 1). We asked about search results from 4 databases: PubMed [11], Google (Google Scholar) [12], Cochrane Library [13], and ClinicalTrials.gov [14]. PubMed is a leading biomedical database offering access to peer-reviewed articles. Google Scholar provides a wide-ranging index of scholarly literature, including medical studies. Cochrane Library specializes in high-quality evidence through SRs and clinical trials. ClinicalTrials.gov, managed by the National Library of Medicine, serves as a comprehensive repository for clinical study information globally. These databases collectively serve researchers by providing access to diverse and credible sources, facilitating literature reviews and evidence synthesis, and informing EBM in the medical field. They play crucial roles in advancing medical knowledge, supporting informed decision-making, and ultimately improving patient care outcomes [11-14]. These 4 databases were easy to access and contained most of the accessible studies. Each question was repeated at least twice. We extracted the answers and evaluated the quality of information based on the title, author, journal, and publication year (Sections S2-S5 Multimedia Appendix 1).

Textbox 1. Mandatory question prompts.

Basic format of questions

- "Could you show RCTs of (A) for Peyronie's disease in (B)?"

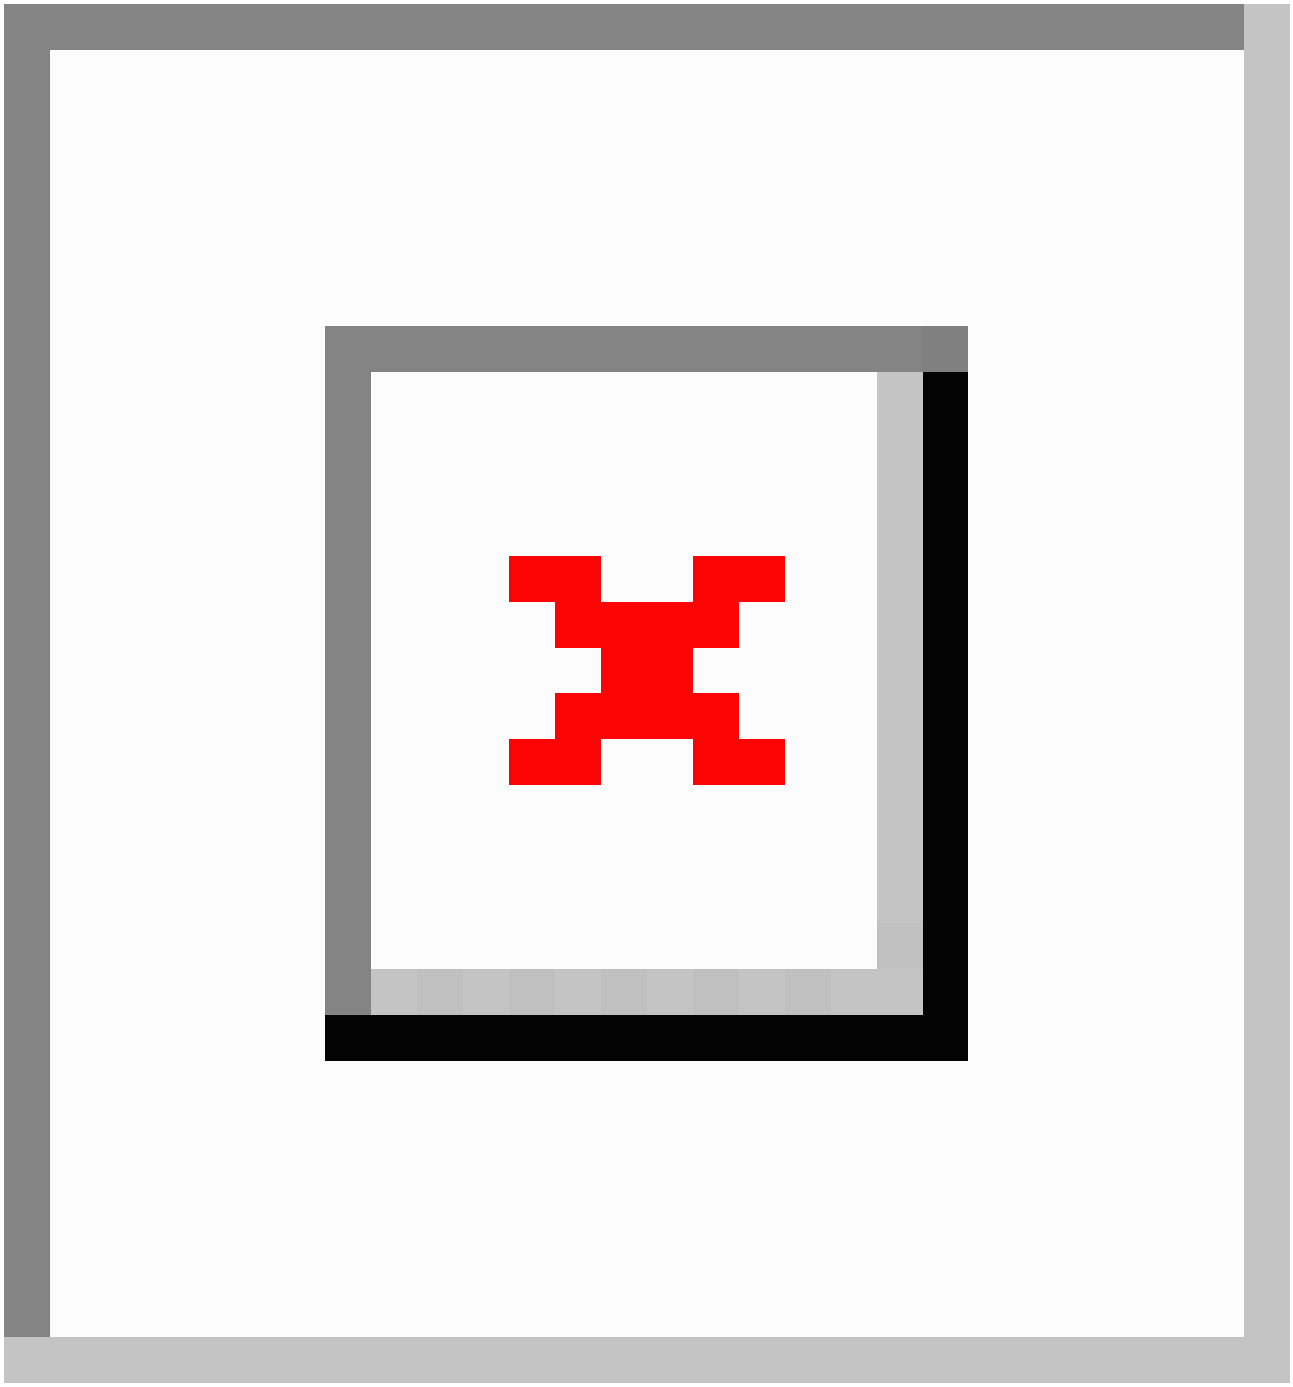
(A) Treatment category and specific treatment

- **Oral therapy**
  - Vitamin E, colchicine, L-carnitine, potassium aminobenzoate, tamoxifen, pentoxifylline, tadalafil, L-arginine, and sildenafil
- **Intralesional therapy**
  - Verapamil, interferon-a2B, collagenase *Clostridium histolyticum*, transdermal electromotive administration, hyaluronidase, triamcinolone, mitomycin C, super-oxide dismutase, and 5-fluorouracil
- **Mechanical therapy**
  - Extracorporeal shockwave therapy, iontophoresis, traction therapy, vacuum, penile massage, and exercise shockwave therapy
- **Topical therapy**
  - 5-Alpha-reductase inhibitors, superficial heat, diclofenac gel, collagenase *Clostridium histolyticum* gel, verapamil gel, potassium aminobenzoate gel, and propionyl-L-carnitine gel

(B) Database

- PubMed
- Google (Google Scholar)
- Cochrane Library
- ClinicalTrials.gov

Figure 2. Logical flow and results focusing on database for ChatGPT. RCT: randomized controlled trial.



We used the GPT-3.5 version of ChatGPT, which was pretrained with data before 2021, for the systematic search and evaluated how many RCTs that were included in Lee et al [9] were present in the search results from ChatGPT. To assess the reliability of ChatGPT's answers, we also evaluated whether the studies presented actually existed. ChatGPT's response style and the amount of information might vary from answer to answer. Thus, we evaluated the accuracy of the responses by prioritizing a match by (1) title; (2) author, journal, and publication year; and (3) other items.

To obtain higher-quality responses, it is important to structure the prompts using refined language that is well understood by the LLM [15-17]. In this study, we performed the following fine-tuning to clearly convey the most important content or information. We first defined roles and provided context and input data before asking complete questions to get responses, and we used specific and varied examples to help the model narrow its focus and produce more accurate results [18,19]. During the prompt engineering, the treatment category, specific treatment, and target databases were structured in order, and the order was changed in the detailed elements to induce consistent answers. Details of this are presented in Multimedia Appendix 1.

Quality Assessment of Answers

To evaluate the quality of individual studies derived from AI answers, we created a structured rating system based on bibliographic information related to the publications (Table 1).

We classified its answers into 4 grades if the title existed: A, B, C, and F. No grade was given for a fake title or no answer.

Table . Grade table based on bibliographic information.

Grade	Title actually exists	PICOS[a]	Essential information				Accessory information				Definition of grade
			Title	Author	Journal	Publication year	Issue number	Page number	DOI	PMID	
A	Yes	✓[b]	✓	✓	✓	✓	✓	✓	✓	✓	All bibliographic information matched
B	Yes	✓	✓	✓	✓	✓	Any X[c]	Any X	Any X	Any X	PICOS and essential information matched, but not accessory information
C	Yes	X[d]	✓	✓	✓	✓	N/A[e]	N/A	N/A	N/A	Essential information matched, but not PICOS
F	Yes	N/A	✓	Any X	Any X	Any X	N/A	N/A	N/A	N/A	Title matched, but not other essential information

[a]PICOS: population, intervention, comparison, outcome, and study design (research questions).

[b]Matched.

[c]Any mismatch in essential information or accessory information.

[d]Mismatch.

[e]N/A: not assessed.

A grade of "A" was given to an answer that was appropriate for the question and perfectly consistent with the actual study. For example, for the question "Could you show all RCTs of medical treatment for Peyronie's disease in Google?" ChatGPT answered "Gelbard MK, James K, Riach P, Dorey F. Collagenase versus placebo in the treatment of Peyronie's disease: a double-blind study. J Urol. 1993; 149(1):56-58." This answer was perfectly consistent with actual study because the authors, title, journal, publication year, issue number, and even page number matched, and it was appropriate because it was an RCT, was about medical treatment for PD, and could be found in Google.

A grade of "B" was given to an answer that was appropriate for the question and the title, author, journal, and publication year matched with the actual study. For example, for the question "Could you show RCTs of Intralesional therapy for Peyronie's disease in Cochrane Library?" ChatGPT answered "Gelbard MK, James K, Riach P, Dorey F. Collagenase versus placebo in the treatment of Peyronie's disease: a double-blind study. J Urol. 1993 Feb; 149(2):56-8. doi: 10.1016/s0022-5347(17)36148-1. PMID: 8426418." This answer was appropriate because it was an RCT, was about intralesional therapy for PD, and could be found in Cochrane Library. However, this answer was consistent with the title, authors, journal, and publication year of actual study but inconsistent with the accessory information for publication month, issue number, page number, DOI, and PMID. So, it was able to specify the presented study with essential information, but the accessory information was not consistent with the actual study.

A grade of "C" was given to an answer that was inappropriate for the question but the title, author, journal, and publication year matched with the actual study. For example, for the question "Could you show RCTs of Pentoxifylline for Peyronie's disease in PubMed?" ChatGPT answered "Gelbard MK, James K, Riach P, Dorey F. Collagenase versus placebo in the treatment of Peyronie's disease: a double-blind study. J Urol. 1993; 149(1):56-8. doi: 10.1016/s0022-5347(17)36091-7. PMID: 8417228." This answer was consistent with the title, authors, journal, and publication year of the actual study, but it was inappropriate because it was not about the use of pentoxifylline for PD.

A grade of "F" was given to an answer that was inconsistent with the author, journal, or publication year of the actual study that matched the title, making it impossible to be specified. Thus, it was considered as a fake study that was generated. For

example, for the question "Could you show RCTs of collagenase *Clostridium histolyticum* for Peyronie's disease in PubMed?" ChatGPT answered "Gelbard MK, James K, Riach P, Dorey FJ, & Collagenase Study Group. (2012). Collagenase versus placebo in the treatment of Peyronie's disease: a double-blind study. The Journal of urology, 187(3), 948-953." This answer was consistent with the title of the actual study but inconsistent with the authors, publication year, and so on.

Searching Strategy for Bing AI

To compare with ChatGPT, we performed the same process with Bing AI [20], also known as "New Bing," an AI chatbot developed by Microsoft and released in 2023. Since Bing AI functions based on the huge AI model "Prometheus" that includes OpenAI's GPT-4 with web searching capabilities, it is expected to give more accurate answers than the GPT-3.5 version of ChatGPT. We performed the conversation with the "Precise" tone. Because Bing AI limited the number of questions per session to 20, we did not arrange questions into 2 logical flows (Section S6 in Multimedia Appendix 1). We compared the number of studies included in the benchmark [9] and provided by Bing AI. We also evaluated the reliability of answers with the same method described above or using links of websites presented by Bing AI (Figure S2 and Section S7 in Multimedia Appendix 1).

Results

Systematic Search Results via ChatGPT

A total of 639 questions were entered into ChatGPT, and 1287 studies were obtained (Table 2). The systematic search via ChatGPT was performed from April 17 to May 6, 2023. At the beginning of the conversation, we gave ChatGPT the role of a researcher conducting a systematic search who intended to perform a meta-analysis for more appropriate answers. At first, we tried to build question format by using the word "find," such as "Could you find RCTs of medical treatment for Peyronie's disease?" However, ChatGPT did not present studies and only suggested how to find RCTs in a database, such as PubMed. Therefore, we changed the word "find" to "show," and ChatGPT presented lists of RCTs. For comprehensive questions, ChatGPT did not give an answer, saying that it did not have the capability to show a list of RCTs as an AI language model. However, when questions were gradually specified, it created answers (Sections S2 and S4 in Multimedia Appendix 1).

Table . Quality assessment of answers from ChatGPT and Bing AI[a].

Searcher, setting, and question level		Grade, n				Studies, n
		A	B	C	F	
ChatGPT						
Database setting						
	Comprehensive question	1	0	3	5	56
	Category-specific question	1	1	8	18	124
	Treatment-specific question	4	7	67	87	545
	Total	6	8	78	110	725
Treatment setting						
	Comprehensive question	0	0	0	1	27
	Category-specific question	0	0	4	8	61
	Treatment-specific question	1	10	85	92	474
	Total	1	10	89	101	562
Total		7	18	167	211	1287
Bing AI						
Comprehensive question		0	0	1	0	1
Category-specific question		0	0	7	0	7
Treatment-specific question		19	0	20	0	40
Total		19	0	28	0	48
Human[b]		24	0	0	0	24

[a]AI: artificial intelligence.

[b]From Lee et al [9].

Of the 1287 studies provided by ChatGPT, only 7 (0.5%) studies were perfectly eligible and 18 (1.4%) studies could be considered suitable under the assumption that they were real studies if only the title, author, journal, and publication year matched (Table 2). Among these, only 1 study was perfectly consistent with studies finally included in Lee et al [9], and 4 studies were matched under the assumption (Sections S1, S3, and S5 in Multimedia Appendix 1).

Specifically, systematic search via ChatGPT was performed in 2 logical flow schemes, database setting and treatment setting (Figure 2 and Figure S1 in Multimedia Appendix 1). With the logical flow by database setting, among the 725 obtained studies, 6 (0.8%) and 8 (1.1%) studies were classified as grade A and grade B, respectively (Table 1). Of these, 1 grade A study and 1 grade B study were included in Lee et al [5]. With the logical flow by treatment setting, among the 562 obtained studies, 1 (0.2%) study was classified as grade A and 10 (1.8%) studies were classified as grade B. Of these, 3 grade B studies were included in the benchmark [9] (Table 2).

It was common for answers to be changed. There were many cases where answers contradicted themselves. In addition, there were cases where the answer was “no capability” or “no RCT found” at first, but when another question was asked and the previous question was asked again, an answer was given. ChatGPT showed a tendency to create articles by rotating some format and words. Titles presented were so plausible that it was almost impossible to identify fake articles until an actual search was conducted. The presented authors were also real people. Titles often contained highly specific numbers, devices, or brand names that were real. There were some cases where it was possible to infer which articles ChatGPT mimicked in the fake answers (Sections S3 and S5 in Multimedia Appendix 1). Considering these characteristics, when generating sentences, ChatGPT seemed to list words with a high probability of appearing among pretrained data rather than presenting accurate facts or understanding questions.

In conclusion, of the 1287 studies presented by ChatGPT, only 1 (0.08%) RCT matched the 24 RCTs of the benchmark [9].

Systematic Search Results via Bing AI

For Bing AI, a total of 223 questions were asked and 48 studies were presented. Among the 48 obtained studies, 19 (40%) studies were classified as grade A. There were no grade B

studies (Table 2). Because Bing AI always gave references with links to the websites, all studies presented by Bing AI existed. However, it also provided wrong answers about the study type, especially as it listed reviews as RCTs. Of the 28 studies with grade C, 27 (96%) were not RCTs and 1 (4%) was about a different treatment. Only 1 study had no grade because of a fake title; it presented a study registered in PubMed while pretending that it was the result of a search in ClinicalTrials.gov. However, the study was not in ClinicalTrials.gov (Section S7 in Multimedia Appendix 1).

Bing AI had more accurate answers than ChatGPT since it provides actual website references. However, it also showed a tendency to give more answers to more specific questions, similar to ChatGPT. For example, with a comprehensive question, Bing AI said "I am not able to access or search specific databases." However, with more specific questions, it found studies or answered "I couldn't find any RCTs' without mention about accessibility." In most cases, Bing AI either failed to find studies or listed too few studies to be used as a systematic searching tool.

In conclusion, of the 48 studies presented by Bing AI, 2 (4%) RCTs matched the 24 RCTs of the benchmark [9].

Discussion

Principal Findings

This paper's researchers sought to determine whether ChatGPT could conduct a real-time systematic search for EBM. For the first time, researchers compared the performance of ChatGPT with classic systematic searching as well as the Microsoft Bing AI search engine. Although Zhou et al [8] suggested that ChatGPT answered qualitative questions based on recent evidence, this study found that ChatGPT's results were not based on a systematic search (which is the basis for an SR), meaning that they could not be used for real-time CDSS in their current state.

With recent controversy regarding the risks and benefits of advanced AI technologies [21-24], ChatGPT has received mixed responses from the scientific community and academia. Although many scholars agree that ChatGPT can increase the efficiency and accuracy of the output in writing and conversational tasks [25], others suggest that the data sets used in ChatGPT's training might lead to possible bias, which not only limits its capabilities but also leads to the phenomenon of hallucination—apparently scientifically plausible yet factually inaccurate information [24]. Caution around the use of LLMs should also bear in mind security concerns, including the potential of cyberattacks that deliberately spread misinformation [25].

When applying the plug-in method in this study, especially when using PubMed Research [26], the process worked smoothly and there was not a single case of hallucination of fake research (by providing information along with a link), regardless of the designation of a specific database engine. Among the responses, 21 RCTs were included in the final SR, and out of a total of 24, all RCTs except 3 were provided. This is a very encouraging result. However, there is no plug-in that allows access to other databases yet, and if the conversation is long, the response speed is very slow. Furthermore, although it is a paid service, it only provides a total of 100 papers, so if more than 100 RCTs are searched, the user must manually search all papers. Ultimately, it is not intended for conducting an efficient and systematic search, as additional time and effort are required. If a more efficient plug-in is developed, this could play a promising part in systematic searches.

Although Sallam's [5] SR suggests that academic and scientific writing as well as health care practice, research, and education could benefit from the use of ChatGPT, this study found that ChatGPT could not search scientific articles properly, with a 0.08% (1/1287) of probability of the desired paper being presented. In the case of Bing AI using GPT-4, this study showed that Bing AI could search scientific articles with a much higher accuracy than ChatGPT. However, the probability was only 4% (2/48). It was still an insufficient probability for performing systematic research. Moreover, fake answers generated by ChatGPT, known as hallucinations, caused researchers to spend extra time and effort by checking the accuracy of the answers. A typical problem with generative AI is that it creates hallucinations. However, this is difficult to completely remove due to the principle of generative AI. Therefore, if it cannot be prevented from the pretraining of the model, efforts to increase reliability and consistency in the use of generative AI in medical care by checking the accuracy from the user's point of view are required, as shown in this study. Unlike ChatGPT, Bing AI did not generate fake studies. However, the total number of studies presented was too small. Very few studies have focused on the scientific searching accuracy of ChatGPT. Although this paper found many articles about the use of ChatGPT in the medical field, the majority concerned the role of ChatGPT as an author. Although the latter might accelerate writing efficiency, it also confirms the previously mentioned issues of transparency and plagiarism.

Wang et al [27] have recently investigated whether ChatGPT could be used to generate effective Boolean queries for an SR literature search. The authors suggest that ChatGPT should be considered a "valuable tool" for researchers conducting SRs, especially for time-constrained rapid reviews where trading off higher precision for lower recall is generally acceptable. They cite its ability to follow complex instructions and generate high-precision queries. Nonetheless, it should be noted that building a Boolean query is not a complex process. However, selecting the most appropriate articles for an SR is critical, which might be a more useful subject to examine in relation to the use of ChatGPT. Moreover, although Aydın and Karaarslan [28] have indicated that ChatGPT shows promise in generating a literature review, the iThenticate plagiarism tool found significant matches in paraphrased elements.

In scientific research, the most time-consuming and challenging task can be the process of filtering out unnecessary papers on the one hand and identifying those that are needed on the other hand. This difficult yet critical task can be daunting. It discourages many researchers from participating in scientific research. If AI could replace this process, it will be easier to collect and analyze data from the selected papers. Recently, commercial literature search services using generative AI models

have emerged. Representative examples include Covidence [29], Consensus [30], and Elicit [31]. The technical details of these commercial AI literature search services are unknown, but they are based on LLMs using GPT. Therefore, these search services are not only insufficient to verify hallucinations but also lack information in the search target databases. Even if there may be mistakes, the researcher should aim for completeness, and unverified methods should be avoided. Although this study did not use a commercial literature search service, it manually searched the target databases one by one. If the reliability and consistency of AI literature search services are verified, the use of these technologies will help medical research greatly

This study suggests that ChatGPT still has limitations in academic search, despite the recent assertion from Zhou et al [8] about its potential in searching for academic evidence. Moreover, although ChatGPT can search and identify guidance in open-access guidelines, its results are brief and fragmentary, often with just 1 or 2 sentences that lack relevant details about the guidelines.

Arguably, more concern should be placed on the potential use of ChatGPT in a CDSS than its role in education or writing draft papers. On the one hand, if AI such as ChatGPT is used within a patient-physician relationship, this is unlikely to affect liability since the advice is filtered through professionals' judgment and inaccurate advice generated by AI is no different from erroneous or harmful information disseminated by a professional. However, ChatGPT lacks sufficient accuracy and speed to be used in this manner. On the other hand, ChatGPT could also be used to give direct-to-consumer advice, which is largely unregulated since asking AI directly for medical advice or emotional support acts outside the established patient-physician relationship [32]. Since there is a risk of patient knowing inaccurate information, the medical establishment should seek to educate patients and guardians about the risk of inaccurate information in this regard.

Academic interest in ChatGPT to date has mainly focused on potential benefits including research efficiency and education, drawbacks related to ethical issues such as plagiarism and the risk of bias, as well as security issues including data privacy. However, in terms of providing medical information and acting as a CDSS, the use of ChatGPT is currently less certain because its academic search capability is potentially inaccurate, which is a fundamental issue that must be addressed.

The limitation of this study is that it did not address various research topics, because only 1 research topic was searched when collecting target literature. In addition, due to the time difference between the start of the study and the review and evaluation period, the latest technology could not be fully applied because it could become an outdated technology in a field of study where technology advances rapidly, such as generative AI. For example, there have already been significant technological advances since new AI models such as ChatGPT Turbo (4.0) were released between the time we started this study and the current revised time point.

This paper thus suggests that the use of AI as a tool for generating real-time evidence for a CDSS is a dream that has not yet become a reality. The starting point of evidence generation is a systematic search and ChatGPT is unsuccessful even for this initial purpose. Furthermore, its potential use in providing advice directly to patients in a direct-to-consumer form is concerning, since ChatGPT could provide inaccurate medical information that is not evidence based and can result in harm. For the proper use of generative AI in medical care in the future, it is suggested that a feedback model that evaluates accuracy according to experts' perspective, as done in this study, and then reflects it back into an LLM is necessary.

Conclusion

This is the first study to compare AI and conventional human SR methods as a real-time literature collection tool for EBM. The results suggest that the use of ChatGPT as a tool for real-time evidence generation is not yet accurate and feasible. Therefore, researchers should be cautious about using such AI. The limitations of this study using the GPT model are that the search for research topics was not diverse and that it did not prevent the hallucinations of generative AI. However, this study will serve as a standard for future studies by providing an index to verify the reliability and consistency of generative AI from a user's point of view. If the reliability and consistency of AI literature search services are verified, the use of these technologies will help medical research greatly.

Abstract

Background: The National Disaster Management Agency (*Badan Nasional Penanggulangan Bencana*) handles disaster management in Indonesia as a health cluster by collecting, storing, and reporting information on the state of survivors and their health from various sources during disasters. Data were collected on paper and transferred to Microsoft Excel spreadsheets. These activities are challenging because there are no standards for data collection. The World Health Organization (WHO) introduced a standard for health data collection during disasters for emergency medical teams (EMTs) in the form of a minimum dataset (MDS). Meanwhile, the Ministry of Health of Indonesia launched the SATUSEHAT platform to integrate all electronic medical records in Indonesia based on Fast Healthcare Interoperability Resources (FHIR).

Objective: This study aims to implement the WHO EMT MDS to create a disaster profile for the SATUSEHAT platform using FHIR.

Methods: We extracted variables from 2 EMT MDS medical records—the WHO and Association of Southeast Asian Nations (ASEAN) versions—and the daily reporting form. We then performed a mapping process to match these variables with the FHIR resources and analyzed the gaps between the variables and base resources. Next, we conducted profiling to see if there were any changes in the selected resources and created extensions to fill the gap using the Forge application. Subsequently, the profile was implemented using an open-source FHIR server.

Results: The total numbers of variables extracted from the WHO EMT MDS, ASEAN EMT MDS, and daily reporting forms were 30, 32, and 46, with the percentage of variables matching FHIR resources being 100% (30/30), 97% (31/32), and 85% (39/46), respectively. From the 40 resources available in the FHIR ID core, we used 10, 14, and 9 for the WHO EMT MDS, ASEAN EMT MDS, and daily reporting form, respectively. Based on the gap analysis, we found 4 variables in the daily reporting form that were not covered by the resources. Thus, we created extensions to address this gap.

Conclusions: We successfully created a disaster profile that can be used as a disaster case for the SATUSEHAT platform. This profile may standardize health data collection during disasters.

Introduction

In Indonesia, disaster management is conducted by the National Disaster Management Agency (*Badan Nasional Penanggulangan Bencana*) [1]. Specifically, health issues during disasters are mandated to health clusters, whose members consist of regional health services, rapid health assessment teams, and emergency medical teams (EMTs) from various institutions. The health cluster collects, records, and reports information on survivors and their health conditions during a disaster [2]. According to the World Health Organization (WHO), collecting patient data requires the use of a nationally accepted reporting form or an approved dataset that is reported periodically. This report must include copies for the patient [3]. The current standard form available in Indonesia is the Rapid Health Assessment Form established by the Ministry of Health (MoH). This form summarized only the number of survivors and their general situation [2]. Meanwhile, the EMTs from various

institutions recorded the survivors' health status using their forms [4]. This information was collected by *Badan Nasional Penanggulangan Bencana* during daily reporting meetings and transferred to Microsoft Excel spreadsheets [5]. This activity is time-consuming and often inaccurate [6]. Additionally, the lack of coordination due to the decreased number of officers affected by the disaster may have impacted data collection and information exchange [7]. Consequently, this affects the handling of survivors at disaster locations and directs them to nearby health facilities.

Several institutions have tried to develop applications to record medical data [8], construct a documentation form [9-11], and create the minimum dataset (MDS) needed during disasters [11,12]. However, none of these are available for general use. To address this problem, the WHO introduced an MDS for EMTs in 2017 for use during disaster events [12]. This form has been tested and used to assess several disasters worldwide [13]. In Southeast Asian countries, the EMT MDS was introduced through the Project for Strengthening the Association of Southeast Asian Nations (ASEAN) Regional Capacity on Disaster Health Management (ARCH Project) [14]. The ARCH Project aimed to strengthen disaster management for ASEAN members through collaboration with the Japan International Cooperation Agency. One of the main goals is to use the WHO EMT MDS standards in the ASEAN region.

Indonesia's MoH launched the SATUSEHAT platform based on Fast Healthcare Interoperability Resources (FHIR) [15]. This action aims to integrate and perform interoperability among health care facilities. Thus, the government has targeted all health care facilities to have electronic medical records by the end of 2023 and be interoperable using this platform [16].

FHIR is a standard for exchanging health care information through health information systems developed by the health care standards organization Health Level Seven International [17]. FHIR uses a representational state-transfer (REST) application programming interface (API), a common web service architecture that aims to make it easier for health care systems to share and access data, eventually improving the interoperability of health care information. The main features of FHIR are modularity, standardized resources, and interoperability, thus making it easy to work with specific data elements such as patient demographics, health conditions, and medications with different health care systems.

With this momentum, we conducted this research to map the WHO EMT MDS form to FHIR so that it can be integrated into the SATUSEHAT platform. This will help survivors of disasters to record, report, and refer to systems.

Methods

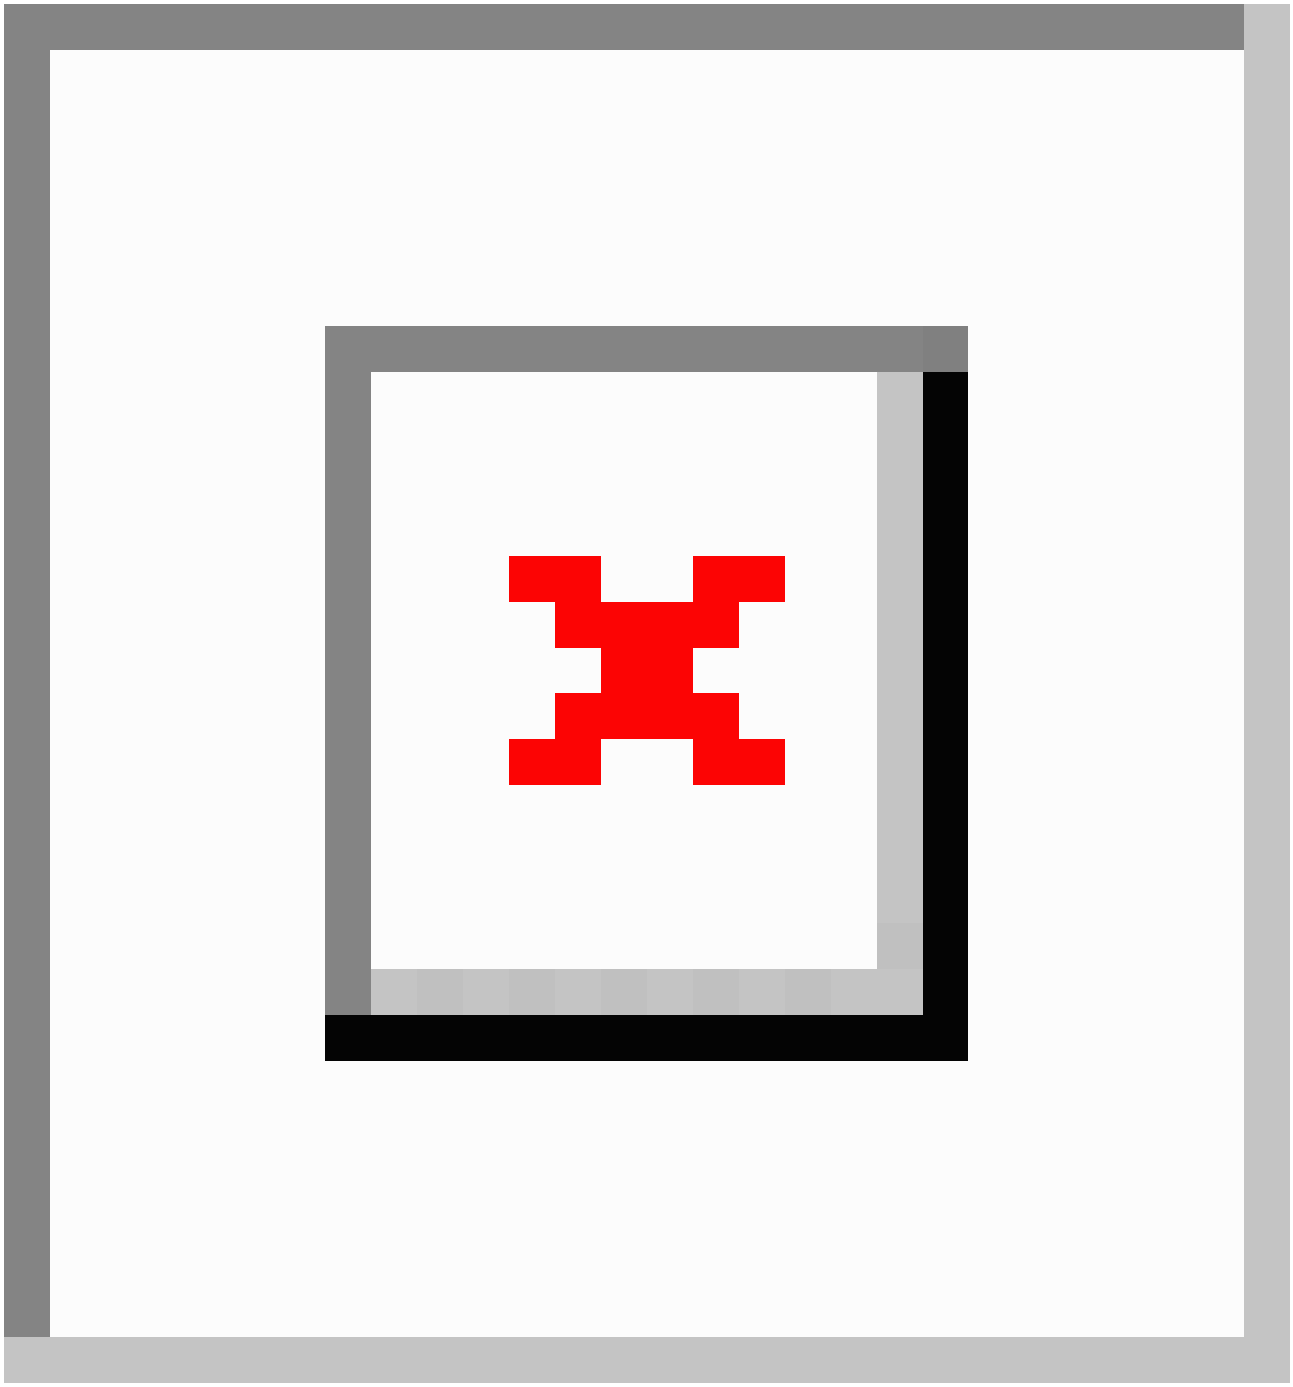
Extract Variables From the Medical Records

The EMT MDS consists of several forms that must be filled out during disasters. The set includes a medical records form combined with a tick-box section and the daily reporting form, both of which are sent to the EMT Coordination Cell (EMTCC). In the medical records section and tick-box form, EMT officers fill in patient data such as identity, medical history, vital signs, physical examination, and therapy management, which must be signed by a doctor. In this study, the tick box only helps to highlight the patient's condition, which is divided into age, sex, health events, procedures and outcomes, and context, without the patient's identity to maintain anonymity. Afterward, the form will be collected by the EMTCC to aggregate the data into the daily reporting form. The daily reporting form is part of the EMT MDS designed by the WHO to be used in the EMTCC office. The daily reporting form itself has already been tested during disasters in some countries [13,18,19]. It contains basic information regarding the team, the location to which the team was assigned, daily summaries of the facility, accumulation of data from the tick boxes as MDS statistics, and information regarding crucial needs and risks [20].

This study extracted data elements from the medical records form and daily reporting form. We obtained 2 variations of medical records from the WHO EMT MDS and the ASEAN EMT MDS, which are adaptations for ASEAN countries developed by the ARCH Project. These forms are illustrated in Figure 1.

We chose this medical record form for Indonesia since the Indonesian government, as a member of ASEAN states, has already been trained to use the EMT MDS during regional collaboration drills on the ARCH Project [21,22]. This project aims to strengthen disaster health management in ASEAN countries and meet the WHO EMT MDS as a standard operational procedure [23]. Thus, digitizing this set will be an appropriate choice.

Figure 1. Form of medical records taken from the (A) WHO EMT MDS, (B) ASEAN EMT MDS, and (C) daily reporting form. ASEAN: Association of Southeast Asian Nations; EMT: emergency medical team; MDS: minimum dataset; WHO: World Health Organization.



Mapping and Gap Analysis

Next, we manually mapped these data elements onto the base resources. Based on the results, we conducted a gap analysis between the data elements and FHIR resources. We divided the EMT MDS elements into the medical record and daily reporting form, including the tick-box section. Next, we examined whether each data element and the FHIR base resources matched.

Profiling and Validation

Profiling is the process of defining the profile created by setting the cardinality and creating an extension to the data elements that have definitions in the resource base. We used the Forge application since it is a common tool used in profiling research [24,25]. Next, we validated the profiles using the SIMPLIFIER.NET website [26].

Implementation

We implemented the profiles in the HAPI framework using an open-source FHIR server [27]. We used the Insomnia application, an open-source application that performs the API testing and development process, to perform the POST request to the server with body content using JSON [28].

Ethical Considerations

Since our research did not involve human subjects and no actual patient data were included in this study, ethics approval was not required.

Results

Mapping

We created a list and group of variables extracted from the WHO and ASEAN EMT MDS medical records. The data were divided into 2 categories: medical and daily reporting forms. Subsequently, the base FHIR was mapped. The list of variables and mapping process results from the WHO EMT MDS and ASEAN EMT MDS medical records forms are shown in Table 1. Meanwhile, Table 2 shows the variables in the daily reporting form mapped to the FHIR resources.

From the 40 resources available in the FHIR ID core, we selected 10, 14, and 9 resources for the WHO EMT MDS, ASEAN EMT MDS, and daily reporting form, respectively, as displayed in Table 3. The total numbers of variables from the WHO EMT MDS medical record form, the ASEAN EMT MDS medical record form, and the daily reporting form with variables that matched the FHIR resources are listed in Table 4.

[e]ASEAN: Association of Southeast Asian Nations.

Gap Analysis

From the gap analysis, we found several data elements that did not match the FHIR resources. Most data came from the daily reporting form. The list is presented in Table 5 . We created extensions for the age, relationship, and estimated date departure elements for this problem. Age did not contain a data element in the FHIR resources. Because age is related to patients, we created an extension of the patient resource to define it. The JSON file is shown in Figure 2.

Relation status is defined as whether the patient's condition is related to a disaster event. Thus, an extension of the condition resource is deemed appropriate to explain this condition. By definition, the estimated date of departure is when the team ends its service at specific locations. This allows the EMTCC to plan another EMT if necessary. Because this definition differs from the operational service hours in which the data element is available in the Location resource, we added an extension under the Organization resource to define the end period of the EMT service.

Sex in medical records uses a different value set from FHIR, divided into 3 groups: male, pregnant female, and nonpregnant female. Although sex is only divided into 2 groups, it adds pregnancy status to the female criteria. Since the pregnancy status already has a code in Logical Observation Identifiers Names and Codes (LOINC; "pregnancy status reported," code 11449 - 6), we bundled the Patient and Observation resources for this variable.

Table . Gap analysis results.

Data elements	Type	Form	Remarks	Possible FHIR[a] resources
Age	String	ASEAN[b] EMT[c] MDS[d] and daily reporting form	No exact definition in the data element of FHIR	Patient
State	Code	Daily reporting form	The data element available in ID core extension	Location
City	Code	Daily reporting form	The data element available in ID core extension	Location
Village	Code	Daily reporting form	The data element available in ID core extension	Location
Gender	Code	Daily reporting form	The definition implicate in 2 resources	Patient and Observation
Relation	Code	Daily reporting form	No exact definition in the data element of FHIR	Condition
Estimated date departure	Date	Daily reporting form	No exact definition in the data element of FHIR	Organization

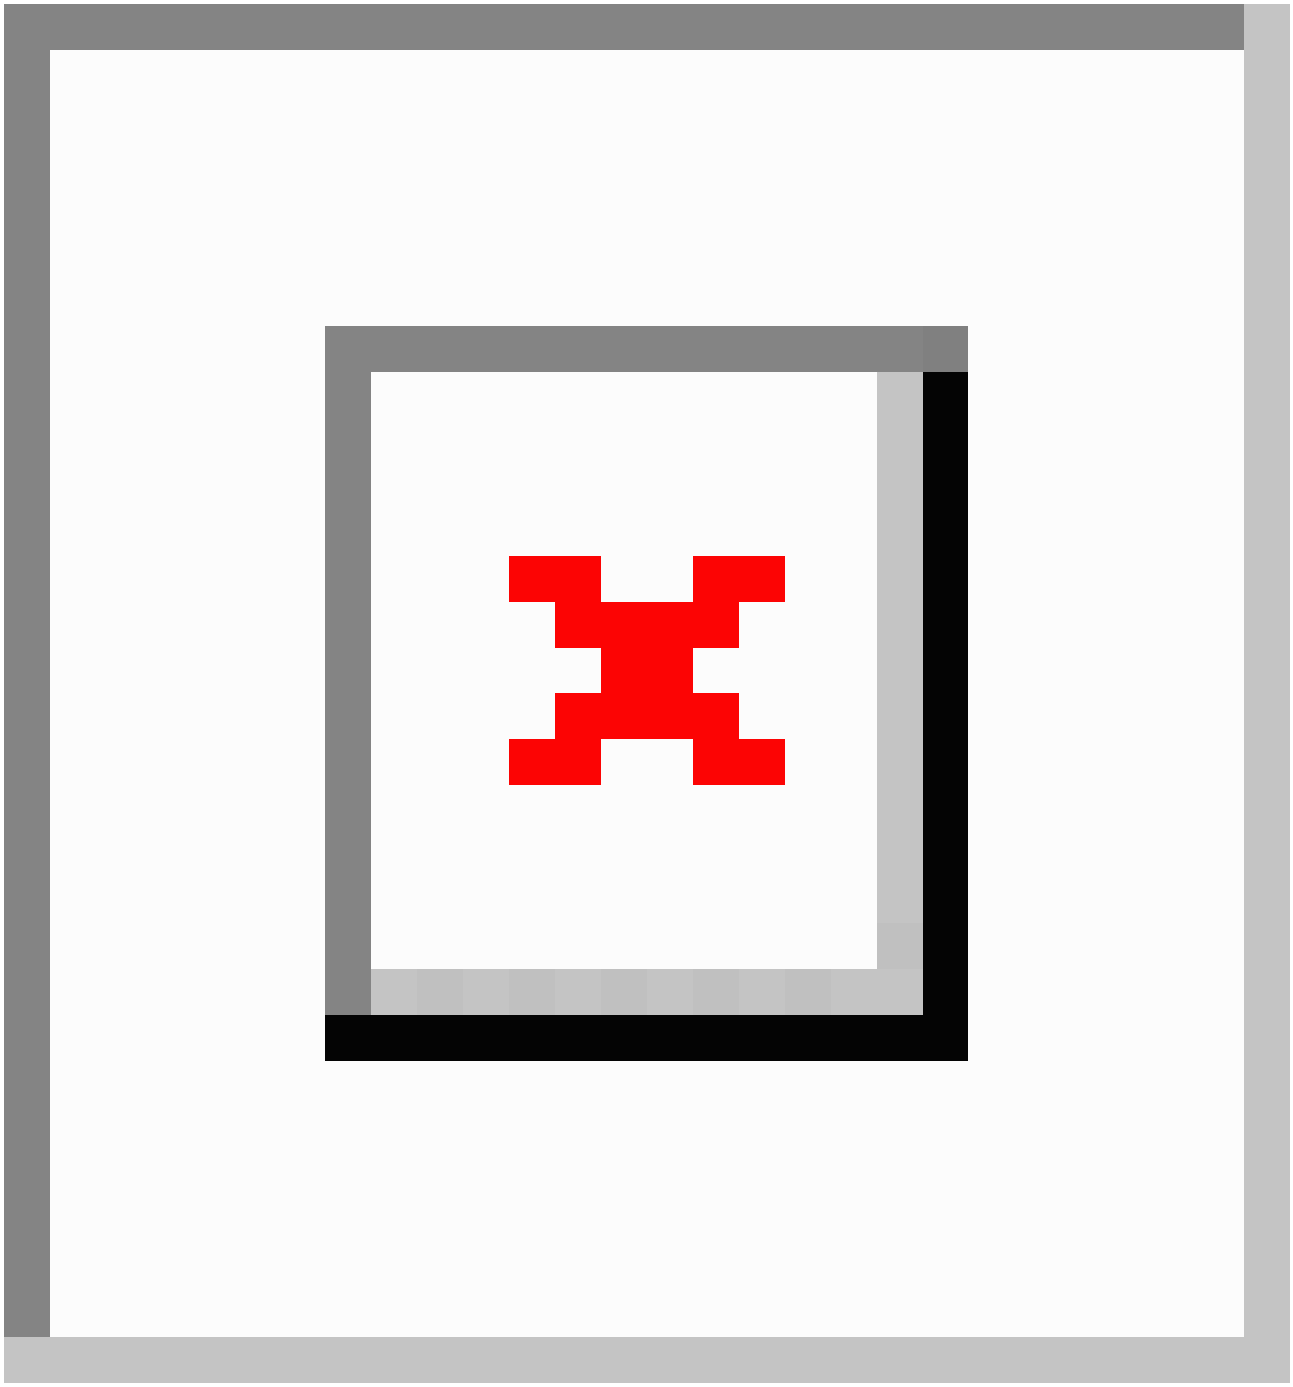
[b]ASEAN: Association of Southeast Asian Nations.

[c]EMT: emergency medical team.

[d]MDS: minimum dataset.

Figure 2. Extensions for (A) age and (B) relation data elements.



Validation and Implementation

We validated the resources for the FHIR ID core using SIMPLIFIER.NET. Example results are shown in Figure 3. The proposed disaster FHIR profile is implemented using the HAPI framework. We used the Insomnia application to perform requests on the FHIR REST server.

We created several mock datasets based on the SATUSEHAT public example [29]. We managed to have samples for each resource. However, we added extensions that are not defined in the SATUSEHAT platform. Afterward, we validated the disaster profile using the HAPI FHIR server. We created a JSON file for each resource to implement the POST protocol. The POST protocol validates the request body and stores the resources in a database. We successfully validated 15 resources used in this profile (an example message is shown in Figure 4).

Figure 3. Validation results on SIMPLIFIER.NET.

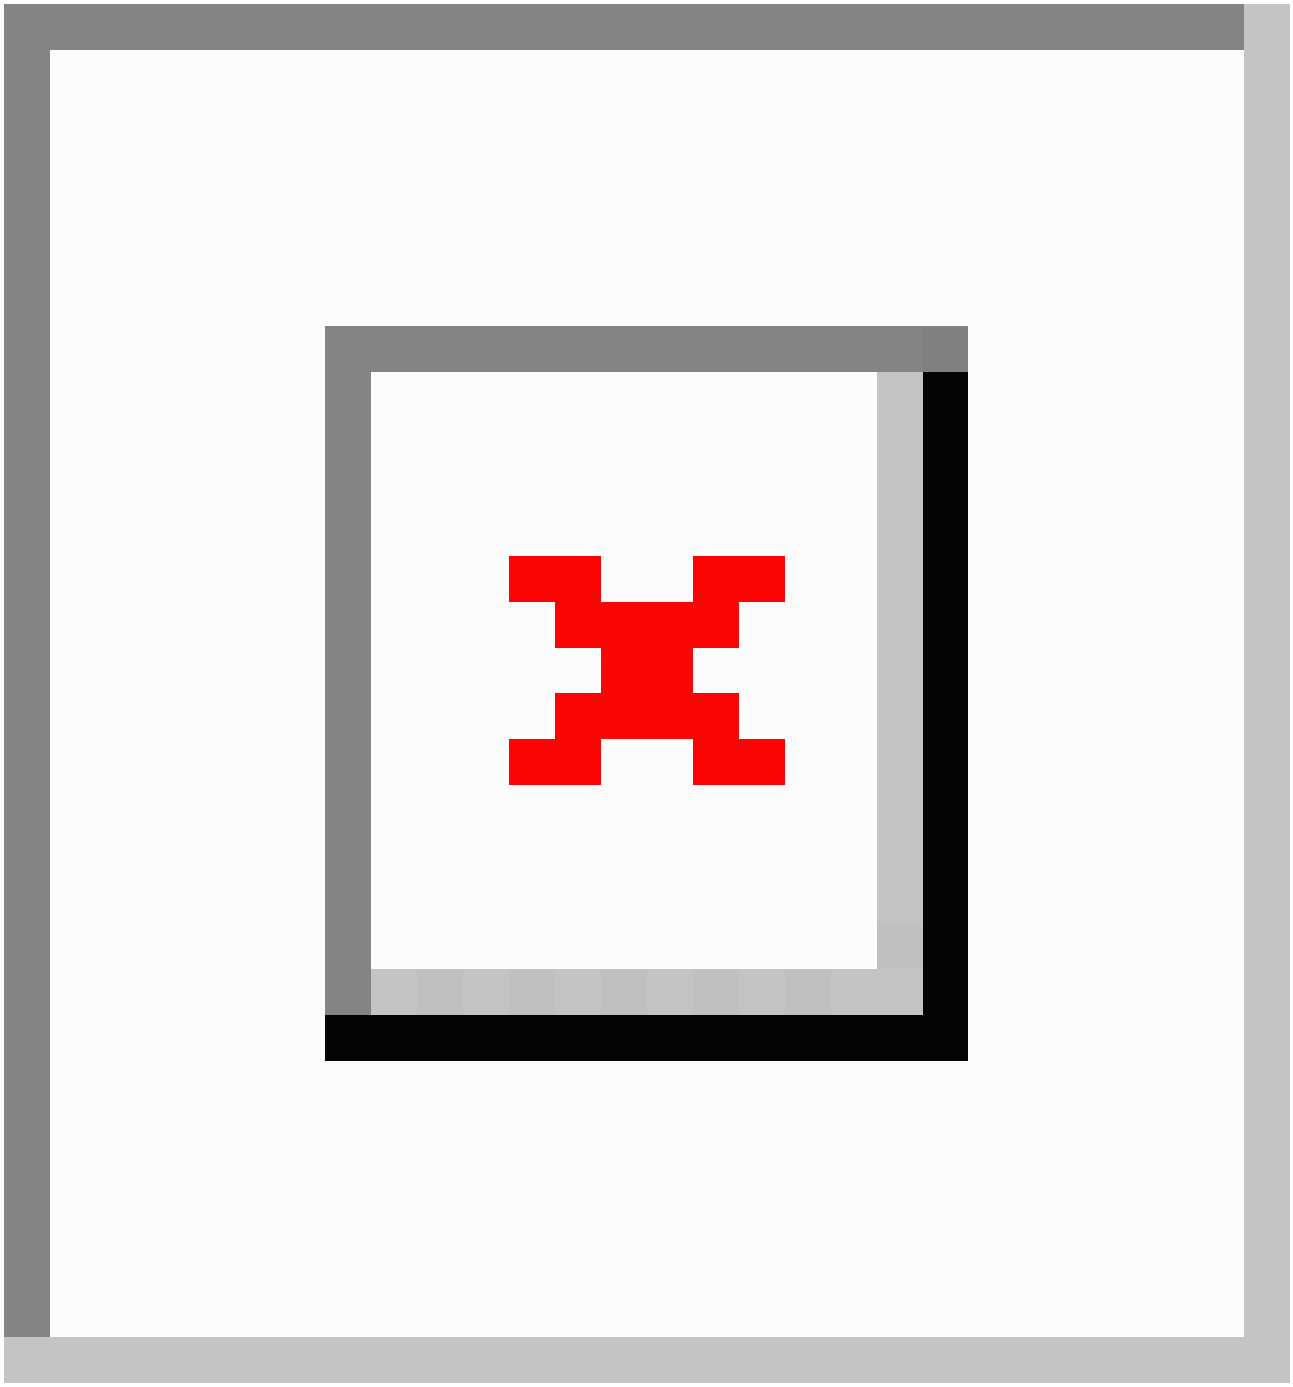


Figure 4. A JSON of the disaster profile was created based on HAPI. The profile mentioned (left) matches with the StructureDefinition resource (right).

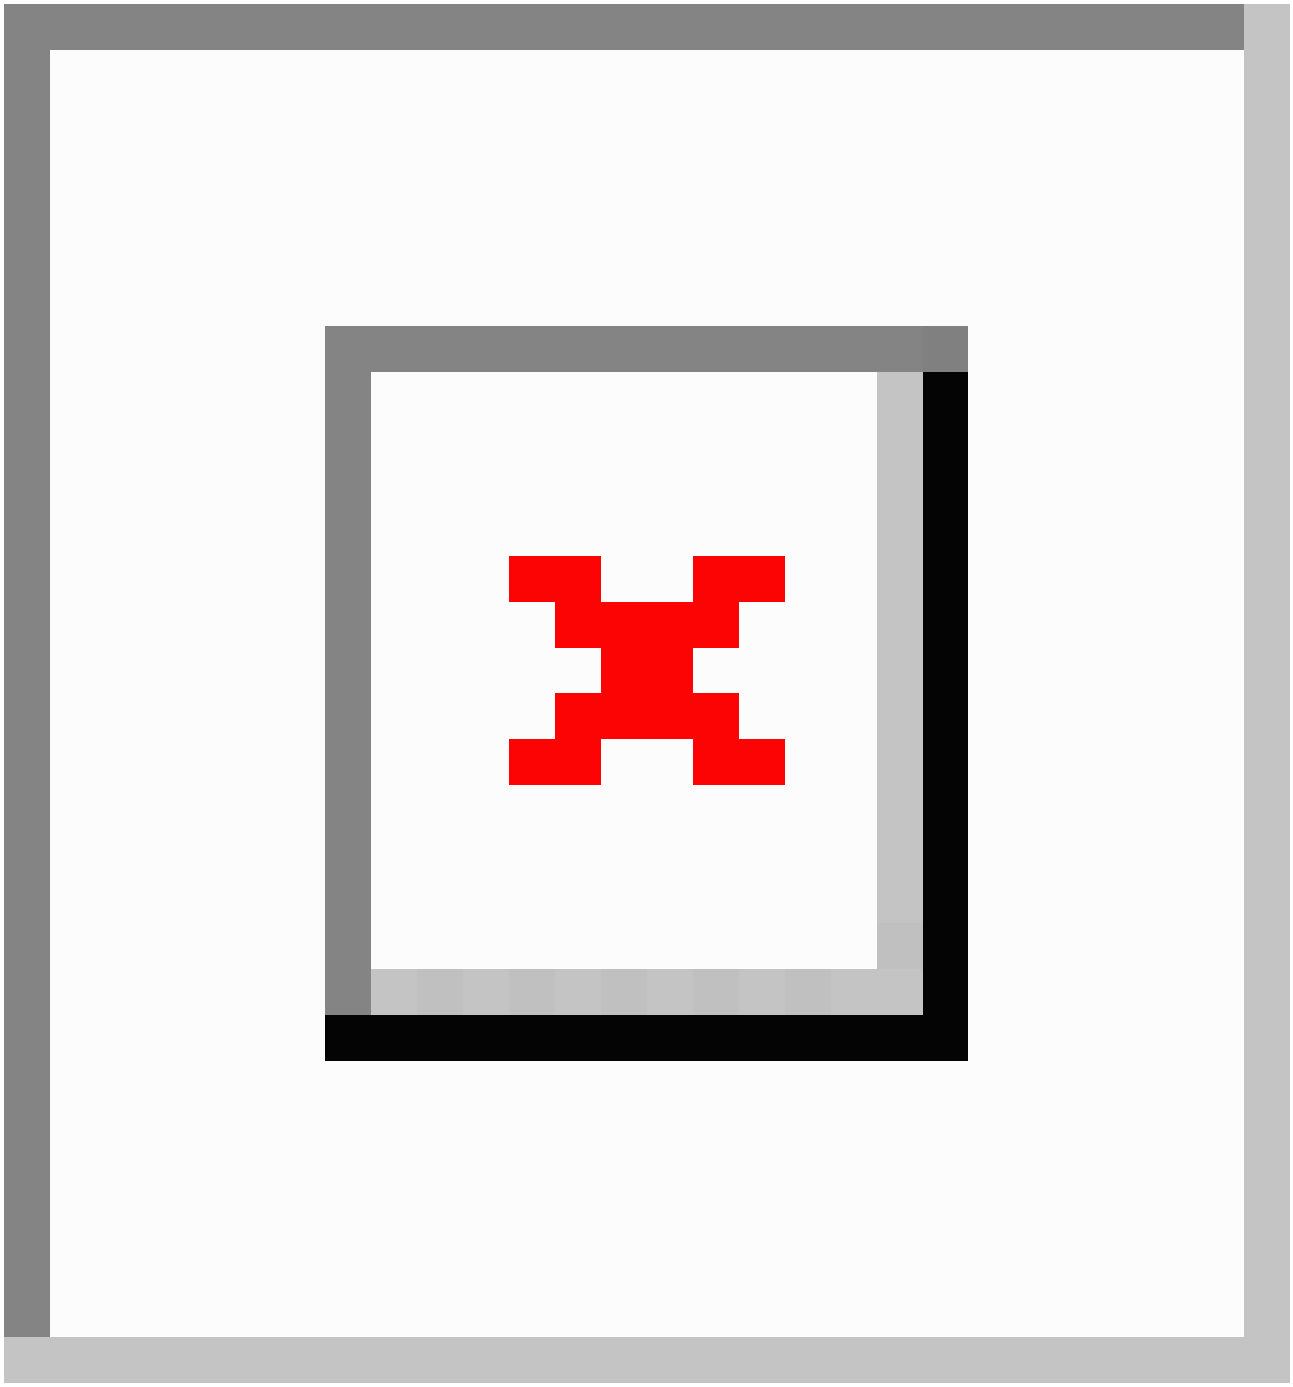

Discussion

Principal Findings

Data collection plays a significant role during disasters. With major calamities requiring support from international aid workers, implementing a standard data format can greatly facilitate the collection of health-related information. We chose the WHO and ASEAN EMT MDS forms to map onto the FHIR profiles. Although the EMT MDS is a standard developed by the WHO for data collection during disasters, the technical implementation designs for disaster situations in which data are transferred manually using an Excel spreadsheet [18]. As daily reports from various sources may be used by the MoH or EMTCC to make decisions, shifting from paper-based documentation to a digital process may increase the efficiency and effectiveness of collecting daily reports from various sources. In this study, we successfully created and validated the profile to the FHIR ID core profile using base resources. A FHIR profile has generally been created for specific use cases; however, few studies have performed disaster-related profiling. Several studies have created profiles related to disasters, such as COVID-19 [30,31].

To the best of our knowledge, this is the first study that has developed FHIR profiles for natural disasters. Our profiles may standardize health data collection, resulting in real-time actionable insights during disaster scenarios. For example, the interoperability facilitated by FHIR allows instant data sharing between disparate health systems, ensuring that international

aid workers and medical facilities can access up-to-date patient records, treatment histories, and socioeconomic backgrounds. This seamless exchange of information is essential for coordinating effective and timely responses, significantly affecting survival rates and recovery outcomes.

Another advantage of using the FHIR format is that it optimizes the usability and quality of the health data. The EMT MDS form only records the number of disaster incidents. For example, if a patient visited twice in a day, 2 reports were generated [20]. Using FHIR, we can retrieve existing patient data from the database. The data entered during a disaster can be saved on the SATUSEHAT platform and reused when referring disaster survivors to nearby health care facilities [32]. By doing so, the quality and safety of patient care can be enhanced. These interoperability features have also enabled us to improve the efficiency of clinical data utilization during and after disasters. Ayaz et al [33] discussed the implementation of FHIR applications in their systematic literature review. Balch et al [34] defined the use of FHIR data standards in machine learning–enabled clinical information systems. Thus, using the data available on the SATUSEHAT platform would be helpful for researchers to perform studies related to disasters, such as identifying patterns of disease outbreaks and improving decision-making processes.

We mapped over 80% of the WHO and ASEAN EMT MDS medical record variables onto FHIR resources. Meanwhile, the variables that cannot be mapped to FHIR resource are mainly in the tick-box sections. Variables that did not have data elements, such as age and sex, were due to the characteristics of the EMT MDS form itself. The EMT MDS form was created to facilitate the collection of data and reports on the conditions occurring in the field [35]. This report form is an accumulation of the various daily report forms used by the EMTCC and MoH to provide care and treatment. Thus, age and sex were classified in a classification format to simplify grouping.

Limitations

This study faced a notable challenge in developing a comprehensive value set for EMT MDS tick-box variables. FHIR uses a standard value set to define medical terminology, such as Systematized Nomenclature of Medicine–Clinical Terms (SNOMED-CT) or LOINC codes. We could not define the value options for health events and procedure variables because the value options from these variables were a group of several conditions. For example, health events have a “major extremity injury” option, which by definition indicates any upper- and lower-extremity injury requiring hospitalization and/or spinal or general anesthesia [36]. However, SNOMED-CT did not have codes for this category; it did have codes to define each of the upper- and lower-extremity injuries (the detailed list is available in Multimedia Appendix 1). Some studies have reported similar findings when mapping the values to SNOMED-CT or LOINC codes [37,38]. A previous study also mentioned that SNOMED-CT requires disaster codification adjustments [39]. One solution that has been done is to submit new codes to the SNOMED-CT or LOINC committee. However, this process is often prolonged without a guarantee of acceptance of the proposed code [40]. An alternative, more immediate solution we considered was to create a new value set that aligns with the WHO EMT MDS standards [41]. This approach aims to bridge the current gap in codification and facilitate more accurate data representation and analysis for disaster health management.

Finally, because this study was based on the concept of the mapping process, we did not perform a functionality test using real data. We used a mock-up dataset to test the POST and GET functions on the FHIR server. In the future, we will conduct tests using data from the SATUSEHAT platform by opening up opportunities for collaboration with the Indonesian MoH. In addition, future work should focus on FHIR-based applications using disaster profiles for health data collection during disaster events.

Conclusions

This research aims to facilitate data collection using international standards, such as the WHO EMT MDS, and transfer it to the SATUSEHAT platform using FHIR as an interoperability standard. The proposed disaster profile was successfully implemented and validated using the FHIR server. This research will be beneficial for facilitating data collection using international standards during disasters and transferring it to a national platform for health care activity using FHIR as an interoperability standard.

Abstract

Background: The increasing demand for personal health record (PHR) systems is driven by individuals' desire to actively manage their health care. However, the limited functionality of current PHR systems has affected users' willingness to adopt them, leading to lower-than-expected usage rates. The HL7 (Health Level Seven) PHR System Functional Model (PHR-S FM) was proposed to address this issue, outlining all possible functionalities in PHR systems. Although the PHR-S FM provides a comprehensive theoretical framework, its practical effectiveness and applicability have not been fully explored.

Objective: This study aimed to design and develop a tethered PHR prototype in accordance with the guidelines of the PHR-S FM. It sought to explore the feasibility of applying the PHR-S FM in PHR systems by comparing the prototype with the results of previous research.

Methods: The PHR-S FM profile was defined to meet broad clinical data management requirements based on previous research. We designed and developed a PHR prototype as a web application using the Fast Healthcare Interoperability Resources R4 (FHIR) and Logical Observation Identifiers Names and Codes (LOINC) coding system for interoperability and data consistency. We validated the prototype using the Synthea dataset, which provided realistic synthetic medical records. In addition, we compared the results produced by the prototype with those of previous studies to evaluate the feasibility and implementation of the PHR-S FM framework.

Results: The PHR prototype was developed based on the PHR-S FM profile. We verified its functionality by demonstrating its ability to synchronize data with the FHIR server, effectively managing and displaying various health data types. Validation using the Synthea dataset confirmed the prototype's accuracy, achieving 100% coverage across 1157 data items. A comparison with the findings of previous studies indicated the feasibility of implementing the PHR-S FM and highlighted areas for future research and improvements.

Conclusions: The results of this study offer valuable insights into the potential for practical application and broad adoption of the PHR-S FM in real-world health care settings.

KEYWORDS

fast healthcare interoperability resources; logical observation identifiers names and codes; personal health record system functional model; personal health records

Introduction

Personal health records (PHRs) are beneficial tools in modern health care, as they allow patients to access clinical information and share it with medical staff in a secure and confidential environment [1]. An increasing number of countries, including the United States [2,3], Japan [4,5], European Union-member nations [6,7], South Korea [8,9], and Indonesia [10], have invested significantly in the development and promotion of PHR systems to enhance the health care experience by improving patients' ability to manage their health information. However, despite the acknowledged benefits of PHRs and substantial investments by various countries, the usage rates of PHR systems have fallen short of expectations [11-13]. In the United Kingdom, over 48.7% of individuals have never interacted with any web-based patient-information-management service [14]. Similarly, in the United States, data from the 2023 Health Information National Trends Survey revealed that more than 43% of people had not accessed their web-based medical records or patient portals even once in the past year [15].

The Personal Health Record System Functional Model Release 1 (PHR-S FM) [16] was developed as a standardized framework for managing personal health information and has been certified as ISO/HL7 (International Organization for Standardization/Health Level Seven International) 16527 [17]. This model outlines a range of possible functionalities in PHR

systems, aiming to provide a standardized framework for designing, developing, and evaluating them. The PHR-S FM includes three main sections: (1) personal health (PH), which manages individual health data, encompassing a wide range of functionalities, from medical history to ongoing health conditions; (2) supportive (S), which facilitates the administrative and financial aspects of health care, thereby enabling smoother patient-provider interactions and backend processes; and (3) information infrastructure (IN), which ensures information privacy, security, interoperability, and ease of use. These 3 main sections contain several subsections, each with various functions. The sections and subsections delineate broad functional domains, whereas the functions offer detailed specifications of the features required in PHRs, adhering to a defined parent-child relationship. Each function is characterized by a function ID and Name and is described by a Statement, with its numbering indicating the parent-child relationship between sections and subsections. For example, a function ID "PH.3.1" would be the parent of "PH.3.1.1."

The PHR-S FM allows researchers to select appropriate functionalities to create a functional profile, which defines a subset of functionalities, thereby facilitating the implementation of PHR. Although the PHR-S FM provides a comprehensive theoretical framework, its practical effectiveness and applicability have not been fully explored. Researchers must precisely specify the actionable functions when creating profiles. However, due to the potential limitations of individual cases, variations may exist in the chosen function list, even if the research objectives are the same.

Harahap et al [18] conducted an extensive systematic review to identify the fundamental functionalities and challenges of the current PHRs. They thoroughly analyzed the essential functionalities required for effective and user-centric PHR systems and created a comprehensive PHR-S FM functional profile containing a subset of functions. This profile encompasses health and administrative records, medication management, communication, appointment management, education, and self-health monitoring. It also considers the challenges faced in PHR implementation, such as interoperability, security and privacy, usability, and data quality. Their functional profile provides a holistic framework for designing and developing PHR systems, ensuring that the systems meet health care users' evolving needs, thereby enhancing the effective deployment and user adaptation of PHR systems.

Building on previous research, this study aimed to design and develop a tethered PHR system prototype to determine the feasibility of providing servers that meet the PHR-S FM function profile. Moreover, this study examined the efficacy of the PHR-S FM by comparing its contents to that of previous studies.

Methods

Personal Health Record System Functional Model

We conducted a comprehensive analysis of Harahap's PHR-S FM profile and dissected each function into its subfunctions to create actionable levels. For instance, we expanded PH.2.5 into PH.2.5.1–PH.2.5.11, PH.3.1 into PH.3.1.1 and PH.3.1.2, and IN.2 into IN.2.1–IN.2.3.

Based on this classification, we created a new PHR-S FM profile to meet the broad requirements of clinical data management and ensure practical feasibility. We prioritized and implemented functions within the PH module that manage widely used core clinical data [7,19], such as medication lists (PH.2.5.6) and test results (PH.2.5.3). We omitted certain functions, including surgical history (PH.2.5.7), family health history (PH.2.5.8), genetic information (PH.2.5.9), social history (PH.2.5.10), nutrition and diet information (PH.2.5.11), communication with home monitoring devices (PH.3.1.2), medication management (PH.3.4), health education (PH.4), and appointment scheduling (PH.6.3). Although these functions are theoretically important, their operational complexity and the substantial resources required for their analysis exceeded the practical scope of this study.

Furthermore, we integrated essential auxiliary functions from the IN and S modules to support the effective operation of the PH module. These included displaying health records, ensuring system interoperability, and managing user access control. However, we excluded functions such as present ad hoc views of the health record (IN.1.3), standards version control (IN.2.2), application integration (IN.2.3), interoperability protocols (IN.2.4), secure messaging (IN.3.10), and insurance management (S.2.1), as they provided limited support and could unnecessarily complicate the prototype.

Finally, we established the PHR-S FM profile for this study (Table 1). In addition, we extracted detailed descriptions of each function from the ISO/HL7 16527 [17] standard (see Multimedia Appendix 1 for more details).

Table . The Personal Health Record System Functional Model Release 1 profile function list.

Function list sections	ID #
PH[a]	PH.1.1, PH.1.2, PH.2.5.1, PH.2.5.2, PH2.5.3, PH2.5.4, PH2.5.5, PH2.5.6, PH3.1.1
S[b]	S.1.3, S.1.5
IN[c]	IN.2.1, IN.3.3, IN.4

[a]PH: Personal Health

[b]S: Supportive

[c]IN: Information Infrastructure

PHR Design and Development

Based on the PHR-S FM profile from this study, we designed the functionality of a PHR prototype. It encompasses 8 distinct functions in the PH section: user demographics (PH.1.2), diagnosis information (PH.2.5.1), medications (PH.2.5.2), imaging test reports and laboratory test reports (PH.2.5.3), allergy information (PH.2.5.4), immunization (PH.2.5.5), visiting records (PH.2.5.6), and vital signs and Patient-Generated Health Data (PGHD; PH.3.1.1) [20]. IN.2.1 explicitly emphasizes the importance of interoperability standards in supporting information sharing between PHR and other systems. We adopted the Fast Healthcare Interoperability Resources Release 4 (FHIR R4) standard [21] to facilitate effective data exchange. FHIR has been widely recognized to effectively overcome data-sharing difficulties between medical information systems and has already become the preferred standard for achieving interoperability [22-24]. Table 2 lists the PHR data categories and their corresponding FHIR R4 resources. This illustrates the 8 types of medical data incorporated into the PHR prototype, specific details captured for each data type, and corresponding FHIR R4 resources. This mapping is essential to ensure data consistency and facilitate interoperability. Moreover, to ensure data consistency and achieve semantic interoperability, we standardized the user-entered PGHD data using the Logical Observation Identifiers Names and Codes (LOINC) system [25] and Unified Code of Units of Measurement (UCUM) system [26] and stored it in the FHIR Observation resources (see Multimedia Appendix 2 for details).

This study used Firely R4 [27] as the FHIR server and successfully developed a PHR prototype based on the PHR-S FM. The PHR prototype was designed as a web application optimized for mobile phones. When users log in, the PHR prototype actively retrieves their medical records to ensure that they always have the latest data. Figure 1 shows the main interface with a clear layout that allows users to access essential functions quickly and intuitively. The prototype is divided into 4 main sections: User Demographics, PGHD, Encounter History, and Comprehensive Records (see Multimedia Appendix 3 for details on the implementation of the PHR prototype, functional demonstration, and verification of consistency with the PHR-S FM functional profile).

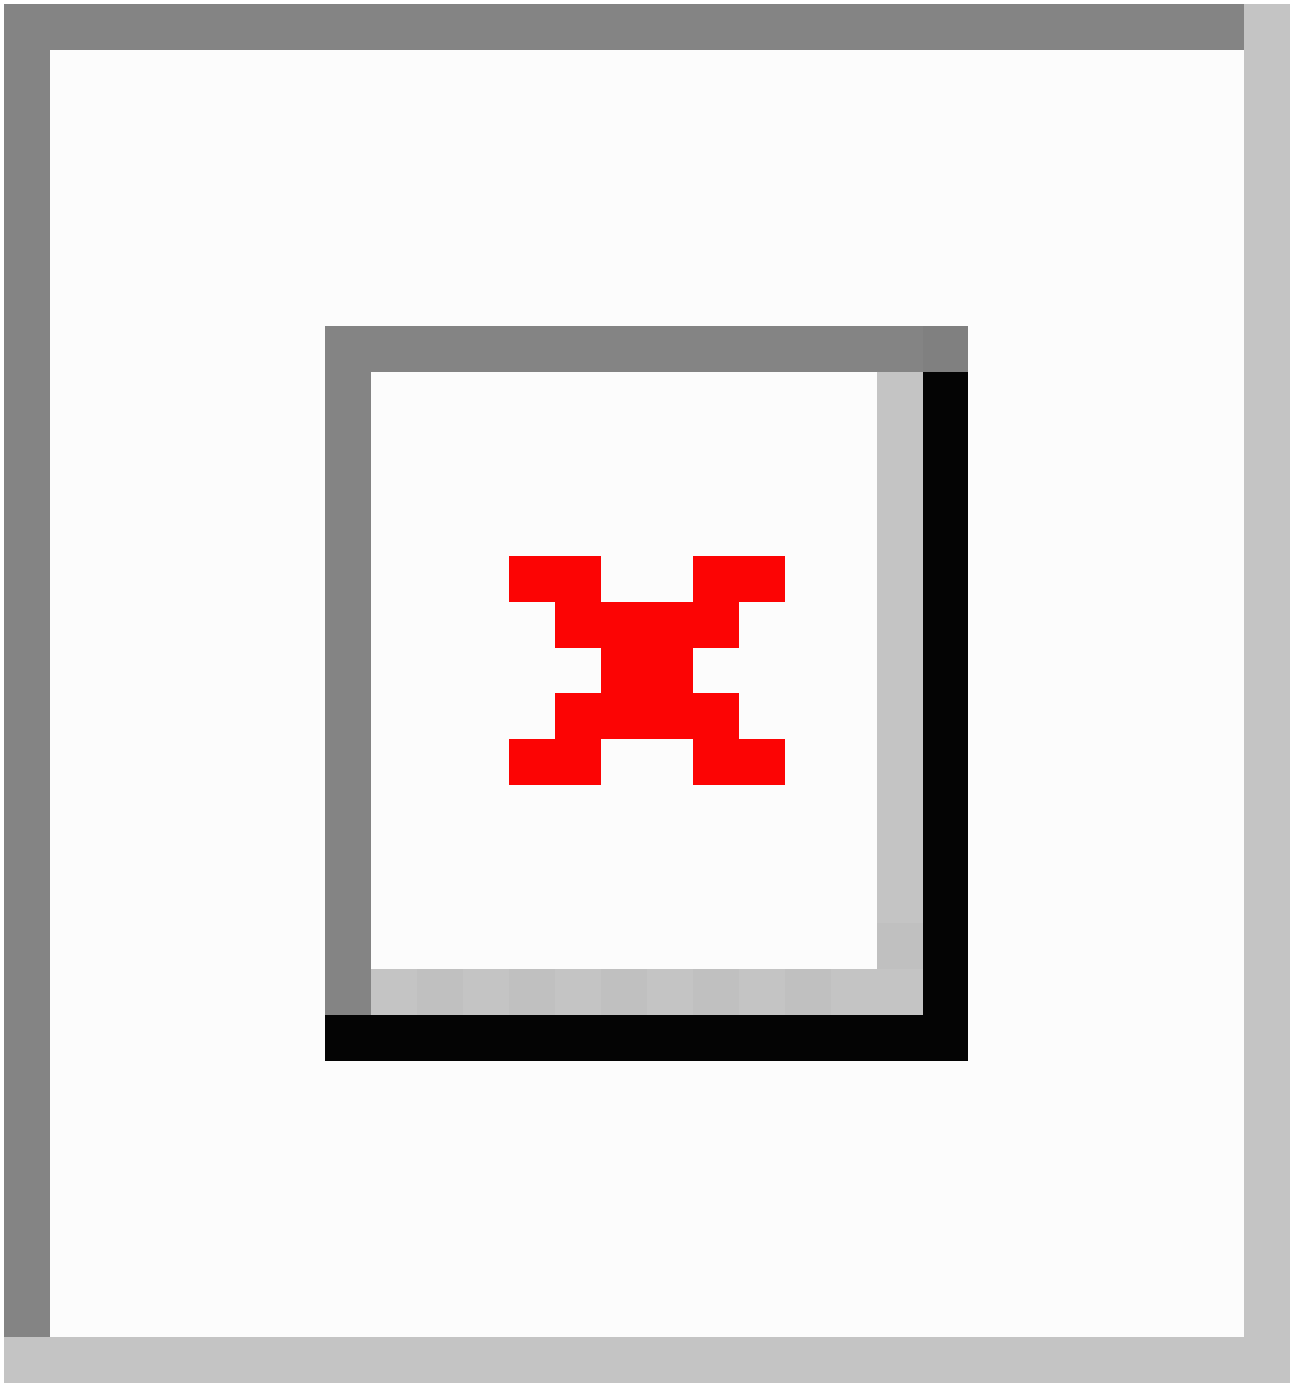
Table . Mapping table from PHR[a] prototype functions to FHIR[b] resources.

PHR-S FM ID#	PHR functions	Details	FHIR resources
PH.1.1, PH.1.2	User Demographics	Name, Gender, Birthday, Age, Phone Number, Address, Email.	Patient
PH.2.5.1	Diagnosis Information	Disease, Date, Doctor.	Condition, Practitioner
PH.2.5.2	Medications	Item Name, Dose/Unit, Way, Frequency, Start-time, End-time, Amount, Group, Property, Doctor.	Medication Request, Practitioner
PH.2.5.3	Test Results	Imaging Test reports: Item Name, Operate Time, PDF Report, Imaging Test Report, Critical Value.conclusion, Conclusion, Performer.	Diagnostic Report, Observation, ImagingStudy, Practitioner
PH.2.5.3	Test Results	Laboratory Test reports: Item Name, Operate Time, PDF Report, Item Detail, Value, Normal Range, Critical Value/ Detailed Test Names, Critical Value / value, Critical Value/ ReferenceRange, Critical Value / abnormal Flag, Performer.	DiagnosticReport, Observation, Practitioner
PH.2.5.4	Allergy Information	Allergen, Note Date, Severity, Reaction, Comment, Performer.	AllergyIntolerance, Practitioner
PH.2.5.5	Immunization	Vaccine Name, Datetime.	Immunization
PH.2.5.6	Visiting Records	Admission Time, Discharge Time, Visit Department, Hospital, Visit Type, Diagnosis, Doctor.	Encounter, Condition, Practitioner, Organization
PH.3.1.1	Observations and Care	Vital Signs: Datetime, Height, Weight, Temperature, Pulse Rate, Heart Rate, BMI Respiratory Rate, Blood Pressure, Pain Severity, Pediatric Head Occipital-Frontal Circumference Percentile, Body Mass Index (BMI) for Age, Pediatric Weight for Height, Head Occipital-Frontal Circumference, Doctor.	Observation, Practitioner, Organization
PH.3.1.1	Observations and Care	Patient-Generated Health Data (PGHD): Height, Weight, Temperature, Steps, BMI, Blood Pressure, Heart Rate, Respiration Rate, Smoking Habits.	Observation, Organization

[a]PHR: personal health record.

[b]FHIR: Fast Healthcare Interoperability Resources R4.

Figure 1. The main interface of the personal health record (PHR) prototype.



Validation

We used the Synthea dataset [28] to validate the effectiveness of the PHR prototype. Synthea was designed to generate realistic and synthetic medical records and has been extensively applied in multiple studies [29-32]. It extracts data from public datasets and statistical models, ensuring their authenticity and representativeness without compromising individual privacy. The dataset comprised comprehensive health records for over 1 million fictional patients in standardized formats, such as HL7 FHIR, C-CDA, and CSV. These records encompassed a wide range of medical information, including medication usage, allergies, medical history, and social health determinants, making them extremely valuable for developing, testing, and demonstrating PHR systems.

We randomly selected 5 patients from the Synthea dataset to validate the effectiveness of the PHR prototype. Their medical data were formatted in FHIR R4 and uploaded to the Firely server for testing. We analyzed FHIR resources and counted the number of FHIR resource types for each patient. The results were then compared with the types and quantities of data displayed in the PHR prototype. The evaluation method involved a quantitative analysis of the number of data entries available in the Synthea dataset against the number displayed in the PHR system, aiming to ascertain the prototype's effectiveness in data representation.

Ethical Considerations

As the Synthea dataset comprised solely synthetic data unrelated to any real individuals, considerations of legal and privacy issues were not required. Moreover, these data could be used for research without requiring patient consent or institutional review board approval.

Comparison With Prior Research

In our study, we conducted a comprehensive search of databases such as PubMed, IEEE Xplore, and ACM Digital Library using the keywords "PHR," "PHR-S FM," and "Personal Health Record System Functional Model." The search yielded 4 studies [33-36], but only 3 of these detailed the PHR-S FM functional profiles used as well as the implementation of PHR functionalities. Specifically, Katehakis et al [33] mentioned a PHR system for chronic care and home health, using the PHR-S FM and experiences from EU projects to ensure interoperability and meet health management needs. The project underscored the importance of adhering to standards like the HL7 PHR-S FM for better adoption of PHR systems. Saripalle et al [34] used HL7 FHIR to design an interoperable mobile PHR following PHR-S FM guidelines, achieving integration with OpenEMR and underscoring the benefits of a modular approach and standards-based API-driven data exchange. Chatterjee et al [35] developed a tethered PHR using FHIR resources and SNOMED-CT (Systematized Nomenclature of Medicine–Clinical Terms) terminology according to PHR-S FM guidelines, focusing on collecting PGHD from diverse sources for electronic health record integration.

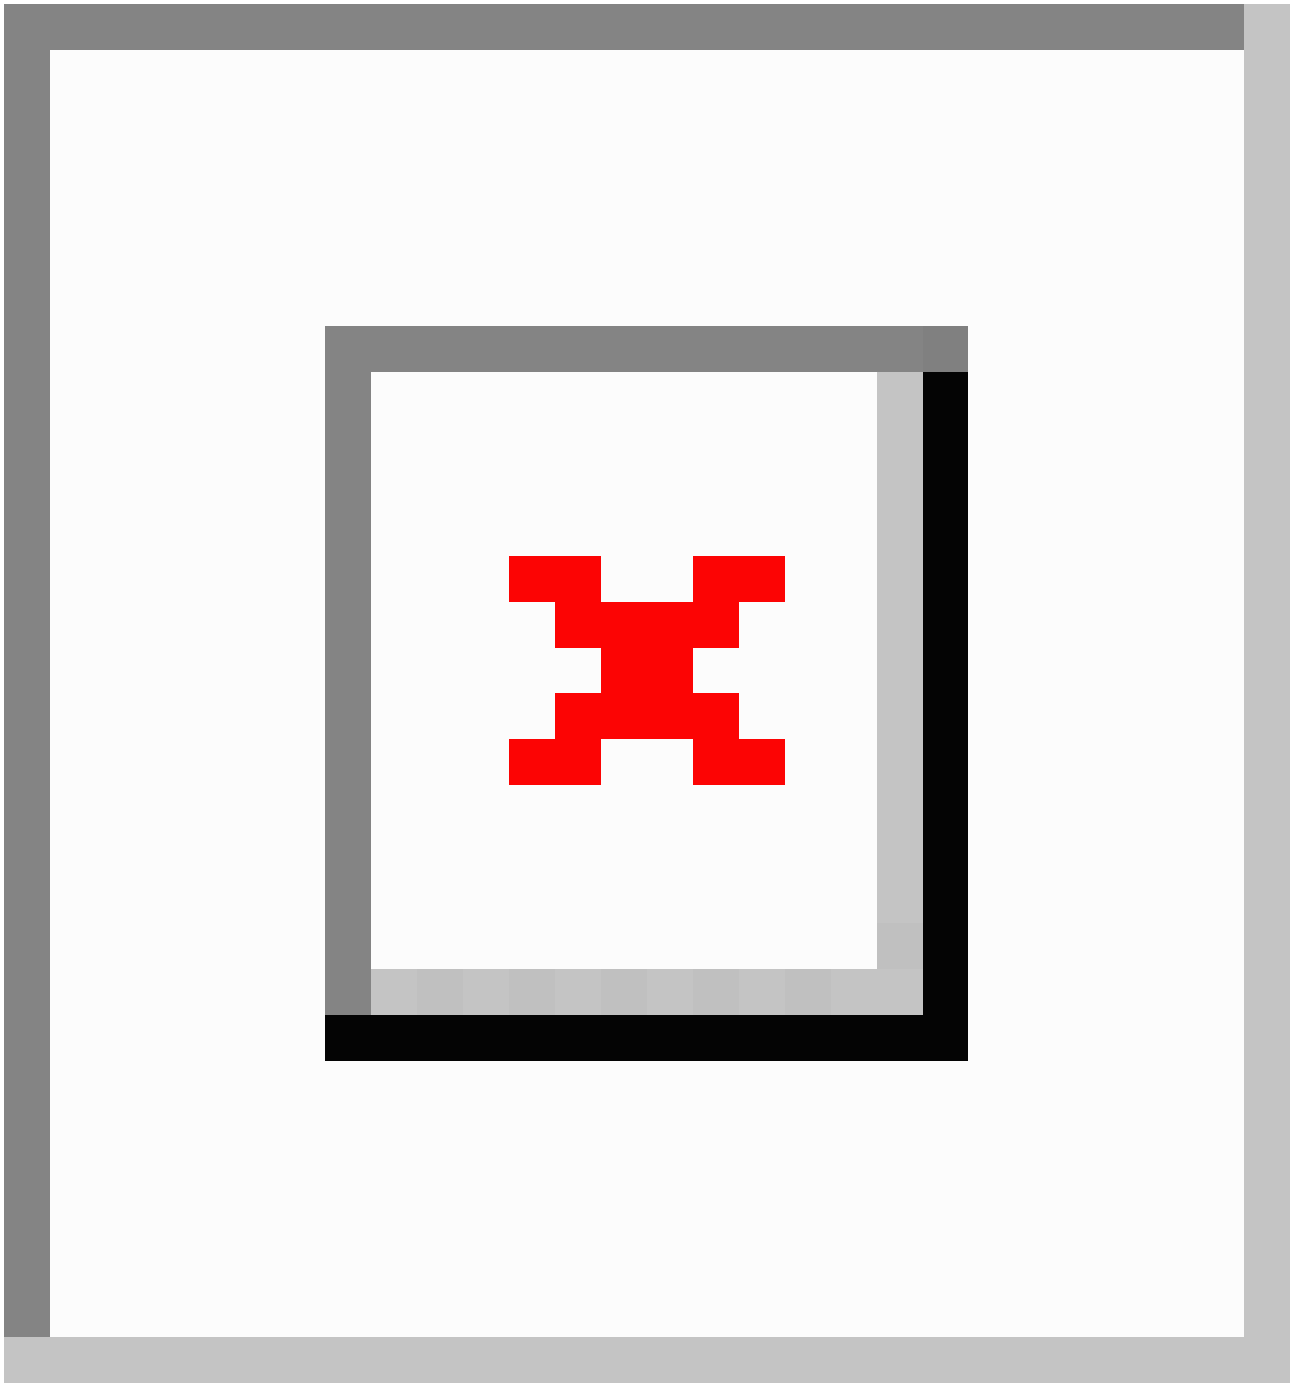
We analyzed and quantified the PHR-S FM functions in these 3 studies [33-35]. Using the PHR-S FM functional profile proposed by Harahap et al [18] as a benchmark, we conducted a comparative analysis of the results of these studies and of the present study to quantify the implementation of each functionality outlined in the profile. We conducted a survey on how many studies had implemented each function. The results were then subjected to a detailed discussion to ascertain the strengths and weaknesses of each PHR-S FM function. This approach aimed to evaluate the feasibility of the PHR-S FM framework and identify potential directions for future research.

Results

PHR Prototype Functionality

In this section, we verify and demonstrate the functionality of the PHR prototype (see Multimedia Appendix 4 for details). Figure 2 shows the sequence of events for communicating the FHIR resources between the PHR and FHIR servers. It outlines all the interactions between the PHR prototype and the Firely server based on FHIR resources. The PHR prototype enables users to create new PGHD, which undergo semantic conversion to ensure consistent terminology and units using LOINC and UCUM standards, then synchronizing them to the FHIR server as FHIR Observation resources. Concurrently, the PHR prototype demonstrates interoperability with the Firely server by using the RESTful API, efficiently retrieves various medical data, including allergies, immunization, vital signs, medications, diagnostic information, and laboratory and imaging test reports, while also uploading newly generated PGHD data back to the Firely server.

Figure 2. Sequence diagram of the synchronization of data between PHR and FHIR server.



Validation

We conducted a quantitative analysis of the PHR prototype using data from 5 patients extracted from the Synthea dataset (See Multimedia Appendix 5 for an example of verifying that the PHR correctly displayed data from Synthea). We identified 1157 data items across these patient profiles, with individual counts of 183, 154, 198, 327, and 295 (see Multimedia Appendix 6). The prototype accurately displayed all data entries contained within the patient profiles, achieving a coverage rate of 100%.

Entries were marked as not applicable if corresponding data points were absent in the patient profiles. The PHR prototype was designed to display 21 distinct FHIR resources and effectively presented data entries covering 20 out of 21 health data categories (95%), including user demographics, diagnosis information, medications, and laboratory test reports.

Specifically, for imaging test reports, no entries were recorded for any of the 5 patients. The PHR prototype could process and display such data, mirroring its performance with allergy information. Despite the absence of data in 4 out of the 5 patient profiles in the allergy category, the prototype successfully displayed all 7 entries for the 1 profile that included allergy data. This demonstrated the prototype's capability to fully render allergy information available in the dataset. This suggested that imaging test reports would be similarly displayed with complete accuracy if these data were available.

Comparison With the Findings of Previous Studies

This study used the PHR-S FM functional profile, as proposed by Harahap et al [18], as a foundational benchmark for conducting a comprehensive comparative analysis of 3 studies that used it. Table 3 presents a comparative analysis of our study with 3 other studies based on the PHR-S FM framework. In Table 3, "✓" was used to identify implemented functions, and "-" was used for unspecified functions. The results indicated that 5 functions were adopted and implemented in 4 studies, all of which originated from the PH module. Another 5 functions were implemented by 3 studies (3/4), 4 of which belonged to the PH module, and 1 was an interoperability function of the IN module. Furthermore, 2 functions were implemented in half of the studies (2/4), including the PH.2.5.10 (Manage Social History) function of the IN module. Moreover, 4 functions were implemented in 1 study (1/4). Of these, the "Manage Surgical History" function attracted attention, as it was the only function of the PH module implemented by only 1 study. In total, 13 functions were not implemented in any study.

Table . Comparative analysis of specific function completions in the PHR-S FM profile.

Discussion

Principal Results

This study developed a PHR prototype guided by the PHR-S FM profile, which successfully managed medical data, including immunizations, allergies, vital signs, medications, diagnoses, and test results. The prototype used LOINC and FHIR R4 for semantic consistency and standardization of user-input data, ensuring data consistency and interoperability. The prototype was validated using the Synthea dataset and demonstrated 100% coverage in accurately displaying patient information. A comprehensive analysis of previous studies revealed the current implementation status of the PHR-S FM framework, which predominantly focuses on the PH module with limited emphasis on the IN and S modules. To the best of our knowledge, this was the first study to examine the feasibility of using PHR-S FM to develop and design PHRs.

Comparison With the Findings of Previous Studies

PHR-S FM Feasibility Analysis

The detailed analysis of the functional implementation revealed significant trends and differences (Table 3). The diversity in the extent of functionality implementation indicated varying levels of focus on specific features in the PHR-S FM framework across different studies.

Widely Implemented Functions

As shown in Table 3, 10 features, including PH.1.2 (Manage PHR Account Holder Demographics), PH.2.5.1 (Manage Problem Lists), and PH.2.5.3 (Manage Test Results), were implemented by at least 3 studies, of which 9 were attributed to PH modules. We found that almost all these functions aligned closely with the PHR core set of necessary criteria outlined in the ONC's Meaningful Use criteria [7]. The widespread adoption of these features may be related to their centrality in patient data management and essential compliance with healthcare standards [7,19].

IN.2.1 (Interoperability Standards), the only function not corresponding to the PH module, is a major theme in current

PHR research; however, with the advent of FHIR, interoperability can be achieved [37]. FHIR released the first version with normative content (FHIR R4) in 2019. Katehakis et al [33] denoted a missed opportunity for interoperability. This indicated that researchers should focus on keeping up to date with the latest technologies related to PHRs to expand and enhance their functionality. In addition, the PHR-S FM community should undertake more initiatives to promote FHIR adoption and improve the interoperability and use of PHR systems. In comparison to the integrated PHR by Katehakis et al [33], both Saripalle et al and Chatterjee et al [35] developed tethered PHRs using FHIR for interoperability. While Saripalle et al [34] integrated multiple health information, it lacked qualitative and quantitative evaluations. Chatterjee et al [35] focused on recording PGHDs, but whether the prototype could effectively retrieve and display medical data from institutions was unclear.

Limited Implementation Functions

Six features were implemented in at least one study. One function, PH.2.5.10 (Manage Social History), was partially implemented in this study, allowing smoking status to be recorded; however, it was not fully implemented due to the variety of data types involved and the complexity of data collection [38].

The PH.2.5.7 (Manage Surgical History) function was uniquely mentioned in Katehakis et al's study [33], which effectively applied the PHR-S FM framework in the context of real research projects in the European Union. This allowed researchers to bypass the complexities of implementing this detailed function. In contrast, the other 3 studies were at the prototype stage. However, other functions mentioned by Katehakis et al [33] were adopted by at least 2 other studies, highlighting the feasibility of the PHR-S FM framework across various research settings.

Functions Not Mentioned

Many functions were not mentioned because the implementation of certain features was not within the scope or the priority of a particular study. Moreover, collecting data for the PHR system was challenging, and some collected data were not useful. For instance, the intricacy of PH.2.5.9 (Manage Personal Genetic Information) and PH.2.5.11 (Nutrition and Diet Information) were infrequently used in PHRs [39]. The limited participation of the IN and S module functions may be attributed to the complexity of their implementation, such as IN.3.10 (Secure Messaging), which ensures the security of communication [40]. Although this function is significant in the PHR system, it faces technical challenges [11]. The S.2.1 (Capture and Read Health Insurance Account and Benefit Information) function was not implemented, likely due to the need for data from multiple sources and a wide variety of types, which rendered it costly and challenging to implement [41]. PHR conformed to the PHR-S FM functional profile, allowing researchers to effectively use it by tailoring the functional profile to suit their research needs. This flexibility emphasized the adaptability of PHR-S FM and demonstrated its use as a dynamic health care research field, despite challenges in achieving certain features.

Furthermore, this study uncovered a significant trend, with the S and IN modules used less frequently than the PH modules. The S module offers users administrative and financial support functionalities, and its implementation can enhance the effectiveness of health care services. Implementing the IN module ensures privacy, security, and interoperability, facilitating access and usability of PHR functions. Both modules are essential components of a comprehensive PHR system. Therefore, researchers should prioritize the S and IN modules when considering PH module functionalities, as they form the backbone that supports the optimal operation of PHRs.

Comparison With Studies Based on Other PHR Frameworks

To delve deeper into the development of PHR systems, this study conducted a comparative analysis with research based on the PHR-S FM and examined other significant studies. Lee et al [42], Li [43], and Song et al [44] presented further perspectives on PHR systems' development. Lee et al [42] developed a PHR prototype that organizes and visualizes personal health information according to a patient-centered journey map. However, their study neither achieved data interoperability nor enabled users to record PGHD data, making the application irrelevant for people without diseases. Li [43] proposed a service-oriented approach to integrating the electronic health record and PHR systems. However, the development and implementation of a service-oriented approach-based environment can be highly complex and expensive. Moreover, compared with the FHIR, they used the HL7 CDA to deliver messages, thereby increasing maintenance difficulty. Song et al [44] developed a patient summary application based on the international patient summary and FHIR R4 standards to mitigate information overload and reduce physicians' and nurses' workloads. Unlike traditional PHRs, which provide a comprehensive display of numerous information items, this application is limited in scope, displaying only the essential international patient summary standard information on a single screen. This design choice aims to simplify the user interface for clinicians but may restrict the availability of more detailed patient data. Thus, this study implemented more functions of the PHR-S FM and created an advanced PHR with more comprehensive functions that can better meet users' functional needs than those of previous studies.

Limitations

Although this study exhaustively explored the feasibility of PHR-S FM functionality, its scope was limited to 29 functions. As the PHR-S FM is a comprehensive framework designed to encompass the full range of functions that may be integrated into a PHR system, this study did not address its full potential. Future research could consider a broader set of features to more thoroughly evaluate the value of the PHR-S FM for practical applications.

In addition, the application developed in this study was a prototype and must be verified for use and evaluated for functionality in the future. Furthermore, the proposed prototype does not currently address privacy and security concerns. The platform SMART on FHIR [45] offers secure access control through the OAuth2 standard, ensuring that only authorized

users and applications can access a patient's PHR. Future research should delve deeper into the integration of this technology in PHRs. Finally, the data types included in the PHR in this study were limited and lacked information on appointments and surgical history. However, our modularly designed PHR allows for the addition of such content in the future without altering the foundational structure.

Conclusions

This study developed a PHR prototype based on the PHR-S FM profile and compared its results with the findings of previous studies to evaluate the framework's feasibility in the application of PHR. The findings demonstrated the us of the PHR-S FM as a valuable tool for PHR development and highlighted its potential to inform future technological enhancements in the PHR domain. The empirical data on function implementation offer a foundation for subsequent PHR system design. Moreover, this study provides actionable recommendations for applying the PHR-S FM in health care settings. The adaptability of the PHR-S FM framework is well suited to evolving health information management demands, suggesting avenues for continued research and optimization.

Abstract

Background: To advance research with clinical data, it is essential to make access to the available data as fast and easy as possible for researchers, which is especially challenging for data from different source systems within and across institutions. Over the years, many research repositories and data standards have been created. One of these is the Fast Healthcare Interoperability Resources (FHIR) standard, used by the German Medical Informatics Initiative (MII) to harmonize and standardize data across university hospitals in Germany. One of the first steps to make these data available is to allow researchers to create feasibility queries to determine the data availability for a specific research question. Given the heterogeneity of different query languages to access different data across and even within standards such as FHIR (eg, CQL and FHIR Search), creating an intermediate query syntax for feasibility queries reduces the complexity of query translation and improves interoperability across different research repositories and query languages.

Objective: This study describes the creation and implementation of an intermediate query syntax for feasibility queries and how it integrates into the federated German health research portal (Forschungsdatenportal Gesundheit) and the MII.

Methods: We analyzed the requirements for feasibility queries and the feasibility tools that are currently available in research repositories. Based on this analysis, we developed an intermediate query syntax that can be easily translated into different research repository–specific query languages.

Results: The resulting Clinical Cohort Definition Language (CCDL) for feasibility queries combines inclusion criteria in a conjunctive normal form and exclusion criteria in a disjunctive normal form, allowing for additional filters like time or numerical restrictions. The inclusion and exclusion results are combined via an expression to specify feasibility queries. We defined a JSON schema for the CCDL, generated an ontology, and demonstrated the use and translatability of the CCDL across multiple studies and real-world use cases.

Conclusions: We developed and evaluated a structured query syntax for feasibility queries and demonstrated its use in a real-world example as part of a research platform across 39 German university hospitals.

Introduction

Background

In the rapidly evolving field of medical research, patient data have emerged as a critical resource. The vast amounts of data generated through clinical encounters, laboratory tests, imaging studies, and other patient interactions hold the potential to significantly advance our understanding of disease processes and treatment outcomes. Clinical Data Repositories (CDRs) are a valuable tool for storing, organizing, and retrieving this wealth of patient data. These repositories facilitate data storage in a structured and standardized manner, enabling researchers to query these data efficiently for various research purposes.

One key aspect of effectively using CDRs is the ability to perform feasibility queries. These queries allow researchers to assess the availability and adequacy of data for specific research questions before embarking on full-scale studies. Doing so can save considerable time and resources by identifying potential issues, such as insufficient sample size or a lack of necessary data elements.

Distributed Data Collections

The landscape of data repositories is not homogeneous. There are 2 primary approaches to data repository management: the classical single repository approach and the federated approach. Traditionally, these repositories have been centralized, pooling data from various sources into a single repository [1]. However, this classical approach has been challenged by the emergence of federated data repositories [1,2].

The classic single repository approach involves a centralized system where all data are stored and managed in one place. This solution offers the advantage of uniformity and ease of data management. It enables efficient data quality benchmarking at scale and the generation of derivatives, harmonized variables, and units of measure for comparable and consistent analytics [1]. However, it is often impractical or impossible to implement, especially when dealing with multiple institutions, each having its own schema for its clinical data repository.

On the other hand, the federated approach involves a network of repositories, each maintained by different institutions. These repositories operate independently but are interconnected for data sharing and collaboration. The data generally remain at the generating site, which offers the advantages of local curation by personnel deeply familiar with the data [1] and maintains data anonymity and security [2]. The data can then be analyzed using a federated approach or, if the correct patient consent is given, be transferred to a central data management unit for a specific analysis.

This approach respects individual institutions' autonomy and data governance policies, making it a more feasible option for multi-institutional collaborations [3-9] and can enhance the scope and depth of clinical research by enabling access to a broader range of data.

Despite the potential benefits of federated data repositories, performing feasibility queries across multiple CDRs presents significant challenges [10]. Each repository contains data originating from different source systems, leading to heterogeneity in data formats, terminologies, and quality. This heterogeneity can significantly complicate the process of data integration and harmonization, making it challenging to perform comprehensive and accurate feasibility queries [10].

Moreover, the federated nature of the system introduces additional complexities. Data privacy regulations and institutional policies may restrict the sharing and use of certain data, further complicating the query process. Additionally, the technical infrastructure required to support secure and efficient data exchange across multiple repositories can be challenging to implement and maintain.

Data Exchange Standards for Interoperability

In a federated network, the commitment to an interoperability standard becomes pivotal to tackling these challenges. Prominent examples include but are not limited to Fast Healthcare Interoperability Resources (FHIR) [11], OMOP CDM [12], i2b2 [13], and OpenEHR [14] share the commonality of being centered around the patients' medical history.

Agreeing on an interoperability standard only partially solves the challenge. While a health care data exchange standard facilitates the conversion of existing data into a common format at each hospital, a distributed feasibility query platform for the data is still missing.

Tools for Feasibility Queries

Besides the data integration standardization, interactive user interfaces enable researchers to design and submit feasibility queries. For this purpose, a multitude of tools for feasibility queries exist (eg, i2b2 [13,15], TriNetX [16], tranSMART [17], SampleLocator [18-20], Observational Health Data Science and Informatics [OHDSI] ATLAS [21], DZHK Feasibility Explorer [22]), each with its own data formats, standards, and query languages, including Structured Query Language (SQL), Clinical Quality Language (CQL), FHIR-Search, and Archetype Query Language (AQL). Consequently, querying across these different tools is difficult as there is no common query representation, and researchers must navigate these diverse tools and formats, particularly when dealing with cross-institutional data or distributed data storage within an institution.

Within the broader context of establishing a feasibility platform as part of the central German Portal for Health Data (FDPG), this research introduces a novel query syntax, serving as an intermediary between user interfaces and data repositories. This syntax is designed to be sufficiently flexible to ensure interoperability while maintaining simplicity. It focuses on the primary needs of a feasibility query, while allowing the syntax to be translated into repository-specific languages like FHIR-Search or CQL.

Our approach is grounded in the broader context of clinical research, where the reuse of eligibility criteria is common, whether in their original form or with modifications. These criteria are instrumental not just for feasibility studies but also for prescreening, data selection, extraction, and validation. Consequently, a need has emerged to decouple the representation of eligibility criteria from their implementation in specific

systems. A mechanism to express complex criteria and combinations thereof in a way that is both intuitive and adaptable to varying implementation needs is required.

In this study, we describe the development and application of the query syntax within the network of the Medical Informatics Initiative (MII), encompassing 39 German university hospitals, specifically, the FDPG feasibility platform and show how it achieves interoperability across different research platforms.

Methods

Requirement Analysis

In our pursuit to create an intermediate query syntax to express eligibility criteria, we performed a requirement analysis. Within it, we combine insight from feasibility queries and cohort selection, with the latter often manifesting as a query output in the form of cohort size rather than a list of discrete patient identifiers.

Our research reviewed existing tooling, namely i2b2, TriNetX, and OHDSI Atlas. We aimed to identify common functionalities and essential features across these tools. To obtain insight into the criteria's structure and complexity, we analyzed existing eligibility criteria from ClinicalTrials.gov [23] and incorporated the findings from Ross et al [24] and Gulden et al [25]. Moreover, we integrated insights from the usability study by Schüttler et al evaluating feasibility tools [26], conducted expert interviews and recursively synchronized the requirements within our project. This multifaceted analysis allowed us to infer a set of requirements crucial for developing our query syntax. These requirements were categorized into query expressiveness, interoperability, and accessibility.

Expressiveness Requirements

The query syntax should:

1. allow for the definition of inclusion and exclusion criteria
2. be expressed in Boolean logic.
3. allow the expression of exclusion criteria.
4. support at least patient as query subject (feasibility queries can be performed on different query subjects: find all patients with specific criteria, find all encounters with specific criteria, find all specimens with specific criteria).
5. use unique identifiers for criteria and concepts.
6. support the following filter on the criterion level:
    - existence of a criterion
    - numeric restriction
    - concept filter
    - time restrictions
    - attribute filters

Interoperability and Accessibility Requirements

The query syntax should:

1. provide an abstract (decoupling) layer between the user interface and the query execution.
2. have a low level of complexity and be easily translatable to different query languages.
3. be suitable for integration with the Health Level Seven International (HL7) FHIR standard used by the MII.
4. use a widely used data exchange format like JSON to ease parsing and generation
5. human readability or writability
6. ideally directly support the use of standard medical terminology (LOINC [Logical Observation Identifiers Names and Codes], SNOMED-CT [Systematized Nomenclature of Medicine–Clinical Terms], *ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*], etc) to lower mapping efforts

Related Work and Existing Solutions

Analyzing the existing solutions, we found that none of the solutions met all the requirements. Most failed to have a formally defined low-complexity feasibility query syntax, and i2b2 was missing the direct relationship with the terminology on the syntax level. FHIR Search and the FHIR standard did not provide the ability to express a feasibility query in the required scope [25] at the time of our research. Other query languages that could have been candidates, like CQL or SQL, are complex or data model specific, making the translation between different data models and their representation, as well as the generation of the syntax by a user interface, challenging.

Evaluation

To evaluate the specification of the query syntax, we compared the final specification with our requirements and additionally demonstrated its applicability beyond the scope of FHIR by applying it to AQL.

We incorporated the solution into a large-scale real-world distributed feasibility query infrastructure, including a user interface, where it was integrated as the central intermediate query syntax. We further evaluated the applicability of the syntax to a wide range of clinical criteria and investigated its translatability, as well as how well it lends itself to creating a user interface for feasibility queries. Beyond the use in our projects based on German data sets and specifications, we also successfully applied the Clinical Cohort Definition Language (CCDL) to the international Synthea [27] data set.

Ethical Considerations

No ethics board decision is required as we are presenting a technical solution without working on patients' data.

Results

Based on the requirements of a team of experts, we created the "Clinical Cohort Definition Language," an intermediate query syntax for feasibility queries. The exchange format for the syntax was chosen to be JSON, which is currently widely used across the software community and is familiar to software developers from user interfaces, REST application programming interfaces (APIs), and query execution backends alike.

Criterion Types and Filters

The atomic component of CCDL is the criterion, serving as the foundational building block for inclusion or exclusion criteria. Each criterion is uniquely identified using a tuple of code system and code (which we named termCode) analogous to FHIR and OMOP-CDM (For conceptual equivalence between concepts

across medical terminologies, multiple termCodes can be provided, eg, the criterion for sleep apnea may be represented by the termCodes G47.3 from *ICD-10* and 73430006 from SNOMED-CT). Each termCode may have an additional "display" attribute, which serves purely as a visual representation to make the interpretation of a CCDL easier for humans. Within our CCDL, the criteria can occur as 1 of 4 different base types of criteria:

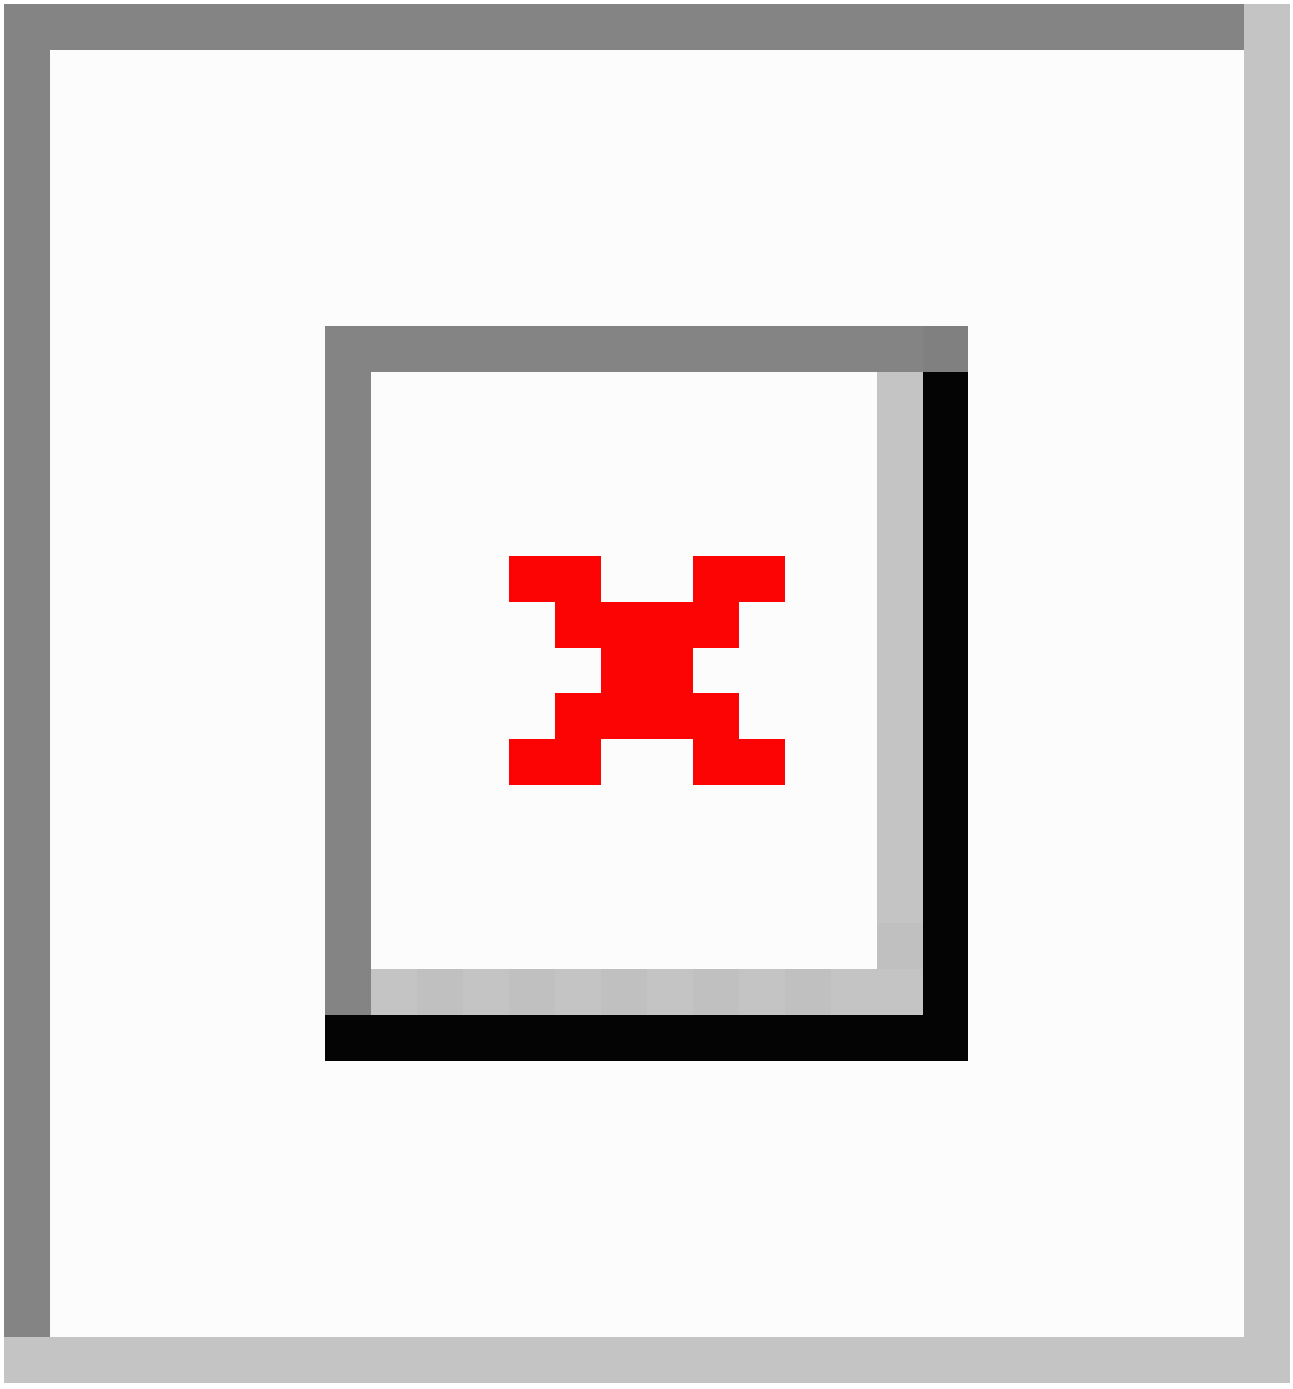
- Exist criteria with no additional filters (eg, conditions or a laboratory concept with no filter, like the existence of a hemoglobin value regardless of the value)
- Comparatively restricted numerical criteria (eg, hemoglobin laboratory value <12 g/dL)
- Range-restricted numerical criteria (eg, hemoglobin laboratory value between 10 and 12 g/dL)
- Value set restricted criteria (eg, gender=female or male)

Additionally, each criterion can be further restricted to a date range (eg, a Condition that occurred between January 1, 2024, and February 5, 2024), and it supports additional "attribute" filters, which can be added to each of the base types of criteria. The attribute filters support similar filters that identify the criterion types, ie, comparative numerical, comparative range, and value set restriction (eg, the body site=skin for a tissue specimen—see Multimedia Appendix 1).

The Explicit Logic Layer

The logic layer of the query aligns with existing solutions (i2b2/tranSMART/TriNetX) in representing the structured query as a combination of conjunctive normal form (CNF) and disjunctive normal form (DNF). Every criterion is embedded into the logic layer in a CNF for inclusion criteria and DNF for exclusion criteria (Figure 1). Inclusion and exclusion criteria are then logically combined via an AND NOT operator by subtracting the result of the exclusion criteria from the result of the inclusion criteria. Every feasibility query also receives a syntax version number and an additional description. The syntax version allows to distinguish the current version from future versions and changes, and the description allows the query to transport additional human-readable information about the query.

Figure 1. Structured query syntax top-level elements and logic layer. Certain criterion types will imply additional intrinsic logical relations. See ValueSet criteria and attribute filters and time restrictions.

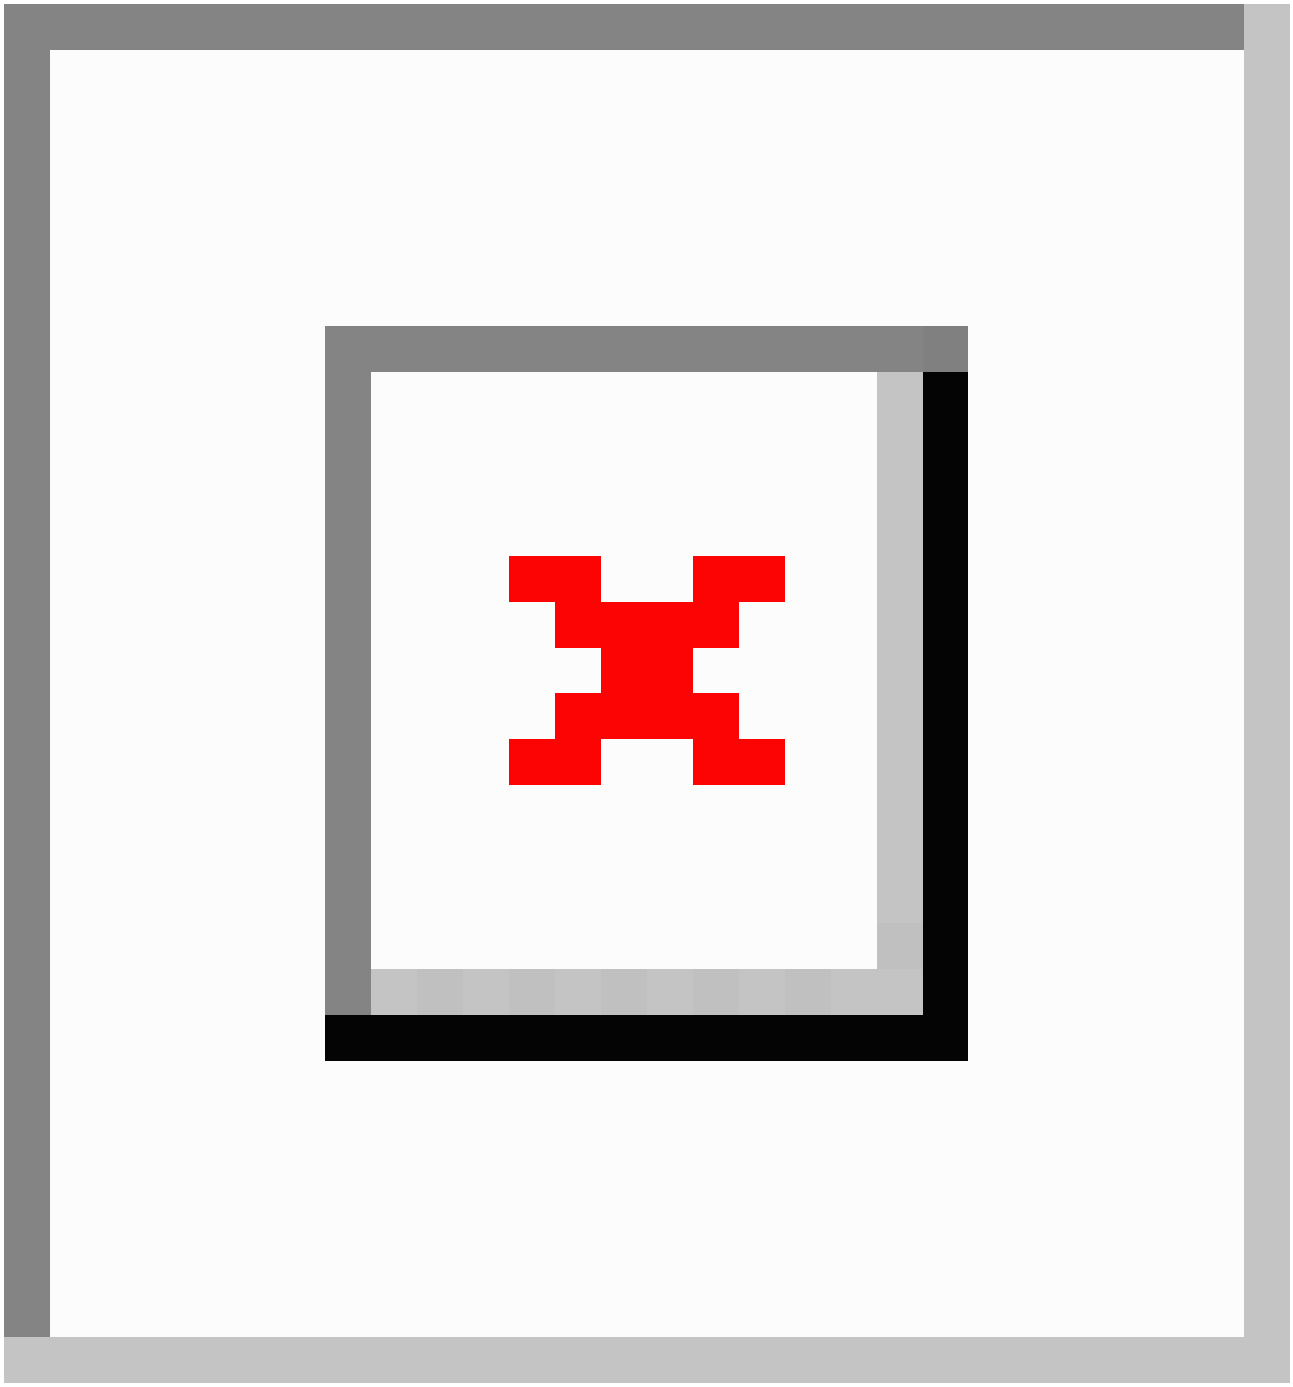


The Implicit Logic (Criteria Expansion)

Apart from the explicit logic layer across criteria, different types of criteria and their filters further impact the execution logic as follows.

ValueSet criteria (see Figure 2D) allow the selection of multiple values (concepts). In this case, the value selections are treated as OR choices. For example, gender = (male, female) expands to: (gender=male) OR (gender=female).

Figure 2. Different types of criteria definitions. (A) Simple conceptual criterion. (B) Numeric criterion with quantitative comparison. (C) Numeric criterion with range restriction. (D) ValueSet criterion.



Attribute filters for each criterion are additional filters that can be set for each criterion. All individual filters on a criterion are combined using AND. For example, a specimen of type “Tissue specimen” and body site “skin” only applies to specimens with the type of Tissue and the body site skin.

The same applies to time restrictions. In this example, the time restriction “between 2020-01-01 and 2021-01-01” will predictably be added using an AND conjunction of the type, body site, and time restriction.

Furthermore, there is an implicit OR expansion of criteria when the criterion-identifying code is a parent code of multiple child codes within a terminology hierarchy. For example, suppose a researcher adds the diagnosis of type 2 diabetes mellitus as a criterion (*ICD-10* code=E11). In that case, it can be expanded to search all subtypes of type 2 diabetes mellitus (E11, E11.3, E11.31, E11.30, E11.1, E11.11, E11.0, E11.01, E11.7, E11.75, E11.74, E11.73, E11.72, E11.4, E11.41, E11.40, E11.8, E11.81, E11.80, E11.2, E11.21, E11.20, E11.5, E11.51, E11.50, E11.6, E11.61, E11.60, E11.9, E11.91, E11.90) combining them using a logical OR operation).

Context-Dependent Criteria

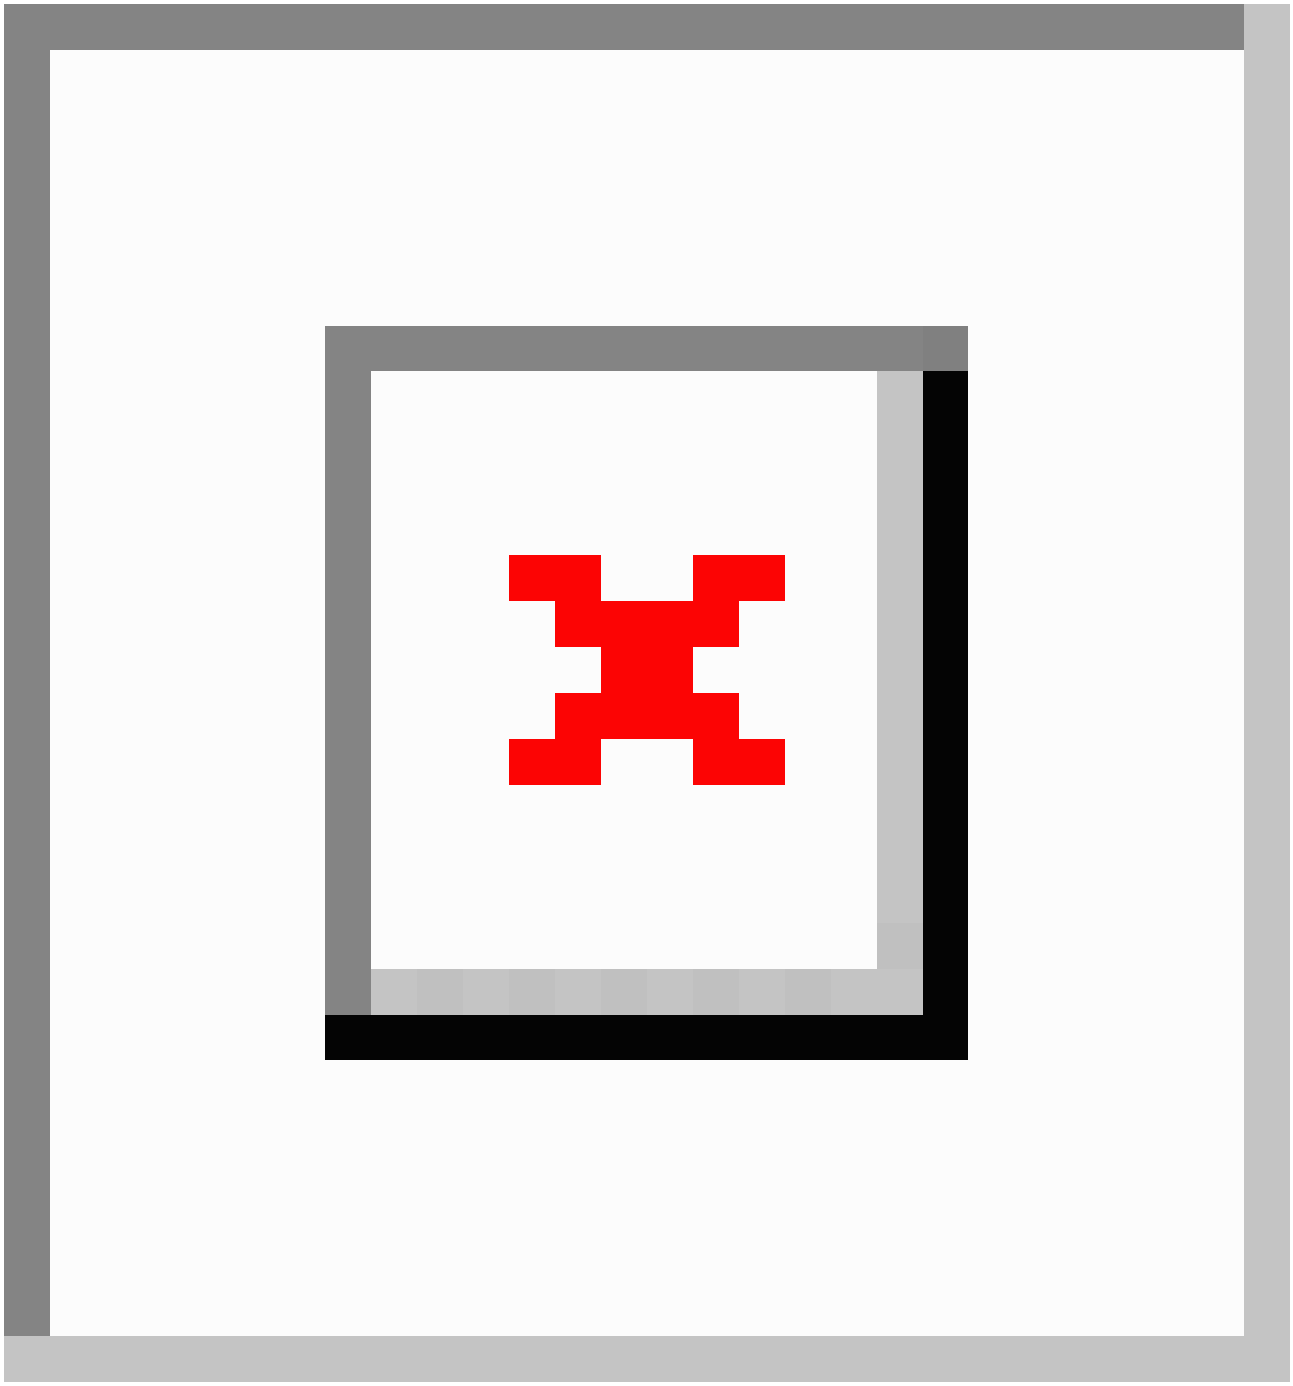
In some cases, a criterion cannot be uniquely defined by its term code within a terminology, making it impossible to map a criterion for execution. One example of this is the use of *ICD-10*

condition codes for causes of death, specimen-specific conditions, or the general condition of a patient.

In modern terminologies like SNOMED-CT, this can be resolved using postcoordination, where a combined code, which carries the context, is created. For example, 419620001|Death|:42752001|Due to|=22298006|Myocardial infarction| which, while in line with SNOMED Compositional Grammar [28], a template to express this is not currently part of the SNOMED-CT implementation.

The syntax we developed here allows for post-coordinated codes; however, we allow for an additional "context" attribute for some use cases where postcoordination is unsuitable. The context attribute is modeled after our termCode attribute and provides an extra term code to identify the context. Figure 3 provides an example for myocardial infarction as condition aand cause of death.

Figure 3. Myocardial infarction in 2 contexts (condition and cause of death).



Data Availability

As a technical solution to define the structure of the CCDL, we decided on the JSON Schema definition and made it publicly available [29]. The schema serves implementation guidance and validation purposes; the git repository also contains documentation examples, test data, and the capabilities to create matching test queries.

Requirement Verification

An analysis was performed based on the structure defined in the JSON schema to evaluate the developed intermediate query syntax. The following table (Table 1) presents the detailed results of this analysis:

This syntax efficiently meets a wide range of expressiveness and interoperability requirements, demonstrating capabilities in defining complex medical queries with standard terminologies and logical operators.

Table . CCDL[a] components and their purpose regarding the expressiveness requirements.

Component	Key properties	Purpose and function	Requirements met
inclusionCriteria	CNF[b] without negation	Conjunction of criteria with logical operators.	Expressive query formulation, boolean logic
exclusionCriteria	DNF[c] without negation	Allows negation of criteria for comprehensive exclusion.	Negation of criteria on a group level, Boolean logic
termCode	code, system, version, display	Identifies concepts using standard coding systems.	Standard medical terminology, uniqueness
criterion	context, termCodes, valueFilter, attibuteFilter, timeRestriction	Sets criteria with defined context, using term codes and filters.	Expressiveness of simple and complex eligibility criteria
timeRestriction	afterDate, beforeDate	Specifies time frame for criteria fulfillment.	Time restrictions
unit	code, display	Standardized unit definition, adhering to UCUM[d] units.	Use of standardized units
valueFilter	type (concept, quantity-comparator, etc)	Varied filtering types for flexible data querying.	Numeric restriction, concept restrictions
attributeFilters	type (concept, quantity-comparator, reference)	Mechanism for detailed filtering at the attribute level.	Detailed filtering, clinical relations

[a]CCDL: Clinical Cohort Definition Language.

[b]CNF: conjunctive normal form.

[c]DNF: disjunctive normal form.

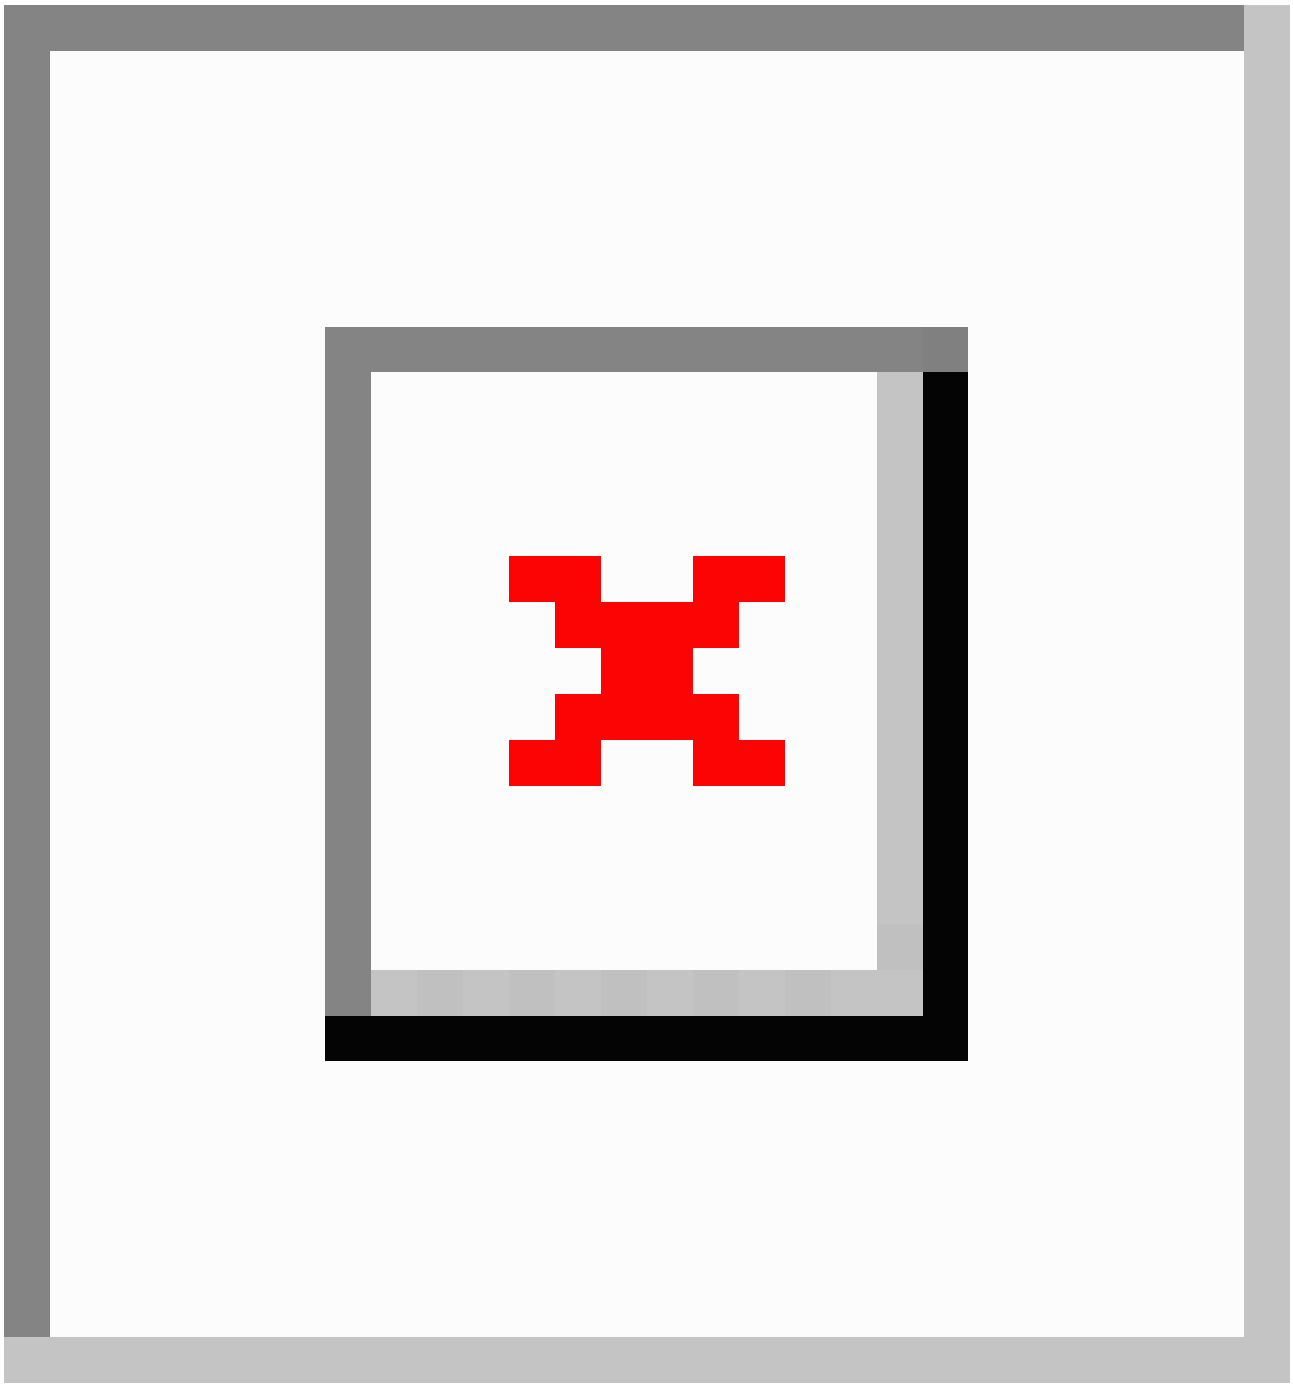
[d]UCUM: ___.

Evaluation and Use of the CCDL in Real-World Scenarios

We believe the potential of the CCDL extends beyond its application in the federated feasibility portal of the German Research Portal for Health. Nevertheless, the CCDL remains a crucial technical solution within the FDPG's feasibility portal.

We created a user interface for the feasibility queries in the FDPG (Figure 4), which generates the CCDL, demonstrating how it lends itself well to building feasibility query user interfaces [30,31]. The CCDL especially supports this as its design follows the typical way of feasibility query creation as seen in platforms such as the FDPG, i2b2, OMOP, and TrinetX. We evaluated the usability of the user interface across multiple projects [32,33] and embedded it in a German-wide distributed research infrastructure [10,34]. These evaluations highlighted the applicability of the CCDL to a feasibility query and that the usability issues found were not due to a lack of expressiveness of the CCDL. We further used the Synthea data set to test the CCDL against [35], demonstrated the ability of the CCDL to represent a wide range of criteria [36], and showed that it could be fully translated to FHIR Search [37], CQL [38], and AQL [39]. At the time of writing, almost 9000 CCDLs have been created and executed across Germany.

Figure 4. Example of a feasibility query in the central German Portal for Health Data (FDPG) feasibility portal to find patients with a leukocyte count within a normal range, with a malignant neoplasm of the brain, available tumor tissue specimen, and a CT scan after January 1, 2020, who did not take doxorubicin.



Discussion

Principal Findings

We presented an intermediate feasibility query syntax that separates concerns between the user interface and the execution of a feasibility query on different research repositories and their specific query languages. The syntax defined here fulfills all the interoperability and accessibility requirements while supporting a broad range of expressiveness requirements we identified by analyzing existing query tools. The solution is fully compatible with established medical terminology standards, notation of parameters, and restriction semantics.

The solution we describe here is compatible with the query logic established by i2b2 and, therefore, tranSMART and TriNetX. This means that tools like i2b2 or similar could be easily extended to produce our syntax.

The CCDL was further used as part of a larger infrastructure for feasibility queries in Germany and is currently used as the interface for feasibility queries within the German research portal for health, supporting feasibility queries across 39 university hospitals in Germany. We successfully created translation components for FHIR Search and CQL in the current implementation. Current research also indicates the adaptability for FHIR Pathling's aggregation API [40], and SQL. The criteria

content and the required reintroduction of data model—dependent information are obtained from an automatically generated search ontology [36].

Related Work

While the expression of eligibility criteria within a specific data model context is well established and adequately discussed in this work, research on a data-agnostic intermediate format for computable eligibility has been sparse in recent years.

Alper et al [41] closely align with our approach of representing eligibility criteria in a structured format, namely the FHIR EvidenceVariable, which currently does not directly support the representation of eligibility criteria but may be refined to do so. Presumably, an FHIR representation would provide a structure beyond the realm of the MII, which could add significant value and improve syntax interoperability. However, in the early stages, the challenges of adopting new solutions could have impeded the development presented here. Our ongoing communication with the HL7 working group, which focuses on Research Studies, gives us confidence that once a suitable FHIR Resource is established or adapted to meet the needs outlined in our publication, the established technical components could be efficiently modified to align with these changes. Parallels can be drawn to implementing structured eligibility criteria, as presented by Yuan et al [42] and Fang et al [43]. Their publications present a half-automated approach to generate feasibility queries based on free text study protocols from ClinicalTrials.gov [23]. Their system is built around the OHDSI data model and uses the concept IDs. After converting the free text criteria, they allow users to edit and download an intermediate representation in JSON format. Unfortunately, no clear implementation guidelines on the format are given by Yuan et al [42] and Fang et al [43]. However, recurring themes include differentiating inclusion and exclusion criteria and defining temporal constraints. To our knowledge, contrary to our approach, they do not allow for further restrictions beyond the value constraint on specific criteria.

Limitations

The separation of concerns, which the CCDL provides, also leads to the need for a mapping to identify the correct way of translating the CCDL information model to the local information model and terminology. The mapping allows the link between the specific data model and the criterion as identified in the CCDL to be created. One example of this is that for FHIR Search, the mapping for a condition criterion identified by a specific *ICD-10* code C50.0 would provide the information that the condition is found in the end point "/Condition" and the search parameter for the term code is "code" – Leading to the translated FHIR Search URL:

[fhir-base-url]/Condition?code=http://fhir.de/CodeSystem/bfarm/icd-10-gm|C50.0."

Further, additional information about the terminology is necessary to allow the selection of criteria within a terminology hierarchy, where the criterion resolves to multiple child criteria. Finally, this then requires the query executor and the CCDL-generating user interface to agree on criteria or terminology entries.

One common requirement currently not supported by the CCDL is temporal interdependencies between different criteria. Therefore, queries like a specific laboratory value within a certain period of diagnosis cannot be currently expressed using the CCDL.

We deliberately decided to delay the implementation of this extension as time dependencies significantly increase the complexity and performance requirements of any query execution.

The data model agnostic nature of the CCDL is inherently valuable. Its full potential—the capability to be used across different health care data models—requires more than technical translation. For cross-model query capability, the existence of the concepts in all target data models must be ensured.

Future Work

The CCDL described here provides a good base to make feasibility queries possible across various research repositories and close the gap between the different research repositories and their access. We have demonstrated the applicability of the CCDL to FHIR Search, CQL, and AQL; however, more repositories and other query languages, such as SQL on FHIR, OHDSI OMOP, or i2b2 might be added in the future. Further, one could imagine how separating the query syntax and execution would theoretically allow one to query different internationally distributed repositories such as FHIR, OMOP-CDM, and i2b2 simultaneously. Additionally, the CCDL is currently limited in how much it can express, and new capabilities will be added in the future. In this pursuit of making the CCDL more expressive, any extension must be weighed against the added complexity and overhead it introduces.

Conclusion

We presented a query syntax for medical feasibility queries, which creates an abstract layer between the user interface and the execution query language. We showed how it is flexible enough to be translated into different query languages and can be used to express various complex feasibility queries. The applicability of the query syntax was further demonstrated by embedding it into a large research project where it is used to query multiple millions of patients across 39 German university hospitals. The CCDL for feasibility queries will be extended in the future to allow more features, and we are currently working on a modified version for data selection and extraction.

Acknowledgments

The project was funded by the German Federal Ministry of Education and Research (BMBF) under the FDPG-PLUS Project (grants 01ZZ2309A, 01ZZ2309C, 01ZZ2309D, 01ZZ2309E, and 01ZZ2309F).

Abstract

Background: Multisite clinical studies are increasingly using real-world data to gain real-world evidence. However, due to the heterogeneity of source data, it is difficult to analyze such data in a unified way across clinics. Therefore, the implementation of Extract-Transform-Load (ETL) or Extract-Load-Transform (ELT) processes for harmonizing local health data is necessary, in order to guarantee the data quality for research. However, the development of such processes is time-consuming and unsustainable. A promising way to ease this is the generalization of ETL/ELT processes.

Objective: In this work, we investigate existing possibilities for the development of generic ETL/ELT processes. Particularly, we focus on approaches with low development complexity by using descriptive metadata and structural metadata.

Methods: We conducted a literature review following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. We used 4 publication databases (ie, PubMed, IEEE Explore, Web of Science, and Biomed Center) to search for relevant publications from 2012 to 2022. The PRISMA flow was then visualized using an R-based tool (Evidence Synthesis Hackathon). All relevant contents of the publications were extracted into a spreadsheet for further analysis and visualization.

Results: Regarding the PRISMA guidelines, we included 33 publications in this literature review. All included publications were categorized into 7 different focus groups (ie, medicine, data warehouse, big data, industry, geoinformatics, archaeology, and military). Based on the extracted data, ontology-based and rule-based approaches were the 2 most used approaches in different thematic categories. Different approaches and tools were chosen to achieve different purposes within the use cases.

Conclusions: Our literature review shows that using metadata-driven (MDD) approaches to develop an ETL/ELT process can serve different purposes in different thematic categories. The results show that it is promising to implement an ETL/ELT process by applying MDD approach to automate the data transformation from Fast Healthcare Interoperability Resources to Observational Medical Outcomes Partnership Common Data Model. However, the determining of an appropriate MDD approach and tool to implement such an ETL/ELT process remains a challenge. This is due to the lack of comprehensive insight into the characterizations of the MDD approaches presented in this study. Therefore, our next step is to evaluate the MDD approaches presented in this

study and to determine the most appropriate MDD approaches and the way to integrate them into the ETL/ELT process. This could verify the ability of using MDD approaches to generalize the ETL process for harmonizing medical data.

Introduction

Multisite clinical studies are increasingly using real-world data to gain real-world evidence, especially during the COVID-19 pandemic [1]. However, not all clinics use the same hospital information system, resulting in heterogeneity of data produced by different hospital information systems. These heterogeneous data are not semantically and syntactically interoperable. Therefore, it is difficult to analyze such data in a unified way across sites. For this, the heterogeneous data need to be harmonized and standardized, for example, by using a common data model (CDM) [2]. For example, the European Medical Agency [3] set up the DARWIN EU (Data Analysis and Real World Interrogation Network European Union) [4] to provide real-world evidence on use and adverse events of medicines across the European Union. DARWIN EU uses the Observational Medical Outcomes Partnership (OMOP) CDM [5] as the base model, which is provided by the Observational Health Data Sciences and Informatics [6] community. To participate in such networks, a transformation of local data is needed. A common approach is to develop an Extract-Transform-Load (ETL) or Extract-Load-Transform (ELT) process. Both are used to harmonize heterogeneous data into the target systems. The only difference between them is the order of processing data. ETL transforms the data before loading them into the target systems, while ELT loads the data into the target systems first, and then transforms the data. Due to the different data formats and source systems, multiple ETL/ELT processes have to be implemented [7-10]. This work is time-consuming and hard to maintain [11].

Using a standard data exchange format can reduce the complexity of transforming heterogeneous data into CDMs. An example is the Fast Healthcare Interoperability Resources (FHIR) [12] format. FHIR is a communication standard and is provided by the Health Level 7 (HL7) [13]. In Germany, the Medical Informatics Initiative (MII) [14] provides a Core Data Set (CDS) [15] in FHIR format for enabling the interoperability of data across all university hospitals. Another German association “the National Association of Statutory Health Insurance Physicians” (KBV, German: Kassenärztliche Bundesvereinigung) [16] also provides a KBV CDS in FHIR format, which provides a stable foundation for the development of the medical information objects [17] (eg, immunization records and maternity records). Although both MII CDS and KBV CDS are based on the German HL7 Basis Profiles [18], the FHIR profiles defined in the 2 CDSs are not identical [19]. This is due to the different requirements of MII and KBV. For example, codes indicating departments within a clinic (eg, 0100 for internal medicine department) are defined in different value-sets and therefore use different coding systems. This also complicates the implementation and maintenance of ETL/ELT processes.

Furthermore, most countries try to standardize their electronic health records (EHR) data for research and to improve the interoperability of the data. Consequently, country-specific FHIR profiles are developed, for example, German HL7 Basis Profiles [18] and the US CDS [20]. Due to different languages (ie, German vs English), different structure definitions (eg, extensions and cardinality) and different coding systems (eg, system URL for International Classification of Diseases, 10, Revision: German Modification [21] vs system URL for International Classification of Diseases, 10, Clinical Modification [22]) used in the FHIR profiles, different ETL processes need to be implemented [8,23]. Although these are just a few examples, it is conceivable that with the expansion of supported use cases, the time required for implementing an ETL/ELT process increases massively, while the maintainability decreases. Therefore, the implementation of a generic ETL/ELT process for harmonizing local health data can guarantee the semantic and syntactic interoperability of research data across sites and countries.

Using metadata for the implementation of ETL/ELT processes is a promising approach, as stated by David Loshin [24]: “in order to organize data for analytical purposes, it will need to be extracted from the original source (source metadata), transformed into a representation that is consistent with the warehouse (target metadata) in a way that does not lose information due to differences in format and precision (structure metadata) and is aligned in a meaningful way (semantic metadata).” A very broad definition of metadata is “data about other data” [25]. Depending on the specific context of use, metadata can be classified into 3 types [26]:

- **Descriptive metadata**: the metadata is used for discovery and identification purposes, for example metadata for source and target data.
- **Structural metadata**: the metadata is used for managing data in information systems, for example, column names and table names in a database.
- **Administrative metadata**: the metadata exists within a database that provides additional information, for example, the name of a person, who has changed the data in a database.

Metadata can be represented by metadata languages (eg, Resource Description Framework and Notation3) [27]. Such languages are also called ontology languages. For enabling the interoperability of data from different source and target systems, rule languages (eg, Rule Markup Language and Semantic Web

Rule Language) can be used to define the transformation rules between them [27]. Therefore, the use of metadata is expected to improve the development and maintenance for transforming FHIR resources to OMOP CDM.

As a side note, we understand any (descriptive and structural) metadata-based approach used for developing ETL/ELT processes as metadata-driven (MDD) approach. This work focuses on providing an overview of the types of MDD approaches and their use in different thematic categories. The overview aims to identify a suitable MDD approach to enhance the data transformation from FHIR to OMOP CDM. This will be achieved by answering the following questions:

- Q1: What are the themes of application for MDD approaches?
- Q2: What types of MDD approaches exist in the literature?
- Q3: What are the reasons for the usage of MDD approaches?
- Q4: What tool was used to implement the MDD approach?

Methods

To answer our 4 research questions, we conducted a literature review. To ensure the transparency of the review process, we followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [28]. We used 4 publication databases (ie, PubMed, IEEE Explore, Web of Science, and Biomed Center) to search for relevant publications from 2012 to 2022 written in German or English (Textbox 1). The first search was performed on August 11, 2022, and the second one was on March 15, 2023, which in turn completed the search through December 31, 2022. The collected publications were loaded into the Zotero Citation Management program (Corporation for Digital Scholarship) [29] and the duplicates were manually removed. To better categorize the publications to be excluded, we defined 8 exclusion criteria (Textbox 2).

This review was a 2-fold process consisting of Title-Abstract-Screening (TAS) and full-text screening (FTS). Both screening processes used the same exclusion criteria listed in Textbox 2. The unique publications were divided into 2 groups based on their publication dates and uploaded to a research collaboration platform, Rayyan (Qatar Computing Research Institute and Cochrane Bahrain) [30], as 2 separate projects. Each publication group was assigned with 4 reviewers. The corresponding author reviewed all publications. The TAS was performed under the blind-modus, so that each reviewer could label the publication independently. The blind-modus was turned off after all publications were tagged and the conflicts were discussed and resolved. After that, all included publications were randomly divided into 2 groups and reloaded into Rayyan as a new project for FTS. Similar to TAS, 4 reviewers were assigned to each publication group and the corresponding author reviewed all publications. The FTS was also conducted under the blind-modus and followed the same review process as the TAS.

We extracted the content of all included publications based on the categories listed in Textbox 3. The extraction of publication content was done by the corresponding author and validated by 4 coauthors. The extracted content was stored in a spreadsheet for further analysis and visualization.

The result of the literature review was visualized using an R-based tool, which was developed based on PRISMA 2020 [31].

Textbox 1. Search string and publication databases.

Search string

PubMed

- ((meta data) OR (meta-data) OR (metadata) OR (ontology) OR (rules)) AND ((extract transform load) OR (ETL) OR (extract load transform) OR (ELT))

IEEE Explore

Web of Science

- (ALL=(metadata) OR ALL=(meta-data) OR ALL=(“meta data”) OR ALL=(ontology) OR ALL=(rules)) AND (ALL=(ETL) OR ALL=(“extract transform load”) OR ALL=(ELT) OR ALL=(“extract load transform”))

Biomed Center (BMC)

- (“meta data” OR meta-data OR metadata OR ontology OR rules) AND (“extract transform load” OR ETL OR “extract load transform” OR ELT)

Textbox 2. Labels and descriptions of exclusion criteria.

Wrong_abbreviation

- Publication does not contain Extract-Transform-Load (ETL) as “Extract-Transform-Load.”
- Publication does not contain Extract-Load-Transform (ELT) as “Extract-Load-Transform.”

Wrong_definition

- Publication does not use metadata in the context of “metadata of data in source or target.”
- Publication does not use rules in the context of “rules for data transformation.”

Only_etl_elt

- Publication describes only ETL/ELT.

Only_metadata

- Publication describes only metadata.

Wrong_focus

- Publication mentioned metadata and ETL/ELT, but the focus is not about data harmonization

Wrong_type

- Publication is not a conference paper or a journal publication

Foreign_language

- Publication is written in other languages than English and German

Wrong_content

- Publication does not mention ETL/ELT or metadata

Textbox 3. Categories for data extraction.

Theme

- The main theme of the work.

Metadata-driven method

- The used metadata-driven method in the work.

Metadata-driven method tool

- Tool which was used to conduct the metadata-driven method.

Purpose

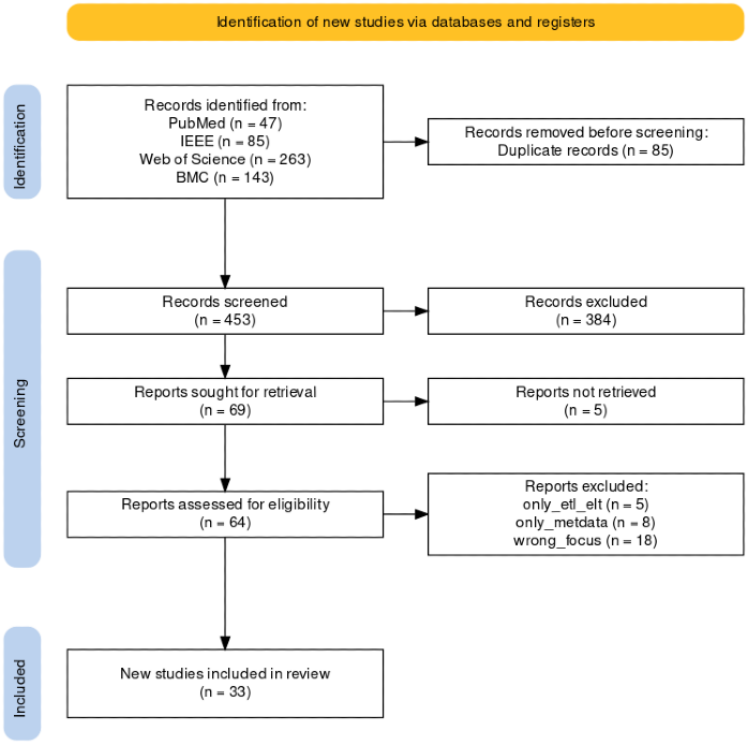
- The purpose of using the metadata-driven method.

Results

Literature Search

The literature search resulted in 538 publications. After removing 85 duplicates, 453 publications were screened during the TAS phase. By using the exclusion criteria defined in Textbox 2 and excluding the publications, which have no full-text, 64 publications were included for FTS. Finally, we included 33 publications in this work. The screening process and results are structured using the PRISMA flow diagram 2020 (Figure 1). A complete list of included publications is available in Multimedia Appendix 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. Generated using an R-based tool (reproduced from Haddaway et al [31], with permission from Neal R Haddaway).



Distribution of Publications

In order to gain an overview of the potential application focuses of MDDs (Q1) and thus an indication of where the approaches have proven beneficial, the focused theme of application was first evaluated. According to the extracted data, the focuses of all included publications are classified into 7 different categories, namely medicine (n=9) [10,32-39], data warehouse (n=13) [40-52], big data (n=4) [53-56], industry (n=4) [57-60], geoinformatics (n=1) [61], archaeology (n=1) [62], and military (n=1) [63]. This shows that data warehouse and medicine are the 2 categories that use the MDD approach the most.

MDD Approaches Used for Various Thematic Categories

Different types of MDD approaches were used across the thematic categories. To gain knowledge about the use of these types of MDD approaches in each category (Q2), the distribution of MDD approaches was investigated. Figure 2 shows the application of different types of MDD approaches in different thematic categories. The most frequently used type of MDD approach was ontology-based, where the ontology (using for example, resource description framework) of the source or target was applied in the ETL/ELT process. This approach was used in 6 categories, particularly in the categories of data warehouse [45-48,50,52] and medicine [10,32,35,37-39]. Another frequently used type of MDD approach was rule-based, which applied transformation rules generated based on the source and target to the ETL/ELT process. The rule-based approach was also widely used in the categories of data warehouse [40-43,49] and medicine [33,34,37,39]. All other MDD approaches besides the ontology-based and rule-based approaches were categorized as “other” (Table 1).

Figure 2. Metadata-driven approaches used in each thematic category.

Table 1. MDD[a] approaches that are categorized as "other."

MDD approach type and publication	Example
UML[b]-based	
Dhaouadi et al [46]	UML class diagram is used for modeling the transformation process
Graphic-based	
Dhaouadi et al [46]	BPMN[c] standard is used for modeling an ETL[d] process
Ad hoc formalisms-based	
Dhaouadi et al [46]	Entity Mapping Diagram is used for representing ETL tasks
MDA[e]-based	
Dhaouadi et al [46]	MDA is a multilayered framework with multiple submodules for separation of the specification of a functionality from its implementation
Message-based	
Novak et al [51]	"Normal message" contains information of mapping and transformation; "command message" configures the (execution) system
Template-based	
McCarthy et al [58]	A transformation template for each data source that manages the complex transformation process
Binding et al [62]	A template contains the mapping patterns which is then used for querying in database
Metadata-based[f]	
Ozyurt and Grethe [36]	Implementing a generic data transformation language to transform heterogeneous data from multiple sources to a common format
Tomingas et al [44]	Metadata of the source and target stored in a knowledge and metadata repository
Suleykin and Panfilov [60]	Metadata of the mapping path stored in a metadata management framework

[a]MDD: metadata-driven.

[b]UML: unified modeling language.

[c]BPMN: Business Process Model Notation.

[d]ETL: Extract-Transform-Load.

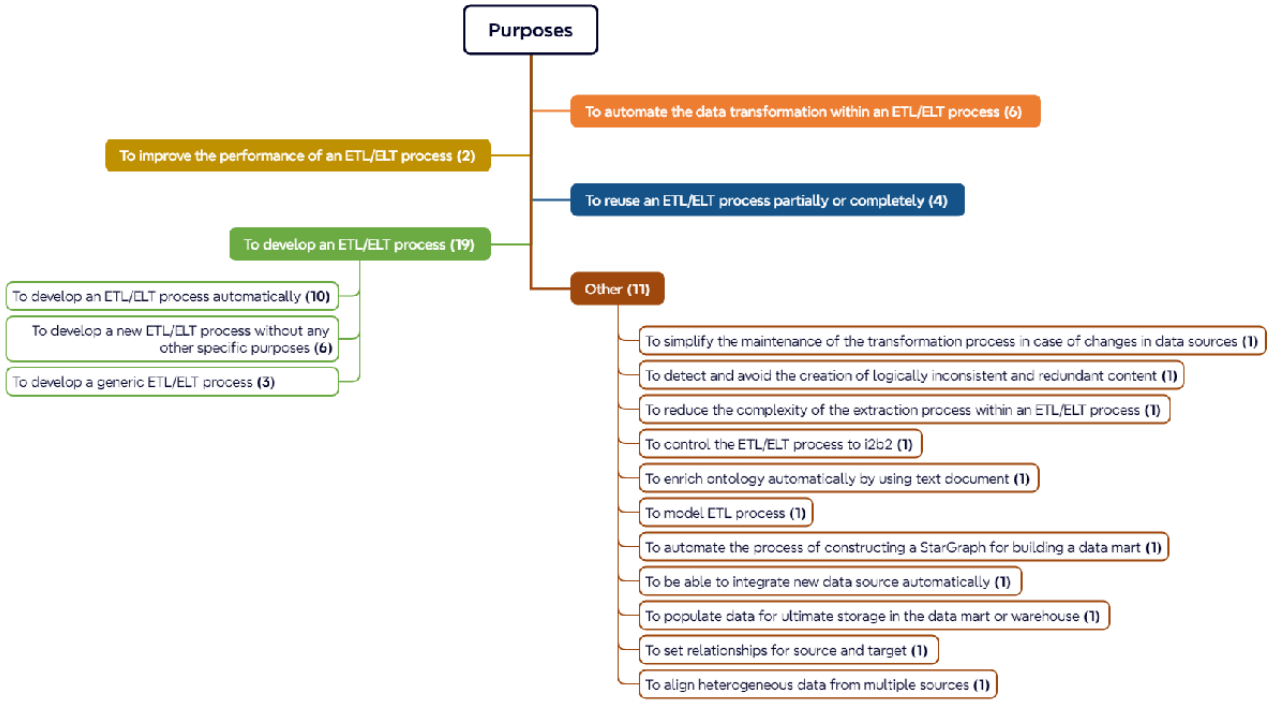
[e]MDA: Model Driven Architecture.

[f]Metadata-based approach: approach uses metadata without any specification.

Purposes of Using MDD Method for Data Harmonization

The purpose of using MDD approaches in each use case was then investigated to clarify the reasons why MDD approaches were used (Q3). Figure 3 shows different purposes of using MDD approaches in developing ETL/ELT processes based on the extracted data. The majority of publications describe the use of MDD approaches to develop an ETL/ELT process. This purpose can be divided into three detailed categories: (1) to automate the development of the ETL/ELT process [35,38,42,46,48-51,60], (2) to develop a generic ETL/ELT process [39,47,52], and (3) to develop a new ETL/ELT process without any further technical specifications [40,45,46,55,57,61]. Additionally, the transformation part of the ETL/ELT process could also be automated by applying an MDD approach [34,37,41,44,58,63]. For example, Chen and Zhao [41] described an MDD approach for the automatic generation of SQL scripts for data transformation. Moreover, using MDD approaches can also help to improve the performance of ETL/ELT processes [43,46] or to partially or fully reuse the ETL/ELT process [10,33,43,62]. Other goals (categorized as "Others" in Figure 3), such as simplifying the maintenance of the transformation process [37] and reducing the complexity of the extraction process [53], can also be realized by using MDD approaches in ETL/ELT processes.

Figure 3. Purposes of using MDD approaches in ETL/ELT process. ELT: Extract-Load-Transform; ETL: Extract-Transform-Load; i2b2: Informatics for Integrating Biology and the Bedside; MDD: metadata-driven.



Relationship Between Use Case and Used MDD Approach

As shown in the previous section, different MDD approaches were applied for different purposes. To further elucidate the reasons for choosing MDD approaches (Q3), the relationship between them was investigated. Table 2 lists the number of publications, which used a type of MDD approach to achieve a specific purpose. The ontology-based approach was used to achieve purposes (1) and (2), and (4)-(7). For example, Huang et al [63] created both local ontology (ontology based on the source data) and global ontology (ontology for the query processing) for the data transformation process, so that the data transformation from local ontology to global can be automated by applying ontology learning, ontology mapping, and ontology rules. Additionally, the ontology-based approach was also used to achieve other goals, such as controlling the ETL process to Informatics for Integrating Biology and the Bedside [32] and reducing the complexity of the extraction process [53]. Similar to the ontology-based approach, the rule-based approach was used to achieve the purposes of (1)-(3) and (5)-(7). Due to the reusability of the transformation rules, it was also possible to simplify the maintenance of the ETL/ELT process by applying rules in the process [37]. Other MDD approaches such as template-based [58,62], message-based [51], and metadata-based [41,44,48] were used to achieve the goals of (1)-(3) and (5)-(7). A metadata-based approach (eg, metadata management framework) can be used to develop the ETL tasks automatically [60]. The detailed information of Table 2 is available in the Multimedia Appendix 1.

Table 2. Relationships between purposes and MDD[a] approaches used.

Purposes		MDD approaches		
Number	Description	Ontology-based, n/N (%)	Rule-based, n/N (%)	Other, n/N (%)
(1)	To automate the data transformation within an ETL[b]/ELT[c] process	2/6 (33)	3/6 (50)	1/6 (17)
(2)	To reuse an ETL/ELT process (partially or completely)	1/4 (25)	2/4 (50)	1/4 (25)
(3)	To improve the performance of an ETL/ELT process	0/2 (0)	1/2 (50)	1/2 (50)
(4)	To develop a generic ETL/ELT process	3/3 (100)	0/3 (0)	0/3 (0)
(5)	To develop an ETL/ELT process automatically	5/9 (56)	2/9 (22)	2/9 (22)
(6)	To develop a new ETL/ELT process (without any other specific purposes)	4/6 (67)	1/6 (17)	1/6 (17)
(7)	Other	5/11 (45)	2/11 (18)	4/11 (36)

[a]MDD: metadata-driven.

[b]ETL: Extract-Transform-Load.

[c]ELT: Extract-Load-Transform.

Tools Used for Implementing MDD Approaches

Finally, we focused on the tools used to implemented MDD approaches (Q4). For achieving various purposes as shown in the previous section, different tools were used. As shown in Figure 4, each type of MDD approach can be implemented by using either an existing tool or a use case specific tool. Based on the included publications, the ontology-base approaches were mostly implemented using Protégé (Stanford Center for Biomedical Informatics Research) [64]. Protégé is an ontology editor, as well as OntoEdit (Institute AIFB, University of Karlsruhe and Ontoprise GmbH) [65]. The main reason for using an ontology editor is its ease of use and maintenance, as well as the various plug-ins. The use of case specific tools, such as ontology generator introduced by Kamil et al [45], generated ontologies based on the data definition language of the relational database. Both types of tools were used for creating and maintaining the ontology, which was then used to establish a generic mapping logic in the ETL/ELT process [32,50,52,54,55,61]. Another type of frequently used MDD approach is rule-based, which is used for phrasing and storing the transformation rules. The transformation rules can be stored in a mapping sheet [49], a CSV file [34], a YAML (YAML Ain't Markup Language) file [33] or a table within a database [43], which were implemented manually. Afterwards, the transformation rules could be used in the ETL/ELT process, for example, to enable the automatic transformation. Other types of MDD approaches can also be implemented by using existing tools (eg, knowledge and metadata repository [66]) or use case specific tools (eg, metadata repository [41] and metadata management framework [60]). For example, Ozyurt and Grethe [36] implemented a generic transformation language using the bioCADDIE Data Tag Suite (bioCADDIE Project) [67] (a metadata schema) to align heterogeneous data from multiple sources, which provided a basis for further analytic queries.

Figure 4. Tools used for developing the metadata-driven approach. MMF: metadata management framework; OWL: Web Ontology Language; YAML: YAML Ain't Markup Language.

Discussion

Principal Findings

Our literature review on the topic "metadata-driven ETL/ELT" includes all publications listed on PubMed, IEEE Explore, Web of Science, and Biomed Center on MDD ETL/ELT process from 2012 to 2022. In some context, the use of metadata is represented specifically using "ontology" or "rules." Therefore, we added "ontology" and "rules" into the search string to expand the search range.

With the review process presented, we were able to provide an overview of the thematic categories to which the MDD ETL/ELT processes were applied (Q1), the types of MDD approaches used in the ETL/ELT processes (Q2), the purposes of using MDD approaches (Q3), as well as the tools used to implement the MDD approaches (Q4).

Across all thematic categories, ontology-based and rule-based approaches are the most used approaches in the data warehouse and the medical thematic categories. In some cases, more than one MDD approach was used in the ETL/ELT process. For example, Del Carmen Legaz-García et al [39] used both ontology-based and rule-based approaches. Therefore, such publications were categorized as both MDD approach types.

Various tools can be used to implement MDD approaches. Unfortunately, we were not able to extract this information from all included publications. The reason for that is that some publications used proprietary or nontransferable approaches (eg, data-specific ontologies [39,62] and rules from Data Vault [DataVaultAlliance] [42]). Some other publications did not explicitly mention or describe the tools they used. Therefore, these publications were not included in the analysis of MDD tools used.

The results indicate that it is promising to implement a generic ETL/ELT process to transform different FHIR profiles to OMOP CDM automatically by applying MDD approaches. However, the results do not provide a trivial solution for this. For example, Huang et al [63] used an ontology-based approach to be able to automate the data transformation in an ETL/ELT process, while Ong et al [34] used a rule-based approach to achieve the same purpose. In some cases, more than one MDD approach were used as complements in order to accomplish the data transformation. For example, Pacaci et al [37] chose an ontology-based approach to automate the data transformation and a rule-based to simplify the maintenance of the transformation process in case of changes in data sources. By applying these 2 approaches in combination, the authors were able to transform EHR data from heterogeneous EHR systems into OMOP CDM. Therefore, determining an appropriate MDD approach and tool to implement a generic ETL/ELT process to transform FHIR to OMOP CDM automatically remains a challenge.

This work aimed to provide an overview of different types of MDD approaches and their tools. Consequently, this review lacks an analysis of detailing the specific traits of each MDD approach. This gap underscores the importance of providing a comprehensive insight into the characterizations of the MDD approaches presented in this study. This analysis will be conducted in the future to provide solid evidence for selecting the most suitable MDD approach and tool, or for considering using multiple MDD approaches in combination to implement the generic ETL/ELT process for transforming FHIR to OMOP CDM.

Conclusions

Our literature review shows that using MDD approaches to develop an ETL/ELT process can serve different purposes in different focus groups (ie, medicine, data warehouse, big data, industry, geoinformatics, archaeology, and military). The results show that it is promising to implement an ETL/ELT process by applying MDD approach for automating the data transformation from FHIR to OMOP CDM. However, the determination of an appropriate MDD approach and tool to implement such an ETL/ELT process remains a challenge. This is due to the lack of comprehensive insight into the characterizations of the MDD approaches presented in this study. Therefore, our next step is to evaluate the MDD approaches presented in this study and to determine the most appropriate MDD approaches and the way of integrating them into the MII CDS FHIR to OMOP CDM ETL process [8]. This could verify the ability of using MDD approaches to generalize the ETL process for harmonizing medical data [11].

Authors' Contributions

All authors contributed substantially to this work. YP did the search string definition and publications for the review-process preparation. YP, FB, Robert G, AH, EH, DK, SL, and AV: screened the title and abstract. YP, FB, Richard G, Robert G, AH, EH, DK, SL, and AV screened the full text. YP did the data extraction. FB, DK, Robert G, and SL performed the data extraction validation. YP wrote the original draft. YP, FB, Richard G, Robert G, AH, EH, DK, SL, AV, and MS reviewed and edited the writing. MS handled the resources. All authors have read and agreed to the current version of the paper and take responsibility for the scientific integrity of the work.

Conflicts of Interest

Abstract

Background: Digital transformation, particularly the integration of medical imaging with clinical data, is vital in personalized medicine. The Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) standardizes health data. However, integrating medical imaging remains a challenge.

Objective: This study proposes a method for combining medical imaging data with the OMOP CDM to improve multimodal research.

Methods: Our approach included the analysis and selection of digital imaging and communications in medicine header tags, validation of data formats, and alignment according to the OMOP CDM framework. The Fast Healthcare Interoperability Resources ImagingStudy profile guided our consistency in column naming and definitions. Imaging Common Data Model (I-CDM), constructed using the entity-attribute-value model, facilitates scalable and efficient medical imaging data management. For patients with lung cancer diagnosed between 2010 and 2017, we introduced 4 new tables—IMAGING_STUDY, IMAGING_SERIES, IMAGING_ANNOTATION, and FILEPATH—to standardize various imaging-related data and link to clinical data.

Results: This framework underscores the effectiveness of I-CDM in enhancing our understanding of lung cancer diagnostics and treatment strategies. The implementation of the I-CDM tables enabled the structured organization of a comprehensive data set, including 282,098 IMAGING_STUDY, 5,674,425 IMAGING_SERIES, and 48,536 IMAGING_ANNOTATION records, illustrating the extensive scope and depth of the approach. A scenario-based analysis using actual data from patients with lung cancer underscored the feasibility of our approach. A data quality check applying 44 specific rules confirmed the high integrity of the constructed data set, with all checks successfully passed, underscoring the reliability of our findings.

Conclusions: These findings indicate that I-CDM can improve the integration and analysis of medical imaging and clinical data. By addressing the challenges in data standardization and management, our approach contributes toward enhancing diagnostics and treatment strategies. Future research should expand the application of I-CDM to diverse disease populations and explore its wide-ranging utility for medical conditions.

Introduction

The accessibility and use of health information in various formats and standards are limited, further limiting the development of advanced data analytics technologies, especially in an era where machine learning and other cutting-edge technologies have become essential for medical research. Integrating these sophisticated analytical tools requires a paradigm shift toward the standardization and harmonization of health care data [1,2]. Standardized data structures are not only beneficial but essential for the effective application of machine learning algorithms as they ensure consistent data quality (DQ), interoperability, and comprehensive analysis across different health care domains. By moving to standardized data formats, we laid the foundation for a more powerful and scalable application of emerging technologies, opening up new possibilities in medical research and patient care.

Several standardization projects and technologies have emerged in response to the demand for integrated approaches [3,4]. Among these, the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) is noteworthy for its advantages in converting diverse sources of data into a consistent format [5,6]. It harmonizes the structure and content of various clinical data sets, facilitating consistent analytical approaches in multi-institutional research. These characteristics ensure high efficiency and accuracy of data interpretation and use, thereby enhancing both the quality and pace of research in the rapidly evolving field of medicine.

Digital Imaging and Communications in Medicine (DICOM) is a universal standard for managing, storing, and transmitting medical images, ensuring interoperability and improved exchange of medical image data and associated information between health care systems. Recent research has focused on the integrated analysis of DICOM and OMOP CDM to promote accessibility to complex medical imaging data and electronic health records [7-11]. These efforts aim to combine detailed imaging metrics with diverse clinical data to contribute to the development of diagnostic and therapeutic strategies through comprehensive data analysis. However, the data duplication problem caused by constructing an instance-level table and the absence of a table that can store annotation data such as labeling (commonly used in image analysis) are major limitations. These limitations must be addressed to effectively manage the complex characteristics of medical imaging data and perform an integrated analysis with clinical information in the OMOP CDM. As the complexity of medical imaging data and the range of DICOM tags increase, effective solutions are required to integrate data seamlessly and consistently.

Lung cancer is the leading cause of cancer-related deaths worldwide and accounts for >20% of all cancer fatalities in South Korea. The etiology, progression, and therapeutic response of lung cancer are intricately linked to a myriad of biological and genetic factors. Therefore, a systematic understanding of the characteristics of lung cancer is paramount for its early detection, prevention, and construction of personalized treatment strategies [12,13]. However, this requires an approach that efficiently integrates high-resolution data across various fields.

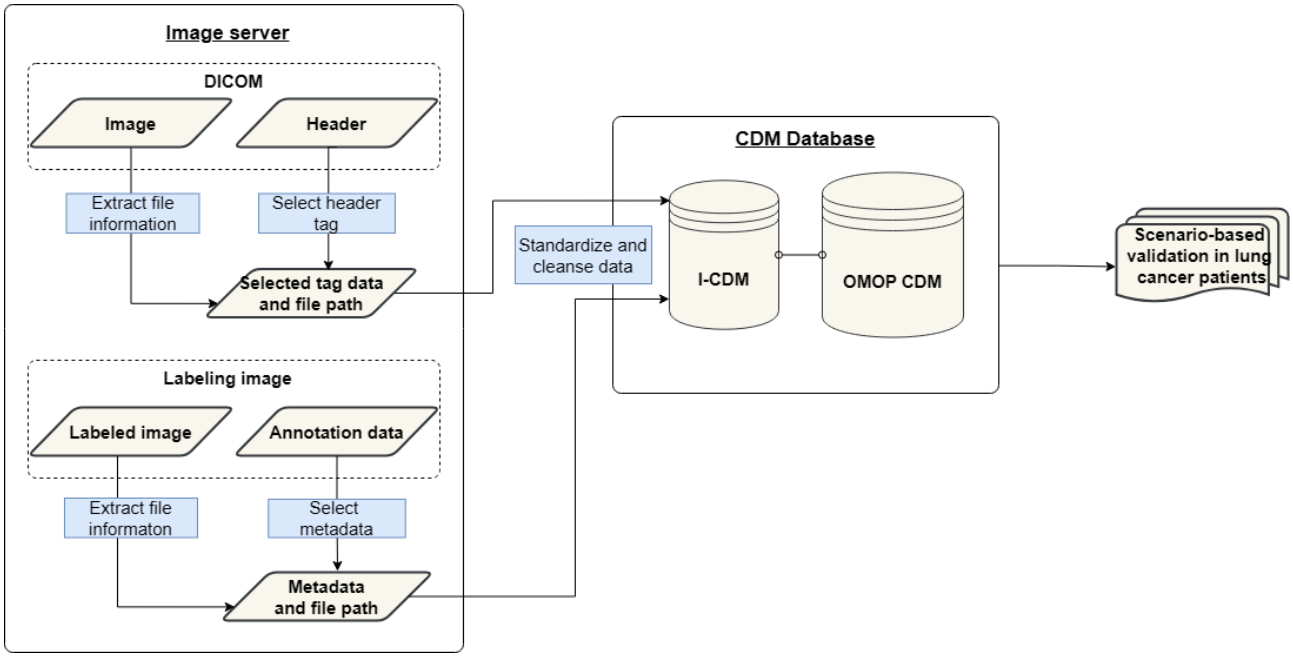
In this study, we propose a method to integrate medical imaging data with the OMOP CDM, aimed at enhancing multimodal research capabilities. This approach involves converting DICOM metadata and its annotation data to fit within the OMOP CDM framework and subsequently integrating it into a designed Imaging Common Data Model (I-CDM). We applied this integrated framework to a specific cohort of patients with lung cancer and brain metastases to not only test the feasibility and utility of our approach but also demonstrate its practical application through a series of research scenarios. Additionally, the use of scenarios was intended to showcase use cases that validate the operational functionality of our proposed model within real-world research settings.

Methods

Overview

We systematically analyzed and selected the DICOM header tags, verified their data formats, and mapped them to the OMOP CDM framework. To ensure consistency and interoperability in the column naming and definitions, we referenced the Fast Healthcare Interoperability Resources (FHIR) image study profiles, constructed I-CDM tables incorporating an entity-attribute-value (EAV) model for scalability, and performed data preprocessing to maintain data integrity. This allowed us to construct and validate a series of scenarios that combined clinical and imaging information from patients with lung cancer using a structured approach while ensuring interoperability. Figure 1 provides a visual overview of the processes used.

Figure 1. Workflow for I-CDM implementation in lung cancer research. CDM: Common Data Model; DICOM: Digital Imaging and Communications in Medicine; I-CDM: Imaging Common Data Model; OMOP: Observational Medical Outcomes Partnership.



DICOM Header Analysis

We selected preliminary DICOM header tags that are universally applicable across a spectrum of modalities through a systematic procedure. To ensure the relevance and appropriateness of these tags, we sought consultation with radiology specialists [14-16]. While the DICOM standard provides a framework, it does not enforce a uniform data format. This lack of uniformity has led to variations in data formats across medical institutions and modalities. Accordingly, we validated the extractable data formats, ensuring that only data from nonempty DICOM header tags are extracted to maintain DQ and relevance. For data values where no standard concepts were unavailable, we introduced new custom concepts that are used consistently and comprehensively within the Observational Health Data Sciences and Informatics (OHDSI) framework. Concurrently, we examined the FHIR standard's ImagingStudy profile of radiological image data to determine the appropriate table and column names [17]. This approach was adopted to ensure that the selected header tags provided comprehensive coverage with respect to established imaging information standards.

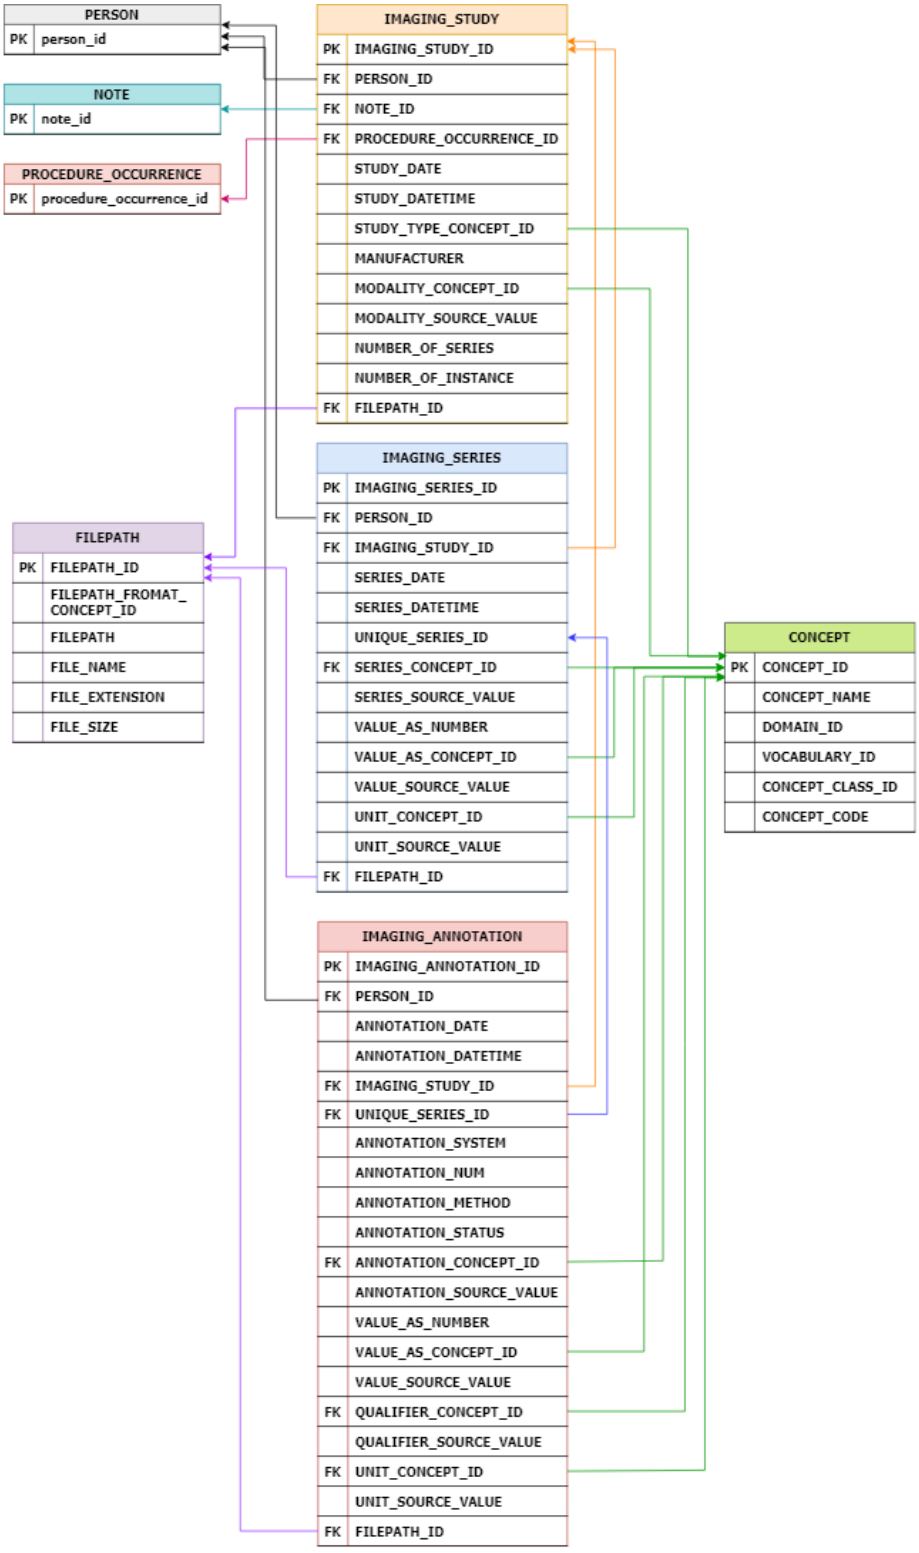
I-CDM Table Modeling

Our database architecture was designed to consolidate a variety of medical imaging data types, including DICOM header tags, study and series-level preprocessing information, and annotation information through labeling. The organization of IMAGING_STUDY, IMAGING_SERIES, IMAGING_ANNOTATION, and FILEPATH tables ensured structured and accessible data collection. The IMAGING_STUDY table refers to the CDM PROCEDURE_OCCURRENCE table associated with the corresponding imaging-order information.

To understand the significance of series-level analysis in medical imaging with reference to the ImagingStudy profile of the FHIR standard, we modeled the IMAGING_SERIES table [18-20] to house values derived from DICOM header tags pertinent to the series. Considering the potential variability in series-specific details owing to distinct imaging equipment or research requirements, we adopted the EAV format. The EAV model provides a data representation framework for the scalable and flexible storage of entities, in which the number and types of attributes (properties and parameters) can vary [21,22]. Using EAV, each attribute-value pair is stored as a separate record, making it easier to populate new data rows without altering the foundational database schema. This model facilitates data expansion without necessitating changes to the foundational table structure.

To observe the emergence and ubiquity of automated labeling tools in radiology, we designed an IMAGING_ANNOTATION table [23-26] structured to retain minimal metadata originating from the tools. Similar to the IMAGING_SERIES table, we used an EAV approach to promote the extension of the metadata. Finally, in response to the importance of the file size in image-oriented research and artificial intelligence implementations, we designed a FILEPATH table. This database captured fundamental attributes, such as file size, location, and specific format. Figure 2 shows the diagram constructed according to the I-CDM table definition. In Multimedia Appendix 1, we provide detailed definitions for each column in the IMAGING_STUDY, IMAGING_SERIES, IMAGING_ANNOTATION, and FILEPATH tables for I-CDM. Multimedia Appendix 1 elucidates the data format and captures broadly the attributes of the I-CDM framework. In addition, it specifies whether a column is mandatory, ensuring comprehensive documentation and consistency across data sets.

Figure 2. Diagram of Imaging Common Data Model workflow and attributes.



We analyzed and mapped the categorically constructed columns to the corresponding CDM concept IDs where feasible. The modality information was mapped to the concept IDs of the Procedure class in the CDM specifically related to the imaging equipment. This mapping enabled cross-validation using the method attributes of the linked procedure. The body part category was also aligned with the CDM concept, resulting in terms like “chest” being mapped to the Procedure class as “chest imaging.” For the *IMAGING_ANNOTATION* table, attributes such as the labeling plane and area were harmoniously mapped to the standard CDM concept IDs. In instances where mapping to standard CDM codes proved challenging, custom concepts were designated without limiting the classes and domains. Here, the original data extracted from the images were consistently included in the source-value column to ensure data fidelity. Additionally, in anticipation of RadLex potentially being adopted as a standard vocabulary within the OHDSI framework, we have also suggested additional RadLex mappings for our

data set. RadLex, developed by the Radiological Society of North America, is a comprehensive terminology system designed to standardize the names of radiological diagnoses, findings, and procedures. It encompasses a wide range of terms used in medical imaging, making it an invaluable resource for enhancing the comprehensiveness of medical imaging vocabularies within our data set. Multimedia Appendix 2 provides a detailed map of the standard terminology used in our I-CDM with their corresponding OMOP CDM concept IDs.

We expanded our methodological framework by developing a Python-based tool, publicly available on GitHub, for automatic conversion and integration of DICOM files into our I-CDM [27]. This tool was designed to work in conjunction with PostgreSQL to effectively create and populate essential tables such as IMAGING_STUDY, IMAGING_SERIES, and FILEPATH directly from specified DICOM file directories. Notably, the tool includes an algorithm to map the extracted DICOM header data systematically to the corresponding CDM concept IDs. This functionality ensures that the medical image data are not only accurately integrated into the I-CDM but also aligned with the standardized terminologies and classifications of the OMOP CDM. For practical applications, we chose the NSCLC-Radiomics open data set from The Cancer Imaging Archive. The NSCLC-Radiomics data set was used solely and only for the purpose of testing our DICOM file–to-PostgreSQL conversion tool, confirming its functionality with generic DICOM files, and providing a publicly shareable example of the processed output. After reading DICOM files from the NSCLC-Radiomics data set, our tool methodically constructs I-CDM tables within PostgreSQL, thereby streamlining the data integration process.

Data Preprocessing for I-CDM Table Construction

Before data preprocessing, all personal identifiers were removed to maintain patient confidentiality and protect personal information. Our first step was to ID and categorize the images into a series, ensuring that each series-specific folder contained only pertinent images, thereby maintaining a hierarchical directory structure. The Series Description in a DICOM header often comprises terms and abbreviations that describe the image characteristics. We performed a detailed analysis of the Series Descriptions of selected images to discern imaging attributes, such as the image plane, the presence of enhanced contrast, and designations such as low-dose, T1, or T2, among others. Based on a combination of these criteria, we designed rule-based naming conventions for folders, aiming for descriptive and meaningful names. Furthermore, we extracted information on the presence of “Black Blood” imaging in magnetic resonance imaging (MRI) scans using DICOM header data, which assisted in preparing data for the construction of the imaging series table.

To construct the imaging annotation table, 2 radiology experts identified and labeled the lesions on the chest computed tomography (CT) and brain MRI scans. Subsequently, we extracted metadata related to the labeled regions, such as area dimensions and characteristics.

Validation of I-CDM for Lung Cancer Studies

Overview

This study sought to define a research cohort comprising patients aged 18 years and older with primary lung cancer and structure the metadata of all chest x-ray, chest CT, and brain MRI images using I-CDM. Using the structured data, we aimed to elucidate the unique and major characteristics of patients with lung cancer by analyzing various scenarios.

Scenario 1: Association of Hypertension on Imaging Frequency in Patients With Epidermal Growth Factor Receptor Mutation-Positive Lung Cancer Receiving Osimertinib

We investigated the association of hypertension on imaging frequency in patients with lung cancer who were prescribed osimertinib, an epidermal growth factor receptor tyrosine kinase inhibitor. By comparing the frequency of CT imaging between groups with and without hypertension, this study aimed to determine whether the presence of hypertension affects imaging frequency in patients undergoing osimertinib treatment.

Scenario 2: Correlation Between Ground-Glass Nodules and Solid Tumor Volume in Lung Cancer

Using annotated data from chest CT scans to compare tumor volumes in patients with lung cancer who have ground-glass nodules (GGNs) with those who have solid nodules, we aimed to explore the relationship between ground-glass opacity nodules and tumor volume in lung cancer.

Scenario 3: Use of Low-Dose CT in Diagnostic Imaging for Lung Cancer

This scenario investigates the number of CT series, each consisting of more than 150 image instances, in patients who have undergone low-dose CT for lung cancer diagnosis. This study aimed to evaluate the adequacy of low-dose CT for providing diagnostic information while minimizing radiation exposure in patients.

Scenario 4: Number of Enhanced T1-Weighted MRI Images With a Slice Thickness of <1 mm in Patients With Lung Cancer Diagnosed at Younger Than 60 Years

This scenario targets patients with lung cancer diagnosed at younger than 60 years of age and involves quantifying the number of enhanced T1-weighted MRI images with a slice thickness of <1 mm. The collected data highlighted the volume of images available for subsequent annotation, and facilitated an in-depth radiological analysis of patient demographics.

Ethical Considerations

This study was approved by the Institutional Review Board of Seoul National University Bundang Hospital (approval B-2202-738-004; date: April 14, 2022). All procedures performed in this study involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

Statistical Analysis

Statistical analyses were performed using R software (version 4.2.2; The R Foundation for Statistical Computing). Descriptive statistics were used to summarize the data, including the calculation of means for continuous variables and frequency counts for categorical variables. The data were categorized as necessary to facilitate further analysis.

Results

Conversion of DICOM Data to the OMOP CDM Format: Realization and Integration in the I-CDM Framework

To systematically organize and efficiently manage the extensive collection of imaging data for the cohort of patients with lung cancer diagnosed between 2010 and 2017, sourced at Seoul National University Bundang Hospital, we structured the I-CDM into 4 basic tables: IMAGING_STUDY, IMAGING_SERIES, IMAGING_ANNOTATION, and FILEPATH (Table 1). The data set included imaging data from follow-ups in 2003-2021.

The I-CDM categorized 282,098 IMAGING_STUDY *records*, which were systematically linked to OMOP. This link provides an extensive overview of patient imaging trajectories and clinical data. The database contains 5,674,425 image series encompassing 47,381,027 individual image instances. Of the 282,098 records in the data set, 282,028 records contained information across various modalities, each containing a corresponding "number of series and instance" columns within the database.

Table 1. Imaging Common Data Model (I-CDM) data summary for lung cancer cohort (number of tables and records for data from 2003 to 2021 for patients diagnosed with lung cancer from 2010 to 2017).

I-CDM table or column name	Record count, n	Records with data, n (%)	Unique values
IMAGING_STUDY	282,098		
Modality	282,098	282,028 (99.9)	3
Manufacturer	282,098	281,940 (99.9)	265
Number of series	282,098	282,098 (100)	35
Number of instance	282,098	282,098 (100)	1825
IMAGING_SERIES	5,674,425		
Body part examined	382,517	382,517 (100)	25
Laterality	85,118	85,118 (100)	3
Slice thickness	411,351	411,351 (100)	1099
Series description	654,247	635,208 (100)	12,535
Window center	685,526	685,526 (100)	29,815
Window width	685,848	685,848 (100)	31,393
Patient position	458,770	444,770 (100)	11
Columns	717,154	717,154 (100)	2020
Rows	717,154	717,154 (100)	2066
Number of instance	717,169	717,169 (100)	626
BB[a]/non-BB	12,943	12,943 (100)	2
IMAGING_ANNOTATION	48,536		
Annotation system	48,536	48,536 (100)	5
Annotation text	3013	2689 (100)	69
Volume	11,153	11,153 (100)	3298
Long axis	31,353	31,333 (100)	159
Surface	3009	3009 (100)	2492
FILEPATH	1,000,361		
File path	1,000,361	1,000,361 (100)	998,844
File size	1,000,361	1,000,361 (100)	681,026

[a]BB: blood-brain barrier contrast.

The IMAGING_SERIES data represents a testament to the scale and complexity of the data set, with the 5,674,425 series illustrating the vast range of radiological examinations included in this framework. A total of 382,517 records detailing the

examined body parts underscored the targeted nature of radiological diagnostics. The data set was also characterized by an array of parameters, with 685,526 records for window centers and 685,848 for window widths. The structural resolution was meticulously captured with 717,154 data points for both the columns and rows, reflecting the intricate images. Each series was contextualized with descriptions recording the purpose and context of the imaging sequence in 654,247 data records. In total, 12,943 images were classified into blood-brain barrier contrast (BB)/non-BB categories to indicate the presence or absence of BB, highlighting the usefulness of specialized imaging sequences for detailed neurovascular assessments.

Table 2 displays the distribution of DICOM data across different modalities for patients with lung cancer, indicating the number of studies and series for each modality. X-ray examinations usually consist of a single series, whereas MRI and CT scans frequently include multiple series per study to accommodate a variety of imaging sequences. This highlights the detailed and complex nature of lung cancer diagnosis and monitoring. The structured categorization within the IMAGING_SERIES table using an EAV model, where the MRI data comprise 11 categories, including the BB/non-BB distinction. This implies a detailed classification of the MRI data, unlike the x-ray data, which are classified into 7 categories representing the variability of the desired parameters for each imaging modality. For x-ray images (n=1,410,844), the features are distributed as follows: number of instances (n=201,755, 14.3%), columns (n=201,755, 14.3%), rows (n=201,755, 14.3%), window width (n=200,938, 14.2%), window center (n=201,755, 14.3%), series description (n=201,755, 14.3%), patient position (n=200,938, 14.2%), slice thickness (n=200,938, 14.2%), body part examined (n=201,755, 14.3%), laterality (n=201,755, 14.3%), and BB_NonBB (n=201,755, 14.3%).

CT images (n=2,982,176) show the following feature distribution: number of instances (n=360,845, 12.1%), columns (n=360,845, 12.1%), rows (n=360,845, 12.1%), window width (n=360,845, 12.1%), window center (n=360,845, 12.1%), series description (n=360,845, 12.1%), patient position (n=360,845, 12.1%), slice thickness (n=360,845, 12.1%), body part examined (n=360,845, 12.1%), laterality (n=286,281, 9.6%), and BB_NonBB (n=116,305, 3.9%).

For MRI images (n=1,281,432), the distribution is: number of instances (n=140,958, 11%), columns (n=140,958, 11%), rows (n=140,958, 11%), window width (n=138,395, 10.8%), window center (n=138,395, 10.8%), series description (n=139,686, 10.9%), patient position (n=142,235, 11.1%), slice thickness (n=142,235, 11.1%), body part examined (n=142,235, 11.1%), laterality (n=80,733, 6.3%), and BB_NonBB (n=91,984, 7.1%).

The IMAGING_ANNOTATION table had 48,536 annotations predominantly sourced from CT and MRI scans. These annotations offer a detailed exploration of the examined regions, with volumetric and long-axis measurements documented. This granular level of detail is critical for the precise characterization and monitoring of diseases supported by a comprehensive understanding of the annotated regions. The FILETATH records within the I-CDM table (totaling 1,000,361) served as a bridge between the CDM tables and actual image file paths, spanning approximately 9.6 terabytes of image data. This illustrates not only the substantial volume of image data but also the expansive nature of our image repository within the I-CDM framework. In addition, DICOM folders were organized in a series, and common imaging characteristics were identified through series descriptions to assign meaningful folder names, further streamlining the data structure for efficient management and retrieval.

Table 2. Count data based on modality and type.

Modality	Study count	Series count
X-ray	201,569	201,770
CT[a]	65,923	373,116
MRI[b]	14,590	142,254

[a]CT: computed tomography.

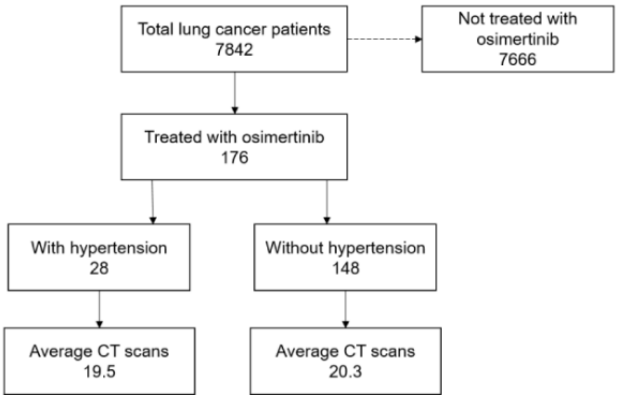
[b]MRI: magnetic resonance imaging.

Validation of I-CDM Scenarios for Enhanced Imaging and Treatment Classification in Patients With Lung Cancer

Scenario 1: Hypertension and Imaging Frequency in Patients Treated With Osimertinib

Among the total cohort of 7842 patients with lung cancer, 176 (2.24% of the total) prescribed osimertinib were diagnosed with hypertension. In the osimertinib arm, 28 (0.36%) patients had hypertension. The average number of CT scans in patients with and without hypertension was 19.5 and 20.3, respectively, indicating that hypertension did not significantly affect the frequency of CT imaging in patients with lung cancer receiving osimertinib treatment. Figure 3 shows this comparison of CT scan frequency over hypertension status among patients treated with osimertinib.

Figure 3. Diagram of CT scan frequency comparison according to hypertension status among osimertinib-treated patients with lung cancer. CT: computed tomography.



Scenario 2: Nodule Characterization and Volume Measurement in CT Imaging

We evaluated 1947 annotated CT scans from 1929 patients and observed that a significant number of GGNs contained solid components, necessitating labeling of both components within the GGNs. Our comparative analysis focused on the mean volume of solid nodules within GGNs compared with those without GGNs. In total, 673 GGNs were identified in 626 patients, of which 649 were classified as having solid nodules. The average volume of the GGN was 8135.616 mm^3, whereas the volume of solid nodules within the GGN was 2578.006 mm^3. In contrast, 1343 solid nodules without GGN were found in 1319 patients, with an average volume of 34,712.58 mm^3. This corroborates the findings of previous studies indicating that solid nodules, especially those not associated with GGNs, tended to be more abundant [28]. Our results provide additional evidence supporting these observations on the nodal nature of lung pathologies.

Scenario 3: Use of Low-Dose CT and Instance Range

Among the 63,446 CT studies conducted in the cohort of patients with lung cancer, which included 2,725,899 series, 48,587 were identified as low-dose imaging studies. Of these, 41,336 included >150 instances. The instance count in the 3 low-dose CT images varied significantly, with the smallest and largest series consisting of three and 633 instances, respectively. This highlights the need for low-dose imaging to capture extensive data while minimizing radiation exposure.

Scenario 4: MRI Imaging With 1-mm Thick Slice and T1 Enhancement

In Scenario 4, which focused on MRIs of 1-mm thick slices under T1 enhancement, our analysis of 137,566 MRI series identified 31,851 series using T1-weighting at the specified slice thickness, 5235 of which were associated with patients aged ≤60 years. This scenario allows the preemptive examination of images to be labeled, integrating image patterns and nodule characteristics with clinical data. This approach not only facilitates the identification of the scale of target images to be annotated but also enables precise quantification of the images that meet the specified criteria. Table 3 shows the categorization of the MRI series using I-CDM, providing a visual summary of the data refined by slice thickness and T1 enhancement and further filtered to include patients aged ≤60 years within the studied patient cohort.

Table 3. Magnetic resonance imaging series analysis using Imaging Common Data Model.

MRI[a] series type	Count
Total MRI series	137,566
T1 weighted	74,692
Contrast enhanced	51,582
Slice thickness ≤1 mm	31,851

I-CDM Data Quality Check

We ensured DQ based on a set of 44 comprehensive DQ rules (outlined in Multimedia Appendix 3), focusing on the Radiation CDM quality assurance framework. These rules encompassed a broad spectrum of checks, including the evaluation of DICOM series and instance counts, data type consistency, and the accuracy of the linkage between the data set and existing clinical tables within the CDM. All data entries successfully met these criteria, indicating compliance with quality standards. Among these rules, those pertaining to interdata relationships and outlier detection were instrumental in validating the integrity of the data set. A selection of these quality checks and their outcomes are presented in Table 4, highlighting the importance of ensuring data quality and integrity within I-CDM.

Table 4. Selected data quality assurance rules and outlier analysis results from Multimedia Appendix 3.

CDM_TABLE, CONTCEPT_NAME, and check description	Threshold	Result (%)	Error (n)
IMAGING_STUDY			
NUMBER_OF_SERIES			
The NUMBER_OF_SERIES must be equal to the number of series in the IMAGING_SERIES table with the same IMAGING_STUDY_ID. This ensures that the number of series recorded in the IMAGING_STUDY matches the actual series entries in the related table	At least 95% match	PASS (99.9)	202
NUMBER_OF_INSTANCE			
The NUMBER_OF_INSTANCE must equal the sum of VALUE_AS_NUMBER for entries in the IMAGING_SERIES table where SERIES_CONCEPT_ID equals NUMBER_OF_INSTANCE, under the condition that they are mapped between the 2 tables. This is to verify that the number of instances (images) reported in the IMAGING_STUDY corresponds to the aggregated count of instances from the series data	At least 95% match	PASS (99.9)	109
NUMBER_OF_SERIES, NUMBER_OF_INSTANCE			
The presence of a Rule of NUMBER_OF_SERIES necessitates the presence of a Rule of NUMBER_OF_INSTANCE.	At least 95% match	PASS (99.9)	1
IMAGING_SERIES			
SERIES_CONCEPT_ID = SliceThickness			
VALUE_AS_NUMBER must exist and be a numeric value for at least 99% of the records	At least 99% of records must have a nonmissing	PASS (99.8)	496
SERIES_CONCEPT_ID = Rows			
VALUE_AS_NUMBER must exist and be a numeric value for at least 99% of the records	At least 99% of records must have a nonmissing	PASS (100)	100
Outliers, defined as values beyond the 1st and 99th percentiles, should be reviewed	Outliers should be under 5%	PASS (1.2)	8952
SERIES_CONCEPT_ID = Columns			
VALUE_AS_NUMBER must exist and be a numeric value for at least 99% of the records	At least 99% of records must have a nonmissing	PASS (100)	—[a]
Outliers, defined as values beyond the 1st and 99th percentiles, should be reviewed	Outliers should be under 5%	PASS (1.0)	7251
SERIES_CONCEPT_ID = BB/non-BB			
Values must be exclusively “Positive” or “Negative”, ensuring they represent these specific states without including the concept IDs 45884084 and 45878583	100% of records must have as one of the specified valid IDs	PASS (100)	—
IMAGING_ANNOTATION			
ANNOTATION_ CONCEPT_ID = Long axis			
VALUE_AS_NUMBER must exist and be a numeric value	No missing values for VALUE_AS_NUMBER	PASS (100)	—
Outliers, defined as values beyond the 1st and 99th percentiles, should be identified and reviewed to ensure they accurately reflect the intended measurements.	Outliers should be under 5%	PASS (0.2)	77
ANNOTATION_ CONCEPT_ID = Volume			
VALUE_AS_NUMBER must exist and be a numeric value	100% of records must be numeric and nonnull	PASS (100)	—
ANNOTATION_ CONCEPT_ID = annotation_text			
VALUE_SOURCE_VALUE must contain a nonempty text value	100% of records must be numeric and nonnull	PASS (100)	—
ANNOTATION_ CONCEPT_ID = surface area			
VALUE_AS_NUMBER must exist and be a numeric value	100% of records must be numeric and nonnull	PASS (100)	—

[a]Not applicable.

Discussion

Principal Results

This study proposes a method for integrating clinical and imaging data using I-CDM. By converting DICOM data into the OMOP CDM format and integrating it into the I-CDM framework, we implemented a systematic approach to efficiently manage medical imaging data. This approach enabled the connection and analysis of clinical and imaging data in different contexts. Additionally, detailed schema overviews for the use cases of integrating I-CDM can be found in Multimedia Appendix 4, and a comparison between MI-CDM and I-CDM is provided in Multimedia Appendix 5.

Limitations

The limitation of this study is its lack of consideration for the resources required for processing DICOM images and integrating annotation information. To customize and add data according to researcher needs using the EAV model, comprehensive knowledge and expertise on DICOM standards and tags are required [29]. Furthermore, integrating image annotation data within the I-CDM framework not only demands sufficient resources [30-32], but also requires advanced data management strategies to expand the integration and harmonization of data sets from various imaging modalities beyond chest CT, x-ray, and brain MRI [33,34]. Moreover, focusing exclusively on a cohort of patients with lung cancer narrowed the scope of the study. Additionally, in our study, the scenarios were designed to validate the functionality of the proposed model using actual medical data. These scenarios were deliberately simplified to ensure effective management within the capabilities of the implemented I-CDM framework. Future research will benefit from the incorporation of expanded annotation data, enabling more complex analyses, such as longitudinal comparisons of tumor sizes pre and posttreatment in individual patients.

Comparison With Prior Work

In this study, diverging from previous Radiology-CDM research, we refined the integration of imaging examination data by linking them with the PROCEDURE_OCCURRENCE table, which enables a more efficient analysis through improved data connectivity. Moreover, unlike previous research that relied on RadLex for standard terminology, this study directly mapped DICOM terms to OMOP CDM standard terminologies. This direct mapping simplifies the process and enables the use of custom codes, thus facilitating a deeper analytical integration of clinical and imaging data. And this study takes a distinct approach compared with recent I-CDM studies [35,36]. Our method enhances the analytical scope by facilitating the storage and management of annotation information. This ensures that imaging-related data, including annotations, can be comprehensively managed within the I-CDM framework. By using the EAV model, our study introduced flexibility in managing various data types and structures, rendering our approach adaptable to evolving research needs and data characteristics. Consequently, it exhibits good flexibility and adaptability, especially in research requiring integrated analysis of clinical and imaging data. Considering the file sizes associated with imaging data, effective file management is essential. Our study used the FILEPATH table to connect I-CDM with the original imaging data, including file extension and size information, to ensure quick access to file details and facilitate efficient management.

Scalability and Applicability of the I-CDM

The lung cancer cohort in this study was initially used to validate the functionality of the proposed I-CDM tables using actual medical image data. In future studies, the model is not only adaptable to lung cancer but also designed to accommodate a wider spectrum of medical conditions, including various tumor types and cardiovascular diseases. By leveraging OMOP CDM's standard vocabulary for "modality_concept_id" and "body part examined" ("value_as_concept_id"), the model can be broadly adapted to accommodate various diseases or different settings beyond lung cancer. This adaptability ensures that any additional data items users might require can be seamlessly integrated by aligning with OMOP CDM standard vocabulary, underlining the framework's potential for broad application across diverse medical data and settings. Furthermore, while RadLex is extensively used in medical imaging vocabularies, it is not yet included as a standard vocabulary in the OHDSI framework. Even if RadLex were incorporated, it would not cover all concepts related to imaging. Therefore, we had to consider various vocabularies to ensure comprehensive coverage. Recognizing this, we aimed to build the I-CDM by maximizing the use of existing OHDSI vocabularies according to OHDSI principles, rather than proposing new vocabularies. We have proactively suggested mapping terms compatible with RadLex within our study wherever possible. In the new scenario, the principle for term selection involves mapping the standard concept to the granularity level of the source data. This is achieved by selecting the term from the standard vocabulary that most accurately represents the clinical meaning. In addition to the features we have currently mapped, our study focused on lung cancer, but for other diseases, there are important concepts in imaging that should be considered. For instance:

- Ultrasound image tags: Commonly used tags include "Transducer Frequency," "Gain," and "Depth of Field," which are critical for analyzing the quality and characteristics of ultrasound images.
- Spine x-ray tags: Relevant tags such as "KVP" (Kilovoltage Peak), "Exposure Time," and "Focal Spot Size" are essential for understanding the technical parameters that affect image quality.
- Body part imaging concepts: Terms like "Entire Thorax," "Entire Liver," and "Entire Pelvis" are crucial for precisely describing the anatomical region being imaged, which can vary significantly depending on the disease or condition being studied.

These examples ensure that the I-CDM framework is adaptable and capable of integrating a wide range of imaging data characteristics and supporting diverse medical conditions and research scenarios.

Conclusions

This study implemented a systematic approach for the efficient management of medical imaging data, achieving integration of clinical and imaging data through the development of the I-CDM framework and the conversion of DICOM data into the OMOP CDM format. Future efforts should strive to broaden the application of the I-CDM framework to encompass various disease populations and include diverse imaging techniques for different body parts, such as abdominal CT, spine MRI, and liver MRI, thereby enhancing its applicability. Expanding its scope to incorporate these imaging modalities is crucial for conducting more comprehensive investigations into the utility of merging clinical and imaging data across different health conditions.

Abstract

Background: Cross-institutional interoperability between health care providers remains a recurring challenge worldwide. The German Medical Informatics Initiative, a collaboration of 37 university hospitals in Germany, aims to enable interoperability between partner sites by defining Fast Healthcare Interoperability Resources (FHIR) profiles for the cross-institutional exchange of health care data, the Core Data Set (CDS). The current CDS and its extension modules define elements representing patients' health care records. All university hospitals in Germany have made significant progress in providing routine data in a standardized format based on the CDS. In addition, the central research platform for health, the German Portal for Medical Research Data feasibility tool, allows medical researchers to query the available CDS data items across many participating hospitals.

Objective: In this study, we aimed to evaluate a novel approach of combining the current top-down generated FHIR profiles with the bottom-up generated knowledge gained by the analysis of respective instance data. This allowed us to derive options for iteratively refining FHIR profiles using the information obtained from a discrepancy analysis.

Methods: We developed an FHIR validation pipeline and opted to derive more restrictive profiles from the original CDS profiles. This decision was driven by the need to align more closely with the specific assumptions and requirements of the central feasibility platform's search ontology. While the original CDS profiles offer a generic framework adaptable for a broad spectrum of medical informatics use cases, they lack the specificity to model the nuanced criteria essential for medical researchers. A key example of this is the necessity to represent specific laboratory codings and values interdependencies accurately. The validation results allow us to identify discrepancies between the instance data at the clinical sites and the profiles specified by the feasibility platform and addressed in the future.

Results: A total of 20 university hospitals participated in this study. Historical factors, lack of harmonization, a wide range of source systems, and case sensitivity of coding are some of the causes for the discrepancies identified. While in our case study, Conditions, Procedures, and Medications have a high degree of uniformity in the coding of instance data due to legislative requirements for billing in Germany, we found that laboratory values pose a significant data harmonization challenge due to their interdependency between coding and value.

Conclusions: While the CDS achieves interoperability, different challenges for federated data access arise, requiring more specificity in the profiles to make assumptions on the instance data. We further argue that further harmonization of the instance data can significantly lower required retrospective harmonization efforts. We recognize that discrepancies cannot be resolved

solely at the clinical site; therefore, our findings have a wide range of implications and will require action on multiple levels and by various stakeholders.

Introduction

Overview

Interoperability, an essential component of contemporary medical informatics, facilitates seamless communication and data exchange between various devices, applications, and health care systems. Semantic interoperability ensures machine interpretation of health care data and, thus, data exchange, integration, and reuse for optimized collaboration between distributed players in health care and medical research. Consequently, it is pivotal in amplifying the efficacy and impact of numerous other medical informatics technologies, advancing the field as a whole.

The Layered Fast Healthcare Interoperability Resources Profile Model: Facilitating Reuse and Interoperability

The Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) addresses syntactic and semantic interoperability [1], providing a standardized framework for data structures known as resources. These resources are essentially a set of attributes that represent specific health care–related concepts. For instance, the *Patient* resource in FHIR might include attributes such as name, administrative gender, birth date, address, and contact details. This standardization of data structure promotes syntactic interoperability. Semantic interoperability is achieved using bindings of attributes to value sets with codes from universally recognized coding systems such as *Logical Observation Identifiers Names and Codes* (LOINC) or *Systematized Nomenclature of Medicine—Clinical Terms* (SNOMED CT).

FHIR also introduces the concept of *Profiling* [2]. FHIR profiles constrain or modify the base FHIR resources to cater to specific use cases or regional requirements. They provide guidelines on how resources should be structured; which attributes should be excluded, mandatory, added, or repeated; what terminology should be used for coded elements; and how these elements should be interpreted. During the development of profiles, domain experts from the medical field are involved at all stages to ensure that the data models capture all the required data. This approach ensures the syntactic consistency of the data and its semantic interpretability. FHIR profiles can be based on other FHIR profiles to constrain them further, allowing a layered structure from the most permissive to the most constrained profile.

The Medical Informatics Initiative

The German government recognized the importance of interoperability in the health care sector and consequently initiated the Medical Informatics Initiative (MII) in 2015 [3]. With the overarching goal of making routine data available for research, the MII aims to digitally connect patient data generated during hospital stays across the country. Four consortia, namely, DIFUTURE [4], HiGHmed [5], Medical Informatics in Research and Care in University Medicine [MIRACUM] [6], and Smart Medical Information Technology for Health care [7], and a central coordination office received funding from the Federal Ministry of Education and Research to establish data integration centers (DICs) responsible for data exchange. With over €400 (US $427 million) million in current total funding, the Federal Ministry of Education and Research supports consortia, DICs, and cross-consortium use cases.

Acknowledging the various accomplishments within the MII until this point [8-10], in this paper, we will place particular emphasis on the Core Data Set (CDS), its implementation at the DICs, and its applicability to the "Aligning Biobanking and DIC Efficiently" [11] use case project, which among others, included federated feasibility studies integrated into the *Forschungsdatenportal für Gesundheit* (German Portal for Medical Research Data [FDPG]) [12].

CDS Profiles

One of the primary responsibilities of the MII is the development and implementation of a unified data model that is binding for all German university hospitals.

The result of this ongoing endeavor within the MII is the CDS, a set of specific FHIR profiles that the local sites have agreed upon collectively. These CDS profiles define the minimum data set that should be included in each DIC. The CDS is subdivided into basic and extension modules, where the basic modules encompass basic health care data such as patient-derived information, conditions, procedures, medication, and laboratory measures, and the extension modules reflect data from specific applications or specialist areas (such as intensive care or oncology) [13]. The CDS is sustainably, nationally coordinated, continuously updated, and adapted to meet changing requirements. The development of the CDS leverages tools such as ART-DECOR for data set modeling and Simplifier.net [14] for creating and publishing FHIR profiles [15].

Upon the successful development of the CDS, the obligation falls to each DIC to make its routine data available as FHIR instance data. DICs integrate and standardize routine health care data at each site, essentially based on extract, transfer, load (ETL) processes with frequent late mappings of proprietary data from source systems. While their operation and management involve complex processes, for the scope of this paper, this conceptualization is sufficient. The data are secured and

standardized through the DIC, promoting efficient and secure cross-institutional data sharing and collaboration.

FDPG: Facilitating Accessible Research

The FDPG is critical in making the data across the 34 sites accessible to medical researchers [12]. It provides the legal and procedural framework to access routine data sets across sites. Among other components, it provides the feasibility platform that gives users a user-friendly view of available data items and allows users to query them across connected sites directly. It aggregates available patient counts for a specific, user-defined search query. To do so, it uses a search ontology automatically generated from FHIR profiles [16]. Users can select concepts from the search ontology and restrict them as needed, for example, by applying comparator values for quantitative laboratory values. The resulting criteria can be combined using Boolean algebra to create complex feasibility queries.

Figure 1 demonstrates the search ontology's user-friendly abstraction for researchers unfamiliar with FHIR:

- *Medical coding:* criteria are based on standard codings referenced in the FHIR profiles (eg, C71 from *German modification of the International Statistical Classification of Diseases and Related Health Problems, 10th revision* [*ICD-10-GM*] for malignant neoplasm of the brain)
- *Value and attribute filters:* specific FHIR attributes such as the value of an observation are modeled as "value filters" to express the "is" relationship between the coding and the value (such as leukocyte counts between 4000 and 10,000/µL). Additional attributes can also be expressed (such as place of collection for specimen) and allow the further refinement of criteria beyond their existence.
- *Time-based filters:* researchers can furthermore apply temporal constraints ("after" a specific date).

All other FHIR attributes are not available to the user to ensure high usability.

The FDPG feasibility tool's primary aim is to make the data findable that are available across the MII's DICs, which are based on the CDS. In its current iteration, the feasibility tool offers a selected subset of CDS criteria. This design choice is driven by the different requirements to be met by the CDS and the search ontology. The CDS profiles are developed for various primary source systems across German university hospitals. Profile specifications are required to be broad in many cases due to the diversity and complexity of these systems. Therefore, generic profiles are preferred, with more detailed models being developed only when necessary for specific content or organizational reasons. This serves DICs well due to having access to the instance data. By contrast, due to its federated nature, the FDPG has no access to the instance data. A more nuanced approach beyond generic modulations, such as accurately modeling the relationship between laboratory concepts and their values instead of simply representing LOINC codes, is required to provide users with criteria beyond determining their presence.

The feasibility tool also navigates the complexity arising from various code systems. For instance, the diagnosis profile accommodates codings from *ICD-10-GM*, SNOMED CT, Alpha-ID, and Orphanet, which are crucial for rare disease research. However, this diversity poses a usability challenge, potentially overwhelming users unfamiliar with these systems. In addition, the overlap in concept expression between *ICD-10-GM* and SNOMED CT can create confusion: users may not realize the necessity of selecting a particular concept from a specific code system or potentially both, contingent on their use case. A significant factor in the FDPG feasibility portal's initial focus on legally mandated code systems is the absence of instance data for certain criteria (eg, as of March 2023, none of the 20 participating sites had SNOMED CT codings for diagnoses), as offering such criteria might frustrate researchers and discourage tool use. Guided by these assumptions, Table 1 provides an overview of the CDS modules, their codings, and their coverage in the FDPG feasibility portal.

The present scope of the FDPG feasibility portal is not fixed, allowing for potential future expansions.

Figure 1. Example of a feasibility query in the German Portal for Medical Research Data feasibility portal to find patients with a leukocyte count within a normal range, those with a malignant neoplasm of the brain, those with available tumor tissue specimen, and those with a computed tomography scan after January 1, 2020, who did not take doxorubicin after January 1, 2023. MII: Medical Informatics Initiative.

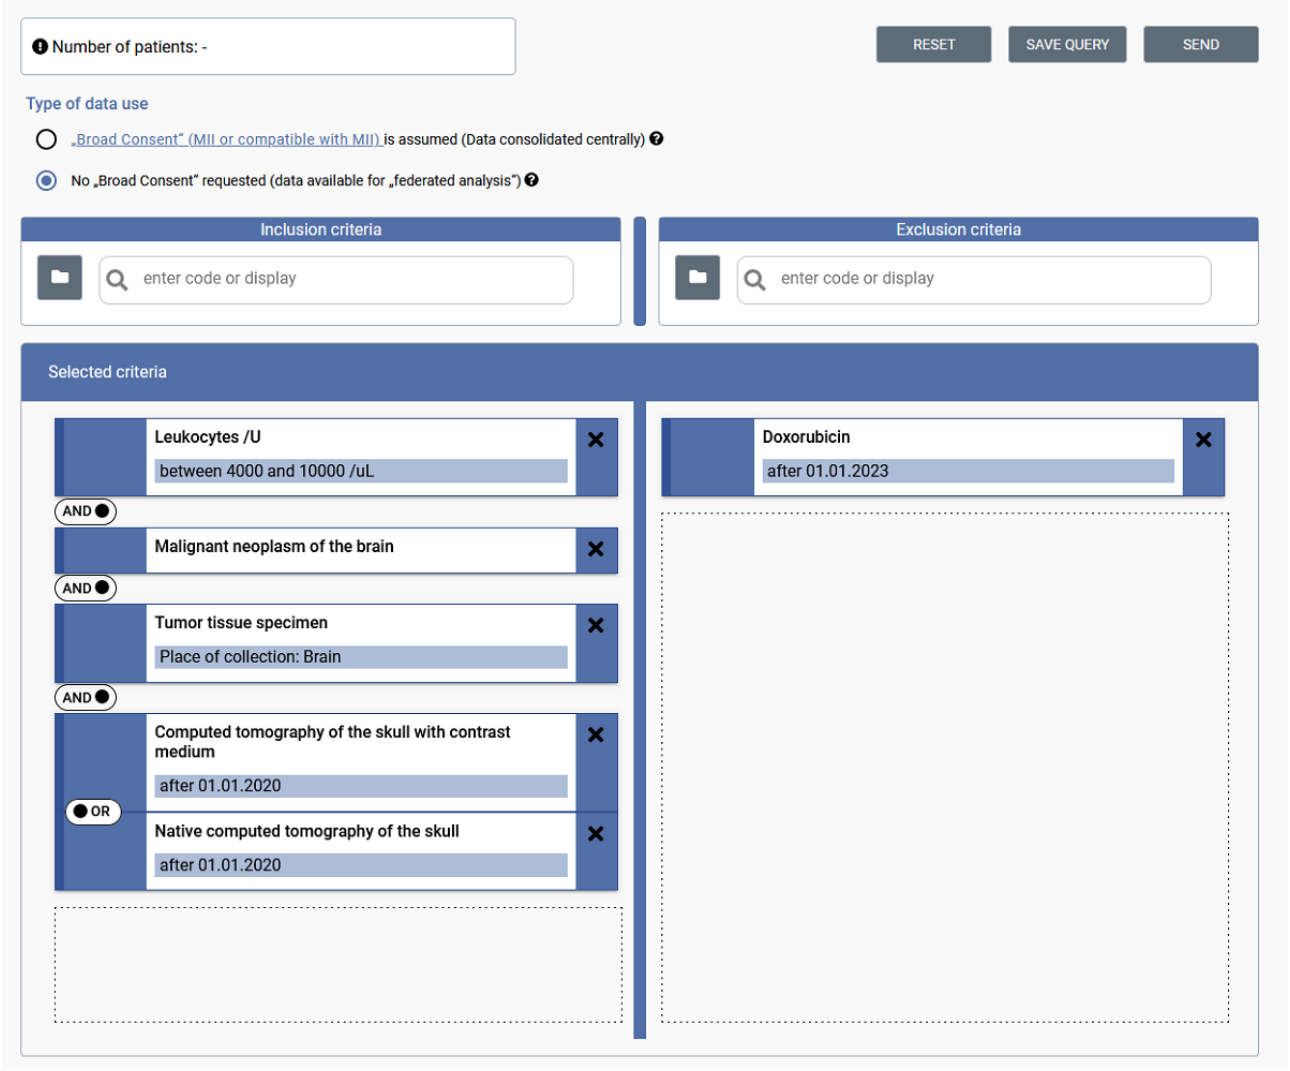

Table 1. Coverage of the Core Data Set (CDS) modules in the German Portal for Medical Research Data (FDPG) feasibility portal.

CDS module	CDS-supported codings	FDPG coverage
Consent	MII[a]_CS_Consent_Policy	MII_CS_Consent_Policy
Diagnosis	*ICD-10-GM*[b], Alpha-ID, SNOMED[c] diagnoses codes, Orphanet	*ICD-10-GM*
Laboratory	LOINC[d]	Defined subset of "TOP300" LOINC codes
Medication	ATC[e]-DE, ATC-EN, PZN[f]	ATC-DE
Person	—[g]	—
Procedure	OPS[h], SNOMED procedure codes	OPS
Specimen	SNOMED specimen codes	Defined subset of "TOP50" SNOMED specimen codes

[a]MII: Medical Informatics Initiative.

[b]*ICD-10-GM*: *German modification of the International Statistical Classification of Diseases and Related Health Problems, 10th revision.*

[c]SNOMED: Systematized Nomenclature of Medicine.

[d]LOINC: Logical Observation Identifiers Names and Codes.

[e]ATC: Anatomical Therapeutic Chemical.

[f]PZN: pharmazentralnummer.

[g]Not applicable.

[h]OPS: Operationen- und Prozedurenschlüssel.

Discrepancy Despite Standardization: Challenges and Opportunities

Figure 2 illustrates the interplay between the source systems, the DICs, the CDS, and the search ontology of the FDPG feasibility portal. Applying the CDS to the heterogeneous primary source data makes the heterogeneous source data interoperable. Despite the standardization, discrepancies can arise by deviating interpretations or erroneous implementations of the CDS. Typically, these can be identified by validating the instance data against the CDS and are addressed in the ETL jobs of the sites. It might be necessary to adjust the CDS implementation guide to provide more clarity. It is important to note that despite these efforts, inherent challenges related to data quality at the source, such as missing, erroneous, or inconsistently entered data, persist [17]. These complexities often necessitate extensive collaboration and resources for resolution and fall outside the direct control of DICs, whose primary function is data integration.

The FDPG feasibility portal cannot exhaustively query all instance data at the clinical sites. Consequently, the instance data can be divided into 2 subsets: the data that should be covered by the search ontology and the currently unsupported data. The latter provides opportunities for future developments but is outside the scope of this paper.

The search ontology's additional constraints and the CDS's limited data harmonization cause discrepancies that prevent the accessibility to instance data that should be available. While presenting challenges, such discrepancies are not unique to this framework but are commonly observed across various industries when implementing standards [18]. They mirror the common rationale behind the organization of Connectathons, which aim to test and improve interoperability.

Outside the governmental context of a Connectathon but maintaining the same objective of advancing interoperability through rigorous testing of multiple systems adhering to the same standard, our approach evaluates the assumptions underlying the FDPG's search ontology against the actual instance data at clinical sites. To achieve this, we use the same FHIR profiles used to develop the search ontology.

Methods

Overview

This research integrates a top-down approach for the definition of data models with an empirical bottom-up methodology (Figure 3). This novel approach addresses discrepancies in data standardization and representation. The representation of the search ontology as an FHIR profile based on the CDS forms the foundation of our top-down perspective (hereinafter referred to as FDPG profiles). The bottom-up approach, conversely, is grounded in an empirical analysis of the instance data.

Being able to rely on FHIR profiles has multiple advantages:

- *Using existing validation software:* unlike custom solutions, our approach leverages existing validation software to analyze and resolve discrepancies, offering a more streamlined and efficient process.
- *Insights from layered FHIR profiles:* the layered structure of FHIR profiles provides multifaceted insights. It not only aids in understanding the search ontology but also evaluates compliance with the CDS. In addition, performing this analysis across different sites sheds light on several aspects: (1) discrepancies in instance data across sites, (2) discrepancies between the CDS and site-specific instance data, and (3) discrepancies between the search ontology and the instance data
- *Leveraging established standards:* working with established technology in the MII allows for transparency and adaptability beyond the current use case.

The strength of our approach lies in its iterative nature, whereby each cycle involves refining the profiles based on the empirical insights gathered, subsequently informing the following empirical analysis. This continuous refinement allows us to transition from differential to data quality analysis. This progression not only targets the resolution of discrepancies but also seeks to enhance the quality and accessibility of the data. By iterating this process, we contribute a new framework for reconciling the tension between data standardization and real-world variability, a common challenge in health care data management. Notably, the approach is not solely focused on the search ontology, as would typically be the case when developing a product. Being a part of the MII community, we hope that our approach will also uncover potential for further harmonization across sites, enhancing the functionality and accessibility of the FDPG feasibility tool and facilitating a wider range of use cases.

Validation Pipeline

To use the FDPG profiles, we developed and deployed a validation pipeline (Figure 4) that can be deployed at each site. A centralized approach was not feasible due to the high standards of data protection adhered to within the MII. The pipeline uses the FHIR Marshal, an HL7 application programming interface validation library extended with a Representational State Transfer application programming interface [19]. The validation library requires the profiles and their dependencies for the validation as well as the referenced terminology resources.

The FHIR profiles are themselves resources, more specifically, FHIR StructureDefinition resources. They are stored in an FHIR server (Blaze) [20] using the *FHIR Populator* tool [21]. This tool is designed to download FHIR profiles from package managers such as Simplifier and their dependencies, subsequently uploading them to our servers. The FHIR Populator also accommodates environments without internet access by offering the capability to upload a previously persisted package.

Regarding terminologies, we analyzed all StructureDefinitions and downloaded the expanded ValueSets from a terminology server based on the binding information. The terminologies are stored in a specialized FHIR server, Termite [22], which implements a minimal set of FHIR Terminology Services for validation and contains all relevant expanded ValueSets and CodeSystems [23].

The process chain uses a Python script to extract equivalence class test samples (for each profile, a maximum of 500 instances) from the local FHIR server. Within the meta information of each resource, the profile it implements is listed. By substituting this profile identifier from the CDS with the corresponding FDPG profile identifier, we can use the standard validation chain to verify the instance data's conformance with the FDPG profiles. The pipeline's output is a JSON file containing the validation results. For improved readability, we also generate a PDF report from these data.

For easy deployment at each site, we provide a configurable docker package containing all publicly available components via GitHub [24]. The pipeline does not require access to external networks and can be easily adapted for different profiles.

FDPG Profiles and Underlying Assumptions

As previously established, the search ontology's current representation and its FHIR profile representation are guided by making the most common and most harmonized instance data in Germany available and iteratively building on that for specific user groups. For the modulation of the current version, we assumed that hospitals across Germany, owing to the country's billing system's requirements, would consistently and correctly use *ICD-10-GM* [25], Operationen- und Prozedurenschlüssel (OPS), and Anatomical Therapeutic Chemical (ATC) codes for diagnosis, procedure, and medication, respectively. Consequently, these profiles can be easily expressed by mandating a coding from the respective code systems. The CDS profile for specimen already limits valid codings to the descendants of the SNOMED CT concept specimen. The search ontology reduces the valid codings further to a subset of the top 50 most common specimen codes. This information was already collected bottom-up before this analysis from metadata across sites, implying a high likelihood of minor to no discrepancies for Specimen in this study.

From a technical perspective, a specific coding is necessary to identify a criterion in the instance data. Beyond requiring a specific coding, the FDPG profiles commonly ensure the existence of a technical reference to the patient, which is crucial for the operation of the FHIR search. A single search ontology profile is sufficient for all modules except laboratory, following these guidelines. As previously established, the laboratory module presents a unique challenge due to its complexity and the interdependence of the value, the LOINC coding, and the number of codings.

Vreeman et al [26] identified that out of the 55,000 codes LOINC offers in practice, only a small subset is required to account for up to 99% of all laboratory observations [26]. Following their example, the MII established a "LOINC TOP300" subset that addresses 80% of all laboratory use cases in Germany [27]. The MIRACUM Metadata Repository (MDR) [11] makes this subset available and guides the current implementation in the feasibility tool of the FDPG.

The LOINC scale type associated with each concept [28] determines whether the laboratory result is quantitative or qualitative. While LOINC provides dimensional requirements, a wide set of Unified Code for Units of Measure (UCUM) units can fulfill that requirement. LOINC also provides exemplary units, but they are not mandatory. Fortunately, a UCUM representation is readily available for quantitative laboratory results in the MDR. The MDR, therefore, presents a machine-processable modulation of the interdependency of the LOINC and its quantitative value.

The MDR does not contain ValueSets for qualitative values, necessitating an alternative approach. If available, the LOINC answer list associated with the respective LOINC code is used for qualitative values, accessed via a terminology server. If unavailable, a general-purpose ValueSet defined by the MII is used. However, this ValueSet contains multiple representations of the same concept, such as 23 different representations for "Absence finding." These various representations were reduced to a single value to enhance usability. Figure 5 illustrates how the information from the MDR is used to refine the CDS profile to specific FDPG profiles for each LOINC coding.

As the name suggests, the MDR is primarily used by the sites of this consortium and is not mandated for any sites in the context of the FDPG. Furthermore, given the nature of the laboratory profiles [29] within Germany concerning the representation of laboratory values cause expected variability.

The FDPG profiles are openly accessible on Simplifier [14].

Guided by these educated assumptions that led to the creation of the FDPG profiles, our hypothesis for this study is threefold. First, we anticipated high uniformity in applying *ICD-10-GM*, OPS, ATC, and specimen codes. Second, we hypothesized a

considerably higher level of variability in the application and interpretation of LOINC codes, with regional disparities in the representation of laboratory values and their units playing a significant role. Third, we anticipated that our approach of refining the FDPG profiles based on the insight of the instance data would allow us to improve interoperability. This study aimed to probe these hypotheses, shedding light on the complexities of harmonizing and standardizing clinical data across different health care regions and coding systems in Germany.

Ethical Considerations

This study did not require an ethics board's approval as it did not involve analyzing individual patient data. Instead, summary statistics on data quality were generated at the participating respective sites, a practice in line with the applicable general data protection regulation.

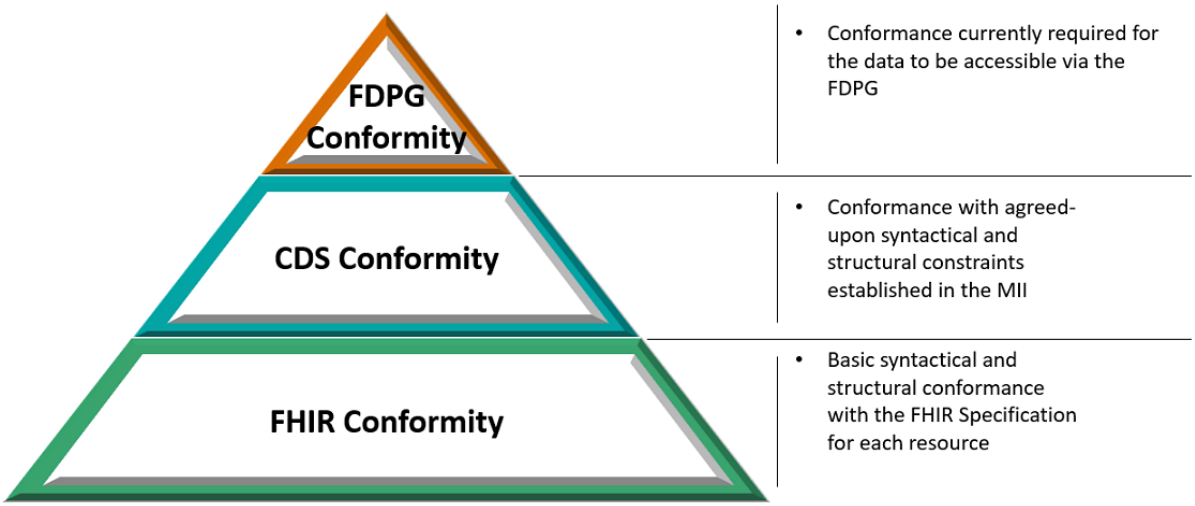
Results

Overview

To evaluate the methodology and tooling, we performed the discrepancy analysis over a wide range of sites (N=20) from all 4 consortia, including sites from western and eastern Germany and with different stages of DIC implementation. We differentiated 3 conformance levels when analyzing the results, as illustrated in Figure 6.

At a base level, all instance data must conform to the FHIR standard and the CDS. Deviations from these specifications are to be regarded as implementation errors. On the topmost level, the FDPG profiles are not binding for the DIC. Instead, they should be perceived as a description of the capabilities of the search ontology that allow insight into the subset of CDS conformant data currently searchable by the FDPG feasibility tool. Discrepancies on that level will be interpreted, and implications and possible solutions will be derived.

Figure 6. Data validation conformance levels. CDS: Core Data Set; FDPG: German Portal for Medical Research Data; FHIR: Fast Healthcare Interoperability Resources; MII: Medical Informatics Initiative.



CDS Compliance

Addressing CDS compliance, the surfaced discrepancies varied in nature and complexity, highlighting several key areas where adherence was lacking, spanning issues such as noncompliance with cardinalities, absent references, the nonfulfillment of rules stated in the profiles, and the use of incompatible codings. Notably, some of the key issues included the absence of the mandatory *status* attribute within the *MedicationAdministration* resources, which has a fundamental role in the context of the resource. Status codes that do not imply the completed administration are likely not relevant to clinical research, but if the status is not entered, no differentiation can be made.

A SNOMED CT–encoded *category* for *Procedure* was another prevalent discrepancy required when an OPS coding was used. While currently not the case, OPS codes might be used in a different context of a *Procedure* to differentiate in these cases the category that would be needed. Furthermore, errors in the *system* URL for codings caused validation errors, revealing an essential need for accuracy in defining codings.

While the above-listed findings in many cases do not directly affect the accessibility of the resources via the FDPG feasibility portal as these attributes are often not queried for, they emphasize the necessity for rigorous attention to CDS compliance in terms of detail and rigor in the data harmonization process for secondary use.

Beyond the issues that can be addressed with clear solutions, such as providing the required elements or adhering to specific rules or codings, we also found discrepancies that originate from misinterpretations of the implementation guides.

One example we found is using unit codes that do not stem from UCUM within the data element *MedicationAdministration.dosage.dose.code* in the Medication module. In discussing this discrepancy, we were pointed to the comment section for this element: “The preferred system is UCUM, but SNOMED CT can also be used (for customary units) or ISO 4217 for currency. The use context may also require a code from a particular system.” However, the profile requires “http://unitsofmeasure.org” as the system URL, causing a contradiction that should be addressed in the documentation.

FDPG Compliance

As anticipated, the additional constraints in the FDPG profiles are the leading cause of discrepancies. However, many of our hypotheses are confirmed within this subset of instance data.

Procedure, Condition, Medication, and Specimen

As expected, *procedure, condition, and medication resources are available with the codings* we anticipated. Unfortunately, our initial validation revealed that the terminology still caused discrepancies, but these can be traced back to the differences in the codes and the display. The national code systems used by the resources are currently not made available as FHIR resources but in their own format, leaving room for different interpretations and leading to different implementations to generate the displays. The Federal Institute for Drugs and Medical Devices (BfArM) responsible for the code systems is aware of this issue and has been assigned to create a central terminology service as the single source of truth for national code systems in Germany according to § 355 subsections 12 and 13 of the German Social Security Code V [30]. Our findings underline the importance of this intent. For the time being, we will ignore the display in the validation process.

Another discrepancy was using uppercase letters in OPS codes (5 of 20 sites) contrary to the FDPG feasibility portal’s expected lowercase codings for OPS. FHIR search to identify codings is case-sensitive unless the CodeSystem indicates case-insensitivity. FHIR server implementations to support case-insensitivity need to obtain this information from the code system information and adjust their internal search process accordingly. This feature is currently not implemented by the Blaze FHIR server. While the Blaze FHIR server might support this feature in the future, we tend not to make this assumption for all FHIR servers and, therefore, would advise adjusting the codings to have uniform upper or lower casing within one CodeSystem as a practical approach to this problem.

While the ATC code system is correctly coded, the possibility of representing medication information is another cause for discrepancies. The CDS defines 6 different representations for indicating that a medication has been prescribed to or taken by a patient. In FHIR, the prescription, the confirmed administration, and the statement of intake of drugs are modeled using different FHIR resources, MedicationRequest, MedicationAdministration, and MedicationStatement, respectively.

Furthermore, 2 options exist for the resources to link the specific code: the resources can reference a Medication resource or provide the CodeableConcept defining the medication. Currently, the FDPG feasibility portal only supports requesting MedicationAdministrations that reference a Medication resource. Moving forward, the FDPG feasibility tool must readdress requesting medication information.

The Specimen instance data could not be analyzed due to a software bug in the validation pipeline.

Consent

For the Consent module, we encountered an erroneous understanding of the code system, setting the permissions given by the patient. As defined by the MII, the code system contains codes that provide specific permission and codes that imply a set of permissions. The implication for those implementing the Consent resource is the erroneous tendency to use only the most encompassing code in an assumed hierarchy, which currently is not explicitly modeled. It is necessary to list all relevant codes, even if their parent code is already present. Sites not including all subsequent codings do not negatively impact the data privacy but exclude patients that should be within the cohort when searching for more specific permission. In future versions, the currently implicit relationship might be modeled in the CodeSystem using the *part of* the relationship. Once changed, it will require the FDPG feasibility portal to request subsequent codes with their parent codes.

We also found consent information from the consent management software generic Informed Consent Service (gICS), widely adopted across the MII [31]. As the name implies,

consent management software is used beyond the use case of federated feasibility queries in the MII. Therefore, consent resources made available by gICS are based on the more permissive profile defined by the official FHIR standard of the HL7 Germany Working Group Consent Management. These extended gICS consent resources can contain more attribute entries than consent resources based on the MII CDS Consent profile; for example, additional provision codings from the gICS defined code system for Consent resources that cause discrepancies when validated for our use case. Despite these findings, the consent resources remain compatible with our use case requirements, as they are based on the same standard, provided they contain all mandatory elements as defined by the MII CDS Consent profile.

Observation (Laboratory Data)

The analysis of the *Observation* resource revealed findings that align with our hypotheses and highlight the intricacies of data harmonization. The inherent flexibility of the laboratory profile, the nonbinding nature of the MIRACUM MDR directives, and regional historical discrepancies manifested in significant heterogeneity.

A recurring issue is using qualitative values for quantitative LOINC codes and vice versa. We observed that the first case is more prominent than the latter, which is attributable to using codings for invalid measurements. In our federated feasibility use case, the indication of an invalid measurement bears a minimal consequence: the omission of patients with erroneous laboratory values would not adversely affect the validity of the result if sufficient patients are identified with a specific laboratory value. However, for use cases that evaluate the data, indicating a value's invalidity is highly relevant and should be addressed in a standardized way. Solutions we uncovered range from using existing codes from various code systems with different granularity, such as indicating invalid measures using the SNOMED CT code for *invalid* or even a specific postcoordinated expression to provide additional insight about the cause, to using in-house code systems. The latter proves inadequate for achieving interoperability across various sites or when explaining the absence of data. In the future, clear guidance must be available to the sites to harmonize this information.

The leading cause for discrepancies that hinder the current accessibility of the laboratory values is the different UCUM units. However, the variety across the participating sites is not as wide as anticipated.

Within the instance data across the sites, we identified 368 different quantitative LOINC codes, with discrepancies in at least 1 site. Again, case sensitivity contributes to a significant number of discrepancies. Overall, 59 differences can be attributed to the inconsistencies between the use of the upper and lower letter "l" for liter. Overcoming this issue would lower the number of total discrepancies and the variety of different dimensions.

The BfArM defines a list of commonly used UCUM units [32]. According to our analysis against this list, discrepancies were attributed to units still predominantly used in eastern Germany. Some units, such as "Gpt/L" for giga particle per liter, are not included in the UCUM code system and are therefore unsupported. Another recurrent issue identified by this comparison is the use of the Greek letters (eg, "µ" instead of "u"). Considering only discrepancies caused by UCUM codes listed by the BfArM reduces the remaining differences to 248. This comparison with the prevalent UCUM units in Germany also revealed that 3 MDR entries differentiate from the BfArM list.

Moreover, 177 (71.4%) out of the 248 remaining discrepancies were due to different multiples of 10 in the representation (eg, ug/dl vs mg/L) with additional units that could be converted by applying more complex calculations such as converting mmol to g or mm [Hg] to kPa. Not having a medical background, we abstain from evaluating the correctness of the units, causing the remaining discrepancies. Importantly, we can show that there is a significant portion (298/368, 81%) of discrepancies that could be resolved by applying simple measures and, importantly, to lower variety in the discrepancies (66 out of the remaining 70 discrepancies would be caused by 1 different representation of a unit, and only 4 requiring the representation of the same value in 2 different units).

Multimedia Appendix 1 provides an excerpt of the table we created for this study and is one of the most important results of this study, as it can foster future developments. The LOINC codes most often found in the instance data are displayed.

Discussion

Principal Findings

Our work confirmed the need for sufficiently constrained profiles to inform the development of the federated feasibility tool. We presented tools and an approach that enables evidence-based decisions instead of the current educated guesses approach to create lower granularity CDS profiles. Performing the discrepancy analysis on the use case presented also granted significant insight into the data quality and alignment of the CDS among university hospital sites and the FDPG.

We also found first improvements in the data quality with the sites that addressed issues regarding the CDS identified in the data quality reports and subsequently undertook a reanalysis. This indicates that the presented tooling can improve data quality for agreed-upon profiles.

Implications for the Future of the FDPG Feasibility Tool

Despite the success in other areas, the high number of discrepancies in laboratory values presents a unique challenge. From a product development perspective, considering the diverse nature of laboratory data, several options emerge:

- The feasibility tool could change its capabilities to query for the existence of a laboratory value. Insight into existing clinical studies from ClinicalTrials.gov indicates that researchers have a high demand for specifying specific ranges for laboratory values. Moreover, it could be argued that aligned with the General Data Protection Regulation, call for "data minimization" capabilities to further

refinement even for feasibility queries could be deemed necessary.
- While theoretically feasible, expanding the range of selectable units to include all the existing ones would necessitate unit conversions by the researcher, likely negatively impacting usability and user awareness.
- Implementing on-the-fly conversions is typical in modern user interface design. However, given current technology constraints and the FDPG feasibility portal's response time requirements, this approach is not viable for handling big data.

Under normal circumstances, this would indicate the necessity to pivot from the current implementation of the feasibility tool; fortunately, the collaborative nature of the MII offers an alternative solution:

- Ideally, alignment of the laboratory values would stem from the primary source system; our empirical findings show (as portrayed in the *Results* section) that for the TOP300 LOINC Codes, the discrepancies can be overcome by applying rather simplistic measures to improve data harmonization. The data already being in a standardized format further enable the development of 1 tooling that suits all sites' needs. The MIRACUM consortium has initiated preliminary efforts in this direction and is available to all MII members [33]. While we would highly advise against mapping LOINC Codings, as implemented in the tooling, it showcases the feasibility of providing a conversion tool. We acknowledge that such tooling might require significant quality assurance (the tool LUMA [34] can support ensuring the used units match the dimensions defined in LOINC) or even the approval as software as a medical device given the existing expertise in the MII [35] and the reoccurring demand for further data harmonization for, for example, distributed machine learning, we regard the endeavor worthwhile.

Harmonizing the data would also give users a broader range of units by converting the selected value to the harmonized representation. There still might be cases where data harmonization of the instance data is not feasible. A fallback to the previously discussed solutions would still prevail in these cases.

Once the main issue of aligning the representation of the values in the search ontology is overcome, it will be necessary to expand the list of LOINC codings and their interdependencies continuously. Already, we found that 15 of the 20 sites had additional LOINC codings in the relatively small sample size of 500 Observations.

Related Work

Addressing the different granularities of FHIR resources and international, national, and domain-specific profiles is a topic that has seen more traction in recent years. With the International Patient Summary (International Organization for Standardization 27269) defining a minimal baseline of elements that need to be present in the electronic health record of a patient and its implementation in FHIR profiles to address the use case of "unplanned, cross border care," it is likely to see a rise of interdependent FHIR profiles. For European countries specifically, the goal of a shared European Health Data Space [36] will require defining an additional layer between the international and national levels. These profiles are not intended to serve all use cases. Figure 7 outlines the different layers based on the work of Vreeman (Vreeman, DJ, unpublished data, July 2023) and Aassve [37] and the role of existing implementation guides within these layers. The layered approach from minimally restrictive to sufficiently restrictive data modeling also offers the opportunity to promote reuse. The role of the CDS is not clearly defined within this model, while the FDPG profiles are sufficiently restrictive for the use case of federated search.

Kramer [38] pinpointed a discernible gap in reusability within FHIR, as revealed through their scrutiny of 125 implementation guides. The layered approach enables the definition of reusable extensions, promotes terminology use, and provides clear guidance on the existing profiles that can be enacted as a baseline.

While some may advocate for an all-encompassing top-down approach for particularly restrictive profiles, we believe that the existing instance data will inevitably require aligning for different reasons: existing instance data based on a less-stringent layer, missing restrictive profiles, or insufficient insight on real-world instance data when creating the profiles. Once this alignment is achieved, the established tooling in this work can be further used for quality assessment. While our work goes beyond the data quality assessment (DQA) of the CDS, it is inherently a part of our examination, if only regarding conformance.

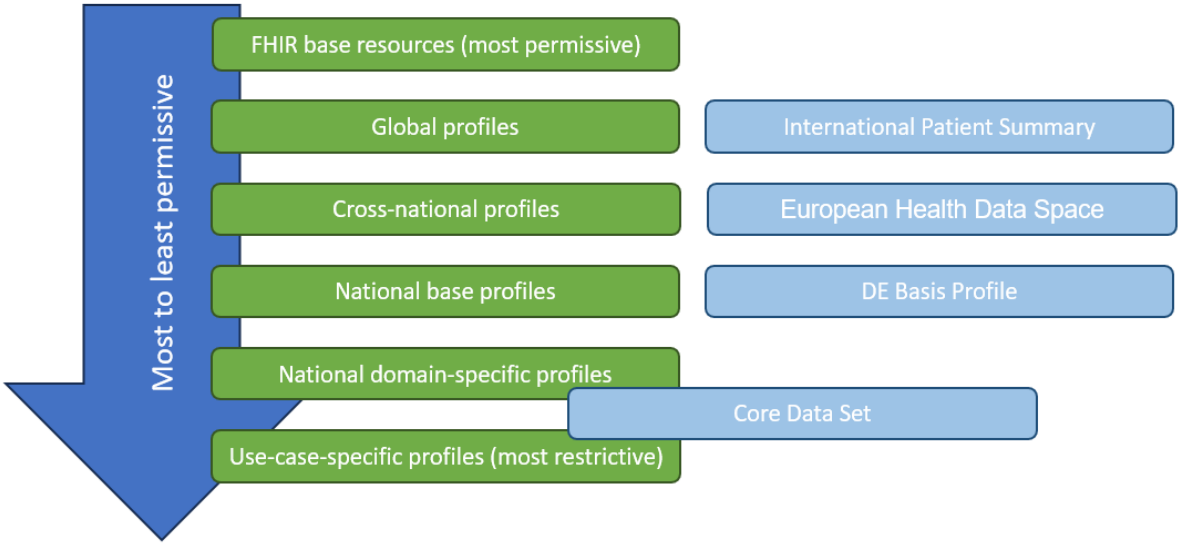
Draeger et al [39] and Kamdje-Wabo et al [40] performed a DQA across DICs in the MII using an R script to analyze specific elements in the instance data regarding their conformance, completeness, and plausibility as defined by Kahn et al [41]. Their findings align with our findings regarding conformance and completeness on a smaller sample set but go much more in depth when assessing plausibility. Ideally, future assessments will synthesize both methodologies: harnessing the robustness of FHIR profile validations as a foundation and superimposing intricate plausibility evaluations. Within the context of the MII, the MIRACUM DQA tool [42-44] assesses the data quality based on abstract data set definitions in the consortium-provided MIRACUM MDR. The same MDR underpinned our FHIR profile formulation for laboratory values.

Consequently, the sites that used the MIRACUM DQA tool had fewer discrepancies in our analysis. Still in the context of the MII but beyond the FHIR standard, the work of Tute et al [45] also applied rule-based evaluation on specific data elements using R. However, the data source they analyzed was an openEHR repository queried with AQL statements.

In the broader scheme of data quality of medical data, we also find the reoccurring topic of addressing data ambiguity. Schmidt et al [46] delve into the significance of data quality in observational health research and the different quality indicators, presenting a comprehensive framework that not only highlights the challenges but also offers software solutions in R to tackle them.

In conclusion, while the push toward defining and refining FHIR profiles and embracing standardized data formats is a significant step forward, it remains a piece of a giant puzzle to achieve interoperability and high data quality in the medical domain, which will ultimately require a multifaceted approach.

Figure 7. Layered Fast Healthcare Interoperability Resources profile model. DE: Deutsche (German).



Limitations

The presented approach requires high effort, limiting its inherent iterative nature. Therefore, it is essential to use all information obtained in each cycle to make informed decisions on the maximally constrained profiles that ultimately lead to profiles that the sites can use independently to access their data quality. The high effort is also why the initial run of discrepancy analysis is already based on educated assumptions. Notably, the method works even if only the required cardinalities and arbitrary values for the required attributes are specified in the profiles. Consequently, the first pass would cause maximum discrepancies and full insight into the instance data.

With the high alignment of educated assumptions, the analysis only evaluates data that should already match the search ontology criteria. LOINC Codes outside the TOP300, different codings for medications, diagnosis, or procedures are not part of the performed analysis and must be revisited once made available in the search ontology.

Compared with data analysis scripts, an advantage of this approach is its easy adaptation and reuse of the validation pipeline to perform DQAs for completeness and correctness. However, while aspects of plausibility can be found in our results, these are not directly related to our approach and must be addressed separately.

Finally, we did not analyze the *Patient* resource due to the federated nature of our analysis and privacy concerns. Being the central part of every feasibility query, sites should use the existing tooling to ensure conformance.

Outlook

We created an individual feedback PDF report containing all discrepancies for every participating site based on our findings. We hope that this feedback will allow the sites to address the identified discrepancies that are not caused by the FDPG profiles but rather are contradictions between the CDS and their ETL processes.

After reaching sufficient maturity, the FDPG profiles will be used to update the search ontology.

Further iterations, when expanding the ontology and between time periods, of the presented approach could be summed up in an iteration study providing insight into the continuous development of the central platform and the DIC.

This work revealed the necessity of extending collaborations between the CDS team, FDPG team, and DICs. While many discussions are still open at this point, first adjustments are already being made, that is, by the representatives of the CDS Consent module who have already implemented our recommendation of using the “part-of” relationship in the CodeSystems hierarchy. Now, it falls to the FDPG team to adjust the feasibility query accordingly in a future release.

We believe that it is pivotal to build on the presented approach to provide sites with tooling that enables them to verify their data quality concerning the CDS and identify if their instance data are available via the FDPG feasibility tool, allowing them to adjust their data or demand adjustments of the feasibility tooling if discrepancies arise. While the current tooling was tailored for this study, further adjustments can and should be made to provide sites with a more actionable report; that is, the report should provide a working link to a resource where a validation error occurred, allowing on-site users to have full access to all information.

We see a high demand for the presented approach. Whether partly to ensure data quality or fully to refine top-down defined profiles with evidence-based information to enhance interoperability. We provide a generic approach and sufficient tooling to make it usable for use cases beyond the FDPG, requiring only slight adjustments to work with other profiles.

Acknowledgments

The authors would like to express their gratitude to all sites taking part in this study and those responsible at the data integration centers who enabled this work by providing their report and even more important feedback on the findings and software, who are listed here in no particular order: Christoph Müller and Florisa Zanier (University Hospital Aachen), Natalia Ortmann and Jean Mascene Mazimpaka (University Hospital Augsburg), Florian Seidel (Charité Berlin), Klaus-Jürgen Quast (University Hospital Bonn), Mirko Gruhl (University Hospital Dresden), Stephan Wojke (University Hospital Frankfurt), Christopher Frank (University Hospital Gießen), Markus Mandalka and Sebastian Berthe (University Hospital Greifswald), Reto Wettstein (University Hospital Heidelberg), Usha Rama Nadan Pandit and Mehrshad Jaberansary (FKZ: 01ZZ2316K, University Hospital Cologne), Andreas Dürschmid and Thomas Wendt (University Hospital Leipzig), Jan Maluche (University Hospital Magdeburg), Sebastian Stöcker (University Hospital Marburg), Fabio Aubele (University Hospital of Munich), and Johannes Oehm (University Hospital Münster). The authors would like to thank the early adopters who paved the way to scale the study from 5 to 20 sites: Marvin Kampf (University Hospital Erlangen), Diana Pietzner (University Hospital Halle), Helmut Spengler and Raffael Bild (University Hospital rechts der Isar), Tobias Hilmer (University Hospital Schleswig-Holstein), and Georg Fette (University Hospital Würzburg). Furthermore, the authors would like to thank Martin Bialke (University Medicine Greifswald) for his feedback on the generic Informed Consent Service for a correct presentation in this paper. Finally, the authors would like to acknowledge all individuals in the Medical Informatics Initiative (specifically representatives from the Core Data Set team and coordinating office Technology, Methods, and Infrastructure for Networked Medical Research) whose insightful feedback was instrumental in shaping this paper.

The project was funded by the German Federal Ministry of Education and Research under the FDPG-PLUS project (grants 01ZZ2309D and 01ZZ2309A). This work was further supported in collaboration with participating sites funded by the NUM-DIZ project (grant 01KX2121).

Authors' Contributions

LR designed the methodology, supervised the initial test run implemented by PB for 5 sites [47], adjusted and performed the discrepancy analysis for 20 sites, and was the primary author of this manuscript. JW contributed significantly to implementing the Fast Healthcare Interoperability Resources Marshal and Populator used in the validation pipeline and offered crucial insights on medical terminology. JG played a pivotal role in coordinating and testing the discrepancy analysis. JI served in an advisory capacity throughout the research process. All authors actively reviewed, provided feedback, and approved the final version of this paper.

Abstract

Cardiovascular drug development requires synthesizing relevant literature about indications, mechanisms, biomarkers, and outcomes. This short study investigates the performance, cost, and prompt engineering trade-offs of 3 large language models accelerating the literature screening process for cardiovascular drug development applications.

(JMIR Med Inform 2024;12:e64143) doi:10.2196/64143

KEYWORDS

biomedical informatics; drug development; cardiology; cardio; LLM; biomedical; drug; cross-sectional study; biomarker; cardiovascular; screening optimization; GPT; large language model; AI; artificial intelligence

Introduction

Cardiovascular drug development requires synthesizing information about indications, mechanisms, biomarkers, and outcomes [1,2]. Large language models (LLMs) leveraging billions of data points could accelerate fundamental, resource-intensive aspects of this process, like screening published literature [3]. However, this depends on the design, development, and implementation of LLM instructions (prompt engineering) that work effectively within the context of cardiology [4-6]. To our knowledge, this is one of the first studies investigating LLMs to accelerate the literature screening process for cardiovascular drug development applications [3,4,6,7].

Methods

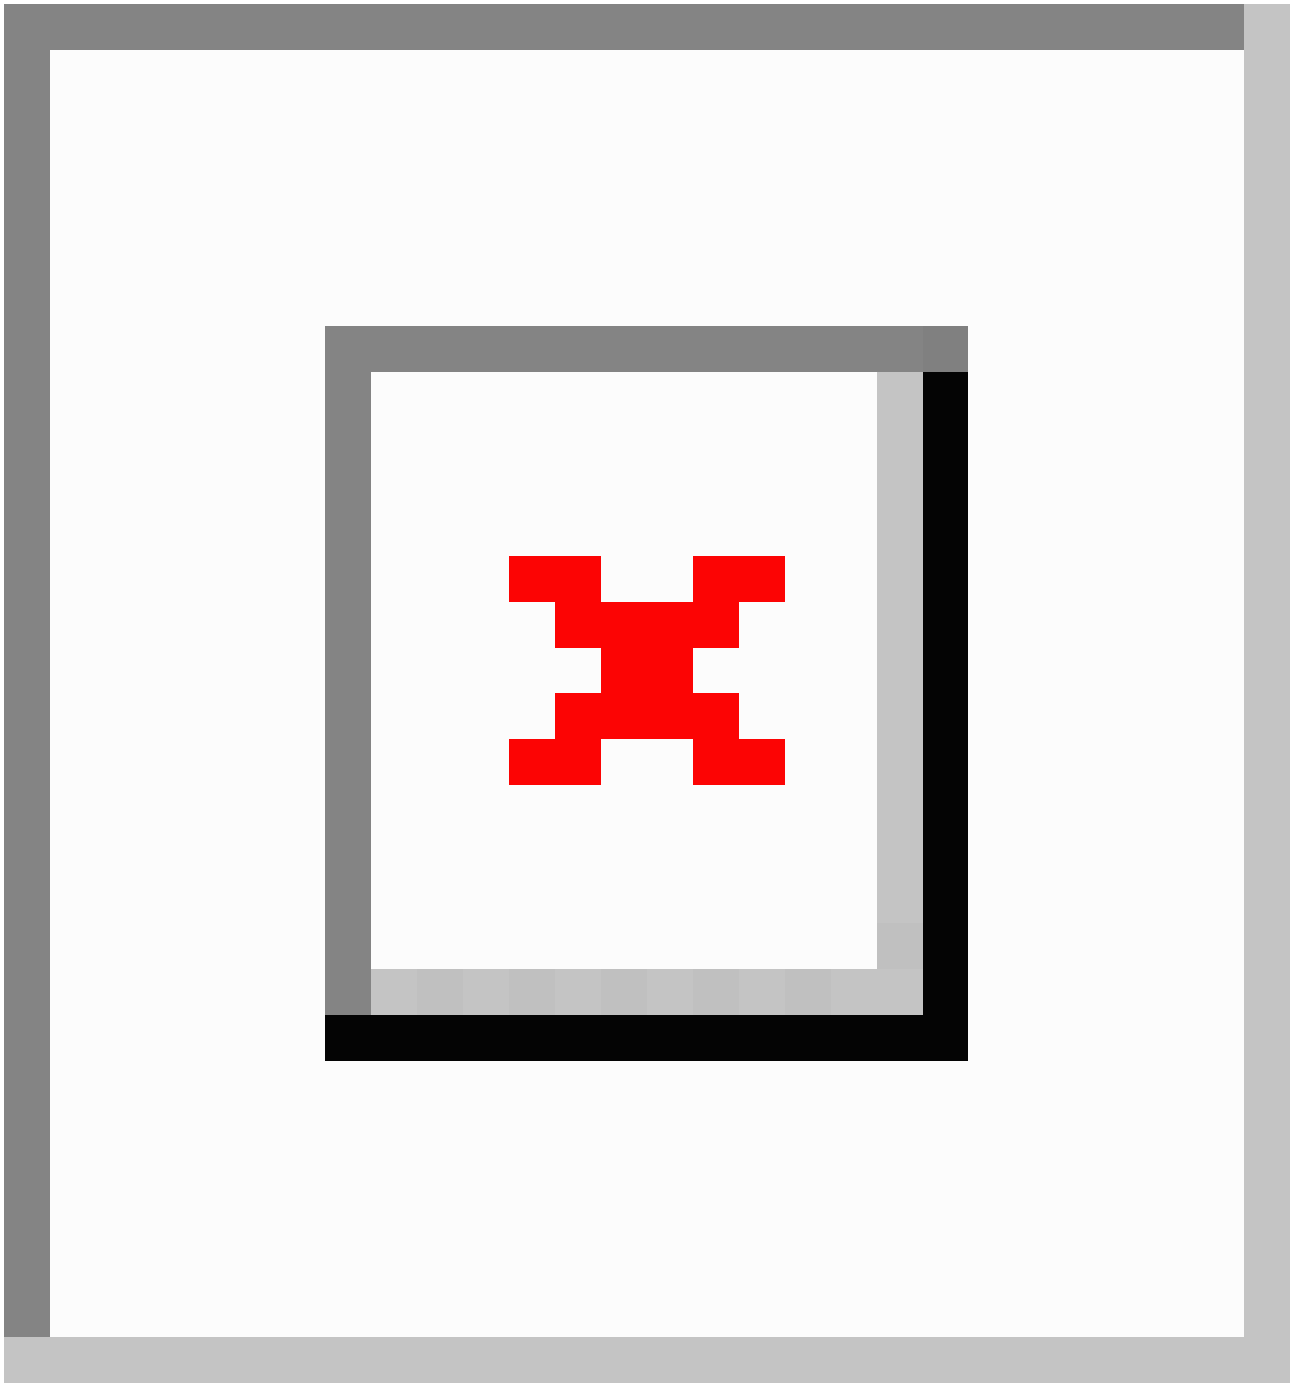
Study Design

Leveraging prior work, a PubMed query using both available Medical Subject Headings (MeSH) and the title and abstract keyword search of MeSH Entry Terms identified observational studies of heart failure that (1) were published from 2013 to 2023, (2) contained at least one relevant biomarker (brain natriuretic peptide, N-terminal pro–atrial natriuretic peptide, N-terminal pro–brain natriuretic peptide, and peak oxygen consumption), and (3) measured long-term outcomes (hospitalization and mortality) [2].

Abstracts were extracted through the PubMed application programming interface (API), and LLM instructions (prompts) were created to assess different screening optimization strategies (Figure 1) across LLMs (GPT-3.5 Turbo [OpenAI], GPT-4 [OpenAI], and Claude 2 [Anthropic PBC]) [5]. The “base” LLM prompt (1) presented abstract text, (2) listed two eligibility screening criteria (ie, values found for at least one biomarker and outcome), and (3) instructed LLMs to determine if abstracts met eligibility criteria and return results in a standardized format. “Technical” optimization was defined as adding delimiters to the base prompt delineating key sections (abstract and criteria), while “content” optimization further instructed LLMs to (1) assume a scientific role and (2) address a cardiology drug development target audience [3,5]. The different prompts used in this study are described in Multimedia Appendix 1. Total units of text processed (“tokens”) were estimated using spaCy, and LLM abstract screening costs were estimated using current API prices per million input and output tokens, respectively, for GPT-3.5 (US $0.50 and US $1.50), GPT-4 (US $30 and US $60), and Claude 2 (US $8 and US $24).

A Python script performed data processing and analysis. Accuracy was assessed by comparing LLM outputs against manual epidemiologist review of study suitability for inclusion, with descriptive statistics calculated for each LLM and prompt type. Performance differences between fully optimized prompts (GPT-3.5 vs GPT-4, GPT-3.5 vs Claude 2, and GPT-4 vs Claude 2) were evaluated using the chi-square test. A P value of <.05 was considered statistically significant.

Figure 1. Biomedical informatics pipeline for comparing different LLM and prompt optimization approaches to abstract screening for cardiovascular drug development. LLM: large language model.



Ethical Considerations

This study did not meet the definition of human participants research and thus did not require institutional review board approval.

Results

Of 69 articles found in PubMed, 32 (46%) met eligibility criteria after manual review; corresponding LLM screening accuracies are summarized in Table 1. By LLM, the best performances came from the base prompt (GPT-3.5), technical and combined prompts (GPT-4), and technical prompts (Claude 2). Overall, combined prompts for GPT-3.5 and GPT 4 performed similarly against each other (P>.99) and against Claude 2 (P=.61 against both).

GPT-3.5 processed a total of 124,826 tokens, while GPT-4 and Claude 2 processed 14.4% (N=142,750) and 15.9% (N=144,703) more tokens, respectively. Total costs for GPT-4 (US $4.89) and Claude 2 (US $1.52) were 75.4 and 23.4 times higher, respectively, than total costs for GPT-3.5 (US $0.06).

Table . Abstract screening accuracies reflecting total abstracts correctly identified by large language models (LLMs) for inclusion and exclusion based on manual review of study suitability, by LLM and prompt optimization type (abstracts: N=69).

Prompt optimization type	Accuracy, n (%)		
	GPT-3.5	GPT-4	Claude 2
Base (none)	43 (62)	40 (58)	35 (51)
Technical	34 (49)	41 (59)	43 (62)
Content	42 (61)	38 (55)	38 (55)
Technical and content	41 (59)	41 (59)	37 (54)

Discussion

Despite the complex and limited public cardiology data integrated into LLMs, our findings were consistent with similar studies for oncology and current LLM abilities to pass medical licensing exams [4,8]. Performance could be further improved by adding specific examples to the prompt (few-shot prompting) or to the LLM training data (fine-tuning) [4,8,9].

Technical optimizations showed modest performance improvements across some LLMs, indicating one practical way to improve accuracy and prompt readability without significantly expanding the size of input prompts. Standardizing outputs helped generate valid responses, although GPT-4 and Claude 2 still had higher costs as a result of more verbose output. Enterprise LLM–based abstract screening will require balancing prompt performance, cost, and complexity with cardiology subject matter expert capabilities and workflows.

Limitations include a small cardiovascular dataset leveraging proprietary LLMs and only a subset of available optimization techniques. Future efforts must engage diverse scientific communities; develop guardrails to ensure safe and responsible LLM use; and apply data-driven best practices that generalize, optimize, and validate LLM applications and their impact on patients with cardiovascular disease.

Conflicts of Interest

All authors are employees of Pfizer. The funding sources had no role in the design and conduct of this study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Abstract

Background: Recent advancements in artificial intelligence (AI) and large language models (LLMs) have shown potential in medical fields, including dermatology. With the introduction of image analysis capabilities in LLMs, their application in dermatological diagnostics has garnered significant interest. These capabilities are enabled by the integration of computer vision techniques into the underlying architecture of LLMs.

Objective: This study aimed to compare the diagnostic performance of Claude 3 Opus and ChatGPT with GPT-4 in analyzing dermoscopic images for melanoma detection, providing insights into their strengths and limitations.

Methods: We randomly selected 100 histopathology-confirmed dermoscopic images (50 malignant, 50 benign) from the International Skin Imaging Collaboration (ISIC) archive using a computer-generated randomization process. The ISIC archive was chosen due to its comprehensive and well-annotated collection of dermoscopic images, ensuring a diverse and representative sample. Images were included if they were dermoscopic images of melanocytic lesions with histopathologically confirmed diagnoses. Each model was given the same prompt, instructing it to provide the top 3 differential diagnoses for each image, ranked by likelihood. Primary diagnosis accuracy, accuracy of the top 3 differential diagnoses, and malignancy discrimination ability were assessed. The McNemar test was chosen to compare the diagnostic performance of the 2 models, as it is suitable for analyzing paired nominal data.

Results: In the primary diagnosis, Claude 3 Opus achieved 54.9% sensitivity (95% CI 44.08%-65.37%), 57.14% specificity (95% CI 46.31%-67.46%), and 56% accuracy (95% CI 46.22%-65.42%), while ChatGPT demonstrated 56.86% sensitivity (95% CI 45.99%-67.21%), 38.78% specificity (95% CI 28.77%-49.59%), and 48% accuracy (95% CI 38.37%-57.75%). The McNemar test showed no significant difference between the 2 models (P=.17). For the top 3 differential diagnoses, Claude 3 Opus and ChatGPT included the correct diagnosis in 76% (95% CI 66.33%-83.77%) and 78% (95% CI 68.46%-85.45%) of cases, respectively. The McNemar test showed no significant difference (P=.56). In malignancy discrimination, Claude 3 Opus outperformed ChatGPT with 47.06% sensitivity, 81.63% specificity, and 64% accuracy, compared to 45.1%, 42.86%, and 44%, respectively. The McNemar test showed a significant difference (P<.001). Claude 3 Opus had an odds ratio of 3.951 (95% CI 1.685-9.263) in discriminating malignancy, while ChatGPT-4 had an odds ratio of 0.616 (95% CI 0.297-1.278).

Conclusions: Our study highlights the potential of LLMs in assisting dermatologists but also reveals their limitations. Both models made errors in diagnosing melanoma and benign lesions. These findings underscore the need for developing robust, transparent, and clinically validated AI models through collaborative efforts between AI researchers, dermatologists, and other health care professionals. While AI can provide valuable insights, it cannot yet replace the expertise of trained clinicians.

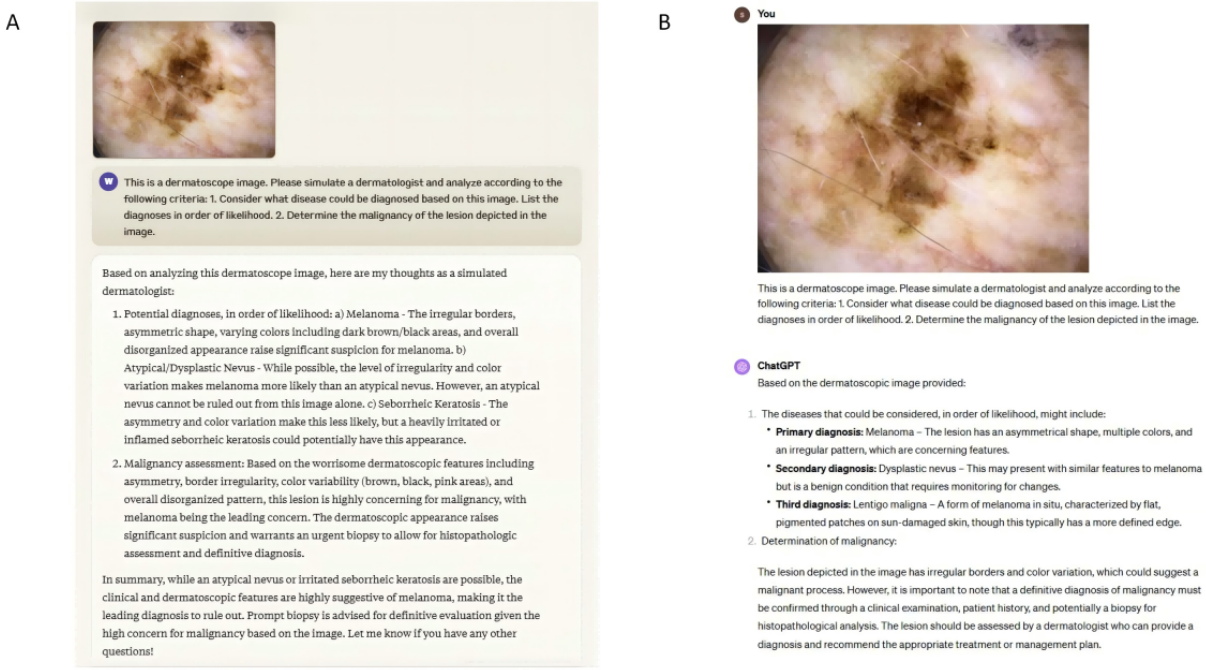
Introduction

Artificial intelligence (AI) has shown great promise in various medical fields, including dermatology [1]. The emergence of large language models (LLMs), such as ChatGPT, has demonstrated their ability to generate human-like responses and assist in clinical decision-making [2]. With the introduction of image analysis capabilities in LLMs [3], their application in dermatological diagnostics has attracted significant interest. Claude 3 Opus, an advanced conversational AI model, has shown promising performance in various natural language processing tasks [4]. This study aims to fill that gap by comparing Claude 3 Opus and ChatGPT with GPT-4. Despite the potential of AI in health care, encompassing diagnosis, treatment, and public health initiatives, these technologies are largely underused in clinical practice [5]. Moreover, the use of AI in health care raises important legal and ethical considerations, particularly for "high-risk" applications such as medical diagnosis [6]. In this context, comparing the diagnostic performance of Claude 3 Opus and ChatGPT can provide valuable insights into their strengths and limitations, guiding the selection and optimization of AI-assisted diagnostic tools in dermatology while taking into account the regulatory landscape.

Methods

We randomly selected 100 dermoscopic images (50 malignant melanomas, 50 benign nevi) from the International Skin Imaging Collaboration (ISIC) archive [7] using a computer-generated randomization process to avoid selection bias. The ISIC archive was chosen due to its comprehensive and well-annotated collection of dermoscopic images, which ensures a diverse and representative sample. Images were included if they were dermoscopic images of melanocytic lesions with histopathologically confirmed diagnoses. Each image was presented to Claude 3 Opus and ChatGPT. The models were given the same prompt, instructing them to provide the top 3 differential diagnoses for each image, ranked by likelihood. The exact prompt was "Please provide the top 3 differential diagnoses for this dermoscopic image, ranked by likelihood. Focus on distinguishing between melanoma and benign nevi." The models' responses were recorded for analysis (Figure 1A, B). We assessed primary diagnosis accuracy, accuracy of the top 3 differential diagnoses, and malignancy discrimination ability. The McNemar test was used to compare the models' performance.

Figure 1. Performance comparison of Claude 3 Opus and ChatGPT with GPT4-Vision in skin dermoscopy image analysis and melanoma diagnosis: application scenarios. (A.) Application scenario of Claude 3 Opus in the analysis process of dermoscopic images. (B) Application scenario of GPT4-Vision in the analysis process of dermoscopic images.



Results

For the primary diagnosis, Claude 3 Opus achieved 54.9% sensitivity (95% CI 44.08%-65.37%), 57.14% specificity (95% CI 46.31%-67.46%), and 56% accuracy (95% CI 46.22%-65.42%), while ChatGPT demonstrated 56.86% sensitivity (95% CI 45.99%-67.21%), 38.78% specificity (95% CI 28.77%-49.59%), and 48% accuracy (95% CI 38.37%-57.75%). The McNemar test showed no significant difference between the 2 models (P=.17; Multimedia Appendices 1-2). For the top 3 differential diagnoses, Claude 3 Opus and ChatGPT included the correct diagnosis in 76% (95% CI 66.33%-83.77%) and 78% (95% CI 68.46%-85.45%) of cases, respectively. The McNemar test showed no significant difference (P=.56). In malignancy discrimination, Claude 3 Opus outperformed ChatGPT with 47.06% sensitivity, 81.63% specificity, and 64% accuracy, compared to 45.1%, 42.86%, and 44%, respectively. The McNemar test showed a significant difference (P<.001). Claude 3 Opus had an odds ratio of 3.951 (95% CI 1.685-9.263) in discriminating malignancy, while ChatGPT had an odds ratio of 0.616 (95% CI 0.297-1.278) (Multimedia Appendix 3).

Discussion

Our study demonstrates the potential of LLMs in assisting dermatological diagnosis, while also revealing their current limitations. Claude 3 Opus showed superior performance in discriminating between malignant and benign lesions compared to ChatGPT. However, both models made errors in diagnosing melanoma and nevi. For example, Claude 3 Opus misdiagnosed several melanomas as benign lesions, while ChatGPT had a higher false positive rate, misclassifying many nevi as melanomas. These findings highlight the need for further development and rigorous clinical validation of AI diagnostic tools before their widespread implementation in dermatology practice (Multimedia Appendix 4). Future research should focus on improving the robustness and interpretability of these models through close collaboration between AI researchers, dermatologists, and other health care stakeholders. Moreover, the potential impact of AI in health care extends beyond technical performance, encompassing legal and ethical dimensions. The European Commission has already proposed legislation for “high-risk” AI applications, providing a framework for the safe and responsible use of medical AI [6]. As LLMs and other AI tools continue to advance, it is crucial to proactively address these regulatory aspects to ensure their beneficial integration into clinical practice. In conclusion, while LLMs such as Claude 3 Opus and ChatGPT show promise in assisting dermatological diagnosis, they are not yet capable of replacing human expertise. Continued research, collaborative development, and proactive regulation are essential for realizing the full potential of AI in dermatology while prioritizing patient safety and ethical standards.

Abstract

Background: The use of large language models (LLMs) as writing assistance for medical professionals is a promising approach to reduce the time required for documentation, but there may be practical, ethical, and legal challenges in many jurisdictions complicating the use of the most powerful commercial LLM solutions.

Objective: In this study, we assessed the feasibility of using nonproprietary LLMs of the GPT variety as writing assistance for medical professionals in an on-premise setting with restricted compute resources, generating German medical text.

Methods: We trained four 7-billion–parameter models with 3 different architectures for our task and evaluated their performance using a powerful commercial LLM, namely Anthropic's Claude-v2, as a rater. Based on this, we selected the best-performing model and evaluated its practical usability with 2 independent human raters on real-world data.

Results: In the automated evaluation with Claude-v2, BLOOM-CLP-German, a model trained from scratch on the German text, achieved the best results. In the manual evaluation by human experts, 95 (93.1%) of the 102 reports generated by that model were evaluated as usable as is or with only minor changes by both human raters.

Conclusions: The results show that even with restricted compute resources, it is possible to generate medical texts that are suitable for documentation in routine clinical practice. However, the target language should be considered in the model selection when processing non-English text.

KEYWORDS

machine learning; ML; artificial intelligence; AI; large language model; large language models; LLM; LLMs; natural language processing; NLP; deep learning; algorithm; algorithms; model; models; analytics; practical model; practical models; medical documentation; writing assistance; medical administration; writing assistance for physicians

Introduction

Background

Physicians are often overloaded with documentation requirements, including writing a doctor's note and a summary of a patient's visit. An analysis of clinical software log files showed that interaction with electronic health records (EHRs) constitutes a large portion of physicians' daily work, approximately one-fourth of which is spent writing documentation [1]. Completion of the documentation in the EHR is perceived as a tedious task, which is often done after work hours [1]. More time spent on documentation after work hours has been shown to be associated with burnout and decreased work-life satisfaction [2].

A promising approach to reduce the time required for documentation is the use of writing assistance based on large language models (LLMs). In a feasibility study, the authors trained previous-generation LLMs (GPT-2 and GPT-Neo) to complete text in medical records [3]. They concluded that the models could be used in medical charting but still have some room for improvement. A large source of error was abrupt changes in the topic, which is common in the documentation of EHRs.

With recent advances in LLM technology and the release of ChatGPT, LLMs have seen widespread adoption in assisting professionals produce text for communication or documentation purposes. For example, under the Copilot brand, Microsoft is building generative artificial intelligence (AI) capabilities into their widely used Office application suite to assist in business

use cases. This leads us to believe that current-generation LLMs could also provide valuable assistance in the health care sector.

Challenges in the Use of LLMs in the Health Care Sector

Among the best-performing LLMs, according to the continuously updated Holistic Evaluation of Language Models [4] at Stanford University, are currently commercial offerings from companies such as OpenAI or Anthropic. With these offerings, the models run on the providers' infrastructure and are accessible via an application programming interface. However, these services cannot be used in a clinical context without further consideration.

First, in many countries, the services do not meet the legal requirements for processing protected health information. In some jurisdictions, legal and regulatory frameworks mandate that data originating from health care providers must be processed within the country's borders or even on-premise. This is particularly problematic for European countries, as the European Union's General Data Protection Regulation prohibits the transfer of protected health information to data centers in the United States, where most providers are located.

Second, clinical software must be thoroughly validated before it is released to end users, and in some cases, it is even subject to the Medical Device Regulation. This conflicts with the update policy of providers of commercial AI solutions. The scope of model updates is usually communicated only a few weeks in advance, for example, 2 weeks in the case of OpenAI [5]. This would not be a problem if these updates were only additive in functionality, but the opaque nature of current LLMs also means that improvements to some aspects of model performance might unexpectedly negatively affect the performance on other tasks [6]. The use of fixed model versions, as offered by some providers, is not practicable in the long term, as older models are often removed after the release of updates; in the case of OpenAI, after 3 months [5].

Training Nonproprietary AI Models for Medical Text

An alternative is the use of nonproprietary AI models. In these models, the architecture as well as the trained parameters are available to the user. This solves the aforementioned problems by giving the user the option to train and deploy these models on any infrastructure and fully control any changes to it.

One of the largest pretrained LLMs is GPT models that enable model training with limited data sets. There are several approaches to applying GPT models to a task. One common approach is to use a very large model that is trained primarily with general text corpora and includes instructions for the task in the input for the model, the so-called prompt. This is sometimes called in-context learning (ICL) or, depending on whether examples are provided, zero-shot or few-shot learning.

ICL works reasonably well on tasks that have a good representation in the base models' training corpus. However, the structure and content of clinical notes differ significantly from the general-purpose text corpora used to train most publicly available LLMs. Even including biomedical text from publications, such as PubMed papers, in the training data could only have minor effects on model performance compared to training on clinical text [7-9]. Lehman et al [9] compared ICL and multiple alternatives such as (1) training from scratch on a clinical corpus, (2) continuing training a pretrained model on the clinical text and then fine-tuning for the downstream task, or (3) directly training the GPT for the downstream task without further pretraining. They show that relatively small specialized clinical models substantially outperform all ICL approaches and conclude that pretraining on clinical text allows for smaller, more parameter-efficient models.

One fact that must be taken into account when using GPT models in a clinical context is that the pretrained models have now become very large. Complete fine-tuning, in which all model parameters are retrained on the task-specific data, is therefore becoming less and less feasible. This is particularly the case if the models have to be trained on site for legal or economic reasons. The computing power available here is usually limited, which restricts the size of the models that can be trained. Accordingly, the choice of models is a trade-off between training time and costs, model accuracy, and maximum sequence length.

One possibility to address the problem of limited working memory is the Low-Rank Adaptation (LoRA) technique [10]. Here, all the model weights are frozen, and only a few very small additional low-rank matrices are added to the query and key parameter matrices of the transformer attention heads and subsequently optimized. This reduces the number of trainable parameters by 10,000 times and the graphics processing unit (GPU) memory requirement by 3 times. Recently, training of quantized models became possible by combining LoRA with quantization [11]. With Quantized Low-Rank Adaptation (QLoRA), a frozen quantized model is fine-tuned by optimizing added low-rank adapters at 16-bit floating-point precision. The QLoRA technique also introduced additional memory-saving mechanisms such as the 4-bit Normal Float (NF4) data type for quantization and paged optimizers [11].

Aim of This Study

In this study, we assessed the feasibility of using nonproprietary LLMs of the GPT variety as writing assistance for medical professionals in an on-premise setting with restricted compute resources, generating non-English medical text. We trained 4 models with 3 different architectures for our task using the Hugging Face Transformers framework [12] and explored their performance using a powerful commercial LLM, namely Anthropic's Claude-v2, as a rater. Based on this, we selected the best-performing model and evaluated its practical usability with 2 independent human raters on real-world data.

Methods

Ethical Considerations

The study was implemented in the outpatient clinic of the Eye Center at Medical Center, University of Freiburg, Germany, and was approved by the responsible ethical review committee (registration 23 - 1444S1). All data used in the study were deidentified and contained no references to patients and practitioners. Informed consent for the anonymization process

was not obtained. Data processing was justified based on the legal basis of "legitimate interest" in accordance with the General Data Protection Regulation and the state hospital law of Baden-Württemberg ("Landeskrankenhausgesetz"). Participants did not receive any financial compensation for their data use, as the data were retrospectively reviewed from existing medical records.

Study Design

The target for assistive text generation was the final part of the medical documentation of an examination or treatment, the so-called epicrisis report. In this report, the doctors write a structured compilation of the information so far documented in the EHR in text form. It contains the relevant medical information of the case and usually consists of three sections: (1) main diagnosis or the patient's reason for visit, (2) therapeutic procedures or medication, and (3) recommendations for further intervention and need for a follow-up appointment.

Data

Data Source and Description

The data pool used for training the models was the EHR records of 82,482 unique patient encounters that span approximately 10 years of clinical practice. The EHR record of an encounter contains all digital information about a patient's examination or treatment in the outpatient clinic, which offers specialist, emergency, and follow-up care. The data are collected in various ways over the patient's visit. Support staff record basic information in structured forms, doctors document the medical history, symptoms and previous or planned treatments are documented in text notes, and diagnostic data from electronic devices are mainly stored in numeric format. The final epicrisis report consists of a stand-alone text, which is filed alongside all other information in the EHR record.

The whole training data set amounts to approximately 140 MB of uncompressed text in Unicode Transformation Format 8 encoding or approximately 29 to 33 million tokens, depending on the tokenizer model used. A data set of 509 patient encounters that occurred after the training set date cutoff was set aside for comparison of model performance in the evaluation. The complete data set consists of German text. The examples used in this paper were translated into English by the authors of the paper.

Preprocessing and Formatting

For the LLM training, all available data in the EHR record were concatenated into 1 continuous text sequence per encounter. The types of information were separated by newlines and prefixed with a descriptor such as "History" or "Pressure Measurement" to form the prompt. If no data were documented in a section, it was left empty. The order of sections matched the order in which the fields are displayed to users in the EHR software interface. The last section of each text sequence was the epicrisis report. If there were separate records for each eye, the individual records were additionally prefixed with an abbreviation indicating the side.

Task training was implemented by inserting special tokens to mark the text to be generated by the final models, that is, the epicrisis report. Each text sequence starts with a special token indicating the beginning of the input data recorded during the patient visit, that is, all other information in the EHR record. A second special token is inserted before the epicrisis report, indicating the start of the generation task. In the training data, this token is followed by the actual report of the attending physician. The text sequence ends with a "Stop of Sequence" token, which indicates that the model should end the generation process.

For instruction-tuned models, the text sequence was prefixed with a so-called system message enclosed in special tokens indicating instructions for the model, reading as follows: "You are an experienced doctor in a German eye hospital. Your writing style is concise, accurate, and respectful. You are writing a short note in German to a colleague about a patient. The letter should contain the provided information."

Models

Model Selection Overview

In the selection of models from openly available pretrained models, we considered hardware costs, feasibility of the training process, language aspects, and performance benchmark results, such as Stanford's Holistic Evaluation of Language Models [4] and the Open LLM Leaderboard on Hugging Face [13]. Most LLMs are predominantly trained in English texts, and currently, there is no model that contains a greater amount of medical text. Consequently, we chose the following 3 models: LLaMA, LLaMA-2-Chat, and BLOOM-CLP-German.

LLaMA

At the start of this study, Meta AI's LLaMA model was among the top performers on several open LLM benchmarks. In contrast to some of its competitors, its training corpus also contains some German text but no clinical content [14]. Since then, more powerful models have been released, but LLaMA still achieves competitive results on many benchmarks.

LLaMA-2-Chat

During our experiments, Meta AI released the successor to LLaMA [15]. Together with the updated base model, they also released an instruction-tuned model aligned with human preferences using reinforcement learning, similar to how ChatGPT was based on GPT-3 [16]. We chose this model to investigate the potential advantage of using an instruction-tuned model.

BLOOM-CLP-German

This model is designed for tasks in German based on the BLOOM architecture from BigScience Workshop et al [17]. It was initialized with the novel cross-lingual and progressive transfer learning (CLP) technique [18], which uses information from a small model trained in a target language and a larger model in a source language. This considerably reduces the training needed to achieve performance on par with that of a model trained from scratch. Although the model is still severely undertrained for its size [19], we included it to study the potential performance gains achieved by a model with a training corpus closer to the target text material.

Training

Overview

We restrict our training setup to 8x NVIDIA RTX 3090 24-GiB consumer-grade GPUs in a single host. We load and train our models using the "transformers" Python library by Hugging Face [12] with the PyTorch [20] backend. Data are preprocessed using Hugging Face's "datasets" Python library [21]. Distributed training on multiple GPUs is implemented via the "accelerate" Python library [22].

For each training process, we randomly sample 5% of the training data as validation data. We regularly evaluate training loss on the validation set during training, about 20 times per epoch. We stop training when the validation loss does not improve in 10 evaluation steps. This amounts to around 13 epochs for most models.

Memory Optimization

For fine-tuning the model for our task, we use the LoRA at full 16-bit precision and QLoRA [11] at reduced NF4 precision techniques. Reducing the precision also reduces the memory use and allows for longer input text sequences with the available memory. With this, we explore the trade-off between computational precision and input context size.

Additionally, we use 2 methods to trade reduced memory requirements for computation time. First, we use gradient checkpointing, a technique that recomputes some network activations during the backward pass on the fly instead of caching them in memory. Second, we use the Zero Redundancy Optimizer technique [23], which includes memory savings achieved by reducing redundancy when training on multiple GPUs as well as offloading some tasks to the CPU, both at the cost of communication overhead. Both make the training process considerably slower but should not impact the task performance of the resulting model.

Specifically, we trained the following model variants: LLaMA with LoRA at floating point 16-bit precision, LLaMA 2 Chat with QLoRA at NF4 precision, BLOOM-CLP German with QLoRA at NF4 precision, and BLOOM-CLP German with LoRA at floating point 16-bit precision.

Inference

Overview

At their core, the decoder part of the transformer architecture models a probability distribution for the next token, given a sequence of input tokens. Both the composition of the initial input tokens and the method of choosing the next token from the produced probability distribution can have a big impact on the quality of the final result.

Completion Prefixing

At inference time, the model receives an input text sequence, often called the prompt. It consists of the input data, as described in the "Preprocessing and Formatting" section, followed by a special token, indicating that the subsequent text should be an epicrisis report. In other words, the model receives a text sequence containing all information from an EHR record except for the attending physician's epicrisis report and is asked to write this report, that is, to generate a text that corresponds in content, structure, and form to the epicrisis reports included in the training data. However, in the qualitative analysis of our initial findings, we found that in some cases the models attempted to continue with the recorded data rather than start writing a final report.

In an effort to improve results without retraining our models, we introduce a simple form of prompt tuning by adding a static suffix to the prompt, that is, forcing the model to begin the generated text with the words "During today's visit...." This suffix represents the typical beginning of the epicrisis report, as almost all reports written by doctors in the training data set start with some variation of these words. We hope that this gives the models an additional signal to complete the text with a summary and recommendations instead of trying to invent more "facts" about the patient's stay. We report and compare the evaluation results on reports generated with and without the completion prefix.

Contrastive Search

For a given input sequence, the trained transformer model produces a probability distribution for the next token. Simply choosing the token with the highest probability often produces text that lacks coherence and diversity. Techniques that maximize the probability over multiple tokens (eg, beam search) or stochastic sampling can enhance coherence and diversity but are not targeted at the problem of repetition that is common to the type of highly standardized text generated in this study. We therefore use a more recently introduced technique, called contrastive search, which has been shown to encourage diversity and produce coherent results while reducing repetitiveness [24,25].

Evaluation

Overview

Evaluating the quality of generated natural language text using (preferably multiple) human raters is costly and time-consuming, especially, if the rating process requires specialized domain knowledge as in this study. On the other hand, there is no obvious way to automate this process. An interesting idea is to use larger and more powerful language models to rate the quality of the output. This technique has recently been used in some publications in the LLM space, for example, in the creation of the LLaMA-2 model and in evaluating the performance of QLoRA training [11,15]. Large commercial language models such as OpenAI's GPT-4 and Anthropic's Claude-v1 model have been shown to achieve agreement rates with human raters of up to 80% when evaluating the output of other models [26].

Automated Evaluation With Claude-v2

We evaluate the generated text in a 2-step process using Claude-v2 by comparing the generated text to the epicrisis reports that were written by physicians for 509 individual patient encounters. In the first step, we extract the text passages that contain relevant information for each of the three main categories of information: (1) main diagnosis or patient's reason for visit, (2) therapeutic procedures or medication, and (3)

recommendations for further intervention and need for a follow-up appointment. In the second step, for each case and category separately, we ask Claude to evaluate whether the extracted passage from the generated report matches the passage extracted from the report written by a human.

Human Evaluation

The suitability of the generated text by the best-performing model is evaluated by 2 independent expert senior physicians. For this purpose, the raters are presented with the basic data from the documentation of 102 patients as well as both versions of the report: the one written by the attending physician and the computer-generated version. The raters assess whether the computer-generated version is suitable as a text template and could be used without major changes.

Results

Model Performance

Table 1 shows the percentage of reports in the test set in which the models matched the extracted diagnosis, follow-up, and therapy recommendation. The highest agreement rates with reports written by a doctor were achieved by the BLOOM-CLP-German model, followed by LLaMA-2 and LLaMA. The ranking was consistent across all the diagnosis, follow-up, and therapy dimensions. On average, the models achieved the highest scores in the diagnosis dimension, followed by the therapy and follow-up dimensions.

Of the BLOOM-CLP-German variants trained with full floating point 16-bit precision LoRA and reduced NF4 integer precision QLoRA, the latter achieved slightly higher agreement rates. In contrast to our intuition, prefixing the model prompt at inference time (see "Completion Prefixing" section) slightly reduced the performance across all models rather than improving it.

Table . Fraction of reports in the test set where the models match the information extracted from the text written by a doctor.

Category	Model (%)								
	BLOOM-CLP-FP16	BLOOM-CLP-FP16-prefix	BLOOM-CLP-QLoRA	BLOOM-CLP-QLoRA-prefix	LLaMA-2-QLoRA	LLaMA-2-QLoRA-prefix	LLaMA-FP16	LLaMA-FP16-prefix	Mean (SD)
Diagnosis	50.10	44.01	55.40	45.78	34.38	32.81	31.24	16.50	38.78 (12.47)
Follow-up	41.45	32.02	43.42	33.79	36.94	31.24	34.97	21.02	34.36 (6.90)
Therapy	43.81	37.33	50.69	42.44	36.54	36.35	29.67	13.95	36.35 (10.99)
Mean (SD)	45.12 (4.47)	37.79 (6.01)	49.84 (6.04)	40.67 (6.01)	35.95 (1.38)	33.46 (2.62)	31.96 (2.72)	17.16 (3.58)	—[a]

[a]Not applicable.

Human Evaluation

A total of 102 reports generated by the BLOOM-CLP German model trained with QLoRA at NF4 precision were rated for suitability by 2 independent expert senior physicians. Of the 102 reports, 95 (93.1%) were evaluated as suitable by both raters, which means that computer-generated reports could be used in this form or with minor changes. Only 7 (6.9%) of the reports were rated as unsuitable by at least 1 of the raters. Cohen κ was run to determine the interrater reliability. There was moderate agreement between the 2 physicians' judgments (κ=0.582, 95% CI 0.217-0.947; P<.001).

The 7 reports that were rated as unsuitable show different anomalies. In 3 of the reports, the model was caught in a loop of repeating nonsensical word sequences, for example, "we recommend local therapy with Bepanthen eye ointment 5x daily on both sides for 5 - 7 days, then 1x daily on both sides for 5 - 7 days, then 1x daily on both sides for 5 - 7 days, then 1x daily on both sides for 5 - 7 days, etc" (26 repetitions). In one case, there is no text output because the patient's appointment did not take place. Only in 3 reports are content-related aspects decisive. In one case, the main diagnosis is not mentioned; in one case, information is missing in the treatment recommendation; and in one case, the time given for the follow-up appointment is incorrect.

Discussion

Principal Findings

Despite being severely undertrained compared to both LLaMA models, the BLOOM-CLP-German model achieved the best performance in our experiments. This suggests that a better alignment of the base model with the reports' language might be more important than a longer training time. We speculate that the German vocabulary in the model's tokenizer better-captured domain semantics compared to the multilingual tokenizers. Additionally, the model might have profited from a larger maximum input sequence length, given the limited memory. This is an effect of the smaller token per character ratio of a tokenizer with a better alignment to the text's language.

Because its vocabulary is closer to our data, BLOOM-CLP-German's tokenizer encodes up to 30% fewer tokens for the same input text compared to LLaMA's tokenizer. This means that we can fit more information into the context window, training and inference consume about half as much memory, and inference is about twice as fast. This makes for

significant cost reductions compared to models with a multilanguage tokenizer.

Of both BLOOM variants trained with LoRA and reduced QLoRA precision, the latter performed better in our analysis. This suggests that the reduced precision is more than offset by the bigger maximum input sequence length, given the memory constraints. We surmise that capturing more context in the model input outweighs compute-optimal training or precision.

In contrast to our intuition, forcing the models to start the generated text with a predefined prefix did not improve the results. We speculated from our manual testing that this technique might eliminate some edge cases where the models sometimes start generating text completely unrelated to the input sequence. While this might still be true, the prefix also might have impacted the models' ability to flexibly react to the input and therefore reduced quality in more cases than improving it.

Feasibility of Nonproprietary On-Site AI

Our manual evaluation clearly shows that it is possible to provide helpful writing assistance using nonproprietary on-site AI technologies. Most of our test samples were rated useful as is or with only minor modifications. Additionally, qualitative analysis of samples rated as unusable showed that these were edge cases where the model produced no output or text that was easily identifiable as an anomaly. Only in very few reports were content-related aspects decisive, that is, the model omitted major details or produced factually incorrect information.

Legal and ethical concerns, as discussed in the "Challenges in the Use of LLMs in the Health Care Sector" section, currently may prevent many health care providers in European countries from using proprietary AI assistance for charting. Nonproprietary models, as used in this study, allow for flexible model deployment to comply with data protection requirements. Full control over the model also addresses legal concerns regarding software certification and some ethical concerns because these models can be more easily inspected regarding potential biases. Therefore, the approach presented in this study should be feasible for most health care providers.

In this study, we chose model sizes around 7 billion parameters. In comparison, GPT-3, the model that powered the first version of ChatGPT, has 175 billion parameters. With careful optimization of trade-offs between training time and cost, model precision, and maximum sequence length, we show that it is still possible to provide helpful writing assistance even with a much smaller model. At our chosen model scale, with around 7 billion parameters operating, the models should be economically accessible to many health care providers or local service providers, making it easier to comply with local regulations and reducing possible dependence on external or foreign service providers.

Limitations

Due to the limited availability of compute time, we were unable to test all combinations of model and training modalities. LLaMA-2 was only trained using QLoRA, and LLaMA only using LoRA, limiting possible comparisons between the base models. Similarly, we only included the instruction-tuned variant of LLaMA-2 and cannot compare to the base model without instruction tuning.

The limited training of the BLOOM model probably affected its accuracy. However, this limitation highlights the importance of language alignment with the undertrained BLOOM model, outperforming both LLaMA models.

While our human raters evaluated our chosen model's outputs favorably, this happened in dedicated research settings. This means that the contextual information available to the human raters was restricted to the limited information included in the study data set. It remains to be shown whether AI writing assistance is still perceived as helpful in a real clinical setting or if the additional mental load caused by having to check the AI's output in a more complex case outweighs its usefulness.

Future Work

Moving forward, leveraging German clinical corpora for pretraining could provide useful in-domain semantics. Techniques such as CLP fine-tuning can enable the use of such data with lower compute requirements. In a future study, we will explore the use of our models in a real-world setting.

Conclusions

This work demonstrates the feasibility of localized AI assistance for clinical note generation using small-scale nonproprietary models. Our results highlight the advantages of language-specific model tuning, providing a promising direction for future research, especially when considering the significant speed and cost advantages of the language-specific model.

Abstract

Background: Artificial intelligence (AI), more specifically large language models (LLMs), holds significant potential in revolutionizing emergency care delivery by optimizing clinical workflows and enhancing the quality of decision-making. Although enthusiasm for integrating LLMs into emergency medicine (EM) is growing, the existing literature is characterized by a disparate collection of individual studies, conceptual analyses, and preliminary implementations. Given these complexities and gaps in understanding, a cohesive framework is needed to comprehend the existing body of knowledge on the application of LLMs in EM.

Objective: Given the absence of a comprehensive framework for exploring the roles of LLMs in EM, this scoping review aims to systematically map the existing literature on LLMs' potential applications within EM and identify directions for future research. Addressing this gap will allow for informed advancements in the field.

Methods: Using PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) criteria, we searched Ovid MEDLINE, Embase, Web of Science, and Google Scholar for papers published between January 2018 and August 2023 that discussed LLMs' use in EM. We excluded other forms of AI. A total of 1994 unique titles and abstracts were screened, and each full-text paper was independently reviewed by 2 authors. Data were abstracted independently, and 5 authors performed a collaborative quantitative and qualitative synthesis of the data.

Results: A total of 43 papers were included. Studies were predominantly from 2022 to 2023 and conducted in the United States and China. We uncovered four major themes: (1) clinical decision-making and support was highlighted as a pivotal area, with LLMs playing a substantial role in enhancing patient care, notably through their application in real-time triage, allowing early recognition of patient urgency; (2) efficiency, workflow, and information management demonstrated the capacity of LLMs to significantly boost operational efficiency, particularly through the automation of patient record synthesis, which could reduce administrative burden and enhance patient-centric care; (3) risks, ethics, and transparency were identified as areas of concern, especially regarding the reliability of LLMs' outputs, and specific studies highlighted the challenges of ensuring unbiased decision-making amidst potentially flawed training data sets, stressing the importance of thorough validation and ethical oversight; and (4) education and communication possibilities included LLMs' capacity to enrich medical training, such as through using simulated patient interactions that enhance communication skills.

Conclusions: LLMs have the potential to fundamentally transform EM, enhancing clinical decision-making, optimizing workflows, and improving patient outcomes. This review sets the stage for future advancements by identifying key research areas: prospective validation of LLM applications, establishing standards for responsible use, understanding provider and patient perceptions, and improving physicians' AI literacy. Effective integration of LLMs into EM will require collaborative efforts and thorough evaluation to ensure these technologies can be safely and effectively applied.

Introduction

Background

Emergency medicine (EM) is at an inflection point. With increasing patient volumes, decreasing staff availability, and rapidly evolving clinical guidelines, emergency providers are overburdened and burnout is significant [1]. While the role of artificial intelligence (AI) in enhancing emergency care is increasingly recognized, the emergence of large language models (LLMs) offers a novel perspective. Previous reviews have systematically categorized AI applications in EM, focusing on diagnostic-specific and triage-specific branches, emphasizing diagnostic prediction and decision support [2-5]. This review aims to build upon these foundations by exploring the unique potential of LLMs in EM, particularly in areas requiring complex data processing and decision-making under time constraints.

An LLM is a deep learning–based artificial neural network, distinguished from traditional machine learning models by its training on vast amounts of textual data. This enables LLMs to recognize, translate, predict, or generate text or other content [6]. Characterized by transformer architecture and the ability to encode contextual information using several parameters, LLMs allow for nuanced understanding and application across a diverse range of topics. Unlike traditional AI models, which often rely on structured data and predefined algorithms, LLMs are adept at interpreting unstructured text data. This feature makes them particularly useful in tasks such as real-time data interpretation, augmenting clinical decision-making, and enhancing patient engagement in clinical settings. For instance, LLMs can efficiently sift through electronic health records (EHRs) to identify critical patient histories and assist clinicians in interpreting multimodal diagnostic data. In addition, they can serve as advanced decision support tools in differential diagnosis, enhancing the quality of care while reducing the cognitive load and decision fatigue for emergency providers. Furthermore, the content generation ability of LLMs, ranging from technical computer code to essays and poetry, demonstrates their versatility and exceeds the functional scope of traditional machine learning models in terms of content creation and natural language processing.

Importance

While interest in applying LLMs to EM is gaining momentum, the existing body of literature remains a patchwork of isolated studies, theoretical discussions, and small-scale implementations. Moreover, existing research often focuses on specific use cases, such as diagnostic assistance or triage prioritization, rather than providing a holistic view of how LLMs can be integrated into the EM workflow. Conclusions based on other forms of machine learning are not readily translatable to LLMs. This fragmented landscape makes it challenging for emergency clinicians, who are already burdened by the complexities and pace of their practice, to discern actionable insights or formulate a coherent strategy for adopting these technologies. Despite the promise shown by several models, such as ChatGPT-4 (OpenAI) or Med-PaLM 2 (Google AI), the absence of standardized metrics for evaluating their clinical efficacy, ethical use, and long-term sustainability leaves researchers and clinicians navigating an uncharted territory. Consequently, the potential for LLMs to enhance emergency medical care remains largely untapped and poorly understood.

Goals of This Review

In light of these complexities and informational disparities, our study undertakes a crucial step to consolidate, assess, and contextualize the fragmented knowledge base surrounding LLMs in EM. Through a scoping review, we aim to establish a foundational understanding of the field's current standing, from technological capabilities to clinical applications and ethical considerations. This synthesis serves a dual purpose: first, to equip emergency providers with a navigable map of existing research and, second, to identify critical gaps and avenues for future inquiry. As EM increasingly embraces technological solutions for its unique challenges, our goal is to provide clarity to the responsible and effective incorporation of LLMs into clinical practice.

Methods

Overview

We adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist [7] and used the scoping review methodology proposed by Arksey and O'Malley [8] and furthered by Levac et al [9]. This included the following steps: (1) identifying the research question; (2) identifying relevant studies; (3) selecting studies; (4) charting the data; (5) collating, summarizing, and reporting the results; and (6) consultation. Our full review protocol is published elsewhere [10].

Identifying the Research Question

The overall purpose of this review was to map the current literature describing the potential uses of LLMs in EM and to identify directions for future research. To achieve this goal, we aimed to answer the primary research question: "What are the current and potential uses of LLMs in EM described in the literature?" We chose to explicitly focus on LLMs as this subset of AI is rapidly developing and generating significant interest for potential applications.

Identifying Relevant Studies

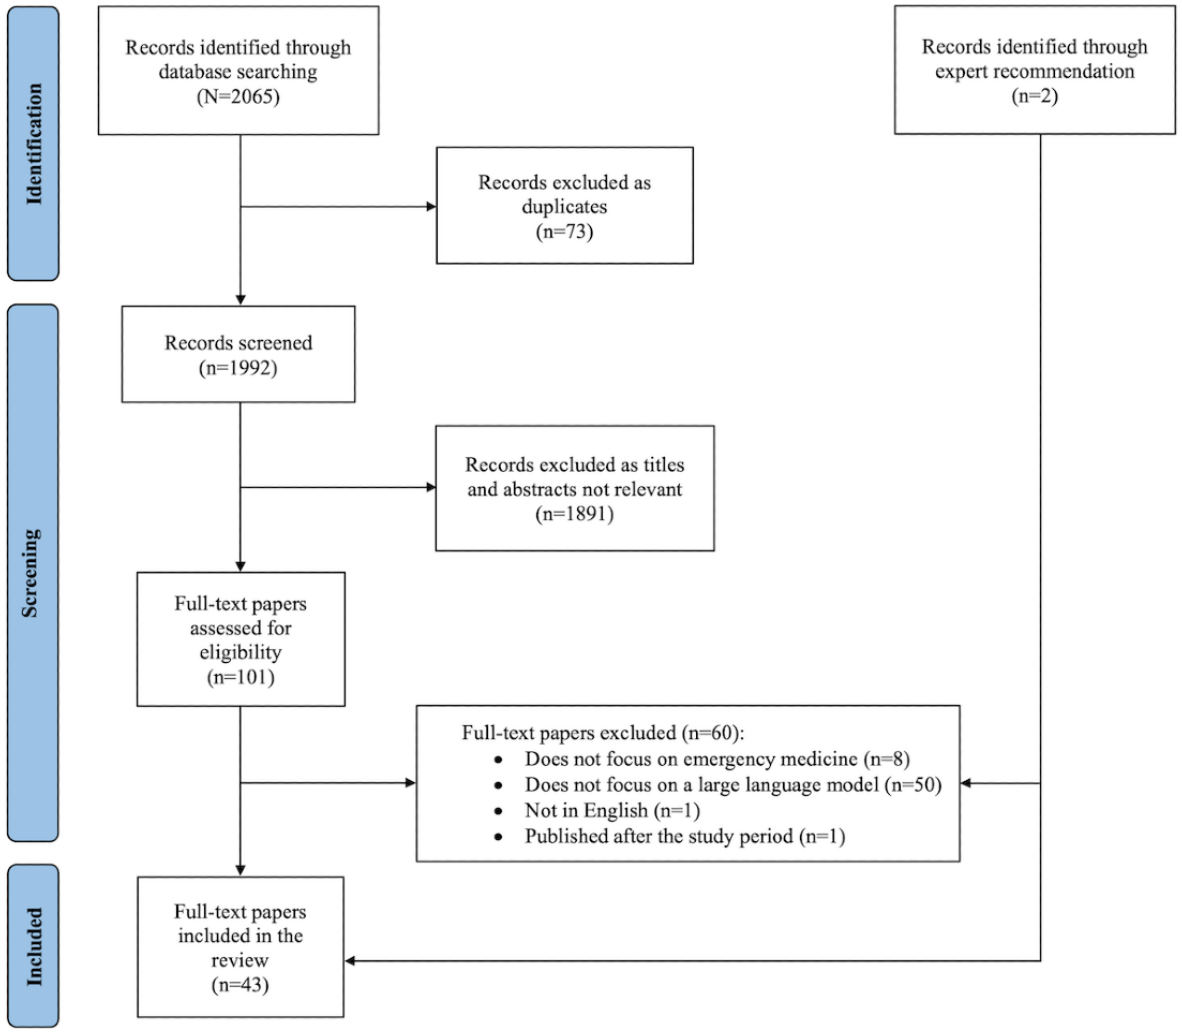
In August 2023, we searched Ovid MEDLINE, Embase, Web of Science, and Google Scholar for potential citations of interest. We limited our search to papers published after January 2018 as the Bidirectional Encoder Representations from Transformers (BERT; Google) model was introduced that year and considered by many to be the first in the contemporary class of LLMs [11]. Our search strategy (Multimedia Appendix 1), created in consultation with a medical librarian, combined keywords and MeSH (Medical Subject Headings) terms related to LLMs and EM. We reviewed the bibliographies of identified studies for potential missed papers.

Study Selection

Citations were managed using Covidence web-based software (Veritas Health Innovation). Manuscripts were included if they discussed the use of an LLM in EM, including applications in the emergency department (ED) and prehospital and periadmission settings. Furthermore, we included use cases related to public health, disease monitoring, or disaster preparedness as these are relevant to EDs. We excluded studies that used other forms of machine learning or natural language processing that were not LLMs and studies that did not clearly relate to EM. We also excluded cases where the only use of an LLM was in generating the manuscript without any additional commentary.

Two investigators (CP and CR) independently screened 100 abstracts, and the interrater reliability showed substantial agreement (κ=0.75). The remaining abstracts were screened by 1 author (CP), who consulted with a second author as needed for clarification regarding inclusion and exclusion criteria. All papers meeting the initial criteria were independently reviewed in full by 2 authors (CP and CR). Studies determined to meet the eligibility criteria by both reviewers were included in the analysis. Discrepancies were resolved by consensus and with the addition of a third reviewer (NA) if needed. Our initial search strategy identified 2065 papers, of which 73 (3.54%) were duplicates, resulting in 1992 (96.46%) papers for screening (Figure 1). Of the 1992 papers, 1891 (94.93%) were excluded based on the title or abstract. In total, 5.07% (101/1992) of the papers were reviewed in full, and 2.11% (42/1992) of the papers were found to meet the study inclusion criteria. During manuscript review, 2 additional papers were brought to our attention by experts, and 1 of these met the inclusion criteria, bringing the total number of included papers to 43.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of search and screening for large language models in emergency medicine.



Charting the Data

Data abstraction was independently conducted using a structured form to capture paper details, including the author, year of publication, study type, specific study population, study or paper location, purpose, and main findings. Data to address our primary research question was iteratively abstracted from the papers as our themes emerged, as explained in the subsequent sections.

Collating, Summarizing, and Reporting the Results

We synthesized and collated the data, performing both a quantitative and qualitative analysis. A descriptive summary of the included studies was created. Then, we used the methodology proposed by Braun and Clarke [12] to conduct a thematic analysis to address our primary research question. Five authors (CP, CR, AC, NA, and RR) independently familiarized themselves with and generated codes for a purposively diverse selection of 10 papers, focusing on content that suggested possible uses for LLMs in EM. The group met to discuss preliminary findings and refine the group's approach. Individuals then independently aggregated codes into themes. These themes were reviewed and refined as a group. Then, 2 authors (CP and CR) reviewed the remaining manuscripts for any additional themes and data that supported or contradicted our existing themes. These data were used to refine themes through group discussion. Our analysis included a discussion and emphasis on the implications and future research directions for the field, based on the guidance from Levac et al [9].

Consultation

To ensure our review accurately characterized the available knowledge and that our interpretations of it were correct, we consulted with external emergency physicians with topic expertise in AI. We incorporated feedback as appropriate. For example, we more completely defined LLMs for clarity and included a table describing common models (Table 1). Our findings and recommendations were endorsed by our consultants.

Table 1. Large language models reported in the identified literature.

Model	Interface	Model size (parameters)	Developer	Year of release
GPT-3.5 Turbo	ChatGPT	175 billion [13]	OpenAI	2022
GPT-4	ChatGPT	Approximately 1.8 trillion (estimated) [14]	OpenAI	2023
Pathways Language Model	Bard	540 billion [15]	Google AI[a]	2023
Embeddings from Language Model	Full model available	93.6 billion [16]	Allen Institute for AI	2018
Bidirectional Encoder Representations from Transformers	Full model available	110 million and 340 million [17]	Google	2018

[a]AI: artificial intelligence.

Results

Overview

Most identified studies (29/43, 67%) were published in 2023. Of the 43 studies, 14 (33%) were conducted in the United States, followed by 6 (14%) in China, 4 (9%) in Australia, 3 (7%) each in Taiwan and France, and 2 (5%) each in Singapore and Korea. Several other individual studies (5/43, 12%) were from various countries (Table 2).

In terms of study type, 40% (17/43) of the papers were methodology studies; 40% (17/43) were case studies; 16% (7/43) were commentaries; and 2% (1/43) each of a case report, qualitative investigation, and retrospective cross-sectional study. In total, 58% (25/43) of these studies addressed the ED setting specifically, followed by 14% (6/43) addressing the prehospital setting and 14% (6/43) addressing other non-ED hospital settings. In total, 7% (3/43) of the studies focused on using LLMs for the public, 5% (2/43) focused on using them for social media analysis, and 2% (1/43) focused on using them for research applications. LLMs used in the reviewed papers (Table 1) included versions of GPT (OpenAI; eg, ChatGPT, GPT-4, and GPT-2), Pathways Language Model (Bard; Google AI), Embeddings from Language Model, XLNet, and BERT (Google; eg, BioBERT, ClinicalBERT, and decoding-enhanced BERT with disentangled information).

We identified four major themes in our analysis: (1) clinical decision-making and support; (2) efficiency, workflow, and information management; (3) risks, ethics, and transparency; and (4) education and communication. Major themes, subthemes, and representative quotations are presented in Table 3.

Table 2. Summary of included studies and identified themes (N=43).

Study	Country	Study type	Purpose	Setting and context	Large language models used	Sample size	Themes
Xu et al [18], 2020	France	Methodology	Classification of visits into trauma and nontrauma based on ED[a] notes	ED	GPT-2 (OpenAI)	16,1930 notes	CDMS[b] and EWIM[c]
Wang et al [19], 2020	China	Retrospective cross-sectional study	Sentiment analysis of social media posts related to COVID-19	Social media	BERT[d] (Google)	99,9978 posts	EWIM
Chen et al [20], 2020	Taiwan	Methodology	Diagnosis identification from discharge summaries	Inpatient	BERT and BioBERT	25,8850 discharge diagnoses	EWIM
Chang et al [21], 2020	United States	Methodology	Categorize free-text ED chief complaints	ED	BERT and Embeddings from Language Model	2.1 million adult and pediatric ED visits	CDMS and EWIM
Wang et al [22], 2021	Singapore	Methodology	Summarize EMS[e] reports for clinical audits	EMS and prehospital	BERT	58,898 ambulance incidents	EWIM
Gil-Jardiné et al [23], 2021	France	Methodology	Classify content of EMS calls during the COVID-19 pandemic	EMS and prehospital	GPT-2	888,469 calls (training), 39,907 calls (validation), and 254,633 calls (application)	EWIM
Shung et al [24], 2021	United States	Methodology	Identify patients with gastrointestinal bleeding from ED triage and ROS data	ED	BERT	7144 cases	CDMS
Tahayori et al [25], 2021	Australia	Methodology	Predict patient disposition from ED triage notes	ED	BERT	249,532 ED encounters	CDMS and EWIM
Kim et al [26], 2021	South Korea	Case study	Assign triage severity to simulated cases	ED	BERT	762 cases	CDMS
Wang et al [27], 2021	China	Methodology	Predict diagnosis and appropriate hospital team from medical record	Prehospital	BERT and ClinicalBERT	198,000 patient records	EWIM
McMaster et al [28], 2021	Australia	Methodology	Identify adverse drug events from discharge summaries	Inpatient	BERT (ClinicalBERT and DeBERTa[f])	861 discharge summaries	EWIM
Chen et al [29], 2021	Taiwan	Methodology	Classify electronic health record data into disease presentations	ED	BERT	1,040,989 ED visits and 305,897 NHAMCS[g] samples	EWIM
Drozdov et al [30], 2021	United Kingdom	Methodology	Generate annotations for CXRs[h] to train model to identify COVID-19 cases	ED	BERT (to generate image annotations)	214,042 CXRs	CDMS
Zhang et al [31], 2022	China	Methodology	Classify EMS cases into disease categories	EMS and prehospital	BERT	3500 records	EWIM
Pease et al [32], 2023	United States	Qualitative investigation	Determine the attitudes of clinicians toward using AI[i] in suicide screening	ED	N/A[j]	3 clinicians	CDMS and RET[k]
Chae et al [33], 2023	United States	Methodology	Predict ED visits and hospitalizations for patients with heart failure	Prehospital (home health care)	BERT (BioclinicalBERT)	9362 patients	CDMS and RET

Study	Country	Study type	Purpose	Setting and context	Large language models used	Sample size	Themes
Huang et al [34], 2023	United States	Methodology	Predict nonaccidental trauma	ED	BERT	244,326 trajectories (test) and 2,077,852 trajectories (validation)	CDMS
Chen et al [35], 2023	Taiwan	Methodology	Predict critical outcomes from ED data	ED	BERT (comparator)	171,275 ED visits	CDMS
Smith et al [36], 2023	Australia	Case study	Determine model performance on EM[l] accreditation examination	ED	GPT-3.5 (OpenAI), GPT-4 (OpenAI), Bard-PaLM[m], Bard-PaLM 2, and Bing (Microsoft Corporation)	240 questions	CDMS, RET, and EC[n]
Gupta et al [37], 2023	United States	Case study	Determine the ability of the model to correctly diagnose simulated cases	ED	ChatGPT	20 cases	CDMS, RET, and EC
Abavisani et al [38], 2023	Iran	Commentary	Potential uses of the model in emergency surgery	Emergency surgery	ChatGPT	N/A	CDMS and RET
Rahman et al [39], 2023	United States	Methodology	Identify cases and patterns in unstructured EMS data	EMS and prehospital	BERT (BioBERT and ClinicaBERT)	40,000 EMS narratives	EWIM
Lam and Au [40], 2023	China	Case study	Evaluate model response to lay questions regarding stroke	General public	ChatGPT	3 questions	EC
Bushuven et al [41], 2023	Germany	Case study	Use of the model to advise parents during pediatric emergencies	General public	ChatGPT and GPT-4	22 cases	CDMS, RET, and EC
Ahn [42], 2023	South Korea	Case study	Use of model to provide a lay-person instruction for cardiopulmonary resuscitation	General public	ChatGPT	3 questions	RET and EC
Preiksaitis et al [43], 2023	United States	Commentary	Potential limitations to using models for clinical charting	General medicine	ChatGPT	N/A	EWIM and RET
Barash et al [44], 2023	Israel	Case study	Use of model to aid radiology referral in the ED	ED	GPT-4	40 cases	CDMS and RET
Dahdah et al [45], 2023	United States	Case study	Use of model to triage based on chief complaints	ED	ChatGPT	30 questions	CDMS and RET
Gottlieb et al [46], 2023	United States	Commentary	Discuss advantages and disadvantages of using the model in research	ED and research	ChatGPT	N/A	RET and EC
Babl and Babl [47], 2023	Australia	Case study	Determine the ability of the model to generate a scientific abstract	Research	ChatGPT	1 abstract	RET and EC
Chen et al [48], 2023	China	Methodology	Use the model to study the functioning of web-based self-organizations	Social media	BERT	47,173 users	EWIM
Bradshaw [49], 2023	United States	Case study	Determine the ability of the model to generate discharge instructions	ED	ChatGPT	1 set of discharge instructions	EWIM and EC
Cheng et al [50], 2023	China	Commentary	Potential uses for the model in surgical management	ED	ChatGPT	N/A	CDMS and EWIM

Study	Country	Study type	Purpose	Setting and context	Large language models used	Sample size	Themes
Rao et al [51], 2023	United States	Case study	Test the model performance in several clinical scenarios	General medicine	ChatGPT	36 clinical vignette	EWIM and EC
Brown et al [52], 2023	Jersey	Case report and commentary	Discuss possible model uses in supporting decision-making and clinical care	ED	ChatGPT	1 case	CDMS and EWIM, RET and EC
Bhattaram et al [53], 2023	India	Case study	The ability of the model to triage clinical scenarios	ED	ChatGPT	5 scenarios	CDMS, RET and EC
Webb [54], 2023	United States	Case study	The ability of the model to be used as a communication skill trainer	ED	ChatGPT-3.5	1 case	RET and EC
Hamed et al [55], 2023	Qatar	Case study	The ability of the model to synthesize clinical practice guidelines for diabetic ketoacidosis	General medicine	ChatGPT	3 guidelines	EWIM and RET
Altamimi et al [56], 2023	Saudi Arabia	Case study	The ability of the model to recommend management in snakebites	ED	ChatGPT	9 questions	CDMS and RET
Gebrael et al [57], 2023	United States	Case study	Predict the disposition of patients with metastatic prostate cancer based on ED documentation	ED	ChatGPT-4	56 patients	CDMS, EWIM, and RET
Sarbay et al [58], 2023	Turkey	Case study	Use of the model for patient triage using clinical scenarios	ED	ChatGPT	50 case scenarios	CDMS, EWIM, and RET
Okada et al [59], 2023	Singapore	Commentary	Discuss possible applications for the model in resuscitation	ED or intensive care unit	GPT-3 and GPT-4	N/A	CDMS, EWIM, and RET
Chenais et al [60], 2023	France	Commentary	Describe the landscape of AI-based applications currently in use in EM	ED	BERT and GPT-2	N/A	CDMS, EWIM, and RET

[a]ED: emergency department.

[b]CDMS: clinical decision-making and support.

[c]EWIM: efficiency, workflow, and information management.

[d]BERT: Bidirectional Encoder Representations from Transformers.

[e]EMS: emergency medical service.

[f]DeBERTa: decoding-enhanced Bidirectional Encoder Representations from Transformers with disentangled information.

[g]NHAMCS: National Hospital Ambulatory Medical Care Survey.

[h]CXR: chest x-ray.

[i]AI: artificial intelligence.

[j]N/A: not applicable.

[k]RET: risks, ethics, and transparency.

[l]EM: emergency medicine.

[m]PaLM: Pathways Language Model.

[n]EC: education and communication.

Table 3. Major themes identified, associated subthemes, and representative quotations.

Major theme and subtheme	Representative quotation
Theme 1: clinical decision-making and support	
Prediction	"Machine-learning and natural language processing can be together applied to the ED triage note to predict patient disposition with a high level of accuracy." [25]
Treatment recommendations	"An under-explored use of AI in medicine is predicting and synthesizing patient diagnoses, treatment plans, and outcomes." [51]
Symptom checking and self-triage	"To our knowledge, this is the first work to investigate the capabilities of ChatGPT and GPT-4 on PALS core cases in the hypothetical scenario that laypersons would use the chatbot for support until EMS arrive." [41]
Classification	"In this proof-of-concept study, we demonstrated the process of developing a reliable NER [named-entity recognition] model that could reliably identify clinical entities from unlabeled paramedic free text reports." [22]
Triage	"...this preliminary study showed the potential of developing an automatic classification system that directly classifies the KTAS [triage] level and symptoms from the conversations between patients and clinicians." [26]
Screening	"We showed that PABLO, a pretrained, domain-adapted outcome forecasting model, can be used to predict both first and recurrent instances of NAT [non-accidental trauma]." [34]
Differential diagnosis building	"These results suggest that ChatGPT has a high level of accuracy in predicting top differential diagnoses in simulated medical cases." [37]
Decision support	"...ChatGPT-4 demonstrates encouraging results as a support tool in the ED. LLMs such as ChatGPT-4 can facilitate appropriate imaging examination selection and improve radiology referral quality." [44]
Clinical augmentation	"AI can serve as an adjunct in clinical decision making throughout the entire clinical workflow, from triage to diagnosis to management." [51]
Theme 2: efficiency, workflow, and information management	
Unstructured data extraction	"The proposed model will provide a method to further extract the unstructured free-text portions in EHRs to obtain an abundance of health data. As we enter the forefront of the artificial intelligence era, NLP deep-learning models are well under development. In our model, all medical free-text data can be transformed into meaningful embeddings, which will enhance medical studies and strengthen doctors' capabilities." [20]
Charting efficiency	"While notes have become more structured and burdensome, the field of data science has rapidly advanced. With such powerful tools available, it seems reasonable to explore their use to automate seemingly mundane tasks such as writing clinical notes. Generative AI models like ChatGPT could be developed to populate notes for patients based on massive amounts of data contained in current EHRs." [43]
Summarization or synthesis	"Although ChatGPT demonstrates the potential for the synthesis of clinical guidelines, the presence of multiple recurrent errors and inconsistencies underscores the need for expert human intervention and validation." [55]
Pattern identification	"This embedding system can be used as a disease retrieval model, which encodes queries and finds the most relevant patients and diseases. In the retrieval demonstration, the query subject was a 53-year-old female patient who suffered from abdominal pain in the upper right quarter to right flanks for 3 days and noticed dizziness and tarry stool on the day of the interview. Through the retrieval, we obtained the five most similar patients with similar symptoms that were possibly related to different diseases." [29]
Workflow efficiency	"Integration of LLMs with existing EHR (with appropriate regulations) could facilitate improved patient outcomes and workflow efficiency." [51]
Theme 3: risks, ethics, and transparency	
Oversight	"Generally speaking, the Ethics Guideline for Trustworthy AI suggested seven key requirements including human agency and oversight, technical robustness and safety, privacy and data governance, transparency, diversity, nondiscrimination and fairness, environmental and societal well-being, and accountability." [59]
Fairness	"[Use of LLMs] could also increase equity by assisting researchers with disabilities such as dyslexia." [46]
Ethical and legal responsibilities	"Legal and ethical implications are associated with using AI in clinical practice, particularly regarding privacy and informed consent issues." [52]

Major theme and subtheme	Representative quotation
Reliance on input data	"...data quality can affect the performance of LLMs and NLP techniques applied to the task of extracting and summarizing clinical guidelines." [55]
Overreliance	"Overreliance on AI systems and the assumption that they are infallible or less fallible than human judgment–automation bias–can lead to errors." [52]
Explainability and transparency	"Creating a clinician-interpretable risk prediction model is essential for clinical adoption and implementation of models because it builds trust in decisionmakers, enables error identification and correction in the model, and facilitates integration into clinical workflows." [33]
Bias propagation	"A risk of bias is possible if the initial training data is not representative of the study population. There is a possibility of compounding of bias and error, leading to incorrect assessment." [53]
Human bias reduction	"AI tools can offer a near real-time interpretation of medical imaging and clinical decision support and may identify latent patterns that may not be evident to clinicians. While humans are prone to cognitive biases, such as prejudice or fatigue, which can hinder their decision-making process, AI can mitigate these biases and improve accuracy in patient care." [52]
Accuracy	"LLMs may not be exposed to the broader range of literature (particularly if studies are located behind paywalls), which may limit the comprehensiveness or accuracy of the data." [46]
Theme 4: education and communication	
Clinician education	"While LLM performance in medical examinations may initially seem to be little more than a novelty, their ability to generate coherent and well-explained content hints at other potential uses. As a medical education tool they could potentially help generate practice questions, design mock examinations or provide additional explanations for complex concepts." [36]
Communication	"Although in its infancy, AI chatbot use has the potential to disrupt how we teach medical students and graduate medical residents communication skills in outpatient and hospital settings." [54]
Content generation	"ChatGPT or similar programmes, with careful review of the product by authors, may become a valuable scientific writing tool." [47]
Research assistance	"Conversational AI has some clear benefits and disadvantages. As the technology further evolves, it is incumbent on the scientific community to determine how best to incorporate LLMs into the research and publication process with attention to scientific integrity, adherence to ethical principles, and existing copyright laws." [46]

Theme 1: Clinical Decision-Making and Support

The first theme we identified is clinical decision-making and support. LLMs have been used or proposed for applications such as providing advice to the public before arrival; aiding in triage as patients arrive at the ED; or augmenting the activities of physicians as they provide care, either through supporting diagnostics or predicting patient resource use.

Several applications focused on advising the public and aiding in symptom checking, self-triage, and occasionally advising first-aid before the arrival of emergency medical services. These included counseling parents during potential pediatric emergencies, recognizing stroke, or providing advice during potential cardiac arrests [40-42]. Wang et al [27] proposed a model that could potentially help patients navigate the complexities of the health care system in China and present to the correct medical setting for the care they need.

Furthermore, LLMs have the potential to efficiently screen patients for important outcomes, such as pediatric patients at risk for nonaccidental trauma, suicide risk, or COVID-19 infection [30,32,34]. These can be implemented based on data in the medical record or as clinical data are obtained in real time.

Early identification of patient risks could help physicians more rapidly identify important diagnoses. Several studies discussed implementations of LLMs that work in conjunction with physicians while caring for patients in the ED [50,51]. Brown et al [52] discuss the potential role of these models in overcoming cognitive biases and reducing errors. These models could be used in developing a differential diagnosis, recommending imaging studies, providing treatment recommendations, or interpreting clinical guidelines [37,44,55,56].

Several studies centered on predicting outcomes such as presentation to the ED, hospitalization, intensive care unit admission, or in-hospital cardiac arrest [25,33,35,57]. Applications of LLMs in the triage process could potentially identify patients who require immediate attention or patients at a high risk of certain diagnoses, such as gastrointestinal bleeding [24,26,53,58,60].

Theme 2: Efficiency, Workflow, and Information Management

The second theme identified is information management, workflow, and efficiency. LLMs show great promise in increasing the usability of data available in the EHR. Interactions with the EHR take up a substantial amount of physician time, and it is often difficult to identify crucial information during critical times [43]. LLMs could serve a variety of information management functions. They could be used to perform audits for quality improvement purposes, identify potential adverse events such as drug interactions, anticipate and monitor public health emergencies, and assist with information entry during

the clinical encounter [19,20,22,23,28,31,39,43,49]. LLMs developed and trained on data from the ED could quickly identify similar patient presentations, recognize patterns, and extract important information from unstructured text [18,20,21,60].

Some authors suggest that LLMs can enhance care throughout the entire EM encounter [30,50-52]. LLMs could potentially be used as digital adjuncts for clinical decision-making because they could generate differentials, predict final diagnoses, offer interpretations of imaging studies, and suggest treatment plans [30,51,52,61]. They may mitigate human cognitive biases and address human factors (eg, time constraints, frequent task switching, high cognitive load, constant interruptions, and decision fatigue) that predispose emergency physicians to error [52].

The flexibility and versatility of the LLMs offer particular benefits to EM practice. The diverse ways in which these models can aid throughout the entire clinical workflow could help physicians process large quantities of complex clinical data, mitigate cognitive biases, and deliver relevant information in a comprehensible format [30,51,52,61]. By streamlining these burdensome tasks, LLMs could help improve the efficiency of care for the high volume of patients the physicians routinely see in the ED.

Theme 3: Risks, Transparency, and Ethics

Despite the potential for advancement and improvement in the care that EM physicians can provide through the inclusion of LLMs in practice, several issues limit their implementation into practice at this time.

The most often discussed risk, mentioned in 11 (26%) of the 43 papers, is the reliability of model responses and the potential for erroneous results [20,21,28-30,44,51,53,55,56,59]. These output errors often result from inaccuracies in the training data, which are most commonly gathered from the internet and unvetted for reliability. Sources of inaccurate responses may be identified by examining the training material, but other errors due to data noise, mislabeling, or outdated information may be harder to detect [21,28,30,56]. Similarly, biases in training data can be propagated to the model, leading to inaccurate or discriminatory results [51,53,57,60,62]. In medical applications, the consequences of the errors can be significant, and even small errors could lead to adverse outcomes [51].

Understanding and mitigating errors in LLMs is challenging due to issues with transparency and reproducibility of model outputs [52-54,59,62]. Better understanding among clinicians of the algorithms and statistical methods used by LLMs is a suggested method to ensure cautious use [52]. Concentrating on making models more explainable or transparent is another potential approach [62]. However, the degree to which this will be feasible, given the complexity of these models, remains to be determined.

Patient and data privacy is another clearly articulated risk of using these models in the clinical environment [35,52,53]. There are some proposed methodologies using unsupervised methods that can train the models with limited access to sensitive information; however, these require further exploration [35]. Patient attitudes and willingness to allow models access to their health information for training and how to address disclosure of this use have not been extensively discussed. Finally, the legal and ethical implications of using LLM output to guide patient care is an often-mentioned concern [52,53,59]. How the responsibility for patient care decisions is distributed if LLMs are used to guide clinical decisions is yet to be determined.

Theme 4: Education and Communication

LLMs offer several opportunities for education and communication. First, several papers noted that the successful integration of LLMs into clinical practice will require physicians to understand the underlying algorithms and statistical methods used by these models [52,59]. There is a need for dedicated educational programs on AI in medicine at all levels of medical education to ensure that the solutions developed align with the clinical environment and address the unique challenges of working with clinical data [34,51,63].

In terms of clinical education, several studies have demonstrated reasonable performance of LLMs on standardized tests in medicine, which could indicate the potential for these models to develop study materials [36]. In addition, these models may be able to help physicians communicate with and educate the patients. Dahdah et al [45] used ChatGPT to answer several common medical questions in easy-to-understand language, suggesting the ability to enhance physician responses to patient queries. Webb [54] demonstrated the use of ChatGPT to simulate patient conversation and provide feedback to a physician learning how to break bad news.

Patient education may be facilitated via these models without physician input as well. As discussed in the previous sections, several authors described applications designed to educate patients during emergencies before they arrived in the ED [27,40-42]. Finally, LLMs could be used to aid in knowledge dissemination. Gottlieb et al [46] and Babl and Babl [47] describe potential applications for LLMs in research and scientific writing. They highlight potential benefits to individuals who struggle with English or have challenges with writing or knowledge synthesis. In addition, models may be used to translate scientific papers more rapidly. However, the use of these models to generate scientific papers raises concerns regarding the potential for academic dishonesty [46,47].

Discussion

Principal Findings

Our review aligns with the growing body of literature emphasizing the great potential for AI in EM, particularly in areas such as time-sensitive decision-making and managing high-volume data [2-5,60]. However, our focus on LLMs and their unique capabilities extends the current understanding of AI applications in EM. Although several specific applications and limitations have been reported and suggested in the literature, our analysis identified 4 major areas of focus for LLMs in EM: clinical decision support, workflow efficiency, risks, ethics, and education. We propose these topics as a framework for understanding emerging implementations of LLMs and as a guide to inform future areas of investigation.

At their core, LLMs and their associated natural language processing techniques offer a way to organize and engage with vast amounts of unstructured text data. Depending on how they are trained and used, they can be operationalized to make predictions or identify patterns, which gives rise to most of our identified applications. Most commercially available LLMs, such as ChatGPT, are trained on massive volumes of text gathered from the internet and then optimized for conversational interaction [64]. This ability to access a breadth of general knowledge and the resulting wide applicability have contributed to the increased use of LLMs by professionals and the public across a variety of fields [65]. As these models become more ubiquitous, there is potential for their use across the care continuum. They could not only support clinical care but also provide an opportunity to offer advice to the public regarding medical concerns. Several papers (3/34, 9%) in our review identified the feasibility of using LLMs to provide first-aid instructions and offer decision support to potential patients seeking care [40-42].

Preliminary work suggests that dedicated training can enhance the ability of these models to make triage recommendations, but prospective implementation has not been tested [27]. LLMs could certainly aid patients in self-triage or with basic medical questions; nevertheless, how this can be effectively and safely implemented needs further exploration, especially with concerns regarding the accuracy of outputs. Possibilities to improve outputs include additional dedicated training of the models to align with the medical and emergency settings to improve their reliability and accuracy. These context-specific models could be equipped with information on the local health care system to help patients identify available resources, schedule appointments, or activate emergency medical services.

In the ED, LLMs could increase workflow efficiency by rapidly synthesizing relevant information from a patient's medical record, structuring and categorizing chief complaint data, and assigning an emergency severity index level [18,21,26,45,53,58]. In addition, quickly accessing data from the medical record could improve the efficiency and thoroughness of chart review. A model's ability to identify subtle patterns in data could offer additional diagnostic support by recommending or interpreting laboratory and imaging studies [30,51,52,61]. By facilitating tasks such as information retrieval and synthesis, LLMs could reduce this burden for clinicians and minimize errors due to buried or disorganized data, potentially contributing to workflow efficiency. Furthermore, they may counteract human cognitive biases and fatigue when used to support clinical decisions [52]. Although some studies have demonstrated reasonable accuracy on focused use cases, further validation of any of these applications across diverse settings and patient populations is required. Thoughtful integration of LLMs has the potential to revolutionize EM by providing clinical decision support, improving situational awareness, and increasing productivity.

However, barriers to seamless implementation exist. As noted by several authors, erroneous outputs remain a concern, given the dependence on training data [28-30,35,51,53,55,56,59]. Information surrounding the most publicly available LLMs today is obscured across three important layers: (1) the underlying training data used—commonly reported to be publicly available data on the internet and from third-party licensed data sets, (2) the underlying architecture of the model—whose exact mechanisms are not always easy to discern, and (3) the intricacies of human-led fine-tuning—often done at the end of development to provide guardrails for output. These layers of obscurity make it difficult to troubleshoot the cause of any single erroneous output.

Regarding privacy and data rights, it is imperative to discuss and implement privacy-preserving methods for patient data. The use of techniques such as data anonymization, differential privacy, and federated learning are instrumental in safeguarding patient information. Data anonymization involves removing or modifying personal identifiers to prevent the association of data with individual patients. Differential privacy introduces randomness into the data or queries to ensure individual data points cannot be isolated [66]. Federated learning enables models to be trained against multiple decentralized devices or servers holding local data samples without exchanging them, thus enhancing privacy [67]. The specific ways in which LLMs will interface with other hospital information systems, such as the EHR, need further exploration, and careful integration is critical to address privacy concerns, especially given the sensitive nature of health care data.

Moreover, the ongoing discussions about the information used in these models underscore the need for continuous scrutiny [52,53,59]. In addition to privacy, the legal and ethical implications of AI-assisted health care require further exploration to establish robust oversight and accountability structures. Without a commitment to explainability and transparency, the use of *black box* LLMs may encounter resistance from clinicians.

Our review reveals several opportunities for future exploration and research. Perhaps the most important is effectively identifying problems that are best solved using LLMs in EM. Our review outlines several immediate areas of potential exploration, including improved communication, translation, and summarization of highly detailed and domain-specific knowledge for providers and patients, but further exploration and prospective validation of specific use cases is required. We expect the potential use cases in EM to grow as LLMs become increasingly complex and develop emergent properties–actions that are not explicitly programmed or anticipated. To bridge the *AI chasm* between innovations in the research realm and widespread adoption, these applications should be identified with significant input from providers in the clinical space who can uniquely identify areas of potential benefit. To accomplish this, a better understanding of the abilities and limitations of LLMs among physicians is needed to optimize their best use and ensure they are effectively implemented, and AI literacy is increasingly described as an essential competency for physicians [68]. We encourage the development of curricula and training programs designed for emergency physicians.

Given the black-box nature of LLMs, standardized frameworks and metrics for evaluation that are specific to health care use cases are needed to evaluate their performance and implementation effectively. These frameworks should encompass an understanding of both the technical capabilities

and constraints of a model, along with the human interaction aspects that affect its use. A crucial part of this assessment involves comparing the performance of LLMs to human proficiency, determining whether the objective is to replace or enhance tasks currently carried out by health care professionals. Thorough testing of models in real time, real-world scenarios is imperative before their deployment. The selection of patient- or provider-focused outcomes is essential, and the effectiveness of models should not be evaluated in isolation. Instead, it is crucial to assess the combined performance of the provider and AI system to ensure that models are effective and practical in real-world settings. Implementing and validating solutions should occur across diverse populations and care environments, with particular focus on cohorts underrepresented in the training data to mitigate potential harm from model biases [69]. Provider perspectives are essential, but equally important are patient perspectives about the use of LLMs in medicine. Impacts on physician-patient communication, patient concerns surrounding privacy, and attitudes toward AI-generated recommendations must be further explored. Collaboration between all relevant stakeholders who develop or will be impacted by LLMs for clinical medicine is essential for developing models that can be used effectively, equitably, and safely.

Limitations

This scoping review has some limitations worth noting. First, we restricted our search to papers published after 2018, when LLMs first emerged. While this captures the current era of LLMs, earlier works relevant to natural language processing in EM may have been overlooked. In addition, despite searching 4 databases and consulting a medical librarian on the search strategy, some pertinent studies may have been missed, and given the rapidly evolving nature of this research area, there are certainly more studies that have emerged since our literature search [70]. However, our review establishes an initial foundation that can be built upon as the field continues to grow. Finally, in an effort to be maximally inclusive in our review, we did not include or exclude papers based on the quality of their evidence. Similarly, we did not make any quality determinations of our included studies. High-quality studies are required to make any determination regarding the efficacy of LLMs for the applications we described, and our review hopefully provides a framework to design these investigations.

Conclusions

This review underscores the transformative potential of LLMs in enhancing the delivery of emergency care. By leveraging their ability to process vast amounts of data rapidly, LLMs offer unprecedented opportunities to improve decision-making speed and accuracy, a critical component in the high-stakes, fast-paced EM environment. From the identified themes, it is evident that LLMs have the potential to revolutionize various aspects of emergency care, highlighting their versatility and the breadth of their applicability.

From the theme of clinical decision-making and support, LLMs can augment the diagnostic process, support differential diagnosis, and aid in the efficient allocation of resources. In the domain of efficiency, workflow, and information management, LLMs have shown promise in enhancing operational efficiencies, reducing the cognitive load on clinicians, and streamlining patient care processes. Regarding risks, ethics, and transparency, the review illuminates the need for meticulous attention to the accuracy, bias, and ethical considerations inherent in deploying LLMs in a clinical setting. Finally, in the realm of education and communication, LLMs' potential to facilitate learning and improve patient and provider communication signifies a paradigm shift in medical education and engagement.

The most urgent research need identified in this review is the development of robust, evidence-based frameworks for evaluating the clinical efficacy of LLMs in EM; addressing ethical concerns; ensuring data privacy; and mitigating potential biases in model outputs. There is a critical need for prospective studies that validate the utility of LLMs in real-world emergency care settings and explore the optimization of these models for specific clinical tasks. Furthermore, research should focus on understanding the best practices for integrating LLMs into the existing health care workflows without disrupting the clinician-patient relationship.

The successful integration of LLMs into EM necessitates a multidisciplinary approach involving clinicians, computer scientists, ethicists, patients, and policy makers. Collaborative efforts are essential to navigate the challenges of implementing AI technologies in health care, ensuring LLMs complement the clinical judgment of EM professionals and align with the overarching goal of improving patient care. The judicious application of LLMs has the potential to fundamentally redefine much of EM practice, ushering in a future where care is more accurate, efficient, and responsive to the needs of patients. Furthermore, by reducing the many burdens that currently encumber clinicians, these technologies hold the promise of restoring and deepening the invaluable human connections between physicians and their patients.

Abstract

Background: Chronic hepatitis B (CHB) imposes substantial economic and social burdens globally. The management of CHB involves intricate monitoring and adherence challenges, particularly in regions like China, where a high prevalence of CHB intersects with health care resource limitations. This study explores the potential of ChatGPT-3.5, an emerging artificial intelligence (AI) assistant, to address these complexities. With notable capabilities in medical education and practice, ChatGPT-3.5's role is examined in managing CHB, particularly in regions with distinct health care landscapes.

Objective: This study aimed to uncover insights into ChatGPT-3.5's potential and limitations in delivering personalized medical consultation assistance for CHB patients across diverse linguistic contexts.

Methods: Questions sourced from published guidelines, online CHB communities, and search engines in English and Chinese were refined, translated, and compiled into 96 inquiries. Subsequently, these questions were presented to both ChatGPT-3.5 and ChatGPT-4.0 in independent dialogues. The responses were then evaluated by senior physicians, focusing on informativeness, emotional management, consistency across repeated inquiries, and cautionary statements regarding medical advice. Additionally, a true-or-false questionnaire was employed to further discern the variance in information accuracy for closed questions between ChatGPT-3.5 and ChatGPT-4.0.

Results: Over half of the responses (228/370, 61.6%) from ChatGPT-3.5 were considered comprehensive. In contrast, ChatGPT-4.0 exhibited a higher percentage at 74.5% (172/222; $P<.001$). Notably, superior performance was evident in English, particularly in terms of informativeness and consistency across repeated queries. However, deficiencies were identified in emotional management guidance, with only 3.2% (6/186) in ChatGPT-3.5 and 8.1% (15/154) in ChatGPT-4.0 ($P=.04$). ChatGPT-3.5 included a disclaimer in 10.8% (24/222) of responses, while ChatGPT-4.0 included a disclaimer in 13.1% (29/222) of responses ($P=.46$). When responding to true-or-false questions, ChatGPT-4.0 achieved an accuracy rate of 93.3% (168/180), significantly surpassing ChatGPT-3.5's accuracy rate of 65.0% (117/180) ($P<.001$).

Conclusions: In this study, ChatGPT demonstrated basic capabilities as a medical consultation assistant for CHB management. The choice of working language for ChatGPT-3.5 was considered a potential factor influencing its performance, particularly in the use of terminology and colloquial language, and this potentially affects its applicability within specific target populations. However, as an updated model, ChatGPT-4.0 exhibits improved information processing capabilities, overcoming the language impact on information accuracy. This suggests that the implications of model advancement on applications need to be considered when selecting large language models as medical consultation assistants. Given that both models performed inadequately in emotional guidance management, this study highlights the importance of providing specific language training and emotional management strategies when deploying ChatGPT for medical purposes. Furthermore, the tendency of these models to use

disclaimers in conversations should be further investigated to understand the impact on patients' experiences in practical applications.

(JMIR Med Inform 2024;12:e56426) doi:10.2196/56426

KEYWORDS

chronic hepatitis B; artificial intelligence; large language models; chatbots; medical consultation; AI in health care; cross-linguistic study

Introduction

Chronic Hepatitis B: A Dual Burden on Patients and Society

Chronic hepatitis B (CHB) imposes significant economic and social burdens. In 2019, approximately 296 million people were affected by CHB, resulting in an estimated 820 thousand deaths [1]. The World Health Organization (WHO) noted that among those chronically infected with hepatitis B and C, about 20% or more would develop end-stage chronic liver disease, such as cirrhosis and hepatocellular carcinoma [2].

Hepatitis B virus (HBV) primarily spreads through blood contact, unprotected sexual intercourse, and mother-to-infant transmission. Effective management of chronic infection necessitates daily monitoring and self-care [3]. Nevertheless, the intricacy of regular monitoring, encompassing multiple tests, such as hepatitis B surface antigen (HBsAg), hepatitis B e-antigen (HBeAg), HBV-DNA, alanine transaminase (ALT), and fibrosis assessment, as endorsed by authoritative bodies in hepatitis B diagnosis and treatment, including the European Association for the Study of the Liver (EASL), presents hurdles to patient compliance [4]. Additionally, the prolonged, often lifelong, administration of antiviral medications contributes to further adherence issues [4,5]. Unique considerations for pregnant individuals and children add another layer of complexity, demanding targeted counseling and specialized management. This intricate management landscape not only burdens patients with emotional stress but also jeopardizes adherence to treatment regimens [6,7]. The complexity of CHB management requires personalized health care strategies, easing individual and societal burdens and emphasizing the importance of diverse health approaches.

ChatGPT as a Prospective Medical Assistant

Currently, artificial intelligence (AI) has become integral in the medical domain, particularly in medical research and clinical practice. Notably, according to Wani et al [8], traditional machine learning methodologies require the supervision of skilled individuals and structured input data, resulting in considerable resource-intensive processes. Recognizing the limitations of traditional approaches, Haug et al [9] proposed chatbots for capabilities in medical practice assistance.

ChatGPT-3.5, which was released in June 2020, underpins ChatGPT's emergence in AI-assisted medical applications. As a large language model (LLM), it shows potential for medical assistance [10], though challenges and concerns persist in its application within the field [11]. The functioning of LLMs involves predicting and generating a coherent and contextually relevant response based on preinput materials, necessitating training on massive amounts of diverse textual data. Various studies have explored ChatGPT's capacity to act as a virtual doctor or medical tutor for diagnosis or treatment [12].

The study by Gilson et al [13] revealed that ChatGPT performed well in medical knowledge assessments, demonstrating potential as a virtual medical tutor. Yeo et al [14] evaluated ChatGPT's performance in answering questions regarding cirrhosis and hepatocellular carcinoma. Most studies have compared its performance to that of real doctors or medical students, aiming to determine whether AI assistants could surpass human medical service providers. However, there are challenges and risks of employing ChatGPT in clinical practice, including the potential generation of plausible yet inaccurate information and ethical considerations [15]. According to these studies, LLMs could potentially assist in medical consulting and auxiliary diagnosis, as well as traditional medical research, treatment, and education, but there are still unidentified risks and problems.

ChatGPT-4.0, which was released on March 14, 2023, is an updated version of the ChatGPT model. Many researchers have compared the applications of ChatGPT-3.5 and ChatGPT-4.0 in medical practice [16-18]. In this research, we included ChatGPT-4.0 as a comparative model to further assess the application problem of this model.

Medical Assistance in Hepatitis B Management With Chinese as the Primary Language

Bearing the highest global burden of hepatitis B, China recorded over 90 million people living with CHB in 2017 [1,2]. Research has revealed troubling trends in treatment noncompliance for HBV in China, including challenges in preventing vertical transmission [19-21]. Beyond China, studies in various regions have highlighted the impact of factors like family income, employment, and patient gender on medical treatment compliance for CHB [22].

Physician encouragement is crucial for patient compliance with medication regimens [23]. Despite a rising number of medical doctors in China, there is a shortage of medical practitioners, including licensed physicians and physician assistants, who face high workloads and burnout rates [24-26]. While research has indicated that Chinese physicians generally adhere to hepatitis B guidelines [27], medical errors due to workload demands could undermine intended impacts on patient compliance [26]. Amidst these challenges, exploring medical assistance using Chinese as the primary working language is crucial. This inquiry is vital for enhancing patient compliance in hepatitis B management and alleviating strain on health care professionals amid work-related stress. However, a study involving ChatGPT's performance in a medical examination in Chinese

emphasized the significance of exploring the cross-language difference in ChatGPT's performance in a future study [28].

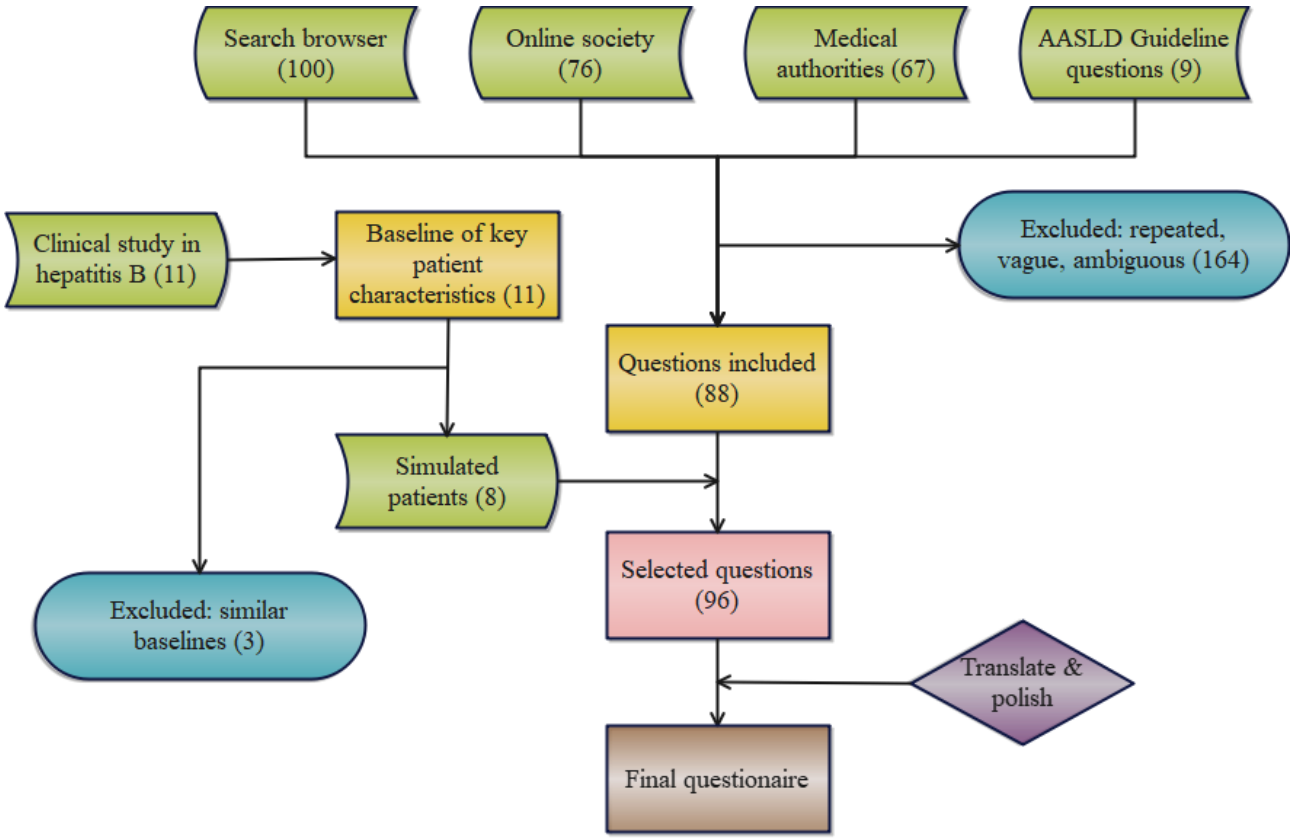
In brief, a dialogue-based medical assistant is being increasingly recognized as essential in clinical practice. Exploring the application of ChatGPT in this domain shows promise for medical research and clinical usage. This study assessed ChatGPT-3.5 and ChatGPT-4.0 in tasks such as diagnosis, providing management advice, and addressing counseling needs among patients with CHB. Given that English data account for the largest proportion of data (approximately 92%) used for the original training of this model [29], it is reasonable to assume that among all the languages included in the pretraining resource, this model performs best in English. However, the Chinese language is used by the world's largest group of CHB patients, underscoring the irreplaceable role of Chinese in studies regarding medical AI assistants. Therefore, this research includes both English and Chinese as working languages and compares ChatGPT's performance in both languages. Additionally, the study compares ChatGPT-3.5 and ChatGPT-4.0 to investigate the improvements from the former version to the latter version. Through this investigation, we aim to uncover the potential of this application and its limitations in medical practice.

Methods

Questionnaire Development Process

Following the workflow shown in Figure 1, we systematically compiled a set of questions relevant to both patients and physicians in clinical practice. This compilation process involved several processes. First, we sourced questions from esteemed professional associations and institutions, such as the WHO, American Centers for Disease Control and Prevention (CDC), American Association for the Study of Liver Disease (AASLD), EASL, and Asian Pacific Association for the Study of the Liver (APASL). Second, we identified queries about hepatitis B found on online social media platforms, particularly in patient support groups and disease-specific forums. The inclusion criteria prioritized relevance to diagnosis, treatment, daily monitoring, lifestyle, and other hepatitis B–related concerns. Questions with precise wording, minimal grammatical errors, and clarity were included, while nonmedical inquiries, ambiguously framed questions, and those related to nonmedical issues were excluded. Questions with significant updates after September 2021 were also omitted. Third, we conducted an exploration of associative keywords following the entry of "hepatitis B" or "HBV" into widely used search engines, such as Google, Bing, and Baidu, in both Chinese and English languages. Fourth, based on diverse published hepatitis B clinical studies, we systematically extracted key patient characteristics, including age, gender, hepatitis B serum markers, HBV-DNA levels, ALT levels, and concomitant diseases. We developed profiles for 8 simulated patients using these data with a random number function. ChatGPT was tasked with providing advice to these simulated individuals on various aspects, including treatment or examination recommendations, treatment strategies, daily monitoring practices, lifestyle adjustments, etc.

Figure 1. Workflow of the questionnaire design process. The specific information of each stage of the questionnaire compiling process is shown. AASLD: American Association for the Study of Liver Disease.



Among all the questions gathered, multiple questions were separated into single entities, while repeated questions were excluded. To avoid ambiguity and misunderstanding resulting from language vagueness, which could potentially impact the assessment of the model's information accuracy, we carefully polished all the collected questions, refined their grammar and phrasing, and performed localized translations between Chinese and English. Examples of revised or excluded questions are provided in Multimedia Appendix 1. In total, we gathered 96 questions about hepatitis B. Among the questions, there were 2 with only an English version and 5 with only a Chinese version. These language-specific questions focused on issues specific to the country or region where the questioner was located.

Section Allocation

We systematically categorized all questions into 5 distinct sections: Term Explanation Questions, Short Answer Questions, Clinical Problem Questions, AASLD Guideline Questions, and Simulated Patient Questions.

The "Term Explanation Questions" section featured 17 terms associated with hepatitis B, including 1 term exclusively for Chinese responses. In the "Short Answer Questions" section, there were 22 questions, with 1 specifically designed for Chinese responses. Questions within the "Clinical Problem Questions" section were primarily sourced from online hepatitis B societies, totaling 40 questions. Within this section, there was 1 question intended solely for English responses and 2 exclusively for Chinese responses. The questions in the "AASLD Guideline Questions" section were derived from the AASLD guidelines for hepatitis B in 2016 and 2018 (updated version) and included 9 questions that were all translated into Chinese. The "Simulated Patient Questions" section consisted of 8 questions related to simulated patient information, as previously constructed. These questions were provided in both English and Chinese versions.

Gathering Responses

The questions were submitted to ChatGPT-3.5 from April 1 to April 30, 2023, with each question forming a separate dialogue. Each question was sent twice for Chinese and English separately to ensure a comprehensive evaluation, and responses were collected. In the case of a system error preventing ChatGPT-3.5 from responding, the question was resubmitted in a new dialogue. All responses were compiled into a table for further assessment.

Assessment of Responses

Two senior physicians independently evaluated all responses. In the case of discrepancies in information accuracy, consistency of repeated responses, and emotional management guidance assessments, a third senior physician with over 30 years of experience in hepatitis B diagnosis and treatment conducted a final review for the ultimate assessment and provided the final scores. The criterion of assessment was discussed and voted on by a committee of 5 senior physicians in hepatitis B diagnosis and treatment. The assessment process referred to the research of Yeo et al [14].

Information Accuracy Assessment

The information accuracy assessment was mainly focused on correctness and comprehensiveness. Four assessment grades (1-4) were assigned: 1, correct and comprehensive; 2, correct but with missing information; 3, a mix of correct and incorrect details; and 4, wholly incorrect or irrelevant information.

Categorization of the Types of Mistakes

Mistakes in responses assessed as "a mix of correct and incorrect details" and "wholly incorrect or irrelevant information" were analyzed, and the types of mistakes were categorized. The mistakes were classified into 5 categories: A, misunderstanding of medical terms or jargon; B, incorrect usage of medical terms; C, mistakes in diagnosis/treatment/management without mistakes in terms or jargon; D, total irrelevant information; and E, a mixture of two or more kinds of mistakes among A-C.

Content Consistency of Repeated Response Assessment

A binary assessment ("Yes" or "No") was employed to indicate the consistency of the 2 responses for each question. This evaluation was independent of the information accuracy assessment and solely focused on the consistency of the response content.

Emotional Management Guidance Assessment

For all responses in the "Clinical Problem Questions" and "Simulated Patient Questions" sections (48 in total; 1 with only an English version and 2 with only a Chinese version), an emotional management guidance assessment was conducted. The assessment comprised three levels: (1) sufficient emotional and psychological management guidance, (2) respectful but lacking or inadequate emotional or psychological management guidance, and (3) disrespectful or negative emotional guidance.

Analysis of ChatGPT's Cautionary Statements Regarding Medical Advice

We quantified the instances where ChatGPT recommended consulting a genuine health care provider or doctor. Meanwhile, we counted the frequency of ChatGPT explicitly stating disclaimers, such as "I am not a doctor" and "I cannot give diagnosis or treatment," among all questions involving clinical practice (including the sections of Clinical Problem Questions, AASLD Guideline Questions, and Simulated Patient Questions).

Parallel Assessment of ChatGPT-4.0's Performance

We replicated the above assessment process for ChatGPT-4.0. Considering that ChatGPT-4.0 is the updated version of the model, we omitted sections involving only basic medical knowledge in the questionnaire. As a more intuitive alternative, we chose closed questions to evaluate the fundamental knowledge differences between the 2 model versions. The assessment of ChatGPT-4.0 included questions from the "Clinical Problem Questions," "AASLD Guideline Questions," and "Simulated Patient Questions" sections of the questionnaires used in the previous assessment. However, mistake analysis was omitted as there were no responses from ChatGPT-4.0 that were assessed as incorrect.

Comparison of ChatGPT-3.5 and ChatGPT-4.0 Using Closed Questions (True-or-False Statements)

In this assessment, we formulated 30 statements based on AASLD guidelines for the treatment of CHB, including all its updates up to September 2021. These statements were input into the models in separate dialogues. We used prompts to ask the models to judge whether the statements were correct and to provide a judgment with "Yes" or "No." The prompts are detailed in Table 1. Each statement was input into the model 3 times, and the response for each iteration was recorded. All responses of the models were collected, and their accuracy and stability (the consistency of 3 responses to a repeated statement) were assessed.

Table 1. An example of the prompts used in closed questions.

Language	Prompts for ChatGPT-4.0	Prompts for ChatGPT-3.5
English	Now, I would like you to act as a hepatologist in the upcoming conversation and determine whether the statements are true and answer with only "Yes" or "No". Here are the statements: []a	Now, I would like you to act as a hepatologist in the upcoming conversation and determine whether the statements are true and answer with only "Yes" or "No", and do not add any explanation. Here are the statements: []
Chinese	现在，我希望你在接下来的对话中扮演一名肝病学医师，判断以下陈述是否正确，并用"是"或"否"来回答: []a	现在，我希望你在接下来的对话中扮演一名肝病学医师，判断以下陈述是否正确，并用"是"或"否"来回答，不要增加任何解释或说明: []

[a]The statements were added in square brackets.

Statistical Analysis

All statistical analyses were performed with the SPSS 26.0 statistical package (IBM Corp). Cohen kappa coefficients were used to determine interobserver reliabilities. Assessment grades were calculated and reported as percentages. Comparative analysis of ranked data employed the Mann-Whitney test. Categorical data were compared using chi-square tests. The Wilcoxon signed rank test was applied to compare the grades of response 1 and response 2 to each question. Statistical significance was set at $P<.05$.

Ethical Considerations

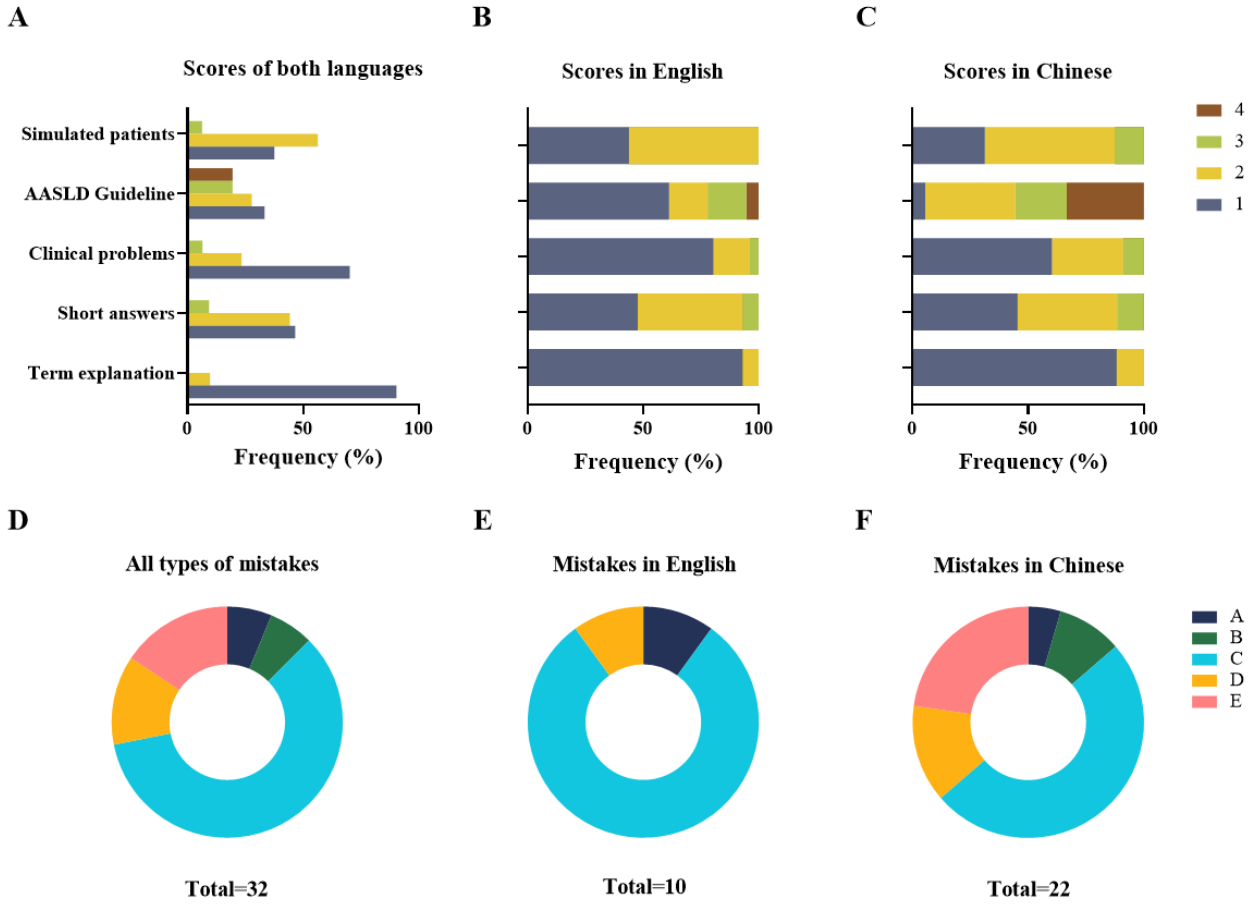
Our study did not use any information of real-world humans. Questions obtained from the internet were all polished and revised, and were included in the model with no personal information. Files of simulated patients were composed based on baseline data of clinical trials of hepatitis B, but the numbers were modified using a random number function to avoid possible leakage of real information.

Results

Information Accuracy Assessment of ChatGPT-3.5

The interobserver reliability κ was 0.6020 ($P<.001$) for the information accuracy assessment. The results of this assessment are shown in Figure 2. Across all the questions, 90.8% (336/370) of responses from ChatGPT-3.5 contained no incorrect information (including comprehensive responses and correct but incomprehensive responses). The likelihood of ChatGPT giving correct and comprehensive responses was 61.6% (228/370), while there was a 29.2% (108/370) probability of responses being correct with missing information (Multimedia Appendix 2). Responses with a mix of correct and incorrect information accounted for 7.3% (27/370) of responses. There were 1.9% (7/370) of responses wholly incorrect or irrelevant to the questions.

Figure 2. Results of the information accuracy assessment and mistake analysis of ChatGPT-3.5. (A) Comparison of the percentage for each grade across all responses in distinct question sections. (B) Percentage of each grade of responses in English in separated question sections. (C) Percentage of each grade of responses in Chinese in separated question sections. (D) Overview of mistake types across all responses. (E) Breakdown of mistake types specifically among responses in English. (F) Breakdown of mistake types specifically among responses in Chinese. In parts D-F, grade A indicates misunderstanding of medical terms or jargon, grade B indicates incorrect usage of medical terms, grade C indicates mistakes in diagnosis/treatment/management without mistakes in terms or jargon, grade D indicates total irrelevant information, and grade E indicates a mixture of two or more kinds of mistakes among grades A-C. AASLD: American Association for the Study of Liver Disease.



The performance of ChatGPT-3.5 varied across the sections, and the differences were statistically significant (P<.0001; Multimedia Appendix 2). The section "Term Explanation Questions" had the highest percentage of responses assessed as complete and comprehensive (26/28, 93% in English and 30/34, 88% in Chinese; Figure 2A), while the section "AASLD Guideline Questions" had the highest percentage of responses totally wrong or irrelevant, or mixed with incorrect information (4/18, 22% in English and 10/18, 56% in Chinese).

The language environment in which ChatGPT-3.5 operated also influenced its performance (Figure 2B). ChatGPT demonstrated poorer performance in Chinese than in English (P=.001), particularly in the sections "Clinical Problem Questions" (P=.03) and "AASLD Guideline Questions" (P=.002). However, performance in the sections "Term Explanation Questions" (P=.54), "Short Answer Questions" (P=.62), and "Simulated Patient Questions" (P=.33) showed no significant difference between the 2 working languages. The evaluation table is presented in Multimedia Appendix 3.

Categorization of the Types of Mistakes of ChatGPT-3.5

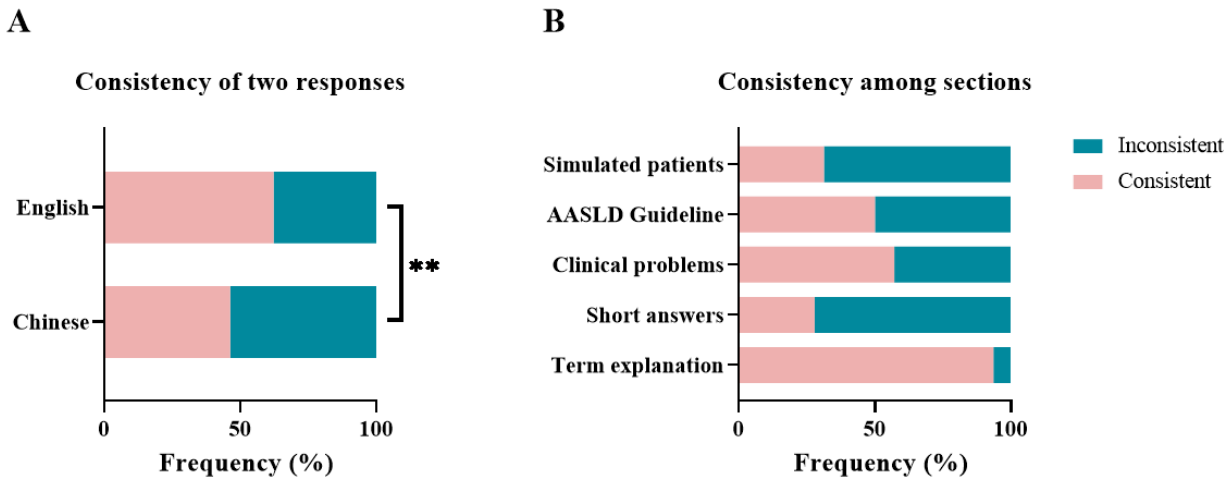
Figures 2D-F summarize the types of mistakes in the responses. In both languages, the most common error pertained to diagnosis, treatment, or disease management (Figure 2D). Notably, in Chinese, 10 out of 32 mistakes (31%) involved incorrect usage or misunderstanding of technical terms (Figure 2F), while in English, there were no such mistakes (Figure 2E). The evaluation table is provided in Multimedia Appendix 4.

Content Consistency of the Repeated Response Assessment of ChatGPT-3.5

The interobserver reliability κ was 0.6532 (P<.001) for content consistency of the repeated response assessment of ChatGPT-3.5. Figure 3 shows the content consistency of repeated responses. For all questions, the probability of content consistency between 2 responses was 54.1% (100/185 pairs of responses). In English, the consistency was 62% (56/90 pairs of responses), while in Chinese, it was 46% (44/95 pairs of responses), showing a significant difference (P=.04; Figure 3A and Multimedia Appendix 2). This disparity was also significant in the section "Clinical Problem Questions" (P=.04; Figure 3B

and Multimedia Appendix 2). The "Term Explanation Questions" section had the highest consistency at 94% (29/31 pairs of responses), while the "Short Answer Questions" section had the lowest consistency at 30% (13/43 pairs of responses). Despite poor content consistency, the responses exhibited similarity in grades (P=.65). The evaluation table is provided in Multimedia Appendix 5.

Figure 3. Assessment of the content consistency of responses to repeated questions. (A) Comparison of content consistency between responses in different working languages. (B) Examination of content consistency in different sections of questions. AASLD: American Association for the Study of Liver Disease. **P<.01.



Emotional Management Guidance Assessment of ChatGPT-3.5

Among responses to questions within the "Clinical Problem Questions" and "Simulated Patient Questions" sections, only 3.2% (6/186) were deemed to provide sufficient emotional management support (Table 2). Related responses are listed in Multimedia Appendix 6. Most responses (180/186, 96.8%) were assessed as "respectful but lacking or inadequate emotional or psychological management guidance." No response was assessed as "disrespectful or negative emotional guidance." ChatGPT-3.5 exhibited comparable performance in both languages (P=.39).

Table 2. Results of the emotional management guidance assessment.

Language	Clinical Problem Questions (n=154), n			Simulated Patient Questions (n=32), n			Total (N=186), n			*P* value
	Grade 1	Grade 2	Grade 3	Grade 1	Grade 2	Grade 3	Grade 1	Grade 2	Grade 3	
Chinese	1	77	0	1	15	0	2	92	0	.48[a]
English	4	72	0	0	16	0	4	88	0	
Total	5	149	0	1	31	0	6	180	0	.39[b]

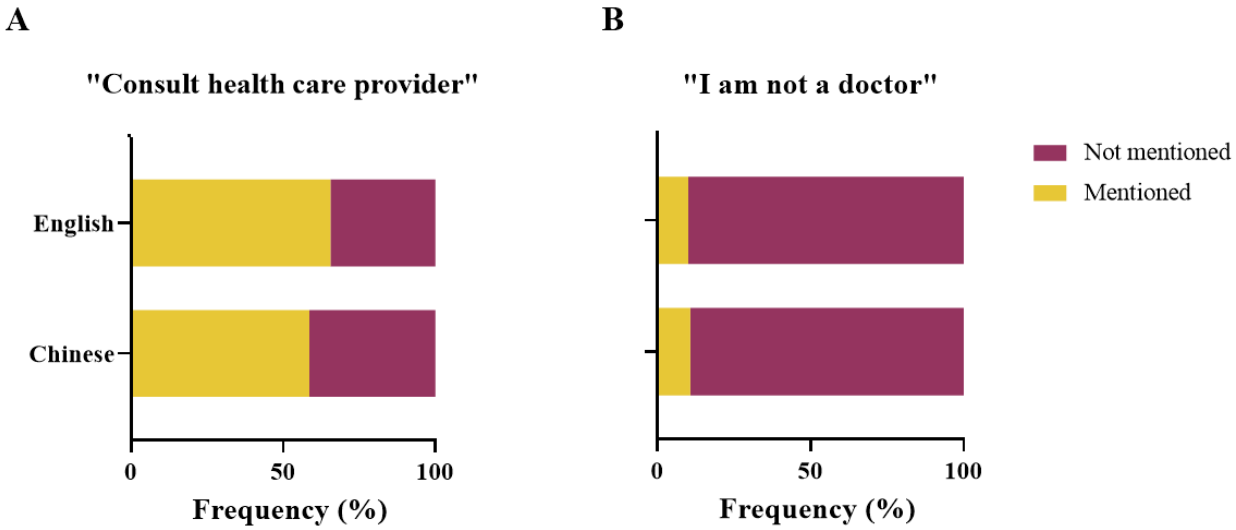
[a]*P* value across the grades of each section.

[b]*P* value between the grades of different working languages.

Analysis of the Cautionary Statements of ChatGPT-3.5 Regarding Medical Advice

Figure 4 shows the results of this assessment. ChatGPT-3.5 exhibited distinct characteristics as a medical assistant. In most responses, ChatGPT-3.5 tended to remind patients to consult a health care provider or a physician (227/370, 61.4%). This percentage was consistent in both English (118/180, 65.6%; Figure 4A) and Chinese (109/190, 57.4%), with no significant difference (P=.20). These responses are listed in Multimedia Appendix 7.

Figure 4. Percentage of ChatGPT cautionary statements regarding medical advice and disclaimers. (A) Percentage of responses that include the recommendation to "consult health care providers or doctors." (B) Percentage of responses containing the disclaimer phrase "I am not a doctor" or "I cannot give diagnosis or treatment".

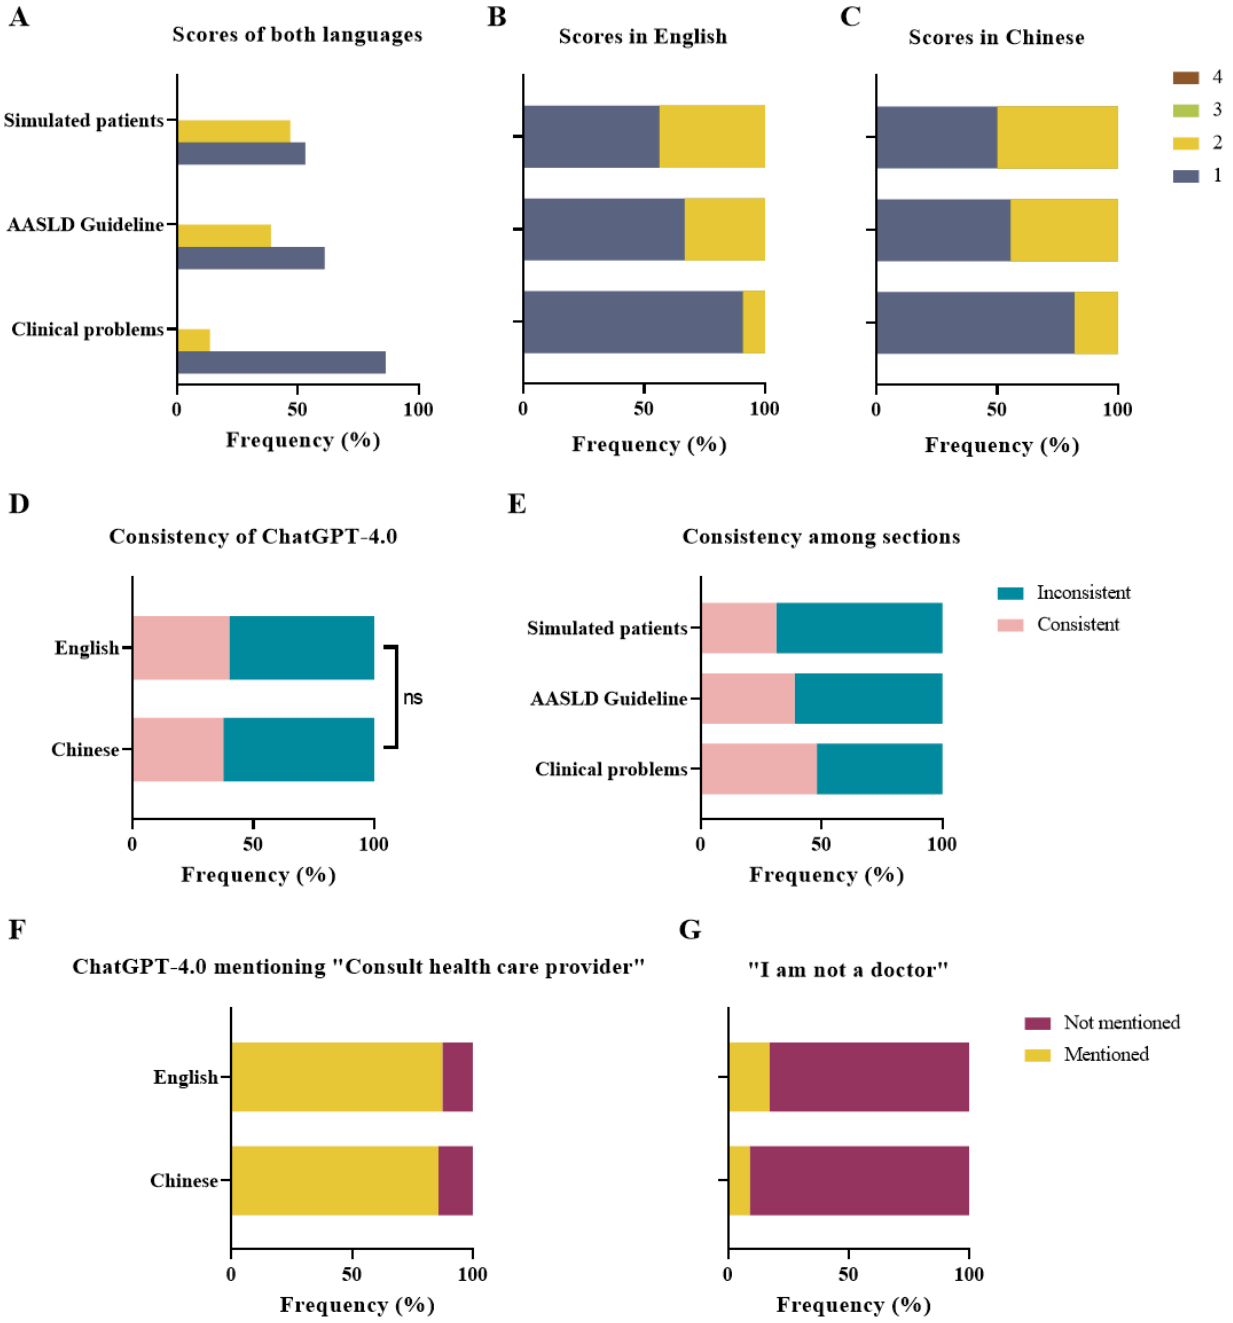


Among all questions involving clinical practice, the probability of ChatGPT-3.5 using the phrase "I am not a doctor" or "As a language model, I cannot give diagnosis or treatment…" was 10.8% (24/222). The probability was 11.6% (13/112) in Chinese and 10.0% (11/110) in English (Figure 4B). No significant difference was observed between the 2 languages (P>.99). These responses are listed in Multimedia Appendix 8.

Parallel Assessment of ChatGPT-4.0 in Sections Involving Clinical Practice

The interobserver reliability κ was 0.6896 (P<.001) for information accuracy assessment. Notably, ChatGPT-4.0 demonstrated distinct performance compared to ChatGPT-3.5. The scores of ChatGPT-4.0 are presented in Figures 5A-C. Across the 3 sections of "Clinical Problem Questions," "AASLD Guideline Questions," and "Simulated Patient Questions," the percentage of responses assessed as complete and comprehensive, as well as "grade 1," was higher for ChatGPT-4.0 than for ChatGPT-3.5 (172/222, 77.5% vs 132/222, 59.5%), with a significant difference (P<.001). Furthermore, variations in grades were observed across the sections (P<.001). The "Clinical Problem Questions" section exhibited the highest percentage of responses assessed as complete and comprehensive for ChatGPT-4.0 (133/154, 86.4%), surpassing that for ChatGPT-3.5 (108/154, 70.1%; P<.001). Importantly, no responses from ChatGPT-4.0 were assessed as "a mix of correct and incorrect details" and "wholly incorrect or irrelevant information." In general, ChatGPT-4.0 demonstrated superior information accuracy compared to ChatGPT-3.5. Moreover, ChatGPT-4.0 showed improved performance in responding to Chinese questions. Although there was a slightly lower percentage of responses assessed as "grade 1" for Chinese (82/112, 73.2%) than for English (90/110, 81.8%), the difference in performance between the languages was not significant (P=.13). The evaluation tables are presented in Multimedia Appendix 9 and 10.

Figure 5. Results of the parallel assessment of ChatGPT-4.0 in sections involving clinical practice. (A) Comparison of the percentage of each grade across all responses in distinct question sections. (B) Percentage of each grade of responses in English in separated question sections. (C) Percentage of each grade of responses in Chinese in separated question sections. (D) Comparison of content consistency between responses in different working languages. (E) Examination of content consistency in different sections of questions. (F) Percentage of responses that include the recommendation to "consult health care providers or doctors." (G) Percentage of responses containing the disclaimer phrase "I am not a doctor" or "I cannot give diagnosis or treatment." AASLD: American Association for the Study of Liver Disease; ns: not significant.



The interobserver reliability κ was 0.6052 (P<.001) for content consistency of the repeated response assessment. ChatGPT-4.0 showed poor consistency in responses to repeated questions. Across all questions, ChatGPT-4.0 provided 44.1% (49/111 pairs of responses) stable repeated responses, and this proportion was lower than that for ChatGPT-3.5 (58/111, 52.3%). However, the difference was not significant (P=.23). Specifically, ChatGPT-4.0's stability percentage was 38% (21/56 pairs of responses) in Chinese and 51% (28/55 pairs of responses) in English (Figure 5D), with no significant difference (P=.16). Among all the sections, responses in the "Clinical Problem Questions" section exhibited the highest rate of consistency at 48% (37/77 pairs of responses; Figure 5E). The difference in consistency across sections was not significant (P=.42). Detailed evaluation tables are provided in Multimedia Appendix 9 and 11.

Regarding responses to questions within the "Clinical Problem Questions" and "Simulated Patient Questions" sections, ChatGPT-4.0's responses were assessed to provide sufficient emotional management support 8.1% (15/186) of the time (Table

3). This performance differed significantly from that of ChatGPT-3.5 (*P*=.04). The percentage was similar between Chinese and English (7/94, 7% and 8/92, 9%, respectively; *P*=.76). No response was assessed as "disrespectful or negative emotional guidance." ChatGPT-4.0 showed similar performance between the 2 sections (10/154, 6.5% for Clinical Problem Questions and 5/32, 15.6% for Simulated Patient Questions assessed as grade 1; *P*=.08). However, among all responses assessed as "unstable," there was no significant difference between the scores of response 1 and response 2 (*P*=.06). All the responses assessed as "sufficient emotional and psychological management guidance" are listed in Multimedia Appendix 12.

Table 3. Results of the emotional management guidance assessment of ChatGPT-4.0.

Language	Clinical Problem Questions (n=154), n			Simulated Patient Questions (n=32), n			Total (N=186), n			*P* value
	Grade 1	Grade 2	Grade 3	Grade 1	Grade 2	Grade 3	Grade 1	Grade 2	Grade 3	
Chinese	5	73	0	2	14	0	7	87	0	.08[a]
English	5	71	0	3	13	0	8	84	0	
Total	10	144	0	5	27	0	15	171	0	.75[b]

[a]*P* value across the grades of each section.

[b]*P* value between the grades of different working languages.

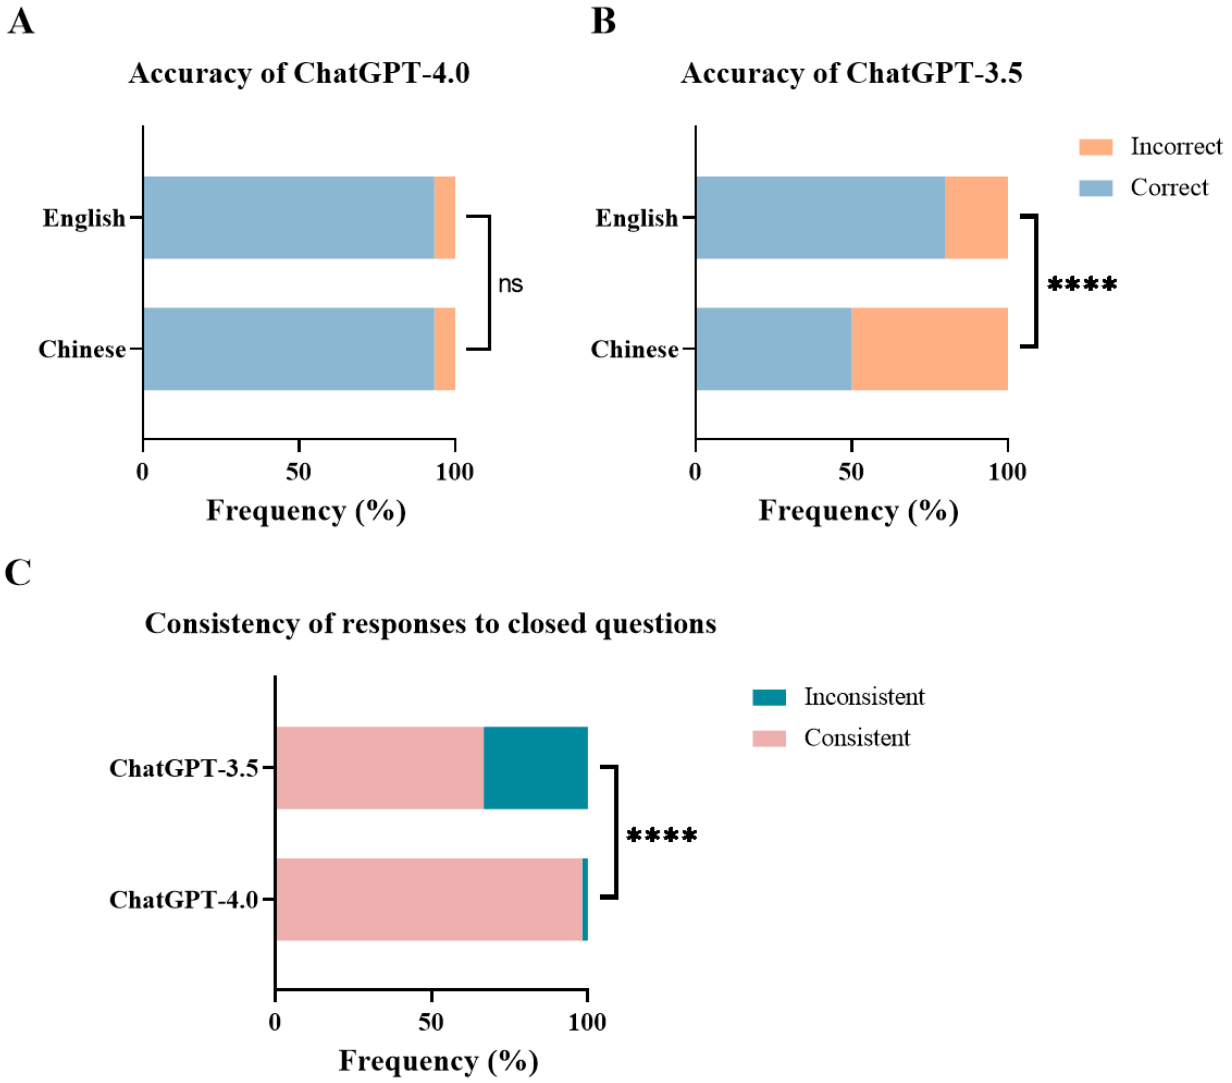
As shown in Figure 5F, ChatGPT-4.0 demonstrated comparable performance to ChatGPT-3.5 across all responses, with 86.5% (192/222) of responses emphasizing the importance of seeking medical assistance. In Chinese, 96 out of 112 responses (85.7%) stressed this need, while in English, 96 out of 110 responses (87.3%) did the same. Notably, no significant difference was observed between the languages (*P*=.73). In responses from ChatGPT-3.5 in the sections "Clinical Problem Questions," "AASLD Guideline Questions," and "Simulated Patient Questions," the total percentage of responses with a medical service recommendation was 81.5% (181/222), which was not different from that for ChatGPT-4.0 (*P*=.15). All responses emphasizing the necessity of seeking medical services are listed in Multimedia Appendix 13.

Figure 5G illustrates that among all responses to questions involving clinical practice, ChatGPT-4.0 used the phrase "I am not a doctor" or "As a language model, I cannot give diagnosis or treatment…" with a probability of 13.1% (29/222). This percentage did not significantly differ from that of ChatGPT-3.5 (*P*=.46). In Chinese, the probability was 8.9% (10/112), while in English, the probability was 17.3% (19/110; Figure 5B). No significant difference was observed between the 2 languages (*P*=.07). These responses are detailed in Multimedia Appendix 14.

Assessment of Responses to Closed Questions Across ChatGPT-4.0 and ChatGPT-3.5

When assessing the accuracy of statements derived from the AASLD guidelines for the treatment of CHB, ChatGPT-4.0 exhibited significantly superior performance compared to ChatGPT-3.5 (Figures 6A and B). ChatGPT-4.0 achieved a correctness percentage of 93.3% (168/180), with the same percentage accuracy in both Chinese and English (93.3% for each language). Conversely, ChatGPT-3.5 yielded an overall accuracy of 65.0% (117/180), with a split of 50.0% (45/90) in Chinese and 80.0% (72/90) in English.

Figure 6. Results of responses to true-or-false questions. (A) Rate of accuracy of ChatGPT-4.0. (B) Rate of accuracy of ChatGPT-3.5. (C) Comparison of the consistency of responses to true-or-false questions between ChatGPT-4.0 and ChatGPT-3.5. ns: not significant. ****P<.0001.



Furthermore, ChatGPT-4.0 displayed enhanced consistency in repeated responses (Figure 6C). Stable responses accounted for 98.3% (59/60) of responses in ChatGPT-4.0, whereas ChatGPT-3.5 provided only 66.7% (40/60) stable responses. The difference in response stability between the models was statistically significant (P<.001). Details are provided in Multimedia Appendix 15.

Discussion

ChatGPT-3.5 Working as a Medical Consulting Assistant

Our evaluation highlighted the proficiency of ChatGPT-3.5 as a medical consultation assistant. ChatGPT-3.5 provided predominantly accurate information, but there was a notable limitation in the comprehensiveness of the responses, indicating a need for targeted medical professional input. Continuous enhancement of LLMs may contribute to more specific and reliable guidance. Despite its strengths, ChatGPT-3.5 displayed limitations in emotional management support, a crucial aspect of chronic disease management [30]. Facilitating emotional modulation is integral to fostering patient willingness for self-management and treatment compliance [7,30].

Therefore, it is imperative to consider emotional cognition and regulation in medical diagnosis and treatment. Our study suggested that the potential for ChatGPT to serve as an emotional management assistant for chronic patients warrants further study, with related localized training considered if LLMs are to be employed in clinical practice as health consultation assistants.

Impact of Working Language on Performance

By revealing ChatGPT's inferior performance in Chinese compared to English, the study emphasized the influence of the choice of working language on stability and correctness. ChatGPT-3.5 showed worse performance on information accuracy in Chinese, implying the insufficient input of knowledgeable materials in Chinese. Both ChatGPT-3.5 and ChatGPT-4.0 showed less stability in Chinese, which was reflected in a lower consistency rate of responses to the same

questions. This challenge stemmed from variations in language resources during the model's original training, primarily centered around English-based medical guidelines. Though there are Chinese versions of these guidelines, the timeliness and accuracy of Chinese materials are limited. To enhance ChatGPT's efficacy in diverse language environments, the model should undergo additional training based on data sourced from specific language resources. This targeted training should focus on potential misunderstandings related to terms and phrasings in local languages, thereby addressing language-specific nuances and enhancing overall performance. Notably, ChatGPT-3.5 exhibited language-specific mistakes, with Chinese responses showing errors related to misunderstanding or incorrect usage of terms. This underscores the importance of targeted language training for LLMs to minimize inaccuracies, especially in medical contexts.

Cautionary Statements and Patient-Oriented Usage

In discussions related to diagnosis and therapy, ChatGPT-3.5 consistently emphasized the importance of consulting a health care provider, indicating a cautious approach. Owing to constraints in both timeliness and accuracy inherent in language models, ChatGPT-3.5 occasionally emphasized its nondoctor status, thus refraining from providing direct diagnosis or therapy in the conversation. However, such statements may imply the unreliability of the medical judgment, especially in a Chinese cultural context. Thus, further inquiries are warranted to evaluate the potential risks and benefits of this response mode, considering its impact on patient trust and compliance challenges.

Implications for Future Development in Clinical Medicine

As AI, including LLMs, is being progressively integrated into clinical medicine, understanding the advantages and disadvantages is paramount. While ChatGPT demonstrates promise as a medical consulting assistant for CHB patients, future research and development should prioritize targeted language input and emotional management training. Besides, establishing and updating prompts, which are in a specific order, and templates based on which LLMs could provide responses in a standardized format would significantly enhance ChatGPT's performance. Overcoming language barriers and addressing emotional support deficiencies will be crucial for maximizing the potential benefits of LLMs in medical assistance.

Comparison of ChatGPT-4.0 to ChatGPT-3.5

ChatGPT-4.0 demonstrated superior performance compared with ChatGPT-3.5 in terms of information accuracy. This improvement aligns with the expected advancements in ChatGPT-4.0 as a more advanced iteration. However, ChatGPT-4.0 did not exhibit better response stability in open-ended questions. This could be attributed to a reduced ability to follow chain-of-thought prompting [31]. Despite this inconsistency, it did not affect the accuracy of information, suggesting that LLMs tend to employ diverse language patterns and content combinations.

In responses to closed questions (30 true-or-false statements based on the AASLD guidelines for the treatment of hepatitis B), ChatGPT-4.0 demonstrated a higher rate of accuracy and stability, indicating substantial improvement in the model's understanding of hepatitis B medical knowledge as the model progressed.

The improvement of ChatGPT-4.0 in terms of information accuracy suggested the tremendous benefit of the model update, but the deficiency in emotional management remained. Therefore, additional training related to emotional management guidance and humanistic care is essential for the preparation of the model before application.

Notably, in responses to open questions, ChatGPT-4.0 displayed interesting changes compared to ChatGPT-3.5. ChatGPT-4.0 included reference information in 5 of the responses, all of which were verified to be accurate. This suggests an enhancement in the format and reliability of ChatGPT-4.0. However, the impact of such changes on the patient experience warrants further exploration. Additionally, ChatGPT-4.0 was more likely to use a direct disclaimer like "I am an AI model..." or "I'm not a doctor..." and even "Disclaimer: I'm not a doctor...," indicating a more stringent approach. However, the increase in possibility was too subtle to be considered significant.

Comparison to Prior Work

Numerous studies have explored the potential application of ChatGPT in clinical practice. Ayers et al [32] observed that ChatGPT tends to deliver longer and more empathetic responses of higher quality compared to real doctors. In a study by Cascella et al [12], ChatGPT demonstrated proficiency in composing medical notes for intensive care unit patients and scientific writing, despite lacking medical expertise. The researchers highlighted the model's effectiveness in providing medical advice and its potential in patient communication [12]. Several studies have evaluated ChatGPT's responses in various medical specialties [14,33-35]. In contrast, our study uniquely focused on ChatGPT's cross-language performance in clinical counseling, revealing that language choice impacts accuracy and answer stability. This emphasizes the importance of language selection for the practical application of LLMs.

Limitations

It is important to acknowledge certain limitations in our study. The evaluation did not comprehensively assess ChatGPT's knowledge and ability in guiding emotional management for patients due to questionnaire resource constraints. The lack of a standardized questionnaire also limited the reliability of the questionnaire used owing to the lack of a related interrater reliability measure. Meanwhile, as the first work in the assessment of medical consulting AI systems for hepatitis B, it was difficult to estimate the possible effects of vagueness, ambiguity, and misunderstanding associated with grammatical mistakes or vagueness of the questions. The researchers revised the questions to address such concerns, which created new concerns about discrepancies between these "standard" questions and practical application scenarios. These problems should be addressed in future research. Additionally, while cautionary statements promote responsible usage, the potential risks and benefits of this approach require further exploration. Future studies should address these limitations for a more

comprehensive understanding of ChatGPT's application in medical assistance.

Conclusion

ChatGPT-3.5 exhibits promising capabilities as a medical consultation assistant, providing accurate yet occasionally less comprehensive information. ChatGPT-4.0, which is an improved version of the model, showed stronger application potential than ChatGPT-3.5. Recognizing their limitations in emotional support and language-specific performance, future developments should prioritize targeted language training and enhanced emotional management features. While cautionary statements underscore responsible usage, the model's potential in aiding patients with CHB is evident. As AI continues to shape the medical practice, refining LLMs for nuanced health care contexts is imperative. Striking a balance among linguistic accuracy, emotional sensitivity, and ethical patient engagement remains important for successful integration into clinical settings.

Acknowledgments

This study was supported by the Young Scientists Fund of the National Natural Science Foundation of China (number: 82100640). The study was also assisted by Ruihong Zhao, Yu Shi, and Hong Zhao.

Authors' Contributions

YW and YC conceived the study, collected and filtered questions, and developed the assessment criteria. YW translated and polished the questions, conducted the questionnaire assessment process, and wrote the manuscript. YC revised the manuscript. JS directed the entire research process, invited 2 independent reviewers, and acted as the final senior specialist.

Abstract

Background: Understanding the multifaceted nature of health outcomes requires a comprehensive examination of the social, economic, and environmental determinants that shape individual well-being. Among these determinants, behavioral factors play a crucial role, particularly the consumption patterns of psychoactive substances, which have important implications on public health. The Global Burden of Disease Study shows a growing impact in disability-adjusted life years due to substance use. The successful identification of patients' substance use information equips clinical care teams to address substance-related issues more effectively, enabling targeted support and ultimately improving patient outcomes.

Objective: Traditional natural language processing methods face limitations in accurately parsing diverse clinical language associated with substance use. Large language models offer promise in overcoming these challenges by adapting to diverse language patterns. This study investigates the application of the generative pretrained transformer (GPT) model in specific GPT-3.5 for extracting tobacco, alcohol, and substance use information from patient discharge summaries in zero-shot and few-shot learning settings. This study contributes to the evolving landscape of health care informatics by showcasing the potential of advanced language models in extracting nuanced information critical for enhancing patient care.

Methods: The main data source for analysis in this paper is Medical Information Mart for Intensive Care III data set. Among all notes in this data set, we focused on discharge summaries. Prompt engineering was undertaken, involving an iterative exploration of diverse prompts. Leveraging carefully curated examples and refined prompts, we investigate the model's proficiency through zero-shot as well as few-shot prompting strategies.

Results: Results show GPT's varying effectiveness in identifying mentions of tobacco, alcohol, and substance use across learning scenarios. Zero-shot learning showed high accuracy in identifying substance use, whereas few-shot learning reduced accuracy but improved in identifying substance use status, enhancing recall and F_1-score at the expense of lower precision.

Conclusions: Excellence of zero-shot learning in precisely extracting text span mentioning substance use demonstrates its effectiveness in situations in which comprehensive recall is important. Conversely, few-shot learning offers advantages when accurately determining the status of substance use is the primary focus, even if it involves a trade-off in precision. The results contribute to enhancement of early detection and intervention strategies, tailor treatment plans with greater precision, and ultimately, contribute to a holistic understanding of patient health profiles. By integrating these artificial intelligence–driven methods into electronic health record systems, clinicians can gain immediate, comprehensive insights into substance use that results in shaping interventions that are not only timely but also more personalized and effective.

Introduction

The use and misuse of psychoactive substances rank as critical risk elements for global health, contributing substantially to the worldwide disease burden [1,2]. Alcohol, tobacco, and illegal drugs are implicated in more than 80 identified conditions that lead to disease and injury [3,4], incurring significant health and societal costs [5-7]. Tobacco use is primarily connected to chronic diseases that often result in death, while alcohol consumption is associated with both acute conditions, such as injuries—both intentional and accidental—and chronic diseases, varying in mortality risk (eg, high risk includes liver cirrhosis and head and neck cancers; low risk covers conditions such as depression and alcohol dependency). Illicit drug use carries risks of infectious diseases, particularly through intravenous methods that may transmit HIV, in addition to heightened risks of suicide and drug use disorders. Unlike tobacco or illicit drugs, alcohol presents a complex profile, as certain levels and patterns of consumption have been shown to have protective effects against some diseases, notably coronary heart disease [8-10].

The documentation of substance use information in patient clinical notes plays an important role in care delivery by impacting clinical decision-making processes. First, it furnishes health care providers with vital information concerning a patient's addiction history, a fundamental component in constructing a comprehensive medical profile [11]. This knowledge is instrumental in devising patient-centered treatment plans that not only address the primary medical concern but also consider the complexities of the use and its potential impact on treatment efficacy [12]. Furthermore, the extraction of this information aids in risk assessment, enabling the identification of patients who may be at higher risk of relapse or complications, thereby allowing for more proactive and tailored interventions [13]. The incorporation of extraction of substance use information from clinical notes directly informs patient treatment approaches. It enables health care providers to design interventions that address not only the immediate health concern but also the underlying addiction issue if exists [14]. The integration of substance use information into treatment planning facilitates the development of harm reduction strategies and medication-assisted therapies, tailored to each patient's unique needs and readiness for change [15]. This patient-centered approach not only enhances treatment outcomes but also fosters a supportive therapeutic relationship, promoting long-term recovery and well-being. Ultimately, this information enhances the precision of clinical decision-making by fostering a holistic understanding of the patient's health, thus underscoring the indispensability of addiction status extraction from clinical documentation in modern health care practice. By incorporating substance use information into risk assessment and treatment decision-making, health care professionals can deliver more precise, effective, and patient-centered care, identifying patients at higher risk of complications, relapse, or adverse outcomes due to their substance use history, ultimately leading to more targeted interventions and improved patient outcomes.

Studies [16,17] have used machine learning techniques to predict treatment outcomes for patients with substance use disorders, demonstrating how addiction status data can inform risk assessment and stratification. Studies [18,19] have explored risk stratification for opioid overdose, incorporating addiction status data and clinical information to identify patients at higher risk, thereby informing targeted interventions and care plans. Researchers also examine how addiction status information informs the development of personalized treatment plans and explore how health care providers tailor interventions to address both the primary medical issue and the underlying addiction concerns [20-22]. Many works emphasize the importance of patient-centered care and how extraction of substance addiction data enhances this approach. They highlight the significance of understanding a patient's history of addiction for delivering more effective and empathetic care [23-28]. However, implications for health care policy and the implementation of substance use data into clinical practice have their own barriers and challenges [29-33].

The traditional process of extracting data related to substance use from clinical notes involves the use of rule-based approaches to parse the unstructured clinical narratives, identifying and categorizing relevant information pertaining to substance use. However, rule-based approaches lack a standardized rule language. On the other hand, the high variability in language found within clinical notes imposes significant limits on the accuracy of traditional techniques that rely on parsing rules to detect text patterns. Clinician typographical errors, abbreviations, and other linguistic variations hinder the effectiveness of these methods. Conversely, deep learning methods have shown impressive efficacy in extracting such information from the intricate and complex texts within clinical notes [34-36]. However, the necessity for extensive, high-quality annotated data sets for training—as information extraction is a supervised task in natural language processing—presents a significant challenge that must be overcome to fully realize the potential of these models in new and practical real-world settings.

Recently, large language models (LLMs) have emerged as a promising solution to this challenge, particularly due to their significant ability to "learn" and adapt to diverse language patterns without the need for additional model training [37]. LLMs demonstrate an unparalleled ability to comprehend nuances of clinical narratives, extracting meaning from diverse and complex medical texts. Although primarily trained on open-source and non–domain-specific texts, generative pretrained transformer (GPT) [38], as a recent development in LLMs, has underscored its effectiveness when applied to clinical notes [39,40]. GPT has also showcased its capability in US medical licensing examinations by achieving or even surpassing human-level performance in perception of clinical context [41]. This exceptional performance may be attributed to several factors, including the extensive model parameters, large pretraining data sets, and instruction tuning and optimization with reinforcement learning human feedback [42]. Recent works

in the extraction of substance use information leverage LLMs such as Bidirectional Encoder Representations from Transformers and T5, with models being fine-tuned specifically for the social determinants of health extraction task [36,43]. The emergence of LLMs has also enabled new training paradigms, including few-shot or zero-shot learning [38,44].

Leveraging GPT (GPT-3.5 model), in this work we explore the extraction of patient's substance use information in specific patients' tobacco, alcohol, and illicit substance use information from their notes and assignment of a status to classifying the individual's engagement with the substance into categories based on time-related factors (ie, past, present, or none). Since prompt engineering is essential when interacting with GPT to obtain high-quality responses, our proposed workflow involves performing zero-shot as well as few-shot prompting. In zero-shot learning, the model is expected to generalize to tasks without having seen any examples from that specific task during training. It relies on understanding the task description and applying previously learned knowledge and patterns to new, unseen situations. In a zero-shot learning scenario, the GPT is instructed to perform a particular task through an input prompt, and it produces text as a response, which serves as the output. For instance, when provided with the prompt: *List mentions of substance use in the following note: <clinical note>*. Then, the GPT extracts the reference to substance use with surrounding information relevant to it and produces the following output text—h/o prior tobacco abuse × 60 pack years—while few-shot learning involves training models on a very small data set. In this prompting setting, the model is designed to learn information from a few examples and generalize that knowledge to new data. We first experimented and formulated prompts to elicit the desired responses from the model. Then we used our finalized prompt in zero-shot learning setting. For few-shot prompting, we add a few examples to our finalized prompt to directly address the types of errors observed in zero-shot learning.

To the best of our knowledge, no scholarly publication has investigated the use of zero-shot and few-shot learning approaches with the GPT-3.5 model in the context of extracting data on patients' substance use as well as determining their usage status. The substance use information is usually scattered throughout multiple clinical notes and may be overlooked by a new provider despite the fact that this information can affect clinical decision-making. By automating extraction of substance use profile from multiple clinical notes, the substance use status can be provided in a summarized format. It can also be used in automated clinical decision embedded into electronic health records (EHR). Secondary analysis of real-world data can be biased if it does not account for substance use profile. Automated extraction of substance use profiles can greatly facilitate generation of real-world evidence from EHR data. Our evaluation aims to provide insights into the capabilities and limitations of LLMs in substance use information extraction. Ultimately, our goal is to contribute to the ongoing development of the use of LLMs in the field of substance use information extraction, with the aim of improving the quality of care.

Methods

Study Design

The main data source for analysis in this paper is Medical Information Mart for Intensive Care III (MIMIC-III) data set. This data set is a widely used and comprehensive source of deidentified health care data. It contains detailed clinical information from more than 60,000 critical care patients admitted to the Beth Israel Deaconess Medical Center in Boston, Massachusetts, spanning a period of nearly a decade. This rich data set includes EHR, laboratory results, prescription records, and clinical notes, making it a valuable resource for medical research, particularly in the fields of critical care, epidemiology, and health informatics. Among all notes in this data set, we focused on discharge summaries. These notes typically provide a comprehensive overview of a patient's hospital stay, including the reason for admission, the treatments and procedures performed, and the patient's medical and social history and recommendations for postdischarge care. The social history section of a discharge summary typically covers various aspects of patients' life, such as their marital status, living situation, occupation, and lifestyle factors. If a patient has a history of addiction, particularly if it is relevant to the reason for his or her hospitalization or has implications for his or her postdischarge care, it is included in this section. The MIMIC-III contains 59,652 discharge summaries of 46,146 patients, among which we selected the patients with history of chronic obstructive pulmonary disease (COPD). Most of the patients with COPD are represented by older adults for whom identification of substance use information plays an important role in establishing an optimal treatment plan. Patients with COPD often have a history of smoking, as cigarette smoking is a primary risk factor for the development of COPD. Many individuals diagnosed with COPD have a significant smoking history. Alcohol and drug addiction are not typically considered direct risk factors for the development of COPD. However, substance abuse can exacerbate COPD symptoms, hinder treatment compliance, and lead to a more rapid decline in lung function in individuals already diagnosed with the disease [45-49].

Among 1646 patients with COPD, we selected discharge summary for 500 random patients, which was shown sufficient for assessing natural language processing pipeline accuracy in previous studies [50-53]. In this study, we use GPT and in specific GPT-3.5 model for generative question answering. We leveraged most capable and most cost-effective model in the GPT-3.5 family, which is GPT-3.5-turbo. This model has been optimized for chat. We accessed this model through the chat completions Application Programming Interface end point for extraction of substance use information, in specific patient's tobacco, alcohol, and illicit substance use, in 2 learning settings: zero-shot and few-shot.

In the zero-shot learning setting, a model is presented with tasks or queries for which it has not received explicit training. It is expected to extrapolate knowledge from its preexisting understanding of language and context to generate meaningful responses. This setting challenges the model to generalize

effectively and showcase adaptability to novel prompts, reflecting its capacity to comprehend and manipulate language beyond the scope of its training data.

On the contrary, few-shot learning involves training a model on a minimal number of task-specific examples. In this setting, GPT is provided with a few examples, allowing it to learn task-specific patterns and nuances. This approach leverages the model's pretrained knowledge to swiftly adapt to new tasks, demonstrating a remarkable capability for transfer learning. Few-shot learning is particularly advantageous when dealing with tasks that require a prompt-specific understanding, as it empowers the model to distill essential information from a handful of examples and apply this knowledge to generate coherent and contextually relevant responses.

Since prompt engineering is essential when interacting with GPT to obtain high-quality responses, we first experimented and formulated prompts to elicit the desired responses from the model. Then we used our finalized prompt in zero-shot learning setting. Multimedia Appendix 1 shows examples of our examined prompts, and Multimedia Appendix 2 shows our finalized prompt along with GPT responses to this prompt on different notes. These multimedia appendices show that we experimented different prompts and our finalized prompt was selected to be as follows:

Using the following patient's text, list tobacco use, illicit substance use, and alcohol use mentions and each one's status ("present," "past," and "none") in the bullets: <clinical note>.

The reason for selecting this prompt is that it provides the most comprehensive and detailed guidance for the task compared with the other prompts. This prompt is the only one that provides a clear and specific set of instructions. It not only asks to list data of tobacco, illicit substances, and alcohol use but also instructs GPT to include the status of usage as being "present," "past," or "none." This specificity helps guide the model to provide a more detailed and informative response. This prompt, in addition, is well structured and unambiguous in its request. It leaves no room for interpretation regarding what information is expected, making it easier for the model to generate accurate and relevant content. Moreover, in the context of medical or health care–related information, knowing the status of use (whether it is current, past, or not present) is critical for patient care and understanding their health history. This prompt includes this essential aspect, making it the most informative and complete prompt. While the last prompt in Multimedia Appendix 1 is also relatively detailed, it does not specify the need to provide the usage status for each category, which can be a crucial element in a medical or clinical context.

Next, we conducted error analysis that involves a detailed examination of the model's outputs to find specific instances where the model is underperforming. This process helps in selecting the most instructive examples to be included for few-shot learning in order to improve the model's performance. Multimedia Appendix 3 shows instances in which GPT underperformed. Considering first text, it can be seen that GPT had errors on assigning the use status of "None" to all type of substances. The clinical text indicates "No hx of tobacco or EtOH," where hx stands for history. The phrase "No hx" explicitly indicates that there is no history, which should correspond to the status of "none" for both tobacco and alcohol use. GPT's output failed to recognize this nuance. It interpreted "No hx" as a lack of mention, rather than an absence of use, and did not assign a status as instructed. GPT, like many language models, relies heavily on context to make predictions. Without a more extensive context, it might be challenging for the model to deduce that "no history of tobacco" implies "None" as tobacco use status without specific training or instructions. On the other hand, the use of negative phrasing, such as "no hx of," can be challenging for models to interpret correctly, especially without specialized training. Moreover, in shorter phrases or isolated sentences, the model may not have enough context to accurately infer the intended meaning. Furthermore, GPT's response "No mention of illicit substance use" suggests that there was no information provided about illicit substances, which is a correct extraction but lacks the explicit assignment of none status.

The second clinical note states: "No h/o tobacco and rare Etoh, no IVDA." Here, h/o stands for history of, Etoh stands for ethyl alcohol, and IVDA stands for intravenous drug abuse. Investigating GPT's response on this text shows that GPT's response was partially incorrect. While it did correctly identify that there is "None" for tobacco use, it failed to echo the specific language of the note, which included "No h/o tobacco," with h/o meaning "history of." In clinical contexts, maintaining the specific terminology used in patient records is crucial for accuracy and clarity.

Similarly, for illicit substance use, GPT's response of "None" is correct in the absence of use but lacks the explicit mention of "no IVDA" found in the clinical note. For alcohol use, the phrase "rare Etoh" suggests infrequent but current use of alcohol. The correct status should be "present" since it implies ongoing use. GPT's output incorrectly marked this as "past," which is an error. The phrase "rare" does not indicate cessation of use but rather infrequency and should be understood within the current context unless historical context is provided to imply past use.

Investigating GPT's response on third text also shows GPT's inability to correctly identify "Denies alcohol/drugs" as "None" for alcohol and illicit substance use. The phrase "Denies alcohol/drugs" is linguistically complex, and the model may not easily interpret its negation. In addressing the identified discrepancies within the model's output, it is imperative to rectify the inaccuracies by aligning the generated responses with the precise medical terminology and context presented in the clinical notes. The process entails reformulating the outputs to accurately reflect the specific language used, such as "No h/o tobacco" to denote a nonhistory of tobacco use. The refined examples, embodying both the exact phrasing and the proper status assignments, should then be systematically integrated into the training regime of the model through few-shot learning. This integration will facilitate the model's proficiency in comprehending and processing medical shorthand and context-sensitive information, thereby enhancing its performance on tasks that involve the extraction of nuanced data from clinical documentation. Through iterative exposure to these corrected instances, the model will incrementally improve its ability to

discern and categorize substance use information with a higher degree of accuracy and reliability, a crucial aspect for applications within clinical settings. Finally, Multimedia Appendix 4 shows the edited prompt for few-shot learning.

Ethical Considerations

No protected health information was collected, and the analytical data set was fully de-identified. To process the data, HIPAA (Health Insurance Portability and Accountability Act)-compliant Microsoft Azure OpenAI Application Programming Interface has been used.

Results

Among the 59,625 discharge summaries included in the MIMIC data set, 2043 were specifically associated with patients having a history of COPD. These particular summaries corresponded to a total of 1646 distinct patients with COPD. From this cohort, a random selection process was applied to obtain discharge summaries for a subset of 500 individuals for further analysis.

Table 1 presents general statistics pertaining to the data set. This table provides demographic information, presenting the distribution of attributes among the surveyed population. The data include the percentage breakdown of individuals based on gender, ethnicity, and marital status. The gender distribution shows a relatively balanced representation, with 53% male and 47% female respondents. This suggests a fair inclusion of both genders in the study. The majority of the surveyed population identifies as "White," constituting 73.16%. "Black," "Asian," and "Other" ethnicities make up 11.69%, 1.52%, and 13.63%, respectively. The marital status distribution reveals that a significant portion of the respondents is married (43.07%), followed by widowed (23.81%) and single (22.29%) individuals. There is also a small percentage with unknown marital status (4.98%), and divorced (4.55%) and separated (1.30%) individuals make up the rest. Accuracy, precession, recall, and F_1-score have been selected as evaluation metrics noting that every metrics have been calculated by manually reviewing all notes in data set.

Table 2 provides an overview of the results obtained from using GPT for the extraction of substance-related mentions and the corresponding status of the usage, comparing few-shot learning and zero-shot learning settings across tobacco, drug, and alcohol categories. The noticeable discrepancy between the accuracy of substance use mentions and status extraction in the zero-shot setting suggests a potential area for improvement, particularly in the nuanced understanding of the status associated with all categories of substance use. To leverage this insight and transition toward few-shot learning, we examined the specific instances where the zero-shot model struggled to accurately extract usage statuses and identified patterns, types of sentences, or contextual cues that may had contributed to the lower accuracy in extraction. Multimedia Appendix 3 shows multiple instances on which GPT made errors. These instances were used to update the finalized prompt for few-shot learning. Multimedia Appendix 4 shows our finalized prompt for few-shot learning.

Table 1. General statistics.

Attributes	Proportion, %
Sex	
Female	47
Male	53
Ethnicity	
White	73.16
Black	11.69
Asian	1.52
Other	13.63
Marital status	
Married	43.07
Widowed	23.81
Single	22.29
Unknown	4.98
Divorced	4.55
Separated	1.30

Table 2. Performance of generative pretrained transformer in a zero-shot and few-shot learning setting.

	Few-shot learning		Zero-shot learning	
	Mention (%)	Status (%)	Mention (%)	Status (%)
Tobacco				
Recall	87	66	93	29
Precision	58	51	98	87
F_1-score	70	57.5	96	43.5
Accuracy	60	40	92	26
Drug				
Recall	88	89	92	34
Precision	93	89	99	100
F_1-score	91	89	95	51
Accuracy	82	79	90	32
Alcohol				
Recall	89	78	89	29
Precision	78	73	99	100
F_1-score	83	76	94	45
Accuracy	71	57	90	29

In zero-shot learning, for tobacco, the precision was at 98%, and for both drug and alcohol mentions, it reached an impressive 99%. The recall for tobacco mentions was 93%, suggesting that the model was able to identify a large majority of the relevant instances. However, the recall for the status of tobacco use was substantially lower at 29%. For drugs, the recall was also high at 92% for mentions but significantly lower at 34% for the status. Similarly, for alcohol, the recall was 89% for mentions but dropped to 29% for the status. The F_1-scores, which balance recall and precision, were quite high for mentions, with tobacco at 96%, drugs at 95%, and alcohol at 94%, indicating strong overall performance in this aspect. Nevertheless, the F_1-scores for the status were lower: 43.5% for tobacco, 51% for drugs, and 45% for alcohol.

After few-shot learning, the accuracy of extraction of status was changed from 26%, 32%, and 29% to 40%, 79%, and 57%, for tobacco, alcohol, and substance use, respectively. The observed changes in the accuracy of extraction of status of the usage, following the incorporation of a new crafted prompt and the inclusion of examples where GPT previously had errors, indicate a 14%, 47%, and 28% improvement in the model's performance in terms of tobacco, drug, and alcohol status use extraction, respectively. On the other hand, few-shot learning led to significant decrease in the accuracy of mentions of substance use across all categories. The accuracy of extraction of tobacco, alcohol, and substance use mentions in zero-shot setting scenario was 92%, 90%, and 90%, respectively. While the accuracy for the use mentions in few-shot setting was 60%, 82%, and 71%, respectively.

Regarding the extraction of mentions of substance use, in few-shot learning, for tobacco, the recall is high at 87%, but precision is comparatively lower at 58%, resulting in a balanced F_1-score of 70%. Similar patterns are observed for alcohol category. While in contrast, precision value for mentions of drug use (93%) is higher than recall value (88%). Zero-shot learning exhibits higher recall in extraction of use mentions for all substance use categories, ranging from 89% to 93%, with precision ranging from 98% to 99%. Consequently, F_1-scores vary between 94% and 96%.

Regarding the extraction of the usage status, in few-shot learning, the recall value for tobacco is 66%, with precision just more than 50% and F_1-score of 57.5%. While in comparison with few-shot learning, zero-shot learning resulted in 37% lower recall and 14% lower F_1-score but 36% higher precision. The same pattern can be seen for alcohol and drug use status extraction across both learning setting, meaning lower recall and higher precision in zero-shot learning compared with few-shot learning resulted in higher F_1-score in few-shot learning. The discrepancies observed in the extraction performance metrics before and after few-shot learning may be attributed to several factors related to model configuration, prompt specificity, and data characteristics. First, the model configuration in few-shot learning involves exposure to specific examples that may not be diverse enough, potentially leading the model to overfit to particular features of the examples provided rather than generalizing effectively. This overfitting could result in reduced precision in mention extraction as the model becomes more sensitive to the nuances of the few-shot examples at the cost of broader applicability.

Second, prompt specificity plays a significant role in directing the model's attention and interpretation mechanisms. In the few-shot scenario, if the prompts are crafted with high specificity toward the status of use, the model's focus might shift from mention detection toward status classification,

explaining the improvement in status extraction accuracy and the concomitant decline in mention extraction accuracy.

Finally, data characteristics, such as the complexity, ambiguity, and representativeness of the clinical notes, can significantly influence the outcomes. Few-shot learning might result in better recall for status extraction if the examples chosen for training closely resemble the test cases, indicating that these examples were well selected to represent the variety of ways that status can be expressed in clinical texts. Conversely, zero-shot learning's higher precision suggests that the model, without the bias of the few-shot examples, might be more conservative and specific in its outputs, thus avoiding false positives.

Discussion

Principal Findings

The process of trying diverse prompts and selecting the one that yields the desired output was instrumental in harnessing the capabilities of GPT to align with objectives of this study. The act of crafting varied prompts allowed to explore the model's versatility and adaptability in correct extraction of patients' substance usage status. By experimenting with different prompt formulations, it becomes feasible to ascertain the prompt's impact on the model's behavior, leading to high accuracy in extraction. The finalized prompt in zero-shot is well structured and unambiguous in its request. It leaves no room for interpretation regarding what information is expected, making it easier for the model to generate accurate and relevant content. Moreover, in the context of medical or health care–related information, knowing the status of substance use (whether it is current, past, or none) is critical for patient care and understanding their health history. This prompt includes this essential aspect, making it the most informative and complete prompt. While the last prompt in Multimedia Appendix 1 is also relatively detailed, it does not specify the need to provide the status of each mention, which can be a crucial element in a medical or clinical context.

Crafting the new prompt by strategically using few-shot learning and tailoring to the challenges observed in the zero-shot setting resulted in increase on the accuracy of extraction of usage status. This approach capitalizes the importance of providing targeted guidance to enhance the model's proficiency in extracting nuanced information related to tobacco, alcohol, and substance uses. While the progress is commendable, it is essential to recognize that model refinement is an iterative process. Continued iterations, incorporating additional examples and refining the prompt, may further enhance accuracy, particularly in scenarios with inherent complexities.

The presented results in Table 2 highlight the contrasting performance of GPT in extracting mentions of tobacco, alcohol, and substance use in both zero-shot and few-shot learning scenarios. In the zero-shot setting, the accuracy for extraction of tobacco, alcohol, and substance use mentions is notably high. However, in the few-shot setting, the accuracy diminishes significantly. On the contrary, few-shot learning led to significant increase in devising the status of substance use compared with zero-shot learning (significant increase in recall and F_1-score). However, this improvement comes at the cost of a reduction in precision in both substance use information extraction and devising the status of the use. Accordingly, the selection between zero-shot and few-shot learning hinges on the goals of the task. Zero-shot learning excels in precisely extracting use mentions, demonstrating its effectiveness in situations in which comprehensive recall is paramount. Conversely, few-shot learning offers advantages when accurately determining the status of use is the primary focus, even if it involves a trade-off in precision.

The models we developed can be integrated with EHR systems to automatically extract and update patient substance use information. This integration facilitates real-time updates to patient profiles, ensuring that health care providers have access to the most current data when making treatment decisions. By embedding our models into clinical decision support systems, health care providers can receive proactive alerts and recommendations based on the extracted data. For example, if a patient's history of substance use changes, the system could automatically suggest modifications to his or her treatment plan or recommend additional screenings.

In acknowledging the limitations of this study, it is important to recognize the constraints imposed by the use of a single model, GPT-3.5, which, while demonstrating substantial capabilities, also exhibits specific challenges in processing complex linguistic structures such as negations and subtle context cues. This limitation notably impacted the accuracy of status identification in zero-shot learning settings, where the model sometimes failed to correctly interpret negations, leading to errors in status assignment.

Furthermore, the study's reliance on the MIMIC-III data set, while extensive, limits the generalizability of findings across diverse demographic and clinical settings. The data set's inherent biases and the specific clinical environment from which it was derived might not fully represent the broader patient populations encountered in different geographic or health care contexts. To address these limitations, future research should consider using a multimodel approach to validate findings and enhance the robustness of the conclusions drawn. Incorporating additional models such as Bidirectional Encoder Representations from Transformers may provide comparative insights and help mitigate the biases of a single model approach. Moreover, expanding the data set to include a wider array of clinical environments and patient demographics would enhance the generalizability of the artificial intelligence tools developed. In addition, the implementation of advanced training techniques, including more sophisticated prompt engineering and error analysis methodologies, could further refine the artificial intelligence's understanding of complex clinical narratives.

Conclusion and Future Work

The extraction of psychoactive substance use status from clinical notes holds significant implications for risk assessment and patient treatment. It empowers health care providers to perform risk evaluations and to devise individualized treatment plans, leading to enhancing the precision and efficacy of care delivery while addressing the complex interplay between medical conditions and addiction. In this study, we investigate the

efficacy of 2 prompt-based approaches—zero-shot and few-shot learning—for extracting patient's substance use information from discharge summaries of patients with COPD using GPT-3. Our findings indicate that GPT-3's few-shot learning capabilities serve as a promising starting point for extracting status of substance use without the need for annotated data. The GPT-3 exhibited high precision but lower recall, suggesting a conservative approach that yields fewer false positives but may miss relevant cases. Conversely, few-shot learning demonstrated a marked improvement in recall, indicating a greater ability to identify relevant instances, yet at the expense of precision. The implications of these findings are significant for the landscape of clinical practice, where the accurate assessment of usage status is crucial for risk assessment and tailoring patient treatment plans. The enhanced recall in few-shot learning suggests its use in scenarios where missing a case of substance use is highly detrimental, while the high precision of zero-shot learning would be preferred in contexts where the cost of false positives is greater. Therefore, researchers and practitioners should carefully consider the emphasis on recall, precision, and the overall balance between the 2 when deciding between these learning scenarios based on the specific requirements of their application. We prompted GPT-3 with only 4 randomly selected samples. More examples for few-shot learning may improve the performance. In addition, our reliance on the MIMIC-III data set, though comprehensive, restricts the generalizability of our findings. The data set's inherent biases and its derivation from a specific clinical environment may not accurately reflect the varied patient populations found across different geographic or health care settings. Despite these limitations, the study presents a significant step forward in our understanding of the capabilities and limitations of advanced language models in the critical domain of health care. As the future work, we investigate the capability of LLMs in extraction of the quantity, frequency, duration, and severity of substance use disorder.

Abstract

Background: Reading medical papers is a challenging and time-consuming task for doctors, especially when the papers are long and complex. A tool that can help doctors efficiently process and understand medical papers is needed.

Objective: This study aims to critically assess and compare the comprehension capabilities of large language models (LLMs) in accurately and efficiently understanding medical research papers using the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist, which provides a standardized framework for evaluating key elements of observational study.

Methods: The study is a methodological type of research. The study aims to evaluate the understanding capabilities of new generative artificial intelligence tools in medical papers. A novel benchmark pipeline processed 50 medical research papers from PubMed, comparing the answers of 6 LLMs (GPT-3.5-Turbo, GPT-4-0613, GPT-4-1106, PaLM 2, Claude v1, and Gemini Pro) to the benchmark established by expert medical professors. Fifteen questions, derived from the STROBE checklist, assessed LLMs' understanding of different sections of a research paper.

Results: LLMs exhibited varying performance, with GPT-3.5-Turbo achieving the highest percentage of correct answers (n=3916, 66.9%), followed by GPT-4-1106 (n=3837, 65.6%), PaLM 2 (n=3632, 62.1%), Claude v1 (n=2887, 58.3%), Gemini Pro (n=2878, 49.2%), and GPT-4-0613 (n=2580, 44.1%). Statistical analysis revealed statistically significant differences between LLMs (P<.001), with older models showing inconsistent performance compared to newer versions. LLMs showcased distinct performances for each question across different parts of a scholarly paper—with certain models like PaLM 2 and GPT-3.5 showing remarkable versatility and depth in understanding.

Conclusions: This study is the first to evaluate the performance of different LLMs in understanding medical papers using the retrieval augmented generation method. The findings highlight the potential of LLMs to enhance medical research by improving efficiency and facilitating evidence-based decision-making. Further research is needed to address limitations such as the influence of question formats, potential biases, and the rapid evolution of LLM models.

Introduction

Artificial intelligence (AI) has revolutionized numerous fields, including health care, with its potential to enhance patient outcomes, increase efficiency, and reduce costs [1]. AI devices are divided into 2 main categories. One category uses machine learning techniques to analyze structured data for medical applications, while the other category uses natural language processing methods to extract information from unstructured data, such as clinical notes, thereby improving the analysis of structured medical data [2]. A key development within natural language processing has been the emergence of large language models (LLMs), which are advanced systems trained on vast amounts of text data to generate human-like language and perform a variety of language-based tasks [3]. While deep learning models recognize patterns in data [4], LLMs are trained to predict the probability of a word sequence based on the context. By training on large amounts of text data, LLMs can generate new and plausible sequences of words that the mode has not previously observed [4]. ChatGPT, an advanced conversational AI technology developed by OpenAI in late 2022, is a general-purpose LLM [5]. GPT is part of a growing landscape of conversational AI products, with other notable examples including Llama (Meta), Jurassic (Ai21), Claude (Anthropic), Command (Cohere), Gemini (formerly known as Bard), PaLM, and Bard (Google) [5]. The potential of AI systems to enhance medical care and health outcomes is highly promising [6]. Therefore, it is essential to ensure that the creation of AI systems in health care adheres to the principles of trust and explainability. Evaluating the medical knowledge of AI systems compared to that of expert clinicians is a vital initial step to assess these qualities [5,7,8].

Reading medical papers is a challenging and time-consuming task for doctors, especially when the papers are long and complex. This poses a significant barrier to efficient knowledge acquisition and evidence-based decision-making in health care. There is a need for a tool that can help doctors to process and understand medical papers more efficiently and accurately. Although LLMs are promising in evaluating patients, diagnosis, and treatment processes [9], studies on reading academic papers are limited. LLMs can be directly questioned and can generate answers from their own memory [10,11]. This has been extensively studied in many papers. However, these pose the problem of artificial hallucinations, which are inaccurate outputs, in LLMs. The retrieval augmented generation (RAG) method, which intuitively addresses the knowledge gap by conditioning language models on relevant documents retrieved from an external knowledge source, can be used to overcome this issue [12].

The STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist provides a standardized framework for evaluating key elements of observational study and sufficient information for critical evaluation. These guidelines consist of 22 items that authors should adhere to before submitting their manuscripts for publication [13-15]. This study aims to address this gap by evaluating the comprehension capabilities of LLMs in accurately and efficiently understanding medical research papers. We use the STROBE checklist to assess LLMs' ability to understand different sections of research papers. This study uses a novel benchmark pipeline that can process PubMed papers regardless of their length using various generative AI tools. This research will provide critical insights into the strengths and weaknesses of different LLMs in enhancing medical research paper comprehension. To overcome the problem of "artificial hallucinations," we implement the RAG method. RAG involves providing the LLMs with a prompt that instructs them to answer while staying relevant to the given document, ensuring responses align with the provided information. The results of this study will provide valuable information for medical professionals, researchers, and developers seeking to leverage the potential of LLMs for improving medical literature comprehension and ultimately enhance patient care and research efficiency.

Methods

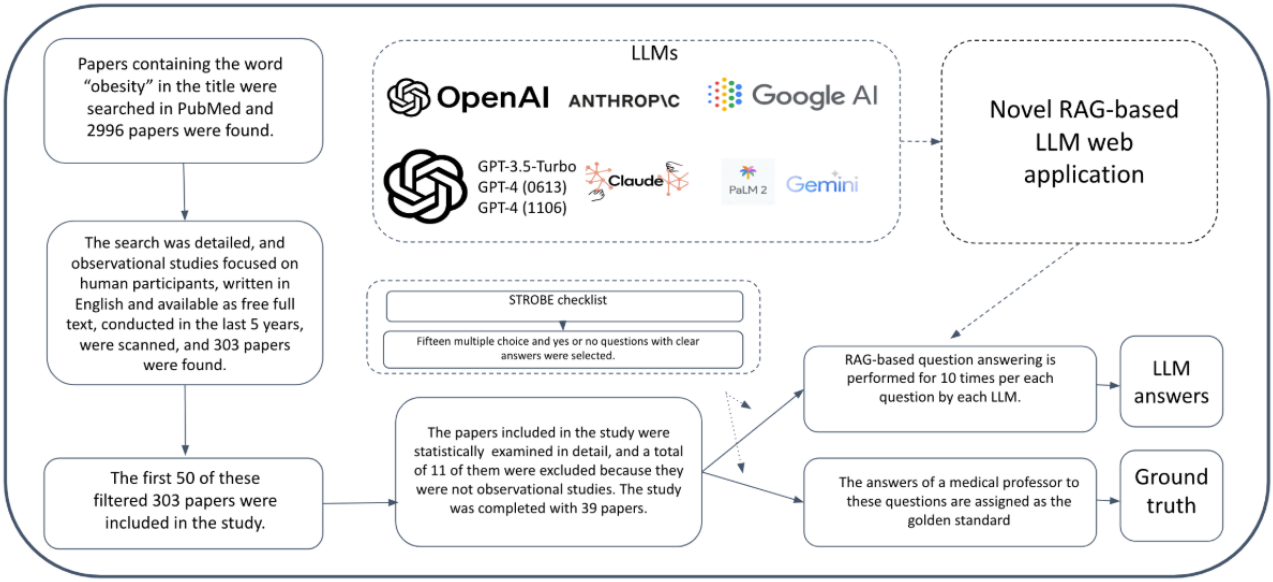
Design of Study

This study uses a methodological research design to evaluate the comprehension capabilities of generative AI tools using the STROBE checklist.

Paper Selection

We included the first 50 observational studies conducted within the past 5 years that were retrieved through an advanced search on PubMed on December 19, 2023, using "obesity" in the title as the search term. The included studies were limited to those written in English, available as free full text, and focusing specifically on human participants (Figure 1). The papers included in the study were statistically examined in detail, and a total of 11 of them were excluded because they were not observational studies. The study was completed with 39 papers. A post hoc power analysis was conducted to assess the statistical power of our study based on the total correct responses across all repetitions. The analysis excluded GPT-4-1106 and GPT-3.5-Turbo-1106 due to their similar performance and the significant differences observed between other models. The power analysis, conducted using G*Power (version 3.1.9.7; Heinrich-Heine-Universität Düsseldorf), indicated that all analyses exceeded 95% power. Thus, the study was completed with the 39 selected papers, ensuring sufficient statistical power to detect meaningful differences in LLM performance.

Figure 1. Flowchart: recruitment and data collection process for evaluating LLM comprehension of medical research papers. LLM: large language model; RAG: retrieval augmented generation.



Benchmark Development

This study used a novel benchmark pipeline to evaluate the understanding capabilities of LLMs when processing medical research papers. To establish a reference standard for evaluating the LLMs' comprehension, we relied on the expertise of an experienced medical professor and an epidemiology expert doctor. The professor, with their extensive medical knowledge, was tasked with answering 15 questions derived from the STROBE checklist, designed to assess key elements of observational studies and cover different sections of a research paper (Table 1). The epidemiology expert doctor, with their specialized knowledge in statistical analysis and epidemiological methods, provided verification and validation of the professor's answers, ensuring the rigor of the benchmark. The combined expertise of both professionals provided a robust and reliable reference standard against which the LLMs' responses were compared.

Table 1. The questions derived from the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist for observational study and answers.

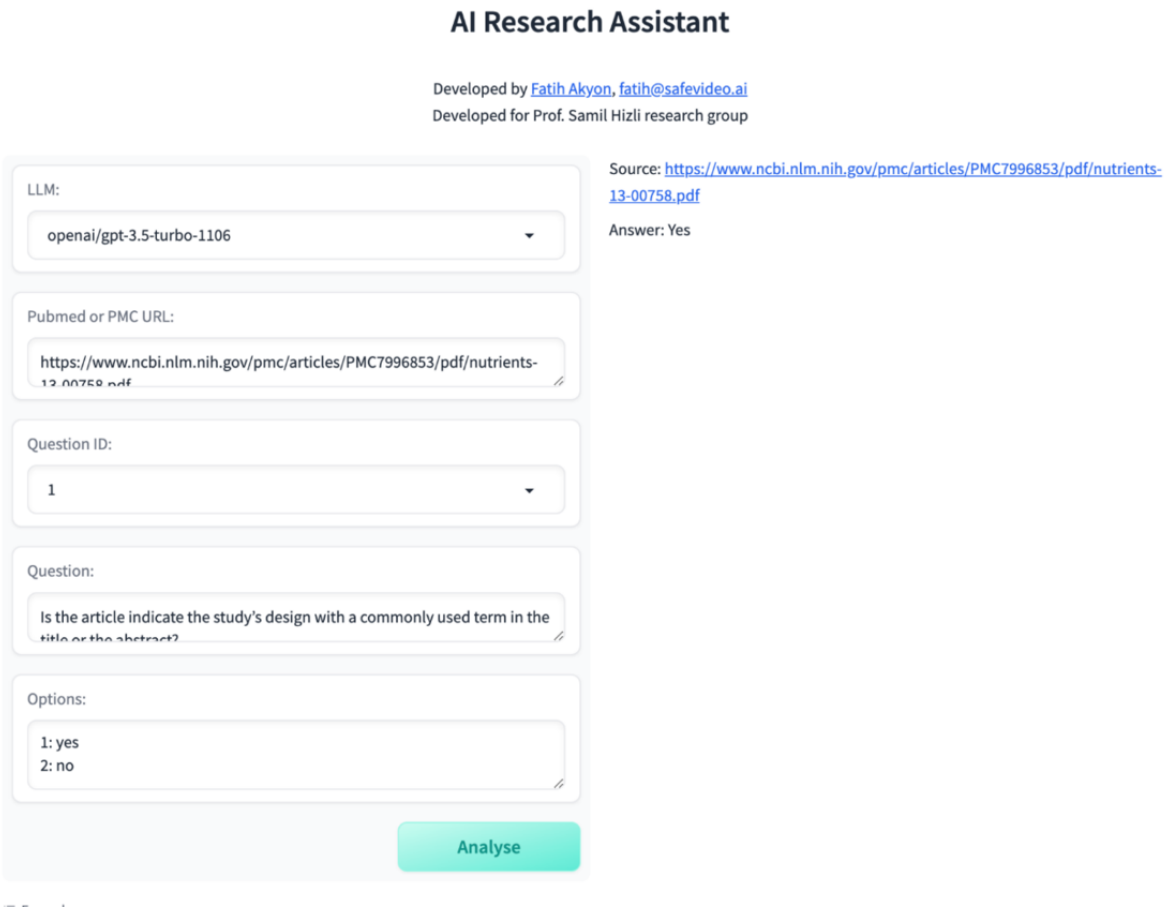
Questions	Answers
Title and abstract	
Q1. Does the paper indicate the study's design with a commonly used term in the title or the abstract?	1. Yes 2. No
Methods	
Q2. What is the observational study type: cohort, case-control, or cross-sectional studies?	1. Cohort study 2. A case-control study 3. Cross-sectional study 4. The study type is not stated in the paper
Q3. Were settings or locations mentioned in the method?	1. Yes 2. No
Q4. Were relevant dates mentioned in the method?	1. Yes 2. No
Q5. Were eligibility criteria for selecting participants mentioned in the method?	1. Yes 2. No
Q6. Were sources and methods of selection of participants mentioned in the method?	1. Yes 2. No
Q7. Were any efforts to address potential sources of bias described in the method or discussion?	1. Yes 2. No
Q8. Which program was used for statistical analysis?	1. SPSS was used for statistical analysis 2. MedCalc was used for statistical analysis 3. SAS was used for statistical analysis 4. STATA was used for statistical analysis 5. R program was used 6. Another program was used for statistical analysis 7. The program for statistical analysis is not specified
Results	
Q9. Were report numbers of individuals at each stage of the study (eg, numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analyzed) mentioned in the results?	1. Yes 2. No
Q10. Was a flowchart used to show the reported numbers of individuals at each stage of the study?	1. Yes 2. No
Q11. Were the study participants' demographic characteristics (eg, age and sex) given in the results?	1. Yes 2. No
Discussion	
Q12. Does the discussion part summarize key results concerning study objectives?	1. Yes 2. No
Q13. Are the limitations of the study discussed in the paper?	1. Yes 2. No
Q14. Is the generalizability of the study discussed in the discussion part?	1. Yes 2. No
Funding	
Q15. Is the funding of the study mentioned in the paper?	1. Yes 2. No

This list of 15 questions, 2 multiple-choice and 13 yes or no questions, has been prepared by selecting the STROBE checklist items that can be answered definitively and have clear, nonsubjective responses. Question 1, related to title and abstract, examines the LLMs' ability to identify and understand research designs and terms that are commonly used, evaluating the model's comprehension of the concise language typically used in titles and abstracts. Questions 2-8, related to methods, cover various aspects of the study's methodology, from the type of observational study to the statistical analysis programs used. They test the model's understanding of the detailed and technical language often found in this section. Questions 9-11, related to results, focus on the accuracy and completeness of reported results, such as participant numbers at each study stage and demographic characteristics. These questions gauge the LLMs' capability to parse and summarize factual data. Questions 12-14, related to the discussion, involve summarizing key results, discussing limitations, and addressing the study's generalizability. These questions assess the LLMs' ability to engage with more interpretive and evaluative content, showcasing their understanding of research impacts and contexts. Question 15, related to funding, tests the LLMs' attentiveness to specific yet crucial details that could influence the interpretation of research findings.

Development of Novel RAG-Based LLM Web Application

The methodology incorporated a novel web application specifically designed for this purpose to assess the understanding capabilities of generative AI tools in medical research papers (Figure 2). To mitigate the problem of "artificial hallucinations" inherent to LLMs, this study implemented the RAG method, which involves using a web application to dissect PDF-format medical papers from PubMed into text chunks ready to be processed by various LLMs. This approach guides the LLMs to provide answers grounded in the provided information by supplying them with relevant text chunks retrieved from the target paper.

Figure 2. Novel retrieval augmented generation–based large language model web application interface. AI: artificial intelligence.



Benchmark Pipeline

The benchmark pipeline itself is designed to process PubMed papers of varying lengths and extract relevant information for analysis. This pipeline operates as follows:

- Paper retrieval: We retrieved 39 observational studies from PubMed using the search term "obesity" in the title.
- Text extraction and chunking: Each retrieved PubMed paper was converted to PDF format and then processed through our web application. The application extracts all text content from the paper and divides it into smaller text chunks of manageable size.
- Vector representation: Using the OpenAI text-ada-embedding-002 model, each text chunk was converted into a representation vector. These vectors capture the semantic meaning of the text chunks, allowing for efficient information retrieval.

- Vector database storage: The generated representation vectors were stored in a vector database (LanceDB in our case). This database allows for rapid searching and retrieval of the most relevant text chunks based on a given query.
- Query processing: When a query (question from the STROBE checklist) was posed to an LLM, our pipeline calculated the cosine similarities between the query's representation vector and the vectors stored in the database. This identified the most relevant text chunks from the paper.
- RAG: The retrieved text chunks, along with the original query, were then combined and presented to the LLM. This approach, known as RAG, ensured that the LLM's responses were grounded in the specific information present in the paper, mitigating the risk of hallucinations.
- Answer generation and evaluation: The LLM generated an answer to the query based on the provided text chunks. The accuracy of each LLM's response was then evaluated by comparing it to the benchmark answers provided by a medical professor.

LLMs

Using this benchmark pipeline, we compared the answers of the generative AI tools, such as GPT-3.5-Turbo-1106 (June 11th version), GPT-4-0613 (November 6th version), GPT-4-1106 (June 11th version), PaLM 2 (chat-bison), Claude v1, and Gemini Pro, with the benchmark in 15 questions for 39 medical research papers (Table 2). In this study, 15 questions selected from the STROBE checklists were posed 10 times each for 39 papers to 6 different LLMs.

Table 2. The generative artificial intelligence (AI) tools compared with the benchmark in study.

Generative AI tool	Version	Company	Cutoff date
GPT-3,5-Turbo	November 6, 2023	OpenAI	September 2021
GPT-4-0613	June 13, 2023	OpenAI	September 2021
GPT-4-1106	November 6, 2023	OpenAI	April 2023
Claude v1	Version 1	Anthropic	—[a]
PaLM 2	Chat-bison	Google	—
Gemini Pro	1.0	Google	—

[a]The company does not explicitly state a cutoff date.

Access issues with Claude v1, specifically restrictions on its ability to process certain medical information, resulted in the exclusion of data from 6 papers, limiting the study's scope to 33 papers. LLMs commonly provide a "knowledge-cutoff" date, indicating the point at which their training data ends and they may not have access to the most up-to-date information. With some LLMs, however, the company does not explicitly state a cutoff date. The explicitly stated cutoff dates are given in Table 2, based on the publicly available information for each LLM.

A chatbot conversation begins when a user enters a query, often called a system prompt. The chatbot responds in natural language within a second, creating an interactive, conversation-like exchange. This is possible because the chatbot understands context. In addition to the RAG method, providing LLMs with well-designed system prompts that guide them to stay relevant to a given document can help generate responses that align with the provided information. We used the following system prompt for all LLMs:

> *You are an expert medical professor specialized in pediatric gastroenterology hepatology and nutrition, with a detailed understanding of various research methodologies, study types, ethical considerations, and statistical analysis procedures. Your task is to categorize research articles based on information provided in query prompts. There are multiple options for each question, and you must select the most appropriate one based on your expertise and the context of the research article presented in the query.*

The language models used in this study rely on statistical models that incorporate random seeds to facilitate the generation of diverse outputs. However, the companies behind these LLMs do not offer a stable way to fix these seeds, meaning that a degree of randomness is inherent in their responses. To further control this randomness, we used the "temperature" parameter within the language models. This parameter allows for adjustment of the level of randomness, with a lower temperature setting generally producing more deterministic outputs. For this study, we opted for a low-temperature parameter setting of 0.1 to minimize the impact of randomness. Despite these efforts, complete elimination of randomness is not possible. To further mitigate its effects and enhance the consistency of our findings, we repeated each question 10 times for the same language model. By analyzing the responses across these 10 repetitions, we could determine the frequency of accurate and consistent answers. This approach helped to identify instances where the LLM's responses were consistently aligned with the benchmark answers, highlighting areas of strength and consistency in comprehension.

Statistical Analysis

Each question was repeated 10 times in the same time period to obtain answers from multiple LLMs and ensure the consistency and reliability of responses. Consequently, the responses to the same question were analyzed to determine how many aligned with the benchmark, and the findings were examined. Only the answers that were correct and followed the instructions provided in the question text were considered "correct." Ambiguous answers, evident mistakes, and responses with an excessive number of candidates were considered

incorrect. The data were carefully examined, and the findings were documented and analyzed. Each inquiry and its response formed the basis of the analysis. Various descriptive statistical tests were used to assess the data presented as numbers and percentages. The Shapiro-Wilk test was used to assess the data's normal distribution. The Kruskal-Wallis and Pearson chi-square tests were used in the statistical analysis. Type I error level was accepted as 5% in the analyses performed using the SPSS (version 29.0; IBM Corp).

Ethical Considerations

This study only used information that had already been published on the internet. Ethics approval is not required for this study since it did not involve any human or animal research participants. This study did not involve a clinical trial, as it focused on evaluating the capabilities of AI tools in understanding medical papers.

Results

In this study, 15 questions selected from the STROBE checklists were posed 10 times each for 39 papers to 6 different LLMs. Access issues with Claude v1, specifically restrictions on its ability to process certain medical information, resulted in the exclusion of data from 6 papers, limiting the study's scope to 33 papers. The percentage of correct answers for each LLM is shown in Table 3, with GPT-3.5-Turbo achieving the highest rate (n=3916, 66.9%), followed by GPT-4-1106 (n=3837, 65.6%), PaLM 2 (n=3632, 62.1%), Claude v1 (n=2887, 58.3%), Gemini Pro (n=2878, 49.2%), and GPT-4-0613 (n=2580, 44.1%).

Table 3. The total amounts of correct answers among large language models (LLMs).

LLM	Total questions asked	Correct answers, n (%)
GPT-3.5-Turbo-1106	5850	3916 (66.9)
GPT-4-0613	5850	2580 (44.1)
GPT-4-1106	5850	3837 (65.6)
Claude v1	4950	2887 (58.3)
PaLM 2-chat-bison	5850	3632 (62.1)
Gemini Pro	5850	2878 (49.2)

Each LLM was compared with another LLM that provided a lower percentage of correct answers. Statistical analysis using the Kruskal-Wallis test revealed statistically significant differences between the LLMs (P<.001). The lowest correct answer percentage was provided by GPT-4-0613, at 44.1% (n=2580). Gemini Pro yielded 49.2% (n=2878) correct answers, significantly higher than GPT-4-0613 (P<.001). Claude v1 yielded 58.3% (n=2887) correct answers, statistically significantly higher than Gemini Pro (P<.001). PaLM 2 achieved 62.1% (n=3632) correct answers, significantly higher than Claude v1 (P<.001). GPT-4-1106 achieved 65.6% (n=3837) correct answers, significantly higher than PaLM 2 (P<.001). The difference between GPT-4-1106 and GPT-3.5-Turbo-1106 was not statistically significant (P=.06). Of the 39 papers analyzed, 28 (71.8%) were published before the training data cutoff date for GPT-3.5-Turbo and GPT-4-0613, while all 39 (100%) papers were published before the cutoff date for GPT-4-1106. Explicit cutoff dates for the remaining LLMs (Claude, PaLM 2, and Gemini Pro) were not publicly available and therefore could not be assessed in this study. When all LLMs are collectively considered, the 3 questions receiving the highest percentage of correct answers were question 12 (n=4025, 68.3%), question 13 (n=3695, 62.8%), and question 10 (n=3565, 60.5%). Conversely, the 3 questions with the lowest percentage of correct responses were question 8 (n=1971, 33.5%), question 15 (n=2107, 35.8%), and question 1 (n=2147, 36.5%; Table 4).

Table 4. Correct answer percentages of large language models (LLMs) for each question.

Question	Correct answers (across all LLMs), n (%)
Q1	2147 (36.5)
Q2	3061 (52)
Q3	2953 (50.2)
Q4	2713 (46.2)
Q5	3353 (57.1)
Q6	3132 (53.3)
Q7	2530 (43)
Q8	1971 (33.5)
Q9	2288 (38.9)
Q10	3565 (60.5)
Q11	3339 (56.9)
Q12	4025 (68.3)
Q13	3695 (62.8)
Q14	2578 (43.8)
Q15	2107 (35.8)

The percentages of correct answers given by all LLMs for each question are depicted in Figure 3. The median values for questions 7, 8, 9, 10, and 14 were similar across all LLMs, indicating a general consistency in performance for these specific areas of comprehension. However, significant differences were observed in the performance of different LLMs for other questions. The statistical tests used in this analysis were the Kruskal-Wallis test for comparing the medians of multiple groups and the chi-square test for comparing categorical data. For question 1, the fewest correct answers were provided by Claude (n=124, 24.8%) and Gemini Pro (n=197, 39.5%), while the most correct answers were provided by PaLM 2 (n=301, 60.3%; *P*=.01). In question 2, Claude v1 (n=366, 73.3%) achieved the highest median correct answer count (10.0, IQR 5.0-10.0), while Gemini Pro provided the fewest correct answers (n=237, 47.4%; *P*=.03). For question 3, GPT-3.5 (n=425, 85.1%) and PaLM 2 (n=434, 86.8%) had the highest median correct answer counts, while GPT-4-0613 (n=164, 32.8%) and Gemini Pro (n=189, 37.9%) had the lowest (*P*<.001). In the fourth question, PaLM 2 (n=369, 73.8%), GPT-3.5 (n=293, 58.7%), and GPT-4-1106 (n=336, 67.2%) performed best, while GPT-4-0613 (n=187, 37.4%) showed the lowest performance (*P*<.001). For questions 5 and 6, GPT-4-0613 (n=209, 41.8%) and Gemini Pro (n=186, 37.2%) provided fewer correct answers compared to the other LLMs (*P*<.001 and *P*=.001, respectively). In question 11, GPT-4-1106 (n=406, 81.2%), Claude (n=347, 69.4%), and PaLM 2 (n=406, 81.2%) performed well, while Gemini Pro (n=264, 52.8%) had the fewest correct answers (*P*=.001). For questions 12 and 13, all LLMs, except GPT-4-0613, performed well in these areas (*P*<.001). In question 15, GPT-3.5 (n=368, 73.6%) showed the highest number of correct answers (*P*<.001; Multimedia Appendix 1).

Discussion

Principal Findings

AI can improve the data analysis and publication process in scientific research while also being used to generate medical papers [16]. Although these fraudulent papers may appear well-crafted, their semantic inaccuracies and errors can be detected by expert readers upon closer examination [11,17]. The impact of LLMs on health care is often discussed in terms of their ability to replace health professionals, but their significant impact on medical and research writing applications and limitations is often overlooked. Therefore, physicians involved in research need to be cautious and verify information when using LLMs. As their reliance can lead to ethical concerns and inaccuracies, the scientific community should be vigilant in ensuring the accuracy and reliability of AI tools by using them as aids rather than replacements, understanding their limitations and biases [10,18]. With millions of papers published annually, AI could generate summaries or recommendations, simplifying the process of gathering evidence and enabling researchers to grasp important aspects of scientific results more efficiently [18]. Moreover, there is limited research focused on assessing the comprehension of academic papers.

This study aimed to evaluate the ability of 6 different LLMs to understand medical research papers using the STROBE checklist. We used a novel benchmark pipeline that processed 39 PubMed papers, posing 15 questions derived from the STROBE checklist to each model. The benchmark was established using the answers provided by an experienced medical professor and validated by an epidemiologist, serving as a reference standard against which the LLMs' responses were compared. To mitigate the problem of "artificial hallucinations" inherent to LLMs, our study implemented the RAG method, which involves using a web application to dissect PDF-format medical papers into text chunks and present them to the LLMs.

Our findings reveal significant variation in the performance of different LLMs, suggesting that LLMs are capable of understanding medical papers to varying degrees. While newer models like GPT-3.5-Turbo and GPT-4-1106 generally demonstrated better comprehension, GPT-3.5-Turbo outperformed even the more recent GPT-4-0613 in certain areas. This unexpected finding highlights the complexity of LLM performance, indicating that simple assumptions about newer models consistently outperforming older ones may not always hold true. The impact of training data cutoffs on LLM performance is a critical consideration in evaluating their ability to understand medical research [19]. While we were able to obtain explicitly stated cutoff dates for GPT-3.5-Turbo, GPT-4-1106, and GPT-4-0613, this information was not readily available for the remaining models. This lack of transparency regarding training data limits our ability to definitively assess the impact of knowledge cutoffs on model performance. The observation that all 39 papers were published before the cutoff date for GPT-4-1106, while only 28 papers were published

before the cutoff date for GPT-3.5-Turbo and GPT-4-0613, suggests that the knowledge cutoff may play a role in the observed performance differences. GPT-4-1106, with a more recent knowledge cutoff, has access to a larger data set, potentially including information from more recently published research. This could contribute to its generally better performance compared to GPT-3.5-Turbo. However, it is important to note that GPT-3.5-Turbo still outperformed GPT-4-0613 in specific areas, even with a similar knowledge cutoff. This suggests that factors beyond training data (eg, the number of layers, the type of attention mechanism, or the use of transformers) and compression techniques (eg, quantization, pruning, or knowledge distillation) may also play a significant role in LLM performance. Future research should prioritize transparency regarding training data cutoffs and aim to standardize how LLMs communicate these crucial details to users.

This study evaluated the performance of various LLMs in accurately answering specific questions related to different sections of a scholarly paper: title and abstract, methods, results, discussion, and funding. The results shed light on which LLMs excel in specific areas of comprehension and information retrieval from academic texts. PaLM 2 (n=219, 60.3%) showed superior performance in question 1, identifying the study design from the title or abstract, suggesting enhanced capability in understanding and identifying specific terminologies. Claude (n=82, 24.8%) and Gemini Pro (n=154, 39.5%), however, lagged, indicating a potential area for improvement in terminology recognition and interpretation. Claude v1 (n=242, 73.3%) and PaLM 2 (n=295, 86.8%) exhibited strong capabilities in identifying methodological details, such as observational study types and settings or locations (questions 2-8). This suggests a robust understanding of complex methodological descriptions and the ability to distinguish between different study frameworks. For questions regarding the results section (questions 9-11), it is evident that models like GPT-4-1106 (n=317, 81.3%), Claude (n=229, 69.4%), and PaLM 2 (n=276, 81.2%) showed superior performance in providing correct answers related to the study participants' demographic characteristics and the use of flowcharts. All LLMs except for GPT4-0613 (n=89, 22.8%) exhibited remarkable competence in summarizing key results, discussing limitations, and addressing the generalizability of the study (questions 12-14), which are critical aspects of the discussion section. GPT-3.5 (n=287, 73.6%) particularly excelled in identifying the mention of funding (question 15), indicating a nuanced understanding of acknowledgments and funding disclosures often nuanced and embedded toward the end of papers. Across the array of tested questions, both GPT-3.5 and PaLM 2 exhibit remarkable strengths in understanding and analyzing scholarly papers, with PaLM 2 generally showing a slight edge in versatility, especially in interpreting methodological details and study design. GPT-3.5, while strong in discussing study limitations, generalized findings, and funding details, indicates that improvements can be made in extracting complex methodological information. We observed that different models excelled in different areas, indicating that no single LLM currently demonstrates universal dominance in medical paper understanding. This suggests that factors like training data, model architecture, and question complexity influence performance, and further research is needed to understand the specific contributions of each factor.

Comparison to Prior Work

LLMs can be directly questioned and can generate answers from their own memory [11]. This has been extensively studied in many medical papers. According to a study, ChatGPT, an LLM, was evaluated on the United States Medical Licensing Examination. The results showed that GPT performed at or near the passing threshold for examinations without any specialized training, demonstrating a high level of concordance and insight in its explanations. These findings suggest that LLMs have the potential to aid in medical education and potentially assist with clinical decision-making [5,20]. Another study aimed to evaluate the knowledge level of GPT in medical education by assessing its performance in a multiple-choice question examination and its potential impact on the medical examination system. The results indicated that GPT achieved a satisfactory score in both basic and clinical medical sciences, highlighting its potential as an educational tool for medical students and faculties [21]. Furthermore, GPT offers information and aids health care professionals in diagnosing patients by analyzing symptoms and suggesting appropriate tests or treatments. However, advancements are required to ensure AI's interpretability and practical implementation in clinical settings [8]. The study conducted in October 2023 explored the diagnostic capabilities of GPT-4V, an AI model, in complex clinical scenarios involving medical imaging and textual patient data. Results showed that GPT-4V had the highest diagnostic accuracy when provided with multimodal inputs, aligning with confirmed diagnoses in 80.6% of cases [22]. In another study, GPT-4 was instructed to address the case with multiple-choice questions followed by an unedited clinical case report that evaluated the effectiveness of the newly developed AI model GPT-4 in solving complex medical case challenges. GPT-4 correctly diagnosed 57% of the cases, outperforming 99.98% of human readers who were also tasked with the same challenge [23]. These studies highlight the potential of multimodal AI models like GPT-4 in clinical diagnostics, but further investigation is needed to uncover biases and limitations due to the model's proprietary training data and architecture.

There are few studies in which LLMs are directly questioned, and their capacities to produce answers from their own memories are compared with each other and expert clinicians. In a study, GPT-3.5 and GPT-4 were compared to orthopedic residents in their performance on the American Board of Orthopaedic Surgery written examination, with residents scoring higher overall, and a subgroup analysis revealed that GPT-3.5 and GPT-4 outperformed residents in answering text-only questions, while residents scored higher in image interpretation questions. GPT-4 scored higher than GPT-3.5 [24]. A study aimed to evaluate and compare the recommendations provided by GPT-3 and GPT-4 with those of primary care physicians for the management of depressive episodes. The results showed that both GPT-3.5 and GPT-4 largely aligned with accepted guidelines for treating mild and severe depression while demonstrating a lack of gender or socioeconomic biases observed among primary care physicians. However, further

research is needed to refine the AI recommendations for severe cases and address potential ethical concerns and risks associated with their use in clinical decision-making [25]. Another study assessed the accuracy and comprehensiveness of health information regarding urinary incontinence generated by various LLMs. By inputting selected questions into GPT-3.5, GPT-4, and Gemini, the researchers found that GPT-4 performed the best in terms of accuracy and comprehensiveness, surpassing GPT-3.5 and Gemini [26]. According to a study that evaluates the performance of 2 GPT models (GPT-3.5 and GPT-4) and human professionals in answering ophthalmology questions from the StatPearls question bank, GPT-4 outperformed both GPT-3.5 and human professionals on most ophthalmology questions, showing significant performance improvements and emphasizing the potential of advanced AI technology in the field of ophthalmology [27]. Some studies showed that GPT-4 is more proficient, as evidenced by scoring higher than GPT-3.5 in both multiple-choice dermatology examinations and non–multiple-choice cardiology heart failure questions from various sources and outperforming GPT-3.5 and Flan-PaLM 540B on medical competency assessments and benchmark data sets [28-30]. In a study conducted on the proficiency of various open-source and proprietary LLMs in the context of nephrology multiple-choice test-taking ability, it was found that their performance on 858 nephSAP questions ranged from 17.1% to 30.6%, with Claude 2 at 54.4% accuracy and GPT-4 at 73.3%, highlighting the potential for adaptation in medical training and patient care scenarios [31]. To our knowledge, this is the first study to assess the performance of evaluating medical papers and understanding the capabilities of different LLMs. The findings reveal that the performance of LLMs varies across different questions, with some LLMs showing superior understanding and answer accuracy in certain areas. Comparative analysis across different LLMs showcases a gradient of capabilities. The results revealed a hierarchical performance ranking as follows: GPT-4-1106 equals GPT-3.5-Turbo, which is superior to PaLM 2, followed by Claude v1, then Gemini Pro, and finally, GPT-4-0613. Similar to the literature review, GPT-4-1106 and GPT-3.5 showed improved accuracy and understanding compared to other LLMs. This mirrors wider literature trends, indicating LLMs' rapid evolution and increasing sophistication in handling complex medical queries. Notably, GPT-3.5-Turbo showed better performance than GPT-4-0613, which may be counterintuitive, considering the tendency to assume newer iterations naturally perform better. This anomaly in performance between newer and older versions can be attributed to the application of compression techniques in developing new models to reduce computational costs. While these advancements make deploying LLMs more cost-effective and thus accessible, they can inadvertently compromise the performance of LLMs. The notable absence of responses from PaLM in certain instances, actually stemming from Google's policy to restrict the use of its medical information, presents an intriguing case within the scope of our discussion. Despite these constraints, PaLM's demonstrated high performance in other areas is both surprising and promising. This suggests that even when faced with limitations on accessing a vast repository of medical knowledge, PaLM's underlying architecture and algorithms enable it to make effective use of the information it can access, showcasing the robust potential of LLMs in medical settings even under restricted conditions.

Strengths and Limitations

While LLMs can be directly questioned and generate answers from their own memory, as demonstrated in numerous studies above, this approach can lead to inaccuracies known as hallucinations. Hallucinations in LLMs have diverse origins, encompassing the entire spectrum of the capability acquisition process, with hallucinations primarily categorized into 3 aspects: training, inference, and data. Architecture flaws, exposure bias, and misalignment issues in both pretraining and alignment phases induce hallucinations. To address this challenge, our study used the RAG method, ensuring that the LLMs' responses were grounded in factual information retrieved from the target paper. The RAG method intuitively addresses the knowledge gap by conditioning language models on relevant documents retrieved from an external knowledge source [12,32]. RAG provides the LLM with relevant text chunks extracted from the specific paper being analyzed. This ensures that the LLM's responses are directly supported by the provided information, reducing the risk of hallucination. While a few studies have explored the use of RAG to compare LLMs, like the one demonstrating GPT-4's improved accuracy with RAG for interpreting oncology guidelines [33], our study is the first to evaluate LLM comprehension of medical research papers using this method. This method conditions LLMs on relevant documents retrieved from an external knowledge source, ensuring their answers are grounded in factual information. The design of system prompts is crucial for LLMs, as it provides context, instructions, and formatting guidelines to ensure the desired output [34]. In this study, it is empirically determined that a foundational system and set of system prompts universally enhanced the response quality across all language models tested. This approach was designed to optimize the comprehension and summarization capabilities of each generative AI tool when processing medical research papers. The specific configuration of system settings and query structures we identified significantly contributed to improving the accuracy and relevance of the models' answers. These optimized parameters were crucial in achieving a more standardized and reliable evaluation of each model's ability to understand complex medical texts. While further research is needed to fully understand the effectiveness of RAG across different medical scenarios, our findings demonstrate its potential to enhance the reliability and accuracy of LLMs in medical research comprehension.

This study, while offering valuable insights, is subject to several limitations. The selection of 50 papers focused on obesity, and the use of a specific set of 15 STROBE-derived questions might not fully capture the breadth of medical research. Additionally, the reliance on binary and multiple-choice questions restricts the evaluation of LLMs' ability to provide nuanced answers. The rapid evolution of LLMs means that the findings might not be applicable to future versions, and potential biases within the training data have not been systematically assessed. Furthermore, the study's reliance on a single highly experienced medical professor as the benchmark, while evaluating, might

limit the generalizability of the findings. A larger panel of experts with diverse areas of specialization might provide a more comprehensive reference standard for evaluating LLM performance. Further investigation with a wider scope and more advanced methodologies is needed to fully understand the potential of LLMs in medical research.

Future Directions

In conclusion, LLMs show promise for transforming medical research, potentially enhancing research efficiency and evidence-based decision-making. This study demonstrates that LLMs exhibit varying capabilities in understanding medical research papers. While newer models generally demonstrate better comprehension, no single LLM currently excels in all areas. This highlights the need for further research to understand the complex interplay of factors influencing LLM performance. Continued research is crucial to address these limitations and ensure the safe and effective integration of LLMs in health care, maximizing their benefits while mitigating risks.

Acknowledgments

The authors gratefully acknowledge Dr Hilal Duzel for her invaluable assistance in validating the reference standard used in this study. Dr Duzel's expertise in epidemiology and statistical analysis ensured the accuracy and robustness of the benchmark against which the LLMs were evaluated. We would also like to thank Ahmet Hamza Dogan, a promising future engineer, for his contributions to the LLM analysis.

Abstract

Background: Generative artificial intelligence (GAI) systems by Google have recently been updated from Bard to Gemini and Gemini Advanced as of December 2023. Gemini is a basic, free-to-use model after a user's login, while Gemini Advanced operates on a more advanced model requiring a fee-based subscription. These systems have the potential to enhance medical diagnostics. However, the impact of these updates on comprehensive diagnostic accuracy remains unknown.

Objective: This study aimed to compare the accuracy of the differential diagnosis lists generated by Gemini Advanced, Gemini, and Bard across comprehensive medical fields using case report series.

Methods: We identified a case report series with relevant final diagnoses published in the *American Journal Case Reports* from January 2022 to March 2023. After excluding nondiagnostic cases and patients aged 10 years and younger, we included the remaining case reports. After refining the case parts as case descriptions, we input the same case descriptions into Gemini Advanced, Gemini, and Bard to generate the top 10 differential diagnosis lists. In total, 2 expert physicians independently evaluated whether the final diagnosis was included in the lists and its ranking. Any discrepancies were resolved by another expert physician. Bonferroni correction was applied to adjust the *P* values for the number of comparisons among 3 GAI systems, setting the corrected significance level at *P* value <.02.

Results: In total, 392 case reports were included. The inclusion rates of the final diagnosis within the top 10 differential diagnosis lists were 73% (286/392) for Gemini Advanced, 76.5% (300/392) for Gemini, and 68.6% (269/392) for Bard. The top diagnoses matched the final diagnoses in 31.6% (124/392) for Gemini Advanced, 42.6% (167/392) for Gemini, and 31.4% (123/392) for Bard. Gemini demonstrated higher diagnostic accuracy than Bard both within the top 10 differential diagnosis lists (*P*=.02) and as the top diagnosis (*P*=.001). In addition, Gemini Advanced achieved significantly lower accuracy than Gemini in identifying the most probable diagnosis (*P*=.002).

Conclusions: The results of this study suggest that Gemini outperformed Bard in diagnostic accuracy following the model update. However, Gemini Advanced requires further refinement to optimize its performance for future artificial intelligence–enhanced diagnostics. These findings should be interpreted cautiously and considered primarily for research purposes, as these GAI systems have not been adjusted for medical diagnostics nor approved for clinical use.

(JMIR Med Inform 2024;12:e63010) doi:10.2196/63010

artificial intelligence; clinical decision support; diagnostic excellence; generative artificial intelligence; large language models; natural language processing

Introduction

Diagnostic Team to Reduce Misdiagnoses

Diagnosis is a crucial step in clinical medicine, where a significant proportion of medical errors and harms are related to diagnostic errors [1]. The formation of a diagnostic team has been proposed as an effective strategy to mitigate the risks associated with misdiagnosis [2,3]. This team should promote collaboration among medical professionals, patients, and their families, and the integration of digital tools to enhance diagnostic accuracy [4]. Several research, including systematic reviews, have shown that the implementation of clinical decision support systems (CDSSs) in clinical settings has significantly improved diagnostic accuracy, patient care, and health care process [5-7].

Digital Tool for Medical Diagnosis

Various digital tools, particularly diagnostic CDSSs, have emerged for medical diagnostics. These systems are designed to provide diagnostic suggestions based on clinical data, aiding medical professionals in clinical decision-making [8]. Traditionally, diagnostic CDSSs, such as symptom checkers and differential diagnosis generators, have relied on fixed algorithms and rule-based systems derived from medical databases and expert input [9-11]. Unfortunately, these systems often experience poor accuracy and inadequate integration into clinical workflows, limiting their practical use in real-world medical settings [4]. In this context, artificial intelligence (AI), especially generative AI (GAI), has introduced a new category of CDSS [12]. This advancement suggests a future shift in how digital tools can support diagnostic processes.

GAI in Medical Diagnosis

GAI systems have shown rapid development and are increasingly influencing various fields, including medicine. This advancement is partly due to the development of machine learning techniques, such as neural networks and natural language processing. GAI represents a shift from rule-based systems to models that can autonomously generate and evaluate new data patterns. Overcoming many limitations faced by traditional CDSSs, GAI systems could significantly enhance future diagnostic processes. Notable examples include ChatGPT developed by Open AI, and Gemini and Gemini Advanced from Google [13]. These systems use advanced large language models (LLMs), which are complex neural networks trained on vast data sets through natural language processing [14]. Recent studies, including one evaluating dermoscopy image descriptions with chatbot responses, have demonstrated promising results in accuracy and diagnostic completeness by ChatGPT [15]. The language model for dialogue applications (LaMDA) developed by Google AI is one such LLM. Their ability to process and generate outputs is particularly promising for future applications in medical diagnostics, where they will analyze complex clinical information and collaborate as part of a diagnostic team.

From Bard to Gemini and Gemini Advanced

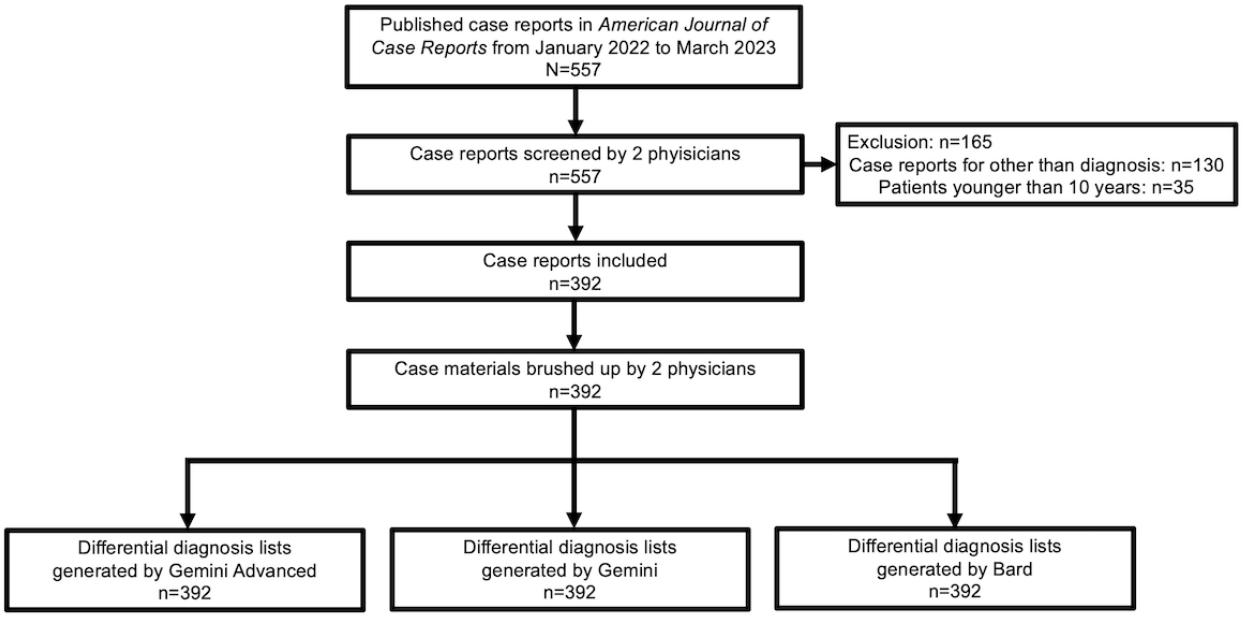
Originally, Bard was developed using the LaMDA model primarily for text generation and conversational AI and later transitioned to the Pathways Language Model (Palm 2). Subsequent developments led to the release of Gemini and Gemini Advanced in December 2023. Gemini Advanced, an upgraded version of Gemini, leverages Ultra 1.0, Google's most advanced model, offered as a fee-based service [16,17]. These developments reflect the rapid pace at which GAI technology is advancing. Recent updates have transformed Bard into Gemini and Gemini Advanced, enhancing their functionalities and applications in various fields. Previous research, including our own, has demonstrated that Bard showed promising results in medicine [18-21]. Moreover, a recent study has shown that several GAI systems, including Gemini Advanced, could achieve notable diagnostic accuracy for multiple-choice questions about clinical vignettes [22]. These findings suggest that even without specific training or reinforcement for diagnostics, GAI systems show potential for reliable use in diagnostics. Despite these advancements, the comparative diagnostic accuracy of differential diagnosis lists by these GAI systems across comprehensive medical fields remains to be fully explored. This study aims to fill that gap by evaluating the diagnostic accuracy of the differential diagnosis lists generated by Gemini Advanced, Gemini, and Bard for case report series across various medical disciplines.

Methods

Overview

An experimental study was conducted to assess the diagnostic accuracy of Gemini Advanced, Gemini, and Bard for a comprehensive case report series. This study was conducted at the Department of Diagnostic and Generalist Medicine (General Internal Medicine) at Dokkyo Medical University, Japan. This study consisted of preparing case materials, generating differential diagnosis lists, evaluating the lists, and analyzing the diagnostic accuracy. Figure 1 shows the study flow, including the inclusion of case materials and the generation of differential diagnosis lists.

Figure 1. Study flow of inclusion case materials and generation of differential diagnosis.



Preparing Case Materials

We focused on a comprehensive series of case reports from the *American Journal of Case Reports*, covering a broad range of medical fields. The structured format of the journal facilitated easy identification of sections containing the case reports and the final diagnoses. Initially, the inclusion criteria were the case reports published in the *American Journal of Case Reports* from January 1, 2022, to March 1, 2023. A PubMed search identified 557 consecutive case reports. After excluding 130 nondiagnostic case reports and 35 pediatric case reports (patients aged 10 years and younger), 392 case reports remained. The exclusion criteria were based on previous research for CDSS [23]. We refined the case reports to prepare the case materials, which typically included the initial case report part to the definitive tests for final diagnosis. The relevant final diagnoses were typically described by the authors. We used only textual data exclusively, omitting image data. Specifically, the title, background, final diagnosis, clinical course following diagnosis, discussion, conclusion, figures, tables, and supplemental materials were excluded from the case materials. The main investigator (TH) conducted this process with validation from another investigator (YH). The PubMed search keywords are shown in Multimedia Appendix 1. For example, in a case report titled "Herpes Zoster Following COVID-19 Vaccine Booster," the final diagnosis was herpes zoster [24]. We extracted the case report part from "An 82-year-old.." to "Vesicular breath sounds were heard equally on both lung fields."

Generating Differential Diagnosis Lists

We used Gemini Advanced, Gemini, and Bard as GAI systems for this research. This was because these systems are popular AI platforms available to the public. These GAI systems were not specifically enhanced for medical diagnosis. Details about the GAI systems used in this study are provided in Table 1. To generate the top 10 differential diagnosis lists from GAI systems, the main investigator typically copied and pasted the case materials into the AI systems with the prompt, that is "Tell me the top 10 suspected illnesses for the following case: (case materials)." This prompt, developed through preliminary research, aimed to generate the top 10 differential diagnosis lists. The first list produced by the GAI systems was used as the differential diagnosis list. The data control setting was adjusted to "Not saving activity," to avoid the influence from the previous conversations. In addition, before starting a new session, the main investigator refreshed the previous session to prevent any influence from previous conversations.

Evaluating the Differential Diagnosis Lists

A total of 2 expert researchers (TI and T Suzuki) independently evaluated the differential diagnosis lists from GAI systems. A score of "1" was assigned if the differential accurately and specifically identified the final diagnosis or was sufficiently close to the final diagnosis. Conversely, a score of "0" was assigned if it diverged significantly from the final diagnosis [25]. When a GAI system could not output the differential diagnosis list, a score of "0" was labeled. When the score was "1," the evaluator assessed its ranking within the list. Any discrepancies were resolved by another expert researcher (KT). All evaluators were blinded to which GAI systems produced the differential diagnosis lists.

Analyzing the Diagnostic Accuracy

In this study, we defined diagnostic accuracy as the inclusion of the final diagnoses in the differential diagnosis lists.

Outcome

In terms of the outcomes, the primary outcome was the total score for correctly identifying the final diagnosis in the top 10 differential diagnosis lists generated by Gemini Advanced, Gemini, and Bard. The total number of included case reports was used as the denominator. The numerator was the number of case reports that correctly identified the final diagnosis in the top 10 differential diagnosis lists. The secondary outcomes were the total score for correctly identifying the final diagnosis in the top 5 differential diagnosis lists and as the top diagnosis generated from Gemini Advanced, Gemini, and Bard.

In addition, we evaluated the top 10 rankings of the most frequently named differential diagnoses across generated differential diagnosis lists by a GAI system to find the underlying patterns. We also assessed whether the items in the differential diagnosis lists corresponded to the names of existing diseases.

Moreover, we analyzed how Gemini Advanced, Gemini, and Bard rank the correct diagnosis on average when it appears in the differential diagnosis lists. This metric helps evaluate not only whether the correct diagnosis is included but also its relative priority among other suggested diagnoses. For cases where the correct diagnosis was missing, we assigned a penalty rank; specifically, we used 11 as the penalty rank.

Statistical Analysis

A chi-square test was used for the categorical or binary variables. The Mann-Whitney *U* test was applied to analyze the average rankings. For multiple comparisons, the Bonferroni correction was applied [26]. The Bonferroni correction adjusts the *P* value by dividing it by the number of comparisons being made, namely 3 GAI systems, that consist of Gemini Advanced, Gemini, and Bard, setting a more stringent threshold for individual tests to be considered significant. The Bonferroni-corrected significance level was defined as a *P* value of <.02. Note that all statistical tests were performed using the R (version 4.2.2; The R Foundation for Statistical Computing) for macOS X.

Ethical Considerations

Given the study's method of using published case reports, approval from an ethical committee was deemed not applicable.

Results

Overview of Outputs From GAI Systems

In total, 392 case reports were included. The distribution of diagnoses in these reports highlighted the prevalence of complex medical conditions, with 22.7% (89/392) of cases being diagnosed as malignancy, 22.4% (88/392) as various infections, and 17.1% (67/392) as vascular diseases.

Bard generated differential diagnosis lists for all 392 cases. In contrast, both Gemini Advanced and Gemini encountered challenges with 3 cases, failing to produce outputs. The cases where outputs were not generated involved complex clinical scenarios that were directly described in the reports as involving overdose, psychological conditions, and vaccination side effects. Representative outputs from Gemini Advanced, Gemini, and Bard are shown in Table 2. The data set of differential diagnoses generated by AI systems in this study, alongside the final diagnosis, are shown in Multimedia Appendix 2.

Table 2. Representative outputs from Gemini Advanced, Gemini, and Bard for final diagnoses.

Gemini Advanced	Gemini	Bard
Herpes Zoster		
• Shingles (Herpes Zoster) • Myocardial ischemia • Costochondritis • Pericarditis • Pleuritis • Pulmonary embolism • Pneumonia • Metastatic malignancy • Aortic dissection • Esophageal spasm	• Shingles (Herpes Zoster) • Myocardial ischemia (Angina) • Costochondritis • Musculoskeletal strain • Pleurisy • Intercostal neuritis • Pulmonary embolism • Pericarditis • Gastritis • Esophagitis	• Herpes zoster (Shingles) • Myocardial infarction (heart attack) • Aortic dissection • Pulmonary embolism • Pneumonia • Thoracic radiculopathy • Costochondritis • Intercostal neuralgia • Costoclavicular syndrome • Tietze syndrome
Diffuse alveolar hemorrhage		
• Pulmonary alveolar hemorrhage • Nocardia pneumonia • Pulmonary embolism • Acute eosinophilic pneumonia • Drug-induced pneumonitis • Legionnaires' disease • Hypersensitivity pneumonitis • Idiopathic pulmonary fibrosis • Bronchiolitis obliterans organizing pneumonia • Acute interstitial pneumonitis	• Pulmonary alveolar hemorrhage • Trastuzumab-induced pneumonitis • Aspirin-exacerbated respiratory disease • Acute heart failure • Pulmonary edema • Nocardia pneumonia • Pulmonary hypertension • Acute interstitial lung disease • Acute chronic kidney disease • Occult gastrointestinal bleed	• Acute radiation pneumonitis • Acute hypersensitivity pneumonitis • Pulmonary edema • Pulmonary embolism • Aspiration pneumonia • Bronchogenic carcinoma • Sarcoidosis • Lymphoma • Wegener’s granulomatosis • Goodpasture syndrome
Glomus tumor		
• Meralgia paresthetica • Soft tissue sarcoma • Fibroma • Myositis ossificans • Neuroma • Hemangioma • Liposarcoma • Lymphoma • Abscess • Malignant peripheral nerve sheath tumor	• Meralgia paresthetica • Lumbar radiculopathy • Femoral neuropathy • Piriformis syndrome • Muscle strain • Myofascial pain syndrome • Glomus tumor • Neuroma • Soft tissue sarcoma (unlikely) • Abscess (unlikely)	• Lipoma • Fibromatosis • Myositis • Neoplasm • Infection • Inflammation • Trauma • Hematoma • Varicose vein • Cellulitis

Diagnostic Accuracy

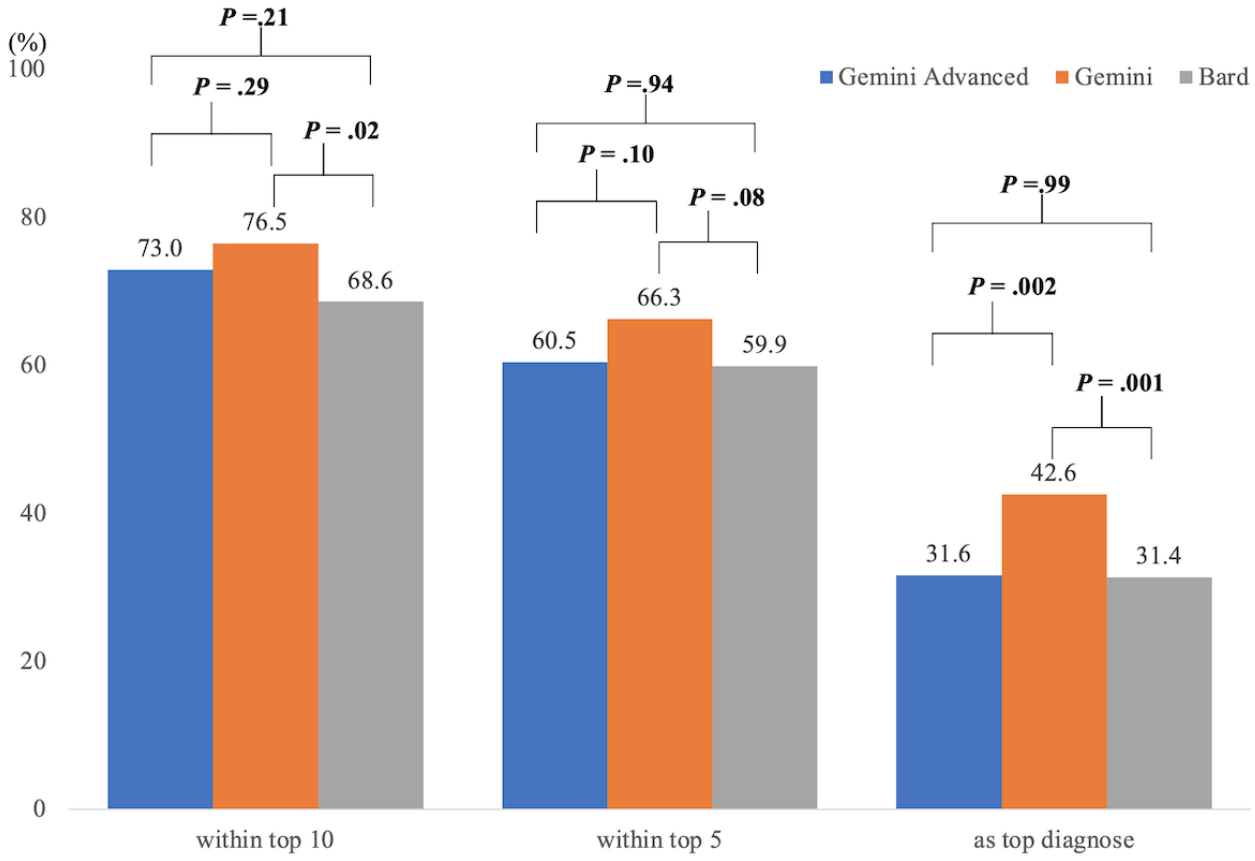
In terms of diagnostic accuracy, the inclusion rates of the final diagnoses within the top 10 differential diagnosis lists were 73.0% (286/392) for Gemini Advanced, 76.5% (300/392) for Gemini, and 68.6% (269/392) for Bard. For the top 5 differential diagnoses, the rates were 60.5% (237/392) for Gemini Advanced, 66.3% (260/392) for Gemini, and 59.9% (235/392) for Bard. The top diagnoses matched the final diagnoses in 31.6% (124/392) for Gemini Advanced, 42.6% (167/392) for Gemini, and 31.4% (123/392) for Bard. Gemini demonstrated higher diagnostic accuracy than Bard both within the top 10 differential diagnosis lists (P=.02) and as the top diagnosis (P=.001). In addition, Gemini Advanced achieved lower accuracy in identifying the most probable diagnosis, compared with Gemini with this result being statistically significant (P=.002). Other comparisons were statistically insignificant. Table 3 and Figure 2 show the diagnostic accuracy by Gemini Advanced, Gemini, and Bard.

Table 3. Diagnostic accuracy of Gemini Advanced, Gemini, and Bard.

Variable	Gemini Advanced (N=392), n (%)	Gemini (N=392), n (%)	Bard (N=392), n (%)	P value[a]		
				Gemini Advanced versus Gemini	Gemini Advanced versus Bard	Gemini versus Bard
Within the top 10	286 (73.0)	300 (76.5)	269 (68.6)	.29	.21	.02
Within the top 5	237 (60.5)	260 (66.3)	235 (59.9)	.10	.94	.08
Top diagnosis	124 (31.6)	167 (42.6)	123 (31.4)	.002	.99	.001

[a]Chi-square test. The Bonferroni-corrected significance level at a P value <.02.

Figure 2. Diagnostic accuracy of Gemini Advanced, Gemini, and Bard. *P* values were derived from the chi-square test. The Bonferroni-corrected significance level at a *P* value <.02.



Most Frequently Named Differential Diagnoses

Regarding the top 10 most frequently named differential diagnoses, all rankings included sepsis, pneumonia, pulmonary embolism, lymphoma, and meningitis. Notably, the top 3 most frequently named differential diagnoses by Gemini Advanced and Gemini were the same. Table 4 shows the top 10 most frequently named differential diagnoses generated by Gemini Advanced, Gemini, and Bard.

Table 4. The top 10 most frequently named differential diagnoses were generated by Gemini Advanced, Gemini, and Bard.

The raking in the top 10 most frequently named differentials, (N)	Gemini Advanced (n)	Gemini (n)	Bard (n)
1	Sepsis (43)	Sepsis (42)	Sarcoidosis (51)
2	Pneumonia (34)	Pneumonia (28)	Sepsis (42)
3	Pulmonary embolism (33)	Pulmonary embolism (20)	Pneumonia (41)
4	Acute kidney injury (28)	Sarcoidosis (15)	Lymphoma (40)
5	Lymphoma (25)	Pericarditis (14)	Pulmonary embolism (39)
6	Urinary tract infection (24)	Meningitis (14)	Meningitis (31)
7	Heart failure (23)	Lymphoma (13)	Inflammatory bowel disease (29)
8	Meningitis (22)	Myocarditis (13)	Tuberculosis (26)
9	Myocardial infarction (20)	Acute kidney injury (12)	Encephalitis (25)
10	Pericarditis (18)	Systemic lupus erythematosus (12)	Myocarditis (24)

Inappropriate Diseases Names

From all differential diagnosis lists output by generative AIs, we identified inappropriate disease names: 11 items from Gemini Advanced, 9 items from Gemini, and 5 items from Bard. Notably, Gemini Advanced and Gemini both erroneously listed "Wegner's granulomatosis," a misspelling of the previous correct term, "Wegener's granulomatosis," which has now been updated to "Granulomatosis with Polyangiitis" [27]. Another error by Gemini Advanced involved "Microcytic colitis," likely a confusion between "microcystic anemia" and "microscopic colitis." Table 5 lists the inappropriate disease names generated by Gemini Advanced, Gemini, and Bard.

Table 5. Inappropriate disease name generated by Gemini Advanced, Gemini, and Bard.

Correct disease name, [cell number in Multimedia Appendix 2]	Inappropriate disease name by Gemini Advanced	Inappropriate disease name by Gemini	Inappropriate disease name by Bard
Drug reaction (Dasatinib)	Drug reation (Dasatinib) [O15]	—[a]	—
Nonketotic hyperglycemic hyperosmolar coma	—	Nonketotic hyperglycemia hyperosmolar coma [X29]	—
Lipedema	—	Lipoderma [U34]	—
Small bowel angiodysplasia	Small bowel angiodisplasia [M40]		—
Granulomatosis with polyangiitis	Granulomatous with polyangiitis (L68), Wegner's granulomatosis [N111]	Wegner's granulomatosis [U186]	—
Costochondritis	Costochondritisa [P86]	—	—
Maxillary sinus carcinoma	—	Maxillary sinus cycinoma [L106]	—
Constrictive pericarditis	Conrictive pericarditis [L110]	—	—
Scleroderma-related interstitial lung disease	—	Scleroderma-related interstitial lung disease [S117]	—
Pericoronitis	—	—	Pericoronatitis [AA133]

Unknown (Transaminase elevation is also not disease name)	Transaminitis elevation (N354)	—	—

[a]Not applicable.

Average Ranking

In terms of average ranking, the scores were 5.25 (SD 4.16) for Gemini Advanced, 4.54 (SD 4.21) for Gemini, and 5.33 (SD 4.29) for Bard. The differences in average rankings were not statistically significant between Gemini Advanced and Gemini (*P*=.99), between Gemini Advanced and Bard (*P*=.17), and between Gemini and Bard (*P*=.99).

Discussion

Principal Findings

In the following, we discuss our principal findings. Our findings indicate that Gemini demonstrated superior diagnostic accuracy compared with Bard, not only within the top 10 differential diagnosis lists but also in identifying the most likely diagnosis. Specifically, Gemini's diagnostic accuracy for the top 10 lists was 76.5% (300/392), compared to Bard's 68.6% (269/392), with a statistically significant difference (*P*=.02). Moreover, as the top diagnosis, Gemini's diagnostic accuracy was 42.6% (167/392) versus Bard's 31.4% (123/392), also significant (*P*=.001). This enhancement in Gemini's diagnostic performance may be attributed to its advanced algorithmic framework, which likely incorporates more nuanced medical data and learns from recent case inputs, leading to more refined diagnostic predictions.

However, the performance of Gemini did not statistically outperform in the top 5 differential diagnosis lists. This outcome may suggest that while Gemini's algorithm is effective in a broader exploratory context, its precision may falter when

constrained to a narrower list of top diagnoses. This indicates that a balance between breadth of exploration and depth of focus is crucial for optimizing diagnostic accuracy in such AI systems.

Conversely, our analysis showed that Gemini Advanced did not perform as well as expected when compared with Gemini. Despite expectations that the advanced model would provide enhanced diagnostic capabilities, it achieved lower accuracy in identifying the most probable diagnosis with 31.6% (124/392) compared to Gemini's 42.6% (167/392), with this result being statistically significant (P=.002). This outcome suggests that the additional features or complexity added in Gemini Advanced may not necessarily translate into improved diagnostic performance. These findings underscore the need for further refinement and optimization of Gemini Advanced to harness its potential for future AI-enhanced diagnostics.

In addition, our analysis identified issues with inappropriate disease naming in the outputs from GAI systems, with Gemini Advanced and Gemini producing outdated or misspelled terms for vasculitis, instead of using the updated name. These inaccuracies highlight the challenges in ensuring up-to-date and precise medical terminology in AI outputs, which is crucial for maintaining trust and reliability in AI-assisted diagnostics. Furthermore, these misspellings are often found in published medical articles, suggesting that GAIs may have learned these errors from these sources. The fact that both Gemini Advanced and Gemini exhibited the same mistakes indicates potential similarities in their underlying models or training data.

Regarding average rankings, there were no statistically significant differences among generative AI systems. This indicates a level of parity in how each model ranks diagnoses when they include the correct diagnosis, suggesting that while there are differences in overall accuracy, the ranking mechanisms of each model are relatively similar.

Given the current performance metrics, our analysis supports prioritizing the adjustment and enhancement of Gemini for future applications in medical diagnostics, rather than Gemini Advanced. Despite the theoretically superior capabilities of Gemini Advanced [17], Gemini's framework appears more aligned with practical diagnostic needs and shows greater promise in real-world applications. However, it is essential to verify this trend across a variety of sources to ensure that these findings are not specific to the data sets used in this study. Further investigations involving diverse clinical environments and different types of medical data are crucial to confirm the consistency and reliability of Gemini's superior performance.

Finally, the comparative analysis of the differentials by Gemini Advanced, Gemini, and Bard revealed consistent inclusion of sepsis, pneumonia, pulmonary embolism, lymphoma, and meningitis among their top 10 differentials. This underscores not only a shared prioritization of these conditions but also the effectiveness of systems in recognizing critical and prevalent diseases. The consistent identification of sepsis, particularly its second-place ranking by Bard, underscores the potential of these AI systems to enhance diagnostic accuracy and reduce errors in the identification of life-threatening conditions [28]. Importantly, the top 3 differentials by Gemini Advanced and Gemini—sepsis, pneumonia, and pulmonary embolism—are among the most harmful diseases where reducing diagnostic errors is crucial [1]. This suggests a potential for GAI systems to alert medical professionals about the inclusion of these important diseases during diagnosis. Such an understanding could facilitate more effective use of these GAI systems in future diagnostics processes.

Strengths

This study had several strengths. First, the strengths of this study lie in its direct comparison of 3 cutting-edge AI systems and its demonstration of the dynamic improvements in their diagnostic accuracy. Unlike some CDSSs like symptom checkers, whose performance has plateaued [29], these GAI systems evaluated in this research show considerable enhancements with each iteration. Second, we evaluated the diagnostic accuracy of GAI systems using a series of case reports. These case reports often describe rare diseases and atypical presentations, as opposed to common diseases and typical presentations [30]. This showcases the system's diagnostic capabilities under challenging conditions. Third, the comprehensive range of medical conditions covered by the differential diagnosis lists generated by the AI systems represents a significant strength of this study. This extensive coverage demonstrates the systems' capacity to handle a broad spectrum of medical knowledge and its applicability to various clinical scenarios.

Limitations

Several limitations should be discussed. First, the use of case report series might not fully reflect real-world clinical scenarios. This limitation arises because case reports typically focus on novel or rare aspects of diseases rather than typical presentations and common diseases [30]. Second, the exclusive use of a single case report journal could introduce selection bias. Third, there was no well-established method for evaluating AI diagnostics. In our study, we used binary evaluation methods. In contrast, other research on CDSSs used several rating methods [31,32] and the ranking averages in the differential diagnosis lists [33]. Fourth, we used only text data; excluding image data could influence the diagnostic performance. These factors limit the generalizability of these findings.

Concerning the GAI systems, all platforms used in this study were not designed for clinical use and have not received approval for medical diagnostics. These systems were not specifically reinforced or enhanced for medical diagnostic purposes. According to a preprint, Med-Gemini, a specialized model in medicine, was developed [34] but is not available to the public. In addition, we could not include all currently available GAI systems; thus, these findings cannot be generalized to other systems or different clinical scenarios. There was also a risk that these GAI systems may have learned from the published case reports used in this study.

Moreover, the use of user data to refine models, as seen in Gemini Advanced and Gemini, highlights significant privacy concerns [35]. Future research should address the development of locally deployable LLM solutions tailored specifically for CDSS. Although our data set is sourced from an open journal, careful consideration must be given to the ethical deployment of these models within health care settings. Finally, given the

rapid pace of GAI technology development, such as the evolution from Bard to Gemini and from ChatGPT-3 to ChatGPT-4 and ChatGPT-4o, our findings may have a limited shelf-life.

Future Direction

Future research will aim to explore the diagnostic accuracy of GAI systems following medical enhancements and adjustments. Once approved for medical use, it will also be essential to investigate the performance of GAI systems across various populations and settings, including remote medical consultations, to ensure their effectiveness in real-world diagnostics. Moreover, assessing the impact of AI-enhanced diagnostics on the decision-making process of medical professionals will be crucial.

In addition, future studies should focus on integrating GAI systems with existing electronic health record systems to understand how AI can augment data accessibility and analysis. This integration will be essential to evaluate how GAI can improve clinical workflows, reduce the cognitive burden and the time to diagnosis, and enhance patient outcomes.

Finally, the development of ethical guidelines and governance frameworks for the use of GAI in diagnostics is imperative [36]. As AI technologies become more prevalent in health care, it is crucial to establish clear protocols that safeguard patient privacy, ensure data security, and maintain transparency in AI decision-making processes.

Comparison With Previous Work

Our research builds on previous findings. We revealed that the diagnostic accuracy of ChatGPT-4 was 86.7% (340/392) for the final diagnoses included in the top 10 differential diagnosis lists, and 54.6% (214/392) for the top diagnosis [37]. ChatGPT-4's performances were still higher than that of Gemini in the lists (76.5% vs 86.7%) and as a top diagnosis (42.6% vs 54.6%); it was similar to Gemini Advanced in the lists (73.0% vs 86.7%) and as a top diagnosis (31.6% vs 54.6%).

Expanding our findings, another study showed that Isabel Pro, a successful CDSS developed by Isabel Healthcare, Ltd [38], correctly identified diagnoses in 87.1% (175/201) of cases, compared with 82.1% (165/201) for ChatGPT-4 in a series of clinical cases [33]. These findings are partly attributed to the earlier launch of Isabel Pro and the ChatGPT series, allowing them to receive more user feedback and undergo updates to improve performance.

In addition, another research focused on multiple choice questions on clinical vignettes revealed that ChatGPT-4 achieved a high accuracy rate of 73.3% for Clinical Challenges from the *Journal of the American Medical Association* (*JAMA*) and 88.7% for Image Challenges from the *New England Journal of Medicine* (*NEJM*). In contrast, Gemini, referred to as Gemini Pro in that study, achieved 63.6% for Clinical Challenges from *JAMA* and 68.7% for Image Challenges from the *NEJM* [22]. While these previous findings and current results revealed certain diagnostic performances of generative AI systems, comparing these results poses significant challenges due to methodological differences. Variations stem from differences in data set preparation, the types of clinical vignettes used, and the specific challenges or images included, which may influence performance outcomes. In addition, the evaluation criteria used to assess accuracy might differ significantly, affecting the comparability. For instance, the scoring systems or the definitions of a "correct" answer could vary, necessitating caution when drawing direct comparisons between these findings and those of this study.

In contrast to the serial evaluation approach of a symptom checker [29], which demonstrated an accuracy of 44.3% (97/219) in the first year and 47.7% (43/90) in the third year without significant difference, the performance of generative AI systems presents a different dynamic. Specifically, the serial evaluation of generative AI indicated that Gemini outperformed Bard over a relatively short period. This superiority can be attributed in part to the adaptability of generative AI systems to incorporate additional data. However, it is crucial to note that this adaptability does not consistently translate into improved diagnostic accuracy, as evidenced by the current comparison between Gemini Advanced and Bard. This observation highlights the nuanced interplay between technological advancement and clinical efficacy, underscoring the need for continued research and validation in integrating these systems into medical practice effectively.

Conclusions

The results of this study suggest that Gemini outperformed Bard in diagnostic accuracy following the model update. However, Gemini Advanced requires further refinement to optimize its performance for future AI-enhanced diagnostics. These findings should be interpreted cautiously and considered primarily for research purposes, as these GAI systems have not been adjusted for medical diagnostics nor approved for clinical use. The potential and limitations highlighted by this study underscore the need for ongoing development and evaluation of GAI systems within medical diagnostics.

Acknowledgments

Abstract

Background: In response to the intricate language, specialized terminology outside everyday life, and the frequent presence of abbreviations and acronyms inherent in health care text data, domain adaptation techniques have emerged as crucial to transformer-based models. This refinement in the knowledge of the language models (LMs) allows for a better understanding of the medical textual data, which results in an improvement in medical downstream tasks, such as information extraction (IE). We have identified a gap in the literature regarding health care LMs. Therefore, this study presents a scoping literature review investigating domain adaptation methods for transformers in health care, differentiating between English and non-English languages, focusing on Portuguese. Most specifically, we investigated the development of health care LMs, with the aim of comparing Portuguese with other more developed languages to guide the path of a non–English-language with fewer resources.

Objective: This study aimed to research health care IE models, regardless of language, to understand the efficacy of transformers and what are the medical entities most commonly extracted.

Methods: This scoping review was conducted using the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) methodology on Scopus and Web of Science Core Collection databases. Only studies that mentioned the creation of health care LMs or health care IE models were included, while large language models (LLMs) were excluded. The latest were not included since we wanted to research LMs and not LLMs, which are architecturally different and have distinct purposes.

Results: Our search query retrieved 137 studies, 60 of which met the inclusion criteria, and none of them were systematic literature reviews. English and Chinese are the languages with the most health care LMs developed. These languages already have disease-specific LMs, while others only have general–health care LMs. European Portuguese does not have any public health care LM and should take examples from other languages to develop, first, general-health care LMs and then, in an advanced phase, disease-specific LMs. Regarding IE models, transformers were the most commonly used method, and named entity recognition was the most popular topic, with only a few studies mentioning Assertion Status or addressing medical lexical problems. The most extracted entities were diagnosis, posology, and symptoms.

Conclusions: The findings indicate that domain adaptation is beneficial, achieving better results in downstream tasks. Our analysis allowed us to understand that the use of transformers is more developed for the English and Chinese languages. European Portuguese lacks relevant studies and should draw examples from other non-English languages to develop these models and drive progress in AI. Health care professionals could benefit from highlighting medically relevant information and optimizing the reading of the textual data, or this information could be used to create patient medical timelines, allowing for profiling.

(JMIR Med Inform 2024;12:e60164) doi:10.2196/60164

KEYWORDS

language model; information extraction; healthcare; PRISMA-ScR; scoping literature review; transformers; natural language processing; European Portuguese

Introduction

The health care sector generates a vast amount of structured and unstructured data, including images from medical exams, text written in electronic medical records (EMRs) or Electronic Health Records (EHRs), and structured data from relational databases that store patient and admission information, as well as all the data collected during a patient's hospitalization [1]. Approximately 30% of the world's data volume is generated by the health care sector, and projections indicate that by 2025, the compound annual growth rate of data for health care will reach 36% [2].

Medical texts present several challenges due to the use of unfamiliar context-specific terminologies that differ from everyday language. In addition, physicians often use abbreviations and acronyms to save time and space. However, the same abbreviation can have different meanings, adding an additional layer of complexity when trying to understand the content of medical texts [3]. All these characteristics pose challenges when attempting to apply artificial intelligence (AI) techniques to interpret the text.

In the field of natural language processing (NLP), the introduction of transformers [4] has revolutionized the field, achieving state-of-the-art performance for numerous NLP tasks [5]. Their general architecture comprises an encoder, which receives the input and builds a representation of it, and a decoder that uses the encoder's representation along with other inputs to generate a target sequence. The introduction of the self-attention mechanism further revolutionized NLP by allowing the model to weigh the importance of different words in a sentence regardless of their position. This enables better handling of long-range dependencies compared with traditional deep learning (DL) architectures like recurrent neural networks (RNNs) and long short-term memory Networks [6]. In the context of medical text, transformers excel in interpreting and extracting medically relevant information by effectively handling context and meaning, even in complex and specialized language.

Transformers can be trained as language models (LMs) on raw text in a self-supervised manner, enabling them to develop a statistical understanding of the text they were trained on [7]. However, the benefits of this approach are only fully realized when fine-tuning a downstream task.

Another important concept is called domain adaptation, which stands for the process of adapting or adjusting something to be suitable within a different domain or context. In the field of machine learning (ML), domain adaptation is used to align the disparity between domains so that the trained model can generalize into the domain of interest [8]. For transformers, domain adaptation involves continuing the pretraining of an LM with text data from a different domain than the one it was originally trained on [9]. This approach allows for leveraging the learning capabilities of general-scope LMs and refining them for specific contexts. For example, if we consider a general-scope LM, one that was trained using textual data from various domains, and continue its pretraining with health care–specific textual data, it will help the LM to refine its understanding of the health care data, leading to improvements when fine-tuning the LM for downstream tasks related to health care. To explore this further, we can take a health care LM who was trained using EMRs from a hospital and continue its pretraining using only text from patients with a specific disease. It will allow the LM to adjust its weights and become more precise when interpreting texts related to that particular disease.

An example of domain adaptation is the BioBERT model [10], which resulted from the continuation of the pretraining of the Bidirectional Encoder Representations from Transformers (BERT) [10] model on biomedical text. The BioBERT model outperformed its predecessor in biomedical named entity recognition (NER), relation extraction, and question-answering tasks. Alzheimer's Disease-BERT [11] and CancerBERT [12] are 2 examples of applying domain adaptation to a more restricted domain. Both models outperformed their respective baselines on downstream tasks related to their respective diseases. Summing up, performing domain adaptation for the health care sector appears inevitable to improve results, for example, for information extraction (IE) models, where a better understanding of medical terminologies and lexicon would make it easier to identify and extract information [13].

The European Portuguese (PT-PT) language does not generate the same amount of data as the English language, resulting in limitations in the literature and the published models. A study published in 2023 by the Ernst & Young Audit highlights the following areas where AI can play a relevant role in Portugal's health care; disease diagnoses, precision medicine, remote monitoring and prevention, data management and hospital efficiency, and health policies [14]. Recently, a project was launched in Portugal, funded by the European Union, with the aim of creating PT-PT NLP solutions for the health care sector. Under this scope, the objective is to create PT-PT medical LM and IE models to automatically identify medically relevant entities.

Therefore, in this study, we aim to present a scoping literature review (SLR), in which we will begin by exploring the creation of health care LMs through domain adaptation and analyze their results. In addition, we aim to focus on the geographical domain to understand the current state-of-the-art for the Portuguese language and compare it to other, potentially more developed, languages to identify further steps. We also want to explore IE models in the health care sector, regardless of their data language, to understand the most commonly extracted medical entities and the methods used in doing so. Despite the literature being rich in studies focused on health care large language models (LLMs), there is a lack of studies that evaluate the current state-of-the-art of health care LMs not only in English but also in other less-resourced languages. This will enable us

to grasp how the community is using the capabilities of transformers and whether the advantages of using them are indeed present in the health care domain. In addition, researchers will have 1 study about health care LMs that could guide their path and help them understand how the literature has developed in their respective languages. Finally, we will present the corresponding discussion and the conclusion drawn from the SLR.

Methods

Overview

To complete our goal, we have conducted an SLR to gain a better understanding of the research conducted in the application of health care–domain LMs and the development of IE models within the health care domain. In the first stage, our study encompasses health care–domain LMs in various languages, with a focus on the Portuguese language. In the second stage, we searched for studies related to IE models to evaluate the methods most frequently used. In terms of methodology, we followed the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) [15] to ensure a systematic and transparent approach in conducting and reporting our scoping review.

Search Strategy and Inclusion Criteria

This SLR was conducted in November 2023 and focused exclusively on studies and reviews published in journals within the last 5 years (2019-2023) that were written in English or Portuguese. It was not an arbitrary data range since limiting the search to the last 5 years ensures that the review includes the most recent and relevant studies, reflecting the latest advancements, technologies, and methodologies in the field. Since BERT [10], one of the most popular transformer architectures, and LM were launched at the end of 2018, we searched for studies from 2019 onward. The primary databases used for this review were Scopus [16] and the Web of Science Core Collection (WOSCC) [17] since both databases are renowned for indexing a wide array of peer-reviewed journals across multidisciplinary fields [18,19]. While acknowledging that additional databases might offer further insights, the significant overlap with these resources ensures that relevant studies are unlikely to be missed.

The criteria were defined to include studies focused on continuing the pretraining of LMs to achieve health care–domain LMs or studies focused on creating IE models within the health care field. Therefore, we formulated a query that includes the training or fine-tuning LMs or IE Models within the context of health care or similar, using EMRs or EHRs as data.

Since there is a significant semantic similarity between LMs and LLMs, we decided to exclude the second from the search query because it has a different purpose from the aim of our study. LLMs are typically composed of more than 7B parameters and are suited for text generation. LMs are models that are not, by themselves, suited to perform any downstream NLP task, needing to be readjusted or fine-tuned with labeled data to be able to perform downstream tasks.

Our final query is as follows: "("Language Model" OR "Masked Language Model" OR "Information Extraction" OR "Content Extraction") AND ("EHR" OR "EMR" OR "Electronic Health Record" OR "Electronic Medical Record") AND ("Fine-Tuned" OR "Fine-tuning" OR "Training" OR "Trained") AND ("Healthcare" OR "Health Care" OR "Clinical" OR "Medical") AND NOT ("Large Language Model" OR "LLM")."

According to our objectives, a study was considered valid if it documented a continuation of the pretraining of an LM to create a health care LM or if it focused on the creation of health care IE models.

Study Selection

To minimize the risk of bias in the study selection, the process was conducted independently by 3 researchers. A total of 2 researchers were responsible for reading and judging the studies according to the inclusion criteria, while the third researcher was involved in cases of disagreement.

Data Charting and Synthesis

A data-charting form was jointly developed by two reviewers to extract relevant information from the selected studies systematically. The form included variables such as study title, year of publication, language focus (English or non-English), domain adaptation techniques for Transformer-based models, healthcare-specific information extraction tasks, evaluation metrics used, and the specific health-related entities being extracted. Both reviewers independently charted the data to ensure comprehensive coverage of healthcare language models in English and non-English languages, with particular attention to languages other than English (referred to as non-English). Discrepancies in the extracted data were discussed and resolved through consensus. As the review progressed, the data-charting form was iteratively updated to capture emerging themes, especially regarding the disparity between language resources and technological development for healthcare information extraction across different languages.

Results

The query retrieved 137 papers, with the vast majority of these studies being retrieved from Scopus, adding up to 90 when compared with the 47 studies WOSCC has yielded. The PRISMA-ScR methodology was then followed, as seen in Figure 1. Since we included studies from sources beyond the 2 selected databases, we adhered to the updated PRISMA-ScR guideline [20]. In the following subsections, we explained the decision to include studies by other methods.

The first step was to identify and remove duplicated papers, resulting in 101 studies. Following a screening of titles and abstracts, 10 records were deemed out of scope, and 1 could not be retrieved, leaving us with 90 fully reviewed studies.

After screening all the papers that matched our criteria, we realized that 30 of them did not meet our inclusion criteria. Some studies referred to the fine-tuning of pretrained LMs for tasks unrelated to IE, or they lacked relevant information to contribute to this study, or even though we excluded them from our search query, they mentioned the use of LLMs.

As we were focused on the Portuguese language, our study also emphasized the geographical domain, with an aim to comprehend the medical data language used in health care LMs. Table 1 resumes the studies focused on the pretraining of LMs separated by the language of their data.

From the reading of Table 1, we can understand that English is the main language, which can be explained by the much higher availability of English data and the overwhelming presence and applicability of this language throughout the world. However, we notice that in the Chinese language, there are studies attempting to fill the gap of being non-English, creating in-domain LMs aware of their benefits. We also found studies in Brazilian Portuguese (PT-BR), Spanish, and PT-PT, and we acknowledge that there might be other studies in different languages, even though they did not match our search query criteria.

Changing the view for the health care IE studies, Figure 2 resumes the distribution of studies by topic.

From the reading of Figure 2, NER appears as the main topic on the IE, with only 2 studies performing Assertion Status and 3 studies focused on solving medical lexical problems.

To provide a more in-depth review of each study, we present the subsequent 3 subsections where we differentiate between non-Portuguese health care LMs, Portuguese health care LMs, and health care IE models.

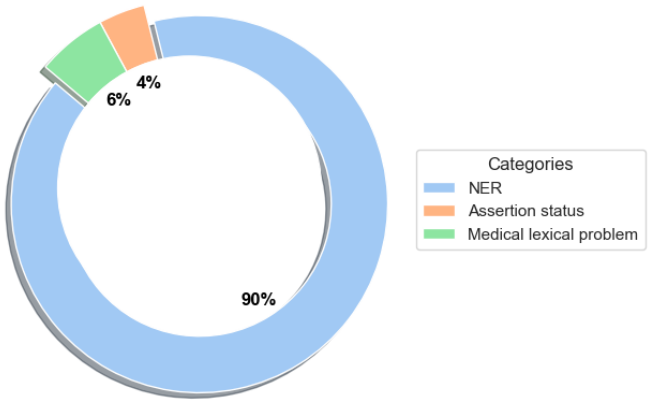
Table 1. Studies for pretraining language models (LMs) were reviewed by their data language.

Medical data language	Reference	Studies, n
English	[11,12,21-25]	7
Chinese	[26-29]	4
Brazilian Portuguese	[30,31]	2
Spanish	[32]	1
European Portuguese	[33]	1

Figure 2. Distribution of health care information extraction (IE) studies by topic. NER: named entity recognition.



Non-Portuguese Health Care Language Models

A study by Zhou et al [12] introduces CancerBERT, a domain-specific LM, that resulted from continuing the pretraining of the BlueBERT model [34] with a cancer corpus, resulting in various checkpoints of CancerBERT. The evaluation was performed for the cancer phenotyping NER task, with the results showing that the CancerBERT model pretrained with the cancer corpus outperformed the checkpoint using the original BERT [10] vocabulary.

A similar approach was conducted in a study by Mao et al [11], where the objective was to predict the risk of disease progression from Mild Cognitive Impairment to Alzheimer disease. A BERT model specifically tailored for Alzheimer disease (ie, AD-BERT) was pretrained with clinical notes, and its comparison with other models in experiments showed the benefits of domain adaptation.

Within the same scope, the identification of fall incidents from EHRs is discussed in the study by Fu et al [21]. A context-aware LM, BERT-based, was trained and integrated into a hybrid architecture along with post hoc heuristic rules. The performance of the BERT-based model was compared with DL methods, and the conclusions highlighted that the BERT model achieved superior results in identifying fall events.

In a study by Wang et al [26], a Chinese medical text corpus was used to pretrain BERT and obtain the Chinese BERT model. The results were aligned with previous studies, and domain adaptation demonstrated better results than traditional DL models and other pretrained LMs.

Studies by Roitero et al [22] and Agnikula Kshatriya et al [23] once again mention the pretraining of BERT models on a medical corpus, achieving comparable or better performance than state-of-the-art models. In a study by Zhang et al [24], an unsupervised adversarial domain adaptation framework with a pretrained LM for clinical event sequences is presented. Another example can be found in a study by Chen et al [25], where a contextual LM is used in combination with rule-based preprocessing methods to develop a model for *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) multilabel classification. The results demonstrate superiority over state-of-the-art models. Studies by Wen G et al and Wen C et al [27,28] refer to the training of a domain-specific pretrained LM on unlabeled medical data, with the evaluation being made through NER.

In the process of reviewing all the papers, we observed references to papers that aligned with our requirements despite not being explicitly included within our search query criteria. It is the case of studies by Zhang et al [29] and Carrino et al [32]. Carrino et al [32] present a large-scale biomedical Spanish LM, where the models were pretrained from scratch, using a RoBERTa [35] base model, and then fine-tuned on 3 clinical NER tasks. The comparison between general-domain and other available Spanish clinical models revealed the superiority of the models presented in the paper. Zhang et al [29] share a similar scenario with BERT being pretrained on Chinese biomedical corpora, and MC-BERT, an in-domain LM, was developed. The results are consistent with previous studies, with MC-BERT outperforming BERT-based models in all evaluated tasks.

Portuguese Health Care Language Models

Our search query did not retrieve any studies for the Portuguese language. To address this scarcity of studies and since it is one of the objectives of this research, we carried out a broader search on Google Scholar [36] to include studies that mentioned the creation of Portuguese health care LMs.

The PT-BR language has already presented several studies, with BioBERTpt [30] being one example. The authors used clinical notes and biomedical abstracts to pretrain 3 BERT-based checkpoints that were fine-tuned for the NER task to assess their performance. The results align with others, showing that the in-domain models achieved better performance. Another example is the study by Schneider et al [31], where several clinical BERT-based checkpoints were developed resulting from the continuation of the pretraining of BERTimbau [35], mBERT [11], and all 3 BioBERTpt checkpoints on 150,000 clinical narratives from cardiology ambulatory. The results of fine-tuning for NER align with previous studies, demonstrating that the in-domain models outperformed general LMs.

For the PT-PT language, we found the literature to be scarcer, with only 1 study being found that mentioned the continuation of the pretraining of an LM to achieve health care–domain LM. Coutinho and Martins [33] propose a BERT-based model for assigning *ICD-10* codes to causes of death by using BERTimbau and continuing its pretraining with death certificates. The

evaluation was made through NER, with all the checkpoints involved being fine-tuned for the classification task, and the findings indicated that transformer models could produce promising outcomes for health care tasks involving the analysis of relatively short documents.

Health Care IE Models

To better organize this section, we decided to categorize the studies by topic. Therefore, the first subsection presents NER studies where the authors attempted to automatically identify and extract medical information. The second subsection contains Assertion Status models, where entities are classified according to their status (present or absent), and finally, the third subsection presents studies that attempt to solve medical lexical problems.

NER

Zhou et al [37] evaluated the performance of CancerBERT along with ML models for the breast cancer phenotype extraction task, with the results proving that CancerBERT has superior learning ability and generalizability for this task. Rahman et al [38] refer to the use of BERT to identify the presence of a diagnosis in EHRs. With BERT's ability to understand the context of text and based on conditions presented in EHRs, a pipeline was successfully designed to identify EHRs with the presence of a diagnosis, reducing the manual note review load. Crema et al [39], use an Italian biomedical BERT model, fine-tuning it for the NER task with the entities of interest, including diagnoses, symptoms, drugs, and medical assessments, achieving an F_1-score of nearly 0.85 values. Entity-BERT was introduced in the study by Lu et al [40], a DL-based model for entity IE that is capable of recognizing entities such as medical terminologies, disease names, or drug information. Zhang et al [41] propose the combination of data augmentation and domain information using the Adapter Transformer Encoder Model for Clinical Event Detection. It uses the BioBERT model to generate word-level features, addressing the issue of many obscure professional terms in EMRs leading to poor recognition performance of the model. The results were reported to be superior to those of other existing models. A multilingual transformer was fine-tuned in a study by Kim et al [42], where researchers successfully extracted alcohol-related information from unstructured clinical notes with an extraction accuracy of 0.84 as measured by the macro F_1-score. Kormilitzin et al [43], initially pretrained a model on the task of predicting the next word and subsequently fine-tuned it for the NER task, extracting various categories of drugs and achieving performance with an F_1-score above 0.95 values. Solarte-Pabón et al [44] evaluate the fine-tuning of several pretrained LMs for the NER task, aiming to identify breast cancer concepts in the Spanish language. The results show that BERT-based and RoBERTa-based LMs exhibit competitive performance on this task. Liu et al [45] propose the use of BERT-BiLSTM-CRF for the NER task of rheumatoid arthritis vocabulary and then MC-BERT for the entity extraction task, with results showing F_1-scores above 90%. Wang et al [46] compare the use of 4 pretrained transformer-based LMs fine-tuned for the NER task with a baseline regular expression model in order to extract ophthalmic examination components, demonstrating that transformers achieve superior results. In the study by Singh et al [47], a pretrained transformer-based LM was fine-tuned with cardiac magnetic resonance imaging annotations to effectively extract measurements from clinical reports, and it achieved high extraction performance without requiring heuristics or expert annotations.

Several studies focus on extracting information about family history, such as studies by Kim et al [48], He et al [49], Silva et al [50], Dai et al [51], and Zhan et al [52]. They use ML methods, incorporating rule-based approaches, multitask-based artificial neural networks (ANN), attention-based neural networks, and even combinations such as convolutional neural networks (CNNs) BiLSTM and BERT. The goal was to automatically extract entities such as people's names, residence, birth date, or death date, and in some cases, there is an additional subtask related to relation extraction, which involves identifying relationships between family members. Overall, the results have proven to be satisfactory, particularly in the NER task.

CNNs are highly popular methods in the scientific community for extracting clinical information and studies by Yang et al [53], Santus et al [54], Mahajan and Rana [55], and Landlosi et al [56] primarily used them, often supplemented with rule-based approaches or feature optimization in some cases. The use of these methods lies in extracting clinical information from EHRs, tasks that could be time-consuming if done manually. Within the broader category of neural networks, RNNs are also a method used for IE in which the authors of studies [57-66] all use RNNs, with BiLSTM-CRF (Bidirectional Long Short-Term Memory - Conditional Random Field) being a very popular network among these studies. The main topics extracted include terms related to specific diseases, drug names with associated attributes (dosage, frequency, duration, route, and condition), adverse drug events, the presence of a diagnosis, or even important information in medical image reports, with the results globally proven to be promising.

Studies [67-69] use ML methods, with the first focusing on automatically classifying the outcomes of specific tasks related to the clinical conditions of stroke survivors, the second aiming to extract useful information in abdominopelvic radiology reports, and the third one focused on extracting travel history mentions from clinical documents. In Malmasi et al [70], the use of different methods to extract low-prevalence concepts is discussed, specifically in the case of insulin rejection by patients with attempts at both sentence-level and token-level approaches using ML and DL methods, but the results showed that it is challenging to automatically identify low-prevalence concepts. Similar proposals have been presented in studies [71-79] using spaCy's [80] pipeline for IE, contextual embeddings such as embeddings from language models (ELMo) [81] and BERT, position-attention mechanisms, knowledge graph embeddings, word segmentation models, or even NLP models developed using Java for extracting medical information, for example, extracting details related to drugs, drug attributes, or diagnoses.

In Lee and Uppal [82], a web-based summarization and visualization tool is introduced for extracting salient information from clinical and biomedical text, featuring sentence ranking by relevance and facilitating early medical risk detection in

clinical settings. Chen et al [83] aimed to create a model to extract concept embeddings from EHRs for disease pattern retrieval and subsequent classification tasks.

Assertion Status

Sykes et al [84] address the issue of negation and non-negation of clinical terms in EHRs. It is an Assertion Status case, in which the text can be characterized by cases where diseases are stated to be absent or only hypothesized. In this study, they propose various methods to address this issue, including rule-based, ML, or DL approaches, and all proposals yielded good results in a test set, achieving an F_1-score of more than 0.95. In Chaturvedi et al [85], a corpus annotated with mentions of pain was developed, considering the presence or absence of pain. It is another example of an Assertion Status problem aimed at facilitating further studies using the corpus to better understand how pain is mentioned in clinical notes.

Medical Lexical Problems

From a different perspective, there have been studies focusing on medical lexical problems. Newman-Griffis et al [86] discuss the presence of ambiguous words and attempts to normalize medical concepts to standardize vocabularies, while the study by Jaber et al [87] addresses the problem of the frequent use of abbreviations by proposing a method, by fine-tuning a pretrained LM, to successfully disambiguate clinical abbreviations. Lee et al [88] propose a typographical error correction model that considers context, based on a masked LM, to address the issue of typographical errors in real-world medical data. They conclude that typographical errors in unstructured text negatively impact the performance of NLP tasks, and their method is robust and applicable in real-world environments.

Discussion

Principal Findings

Continuing the pretraining of LMs to develop health care LMs has proven beneficial. The most common method to evaluate this approach is by fine-tuning both the baseline and the in-domain LM on downstream NLP tasks and comparing the results.

In IE models, NER is the most popular topic aimed at automatically identifying and extracting medically relevant information. Transformers are the preferred technology for this purpose, with fine-tuning of medical LMs consistently achieving superior results.

To conclude our SLR, we engaged in a deeper discussion divided into health care LMs and health care IE models.

Health Care Language Models

On a global scale, we have identified numerous studies that continued the pretraining of LMs to develop domain-specific LM, specifically medical LMs. In general, the findings across almost all of these studies substantiate the advantages of in-domain training before undertaking any other downstream tasks. The favorite evaluation task is NER, with almost every study mentioning the fine-tuning of LMs for the NER task.

As shown in Table 1, English and Chinese are the languages with the most studies and published models due to the available resources in terms of data and hardware power. The level of domain adaptation for these languages is more advanced, with dedicated health care LMs developed for specific diseases such as Alzheimer Disease-BERT [11] and CancerBERT [12], which represent very focused domains. These studies offer advantages by achieving better performance in extracting specific concepts from textual data related to these diseases compared with general health care LMs.

For non-English languages, the process is not so developed, which can be considered as expected since they have their known limitations, such as the scarcity of data and resources available. Nevertheless, there have been concerted efforts to create general health care LMs, underscoring the community's recognition of the use of these models. The Portuguese language fits this context, and despite initial strides that have already been taken, there exists ample room for improvement, particularly in the context of PT-PT where the only published study is [33], yet, to the best of our knowledge, the model is not publicly available.

Non-English languages, particularly Portuguese, should draw inspiration from advancements and results in medical domain adaptation studies. Despite limited resources and available data, efforts should first focus on creating general medical LMs. In a subsequent phase, efforts should be directed toward narrowing down to specific diseases while performing domain adaptation. This approach ensures that knowledge previously acquired by the LMs is refined within the medical domain and then adapted to smaller medical domains without losing the previously acquired knowledge completely. This initiative aims to foster the development of AI technologies in Portuguese, thereby promoting health care equality and access in languages with fewer resources. These models can be further fine-tuned for medical NLP tasks, such as IE, aimed at automatically identifying or highlighting specific information or structuring medical information extracted from textual data for ML analysis to aid health care professionals.

Health Care IE Models

Several methods have been used to create health care IE models. The most common method is the use of transformers, followed by the application of other DL and ML methods (Table 2). As previously discussed, the most popular topic was NER, where authors attempted to identify and extract medically relevant information.

The results indicate that the most successful approach involves using pretrained LMs fine-tuned for IE tasks, benefiting from the contextual understanding of the text to achieve better results. The most commonly identified entities were diagnoses or diseases and drugs, along with specific phenotypes related to certain diseases.

Table 2. Number of studies used per method.

Methods	Articles
Transformers	16
Other DL[a]	15
RNN[b]	10
Other ML[c]	9
CNN[d]	5
Rule-based	4

[a]DL: deep learning.

[b]RNN: recurrent neural network.

[c]ML: machine learning.

[d]CNN: convolutional neural network.

It is also relevant to mention that in our query, 2 studies were focused on Assertion Status. This task involves classification at the sentence level aimed at assessing an entity based on its presence or absence in the text. Examples of absence include negation or hypothesizing medical information. From another perspective, to address the problems presented by medical text, we also found 2 studies that propose solutions to disambiguate the multitude of abbreviations present in medical text and 1 study that presents a typo correction model. Both solutions aimed to improve text quality and seek to correct issues in the text that are considered inevitable by health care professionals. These 5 studies could also be seen as an improvement to NER results. The ones focused on correcting the text could be viewed as a preprocessing step that would enhance the understanding of the medical text, while the Assertion Status studies could help ascertain whether an identified entity is present or absent in a patient's condition. When compared with the distribution of NER, these 2 topics lack development, as together, they account for only 10% of the health care IE studies found. The community would benefit from more studies using different technologies and identifying new challenges to be solved.

Conclusions

Our SLR highlights the benefits of in-domain training for health care LMs and the effectiveness of transformers in IE tasks, addressing a research gap regarding the lack of studies on health care LMs. Transformers excel in NER, identifying diagnoses, diseases, drugs, and phenotypes. English and Chinese lead in research and LM development, while non-English languages such as Portuguese show promise but need exploration. Challenges include Assertion Status and text disambiguation, necessitating diverse methodologies and research in health care IE.

We have identified several health care–domain LMs, but there is a clear gap for non-English languages where the data and resources available are low. There is much to improve in those languages, with Portuguese being an example. The benefits of creating a medical-domain LM are already proven, and the health care sector could benefit greatly from a symbiosis with AI. Therefore, non-English languages should be motivated by the scarce studies already published and try to replicate them for their own language in order to fill this existing gap.

From another point of view, the use of transformers appears to be the better technique to automatically identify medical information. Despite the annotation process for any supervised learning task being very time-consuming, transformers achieve better results on fewer annotations, making their usage on new tasks relatively easier. This task also benefits from an in-domain medical LM. The entities most commonly extracted are diagnosis or disease, posology-related entities, symptoms, and phenotypes related to specific diseases.

Despite our belief that this was the right choice, we highlight the 2 databases that we searched, and we acknowledge that, despite our best efforts, there is always a possibility that not all relevant papers will be found when formulating a query. These are the limitations of our study. The chosen timeframe may also limit the availability of relevant studies, even though we believe it is the right timeframe to include studies that establish the current state-of-the-art with new technologies. While we focused on the Portuguese language, we acknowledge that our conclusions cannot be generalized to all non-English languages. However, other languages with similar characteristics in terms of available data and resources can certainly gain insights from this SLR.

Globally, the development and research in these topics for the English language are very advanced compared with non-English languages. In English, several studies have been presented that perform domain adaptation for smaller domains, such as specific-disease LMs, which have improved results in extracting medical information related to these diseases. The next steps should involve continuing the pretraining for different medical areas or diseases to ensure the most comprehensive coverage with LMs. In addition, fine-tuning the already available models to meet the specific requirements of health care professionals is essential.

Non-English languages are still performing domain adaptation for general domains, such as medical or biomedical fields, and should be motivated by these studies to overcome the barriers inherent in their respective language. In the next step, they should focus on performing domain adaptation, aiming to narrow down to specific medical areas or diseases. They should strive to replicate studies on Assertion Status or even those focused on resolving the frequent presence of abbreviations and typos

in the text. In non-English languages where there is a scarcity of available data, it would be beneficial to have open corpora, even if distributed under licenses that protect data privacy, to enable more researchers to develop models.

These types of studies are important to assess and guide the development of non-English languages trying to bridge the gaps and capitalize on the opportunities provided by these technologies to promote equity and improve access to health care all over the world. The differences in the available data and resources are almost impossible to correct but at least should be minimized.

This effort aims to harness AI to enhance health care by developing advanced LMs tailored for non-English languages, thereby supporting health care professionals with decision-making tools that alleviate their workload and improve patient care indirectly.

Acknowledgments

MN's work was supported by the project Blockchain.PT, (PRR RE-C05-i01.02: AGENDAS/ALIANÇAS VERDES PARA A INOVAÇÃO EMPRESARIAL).

Abstract

Background: Artificial intelligence (AI) has shown great promise in assisting medical diagnosis, but its application in renal pathology remains limited.

Objective: We evaluated the performance of an advanced AI language model, Claude 3 Opus (Anthropic), in generating diagnostic descriptions for renal pathological images.

Methods: We carefully curated a dataset of 100 representative renal pathological images from the *Diagnostic Atlas of Renal Pathology* (3rd edition). The image selection aimed to cover a wide spectrum of common renal diseases, ensuring a balanced and comprehensive dataset. Claude 3 Opus generated diagnostic descriptions for each image, which were scored by 2 pathologists on clinical relevance, accuracy, fluency, completeness, and overall value.

Results: Claude 3 Opus achieved a high mean score in language fluency (3.86) but lower scores in clinical relevance (1.75), accuracy (1.55), completeness (2.01), and overall value (1.75). Performance varied across disease types. Interrater agreement was substantial for relevance (κ=0.627) and overall value (κ=0.589) and moderate for accuracy (κ=0.485) and completeness (κ=0.458).

Conclusions: Claude 3 Opus shows potential in generating fluent renal pathology descriptions but needs improvement in accuracy and clinical value. The AI's performance varied across disease types. Addressing the limitations of single-source data and incorporating comparative analyses with other AI approaches are essential steps for future research. Further optimization and validation are needed for clinical applications.

(JMIR Med Inform 2024;12:e65033) doi:10.2196/65033

KEYWORDS

artificial intelligence; Claude 3 Opus; renal pathology; diagnostic performance; large language model; LLM; performance evaluation; medical diagnosis; AI language model; diagnosis; pathology images; pathologist; clinical relevance; accuracy; language fluency; pathological diagnosis

Introduction

Artificial intelligence (AI) has demonstrated remarkable capabilities in analyzing complex medical data and assisting clinical decision-making across various fields [1]. In particular, AI's potential for interpreting histopathological images has been increasingly recognized, offering novel insights into disease pathogenesis and diagnosis [2]. However, the application of AI in renal pathology, a field characterized by high complexity and variability, remains relatively unexplored. Recent advancements

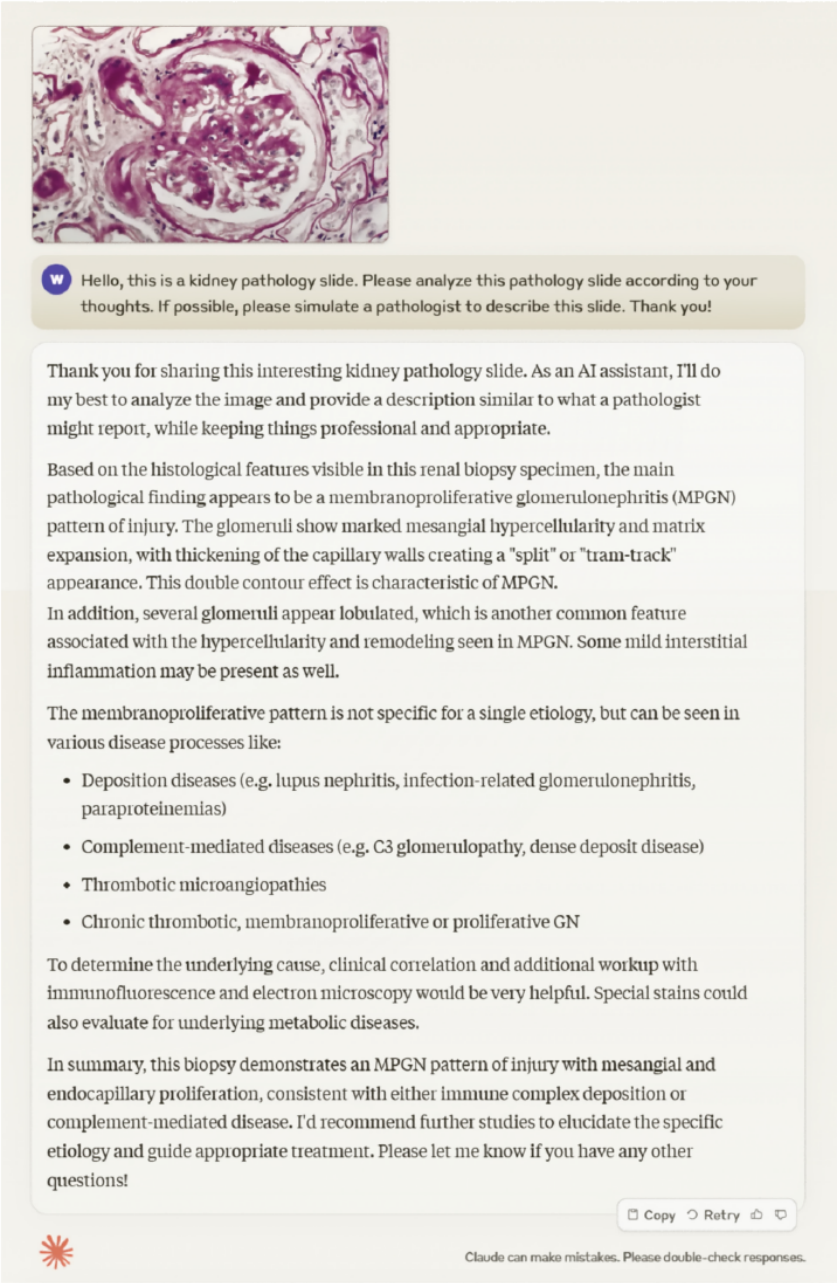
in natural language processing, such as the development of large language models (LLMs) like GPT-3 (OpenAI) and Claude 3 Opus (Anthropic), have opened up new possibilities for AI-assisted pathological diagnosis [3,4]. These models can capture semantic and contextual information from textual data and generate coherent, human-like responses. Despite the proven utility of AI in other pathology domains, such as oncology and dermatology, its performance and feasibility in renal pathology have not been systematically evaluated. To address this gap, we conducted a pioneering study to investigate the potential of using Claude 3 Opus, a state-of-the-art AI language model, for renal pathological diagnosis. By assessing the model's ability to generate accurate and clinically relevant diagnostic descriptions for a wide range of renal pathologies, we aimed to provide initial evidence and insights into the strengths and limitations of AI in this challenging field.

Methods

We carefully curated a dataset of 100 representative renal pathological images from the *Diagnostic Atlas of Renal Pathology* (3rd edition) [5]. The image selection process aimed to cover a wide spectrum of common renal diseases, ensuring a balanced and comprehensive dataset. The number of images per disease type ranged from 2 to 9 (eg, immunoglobulin A nephropathy: n=5; acute tubular injury: n=4; diabetic nephropathy: n=9), proportional to the relative prevalence and morphological diversity of each condition. Multimedia Appendix 1 provides the complete list of images and their corresponding disease labels.

Claude 3 Opus, an advanced AI language model, was used to generate diagnostic descriptions for each image. For each image, the model was given the following prompt: "Describe the key morphological features and provide a diagnostic impression for this renal biopsy image." No additional disease-specific information or background knowledge was provided, allowing us to assess Claude 3 Opus's standalone performance in renal pathology interpretation. The generated descriptions were evaluated by 2 experienced renal pathologists using a comprehensive 5-point scale across 5 key dimensions: clinical relevance, accuracy, language fluency, detail completeness, and overall clinical value. These evaluation dimensions were selected based on established frameworks for assessing the quality and utility of pathology reports [6,7]. They collectively cover the essential aspects of an effective pathology description, from clinical applicability and correctness to clarity and comprehensiveness. Descriptive statistics (means and SDs) of the evaluation scores were calculated for each pathological type. The interrater agreement between the 2 pathologists' scores was assessed using the Cohen κ statistic. Figure 1 shows an example of a prompt to Claude 3 Opus and its response.

Figure 1. Example of a prompt to Claude 3 Opus and its response.



Results

The performance evaluation results for Claude 3 Opus in generating renal pathological descriptions are presented in Table 1. The AI model achieved a high overall score in language fluency (mean score 3.86, SD 0.68), indicating its ability to produce grammatically correct and easily readable reports. However, the model's performance in other key aspects was suboptimal, with lower scores for clinical relevance (mean score 1.75, SD 0.77), accuracy (mean score 1.55, SD 0.66), detail completeness (mean score 2.01, SD 0.84), and overall clinical value (mean score 1.75, SD 0.74). Notably, the AI model's performance varied across different renal pathological types. Higher scores (>4) were observed for certain diseases, such as membranoproliferative glomerulonephritis and subacute bacterial endocarditis–associated glomerulonephritis, suggesting the model's potential in assisting the diagnosis of these specific conditions. Conversely, the model's performance was subpar for several other types, including acute interstitial nephritis (mean score 1.00, SD 0.00) and collapsing glomerulopathy (mean score 1.17, SD 0.24), indicating limitations in capturing their key diagnostic features. The inter-rater agreement analysis revealed substantial agreement between the 2 pathologists on clinical relevance (κ=0.627) and overall clinical value (κ=0.589), as well as moderate agreement on accuracy (κ=0.485) and detail completeness (κ=0.458).

Table 1. Performance of Claude 3 Opus in generating descriptions for 100 renal pathological images across 27 disease types.

Standard pathological diagnosis	Clinical relevance, mean score	Accuracy of description, mean score	Language fluency, mean score	Detail completeness, mean score	Overall clinical applicability, mean score
Immunoglobin A nephropathy (n=5)	2.10	1.10	4.30	2.90	1.90
Immunoglobin G4–related tubulointerstitial nephritis (n=3)	1.67	1.17	4.33	2.50	1.67

Overall	1.75	1.55	3.86	2.01	1.75

Discussion

Principal Findings

This study provides initial evidence for the potential of advanced AI language models, such as Claude 3 Opus, in assisting renal pathological diagnosis. The model demonstrated promise in generating fluent and readable pathological descriptions, which could streamline the reporting process and alleviate pathologists' workloads. However, the suboptimal performance in accuracy, clinical relevance, and overall value highlights the need for further improvement before clinical implementation. The interrater agreement analysis revealed substantial agreement for clinical relevance and overall value, but only moderate agreement for accuracy and completeness. This discrepancy might stem from the inherent subjectivity in evaluating granular aspects of pathology descriptions. Pathologists' individual expertise, expectations, and interpretive styles could influence their assessments of accuracy and completeness. Developing standardized scoring rubrics and involving larger, multicenter

expert panels in future studies could help mitigate this variability and improve evaluation reliability [8,9].

The AI model's performance varied notably across different renal pathological types. The higher scores for conditions like membranoproliferative glomerulonephritis and infection-related glomerulonephritis could be attributed to their distinct morphological features, such as characteristic immune-complex deposits or structural alterations [10]. These overt patterns might be more readily discernible by the AI algorithms. Conversely, the lower performance for diseases like acute interstitial nephritis and collapsing glomerulopathy might reflect their subtler or more heterogeneous histological manifestations [11], posing challenges for automated interpretation.

While Claude 3 Opus exhibited potential in generating fluent descriptions, the limited accuracy and clinical relevance underscore the challenges of applying LLMs to complex medical image data. As highlighted by recent studies [12,13], LLMs excel at processing textual information but may struggle with the intricacies of specialized visual tasks like histopathology interpretation. Continued research on architectures and training strategies tailored for medical vision applications is crucial for realizing the full potential of AI in this domain.

Our study's reliance on images from a single atlas dataset may have introduced some biases and limits the generalizability to real-world clinical scenarios. Although the *Diagnostic Atlas of Renal Pathology* is widely recognized as a high-quality reference, external validation using diverse, multicenter biopsy datasets is essential to assess the robustness and transferability of our findings [14]. Future studies should prioritize prospective validation on independent clinical cohorts to establish the real-world performance of AI models like Claude 3 Opus.

Comparing the performance of Claude 3 Opus with other AI models or traditional diagnostic methods could offer valuable insights into its relative strengths and areas for improvement. While direct comparisons were beyond the scope of this initial study, recent work has reported promising results with deep learning–based approaches for renal pathology classification. Shen et al [15] developed a convolutional neural network (CNN) model that achieved an accuracy of 87.5% in classifying 6 common glomerular diseases. Similarly, Hermsen et al [16] demonstrated the effectiveness of a multiclass CNN for diagnosing various renal pathologies, with an area under the receiver operating characteristic curve ranging from 0.88 to 0.99. These studies highlight the potential of specialized AI architectures for renal pathology diagnosis, serving as benchmarks for evaluating the performance of LLMs like Claude 3 Opus. Future research should aim to conduct head-to-head comparisons and explore synergistic integrations of LLMs with image-based AI models to leverage their complementary strengths.

To fully realize AI's potential in renal pathology, future research should focus on optimizing the model's training process with comprehensive and balanced datasets, incorporating expert feedback into the learning process, and integrating AI with advanced digital pathology tools for more accurate and objective diagnoses. The scarcity of large-scale annotated datasets and concerns about AI interpretability remain major challenges to be addressed. Amidst these challenges, the collaboration between AI researchers, pathologists, and clinicians is crucial for developing reliable and clinically applicable AI models. Standardized evaluation frameworks and best practices for the responsible use of AI in pathology are also needed. As AI continues to advance, we anticipate its increasing role in enhancing diagnostic accuracy and efficiency, ultimately benefiting patient care.

Conclusion

In conclusion, our study provides an initial assessment of Claude 3 Opus's potential for AI-assisted renal pathology diagnosis. While the model showed promise in generating fluent descriptions, improvements in accuracy and clinical relevance are necessary for practical implementation. The observed performance variations across disease types highlight the need for targeted model optimizations. Addressing the limitations of single-source data and incorporating comparative analyses with other AI approaches are essential steps for future research. As AI continues to advance, close collaboration between pathologists, AI researchers, and clinicians will be instrumental in developing reliable, integrated diagnostic solutions that enhance patient care in renal pathology.

Abstract

Background: Transformer-based language models have shown great potential to revolutionize health care by advancing clinical decision support, patient interaction, and disease prediction. However, despite their rapid development, the implementation of transformer-based language models in health care settings remains limited. This is partly due to the lack of a comprehensive review, which hinders a systematic understanding of their applications and limitations. Without clear guidelines and consolidated information, both researchers and physicians face difficulties in using these models effectively, resulting in inefficient research efforts and slow integration into clinical workflows.

Objective: This scoping review addresses this gap by examining studies on medical transformer-based language models and categorizing them into 6 tasks: dialogue generation, question answering, summarization, text classification, sentiment analysis, and named entity recognition.

Methods: We conducted a scoping review following the Cochrane scoping review protocol. A comprehensive literature search was performed across databases, including Google Scholar and PubMed, covering publications from January 2017 to September 2024. Studies involving transformer-derived models in medical tasks were included. Data were categorized into 6 key tasks.

Results: Our key findings revealed both advancements and critical challenges in applying transformer-based models to health care tasks. For example, models like MedPIR involving dialogue generation show promise but face privacy and ethical concerns, while question-answering models like BioBERT improve accuracy but struggle with the complexity of medical terminology. The BioBERTSum summarization model aids clinicians by condensing medical texts but needs better handling of long sequences.

Conclusions: This review attempted to provide a consolidated understanding of the role of transformer-based language models in health care and to guide future research directions. By addressing current challenges and exploring the potential for real-world applications, we envision significant improvements in health care informatics. Addressing the identified challenges and implementing proposed solutions can enable transformer-based language models to significantly improve health care delivery

and patient outcomes. Our review provides valuable insights for future research and practical applications, setting the stage for transformative advancements in medical informatics.

KEYWORDS

transformer-based language models; medicine; health care; medical language model

Introduction

Background

Transformer models have revolutionized natural language processing (NLP) with their exceptional state-of-the-art performance in various applications such as conversation, translation, text classification, and text generation. A transformer model is a type of deep learning model designed to process and generate sequences of data, such as text. The key innovation of transformer models is the self-attention mechanism, which allows the model to weigh the importance of different words in the input sequence, regardless of their position. Self-attention allows the model to focus on different parts of an input sequence simultaneously, rather than processing the sequence in a fixed order. This mechanism enables the model to capture complex patterns and relationships within the context more effectively than previous models, which is particularly useful for understanding and generating natural language. These models hold significant promise for the health care sector, addressing clinical challenges and unlocking new opportunities in medical informatics (eg, disease prediction, clinical decision support, and patient interaction).

Since the introduction of the transformer model by Google [1] in 2017, it has become the foundation for various pretrained language models (PLMs). PLMs are transformer models that have been initially trained on a large text corpus before being fine-tuned for specific tasks. This pretraining allows the models to leverage vast amounts of unstructured data to improve their performance in various NLP tasks. Two of the most widely used PLM architectures in medical research are Generative Pre-trained Transformer (GPT) and Bidirectional Encoder Representations from Transformers (BERT). GPT is designed to generate coherent text based on a given input, making it useful for tasks like dialogue generation [2]. BERT, on the other hand, is designed to understand the context of words in a sentence from both directions, making it highly effective for tasks like question answering and text classification [3]. Transformer-based language models have revolutionized the field of NLP and continued to advance the state-of-the-art in NLP with their impressive performance.

Despite the success of transformer-based language models in many domains, there is a significant gap in comprehensive reviews specifically focused on their application in the health care domain. In health care, transformer-based language models have been used for crucial tasks such as disease prediction, decision-making, and image analysis [4]. With the abundance of free text sources, such as medical documentation in free text, including social media, electronic medical records (EMRs), physician-patient conversations, and online encyclopedias, more significant challenges to language models are needed. The application of NLP in health care is not without controversy, particularly concerning data privacy, ethical implications, and the integration of artificial intelligence (AI) systems into clinical practices. Debates continue about the extent to which AI can replace human judgment, the transparency of AI decision-making processes, and the potential biases in AI models trained on unbalanced datasets. By addressing these concerns, our paper contributes to the timely and critical discourse on the responsible deployment of transformer-based language models in health care, emphasizing the need for transparency, fairness, and ethical considerations in AI development.

Objective

The objective of this paper is to provide a comprehensive scoping review of task-specific transformer-based language models in health care. By focusing on models pretrained on medical corpora, we aim to address the gap in existing literature where detailed surveys specifically tailored to health care applications are lacking. We seek to highlight the strengths, limitations, and potential of these models, offering valuable insights for future research and practical applications in medical informatics.

Related Work

While many review studies of NLP have been conducted in the medical field [5-13], on transformer-based language models [14-20], and in health-related domains [21-25], comprehensive surveys and broader and up-to-date transformer-based language models in health care are lacking, leaving a gap in understanding their full potential and limitations. Pandey et al [5] introduced RedBERT, a model focusing on topic discovery and deep sentiment classification of COVID-19 online discussions, demonstrating the application of NLP in understanding public health concerns. Iroju and Olaleke [6] conducted a systematic review of NLP applications, identifying key areas where NLP can enhance clinical decision-making and patient care. Similarly, Locke et al [7] provided a comprehensive overview of NLP in medicine, emphasizing the potential of NLP technologies in transforming medical practice. Adyashreem et al [8] surveyed various NLP techniques in the biomedical field, shedding light on how these techniques can be applied to biomedical text for improved information extraction and analysis. Wang et al [9] reviewed the application of NLP in clinical medicine, highlighting the advancements and challenges in integrating NLP with clinical workflows.

Khanbhai et al [11] applied NLP and machine learning techniques to patient experience feedback, providing insights into patient satisfaction and areas for improvement in health care services. Casey et al [12] focused on NLP applications in radiology reports, identifying how NLP can streamline the interpretation and reporting of radiological findings. Zhou et al

[13] discussed the broader applications of NLP for smart health care, envisioning a future where NLP-driven systems enhance patient care and operational efficiency.

In the realm of transformer-based language models, Zhang et al [14] surveyed their applications in bioinformatics, highlighting how these models have advanced the analysis of biological data. Yang [15] and Lin et al [16] explored the progress and applications of transformer models in Korean and general NLP tasks, respectively, highlighting their growing importance and versatility. Chitty-Venkata et al [17] reviewed neural architecture search for transformers, underscoring the potential of these models in optimizing NLP tasks. Gillioz et al [18] provided an overview of transformer-based models for various NLP tasks, illustrating their adaptability and efficiency. Han et al [19] focused on multimodal pretrained models, emphasizing their capability to handle diverse data types, including text, image, and audio. Greco et al [20] and Albalawi et al [21] discussed transformer models' applications in mental health and Arabic social media, respectively, highlighting their potential in understanding and addressing specific health-related issues. Kalyan et al [22] and Shamshad et al [23] provided comprehensive surveys on biomedical PLMs and their applications in medical imaging, respectively, showcasing the transformative impact of transformers in these fields.

Our review categorizes these models into 6 key tasks: dialogue generation, question answering, summarization, text classification, sentiment analysis, and named entity recognition (NER). Ultimately, advancements in transformer-based language models hold the promise of significantly transforming health care delivery and improving patient outcomes. By enabling more accurate disease prediction, enhancing clinical decision support, and facilitating better patient-provider communication, these models can lead to more efficient, effective, and personalized health care. Our review underscores the broader implications of these technologies, advocating for continued research and development to harness their full potential in revolutionizing medical informatics and patient care.

Methods

Information Source and Search Strategy

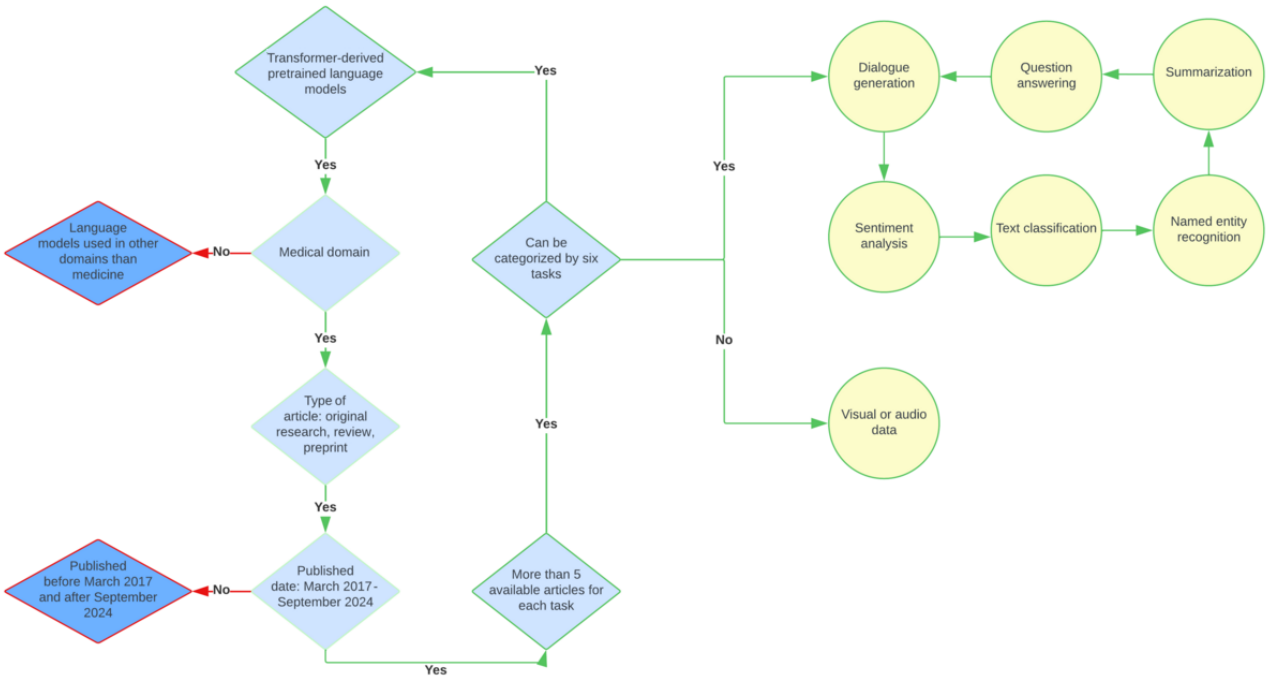
We followed the Cochrane scoping review protocol to conduct and map the available literature in an efficient and systematic approach. This method involves defining the research question, identifying relevant studies, selecting studies based on predefined criteria, charting data, and summarizing the results to clarify key concepts and identify research gaps [24].

Our research team (mainly HNC and TJJ) conducted a comprehensive literature review for identifying studies in the field that met the inclusion and exclusion criteria. The screening and selection of papers were conducted by 2 independent reviewers (HNC and TJJ). Initially, titles and abstracts were screened to identify relevant studies. Full texts of potentially eligible studies were then reviewed to ensure they met the inclusion criteria. Disagreements between reviewers were resolved through discussion and consensus, with a third reviewer (YHK) consulted if necessary. Our literature search was conducted across several scientific databases, including Google Scholar and PubMed, which were selected for their comprehensive coverage of relevant journals and peer-reviewed studies in the medical and academic fields. We covered publications from January 01, 2017, to September 30, 2024, and used specific combinations of keywords and Boolean operators, such as "transformer-based AND language models AND medical domain," "health care AND language models," "NLP AND medicine AND survey," and "GPT AND BERT AND health care." Data extraction involved summarizing key findings, model names, and training datasets. The extracted data were cross-verified by both reviewers to ensure accuracy and consistency. Any discrepancies were resolved through discussion.

We included studies that involved transformer-derived models applied to medical tasks, were published in peer-reviewed journals, and were written in English. The exclusion criteria involved studies focusing solely on non-text data (eg, audio, image, and video) or those not meeting the inclusion requirements. The selection of tasks (dialogue generation, question answering, summarization, text classification, sentiment analysis, and NER) was based on their critical role in advancing health care applications of transformer models. The specific process is illustrated in Figure 1, with details of each stage of filtering from the initial identification of articles to the final selection. The inclusion criteria were rigorously applied at each step, beginning with the screening of titles and abstracts, followed by a full-text review, and culminating in the inclusion of studies that met all predefined criteria. This methodical approach allowed us to compile a comprehensive and focused set of articles for our scoping review, ensuring that our findings are both robust and reliable.

These tasks cover a wide range of functionalities essential for improving clinical workflows, enhancing patient interactions, and facilitating efficient information retrieval and analysis, making them vital for the advancement of transformer-based language models in the medical domain. Languages and model types were chosen to represent a diverse range of medical contexts and applications.

Figure 1. Article filtering process with inclusion criteria.



In this section, studies that have used language models in health care applications were examined. Based on the literature review, Table 1 provides a comprehensive list of transformer-based models applied in the medical domain, comparing each task based on the authors, model name, training dataset, PLM model, key metric, score, and purpose or findings of the study. These English-written PLMs in the health care domain were categorized into 6 distinct tasks, namely dialogue generation, question answering, summarization, text classification, sentiment analysis, and NER. The articles within each task are listed in no sequential order. In Figure 2, the evolution timeline of transformer-based language models provides an overview of significant models that have been developed for use in medicine. It illustrates key milestones and the deployment criteria used to guide the inclusion of studies in our review. This historical context provides a foundation for understanding the methodological choices made in our scoping review. This visual representation highlights the emergence of models over time and their increasing significance in health care applications. We provide insights into the progress made in this field and anticipate future advancements by tracking the development of these models.

Table 1. Summary of the applications of pretrained language models subdivided into tasks.

Task and author (year)	Model name	Training dataset	PLM[a] model	Key metric	Score (%)	Key findings
Conversation						
Varshney et al [26], 2023	Medical Entity Prediction (MEP)	UMLS	BERT	Accuracy	85	Integrated triples from knowledge graphs to enhance medical predictions using a large pretrained model.
Yuan et al [27], 2022	BioBART	PubMed	BART	Rouge-2	65	Adapted and improved biomedical context understanding through advanced generative techniques.
Zhao et al [28], 2022	MedPIR	MedDG, MedDialog	BERT, GPT	F1	82	Used a knowledge-aware dialogue graph encoder (KDGE) and recall-enhanced generator (REG) to improve clinical responses.
Chen et al [29], 2023	OPAL	Wikipedia, WOZ, CamRest676	BART	BLEU	21.5	Tailored for task-oriented medical dialogues by incorporating domain-specific ontologies.
Liang et al [30], 2021	MKA-BERT-GPT	MedDG, MedDialog-CN	BERT, GPT	Relevance improvement	15	First scalable model to integrate a medical knowledge graph into a large pretrained model, enhancing biomedical understanding.
Compton et al [31], 2021	MEDCOD	KB, doctor edits	GPT-3	Emotive accuracy	90	Generated diverse, emotive, and empathetic sentences for health care interactions.
Li et al [32], 2023	ChatDoctor	5000 doctor-patient conversations	LlaMA	Precision, recall, F1	83.7, 84.5, 84.1	Fine-tuned LLaMa model using tailored doctor-patient dialogues for medical NLP[b] tasks.
Tang et al [33], 2023	-w terms+AL	MedDialog	BART	Annotation accuracy	87	Automated large-scale medical conversation text annotation with terminology extraction.
Zeng et al [34], 2020	Transformer-DST	MultiWOZ	BERT	DST accuracy	54.6	Proposed a transformer-based framework using a flat encoder-decoder architecture for dialogue state tracking in medical contexts.
Suri et al [35], 2021	MeDia-BERT	MeDiaQA	BERT	Accuracy	64.3	Employed a hierarchical approach to medical dialogue analysis, including multiple-choice question answering.
Phan et al [36], 2021	SciFive	PubMed	T5	Accuracy	86.6	A medical T5 text-to-text model effective for various clinical downstream tasks.
Wu et al [37], 2023	PMC-LLaMA	PubMed, 30K Medical Books	LlaMA	Accuracy	64.43	Transitioned a general-purpose model to a high-performing medical language model via comprehensive fine-tuning, achieving state-of-the-art performance in medical question answering.
Zhang et al [38], 2023	HuatuoGPT	Huatuo26M	GPT	BLEU, ROUGE, distinct	25.6, 27.76, 93	Chinese health care LLM: Tailored for the Chinese medical domain, providing state-of-the-art results in medical consultation tasks.
Question answering						
Lee et al [39], 2019	BioBERT	PubMed, EHR[c], clinical notes, patents	BERT	MRR improvement	12.24	First domain-specific BERT-based model for biomedical text mining, outperforming standard BERT in medical tasks.
Luo et al [40], 2023	BioGPT	PubMed	GPT	Accuracy	78.2	Pretrained on a 15M PubMed corpus, this model outperforms GPT-2 in biomedical text generation.
Shin et al [41], 2020	BioMegatron	Wikipedia, news, OpenWebtext	Megatron-LM	Bias	40	Enhanced the representation of biomedical entities across a large corpus for better entity understanding.
Rasmy et al [42], 2020	MED-BERT	Cerner Health Facts, Truven	BERT	AUC[d]	20 boosts	First proof-of-concept BERT model for integrating electronic health records.
Yasunaga et al [43], 2022	LinkBERT	Wikipedia	BERT	Improvement	5	Effective in multi-hot reasoning and few-shot question answering by linking documents.
Michalopoulos et al [44], 2020	UmlsBERT	MIMIC-III	BERT	F1	86	Learned the association of clinical terms within the UMLS metathesaurus.

Task and author (year)	Model name	Training dataset	PLM[a] model	Key metric	Score (%)	Key findings
Zhang et al [45], 2021	SMedBERT	ChineseBLUE	BERT	Accuracy	78	Introduced a mention-neighbor hybrid attention model for heterogeneous medical entity information.
Yang et al [46], 2022	ExKidney-BERT	EMR[e]	BERT	Accuracy	95.8	A specialized model focused on renal transplant-pathology integration.
Mitchell et al [47], 2021	CaBERTnet	Pathology reports	BERT	Accuracy	85	An automatic system for extracting tumor sites and histology information.
Trieu et al [48], 2021	BioVAE	PubMed	SciBERT, GPT2	VAE	72.9	First large-scale pretrained language model using the OPTIMUS framework in the biomedical domain.
Khare et al [49], 2021	MMBERT	COntext (ROCO)	BERT	Accuracy	72	Proposed masked language modeling for radiology text representations.
Yasunaga et al [43], 2022	BioLinkBERT	Wikipedia, Book Corpus	BERT	BLURB	84	A novel linking method for predicting document relations in pretraining models.
Nguyen et al [50], 2022	SPBERTQA	ViHealthQA	SBERT	Mean average precision	69.5	A 2-step question answering system addressing linguistic disparities with BM25 and Sentence BERT.
Luo et al [51], 2023	BioMEDGPT	PubMed	GPT	Accuracy	76.1	First multimodal GPT capable of aligning biological modalities with human language for medical text analysis.
Toma et al [52], 2023	Clinical Camel	PubMed, USMLE, MedMCQA	LlaMA-2	Five-shot accuracy	74.3, 54.3, 47.0	A model that outperforms GPT-3.5 by using efficient fine-tuning techniques.
Han et al [53], 2023	MedAlpaca	Medical flash cards, Wikidoc	Alpaca	Accuracy	21.1-24.1	Highlighted privacy protection in medical artificial intelligence and demonstrated significant performance enhancements in medical certification exams through fine-tuning.
Singhal et al [54], 2023	MedPaLM-2	MedMCQA, MedQA, PubMedQA, MMLU	PaLM	Accuracy	67.6	Instruction prompt tuning undergoes rigorous human evaluation to assess harm avoidance, comprehension, and factual accuracy.
Chen et al [55], 2023	MEDITRON	PubMED	LlaMA-2	Accuracy	79.8	Achieved 6% improvement over the best public baseline and 3% gain over fine-tuned Llama-2 models.
Summarization						
Yan et al [56], 2022	RadBERT	Open-I chest radiograph report	BERT	Accuracy, F1	97.5, 95	Adapted a bidirectional encoder representation for radiology text.
Du et al [57], 2020	BioBERTSum	PubMed	BERT	ROUGE-L	68	Introduced the first transformer-based model for extractive summarization in the biomedical domain.
Li et al [58], 2022	Clinical-Longformer & Clinical-Big Bird	MIMIC-III	Longformer, Big Bird	F1	97	Reduced memory usage through sparse attention in a long-sequence transformer.
Moro et al [59], 2022	DAMEN	MS2	BERT, BART	Accuracy	75	Developed a multi-document summarization method using token probability.
Chen et al [60], 2020	AlphaBERT	HER (NTUH-iMD)	BERT	Accuracy	69.3	Designed a diagnoses summarization model based on character-level tokens.
Alsentzer et al [61], 2019	Bio+Clinical BERT	MIMIC-III	BERT	F1	11 improvements	Released the first BERT-based model specifically for clinical text.
Cai et al [62], 2021	ChestXRay-BERT	MIMIC	BERT	Accuracy	73	Automatically generates abstractive summarization of radiology reports.
Yalunin et al [63], 2022	LF2BERT	UMLS, EHR	BERT	ROUGE-1 F1, ROUGE-2 F1, ROUGE-L F1	67, 56.4, 64.5	Developed a neural abstractive model for summarizing long medical texts.
Balde et al [64], 2024	MEDVOC	PubMed, BioASQ, EBM	GPT	ROUGE	51.49, 47.54, 19.51	Efficiently reduced fine-tuning time and improved vocabulary adaptation for medical texts.

Task and author (year)	Model name	Training dataset	PLM[a] model	Key metric	Score (%)	Key findings
Text classification						
Yang et al [65], 2022	GatorTron	Clinical notes, UF Health clinical corpus MIMIC-III, PubMed, Wikipedia	GPT	Pearson correlation	89	Outperformed previous biomedical and clinical domain models.

Results

Selected Studies

A total of 75 models were identified through our comprehensive review. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart is presented in Figure 3. The PRISMA checklist is presented in Multimedia Appendix 1. These papers encompass various research areas related to transformer-based models and their applications in the medical domain. The selection of these papers was based on predefined inclusion criteria, ensuring the relevance of each study to the scope of our review.

Applications of Language Models in Health Care: Task-Specific

Dialogue Generation

Conversation generation generates responses to a given dialogue. GPT models, including DialoGPT and DialogBERT, can effectively generate human-like dialogues based on large corpora and contextualized representations of text [25,102-105]. In the medical domain, conversation generation focuses on developing conversations related to medical information [106]. Chatbots in health care can be classified into 6 types: screening and diagnosis, treatment, monitoring, support, workflow efficiency, and health promotion. These tasks involve aiding patient consultation, acting as a physician's decision support system, collaborating with interdisciplinary research, and providing care instructions and medical education [107,108].

The key models are MEP, BioBART, MedPIR, MEDCOD, Transformer-DST, MeDiaBERT, ChatDoctor, and SciFive.

Research efforts on conversation generation in medicine have also incorporated knowledge graphs. MKA-BERT-GPT was the first scalable work to integrate a medical knowledge graph mechanism into a large pretrained model. Meanwhile, MedPIR proposed a recall-enhanced generator framework by using a knowledge-aware dialogue graph encoder to strengthen the relationship between the user input and the response via past conversation information [28,30]. They achieved an F1 score of 82% and a bilingual evaluation understudy (BLEU) score of 21.5. Varshney et al [26] proposed the Masked Entity Dialogue (MED) model to train smaller corpora texts, addressing a 10% improvement in entity prediction accuracy for the problem of local embeddings in entity embeddings by incorporating conversation history into triples in the graphs, resulting in an automatic prediction of the medical entities model.

On the other hand, MEDCOD [31] used the GPT pretrained model to integrate emotive and empathetic aspects into the output sentences, which further imitates a human physician–like feature to better communicate with patients. The Transformer-DST [34] model addresses dialogue state tracking,

optimizing state operation prediction, and value generation with high accuracy by suggesting to ask the DST model to consider the whole dialogue and the previous state. Moreover, MeDiaBERT [35], using a hierarchical approach, achieves 63.8% accuracy in multiple choice medical queries by building a transformer encoder contained within another in a hierarchical manner.

BioBART [27], a BART-based model, used patient descriptions and conversation histories as input for the model to autoregressively generate replies to user inputs. The model outperformed the BART model by 1.71 on Rouge-2 with a BLEU score of 4.45, and pretraining on PubMed abstracts supported the model's performance. OPAL [29] and -w terms+AL models also used BART for pretraining. OPAL's proposed method involves 2 phases: pretraining on large-scale contextual texts with structured information extracted using an information-extracting tool and fine-tuning the pretrained model on task-oriented dialogues. The results showed a significant performance boost, overcoming the problems created by annotated data with large structured dialogue data. Recently, the -w terms+AL model proposed a framework for improving dialogue generation by incorporating domain-specific terminology through an automatic terminology annotation framework using a self-attention mechanism [33].

While other models are based on BERT, GPT, or BART, ChatDoctor [32], SciFive [36], and PMC-LLaMA [37] use LLaMA or T5 PLMs. To improve accuracy and provide informed advice in medical consultations, ChatDoctor used Meta's open-source LLaMA [109], which was fine-tuned using real-world patient-physician conversations and autonomous knowledge retrieval capabilities, achieving 91.25% accuracy. SciFive, a Text-To-Text Transfer Transformer–based model, was pretrained on large biomedical corpora, indicating its significant potential for learning large and extended outputs. The SciFive model was trained using a maximum likelihood objective with "teacher forcing" [110] for multi-task learning by leveraging task-specific tokens in the input sequence. Both models outperformed previous baseline methods.

More recently, the HuatuoGPT model [38], specifically tailored for the Chinese medical domain, provided state-of-the-art results in medical consultation tasks.

Question Answering

The question-answering task involves answering questions posed by users based on the texts in documents. It aims to generate an accurate response that directly answers the question input, contributing to clinical decision-making, medical education, and patient communication. Allowing physicians and researchers to obtain valuable answers quickly from electronic health records (EHRs) and various medical literature will effectively reduce the time and effort required when the procedure is done manually. While the dialogue generation and question-answering tasks both involve providing answers, the former focuses on generating responses within a conversation, whereas the latter focuses on developing specific answers to user questions.

The key models are BioBERT, BioGPT, BioMegatron, Med-BERT, UmlsBERT, SMedBERT, and BioVAE.

BERT-based language models have become increasingly popular in biomedical text mining as they can understand the context and generate accurate predictions. BioBERT [39], the first domain-specific BERT-derived transformer language model for biomedical text mining applications, achieved 89% accuracy on the MedQA dataset and outperformed BERT in medical text applications. A BioMegatron model [41], based on Megatron-LM [111], was also experimented on a question-answering task, and it was found that the domain and task-specific language model affected the overall performance rather than the model size. Shin et al [41] found that model size is not closely related to the performance rate, but rather the domain and task-specific language model affects the overall performance. Med-BERT [42], another BERT-inspired model, improved the prediction accuracy by 20% in disease prediction studies by pretraining on EHR datasets.

More recently, researchers have built BERT-based models for specific domains and tasks [112]. UmlsBERT [44] first built a semantic embedding linking concepts with the words in the UMLS Metathesaurus and proposed multi-label loss function–masked modeling. SMedBERT [45] also presented a similar approach with the knowledge semantic representation but structured the neighboring entities to learn heterogeneous information. UmlsBERT and SMedBERT enhanced performance, with F1 scores of 84% and 86%, respectively. Similarly, LinkBERT and BioLinkBERT [43] incorporated ontological knowledge to better understand a linking system between entities in the corpus. LinkBERT used a multi-task learning framework on several related tasks simultaneously to extract relations between entities in the corpus more effectively. ExKidneyBERT, CaBERTnet, and MMBERT extracted more precise answers from individual departmental reports [46,47,49].

On the other hand, BioVAE [48] used the OPTIMUS framework pretrained with SciBERT [113] and GPT-2 [114,115] and outperformed the baseline models on biomedical text mining. To address the issues on linguistic disparity, SPBERTQA [50] proposed a 2-stage multilingual language model pretrained on the SBERT model [116] to reply to user questions using multiple negative ranking losses with Bert multilingual 25.

However, previous studies using the BERT structure are a better fit for understanding the context, rather than generating texts. To this end, BioMedLM, a GPT architecture model, was built mainly for biomedical question-answering tasks [117] in recent studies of question-answering benchmarks and achieved 50% accuracy on summarizations of the patient's quest even in real situations with fewer data. BioGPT [40] applied a 2-step fine-tuning method to remove the noise in data and achieved 6.0% improved results compared with BioLinkBERT in the medical domain for question-answering tasks.

Recent studies have introduced significant advancements, such as BioMEDGPT [51], the first multimodal GPT for aligning biological data with human language, achieving 76.1% accuracy. Clinical Camel [52], using LLaMA-2, demonstrated superior performance with 5-shot accuracy ranging from 47.0% to 74.3%, outperforming GPT-3.5. MedAlpaca [53] focused on privacy

and medical certifications, attaining 21.1%-24.1% accuracy. MedPaLM-2 [54] reached 67.6% accuracy through instruction prompt tuning, and MEDITRON [55] achieved 79.8% accuracy, marking a 6% improvement upon existing models and setting a new benchmark.

Summarization

For many years, the medical field has suffered from the challenge of finding efficient and rapid access to understanding the fast-growing and immensely increasing amount of data formation. The key to timely and efficient clinical workflow is providing automatic summarization in clinical text. Summarization in health care is an important technique in NLP as it automatically summarizes the medical contexts into a concise summary of text. Summarization can be applied to medical records, literature, clinical trial reports, and other types of medical texts that aim to provide clinical providers with quick access to relevant information, without the need to skim through lengthy documents. Overall summarization can aid clinicians with decision-making through effective and prompt communication during the physician-patient meeting, as well as knowledge discovery for medical research [57].

The key models are BioBERTSum, AlphaBERT, ClinicalBertSum, ChestXRayBERT, RadBERT, LF2BERT, and DAMEN.

To alleviate the problems of biomedical literature summarization, which can have difficulties in learning sentence and document-level features, Du et al [57] proposed the first PLM for medical extractive summarization application called BioBERTSum. BioBERTSum captures a domain-aware token and sentence-level context by using a sentence position embedding mechanism that inserts structural information into a vector representation. It achieved a ROUGE-L score of 0.68, outperforming standard BERT models. AlphaBERT [60] proposed a diagnostic summary extractive model using a character-level token to reduce the model size and achieved a ROUGE-L score of 0.693, reducing the burden of physicians in the emergency department regarding reading complex discharge notes of patients.

To better use clinical notes, ClinicalBertSum [118] used the ClinicalBERT, SciBERT, and BertSum models during the fine-tuning and summarization process to automatically extract summaries from clinical abstracts. Similarly, ChestXRayBERT used BERT to perform an automatic abstractive summarization on radiology reports [62], with ROUGE-1 scores of 0.70 and 0.73, respectively. RadBERT [56], which was fine-tuned for radiology report summarization, achieved 10% fewer annotated sentences during the training, demonstrating the benefit of domain-specific pretraining to increase the overall performance.

LF2BERT [63] applied a Longformer neural network and BERT in an encoder-decoder framework to process longer sequence inputs and performed better than human summarization, according to doctors' evaluations. DAMEN [59] used BERT together with BART to discriminate important topic-related sentences in summarization, outperforming previous methods to summarize multiple medical literature via the token probability distribution method. The proposed probabilistic method selected only related significant chunks of information and then provided the probabilities of the tokens within the chunk, rather than the sentence level, to effectively reduce redundancy. Moreover, to overcome the long sequence issue, Li et al [58] comparably proposed Clinical-Longformer and Clinical-Big Bird pretrained on the Longformer [58] and Big Bird [119] models, respectively. Both proposed models used sparse attention mechanisms and linear level sequence lengths to mitigate memory consumption, thus increasing long-term dependency to train extensive clinical notes.

Recent development has also introduced MEDVOC [64], which uses GPT architecture to improve the adaptation of vocabulary in medical texts. By efficiently reducing fine-tuning time, MEDVOC achieves competitive performance, with ROUGE scores of 51.49, 47.54, and 19.51 across different datasets, such as PubMed, BioASQ, and EBM, respectively.

Text Classification

The medical text classification task categorizes medical text datasets into predefined categories based on the content and context within the text [120]. Disease classification, medical image classification, drug classification, and sentiment analysis are some of the standard text classification applications in health care.

The key models are jpCR+jpW, BioMed-RoBERTa, ClinicalBERT, Mask-BERT, KG-MTT-BERT, EduDistilBERT, PathologyBERT, KD distilledBERT, MatSciBERT, and Bioformer.

Wada et al [120] proposed a BERT model, jpCR+jpW, that uses a classification method. The method pretrains the medical BERT model once following the up-sampling step of domain-specific word amplification. This is done to achieve better performance on a smaller medical corpus. Similarly, BioMed-RoBERTa [70] used the RoBERTA model and applied a domain and task-adaptive pretraining strategy with a simple data selection approach for domain-specific classification. By pretraining on domain-specific and unlabeled data, the model achieved 87% accuracy. ClinicalBERT [67] represents clinical notes effectively, with a word similarity accuracy of 90% to generate visualized and interpretable embeddings for capturing semantic associations between clinical texts.

Yogarajan et al [121] suggested applying multi-labels (eg, using more than 300 labels for longer documents) to enhance the performance of medical classification tasks. Furthermore, to solve the imbalance class problems, Rodrawangpai et al [122] demonstrated a framework of adding normalization layers and dropout to BERT-based models, which improved the classification performance by 4% on data that included imbalance target labels. Similar efforts have been made by Nguyen [50] to address label-abandoning problems in medical abstract classification. The author proposed that a BERT model with label attention in the fine-tuning process raised the F1 score by 0.3 and supported the explainability of the prediction results. Learning is difficult with insufficient labeled data in a low-resource experiment setting. To alleviate this problem, Mask-BERT [71] proposed a framework for few-shot learning, where the mask is applied to the input text and enables the

gathering of more definitive tokens. Masked learning leads to filtered results on anchored samples from the data being used for representation, increasing the robustness of the output features.

Several language-specific models have been developed, including RuBioBERT and RuBioRoBERTa [123] for Russian text, BERTurk [124] for Turkish text, BioGottBERT for German text [88], and a Spanish text model [125], demonstrating the applicability of BERT-based models beyond English. Moreover, various disease-specific classification models have been developed. For example, PathologyBERT [126] is a pretrained masked language model used for classifying the severity of breast cancer diagnoses, raising the importance of applying domain-specific tokenization. KD distilled_BERT [127] is a response-embedded knowledge distillation framework that used pretrained BERT for depression classification and achieved a high accuracy of 97%. MatSciBERT [68] presents a biomedical domain-specific classification model on abstracts of the literature with binary classification application. The model extracted the context of the embeddings alongside the topic and had 2.75% higher accuracy than SciBERT.

To overcome the over-fitting and dimensionality problems for extracting numerous features in the text classification task, AFKF [128] proposed a fusion block with Kalman filters onto features of EMRs. This led to a 20% increase in accuracy compared with previous models. Likewise, to classify the features in EMRs, BERT-MSA [129] showed that a multilayered self-attention mechanism improved accuracy in obtaining relevant features. EduDistilBERT [130] demonstrated that adapting a smaller BERT model with limited parameter usage increases overall performance by 95% while reducing the computation cost. Another BERT-based fusion approach by Al-Garadi et al [131] explored architecture to fuse BERT, ALBERT, and RoBERTa model probabilities using a naive Bayes classifier, achieving an F1 score of 0.67 in classifying medication abuse texts.

Recently, the Bioformer [69] model demonstrated a 60% reduced model size and a 2- to 3-fold increase in performance speed. The model used a whole-word masking approach with 15% masking, which provided contextual information. However, KG-MTT-BERT [72] raised a question on limitations for multi-type clinical text classification. Concatenating numerous texts may be more efficient in developing relevant contextual information, and using only BERT may misplace crucial details. Therefore, the model extended the BERT model with a knowledge graph during fine-tuning, demonstrating effective handling in classifying patients into diagnosis-related groups.

Although the models were pretrained on the BERT model, Gao et al [132] showed that BERT-structured models did not gain better accuracy on clinical classification tasks, such as classifying discharge summaries or pathology reports, compared with nontransformer language models. Gao et al asserted that, in addition to the knowledge obtained through the entities, grammar patterns should also play a role in the model's mechanism. Furthermore, beyond the applications mentioned above, text classification can be used with other tasks. For example, Wang et al [133] applied a question-answering task along with the classification task by using the BERT model to classify texts in question inputs from patient inquiries regarding their symptoms.

Recent advancements in text classification models include TransformEHR [73], which uses BERT and longitudinal EHR data for clinical disease prediction, achieving area under the receiver operating characteristic curve and area under the precision-recall curve scores of 81.95 and 78.64, respectively. MeDa-BERT [74] tailored embeddings for Danish medical text, with accuracy ranging from 86.7% to 97.1%. SCHOLARBERT [75] leveraged public resource-driven datasets for scientific NLP, obtaining an F1 score of 85.49%. MediGPT [76] improved medical text classification tasks, with accuracy and F1 scores of 90.0% and 88.7%, respectively, showing a 22.3% performance gain over traditional methods.

Sentiment Analysis

The sentiment analysis task captures and identifies expressions and opinions [134] in medical contexts, including clinical notes, social media posts related to medicine, or patient feedback. For instance, sentiment analysis can capture the perception of people expressed in social media during the COVID-19 outbreak [135-137]. Emotions, such as positive, neutral, and negative sentiments, expressed by the public dominated during the pandemic [138]. Additionally, multi-label sentiment classification proved that the BERT model provided better performance compared with the LSTM model [139]. Moreover, the opinions of patients and physicians can be used to describe the symptoms and diagnosis to facilitate the decision-making process and support the decisions in clinical patterns [77]. The primary goal of sentiment analysis in health care is to provide insights into patient experiences, such as attitudes toward health care services and overall medical experience satisfaction. It not only assists patients but also supports clinicians to identify any underlying issues in patient care.

The key models are MentalBERT, MeentalRoBERTa, SINA-BERT, SGTN, RedBERT, T-BERT, AKI-BERT, TopicBERT, TweetBERT, and BelabBERT.

In mental health, patients' written texts have become a valuable source for supporting hypotheses and providing insights into the emotions expressed by patients [85,140]. While more research using PLMs needs to be conducted in this field, MentalBERT, MentalRoBERTa [77], PsychBERT [140], and belabBERT [85] applied mental health texts and achieved sentiment classification accuracies of 75%, 86%, and 90%, respectively. Additionally, transformer language models have been studied for sentiment analysis in languages other than English. Some language models are being developed to accommodate the unique structure and characteristics of different languages.

To achieve an effective model adaptation, researchers have explored HeBERT and HebEMO [141] for Hebrew, AraBERT and MARBERT [142] for Arabic, SINA-BERT [78] for Persian, and Fine-tuned BERT [143] for Chinese. However, few studies have conducted disease-specific sentiment analysis. RedBERT [80] involved a sentiment model for COVID-19, where BERT

was used for classifying sentiments of Reddit comments to grasp insights into the pandemic. Mao et al [82] proposed AKI-BERT, where the model was developed to support the early prediction of acute kidney injury.

Social media data are often used as a source for medical sentiment analysis as they are more informal and conversational, making them useful for modeling the nuances of language models. The COVID-TWITTER-BERT model [144], which was pretrained on Twitter messages regarding COVID-19, showed improved performance on COVID-19–related datasets. In particular, TweetBERT [84] exhibited improved performance on COVID-19–related and biomedical datasets. TwitterBERT was evaluated on 12 different biomedical datasets and outperformed previous BERT models, such as SciBERT [113] and BERT [145].

Comparably, TopicBERT [83], a memory-efficient BERT model, fine-tuned and enhanced sentimental analysis performance, and a complementary topic framework was applied to improve its performance. Beyond the proposed frameworks presented above, AlBadani et al [79] proposed a graph transformer model, SGTN, which used BERT to pretrain node embeddings and aggregated neighboring information to efficiently learn sentiments. It showed 5% improvement over baseline models.

Named Entity Recognition

The NER task identifies the named entities in unstructured text data. In health care, NER is used to automatically extract and define relevant medical entities, including diseases, medications, procedures, and other clinical concepts, from medical texts in research papers or EMRs [146,147]. The common applications of NER in medicine are as follows: (1) identify and analyze medical entities and relationships in medical literature to support biomedical findings [148]; (2) extract patient data, such as diagnosis, medication, laboratory results, and physical measurements, from EMRs to improve the decision-making for clinicians and the overall care [149]; and (3) extract and categorize data from medical claims and hospital admission and discharge data to improve health care management and resource allocation [150,151].

The key models are Bio+ClinicalBERT, Med-BERT, G-BERT, BioALBERT, GatorTron, ELECTRAMed, CamemBERT, BioGottBERT, Ra-RC, and RG-FLAT-CRF.

Numerous language models have been developed to implement EMR or EHR data for NER tasks in the clinical field. Bio+Clinical BERT [61] achieved superior results in clinical texts, with an F1 score of 83%. While the ClinicalBERT and Clinical BioBERT models were trained on EHRs, the Bio+Clinical BERT model did not perform well on deidentification text. Other models, such as G-BERT, also used EHR data to propose a language model that combined graph neural networks and BERT for representing medication information and predicting drug recommendations [87]. MedGPT [96] effectively processed noises by organizing medical text in multi-step procedures. In the first stage of the proposed model, unstructured data were converted into a standardized ontology using NER+L. Then, GPT was used for forecasting diagnosis events.

Moreover, studies attempted to tackle problems regarding representing and learning long medical entities [94,152]. Liu et al [152] proposed Med-BERT, using a Span-FLAT method for longer medical entities, and it achieved an F1 score of 84%. By contrast, the BIBC model built by Yang et al [94] captured both local and global sequence features to efficiently solve long text input issues. Additionally, models were trained on an extensive collection of biomedical texts to overcome the limited amount of training data. For example, BioALBERT and GatorTron attempted to develop a large medical language model [65,93]. BioALBERT used vocabulary specifically tailored to the biomedical domain and applied the ALBERT structure. On the other hand, GatorTron used the byte pair encoding algorithm and was pretrained on the GPT model to scale up the language model up to 8.9 billion parameters, showing 9.6% accuracy improvement. Furthermore, the datasets in the medical domain face the challenge of not only limited training data but also low-quality labeled training data. Therefore, multi-task learning was presented by Khan et al [92], and the slot tagging problem was approached with MT-BioNER, a multi-task transformer-based model that enhanced memory performance and time efficiency in slot tagging, with 10% better performance than single-task models.

While recent studies have heavily relied on BERT-based structures, transformer models used other PLMs for improving NER tasks. ELECTRAMed [91] proposed an ELECTRA-based model for the biomedical domain, which reduced the sequence length and training phases. Additionally, many models have focused on multilingualism, including the CamemBERT, BioGottBERT, Ra-RC, and RG-FLAT-CRF models [95,153,154], focusing on efficiently learning features in languages other than English, such as French, German, and Chinese.

More recent studies include HeartBERT [98], which emphasizes department-specific models, focusing on cardiology and achieving 74% accuracy. UMLS-KGI-BERT [99] introduced graph-based learning for clinical text extraction, with a precision of 85.05%. CardioBERTpt [100], which is specialized in Portuguese cardiology terms, improved NER performance, with an FL-score of 83%. Finally, TocBERT [101], which is fine-tuned on the MIMIC-III dataset, outperformed rule-based methods for segmenting discharge summaries, achieving an F1 score of 84.6%.

Discussion

Principal Findings

This study examined previous studies on transformer-based language models in the medical domain. We reviewed a total of 75 recently studied models that aligned with our inclusion criteria. The initial step of the method involves categorizing the models based on the tasks they perform, such as dialogue generation, question answering, summarization, text classification, sentiment analysis, and NER. Then, each study is analyzed based on the key findings, frameworks, pretraining

models used, and model names. Finally, the limitations of each task application are discussed. The use of transformer-derived language models in medicine has shown numerous advantages, such as high accuracy, language comprehension, automated diagnosis, adaptability, and efficiency. However, these models also face several challenges, including the lack of standardization, the need for domain-specific knowledge, limited annotated training data, safety concerns, interoperability and interpretability issues, integration complexities, ethical considerations, and evaluation issues. In this discussion section, we explore key limitations and future directions of models in terms of each task and the generalizability of the explored models across different health care settings and population considerations. Model challenges, their potential solutions, and the future of natural language models in the medical domain will be discussed.

Specific Task-Based Challenges and Future Directions

Dialogue Generation

Dialogue generation models like DialoGPT and ChatDoctor face challenges such as handling the complexity and specificity of medical terminology, ensuring data privacy, and providing accurate, contextually relevant, and empathetic responses. Privacy and security issues are critical since these models deal with sensitive patient information. The risk of privacy, chances of errors, ethical constraints, and security issues remain to be addressed. The challenge comes from the specificity and complexity of medical terminology, although the medical dialogue system certainly should provide only accurate and informative knowledge tailored to the level of expertise of the end user. Therefore, human experts need to conduct regular risk and security audits.

The following suggestions are made to further improve medical dialogue research. First, continuous learning and training of the dialogue system are necessary to incorporate up-to-date knowledge for users. Additionally, language translation could be integrated into the dialogues to enable universal access to data and promote a more profound exchange of insights without language barriers. Moreover, chatbots [107] should be integrated in a real medical setting to reduce medical costs and physician burdens. Proper and accurate usage of the dialogue system may assist patients in navigating through the vast amount of freely available online data, finding correct information, and avoiding falsified or unsolved answers. Lastly, automated data augmentation techniques can be used to create unbiased dialogues. These suggestions can lead to further advancements in medical dialogue research, leading to more efficient communication between patients and medical professionals.

Question Answering

Medical question-answering systems like BioBERT and UmlsBERT struggle with the complexity of medical terminology for nonexperts in the medical field. Patients who are experiencing an illness may find it difficult to filter and search for relevant information. These models need to handle diverse linguistic data and adapt regional variations in medical practices. One approach to addressing these limitations is to integrate multilingual models to handle questions in various languages. Another approach is the incorporation of region-specific medical data to improve model generalizability and accuracy. Further, enhancing the ability to integrate summarization tasks on top of the question-answering system may provide comprehensive responses. However, such a multi-task system requires several human experts to evaluate the provided answers in order to judge the task performance accurately.

Summarization

Medical summarization is a crucial application in language model tasks to facilitate the hospital's process and significantly reduce the workload and burnout of clinicians. However, challenges emerge due to the complexity of health care terminologies and the need for expert knowledge to comprehend them. The ability to achieve concise and faithful summaries is critical for avoiding physician burnout and patient dissatisfaction. Models like BioBERTSum and ClinicalBERTSum face challenges in learning sentence and document-level features, handling complex medical terminologies, and ensuring summaries are concise and accurate. The risk of physician burnout due to extensive documentation can be mitigated by effective summarization. Future work can focus on developing a system of human expert assessments to validate the summarization quality. Additionally, combining extractive methods and abstractive summarization methods is suggested. A fine-tuned summarization model for a particular task should consider tense information and personal information. We recommend building an ensemble method to improve pretraining and fine-tuning datasets for summarization effectiveness. Medical summarization is a crucial application in language model tasks to facilitate the hospital's process and significantly reduce the workload and burnout of clinicians.

Text Classification

Improving the accuracy and effectiveness of classification tasks poses several challenges and limitations that need to be addressed. Models, such as BioMed-RoBERTa and ClinicalBERT, need to address issues related to class imbalance, limited annotated data, and the complexity of medical terminologies. Limited training data, for instance, can be addressed by collaborating with different institutions to gather various information options in vocabulary usage and text structure, and high-quality annotated data can thus be developed. Ambiguity, variation, concept drift, data privacy, language complexity, and class imbalance can be addressed by employing domain-specific approaches, and pretraining language models can be leveraged on similar datasets. Domain-specific approaches can resolve ambiguity issues and achieve active learning to reduce the reliance on large volumes of labeled data. These strategies will facilitate better model performance results.

Sentiment Analysis

Despite previous research results, medical sentiment analysis remains a challenging task due to personalized information required to accurately measure meaning and interpret emotions in context. MentalBERT and RedBERT, for instance, need to accurately interpret emotions in medical contexts, handle personalized information, and manage the complexity of evaluating representations in the biomedical domain [155].

Organizing emotions in context requires sentiments, including sarcasm, emojis, and misspelled words, which create subjectivity, as noted by Brezulianu et al [156].

These limitations can be overcome by defining emotional polarity for annotations and integrating cultural, economic, and medical contexts into the model. Future research should consider using a domain-specific sentiment dataset, adapting the specific medical source (despite the lack of an available dataset, mostly from a single source), creating highly effective and defined labels in data, performing analysis based on the context, building both the explicit and implicit sentiment lexicon, and addressing the lack of a mental health–related sentiment lexicon. By addressing these challenges, future work can develop more accurate and effective medical sentiment analysis language models.

Named Entity Recognition

NER downstream tasks are imperative to address its limitations. The limited annotated data in medical text datasets is a major challenge due to the high cost and time involved in labeling, resulting in limited labeled data for model training. The Bio+ClinicalBERT and Med-BERT models face challenges in handling limited annotated data, normalizing various terminologies, and ensuring accurate entity extraction across different medical texts.

Therefore, we suggest collaborative effort among health care providers, biomedical researchers, and computer engineering experts to develop effective and robust NER models. Improving the annotation algorithms and creating extensive and accurately labeled medical text datasets can significantly enhance the performance. Moreover, standardized clinical entities can prevent ambiguity arising from abbreviations and context. The use of transfer learning techniques and domain PLMs can be beneficial in addressing the limited annotated data issue. Developing domain-specific dictionaries and ontologies can aid in improving the model performance.

Generalizability Challenges

Health care systems vary widely in their practices, protocols, and terminologies. For instance, a model trained on data from the United States may not perform optimally in a health care setting in Asia or Europe due to differences in clinical infrastructure and settings. The availability of resources, such as EHRs and technological infrastructure, can also differ between urban and rural settings, and between developed and underdeveloped countries. This variability can significantly affect the implementation and performance of the models.

Moreover, patients from different ethnic and cultural backgrounds may present symptoms differently and may have varying health behaviors, and models need to account for these varying characteristics to avoid biases and ensure equitable health care delivery. Moreover, multilingual populations pose a challenge for language models trained predominantly on English language data. The inclusion of diverse linguistic data during model training can mitigate this issue with a language-specific pretraining stage followed by a shared fine-tuning stage to improve the model's applicability across different regions.

By incorporating diverse datasets during training, language models can support personalized medicine initiatives. This involves tailoring medical treatments to individual patient characteristics, leading to more effective and efficient care. Developing adaptable models that can be fine-tuned with local data ensures scalability across different health care settings, to address regional variations in medical practices and patient demographics.

Standardizing Medical Data for Improved Model Performance

The quality and consistency of medical data may vary across health care settings. Models trained on high-quality standardized data may not perform as well when applied to settings with less structured and lower quality data. The lack of standardized terminologies in medical texts, which encompass a vast array of terminologies from disease-specific to domain-specific language, is a notable challenge. Currently available datasets often have a restricted range of medical entities, posing difficulties in accurately extracting relevant entities.

To address this, we suggest creating standardized clinical entities. This would enable the normalization of different names or abbreviations to accurately normalize entities for standard medical terminology, thereby improving data consistency and model performance. Building standardized forms that are widely adopted and available in multiple languages will facilitate standardized medical learning. Additionally, developing domain-specific models has proven effective in enhancing model performance. For instance, an open-source package for detecting clinical entities from medical texts, which can recognize risk factors, medications, and diagnoses, can be developed to support this initiative.

The fuel of building and training language models is data. Collecting accurate information and precisely fabricating the data design during the preprocessing step is crucial. The challenges in creating such quality data for medical language models include a lack of key annotation and limited training data. Annotating medical text is time-consuming and costly, resulting in limited labeled data for training models. First, using diagnosis codes on weak supervision for training labels is suggested. Second, the pipeline should support the automated retrieval of datasets and multiple types of clinical entities to enable the preservation of annotation relationships across different languages. The automated retrieval of datasets and the development of speedy and supportive algorithms can aid in data integration and preprocessing. In addition to technical solutions, emphasizing the importance of multidisciplinary collaboration can significantly enhance the development and implementation of these models. By integrating expertise from various fields, we can overcome challenges, develop innovative solutions, and further advance the field of AI in health care. Collaborative efforts among data scientists, clinicians, bioinformaticians, and ethicists are crucial for building robust, reliable, and ethically sound models.

Ethical Considerations

Interoperability and cybersecurity pose significant challenges in medicine. EMRs and clinical decision support systems often

have difficulty interacting with each other, leading to inefficiencies in patient care. To overcome these challenges, it is important to develop strategies focused on informed consent, safety, transparency, and algorithmic fairness for bias prevention. Ensuring that patients provide informed consent for the use of their data is critical. This involves informing patients about the use of their data, the benefits and risks, and their rights to withdraw consent at any time. This process upholds patient autonomy and enhances trust in AI systems.

Safety and transparency are fundamental to the ethical deployment of AI models in health care. Models handling sensitive patient data and providing clinical recommendations, such as BioBERTSum, must be rigorously validated and continuously monitored to detect and rectify errors promptly. Transparency can be achieved by making algorithms and decision-making processes understandable to users. This includes documenting how models are trained, the types of data used, and the underlying mechanisms of the algorithms.

Ensuring algorithmic fairness is crucial to prevent biases in AI models, which could lead to unequal treatment of patients. AI models trained on biased datasets can perpetuate existing disparities in health care. For example, models must include diverse and representative data to avoid underrepresentation of certain populations, ensuring fairness and accuracy across different groups such as ethnicity, cultural background, gender, and age. By addressing these ethical considerations within mitigated guidelines, we can ensure the reliability of transformer language models in medicine to improve overall health care while preserving fairness.

Evaluation Metrics

Furthermore, the rapid evolution of medical knowledge poses a challenge for language models to adapt and remain up to date with innovative discoveries. Ensuring the interpretability of language models is also crucial to address the trust issue and support the decision-making process. To evaluate medical language models, multiple metrics, including the F1 score, Biomedical Language Understanding Evaluation, Biomedical Language Understanding & Reasoning Benchmark (BLURB), and Chinese Biomedical Language Understanding Evaluation [157], should be used to overcome unbalanced performance issues.

Conclusion

We presented a comprehensive survey of task-specific transformer-derived models employed for diverse medical tasks, demonstrating their significant potential in the medical domain. Numerous studies have highlighted their capabilities in improving health outcomes, extending beyond disease prediction and medical classification studies. Our work clearly delineates the applications of transformer-based language models in various medical tasks such as dialogue generation, question answering, summarization, text classification, sentiment analysis, and NER. We identified innovative models and their unique contributions to the field. These findings distinguish our work from existing literature by providing a detailed, task-specific analysis of transformer-based models in health care.

Despite the promising advancements, several challenges must be addressed to develop effective models. These include standardization, limited annotated data, interoperability, and ethical considerations. To overcome these challenges, it is crucial to emphasize multidisciplinary collaboration. Future research should investigate transformer models that incorporate visual or audio data sources to provide a more comprehensive understanding of medical contexts.

Developing models that support patients' experiences and assist health care practitioners in focusing solely on critical tasks by providing evidence-based recommendations and identifying potential diagnostic and treatment options can remarkably improve patient care. AI-driven tools rationalize administrative tasks, reduce paperwork, and improve workflow efficiency, eventually saving time for health care providers. Further, policymakers can leverage insights from transformer-based models to inform health care policies and allocate resources more effectively, ensuring equitable health care delivery.

This review solely focused on transformer language models that used text data. While the findings are promising, the applicability of these models may vary across different medical settings and populations. Our findings highlight the transformative potential of transformer-based language models in the medical field. By addressing the identified challenges and focusing on innovative research directions, the health care domain can advance significantly. We encourage researchers to build upon our work, address these challenges, and explore new frontiers in medical AI to improve patient care and clinical decision-making.

Abstract

Evidence-based medicine, rooted in randomized controlled trials, offers treatment estimates for the average patient but struggles to guide individualized care. This challenge is amplified in complex conditions like congenital heart disease due to disease variability and limited trial applicability. To address this, medicine-based evidence was proposed to synthesize information for personalized care. A recent article introduced a patient similarity network, CHDmap, which represents a promising technical rendition of the medicine-based evidence concept. Leveraging comprehensive clinical and echocardiographic data, CHDmap creates an interactive patient map representing individuals with similar attributes. Using a k-nearest neighbor algorithm, CHDmap interactively identifies closely resembling patient groups based on specific characteristics. These approximate matches form the foundation for predictive analyses, including outcomes like hospital length of stay and complications. A key finding is the tool's dual capacity: not only did it corroborate clinical intuition in many scenarios, but in specific instances, it prompted a reevaluation of cases, culminating in an enhancement of overall performance across various classification tasks. While an important first step, future versions of CHDmap may aim to expand mapping complexity, increase data granularity, consider long-term outcomes, allow for treatment comparisons, and implement artificial intelligence–driven weighting of various input variables. Successful implementation of CHDmap and similar tools will require training for practitioners, robust data infrastructure, and interdisciplinary collaboration. Patient similarity networks may become valuable in multidisciplinary discussions, complementing clinicians' expertise. The symbiotic approach bridges evidence, experience, and real-life care, enabling iterative learning for future physicians.

KEYWORDS

artificial intelligence; clinical practice; congenital heart disease; decision-making; evidence-based medicine; machine learning; medicine-based evidence; patient similarity networks; precision medicine; randomized controlled trials

Evidence-based medicine (EBM), built on the foundations of randomized controlled trials (RCTs), is good at providing average estimates for treatments or outcomes in the average patient. While EBM has resulted in important clinical guidelines, it does not solve the real clinical quandaries: patients appear for care individually, each may differ in important ways from an RCT cohort, and the physician will wonder each time if following EBM will provide best guidance for this unique patient. This is particularly the case for complex and heterogeneous populations, such as those with congenital heart disease (CHD). Indeed, in congenital cardiology, RCTs are both difficult to conduct and commonly not definitive. The complexity of disease, clinical heterogeneity within lesions, and the small number of patients with specific forms of CHD severely degrade the precision and value of estimates of average treatment effects in the average patient provided by RCTs.

In response to mounting concern about the value of EBM for decision-making, we have previously proposed medicine-based evidence (MBE) as a means of synthesizing all available information and applying it to the individual patient [1]. Briefly, we proposed that whenever a physician needs to decide a patient's treatment plan, a library of patient profiles would be interrogated. A nearest neighbor algorithm would then find "approximate matches," a group of patients who share the greatest similarity with the index case. Some of these matches would and others would not have received a certain treatment or developed a certain outcome, such that specific analyses tailored to the clinical question could be performed within this pool of approximate matches. We envisioned that this approach would represent a major step toward true personalized medicine, as individualization of treatment would shift from today's intrinsically subjective human-driven assessment toward a more objective, data- and model-driven process that is more descriptive, integrative, and predictive.

In their recent article, Li et al [2] introduced CHDmap, an innovative patient similarity network (PSN) designed to prognosticate outcomes among patients with CHD. By leveraging comprehensive clinical and echocardiographic data sets from 4774 surgical cases, the PSN manifests as an interactive, zoomable electronic cartography, wherein each node symbolizes an individual patient, and internode distances delineate their similarity. This user-centric software empowers practitioners to delineate specific patient attributes—such as age, gender, CHD classification, and echocardiographic metrics—tailoring the analysis to the case at hand. The program subsequently uses a k-nearest neighbor algorithm to identify a cohort of closely resembling peers according to the top-k parameter or similarity threshold. This assemblage of approximate matches serves as the foundation for diverse predictive analyses, encompassing variables like hospital length of stay, complications, and survival. This way, CHDmap allows for conducting real-time clinical trials that are specifically tailored to the individual patient, based on historical cases with a similar clinical profile. A key finding from the study by Li et al [2] was the tool's dual capacity: not only did it corroborate clinical intuition in many scenarios, but in specific instances, it prompted a reevaluation of cases, culminating in an enhancement of overall performance across various classification tasks.

The tool has been made publicly available [3] and represents a promising technical rendition of the MBE concept. According to the authors, future generations of the software will be uploaded in time, further expanding the possibilities of CHDmap, including the following: (1) Labeling and visualization of increasingly complex and rare CHD types—currently, only some major subtypes (atrial septal defect, patent foramen ovale, ventricular septal defect, patent ductus arteriosus) are depicted in the map overview; as the underlying data set expands, patients with more complex anatomy may be visualized as well. (2) More granularity in data—in a similar manner, the width of the underlying data set (ie, number of cases) and its depth (ie, number of variables) will likely increase, allowing for more precise matching and examination of more aspects of decision-making. (3) Long-term outcomes—currently, only in-hospital outcomes can be considered within CHDmap, but future generations of the software may allow for long-term outcomes to be analyzed. (4) Comparisons of specific treatment options—once in-depth data on various treatments become available, the optimal treatment for an individual patient may be examined through real-time clinical trials within CHDmap, where outcomes after initiation of various treatments are compared among a group of approximate matches. (5) Artificial intelligence–driven weighting of indicators—the default setting in CHDmap allocates to each indicator the same weighting, whereas physicians can modify these weights based on their prior knowledge; the latter option allows accounting for the fact that weights are likely to differ depending on the clinical setting and the question at hand. With future generations of CHDmap, the authors may implement an artificial intelligence model to dynamically allocate weights to each of the indicators.

CHDmap undeniably signifies a significant stride toward the actualization of MBE. Just as with any statistical methodology, the principles of implementation science will play a pivotal role in optimizing the widespread integration of this tool into clinical practice [4]. Medical practitioners will need to be trained to use these tools correctly and to ensure they are aware of the perks and pitfalls of the PSN (eg, knowing that there is a trade-off between increasing similarity and increasing statistical power or being able to correctly interpret the certainty associated with a specific prediction). Data infrastructure will need to be in place, and continued efforts should be made to establish multicenter clinical registries with in-depth and up-to-date information collection. Furthermore, collaboration between health care professionals and experts in data science will be required to ensure these novel technologies can benefit our patients, taking into account issues regarding data quality and privacy.

Finally, at some point in the future, tools like CHDmap may become routinely used to support team discussions. Rather than replacing the clinician, they should be embraced as assistive technology enhancing overall clinical efficacy. This symbiotic approach serves to harmonize real-life patient care with prior experience and established evidence. This way, we can truly start to achieve the incremental benefits of future generations of physicians learning from previous ones.
